Clopyralid (Reclaim®)[37,280]		Sugar beets, corn, grass seed, conifers, and pasture	70–560
Fluroxypyr (VISTA®)[37,280]		Small grains, apple orchards, plantations, conifer forests, and corn	180–400
Picloram (Tordon®)[37,280]		Industrial weed control, forestry, pasture, and range land	35–1120
Triclopyr (Brush-B-Gone®)		Plantation crops, pastures, conifer forests, and grasslands	720–8000

TABLE 16.73 (continued)
Structures, Uses, and Hazard Profiles for the Phenoxy, Benzoic, and Pyridine Acid Herbicides That Mimic Indole Acetic Acid (Auxin) (HRAC Code O)

	Irritation		LD_{50} (mg/kg)				
Herbicide	**Eye**	**Skin**	**Oral**	**Dermal**	**LC_{50} (mg/L) Inhalation**	**Sensitization Potential**	**Signal Word**
2,4-D	Severe irritant	Moderate irritant	639	>2000	1.8	Negative	Warning
MCPA	Corneal opacity	Nonirritant	1400	>2000	>6.3	Negative	Danger
Dicamba	Corrosive	Nonirritant	1851	>2000	>9.6	Positive	Danger
Clopyralid	Severe irritant	Slight irritant	4300	>2000	1.3	Negative	Warning
Fluroxypyr	Mild irritant	Nonirritant	>5000	>2000	>2.0	Negative	Caution
Picloram	Moderate irritant	Nonirritant	4012	>2000	>0.035	Positive	Danger
Triclopyr	Minimal irritant	Nonirritant	803	>2000	>4.8	Positive	Caution

Herbicide	**Species/Study**	**NOEL (mg/kg/day)**	**Toxicity Study**	**Hazard Indicator**
2,4-D[476,477]	Rat/2 years	5.0	Mutagenicity	No evidence
	Dog/52 weeks	1.0	Developmental	Not teratogenic
	Mouse/18 months	1.0	Reproductive	No evidence
	RfD or ADI	0.01	Oncogenicity	D (not classifiable)
MCPA[478]	Rat/2 years	4.4	Mutagenicity	Not mutagenic
	Dog/52 weeks	0.2	Developmental	Not teratogenic
	Mouse/18 months	15.4	Reproductive	Not a reproductive toxin
	RfD or ADI	0.0044	Oncogenicity	Not likely to be carcinogenic in humans
Dicamba[479,480]	Rat/2 years	125	Mutagenicity	Positive (*B. subtilis*; UDS)
	Dog/52 weeks	60	Developmental	Not teratogenic
	Mouse/18 months	108	Reproductive	No evidence
	RfD or ADI	0.6	Oncogenicity	D (not classifiable)
Clopyralid[481]	Rat/2 years	50	Mutagenicity	No evidence
	Dog/52 weeks	100	Developmental	Not teratogenic
	Mouse/18 months	500	Reproductive	No evidence
	RfD or ADI	0.5	Oncogenicity	E (No evidence)
Fluroxypyr[482]	Rat/2 years	100	Mutagenicity	Not mutagenic
	Dog/52 weeks	150	Developmental	Not teratogenic
	Mouse/18 months	300	Reproductive	Not a reproductive toxin
	RfD or ADI	0.5	Oncogenicity	No evidence for carcinogenicity in rats or mice
Picloram[483]	Rat/2 years	20	Mutagenicity	Not mutagenic
	Dog/52 weeks	35	Developmental	Not teratogenic
	Mouse/18 months	500	Reproductive	Not a reproductive toxin
	RfD or ADI	0.2	Oncogenicity	E (No evidence)
Triclopyr[484]	Rat/2 years	12	Mutagenicity	Not mutagenic
	Dog/52 weeks	5	Developmental	Not teratogenic
	Mouse/18 months	135	Reproductive	Not a reproductive toxin
	RfD or ADI	0.05	Oncogenicity	D (not classifiable)

TABLE 16.74
Structures, Uses, and Hazard Profiles for the Semicarbazone Herbicide Diflufenzopyr-sodium (Distinct®) (HRAC Code P)

Structure	Principal Use/Crop	Application Rate (g a.i./ha)
	Inhibits transport of auxins via protein binding—used as a systemic postemergent herbicide in corn and noncrop pastures	9–185

Irritation		LD_{50} (mg/kg)				
Eye	**Skin**	**Oral**	**Dermal**	**LC_{50} (mg/L) Inhalation**	**Sensitization Potential**	**Signal Word**
Mild irritant	Nonirritant	>5000	>5000	>2.93	Negative	Caution

Species/Study	NOEL (mg/kg/day)	Toxicity Study	Hazard Indicator
Rat/2 years	236	Mutagenicity	Not mutagenic
Dog/52 weeks	26	Developmental	Not teratogenic
Mouse/18 months	1004	Reproductive	Not a reproductive toxin
RfD	0.26	Oncogenicity	No evidence of carcinogenicity in rats or mice

CONCLUSIONS AND QUESTIONS

According to a Byzantine proverb, "He who has bread may have many problems, but he who lacks it has only one." In a world where the current population is burgeoning, one might say that collectively we face more than 6.6 billion individual problems, ultimately leading to only one question: How will we sustain and possibly increase food production in the face of declining arable land and the future demand to convert a part of biomass production into energy production? A corollary question is: How will we produce food locally where it is needed or redistribute it from regions of high productivity to other needy parts of the world? All this must be done in the face of strident attacks, at least in the developed countries, against the basic sciences and the economy of food production that up to now have permitted the diversion of human resources away from growing food to other economic, political, and cultural activities.

So, how will we overcome these apparently insurmountable challenges? Perhaps we should look to the past 60 years, the period of time that might be considered the period of modern agriculture, for clues as to what has worked and what has failed. The most noticeable advances have included the following:

- The development of strains of plants that are resistant to disease or result in a greater yield using conventional breeding techniques or, more recently, molecular marker–assisted breeding methods
- The introduction of mechanized farming methods that resulted in a reduction in the reliance on human or animal labor
- The utilization of cropping practices and fertilizers to enhance productivity
- The use of agricultural chemicals to enhance yield by reducing loss to disease and the destruction by pests
- The development of highly effective pesticides that control pests with a near-pharmacologic level of potency (i.e., grams active ingredient per hectare)

One must also acknowledge, however, that there have been some failures to achieve the main goal of pesticide science—namely, to achieve the selectivity of effect and thereby to prevent unwanted effects on animals or the environment. Thus, pesticide development is about one thing and one thing only: selectivity. The mission of pesticide scientists is to find chemicals that control pests at some reasonable and economically achievable dose, ultimately by interfering with a fundamental life process of the pest, without having any effect on beneficial plants, insects, or mammals, including humans.

In reviewing the more than 50 different MOA discussed in this chapter, one cannot help but be amazed at the ingenuity of the researchers who have spent their lives in this hunt for better and more effective pesticides. These men and women have achieved success mainly using relatively crude biological screening tools combined with ingenious chemical synthesis strategies, which, with luck and a lot of persistence, have led to the discovery of pesticide candidates that have then undergone extensive optimization to finally become useful agricultural tools. In hindsight, once the molecular mechanisms have been described, it is incredible that the specificity of effect was achieved using what could be best described as an intelligent random search process. Even today, with high-throughput screening methods and the use of combinatorial chemistry, the crop protection industry has not turned to rational design, largely because the science still is not there to build a molecule from the ground up based on what is currently known about molecular targets. Using traditional methods, then, it may still be possible to increase selectivity, lower use rates, and identify chemicals with new MOA. The incorporation of genes that create tolerance in beneficial plants and the expression of pesticides by the species that are to be protected are examples from the recent past. In the future, it is likely that plants and animals will continue to be genetically modified or bred using more sophisticated selection methods to achieve improved traits that create greater health benefits or facilitate the preprocessing of food and fiber. Targeted delivery of pesticides, whether derived from natural sources or that are the result of chemical optimization of what has been designed by nature, may be another way to move toward solutions that have lower environmental impact. Whatever the outcome, the next 50 years should prove to be critical, given current population predictions and the emerging environmental and energy crises.

QUESTIONS

16.1 Farmers must contend with some 80,000 plant diseases, 30,000 species of weeds, 1000 species of nematodes, and more than 10,000 species of insects. Today, national and international agricultural organizations estimate that as much as 45% of the world's crops continue to be lost to these types of pests. In the United States alone, about $20 billion worth of crops (one-tenth of production) is lost each year. What do you think would be the status of our national food production capacity without the use of pesticides?

16.2 Who ensures that pesticides can be used without unacceptable hazard to the consumer to protect food crops and maximize yields?

16.3 How stringent are the testing requirements for the registration of a pesticide when compared to those for products used in the household, the yard, industrial situations, or even in the pharmaceutical industry?

16.4 Has the introduction of pesticides into your food supply had a positive or negative impact on your life?

16.5 What crop protection chemical's human life-saving potential has been rivaled only by the introduction of penicillin?

16.6 Are organically grown foods really less hazardous or more nutritious than those grown with the aid of pesticides, and if so, why?

KEYWORDS

Fungicides, Insecticides, Herbicides, Pesticides, Human, Health

17 Metals

Janis E. Hulla

CONTENTS

The views expressed in this chapter are those of the author and do not necessarily represent the views of the U.S. Army Corps of Engineers, Army, or Department of Defense.

INTRODUCTION

Scope

The U.S. laws that are related to exposure to toxic substances, and the federal agencies responsible for implementing them, are discussed in Chapter 2 of this textbook and appear in Table 2-1 of the fifth edition.[1] The list includes agencies responsible for managing exposures related to drugs, consumer products, and environmental contaminants. Included are laws that protect plants and animals in addition to humans. The scope of this chapter includes fundamental concepts that are relevant to each of these three receptor groups. The chapter's focus is the human health effects of essential and nonessential metals. The radiation biology and toxicity of radioactive metals are discussed in Chapter 18 of this text.

A history of the U.S. government's management of risks associated with exposure to chemicals is summarized in Chapter 2 of this book. Included is a discussion of the 1983 National Research Council publication, *Risk Assessment in the Federal Government: Managing the Process*.[2] This publication defined four components of the federal risk assessment process still used today: (1) hazard identification, (2) dose–response assessment, (3) exposure assessment, and (4) risk characterization. Components of these four processes that are specific to essential and nonessential metals are discussed in this chapter.

In the scientific vernacular, a metal is any element characterized by ductility, luster, being electropositive with a tendency to lose electrons, and having the property of conducting heat and electricity. Scientists may refer to the periodic table of elements where metals are distinguished from alkali metals, alkaline earth metals, metalloid metals,

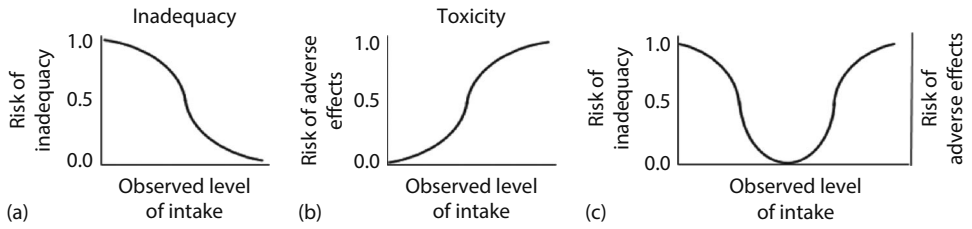

FIGURE 17.1 Hypothetical U-shaped dose–response curve for essential trace element. (a) Adverse effects at low doses due to dietary deficiency. (b) Adverse effects at high dose due to toxicity. (c) U-shaped curve for a hypothetical trace metal essential nutrient. (Adapted from Olin, S.S., *J. Nutr.*, 128, 364S, 1998.)

lanthanide metals, and actinide metals based on their atomic structure. In this chapter, *metals* is used as a general term referring to all 286 elements within these categories. Of the 286 metals, only the dietary essential metals and the metals for which there is evidence of toxicity are described in this chapter. The toxicological characteristics of metal-containing nanomaterials are outside this chapter's scope.

Essential and Nonessential Metals

The scope of this chapter includes (1) dietary essential metals and (2) toxic metals. Quantifying dose is fundamental to defining the toxicity and/or essentiality of metals. This concept is perhaps best illustrated by the U-shaped dose–response curves of metals that are both trace essential nutrients and toxic at high dose. Toxicity at high dose, as illustrated by Figure 17.1b, is generally understood. Perhaps less well recognized is that, for trace essential nutrients, toxicity can result from dietary insufficiency as illustrated in Figure 17.1a. Metals that are both essential at low dose and toxic at high dose demonstrate U-shaped dose–response curves as illustrated in Figure 17.1c.

Physical and Chemical Determinants of Metal Essentiality and Toxicity

The chemical determinants of metal toxicity include the strength with which a metal complexes with a ligand and the significance of the biological function of that molecular ligand. Metals are Lewis acids forming cations, and they are electron-accepting species. Lewis bases form anions, are electron donors, and are ligands for metals. *Soft* metals and ligands are characterized as having electrons that are mobile within the electron cloud. The electron clouds of soft species are easily deformed and polarized. Soft species preferentially form covalent bonds. Conversely, *hard* metals and ligands are species with an electron cloud that is relatively rigid and relatively less likely to be polarized. Hard metal species preferentially form ionic bonds during complex formation. The hard, borderline, and soft acid metals that are most significant biologically are listed in Table 17.1. Bonds between (1) hard acid metals and soft base ligands or (2) soft acid metals and hard base ligands are relatively weak and, therefore, relatively rare.

Hard acid metals are oxygen-seeking. They tend to bond to hard base ligands that contain, for example, –OH, –COO–, and $–OPO_3H^-$, greater than C=O. Soft acid metals preferentially bond to soft base ligands containing nitrogen, for example, $–NH_2$ and greater than NH, and sulfur, for example, –SH and –S–S–.[3] The borderline metals demonstrate relatively equal affinity for oxygen, nitrogen, and sulfur. The soft acid metals are more toxic than hard acid metal because (1) the processes of biological absorption, distribution, metabolism, and excretion put them in contact with biomolecule ligands that function to maintain homeostasis and (2) the thermodynamics favor reactions that result in dysfunction, for example, the displacement of endogenous essential metals in metalloenzymes.

TABLE 17.1
Classification of Metal Ions as Hard, Borderline, or Soft Acids

Hard acids	Al^{3+}, Ba^{2+}, Be^{2+}, K^+, Na^+, Mg^{2+}, Sr^{2+}, Ca^{2+}, Li^+
Borderline between hard and soft acids	Sn^{2+}, Cd^{2+}, Co^{2+}, Cu^{2+}, Fe^{2+}, Fe^{3+}, Ni^{2+}, Pb^{2+}, Zn^{2+}, Mn^{2+}
Soft acids	Ag^+, Cu^+, Hg^{2+}, Au^+, CH_3Hg^+, Tl^{3+}, Tl^+, Bi^{3+}

Source: Framework for Metals Risk Assessment, Office of the Science Advisor, Risk Assessment Forum, EPA 120/R-07/001, March 2007.

The metal coordination cavities of metalloproteins match physical characteristics, such as ionic radius and geometry, of their endogenous essential metals. Replacement of coordinated essential metals by nonessential metals results in different stability or conformation such that the normal function is disrupted. This is an important principle in metals toxicology.

Biological Determinants of Metal Toxicity

In addition to the ionic states mentioned earlier, metals occur as elements and as organometallic compounds and adhere to air particulates. Each of these chemical forms is a unique exposure, kinetic and dynamic determinant. Another important component of pharmaco- and toxicokinetics of metals is the potential to bind to transport proteins and to storage proteins. For example, the metal-binding protein, metallothionein, sequesters both essential and toxic metals. Some

TABLE 17.2
Examples of Metal-Binding Storage and Transport Proteins

Metal-Binding Proteins	Metals	Function
Metallothionein	Silver, mercury, copper, bismuth, cadmium, lead, and zinc	Transportation
Transferrin	Iron, aluminum, and manganese	Transportation
Ferritin	Iron, cadmium, zinc, aluminum, and beryllium	Storage

common examples of metal-binding proteins are shown in Table 17.2. The location of these binding proteins defines the organ sensitivity for some metals. Further, the disruption of the normal function of metal binding is a common component of toxicological modes of action.

Chemical State and Toxicokinetics

Exposure to metals most commonly occurs via ingestion and inhalation. Exposure to metals bound to particulates occurs via inhalation. Exposure to elemental mercury can also occur via inhalation because it is volatile. Exposure to elemental metals and organometals can occur via the dermal route since they are uncharged and lipophilic. Ingestion is the common route of exposure for the water-soluble metal ions. Ingestion is also a common route of exposure for metals that bioaccumulate in the food chain. Some organometallic compounds of arsenic, lead, mercury, and tin are listed in Table 17.3. These compounds also have the potential to bioaccumulate.

Duration of exposure impacts both qualitative and quantitative toxicology. The amount of impact changes in exposure duration depends on the toxicokinetics of the metal. For example, daily doses of cadmium will accumulate in the kidneys and toxicity will develop. Conversely, essential elements are excreted so efficiently that daily intakes below the upper limits are tolerated over a lifetime. In this context, physiologically based pharmacokinetic (PBPK) modeling is a very useful tool for evaluating the toxicity of metals. Models integrate information on the effects of exposure routes, chemical forms, age at exposure, duration of exposure, and interindividual variation on absorption, distribution, excretion, and target organ sensitivity. Also useful are the data held in the National Library of Medicine's Comparative Toxicogenomics Database. This database links human diseases and data generated by high-throughput chemical screening experiments.[4] The database is designed to elucidate molecular mechanisms by which environmental chemicals affect humans. The increasing availability of information on modes of action increases the reliability of PBPK modeling.

TABLE 17.3
Examples of Organometallic Compounds

Metal	Organometallic Compound
Arsenic	Methylarsonic acid, dimethylarsenic acid, trimethylarsine, trimethylarsine oxide
Lead	Tetraethyllead, ethyltrimethyllead, dimethyldiethyllead
Mercury	Methylmercury, dimethylmercury
Tin	Tributyltin, tributyltin oxide

Chemical State and Toxicodynamics

The essentiality of some metals is related to the essential physiological role of the metal in, for example, enzymatic reactions, energy metabolism, and neurotransmission or as a structural component such as bone. The toxicity of a nonessential metal may be related to a dynamic substitution for an essential metal in these functional roles. Metal toxicity may also be related to its covalent or noncovalent reaction with enzymes, membranes, or DNA. Toxicity may also be induced by stimulating the production of active oxygen species.[5] Redox active metals like iron, chromium, manganese, nickel, copper, and cobalt can participate in redox cycling, producing reactive radicals such as the superoxide anion radical and nitric oxide. Exposure to metals with subsequent formation of reactive oxygen species can overwhelm the body's antioxidant protection and subsequently induces DNA damage, lipid peroxidation, and/or protein modification. Such chemical changes underlie numerous diseases, including cancer, cardiovascular disease, diabetes, atherosclerosis, neurological disorders, and chronic inflammation.

The toxicodynamics of lead, cadmium, and arsenic are thought not to involve redox cycling. Their toxic effects are primarily mediated through bonding to sulfhydryl groups of proteins and depletion of antioxidants such as glutathione. Zinc, also a nonredox cycling metal, is an essential component of numerous proteins involved in the defense against oxidative stress and is thought to play a neuroprotective role. In these contexts, zinc deficiency is potentially a special case among the essential metals.[6]

The variety of potential physiological effects makes it difficult to determine which action is responsible for toxicity and to identify the most sensitive target organ. In some cases, organs are most sensitive for a biochemical reason. For example, thallium interferes with energy metabolism, and the target organs are those with the highest energy requirement. In other cases, the most sensitive organ is simply the organ in which the accumulation is greatest. For example, cadmium and uranium accumulate in the kidney.

In summary, the fundamental determinants of metal toxicity are the strength with which a metal complexes with a ligand, the biological significance of the function of that molecular ligand, and the potential of a metal to participate in the generation of reactive oxygen species.

Treatment of Toxic Effects of Metals

Chelators are usually the preferred medical treatment of metal toxicity. Unlike many other drugs, chelators do not target specific effectors in a toxicity mode of action. Rather, metal chelation therapy relies on metal ions' reactivity to

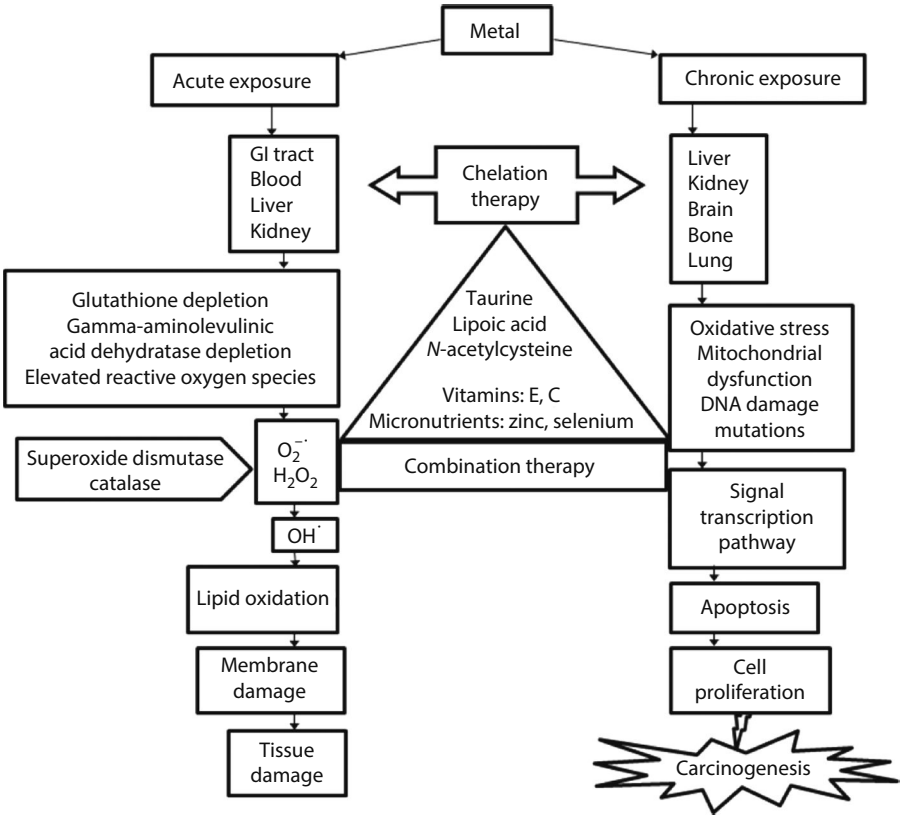

FIGURE 17.2 Strategies for the treatment of acute and chronic metal exposures. (From Flora, S.J.S. and Pachauri, V., *Int. J. Environ. Res. Public Health*, 7(7), 2745, 2010, an open source publication.)

form complex structures that are efficiently excreted. For example, 2,3-dimercaprol has long been the preferred therapy for lead or arsenic poisoning.

Serious side effects have been associated with therapy using some of the metal chelators. This has led to the development of less toxic analogues. Hydrophilic chelators like meso-2,3-dimercaptosuccinic acid effectively promote renal metal excretion. Yet, the trade-off for efficient excretion is that the hydrophilicity limits access to intracellular metals. Newer strategies attempt to address these limitations by combining structurally different chelating agents or by combining an antioxidant with a chelating agent (see Figure 17.2). Prevention of excessive exposure is still the best way to reduce the potential for metal toxicity.[7]

U.S. GOVERNMENT'S RISK MANAGEMENT PARADIGM FOR METALS

The four components of the U.S. federal risk assessment, (1) hazard identification, (2) exposure assessment, (3) dose–response, and (4) risk characterization, are applied to both essential and nonessential metals. The National Academy of Sciences' Food and Nutrition Board of the Institute of Medicine (IOM) evaluates each component during the development of dietary reference intake (DRI) values.[8] The U.S. Environmental Protection Agency's (EPA) 2007 document titled *Framework for Metals Risk Assessment* describes how metal-specific principles should be considered in each of the components of the health risk assessment process.[9]

Safety Evaluation and Hazard Identification

Since metals may be intended and unintended components of commercial products such as food, food supplements, drugs, cosmetics, pesticides, as well as environmental contaminants, they are subject to a multiplicity of U.S. statutes designed to advise on and/or to regulate exposure. The initial step of the U.S. government's risk assessment process is hazard identification. *Hazard identification* is used when the substance being evaluated is an environmental contaminant. *Safety evaluation* is more commonly used when the substance being evaluated is a drug or nutrient. The Food and Drug Administration (FDA) safety evaluation process[10] shares many of the components of other agencies' hazard identification framework.[11] Toxicity testing is frequently conducted as part of the hazard identification and safety evaluation processes. Guidelines for toxicity testing have been established by the U.S. National Toxicology Program (NTP)[12] and the International Conference on Harmonisation.[13]

Notable among the U.S. laws that dictate toxicity testing of metals to which humans are intentionally or unintentionally exposed are the Food, Drug, and Cosmetic Act (FDCA)

and the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). The federal agencies responsible for their implementation are the FDA and EPA, respectively. The FDCA dictates that safety evaluations be conducted before pharmaceuticals and food additives are approved. The FIFRA dictates that safety evaluations be conducted before pesticides are registered. In contrast, the Toxic Substances Control Act (TSCA), which controls new and existing industrial chemicals that are not regulated by other statutes, does not require manufacturers to conduct toxicity testing. However, under TSCA, the EPA may dictate that toxicity testing be conducted in response to environmental concerns. The EPA also is responsible for setting a tolerance for pesticide residues under the FDAC and has the authority to implement safety assessments in response to environmental concerns under other federal legislations, including the Safe Drinking Water Act (SDWA), Clean Water Act (CWA), Clean Air Act (CAA), Resource Conservation and Recovery Act (RCRA), Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), and the National Pollutant Discharge Elimination System (NPDES). The Occupational Safety and Health Administration (OSHA) and the National Institute of Occupational Safety and Health (NIOSH) have statutory authority to do hazard identifications under the Occupational Safety and Health Act. The NTP is charged with coordinating federal toxicity testing and developing testing methods.

Metals Exposure Assessment and Intake Assessments

Intake assessment is the phrase used when the exposure being assessed is to a drug or nutrient. *Exposure assessment* is used when the exposure being assessed is to an environmental contaminant. The goal of both types of assessments is to characterize the anticipated amount of the substance, duration of exposure, exposure routes, and, for environmental contaminants, the source.

Human activities such as mining and smelting, fossil fuel burning, and fertilizer-intensive agriculture have increased human exposure to metals far above those of the preindustrial environment. Some of the earliest information that linked adverse health effects to environmental exposure was the toxicity observed in workers who inhaled metals as fumes or dusts. Workers commonly displayed adverse lung effects that included mild self-limiting metal fume fever due to acute exposure. As a consequence of chronic exposures, these workers displayed benign pneumoconiosis or severe chronic obstructive lung disease.

Development of biomarkers as a tool to quantify environmental exposure to metals is a major advancement in the science of exposure assessment. Biomonitoring for blood and/or urine exposure biomarkers enables investigators to link exposure to health effects in the general population. Biomarkers provide more precise quantification of tissue exposure than is possible by traditional means, particularly for the general population that may be exposed by several routes, all of which may vary in time and location.

Several metals are considered to be carcinogenic by the inhalation route, but not by the oral route. This determination is based on the observations of (1) an increased rate of lung, but not other forms of cancer among workers and experimental animals exposed by inhalation and (2) no increase in cancer rate among experimental animals exposed orally. However, it cannot be ruled out that this may be due to a difference in potency that is related to the route of exposure. It could be argued that most mechanisms by which a metal is carcinogenic to lung tissue could operate in other tissues too. In these contexts, it is noteworthy that certain metals such as arsenic are known to be both lung carcinogens and systemic carcinogens.

Exposure to metals via the dermal route is less common than oral or inhalation exposures. A few metals are readily absorbed through the skin. A case of transdermal exposure to dimethylmercury that resulted in the death of a laboratory researcher was reported in 1999.[14] The parenteral route of exposure is also less common. However, cancers can be induced in experimental animals by implantation of solids. *Solid-state* carcinogenesis in humans is relevant in the context of implanted metal prosthetic devices.[15] Therefore, studies using parenteral routes of exposure are useful if the goal is to evaluate human parenteral exposure from medical procedures.

The age at which an individual is exposed is relevant to the exposure assessment. Infants and young children may be particularly sensitive to toxic effects of metals. They often absorb a greater fraction of ingested metals than older children or adults because some developing systems, particularly the nervous system, are more sensitive to toxic effects than mature systems. Additionally, the high rate of DNA replication during development is thought to make fetuses, infants, and children more sensitive than adults to genotoxicants. Further, the elderly may be more sensitive than healthy adults to the toxic effects of metals due to diminution of homeostatic and adaptive mechanisms. For these reasons, an uncertainty factor for individual variability may be applied when advisory, screening or regulatory levels of exposure are being calculated.

Metals Dose–Response Assessment

In 2009, the U.S. EPA revised its risk assessment process and, in response to recommendation from the National Academy of Sciences, made further improvement in 2011.[16] An EPA Integrated Risk Information System (IRIS) risk assessment is now a seven-step process that includes assembling a set of relevant data and surveying the data to determine the organ exhibiting an adverse effect at the lowest dose. The assessment of noncarcinogens identifies the no-observed-adverse-effect level (NOAEL) or the lowest-observed-adverse-effect level (LOAEL). Uncertainty factors are applied in the face of scientific uncertainties such as those encountered in extrapolating animal data to humans. The dose–response assessment of noncarcinogens yields a reference level below which no effects are expected to occur. A different process is used to quantify the cancer risk. It uses a weight-of-evidence approach to determine whether the element has the

potential to cause cancers in humans.[17] The cancer assessment assumes that any exposure carries some cancer risk and builds in safety margins by using the most sensitive sex/species/organ carcinogenic response and by using the upper 95th confidence limit of the dose–response slope. In 2005, the EPA revised its cancer classification scheme, and now it uses standard descriptors of conclusions rather than letter designations. However, many EPA IRIS profiles retain the EPA's 1986 letter classifications of cancer groups.

Risk Characterization of Essential Metals and Nonessential Metals

The characterization of risks related to exposure to either essential or nonessential metals integrates information about the hazards, exposures, and dose–response. The risk characterization provides an estimate of the likelihood that any of the identified adverse effects will occur. An integral component of risk characterization is definition of the assumptions and descriptions of the qualitative and quantitative uncertainties. Depending on the goals of the risk assessment, the foundation for establishing an advisory, screening, or regulatory level may be provided in the risk characterization.

U.S. GOVERNMENT'S RISK MANAGEMENT OF EXPOSURE TO METALS

The EPA, FDA, USDA (U.S. Department of Agriculture), NIH (National Institutes of Health), OSHA, and CDC (Centers for Disease Control and Prevention)/Agency for Toxic Substances and Disease Registry (ATSDR) are among the U.S. federal government agencies involved in managing metal-related risks. These agencies conduct research and evaluate research data to derive concentrations of essential and nonessential metals. These concentrations are used as advisory, screening, or regulatory levels. Only some of the concentrations derived by the EPA, ATSDR, NIOSH, and OSHA are cited in this chapter.[18–20] Other nations and international governmental and nongovernmental organizations also develop advisory, screening, and regulatory levels for metals. For example, the American Conference of Governmental Industrial Hygienists (ACGIH) publishes an annual list of chemicals for which the organization has derived, or is in the process of deriving, threshold limit values (TLVs). The reader is encouraged to become familiar with the various types and sources of advisory, screening, and regulatory levels. Some can be found in the ATSDR's toxicology profiles of the individual metals. The International Toxicity Estimates for Risk (ITER) database is also an excellent source for advisory, screening, and regulatory levels.[21]

Advisory Levels

Dietary Reference Intakes

In 2006, the Food and Nutrition Board of the IOM, in partnership with Health Canada, developed the latest DRIs.[8] The DRIs are advisory concentrations and include (1) an estimated average requirement (EAR), (2) a recommended dietary allowance (RDA), (3) an adequate intake (AI) level, where an RDA cannot be estimated, and (4) tolerable upper intake levels (ULs) above which risk of toxicity would increase. DRIs are revised and published periodically by the board through a process of convening expert committees to estimate the mean dietary requirement for the general population. DRIs are developed for specific female and male life stages, pregnant women, and lactating women. The dietary essential metals for which the board derived at least one of the DRIs include chromium, copper, iron, magnesium, manganese, molybdenum, potassium, sodium, and zinc. The board also derived ULs for three nonessential metals, boron, nickel, and vanadium, because they may be present in the diet. Arsenic and silicon may also be in the diet, but it was determined that there was insufficient data on which to derive upper limits for these elements. DRIs are not enforced as regulations. Rather, federal agencies use them to advise their constituents. The USDA uses DRIs to plan and assess the diets of healthy people and to advise the public.[22] The FDA uses DRIs as tools for advising industry on how to respond to product premarket requirements and labeling. The DRIs' relationships between levels of intake and risks of adverse effect are depicted graphically in Figure 17.3.

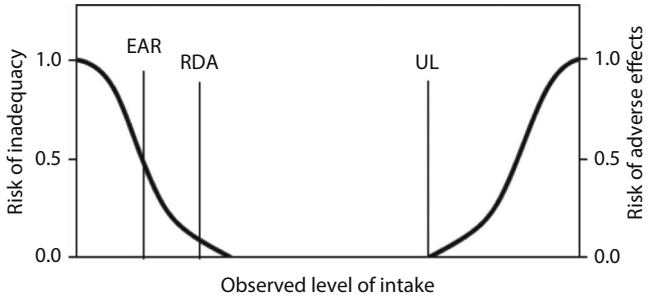

FIGURE 17.3 Relationships between levels of intake and risks of adverse effect: EAR—estimated average requirement; RDA—recommended dietary allowance; and UL—tolerable upper intake level. (Reprinted from *Dietary Reference Intakes: The Essential Guide to Nutrient Requirements*, National Academies Press, Washington, DC, 2006. With permission.)

Screening Levels

Minimal Risk Levels

The CDC, through the ATSDR, develops minimal risk levels (MRLs).[23] The MRL is defined as an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse, noncancer, health effects over a specified duration of exposure. MRLs serve as a screening tool to help public health professionals decide where to look more closely to evaluate risk of adverse health effects from exposure. The CDC's legislative authority to define MRLs is derived from the CERCLA. The derivation of a metal's MRL is published as a component in the agency's toxicological profile of that metal as an environmental contaminant.

Toxicity Values

EPA's "Framework for Metals Risk Assessment" was released in 2007. It outlines key principles about metals and describes how they should be considered in conducting human health and ecological risk assessments.[9] The EPA derives oral reference doses (RfDs) and inhalation reference concentrations (RfCs) based on nonneoplastic endpoints. These reference values are derived using a process similar to the ATSDR's process for developing MRLs. ATSDR's MRLs and EPA's reference values estimate an exposure to the human population, including susceptible subgroups, that is likely to be without an appreciable risk of adverse health effects over a lifetime. For cancer endpoints, the EPA derives a slope factor. The slope factor is defined as an upper bound, approximating a 95% confidence limit, on the increased cancer risk from a lifetime exposure to a substance.[24] Derivation of the three types of toxicity values is the responsibility of the EPA's IRIS, and the process is commonly referred to as the IRIS risk assessment process.[16] Toxicity values, and related documentation, are deposited in the IRIS database.[19]

Regional Screening Levels

The EPA uses toxicity values and default exposure assumptions to calculate regional screening levels (RSLs). RSLs are used on environmental cleanup sites to screen concentrations of contaminants as a first step in determining if cleanup is required. If a site has metal concentrations in the media, that is, air, soil, or water, that are higher than the corresponding RSLs, a quantitative site-specific risk assessment may be conducted. In this process, site-specific exposure parameters are developed and used with the IRIS toxicity values according to "Risk Assessment Guidelines for Superfund" to determine the need for, and extent of, remediation.[25]

Recommended Exposure Limits

NIOSH develops recommended exposure limits (RELs) for hazardous substances, including metals, in workplace air. A REL is a time-weighted average (TWA) concentration for up to a 10 h work shift during a 40 h work week. NIOSH also develops other advisory levels, for example, short-term exposure limits (STELs). The STEL is a 15 min TWA and an exposure that should not be exceeded at anytime during the work week. OSHA considers NIOSH advisory limits in developing the enforceable permissible exposure limit (PEL) regulation (see the following).

Threshold Limit Values

The ACGIH is a nongovernmental organization that publishes an annual list of chemicals for which the organization has derived, or is in the process of deriving, advisory levels such as the TLVs.[26] TLVs are TWA workplace air concentrations for a normal 8 h workday and a 40 h workweek. Like the NIOSH RELs, TLVs are advisory and not enforceable regulations.

Regulatory Levels

Permissible Exposure Limits

The OSHA has jurisdictions that include promulgation and enforcement of PELs. PELs are regulatory limits on the amount or concentration of a substance in the air. OSHA PELs are based on an 8 h TWA exposure. Approximately 500 PELs have been established.

Maximum Contaminant Levels

The National Primary Drinking Water Regulation gives the EPA the authority to derive maximum contaminant levels (MCLs) for hazardous substances including metals. MCLs are enforceable standards that apply to public water systems. MCLs protect drinking water quality by limiting the levels of specific contaminants that can adversely affect public health and are known or anticipated to occur in water.

ESSENTIAL METALS

Calcium

Sources of Calcium Exposure

Calcium is naturally occurring in calcite, gypsum, fluorspar, and dolomite rock formations. Calcium compounds may enter the atmosphere in the form of dust or other fine particles. Occupational exposure to calcium occurs via inhalation of particulate matter in settings where commercial products are made from these materials. The general population may be exposed to calcium via inhalation of ambient air, ingestion of food, and drinking water that contain calcium compounds or ions.[27]

Calcium Essentiality

Calcium is essential both for the physical structure of bone and for normal physiological functions such as nerve conduction, muscle contraction, blood clotting, regulation of vascular smooth muscle tone, the calcium (II) component of current across membranes, enzyme activation, and acetylcholine synthesis. Calcium (II) is also a second messenger.[28,29] The bodies of healthy men and women contain about 1300 and 1200 g of calcium, respectively. About 99% of calcium is located in bone and teeth with the remaining 1% in extracellular fluids, intracellular structures, and cell membranes. In adults, blood serum calcium ranges from 8.5 to 10.4 mg/dL with tight physiological controls. Decreased body calcium leads to loss of bone mineralization, reduction of bone strength, increased susceptibility to fractures, and may increase blood pressure, particularly among pregnant women. Calcium deficiency is also associated with convulsions and tetany.[30]

Adverse Health Effects of Calcium

Calcium is not a very toxic metal, but adverse effects may occur at intakes greater than the tolerable upper limit (UL). Intestinal absorption of calcium decreases as intake

increases. However, very large intakes of calcium can increase the calcium body burden as well as interfere with the absorption of magnesium,[31] zinc, and iron.[32] Very large chronic intakes are associated with hypercalcemia and/or hypercalciuria. Mild hypercalcemia leads to constipation, anorexia, nausea, and vomiting. With increased hypercalcemia, symptoms include confusion, delirium, stupor, and coma. Symptoms of chronic calcium excess include soft tissue calcification, kidney stones, and renal failure. Calcium supplementation is associated with a modest increased risk of cardiovascular events.[33,34]

Toxicokinetics of Calcium

Twenty to thirty percent of ingested calcium is absorbed in the small intestine depending on the presence of vitamin D metabolites, pH in lumen, and on dietary factors, such as calcium binding to fiber or phytates. Calcium absorption is increased when a calcium deficiency is present. Intracellular calcium overload has been proposed to result in a breakdown of high-energy phosphates.[30]

Toxicodynamics of Calcium

Calcium plays an important role in muscle contraction. Calcium release from the sarcoplasmic reticulum is initiated by an action potential. The intracellular calcium activates contraction by binding to troponin and preventing its inhibition of the actin–myosin interaction. As calcium is pumped back into the sarcoplasmic reticulum, troponin inhibition is restored and the muscle relaxes. Cytotoxic effects induced by toxic concentration of calcium also include blebbing of the plasma membrane, activation of calcium-dependent phospholipases, stimulation of calcium-dependent neutral proteases, and calcium-activated DNA fragmentation.[35]

Advisory, Screening, and Regulatory Levels of Calcium

In 2006, the Food and Nutrition Board released their new DRI for calcium.[8] An RDA was not derived for calcium. There was an insufficiency of data to derive the requisite EAR (Figure 17.3) from which an RDA is calculated. In these cases, an AI is usually developed (Table 17.4). The AI for calcium is 1300 mg/day for ages 9–18, 1000 mg/day for ages 19–50, and 1200 mg/day for ages greater than 51.[8] The intakes are designed to maximize calcium retention, promote bone strength, and prevent osteoporosis. The UL is 2.5 g/day. The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Chromium

Sources of Chromium Exposure

The chromium content of food varies widely and is thought to be influenced by geochemical factors.[36] Cereals are usually a significant source of chromium (III) in the diet, but content varies widely. Whole grains typically contain more chromium (III) than refined grains. Meats, poultry, and fish contribute one to two micrograms per serving. Some beers and wines also contain chromium.

Di- and trivalent chromium compounds occur in natural ores. Hexavalent chromium (VI, or chromate) rarely occurs naturally but is produced from anthropogenic sources. The production and use of chromium compounds in metal alloys, pigments, metal finishing, leather tanning, and wood preservation may result in their release to the environment. Chromium compounds are also released into the atmosphere attached to particulates via the combustion of natural gas, oil, and coal. Chromic acid mists are air contaminants in metallurgical operations. Dermal exposure to chromium occurs during the processing of cement.

Chromium Essentiality

Chromium (III) plays a role in the metabolism of glucose and lipids.[8] Dietary deficiency is associated with increased risk of diabetes and cardiovascular diseases.[37] However, there are insufficient data to determine with confidence the value of dietary chromium supplementation as a treatment for diabetes.[38] The typical daily food intake of chromium ranges from 25 to 224 mg with an average of 76 mg. Chromium picolinate is used as a dietary supplement.[27]

Toxicokinetics of Chromium

Only about 1% of oral intake of chromium (III) is absorbed in the gastrointestinal tract. Absorption of chromium (VI) is higher, 3%–6%.[39] Chromium that is absorbed gets excreted in the urine, and chromium not absorbed is excreted in the feces.[8] Chromium (VI) readily crosses cell membranes via ion transport systems. Once inside the cells, chromium (VI) gets reduced to chromium (III) by thiols. In the blood, chromium (III) is mainly bound to transferrin while chromium (VI) is taken up by erythrocytes. Chromium is stored in the liver, spleen, soft tissues, and bone. Chromium may be transferred to infants via breast milk.[27]

Adverse Health Effects of Chromium

Patients who did not receive chromium supplementation in their total parenteral nutrition displayed unexplained weight loss, peripheral neuropathy, impaired glucose transport, increased insulin requirement, elevated plasma free fatty acids, and low respiratory quotient.[8]

Chromium (III) has low toxicity due to poor membrane permeability. In contrast, chromium (VI) readily crosses cell membranes and is toxic due to its strong oxidation characteristics. Symptoms of acute toxicity include vomiting, gastrointestinal bleeding, and cardiovascular shock. Liver necrosis, kidney tubular necrosis, and damage to the blood-forming tissues can occur. Long-term occupational exposure to chromium is associated with either low molecular weight proteinuria or with elevated levels of the proteins normally found in the urine.[40] The endpoint on which the EPA's chromium acid mist RfC was calculated is nasal septal atrophy.[30,41]

TABLE 17.4
Examples of Advisory DRIs, Chronic Toxicity Values, and Cancer Classifications for Essential Metals

U.S. Dietary Reference Intake and Toxicity Values for Essential Metals

	Dietary Reference Intake[a]		Chronic Oral Toxicity		Chronic Inhalation Toxicity		Carcinogenicity	
Essential Metal	RDA or AI[b] (mg/d)	UL (mg/d)	RfD[c] (mg/kg/day)	MRL[d] (mg/kg/day)	RfC[c] (mg/m^3)	MRL[d] (mg/m^3)	IUR[c] per ($\mu g/m^3$)	Cancer Classification[e]
Potassium	4700	—	—	—	—	—	—	—
Calcium	1000	2500	—	—	—	—	—	—
Sodium	1500	2300	—	—	—	—	—	—

Chromium (VI)[g]	0.025 females	—	0.003	0.001	8×10^{-6}[j] 1×10^{-4}[k]	5×10^{-6}	1.2×10^{-2}	Inhalation: A Ingestion: D
Cobalt[h,l]	—	—	—	—	—	0.0001	—	Group 2B-IARC

Dashes indicate the absence of a value or that no information is available.

[a] The RDA values are specific for males and/or nonpregnant, nonlactating females, 31–50 years of age. The UL values are specific for males and/or nonpregnant, nonlactating females, 19–70 years of age.[8]

[b] Adequate intakes are shown in plain text, RDAs in bold. The value shown is for both males and females except where a gender-specific value is shown.

[c] *Source:* The RfDs, RfCs, and IUR are taken from the EPA's Integrated Risk Information System.[19]

[d] *Source:* The chronic MRLs are from the Agency for Toxic Substances and Disease Registry (ATSDR).[298]

[e] In 2005, the EPA revised its classification scheme such that now it uses standard descriptors of conclusions rather than letter designations. However, many EPA IRIS profiles retain the EPA's 1986 letter classifications of cancer groups: Group A (known human carcinogen) and Group D (not classifiable as to human carcinogenicity). The IARC Group 2B is classified as possibly carcinogenic to humans.

[f] The UL for magnesium represents intake from a pharmacological agent only and does not include intake from food and water.

[g] ATSDR has not derived a chronic MRL. The agency did derive an interim guidance value of 0.16 mg/kg/day that it recommended for use in ATSDR public health assessments.

[h] Copper, chromium (VI), and cobalt are undergoing EPA reassessment or review.[361]

[i] The RfD was derived for insoluble chromium (III) salts.

[j] The RfC was derived for chromic acid mists and soluble chromium (VI) aerosols.

[k] The RfC was derived for chromium (VI) particulates.

[l] Cobalt is an essential metal as it is a component of vitamin B_{12}. However, DRIs are not established for cobalt specifically.

Toxicodynamics of Chromium

There is evidence that chromium (III) potentiates the action of insulin. Although the mechanism of action is still being investigated, there is evidence that chromium (III) increases insulin binding to cells, increases insulin receptor number, and activates insulin receptor kinase.[42]

Hexavalent chromium is the most important valence from a toxicological perspective because it is readily absorbed by all tissues. Chromate is structurally similar to phosphate and sulfate and enters cells via the general anion channel protein.[40] Dermal exposure to potassium dichromate and other chromium compounds can lead to the development of a sensitization reaction. The resulting hypersensitivity results from chromium binding to proteins and becoming antigenic.

The carcinogenicity of chromium in the respiratory system was established in the late nineteenth century with the nasal tumors first described among Scottish chrome pigment workers.[43] Chromium-induced carcinogenesis has been reviewed in the recent literature.[40,44] The mechanism of action is believed to be from a direct modification of DNA.[45,46] After hexavalent chromate enters a cell, it is rapidly reduced to chromium (III). During the reduction process, unstable and reactive

intermediates, including chromium (IV), chromium (V), hydroxide, thiyl radicals ($RS^{\bullet}$) and organic radicals ($R^{\bullet}$), and active oxygen radicals are formed. It is believed that these moieties are responsible for chromium carcinogenicity.[44] Because chromium (VI) is readily absorbed by all tissues, one could postulate that chromium-induced cancers should be noted in other organs. Although the evidence is not as strong, exposure to hexavalent chromium is associated with an increased incidence of many types of cancers.[30,40]

Advisory, Screening, and Regulatory Levels of Chromium

In 2006, the Food and Nutrition Board developed gender-specific AI levels for chromium that are not valence-specific (see Table 17.4). In an earlier publication, board members found that there was not sufficient evidence to raise concern regarding the safety or toxicity of chromium picolinate for intake up to 1.6 mg of chromium picolinate/day, or 200 µg of chromium (III)/day, for 3–6 months.[47] This conclusion is consistent with the findings published in the 2000 ATSDR toxicological profile for chromium, and the Food and Nutrition Board did not derive an upper limit for chromium. The U.S. EPA places chromium (III) in Group D (not classifiable as to human carcinogenicity), and as of May 2012, an RfC was not developed. In contrast, the EPA determined that chromium (VI) is a Group A human carcinogen via inhalation. In 1998, the agency published an inhalation unit risk (IUR) value of 1.2×10^{-2}. The U.S. EPA's toxicity values and the ATSDR's MRLs for chromium are shown in Table 17.4. To protect workers, OSHA establishes regulatory levels, PELs, for air in occupational environments. In May 2012, the PELs for chromium (VI) and chromium (III) were 5×10^{-6} and 5×10^{-4} µg/m^3, respectively. Chromium is also regulated as a hazardous air pollutant under section 112 of the CAA. It is noteworthy that a bill to amend the SDWA to require a health advisory and drinking water standard for chromium (VI) was proposed in the U.S. House of Representatives, in March 2012. If implemented, an MCL for chromium (VI) would be the first valence-specific federal drinking water regulation. The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Cobalt

Sources of Cobalt Exposure

Cobalt is a hard silvery metal widely distributed in rocks and soils and always occurs with nickel and usually with arsenic.[48] It is primarily used in the production of superalloys, as a drier in paints, in magnets, and the production of prosthetic devices. Occupational exposure occurs in the hard metal industry, among cobalt blue dye plate painters and coal miners. This exposure is reflected in elevated levels of cobalt in tissues and body fluids. Exposure to cobalt also occurs via the use and implantation of medical devices. Patients with cobalt-containing metal-on-metal total hip replacements were found to have blood cobalt concentrations up to 50 times higher than controls.[49]

Cobalt Essentiality

Cobalt is an essential component of vitamin B_{12}, also called hydroxycobalamin, which is involved in intermediary metabolism, nucleic acid synthesis, and single-carbon metabolism. It is required to prevent macrocytic megaloblastic anemia, atrophic gastritis, achlorhydria, neurological degeneration, and dementia.[28] The only recognized requirement for cobalt is a component of vitamin B_{12}.

Adverse Health Effects of Cobalt Intoxication

Cobalt can cause allergic dermatitis and cross-reaction with nickel is frequent.[50] Inhalation exposure to cobalt alloyed to tungsten carbide is associated with hard metal disease, which is characterized by interstitial fibrosis and restrictive respiratory impairment.[51] Cobalt by itself has caused occupational asthma in diamond polishers, and the effect has been attributed to an immunologic mechanism with cobalt acting as a hapten.[52]

The carcinogenicity of cobalt is uncertain. Animal studies are positive only for subcutaneous, intramuscular, or intratracheal administration, but not for inhalation. The excess rates of lung cancer observed in men occupationally exposed to cobalt dust could be explained by simultaneous exposure to nickel, arsenic, and/or tobacco.[53] In a 2006 review of cobalt and its compounds, the International Agency for Research on Cancer (IARC) concluded that cobalt metal without tungsten carbide, cobalt sulfate, and other soluble cobalt (II) salts are possibly carcinogenic to humans (Group 2B).[54]

Toxicokinetics of Cobalt

For the general population, ingestion is the primary route of exposure to cobalt.[48] The absorption, distribution, and excretion of cobalt is not well studied. However, a biokinetic model, developed to estimate levels of cobalt in whole blood and urine resulting from ingestion of supplements, returned predicted levels consistent with those measured in humans following ingestion of known doses.[55]

Toxicodynamics of Cobalt

Cobalt-caused occupational asthma is attributed to an immunologic mechanism with cobalt acting as a hapten.[52] Inhalation exposure to cobalt is also associated with hard metal disease. The toxic mechanism of hard metal particles is thought to involve both cobalt sensitivity and the generation of oxygen radicals by the carbide particles.[51,56] More recent data indicate hard metal dust is genotoxic both in *in vitro* and *in vivo* systems.[57] Based on these findings, and evidence that the production of active oxygen species and inhibition of DNA repair are the likely modes of action, IARC classifies cobalt as a Group 2B possible human carcinogen.[21,27]

Advisory, Screening, and Regulatory Levels of Cobalt

Although cobalt is an essential metal, the Food and Nutrition Board has not developed DRI values for cobalt. Rather, the

requirement for cobalt is implicit in the recommendation for vitamin B_{12} intake. The U.S. EPA has not derived toxicity values for cobalt. However, the ATSDR established an MRL for chronic inhalation toxicity, 0.1 μg/m^3 (Table 17.4). OSHA's regulatory PEL for cobalt metal dust and fume is 0.1 mg/m^3 whereas the NIOSH advisory REL is 0.05 mg/m^3. The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Copper

Sources of Copper Exposure

Copper occurs naturally as free metal and occurs in compounds in (I) or (II) valence states. Copper enters the environment by discharge from steel and pulp mills and erosion of natural deposits. The ingestion of copper in the diet is the primary source for copper intake. Occupational exposure is primarily due to inhalation of particulates containing copper present in smelting, welding, or other metal works.[27]

Copper Essentiality

Copper is incorporated into several enzymes involved in (1) hemoglobin formation, (2) carbohydrate metabolism, (3) catecholamine biosynthesis, and (4) cross-linking of collagen, elastin, and hair keratin.[58] These enzymes include cytochrome C oxidase, dopamine β-hydroxylase, ascorbic acid oxidase, and superoxide dismutase. Cytochrome C oxidase is important in energy production because it catalyzes a key reaction. Superoxide dismutase is present in the liver, lung, blood, and brain where it plays a protective role in reducing superoxide radicals to hydrogen peroxide. Copper deficiency can be a result of malnutrition or excess intake of zinc. Clinical manifestations of copper deficiency include macrocytic anemia, neutropenia, and bone abnormalities.[27]

Adverse Health Effects of Copper

Copper toxicity from ingestion is characterized by vomiting, diarrhea, nausea, abdominal pain, hemolytic anemia, hepatic and renal necrosis, and death. Industrial exposure may occur to copper fumes, resulting in metal fume fever with dyspnea, chills, headache, and nausea.[59] Dermal irritation and contact allergic dermatitis have been associated with copper jewelry, intrauterine contraceptive devices, and occupational exposure to electroplating and copper-containing agricultural products.[60]

Toxicokinetics of Copper

Copper is readily absorbed following oral ingestion, but homeostatic mechanisms limit further intake once requirements are met. Newly absorbed copper is transported to body tissues primarily by albumin, transcuprein, and ceruloplasmin. Copper can be dermally absorbed from copper-containing topical products. Copper is deposited mainly in hepatocytes with lesser amounts in the kidney.[61] Copper is either active or in transit with little or no excess copper being normally stored.[62] Biliary excretion is the major route with small amounts excreted in the urine. Considering these homeostatic mechanisms following oral intake, absorption through the inhalation or dermal routes may allow toxic levels to pass unimpeded into the blood.[63]

Toxicodynamics of Copper

The role of copper in normal immune response is beginning to be elucidated. There is evidence that the mode of action for impaired DNA synthesis, observed in T lymphocyte from copper-deficient lab animals, involves limitation of interleukin 2 activity.[64] There are two well-characterized genetic disorders that provide information on the role of copper transport proteins in disease mechanisms. Wilson's disease is due to an autosomal recessive miscoding of the gene *ATP7B*.[65] Defects in this gene are associated with accumulation of copper in the liver and brain. In addition, there is decreased concentration of plasma ceruloplasmin, impaired biliary copper excretion, and hypercupremia, resulting in hepatic and renal lesions and hemolytic anemia.[58] Menkes' disease is a systemic lethal disorder characterized by neurodegenerative symptoms and connective tissue manifestations. It is an X-linked recessive inherited disease that is attributable to defects in the *ATP7A* gene, which codes for a copper transport protein.[66] In Menkes' disease, copper transport from the intestine to the portal vein and transport into the brain is blocked. Copper accumulates in red blood cells while there is systemic copper deficiency.

Advisory, Screening, and Regulatory Levels of Copper

The RDA and upper limit for copper intake, for a selected segment of the adult population, are provided in Table 17.4. For adult men and nonpregnant women aged 19–70 years, the RDA is 900 μg/day and the UL is 10 mg/day. The EPA's MCL for drinking water is 1.3 mg/L.[67] The NIOSH REL and OSHA PEL for copper fume are each 0.1 mg/m^3 and for copper dusts and mists, 1 mg/m^3.[20] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Iron

Sources of Iron Exposure

Iron is a silver white solid metal found in the natural environment mainly in combination with other elements such as oxides, carbonates, sulfides, and silicates. It is the second most abundant metal and the fourth most abundant element in the earth's crust. The use of iron in agriculture, metallurgy, drugs, or other consumer products results in its release to the environment. The mining and processing of iron ores also may result in the release of iron compounds to the environment. Dietary iron is available as either heme or nonheme iron. Heme iron is found in meats and is relatively

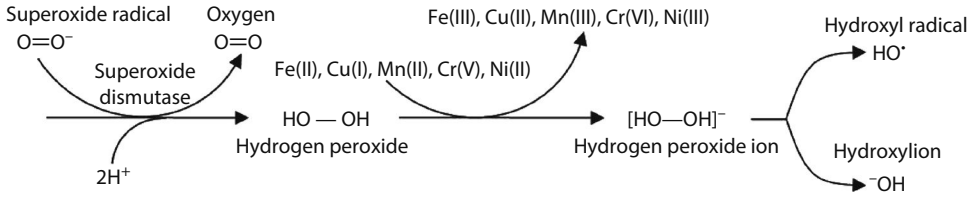

FIGURE 17.4 Conversion of superoxide anion radical to hydrogen peroxide can occur spontaneously, or it can be catalyzed by superoxide dismutase. Cleavage of hydrogen peroxide to hydroxyl radical and hydroxyl ion is catalyzed by the metal ions shown and is called the Fenton reaction.

well-absorbed compared with nonheme iron, which is also found in meats, grains, and vegetables.[30]

Iron Essentiality

Iron exists in two stable oxidation states, oxidized ferric (III) and reduced ferrous (II), which accounts for its essentiality as a trace element and its crucial role in the oxygen and electron transport reactions of living cells. Early symptoms of iron deficiency are nonspecific and include fatigue and weakness. This progresses to iron deficiency anemia characterized by microcytic hypochromic anemia. These symptoms resolve after administration of iron.[30]

Adverse Health Effects of Iron

Acute iron poisoning is the most common fatal poisoning in children reported to poison control centers in the United States.[68] Acute iron poisoning via the oral route is characterized by four distinct clinical stages, but individual patients do not always demonstrate each stage.[69] Stage I occurs 0.5–2 h after ingestion and is characterized by the onset of acute gastrointestinal symptoms including vomiting and diarrhea, but central nervous system (CNS) symptoms such as lethargy and coma may be present in severe cases. Stage II occurs 6–24 h after ingestion, and the victim may be asymptomatic or appear to have improved. Stage III occurs 12–48 h after ingestion and is characterized by gastrointestinal perforation, coma, convulsions, cardiovascular collapse, hepatic and renal failure, and metabolic acidosis. Stage IV occurs three to four weeks after ingestion with the appearance of gastrointestinal scarring.

Chronic oral iron intoxication leads to hemosiderosis, a condition in which there is a generalized increase in the iron content in the body tissues, particularly the liver and spleen. Oxidative damage associated with elevated brain iron has been suggested as a risk factor for early age onset of neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease.[70] Increased iron stores have been reported to contribute to the development of noninsulin-dependent diabetes.[71] Also, hepatotoxicity is typically seen in patients with chronic iron overload with progression from portal fibrosis to cirrhosis.[72]

Toxicokinetics of Iron

Intestinal absorption of iron depends on iron status. Ten percent of the total (heme plus nonheme) is absorbed when the iron status is normal, but up to 20% can be absorbed in deficiency states. Iron is lost through the shedding of cells, sweat, nails, hair, blood loss, menstruation, and in the urine. Humans are unable to eliminate iron as efficiently as it is absorbed. Thus, the body regulates iron stores by limiting absorption.[73] Dietary calcium phosphate, bran, phytic acid, and plant polyphenols inhibit absorption of nonheme iron. Divalent iron is taken up by intestinal mucosa and converted to the trivalent form. The trivalent form is bound to transferrin.[59] Iron is transported to the liver or spleen bound to transferrin and stored as ferritin, which has a large iron storage capacity and prevents iron from participating in the Fenton reaction (Figure 17.4). Of the typical 4 g of body iron stores found in adults, 66% is bound as hemoglobin, 10% in myoglobin, a minute amount in iron-containing enzymes, and the rest as intracellular storage proteins, ferritin and hemosiderin.

Toxicodynamics of Iron

Ferrous iron catalyzes lipid peroxidation. This can cause disruption of mitochondrial membranes and the Krebs cycle. The subsequent accumulation of lactic acid from anaerobic metabolism may result in severe metabolic acidosis. Iron also shunts electrons from the electron transport system by acting as an electron sink. The result is also metabolic acidosis. Free iron is an oxygen-reactive substance, is highly toxic to cells, and enhances the formation of free radicals and peroxidation of membrane lipids.[74] Free radical stress and lipid peroxidation have both been suggested as factors in the etiology of diabetes.[75]

Advisory, Screening, and Regulatory Levels of Iron

The RDA and UL for iron for men and nonpregnant women aged 19–70 are shown in Table 17.4.[8] The U.S. EPA has not derived toxicity values and the ATSDR has not established chronic MRLs for iron. The NIOSH REL and OSHA PEL for iron oxide dust and fume are 5 and 10 mg/m^3, respectively. NIOSH also established an REL for soluble iron salts, 1 mg/m^3. The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Magnesium

Sources of Magnesium Exposure

Magnesium is widely distributed in the environment in the form of rocks and minerals such as olivine, montmorillonite, and dolomite. Magnesium salts are also a component of sea salt and are released to the air as sea spray. Commercial

uses of magnesium salts include lightweight metal alloys, fertilizer, construction materials, pharmaceuticals, cosmetics, and chemical intermediates. Magnesium is released to the environment by erosion and in industrial waste streams. Occupational exposure may occur through inhalation and dermal contact with magnesium compound at workplaces where magnesium-containing products are produced or used. Environmental monitoring data indicate that the general public is exposed to magnesium via inhalation of ambient air, ingestion of food and drinking water, and by dermal contact.[27]

Magnesium Essentiality

Magnesium is essential to a large number of biochemical and physiological processes, including neuromuscular conduction in skeletal and cardiac muscles.[59] It is also an important structural component of bone.[8] Magnesium deficiency may cause metabolic changes that contribute to heart attacks and strokes and may be a risk factor for postmenopausal osteoporosis. Magnesium deficiency also results in reduced levels of potassium and calcium, as well as symptoms of nausea, muscle weakness, irritability, and mental confusion.[76] Magnesium deficiency is associated with alcoholism. Alcoholics are more likely to experience dietary insufficiency than members of the general population. They excrete more magnesium in their urine and, with cirrhosis of the liver, there may be less albumin available to bind magnesium.[77]

Adverse Health Effects of Magnesium

Oral exposure to magnesium is not toxic except in individuals with impaired renal function. These individuals may experience nausea, vomiting, and hypotension, followed by central nervous system (CNS) depression with a drop in blood pressure and respiratory paralysis.[8] Inhalation exposure to magnesium oxide can cause metal fume fever.[59]

Toxicokinetics of Magnesium

Magnesium is absorbed mainly in the small intestine. Calcium and magnesium are competitive with respect to their absorption sites, and excess calcium may partially inhibit the absorption of magnesium. Plasma concentrations of magnesium are regulated within a narrow range (0.65–1.0 mM), primarily by adjustments in the reabsorption of filterable magnesium in the loop of Henle, but also by the passive buffering by bone magnesium.[8] In blood plasma, about 65% is in the ionic form while the remainder is bound to protein. The former is what appears in the glomerular filtrate. Excretion also occurs in the feces, sweat, and milk.

Toxicodynamics of Magnesium

Magnesium is a cofactor of many enzymes involved in intermediary metabolism. In the glycolytic cycle that converts glucose to pyruvate, there are seven enzymes that require magnesium (II). Magnesium is also involved in the citric acid cycle and in the beta-oxidation of fatty acids.[78] The neurological effects of magnesium toxicity include synaptic blockage and impaired reuptake of neurotransmitters. Magnesium-mediated neuromuscular toxicity involves decreases in acetylcholine release from the prejunctional motor neuron and decreases motor endplate sensitivity of acetylcholine.[27,30]

Advisory, Screening, and Regulatory Levels of Magnesium

The RDA and UL for magnesium are shown in Table 17.4. The EPA has not derived toxicity values for magnesium nor has the ATSDR derived chronic MRLs. NIOSH has not established an REL for magnesium oxide fume. The OSHA PEL is 15 mg/m^3. RELs and PELs are developed for total and respirable magnesium carbonite.[20] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Manganese

Sources of Manganese Exposure

Manganese is a silver-gray-colored soft metal, which occurs in ores mainly as oxides.[59] Manganese and its compounds are used in numerous products and applications, including iron and steel alloys, dry cell batteries, paints, inks, fertilizers, and fungicides.[79] Manganese cyclopentadienyl tricarbonyl (MMT) is a gasoline octane enhancer in use since 1970. The major combustion products of MMT are manganese particulates of manganese phosphate with some sulfates and a small amount of oxides. Manganese occurs in human diets that include meats, poultry, nuts, grains, green leafy vegetables, and tea.[27]

Manganese Essentiality

Manganese is an essential trace metal that is a component of several mitochondrial enzymes, pyruvate carboxylase, and superoxide dismutase. It activates a wide variety of enzymes, including decarboxylases, transferases, and hydrolases. Although manganese deficiency has not been observed in the human population, suboptimal manganese intake may be a concern because in animals, manganese deficiency can cause impaired growth, skeletal abnormalities, and altered metabolism of carbohydrates and lipids.[80]

Adverse Health Effects of Manganese

The primary toxic effect of occupational inhalation exposure is neurological damage.[81] However, inhalation exposure to manganese can also affect the lung directly, causing metal fume fever, pneumonitis, chronic obstructive lung disease, and pneumonia.[80] The neurological effects of inhalation of manganese dusts, termed manganism, typically begin with weakness and lethargy and may progress to disturbances in speech and gait, a masklike face, tremor, and possibly hallucinations and psychosis. Symptoms may resemble Parkinson's disease, but there is only minimal response to L-dopa therapy.[81]

Toxicokinetics of Manganese

Occupational inhalation exposure is the primary route for manganese toxicity. Manganese applied to the nasal cavity in rats is taken up in the olfactory receptor cells and transported

along the primary neurons to the olfactory bulb, with subsequent migration into most parts of the brain. This route circumvents the blood–brain barrier.[82,83] Only between 3% and 10% of dietary manganese is absorbed in normal adults, and total body stores are controlled by a complex homeostatic mechanism regulating absorption and excretion. Calcium, iron deficiencies, age, and other factors may increase manganese absorption.[80]

Toxicodynamics of Manganese

The pathobiochemical aspects of manganism involve the striatum and globus pallidus. Cell damage may be due to the autooxidation of dopamine with the formation of free radicals.[84]

Advisory, Screening, and Regulatory Levels of Manganese

The AI, UL, RfD, RfC, and chronic MRLs for manganese are shown in Table 17.4. The EPA places manganese in Group D, not classifiable as to human carcinogenicity. This classification is based on inadequate evidence in humans and animals.[19] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Molybdenum

Sources of Molybdenum Exposure

The primary molybdenum-containing ore is molybdenite (MoS_2), with minor ores being powellite ($CaMoO_4$) and wulfenite ($PbMoO_4$). Metallic molybdenum is used in a number of important applications, such as in high temperature and tool steel alloys, and in missile and aircraft parts. Molybdenum disulfide is used as a dry lubricant or as a component in lubricants. Dental technicians exposed to dust of vitallium alloy, which contains chromium, cobalt, and molybdenum, can develop pneumoconiosis that is clearly different from hard metal lung disease associated with cobalt exposure. Occupational exposure to molybdenum compounds may also occur through inhalation and dermal contact at workplaces where molybdenum compounds are used. As molybdenum occurs naturally in the environment, the general public can be exposed to small amounts of molybdenum via inhalation and ingestion of food and drinking water.[27] Dietary sources of molybdenum include legumes, grains, and nuts. The content of molybdenum in these foods is highly dependent on the soil content in which they were grown. Animal products, fruits, and vegetables are generally low in molybdenum.[8]

Molybdenum Essentiality

Molybdenum is a cofactor of several enzymes, including aldehyde oxidase, xanthine oxidase, and sulfite oxidase. In this context, molybdenum functions in the catabolism of purines and pyrimidines and sulfur amino acids. The essentiality of molybdenum was established based on a genetic defect that prevents sulfite oxidase synthesis and leads to severe neurological damage and early death. A molybdenum deficiency syndrome has not been observed in humans or animals. The UL for molybdenum is based on impaired reproduction and growth in animals.[8]

Adverse Health Effects of Molybdenum

The oral toxicity of molybdenum is low presumably because it is rapidly excreted in the urine at relatively high levels of intake.[8] The acute oral toxicity of high concentrations of some molybdenum compounds is related to their solubility. In animal studies, acutely toxic oral doses of molybdenum resulted in severe gastrointestinal irritation with diarrhea, coma, and death from cardiac failure. Animal subchronic and chronic oral exposures can result in growth retardation, anemia, hypothyroidism, bone deformities, sterility, liver and kidney abnormalities, and death.[27]

In studies conducted in regions of high molybdenum soil concentrations, human residents were found to have elevated concentrations of uric acid in the blood and urine, increased blood xanthine oxidase activity, and gout-like symptoms. Studies of workers chronically exposed to molybdenum showed increased incidences of elevated levels of molybdenum in blood plasma and urine and high levels of ceruloplasmin and uric acid in blood serum. Occupational exposure to molybdenum may also result in increased serum bilirubin levels and decreased blood IgA/IgG ratios due to a rise in alpha-immunoglobulins. Pulmonary effects of chronic exposure are reported in one study of 3 of 19 workers. The findings were indicative of pneumoconiosis.[27]

Toxicokinetics of Molybdenum

The oral absorption of molybdenum is thought to be passive rather than actively mediated because absorption is very efficient over a wide range of intake levels. It is thought that molybdenum is transported in the plasma by alpha-2-macroglobulin and that up to 97% of molybdenum in erythrocytes is protein-bound. Urinary excretion is the primary pathway of elimination and the amount eliminated is directly related to the dietary intake.[8]

Toxicodynamics of Molybdenum

Little is known about the mechanism of action of molybdenum toxicity. However, in animals, excessive intake of molybdenum causes a physiological copper deficiency. It is suggested that the mechanism may involve formation of a copper–tetrathiomolybdate complex in the reductive environment of the gastrointestinal tract. It is believed that this might reduce the biological utility of copper.[85]

Advisory, Screening, and Regulatory Levels for Molybdenum

The RDA, UL, and RfD for molybdenum are shown in Table 17.4. The ATSDR has not established chronic MRLs and the EPA has not established an RfC or IUR level. Neither the EPA nor IARC provides information on the cancer categorization of molybdenum. The OSHA PEL for molybdenum metal is 15 mg/m^3. The PEL for soluble compounds of molybdenum is 5 mg/m^3. NIOSH has not established an REL for either form of molybdenum. The advisory, screening, and

regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Potassium

Sources of Potassium Exposure

Elemental potassium is a highly reactive soft metal with a silver-colored appearance. Elemental potassium is not found in nature. However, potassium compounds are common in the earth's crust. Dietary sources of potassium as bicarbonate precursors include leafy greens, root vegetables, and vine produce such as tomatoes, cucumbers, and pumpkins. Meat, milk, and grains contain more.[27]

Potassium Essentiality

Potassium is the principal cation of intracellular fluid, accumulating to a concentration about 30 times higher than in plasma. Potassium in plasma is involved in nerve transmission, muscle contraction, and blood pressure homeostasis. The gastrointestinal absorption of potassium is nearly complete. Plasma concentrations are kept within a narrow range by regulation of urinary excretion, and by depletion of body stores in cases of low potassium intake. Dietary potassium deficiency is rare. Moderate potassium deficiency is characterized by increased blood pressure, increased risk of kidney stones, increased salt sensitivity, and possibly increased risk of stroke. Frank hypokalemia results in cardiac arrhythmias, muscle weakness, and glucose intolerance.[8]

Adverse Health Effects of Potassium

Dermal and ocular thermal burns and necrosis due to the formation of potassium hydroxide are the primary effects following exposure to elemental potassium. Dietary potassium is not toxic in healthy individuals if sufficient water is ingested and renal function is adequate to maintain homeostasis. Cardiac and related effects are the most important risks of supplemental potassium chloride overdose. The symptoms may range from nausea, vomiting, and diarrhea with abdominal discomfort to weakness, muscle cramps, ascending paralysis, dysarthria, hypotension, and arrhythmias.[27]

Toxicokinetics of Potassium

Healthy individuals absorb about 85% of their dietary potassium. The steady-state correlation between intake and urinary excretion is high with about 77%–90% of injected potassium being excreted in the urine. The rest is excreted in the feces and sweat.[27]

Toxicodynamics of Potassium

The high intracellular concentrations of potassium are maintained by the sodium–potassium ATPase pump. Changes in plasma insulin can affect extracellular and plasma potassium concentrations because insulin stimulates the pump. Potassium appears to moderate the effect of increased sodium intake on elevating blood pressure, probably by affecting renal sodium excretion.[86]

Advisory, Screening, and Regulatory Levels for Potassium

The AI for potassium is 4.7 g/day for both adult men and women (Table 17.4). The EPA has not derived toxicity values for potassium and the ATSDR has not derived chronic MRLs. Neither the EPA nor IARC provides information on the cancer categorization of potassium. OSHA has not established a PEL for potassium or potassium compounds other than potassium cyanide. The NIOSH ceiling REL for potassium hydroxide (synonymous to caustic potash and lye) is 2 mg/m^3.[20] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Sodium

Sources of Sodium Exposure

Sodium is a highly reactive soft metal with a silver appearance that is not found in the elemental form in nature. Sodium compounds are present in seawater and are ubiquitous in nature in the form of halides, silicates, and carbonates. Sodium is typically consumed as sodium chloride, which accounts for about 90% of total dietary intake.[27]

Sodium Essentiality

Sodium is the principal cation of extracellular fluid and the primary regulator of extracellular fluid volume. Sodium also regulates osmolarity, acid–base balance, and membrane potential and participates in active transport across cell membranes. Sodium deficiency is very uncommon but may occur after heavy and prolonged sweating, chronic diarrhea, or renal disease and constitutes a medical emergency.

Adverse Health Effects of Sodium

Dietary sodium is not toxic if sufficient water is ingested and renal function is adequate to maintain homeostasis. Lifelong excess intake of sodium may predispose sensitive individuals to hypertension, and individuals diagnosed with high blood pressure are commonly advised to limit sodium intake to 1–2 g/day or less.[86] Dermal and ocular thermal burns and necrosis due to the formation of sodium hydroxide are the primary effects following exposure to elemental sodium.

Toxicokinetics of Sodium

Sodium is typically consumed as sodium chloride and is 98% absorbed in the small intestine. Renal excretion of sodium maintains homeostasis, over a wide range of intakes and losses, via aldosterone control of tubular excretion.[30]

Toxicodynamics of Sodium

Sodium regulates extracellular fluid and plasma volumes and functions to regulate the electrical potential and active transport across the cell's plasma membrane. The rennin-angiotensin-aldosterone axis regulates blood volume and

pressure by promoting sodium retention and reabsorption in the kidneys. These effects are counterbalanced by atrial natriuretic peptide, which functions to reduce blood volume and pressure via increased glomerular filtration with increased sodium excretion.[30]

Advisory, Screening, and Regulatory Levels for Sodium

The dietary AI and UL for sodium are shown in Table 17.4. The UL is based on sodium's effect on blood pressure. The Food and Nutrition Board acknowledges that a lower UL may be appropriate for sensitive individuals such as older individual, African Americans, and individual with hypertension. The EPA has not derived toxicity values for sodium and the ATSDR has not derived chronic MRLs. Neither the EPA nor IARC provides information on the cancer categorization of potassium. OSHA has not established a PEL for sodium bisulfite; the NIOSH REL is 5 mg/m^3. The OSHA PEL and NIOSH REL for sodium hydroxide (caustic soda) are both 2 mg/m^3.[20] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Zinc

Sources of Zinc Exposure

Zinc is found in almost all minerals in the earth's crust. Zinc is a bluish-white, soft metal extracted from ore and is used in alloys, for galvanizing iron to prevent corrosion and oxidation, and in cosmetics, pharmaceuticals, and dry cell batteries.[87] At temperatures approaching its boiling point, zinc volatilizes and oxidizes to the white fume of zinc oxide. Dietary sources of zinc include red meat, some seafood, whole grains, and fortified breakfast cereals.[27]

Zinc Essentiality

Zinc is an essential trace element and is a required component of many enzymes. Zinc is stored in bone and muscle but is not readily released from these stores during deficiency. The enzymes in which zinc is a catalytic component include RNA polymerase, alcohol dehydrogenase, and alkaline phosphatase. In other enzymes, such as copper-zinc superoxide dismutase, zinc is a structural component. Zinc is also a structural component in some proteins involved in gene regulation. These proteins include the retinoic acid receptor and vitamin D receptor. Zinc may also influence apoptosis and protein kinase C activity.[8] Zinc is involved in many metabolic functions. Symptoms of mild deficiency are diverse and inconsistent. Severe zinc deficiency causes hypogonadism and dwarfism, which are alleviated with zinc supplementation. While the signs and symptoms of zinc deficiency include loss of appetite, growth retardation, and slow wound healing, no single enzyme function has been identified as associated with these signs of zinc deficiency. Low zinc status is observed in 30%–50% of people with alcoholism.[8]

Adverse Health Effects of Zinc

Inhalation exposure to zinc oxide fume can cause metal fume fever. Zinc chloride fume is a corrosive material, which has caused chemical pneumonitis, alveolar and bronchial obliteration, and death. Zinc has low human toxicity by the oral route, but high levels can cause gastrointestinal distress.[88] Long-term oral intakes of zinc at levels of 18.5–25 mg/day can interfere with copper absorption, and intakes 10–30 times the RDA can impair immune responses and decrease serum high-density lipoprotein.[8]

Toxicokinetics of Zinc

Zinc compounds are absorbed orally and excreted primarily in the feces. Plasma zinc concentrations remain relatively stable unless low or high intakes occur over prolonged periods. Gastrointestinal absorption of zinc is higher when body stores are lower and is also higher from more refined diets. Zinc is absorbed via both carrier-mediated and passive diffusion. The carrier-mediated absorption mechanism may be saturable. Intestinal metallothionein can inhibit zinc absorption by competing with the carrier-mediated transport.[27] Absorbed zinc is bound to albumin and transferred to the intestine via the portal system. Most of the body's zinc is stored in muscle and bone with about 0.1% of total zinc present in the plasma. Excretion is primarily in the feces with less than 10% excreted in the urine.[27]

Toxicodynamics of Zinc

Zinc has catalytic, structural, and regulatory biological functions. For example, zinc is an essential component of numerous proteins involved in the defense against oxidative stress. It has been shown that depletion of zinc may enhance DNA damage via impairments of DNA repair mechanisms.[6]

Advisory, Screening, and Regulatory Levels for Zinc

The RDA, UL, RfD, and oral chronic MRL for zinc are shown in Table 17.4. The critical effect on which the UL is based is zinc's effect on copper metabolism, that is, reduced copper status. The RfC, IUR, and chronic inhalation MRL have not been derived for zinc. Neither the EPA nor IARC has developed a cancer classification for zinc. The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

HIGHLY TOXIC METALS

The cancer classifications and some of the available quantitative toxicity advisory, screening, and regulatory values for the highly toxic metals, lead, cadmium, mercury, and arsenic, are provided in Table 17.5. These values are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

TABLE 17.5
Examples of Advisory Chronic Toxicity Values and Cancer Classifications for Highly Toxic Metals

U.S. Toxicity Values for Highly Toxic Metals

[a] Many IRIS profiles retain the EPA's 1986 letter classifications of cancer groups. These include the following: Group A (carcinogenic to humans), Group B1 (probable human carcinogen [limited human data]), Group B2 (probably carcinogenic to humans [inadequate human data]), Group C (possibly carcinogenic to humans), Group D (not classifiable as to human carcinogenicity), and Group E (evidence of noncarcinogenicity for humans). In 2005, the EPA revised its classification scheme such that now it uses standard descriptors of conclusions rather than letter designations. IARC classifications are as follows: Group 1 (carcinogenic to humans), Group 2A (probably carcinogenic to humans), Group 2B (possibly carcinogenic to humans), Group 3 (not classifiable as to its carcinogenicity to humans), and Group 4 (probably not carcinogenic to humans).

Arsenic

Sources of Arsenic Exposure

Arsenic is a component of copper, cobalt, and nickel ores; and arsenic trioxide, As_2O_3, is a toxicologically significant form that is released into the environment by smelting. Other anthropogenic sources include wood preservatives and some agricultural chemicals. Arsenic is also used to make gallium arsenide for light-emitting diodes, lasers, and solar devices and as a doping agent.[27] Arsine, AsH_3, is a gaseous form of arsenic that is formed whenever arsenic is in the presence of hydrogen. For example, it can be generated in metal tanks storing acids that contain arsenic impurities.

By modeling data from the National Health and Nutrition Examination Survey, investigators defined a mean total arsenic exposure from food. That value, 0.38 μg/kg/day, is approximately 14 times higher than the mean arsenic exposures from the drinking water. The mean inorganic arsenic exposure from food is 0.05 μg/kg/day (1.96 μg/day), which is approximately two times higher than the mean inorganic arsenic exposures from the drinking water. The modeled exposure and dose estimates matched well with the duplicate diet data and measured arsenic biomarkers. The major food contributors to inorganic exposure were vegetables (24%); fruit juices and fruits (18%); rice (17%); beer and wine (12%); and flour, corn, and wheat (11%). Approximately 10% of total arsenic exposure from foods is the more toxic inorganic arsenic.[89–91]

Adverse Health Effects of Arsenic

Acute ingestion of several hundred milligrams or more of a soluble arsenic compound, such as sodium arsenite or arsenic trioxide, is characterized by systemic findings that appear in stages over the course of hours to weeks. The initial stage typically begins 30 minutes to several hours following ingestion. Gastrointestinal hemorrhaging occurs, leading to profound losses of fluid and electrolytes. It is accompanied by vasodilation, hypotension, and metabolic acidosis. In severe acute intoxication, death may occur within hours from shock or ventricular arrhythmias. If the individual survives the initial phase, a second phase of cardiovascular symptoms, for example, congestive heart failure, noncardiogenic pulmonary edema, and ventricular arrhythmia, may appear within 1–7 days. The third phase of acute arsenic intoxication is characterized by pancytopenia and sensorimotor peripheral neuropathy. This phase generally appears 1–4 weeks after the initial high dose ingestion.[92]

The therapeutic use of inorganic arsenite in the treatment of cancer has yielded information on the clinical features of low-level arsenic intoxication. Recent therapeutic protocols for the treatment of refractory or relapsed acute promyelocytic leukemia and numerous other malignancies have administered between 10 and 20 mg of intravenous As_2O_3 daily for 2-month courses. Cardiotoxic effects have included frequent prolongation of the QTc interval on the electrocardiogram.

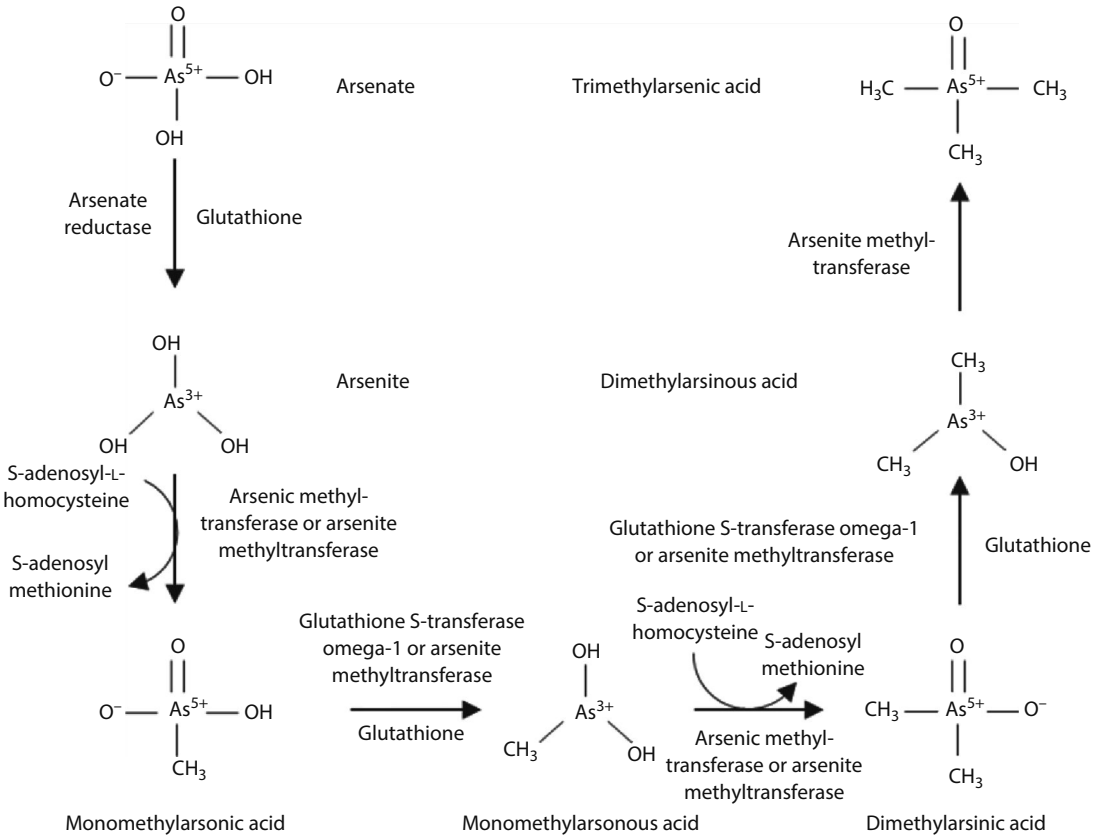

FIGURE 17.5 The interconversion of arsenate and arsenite and their conversion to monomethylarsonic acid, dimethylarsenic acid, monomethylarsonous acid, dimethylarsinous acid, and trimethylarsenic acid take place primarily in the liver.

Malignant ventricular arrhythmias, including fatal torsades des pointes, have been reported.[93] Other notable toxicity in this setting has included peripheral neuropathy, gastrointestinal disturbance, and hepatotoxicity.[94]

The most common early signs of chronic arsenic poisoning are muscle weakness and hyperpigmentation of the skin. Epidemiological studies have linked chronic arsenic ingestion, particularly from naturally occurring arsenic in drinking water, to a strikingly broad spectrum of serious chronic illness. These include peripheral vascular occlusion and a type of gangrene termed blackfoot disease. Chronic exposure to inorganic arsenic induces cancer in human lungs, urinary bladder, skin, kidney, and liver. The majority of deaths are from lung and bladder cancer.[95] Epidemiological investigations conducted in Taiwan, Chile, and Argentina made the link between arsenic ingestion and risk for lung cancer and bladder cancer. Epidemiological studies of smelter workers, pesticide-manufacturing workers, and case reports of lung cancer in arsenical pesticide applicators showed strong associations between exposure and an increased incidence of lung cancer.

Toxicokinetics of Arsenic

Major routes of absorption of inorganic arsenic in the general population are inhalation and ingestion. Inhaled inorganic arsenic deposited in the lungs is eventually absorbed. Most ingested soluble inorganic arsenic is absorbed and excretion occurs primarily in the urine.[30] Insoluble forms pass through the gastrointestinal tract with negligible absorption.[96] Two processes are involved in the metabolism of arsenate and arsenite: (1) the interconversion of arsenate and arsenite and (2) the conversion of these moieties to monomethylarsonic acid and dimethylarsenic acid. The methylation process, illustrated in Figure 17.5, was once thought to be a detoxification mechanism since the methylated forms of arsenic were believed to be less toxic and methylation results in lower tissue retention.[97] However, the identification of highly toxic trivalent methylarsenicals has challenged this hypothesis.[98]. Long-term accumulation of inorganic arsenic does not generally occur in physiologically active compartments in the body. However, arsenic concentrates in the skin, hair, and nails because arsenic reacts with thiol groups, and Mees' lines, horizontal white lines on the fingernails, appear in exposed individuals as the exposed nail grows.[99]

Toxicodynamics of Arsenic

Although arsenic can exist in several valence states, the (III) and (V) states are the most prevalent, with arsenite (III) being more toxic than arsenate (V). Arsenic is believed to exert its toxic effects through at least two mechanisms, depending on its valence state. Through the process of arsenolysis, arsenate inhibits adenosine triphosphate (ATP) synthesis by

uncoupling mitochondrial oxidative phosphorylation. It is thought that arsenate is substituted for inorganic phosphate in the formation of ATP and that the unstable arsenate ester is then rapidly hydrolyzed. Arsenite reacts with thiol groups on the active sites of many enzymes and tissue proteins, such as keratin in skin, nails, and hair.[100] One mechanism of carcinogenicity is postulated to involve the multistep metabolism of pentavalent arsenic to dimethylarsenic acid during which free radicals are produced.[59,100] There is also evidence that reduced glutathione can chemically reduce pentavalent arsenicals to trivalent arsenicals, which then disrupt tubulin polymerization directly. In this context, arsenic may indirectly induce stable chromosome aberrations that can lead to cancer.[101]

Arsine, AsH_3, is a highly toxic gaseous hydride of trivalent arsenic, and its toxic effects are distinct from the other arsenic compounds. Arsine binds hemoglobin, resulting in rapid hemolysis and hematuria. The third effect of the classic arsine triad is abdominal pain.[59]

Screening and Regulatory Levels of Arsenic

The EPA classifies arsenic as a Group A known human carcinogen. IARC places arsenic in Group 1, carcinogenic to humans. The EPA's RfD, oral slope factor and unit risk value for arsenic, and the RfC for arsine are shown in Table 17.5.[19] The ATSDR's MRL for chronic oral toxicity is also shown in Table 17.5. OSHA's PELs for inorganic arsenic, organic arsenic, and arsine are 0.010, 0.5, and 0.2 mg/m^3, respectively.[20] An estimated lethal dose of arsenic (III) for a 70 kg human is 70–180 mg.[27] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Cadmium

Sources of Cadmium Exposure

Cadmium is a soft silver-white transition metal. Cadmium compounds are naturally occurring and often found in association with zinc ore. In the environment, cadmium occurs as cadmium (II) and usually as particulate matter when released to air.[59] Cadmium is used primarily in the production of batteries but also for pigments in plastics, ceramics, and glasses, as stabilizers for polyvinyl chloride, as coatings on steel and some nonferrous metals, and as a component of specialized alloys.[102]

Adverse Health Effects of Cadmium

Cadmium affects nearly every organ system if the dose is high enough. Acute effects depend on the route of exposure. Symptoms of acute inhalation exposure to cadmium develop 4–10 h postexposure and initially simulate metal fume fever (fever, nausea, vomiting, headache, cough, dyspnea, nasopharyngeal irritation). These adverse effects can progress to chemical pneumonitis and a potentially fatal pulmonary edema.[103,104] A fatal dose can be inhaled by exposed individuals who are unaware of the presence of cadmium.[105] Fatal doses have been estimated at 50 mg/m^3 for 1 h and 9 mg/m^3 for 5 h.[106] Recovery following acute high-level exposure or chronic exposure at lower levels may be accompanied by pulmonary fibrosis.

Oral exposure to cadmium is rarely fatal because the associated gastrointestinal irritation leads to vomiting, eliminating most of the dose before absorption. Chronic inhalation or ingestion of cadmium results in kidney damage, characterized by tubular and/or glomerular dysfunction with proteinuria and low concentrating capacity.[107]

Excess inhalation or ingestion of cadmium can also lead to abnormalities of calcium metabolism, and susceptible individuals may develop a painful bone disease that was first discovered in a cadmium-contaminated area in Japan and termed itai-itai (ouch-ouch) disease.[108] The disease is characterized by osteomalacia and osteoporosis with an increased tendency to spontaneous fracture. It is associated with bone pain and renal tubular dysfunction. Cadmium increases bone resorption and inhibit bone formation in both *in vivo* and *in vitro* systems.[109] It is hypothesized that cadmium causes prolonged urinary calcium loss, leading to the skeletal demineralization and increased risk of fractures.[110]

Cadmium exposed populations are not reported to have elevated death rates associated with cardiovascular disease. Although intravenous cadmium administration produces a hypertensive response in rats, no difference in blood pressure was found between high- and low-exposure workers after adjusting for age, weight, and cigarette smoking.[111]

Cadmium-induced testicular damage leads to infertility in experimental animals and may damage the reproductive ability of cadmium-exposed workers.[112]. Maternal and fetal toxicity of cadmium is well documented in rodents.[102,113] Elevated levels of cadmium in neonates are associated with a decreased birth weight. Further research is required to determine if developmental effects of cadmium are of concern at environmental levels.

The NTP and IARC have linked cadmium to lung cancer in humans. Cadmium's link to other human cancers is less clear. Prostate tumors have been reported in male rats after oral cadmium exposure, and several studies suggest a role for cadmium in human prostate cancer.[114–117] Additionally, occupational exposure to cadmium is associated with an increased risk of renal cell carcinoma.[118]

Toxicokinetics of Cadmium

Dermal absorption of cadmium compounds is negligible. The primary routes of exposure for humans are inhalation and ingestion. Cadmium absorption following inhalation exposure is dependent on particle size and solubility. Between 10% and 50% of inhaled cadmium will be absorbed. The absorption is greater for small particles and fumes than for large particle dust. Poorly soluble inhaled particles are deposited on the ciliated tracheobronchial mucosa, transported to the pharynx, and swallowed into the gastrointestinal tract.[27] When exposure occurs by smoking cigarettes, cadmium is in the form of submicron aerosols and absorption of the inhaled

amount is between 25% and 50%. Tobacco plants are known to concentrate cadmium independent of the soil content and it is estimated one pack/day smokers can absorb 1–3 μg cadmium/day. Cadmium oxide is reported to be highly bioavailable, and smokers are known to have higher levels of cadmium in their blood (4–5 times higher) and kidneys (2–3 times higher) than nonsmokers.[110]

In humans, about 5% of ingested cadmium is absorbed. However, cadmium and iron are both absorbed through a common pathway involving the divalent metal transporter-1 (DMT-1).[119] Iron deficiency results in increased expression of intestinal DMT-1 and is therefore associated with increased cadmium absorption.[110,120] In individuals with iron deficiency, the gastrointestinal absorption rate may be as high as 20% but has been reported to be as high as 90%.[107,121]

Toxicodynamics of Cadmium

Absorbed cadmium is first transported to the liver where it induces metallothionein synthesis and is sequestered as cadmium-metallothionein. Small amounts of liver cadmium-metallothionein are released into the plasma following normal cell turnover, filtered with the primary urine, reabsorbed into the proximal tubular cells where lysosomes degrade the metallothionein portion releasing cadmium. Once released, cadmium again induces renal metallothionein synthesis. Renal damage results when the kidneys can no longer produce sufficient metallothionein to sequester the cadmium ion and prevent its interaction with critical macromolecules. Free cadmium inactivates metalloenzymes, activates calmodulin, and/or damages cell membranes through activation of oxygen.[122] Increased urinary excretion of β_2-microglobulin, a low molecular weight protein normally reabsorbed in the proximal tubule, is an early indicator of renal damage.

The mechanism(s) of cadmium carcinogenesis are not clearly understood. Cadmium is a poor mutagen but may act as an epigenetic or indirectly genotoxic carcinogen. Potential mechanisms include inhibition or faulty DNA repair, aberrant gene activation, and suppressed apoptosis.[121]

Although the mechanism of cadmium-induced testicular toxicity is poorly understood, cadmium treatment is known to increase vascular permeability in rat testis, and one theory is that the damage is the result of testicular blood vessel toxicity.[123] Other evidence suggests cadmium-induced testicular toxicity is associated with oxidative damage through the production of reactive oxygen species.[124] In support of this theory, it has been reported that zinc-deficient rats are more susceptible to cadmium-induced testicular damage.[125] Other researchers report ascorbic acid and/or alpha-tocopherol supplementation protect rats from cadmium-induced testicular damage.[126,127]

Screening and Regulatory Levels of Cadmium

The EPA has derived an RfD for cadmium based on the highest level of human renal cadmium not associated with significant proteinuria. Separate values were derived for food and water exposure, assuming 2.5% absorption of cadmium from food and 5% from water with a 0.01% per day excretion. A kidney concentration of 200 μg/g wet human renal cortex is considered the no-observable-effect-level.[19] The resulting RfD values are 0.001 mg/kg/day (food) and 0.0005 mg/kg/day (water) (Table 17.5). An RfC for chronic cadmium inhalation exposure was not developed.

The ATSDR has calculated chronic MRLs for cadmium based on human studies with measured exposures. The chronic oral MRL is 0.0001 mg/kg/day and the chronic inhalation MRL is 0.00001 mg/m^3 (Table 17.5). The average nonsmoking American absorbs approximately 1–3 μg of cadmium per day from the diet, which is only two to four times lower than the oral MRL.[102]

The EPA places cadmium in Group B1, a probable human carcinogen based on evidence in humans and animals.[19] The EPA's IUR is 1.8×10^{-3} per μg/m^3. The World Health Organization's IARC designated cadmium and cadmium compounds as carcinogenic to humans (Group 1) based on evidence of lung cancer (Table 17.5).[112,128] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Lead

Sources of Lead Exposure

Lead is the most widely used nonferrous metal. The usual valence state of lead in inorganic lead compounds is (II). Lead and lead compounds have been used in many industrial applications, including batteries, ammunition, paints and varnishes, gasoline, radiation shields, medical equipment, solder, glass, and ceramic glazes. Children are primarily exposed by ingestion. Lead poisoning in children caused by ingestion of lead paint was first noted in Australia and became recognized as a public health problem in the United States in the 1920s. Children have also been exposed by household renovation, fishing sinkers, imported lead-contaminated candy, and the use of imported ceramic dinnerware.[129–132] Adults are primarily exposed occupationally by inhalation. Excessive blood lead levels, greater than 40 μg/dL, have been reported in automobile radiator repair mechanics, and *take-home* lead is a potential source of elevated blood lead level in their children.[133] Excessive blood lead levels are also reported in other lead-related industries such as ceramics and furniture-stripping.[134]

A less common source of exposure is the lead in crystal that leaches into alcoholic beverages. Lead contents as high as 21.5 mg/L are reported in beverages stored in crystal decanters.[135] The lead content of various calcium supplements has been tested, and significant levels of lead was detected in over one-quarter of the 70 different brands examined.[136] Additionally, dissolution of retained lead gunshot has resulted in lead poisoning.[137]

The major sources of exposure have been reduced by the actions of federal agencies.[138] The EPA's phaseout of lead in gasoline started in 1973 and was completed in 1995. The EPA also banned lead in plumbing, fixtures, fittings, and solder.

In 1978, the U.S. Consumer Product Safety Commission banned the use of paint containing more than 0.06% lead by weight for interior/exterior residential surfaces, toys, and furniture. In 1995, FDA eliminated lead-solder in food cans. Subsequently, results of two National Health and Nutrition Examination Surveys, NHANES II (1976–1980) and NHANES III (phase I, 1988–1991; phase II, 1991–1994), indicate a substantial decline in blood lead level.[139–142] In 1994, it was estimated that 890,000 (4.4%) U.S. preschool children had a blood lead level of 10 μg/dL or higher.[140] Further reductions in blood lead level will require primary prevention efforts to reduce exposure to lead remaining in housing and soil.[143]

Adverse Health Effects of Lead

Early symptoms of chronic poisoning in children are often nonspecific, including headaches, anorexia, vomiting, and constipation. The adverse effects progress to anemia with basophilic stippling of red cells, Burton's line (a bluish grey line along the gums), chronic nephritis, peripheral neuropathy (manifested as wrist and/or foot drop), and radiographs of long bones revealing lead deposits. Frank encephalopathy occurs when blood lead concentrations are greater than 80 μg/dL and is characterized by ataxia, coma, convulsions, cerebral edema, and death. The long-term neurological consequences of childhood lead poisoning became well recognized in 1943 when Byers and Lord followed up 20 cases and found poor academic performance in all but one. In 1975, de la Burde and Choate reported school failure due to learning and behavioral problems in asymptomatic lead-exposed children. Asymptomatic children in first and second grade with elevated dentine lead levels scored lower on standardized tests, especially in areas measuring verbal performance and auditory processing. They were also more likely to exhibit disruptive behavior relative to controls.[144] Reexamined 11 years later as adolescents, those with greater lead exposure were more at risk for dropping out of school, reading disability, absenteeism, poor hand–eye coordination, and low scholastic class standing.[145,146]

In adults, early symptoms are often nonspecific and include fatigue, depression, sleep disturbance, anorexia, intermittent abdominal pain, nausea, constipation, diarrhea, and myalgia. Blood lead level is the single best diagnostic test for lead exposure. Animal experimentation and many epidemiologic studies suggest low increases in blood lead levels may elevate blood pressure, but the results are not definitive.[147,148] No consistent relationship between blood pressure and blood lead level was found after the examination of the NHANES III dataset.[149] However, in more recent studies, blood lead levels were significantly correlated with higher blood pressure among black men and women, but not white or Mexican-American participants.[150] Blood lead levels were also correlated with higher blood pressure among individuals working in the battery industry.[151] Other researchers suggest long-term lead accumulation, measured as bone lead, as opposed to blood lead level, which reflects recent exposure, may be associated with developing hypertension.

There is evidence of neurotoxicity, nephrotoxicity, and reproductive effects in adults. Reversible slowing of nerve conduction velocity has been observed at blood lead levels as low as 30 μg/dL and adverse effects on reaction time, mood, and visual–motor coordination at 30–50 μg/dL. Overt neurotoxicity, wrist drop, is reported at levels in excess of 80 μg/dL. Chronic irreversible nephropathy requires high and sustained exposure, but low-level lead exposure, blood lead level less than 10 μg/dL, is associated with renal impairment. Morphological alterations and decreases in sperm count, density, and motility have all been reported in heavily exposed males at blood lead level greater than 40 μg/dL.[152] Paternal occupational lead exposure has been reported to increase the risk of low birth weight and prematurity and to decrease cognitive scores in their children. Lead readily crosses the placenta to the fetus, and maternal blood lead levels in excess of 15 μg/dL are associated with low birth weights and preterm delivery, and blood lead in excess of 30 μg/dL, with spontaneous abortions.[153] Anemia is not seen until blood lead levels are in excess of 50 μg/dL.

Toxicokinetics of Lead

Inhalation and ingestion are the main routes of exposure for inorganic lead. In cases of occupational exposure, 35%–40% of inhaled lead dust or fume is deposited in the lungs with extensive (95%) blood absorption.[154,155] Children absorb 50% of an ingested dose through the gastrointestinal tract. In contrast, adults absorb 10% of an ingested dose, but gastrointestinal absorption will vary with solubility, nutritional status, fasting, and inversely with particle size. Elimination is mainly in the urine, with lesser amounts in the feces, sweat, hair, and nails.

Toxicodynamics of Lead

Lead's ability to substitute for divalent cations and bind sulfhydryl groups underlies systemic toxic effects that are manifested in, for example, the immune, cardiovascular, urinary, and nervous systems. The vulnerability of astrocytes to the toxic effects of lead is suggested as a key etiologic factor in lead-induced neurotoxicity. Astrocytes sequester lead up to a 55 times greater concentration than the surrounding extracellular fluid, and lead reduces astrocytes' glutamine synthetase activity in a dose-dependent manner. This compromises the ability to maintain extracellular levels of glutamate, a function crucial to homeostatsis.[156] There is also evidence to support the hypothesis that lead substitution for calcium in several intracellular regulatory pathways underlies some aspects of lead neurotoxicity. In this context, it is noteworthy that lead activates calcium calmodulin-dependent phosphodiesterase and calcium calmodulin inhibitor-sensitive potassium channels, and, at picomolar concentrations, lead activates calcium calmodulin-independent protein kinase C.[27]

Lead inhibits a large number of enzymes by binding to sulfhydryl groups. Lead enzyme inhibition is a component in some of the mechanisms proposed for lead-induced carcinogenesis. Possible mechanisms include inhibition of

regenerative repair, inhibition of DNA synthesis or repair, generation of reactive oxygen species with oxidative damage to DNA, substitution of lead for zinc in transcriptional regulators, interaction with DNA-binding proteins, and aberrant gene expression.[98]

Screening and Regulatory Levels of Lead

Since 1970, the CDC has repeatedly reduced the action level for blood lead. As new information has emerged about the neurological, reproductive, and possible hypertensive toxicity of lead, and as parameters that are more sensitive are developed, the blood lead levels of concern for lead exposure have been progressively lowered by the CDC from 70 to 10 µg/dL (Figure 17.6).

Although the CDC set 10 µg/dL as the blood lead level of concern in 1991, this is not interpreted to mean there are no adverse effects below this level. Cognitive deficits are associated with blood lead levels below 5 µg/dL.[157] There is evidence to support that there is no threshold for the toxic effects of lead.[158–160] In this context, it is important to note that in January 2012, a committee of experts recommended that the CDC establish a reference value of 5 µg/dL based on the 97.5 percentile distribution of blood lead levels among children aged 1–5.[161] The committee also recommended that the CDC replace the term *blood lead level of concern* because it has the potential to be misinterpreted as a toxicity threshold.

Because the adverse health effects associated with lead occur at blood lead levels so low as to be without a threshold, the EPA considers it inappropriate to derive toxicity values for lead.[19] However, the EPA did derive an RfD for tetraethyllead, 0.0001 µg/kg/day (Table 17.5). The ATSDR has not derived a chronic oral MRL or a chronic inhalation MRL for lead (Table 17.5). Although the EPA classifies lead as a Group B2 probable human carcinogen, the agency considers it inappropriate to quantify the carcinogenic risk from oral exposure because toxicokinetic differences between humans and animals cannot be taken into account using the standard procedures. IARC considers inorganic lead compounds as *probably carcinogenic to humans* (Group 2A) and organic lead as *not classifiable as to their carcinogenicity to humans* (Group 3).[162] These screening values and cancer classifications are shown in Table 17.5. Epidemiological data suggest a role for lead in human carcinogenicity.[163] Lead has been suggested to play a *facilitative* role in carcinogenicity by inhibiting DNA repair and/or otherwise enhancing the DNA damage of other genotoxic compounds.[164]

The NIOSH REL for metallic lead, lead oxides, and lead salts (including lead soaps but excluding lead arsenate) is 0.050 mg/m^3. NIOSH further recommends that air concentrations be maintained so that worker blood lead levels remains below 0.060 mg/dL. The OSHA PEL for lead is also 0.050 mg/m^3. However, OSHA considers *lead* to mean all inorganic lead compounds (lead oxides and lead salts) and the class of lead compounds called soaps. All other lead compounds are excluded from the OSHA definition. The NIOSH REL is an advisory level while the OSHA PEL is a regulatory level.[20] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Mercury

Sources of Mercury Exposure

Mercury is a silver-white fluid trace metal found in igneous and sedimentary rocks and as mercury sulfide in cinnabar ore. Mercury occurs naturally as elemental mercury and as inorganic and organic mercury compounds. Release of elemental mercury vapor from the earth's crust with direct discharges to the atmosphere is the major natural source of mercury in the environment. Other important sources include smelting, gold refining, cement production, and burning of fossil fuel. Industrial applications of mercury include its use as a cathode in the electrolysis of sodium chloride. Mercury has also been used in pesticides. Agricultural products treated with mercurial fungicides are a major dietary source of mercury compounds. Atmospheric fallout from burning fossil fuels deposits inorganic mercury compounds in soil and water where it may be methylated by the microflora to form methylmercury. Edible fish can concentrate methylmercury. Fish harvested from mercury-polluted water

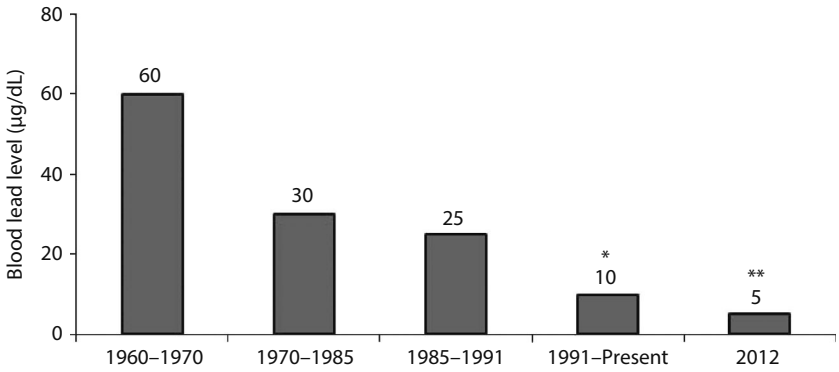

FIGURE 17.6 The graphic illustrates the progressive lowering of CDC-recommended action level for blood lead in children. *The current CDC-recommended blood lead action level is 10 µg/dL. **In 2012, the CDC proposed to reduce the action level to 5 µg/dL.

is a major source of methylmercury in the diet. Due to the potential for environmental release, the use of mercury in some commercial products, for example, paint and batteries, is now restricted.[27]

The use of dental amalgam fillings has generated concern, both because exposure of dental workers may exceed occupational standards and because a variety of illnesses in the general public, including developmental, neuronal, and renal illnesses, have been attributed to dental mercury exposure.[165,166] Conditions other than contact dermatitis have not been firmly linked to dental amalgam.[167–169] Whether amalgam should continue to be used for new dental fillings remains controversial[170] even in the face of reviews that supported its safety.[171,172] Additional research is needed before the potential for dental amalgams to cause harm, and the benefit of substituting more costly or less durable materials, can be fully evaluated. The evaluation must include the potential risk of effects on the fetus.[173] Mercury is also present in the pharmaceutical preservative thimerosal. The scientific evidence accumulated to date does not support a causal association between autism and exposure to thimerosal as a component of vaccines.[174]

Adverse Health Effects of Mercury

The CNS is the critical organ for mercury vapor exposure. Acute inhalation exposure to mercury vapor irritates the respiratory tract and may be followed by chest pains, dyspnea, coughing, hemoptysis, and interstitial pneumonitis leading to death. Low-level exposure gives rise to psychotic reactions characterized by delirium, hallucinations, and suicidal tendency. Chronic exposure to the vapors produces CNS toxicity, including muscle weakness and tremors, nervousness, memory loss, and anorexia. Occupational exposure to metallic mercury has long been associated with the development of proteinuria. Acute elemental mercury ingestion is usually of no significance due to poor absorption from the gastrointestinal tract. Inorganic mercury compounds generally demonstrate local irritant or corrosive activity. The kidney is the critical organ following the ingestion of inorganic divalent mercury salts. Ingestion of mercuric compounds, for example, mercuric chloride, can cause ulcerative gastroenteritis and tubular necrosis leading to death. Chronic effects of inorganic mercury compounds produce CNS toxicity similar to that noted for elemental mercury.[175]

Methylmercury is neurotoxic and the effects are both dose- and time-dependent. Ataxia is an early symptom followed by slurred speech, weakness, vision and hearing loss, tremors, coma, and death. Well-documented poisonings from contaminated fish and grains occurred in Japan and Iraq.[176,177] Additionally, methylmercury is a well-known neuroteratogen. The fetus is more sensitive to the toxic effects of methylmercury than adults. In the fetus, it affects normal neuronal development, leading to altered brain architecture and decreased brain size. Contact dermatitis may occur to both inorganic and organic mercurials with cross-sensitivity to each being reported.[173]

Toxicokinetics of Mercury

The primary route through which the general public is exposed to mercury is the diet, and the primary food is fish and fish products. About 15% of inorganic divalent mercury is absorbed from the gastrointestinal tract in adults and retained in body tissues. Inorganic mercury is nonuniformly distributed after absorption. The highest concentration is found in the kidneys. Mercury and mercury compounds are excreted in urine, feces, and through respiration. The oxidation of inhaled metallic mercury vapor to divalent mercury takes place in red blood cells soon after absorption. Some elemental mercury remains dissolved in the blood long enough for it to be carried to the blood–brain barrier and the placenta. Because of the short transit time from the lung to the brain, about 97% arrives unoxidized. Its lipid solubility and high diffusibility allow rapid transit across the blood–brain barrier and placenta. Oxidation of the mercury vapor in brain and fetal tissues converts it to the ionic form, which is much less likely to cross back over the blood–brain and placental barriers. Results of both human and animal studies indicate that about 80% of metallic mercury vapor is retained by the body, whereas liquid metallic mercury is poorly absorbed in the gastrointestinal tract. Methylmercury in the diet is almost completely absorbed into the bloodstream and distributed to all tissues.[27] The uptake of methylmercury is thought to proceed through a process where it complexes with cysteine in the gastrointestinal tract and is then transported from the blood into endothelial cells by the same amino acid transporter that normally transports methionine. Uptake by the transporter is thought to occur because the methylmercury–cysteine complex is so similar in structure to methionine (Figure 17.7).

Toxicodynamics of Mercury

The toxicity of mercury is mediated through its covalent binding and inactivation of normal cellular functions. Divalent mercury binds to sulfhydryl groups, as well as to carboxyl, amide, amine, and phosphoryl groups.

The systemic toxicity of mercury compounds is attributable to the wide variety of cellular ligands that are potentially affected. For example, divalent mercury ions form coordination or chelation complexes with erythrocytes, causing agglutination and hemolysis. Also, divalent mercury can accumulate in liver lysosomes and, as concentrations increase, the lysosomes rupture and release destructive acid hydrolases.[27,178] The neurotoxic effect seen after exposure to metallic mercury vapor is attributable to the divalent mercury ion formed through oxidation in the brain tissue. One possible mechanism is the divalent ions' interference with enzyme function by binding to sulfhydryl groups. Transport through the cell membrane via the formation of carrier complexes, such as sodium and calcium channels, is also a possibility although this has not been demonstrated.

The inhibition of protein synthesis is one of the earliest detectable biochemical effects of methylmercury in the adult brain. Methylmercury can also react directly with important receptors in the nervous system, as shown by its effect on

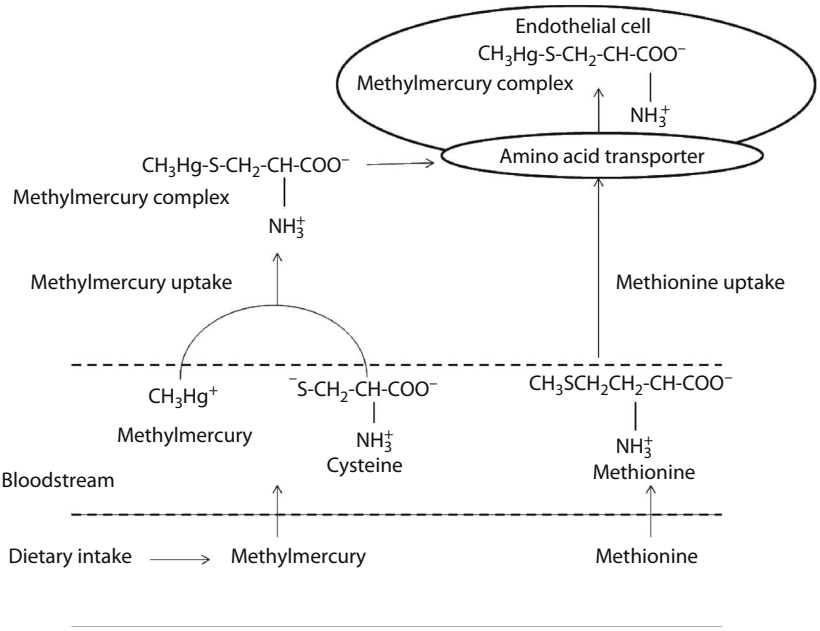

FIGURE 17.7 The complex formed when methylmercury binds cysteine has a similar structure to methionine. One of the ways cellular uptake of the methylmercury–cysteine complex is thought to proceed is through a process where it is transported into the cell by the same amino acid transporter that normally transports methionine.

acetylcholine receptors in the peripheral nerves. It has also been suggested that the carbon–mercury bond in methylmercury undergoes homolytic cleavage to release methyl free radicals that peroxidize lipid constituents of neurons.[27]

Screening and Regulatory Levels of Mercury

The EPA's RfD and the ATSDR's chronic oral toxicity MRL for methylmercury are shown in Table 17.5. Neither agency has derived chronic oral toxicity values for elemental mercury. The EPA's cancer assessment for oral exposure to methylmercury places it in Group C. IARC classifies methylmercury as Group 2B, possibly carcinogenic to humans. IARC places metallic mercury and inorganic mercury compounds in Group 3, not classifiable as to their carcinogenicity to humans.[162] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

OTHER TOXIC METALS WITH RfDs

Aluminum

Sources of Exposure to Aluminum

Aluminum is an abundant element in the earth's crust and occurs in the form of silicates, oxides, and hydroxides, combined with other elements such as sodium and fluorine and as complexes with organic matter. It is not found as a free metal because of its reactivity. It is extracted from bauxite ore. It is highly concentrated in soil-derived dusts from such activities as mining and agriculture, and in particulate matter from coal combustion. Aluminum metal has a wide variety of uses including structural materials for construction automobiles and aircraft and in the production of metal alloys. Compounds of aluminum have a wide variety of uses, including production of glass, ceramics, rubber, wood preservatives, pharmaceuticals, and waterproofing textiles. Natural aluminum minerals, especially bentonite and zeolite, are used in water purification, sugar refining, brewing, and paper industries. Aluminum is released to the environment both by natural processes and from anthropogenic sources. It is naturally present at low levels in most foods, but the primary source of dietary aluminum is from food additives.[27,179] On average, American adults consume 2–25 mg of aluminum daily from food and beverages, with average amounts being 8.2 mg/day for males and 7.1 mg/day for females.[180] Over-the-counter antacids contain large amounts of aluminum hydroxide, and millions of consumers are dermally exposed to aluminum salts from the use of antiperspirants.[181]

Adverse Health Effects of Aluminum

Large oral doses of aluminum results in a toxic syndrome of gastrointestinal tract irritation and interference with phosphate absorption. Industrial exposure to high concentrations of aluminum-containing airborne dusts has resulted in a number of cases of occupational pneumoconiosis. Most of these exposures were chronic and other substances were involved in nearly all instances. It has been hypothesized that aluminum is a risk factor for Alzheimer's disease. However, epidemiologic studies do not show an association between occupational aluminum exposure and the incidence of Alzheimer's disease. Canadian miners, between 1944 and 1979, were exposed to high concentrations of aluminum and aluminum oxide powder preceding each shift as

a prophylactic treatment against silica lung disease. In an initial study of this population, there was no increased incidence of neurological disorders in exposed miners, but there was an increase in neurological impairment as measured by cognitive testing.[182] A follow-up study was conducted to address several methodological weaknesses in the initial study. No statistically significant differences were noted between exposed and nonexposed miners in either neurological disease or cognitive impairment incidence. A more recent study showed no association between occupational exposure to aluminum and the incidence of Alzheimer's disease.[183] Similarly, a methodological improved follow-up study, to an earlier study that found an association between aluminum in drinking water and the incidence of Alzheimer's disease, found no evidence of an association.[184] However, in early investigations, injection of aluminum salts into the brain of rabbits resulted in the development of neurofibrillary tangles, which are indicators of Alzheimer's disease.[185] While a direct causal role for aluminum has not been definitively demonstrated, epidemiological evidence suggests that elevated levels of aluminum in the brain may be linked to the development or progression of Alzheimer's.[186,187] Aluminum is certainly neurotoxic. In renal dialysis patients, excessive parenteral exposure to aluminum can cause a progressive, fatal neurological syndrome known as dialysis dementia.[188]

Toxicokinetics of Aluminum

Aluminum salts are absorbed in small amount from the lung and gastrointestinal tract. The plasma proteins bind and accumulate aluminum. One day postinjection of humans with aluminum citrate, 99% of the aluminum remaining in the circulation was found in the plasma, with 80% of that fraction largely bound to transferrin, 10% bound to albumin, and the remainder associated with lower molecular weight proteins. This plasma protein binding of aluminum is saturable. During dialysis with aluminum-containing dialysate, plasma aluminum levels reach a plateau. Aluminum is widely distributed to the organs, including the lung, liver, bone, muscles, and brain. The highest levels have been found in lung tissue. The marked protein binding of aluminum in plasma leaves only a small fraction of the total aluminum available for filtration in the kidney. Renal clearance of aluminum is approximately 5%–10% of that of urea or creatinine clearance.

Toxicodynamics of Aluminum

In a 1977 study, a positive correlation between increased serum parathyroid hormone and serum aluminum levels in dialysis patients was reported.[189] Studies suggest that aluminum distribution in tissue can be influenced by increasing the concentration of parathyroid hormone. The absorption of aluminum from the gastrointestinal tract of rats was enhanced by injections of parathyroid hormone with increased deposition of the metal in the kidney, muscle, bone, and the gray matter of the brain, but not in the liver or in the white matter of the brain. Thus, the parathyroid hormone exerted a specific effect on the absorption and distribution of aluminum.[190] There is some evidence implicating aluminum as an important factor in downregulation of neuronal protein metabolism. It is hypothesized that aluminum exposure may cause Alzheimer's disease by electrostatically cross-linking proteins, such as the methionine-containing histone H1, and DNA.[191]

Advisory, Screening, and Regulatory Levels for Aluminum

The EPA has not derived an RfD for aluminum but has derived one for aluminum phosphide, 0.0004 mg/kg/day. The ATSDR's chronic oral MRL for aluminum is 1 mg/kg/day.[21] The NIOSH REL for total aluminum exposure is 10 mg/m^3. OSHA's PEL for total aluminum is 15 mg/m^3. The REL and PEL for respirable aluminum are both 5 mg/m^3. OSHA has not established a PEL for aluminum welding fumes; the REL is 5 mg/m^3. Limits are also established for alumina, and soluble salts of aluminum.[20] Neither the EPA nor IARC has fully evaluated the carcinogenicity of aluminum. The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Antimony

Sources of Antimony Exposure

Antimony is a brittle silver-colored metal extracted from ores. Antimony trioxide is primarily used as a flame retardant in rubber, plastics, pigments, adhesives, textiles, and paper. The metal hydride of antimony is a colorless highly toxic gas used in the manufacture of semiconductors.[59] Pentavalent antimonials have been used as a therapeutic for the treatment of leishmaniasis and schistosomiasis.[27]

Adverse Health Effects of Antimony

Ingestion of antimony compounds is associated with gastrointestinal, cardiac, dermatological, hepatic, and neurological toxicity in humans and animals. Acute inhalation exposure to antimony trichloride or antimony pentachloride can cause pneumonitis. Long-term inhalation exposure to antimony can cause benign pneumoconiosis and may raise blood pressure. Dermatological reactions to antimony include eczema and pustules. These effects exhibit signs of an acute inflammatory response but do not appear to be an allergic reaction. The major toxic side effects associated with parenterally administered antimonials, therapeutics used to treat leishmaniasis and schistosomiasis, are cardiotoxicity and pancreatitis.[192]

Both antimony (III) and antimony (V) compounds are generally negative in nonmammalian genotoxicity tests, while mammalian test systems have returned positive results for antimony (III) but not antimony (V) compounds. Assessments of chromosome aberrations have been inconsistent. IARC concluded that animal carcinogenicity data were sufficient for Sb_2O_3 to be classified as possibly carcinogenic to humans.[57,193]

Toxicokinetics of Antimony

The distribution of antimony is not homogeneous within organs or tissues and is dependent on valence state and exposure route. For example, antimony (III) is concentrated in red blood cells and liver, whereas the antimony (V) is primarily concentrated in the plasma. After acute oral, chronic oral, or parenteral exposure to antimony, the highest organ concentrations are found in the thyroid, adrenals, liver, and kidney. Antimony absorbed via the lung may have a longer biological half-time. At the autopsy of deceased antimony smelter workers, high levels were found in the lung and bone tissues but not in liver or kidney. The intestinal absorption of antimony (III) is lower than the pentavalent compound. Both tri- and pentavalent antimonials are excreted in feces and urine.[27]

Toxicodynamics of Antimony

The therapeutic mode of action of pentavalent antimonials is still being investigated. However, there are data that suggest direct involvement of antimony (V). Other data suggest that thiols and ribonucleosides may also participate in the therapeutic mode of action.[194] As with other metals, the mechanisms for the toxic effects of antimony compounds include binding to sulfhydryl groups and inhibiting protein and carbohydrate metabolism. Antimony (III) has also been shown to be a potent inducer of liver and kidney heme oxygenase, the rate-limiting enzyme in heme degradation, in both organs.[27] The cancer mechanisms of action are thought to include production of active oxygen species and indirect interference with DNA repair systems.[57]

Screening and Regulatory Levels for Antimony

The EPA has derived a chronic oral RfD of 0.4 μg/kg/day. The EPA has not derived an RfC, and the ATSDR has not derived either a chronic oral or inhalation MRL (Table 17.5). Antimony has not been evaluated by the EPA for its potential to cause cancer in humans.[19,195] The IARC classification of antimony trioxide is Group 2B, possibly carcinogenic to humans via inhalation and ingestion. The Group 2B classification is based on inadequate evidence of carcinogenicity in humans and sufficient evidence of carcinogenicity in experimental animals.[193] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Barium

Sources of Barium Exposure

Barium is a silvery-white alkaline earth metal and is found in nature in combination with other elements.[196] Barium compounds are used primarily as lubricating agents in drilling muds, but also in the manufacture of paints, bricks, tiles, glass, rubber, and pesticides. Barium sulfate is safely used medically as a contrast agent in x-ray diagnosis because it is not efficiently absorbed across the gastrointestinal lumen. Occupational exposure to barium may occur through inhalation and dermal contact at workplaces where it is produced or used. The general population may be exposed to barium via inhalation of ambient air and ingestion of food and drinking water.[27]

Adverse Health Effects of Barium

The barium ion is highly reactive, and its toxicity is dependent on the solubility of the specific compound, with water-soluble compounds, for example, chloride, hydroxide, and nitrate, being more toxic than insoluble compounds, for example, sulfate and carbonate. Soluble barium compounds may cause local irritation of the eyes, nose, throat, bronchial tubes, and skin. The acute effects of barium ingestion in animals include salivation, nausea, diarrhea, tachycardia, hypokalemia, twitching, flaccid paralysis of skeletal muscle, respiratory muscle paralysis, and ventricular fibrillation.[27,197] High-dose human exposure to barium consistently results in adverse effects that include ventricular tachycardia, hypertension and/or hypotension, and muscle weakness and paralysis. Hypokalemia is reported in a number of individuals exposed to high doses of barium.[198] Ingestion of gram quantities of soluble barium salts may be fatal, with death resulting from cardiac arrest. Various studies have demonstrated the detrimental effect of barium on ventricular automaticity and pacemaker current in the heart. Symptoms of poisoning start with the gastrointestinal muscles leading to nausea, vomiting, and diarrhea. This progresses to the skeletal and cardiac muscles with ventricular fibrillation followed by death due to respiratory muscle paralysis. Occupational exposure to inhaled barium sulfate can cause a benign pneumoconiosis (baritosis), which resolves with cessation of exposure.[27] A dose–response assessment of NOAEL and LOAEL values determined that kidney effects are the most sensitive endpoint for adverse health effects related to chronic soluble barium ingestion in mammals.[16]

Toxicokinetics of Barium

Exposure to barium can occur through the air and diet. About 90% of barium is concentrated in the bone; the remainder goes to soft tissues such as the aorta, brain, heart, kidney, spleen, pancreas, and lung. The highest concentration of barium in soft tissues of humans was found in the large intestine, muscle, and lung. Barium deposition in the bone occurred preferentially in the active sites of bone growth. Inhaled barium can be absorbed through the lung or directly from the nasal membrane into the blood. Barium is eliminated in the urine and feces, the rates varying with the route of administration.[27]

Toxicodynamics of Barium

There is evidence that many of the toxic effects of barium are due to increases in intracellular potassium levels and extracellular hypokalemia. Barium is a competitive potassium channel antagonist that blocks the passive efflux of intracellular potassium, resulting in a shift of potassium from extracellular to intracellular compartments. The intracellular translocation of potassium results in a decreased resting membrane

potential, making the muscle fibers electrically unexcitable and causing paralysis. Barium also possesses chemical and physiological properties that allow it to compete with and replace calcium. This particularly affects functions related to the release of adrenal catecholamines and neurotransmitters such as acetylcholine and norepinephrine.[27]

Screening and Regulatory Levels for Barium

The EPA has derived an oral RfD for barium, 0.2 mg/kg/day. The ATSDR's oral MRL is also 0.2 mg/kg/day. Neither a chronic inhalation MRL nor an RfC is established. Under the EPA's 1986 Guidelines for Carcinogen Risk Assessment, barium is placed in Group D, not classifiable as to human carcinogenicity. Under the proposed guidelines for carcinogenic risk assessment, barium is considered not likely to be carcinogenic to humans following oral exposure, and its carcinogenic potential cannot be determined following inhalation exposure (Table 17.6).[19] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Beryllium

Sources of Beryllium Exposure

Beryllium is an alkaline earth metal and is extracted primarily from beryllium-silicate ore and beryllium-aluminum oxide-silicate ore. The primary uses of beryllium are as a structural metal in lightweight applications, in metal alloys, and in nuclear reactor technology. The most probable human exposure is occupational exposure. Among workers who may be exposed to beryllium are the ore miners, beryllium alloy makers and fabricators, phosphorus manufacturers, ceramic workers, missile technicians, nuclear reactor workers, electric and electronic equipment workers, and jewelers. Occupational exposure to beryllium may be through inhalation of airborne dust and dermal contact with beryllium. Environmental monitoring data indicate that the general population will be exposed to beryllium via inhalation of ambient air and ingestion of contaminated food and drinking water.[27]

Adverse Health Effects of Beryllium

Although beryllium and its compounds can cause contact dermatitis, the primary target organ is the lung. Two types of beryllium-induced lung injury can occur: acute and chronic. Chronic beryllium disease was first reported in 1946 as a delayed pneumonitis. The disease, berylliosis, is characterized by granuloma formation, fibrosis, emphysema, reduction in vital capacity of the lung, and reduced total lung capacity.[199] The chronic disease has two forms: one that occurs during exposure and the other that becomes evident 10 or more years after the cessation of exposure. The mechanism of the delayed onset is not known. The lack of a dose–response relationship between the extent of exposure and development of the disease, long latency period between

[a] EPA Group A—known human carcinogen, EPA Group B1—probable human carcinogen (limited human data), EPA Group D—not classifiable as to human carcinogenicity, IARC Group 2B—possibly carcinogenic to humans.

[b] The unit risk should not be used if the air concentration exceeds 4 μg/m^3, since above this concentration, the unit risk may not be appropriate.

exposure and onset, and the low incidence among beryllium-exposed individuals suggest that the disease is immune mediated. Chelation treatment has little effect on the course of the disease whereas corticosteroid treatment has been effective in disease suppression.[27,59]

Beryllium dermatitis is a hypersensitivity reaction that is usually noted 1–2 weeks after exposure to soluble beryllium salts. Patch tests of individuals with soluble beryllium salts provoke a positive response. Beryllium can also induce dermal ulceration if particles of beryllium salts become imbedded in the skin. The ulceration can be long-lasting and surgical intervention may be required to resolve the condition. Beryllium compounds are also carcinogenic.[59] Based on the limited evidence of carcinogenicity in humans exposed to airborne beryllium and sufficient evidence of carcinogenicity in animals, beryllium is classified as a B1 probable human carcinogen.[19]

Toxicokinetics of Beryllium

The lungs and pulmonary lymph nodes retain inhaled beryllium. Ingested beryllium is retained in the bone. Urinary excretion of beryllium occurs slowly. Beryllium in plasma is not filtered by the glomerulus. Rather, it is excreted into the tubule, a process that damages the tubular epithelium.[85]

Toxicodynamics of Beryllium

The pathogenesis of chronic beryllium disease involves a beryllium-specific delayed-type hypersensitivity reaction. It is thought that beryllium acts as an antigen, either alone or as a hapten, to stimulate beryllium-specific CD4+ cells proliferation via the interleukin-2 receptor pathway. Lymphokines are released by activated lymphocytes and may initiate and perpetuate the formation of granulomas and lead to macrophage recruitment. Transport of beryllium itself or beryllium as a hapten to sites outside the lung most likely accounts for extrapulmonary granulomas, possibly caused by local beryllium-specific CD4+ cells. This mechanism would account for the universal finding of pulmonary involvement in beryllium disease, with variable evidence of granulomas outside the lung. Beryllium has been detected many years after the last exposure in tissues, including lung, thoracic lymph nodes, liver, spleen, skin, and muscle.

Advisory, Screening, and Regulatory Levels for Beryllium

The EPA has established an RfD for beryllium of 2 μg/kg/day, an RfC of 0.02 $\mu g/m^3$, and an IUR level of 0.0024 per $\mu g/m^3$. The agency classifies beryllium as a Group B1 probable human carcinogen via inhalation. The EPA states that there are insufficient data to determine the carcinogenicity of beryllium when ingested (Table 17.6). IARC reviewed the available literature and, in 1993, published its findings that there was sufficient evidence in humans and animals for the carcinogenicity of beryllium.[112] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Boron

Sources of Boron Exposure

Boron is a solid element that always occurs in nature bound to oxygen in the form of inorganic borates. Boron enters the environment mainly through the weathering of rocks, boric acid volatilization from seawater, and volcanic activity. Boron and associated compounds have many industrial applications, including the production of borosilicate glass, laundry bleaches, wood preservatives, fire retardants, pesticides, fertilizers, cosmetics, and pharmaceuticals. Anthropogenic sources of boron in the environment include agriculture, wood burning, power generation using coal and oil, glass manufacturing, mining, leaching of treated wood, and sewage disposal.[27,200] People working in related industries are exposed occupationally. The general public's exposure is primarily dietary. Boron is an essential plant nutrient and occurs naturally in fruits and vegetables. In the adult American population, the daily median boron intake is 1 mg/day.[201]

Adverse Health Effects of Boron

The oral lethal dose in adults is reported as 15–20 g, but 80–297 g has been tolerated in a single ingestion.[202,203] The progression of effects of boron toxicity is hemorrhagic gastroenteritis with weakness, lethargy, headache, restlessness, and tremors. Frequently, the skin shows signs of erythema with a boiled lobster appearance and exfoliation.[204,205] Shock syndrome may proceed with cold clammy skin, cyanosis, slow pulse, and low blood pressure. Signs of kidney injury or liver damage may be reported. Death generally occurs several days after ingestion and results from renal toxicity, circulatory collapse, and shock.

Animal experiments indicate that chronic oral exposure to boric acid or borax is toxic to the male reproductive system with testicular lesions being observed in rats, dogs, and mice.[206,207] The available data suggest that the Sertoli cells are the primary site of reproductive toxicity. Boric acid is a developmental toxicant in all three of these mammalian species with the most sensitive endpoints being decreased fetal body weight and malformations/variations of the ribs.[207,208] At present, there are insufficient human data to determine if boron causes male reproductive toxicity in humans, but boric acid is considered a high-priority chemical for study with respect to human reproductive health.[209,210]

Toxicokinetics of Boron

Borates are absorbed from mucous membranes and abraded skin, but not from intact or unbroken skin.[211] Most dietary boron is hydrolyzed within the gut to yield $B(OH)_3$, which, as a neutral compound, is easily absorbed. Borate excretion occurs mainly through kidneys. Pharmacokinetic data indicate that boron, administered as boric acid, is absorbed rapidly and virtually completely from the gastrointestinal tract, as evidenced by recovery of greater than 90% in urine. Regardless of the compound or route of exposure, once in the body, boron forms weak complexes with hydroxyl, amino, and thiol groups.[212]

Toxicodynamics of Boron

The mechanism of boron absorption has not been studied, but a passive, nonmediated diffusion process involving $B(OH)_3$ is likely. Because boron forms labile complexes in aqueous solution, transport is probably as free boric acid rather than a complex.[213] Biochemical and physiological consequences of boron deprivation in humans suggest it affects calcium and magnesium metabolism.[214]

Screening and Regulatory Levels for Boron

Borates have long been known to be essential for plants, but a specific biochemical role remains to be determined.[215] Although boron deficiency has been reported in rats, chickens, and humans, as of yet, no requirement has been established in humans. However, a boron UL was set for adults at 20 mg/day.[8,213,214] The EPA's RfD for boron is 0.2 mg/kg/day. Decreased fetal body weight was considered the critical effect. The ATSDR has not established chronic MRLs for boron (Table 17.6). An NTP 2-year carcinogenesis bioassay found no evidence of carcinogenicity.[216] Under the EPA's draft revised guidelines for carcinogen risk assessment, the data are considered inadequate for an assessment of the human carcinogenic potential of boron.[16] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Nickel

Sources of Nickel Exposure

Nickel occurs naturally in soils, sediments, water, air, plants, and animals. Large amounts of nickel are released into the environment as a result of such natural phenomena as volcanic eruptions or from industrial activities, including mining, alloy production, power plants, and incinerators operations. Human exposure to nickel occurs via inhalation of dust particles, ingestion of contaminated food and water, and dermal contact with nickel-containing materials or soil. Nickel is used in a wide variety of applications, with 80% of the nickel in the United States being used in the production of nickel metal and alloys.[27,59]

Adverse Health Effects of Nickel

Animal experiments have indicated that nickel compounds can be nephrotoxic, hepatotoxic, immunotoxic, and teratogenic. The allergic reaction to nickel is the most common adverse health effect in humans.[27] Allergic asthma is rare but case reports have been published.[59] Acute inhalation exposure to metallic nickel can cause metal fume fever.[217] Nickel carbonyl is a colorless and volatile liquid that is particularly hazardous. It has been estimated that exposure to 30 parts per million nickel carbonyl for 30 min may be lethal in humans.[218] Acute inhalation exposure to this material can cause immediate and delayed toxic effects. Headache, dizziness, and nausea are the immediate manifestations. Ten to thirty-six hours after exposure, substernal pain, coughing, and dyspnea, consistent with chemical pneumonitis, are observed. Recovery is protracted and is characterized by fatigue upon slight exertion. Short-term exposure to 150 parts per billion $Ni(CO)_4$ can cause immediate, but not delayed, symptoms, whereas short-term exposure to concentrations on the order of a few parts per million can cause the more severe delayed-type reactions.[59] Inhalation of nickel compounds can cause lung cancer. Epidemiologic studies show the association between occupational exposure to nickel refinery dust and nickel subsulfide and lung and nasal cancer.[19] The latency period for nickel-induced lung cancer is 13–14 years, and for nasal cancer, it was 15–24 years after first employment.[59]

Toxicokinetics of Nickel

Inhalation, dermal contact, and ingestion are the primary routes of exposure to nickel. Nickel metal is poorly absorbed by the skin, but compounds such as $NiCl_2$ and $NiSO_4$ can penetrate occluded skin.[219] The deposition of nickel particles into the nasopharyngeal, pulmonary, or bronchial regions of the respiratory tract is dependent on the particle size. Water-insoluble nickel compounds enter cells by phagocytosis and are contained in cytoplasmic vacuoles, which are acidified, thus accelerating the dissolution of soluble nickel from the particle.[27]

Toxicodynamics of Nickel

Like the other metal carcinogens, nickel-induced carcinogenicity involves multiple molecular mechanisms. The proposed mechanisms of nickel-induced carcinogenesis include a chain of events where nickel compounds enter the cell, triggering intracellular calcium ion mobilization with the induction of the hypoxia-inducible factor-mediated pathways. Also proposed are pathways where nickel enters the nucleus, directly binds to DNA, forms reactive nickel–oxygen complexes that oxidatize thymine and cytosine, and forms 8-hydroxyguanidine. It is proposed too that the genes located near nickel-damaged heterochromatin are silenced resulting in epigenetic loss of histone acetylation and DNA hypermethylation leading to increased susceptibility to neoplastic transformation. Nickel compounds can also downregulate the p53 tumor suppressor gene, activate the c-Myc proto-oncogene, and induce the AP-1 transcription factor, resulting in cellular proliferation and cancer development.[219]

Advisory, Screening, and Regulatory Levels for Nickel

The essentiality of nickel in humans was assessed in 2001 with a decision not to establish DRI values.[213] However, a UL was established for nickel, 1 mg/day. The only toxicity factor that the EPA has derived for the soluble salts of nickel is the RfD, 20 μg/kg/day (Table 17.6). Neither an RfD nor an RfC is established for nickel subsulfide, nickel refinery dust, or nickel carbonyl. The ATSDR established a chronic inhalation MRL of 0.00009 mg/m^3 for nickel refinery dust and nickel-soluble salts. The EPA classified nickel subsulfide and nickel refinery dust as Group A human carcinogens on the basis of animal and epidemiologic carcinogenicity data. The EPA places nickel carbonyl in Group B2, probable human

carcinogen, and neither a slope factor nor an IUR is established. IARC places nickel compounds in Group 1, carcinogenic to humans, and metallic nickel in Group 2B, possibly carcinogenic to humans.[220] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Silver

Sources of Silver Exposure

Alloys of silver are used in jewelry, tableware, photographic materials, electronics, dental products, and as topical antibacterial agents for the treatment of burn wounds.[59,221] Occupational exposure occurs during mining and silver metallurgy. Occupational exposure to silver may occur through inhalation of dust and dermal contact with elemental silver and silver compounds.

Adverse Health Effects of Silver

Silver is generally low in toxicity. However, silver nitrate is corrosive and a large acute dose can cause severe gastroenteritis, shock, convulsions, and death.[27] Chronic exposure to silver results in argyria, a blue-gray discoloration of the skin, mucous membranes, and eyes. Silver sulfadiazine, used in the management of burn wound sepsis, has resulted in argyria, ocular injury, leucopenia, and toxicity in kidney, liver, and neurological tissues. Silver may affect the immune system and contact dermatitis has been observed following exposure to various silver compounds.[222]

Toxicokinetics of Silver

Elemental silver is absorbed following inhalation, ingestion, or topical application. Excretion from oral, respiratory, or topical exposure is primarily through the gastrointestinal tract. Mucociliary escalator activity accounts for removal of silver following respiratory exposure. Clearance of radioactive silver metal dust in a man who was accidentally exposed illustrated the rapid removal of silver from the lungs primarily by ciliary action, with subsequent ingestion and ultimate elimination in the feces. Radioactive silver was detected in the feces up to 300 days after exposure but was not detected in urine samples.[27,222] The deposition of silver in tissues is the result of the precipitation of insoluble silver salts such as silver chloride and silver phosphate. The highest concentrations of silver are usually found in the liver and spleen and to some extent in the muscle, skin, and brain.[27]

Toxicodynamics of Silver

Toxicity of silver and silver compounds is attributed to the free silver ion interacting with sulfhydryl, amino, carboxyl, and other groups on membrane or enzyme proteins.[221] Light catalyzes the reduction of silver salts deposited in skin to metallic silver. Elemental silver is subsequently oxidized to silver sulfide, which accounts for the gray skin discoloration that is indicative of argyria.[27]

Screening and Regulatory Levels for Silver

Silver is not considered to be a carcinogen or a reproductive or developmental toxicant.[222] The EPA's cancer evaluation is Group D, not classifiable. The EPA has derived an RfD for silver, 5 μg/kg/day.[19] Neither an RfC nor chronic MRLs are derived for silver. OSHA's PEL and NIOSH's REL for silver dust and soluble compounds are both 0.01 mg/m^3.[20,27] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Strontium

Sources of Strontium Exposure

Strontium is naturally occurring and found in rocks, soil, dust, coal, and oil. Naturally occurring strontium is not radioactive. It is estimated that 85% of all strontium consumed in the United States is used in the manufacture of ceramics and glass products, primarily in television faceplate glass and secondarily in ceramic ferrite magnets. Strontium salts are also used in the manufacture of pigments and electrical materials, and strontium salts give a characteristic red color to flames and fireworks. Occupational exposure to strontium may occur through inhalation of strontium compounds at workplaces where strontium is produced or used. The general population may be exposed to strontium via inhalation of ambient air, ingestion of food, and drinking water containing strontium.[27,223]

Adverse Health Effects of Strontium

Acute poisoning from ingestion of strontium compounds results in a sequela of headache, flushing of skin, vomiting, dizziness, marked fall of blood pressure, cyanosis, convulsions, coma, and eventually respiratory paralysis. Death is due to respiratory failure. Young, still growing, humans and animals are more susceptible than adults to the chronic effects of strontium compounds. Widening of the epiphyseal plate is observed at lower levels of dietary strontium. Since strontium metabolism is controlled by calcium, dietary calcium plays a protective role in strontium toxicity. Ingestion of food and water contaminated with strontium nitrate and nitrites is associated with the formation of methemoglobinemia. Reports of adverse effects following inhalations are rare.[27]

Toxicokinetics of Strontium

Estimates for the percentage of ingested strontium that is absorbed from the gastrointestinal tracts of humans vary from 5% to 30%. Intravenously administered ionic strontium forms colloidal or particulate strontium phosphate or binds to plasma proteins to form partly diffusible complexes. The protein complexes are distributed to the skeleton, kidneys, liver, spleen, brain, aorta, and other soft tissues. Strontium is similar to calcium in its chemical reactions and strontium kinetics are controlled by calcium levels in the tissues. Ninety-nine percent

(99%) of the typical body burden of strontium is found in bone, especially the epiphyseal region. In humans, the excretion of absorbed strontium is about 90% through urine. Unabsorbed dietary insoluble salts are excreted in the feces.[27,223]

Toxicodynamics of Strontium

Bone is the target organ following chronic strontium toxicity. High doses inhibit calcification of the epiphyseal cartilage and cause deformities of long bones. Strontium causes these effects by substituting for calcium in the hydroxyapatite crystal during calcification or displacing calcium from existing calcified bone. The metabolic basis of strontium's effect on calcium metabolism is thought to be inhibition of calcium absorption by dietary strontium as a result of a block in the renal synthesis of 1,25-dihydroxycholecalciferol (vitamin D_3) from 25-hydroxycholecalciferol.[190] In contrast to the toxic effects, pharmacologic treatment with low doses of strontium suppresses bone resorption, and strontium ranelate treatment has reduced the risk of vertebral fractures and increased bone mineral density in postmenopausal women with osteoporosis.[224,225]

Advisory, Screening, and Regulatory Levels of Strontium

The EPA has derived an RfD for strontium of 0.6 mg/kg/day. The EPA has not adequately evaluated stable strontium for carcinogenic potential and IARC does not list it. Strontium chromate is a human carcinogen via inhalation, but this is due to the presence of hexavalent chromium, which is a genotoxic carcinogen.[19] ATSDR has developed an intermediate-duration MRL of 2.0 mg/kg/day for strontium, but the agency has not developed chronic MRLs.[21,223] OSHA has not established regulatory levels, and NIOSH has not established advisory levels for strontium and strontium compounds.[20] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Uranium

Sources of Uranium

Uranium is a soft, malleable metal. The primary uranium ores are pitchblende (uranium oxide) and carnotite, a uranium-/vanadium-containing mineral. Uranium is primarily used as nuclear fuel, but there are some minor uses, such as a colorant in ceramics or glass, or as depleted uranium, a by-product of the uranium enrichment process used in armor-piercing projectile. Occupational exposure to uranium may occur through inhalation and/or dermal contact at workplaces where uranium compounds are liberated from mining, grinding, and milling of ores, packaging nuclear fuel rods, smelting operations, or the production of fluorescent glass.[27] The first significant military exposure occurred in friendly fire incidents.[226] The general population may be exposed to uranium via inhalation of ambient air or ingestion of food and drinking water containing uranium compounds.[27,227]

Adverse Health Effects of Uranium

The chemical toxicity of uranium and its salts is primarily manifested as kidney damage. Acute arterial lesions may occur after acute exposures. Soluble uranium, present in plasma as the uranyl ion complexed with bicarbonate, produces systemic toxicity in the form of acute renal damage and renal failure, which may be fatal. The classic signs of renal impairment include albuminuria, elevated blood urea nitrogen, and loss of weight. Renal damage is brought about by filtration of the bicarbonate complex through the glomerulus, bicarbonate reabsorption by the proximal tubule, liberation of uranyl ion, and subsequent damage to the proximal tubular cells.

Toxicokinetics of Uranium

Uranium is absorbed from the intestine or by the lungs, enters the bloodstream, and is rapidly deposited in the tissues, predominantly kidney and bone, or excreted in the urine. The uptake and fate of ingested uranium are controlled by the total quantity ingested and, to a lesser extent, the particular chemical form. In general, the smaller the amount ingested, the greater the fraction absorbed. There are data to indicate that between 12% and 30% of the ingested uranium is absorbed from the intestinal tract into the bloodstream. Of the absorbed uranium, approximately 80% is excreted, 10% goes to the kidneys, and the remaining 10% is deposited in the skeleton.[27] The kidney retention is believed to be brief. Because of efficient renal clearance of circulating uranium, redistribution of uranium deposits is inefficient and the body burden of uranium probably reflects recent dietary intakes.[190] Pulmonary absorption of uranium may be as high as 20% in humans.[27]

Toxicodynamics of Uranium

Oxidation of tetravalent uranium to hexavalent uranium is likely to occur *in vivo*. On entering the body, soluble uranium immediately forms complexes with anions, bases such as bicarbonate, citrate, malate, and lactate. Pentavalent uranium compounds have great affinity for phosphate-containing molecules and tissues, carboxyl and/or hydroxyl groups such as proteins, nucleotides, and bone tissue.[27] Phospholipid constituents of cell membranes that regulate membrane properties and cell membrane interactions and membrane-bound enzymes such as Na-K ATPase are potential sites of uranium action. The effects on lysosomes, mitochondria, and calcium metabolism and the insult to the microvilli of brush border membranes may also be potential sites of toxic action, resulting in reduced sodium and consequently reduced glucose, amino acid, and protein resorption, even before extensive cell damage occurs.[27,59] An implantation study in the rat indicated that urinary mutagenicity might be used as a biomarker to detect exposure to internalized depleted uranium in potentially exposed soldiers.[226]

Advisory, Screening, and Regulatory Levels of Uranium

The EPA developed an RfD for soluble salts of uranium, 3 μg/kg/day. The EPA has not derived an RfC for uranium

or soluble uranium salts.[19] The ATSDR's chronic inhalation MRLs for uranium and soluble uranium salts are 0.8 and 0.04 μg/m^3, respectively. No direct evidence exists that stable uranium is carcinogenic to humans or animals. The EPA's carcinogenicity assessment has been withdrawn, pending further review (Table 17.6).[19,21] NIOSH defines both soluble and insoluble uranium compounds as potentially carcinogenic and has not established RELs. The OSHA PEL for insoluble uranium compounds is 0.25 mg/m^3. The PEL for soluble uranium compounds is 0.05 mg/m^3.[20] Based on economic considerations, the EPA established a drinking water MCL of 30 μg/L. The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Vanadium

Sources of Vanadium

Vanadium is a white to gray common trace metal, which occurs in nature only in combination with oxygen, sodium, sulfur, and chloride. Occupational exposure to vanadium occurs predominately through the inhalation route of exposure and in settings such as mining of vanadium-bearing ores, steel mills where vanadium pentoxide is used, or during the cleaning of boilers fired by oil containing vanadium. The general population can be exposed to vanadium via inhalation of ambient air or by ingesting food or water containing vanadium.[27,228]

Adverse Health Effects of Vanadium

A greenish-black discoloration of the tongue, gastrointestinal symptoms, neurotoxicity, and renal toxicity are reported in workers exposed to vanadium pentoxide. Inhalation of vanadium pentoxide is associated with tracheobronchitis and inflammation. The progression of pathological lung changes with exposure and time is thought to affect the pattern and/or extent of vanadium lung deposition.[229] Oral exposure to vanadium can be toxic to the gastrointestinal, renal, and neurological systems. Vanadium deficiency is known to occur in laboratory animals on a very strict diet, and there is evidence that vanadium helps regulate some phosphoryl transfer enzymes.[213,230] Measurable responses of human subjects to variations in dietary intake of vanadium have been demonstrated. However, dose–response data are absent and the responses are not consistently observed. Thus, data are insufficient to estimate dietary requirements.[213]

Toxicokinetics of Vanadium

Elemental vanadium and vanadium compounds are absorbed from the respiratory tract. Their absorption from the gastrointestinal tract and skin is poor. Within tissues, vanadium (III) and (IV) predominate due to the reducing conditions. However, plasma is high in oxygen and vanadium (V) predominates. Compared with the vanadium (V) compounds, erythrocytes are slower to uptake vanadium (IV) compounds. Vanadium compounds are distributed to internal organs and can reversibly bind to blood transferrin protein. Vanadium is rapidly excreted in feces and urine following the termination of exposure, but there are data indicating that vanadium might accumulate in bone.[228]

Toxicodynamics of Vanadium

Vanadium can reversibly bind to transferrins in the blood and then be taken up into erythrocytes. Vanadium (V) is considered more toxic than vanadium (IV), because vanadium (V) is reactive and is a potent inhibitor of the plasma membranes sodium/potassium-ATPase. Vanadium (V) can also inhibit numerous enzymes that hydrolyze phosphate esters, including ribonuclease and alkaline phosphatases. A decrease in glutathione, nicotinamide adenine dinucleotide phosphate (NADPH), and nicotinamide adenine dinucleotide (NADH) occurs within an hour after intraperitoneal injection of sodium vanadate in mice. It is believed that vanadate requires the cytochrome P-450 components for oxidation to the vanadium (IV). A consequence of this action is the diversion of electrons from the monooxygenase system, resulting in the inhibition of drug dealkylation.[27]

Advisory, Screening, and Regulatory Levels for Vanadium

Although the Food and Nutrition Board has not estimated an EAR or AI for vanadium, it did estimate a UL of 1.8 mg/day. This value is for adults and is based on animal data.[213] The EPA derived an RfD for vanadium pentoxide of 5 μg/kg/day. The EPA has not derived an inhalation RfC for vanadium and has not evaluated the potential human carcinogenicity of vanadium.[19] The ATSDR's chronic inhalation MRL for vanadium is 0.0001 mg/m.[228] The NIOSH ceiling RELs for vanadium dust and vanadium fume are both 0.05 mg/m^3. OSHA's PEL for vanadium pentoxide dust and fumes were vacated by the Eleventh Circuit Court of Appeals in 1993.[20]

Table 17.6 shows the quantitative toxicity values derived by the EPA for the metals listed in this section. Using the RfDs as the criteria, the metals are listed in order of most to least toxic. The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

METALS FOR WHICH REFERENCE DOSES HAVE NOT BEEN ESTABLISHED

Bismuth

Sources of Exposure to Bismuth

Elemental bismuth is a soft, lustrous metal, which can occur naturally or in combined forms in ores. Bismuth is used in low-melting alloys. Compounds of bismuth are used as coloring agents in cosmetics, and in pharmaceuticals, including those used for diarrhea, gastroesophageal reflux, and in

ulcer therapy. Occupational exposure to bismuth occurs via inhalation of airborne dust and dermal contact. The general population is exposed to bismuth primarily through the use of cosmetic products and ingestion of pharmaceuticals containing bismuth compounds such as bismuth subnitrate and bismuth subsalicylate.[27]

Adverse Health Effects of Bismuth

In occupational settings, bismuth is considered one of the less toxic of the heavy metals. However, bismuth absorbed in industrial settings may complicate a diagnosis of lead poisoning, since the dark line in the gums, which is often present in lead poisoning, is also produced by bismuth. Oral exposure to bismuth and its salts can cause mild kidney damage, and toxicity has occurred from its use in medicine. Other toxic effects include malaise, albuminuria, diarrhea, skin reactions, and sometimes serious exodermatitis. Large doses can be fatal.[27] There are data that indicate that bismuth is not carcinogenic. Rats exposed to bismuth oxychloride in the diet for 2 years at doses up to 2.0 mg/kg/day were found to have no increased incidence of tumors.[231]

Toxicokinetics of Bismuth

Insoluble bismuth salts are poorly absorbed orally or dermally. Unabsorbed bismuth compounds are excreted in the feces.[27] Because bismuth induces the production of metallothionein, it is thought that bismuth may bind metallothionein in the blood. The organ distribution of bismuth compounds has been determined from the autopsies of clinically treated patients, and it is similar to that of other heavy metals: the greatest affinity for the kidneys. Bismuth crosses the placental. Newborn animals exhibit the same concentration as their bismuth-treated mothers. Bismuth is also excreted into the milk, but in lower concentration than in the urine.[27,59]

Toxicodynamics of Bismuth

Bismuth subsalicylate is an over-the-counter drug used in ulcer therapy. It does not neutralize gastric acid, but it provides cytoprotection by enhancing secretion of mucous and HCO_3^-, inhibition of pepsin activity, and the formation of bismuth protein complexes that may afford a protective barrier against peptic digestion. Bismuth subsalicylate is also used to treat diarrhea. It is hydrolyzed in the stomach, yielding salicylate and bismuth salts. The salicylate is absorbed. The bismuth salts are not absorbed and interfere with adhesion of bacteria to mucosal cells. Toxic bismuth levels are generally not reached with normal use, although salicylism has been reported following the use of bismuth subsalicylate.[232]

Advisory, Screening, and Regulatory Levels for Bismuth

NIOSH has established RELs for bismuth telluride of 10 and 5 mg/m^3 for total and respirable fractions, respectively. The OSHA PELs for bismuth telluride are 15 and 5 mg/m^3 for total and respirable, respectively.[20] The EPA has not developed an IRIS profile for bismuth compounds. The ATSDR has not developed a toxicity profile or MRLs for bismuth compounds. The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Cerium

Sources of Exposure to Cerium

Cerium is a lanthanum rare earth metal and is used in fireworks and cigarette lighter flints, self-cleaning ovens, and as an abrasive for polishing glass. Cerium is maybe added to the support surface for improved performance of automotive catalytic converters. Adverse effects are reported from occupational exposures to heavy metals, including cerium, which occurred during optical lens manufacturing. Cerium nitrate is used for the topical treatment of extensive burns.

Adverse Health Effects of Cerium

Occupational inhalation exposure has been reported to cause a pneumoconiosis without pulmonary functional impairment.[233] Intravenous administration of cerium chloride produces severe hepatotoxicity in rats.[30,234] There are data that indicate an acute exposure does not cause immune sensitization, but these data do not rule out immune responses after prolonged exposures.[27]

Toxicokinetics of Cerium

Cerium is poorly absorbed by the gastrointestinal tract. Particles of soluble or insoluble cerium ingested as a result of mucociliary clearance from the lung are unlikely to be reabsorbed. Retention in the lung is greater for less soluble forms of cerium, such as the cerium oxides, than for more soluble forms, such as the cerium chlorides. In humans, about 5%–10% of the deposited particles that have intermediate clearance are absorbed into the blood from the nasopharyngeal region and about 50% from the tracheobronchial region. In contrast, only 1% of the deposited particles with slow clearance are absorbed into the blood from these regions. Soluble forms of cerium are rapidly dissolved and absorbed into the circulation. It is estimated that the internal organ transfer rates are the same for cerium chloride and cerium oxide. Cerium in the blood is deposited to the liver, skeleton, and to a lesser extent, spleen and kidney. Deposition to the brain and heart has not been studied after inhalation exposure. About 80%–90% of the initial body burden of slow and intermediate cerium compounds is cleared within 7 days after inhalation.[27,235]

Toxicodynamics of Cerium

The rarity of cerium toxicity is attributable to its low gastrointestinal absorption. However, it is suggested that once absorbed, cerium may exert diverse biological effects due to its resemblance to calcium. Cerium nitrate is used for the topical treatment of extensive burns. In this context, cerium's direct antiseptic effects help prevent postburn sepsis and systemic inflammatory response by fixing burn toxins.[236]

Advisory, Screening, and Regulatory Levels for Cerium

The EPA has not derived toxicity values for cerium. However, the EPA developed an RfC for cerium oxide particles specifically with a mass median diameter of approximately 2 μm and a geometric standard deviation of 1.8–1.9. The use of this RfC for cerium compounds outside these specifications or for compounds other than cerium oxide is not recommended.[19] There are no MRLs developed for either chronic oral or chronic inhalation exposure to cerium.[237] Neither an REL nor a PEL has been developed for cerium.[20] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Gallium

Sources of Exposure to Gallium

Gallium is a relatively rare metal. It is commonly associated with zinc, germanium, and aluminum and primarily in the mineral, germanite. Gallium is used in the manufacture of alloys, and gallium arsenide and gallium aluminum arsenide are used in electronic components of photovoltaics and lasers. Gallium is present in coal. The general public may be exposed to particulate forms of gallium compounds released to the ambient air. Occupational exposure to gallium compounds may occur through inhalation of dust and dermal contact.[27] Medical patients may be exposed to gallium in its use in diagnostic radiology, its use as an antineoplastic agent,[238] or its use in the control of cancer-related hypercalcemia.[239,240]

Adverse Health Effects of Gallium

There are limited indications of occupationally related toxicity. Occupational exposure to GaF_3 fumes resulted in a rash with subsequent reversible neurological effects consisting of muscular weakness. No adverse effects were noted in a reproduction study conducted in male mice.[241]

Toxicokinetics of Gallium

Gallium (III) is the primary oxidation state for gallium compounds. Gallium pharmacokinetics were examined in clinical trials of gallium nitrate. When administered as an intravenous infusion over 30 min, a biphasic gallium urinary excretion pattern was observed. The first half-life was 8–26 min, and the second half-life was 6–196 h. The second phase was attributed to gallium binding to transferrin in the circulation. Sixty-nine to ninety-one percent of the gallium dose administered was excreted in the urine during the first 24 and 48 h.[242,243] In rats, renal toxicity is noted with the formation of precipitates of gallium complexed with calcium and phosphate.[59]

Toxicodynamics of Gallium

The chemical characteristics of gallium suggest that it may interact with cellular processes and biologically important proteins, especially those of iron metabolism. This potential has led to the development of certain gallium compounds as diagnostic and therapeutic agents in medicine especially in the areas of metabolic bone disease, cancer, and infectious disease. Gallium accumulates at the interface of the collagen and mineral components of bone and alters crystal solubility. Significant increases in bone calcium content occur in gallium-treated bone, which also makes bone less likely to be resorbed. In addition, gallium acts by blocking osteoclast activity without affecting the cell's viability. It is thought that the mechanism of antineoplastic activity of gallium is a two-step process in which the first step involves the targeting of transferrin-gallium to transferrin receptor-bearing tumor cells. In the second step, gallium perturbs cellular iron metabolism by interfering with transferrin receptor-mediated uptake of iron. This leads to a condition of tumor cell iron deprivation and inhibition of the iron-dependent function of ribonucleotide reductase, the enzyme essential for deoxyribonucleotide synthesis.[243]

Advisory, Screening, and Regulatory Levels for Gallium

The EPA has not derived toxicity values for gallium.[19] The ATSDR has not developed a toxicity profile or MRLs for gallium.[18] There are no NIOSH RELs or OSHA PELs for gallium or its compounds.[20] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Germanium

Sources of Exposure to Germanium

Germanium metal has a metallic appearance but is very brittle, much like glass. Germanium is not found in the free state but always in combination with other elements such as silver, copper, and arsenic. It is used in the semiconductor industry and was used in the first transistor. Germanium is often used in combination with other materials, such as arsenic and antimony, and alloyed with aluminum, gallium, and indium. It is also used in certain optic applications because the pure metal is transparent to infrared radiation. Industrial exposures to the dusts and fumes of germanium metal occur during extraction from ore and metal fumes from welding operations.[27,59] Germanium oxide and germanium sesquioxide have been used in elixirs for the treatment of cancer and acquired immune deficiency syndrome.[244]

Adverse Health Effects of Germanium

In longer-term oral animal studies, germanium and germanium oxide have been shown to be nephrotoxic, neurotoxic, and myotoxic.[245,246] The potential for germanium to induce lung injury is unclear. In one four-week inhalation toxicity study of germanium powder in rats, histopathologic changes consistent with pulmonary toxicity were present but, a follow-up study using germanium dioxide did not report treatment-related microscopic histopathologic effects in the lung.[247] Germanium does not appear to be carcinogenic. Certain germanium compounds appear to have antineoplastic activity.[248] In a lifetime feeding study in rats, animals receiving 5 parts per million sodium germanate in water had a significantly lower incidence of tumors than the control

animals.[249] To date, there have been at least 31 reported cases of toxicity associated with oral intake of germanium compounds, of which nine were fatal.[244] Nephrotoxicity is the primary manifestation of germanium intoxication.[30,244,250] Germanium compounds are not mutagenic. High doses of germanium may result in an increased embryonic resorption. Malformations have been reported only after administration of dimethyl germanium oxide to pregnant animals.[248]

Toxicokinetics of Germanium

Germanium is well-absorbed; its concentration in human urine is about the same as the concentration in the diet. Germanium in various forms is absorbed from the gastrointestinal tract and excreted in the urine (68%) and the feces (9.7%) within 24 h of administration. It is fairly equally distributed between plasma and red blood cells. Since it leaves the bloodstream in a few hours, it is likely that germanium is transported in the blood unbound to proteins. Germanium is widely distributed in body tissue and not selectively retained by any single tissue. The clearance rate of inhaled germanium particles is reported to be exponential with 52% excreted in 24 h and 18% retained for 7 days postexposure. Inhaled germanium enters the circulation and appears in the kidney and liver 1 h after exposure.[27]

Toxicodynamics of Germanium

An antineoplastic activity of germanium may be attributable to an ability to inhibit the mutagenic activity of other substances.[248]

Advisory, Screening, and Regulatory Levels for Germanium

The NIOSH REL for germanium tetrahydride is 0.6 mg/m^3. OSHA has not derived a PEL for germanium or germanium compounds.[20] The EPA has not developed an IRIS profile, and ATSDR has not developed a toxicity profile or MRLs for germanium or germanium compounds.[18,19] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Gold

Sources of Exposure to Gold

Gold's excellent heat and electrical conductivity and malleability have made it important in industrial applications. Medically it is used either orally or by intramuscular injection to slow the progression of rheumatoid arthritis, but treatment is associated with a high incidence of toxicity.[3] While gold compounds are not commonly used or encountered in the environment, occupational exposure to gold may occur through inhalation and dermal contact with gold at workplaces where gold is processed or used. Environmental monitoring data indicate that the general public may be exposed to gold via inhalation of ambient air, ingestion of food, and dermal contact with gold.[27]

Adverse Health Effects of Gold

Adverse skin and mucous membrane effects, including dermatitis, stomatitis, and pruritus, are most frequent. The incidence and severity of these effects are less for oral as opposed to parenteral treatment.[251] A mild proteinuria is the most common renal effect, but gold-induced nephrosis may occur. Aplastic anemia is relatively rare and has been associated with poor prognosis, which may improve with bone marrow transplantation.[252,253] Although traditionally regarded as inert, gold is being recognized as a common contact allergen.[254,255] In Sweden, it is second only to nickel, and a report from the North American Contact Dermatitis Group ranks it among the 10 most common allergens in the United States.[256] Gold was named Contact Allergen of the Year in 2001 by the *American Journal of Contact Dermatitis*.[257] Eyelid dermatitis was found in 7.5% of patients with a positive gold patch test reaction.[258] Gold allergy is more common in women than men and is linked to nickel and cobalt allergy. Gold hypersensitivity is characterized by late reactions, and failure to monitor the test site for a minimum of three weeks may result in false negatives.[30]

Toxicokinetics of Gold

Gold salts are poorly absorbed from the gastrointestinal tract. After injection of soluble salts, gold is excreted in the urine. Ingested insoluble gold compounds are excreted in the feces. Gold is thought to have a long biological half-life since detectable blood levels can be demonstrated for 10 months after cessation of treatment. Gold (III) binds strongly to metallothionein.[27]

Toxicodynamics of Gold

In vitro studies designed to simulate the oxidative conditions found inside lysosomes suggest that a redox system might be operating. It is postulated that $AuCl_3$ is formed from gold (I) thiomalate during an oxidative burst in phagocytic immune cells. Since $AuCl_3$ is a better oxidant than Au (I), it dominates both the anti-inflammatory and toxic effects of gold salts. Studies of the reduction of $AuCl_3$ and its derivatives by serum albumin and various thiols and thiol-ethers suggested that the reduction occurs over a slower time frame than the hypochlorite oxidation of gold (I).[27]

Advisory, Screening, and Regulatory Levels for Gold

The EPA has not developed an IRIS profile for gold or gold compounds.[19] The ATSDR has not developed MRLs or a toxicology profile for gold or gold compounds.[18] NIOSH has not developed an REL for gold or gold compounds, and OSHA has not developed PELs.[20] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Hafnium

Sources of Exposure to Hafnium

Hafnium is a gray metallic element having a silver-like luster and is found in association with zirconium ores. It has

outstanding corrosion resistance and is used for this characteristic in atomic reactors, electronic components, and alloys. It has been evaluated for its antimicrobial properties as a coating on surgical implants.[93] Occupational exposure to hafnium may occur through inhalation and dermal contact at workplaces where hafnium is produced or used. Monitoring data indicate that the general population may be exposed to hafnium via inhalation of ambient air, ingestion of food, or drinking water.[27]

Adverse Health Effects of Hafnium

Hafnium compounds show moderate toxicity in acute animal tests by several routes of administration.[259] Hafnium is poorly absorbed orally, and the dust is considered to have relatively low toxicity.[260] Workers exposed to 150 mg/m^3 of hafnium- and zirconium-containing dusts showed no adverse effects after 2–6 years.[261] In occupational settings, overexposure to hafnium and its compounds may cause mild irritation of the eyes, skin, and mucous membranes. The NIOSH REL is based on the risk of liver damage, and eye and skin irritation in animals.

Toxicokinetics and Toxicodynamics of Hafnium

Hafnium can be absorbed into the body by inhalation of its aerosol. The absorption following oral administration of various chemical forms of a hafnium radioisotope was found to be between 0.04% and 0.13% of the ingested dose. Absorption was increased by fasting. Studies in rodents indicate that hafnium concentrates in the liver and skeleton.[27] The irritation of eyes and skin is attributed to the chemical reactivity that is characteristic of all metals.

Advisory, Screening, and Regulatory Levels for Hafnium

The NIOSH REL and OSHA PEL, for hafnium and hafnium compounds, are both 0.5 mg/m^3.[20] The EPA has not developed an IRIS profile, and the ATSDR has not developed a toxicity profile for hafnium.[18,19] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Indium

Sources of Exposure to Indium

Indium is not found in the free state, but most commonly, in association with copper, zinc, and sulfur. Indium is used in surface protection of metals, and in many alloys, because of its ability to increase hardness. Indium compounds are also used in the photovoltaic and semiconductor industry. Industrial exposures to indium occur during extraction and purification, in plating and the manufacture of certain electronic instruments.[59]

Adverse Health Effects of Indium

Soluble indium compounds are more toxic than their insoluble indium compounds. The acute lethal dose range for the soluble indium chloride in rabbits, rats, and dogs is 0.33–3.6 mg/kg,[262] whereas the minimum lethal dose for insoluble indium oxide in rats is 955 mg/kg.[94]

Indium compounds are toxic when inhaled. A review of seven cases of occupational exposure found that slightly soluble indium compounds cause interstitial as well as emphysematous lung damage.[263] Copper indium diselenide and indium trichloride, when acutely administered intratracheally to rats, at doses higher than would be expected in an industrial exposure, induced a persistent inflammatory response.[264–266] Copper indium diselenide was only slightly fibrogenic to the lung. This is consistent with its limited solubility.[264] Subchronic inhalation of indium sesquioxide in rats induced a persistent inflammatory response, and no fibrosis was noted. Hamsters were treated once per week for 15 weeks with either indium arsenide or indium phosphide by intratracheal installation and were examined at the end of their lifespan. Adverse histopathologic findings were significantly higher in the treated groups.[267]

Several studies have investigated the reproductive and developmental toxicity of indium compounds. Indium arsenide, administered intratracheally, reduced epididymal sperm counts in rats, but not in hamsters.[268,269] Intratracheal instillation of indium chloride in mice did not affect reproductive performance of either males or females, but it was fetotoxic.[270] Indium trichloride was a developmental toxin in mice and rats when administered intravenously.[271]

Toxicokinetics of Indium

Absorption of indium compounds is highly dependent on form. Insoluble indium compounds are poorly absorbed and distributed, whereas soluble compounds, such as $InCl_3$ and $In_2(SO_4)_3$, are rapidly absorbed and distributed.[59,272] The primary route of indium excretion is also determined by the chemical form administered. Ionic indium is mainly excreted in urine while colloidal indium complexes are primarily excreted in feces. Muscle, skin, and bone constitute the main storage sites.[27]

Toxicodynamics of Indium

Indium chloride exerted inhibitory actions on the enzyme ALA-dehydratase in kidney following acute *in vivo* exposure. It is thought that indium alters the excretion of several other enzymes in the heme pathway in a highly specific manner.[27]

Advisory, Screening, and Regulatory Levels of Indium

The NIOSH REL for indium and indium compounds is 0.1 mg/m^3. OSHA has not published a PEL for either indium or indium compounds.[20] Neither the EPA nor ATSDR has developed toxicological profiles for indium.[18,19] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Lithium

Sources of Exposure to Lithium

Lithium is a silvery-white metal and the lightest solid element. Although it is used in batteries, organic synthesis (Grignard reagent), in the space industry, as a swimming pool sanitizer, and in air conditioners, occupational intoxication has not been reported.[273] Lithium hydride in contact with water releases flammable hydrogen gas. Thus, it must be stored under airtight anhydrous conditions.[30,59]

Adverse Health Effects of Lithium

Inhalation exposure to lithium hydride can cause pulmonary edema, but the hydride rather than the lithium is likely responsible.[217] Signs of lithium toxicity are primarily neurologic and range from fine tremors and muscle weakness, in mild cases, to dysarthria, hyperreflexia, coma, and collapse. Lithium therapy may produce lasting neurologic consequences.[274,275] Renal symptoms of intoxication include polyuria, polydipsia, and renal failure.[276] Lithium therapy during pregnancy has been associated with an increased risk of cardiac anomalies, and there are sufficient animal and human data to indicate lithium can cause developmental toxicity.[30,277]

Toxicokinetics of Lithium

There is no specific antidote for lithium intoxication, and treatment is based on limiting absorption and enhancing excretion.[278] Hemodialysis is used to enhance excretion.[276] There is some evidence that sodium polystyrene sulfonate reduces the half-life of lithium and that it is capable of promoting lithium elimination in chronic intoxications.[279] However, development of hypokalemia may represent a potential limitation in the use of sodium polystyrene sulfonate for the treatment of lithium toxicity.[30,280]

Toxicodynamics of Lithium

Lithium has properties similar to sodium, and substitution for sodium and/or potassium is thought to account for the adverse effects.[281] Oral lithium salts, such as lithium carbonate and lithium citrate, are widely used in the treatment of manic-depressive disorders. Routine serum monitoring is required because of the narrow therapeutic index.[281,282] The same levels of lithium are devoid of psychotropic effects in individuals not suffering manic-depressive disorders.[281]

Advisory, Screening, and Regulatory Levels for Lithium

The NIOSH REL and the OSHA PEL for lithium hydride are both 0.025 mg/m^3.[20] The EPA has not developed an IRIS profile for lithium.[19] The ATSDR has not developed MRLs or a profile for lithium.[18] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Niobium

Sources of Exposure to Niobium

Niobium is a white-colored soft metal found in ores in combination with tantalum and other elements.[59] Niobium is used in alloys and may find use in surgical implants and dental applications.[283–285]

Adverse Health Effects of Niobium

Acute and chronic animal tests have been conducted on several niobium compounds.[286–288] Parenteral administration of niobium pentachloride results in decreased respiration, lethargy, and death. The compound is a moderate to severe skin irritant. Life-term studies of sodium niobate in mice and rats did not show carcinogenicity.[249]

Toxicokinetics and Toxicodynamics of Niobium

Niobium is poorly absorbed from the gastrointestinal tract. The irritation of eyes and skin that results from exposure to niobium is attributed to the chemical reactivity that is characteristic of all metals.[30]

Advisory, Screening, and Regulatory Levels for Niobium

No reports of occupational health hazards from dust or fumes associated with forging or other fabrication techniques of niobium metal and alloys have been recorded.[59] NIOSH has not established a, REL, and OSHA has not established a PEL for niobium.[20] The EPA has not developed an IRIS profile for niobium.[19] The ATSDR has not developed MRLs or a profile for niobium.[18] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Osmium

Sources of Exposure to Osmium

Osmium is found in combination with platinum and nickel-bearing ores. Osmium can form many compounds with oxidation states ranging from 0 to +8, with the most common valances being +2 and +3. Osmium tetroxide is a noncombustible, colorless to pale yellow solid, with a disagreeable chlorine-like odor. An osmium–tungsten alloy has been used for filaments for incandescent lamps. Osmium–iridium alloy is extremely hard and is employed for pen nibs, engraving tools, and watch bearings. Occupational exposure to osmium and osmium compounds may occur through inhalation of dust, and by dermal contact at workplaces where metals are mined or processed or where osmium compounds are produced or used. Since osmium has a low abundance in the environment and limited uses, exposure to the general population is expected to be low.[27]

Adverse Health Effects of Osmium

Metallic osmium and most of compounds other than osmium tetroxide are not considered highly toxic. Osmium tetroxide

has been shown to be toxic in animals and in man. The oral LD_{50} for osmium tetroxide is reported to be 14 mg/kg in the rat and 162 mg/kg in the mouse. The intraperitoneal LD_{50} for the mouse is 14 mg/kg.[59] The reported LC_{50} for the rat and mouse is 400 mg/m^3. In humans, inhalation exposure to OsO_4 can cause irritation of the nose and throat, which can persist for at least 12 h. Industrial exposure to osmium tetroxide concentrations ranging from 0.1 to 0.6 mg/m^3 induced lacrimation and disturbances in vision. Other complaints included conjunctivitis, cough, and headache. Recovery usually occurred within a few days.[30] One human fatality has been reported, resulting from inhalation of osmium tetroxide. Death was attributed to capillary bronchitis and pulmonary edema.[289]

Toxicokinetics and Toxicodynamics of Osmium

Osmic acid was previously used as a local treatment of rheumatoid synovitis. Of the 1% osmic acid solution injected into arthritic joints, most was excreted in the urine with none accumulating in the contralateral knee, the regional lymph nodes, the liver, or the heart.[27] The irritation of the nose and throat following exposure to OsO_4 is attributable to the chemical reactivity that is characteristic of metals.

Advisory, Screening, and Regulatory Levels of Osmium

The NIOSH REL and the OSHA PEL for osmium tetroxide are both 0.002 mg/m^3.[20] The EPA has not developed an IRIS profile for osmium.[19] The ATSDR has not developed MRLs or a profile for osmium.[18] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Platinum

Sources of Exposure to Platinum

Although platinum is relatively rare, it is found both as the pure metal and in combination with nickel, copper, and gold.[59] Platinum is used as a catalyst in the automotive, chemical, and pharmaceutical industries; and its nobility, or resistance to oxidation, makes it important in the manufacture of laboratory equipment.[30]

Adverse Health Effects of Platinum

Metallic platinum is relatively inert. The complex salts are frequent sensitizers producing conjunctivitis, urticaria, dermatitis, and eczema following inhalation and/or dermal exposure.[30,290] A syndrome, formerly known as *platinosis*, is characterized by lacrimation, sneezing, rhinorrhea, cough, dyspnea, bronchial asthma, and cyanosis.[290] *Platinosis* might be taken to indicate pneumoconiosis and fibrosis, but these are not part of platinum allergy syndrome. Thus, the condition is more accurately referred to as an allergy to platinum compounds containing reactive halogen ligands.[291] Cisplatin has been used as a chemotherapeutic agent against various cancers, especially testicular and ovarian tumors, despite nephrotoxicity at therapeutic doses.[290] More recently, carboplatin has been used with comparable efficacy and less toxicity for many types of cancer. In these cases, thrombocytopenia is the major side effect.[290,292] Platinum (IV) is capable of inducing oxidative DNA damage.[293] However, no increased risk of cancer has been reported from occupational exposure to platinum.[30,290]

Toxicokinetics and Toxicodynamics of Platinum

A report on the tissue distribution of a single oral dose of cationic platinum in rats indicated almost all the dose was excreted in the feces. Intravenous administration to rats of small doses of labeled Na_2PtCl_4 showed higher platinum retention in the liver, kidneys, spleen, and muscle than in the bones. About 35% of the dose was excreted within 24 h in urine and feces. The low fecal excretion suggested an enterohepatic excretion pathway.[27] The platinum allergy symptoms are elicited by either an immediate (type I) or delayed (type II, within 24 h) hypersensitivity reaction.[290]

Advisory, Screening, and Regulatory Levels for Platinum

NIOSH has not established an REL, and OSHA has not established a PEL for platinum or platinum compounds.[20] The EPA has not evaluated the toxicity of platinum.[19] The ATSDR has not developed a profile or MRLs for platinum or platinum compounds.[18] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Rhodium

Sources of Exposure to Rhodium

Rhodium is a silver-white hard metal that can form highly corrosive resistant alloys and coatings used in electrical contacts, reflectors, and jewelry.[290] Antimalarial activity is reported for a rhodium–chloroquine complex.[294] Occupational exposure to rhodium and rhodium compounds may occur through inhalation of dust and by dermal contact at workplaces where rhodium is produced or used. The general population may be exposed to rhodium via inhalation of air.[27]

Adverse Health Effects of Rhodium

Only a limited toxicity profile has been developed for rhodium and its compounds. Sensitizing activity of hexachlororhodiate related to occupational exposure is reported.[27] Rhodium trichloride is moderately low in acute toxicity. Intravenously administered rhodium trichloride of approximately 200 mg/kg is lethal in rats and rabbits with death possibly due to CNS depression.[295] Oral rhodium trichloride was low in toxicity with an LD_{50} greater than 500 mg/kg.[290] A chronic feeding study showed slight carcinogenic activity in mice.[296]

Toxicokinetics and Toxicodynamics of Rhodium

There are data to suggest that rhodium is clastogenic through a mechanism involving oxidative damage to DNA.[293] Complexes of rhodium (III) can intercalate into the DNA strand and are photo-oxidants that promote DNA strand cleavage or electron transfer through the double helix.[27]

Rhodium (II) compounds irreversibly inhibit the activity of enzymes that have essential sulfhydryl groups. Enzymes without essential sulfhydryl groups are not affected.[27]

Advisory, Screening, and Regulatory Levels for Rhodium

Neither the EPA nor the ATSDR has developed toxicity profiles for rhodium. Elemental and rhodium compounds are not classifiable as human carcinogens. The NIOSH REL and OSHA PEL for metal fume and insoluble compounds are both 0.1 mg/m^3. The REL and PEL for soluble compounds of rhodium are both a hundred times lower, 0.001 mg/m^3.[20] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Tantalum

Sources of Exposure to Tantalum

Tantalum is a gray hard metal found in ores in combination with niobium and other metals. It is used in electric capacitors, as the carbide for tools, and has a wide range of uses in medical diagnostic and surgical implant applications.[59,297] This includes tantalum gauze used in the repair of hernias, implant plates and screws, and radiographic lung and bone markers.[297]

Adverse Health Effects of Tantalum

Elemental tantalum and its principal oxide are essentially nontoxic *in vitro* and *in vivo*.[285] Furthermore, occupational exposure to tantalum and its oxide has shown no overt adverse health effects.[30] Irritation of skin, eyes, and the respiratory tract and cases of hard metal pneumoconiosis are reported in settings where workers are exposed to a mixture of metals that includes tantalum.[27] There are a few case studies that report allergic responses to tantalum used in surgical implants.[27]

Toxicokinetics and Toxicodynamics of Tantalum

A study of the clearance of radiolabeled tantalum metal powder following its introduction into the respiratory tract of dogs is reported. Results showed a prolonged alveolar clearance phase with a mean biologic removal half-life of greater than 2 years. Studies of humans exposed via inhalation of radioactive contamination indicated that approximately 93% of the activity was eliminated entirely in the feces in 7 days.[27] Irritation of skin, eyes, and the respiratory tract and reports of hard metal pneumoconiosis are attributable to chemical reactivity characteristic of metals.

Advisory, Screening, and Regulatory Levels of Tantalum

The NIOSH REL and OSHA PEL, for tantalum metal and oxide dust, are both 5 mg/m^3.[20] The EPA has not developed an IRIS profile for tantalum.[19] The ATSDR has not developed MRLs or a toxicity profile for tantalum.[298] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Tellurium

Sources of Exposure to Tellurium

Tellurium has a number of industrial uses and is also found in a variety of food products, for example, condiments, dairy products, nuts, and fish, in high concentrations.

Adverse Health Effects of Tellurium

There are no reports of serious illness or death in workers exposed to tellurium and its compounds other than sodium tellurite.[30] Two fatalities occurred after unintentional treatment with 2 g of sodium tellurite by ureteral catheter.[299] The autopsy revealed acute fatty degeneration and edema of the liver. Pneumonitis and hemolytic anemia are prominent features of acute tellurium intoxication.[300] Tellurium hydride has been shown to be highly toxic, causing pulmonary irritation and intravascular hemolysis.[301] Acute oral or parenteral tellurium intoxication resulted in numerous symptoms, with hematuria noted in all animals treated.[300] Weanling rats fed 1% tellurium in the diet developed a peripheral neuropathy characterized by a transient demyelinating/remyelinating event.[302,303]

Toxicokinetics and Toxicodynamics of Tellurium

Absorbed tellurium is slowly metabolized to dimethyl telluride and is excreted in urine, sweat, and breath.[304] Dimethyl telluride is responsible for the *garlic breath* that is associated with tellurium exposure.[305] Ninety percent (90%) of the body stores of tellurium are in bone.[27]

Advisory, Screening, and Regulatory Levels of Tellurium

The NIOSH REL and OSHA PEL is 0.1 mg/m^3 for tellurium and tellurium compounds except tellurium hexafluoride and bismuth telluride. The REL and PEL for tellurium hexafluoride are both 0.2 mg/m^3.[20] The EPA has not developed an IRIS profile for tellurium.[19] The ATSDR has not developed MRLs or a profile for tellurium.[298] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Thallium

Sources of Thallium

Thallium occurs naturally in the environment and is present in nearly all environmental media. Thallium sulfate was widely used as a rodenticide, but its use was banned in the United States in 1972. Thallium is easily taken up by plants through the roots, entering the food chain, and trace amounts of thallium are found in nearly all plant and animal species,

as well as foodstuffs. Historically, it has been used to treat gout, venereal disease, dysentery, ringworm, and tuberculosis. It is currently used in the electronics industry and in the manufacture of prisms, costume jewelry, pigments, low-temperature thermometers, and infrared spectrometers. Occupational exposure to thallium compounds may occur through inhalation and dermal contact at workplaces where thallium and thallium compounds are produced or used or during the handling of pyrites or flue dusts. The general public can be exposed to small amounts of thallium via inhalation of ambient air and ingestion of food and drinking water. Due to the limited commercial applications of thallium compounds, the exposure of the general public to thallium compounds is expected to be small.[27,306] Thallium intoxication from contaminated heroin and cocaine, presumably imported from areas where thallium is still used as a rodenticide, has been reported.[307,308]

Adverse Health Effects of Thallium

The principal clinical features of thallotoxicosis are gastroenteritis, peripheral neuropathy of unknown etiology, and alopecia.[309] Thallium is well-absorbed following oral ingestion and causes severe gastrointestinal symptoms followed by painful paresthesia of the extremities, motor paralysis, and death from respiratory failure. Individuals surviving the acute phase suffer characteristic scalp alopecia about 10 days postingestion.[309–312] Mees' lines are often seen on finger nails 2–4 weeks after exposure.[302] Alopecia combined with a painful peripheral neuropathy are suggestive of thallium poisoning, but a definite diagnosis requires demonstrating elevated thallium levels in hair, nails, feces, saliva, blood, or urine.[313]

Toxicokinetics of Thallium

Thallium ion is absorbed and distributed like potassium ions because it has the same charge and similar ionic radius. Thallium is easily absorbed by the skin as well as by the respiratory and gastrointestinal tracts. The prolonged body retention of thallium is attributed to an enterohepatic recirculation. Following inhalation of thallium oxides and salts, thallium is rapidly absorbed from mucous membranes of respiratory tract, mouth, and lung. After absorption into blood, thallium ion may be absorbed into erythrocyte or transported in the plasma in its ionic form. Thallium ion does not combine with the albumin or other proteins and is rapidly distributed to the tissues. It easily passes through the blood–brain and placental barrier and is excreted in the milk of lactating animals.[27]

Toxicodynamics of Thallium

Because thallium's structure is similar to potassium, it alters potassium-dependent processes. Thallium toxicosis likely involves the substitution of the thallous ion for potassium in the sodium/potassium ATPase pump and/or interference with sulfhydryl enzymes. Presumably, alopecia and Mees' lines result from thallium's interference with the formation of disulfide bonds.[309] Interference with tissue riboflavin, with subsequent effects on metabolic pathways, has also been suggested.[314] Thallous ion accumulation in lens occurs by active transport. An unexpected finding was the high storage of thallium in melanin-containing eye structures. Chelating agents, such as sodium diethyldithiocarbamate, have caused a redistribution of thallium to target organs, with an increase in toxicity.[315] In October 2003, the USFDA approved a Prussian blue formulation for suspected thallium poisoning.[313] Prussian blue's crystal lattice makes it an effective ion exchanger for univalent cations in general, and its therapeutic use depends on the preferential binding of thallium over potassium.

Advisory, Screening, and Regulatory Levels for Thallium

EPA reviewed information, but an RfD for soluble salts of thallium was not estimated due to difficulties in the selection of appropriate endpoints. An RfC has not been derived for thallium. ATSDR did not derive chronic-duration oral or inhalation MRLs. Thallium is placed in Group D, not classifiable as to human carcinogenicity, based on two inadequate negative studies in humans and a lack of animal studies designed to examine carcinogenic endpoints.[19,21] The OSHA PEL and NIOSH REL for soluble thallium compounds are both 0.1 mg/m^3.[20] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Tin

Sources of Exposure to Tin

Tin is a soft white metal, which occurs in combination with other chemicals, for example, chlorine and oxygen.[316] It is alloyed with other metals to make pewter, solder, bronze, and a special cast bronze termed bell metal (up to 24% tin), which is noted for its tonal quality.[59] Most of the tin used in the United States is for plating steel cans. The fluoride is used in toothpaste, and the chloride is used to make frost-free windshields.[317] Organotins function as antimicrobials in agriculture and industry, as stabilizers in polyvinylchloride plastics, and as marine antifouling agents.[59] Although Schwarz et al. reported in 1970 a significant growth effect of dietary tin in weanling rats maintained on purified diets, this has not been independently confirmed, and tin is not considered to be essential.[8,30,318]

Adverse Health Effects of Tin

Soluble salts of inorganic tin are gastric irritants, producing nonspecific signs of nausea, vomiting, and diarrhea. Rats maintained on diets containing 0.3% soluble inorganic tin salts, such as stannous chloride, experienced growth retardation and anemia.[319] Acute inhalation exposure to tin can cause metal fume fever, and chronic exposure can cause a benign pneumoconiosis, stannosis.[217] Organotins, especially the trialkyl derivatives, are highly toxic. The rat acute oral LD_{50} is 10 mg/kg.[320] Triethyltin compounds are skin irritants and potent neurotoxins producing a decrease in myelin content of the CNS and edema of the white matter.[321]

Toxicokinetics of Tin

Inorganic tin compounds are poorly absorbed from the gastrointestinal tract. Rats dosed orally absorbed 2.8% of tin (II) and less than 1% of tin (IV).[322]

Toxicodynamics of Tin

Injected stannous chloride is a potent inducer of rat renal microsomal heme oxygenase, enhancing heme breakdown.[323] Diets supplemented with high levels of iron and copper protected rats from the anemia but did not alleviate growth depression.[324] Tin has adverse effects on the absorption and metabolism of the essential elements iron, copper, and zinc.[319,324,325] Uncoupling of oxidative phosphorylation has been proposed as the mechanism of action.[326] Butyltins have been shown to inhibit human placental cytochrome P450 aromatase activity when measured *in vitro* and to affect male sexual development in rats.[327,328]

Advisory, Screening, and Regulatory Levels for Tin

The NIOSH REL and the OSHA PEL for metallic tin and for other inorganic tin compounds, except the tin oxides, are both 2 mg/m^3. OSHA has not established PELs for the tin oxides. The NIOSH REL for both tin (II) oxide and tin (IV) oxide is 2 mg/m^3. The NIOSH REL and the OSHA PEL for organic tin compounds are both 0.1 mg/m^3.[20] The EPA has not defined toxicity values for elemental tin. The RfD for tributyltin oxide is 0.0003 mg/kg/day; an RfC is not established.[19] The chronic oral MRL for tributyltin oxide is 0.0003 mg/kg/day. The ATSDR has established intermediate and chronic oral MRLs for other forms of tin, including tributyltin oxide and dibutyltin dichloride.[329] The EPA has not evaluated tin and tin-containing compounds for carcinogenicity. The EPA puts tributyltin oxide in its Group D classification, not classifiable as to human carcinogenicity.[19] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Titanium

Sources of Exposure to Titanium

Titanium is a silver-gray-colored metal that can occur naturally in several forms. Titanium is a component of several alloys and is used in surgical implants where it is considered nontoxic.[330] Titanium dioxide, the most common oxide of titanium, is extensively used as a white pigment in paints, plastics, inks, and cosmetics.[59,331] Occupational exposure to titanium primarily occurs in the mining and production of the metal, and in the production and processing of titanium dioxide and carbide. Occupational exposure to titanium compounds may occur through dermal contact and inhalation titanium dioxide dust and inhalation of titanium tetrachloride vapor.[27] For the general population, food is the principal source of exposure to titanium. Dermal exposure may occur with the use of a variety of drug and cosmetic applications. Titanium compounds are used as sunscreens, for treatment of herpes simplex, in dermatological and cosmetic formulations, and in a variety of tablet-coating formulations.[27]

Adverse Health Effects of Titanium

Titanium dioxide is considered to be essentially nontoxic by the oral, dermal, and inhalation routes. A 2-year feeding study of titanium dioxide at maximum doses of 2.5 g/kg/day in rats and 6.4 g/kg/day in mice found no evidence of carcinogenicity. However, the dose–response relationship was statistically significant for thyroid tumors in female rats and keratoacanthomas in male rats.[30,332–334] Toxicity from respiratory exposure to titanium dioxide has been investigated. A 2-year inhalation study was conducted in rats with acceptable results at a level of 10 mg/m^3. The high levels produced squamous cell carcinomas, which are postulated to be the result of saturation of normal pulmonary clearance mechanisms.[335] Epidemiological findings and related information do not conclusively support a relationship between occupational exposure to titanium dioxide and pulmonary fibrosis, cancer, or other adverse health effects.[30]

Toxicokinetics and Toxicodynamics of Titanium

Three percent of ingested titanium is absorbed, and in man, most of the absorbed titanium is excreted in the urine. The highest concentration of the retained dose is found in the spleen and adrenals followed by the striated muscle, liver, and kidney. Titanium has been found in the lungs and kidneys of infants, indicating that it crosses the placenta.[27]

Advisory, Screening, and Regulatory Levels for Titanium

The titanium tetrachloride chronic inhalation MRL is 0.0001 mg/m.[320] The OSHA PEL for titanium dioxide is 15 mg/m^3. NIOSH defined titanium dioxide as a potential occupational carcinogen and for this reason has not established an REL.[20] The EPA has not developed an IRIS profile for titanium.[19]

Tungsten

Sources of Exposure to Tungsten

Tungsten occurs in nature in combination with iron, manganese, and calcium. The major use of tungsten is in cutting and wear-resistant materials.[59] Tungsten-iron shot is also in use as a less toxic replacement for lead shot.[336]

Adverse Health Effects of Tungsten

The bulk of inhaled tungsten oxide is rapidly excreted in dogs.[337] Although exposure to soluble tungsten compounds can be toxic in experimental animals,[338] insoluble tungsten compounds have a low order of toxicity.[336,339,340] Male and female rats given sodium tungstenate in water for 2½ years at

doses of 0.25 and 0.29 mg/kg/day had no significant increase in tumor incidence.[286] Pulmonary fibrosis observed in men with inhalation exposure to cobalt-cemented tungsten carbide has been attributed to cobalt.[59,341] Evaluation of workers with long-term exposure to tungsten or its insoluble compounds showed no development of pneumoconiosis.[30]

Toxicodynamics of Tungsten

The tungsten ion antagonized the normal metabolic action of the molybdate ion and, therefore, can inhibit molybdate-dependent enzymes.[342–345]

Advisory, Screening, and Regulatory Levels for Tungsten

The NIOSH REL for tungsten metal and insoluble compounds is 5 mg/m^3. The REL for soluble compounds is 1 mg/m^3. OSHA has not established PELs for tungsten metal or tungsten compounds.[20] The EPA has not developed an IRIS profile for tungsten.[19] The ATSDR has not developed MRLs or a toxicology profile for tungsten.[298] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Yttrium

Sources of Exposure to Yttrium

Yttrium is a reactive rare earth lanthanide and is silvery white in color.[59] It is used as an alloying agent in stainless steels requiring high resistance to corrosion. When used in combination with zirconium, it improves the strength of magnesium castings. In the electronics industry, it is used as the matrix producing the red color in television screens.[59]

Adverse Health Effects of Yttrium

Yttrium chloride has been reported to cause granulomatous changes in the rat lung following intratracheal instillation. The liver and spleen are reported to be the primary target organs following intravenous injection.[346,347] Despite a long history of industrial use, there are no definitive reports of adverse effects in workers.[59] The LD_{50} for yttrium chloride following intraperitoneal injection in rats is 132 mg/kg body weight.[348]

Advisory, Screening, and Regulatory Levels of Yttrium

The EPA has not derived toxicity values for yttrium.[19] The ATSDR has not developed MRLs or a toxicology profile for yttrium.[18] The NIOSH REL and OSHA PEL for yttrium metal and compounds is 1 mg/m^3.[20] The EPA has not developed an IRIS profile for ytterbium.[19] The advisory, screening, and regulatory values provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

Zirconium

Sources of Exposure to Zirconium

Zirconium is a grayish white element that is produced from two main sources of ore, zircon ($ZrO{\cdot}SiO_2$) and baddeleyite (ZrO_2). Zirconium is used for the cladding in nuclear fuel rods, and zirconium compounds are also used in foundry and sandblasting applications. Industrial exposure occurs during mining and purification operations. A significant percentage of the general population is exposed dermally to aluminum zirconium chlorohydrate complexes in commercially marketed antiperspirant products.

Adverse Health Effects of Zirconium

Zirconium oxide has a low order of toxicity via the inhalation route in animals. Slight toxicity was noted in dogs when exposed to an airborne mist of zirconium chloride at 6 mg/m^3 for 2 months.[349] Zirconium oxide and zirconium chloride exposure at 3.5 mg/m^3 for 1 year had no measurable adverse effect on the animals exposed.[59] Similarly, in most studies of industrially exposed workers, no adverse effects have been associated with inhalation exposure to zirconium fumes or zirconium compounds.[350–352] However, several cases of either fibrotic[353] or granulomatous[354,355] changes in the lung associated with inhalation exposure to zirconium compounds have been reported. Long-term exposure of mice to zirconium sulfate was not associated with increased tumor incidence.[248]

Certain zirconium compounds, such as zirconium lactate, when applied to human skin[59,356–358] or the skin of experimental animals,[359] can produce dermal granulomas of allergic origin. Aluminum zirconium chlorohydrate complexes, used as active ingredients in antiperspirants, do not appear to cause these granulomatous reactions. However, because of risk/benefit considerations, the USFDA and other global regulatory authorities banned the use of these materials in aerosolized drug and cosmetic products.[360]

Toxicokinetics and Toxicodynamics of Zirconium

The absorbed zirconium is either sequestered in skeleton or excreted very rapidly. Less than 1% of daily intake of zirconium of humans is excreted in the urine due to the poor absorption from the gastrointestinal tract. Absorbed zirconium is excreted in human milk. It is thought that a mechanism that maintains zirconium homeostasis is present in man.[27] Zirconium salts are used in the treatment of plutonium poisoning because it displaces the plutonium from its deposition in the skeleton and prevents deposition when treatment is started early.

Advisory, Screening, and Regulatory Levels of Zirconium

The NIOSH REL for zirconium metal and compounds, except zirconium tetrachloride, is 5 mg/m^3. The OSHA PEL is also 5 mg/m^3, but this is for zirconium metal only.[20] The ATSDR has not developed MRLs or a toxicology profile for zirconium.[18] The EPA has not developed an IRIS profile for zirconium.[19] The advisory, screening, and regulatory values

provided herein are revised as new information becomes available. The reader is referred to the responsible agencies/organizations for the most up-to-date values.

QUESTIONS

17.1 How are essential metals distinguished from nonessential metals?

Answer: Quantifying dose–response is fundamental to distinguish essential and nonessential metals. The concept is illustrated by hypothetical dose–response curves. Only essential metals exhibit increasing toxicity with decreasing dose (Figure 17.1a). Thus, only essential metals can generate a U-shaped dose–response curve (Figure 17.1c).

17.2 What are the three fundamental determinants (physical, chemical, or biological) of metal toxicity?

Answer:

a. The strength with which a metal complexes with a molecular ligand. This is a physical–chemical determinant that characterizes nonessential metals' potential to displace essential metals from metalloproteins.
b. The biological significance of the function of the metalloprotein in which the essential metal has been displaced.
c. The potential of a metal to participate in generation of reactive oxygen species.

17.3 Serious side effects are associated with therapy using some of the metal chelators. Newer analogs like the hydrophilic chelator, meso-2,3-dimercaptosuccinic acid, are less toxic because they effectively promote renal metal excretion. What is the limitation of hydrophilic chelators, and what are the two new strategies for addressing this limitation?

Answer: The trade-off for the benefit of efficient excretion is that hydrophilicity limits access to intracellular metals. Newer strategies attempt to address this limitation by (1) combining structurally different chelating agents or (2) coadministering antioxidants (see Figure 17.2).

17.4 Why have zirconium salts been used to treat acute and chronic plutonium poisoning?

Answer: The strategy was to exchange the low metal toxicity of zirconium for the higher toxicity of the plutonium radionuclide. This is possible because the ionic radius of zirconium is similar to plutonium, and this enables zirconium to displace plutonium from its deposition in the skeleton and to prevent the deposition when treatment is started early.

17.5 The toxicity of inorganic lead is well documented. Why has neither an RfD nor chronic MRLs been established for lead?

Answer: The adverse health effects associated with lead occur at blood lead levels so low as to be without a threshold.

18 Radiation Toxicity

Roger O. McClellan

CONTENTS

INTRODUCTION

The toxicology of ionizing radiation is a highly specialized area of toxicology of substantial breadth and depth. It is obvious that it cannot be covered in great detail in a single textbook chapter. Nonetheless, recognition that life exists within a *sea of ionizing radiation* of natural origin and that a number of important medical and industrial applications of radiation may result in exposure of humans and other life forms to radiation doses above the background requires that well-educated toxicologists be informed about basic concepts of radiation toxicology. Moreover, many of those basic concepts are also relevant to understanding the toxic effects of nonradioactive agents; to assessing their hazard, exposure, dose, and health risks; and to controlling those health hazards and risks. To meet the needs articulated earlier, the presentation of this chapter is of a survey nature with specific and general references provided that will assist the interested reader in obtaining a more detailed understanding of the subject.

Despite the survey nature of this chapter, it is important to recognize that radiation as a toxic agent has been more extensively investigated than any other single toxic agent or broad class of toxicants. The extraordinary amount of information resulting from those investigations has been reported in detail in innumerable original scientific papers and reviews published in peer-reviewed scientific journals. The vast majority of the papers have been published in English language journals; however, many have also appeared in journals published in the major languages of the world. In addition to the papers published in scientific journals, many nonclassified government reports contain detailed research findings and analyses of research conducted between the 1940s and the 1980s.

In addition to the published original research findings, a number of authoritative scientific organizations have regularly issued integrative reports summarizing current knowledge on the health effects of exposure to radiation and radioactive materials. Most notable are the reports of the National Council on Radiation Protection and Measurements (NCRP), a U.S. organization; the International Commission on Radiological Protection (ICRP); the United Nations scientific Committee on the Effects of Atomic Radiation (UNSCEAR); the International Atomic Energy Agency (IAEA), the Atomic Bomb Casualty Commission (ABCC), now operating as the Radiation Effects Research Foundation (RERF); and various committees on Biological Effects of Ionizing Radiation (BEIR) of the National Research Council (NRC) of the U.S. National Academies.

This chapter is concerned with ionizing radiation, which is energy in the form of waves or particles that during passage through matter transfer energy to the matter. The transfer of energy can remove electrons from the orbit of atoms, leading to the formation of ions, hence the term *ionizing radiation*. There are two general types of ionizing radiation: electromagnetic and particulate radiation. The electromagnetic radiation includes x-rays and gamma rays. The particulate radiation includes alpha particles, beta particles, positrons (positive electrons), neutrons, protons, and heavy ions (such as charged nuclei). This chapter is not concerned with nonionizing radiation such as ultraviolet radiation, radiofrequency radiation such as microwaves, and extremely-low-frequency radiation such as that associated with electric power lines. Suffice it to note, ionizing radiation is far more harmful to living organisms per unit of energy deposited than nonionizing radiation, since ionizing radiation can cause damage to deoxyribonucleic acid (DNA). Ionizing radiation can be measured in air, liquid media, or tissue. Radiation exposure is the absorption of ionizing radiation by an object such as the mammalian body, tissues, or organelles. Radioactivity is the property or characteristic of an unstable atomic nucleus to transform with the emission of energy in the form of rays or particles.

Readers interested in more detailed coverage of the fundamentals of radiation and its effects on living systems will find the textbooks of the following authors useful: Bushong (2013), Hall and Giaccia (2012), Turner (2007), Mettler and Upton (2008), and Till and Grogan (2008). The historical treatise (Stannard and Baalman, 1988) remains a valuable reference on the toxicity of radioactive materials. The classic document on the effects of nuclear weapons by Glasstone and Dolan (1977) provides a historical context for considering the health effects associated with detonating nuclear weapons. Moreover, reading about the effects of nuclear weapons will emphasize the importance of achieving international control of them. In addition, it is important for toxicologists and other scientists to distinguish between concern for the effects of nuclear weapons and the very different issues related to peaceful uses of nuclear energy, radiation sources, and radionuclides. A nuclear weapon and a nuclear reactor are not equivalent.

To aid the reader, some definitions are provided in Table 18.1 for key words and phrases regularly used in radiation science that will augment the "Glossary" at the end of this textbook. Table 18.2 provides a concise summary of the major units used in radiation science and radiation protection. These radiation units evolved as the field of radiation science, and radiation protection developed. The earliest units, termed conventional units, were ultimately superseded by the newer International System of Units (SI), which were most enthusiastically embraced first in Europe and have been accepted much more slowly in the United States. As you read this chapter, take care in identifying the specific units being used since both conventional units and International Units are used consistent with what the authors used in the various original papers and reports. Moreover, it is important to recognize units such as a curie or becquerel (Bq) with different prefixes can be used to describe concentrations of radioactivity spanning many orders of magnitude analogous to going from micrograms to kilograms of chemical mass.

It was a special pleasure for me to prepare this chapter on radiation toxicity since it provided me the opportunity to revisit how my career has been impacted by my personal relationship with the world of radiation, which I note at various places in the chapter. This includes moving in 1944 to Richland, Washington, adjacent to the

TABLE 18.1
Key Definitions in Radiation Science and the Effects of Radiation on Health

ALARA	Principle that states that radiation exposure should be kept as low as reasonably achievable when social and economic factors are taken into account.
Alpha particle	Particle with mass equivalent to a helium nucleus, two protons and two neutrons.
Atom	Smallest particle of an element that cannot be divided or broken by chemical means.
Beta particle	A charged particle of very small mass emitted spontaneously from the nuclei of certain radioactive elements. Physically, a beta particle is identical to an electron moving at high velocity.
Deterministic effect	A biological response whose severity increases with absorbed dose. A dose threshold usually exists.
Element	One of the distinct, basic varieties of matter occurring in nature.
Fission	The process whereby the nucleus of a particular heavy element following the absorption of a neutron splits into two nuclei of lighter elements with the release of substantial energy. Controlled and sustained fission occurs in a nuclear reactor. Fission of ^{239}Pu and ^{235}U is a key component of the detonation of nuclear weapons.
Fusion	The process whereby the nuclei of lighter elements, especially those of hydrogen (deuterium and tritium), combine to form the nucleus of heavier elements with the release of substantial energy. A thermonuclear weapon involves fission followed by fusion.
Gamma rays	Electromagnetic radiation of variable energy originating in atomic nuclei. Physically, x-rays and gamma rays are identical.
Ionizing radiation	Radiation capable of causing ionization.
Irradiated	Referring to matter that intercepts radiation and absorbs part or all of it: exposed.
Isotopes	Forms of the same element having identical chemical properties but differing in atomic mass (due to different numbers of neutrons in their respective nuclei) and nuclear properties (radioactivity).
Linear energy transfer (LET)	Measure of the rate at which energy is transferred from ionizing radiation to tissue. Expressed in kiloelectron volts per micrometer of soft tissue.
Nuclide	An atomic species of an element distinguished by the composition of its nucleus, i.e., the number of protons and neutrons.
Radioactive half-life	The time required for the activity of a given radionuclide to decrease to half its initial value due to radioactive decay.
Radionuclide or radioisotope	An isotope or nuclide that is unstable and will spontaneously decay by emission of alpha or beta particles.
Stochastic effects	Probability or frequency of the biological response to radiation as a function of radiation dose. Disease incidence, such as cancer, increased proportionally with dose, and the absence of a threshold is usually assumed. The severity of the disease is not influenced by dose.
X-rays	Penetrating, ionizing electromagnetic radiation that has a wavelength much shorter than that of visible light. Physically, x-rays and gamma rays are identical.

TABLE 18.2
International Units for Radiation and Radioactivity Compared to Old Units

International Units	Description	Old Units
Becquerel (Bq)	Radioactivity, the spontaneous decay of atomic nuclei 1 Bq = 1 disintegration/s	Curie = 3.7×10^{10} Bq
Gray (Gy)	Dose to tissue 1 Gy = energy uptake of 1 J/kg	Rad[a] = 10 mGy
Sievert (Sv)	Effective dose,[b] dose normalized to effects of gamma radiation by applying a W_R based on the relative biological effectiveness (RBE) of the radiation of interest, to the absorbed dose in an organ or tissue to derive the equivalent dose. The effective dose is usually expressed as millisievert (mSv). 1 mSv = 10^{-3} Sv	Rem[c] = 10 mSv

[a] Rad, originally radiation absorbed dose.
[b] Allows conversion of dose from gamma, beta, or alpha radiation to a standard unit.
[c] Rem, originally based on roentgen equivalent man.

emerging Hanford Nuclear Site; working with scientists at the Hanford Laboratories as a high school and university student beginning in 1950; serving on the staff of the Hanford Laboratories full time in 1960–1964, a special assignment with the Division of Biology and Medicine of the U.S. Atomic Energy Commission (AEC) in 1965–1966; serving as the director of the Inhalation Toxicology Research Institute at the Lovelace organization in Albuquerque, New Mexico, from 1966 to 1988; and serving as the president of the Chemical Industry Institute of Toxicology from 1988 to 1999. In each of these organizations, I had the pleasure of working with exceptionally competent scientists, engineers,

and support personnel who valued the use of a multidisciplinary teamwork approach to address important societal issues. The teamwork approach extended broadly to other research organizations, government agencies, scientific societies, and entities like the NCRPs, which I served on from 1971 to 2001, and the National Academies that were part of a broader collaboration creating scientific knowledge to inform important societal decisions. I hope you will indulge my personal and historical approach to reviewing radiation toxicology from its roots to the present time.

KEY CONCEPTS

This chapter will be useful for the reader to have in mind four overarching concepts or themes that will aid in understanding the health effects of radiation: (1) Radiation and radioactivity are readily measured; (2) radiation and radioactivity are everywhere; (3) exposure–dose–response relationships are of prime concern; and (4) not all doses of ionizing radiation are equally effective in causing effects. It will be evident that these concepts are also important to understand and assess the health hazards and risks of chemicals.

Radiation and Radioactivity Are Readily Measured

The first concept is that both ionizing radiation and radioactivity are readily measured and quantified down to extraordinarily low levels. Indeed, the ease with which radiation or radioactivity can be measured is a great advantage to conduct research on radiation and radioactivity and evaluate potential health risks. However, the ability to measure extraordinarily low levels also presents the challenge of differentiating between quantities of radiation and radioactivity that can be measured at exceptionally low levels and have no associated harm versus measured quantities that may be harmful. A statistically significant measurement of radiation or radioactivity does not automatically equate to a harmful level. It is also important to recognize that units of measured radiation and measured radioactivity are not interchangeable.

Radiation and Radioactivity Are Everywhere

The second concept is that human kind and all living things exist in a sea of radiation and radioactivity. Humans and other organisms can be exposed to ionizing radiation originating from both external and internal sources. The pathways for radioactivity to reach humans and give rise to internal irradiation are illustrated in Figure 18.1.

Sources external to the body include cosmic radiation and radiation coming from naturally occurring radionuclides in the environment, direct radiation from nuclear detonations such as occurred at Hiroshima and Nagasaki and from nuclear weapons tests and external exposure from deposited radioactivity dispersed from testing of nuclear weapons or released from accidents such as occurred at Windscale, Chernobyl, and Fukushima. Many medical diagnostic and therapeutic applications of radiation also involve the use of external sources. The external nature of these radiation exposures is different from the case with chemicals where exposure usually refers to chemicals entering the body. The external exposures to ionizing radiation can be very brief, essentially instantaneous as occurs immediately with detonation of a nuclear weapon or in many medical procedures (Figure 18.2). Protracted external exposures, overextended periods of time, can occur such as from cosmic rays or gamma rays from released radioactivity contaminating surfaces.

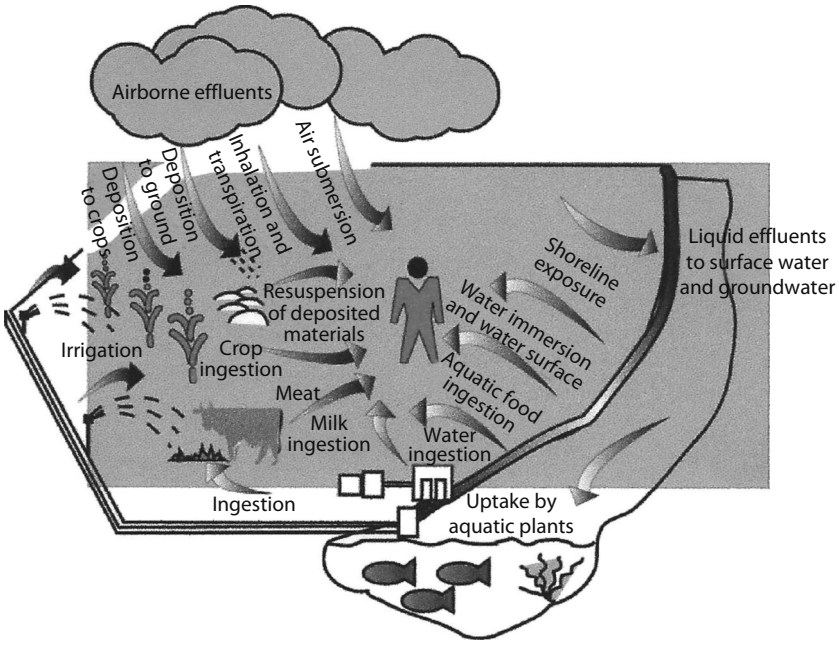

FIGURE 18.1 Schematic representation of pathways for radioactivity to reach humans. (From Till, J.E. and Grogan, H.A., eds., *Radiological Risk Assessment and Environmental Analysis*, Oxford University Press, New York, 2008.)

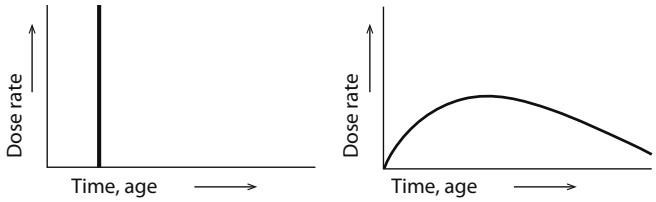

FIGURE 18.2 External brief radiation exposure and resulting tissue dose occur simultaneously while the intake of radioactivity results in a protracted tissue dose.

The situation is quite different for internally deposited radionuclides entering the body via the pathways illustrated in Figure 18.1. Radionuclides of natural origin and man-made may enter the body by ingestion, by inhalation, through wounds, and by absorption through the skin or by purposeful injection in a medical application. Entry of radionuclides taken into the body by these avenues is similar to what occurs with chemicals. However, ionizing energy from internally deposited radionuclides is released over a period of time dependent upon the physical half-life of the radionuclide and the biological characteristics of the radionuclide itself or the chemical compound or matrix in which it is incorporated. The time course for exposure and delivery of the radiation dose is not the same for internally deposited radionuclides.

Soon after the discovery of naturally occurring radioactive elements, their wide distribution in nature became evident. This evidence for the widespread distribution of naturally occurring radionuclides mounted as new and more sensitive radiation detection instruments and measurement techniques were developed. The likelihood of man-made radionuclides, such as those produced by nuclear fission being released and distributed in the environment, was appreciated early in the development of the Manhattan Project for each major production site, such as Hanford and Oak Ridge. The schematic rendering in Figure 18.1 illustrates the pathways for such releases. Because radioactivity can be readily detected and quantified, it can be readily traced in the environment. For example, at Hanford, a large quantity of water passed through the reactors for thermal cooling, was retained briefly in ponds to allow cooling of the water and decay of short-lived radionuclides, and was then released to the Columbia River. Trace quantities of some stable elements in the cooling water were activated to become radioactive. For example, chromate was added to the reactor cooling water to inhibit corrosion. Trace amounts were activated to ^{51}Cr. Trace quantities of phosphorus was activated to ^{32}P. The fuel elements containing uranium occasionally ruptured, releasing fission or activation products such as ^{65}Zn. The radionuclides in the water were available for uptake by aquatic biota, including fish. The fish may then be caught and consumed by people.

The pathway of reactor effluent–river water–fish for human contamination was recognized and studied at the Hanford Nuclear Site. Waterfowl were found to have ingested contaminated aquatic biota and recognized as a source of human contamination. With the initial dissolution and chemical processing of irradiated uranium fuel elements at Hanford, it became apparent that volatile radionuclides such as ^{131}I could be released to the atmosphere and deposited as *fallout* on forage, which would then be ingested by grazing animals. ^{131}I was soon detected in the thyroids of wild rabbits and deer on the plant site and in the thyroids of coyotes that had ingested the contaminated rabbits. Concern was immediately raised for the transfer of ^{131}I to domestic sheep and cattle. The potential was recognized for ^{131}I deposited on forage to be ingested by dairy cows with contamination of milk potentially ingested by humans and resulting in thyroid uptake and irradiation.

It was also recognized that river water contaminated with radioactivity might be used for irrigation. This could be a source of uptake by plant roots or foliar deposition and absorption if sprinkler irrigation were used. Dairy cattle could ingest contaminated pasture or hay with subsequent transfer to milk. This pathway was found to be operative for trace quantities of ^{65}Zn released from the Hanford reactors. As a student, I studied how soil characteristics such as pH influenced the uptake of ^{65}Zn by bean plants. At Hanford, there were also instances in early operations in which radioactive particles were released from the stacks of the fuel-reprocessing facility. The *hot* particles containing ^{106}Ru were readily detected on the plant site and became of concern as a source of skin irradiation if deposited on the skin of humans or animals.

Exposure–Dose–Response Relationships

The third concept that must be addressed to understand the health effects of radiation and radioactivity is the nature of the exposure–dose–response relationship for a range of health endpoints. An overarching conceptual framework for considering the multiple events linking exposure to external radiation or radionuclides with tissue dose, mechanistic events, and health responses is shown in Figure 18.3. This framework shows acute effects, including lethality associated with high levels of external radiation exposure and very large radionuclide intakes over short periods of time that are required to produce the radiation doses required to cause lethality in a matter of days to months. Much greater attention and controversy relate to chronic or late-occurring health effects such as heritable effects in the progeny of irradiated individuals or cancers caused by irradiation with cancers appearing after a latent period of years to decades.

In the case of radiation, it is important to distinguish between exposure and dose. Exposure refers to a measurement of the ionization produced in air, for example, from gamma rays or x-rays. Radiation exposures, that is, ionization in air, can be measured down to very low levels. Exposure also refers to the intake of radioactivity such as by oral intake or inhalation. Dose is the amount of radiant energy absorbed by the body, organ, or specific tissue volume from either external sources or internally deposited radioactivity. The radiation dose can be measured or calculated with a high degree of precision. Thus, in the field of radiation toxicology and radiation protection when reference is made to dose, it has a very specific meaning. This situation is very different

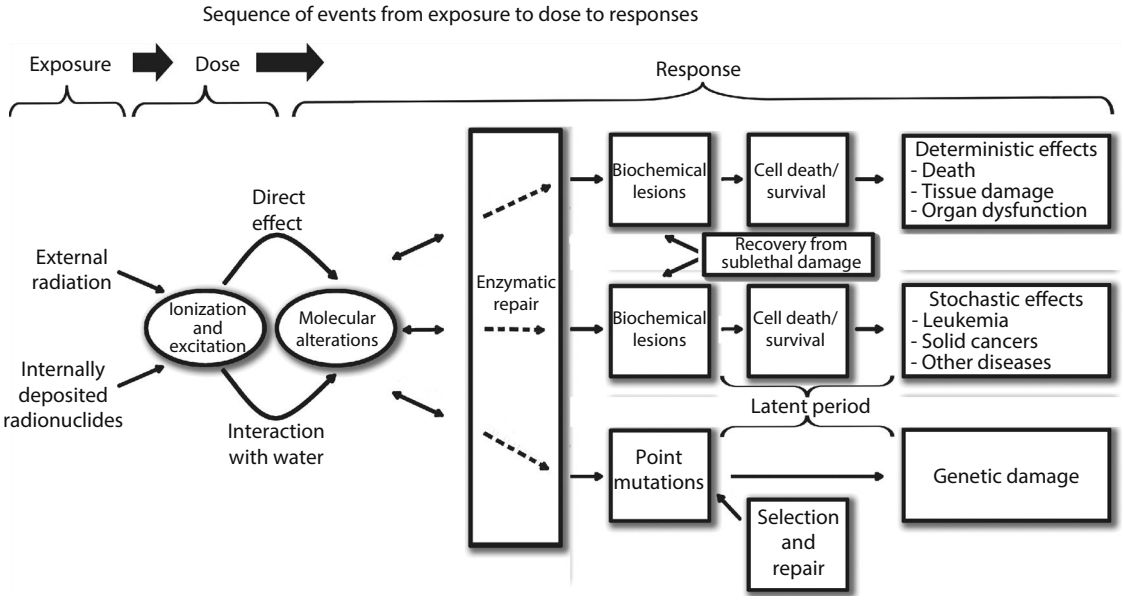

FIGURE 18.3 Conceptual framework linking events from exposure to external sources or internally deposited radioactivity to dose to biological responses. (Adapted from Bushong, S.C., *Radiological Science for Technologists: Physics, Biology and Protection*, 10th edition, Elsevier/Mosby, St. Louis, MO, 2013.)

from the field of chemical toxicology where the words *exposure* and *dose* are frequently used in interchangeable fashion.

A related issue linked to the dose–response relationship is the nature of the responses considered in two broad categories—deterministic effects or stochastic effects, terms commonly used in radiation biology and radiation protection. Deterministic effects or responses occur above some threshold dose of radiation and increase in severity as the radiation dose increases. At lower radiation doses, deterministic effects are not observed. Erythema or reddening of the skin and development of cataracts of the lens are classic deterministic effects. Stochastic effects, occurring at random, are those responses or diseases whose probability of occurrence is a function of radiation dose in the absence of a threshold with the severity of the response or disease being independent of the radiation dose. In general, the initial event leading to a stochastic response is thought to occur in a single cell. Induction of cancer is a classical stochastic effect of radiation.

Paul Henshaw (1941) published one of the earlier and very insightful discussions of the nature of dose–response relationships for different kinds of responses. In this landmark paper, he discussed two fundamental dose–response relationships for radiation: (A) a no-threshold dose–response relationship with the response incidence increasing with dose and (B) a threshold dose–response relationship with a threshold dose below which responses would not be observed (Figure 18.4). He also discussed the various types of injury and responses that radiation exposure produced and which type of curve was applicable to the response. Later the effects associated with curve A would be identified as stochastic effects and those associated with curve B as deterministic effects. This issue has received substantial attention in the field of radiation research and in the development of radiation protection guidance. Ironically,

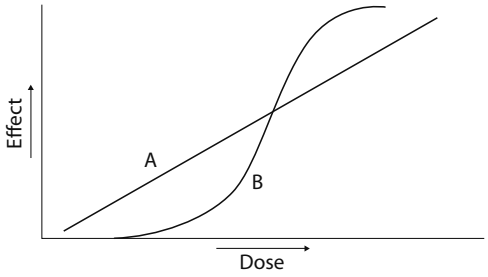

FIGURE 18.4 Schematic rendering of two fundamentally different dose–effect relationships for radiation. (Adapted from Henshaw, P.S., *J. Natl Cancer Inst*., 1, 789, 1941.)

this same issue came to the forefront only decades later in the field of chemical toxicology and in the development of guidance and regulations to protect against chemical hazards. Post–World War II, discussion began of the potential for hormetic effects with low radiation doses.

Not All Radiation Is Equally Effective in Causing Effects

The fourth concept must be considered in understanding the effects of radiation: The effectiveness of a given absorbed dose of ionizing radiation will be influenced by both radiation quality and the rate at which a given dose is delivered. In addition, the biological characteristics of the organ or tissue receiving the radiation dose will influence the nature of the health response. The quality of radiation is a function of the linear energy transfer (LET) of the radiation, for example, low-LET gamma or x-ray photons or beta particles compared with high-LET alpha particles. The influence of radiation quality is

usually assessed by comparing the Relative Biological Effects (RBEs) of a particular radiation with low-LET gamma irradiation or x-irradiation. Another consideration is that the effectiveness of a given absorbed dose of radiation may be influenced by the dose rate at which the dose is delivered (recall Figure 18.2). These latter issues are of particular concern for internally deposited radionuclides, situations that are analogous in some ways to internally deposited chemicals.

As you proceed through the chapter, these three themes will emerge and recur. In the conclusion to the chapter, these themes will be reviewed in the context of radiation as well as the insights they provide for chemical toxicology and risk assessment.

HISTORY OF RADIATION AND RADIOACTIVITY

Discovery of Radiation and Radioactivity to Discovery of Fission

Radiation and radioactivity have been part of the universe from its origin with detailed knowledge of radiation and radioactivity evolving as a result of human curiosity, serendipitous discoveries, and purposeful research. As will be discussed later, human activity has resulted in the creation of some unique, new radioactive elements and many new radionuclides of existing naturally occurring elements. Moreover, human activities have resulted in enhanced concentrations of some naturally occurring radioactive materials (NORM).

The German physicist, Wilhelm Conrad Roentgen, in 1895, discovered a new kind of rays emitted by a gas discharge tube that could blacken photographic films. Roentgen was studying the conduction of cathode rays, now known as electrons, through a glass tube partially filled with gas. This tube, called a Crookes' tube after its founder, was a forerunner of today's fluorescent light bulb. So that Roentgen could better see the light produced in the tube, he darkened the room and covered the tube with paper. By chance, a few feet away was a photographic plate coated with a fluorescent material, barium platinocyanide. When he activated the tube, he noted that the fluorescence plate glowed, and the intensity increased when he moved the plate closer to the tube. Because the rays represented the unknown, he called them x-light or x-rays. Roentgen soon discovered that the x-rays could be used to visualize the skeleton. He published the first medical radiograph, an image of the skeleton in his wife's hand. On January 23, 1896, *Lancet* reported the first medical diagnostic use of x-rays in medicine. The report detailed the finding of a broken part of a knife in a drunken sailor who was paralyzed until the piece of the knife was removed. In 1896, an Austrian surgeon, Leopold Freund, demonstrated that treatment of a hairy mole with x-rays caused the mole to disappear. This represented the first therapeutic medical application of radiation. Today, both diagnostic and therapeutic applications of radiation are an integral part of the practice of medicine.

The second edition of Gmelin's *Handbook of Chemistry*, in 1824, included a description of uranium. By the mid-1800s, it was being used in homeopathic medicine to treat diseases such as diabetes. In 1895, Ernest Rutherford showed that uranium *emanations* had the spectral line of helium. In 1896, Antoine Henri Becquerel discovered radiation emissions from uranium compounds. Pierre and Marie Curie in 1898 isolated polonium and radium from pitchblende ore containing uranium and its decay products and coined the term *radioactivity* to describe these materials as distinct from radiation. Rutherford in 1904 showed that alpha particles are helium atoms and worked out the decay scheme for the uranium series as will be discussed later.

The pitchblende ore and the elements uranium, radium, and polonium used by the early investigators came from mines in Schneeberg and Joachimstal in the Erz Mountains of Central Europe. It was known in the 1400s that miners there suffered a chronic respiratory malady. In 1879, two German investigators, Härtung and Hesse, showed that a majority of the deaths of miners were due to malignant lung tumors. In the early 1900s, the tumors were confirmed to be of bronchogenic origin, and it was suggested that radium and radium emanations had a causative role. Ironically, the Schneeberg/Joachimstal experience would be repeated in the mid-1900s in miners working in uranium mines in the western slope of the U.S. Rocky Mountains, yet later in uranium mines in other countries, and even later in tin mines in China.

It is reported that Becquerel carried a vial of radium in his vest pocket, which inadvertently produced erythema and ulceration in his underlying skin. It is said that Pierre Curie purposefully repeated the experience producing a radiation burn on his forearm and studied the subsequent healing.

The use of x-rays as a medical diagnostic procedure and use of implanted radon needles to treat cancer grew rapidly in Europe and North America and soon gained worldwide acceptance. X-ray machines for diagnostic purposes were considered essential in even small hospitals and clinics. Large x-ray machines with higher-energy x-rays for cancer treatment were found in all major hospitals. During the early 1900s, hospitals in major cities had facilities for loading needles with radon for implantation into cancers. As an aside, I learned that one of my great grandmothers traveled, in 1910, from a small town in Iowa by train to Chicago to be treated for cancer with surgery and radiation.

Soon after Roentgen's discovery of x-rays, research began on the potential, injurious effects of exposure to x-rays. Later, the research would expand to include naturally occurring radionuclides. The results of much of that early research were reviewed by Henshaw (1941). These studies soon demonstrated damaging effects on the reproductive organs and hematopoietic tissue. While studying the effects of x-rays on plants, Atkinson (1898) was bewildered that deleterious effects were not always observed at low doses. This may be the first report of hormetic effects of radiation.

In the early 1900s, gas mantles began to be manufactured using thorium (Thorotrast), which began to be used as a contrast medium in diagnostic radiology.

In the early 1900s, it was discovered that trace quantities of radium and thorium salts could be mixed with phosphors,

which resulted in phosphorescence. Subsequently, young women were employed to paint watch and instrument dials using this mixture. Tipping the fine brushes on their lips resulted in the women ingesting the radium and thorium, which translocated to the skeleton. Later, these individuals would develop hematopoietic anomalies, bone disease, and bone cancer. This tragic experience will be discussed later.

In this same era, it became fashionable to visit spas, especially those with radioactive water and radon in the air, for the alleged therapeutic benefits. Nostrums containing radium and radon soon came on the market. Throughout the 1920s, many individuals were injected with radium or ingested it for a variety of real and fancied disorders. A prominent industrialist regularly ingested sufficient radiothor, a mixture of ^{226}Ra and ^{222}Ra (radiothorium); when he died of radium poisoning, it attracted national attention.

Rutherford, in 1919, observed that bombardment of nitrogen atoms by alpha particles from natural sources produced oxygen. Between 1933 and 1934, Jean Frederic Joliot and Irene Curie (Pierre and Marie Curie's daughter) were the first to produce a new radioisotope by transmutating another element. They bombarded various light metals with alpha particles from ^{210}Po, producing new radioelements. Bombarding boron produced ^{13}N, bombarding aluminum produced ^{30}P, and bombarding magnesium produced ^{27}Si.

In the 1920s, George de Heresy began conducting *tracer* studies of the uptake and translocation of lead in plants, tracing a stable element, lead, by using one of its radioactive decay products. These studies were soon extended to animals.

H.S. Müller (1927) made the seminal finding that exposure to x-rays increased the mutation rate of fruit flies. He irradiated adult flies with high doses of x-rays and then measured the frequency of lethal mutations in the progeny. He reported that the response was linear with increasing dose and did not have a threshold. It is ironic that the Müller (1927) paper is frequently cited for the discovery of the mutagenic effects of radiation. This is actually not the case. Indeed, Müller cites a number of papers discussing the mutagenic effects of radiation, including the Mohr (1919) paper. Of special note is a paper by Oliver (1930), who worked with Müller at the University of Texas. The paper provides quantitative data on the effects of radiation on induction of mutations in *Drosophila*. Because of its historical importance, the Oliver (1930) data are plotted in Figure 18.5. It is noteworthy that the doses were very high, ranging from 1000 to 4000 R. Radiation exposure soon became a favorite approach to inducing genetic alterations, especially in *Drosophila* and many plant species, and a favorite tool of plant breeders developing new and improved commodity crops such as wheat.

In 1932, Ernest Lawrence at the University of California (UC)-Berkeley, invented the cyclotron, a device that created high-speed protons without using high voltages. The first cyclotron was 12 cm in diameter. The accelerated high-speed protons in the cyclotron could be used to bombard an array of different target materials, producing new radioisotopes.

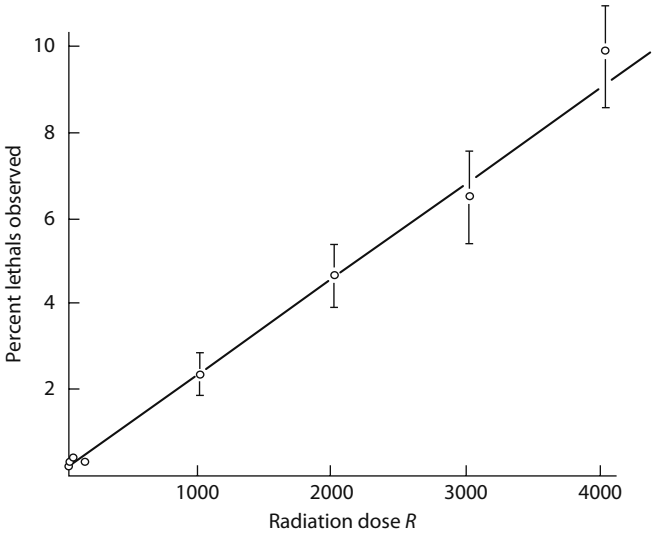

FIGURE 18.5 Dose–response relationship for induction of mutations in x-irradiated *Drosophila*. Note the substantial radiation doses studied. (From Oliver, C.P., *Science*, 71, 44, 1930.)

Ernest Lawrence's brother, John Lawrence, was a physician. This no doubt served as a stimulus in developing many radioisotopes that had potential application in biomedical research and medical practice. With the availability of many new radioisotopes produced by the cyclotron, the opportunities for tracer studies of the uptake and fate of elements in various chemical forms were virtually limitless. John Lawrence, Joseph Hamilton, and others at UC-Berkeley conducted many of the early radiotracer disposition studies in laboratory animals and people as they worked their way through many elements in the periodic table. It had never been so easy to obtain quantitative data on the disposition of different elements in different chemical forms.

The first *radiotracer* studies in domestic animals were conducted at the Agricultural Experiment Station, *The Farm*, at Davis, CA. This was originally a part of the UC-Berkeley system. Dr. Max Kleiber conducted the animal radiotracer studies. Kleiber came to the UC in 1929 to conduct studies on energy metabolism in animals. The story is told that Dr. John Lawrence had some extra ^{32}P, deemed unsuitable for injection into humans, called Kleiber, and offered it for injection into a cow. Kleiber went on to conduct numerous studies in a wide range of animal species with many different radiotracers.

With the availability of ^{59}Fe, it was natural that John Lawrence and his colleagues would conduct some of the earlier radiotracer studies on erythropoiesis in animals and humans. In 1936, Lawrence treated a polycythemia patient with ^{32}P to irradiate the bone marrow. This was probably the first therapeutic use of a man-made radionuclide.

On the threshold of World War II, Henshaw (1941) published a seminal paper that reviewed very succinctly what was known about the effects of exposure to x-rays. This included the various types of injury that had been observed up to that time with considerable focus on what he termed *radiogenetic changes*. He presented two conceptual dose–response

frameworks (Figure 18.4) for radiation exposure and discussed the use of *tolerance dose* in radiation protection, including its limitations for protecting against *radiogenetic effects*.

In December 1938, German chemists Otto Hahn and Fritz Strassmann sent a manuscript to *Naturwissenschaften* (January 6, 1939) reporting that they had detected the much lighter element, barium, after bombarding uranium with neutrons. They shared these results by mail with Lisa Meitner, who had lost her German citizenship because of her Jewish lineage and relocated to Sweden, and her nephew, Otto Frisch, who was visiting her. Meitner and Frisch correctly interpreted the results as being nuclear fission, a splitting of the atom (*Nature*, February 11, 1939). Frisch called the process fission as an analogy to binary fission in biological cells, and the resulting new fission products were called daughter products. The fields of physics and biology were joined!

Events after Discovery of Fission

The discovery of fission had significant consequences. Fission was key to the development of what were initially called atomic bombs, later identified as nuclear bombs or weapons, and yet later the development of nuclear power reactors. The United States, early during World War II, created the Office of Scientific Research and Development to coordinate research aligned with national defense, including research on nuclear materials. This office sponsored Enrico Fermi's research to demonstrate that a self-sustaining chain reaction of nuclear fission in natural uranium could be produced and that uranium could be transmutated to higher atomic number elements. Fermi, using space under the Stagg's field grandstand at the University of Chicago, assembled a *pile* of highly purified graphite to moderate the neutrons from natural uranium. Frank Spedding at Iowa State University produced the high-purity uranium. On December 2, 1942, Fermi and his crew demonstrated that a sustained chain reaction producing neutrons in the uranium pile could be started and stopped by introducing neutron-absorbing materials such as boron.

In early 1943, the responsibilities of the Office of Scientific Research and Development were transferred to the U.S. Army Corps of Engineers and a new secret entity created, the Manhattan Engineer District. The history of the Manhattan Project has been chronicled by Hewlett and Anderson (1962), Rhodes (1986), and Kelly (2007). The Manhattan Project had the specific purpose of developing an atomic bomb as soon as possible, anticipating the use of atomic bombs in ending World War II. Creation of atomic bombs involved the production of sufficient quantities of two highly purified fissile materials, ^{235}U and ^{239}Pu, and development of a means to assemble them into a weapon. A fissile material is capable of sustaining a chain reaction of nuclear fission with thermal neutrons. The project, under the direction of General Leslie R. Groves, involved activities at multiple sites, including several universities, most notably the University of Chicago, Iowa State University, and UC-Berkeley. Three specialized sites were created de novo to meet the unique needs of the project. A laboratory site at Los Alamos, New Mexico, under the direction of J. Robert Oppenheimer, was created to design, fabricate, and test the first atomic bomb and manufacture additional atomic bombs. The UC was the prime contractor.

A site at Oak Ridge, Tennessee, would house unique facilities to separate ^{235}U from a mixture of ^{235}U and ^{238}U and an experimental pile or reactor. Natural uranium only contains about 0.72% ^{235}U by weight; devise methods for concentrating the ^{235}U to 2–5% and higher to support a continuous nuclear chain reaction in a carbon/water-moderated reactor and to substantially higher concentrations and purity for use in a bomb. The Oak Ridge facility used a combination of thermal diffusion followed by gaseous diffusion and electromagnetic isotope separation to provide material for a bomb. The ^{235}U was shipped to Los Alamos for fabrication into one type of bomb. The Union Carbide Company, a diversified chemical company, was the prime contractor for the Oak Ridge site. A decision was made that the population of the combined population of the Oak Ridge, Tennessee area and nearby Knoxville, Tennessee was too large to consider using it as a site for large nuclear reactors and chemical separation facilities required to produce kilogram quantities of ^{239}Pu for constructing a second type of bomb.

Thus, it was determined that a third large remote site would be needed for a *plutonium production complex*. The site had to be remote from any significant population, accommodate a large *hazardous manufacturing area*, and have an abundant supply of clean water and electrical power. In January 1943, General Groves, acting on the advice of Colonel Franklin T. Mathias and DuPont engineers, selected a site in southeast Washington for what was initially called the Hanford Engineering Works (HEW). The U.S. government exercised *eminent domain* and quickly displaced about 1500 residents of three small farming communities (Hanford, White Bluffs, and Richland, Washington) in the area. Hanford was the name of the community that would become the construction camp used until the reactors and fuel-reprocessing facilities were completed. Then the town site was abandoned. The E. I. DuPont de Nemours and Company was selected as the initial prime contractor for the Hanford site based on the company's unique capabilities to design, construct, and operate facilities producing highly hazardous materials. Recall that the DuPont Company was originally founded as a gun powder mill and evolved into a diversified chemical company. A workforce that soon exceeded 40,000 individuals began constructing (1) three uranium-fueled *piles*, (2) a fuel fabrication facility, (3) a chemical separation complex to separate ^{239}Pu from irradiated fuel elements, (4) support facilities, and (5) the vastly enlarged Richland community to provide permanent housing for plant workers. Findlay and Herly (2011) provide a historical account of the development of the Hanford project.

The *piles* or reactors each contained 1100 tons of graphite with transverse aluminum tubes loaded with 180 tons of uranium fuel and cold water flowing through the tubes to cool the reactor. Radiation safety was of paramount concern.

A team led by the late Herbert M. Parker, who would become a legend in the radiation protection field, assumed the responsibilities for it and related research activities. In the fall of 1944, I moved to Richland, Washington, to join my parents who were employed in the construction phase of the HEW. My father would later spend most of his work career in the chemical separations plant operations of the HEW.

In September 1944, the 100-B reactor at Hanford went critical with Enrico Fermi presiding over the start-up operation. After an initial glitch, some changes were made, and the neutron flux increased and stabilized. The uranium fissioned just as it had in the carbon black and uranium pile Fermi and his colleagues had built at the University of Chicago. The sustained and controlled chain reaction created a plethora of fission products, including ^{131}Te that quickly decayed to ^{131}I and large quantities of ^{90}Sr and ^{137}Cs. A small portion of the ^{238}U atoms transmutated to ^{239}Np, which then decayed to ^{239}Pu. In December 1944, *green* spent fuel rods began to be processed at Hanford using the methods developed by Glenn Seaborg and his team at UC-Berkeley and the University of Chicago. Many decades later, Glenn Seaborg visited the Lovelace laboratories in New Mexico where we were conducting research on the toxicity of inhaled plutonium. He related that he shipped some of the first plutonium he isolated at the University of Chicago to his colleague, Joseph Hamilton, at UC-Berkeley, to study its disposition in rats. The descriptor *green* was used for fuel elements that were processed shortly after an extended period of neutron irradiation and, thus, still contained large quantities of short-lived radionuclides.

The chemical separations process at Hanford yielded small quantities of ^{239}Pu, lots of fission products, and of course, residual uranium. By February 1945, ^{239}Pu was being shipped to Los Alamos, New Mexico; by July, enough was available to fabricate the first atomic fission bomb. As an aside, ^{239}Pu would be the principal product of the Hanford site for more than three decades. Ultimately, nine nuclear reactors were built and operated at Hanford. Most were shut down by 1971, and the last, a dual purpose (plutonium production and generation of electricity), was shut down in 1987. The radioactive fission products and other waste stored in underground tanks remain as a legacy. The Hanford cleanup continues today. Dalton et al. (1999) provide an interesting account of the cleanup issues for the Hanford site compared and contrasted with those at the Russian Mayak site to be discussed later.

Atomic Bomb

On July 16, 1945, at the Trinity Site in central New Mexico, the first atomic bomb with ^{239}Pu as the fissile material was detonated under the watchful eye of Robert Oppenheimer, who headed the bomb design and fabrication team at Los Alamos. Oppenheimer was reported to have quoted a passage from Bhagavad Gita: "If the radiance of a thousand suns were to burst at once into the sky, that would be like the splendor of the Mighty one … I am become Death, the shatter of worlds." The world would never be the same!

Downwind from the Trinity detonation, some cattle, sheep, and burros were grazing in the fallout field (Szasa 1984). Within weeks, the backs of some dark-skinned Hereford cattle and burros were showing white spots, a result of beta radiation skin burns from radioactive fallout particles. Soon, the U.S. government started to buy some of the cows and burros and ship them to Manhattan Project laboratories at Los Alamos and later to Oak Ridge, Tennessee. This probably qualifies as the first U.S. government radiation injury indemnification program!

On August 6, 1945, a previously untested ^{235}U bomb called Little Boy was dropped on Hiroshima, Japan, and on August 9, 1945, a ^{239}Pu bomb called Fat Man, similar to the device detonated at the Trinity Site, was dropped on Nagasaki, Japan. Within a short period of time, Japan surrendered, ending World War II. The extensive follow-up studies on the Japanese atomic bomb survivors will be discussed later.

Radioactive Fallout from Nuclear Weapons Testing

After World War II ended, the United States continued the development, manufacture, and testing of nuclear weapons. On July 1 and 25, 1946, the United States detonated nuclear fission bombs at Bikini Atoll in the Pacific Ocean.

On January 1, 1947, the activities of the Manhattan Project were transferred to a newly created civilian agency, the U.S. AEC, ostensibly a shift from military to civilian control of nuclear weapons and energy. The history of the AEC has been reviewed in depth by Hewlett and Anderson (1962) and Hewlett and Duncan (1969). The AEC was responsible for continuing the development and production of nuclear weapons based on *orders* from the military, developing nuclear reactors to generate electricity and propel naval vessels and, in general, advancing peaceful uses of nuclear energy through basic and applied research. Nuclear weapons testing in the Pacific by the United States continued in 1948.

Later, in 1974, the activities related to oversight of commercial nuclear reactors for generating electrical power were delegated to a newly created U.S. Nuclear Regulatory Commission with other activities continued under a newly created Energy Research and Development Agency (ERDA). In 1977, ERDA became the U.S. Department of Energy (DOE).

As World War II came to a close, the Union of Soviet Socialist Republics (USSR) accelerated its efforts to develop a nuclear bomb. Aided by intelligence on the U.S. nuclear efforts and the British nuclear efforts, which were closely coordinated with those of the United States, the USSR followed a similar path in building reactors and separation facilities at the Mayak Production Association (MPA) site in Russia to produce ^{239}Pu. Soon after the USSR began processing irradiated fuel elements in 1949, the U.S. Air Force detected airborne concentrations of fission products. It has been said that the detection of ^{131}I in the atmosphere stimulated U.S. efforts to establish the relationship between atmospheric ^{131}I concentrations and the release of ^{131}I from separation facilities processing *green fuel*. This led to the December 1949 *Green Run* test conducted at Hanford, which

will be described later. On August 29, 1949, the USSR detonated a *Fat Man*–type ^{239}Pu device. Ironically, one of the earlier measurements of fallout radionuclides from the Soviet test was made at Hanford. The nuclear arms race was soon public and accelerating! The Cold War began.

In December 1950, President Harry Truman established the Nevada Test Site (NTS) for continental nuclear tests. On January 27, 1951, a 1 kton warhead was dropped from an airplane at the NTS. This was the first of 126 atmospheric tests the United States conducted between 1951 and 1962.

The nuclear tests continued in the Pacific in 1951 and 1952 when the first hydrogen fusion devices were detonated. The testing of a very large hydrogen fusion bomb in 1954 resulted in contamination of a number of Pacific Atolls (Conrad et al. 1980). A Japanese fishing boat, the Fifth Lucky Dragon, was exposed, and one of the crew died of radiation sickness. The population of the Marshall Islands was exposed to high levels of radiation with an increased incidence of thyroid cancers observed later. The Partial Test Ban Treaty signed in 1963 forbade the testing of nuclear weapons in the atmosphere and under water. Additional tests resulting in the release of fission products to the atmosphere were conducted at the NTS through mid-1963. Other tests were conducted underground, in some cases with leakage of fission products to the atmosphere. Other countries also conducted nuclear weapons tests as they developed nuclear weapons. The United States and other nuclear powers signed the Comprehensive Test Ban Treaty in September 1996, making a legal commitment to never again test nuclear weapons.

Under the auspices of the AEC, a number of national laboratories (NLs) were created: the Los Alamos NL; Sandia NL; Lawrence Berkeley NL; Argonne NL; Pacific Northwest NL; which grew out of Manhattan Project activities at Hanford; and later Brookhaven NL and Lawrence Livermore NL. These labs were all built with U.S. government funds and operated by contractor organizations. In addition, specialized laboratories were created at a number of locations, including the University of Rochester, University of Chicago, University of Utah, UC at Los Angeles, UC at Davis, and the Lovelace Foundation for Medical Education and Research. These laboratories augmented by numerous scientists working in university and private laboratories with financial support from the AEC, ERDA, and DOE would make major contributions to advances in nuclear science and, most significantly, understanding the biological and health effects of radiation and radioactivity. To a large extent, these advances predated major developments in chemical toxicology. Many of the major advances in physics, chemistry, biology, medicine, and, I would include, the fields of toxicology and risk assessment made in the last half of the twentieth century are traceable to the research programs that grew out of the Manhattan Project and later were supported by the AEC, ERDA, and DOE (Hewlett and Anderson 1962; Hewlett and Duncan 1969). Some of the roots of my own special areas of interest, inhalation toxicology and the health effects of airborne materials, are clearly traceable to concern over the health effects of radiation and radioactive materials and research conducted at the NLs and in universities and special laboratories under the auspices of the AEC. Many of these developments are reviewed by Stannard and Baalman (1988). My own personal career was strongly influenced by a temporary assignment in the Division of Biology and Medicine of the U.S. Atomic Energy Commission (1965–1966). I gained much from working with many seasonal professionals, and especially from sharing an office with the late Paul Henshaw (recall his 1941 classic paper).

Nuclear Reactor for Electrical Generation and Propulsion

Electricity was first produced by thermal energy from a nuclear reactor on December 21, 1951, at the National Reactor Testing Station located at a remote site in southern Idaho and operated by Argonne NL. That site, now the Idaho NL, was initially created as a test site for reactors that could be used to generate electricity or propel naval vessels or even aircraft. The first nuclear-powered naval vessel, a submarine, the USS Nautilus, went to sea on January 17, 1955. Many other nuclear-powered vessels, both submarines and surface, followed. Later, the Los Alamos NL would provide leadership for developing nuclear-powered rockets for space exploration.

The nuclear reactor designs developed for naval propulsion by General Electric Company and Westinghouse Company as AEC contractors served as the basic design for the first commercial reactors used to generate electrical power. The IAEA (2012) estimated that nuclear reactors contributed 5.7% of the world's energy in 2011. Today, nuclear power generates about 20% of the electrical power used in the United States. Nuclear power generates a significant portion of electrical power in France and Japan, countries with limited fossil fuel reserves.

In the early 1970s, a major program was initiated in the United States to develop a breeder reactor that would both use ^{239}Pu as a nuclear fuel and produce additional fuel. Similar efforts were conducted in other countries, most notably France and Japan, and later in Russia. The U.S. program was discontinued during the administration of President Carter when the United States also decided to discontinue reprocessing irradiated nuclear fuel. This occurred for multiple reasons, including concern for how to handle and store the fission product waste and the processed fuel components and for the misuse of ^{239}Pu. Other countries such as Japan, France, and Russia continued to process irradiated fuel and explore how ^{239}Pu could be used as a reactor fuel, that is, mixed oxide (uranium and plutonium) fuel. France has continued to reprocess irradiated fuel elements, recovering uranium for reuse as a fuel and storing the waste. The Lovelace research team published an early risk assessment for a breeder reactor system (Cuddihy et al. 1977). An ironic conclusion of that study was that conventional coal-fired power plants of that era emitted greater quantities of naturally occurring radioactivity than the estimated alpha particle-emitting materials postulated to be released from the ^{239}Pu-fueled breeder reactor system, assuming it was designed and operated as specified.

In the United States, large quantities of irradiated and unprocessed uranium fuel rods continue to be stored, awaiting resolution of the long-term nuclear waste storage dilemma. A recent paper by North (2013) details the many trials and tribulations of the United States in developing a high-level nuclear waste site as a geological repository. A site at Yucca Mountain in Nevada was thoroughly researched for more than three decades as a possible site and then abandoned. Ironically, the Waste Isolation Pilot Plant (WIPP), located in a salt bed geological structure near Carlsbad, New Mexico, has been operated successfully for more than two decades as a repository for low- and intermediate- level radioactive waste originating in U.S. nuclear defense activities at locations such as Hanford and Los Alamos. Unfortunately, legislation restricts WIPP from accepting radioactive waste from the civilian nuclear program.

Radiation, Radionuclides, and Medicine

From the time of their discovery to the present, the use of radiation and radionuclides in medicine has continued to grow. Bushong (2013) has noted that for seven decades after Roentgen's discovery of x-rays in 1895, diagnostic radiology continued to evolve as an essential part of modern medicine. During this time, there were many technological advances and marked increases in the use of radiation and radioactive materials to diagnose disease. More recently in the last quarter of the twentieth century, marked advances in radiation instrumentation joined with new computer technology led to new machines and procedures. These advances include the routine use of multislice helical computed tomography (CT), computed radiography, digital radiography, digital fluoroscopy, and magnetic resonance imaging.

Other diagnostic modalities, such as positron emission tomography using radiolabeled pharmaceuticals, have been developed and widely used. These medical applications have included the use of short-lived technetium-99m, thallium-201, rubidium-82, fluoride-18, oxygen-15, and nitrogen-13. Numerous medical centers now have cyclotrons to produce the short-lived radionuclides that are an essential part of modern nuclear medicine. With the introduction of new instrumentation and procedures, the diagnostic information available has increased, and the radiation dose to individual patients has decreased.

In recent years, CT has been shown to be a convenient, accurate, and rapid diagnostic procedure with over 70 million CT scans performed annually in recent years in the United States (Brenner 2010). Compared with conventional x-ray examinations, the organ dose from a CT scan is typically 100 times higher (on the order of 5–100 mSv). This has raised concern over both the radiation dose to individual patients and the collective population dose from the increased use of CT scans. In my opinion, it is important, when considering diagnostic procedures, to recognize that these procedures are being conducted to obtain diagnostic information of value to the patients. There is a clear benefit to the individuals receiving the radiation dose.

In the last half of the twentieth century, substantial advances have been made in the use of radiation to treat cancer. These advances involved the development of improved devices for delivering precise doses of ionizing radiation to well-defined volumes of cancerous tissue while minimizing the radiation dose to adjacent normal tissue. For some specific cancers, such as prostate cancer, radioactive sources have been implanted to deliver the radiation dose to cancerous tissue much like the use of radon needles implanted into tumors more than a half century earlier.

SOURCES OF RADIATION EXPOSURE AND DOSE

In this section, the sources of radiation dose to populations will be briefly reviewed. Table 18.3 shows the radiation dose from different sources, providing perspective for the discussion of individual sources that follows. Note that natural background radiation and man-made or anthropogenic radiation sources contribute about equally to the average radiation dose.

Natural Environmental Radiation

Natural environmental radiation comes from three sources: cosmic radiation, terrestrial radiation, and internally deposited radionuclides. Cosmic radiation is that originating in galactic space and the solar systems and impinging on the earth's environment. It consists of an array of high-energy

TABLE 18.3
Relative Contribution of Different Radiation Sources to the Average Radiation Dose Received by the U.S. Public for 2006

Radiation Source	Millisieverts (mSv)	Percent
Background		
Space radiation	0.31	5
Internal radionuclides	0.31	5
Terrestrial dose	0.19	3
Radon and thoron	2.29	37
Background	3.10	
Anthropogenic		
Computer tomography (CT)	1.49	24
Nuclear medicine	0.74	12
Interventional fluoroscopy	0.43	7
Conventional radiography/ fluoroscopy	0.31	5
Consumer products	0.12	2
Occupational	<0.1	<0.1
Industrial	<0.1	<0.1
Anthropogenic	3.10

particles such as neutrons, protons, electrons, mucons, and pions and high-energy nuclei and gamma photons. The flux is sufficient that it is of concern for astronauts in space. Cosmic radiation intensity decreases as it nears the earth and is greater in high-flying aircraft than at the earth's surface. Terrestrial radiation exposure comes from deposits of uranium, thorium, and other radioactive sources in the earth.

Three series of naturally occurring radionuclides are important: (1) the uranium series extending from ^{238}U (a half-life of 4.468 billion years) to stable ^{206}Pb, (2) the actinium series extending from ^{235}U (a half-life of 704 million years) to stable ^{207}Pb, and (3) the thorium series extending from ^{237}Th to stable ^{208}Pb. In each series, multiple elements and radionuclides of varied radioactive half-life are involved with emissions of alpha particles, beta particles, and gamma rays of varied energy. The uranium and actinium series are of special interest because they begin with very long-lived radionuclides of U. Uranium ore, which contains 99.72% ^{238}U, 0.72% ^{235}U, and traces of ^{234}U, has been mined and extracted to provide various decay products and, most importantly, as a source of ^{235}U to fuel nuclear reactors. The uranium series is of special interest because it includes radon (^{222}Rn), which is a noble gas found in high concentrations in uranium mines, some other types of mines, in some homes, and other structures in geographic areas with high concentrations of uranium.

The earliest work on the association between working in uranium mines and increased risk of lung cancer considered radon gas itself to be the causative agent. John Harley, in his doctoral thesis research, demonstrated that the linkage was more complex and involved both radon and its decay products (Harley 1953). Radon decays by alpha emission to ^{218}Po, which, in turn, decays by alpha emission to ^{214}Bi, which decays to ^{210}Pb, which has a half-life of 21 years. Exposure via inhalation to ^{222}Rn inevitably involves exposure to ^{218}Po and ^{214}Bi, which in the air aggregate with other particles. Using today's nomenclature, these particles would be considered nanoparticles. The doses from the alpha emissions of ^{218}Po and ^{214}Bi are the significant contributors to the radiation dose from ^{222}Rn and its decay products, which with exposure for sufficient duration and concentration can increase the risk of lung cancer (Harley and Pasternack 1982).

When field studies were conducted in the 1950s and 1960s to evaluate the exposure of uranium miners to radon and daughter products, the approach used measurements of total airborne alpha activity. The results were expressed as a working level (WL)—an equilibrium mixture of the decay products of the alpha decay products of radon equal to 100 pCi/L (3700 Bq/m^3). Exposure of a miner for 170 h at this concentration is identified on a working level month (WLM). Later, analyses such as those of BEIR VI (NRC 1999) had to convert exposure measurements expressed in WLM units to SI units (Bq/m^3) and then an even more uncertain extrapolation to absorbed dose (Gy).

Other naturally occurring radionuclides that can enter the body are also of interest as contributors to radiation exposure from natural and unavailable sources. All potassium contains ^{40}K, which has a half-life of 1.248×10^9 years and decays by beta emission. It is the largest source of internal radiation exposure for humans and other mammals next to the exposure from inhaled Rn and its decay products (Table 18.3). It is estimated that the adult human body contains about 150 g of K. The ^{40}K content in the adult human body is estimated to yield 4400 disintegrations per second. ^{40}K decays to ^{40}argon, and thus, the ratio of ^{40}K to ^{40}Ar can be used for radio-dating the age of some specimens.

Another naturally occurring radionuclide is ^{14}C present in carbon. It decays by beta emissions with a half-life of 5740 years and is constantly being replenished in the atmosphere. Since carbon is an essential component of all living things, ^{14}C is present in all living things. As trees sequester C, they sequester ^{14}C in proportion to what is in the atmosphere. When trees die, the ^{14}C present continues to decay. The ratio of ^{14}C to C can then be used for dating the age of wood specimens.

It is important to recognize that the radiation dose received by individuals from natural sources will vary dependent upon where they live. The elevation of their location will influence the radiation dose of cosmic origin. The local geologic sources will influence the radiation dose from naturally occurring radioactivity. The greatest variation in radiation dose to individuals will be associated with the dose to the respiratory tract from inhaled radon and daughters. This is the case since the concentration of natural uranium, the source of radon gas, varies widely across the United States and around the world.

Nuclear Weapon Detonations

As discussed elsewhere, the potential for atmospheric release of large quantities of radioactivity with detonation of a nuclear bomb was anticipated before the first nuclear weapon was tested at the Trinity Site in New Mexico. With detonation of the fissile ^{239}Pu device at the Trinity Site, that potential was fully realized with the release of a wide array of fission product radionuclides that were carried downwind and deposited as *fallout*. Over the next several decades with atmospheric testing of many nuclear weapons, the distribution of these fallout radionuclides through the ecosystem, uptake by humans, and their health effects would be studied extensively. Although many different radionuclides are released by fissioning of ^{235}U and ^{239}Pu in nuclear weapons, attention has been focused most intensely on ^{131}I (half-life, 8.05 days), ^{90}Sr (half-life, 28 years), and ^{137}Cs (half-life, 30 years). This was the case because these radionuclides are produced in abundance in a nuclear detonation and enter the agricultural ecosystem with passage via forage, ingestion by cows, transfer to milk, and ingestion by humans. When ingested, the radionuclides are avidly retained. Just like stable iodine, the ^{131}I is taken up by the thyroid and irradiates the thyroid tissue. Stable strontium and ^{90}Sr behave metabolically like Ca and concentrate in bone, and the decay of the ^{90}Sr and its daughter ^{90}Y irradiates the skeleton and bone marrow. Stable cesium and ^{137}Cs behave like K; thus, ^{137}Cs distributes throughout the body like potassium, resulting in essentially total body

TABLE 18.4
Radionuclide Releases from Reactor Accidents (Amount in Terabecquerels [TBq] = 10^{12} Bq)

Radionuclide	Half-Life	Windscale (United Kingdom) (October 10, 1957)	Three Mile Island (United States) (March 28, 1979)	Chernobyl (Ukraine) (April 26, 1986)	Fukushima (March 11, 2011)
^{133}Xe	5.3 days	12,000	—	6,500,000	17,000,000
^{131}I	8.05 days	740	1.	~1,760,000	~200,000
^{137}Cs	30 years	22	0.0015	~85,000	~30,000
^{134}Cs	2.0 years	—	—	~54,000	—
^{90}Sr	28 years	—	0.0022	~10,000	—

irradiation. The detonation of hydrogen fusion bombs, developed later, resulted in the release of a generally similar array of radionuclides. This is the case because the fissioning of fissile material is used to trigger the fusion.

Nuclear Reactor and Other Accidents

In addition to concern for radionuclides released in nuclear explosions, there has been concern from the beginning of operation of nuclear reactors for accidental release to the environment of U fuel, fission product radionuclides, and the transmutated radioactive elements such as ^{239}Pu. It is important to recognize that the spectrum of fission products released from the instantaneous explosion of a nuclear weapon is different from the spectrum of those radionuclides released from a reactor or a chemical plant processing irradiated fuel. The reactors and irradiated fuel elements contain fission products produced from fissioning of the uranium, plutonium, and thorium fuel and activation of nuclides formed over the extended time course of irradiation of the fuel, which may be several years in duration. One key difference between the sources is that detonation of nuclear weapons results in the release of both ^{131}I and numerous iodine radionuclides or precursors that have much shorter half-lives than ^{131}I. The shorter-lived radioiodines are not present in abundance in releases from a reactor. A second difference is that after a relatively short period of operation, a reactor core will contain ^{134}Cs in addition to ^{137}Cs. A nuclear detonation produces very little ^{134}Cs. The ^{134}Cs has a half-life of 2.0652 years.

Nuclear reactor accidents with the release of radioactivity have occurred in England, the United States, Ukraine, and Japan (Table 18.4). The Windscale accident involved a reactor designed to produce ^{239}Pu and later modified to also produce tritium (^{3}H) for use in fusion weapons. Unlike most other nuclear reactors, the Windscale reactor was air-cooled, posing special issues for its control.

The Three Mile Island reactor in Pennsylvania was part of a commercial nuclear electrical generating complex. The accident involved a meltdown of a substantial portion of the reactor core. Fortunately, the operating system and containment operated as planned, and the radionuclide releases were remarkably small.

Although used to generate electricity, the Chernobyl reactor, located in the Ukraine near Kiev, was similar in many respects to the ^{239}Pu-producing reactors that operated at the Hanford site. This included the absence of the kind of containment vessel used to house commercial reactors providing thermal energy for generation of electrical power in the United States and other countries outside the sphere of the former USSR. The substantial release of radioactivity in the Chernobyl accident (Table 18.5) was not unexpected in view of the very ineffective containment system. A reactor of this type would not have been constructed and could not have been licensed for commercial use in the United States, Western Europe, or Asia. Radioactivity from Chernobyl was injected over a number of days into the atmosphere. The releases from Chernobyl were first reported to the public from Sweden. The released radioactivity deposited in readily measurable levels across Europe and distributed in trace levels around the globe.

The particulate nature of some of the radionuclides released from Chernobyl and the associated *fallout* is evident from the autoradiograph (Figure 18.6) of a leaf I collected in a park in the fall of 1986 in Kiev, Ukraine, about 80 km south of Chernobyl. The surface area of tree leaves collected substantial amounts of *fallout* radioactivity. My colleagues and I also analyzed fallout particles collected from a shipping crate obtained from a site slightly closer to Chernobyl. We found that some of the fallout particles contained not just fission product radionuclides, but also uranium, clear evidence that

TABLE 18.5
Radionuclide Releases from Chernobyl Reactor Accident (Amount in Pbq, a PBq = 10^{15} Bq)

Radionuclide	Half-Life	Core Inventory (PBq)	Amount Released (%)	Activity (PBq) Released
^{33}Xe	5.3 days	6500	100	6500
^{131}I	8.0 days	3200	50–60	~1760
^{134}Cs	2.0 years	180	20–40	~54
^{137}Cs	30.0 years	280	4–6	~85

fuel was released from the core of the Chernobyl accident. The most significant sources of internal irradiation to the public were from ^{131}I, ^{137}Cs, and ^{134}Cs. The ^{134}Cs and ^{137}Cs deposited everywhere and were also a source of external radiation exposure.

The Fukushima, Japan, accident was triggered by a series of earthquakes and a tsunami impacting multiple nuclear reactors that were part of a large nuclear electricity-generating station built on the seashore at a low elevation. The successive *monster* ocean waves hitting the Fukushima site destroyed even their backup systems. The fact that the releases of radioactivity from the Fukushima reactors were not greater was a testimonial to the containment systems that remained largely effective. The most substantial release was of the noble gas, ^{133}Xe, which is not metabolized. It serves as an external radiation source when individuals are immersed in a cloud containing ^{133}Xe. The ^{131}I and ^{137}Cs were the major sources of internal irradiation. Details of the exposures from the reactor accidents will be discussed later.

It is important to note that highly sensitive radiation monitoring instruments and methods can detect extraordinarily low concentrations of radioactivity in air, water, tissues, and other samples. Radioactivity injected into the atmosphere by nuclear explosions, burnup of space systems with radioactive (^{238}Pu) power sources, and nuclear reactor accidents (such as Chernobyl) have been followed around the globe. Ultralow concentrations of ^{239}Pu, either from Pu not consumed during detonation of ^{239}Pu weapons or produced during the detonation of nuclear weapons, have been detected around the globe.

External Radiation Exposure and Dose

Human populations can be exposed to external radiation in multiple ways (Table 18.3). This includes cosmic and terrestrial radiation of natural origin. In addition, populations may be exposed to radiation from deposited radioactivity from nuclear weapons testing, nuclear reactor accidents, mishandling of nuclear waste, and, potentially, terrorist activities. I mention terrorist activities for completeness. However, in my opinion, it is very unlikely that terrorist devices would disperse sufficient radioactivity to be of concern for producing health effects either as a distributed external radiation source or from inhalation or ingestion of dispersed radioactivity. However, even small quantities of dispersed radioactivity of any kind can still create public alarm and require a substantial cleanup effort.

While all members of populations can receive external radiation exposure from natural sources, it is important to recognize that individuals can receive significant external radiation exposures from medical applications (Tables 18.3 and 18.6). The numbers of purposeful radiation exposures to obtain diagnostic information vary among individuals. Some individuals may never have medical situations that ever involve radiation exposure from a diagnostic procedure. On the other hand, some individuals may have medical conditions that require the use of repeated diagnostic or interventional procedures involving external radiation exposure. In recent years, the use of CT scans has increased dramatically. Concern has been raised as to the radiation exposure received by patients that have received multiple CT scans (Hall and Brenner 2008; Brenner 2010).

Radionuclide Exposure Pathways and Dose

As evident from Figure 18.1, exposure to radionuclides of natural origin or associated with human activity can occur in multiple ways. The most significant exposure pathway for naturally occurring radionuclides involves inhalation of radon and its daughter products. For the average individual in the United States, inhalation of radon and daughter products

results in an annual dose of just over 2.0 mSv. The exposure from radon and its daughter products across the population is quite variable. Individuals living in low-radon areas or even individuals living in high-radon areas, but having well-ventilated homes and workplaces, will receive limited doses of radon. Individuals in areas with high levels of radon from high levels of uranium in the soil and living in poorly ventilated homes may receive radon and associated daughter products, leading to irradiation of the conducting airways of the respiratory tract that are substantially above the national average.

From 1946 through 1963 when numerous atmospheric tests of nuclear weapons were conducted, individuals around the globe were exposed to fallout radionuclides. Individuals living near test sites, such as those living downwind of the NTS, received the highest exposures to fallout radionuclides and the associated highest radiation doses. The dose to individuals from inhalation of the airborne radioactivity was quite low. The highest radiation doses were those from radionuclides such as ^{131}I, ^{137}Cs, and ^{90}Sr moving through the agricultural food chain. The most significant of these pathways is that involving contamination of pasture or hay, ingestion of the contaminated pasture grass or hay by cows, secretion in the milk, and ingestion of the milk by people. Table 18.7 presents some representative values for secretion of ^{90}Sr, ^{131}I, ^{137}Cs, and ^{144}Ce in cow's milk.

Because ^{131}I is concentrated in the milk and, when ingested, concentrated by the thyroid, ^{131}I is of special concern. The extent to which the thyroid concentrates ^{131}I is apparent from the distribution data shown in Table 18.8. Because ^{131}I has a radioactive or physical half-life of 8.05 days, it is of primary concern soon after a nuclear detonation or release from a reactor or nuclear fuel processing plant. In 40 days, the amount of ^{131}I will have undergone five half-lives of decay, and only 1/32th of the original ^{131}I will remain.

When the original ^{239}Pu-producing reactors in the United States, and later in the USSR, were started up, there was a desire to quickly process the irradiated fuel and separate out the ^{239}Pu for use as a fissile material in bombs. As a result, *green* fuel elements, which had recently been irradiated and, thus, contained high concentrations of ^{131}I, were processed. Later, it became standard practice to allow the irradiated fuel to *cool* and age, thereby reducing the content of short-lived radionuclides like ^{131}I before the fuel was processed. Ironically, the largest release of ^{131}I from the Hanford complex occurred on December 2, 1949, with an experiment code named *Green Run*. It was designed to simulate what occurred in late 1944 and early 1945 at Hanford and what was presumably happening earlier in 1949 in the USSR when *green* fuel was processed. Soon after the uranium fission reactors began operation and fuel reprocessing was initiated, the United States and USSR were eager to recover ^{239}Pu for the manufacture of nuclear weapons. Recovery involved processing irradiated fuel that had only been cooled for a few weeks. The *Green Run* experiment involved processing of *green* fuel and anticipated the gathering of extensive data on meteorological conditions and ^{131}I concentrations from the site to hundreds and, indeed, thousands of miles downwind. The goal was to create an algorithm to relate the ^{131}I concentrations in the air to the amount of irradiated uranium fuel being processed, including the ^{239}Pu content. It was thought that these data would be useful in interpreting data on airborne ^{131}I originating in the USSR and estimating the Soviet production of ^{239}Pu. Unfortunately, meteorological conditions changed abruptly soon after processing of the fuel began, resulting in stagnant conditions and fumigation of eastern Washington with ^{131}I. This release of 8000 curies of ^{131}I and the associated population exposures were the largest in the history of the Hanford operations. An epidemiological study conducted later did not detect an increase in thyroid cancer in the exposed population (Davis et al. 2004). An alternative interpretation has been provided by Hoffman et al. (2007).

The release of ^{131}I from the Hanford operations and concern over fallout of ^{131}I from nuclear weapons testing stimulated the conduct of an extensive research program on numerous studies of ^{131}I metabolism and toxicity in sheep and swine at Hanford, including long-term studies of the effects of daily ingestion of ^{131}I by sheep (McClellan and Bustad 1964; Bustad et al. 1965a; McClellan 1995). As a high school student, I helped care for an off-site flock of control sheep for this study. Regular monitoring of the thyroids of the sheep maintained off the Hanford site revealed increased levels of ^{131}I associated with recent nuclear weapons tests. Fallout ^{131}I traveled around the globe.

In the early 1960s, Hanford scientists conducted a multifaceted study to simulate a single brief release of ^{131}I in order to

TABLE 18.7
Fraction of Orally Administered Dose of ^{90}Sr, ^{131}I, ^{137}Cs, and ^{144}Ce[a] Secreted in Milk of Dairy Cows

Radionuclide	Oral Dose Secreted in Milk (%)
^{90}Sr	0.08–2
^{131}I	5–10
^{137}Cs	~10
^{144}Ce[a]	<0.01

[a] ^{144}Ce is poorly absorbed from the gastrointestinal tract.

^{131}I Concentrations in Blood, Milk, Thyroid, and Other Tissues

Organ, Tissue, Secretion, or Excretion	Dose (%)/kg or Liter
Blood	0.17
Muscle	0.02
Spleen, pancreas	0.08
Kidney, liver	0.14
Ovary, salivary glands	0.10
Feces	0.50
Milk	0.50
Thyroid	320,000

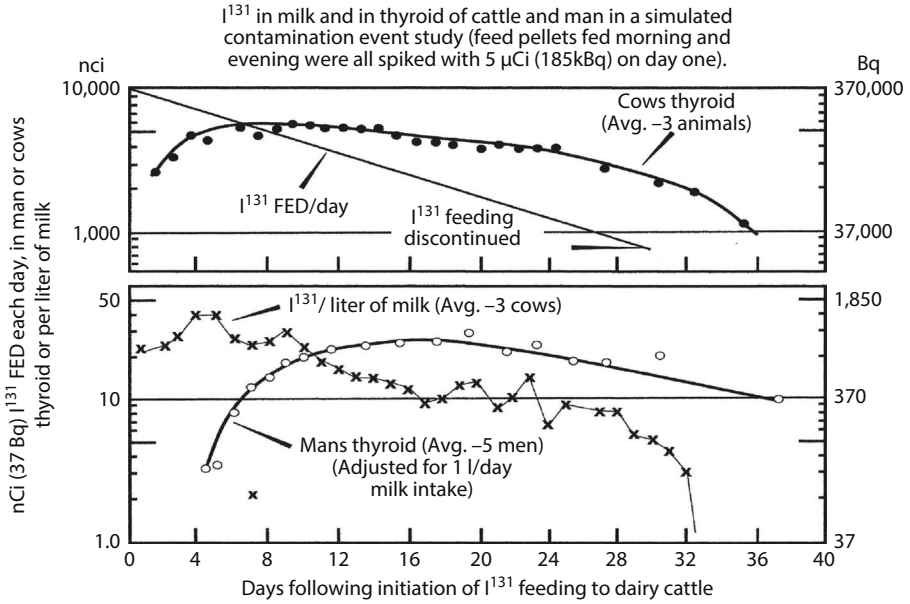

FIGURE 18.7 Interrelationships for radioiodine (^{131}I): intake by cows, concentration in cow's thyroid and milk, and human thyroid. (Adapted from Bustad, L.K. et al., The significance of radionuclide contamination in ruminants, in: *Physiology of Digestion in the Ruminant*, ed. Dougherty, R.W, Butterworth, Washington, DC, pp. 131–143, 1965.)

understand the feed–cow–milk–human intake–thyroid burden relationships (Bustad et al. 1963, 1965a). The results are shown in Figure 18.7. A large number of feed pellets were spiked with ^{131}I on the first day of the study and fed each day to the cows. The radioactive decay of the ^{131}I (half-life of 8.05 days) resulted in the cows receiving less ^{131}I each day. The thyroids of the cows were regularly monitored along with the ^{131}I content of the milk. Human volunteers ingested aliquots of the milk containing trace amounts of ^{131}I each day, and their thyroids were monitored. These data clearly show the quantitative relationship between ^{131}I in the cow's thyroid, cow's milk, and human thyroid. It was very valuable information in interpreting the impact of the ^{131}I releases in the Chernobyl and Fukushima accidents. Indeed, it is understood that these data were used to set limits on the release of ^{131}I-contaminated milk for human consumption and used to guide agricultural practices (shift of cattle from pasture to stored feed) in order to limit the ^{131}I exposure of cows with the goal of reducing the ^{131}I milk contamination and human intake.

The use of oral stable iodine administered shortly before or soon after exposure to ^{131}I has been advocated as a means of releasing the radiation dose to the thyroid by blocking or reducing ^{131}I uptake. It is important to note the intake of large quantities of stable iodine is hazardous to some individuals who are sensitive to stable iodine intake. In my opinion, the most effective means of reducing the thyroid dose from ^{131}I is not to drink contaminated milk. The potential dose from inhaling ^{131}I is quite low compared with the radiation dose from ingested ^{131}I. As an aside, administration of stable iodine orally to dairy cows did reduce the ^{131}I dose to the cow's thyroid and modestly reduced the ^{131}I content of the milk.

Two other radionuclides, ^{90}Sr and ^{137}Cs, are of concern due to their presence in fallout from the detonation of nuclear weapons. ^{90}Sr has a radioactive half-life of 29.1 years and decays by beta emission to ^{90}Y, which decays by beta emission with a half-life of 64 h. Because of the short half-life of ^{90}Y, equilibrium is quickly established between ^{90}Sr and ^{90}Y. ^{90}Sr behaves metabolically like calcium in ecosystems and in the mammalian body. Thus, it is relatively readily absorbed from the gastrointestinal tract, translocated to, and incorporated into bone where beta particle decay of the ^{90}Sr and its short-lived daughter ^{90}Y irradiates bone and bone marrow. With ^{90}Sr, as with ^{131}I, there is concern for the forage–cow–milk–child pathway. Because of the long radioactive half-life, the ^{90}Sr will remain in the ecosystem for years. This raises concern for ingestion by cows of ^{90}Sr-contaminated pasture and hay. Because of the abundance of ^{90}Sr in weapons fallout, the toxicity of ^{90}Sr was the subject of substantial research beginning in the late 1940s.

^{137}Cs has a radioactive half-life of 30.17 years, decaying to ^{137}Ba with a half-life of 2.6 min. ^{137}Cs is metabolized like K and other alkali metals and is readily absorbed from the gastrointestinal tract, distributed in all the soft tissues of the body, and secreted in milk. As with ^{131}I and ^{90}Sr, there is concern for the forage–cow–milk–child route of exposure for ^{137}Cs. Table 18.9 provides data on the tissue distribution of ingested ^{137}Cs in sheep and goats and illustrates the relatively uniform concentration of ^{137}Cs in soft tissues of the body. These data indicate the need to consider the forage–meat–human consumption pathway in addition to the pathway via cow's milk when evaluating human exposures.

The NCRP (2007) reviewed the literature on ^{137}Cs in the environment, including transfer through foodstuffs to humans. For transfer from livestock feed (daily intake) to milk (concentration per liter), the report cited values of 0.0048–0.01 with a best estimate of 0.01. For transfer from livestock feed (daily intake) to meat (concentration per kg), the report cited values of 0.004–0.06 with a best estimate of 0.05.

Brain	—	5
Ovary	—	13
Testis	9	—
Blood plasma	0.5	1
Femur	1	—

The importance of the forage–meat–milk pathway was also recognized when studies were conducted on native populations in northern Alaska that depended on caribou as a source of meat (Hanson and Palmer 1965; Hanson 1967). It was soon apparent that high concentrations of ^{137}Cs in caribou meat and then in people were traceable to deposition of fallout ^{137}Cs on lichens. The lichens grow very slowly and avidly take up minerals, including ^{137}Cs from the atmosphere. The caribou graze in lichen *pastures* in a cyclic fashion over several years, allowing for accumulation of the ^{137}Cs in the lichens. Detailed studies established quantitatively the linkage between ^{137}Cs content in lichens, caribou meat, and the body content in the native individuals as well as wild carnivores. The ^{137}Cs concentrations increased by about a factor of 2 at each successive trophic level of the food chain from lichens to caribou to man.

^{134}Cs is a shorter-lived radionuclide of Cs that decays with beta and gamma emissions and a half-life of 2.0652 years. It is present in quantities about equal to ^{137}Cs in the fuel core of a typical nuclear reactor that has been operating for some time. Fallout from nuclear weapons detonations does not contain significant amounts of ^{134}Cs. Thus, ^{134}Cs received little attention as a source of human exposure during the nuclear weapons testing and fallout era. Of course, its behavior in the environment and body of animals and humans can be predicted from knowledge of ^{137}Cs when corrections are made for the differences in radioactive half-life. The accidents at Chernobyl and Fukushima resulted in substantial releases of ^{134}Cs (Table 18.4).

Following the Chernobyl accident, some of the radioactive plume moved north and northwest over Scandinavia. Not surprisingly, $^{134–137}$Cs was detected on pastures, including the lichen pastures in the area that used to be called Lapland and is now called Sami Land. $^{134–137}$Cs was soon detected in the carcasses of sheep and reindeer. Norway and Finland set relatively high limits on the concentrations of $^{134–137}$Cs, that is, 6000 Bq/kg, that would be allowed in sheep or reindeer meat intended for human consumption. In these countries, only a small portion of the reindeer and sheep carcasses exceeded these limits. On the other hand, Sweden set quite low limits, initially at 300 Bq/kg, and then raised them to 600 Bq/kg as the allowable levels of $^{134–137}$Cs. As a result, thousands of reindeer carcasses contaminated with $^{134–137}$Cs were confiscated and frozen in Sweden and stored awaiting a decision on their potential use. I participated in a meeting in Stockholm the winter after the Chernobyl accident to provide advice as to what to do with the thousands of stored carcasses contaminated with trace quantities of $^{134–137}$Cs. I reasoned that the Sami population warranted special consideration because they had the potential for regularly eating reindeer meat. It would be desirable for them to shift from reindeer meat in their diet to noncontaminated beef or mutton. For most non-Sami people, the reindeer meat was a delicacy eaten only a few times a year. My recommendation was that it was *safe* to allow release of the frozen reindeer carcasses for sale to the occasional consumer. It is my understanding that, unfortunately, the carcasses were destroyed.

With $^{134–137}$Cs released in a nuclear reactor accident, there is concern beyond the forage–cow–milk and meat pathway for human intake. That concern is for external gamma radiation exposure of people in the contaminated area from the deposition of $^{134–137}$Cs on soil, vegetation, roadways, and buildings. This has proved to be a major source of exposure following the Chernobyl and Fukushima accidents although the radiological impact was much greater for Chernobyl.

INTRODUCTION TO RADIATION EFFECTS: AN INTEGRATIVE PARADIGM

The effects of radiation on living systems begin with interaction at the atomic and molecular level (Figure 18.3). The interactions take the form of ionization or excitation of orbital electrons and result in deposition of energy in tissue. The ionizations can directly affect biological molecules, principally DNA. In addition, there may be indirect action of radiation mediated by free radicals that can diffuse far enough to reach target molecules. The latter is noteworthy since water constitutes about 80% of the human body. When atoms are ionized, their chemical-binding properties change. The ionization may result in breakage of molecules or relocation of atoms within the molecule. These changes, in turn, can alter cell function, including causing cell death. Ionization of water or biological molecules is an initial step in a complex multistep process illustrated in Figure 18.3. All of these mechanistic steps have been investigated in extraordinary detail over the past half century and reinvestigated as more sophisticated cellular, biochemical, and molecular methods have been developed. Many of the papers describing this research were identified within the 100 most cited papers published in the journal *Radiation Research* (RRJ 2012). The textbooks by Bushong (2013), Hall and Giaccia (2012), Mettler and Upton (2008), and Turner (2007) all provide an in-depth coverage of the vast literature on mechanisms of action of ionizing radiation.

The ionization in cells can result in cell death, mutations, and other alterations in cell function. Cell killing and functional alterations in surviving cells can alter organ function and with sufficiently high doses lead to death of the individual. The most common form of cell death from radiation is mitotic death. The irradiated cells die as they attempt to divide because of

severe damage to their chromosomes. The cell-killing properties, which were recognized soon after the discovery of x-rays, are the basis of the effectiveness of ionizing radiation in cancer therapy. The goal of radiation therapy is to kill cancerous cells and minimize damage to adjacent normal tissues.

In the 1950s, rapid advances were made in culturing cells in vitro. With a keen interest in radiation effects, it is not surprising that many investigators started to study the effects of x-rays and other forms of radiation on cultured cells. Puck and Markus (1956) were among the first to report the results of such experiments. They initially studied the now very famous Hela cells, a human cell line that originated from a patient at Johns Hopkins University (Figure 18.8). Experiments of this type have been conducted innumerable times with normal and malignant cells of all kinds from humans and laboratory animals. The results have been remarkably similar, a survival curve with a shoulder followed by a slope that is a straight line on a log-linear plot. The size of the shoulder is quite variable. For some cell lines, the curve is not straight but bends continuously so a linear–quadratic (LQ) function is a better fit and then has no meaning. The D_o value for the survival curve (i.e., the reciprocal of the slope) is defined as the dose required to reduce the surviving cells to 37%. The D_o of the survival curves for most x-irradiation cell lines cultured in vitro is typically in the range of 1–3 Gy. Some cells that have impaired DNA repair capacity may have D_o values as low as about 0.5 Gy. If the radiation dose is fractionated with sufficient time between fractions for repair to occur, the survival curve shifts to the right.

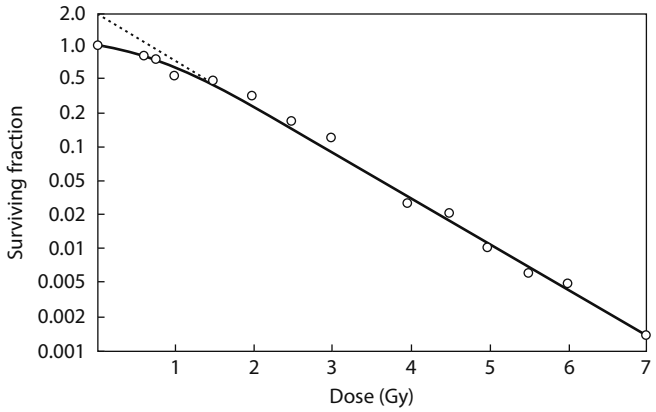

FIGURE 18.8 Survival curve for Hela cells in culture exposed to x-rays. (From Puck, T.T. and Markus, P.I., *J. Exp. Med.*, 103, 653, 1956.)

Gray (1965) based on studies in irradiated mice with leukemia as the endpoint called attention to the role of cell killing and induction of transformed cells in producing leukemia as illustrated in Figure 18.9. In his studies with mice, he observed a bell-shaped dose–response relationship for leukemia. He attributed this to a dose-related increase in the proportion of normal cells transformed to a malignant state and a dose-related decrease in the probability that transformed cells survive radiation exposure. While the interpretation may not be quantitatively precise, it does draw attention to the critical interplay between cell survival and mutational events and subsequent cell transformation in the induction of cancer in irradiated individuals. The role of these two events is explicitly incorporated in the classical Moolgavkar–Vinson–Knudson model of carcinogenesis (Moolgavkar and

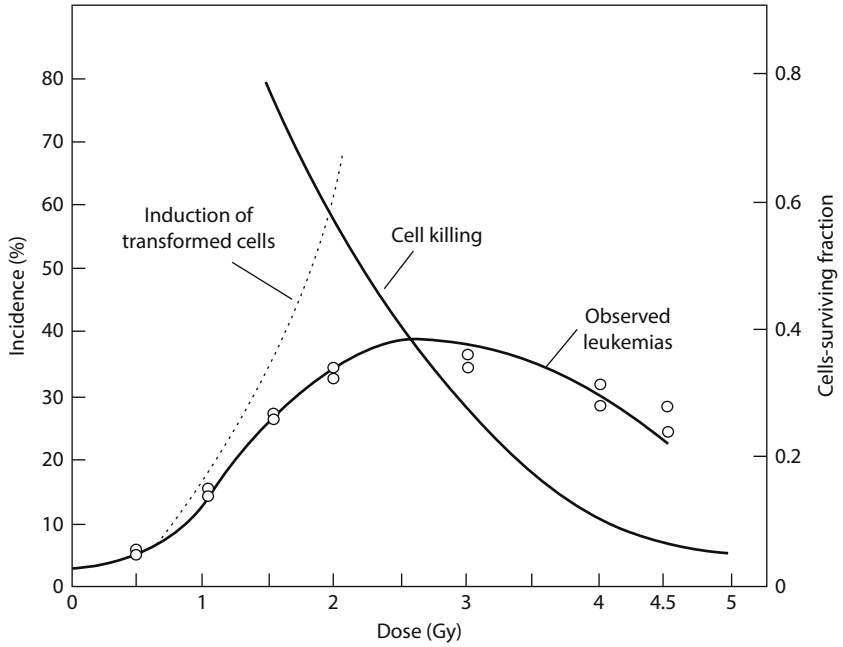

FIGURE 18.9 The postulated role of cell killing and induction of cell killing in producing leukemia in irradiated mice. (From Gray, L.H., Radiation biology and cancer, in: *Cellular Radiation Biology: A Symposium Considering Radiation Effects in the Cell and Possible Implications for Cancer Therapy: A Collection of Papers*, eds. M.D. Anderson and Tumor Institute, Lippincott, Williams and Wilkins, Philadelphia, PA, pp. 8–25, 1965.)

Venzon 1979; Moolgavkar and Knudson 1981; Moolgavkar 1986; Moolgavkar et al. 1988, 1999; Dewanji et al. 1989).

The dose–response relationships for induction of chromosomal aberrations in somatic and germ cells vary with the quality of the radiation, cell type, and species studied. It is obvious that for mutations to be induced and passed to subsequent generations of cells, the irradiated cells must survive. Thus, for x-ray or gamma rays, the induction of mutations can only be studied at relatively low radiation dose with brief exposures. Of course, if the radiation dose is protracted, higher total radiation doses can be studied because of the dose-sparing effect of dose protraction (recall Figure 18.2). With internally deposited radionuclides, the radiation dose rates are relatively low, so higher total doses can be studied. The results of studies by Brooks (2013) on the induction of chromosomal aberrations in vivo in liver cells in Chinese hamsters are summarized in Figure 18.10. The base case is the effects of acute ^{60}Co gamma radiation.

At the lowest radiation doses, the relationship between radiation dose and aberrations per cell is linear and then at higher doses sweeps up, reflecting the interactions associated with high radiation doses. At low total doses, chronic gamma irradiation (<5 Gy/day) and acute gamma irradiation are equally effective in producing aberrations. This would equate to an RBE of 1.0. The RBE factor has classically been used to adjust measurements of dose for radiation at different kinds (gamma rays or x-rays as a base and alpha and beta particles and neutrons) to equal effectiveness in producing biological effects. At higher total radiation doses, the relationship between dose and aberration frequency is essentially linear. It is noteworthy that when the radiation dose is delivered by internally deposited ^{144}Ce–^{144}Pr, which decays by emission of beta particles, the dose–response relationship is remarkably similar to protracted external gamma irradiation. This is to be expected since both are low-LET radiation. The nature

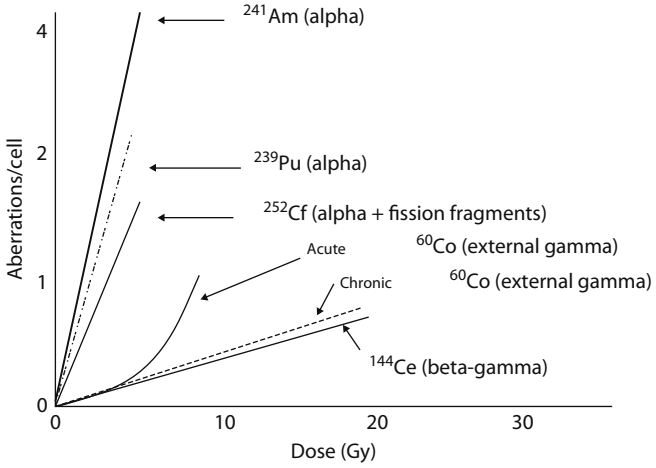

FIGURE 18.10 Dose–response relationship for in vivo induction of chromosome aberrations in liver cells of Chinese hamsters by high LET (alpha particles from ^{241}Am, ^{239}Pu, and ^{252}Cf) and low LET (^{60}CO gamma rays and ^{144}Ce-^{144}Pr beta particles). (From Brooks, A.L., *Health Phys*., 105, 407, 2013.)

of the dose–response relationship for the internally deposited alpha-emitting radionuclides (^{241}Am, ^{239}Pu, and ^{252}Cf) is quite different. The alpha radiation, which has a high LET, is much more effective in producing aberrations than is the low-LET radiation. As will be described later, the alpha-emitting radionuclides are also highly effective in inducing cancer.

The induction of mutations in somatic cells increases the probability of cancer occurring after a variable latent period, over and above the background incidence. The induction of mutations in germ cells is key to induction of genetic effects in the progeny of the irradiated parents.

The health impact of any radiation dose, delivered either from external exposure or internally deposited radionuclides, is a function of (1) the quality of the radiation, (2) the rate at which the dose is delivered, (3) the total dose delivered to critical tissues, and (4) the time elapsed from when the radiation dose was delivered. These factors all influence the probability of cells being killed, mutations being induced, cells being damaged, damage in cells being repaired, and surviving cells having mutations that manifest in their progeny. It is important to recognize that these radiation-induced events all occur in company with the similar events occurring naturally or induced by other factors. Irradiated cells do not respond in isolation.

One of the most recent developments in radiation biology has been the discovery of a bystander effect. It has been recognized for some time that targeted cytoplasmic irradiation can result in mutational changes in the nuclein of hit cells. It is now known that cells not directly hit by alpha particles or other higher-energy ions also contribute to the response of bystander ells (Wu et al. 1999). The clinical significance of the finding is still being discussed. Multiple authors (Lorimore et al. 2003; Azzam and Little 2004; Blyth and Sykes 2011) have provided a comprehensive review of current knowledge of radiation-induced bystander effects, including their relevance to human exposures.

A critical difference between time dimensions of delivery of the radiation dose from external sources and internally deposited radionuclides was illustrated earlier in Figure 18.2. With external exposure, the dose is typically received over a very short time period with the exception of low-level exposure from natural background. Exposure and delivery of the dose occur at the same time. While the radiation dose to various portions of the body may vary, the radiation dose among the tissues of the body is relatively uniform unless some portion of the body has been purposefully irradiated and other portions shielded. Of course, it is possible for an individual to receive multiple brief exposures.

The situation is quite different for internally deposited radionuclides. An individual may be briefly exposed to a radioactive aerosol at an industrial setting. The radiation dose to the respiratory tract and other body tissues will be dependent on the particle size, the chemical characteristics of the material inhaled and its solubility, and obviously the physical half-life and emission characteristics of the radionuclide(s). The time course for exposure, for example, by inhalation or ingestion, versus the time course for delivery of the radiation

dose is different. Moreover, the radiation dose rate and cumulative radiation doses received by different organs and, indeed, various cell types and tissues within a given organ may be markedly different, dependent on the distribution of the radionuclide within the organ.

A measure of the rate at which energy of differing quality is transferred to tissue, LET is expressed in units of kiloelectron volts of energy transferred per micrometer of track length in tissue (keV/μm). The LET of typical diagnostic x-rays is about 3 keV/μm. These x-rays have an RBE of 1.0 serving as a base for considering the RBE of other radiation. Beta particles will typically have an RBE of about 1.0, while alpha particles have an RBE of about 20 as was shown in Figure 18.10 for induction of chromosomal aberrations. As the LET of the radiation increases, the RBE also increases. After reaching a maximum, the RBE for radiation with an LET above 100–200 keV/μm decreases due to overkill.

The penetrating ability of x-rays and gamma rays originating outside of the body is a function of the photon energy. High-energy photons can penetrate to considerable depths in tissue, and a substantial portion may pass through the body, the basis for diagnostic x-ray radiographs. Gamma emissions from decaying radionuclides within the body may, with sufficient energy, result in the gamma photons leaving the body. Thus, the body may serve as a radiation source. Gamma photons such as those from the decay of internally deposited $^{134-137}$Cs deliver radiation dose to both the organ containing the radiocesium as well as adjacent organs (Boecker 1972).

Gamma photons and beta particles in fallout particles when deposited on the skin irradiate the underlying dermal cells. The vast majority of the radiation dose to the underlying tissue is typically from the beta particles. The distance that the beta particles travel in tissue is dependent upon their energy. Beta particles from the decay of internally deposited radionuclides effectively irradiate the tissue in which the radionuclide is deposited, such as lung, liver, or bone. Beta-emitting radionuclides, when present at high concentrations such as in lung-associated lymph nodes, may result in irradiation of adjacent organs such as the heart and lung. The range of alpha particles is quite short such that all of their energy is released as they traverse only a few cells.

The sensitivity of tissue to radiation damage, especially for radiation below 10 keV/μm, is influenced by its degree of oxygenation. Well-oxygenated tissue is more sensitive to radiation damage than when the tissue is anoxic, the oxygen effect. The oxygen enhancement ratio is a ratio of the dose necessary under anoxic conditions to produce a given effect in comparison with the dose necessary to produce the same effect under aerobic conditions. The oxygen enhancement ratio is on the order of 3.0 for x-rays and gamma photons with an LET of 0.1–0.5 keV/μm decreasing to an oxygen enhancement ratio of about 2.0 for 5 keV/μm radiation and an absence of any oxygen enhancement for radiation with an LET of greater than 50 keV/μm.

Protraction and fractionation of the radiation dose have a profound effect on the effectiveness of the irradiation, whether it is originating externally or from internally deposited radionuclides. If the length of time over which a given dose is delivered, that is, the dose rate is decreased, the effectiveness of a given total dose is decreased. The same reduction in effectiveness is observed if the same total dose is delivered in equal fractions over a number of days.

The situation for internally deposited radionuclides is complicated by multiple factors: the nature of the exposure (a brief intake versus chronic intake), the route of exposure (inhalation, ingestion, or a wound), the biological characteristics of the radioactive material (e.g., its solubility and elemental characteristics), how it distributes in the body, the radiation emissions, and the physical half-life of the radionuclide(s). With a brief intake, the effective half-life (a function of both biological and physical half-life) will determine how the dose rate decreases over time postexposure. For example, a short-lived radionuclide, such as ^{90}Y with a half-life of 64 h, will result in a dose delivered at a steadily decreasing dose rate with essentially all of the dose delivered in a matter of 10 days or so. In contrast, a long-lived radionuclide, such as ^{90}Sr, with a physical half-life of 28.8 years and an effective half-life in the body of several hundred days will deliver a steadily decreasing dose rate such that the total dose will be delivered over several years. Multiple intakes of a radionuclide will result in a steady increase in the amount of internally deposited radioactivity in the tissues with a corresponding increase in the radiation dose rate. Dependent upon the duration of intake and the decay half-time of the radionuclide, an equilibrium relationship may be reached between intake and body burden. Every exposure to internally deposited radionuclides results in protracted radiation exposure. The reduced effectiveness of radiation dose protraction from internally deposited radionuclides, especially for long-lived radionuclides, is well documented as will be discussed later.

EFFECTS OF EXTERNAL RADIATION EXPOSURE

Acute Effects of External Exposure

Acute effects of external radiation exposure, including acute radiation-induced lethality, have been studied in detail in many species. As will be discussed later, the early literature refers in a generic manner to early deaths being due to multiple acute radiation syndromes, while more recent literature uses the term *acute radiation sickness* (ARS; Mettler and Upton 2008). The descriptor *acute* relates to deaths occurring within a few months of external exposure to radiation or a very substantial intake of radioactive material and delivery of substantial radiation doses over a relatively short period of time. The term *syndromes* refers to the predominant underlying tissues that are injured—neurovascular, gastrointestinal, hematopoietic, and cutaneous—and involved in death at various absorbed radiation doses. This division into distinct phases and tissues may be misleading because at doses above a few gray, many tissues are damaged, and the condition of the subject results from interactions among multiple mechanisms in multiple organs and tissues producing a range of clinical signs and symptoms. Thus, the more modern term, ARS, is more appropriate.

Many thousands of individuals died of ARS following the bombings of Hiroshima and Nagasaki, and, as will be discussed later, many thousands of individuals survived the bombings, including many who had experienced ARS. However, the catastrophic nature of these bombings limited the amount of detailed clinical data that could be acquired on the victims. It is important to recall that the Japanese victims received very brief, essentially instantaneous, exposures to gamma and x-ray photons and, at Nagasaki, some neutrons (Recall Figure 18.2). These individuals were also impacted by the blast wave and thermal radiation exposures coming from the detonation of the weapons. It is estimated that for a typical nuclear detonation, the distribution of energy released is as follows: (1) blast (pressure shock wave)—50%, (2) thermal radiation (including light)—35%, and (3) nuclear radiation (both prompt and delayed)—15% (Glasstone and Dolan 1977). It should not be surprising then that most of the awesome destructive impact of a nuclear detonation is associated with the blast wave and thermal radiation. The impact of the blast and thermal energy released was dominant close to the point of detonation or epicenter and caused injury and death of thousands of individuals. The radiation exposures and resulting tissue doses are of concern at greater distances from the point of detonation where the blast overpressure and thermal energy are lower. Inhalation and ingestion of radioactive materials did not have a substantial role in the deaths observed following the Japanese bombings and was not a significant source of long-term radiation exposure.

The most useful information on ARS is based on the subjects included in registries, especially that maintained by the IAEA, which includes about 400 cases (IAEA 1998). About one-fourth of the cases died of ARS, and about three-fourths survived despite having some signs and symptoms of ARS. The number of survivors provides valuable insights into the management of acute radiation exposure cases. As an aside, about one-third of the cases are from the Chernobyl accident, either employees at the reactor when the accident began or first responders. Essentially all ARS cases are attributed to external radiation exposures. One fatality has been documented from medical misadministration of ^{198}Au, several cases related to combined external exposure from an internal intake of ^{137}Cs, and one case attributed to intake of ^{210}Po, a short-lived alpha emitter, in a purposeful poisoning case.

The IAEA (1998) has carefully analyzed all of the cases and drawn some general conclusions that are presented in Tables 18.10 through 18.12. The tables are adapted from the IAEA (1998) report, which provides an extensive discussion of the findings on which these summary tables are based. These tables are also discussed in Mettler and Upton (2008), which I view as the most recent comprehensive text on the

TABLE 18.10
Prodromal Phase of Acute Radiation Sickness

	Degree of ARS and Approximate Dose of Acute WBE (Gy)				
Symptoms and Medical Response	**Mild (1–2 Gy)**	**Moderate (2–4 Gy)**	**Severe (4–6 Gy)**	**Very Severe (6–8 Gy)**	**Lethal[a] (>8 Gy)**
Vomiting onset	2 h after exposure or later	1–2 h after exposure	Earlier than 1 h after exposure	Earlier than 30 min after exposure	Earlier than 10 min after exposure

[a] 1 Gy = 100 rad.

[b] In very severe cases, with a dose >50 Gy, deaths precede cytopenia.

medical effects of ionizing radiation. All of the acute clinical responses discussed would be considered as deterministic effects.

Associated with the Chernobyl accident, 134 patients were considered to have the ARS (Gusev et al. 2001; Mettler et al. 2007; Mettler and Upton 2008). This group comprised 28 individuals who died, including 20 deaths among 21 individuals who received 6.5–16 Gy (very severe ARS), 7 deaths of 22 patients who received 4.2–6.4 Gy (severe ARS), and 1 death of 50 patients who received 2.2–4.1 Gy (moderate ARS). In retrospect, three of the deaths were believed to have occurred unnecessarily as a result of inappropriate bone marrow transplantation. The transplant surgeon participating in the treatment of these cases was very experienced with treating patients purposely exposed to known quantities of radiation with precisely calculated and delivered bone marrow doses before receiving a bone marrow transplant. The situation is quite different in an accident when the actual radiation exposure and dose received by the subject must be estimated from clinical signs and symptoms. Treatment of individuals with doses below 9 Gy only worsened the ARS results due to complications associated with immunological rejection of the bone marrow transplant. Mettler and Upton (2008) suggest that only a small percentage of radiation accident

TABLE 18.13
Representative Lethal Dose 50% (30 Days) Values for Various Mammalian Species

victims would benefit from bone marrow transplantation, those patients that received sufficiently high radiation doses to completely destroy their original marrow cells, but sufficiently low to have minimal other radiation-induced effects.

Mettler and Upton (2008) have estimated the radiation dose required to kill 50% of individuals within 60 days in the absence of medical intervention as 3.5–4.0 Gy, air or surface dose. This would correspond to a midline tissue dose of about 2.7 Gy. As noted earlier, numerous studies have been conducted on acute radiation effects in species other than man. Some representative lethal doses (50% deaths within 30 days) are shown in Table 18.13. The range of values is remarkably narrow from about 2.5 to 7.5 Gy. Caution should be exercised in interpreting differences in the $LD_{50/30}$ values between species as being true interspecies differences. The studies were conducted at different times with different radiation sources and subjects that were in different environments on different diets and with different internal microbial flora.

Heritable Effects

Observations by Müller (1927), Oliver (1930), and others that exposure to high doses of x-rays caused a readily observable dose-dependent increase in mutations in the fruit fly, *Drosophila melanogaster*, galvanized both scientific and public concern for an increase in *genetic* disease in the progeny of irradiated individuals. Other studies would follow showing the effect varied for different stages of meiosis (Marshak 1935). Today, it is recognized that the term *heritable effects* is more descriptive in recognizing that the cancer induction by radiation exposure is a *genetic* effect, a fact that was not well recognized and accepted until much later. Concern for radiation-induced heritable effects was a dominant factor in the early setting of the maximum permissible exposure limit for radiation workers. In the 1950s, based on the results of studies with x-irradiated fruit flies, it was thought that exposure to 50–150 R (0.5–1.5 Gy) would double the spontaneous mutation rate. It was also thought that effects of radiation exposure on heritable effects was cumulative over multiple generations and would increase the burden of heritable disease for the human race. It is also important to recognize that in the 1940s and 1950s, the cancer-inducing ability of radiation was not as apparent as it is now. Early results from the studies of the Japanese atomic bomb survivors indicated an increase in leukemia (Folley et al. 1952; Ishimaru et al. 1971; Richardson et al. 2009); however, an increase in solid cancers had not yet been observed in the 1950s. Thus, it was reasonable then to view radiation induction of heritable effects as a greater concern than cancer induction.

Two avenues of research would produce results that would temper and, indeed, change the early conclusions and result in later radiation protection standards being increasingly dominated by concern for cancer induction rather than heritable effects. A major influence came from the research of W. L. (Russell 1963, 1965) Russell and his colleagues at Oak Ridge NL who used about seven million inbred mice to investigate the influence of radiation exposure on seven specific locus mutations. These studies showed different radio sensitivities for the mutation rates of different loci. In the mouse, they also found a substantial dose rate effect: dose protraction resulted in fewer mutations than a single acute dose. Recall the results in Figure 18.10 for the induction of chromosomal aberrations in Chinese hamsters given acute versus chronic gamma irradiation. Moreover, Russell and colleagues (1963) also found that increasing the interval between irradiation and conception markedly reduced the effectiveness of a given dose. However, those results had to be tempered by recognition that the oocytes of female mice were very sensitive to radiation and were killed by quite low radiation doses.

The fourth BEIR Committee (NRC 1990) and the UNSCEAR (1988) estimated the doubling dose for inducing heritable mutations in humans was at least 1 Gy for low-dose-rate, low-LET irradiation. Sankaranarayann and Chakraborty (2000) and Neel (1998) discussed this shift in view. A report edited by Neel and Schull (1991) summarizes a wealth of information obtained from studies on the children of the atomic bomb survivors.

An important line of evidence for external radiation exposure inducing heritable effects has come from the study of the cohort of 31,150 children born to parents who received significant exposure from the Japanese A-bombings (Neel et al. 1990). A range of indicators of heritable effects were evaluated. The difference in measured markers of heritable effects between the children of parents proximally or distally exposed was in the direction to be expected if there were a heritable effect of radiation. However, none of the findings was statistically significant. Schull et al. (1981) in an appraisal of the data on the children of Japanese atomic bomb survivors estimated that the doubling dose could be 1.56 Sv for the acute instantaneous external radiation exposure of the parents from detonation of the A-bombs. Neel et al. (1990) indicate that considering all heritable outcomes, the best estimate of the doubling dose for humans is between 1.7 and 2.2 Sv. These results suggest that humans are not as sensitive to the

genetic effects of radiation as mice (Neel 1998). UNSCEAR (2005) provides a comprehensive review of the hereditary effects of ionizing radiation.

Hall and Giaccia (2012) noted that the concern of the ICRP for heritable effects as part of the total radiation detriment has shifted over the decades. Heritable effects were viewed as the dominant controlling effects for radiation protection purposes in 1955 and earlier; this was reduced to 25% in 1971 and further reduced to 18% in 1991. By 2007, it was viewed as only 4% of the total radiation detriment. Over this total time period, heritable effects of radiation continued to be viewed as increasing as a linear function of dose without a threshold. The BEIR V (NRC 1990) estimates that the heritable risk of radiation is about 0.2% per Sv for the general population and about 0.1% per Sv for a working population. Thus, a dose limit for radiation workers of a maximum of 50 mSv/year is viewed as adequately protective of potential heritable effects.

Late-Occurring Effects of External Radiation Exposure

A very large body of information exists on the late-occurring effects of external radiation exposure, and Mettler and Upton (2008) have discussed this literature in detail. Shore (2013) has recently provided a succinct summary of the epidemiological findings on radiation and cancer. The International Agency for Research on Cancer (IARC 2000) published a monograph on reviewing the cancer hazards of x-irradiation and gamma irradiation and neutrons. Unfortunately, the review focused on cancer hazard and did not rigorously consider the quantitative relationship between dose and cancer outcome. The fact that ionizing radiation is a cancer hazard is well established. The issues today are concerned with dose–response relationships, especially at low dose rates and low total doses.

Some of the major populations studied to evaluate the effects of external radiation exposure are listed in Table 18.14. The best information available on humans has been obtained from detailed studies, still ongoing, of the survivors of the atomic bombings of Hiroshima and Nagasaki and, to a lesser extent, from individuals accidentally or purposefully exposed, as in the case of patients receiving either diagnostic or therapeutic x-irradiation. In all but a few of these situations, the radiation exposures were instantaneous as with the atomic bomb exposures or were quite brief, high-intensity exposures as illustrated earlier in Figure 18.2. It is important to recognize that very little of the information on late effects of human exposures to external radiation involves well-characterized absorbed doses from chronic external radiation exposure.

TABLE 18.14
Human Populations Studied Following External Exposure to X-Radiation or Gamma Radiation

Population	Effect	Key Reference
Atomic bomb survivors	Cancer and other diseases	Ozasa et al. (2012)
Prenatal irradiation	Leukemia Cancer	Doll and Wakeford (1997)
Ankylosing spondylitis patients	Cancer	Court Brown and Doll (1965)
Radiologists	Leukemia	Matanowski et al. (1975) Smith and Doll (1981)
Thymic enlargement	Thyroid cancer	Shore et al. (1993)
Tinea capitis	Thyroid cancer	Shore et al. (2003) Ron et al. (1989)

An extraordinarily large body of information exists on late-occurring effects observed in a number of laboratory animal species such as rats, mice, dogs, and burros following brief, fractionated, or protracted whole-body exposure to external radiation. The information obtained in the laboratory animal studies complements the human experience and is especially valuable in interpreting and extending the findings in exposed human populations. I emphasize populations since the effects of primary concern are largely stochastic effects, with the emphasis on the occurrence of cancer, whose probability of occurrence increases with dose, and the severity of the effect is independent of dose. Thus, relevant information can only be obtained from studying populations of laboratory animals. Indeed, the probability of radiation exposures in excess of background resulting in an increased occurrence of disease, including cancer, over and above the background incidence is so low that quite large populations must be studied to obtain statistically significant results. To provide perspective, assume the background incidence of an endpoint, such as a specific kind of cancer, is 1%. It will be necessary to have a group size of 400 to detect a statistically significant increase in the endpoint over background incidence with 95% confidence. The statistically significant increase would be an incidence of 5% corresponding to a relative risk (RR) of 5.0. It is apparent that laboratory animal bioassays as well as studies of small human populations are *blunt* approaches for detecting increases in late-occurring, relatively infrequent diseases. It is important to note that the clinical course and morphological characteristics, both gross and microscopic, of the radiation-induced cancers are the same as those occurring spontaneously and of unknown etiology. A radiation-induced cancer does not carry a special unique signature related to its radiogenic origin.

Although the results of the long-term studies of external radiation in laboratory animals are extraordinarily elegant, those data have not generally been viewed as suitable for developing quantitative dose–response estimates of human cancer risks. The situation might have been different if data on exposed human populations were not available. However, when data are available from human studies, they will always, and in my view, appropriately *trump* the use of animal data in developing quantitative dose–response estimates for humans and in developing radiation protection standards and guidance. The primary use of results from animal studies is to aid in understanding the results of the studies of exposed human populations and in extrapolating the human data to unique

exposures such as with different radiation quality. The utility of data from in vitro cellular- and molecular-level studies, especially using cells from species other than humans, is frequently treated in the same manner.

Contrary to the perception of most of the public and many scientists in other fields, and even some radiobiologists, radiation is a rather weak carcinogen. Remarkably high levels of radiation exposure are required to identify statistically significant increases in cancer incidence over background levels. It is useful to recall that in countries having well-developed economies and long-lived populations, about one in three individuals (estimates of 40% or 42% have also been given) will develop cancer over their life span and about one in four individuals will die with a cancer. Throughout this chapter, the word *cancer* will typically be used in its broadest definition, malignant solid tissue tumors and leukemias, unless otherwise noted.

Before proceeding to discuss radiation-induced cancer, it is appropriate to briefly discuss another late-occurring radiation-induced effect, cataracts. Radiation induction of cataracts has typically been viewed as a deterministic effect with a dose threshold and for which the severity increased and latency decreased as the radiation dose increased above the threshold. The ICRP (2007) estimated that brief exposures with doses of at least 0.5–2 Sv are required to cause detectable lens capacities, and doses of over 5 Sv are required to produce vision-impairing cataracts. Shore et al. (2010) analyzed the dose–cataract response relationship for 3994 A-bomb survivors. They reported a best dose-threshold estimate of 0.1 Gy (confidence interval [CI]: <0, 0.8 Gy). However, the data were compatible with there being no dose threshold or a threshold of up to 0.8 Gy but not higher. Detailed observations over their lifetime of large populations of individuals irradiated at doses substantially above the background may reveal that for late-occurring diseases, the distinction between deterministic and stochastic effects may become less distinct than currently thought.

Radiation-induced cancers were observed quite soon after the discovery of radiation and radioactivity. The association between radiation exposure and the occurrence of clinical injury and cancer was obvious on a case-by-case basis. That these cases were observed so soon, with a very short latent period between radiation exposure and the clinical manifestation of the cancers, is a reflection of the extraordinarily high repeated radiation exposures and resultant very large tissue doses these individuals received. The total doses received were likely very high because the repeated, sometimes daily, radiation exposures and tissue doses were sufficiently low so as to avoid acute serious injury. For example, both Marie and Irene Curie are thought to have died of leukemia. Many physicians, dentists, and x-ray technicians who were early users of x-rays also developed skin cancers.

Studies on a number of populations irradiated during medical procedures have given valuable insights into the quantitative relationships between external exposure and the resultant tissue dose and the occurrence of cancer. Pre-1950, it was common practice to use x-rays to treat children with

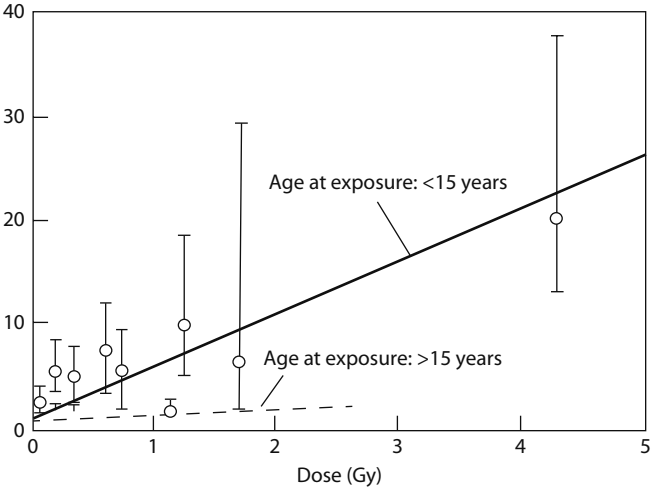

FIGURE 18.11 RR of thyroid cancer after exposure to acute doses of external low-LET radiation. (From Ron, E. et al., *Radiat. Res.*, 141, 259, 1995.)

enlarged thymus glands, diseases of the tonsil and nasopharynx, or tinea capitis (ring worm). A follow-up of these populations revealed a dose-related increase in thyroid cancer (Ron et al. 1995) (Figure 18.11). The cancers occurred in the thyroid because the thyroid glands were in the radiation exposure field since the x-ray beams were not as well collimated as today. The excess relative risk (ERR) was estimated to be 7.7% per Gy for the individuals irradiated at less than 15 years of age. The excess risk for individuals irradiated over 15 years of age was substantially reduced. Radiation-induced tumors develop slowly and often can be successfully treated by surgery or with radioiodine. Thus, the mortality rate for thyroid cancer is estimated to be about 5% (Hall and Giaccia 2012).

Dose-related increases in breast cancer have been observed in a number of populations (Boice et al. 1979). The populations studied included women treated with x-rays for postpartum mastitis and patients who were repeatedly examined fluoroscopically following the induction of pneumothorax to treat pulmonary tuberculosis. The dose–response data for breast cancer were considered to be reasonably well fit by a linear function.

By far the most comprehensive data on the effects of external radiation exposure have come from the detailed follow-up of the survivors of the atomic bombings of Hiroshima and Nagasaki. A cooperative effort by the governments of Japan and the United States was initiated soon after World War II to follow these populations and assist in coordinating their medical care. The initial effort was carried out by the ABCC, which became the RERF. The U.S. DOE and its predecessor organizations provided government funds for both entities via the U.S. National Academy of Sciences (NAS). This cooperative effort continues today. The goals of the program include care of the populations and scientific studies to gain insights into the long-term effects of brief external exposure to radiation. There are three ABCC/RERF study groups. The Life Span Study (LSS) includes about 120,321 individuals,

82,214 in Hiroshima and 38,107 in Nagasaki. Information from this group provides valuable insights into radiation-induced cancer incidence and cancer mortality. The in utero cohort includes about 3300 individuals who received in utero exposure as a result of their mother's exposure. Valuable information from this population has been obtained on the incidence of malformations, growth retardation, microcephaly, and mental retardation. The 77,000 children born to survivors of the atomic bombings, the so-called F_1 generation, are the third population group. Observations in this group provide valuable data for assessing heritable effects (Neel et al. 1990). It is important to note that radiation exposure and organ doses for each individual in the ABCC/RERF cohort has been carefully estimated taking into account precisely where the individuals were when the bombs exploded and any shielding between them and the detonation (Cullings et al. 2006; Young and Bennett 2006).

Ozasa et al. (2012) have published an overview of cancer and noncancer disease mortality for the atomic bomb survivors from 1950 through 2003. This report of Ozasa et al. (2012) is the 14th in a series on the mortality of the LSS cohort with the first report published in 1962 (Beebe et al. 1962). The reports contain detailed information on dosimetry, medical follow-up, and the statistical methods used to analyze and model the data. No other large population exposed to any other toxic agent has been studied as exhaustively over more than a half century, and continuing today, as the population of Japanese atomic bomb survivors.

The efforts of the ABCC/RERF scientists and staff and the cooperation of the atomic bomb survivors and their children have been remarkable! The observed and excess deaths for the LSS are summarized in Table 18.15. In addition to the 86,611 individuals shown in this table by dose level, another group of individuals who were not in the cities at the time of the bombings has been followed. Some individuals have viewed that population as a control group; however, the RERF scientists have taken an alternative approach in analyzing the data as discussed in the following. The summary data reported by Ozasa et al. (2012) extend through 2003. Thus, if an individual had been a year old at the time of bombing in 1945, he or she would have been 59 years old in 2003. Other individuals in the surviving population would have been older in 2003.

When considering the findings from the studies of the Japanese survivors, it is important to recall that they include some 624 individuals with very high radiation exposures (doses over 2 Gy). Recall the earlier discussion of acute radiation diseases. If those individuals with radiation doses of over 2 Gy had received only slightly higher radiation exposures, some would have died from acute radiation injury. By analogy to animal bioassays, the individuals in the LSS cohort in this highest dose range received maximum tolerated doses.

It is of interest to note that of the 86,601 individuals alive in 1950, a total of 46,614 individuals or 53.8% of the individuals had died by 2003 with 46.2% surviving. The 10,929 cancer deaths represent 23.4% of the deaths to date. The RERF scientists have *not* estimated the number of excess deaths attributed to radiation by comparing the number of deaths in the irradiated groups with that in a control population. Alternatively, they have calculated the number of excess cases by modeling using a linear dose–response model with effects modification. Table 18.15 shows the number of excess cases for cancer and noncancer diseases in each dose interval as well as the fraction of cases attributed to radiation exposure. The portion of radiation-attributable cases increases in each dose group, reaching 56.5% for cancer and 16.3% for noncancer effects in the highest-dose group (over 2 Gy). As expected, most of the excess cases estimated to be attributed to radiation exposure are in the highest radiation dose intervals. Some readers may be surprised to note the relatively modest number of estimated excess cancer cases. As noted earlier, despite popular opinion to the contrary, radiation is a relatively weak carcinogen. For the Japanese A-bomb LSS cohort through 2003, 527 cancer deaths and 353 deaths from

[a] Nonneoplastic blood diseases were excluded from noncancer diseases.

[b] Based on the ERR as defined from the linear model with effect modification: $\gamma_o(c,s,b.a)[1 + \beta_1 d \cdot \exp(\tau\, e + \upsilon\, 1n(a)) \cdot (1\, \sigma\, s)]$.

diseases other than cancer were estimated to be attributable to radiation exposure. Over half of the estimated excess deaths were individuals that received doses in excess of 0.5 Gy. To provide perspective, recall that Mettler and Upton (2008) estimated a midline tissue dose of 2.7 Gy would result in 50% of the irradiated individuals dying within 60 days.

Of the 86,611 subjects with estimated doses for 15 organs, 50,620 (58%) had died during the 1950–2003 follow-up period. This included 99.6% of those who were 40 years or older when exposed; if alive in 2003, they would have been 98 or more years old. About 80% of those less than 20 years of age in 1945 were still alive. Twenty-two percent of the deaths were due to solid cancers, 1.4% to lymphoid and hematopoietic malignancies, 71% to nonneoplastic diseases, and 5% to external causes. The estimated excess risk values for major causes of death are shown in Figure 18.12. The ERRs were

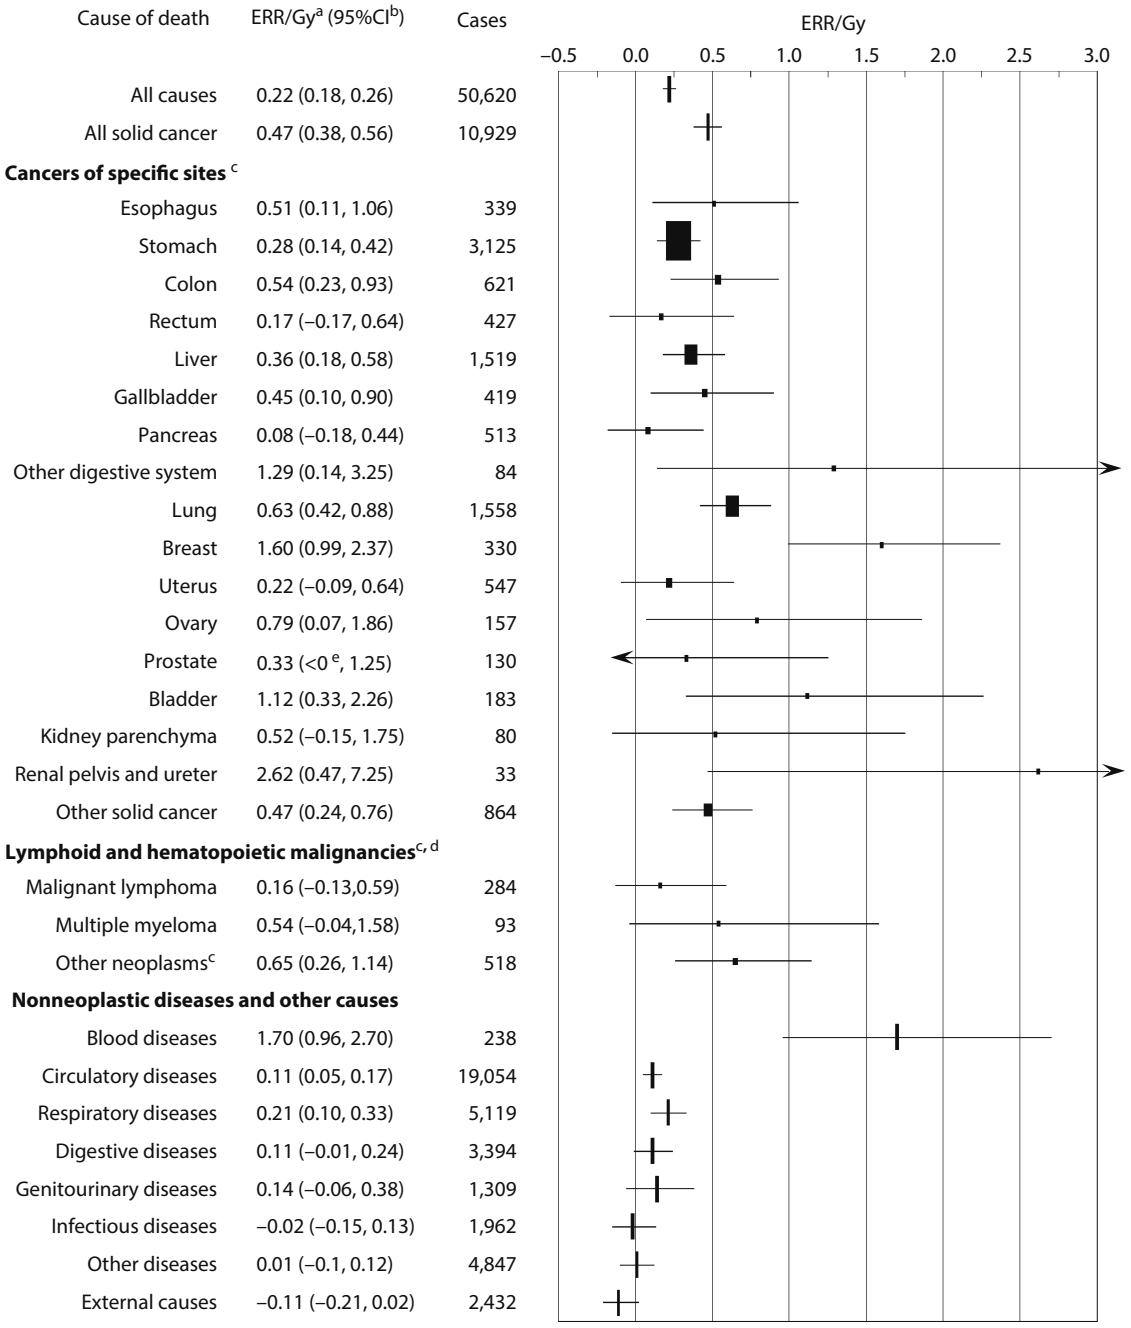

FIGURE 18.12 Estimates of ERR per gray and 95% CI for major causes of death in the Japanese A-bomb survivors. [a]ERR was estimated using the linear dose model, in which city, sex, age at exposure, and attained age were included in the background rates, but not allowing radiation effect modification by those factors. [b]Confidence interval. Horizontal bars show 95% CIs. [c]The size of plots for site-specific cancers was proportional to the number of cases. [d]ERR (95% CI) of leukemia was 3.1 (1.8, 4.3) at 1 Gy and 0.15 (−0.01, 031) at 0.1 Gy based on an LQ model with 318 cases (not displayed in the figure). [e]The lower limit of 95% CI was lower than zero, but not specified by calculation (1950–2003). (From Ozasa, K. et al., *Radiat. Res.*, 177, 229, 2012.)

calculated using the simple linear statistical dose–response model. As expected, the most stable estimate was found for the cancers of specific sites with the largest number of cases such as stomach, liver, and lung cancer. Ozasa et al. (2012) also reports how the estimates of effect modification of ERR were influenced by sex, age at exposure, and attained age.

The sex-averaged ERR per gray for all solid cancers was 0.42 (95% CI; 0.32, 0.53). The lowest dose range with a significant ERR for all solid cancers was 0–0.20 Gy with an estimated ERR of 0.56 Gy^{-1} (95% CI; 0.15, 1.04, P = 0.01) and included 74,444 persons with 9063 solid cancer deaths. An estimated 97 excess solid cancer deaths were in this group. The authors noted as follows: "The maximum likelihood estimate of a dose threshold was 0.0 Gy (i.e., no threshold with an estimated upper bound of 0.15 Gy for 95% CI as determined by minimizing the deviance" (Ozasa et al. 2012). The ERR per gray was highest for those exposed at 10 years of age or younger and decreased with each decade of age at exposure and for all ages decreased with attained age.

Both linear and LQ models were evaluated. Figure 18.13 shows the ERR for solid cancers using alternative models. The authors reported as follows: "The linear dose–response relationship provided the best fit to the solid cancer data across the entire dose range in this study, but significant upward curvature was observed over the truncated dose range of 0.2 Gy."

In considering the data presented in Ozasa et al. (2012) on lymphoid and hematopoietic malignancies, it is important to note that most excess cases of leukemia occurred shortly after the atomic bombings and before the LSS was assembled (Folley et al. 1952; Ishimaru et al. 1971; Richardson et al. 2009).

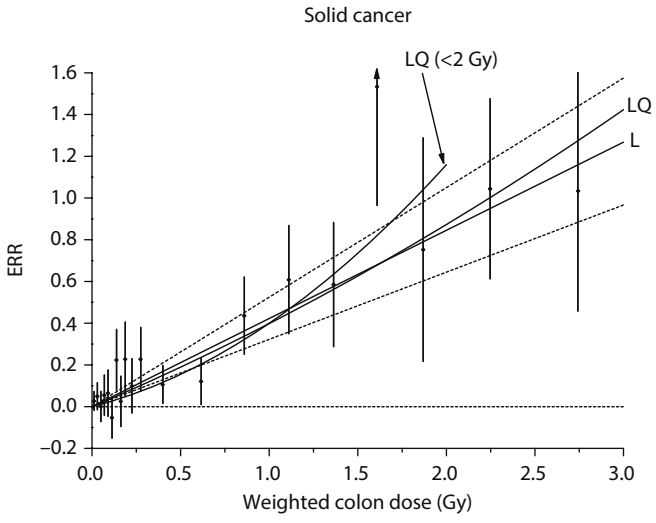

FIGURE 18.13 ERR for all solid cancers in relation to radiation exposure. The black diamonds represent ERR, and the bars are the 95% CI for the dose categories together with trend estimates based on linear (L) with 95% CIs (dotted lines) and LQ models using the full dose range and LQ model for data restricted to dose <2 Gy. (From Ozasa, K. et al., *Radiat. Res.*, 177, 229, 2012.)

The data presented in Ozasa et al. (2012) have already stimulated considerable discussion. The data have been reanalyzed and an alternative interpretation provided by Doss (2013). They reanalyzed the atomic bomb survivor data using a more flexible model that allowed the line of best fit to cross the Y-axis at any location and would also allow for negative predicted ERRs (Figure 18.14). They note, "The flexible model does not show a monotone increase in ERR from zero dose, but it becomes monotone and increases only after the dose reaches 0.27 Gy. Also, the point-wise 95% CI are below zero for most doses below 0.49 Gy. This does not prove there is a threshold effect at 0.27 Gy or 0.49 Gy, but it does demonstrate that there is too much variability in the data to suggest that the threshold for the harmful effects of radiation is zero." Thus, the debate over excess risks of low-level radiation exposure continues.

As noted in Figures 18.12 and 18.13, the risks were elevated for some noncancer diseases, resulting in an estimated 353 excess cases, the attributable fraction representing about 1% of the total noncancer deaths. The elevated risk of diseases of blood and blood-forming organs may be genuinely due to radiation or to possible misdiagnoses of hematopoietic malignancies as nonneoplastic diseases at early time period.

The risk of circulatory diseases was significantly higher. This is of special note since deaths due to circulatory diseases are the leading cause of death in developed countries and typically occur late in life. Shimizu et al. (2010) have reported a more detailed analysis of the relationship between radiation exposure and circulatory disease in the LSS cohort for 1950–2003. This included 19,054 deaths—9622 from

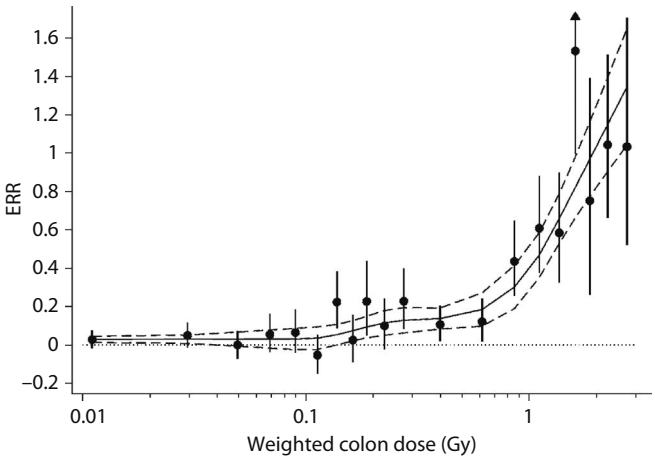

FIGURE 18.14 ERR for all solid cancer in atomic bomb survivors in relation to radiation exposure. The black circles and error bars represent ERR and 95% CIs for the dose categories. Data from (Ozasa et al., 2012). Solid line—fit to the ERR data using a multiple linear regression in which weighted log colon dose was entered into the model using a restricted cubic spline transformation with five knots. Regression weights were equal to the inverse of the variance of the point estimates. Dashed lines are 95% CI of the fit. Figure from performing analysis equivalent to Doss et al. (2012) with the corrected data in Ozasa et al. (2013). Figure provided by Brian L. Egleston. (From Doss, M., *Dose Resp J.* 11, 480, 2013.)

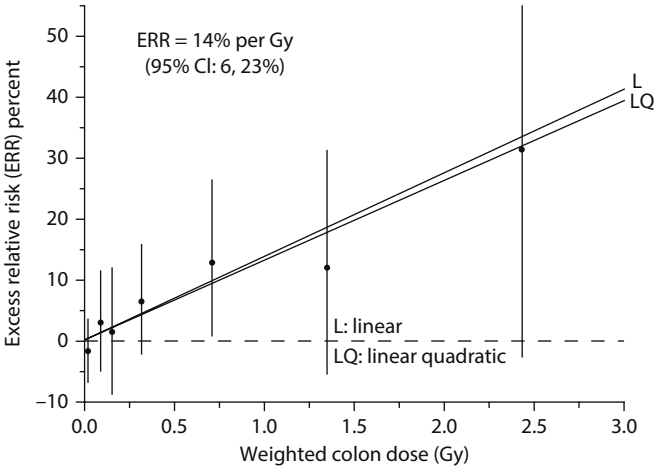

FIGURE 18.15 Heart disease mortality in the Japanese A-bomb survivors, adjusted for gender, age at exposure, attained age, diabetes, obesity, and other factors. (From Shimizu, Y. et al., *Br. Med. J.*, 340, b5349, 2010.)

stroke; 8463 from heart disease; and 969 from other circulatory diseases. They estimated that the excess risk over the full dose range was 11% Gy (95% CI 5%–17%, $P < 0.001$) with an estimated 210 excess deaths from radiation exposure. "For strokes, the estimated excess risk per Gy was 9% (95% CI 1%–17%, $P = 0.02$) on the basis of a linear dose–response model, but an indication of possible upward curvature suggested relatively little risk at low doses. For heart disease, the estimated ERR per Gy was 14% (6%–23%, $P < 0.001$); a linear model provided the best fit, suggesting excess risk even at lower doses. However, the dose–response over the restricted dose range of 0–0.5 Gy was not significant" (Figure 18.15).

The meta-analysis (Little et al. 2009) of circulatory disease from exposure to low-level ionizing radiation supports the results of Shimizu et al. (2010). These recent findings on the possible relationship between radiation exposure and circulatory disease are of keen interest. They suggest that for late-occurring diseases, the distinction between deterministic and stochastic effects may not be as distinct as previously thought.

The risk of respiratory deaths was also increased with influenza and pneumonia accounting for 63% of the respiratory deaths. At early time periods, they were associated with acute epidemics. More recently, these deaths are associated with terminal diseases among the elderly.

It is important to recall that in 2003, 42% of the atomic bomb survivors were still alive 58 years after the bombings of Hiroshima and Nagasaki. They included 80% of those individuals 20 years and younger when irradiated in 1945. Based on the normal pattern of age-related mortality in the general population, most of these individuals would ultimately be expected to die from noncancer diseases of the circulatory system, cancer, and respiratory system, the most common causes of death in the elderly. From 1950 through 2003, deaths from these three causes represented 70% of the total deaths (circulatory, 38%; respiratory, 10%; and cancer, 20%).

The brief description of the latest results from observations on the LSS cohort does not do justice to this remarkable study. Individuals interested in a more in-depth understanding of the late-occurring effects of radiation exposure, and other agents that may cause cancer, are encouraged to read the Ozasa et al. (2012) paper and earlier reports on the LSS series. I encourage the interested reader to go to the RERF site (http://www.temple.edu/newtechlab/TRACES/radeffect.html) where all published reports and papers are available online. As noted elsewhere, I am not aware of any other extended retrospective study in a large population that matches the rigor of the studies of the LSS cohort with regard to estimation of individual doses, medical follow-up, and analysis. As will be discussed later, the LSS cohort studies are especially important because these findings with radiation-induced cancer have been generalized to other cancer-causing agents, especially with regard to the nature of the dose–response relationship. As an aside, most long-term epidemiological studies of human populations exposed to chemicals use an exposure metric, such as exposure intensity or cumulative exposure. It has rarely been possible to estimate a tissue dose metric for large populations exposed to chemicals.

Two additional populations exposed to external radiation warrant discussion: the Russian Techa River Cohort and the 15-Country Collaborative Study of Nuclear Industry Workers. The Techa River population is of interest because they received protracted low-dose-rate radiation exposures and modest total radiation doses. The cohort consists of 29,370 individuals who lived between 1950 and 1960 along the Techa River in the southern Ural Mountains in Russia. Between 1949 and 1956, approximately 10^{17} Bq of uranium fission products was released into the Techa River from the MPA. Subsequently, individuals living along the river received external gamma radiation exposure from contaminated river sediments and floodplain soil and internal radiation exposure from ^{90}Sr, ^{137}Cs, and other radionuclides from the consumption of contaminated water, milk, and food products. The book by Dalton et al. (1999) compares and contrasts the MPA operation and the Techa River population with the Hanford Operations and associated population. The book suggests a degree of similarity that I do not think exists based on my own experience growing up near Hanford. One of the difficulties with the book is it never relates the population exposures for the two populations and focuses on the quantities of radioactive waste at the two sites. Fortunately, the Hanford waste was placed in storage tanks, and, unfortunately, in the early days, the MPA waste was released directly to the environment.

A study of the long-term health effects of the Techa River population was initiated in 1967 (Kossenko et al. 2005). The results of extensive efforts to reconstruct the radiation doses received by the individuals have been reported (Degteva et al. 2006; Tolstykh et al. 2011). An increase in the incidence of leukemia (follow-up from 1953 to 2005) and solid cancers (follow-up from 1956 to 2006) has been reported (Krestinina et al. 2007, 2010). The most recent report (Schonfeld et al. 2013) documents the solid

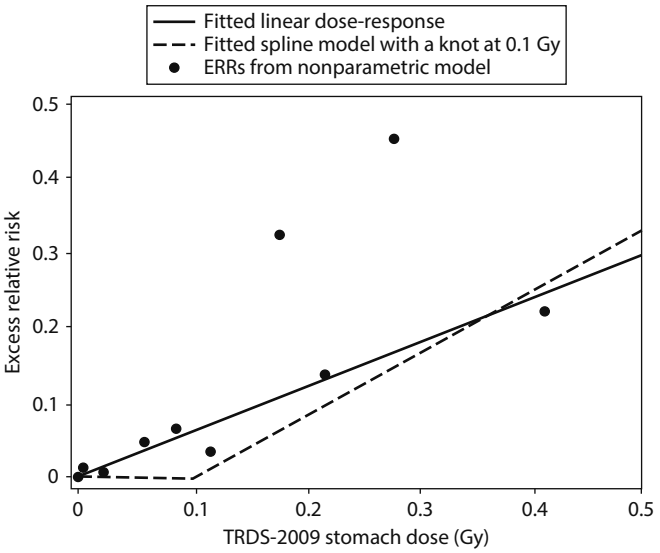

FIGURE 18.16 Solid cancer mortality dose–response relationship in the Techa River Cohort based on TRDA 2009 stomach doses. Circles represent ERR by dose categories from a nonparametric model. Fitted linear dose–response (solid line) and fitted spline model with a knot at 0.1 Gy (dashed line) are also shown. (From Schonfeld, S.J. et al., *Radiat. Res*., 179, 183, 2013.)

cancer mortality for the Techa River Cohort from 1950 to 2007. A total of 2303 solid cancers were observed with 927,743 person-years of follow-up. It was estimated that 2253 cases were background, and 50 cases, about 2% of the total, were excess cases attributed to radiation exposure (Figure 18.16). The linear ERR per gray was 0.61 (95% CI 0.04–127, P = 0.03). This potency estimate is remarkably similar to that observed for the Japanese atomic bomb survivors (Ozasa et al. 2012). The figure also shows the results for a fitted spline model with a knot at 0.1 Gy. Thirty of fifty estimated excess cancer cases were related to 71,537 person-years of follow-up for individuals estimated to have received over 0.1 Gy. The authors concluded as follows: "The data were consistent with a linear dose–response model, but could also be described by models in which the risk at low doses (<0.1 Gy) is less than predicted by the linear model."

The largest epidemiological study of radiation exposure and cancer risk is the 15-Country Collaborative Study of cancer risk among radiation workers in the nuclear industry that is coordinated by the IARC (Cardis et al. 2007; Thierry-Chef et al. 2007; Vrijheid et al. 2007). This study includes 407,391 nuclear industry workers who had been monitored individually for external radiation exposure. Some individuals in the cohort started working in the nuclear industry as early as 1943 at Oak Ridge and 1944 at the Hanford site. As an aside, my father (now deceased) and I are both in the Hanford subcohort. The nuclear industry for this study is used to refer to facilities engaged in the production of nuclear power, the manufacture of nuclear weapons, the enrichment and processing of nuclear fuel, or reactor or weapons research. Uranium mining is not included.

The last report (Cardis et al. 2007) was based on 407,392 nuclear workers with 5,192,710 person-years of follow-up. The overall average cumulative recorded dose was 19.4 mSv with a total recorded collective dose of 7892 Sv. There were 18,993 deaths from all causes and 5233 cancer deaths, about 27% of the all-cause mortality. There was statistically significant association between radiation dose and all-cause mortality (ERR of 0.42 per Sv, 90% of CI, 0.07, 0.79). This was mainly attributed to a dose-related increase in all cancer mortality with an ERR/Sv of 0.97, 90% CI, 0.28, 0.77. The authors noted that stratification on duration of employment had a large effect on the ERR/Sv, reflecting a strong, healthy worker effect in these cohorts. The authors note that the ERR for all cancers, excluding leukemia (0.97 per Sv), is higher than, but statistically compatible with, the estimate derived from male adult atomic bomb survivors (0.32 per Sv) and the BEIR VII estimate of 0.26 per Sv for exposure at ages of 30 and above and attained age of 50. Most of the 32 cancer types or groupings of cancer studied had little or no association with radiation dose. Lung cancer was the only cancer to show a statistically significant rise in ERR. The authors note that smoking confounding may be an explanation for the positive association found for lung cancer rather than radiation exposure. They further note that the association with lung cancer should be interpreted with caution and point out the need for further investigation in studies with better ascertainment of smoking habits and other occupational exposures.

EFFECTS OF INTERNALLY DEPOSITED RADIONUCLIDES

Human Experience

A substantial body of information exists on the late-occurring effects of internally deposited radionuclides in human populations. Mettler and Upton (2008) have reviewed these studies and others. Some of the key populations studied are listed in Table 18.16.

The earliest evidence of the cancer-causing potential of exposure to internally deposited radionuclides, as already noted, came from the miners in Central Europe who developed respiratory maladies later to be identified as lung cancers. This experience recognized in the mid-nineteenth century was to be repeated in North America in the mid-twentieth century when uranium mining was initiated on a large scale and yet later in the late twentieth century in China. The development of quantitative estimates of the lung cancer–causing potential of exposure to radon and its daughter products from studies of the uranium miners has been challenging for multiple reasons. First, it has been difficult to assemble the population cohorts because workplace records were not always complete for the early years when the exposures to radon and its daughter products were likely highest and the lung cancer risk greatest. Second, it has been challenging to quantitatively estimate the radiation dose to the miners from radon and its daughter products throughout the work times of the miners. Third, the challenge of estimating

TABLE 18.16
Key Human Populations Studied Following Intake of Radioactivity

the cigarette smoking history of the workers, especially that of deceased workers, has been difficult. Knowledge of the cigarette smoking history of the subjects in any epidemiological study of the association of any occupational or environmental factor with lung cancer is critical because of the clear and substantial role of cigarette smoking in causing lung cancer. In most studies of lung cancer, the individuals with a long history of cigarette smoking will have a tenfold or greater increase in lung cancer compared to nonsmokers. Indeed, the Smoking-Attributable Mortality, Morbidity, and Economic Cost (SAMMEC software; SAMMEC 1992) analysis as cited in BEIR VI (1999) stated the following: "For lung cancer, the relative risk values assumed, versus never-smokers, are 22.4 and 9.4 for male current and former smokers, respectively, and 11.9 and 4.7 for females."

BEIR Committee VI (BEIR 1999) reviewed the lung cancer risks of exposure to radon. The BEIR VI analysis included over 65,000 workers in underground miners from 11 different studies conducted in 6 countries. Although most of the miners had been employed in uranium mines, three of the populations had worked in other kinds of mines, including over 17,000 Chinese workers mining tin. Detailed smoking data (duration, rate, and cessation) were only available in 5 of the 11 studies. In considering these studies, it is important to recognize that for the uranium miners, the period of follow-up was from 1943 to 1990. By 1990, most countries had implemented regulations and related control strategies to limit the exposures of miners to radon and its daughters. The most effective control of radon and its daughter products in mines is enhanced ventilation.

The primary purpose of the BEIR VI Committee analyses and deliberations was to reexamine the risk of health effects on exposure to radon in homes. In placing reliance on the use of the miner data, the report noted the following: "Another critical issue in the extrapolation of risks to the general population is that exposure rates in homes are a thousand-fold to a hundred-fold less from those in mines." Other key considerations in extrapolating from the miners to the general population are that the miner population consisted primarily of men, and their smoking history was likely different than the general population. Concern for the general population would include concern for both genders and individuals with exposures starting at birth.

A key consideration in extrapolating from the miner populations to the general population is the nature of the exposure–response relationship extending to the lower exposures of the general population. The BEIR IV Committee chose to use a linear relationship between risk and low doses of radon progeny without a threshold. That choice was based primarily on mechanistic considerations, which were summarized as follows:

> Those considerations are related to the stochastic nature of energy deposition by alpha particles; at low doses, a decrease in dose simply results in a decrease in the number of cells subjected to the same insult. That observation, combined with the evidence that a single alpha particle can cause substantial permanent damage to a cell and that most cancers are of monoclonal origin, provides the mechanistic basis of the use of a linear model at low doses. In addition,— exposure-response relationships estimated from the observational studies in miners with the lowest exposures, and from the case-control studies of indoor radon, are consistent with linearity.

The RRs from the pooled analysis of underground miner studies are shown in Figure 18.17. Note that the data are plotted as RR relative to radon concentration in contrast to the earlier discussions of external radiation effects in which a dose metric was used. The analysis was restricted to exposures under 50 WLMs, the RRs from meta-analysis of indoor-radon studies that are also reviewed in BEIR VI, and an estimated linear RR based on an ecologic analysis by Cohen (1995).

In considering Figure 18.16, it is important to recognize that only 5.7% of homes in the United States are estimated to have radon levels above 148 Bq/m^3, the level approximating the U.S. EPA's guidance level (4 pCi/L) for remedial action to reduce residential radon levels. The committee estimated that eliminating exposures at concentrations above 148

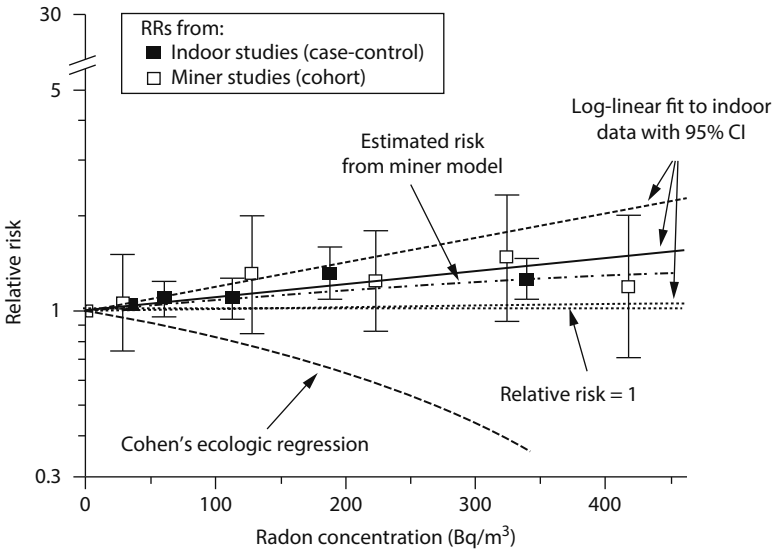

FIGURE 18.17 Summary RR from meta-analysis of indoor-radon studies and RRs from pooled analysis of underground miner studies, restricted to exposures under 0.175 Jhm–3 (50 WLM). Included are RR of 1, fitted exposure–response and its 95% CI from indoor-radon studies, and estimated linear RR based on ecologic analysis by Cohen (1990). (From NRC, *Health Effects of Exposure to Radon: Committee on Health Risks of Exposure to Radon*, BEIR VI, National Academy Press, Washington, DC, 1999.)

Bq/m^3 results in an effective attributable risk of about 4%. The committee then noted the following: "Thus, 10–15% of all lung cancers are attributable to indoor radon, and eliminating exposures in excess of 148 Bq/m^3 (4 pCi/L) would reduce the lung cancer burden from radon to 7–11% of all lung cancer cases." Of course, this conclusion is dependent on the assumption of a linear exposure–response relationship below 148 Bq/m^3, the exposure range where all data points are statistically indistinguishable from the *control* risk. I served on the BEIR VI Committee and suggested, with some other committee members, that it was important to recognize that the burden of excess lung cancer risk at all levels of radon exposure, including the low levels, was borne primarily by the cigarette smokers. The important message should not be lost if you are concerned about lung cancer; quit smoking, then check the radon level in your home, and if the level is high, take action to reduce it. This message is clear from a graphic rendering as prepared by Brooks (2013) (Figure 18.18). In my opinion, the Brooks' graphic illustrates the importance of focusing on the disease of concern, in this case, lung cancer, and not becoming excessively concerned with a specific etiological agent.

The next population exposed to internally deposited radionuclides that warrants discussion are the radium dial painters studied principally in the earliest days in the United States by physicians in New Jersey, later intensely by scientists at the Massachusetts Institute of Technology (MIT), and later yet by scientists at the Argonne Cancer Hospital (a part of the University of Chicago) and Argonne NL. The MIT team was a major contributor in developing a radon breath exhalation

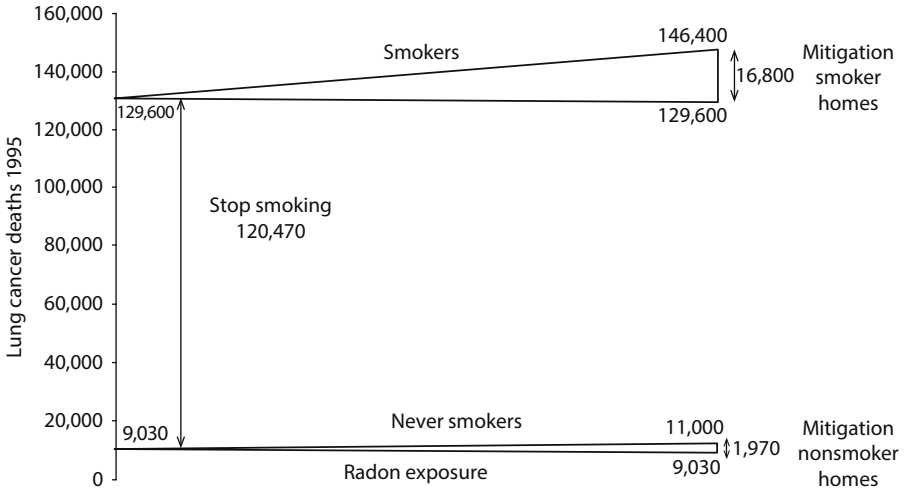

FIGURE 18.18 Relationship between exposure to radon and its daughter products and lung cancer and the impact of cigarette smoking and mitigation of radon and daughters. (From Brooks, A.L., *Health Phys.* 105, 407, 2013.)

test and, later yet, the use of a Na iodide crystal detector for estimating the bone burden of ^{226}Ra in subjects.

Information from the radium dial painter studies was key early in World War II to provide radiation protection guidance for the workers in the Manhattan Project who would be handling large quantities of the newly discovered ^{239}Pu. Very soon after that discovery when only minute quantities were available, Glenn Seaborg, who discovered ^{239}Pu, insisted that animal studies be conducted to determine its fate in the body. It was discovered that ^{239}Pu given intravenously to rats went primarily to liver and bone. Thus, based on the radium dial painters' experience, there was concern for ^{239}Pu-causing bone cancer. Soon studies were initiated in which patients, thought to be terminally ill, were administered trace quantities of ^{239}Pu to provide information on the ^{239}Pu excretion pattern as an aid in developing procedures for monitoring workers potentially exposed to ^{239}Pu by collecting and analyzing their urine for ^{239}Pu. The approach to assessing the potential ^{239}Pu hazard was straightforward as illustrated in the following:

$$\frac{^{239}\text{Pu (Estimated human hazard)}}{^{226}\text{Ra (Known human hazard)}} = \frac{^{239}\text{Pu (Animal experience)}}{^{226}\text{Ra (Animal experience)}}$$

The human experience with ^{226}Ra came from the dial painters. The initial animal experience came from studies in rats and was based on ^{226}Ra and ^{239}Pu tissue distribution data and calculated radiation dose to the skeleton. It is fortunate that ^{226}Ra and ^{239}Pu have one marked difference in their biological behavior. ^{226}Ra, like Ca, is absorbed rather readily from the gastrointestinal tract while ^{239}Pu is very poorly absorbed. As will be discussed later, a major program was initiated post–World War II at the University of Utah to conduct cancer bioassay studies of bone-seeking radionuclides using beagle dogs.

A major criticism of the several cohorts of radium dial painter patients was that the cohorts were assembled in an ad hoc manner not consistent with the expectations of many expert epidemiologists. It was true that the cohorts were initially heavily populated with individuals seeking attention because of their health concerns and there was no contemporary control population. Later, the investigators expended substantial effort to try to locate as many individuals employed as dial painters as could be found. On the positive side, a few epidemiology studies of occupational hazards have rigorous estimates of the body burden (and, thus, dose) of the agent of concern as were developed for the radium dial painters, and numerous publications document the saga of the studies. Excellent summaries can be found in the proceedings of a conference held October 6–9, 1975 (Jee 1976), a summary document on the U.S. radium dial painter studies (Rowland 1994) and several of the last papers from the MIT program (Evans et al. 1972; Evans 1974).

Figures 18.19 and 18.20 summarize the key findings from the radium dial painters studies showing a body burden–related increase in the incidence of bone cancers. Figure 18.19 shows the high incidence, over 20%, in individuals with burdens calculated to have a cumulative skeletal dose of 1000 cGy or greater and an absence of an effect below 500 cGy. It is important to recall some of these dial painters were ingesting radium every

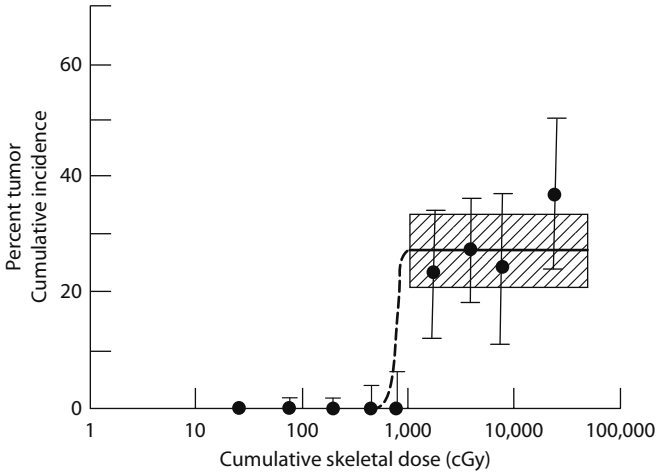

FIGURE 18.19 Cumulative bone sarcoma incidence in people exposed to ^{226}Ra as a function of cumulative dose to the skeleton.

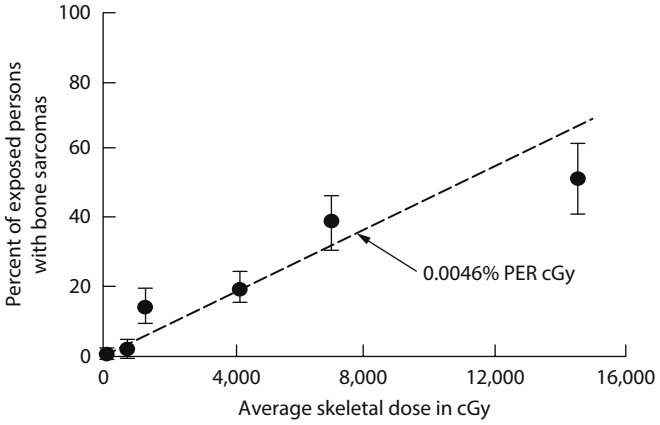

FIGURE 18.20 Hypothetical linear dose–response model fit to bone sarcoma rates in people exposed to ^{226}Ra as a function of lifetime skeletal dose.

working day for several years as they tipped the brushes with their lips. The acute effects were minimal, so they accumulated large body burdens of radioactivity, and the effects were not manifest until later. Robley Evans interpreted this dose–response relationship as reflecting a *practical threshold*, a potential for an increase in bone cancers at lower doses limited by the natural life span of the subjects. If cancers were potentially initiated by the radiation dose to the skeleton from ^{226}Ra, the individuals did not live long enough to manifest them. An alternative interpretation of the same data is shown in Figure 18.20 (Mays and Lloyd 1972). Note the dose scale is different than in Figure 18.19 yielding what appears to be a linear dose–bone cancer response for ^{226}Ra. The *practical threshold* advocated by Evans et al. (1972) and shown clearly in Figure 18.19 has apparently disappeared (Figure 18.20). It is apparent that how data are summarized and presented can profoundly influence how they are interpreted. Two additional presentations of the same basic data on the radium dial painters are shown in Figures 18.21 and 18.22 (Raabe 2010). Figure 18.21 is a 2D logarithmic plot of a fitted 3D model for ^{226}Ra-induced disease

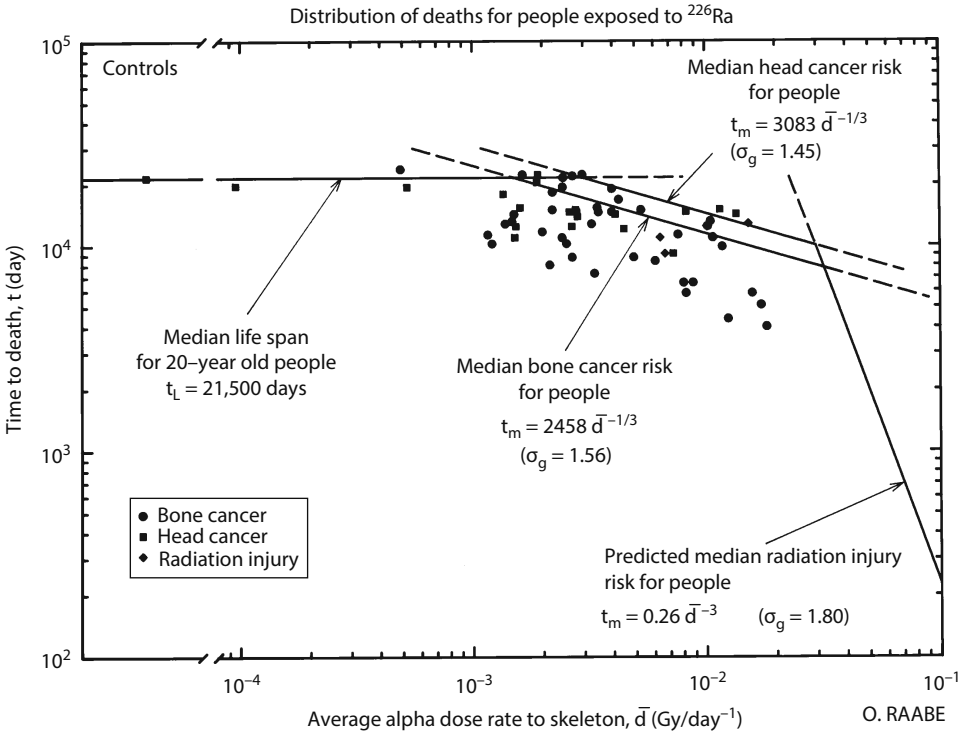

FIGURE 18.21 A 2D logarithmic representation of the fitted 3D model for radiation-induced bone sarcoma and radiation-induced head carcinoma deaths in people after intake of ^{226}Ra based on the U.S. radium studies (Rowland 1994). The cases appear displaced from the median lines because of the simultaneous combined risk of the two types of fatal radiation-induced cancer. (From Raabe, O.G., *Health Phys*., 98, 515, 2010.)

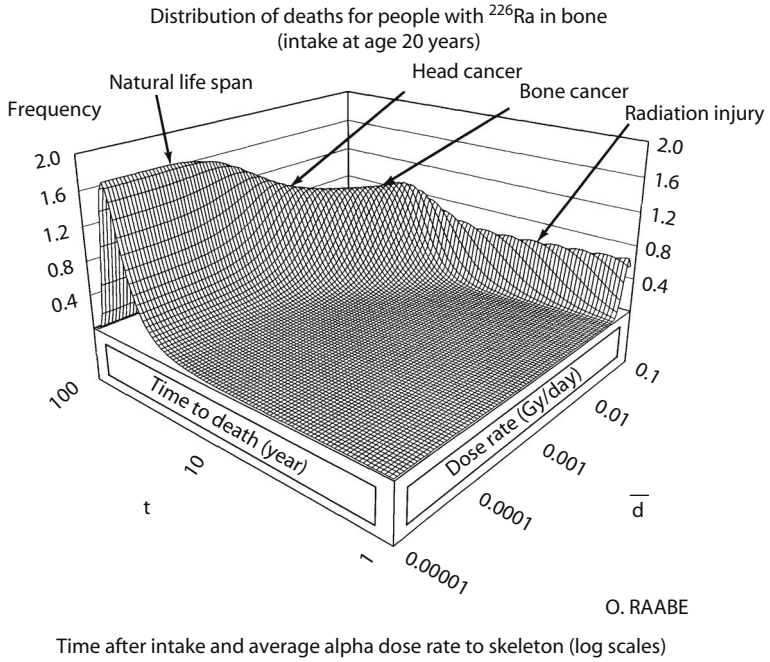

FIGURE 18.22 A 3D logarithmic representation of the skeletal alpha radiation average-dose-rate/time/response relationships for people after intake of ^{226}Ra shown as the probability density distribution frequency of the combined risk of dying from causes associated with natural life span, radiation-induced head carcinoma, radiation-induced bone sarcoma, and radiation injury, as a function of time-weighted average dose rate to skeleton and elapsed time after intake. (From Raabe, O.G., *Health Phys*., 98, 515, 2010.)

shown in Figure 18.22. This figure is a graphic depiction of average-dose-rate/time/response models with Weibull probability distribution fit by maximum likelihood methods (Raabe 1987). The *practical threshold* advanced by Evans et al. (1972) and Evans (1974) is apparent in both plots.

As soon as ^{131}I became available, it was used to treat various thyroid diseases. From this experience came suggestive evidence of its cancer-causing capabilities that complemented what was known from x-irradiation of the thyroid gland. The exposure of Marshall Island residents as a result of weapons testing in the Pacific Ocean also provided early insight into the cancer-causing capabilities of exposure to short-lived ^{132,133,135}I and the 8-day half-life of ^{131}I (Conrad et al. 1966, 1980). The excess of thyroid cancer observed in the Marshallese was likely a result of irradiation with the short-lived radionuclides as well as the ^{131}I. The short-lived radioiodines were more effective per gray than the ^{131}I. There is also some evidence of the role of ^{131}I in inducing thyroid cancer as a result of releases of ^{131}I from the Chernobyl reactor accident (Gavrilin et al. 2004).

A number of studies have been conducted on populations of individuals who received ^{131}I for medical purposes. In general, these studies have shown no excess of thyroid cancers related to the radiation dose from administered ^{131}I, an outcome very different than noted for exposure of the thyroid to external LET radiation (Ron et al. 1995). Dobyns et al. (1974) studied 16,000 patients with hyperthyroidism treated with ^{131}I and found no increase in thyroid cancer. The dose to the thyroid was a mean of over 85 Gy. Ron et al. (1998) reported on the follow-up of 35,593 adult patients that received therapeutic doses of ^{131}I, doses to the thyroid on the order of 100 Gy. A small increase in thyroid cancer incidence was observed, most within 4 years of treatment, suggesting the cancers may have been related to the underlying disease for which they were treated. There was no statistically significant increase in mortality related to either ^{131}I treatment. It is apparent that the protracted exposure of the thyroid from ^{131}I, recall its 8.05-day half-life, is much less effective than acute irradiation of the thyroid by x-irradiation. This same increased effectiveness of brief exposures to high-dose-rate x-rays compared to protracted irradiation of the thyroid from ^{131}I was observed in sheep (McClellan et al. 1963).

One of the most important sources of information on the human effects of plutonium came from studies of workers at the MPA facilities in Russia. These studies conducted jointly by Russian and U.S. scientists reflect a positive outcome of the end of the Cold War. The MPA in the Russian Federation was built to produce ^{239}Pu for the Soviet Nuclear Weapons Program. It included uranium-fueled reactors and fuel-reprocessing facilities remarkably similar to those built and operated at Hanford, Washington. The first reactor became operational in June 1948; irradiated fuel began to be processed in February 1949. Recall that the U.S. Air Force detected airborne ^{131}I from the MPA fuel reprocessing in early 1949. This, in turn, led to the *Green Run* experiment described earlier. Weapons-grade plutonium produced from the MPA was used in the first Soviet A-bomb detonated on August 29, 1949. It is now apparent that MPA workers received significant external radiation exposure as well as internal contamination, including substantial burdens of ^{239}Pu. As discussed earlier, substantial amounts of radionuclide contamination was also released to the local environment, especially the Techa River. The MPA nuclear workers (Sokolnikov et al. 2008), the Mayak residents, and the Techa River Cohort have all been the subject of extensive investigations (Schonfeld et al. 2013).

A cohort of MPA workers initially hired between 1948 and 1972 has been assembled. This population of 17,740 workers is of special interest because of their exposure to ^{239}Pu. By December 31, 2003, a total of 681 lung cancer deaths, 75 liver cancer deaths, and 30 bone cancer deaths had occurred. Of the 786 cancer deaths observed, 239 (30%) were attributed to plutonium exposures (Sokolnikov et al. 2008). Significant plutonium dose–response relationships were observed for the cancers in the three organs, with the lung and liver cancer risks reasonably described by linear functions (Figures 18.23 and 18.24). At attained age 60, the ERRs per gray for lung cancer were 7.1 for males and 15 for females, the averaged attained age ERRs for liver cancer were 2.6 for males and 29 for females, and the ERRs for bone cancer were 0.76 for males and 3.4 for females. Note that the dose metric used is in gray without a conversion using a quality factor (QF) or radiation-weighting factor (W_R) to convert to Sv. Although the occupationally exposed MPA cohort and the atomic bomb survivor cohort differ in many ways beyond the type of radiation exposure sustained, it is still of interest to cautiously compare them by developing RBEs. The ERR per gray for lung cancer in the MPA cohort was 7.1 for males and 15 for females compared with 0.63 for the atomic bomb survivors representing a crude RBE of 11 for males and 24 for women compared with the W_R factor of 20 for alpha particles assigned by the ICRP. The ERR per gray for liver cancer in

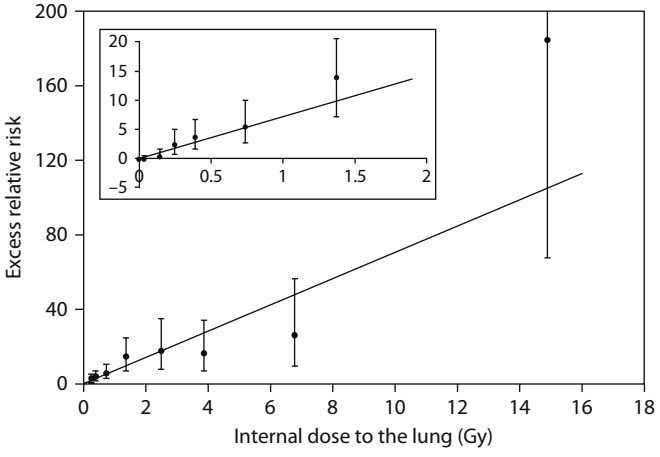

FIGURE 18.23 ERR (with 95% CI) of lung cancer by categories of plutonium dose to the lung for Mayak Production Association workers. Data shown for males at age 60 with an estimated linear function relating dose to ERR. (From Sokolnikov, M.E. et al., *Int. J. Cancer*, 123, 905, 2008.)

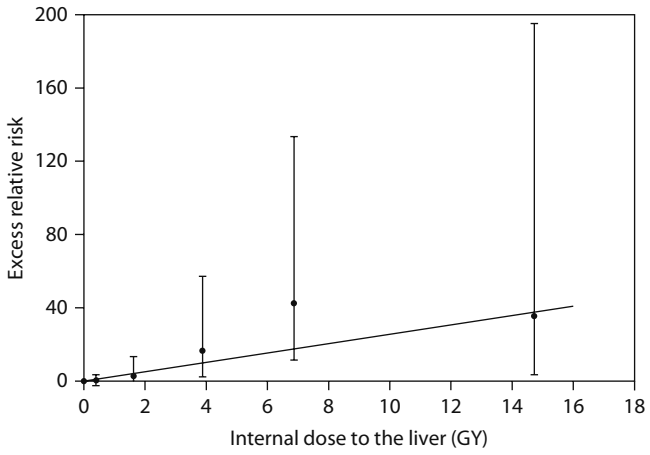

FIGURE 18.24 ERR (with 95% CI) of liver cancer by categories of liver dose for Mayak Production Association workers. Data shown for males of all ages with an estimated linear function relating dose to ERR. (From Sokolnikov, M.E. et al., *Int. J. Cancer*, 123, 905, 2008.)

the MPA cohort was 2.6 for males and 29 for females compared with 0.36 for the atomic bomb survivors representing a crude RBE of 7 for men and 80 for women. In my opinion, these crude comparisons give confidence that the W_R of 20 for alpha particles is reasonable. Tokarskaya et al. (2006) have noted that the liver cancer risk in the MPA works was likely an influence of both plutonium exposure and alcohol consumption. In considering the MPA findings, it is also of interest to recall the mutation data comparing alpha and low-LET gamma irradiation shown in (Figure 18.10). The comparative potency of high LET versus low LET in the short-term mutagenicity study was remarkably predictive of the long-term carcinogenic effects in humans.

An updated analysis of lung cancer data for the MPA workers including follow-up through 2008 has been published by Gilbert et al. (2013). The Gilbert et al. (2013) analysis is based on improved plutonium and external dose estimates allowing special attention to be given to the joint effect of plutonium exposure and smoking and the shape of the plutonium dose–response function. This results in improved models for assessing the risk of plutonium exposures for future nuclear operations. However, it is important to recognize that the U.S. regulatory policy has always had a goal of zero plutonium exposure. Thus, any time there was potential for exposure to plutonium, workers wore full-face respirators or full-body suits with supplied air. All workers with potential for exposure to plutonium participated in bioassay surveillance programs that involved regular collection of urine samples and radioanalysis.

The results of the Gilbert et al. (2013) analysis are presented graphically in Figure 18.25. The dose–response relationship for lung cancer is well described by a linear function, and an LQ function did not significantly improve the fit ($P > 0.5$). A statistically significant plutonium dose–response relationship was observed for workers exposed prior to 1964, but not for post-1964. The ERR per gray for males at age 60 was 7.4 (95% CI of 5.0–11), only slightly higher than the earlier analysis of Sokolnikov et al. (2008). For women over age 60, the ERR per gray was 24 (95% CI of 11–56) compared with 15 observed in the earlier analysis.

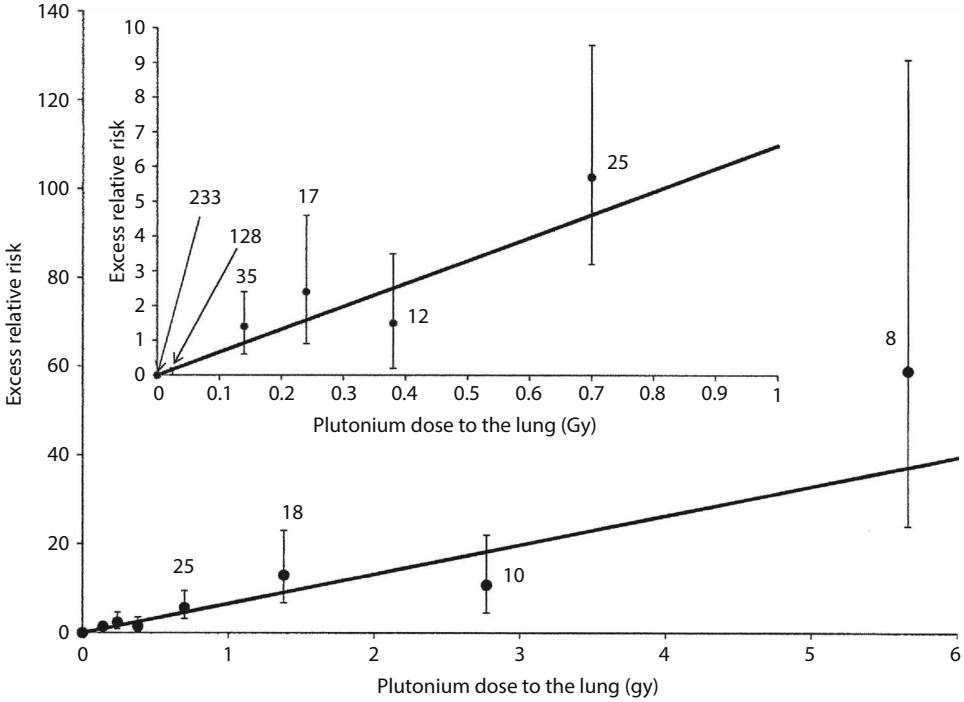

FIGURE 18.25 ERR (with 95% CI) of lung cancer and the number of lung cancer deaths by categories of plutonium dose to the lung. Shown for males at age 60. Estimated linear function also shown. (From Gilbert, E.S. et al., *Radiat. Res*., 179, 332, 2013.)

The authors noted that 98% of the plutonium person-years of exposure were for lung doses of less than 1 Gy and 91% had lung doses less than 0.2 Gy. Thus, no extrapolation is necessary in this low-dose region.

The authors (Gilbert et al. 2013) noted that while there was uncertainty in estimating risks below 0.2 Gy, confidence in the finding was enhanced by the findings with occupational exposure to radon (NRC 1999). Analysis of the 12,708 workers with information on smoking indicated that the relationship of plutonium exposure and smoking was likely submultiplicative ($P = 0.011$) and strongly indicated that it was superadditive ($P < 0.001$), a finding similar to that reported earlier by Tokarskaya et al. (2002). A study of smoking and plutonium exposure conducted in rats (Mauderly et al. 2010) gave results consistent with the findings in the Mayak workers.

The findings in the MPA workers with excess cancer risk associated with exposure to plutonium contrast sharply with the absence of such findings in the U.S. nuclear weapons complex in workers handling plutonium. The findings of lung, liver, and bone cancers in the MPA plutonium workers are consistent with the observations in dogs that inhaled plutonium, as will be discussed later.

The U.S. and British experience contrasts sharply with the Mayak experience. Lung cancer in U.S. and British plutonium workers was consistent with their cigarette smoking history. The maximum body burden of plutonium among U.S. and British workers was 3.2 kBq (Wiggs et al. 1994; Voelz et al. 1997; Omar et al. 1998; Brown et al. 2004; Wing et al. 2004). More than 400 MPA workers had plutonium burdens that exceeded this level.

The workers in the MPA inhaled high concentrations of ^{239}Pu released in the workplace over long periods of time. Follow-up studies of the MPA workers are still underway, including reconstruction of their exposures to ^{239}Pu and other radionuclides and external exposures. They are a unique population because the exposures to ^{239}Pu were quite high, much higher than encountered by ^{239}Pu workers in the United States or other countries. The data from the MPA cohort are likely to be the cornerstone of any future standards for ^{239}Pu and other actinide radionuclides.

The information on the Thorotrast patients with thorium dioxide administered in a colloidal form provides a unique source of information on alpha particle irradiation of the liver, spleen, and cancer induction. Thorotrast was used as a contrast agent in many countries before the risks of its use became known. The Japanese studies date to World War II and include soldiers treated for war wounds. Rate ratios for all-cause mortality and specific diseases began to increase 20 years after the administration of Thorotrast. Rate ratios for liver cancer, liver cirrhosis, leukemia, and lung cancer were 35.9, 6.9, 12.5, and 2.0 times, respectively, higher than controls (Mori et al. 1999). The radiation doses were not well characterized but undoubtedly were high. In addition, the potential exists for the chemical effects of the colloidal thorium dioxide contributing to the development of these chronic diseases.

Another population of special interest is the cohort of patients with ankylosing spondylitis treated in Germany from 1945 to 1955 with injections of Peteosthor, a mixture of short-lived ^{224}Ra (half-life of 3.66 days), red dye eosin, and colloidal platinum. As it turned out, the ^{224}Ra went to bone whether it was injected in a pure form or in Peteosthor. A total of 899 patients have been followed in a special cohort. The cohort is of particular interest because the ^{224}Ra decays by alpha particle emission with a half-life of 3.66 days compared with the 1600-year half-life of ^{226}Ra. The administered doses were quite large, 0.66 MBq/kg, and the mean bone surface doses were correspondingly high, 30 Gy. The most striking finding as of the 1998 follow-up was the occurrence of 56 malignant bone cancers that peaked about 8 years after the administration of ^{224}Ra compared with an expected less than one case.

Laboratory Animal Experience

Introduction to Laboratory Animal Studies

Studies of the toxicity of internally deposited radionuclides were conducted as part of the Manhattan Project at the University of Chicago, UC-Berkeley, and the University of Rochester. Post–World War II, the University of Chicago programs became the core of the Argonne NL. The Argonne NL toxicology research efforts on internally deposited radionuclides were substantially expanded to focus on ^{90}Sr-causing bone cancers in laboratory animals and the occurrence of bone cancers in the radium dial painters as just discussed.

The University of Rochester program during World War II focused on the inhalation toxicity of inhaled uranium and concluded that its primary effects were related to the chemical characteristics of uranium rather than its radiological characteristics (Stannard and Baalman 1988). This program continued post–World War II focusing on the inhalation toxicity of a number of radionuclides and basic radiobiological research. Perhaps the most substantial contributions from the University of Rochester were the development of practical and scientific inputs to the fields of aerosol science and inhalation toxicology and the training of many students. The first president of the Society of Toxicology, Harold Hodge, was a member of the University of Rochester team. The UC-Berkeley efforts post–World War II became a part of the Lawrence Berkeley Laboratory. Later, the Lawrence Livermore National Laboratory (LLNL) was developed as a competitor of the Los Alamos National Laboratory (LANL) for the design and development of nuclear weapons. Even later, LLNL would develop a radiation effects research program linked to the *Plowshare Program*, an AEC effort to use nuclear detonations for peaceful uses such as blasting harbors or canals or stimulating production of natural gas.

This section of the chapter will focus on a series of projects concerned with the effects of injected, ingested, or inhaled radionuclides, especially those concentrating in bone (Table 18.17). The IARC has reviewed the results of studies on internally deposited radionuclides with regard to cancer hazard (IARC 2001). As traditional in its reviews,

TABLE 18.17
Major Life Span Studies with Internally Deposited Radionuclides in Beagle Dogs with Multiple Exposure Levels and Life Span Observation

Laboratory	Radionuclides	Route of Administration
University of Utah	^{226}Ra, ^{228}Ra, ^{228}Th, ^{239}Pu, ^{241}Am, ^{90}Sr	Single intravenous injection
UC-Davis	^{226}Ra	Multiple intravenous injections
	^{90}Sr	Chronic ingestion
Hanford	$Pu^{238}PuO_2$, $^{239}RaO_2$, ^{239}Pu $(NO_2)_4$	Inhalation of polydisperse aerosols
Lovelace	^{90}Y, ^{91}Y, ^{144}Ce, and ^{90}Sr Chloride	Inhalation of polydisperse aerosol
	^{137}Cs Cl_2	Intravenous injection
	^{90}Y, ^{91}Y, ^{144}Ce, and ^{90}Sr in FAPs	Inhalation of polydisperse aerosol
	$^{238}PuO_2$ and $^{239}PuO_2$	Inhalation of monodisperse particles

IARC focuses only on the cancer hazard and did not rigorously address dose–response relationships. Thus, the IARC review essentially documents what is well known—internally deposited radionuclides were a carcinogenic hazard. At the conclusion of World War II, substantial uncertainty remained as to the toxic potential of ^{239}Pu in humans. It was anticipated that ^{239}Pu would continue to be a vital part of the continuing nuclear weapons program and would have a role in civilian nuclear programs. The very preliminary research conducted during World War II indicated the utility of the approach that leveraged off of the radium dial painters' experience. There were concerns that the rat might not be a good experimental model for studying ^{239}Pu because the ratio of bone to liver content of ^{239}Pu in the rat appeared to differ from that observed in humans and dogs. Moreover, the liver burden of ^{239}Pu in the rats appeared to clear relatively rapidly as contrasted to observations in humans and dogs. This finding would later be found to be generally applicable to how the rat metabolizes both lanthanide and actinide elements.

The decision was made that the issue of the comparative toxicity of ^{238}Pu, ^{226,228}Ra, and ^{228}Th, the latter three radionuclides linked back to the radium dial painters' experience, should be studied in a dedicated program using beagle dogs, a relatively long-lived species, as the experimental subject (Jee 1976). The University of Utah, which was starting a medical school, was selected to carry out what was anticipated to be a long-term program, perhaps 20 years, because the beagle dogs were expected to have a life span of about 15 years. To mimic the brief oral intake of radioactivity by the dial painters and minimize issues with radioactive contamination, it was decided to give young adult beagle dogs a single intravenous injection of the radionuclide. For each radionuclide, there were multiple dose level groups.

Soon after the University of Utah program was initiated, concern increased over ^{90}Sr as an important component of weapons fallout. As an alkaline earth element, it behaves in the body like Ca and deposits in the skeleton where it serves as a source of beta particle irradiation of bone, bone surfaces, and bone marrow. This gave rise to concern for its potential to cause bone cancer and leukemia. The decision was made to add ^{90}Sr to the University of Utah experimental matrix.

As the University of Utah program moved forward in the 1950s, even more concern developed for the potential effects of fallout of ^{90}Sr recognizing that all children ingesting milk were being exposed to low concentrations of fallout ^{90}Sr via the contaminated pasture/forage–cow–cows' milk–intake by children pathway. Concern also developed that the single intravenous injection approach used at the University of Utah did not adequately mimic the pattern of exposure of children ingesting ^{90}Sr in milk from dairy cows or their mother's milk. This led to the decision to create another dedicated laboratory program at the UC-Davis to study the effects of bone-seeking radionuclides.

Scientists at the UC-Davis were already conducting whole-body x-irradiation studies with beagle dogs for the U.S. Air Force, so it was considered reasonable to leverage on that experience by adding radionuclide toxicity studies to their research agenda. The UC-Davis program was envisioned as linking to the University of Utah studies. Young adult female beagle dogs were given a series of injections of ^{226}Ra (to better mimic the intake of the dial painters) or fed food containing ^{90}Sr. Thus, the offspring of these dams were exposed to the radionuclides in utero and during lactation by ingesting their mother's milk. After weaning, they were provided ^{90}Sr-contaminated feed. Multiple dose levels were used and the animals observed for life.

In 1959, a somewhat similar program with ^{90}Sr was initiated at the Hanford Laboratories (McClellan and Bustad 1964). For that study, it was decided to utilize miniature pigs weighing about 70 kg at maturity as the experimental subjects. Female pigs were given a dose of ^{90}Sr in their feed each day, bred, and gave birth to offspring that were entered into the experiment. Thus, this F_1 generation and a later F_2 generation were exposed to ^{90}Sr in utero and early in life by ingesting their mother's milk. At weaning, they began receiving an oral dose of ^{90}Sr each day and were observed for development of leukemia and bone cancers. As in the other radionuclide studies, multiple levels of ^{90}Sr were studied.

As noted earlier, the Hanford site was the earliest and primary U.S. production site for ^{239}Pu. Later, the AEC would develop the capability to produce plutonium and tritium at a complex in Savannah River, Georgia. Operation of the uranium-fueled reactors and reprocessing plants led to concern for potential exposure of workers to ^{239}Pu and various fission products. This led to the early development of a research program at Hanford on the inhalation toxicity of various radionuclides with a focus on inhaled ^{239}Pu. The physical half-life of ^{239}Pu is 24,110 years. Again, the beagle dog was used as the experimental animal. A series of studies were initiated in the late 1950s in which beagle dogs received single, brief

inhalation exposures to ^{239}Pu, the disposition of the radionuclide was evaluated, and the animals were observed for their lifetime. Studies were conducted with both ^{239}Pu oxide and ^{239}Pu nitrate, and multiple dose levels were used.

In the early 1960s, it became apparent that shorter-lived ^{238}Pu (radioactive half-life of 87.7 years) would be useful as a thermal electric power source in space, part of what was initially called the Space Nuclear Applications Program (SNAP). This raised concern for the potential toxicity of ^{238}Pu to workers and, with accidental release, exposure of the public. Concern for the toxicity of ^{238}Pu was further heightened when the launch of a unit, SNAP 9a, containing 17,000 C of ^{238}Pu metal was aborted over east Africa. The unit *burned up*, releasing the ^{238}Pu into the atmosphere at a high altitude. The form of the ^{238}Pu was changed in later SNAP units from metal to pellets of ^{238}Pu oxide, which in the event of an accident would be more resistant to burning. This led to the addition of ^{238}Pu to the experimental program at Hanford and Lovelace.

With continued use of uranium-fueled reactors to produce ^{239}Pu and the beginning of the civilian nuclear reactor program for generation of electricity, concern developed over the potential consequences of an accident involving a nuclear reactor or a fuel-reprocessing plant and release of mass quantities of fission product radionuclides. The staff at the Brookhaven NL prepared the landmark report that scoped the issue (USAEC 1957). The scoping study, sometimes referred to as the WASH-740 or Brookhaven National Laboratory study, estimated the possible effects of a *maximum credible accident* for a commercial nuclear reactor generating electrical power. The report postulated total release of the reactor fuel core of uranium and associated radionuclides with the plume of released radioactivity traveling over New York City. It projected 3400 deaths, 43,000 injuries, and property damage of $7 billion (1957 dollars). Needless to say, numerous assumptions were used in projecting mortality and morbidity and substantially impacted the calculated health risks.

An examination of key input parameters in the analysis based on current knowledge revealed that essentially no information was available on the health effects of the fission products that were postulated to be released and potentially available to be inhaled by *downwind* populations. To address this shortcoming, the AEC in 1960 initiated the Fission Product Inhalation Program at the Lovelace Foundation for Medical Education and Research in Albuquerque, New Mexico. Over the years, this program would evolve into what was called the Lovelace Inhalation Toxicology Research Institute. I had the pleasure of providing leadership for that program from 1966 to 1988. The program continues today as part of the Lovelace Respiratory Research Institute. Although the research program would use many different laboratory animal species, the major core inhalation studies used beagle dogs as in the programs at the University of Utah, UC-Davis, and Hanford. The AEC's Division of Biology and Medicine that funded the four programs viewed them as scientifically interrelated since all were concerned with the health effects of internally deposited radionuclides.

In 1967, the scope of the long-term program at Lovelace was finalized (McClellan et al. 1986). The approach was to study major beta-emitting radionuclides found in a reactor inventory: ^{90}Y, ^{91}Y, ^{144}Ce, and ^{90}Sr. Each of the radionuclides has different radiological characteristics; however, all of their beta particle emissions are the major source of their radiation dose to tissues. The radionuclides would be administered via inhalation in a relatively soluble form as a chloride and in a relatively insoluble form achieved by incorporating the radionuclides into fused aluminosilicate particles (FAPs). When inhaled in a soluble form, the radionuclides translocated from the lung to other tissues as predicted based on their chemical characteristics: Y and Ce to liver and skeleton and Sr to bone. Soluble ^{137}Cs was also studied. However, for the LSS, the dogs were administered with the ^{137}Cs intravenously since it was observed that soluble ^{137}Cs distributed throughout the body whether it was ingested, inhaled, or injected (Boecker 1969a,b). The use of intravenous injection rather than inhalation exposures to deliver the ^{137}Cs substantially reduced the potential for radiation exposure of personnel.

Multiple approaches were considered for delivering relatively insoluble radioactive particles to the respiratory tract, including creating oxide aerosols of each radionuclide of interest. Ultimately, the decision was made to use a common vector (FAPs) that would contain the various radionuclides. These particles were created by exchanging the cation radionuclides, such as ^{144}Ce, into montmorillonite clay. The clay suspension was washed to remove any unbound cation. The suspension of the radiolabeled clay particle was aerosolized and the aerosol passed through a high-temperature furnace to fuse the radiolabeled particles. The result was a suspension of radiolabeled glass particles that were used to expose the laboratory animals in a nose-only inhalation exposure system.

The deposition and retention of the FAPs in the respiratory tract and their dissolution were determined by the FAP matrix. However, the pattern of irradiation of the lung was determined by the physical half-life of the radionuclide ^{90}Y (64 h), ^{91}Y (58.5 days), ^{144}Ce (285 days), and ^{90}Sr (28.8 years). Thus, the pattern of chronic beta irradiation differed for each radionuclide: the dose from ^{90}Y-FAP was delivered at a decreasing dose rate over a few weeks, the lung dose from ^{90}Sr-FAP over several years, and intermediate time durations for ^{91}Y-FAP and ^{144}Ce-FAP. The study of each radionuclide and form involved multiple dose levels and detailed medical evaluation of the animals for their life span.

As noted earlier, concern developed in the 1960s over the potential hazards associated with an accidental release of ^{238}Pu from a SNAP thermal electric device. The SNAP accident with the release of ^{238}Pu over Africa at a high altitude raised questions as to whether the potential for inhaled ^{238}Pu causing lung cancer would be altered if it were inhaled as many, very small particles versus a few large particles. Contrasting views were presented by Bair et al. (1974) and Tamplin and Cochran (1974). During this era, increased interest also developed in the use of ^{239}Pu as a reactor fuel. Indeed, the U.S. Breeder Reactor Programs in the late 1970s included plans for constructing a prototype breeder reactor,

using a ^{239}Pu–uranium mixed oxide fuel, to generate electrical power at Oak Ridge. This intensified concern for the potential hazards of ^{239}Pu. At that time, it was not anticipated that any effects would be observed in U.S. plutonium workers, and most importantly, the experience at the MPA facility in Russia had not yet come to light. Thus, it was thought that studies in beagle dogs with inhaled plutonium were critical to estimating human hazards.

To address the uncertainties in the inhalation toxicity of ^{238}Pu and ^{239}Pu, Lovelace developed a technique for producing monodisperse aerosols of ^{238}Pu and $^{239}PuO_2$ (Kotrappa et al. 1972; Kotrappa and Moss 1971). The typical aerosol used in the inhalation exposure studies at Lovelace and Hanford was polydisperse in size distribution with an aerodynamic diameter of about 2 μm and a geometric standard deviation of about 2. These polydisperse aerosols are not remarkably similar to the aerosols used in most studies of the inhalation toxicity of chemicals. It is a challenge to produce monodisperse aerosols. A new system developed at Lovelace produced monodisperse Pu particles with an aerodynamic size ranging from 0.5 to 4.0 μm and, most importantly, a geometric standard deviation of less than 1.2. As a result, it was possible to select specific monodisperse sizes for study (^{239}Pu oxide, 0.75, 1.5, and 3.0 μm; ^{238}Pu oxide, 0.75 and 1.5 μm). As noted earlier, ^{239}Pu has a half-life of 24,110 years compared with 87.7 years for ^{238}Pu. Thus, the same amount of radioactivity was contained in a few particles of ^{238}Pu compared with many particles of ^{239}Pu, and for a given sized particle, the alpha emissions will be many times greater for a $^{238}PuO_2$ particle than a $^{239}PuO_2$ particle. For either ^{238}Pu or ^{239}Pu particles, the smaller the diameter, the lower the physical mass and the lower the alpha particle emission rate.

Thus, it was possible to design inhalation toxicity studies in which the amount of radioactivity inhaled and the number of particles deposited in the lung differed. With this approach, it was possible to test whether a few ^{238}Pu particles with very nonuniform irradiation of the lung were more, equally, or less effective in producing lung cancer than more uniform alpha irradiation of the lung from many ^{239}Pu particles. It turns out the more uniform the alpha irradiation from ^{238}Pu or ^{239}Pu, the greater the lung cancer hazard.

Linking Exposure to Dose for Radionuclide Toxicity Studies

Detailed studies were conducted to determine the pattern of retention of the specific radionuclide and chemical form in the body in all of the animal studies (recall Table 18.17) with injected, ingested, or inhaled radionuclides. Scientists studying the toxicity of internally deposited radionuclides recognized that exposure, whether measured as the quantity injected or ingested, was at best a poor surrogate for tissue dose (recall Figure 18.2). With inhaled radionuclides, the situation is even more complicated than with injection or ingestion. It is not sufficient to know the air concentration and duration of exposure or even the amount of radioactive material deposited in the respiratory tract. As a starting point, it is necessary to characterize the aerodynamic size distribution of the aerosol used for animal exposures since aerodynamic size is the primary determinant of the fraction of the aerosol that will be deposited and where it deposits in the respiratory tract. In addition, there is a need to know the concentration and duration of the exposure. In the studies conducted at Lovelace, a whole-body plethysmograph was used during the dog exposures to measure the respiration of the dog (Boecker et al. 1964). Knowing the volume of contaminated air inspired and the radionuclide concentration, it was possible to develop accurate estimates of the total amount of radioactivity inhaled. In some cases, the radiological characteristics of the radionuclide studied allowed the body and lung burden of radionuclides to be determined by external monitoring of radiation emissions detected externally in a whole-body counter, scanner, or imaging system. In other cases, the initial respiratory tract and lung burden may be accurately estimated based on the radioanalysis of tissues and excreta. Using this array of data, it was possible to accurately determine the fractional deposition of the inhaled radionuclide and follow the pattern of retention and translocation of each radionuclide and aerosol form for a period of time determined by the physical half-life of each radionuclide.

The information from the radionuclide retention and tissue distribution studies provided essential input for calculating the time course of internal irradiation of the various organs and tissues, taking account of the tissue content and the specific emissions of each radionuclide. The generic biokinetic model (Figure 18.26) was used for integrating and interpreting the data. The duration of the biokinetic studies varied dependent on the physical half-life of the radionuclide studied with some disposition studies for short-lived radionuclides being a week or so in duration, while those with long-lived radionuclide studies extended over years. In addition, for the long-lived radionuclides, the organ burden of radioactive material could be determined for dogs in the LSS when they died.

Several examples will be given to illustrate the kind of results that were obtained. The first example is the retention of ^{137}Cs in the beagle dog following inhalation of ^{137}Cs chloride (Figure 18.27) (Boecker 1969a,b). It is apparent that the concentration of ^{137}Cs found in the several specific tissues and averaged across the total body is very similar, reflecting the rapid translocation of ^{137}Cs from the lung to other tissues. This pattern was fully expected recognizing the Cs was behaving like K. The exception to the relatively uniform tissue distribution was the lower content of ^{137}Cs in the femur, reflecting the fact that it is largely a calcified bone with only the active red marrow accumulating Cs.

The contrast in the disposition of the radionuclide, ^{144}Ce, inhaled as a relatively soluble $CeCl_3$ or in a quite insoluble form, ^{144}Ce, within a fused aluminosilicate matrix, is apparent in Figures 18.28 and 18.29 (Boecker and Cuddihy 1974; Muggenburg et al. 2001). In both cases, radioactive particles deposited in the upper respiratory tract, trachea, and bronchi were rapidly cleared to the oropharynx, ingested, and excreted in the feces. This is the case since either form of

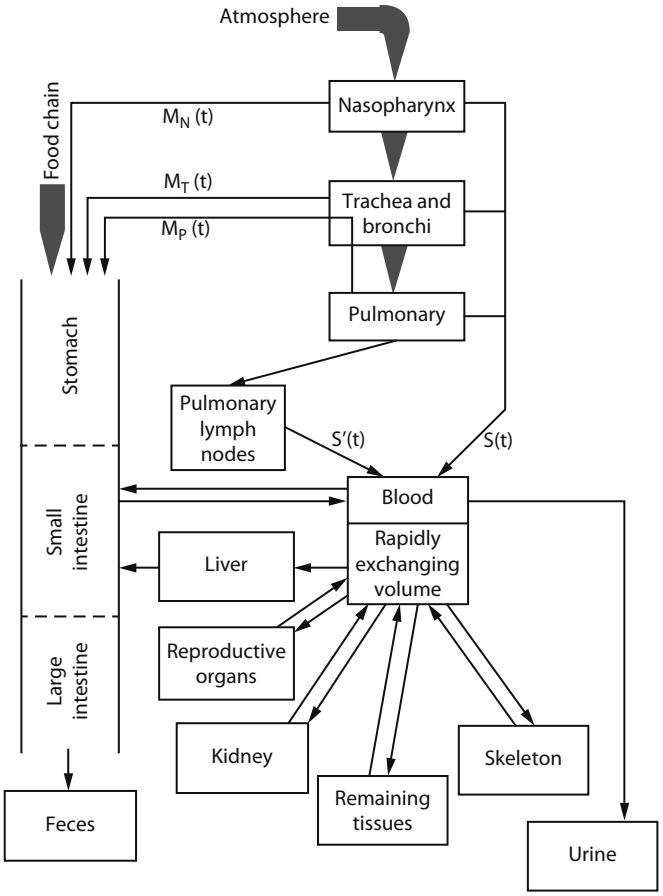

FIGURE 18.26 General model used to simulate organ distribution and retention patterns for inhalation, ingestion, or injection of radioactive elements. Clearance of material from the respiratory tract is considered to involve competing mechanical clearance to the gastrointestinal tract, M(t), or lymph nodes and dissolution with absorption into blood, S(t). Both rates may be time-varying functions depending upon the physical–chemical characteristics of the inhaled material. Other transfer rates are considered to be first-order unless better information is available for particular radionuclides. (From Cuddihy, R.G. et al., *Health Phys*., 30, 53, 1976.)

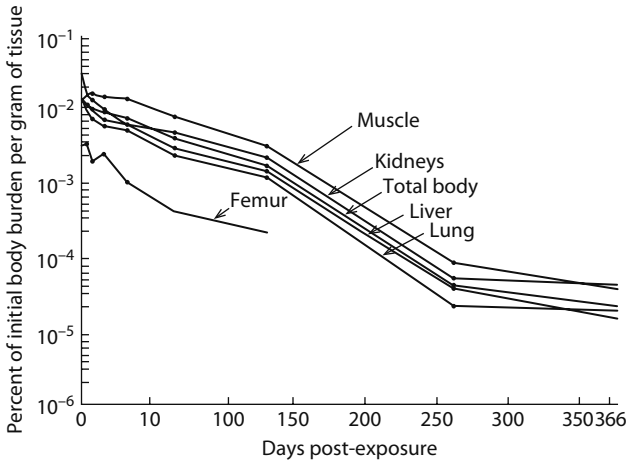

FIGURE 18.27 Distribution of ^{137}Cs in beagle dogs following a single brief exposure to $^{137}CsCl_2$ particles. (From Boecker, B.B., *Proc. Soc. Exp. Biol. Med.*, 130(3), 966, 1969.)

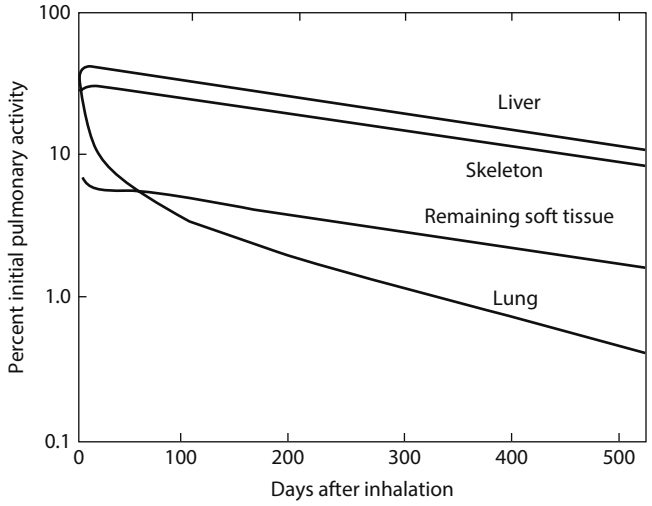

FIGURE 18.28 Distribution of ^{144}Ce in beagle dogs following a single brief exposure to $^{144}CeCl_3$ particles. (From Boecker, B.B. and Cuddihy, R.G., *Radiat. Res*., 60, 133, 1974.)

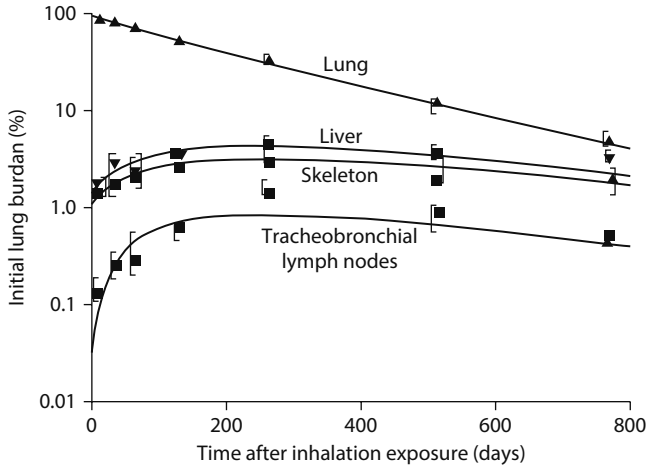

FIGURE 18.29 Distribution of ^{144}Ce in beagle dogs following a single brief inhalation exposure to ^{144}Ce incorporated into FAPs. The ^{144}Ce in the lung (●) clears over time and appears in liver, skeleton and tracheobronchial lymph nodes (●). (From Muggenburg, B.A. et al., *Radiat. Res*., 146, 171, 2001.)

Ce is poorly absorbed from the gastrointestinal tract. Data in both figures are plotted as percent retention of the ^{144}Ce initially deposited in the pulmonary region.

When ^{144}Ce is inhaled as ^{144}Ce chloride, the ^{144}Ce is rapidly translocated to the liver and skeleton as expected for a lanthanide rare earth element (Figure 18.28). The portion in liver and skeleton soon exceeds the lung burden of ^{144}Ce. The portion translocated to liver and skeleton is avidly retained in those organs. The situation is quite different when the ^{144}Ce is inhaled in a relatively insoluble matrix (Figure 18.29) (Cuddihy et al. 1976). In this case, the ^{144}Ce in the FAP is avidly retained in the lung. The ^{144}Ce slowly leaves the lung as FAPs dissolve, and the ^{144}Ce is translocated to the liver and skeleton. Note that the ratio of ^{144}Ce in liver to skeleton is quite similar to that observed for the translocated ^{144}Ce when

it was inhaled as ^{144}Ce chloride and rapidly translocated to these organs. As typically observed with a material inhaled as relatively insoluble particles, translocation to the tracheobronchial lymph nodes is observed. Note that data in Figures 18.28 and 18.29 are given a percent initial lung burden in each organ or tissue. Because the tracheobronchial lymph nodes are quite small, the concentration of radioactivity is quite high as is the corresponding radiation dose.

When inhaled or injected in the same chemical form, different radionuclides of the same element, for example, ^{85}Sr and ^{90}Sr or ^{90}Y and ^{91}Y, inhaled in the same chemical form, have similar disposition in the body when corrections are made for the differences in physical half-life. However, the situation can be different when the radionuclides have markedly different half-lives and specific activities. This is the case for ^{238}Pu (half-life of 87.7 years) versus ^{239}Pu (half-life of 24,110 years). In this case, the ^{239}Pu oxide particles are much more avidly retained in the lung than are the ^{238}Pu oxide particles. It is thought that the intense alpha decay within the ^{238}Pu oxide particles results in the particle fragmenting and having an increased rate of dissolution with the dissolved ^{238}Pu translocating from the lung to other tissues, principally the skeleton and liver. By about 500 days after inhalation of ^{238}Pu oxide particles, approximately equal amounts of the initial lung burden are found in lung, liver, and skeleton. The translocation from lung to liver and skeleton continues with avid retention of the ^{238}Pu in liver and skeleton. There is also some accumulation in the tracheobronchial lymph nodes and kidney. It is noteworthy that the general pattern of disposition of the actinide Pu is generally similar to that of the lanthanide element Ce.

At Hanford, dogs were also exposed to ^{238}Pu $(NO_3)_4$, which was retained much less avidly in the lung than $^{239}PuO_2$ and somewhat less avidly than $^{238}PuO_2$. Both ^{238}Pu and ^{239}Pu distributed primarily to the skeleton and liver after leaving the lung. Wilson et al. (2009) compared the findings from the Hanford and Lovelace studies with inhaled ^{238}Pu (NO_3), $^{238}PuO_2$, and $^{239}PuO_2$ in dogs with the findings in the workers at the MPA. As an initial step in the comparison, Wilson et al. (2009) estimated the absorbed dose from alpha irradiation of the lung, liver, and skeleton (Figure 18.30). The influence of both the radionuclides (^{238}Pu versus ^{239}Pu) and form (oxide versus nitrate) normalized to a 10 KBq deposited lung burden is apparent. It is noteworthy that in the Hanford studies with $^{239}PuO_2$ dogs that died at long time periods, postinhalation exposure had a substantial portion of the retained body burden in the lung-associated lymph nodes (Park et al. 2012).

In closing this discussion of the fate of plutonium, it is appropriate to note that a meeting on *plutonium contamination in man* was convened in 1966 to discuss approaches to treatment of accidental worker exposures at the AEC's Rocky Flats facility in Colorado, where large quantities of plutonium and uranium metal were machined. From this meeting came the idea of creating a registry of plutonium and uranium workers to receive donated tissues and bodies from workers who had been exposed to plutonium and uranium. The intention was to have exposure records, in-life bioassay results, and tissue analysis results maintained in one location for detailed study and evaluation. The activity continues today as the U.S. Transuranium and Uranium Registries (USTUR) operated by Washington State University at Richland for the U.S. DOE (http://www.ustur.wsu.edu). It is not appropriate to review here all of the USTUR findings. It can be noted that observations made on the fate of Pu and U in workers exposed during the course of their work are in general agreement with the findings in the dog studies. The unique value of the registry is apparent from the work of Nielsen et al. (2012). They used tissues from the registry to compare the microdistribution of

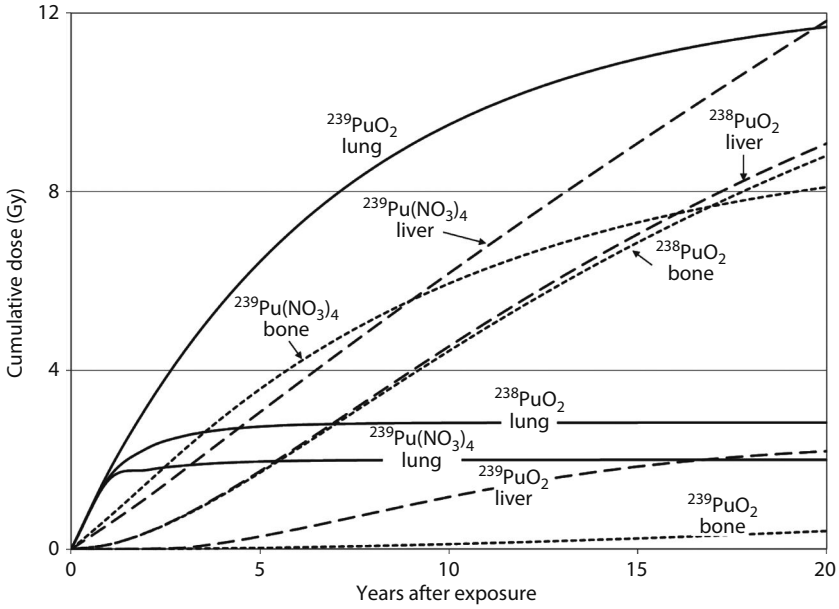

FIGURE 18.30 Cumulative absorbed dose to the lung, bone, and liver over time for a 10 kg dog exposed to 10 kBq of $^{238}PuO_2$, $^{239}PuO_2$, or ^{239}Pu $(NO_3)_4$. (From Wilson, D.A. et al., *Health Phys*., 96(2), 175, 2009.)

^{239}Pu in the respiratory tract of a worker accidentally exposed to ^{239}Pu $(NO_3)_4$ with the tissues of dogs exposed to different forms of ^{239}Pu. It is noteworthy that most of the tissue samples from workers contain such small amounts of radioactivity that it has been necessary for the USTUR scientists to develop new and innovative techniques for quantifying the retained radioactivity (Hare et al. 2010). It is apparent that U.S. workers in the facilities at Hanford, Los Alamos, and Rocky Flats did not receive exposures to plutonium similar to the high-level exposures of the Russian workers at the MPA discussed earlier. Most of the specimens from U.S. plutonium workers in the USTUR have radioactivity content substantially below that of specimens from MPA workers.

Effects of Internally Deposited Radionuclides in Laboratory Animals

The studies conducted at the University of Utah with injected radionuclides, at the UC-Davis with injected and ingested radionuclides, at the Hanford Laboratories (designated later as the Pacific Northwest Laboratories), and at the Lovelace Laboratory all had a primary focus of understanding the potential for induction of cancer (Thompson 1989). Hence, in all four laboratories, the studies involved detailed clinical observations on each subject until they died or were euthanized because of clinical illness and a desire to avoid pain associated with what was thought to be a life-threatening clinical condition. It is important to emphasize again that the tissue burden and radiation dose received were estimated for each subject allowing for detailed analyses as dose–response relationships for populations of the subjects. The original investigators and others have reported the results of the LSS in a number of publications. It was possible for other investigators to conduct secondary analyses since the laboratories conducting the studies frequently published detailed information on the various studies, including information on each animal. Some examples of key results from the LSS will be presented here.

It was generally thought at the initiation of the *internal emitter* programs that the primary late effects would be cancer and that would be the focus of the research with observations made over the life span of the experimental subjects. In the case of the Lovelace Inhalation Toxicology Program, there was an interest in evaluating the acute health effects of exposure to fission products that workers or other individuals close to the location of an accidental release might encounter.

The results of the controlled exposure studies with dogs exposed to radioactive aerosols with sufficient body burdens of radioactivity to cause early effects played a key role in the development of the health effects models developed for the conduct of nuclear power plant consequence analyses (Scott 1979; Scott and Hahn 1980; Scott et al. 1984; Evans et al. 1993). Moreover, it was recognized that evaluating the health effects of a brief exposure to a high-concentration radionuclide aerosol would establish an anchor point analogous to the maximum, for these radiation toxicity studies, tolerated dose used to establish the highest exposure levels in chronic bioassays of chemicals. When the inhalation studies with radionuclides were initiated, it was not known the degree to which protracted delivery of the radiation dose from inhaled radionuclides would be less effective than brief external radiation exposures.

The results of the Lovelace studies with beta-emitting radionuclides (^{90}Y, ^{91}Y, ^{144}Ce and ^{90}Sr) have been reported in a number of peer-reviewed publications. Summary papers on ^{137}CsCl are Boecker (1972) and Redman et al. (1972); on $^{91}YCl_2$ are Muggenburg et al. (1998); on $^{144}CeCl_3$ are Boecker and Cuddihy (1974a), Hahn et al. (1996), and Hahn et al. (1997); on $^{90}SrCl_2$ are Gillett et al. (1987, 1992); on ^{90}Y-FAP are Hobbs et al. (1972) and Mauderly et al. (1973); and on ^{144}Ce-FAP are Hahn et al. (1973a,b), Hahn and Boecker (1980), and Mauderly et al. (1980a). A paper by McClellan et al. (1986) provides an overview of the experimental approach and results.

The results will be briefly summarized here. In the studies with soluble forms of these radionuclides, the predominant deterministic effects related ARS-bone marrow damage from beta irradiation of the marrow by the radionuclides deposited in the skeleton. The primary stochastic effects were induction of cancers in the lungs, skeleton, and liver. The site of occurrence and incidence were organ dose dependent.

With the radionuclides inhaled in a fused aluminosilicate vector, the principal deterministic effects were fibrosis and associated cardiopulmonary functional effects. The principal stochastic effects were induction of cancers in the lungs, nasal cavity, and tracheobronchial lymph nodes. The sites of occurrence and incidence were organ dose dependent.

The answer to the important question of dose protraction effects is shown in Figure 18.31 where the risk of developing ARS related to bone marrow damage from either brief exposure to external 1 MeV x-rays or gamma rays is compared to that of dogs injected with ^{137}Cs (Scott et al. 1988). As discussed earlier, ^{137}Cs distributes throughout the body like K. Thus, the internally distributed ^{137}Cs is a source of protracted whole-body exposure to beta particles and gamma rays from decay of the ^{137}Cs. The internal dose decreases with an effective half-life of about 30 days. It was found that the internal radiation dose from the ^{137}Cs was about one-fourth as effective as a very brief exposure to the external x-radiation or gamma radiation.

Similar results for acute hematopoietic effects were observed in the beagle dogs that inhaled ^{91}Y, ^{144}Ce, or ^{90}Sr as a chloride. The relatively soluble radionuclides were rapidly absorbed from the lungs with translocation based on their elemental characteristics. All three elements were translocated to bone. The lanthanide elements Y and Ce were also translocated to the liver. With ^{90}Sr, ^{91}Y, ^{144}Ce, and ^{137}Cs, the beta emissions were the primary source of irradiation of the tissues, including the bone marrow. As may be noted in Figure 18.31, a dose of about 1000 rad delivered to whole body and bone marrow (^{137}Cs) or primarily to bone marrow (^{91}Y, ^{144}Ce and ^{90}Sr) over 30 days is required to produce deaths from hematopoietic injury as compared with the much smaller total dose from acute x-irradiation delivered essentially instantaneously (recall Figure 18.2) (Figure 18.32).

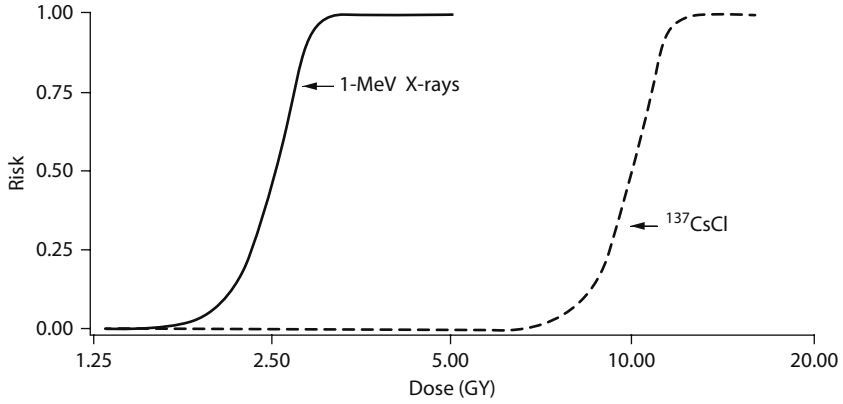

FIGURE 18.31 Comparative effect of acute x-irradiation (1-Mev x-rays) versus protracted irradiation (^{137}CsCl) in producing bone marrow syndrome in dogs. (From Scott, B.R. et al., *Risk Anal.*, 8(3), 393, 1988.)

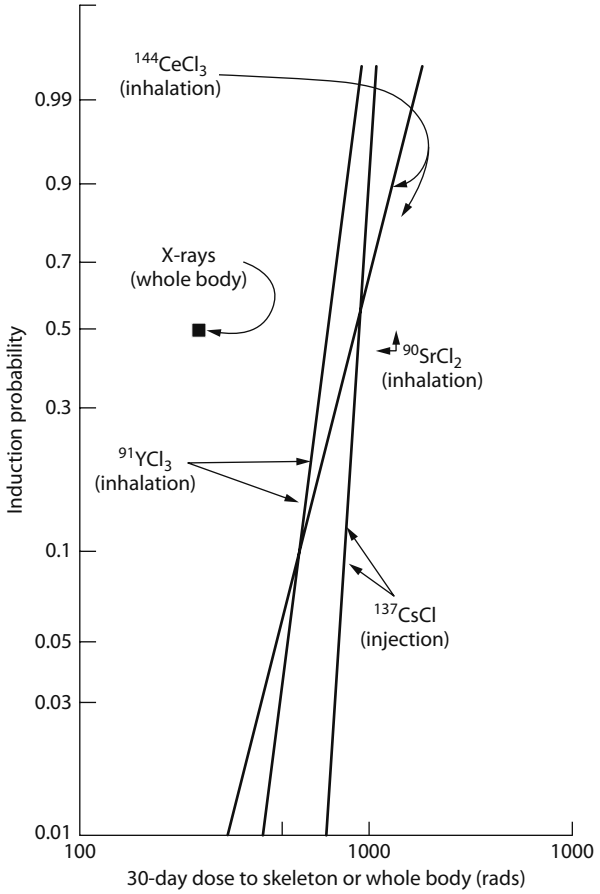

FIGURE 18.32 Decreased effectiveness of protracted internal beta irradiation from soluble forms of ^{91}Y, ^{144}Ce, or ^{90}Sr inhaled or injected ^{137}Cs in producing deaths due to hematopoietic injury. For comparison a value (■) is shown for x-rays (whole body) irradiation is shown. (From Scott, B.R., *Health Phys*., 36, 323, 1979.)

For inhalation exposure to relatively insoluble radionuclides that result in substantial radiation doses to the lungs, a primary early deterministic effect was development of pneumonitis. Summary radiological information on the four beta-emitting radionuclides incorporated into FAPs is given in Table 18.18 (Scott 1980; Scott et al. 1990). In these studies, the

TABLE 18.18
Physical and Effective Half-Lives and the Length of Time Required for Deposition of 90% of the Total Dose

Radionuclide-Infused Aluminosilicate Particles	Physical Half-Life	Effective Half-Life in Lung (9 days)	Time to Deliver 90% of Total Dose
^{90}Sr	29 years	600	5.5 years
^{144}Ce	285 days	175	1.6 years
^{91}Y	59 days	50	0.5 years
^{90}Y	2.6 days	2.5	8 days

FAPs were cleared in a similar manner with long-term retention in the lungs. The difference in effective half-life and the resulting differences in the pattern of irradiation of the lungs were a reflection of the different physical half-lives for the four radionuclides. The survival curves for radiation-induced pneumonitis producing deaths within 500 days of inhalation exposure for the four radionuclides are shown in Figure 18.33 and compared to a similar clinical outcome resulting from brief x-irradiation of the lungs (Van Dyk et al. 1981;

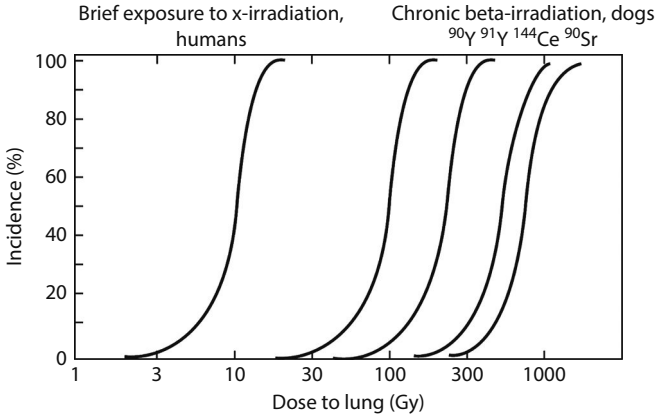

FIGURE 18.33 Decreased effectiveness of protracted internal beta irradiation compared with very brief external x-irradiation in producing pneumonitis. (From Scott, B.R. et al., *Risk Anal.*, 8(3), 393, 1988.)

Scott et al. 1988). The sparing effect of dose protraction is clear. Compared with brief x-irradiation exposures protracting the delivery of 90% of the dose over about 8 days, ^{90}Y requires a radiation dose nearly 10 times greater than from brief x-irradiation to produce equivalent clinical effects. With ^{91}Y, 90% of the dose is delivered in about 6 months and about 20 times more radiation dose is required. With ^{144}Ce and ^{90}Sr, 90% of the radiation dose is delivered over 1.6 years or longer, so it takes a dose 30 times greater to produce equivalent clinical effects as a brief exposure to x-irradiation. It is clear that dose protraction substantially reduces the effectiveness of each gray of dose. The threshold dose for brief x-irradiation causing pneumonitis was about 2 Gy delivered to the lungs. The threshold radiation dose for ^{90}Y-FAP was increased to about 15 Gy, for ^{91}Y-FAP to about 50 Gy, for ^{144}Ce-FAP to about 100 Gy, and for ^{90}Sr-FAP to about 300 Gy related to protraction of the low-LET beta dose to the lungs.

The results of the studies at both Lovelace and Pacific Northwest Laboratories (PNL) with dogs inhaling ^{238}Pu and ^{239}Pu have been published in numerous open literature publications. Some key references on the effects of $^{239}PuO_2$, $^{238}PuO_2$, and $^{238}Pu(NO_3)_2$ are Muggenburg et al. (1983, 1986, 1996, 1999, 2008), Park et al. (1997, 2008, 2012), and Mauderly et al. (1980b).

The primary deterministic effects observed were lymphopenia and pulmonary pneumonitis and fibrosis, although, as discussed later, the issue of whether the pulmonary noncancer effects were deterministic or stochastic is a matter of definition. The primary stochastic effects were principally lung cancer and, at lower incidence, liver and bone cancer. The sites of occurrence of the plutonium-induced cancers and incidence were organ dose dependent.

Pneumonitis was seen in dogs that inhaled ^{238}Pu or ^{239}Pu oxide, which resulted in higher-LET alpha irradiation of the lungs. Both radionuclides have very long half-lives and when inhaled in the oxide form have a long retention time in the lungs. This results in protracted alpha irradiation. Muggenburg et al. (1999, 2008) and Park et al. (1997, 2008, 2012) have noted that this results in some cases of pneumonitis developing several years after the single brief inhalation exposure to the Pu oxide aerosols. Wilson et al. (2009) examined the time course of a diagnosis of lung fibrosis or lung cancer in 359 dogs exposed to either $^{238}PuO_2$ or $^{239}PuO_2$ in the Lovelace experiments (Muggenburg et al. 1999, 2008). The time course of the two diseases is shown in Figure 18.33. Note that both lung fibrosis and lung cancer were observed in control dogs with the earliest cases at about 12 years after the initiation of the studies when the dogs were just over a year old. In contrast, the first cases of lung fibrosis (in the dogs with the highest lung burdens and largest alpha radiation doses) were observed about 1 year after exposure to $^{239}PuO_2$ and about 2 years after exposure to $^{238}PuO_2$. Additional cases of lung fibrosis were observed in dogs with lower lung burdens of ^{239}Pu or $^{238}PuO_2$ at later times. A model with a linear function of dose (Figure 18.34) best describes the hazard function for developing lung fibrosis. A threshold is apparent for $^{238}PuO_2$-induced lung fibrosis at about 0.7 Gy and for

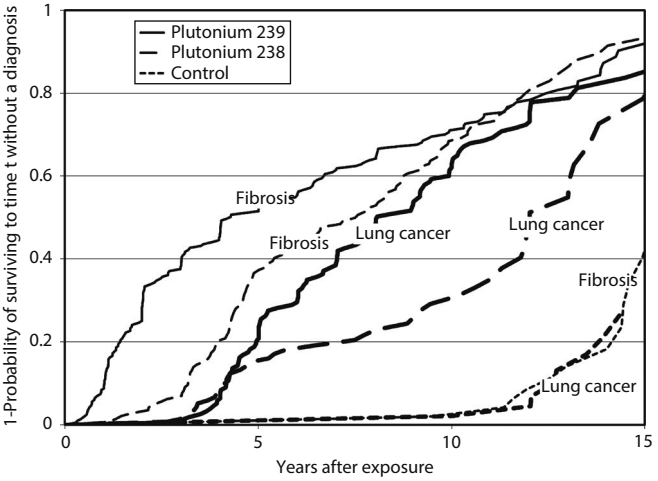

FIGURE 18.34 The unadjusted probability of a diagnosis of lung fibrosis or lung cancer by years after exposure for dogs exposed to $^{239}PuO_2$ or $^{238}PuO_2$. (From Wilson, D.A. et al., *Health Phys*., 96(2), 175, 2009.)

$^{239}PuO_2$ at about 1.5 Gy. The $^{238}PuO_2$ particles were more effective than the $^{239}PuO_2$ particles. This may have been influenced in part by the alpha decay–related fragmentation of the $^{238}PuO_2$ particles (Diel and Mewhinney 1983). Note that the doses have been expressed as gray units without any consideration of RBE or W_R and a conversion to Sv.

In the lifespan studies conducted in the four laboratories (Table 18.19 and Figure 18.35), an excess of cancers was observed compared with the occurrence of cancers in the control dogs. The site of the cancers was closely related to the organs and tissues irradiated. Hence, these cancers were primarily observed in the lungs, skeleton, and liver. Numerous papers have been published on the results of the studies; in this chapter, key results will be briefly summarized. In considering the results, the reader should take special care to note that in the figures, different scales have been used in accordance with the published material. In some cases, results are presented as the number of observed cases, while in others, the results are expressed as RR. The dose metric may be average dose to an organ/tissue, cumulative dose to death or with a specified lag. The original authors used

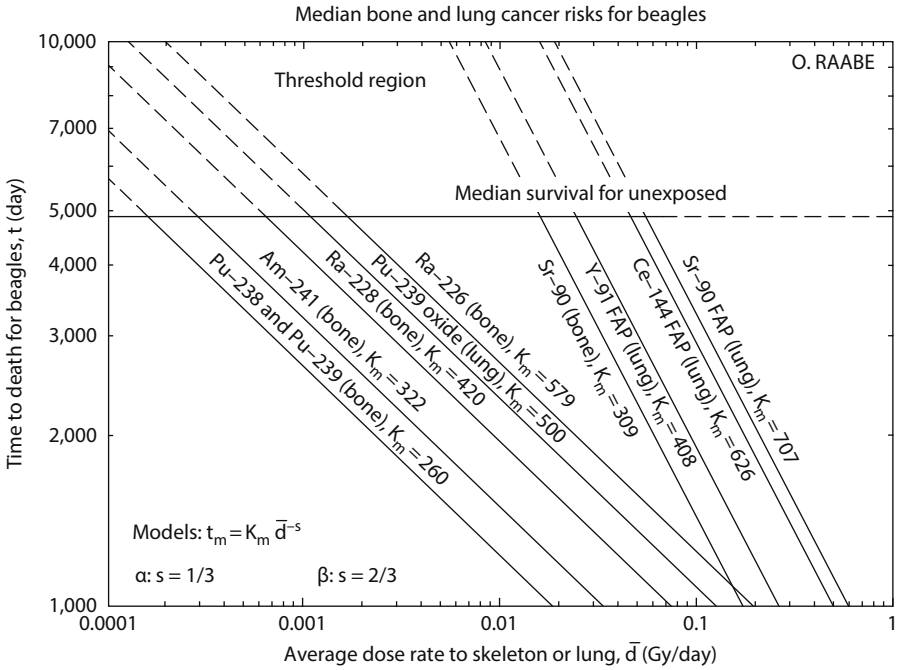

FIGURE 18.35 Illustration of bone sarcoma and lung carcinoma risk functions for beagles demonstrating similar target organ average-dose-rate/time/response patterns with life span virtual thresholds at low dose rates. The positions of the lines vary because of inherent differences in irradiation of the target cells by the different radionuclides and forms. Data were selected from lifetime laboratory studies of internally deposited radionuclides in beagles, including skeletal deposits of ^{90}Sr after exposure by ingestion at Davis and by injection at Utah; lung deposits of inhaled ^{144}Ce, ^{91}Y, and ^{90}Sr in FAP at ITRI; lung deposits of inhaled $^{239}PuO_2$ a PNL; skeletal deposits of injected ^{226}Ra at Davis and Utah; inhaled $^{238}PuO_2$ at ITRI; and skeletal deposits of injected ^{226}RA and ^{241}Am at Utah. (From Raabe, O.G., *Health Phys*., 98, 515, 2010.)

both arithmetic and logarithmic scales and, in some cases, logarithmic–logarithmic scales and even 3D slots.

The study results with inhaled radionuclides and induction of lung cancer will be considered in detail. In considering these results, it is important to note that when these studies were initiated, the only significant data available on induction of lung cancer by inhaled radionuclides were the emerging quantitative data from the studies of exposure to radon and its daughter products that produced lung cancer in miners. It is now apparent that exposure to radon and its daughter products results primarily in alpha particle irradiation of the cells lining the conducting airways. This pattern of irradiation of the respiratory tract cannot be readily extrapolated to other inhaled radionuclides where the radiation dose is primarily delivered to the more distal airways and pulmonary region as occurs with inhalation of respirable-sized particles.

To understand late-occurring effects of the internally deposited radionuclides, Raabe (2010) developed summary comparative potency estimates by modeling data published by the original investigators at the University of Utah, UC-Davis, PNL, and Lovelace. These effects were best described by 3D average-dose-rate/time/response surfaces that compete with other causes of death during an individual's lifetime. Recall the 3D plot in Figure 18.22. A 2D summary plot of Raabe's (2010) results for nine different exposure scenarios is shown in Figure 18.35. In four scenarios, the target organ is the lung, and in five scenarios, it is the skeleton. Four of the scenarios involve low-LET beta irradiation of lung or skeleton, and five involve high-LET alpha irradiation of lung or skeleton. Raabe (2010, 2011) makes a strong case for using average radiation dose rather than cumulative dose in modeling the effects of the internally deposited radionuclides. In this chapter, the results are presented as published by the original authors. Both approaches have pros and cons that deserve careful consideration and are beyond the scope of this chapter. Using maximum likelihood survival regression methods, the characteristic logarithmic slope for cancer induction for each dose pattern and organ was estimated. Across this range of dose patterns for low-LET beta irradiation, with dose protraction, there was a sparing effect of more than a factor of 4.

The beta-emitting radionuclides all yielded Weibull cancer risk power function distributions with negative slopes of about two-thirds, as will be noted later. In contrast, Raabe (2010) found that for alpha irradiation, the negative slopes were about one-third. He interpreted these results as indicating two beta particles were needed to cause the same cellular transformation as that produced by one alpha particle.

Wilson et al. (2009) and Raabe (2010) modeled the data from studies of the alpha-emitting ^{239}Pu and ^{238}Pu conducted at Lovelace and Battelle. Shown in Figure 18.36 is a traditional hazard function plot of the cumulative hazard function for lung cancer induction by lung irradiation from inhaled ^{239}Pu and ^{238}Pu developed by Wilson et al. (2009).

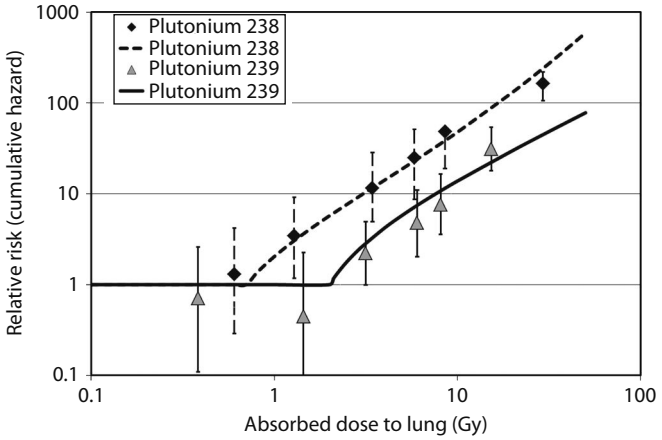

FIGURE 18.36 Estimated cumulative hazard of lung fibrosis in dogs for various levels of initial lung burden of $^{238}PuO_2$ or $^{239}PuO_2$, with 95% CI, and the fitted hazard functions of cumulative dose to the lung. (From Wilson, D.A. et al., *Health Phys*., 96(2), 175, 2009.)

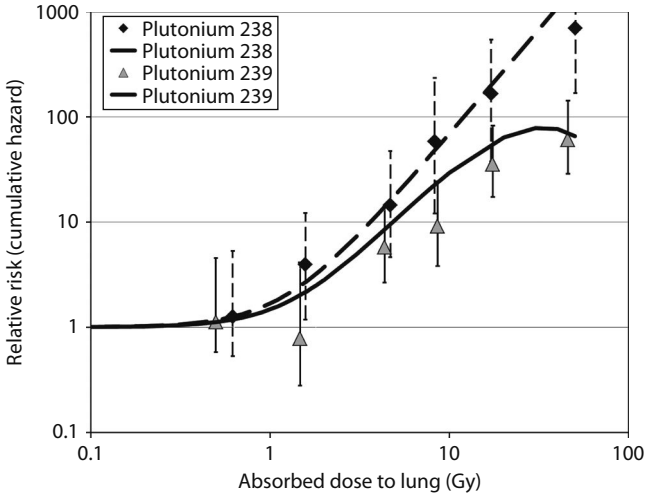

FIGURE 18.37 Estimated cumulative hazards of lung cancer for each level of initial lung body burden, with 95% CIs, and fitted hazard functions of cumulative dose to the lung from inhaled $^{238}PuO_2$ and $^{239}PuO_2$. (From Wilson, D.A. et al., *Health Phys*., 96(2), 175, 2009.)

They explored a range of models of dose–response relationships, including use of various lag periods. They found that

> Models of the risk of lung cancer using doses adjusted for thresholds from 0 to 1 Gy were not significantly different; thresholds over 1 Gy were significantly worse. The models were significantly improved by adjusting the cumulative dose estimates to account for lags of at least 1 year. In models with the dose-response function as the predictor variable, the hazard of lung cancer was consistent with a linear-no threshold model in the combined data and in dogs exposed to $^{239}PuO_2$. However, when covariates were added, the linear-no threshold model was not the best choice; the lung cancer hazard was better described with a model incorporating a quadratic dose-response function.

A comparison of Figures 18.36 and 18.37 illustrates that over the dose range of 1–10 Gy, lung fibrosis and lung cancer are competing risks.

Raabe (2010) modeled the lung cancer data from both the Lovelace and Pacific Northwest Laboratory studies of inhaled ^{239}Pu and ^{238}Pu. His analyses are of special interest because they provide a basis for considering the comparative potency of the several different alpha radiation dose patterns (Figure 18.36 and Table 18.20). He found that the $^{239}Pu(NO_3)_4$ aerosol exposure was most potent at inducing lung cancer. As noted by Wilson et al. (2009), a $^{239}Pu(NO_3)_4$ particle will contain less ^{239}Pu than a $^{239}PuO_2$ particle of the same physical size as a $^{239}PuO_2$ particle because of the substantial contribution of the nitrate to the total mass. Thus, it will take more $^{239}Pu(NO_3)_4$ particles to deliver the same total radioactivity and initial radiation dose with the dose delivered over a greater portion of the lung. Another phenomenon to consider as an influencing factor is the radiation-induced fragmentation reported by Diel and Mewhinney (1983). The $^{238}PuO_2$ aerosols studied at the Pacific Northwest Laboratory was about a factor of 4, less effective than the $^{239}Pu(NO_3)_4$. This difference is relatively modest in view of the range of particle sizes (both polydisperse and monodisperse) and the two different chemical forms studied.

Fourteen different exposure scenarios (Table 18.21) with seven different elements and ten different radionuclides were studied that resulted in an excess of bone cancer. Figure 18.38 is a classical dose–response plot for the incidence of fatal leukemia, bone sarcoma, oral/nasal carcinoma, and periodontal carcinoma in dogs fed ^{90}Sr, from exposure started in utero and continued to adulthood at the UC-Davis. Raabe (2010) interpreted the data as demonstrating a life span virtual threshold for all radiation-induced cancers occurring at calculated cumulative skeletal beta radiation doses above 10 G (10 Sv). He further noted that the absence of bone sarcoma cases in the three lowest dosage groups was significantly less than those found in controls (<0.047).

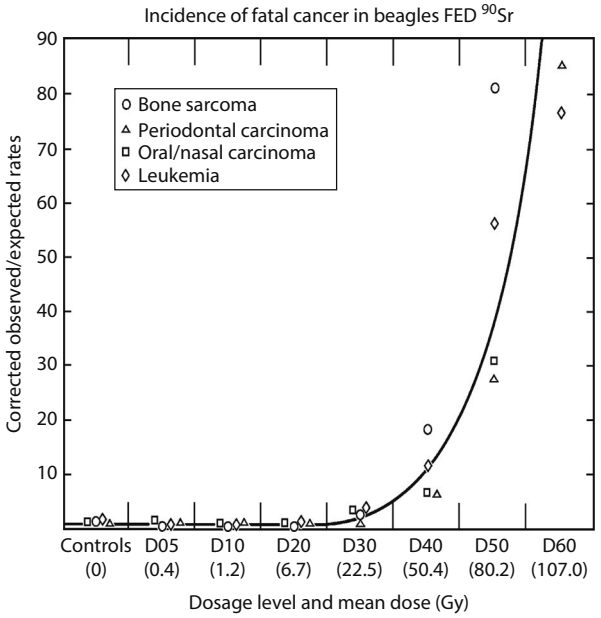

FIGURE 18.38 Survival analysis using the method of Peto et al. (1980) for the incidence of fatal leukemia, bone sarcoma, oral/nasal carcinoma, and periodontal carcinoma in beagle dogs exposed to ^{90}Sr in utero and fed ^{90}Sr to young adulthood at the UC-Davis as a function of dose group (with mean cumulative beta radiation dose to the skeleton). (From Raabe, O.G., *Health Phys*., 98, 515, 2010.)

The bone cancer results from studies conducted at the University of Utah and UC-Davis with injected ^{226}Ra, at UC-Davis with ingested ^{90}Sr, at the University of Utah with injected ^{90}Sr, and at Lovelace ITRI with inhaled ^{90}Sr are shown in Figure 18.39 (Raabe 2010). Note that this plot includes only the dogs dying with a bone cancer and does not include dogs that died of other causes. The median life span for the control dogs for the several studies is shown. The data for the two studies with ^{226}Ra and the other three studies are quite closely grouped; the range of data points on the dose metric and the average dose rates to skeleton are a reflection of the calculation of dose for each subject as contrasted to presentation of the data shown in Figure 18.38 by dose group.

The difference in the dose–response relationships for groups of dogs administered ^{226}Ra (alpha irradiation) and ^{90}Sr (beta irradiation) is striking. As noted earlier, Raabe (2010) interpreted the difference as related to a different mode of action for the alpha versus beta irradiation. It is noteworthy that with a high dose rate, approximately 0.1 Gy/day, the effects of the two types of irradiation in bone sarcoma induction are about equally as effective per gray in causing bone cancer. At dose rates an order of magnitude lower, the alpha irradiation is about four times as effective per gray as the beta irradiation. At even lower dose rates of greater relevance for occupational exposure and, certainly, for environmental exposure of people, the difference in relative effectiveness per gray is even more pronounced with the high-LET alpha irradiation being about 10 times as effective as the low-LET beta irradiation.

Using a similar analytical approach for all the studies, Raabe (2010) calculated the relative carcinogenic and dosimetric potency estimates for each of the 14 types of exposure (Table 18.21). The ^{228}Th, ^{239}Pu, and ^{238}Pu, which deposit preferentially on bone surfaces, are high-LET alpha emitting as the most potent. The low-LET beta emitter ^{90}Sr and high-LET alpha emitter ^{226}Ra were least potent. The ^{90}Sr deposits throughout the skeleton accompanying Ca. However, the relatively energetic beta particles from ^{90}Sr and its short-lived daughter ^{90}Y provide relatively uniform irradiation of the skeleton. In contrast, although ^{226}Ra deposits throughout the skeleton like Ca, much of the alpha emissions are *wasted* radiation because of the short track length of the alpha particles in dense bone. Only a portion of the alpha particle energy is dissipated in cells lining the bone surface, the cells that are presumed to be the origin of the bone cancers.

An excess of liver cancer was observed in the beagle dogs that inhaled $^{238}PuO_2$ or $^{239}PuO_2$ $(NO_3)_4$. Both types of exposure resulted in the translocation of plutonium from the lungs to liver (Figure 18.30). Liver cancer mortality increased significantly in the dogs receiving $^{239}PuO_2$ with cumulative liver doses above 0.2 Gy and in the dogs receiving $^{238}PuO_2$ with cumulative liver doses above 1.0 Gy. With both types of exposures, the cumulative liver doses were less than 3.0 Gy. The difference in the apparent threshold doses for $^{238}PuO_2$ may relate to its more gradual release from the lung than in the case of ^{239}Pu $(NO_3)_4$, which left the lungs more rapidly. A portion of the alpha dose from $^{238}PuO_2$ may have been *wasted*.

In considering the very substantial amount of data from the dogs administered internally deposited radionuclides, a key question is its relevance to predicting human hazard and risk. Recall that when the studies with beagle dogs were initiated, no human data were available on these radionuclides

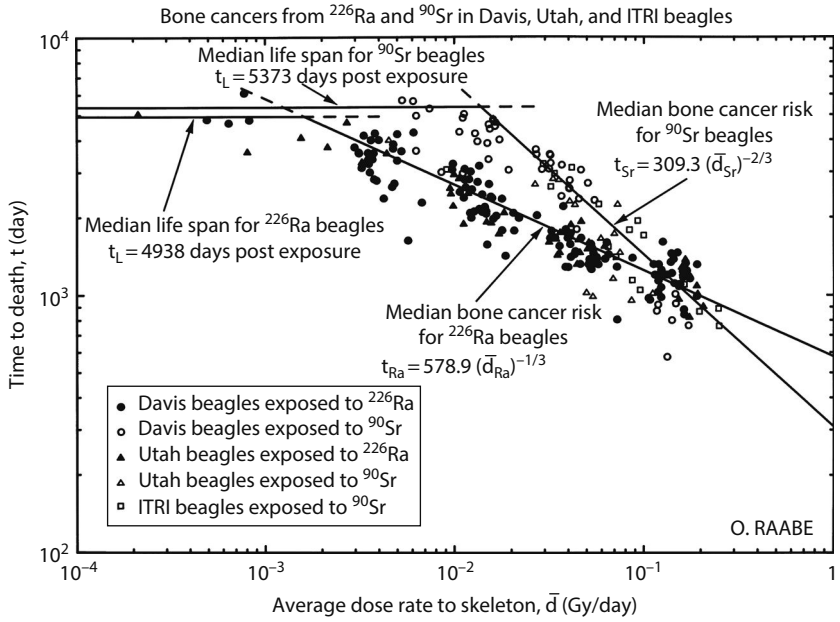

FIGURE 18.39 Comparison of bone sarcoma cases in beagle dogs at UC-Davis, the University of Utah, from injected ^{226}Ra, at UC-Davis with ingested ^{90}Sr, at the University of Utah with injected ^{90}Sr, and from Lovelace ITRI with inhaled ^{90}Sr as a function of the average alpha or beta radiation dose to the skeleton. (From Raabe, O.G., *Health Phys*., 98, 515, 2010.)

with the exception of ^{226}Ra and, to a lesser extent, ^{228}Th, information gained from the radium dial painter studies. The University of Utah dog studies would later predict, using the ratio approach discussed earlier, that ^{239}Pu reaching the skeleton would be about 10 times as potent as ^{226}Ra in producing bone cancer.

An alternative approach to assessing the predictive nature of the dog study results is to directly compare the observed effects of $^{239}Pu(NO_3)_4$ and $^{239}PuO_2$ in the dogs purposefully exposed and workers occupationally exposed at the MPA complex starting in 1948. That is exactly the approach taken by Wilson et al. (2010). The MPA worker data are from Sokolnikov et al. (2008) who analyzed data on 17,740 workers (25% females) observed until death, lost to follow-up, or through December 31, 2003. The workers typically had multiple exposures to $^{239}Pu(NO_3)_4$ and $^{239}PuO_2$ during their employment, which in some cases dated to 1948. Mortality included 354 lung cancer deaths, 40 liver cancer deaths, and 11 bone cancer deaths as discussed earlier. It is obvious that some of the workers smoked cigarettes and consumed alcohol (Tokarskaya et al. 2002, 2006). The beagle dog population consisted of 837 dogs exposed to $^{239}PuO_2$, $^{238}PuO_2$, or $^{239}Pu(NO_3)_4$ at either Lovelace ITRI or Pacific Northwest Laboratory and followed for their life span. In this population, 231 lung cancer deaths, 45 liver cancers, and 158 bone cancers were observed. It is obvious that none of the dogs smoked or consumed alcohol. Half of the dogs were females and half were males. None of the female dogs was allowed to reproduce.

The lung cancer mortality rates for the MPA workers (354 cases) and the dogs (231 cases) are shown in Figure 18.40. The overall agreement is striking with the greatest deviation at the highest lung doses for the MPA workers. In my opinion, the similarity in dose–response relationship for the workers occupationally exposed and dogs purposefully exposed is especially remarkable considering the much greater uncertainty in estimating lung doses for workers than for the dogs and the always challenging issue of accounting for cigarette smoking as a major confounder.

The liver cancer mortality rate for the MPA workers (14 controls, 26 exposed) and the beagle dogs (7 controls, 39 exposed) is shown in Figure 18.41. Again, the similarity in the dose–response relationships for workers and dogs is remarkable, especially for liver cases below 3.0 Gy. The lower dose groups included 34 of the 35 cases observed in exposed dogs and 14 of the 26 cases observed in workers. Twelve of the liver cancers were observed in workers with liver doses of over 3.0 Gy. An additional critical factor in considering liver cancer mortality is the role of alcohol consumption as a confounder in the worker population (Tokarskaya et al. 2006).

Recalling that concern for ^{239}Pu-producing bone cancer was a major driver of the U.S. research program starting in World War II, it is ironic that bone cancer proved to be a less significant outcome than the development of lung and liver cancer. The MPA workers cohort only experienced 11 cases of bone cancer, 5 in controls, 3 in the 0.3–0.5 Gy subgroup, and 3 in the subgroup with estimated bone doses of over 10 Gy. The low number of bone cancers in the MPA workers (5 in controls and 6 in exposed workers) contrasts with the beagle dogs (1 case in a control and 157 cases in exposed dogs). This contrast deserves further investigation and suggests the possibility that the dog is more sensitive to induction of bone cancer by alpha irradiation than people.

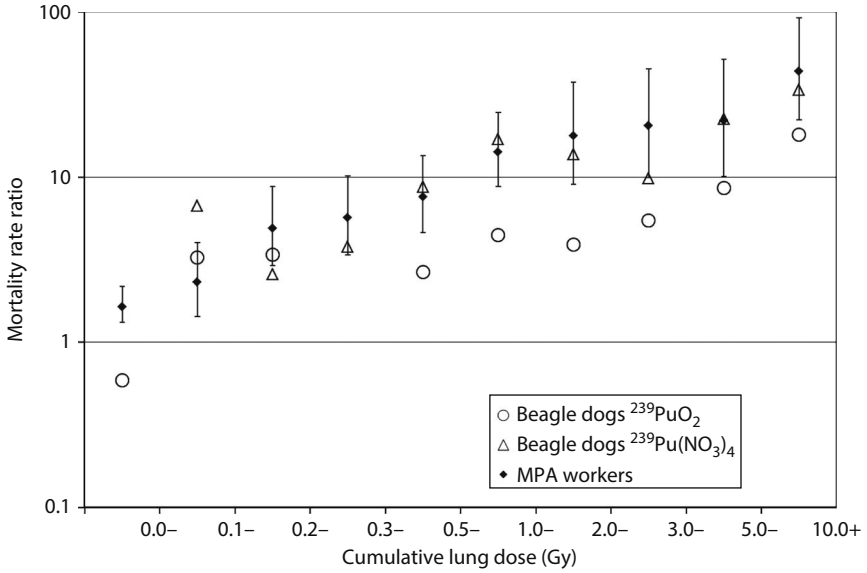

FIGURE 18.40 Lung cancer mortality rate ratio (with 95% CIs) for Mayak Production Association workers with known plutonium exposure plotted with rate ratios in beagle dogs exposed by inhalation to plutonium by level of cumulative lung dose. (Adapted from Wilson, D.A. et al., *Health Phys*., 98(1), 42, 2010.)

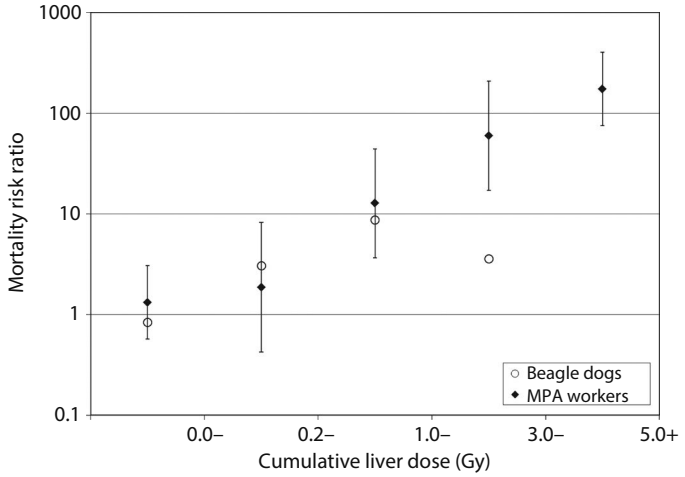

FIGURE 18.41 Liver cancer mortality rate ratios (with 95% CIs) for Mayak Production Association workers with known plutonium exposure plotted against rate ratios in beagle dogs exposed to plutonium by level of cumulative liver dose. (From Wilson, D.A. et al., *Health Phys*., 98(1), 42, 2010.)

Wilson et al. (2010) modeled the data in several ways. In general, the linear dose–response models fit the data reasonably well. They noted that linear function of dose given in Sokolnikov et al. (2008) did not fit the data as well as a quadratic function with inclusion of a cell-killing response function. It is likely that additional attention will be given to these valuable data sets in the future to gain further insight into the biological mechanisms involved in the two species. Indeed, Gilbert et al. (2013) have already updated the MPS worker data providing an additional 5 years of follow-up.

It would be very useful to conduct a critical analysis of extensive data available from rats exposed to plutonium aerosols and assess how well the dose–response relationships for plutonium-exposed rats relate to the observations on beagle dogs and humans. Such an analysis could be especially useful since the results of inhalation studies with rats have been used to assess human hazards of a number of chemical toxicants.

In my opinion, the Wilson et al. (2009) reanalysis offers reassurance that risk estimates for intake of radionuclides and associated alpha irradiation of lung, liver, and skeleton developed from the MPA workers and the beagle dog studies are not likely to underestimate the true risk of radiation-induced disease. It is useful to recall that Cantril and Parker (1945) noted that human misfortune was the cornerstone of radiation protection guidance at that time drawing heavily on the radium dial painter experiences for radionuclides deposited in the skeleton. Now more than a half century later, rigorous data analysis from another unfortunate experience,

that of the MPA workers, validates the importance of the dog studies with internally deposited radionuclides as predictors of radiation-induced effects in humans.

RADIATION COUNTERMEASURES

Pharmaceutical Approaches

Since the late 1940s, there has been interest in the development of agents that could be used to protect against radiation risks. Recent acts of terrorism and concern for the potential use of devices that might involve radiation exposure have renewed interest in the development of such agents (Weiss and Landauer 2009; DuMont et al. 2010; Williams et al. 2010; Mettler et al. 2011; Koukourakis 2012). There are three major classes of radiation countermeasure agents: radioprotectants, radiation mitigators, and therapeutic agents. Radioprotective agents are intended for use before irradiation. Radiation mitigators are given after irradiation but before expression of tissue injury. Therapeutic agents are intended for use after irradiation as palliative or supportive measures as indicated by clinical signs and symptoms.

Thousands of agents have been tested for radioprotective effects (Weiss and Landauer 2009). In view of the role of free radicals in producing tissue injury from irradiation, much attention has been directed toward evaluating compounds with antioxidant properties. This has led to substantial research on sulfhydryl compounds. Unfortunately, at doses of these compounds required to provide some protection against acute radiation injury, the sulfhydryl compounds produce nausea and vomiting (Grdina et al. 2002). In his comprehensive review, Koukourakis (2012) identifies more than 60 compounds with radioprotective activity linking them to specific mechanisms of radiation injury. One of these compounds, aminothiol, amifostine (Ethyol, Medimmune), is the only agent approved by the U.S. Food and Drug Administration for clinical use (Wasserman and Brizel 2001). It is limited to use for some radiotherapeutic situations to reduce xerostomia or dry mouth. Unfortunately, it has serious side effects requiring careful medical monitoring of the patient. Looking to the future, Williams et al. (2010), based on a literature review, have recommended animal models that may prove useful in developing medical countermeasures to radiation exposure.

Reducing Radiation Dose

The only radioprotective agent generally accepted for use in treating large, accidentally exposed populations is potassium iodide to block unbound ^{131}I from accumulating in the thyroid. However, in considering its use, it is important to recognize that some individuals are sensitive to potassium iodide. Thus, special care should be exercised in using it in situations involving accidental release of ^{131}I. It is obvious that the preferred approach is to limit ^{131}I intake, which can be accomplished in many situations by avoiding ingestion of ^{131}I-contaminated milk.

The U.S. Food and Drug Administration in 2003 approved the use of Prussian blue (PB; Radiogardase) for reducing body burdens of radiocesium (Thompson and Church 2001). Melo et al. (1996), in studies at Lovelace, demonstrated the effectiveness of PB in enhancing the elimination of ^{137}Cs from beagle dogs. The reductions in the average total whole-body doses by PB were age-related: 51% in immature dogs (4.7 months), 31% in young adults (2.4 years), and 38% in aged dogs (13.5 years). The ratio of fecal to urinary ^{137}Cs was enhanced by PB administration from 0.8 in untreated dogs to 2.2 in treated dogs. A key question with PB is what level of ^{137}Cs intake would warrant treatment by this agent.

Chelation Therapy

Since the beginning of nuclear operations in the mid-1940s, there has been interest in approaches to removing radionuclides that have been inhaled or entered via puncture rounds. ^{239}Pu handled in a variety of forms as $^{239}PuO_2$, $^{239}Pu(NO_3)_4$, and as a metal has been of special concern. Early research demonstrated that chelating agents administered intravenously were effective in removing soluble plutonium (Taylor et al. 2007; Durbin 2008; Kazzi et al. 2013). Zinc diethylenetriamine pentaacetate (DTPA) has been shown to be effective in removing plutonium and americium when administered intravenously or by inhaling a nebulized aerosol. In the case of ^{239}Pu or ^{241}Am in wounds, the usual approach has been to surgically remove as much of the radioactive material as possible and then administer DTPA intravenously (NCRP 2008). The U.S. Food and Drug Administration has given limited approval for the use of Ca- and ZN-DTPA to treat workers accidentally contaminated with plutonium, americium, and other actinides. It has encouraged pharmaceutical companies to seek approval for wider usage in the event of population exposures to actinide radionuclides. As an aside, based on my experience in aerosol science and in studying the health effects of inhalation exposure to actinides, I cannot envision situations in which the air concentrations of actinides and the associated projected radiation doses would warrant mass treatment of populations with DTPA.

Bronchopulmonary Lavage

In the late 1950s and 1960s, widespread interest developed in using lung fluid and cells recovered by lung lavage as a diagnostic tool in human clinical medicine. Interest in the technique was further stimulated when fiber-optic bronchoscopes became available and could be used to recover fluid and tissue from specific areas of the airways and lung. A pioneer in the field, Ramirez-Rivera et al. (1963), described their use of whole-lung lavage to remove material from the lungs of patients with pulmonary alveolar proteinosis. This work served as a stimulus to Lovelace ITRI scientists to explore the use of bronchopulmonary lavage in order to obtain samples of lung surfactant for evaluation, for biochemical and cytological evaluation as a diagnostic tool, and most importantly, for evaluation of the use of bronchoalveolar lavage (BAL) as a therapeutic procedure for removing inhaled radioactive particles (Pfleger et al. 1969; Henderson et al. 1974, 1975).

The bronchopulmonary lavage procedure can be carried out in several ways in dogs, primates, and human subjects.

The basic procedure is conducted with the individual under general anesthesia and intubated with either a single or double lumen catheter; the latter allows separation of the two lungs. The lavage procedure involves introducing saline fluid and removal of the fluid from the lungs by gravity. Typically, the procedure is repeated several times. In a well-oxygenated patient, the entire lung can be washed several times.

Multiple studies were conducted at Lovelace ITRI with dogs exposed to radioactive aerosols, including $^{239}PuO_2$ (Pfleger et al. 1969; Boecker et al. 1974; Felicetti et al. 1975; Muggenburg et al. 1976, 1977, 1980, 1990). The lavage procedure was found to be effective in removing inhaled, relatively insoluble radioactive particles from the pulmonary region. The largest amount of radioactivity was removed if the lavage procedure was carried out soon after the radioactive particles were inhaled but decreased over time. However, particles could be removed by bronchopulmonary lavage as long as 8 months after a single brief exposure to radioactive particles. It is doubtful that the particles remained in the alveolar region for that long. Rather, their presence in the lung and lung lavage fluid many months after a brief inhalation exposure probably reflected continued movement of macrophages carrying particles between the alveoli and interstitial lung tissue. The Lovelace ITRI studies demonstrated that typically 40%–60% of the initial lung burden of radioactive particles could be removed by lavage if the procedure was used soon after the inhalation exposure. Moreover, the use of chelation therapy increased the removal of the radionuclides that had become solubilized. The risk of radiation-induced disease from the inhaled radionuclides was reduced proportionally.

A worker from the Rocky Flats facility was exposed to a ^{239}Pu aerosol in an accident when a container exploded and dispersed the ^{239}Pu into the laboratory. The worker was aware of the research conducted at Lovelace with the BAL procedure. He and his physician requested that he be treated in Albuquerque, New Mexico, with BAL and intravenous Zn-DTPA. It was estimated that his lungs contained about 0.5 μCi of ^{239}Pu. To complement the Lovelace team of scientists and physicians, a physician and an anesthesiologist from Duke University Medical Center, who routinely performed BAL on children to treat cystic fibrosis and alveolar proteinosis, were added to the team. One lung was subjected to BAL followed 2 days later by BAL of the other lung and then on the fourth day BAL of the lung initially washed. In addition, DTPA was given intravenously. The BAL fluid that was recovered was straw colored and contained many macrophages with engulfed ^{239}Pu. Many macrophages found in lung fluid also contained debris characteristically recovered from the lungs of smokers or recent former smokers. This patient indicated he had been a smoker. A total of about 30% of the initial lung burden of ^{239}Pu was recovered in the BAL fluid and urine. The use of BAL in treating humans accidentally exposed to plutonium has been reviewed (Dean 1997; Morgan et al. 2010). Any use of the BAL procedure and Zn-DTPA, as with any medical procedure, requires an evaluation of the potential risks and benefits to the patient of reduced risk of radiation-induced diseases. The greatest risks associated with the use of the procedure are the risks associated with general anesthesia, a common medical procedure.

RADIATION HORMESIS

Thus far in this chapter, primary consideration has been given to two fundamentally different dose–response relationships for radiation: the sigmoid curve with a threshold usually associated with deterministic health outcomes and the linear no-threshold (LNT) model used to describe stochastic effects such as cancer and hereditable effects. The LNT model has been accepted as the model of choice for radiation protection purposes by the BEIR Committee, the NCRP, and the ICRP.

An alternative model that has received substantial attention invokes the concept of hormesis, derived from the Greek word *hormaein*, to excite. The concept of hormesis had its roots in the cellular pathology studies of Virchow in the nineteenth century. The hormesis hypothesis, which is not restricted to radiation, states that low-level stress from different agents or environments stimulates a system of protective biological processes at the cellular, molecular, and organismic levels, decreasing the incidence of cancer and other deleterious health effects below the spontaneous level. In short, adaptive responses such as antioxidant defenses, enzymatic repair of DNA, removal of DNA lesions, apoptosis, and immunologic stimulation are triggered by low doses of various agents, while the harmful stochastic effects, such as cancer, are observed at higher doses.

The potential for radiation having hormetic effects was advanced soon after the discovery of x-rays (Atkinson 1898) and was at least partially the basis for the public flocking to radon spas for their alleged health benefits in the early 1900s and, indeed still today, in some parts of the world. As already noted, the Manhattan Project stimulated the conduct of many studies of radiation effects on many health endpoints, including LSS. One of the earliest was by Lorenz and colleagues at the National Cancer Institute with mice, which suggested that protracted exposure to low doses of radiation increased life span compared with the nonirradiated controls (Lorenz 1950; Lorenz et al. 1955). Other investigators soon reported similar results in mice and rats (Carlson et al. 1957; Brown et al. 1963). In other cases, attempts to reproduce the hormetic effects were unsuccessful (Bustad et al. 1965a). Indeed, it is noteworthy that the life span of the Japanese atomic bomb survivors with doses of less than 149 mGy was reported to be prolonged (Mine et al. 1990). Colonge and Preston (2000) provide more recent evaluation of the longevity of atomic bomb survivors. There has been an increased interest in radiation hormesis in recent decades (Luckey 1980, 1991, 2007; Calabrese 1992, 2011; Calabrese et al. 1999; Calabrese and Baldwin 2000, 2003; Upton 2001; Scott 2005, 2007, 2008; Sanders 2010). Readers interested in exploring this topic in detail will find the 217-page book by Sanders especially useful. Much of the debate has centered on the estimation of risks for low dose rate and low dose in setting radiation protection standards and criteria for cleanup of radioactively

contaminated sites (Little et al. 2009; Tubiana et al. 2009; Feinendegen et al. 2011). This issue was the basis of a conference I coorganized with sponsorship by the Council of Scientific Society Presidents (CSSP) (1998) to create a strategy for developing a science-based policy approach to addressing conflicting views on assessing the health risks of low-level exposure to ionizing radiation. The CSSP conference, in turn, had major influence on the creation of the U.S. DOE's Low-Dose Radiation Research Program that continued for about a decade (1998–2008) exploring doses below about 100 mSv. The program emphasized a multiparametric approach extending from molecular-level observations to those at the level of the mammalian organism (Brooks 2005; Brooks and Couch 2007; Dauer et al. 2010). Additional information on the DOE Low-Dose Program can be found at http://www.lowdose.energy.gov.

In recent years, the debate over the use of the LNT model in radiation risk assessment and standard setting has been extended into the chemical toxicology risk assessment and standard setting arenas. The argument for hormesis is based on the premise that the LNT routinely overestimates health risks for cancers induced by low-LET radiation exposure, especially for low dose rate and low total doses. It further acknowledges that at high doses, ionizing radiation and certain chemicals (or their metabolites) that damage DNA may share common mechanisms in producing cancer. The hormesis argument is that these mechanisms not be operative with low-level chronic exposure to chemicals and ignore repair mechanisms; thus, extrapolation of the LNT model based on radiation experience to assess the risks of chemical exposures is not appropriate. Abelson (1994), a longtime editor of *Science*, addressed this issue in one of his classic editorials:

> To calculate effects of small doses, a linear extrapolation from large doses to zero is employed. The routine use of this procedure implies that the pathways of metabolism of large doses and small doses are identical. It implies that mammals have no defense against effects that injure DNA. It implies that no dose, however small, is safe. Examples of instances in which these assumptions are invalid become numerous …. The use of linear extrapolation from huge doses to zero implies that one molecular event can cause cancer. This assertion disregards the fact of natural large-scale repair of damaged DNA.

Sanders (2010) reviews substantial data to support Abelson's argument (1994). Sanders' arguments use data extending from the molecular level to intact organisms to populations of laboratory animals and people. He notes the adult human body contains more than 100 trillion cells of about 100 cell types. With 10^{11} cell divisions a day, about 10^{16} new cells are created over a 70-year life span. All of these cells are attacked by reactive oxygen species a million times a day; however, the chance of one of those cells ultimately undergoing genetic changes such that its cell progeny leads to a lethal cancer during a lifetime is about 25%. Table 18.22 provides a comparison of DNA damage from reactive oxygen species and natural background of about 2 mSv/year.

TABLE 18.22
Comparison of DNA Damage from Reactive Oxygen Species and a Background Level of 2 mSv/year

Type of Damage	Spontaneous ROS	2 mSv/year
DNA oxidative adducts/cell/day (Pollycove 2002)	10^6	1×10^{-3}
DNA damage/cell/year (Billen 1990)	70×10^6	4
Double-stranded DNA breaks/cell/year (Stewart 1999)	40	~0.1

Source: Reprinted with permission from Sanders, C.L., *Radiation Hormesis and the Linear-No-Threshold Assumption*, Springer-Verlag, Berlin/Heidelberg, Germany, 2010, Table 2.1.

The author of this chapter has been an ardent proponent of the concept of hormesis beginning with admonishment from two grandmothers: "Everything in moderation, avoid excesses." That common sense view was reinforced by my experience as a student in veterinary medicine studying nutritional diseases and learning that every vitamin and trace element has an optimum intake with both deficiencies and excesses causing disease. Later, as a scientist studying radiation and chemicals, I was struck by variable responses to exposure to low-level radiation, especially on life span. However, in my view, the variable hormetic responses for different endpoints to various agents and among varied populations create a dilemma for devising a scheme for developing protective guidance for radiation and chemicals that takes account of hormesis. Indeed, to date despite much-heated discussion over hermetic responses for both radiation and chemicals, no one has proposed a specific strategy for incorporating the consideration of hormesis in a regulatory system to protect against the risks of either radiation or chemical exposure.

MEDICAL CONSEQUENCES OF NUCLEAR ACCIDENTS

Mettler and Upton (2008) in their book, *Medical Effects of Ionizing Radiation*, provide an excellent review of the medical consequences of a number of accidents involving radiation exposure, including the Three Mile Island and Chernobyl accidents in the context of the knowledge about the acute and chronic effects of radiation. The insights of Fred A. Mettler are especially valuable since he participated in the medical care and follow-up of the Chernobyl first responders. Included in their book is a chapter on "Perceptions of radiation and psychological effects." Fear of radiation, that is, radiation phobia, is a real phenomenon that was clearly evident in all the accidents, irrespective of the magnitude of the radioactive releases. Moreover, it has been recognized as a real phenomenon for years as the public reacts to announcements of potential sitings of nuclear facilities and radioactive waste sites (Slovic 1987). Bromet (2013) has recently reviewed the emotional consequences of nuclear power plant disasters.

The Three Mile Island accident, as noted earlier, involved a minimal release (Table 18.4). As noted by Mettler and Upton (2008), the image of an accident was fueled by media coverage. "The maximum radiation dose at the plant boundary for the course of the entire 'accident' was less than 1 mGy, substantially less than the dose from an abdominal x-ray." Baum et al. (1983) have chronicled the emotional and psychological response of the incident of the Three Mile Island incident. Talbott et al. (2003) reported no untoward health responses in 20 years of follow-up of residents who lived near Three Mile Island.

A comprehensive review of the medical consequences of the Chernobyl accident has been published (WHO 2006) and summarized by Mettler and Upton (2008). They noted, "The mental health impact of Chernobyl is the largest public health problem caused by the accident to date," while also noting it was, by far, the worst industrial disaster on record. The extraordinary quantities of radioactive material released in the Chernobyl accident were noted earlier. When the author visited Kiev, near Chernobyl, in the fall of 1986, the enhanced level of radioactivity in the environment was clearly evident. However, to provide context, the readily measurable increase in background radiation levels was equivalent to that experienced by a resident of Chicago, Illinois, moving to Denver, Colorado. Cardis et al. (2005) have reported an excess risk of thyroid cancers in a case–control study with 276 cases of childhood (less than 15 years of age at the time of the accident) thyroid cancers compared with 1300 control cases. A few cases received over 2 Gy with most of the cases receiving less than 0.5 Gy. The ERR per gray was on the order of 5–10. Using information on increased background radiation levels across Europe attributed to the Chernobyl accident, Cardis et al. (2006) estimate that the accident may have resulted in 2400 excess leukemia cases and 1650 excess leukemia deaths, an attributable fraction of 0.04%. As Mettler and Upton (2008) noted it would not be possible to detect this small of a hypothetical increase.

The Fukushima accident in Japan beginning on March 11, 2011, was an extraordinarily complex event triggered by an earthquake and a tsunami that caused huge loss of life (over 20,500 killed), property damage, and relocation of large populations (over 320,000 people) whose homes, schools, and places of work were destroyed. Ohnishi (2012), Yamashita (2013), and WHO (2013) have described the disaster. Laid on top of this was the release of a large quantity of radioactivity from the severely damaged nuclear station (Table 18.4). The actions of Japanese officials and the local populations were exemplary, resulting in a substantial reduction of potential radiation exposure from the passing cloud of radioactive material, ingestion of radioactively contaminated foodstuffs, and external radiation exposure originating from deposited radioactivity. The response to the accident was a testimonial to the disciplined character of the Japanese people.

The WHO (2013) has developed preliminary dose estimates for populations exposed as a result of the Fukushima nuclear accident associated with the 2011 Great East Japan earthquake and tsunami. The results are reassuring. The estimated maximum thyroid effective dose was 35 mSv, 26 individuals received 16–35 mSv, and 1054 received less than 15 mSv. In contrast, the mean thyroid dose for 1576 cases following the Chernobyl accident was 490 mSv (Cardis et al. 2005). The estimated external exposure doses for Fukushima are also low, with very few in the range of 5–15 mSv and most less than 1 mSv. Based on these dose estimates, it is very unlikely that an associated increase in cancer will be observed. It is especially noteworthy that a comprehensive medical follow-up plan has already been initiated. As anticipated, whenever a population is given detailed medical examinations, an increase will be observed in the number of medical conditions observed irrespective of their origin. It is quite possible that a positive outcome of the program will be increased diagnosis and treatment of health conditions that would have otherwise not been observed until later and possibly gone untreated.

Boice (2012), a very experienced epidemiologist who has conducted many studies on populations exposed to radiation and currently serves as the president of the NCRP, has offered a useful perspective on the Fukushima accident. He noted that

> Studies of the Fukushima population should be and are being considered for reassurance and health care reasons. Apart from the extreme psychological stress caused by the horrific loss of life following the tsunami and the large-scale evacuation from homes and villages, such studies have limited to no chance of providing information on possible health risks following low dose exposures received gradually over time – the estimated doses (to date) are just too small.

RADIATION PROTECTION STANDARDS

Development of Radiation Protection Standards

Relatively soon after the discovery of radiation and radioactivity and recognition that radiation could produce harmful effects, action was taken to develop guidance to limit adverse health effects in the people using radiation and radioactivity. The first actions were voluntary and involved defining levels of exposure to x-rays that would or would not harm the skin: in short, the identification of a threshold dose. In 1902, Rollins proposed a tolerance dose: if a photographic plate is not fogged in 7 min, the radiation is not of harmful intensity. This represented the first association of an exposure or dose metric with a health outcome. Guidelines evolved most rapidly in Great Britain, which quickly embraced the use of radiation in the practice of medicine. It developed relatively comprehensive radiation protection guidelines as early as 1915.

Radiologists, medical doctors who specialized in using radiation in their practice of medicine, took a leadership role in creating international radiation protection criteria. This was also an era in which the disciplines of medical physics and radiological physics were developing with individuals trained in physics applying their expertise to medical issues. Different methods for measuring the intensity of x-rays were being advanced, and most importantly, concern was

increasing for the harmful effects of radiation. The British Institute of Radiology was one of the first professional societies to focus on these issues. In 1925, it invited delegates from a number of countries to the *First International Congress of Radiology*, which was convened in London. At the *Second International Congress of Radiology* in Stockholm in 1928, representatives from a number of countries met to prepare x-ray protection guidelines. This meeting resulted in the creation of the International X-Ray and Radium Protection Committee. After World War II, this committee evolved into the ICRP and the International Commission on Radiation Units and Measurements that continue today.

Lauriston Taylor, an employee of what was the U.S. National Bureau of Standards (NBS), attended the 1928 meeting in Stockholm. He brought the radiation protection criteria that had been agreed to at Stockholm back to the United States. Under Taylor's leadership, the advisory committee on X-Ray and Radium Protection was created under the auspices of the NBS. In 1946, the advisory committee was renamed the NCRP. In 1964, the NCRP received a U.S. Congressional charter to serve as an independent body to provide advice and recommendations on radiation protection matters in the United States. The NCRP continues today as an independent body governed by a self-elected council of 60 members. The author served as a member of the NCRP Council from 1971 to 2001 and has been designated as a distinguished emeritus member. The various reports prepared and issued by the NCRP have significantly impacted radiation protection in the United States. As of late 2012, the NCRP had issued 173 authoritative reports offering advice and guidance on a wide range of radiation protection topics germane to its mission. However, it is important to recognize that various laws have delegated legal responsibility for radioactive protection matters in the United States to the Nuclear Regulatory Commission, the Environmental Protection Agency, the Food and Drug Administration, the DOE, and state and local agencies.

It is noteworthy that various advisory committees of the NRC, most notably a continuing series of committees, have had a major role in the United States in interpreting literature on the health effects of ionizing radiation. These reports have had substantial influence on U.S. government agencies, especially on the Environmental Protection Agency after it was created. The first NRC report (NRC 1999) was a critique of the first UNSCEAR report (UNSCEAR 1958), which was soon followed by the Biological Effects of Atomic Radiation (BEAR) report (NRC 1960). The BEIR Committee has issued four reports focused on the effects of exposure to low levels of ionizing radiation (NRC 1972, 1980, 1990, 2006). In addition, the BEIR Committee issued a report on radon and other internally deposited alpha-emitting radionuclides (NRC 1988) and a seminal report later that was exclusively concerned with estimating the risks of residential exposure to radon (NRC 1999).

Evolution of a Radiation Protection System

As noted earlier, both U.S. national and international systems to guide radiation protection activities evolved rapidly in the 1920s and 1930s and was in place at the beginning of World War II. Taylor (1981) reviewed these activities in detail for the period from 1928 to 1974. Hendee (1993) and Jones (2005) have provided useful reviews of the history of radiation protection standards. As noted, a cornerstone of early radiation protection guidance was the concept of a tolerance dose. Cantril and Parker (1945) prepared a document dated January 5, 1945, intended to describe for workers at the Hanford site and other Manhattan Project sites the health risks of exposure to radiation and radionuclides. The document was intended for release before the start-up of the Hanford reactors in September 1944 and the beginning of fuel reprocessing in December 1944; however, release was delayed related to security classification concerns. In any event, the document was released coincidently with the start of major fuel reprocessing at Hanford and the associated handling of large quantities of fission product radionuclides and plutonium. As an aside, the radiation protection activities at Hanford, Oak Ridge, and Los Alamos proved effective as judged by the lack of observed radiation effects in workers. This stands in sharp contrast to the Mayak experience discussed earlier.

Herbert M. Parker, a radiological physicist trained in England, came to the United States in the late 1930s to work with Seymour T. Cantril, a radiation oncologist at Swedish Hospital in Seattle, Washington. Parker would later assume responsibility for developing and managing the radiation protection program at Hanford where I had the opportunity to work under him. Cantril and Parker provided remarkable insight into key issues concerning radiation risks that remain today and, most importantly, extend to nonradiation materials. A quote from the Cantril and Parker document is germane:

> In reviewing the subject of tolerance dose, it is most striking that animal experimental evidence has played practically no part in arriving at present day levels. In summary, there are only three tolerance levels, which have been established and accepted as a working basis for occupational exposure.
>
> 0.1 r per day for external X and gamma radiation
> 1×10^{-14} curie/cc for radon in the air of working rooms
> 0.1 μg of radium as the maximum allowable amount deposited in the body of a radium dial painter
>
> Each of these levels has been established by adding a safety factor to the amount, which has been known to produce lasting injury to persons so exposed. It is of interest also to note that in each case the factor does not exceed 10, and is more likely considerably less than 10. Human misfortune rather than animal experimentation were the basis for these levels.

In the same document, Cantril and Parker (1945) discuss LNT and threshold dose–response relationships (recall Figure 18.3), drawing heavily on Henshaw's earlier discussion of this topic (Henshaw 1941). Discussion and debate over the use of these two different dose–response relationships for exposure to ionizing radiation and chemicals continue today.

As discussed earlier, the Manhattan Project included initiation of a substantial research program on the health and

environmental effects of external radiation exposure and internally deposited radionuclides. This program was substantially expanded in the United States by the AEC. Similar, but more modest, research programs were initiated in the United Kingdom, France, the Soviet Union, and yet later in Japan. Substantial advances were made in understanding heritable and somatic effects of radiation in humans and the movement of radionuclides in the environment during the late 1940s and 1950s.

The NCRP in 1953 published Handbook 52, "Maximum permissible amounts of radioisotopes in the human body and maximum permissible concentrations in air and water" (NCRP 1953). These standards were intended primarily for nuclear workers; however, the report stated that the permissible concentrations were *for use beyond the control area*. NCRP Handbook 59 released in 1954 recommended that "in the course of their normal activities, protective measures be taken to make sure that no minor actually receives a weekly rate higher than one-tenth the respective permissible weekly doses for the critical organs" (NCRP 1954). In 1957, the NCRP issued an addendum to Handbook 59. It specified an occupational dose rate exposure limit of 15 rem per year, but the maximum accumulated dose was limited to five times the number of years beyond age 18 (NCRP 1957). This was adapted out of concern for what were then viewed as genetic effects, now more appropriately viewed as heritable effects. With regard to internally deposited radionuclides, the report recommended: "For individuals outside of the controlled area, the maximum permissible concentrations should be one-tenth of those for occupational exposure" (NCRP 1957). It also identified a per capita dose limit of 0.5 rem outside the control area for radiation from a controlled area. Out of concern for heritable effects, it noted that radiation exposure should be limited to a small portion of the total population.

NCRP Handbook 69 (NCRP 1959) further noted that radiation or radioactivity outside of a control area, attributable to control area operations, shall be such that it is improbable that any individual will receive a dose of more than 0.5 rem in any year from external radiation. It also noted that the maximum permissible body burden of radionuclides in persons outside the control area and attributable to the operations within the control area should not exceed one-tenth that for radiation workers. This included for internally deposited radionuclides the identification of critical organs based on the organs receiving the highest radiation dose from a particular radionuclide and chemical form.

In 1960, the NCRP (1960a,b) published a report of an ad hoc committee that stated, "We recommend the population permissible dose for man-made radiation be based on natural background level." They went on to note, "Although it is not our responsibility to determine the exact level, we believe that the population permissible somatic dose for man-made radiation, excluding medical and dental sources, should not be larger than that due to natural background radiation, without a careful examination of the reasons for, and the expected benefits to, society for a larger dose." The report assumed a background dose rate of 100 mrem per year.

These interrelated recommendations explicitly rejected the concept of a tolerance dose and advanced the idea of acceptable risk in contrast with no risk at some low level of radiation exposure. The move to adoption of an LNT predictive model of radiation injury for exposed populations had begun.

In 1958, the UNSCEAR (UNSCEAR 1958) issued its first report on the effects of radiation exposures on humans. It estimated the adverse effects of low-level radiation exposure using both the threshold and no-threshold models of radiation-induced risk. The report noted the difficulty of estimating with any precision the possible consequences of radiation exposure at low levels. It specifically noted the delayed effects of exposure and that the effects were not distinguishable from those produced by radiation occurring spontaneously or produced by other agents. Those who drafted the report were aware of the appearance of radiation-induced leukemia in the Japanese atomic bomb survivors who had received substantial radiation doses. UNSCEAR (1958) concluded that both the threshold and nonthreshold values had equal validity. The NRC Committee on Pathologic Effects of Atomic Radiation offered a commentary taking exception to the UNSCEAR conclusions and urged that greater attention be given to nonlinear relationships between dose and effect (NRC 1959). Later, UNSCEAR reports would emphasize that extrapolation of the LNT curve to low levels provided an upper limit to the risk of low-level exposures (UNSCEAR 1962, 1964). The ICRP endorsed this position (ICRP 1966) and reemphasized that viewpoint in its most recent report (ICRP 2007). The controversy over estimating radiation risks at low dose levels sparked substantial public interactions during a period in which concern was increasing about the effects of radioactive fallout from nuclear weapons tests. This was also a time period when tensions increased over permissible levels of radiation exposure for medical applications, with clear benefits to the individual, and radiation exposure from fallout and other nuclear operations without the exposed population receiving any benefits.

H.M. Parker (1960), in his congressional testimony, offered some useful insights on some aspects of the controversy: "In the period between 1945 and 1950, the information available on the genetic effects and the increasing suspicion that not all somatic effects of radiation were of a threshold type (i.e., a type that requires a minimum dose before manifestation) led to the change in terminology from 'tolerance dose' to the present 'maximum permissible dose.'" It was at this point that the concept of acceptable risk appeared.

I am convinced that the terminology was changed from one form to the other specifically to underline the acceptance of a no-threshold-dose concept for the production of gene mutations by radiation (p. 26 et seq. of handbook 59) (NBS 1959). From a language point of view, one could equally well have changed from a *maximum permissible dose* to *tolerable dose* or *tolerance dose*. The intent to change to an *acceptable risk* line of reasoning was partially obscured by an arbitrary choice of words.

The fundamental change in approach at this point has not always been sufficiently emphasized. The earlier clinical observations clearly pointed to the existence of threshold effects and perhaps conditioned observers to expect all deleterious effects to have a threshold. It was, for example, probably impossible to produce reddening of the skin with less than some prescribed dose. If such a threshold applied to every radiation effect, an intelligent, wholly technical, search could be made to define such thresholds with precision, and persons exposed to lesser amounts would be protected in the fullest sense.

If there is no threshold dose, there is no absolutely safe dose in the same sense. The determination of permissible limits then involves value judgments outside the areas of scientific and technical competence. It is essential that qualified observers recognize this limitation and reexamine their own role. I believe that it is equally essential that these same observers continue to play a basic role in recommending standards. This follows from the principle of better acceptance of standards having the authority of knowledge and from one further much-overlooked factor, that is, that although present-day standards appear to be established in detail by the considerations of physicists, biologists, and other scientists, they are basically validated by clinical experience. This experience does go beyond reproducible science and does include value judgments in accordance with the Hippocratic oath. Because some aspects of the genetic effects are beyond clinical observation, there is a needed separate voice of authority from geneticists. Then, because the decisions are necessarily based on cultural reactions to human welfare, many generations hence, the whole structure of ethical opinion must be included in some fashion.

The firm resolution of the evidence concerning the response at a very low dose rate and low total dose as to whether relevant radiation effects are threshold, nonthreshold and linear, or nonthreshold and nonlinear is the most important factor in establishing the authority of knowledge for radiation standards.

There is yet no complete definitive, scientific answer to these questions. The assumption of a nonthreshold type of response for somatic as well as genetic effects in setting limits, while plausible, is an assumption, and numerical estimates of effects calculated on this basis must be treated with reservation.

It is frequently indicated that the assumption of a nonthreshold response is a *safe* assumption. This can be followed by a stipulation that permissible exposures are zero. However, there are other consequences to the nation as a whole from eliminating radiation or radiation exposures. These consequences can be expressed in terms of a limitation in our ability to attain the many benefits that radiation can bring. In essence, then, the risk principle states that radiation exposure and the potential damage from radiation should be balanced against the benefits of radiation and the limits set at some level where the optimal benefits are attained, as compared with the losses. "To establish such limits for radiation and equally carefully for any other agent or influence on the national life, projected over an indefinite number of generations, is a Herculean task" (Parker 1960, pp. 4–6).

The testimony that Parker gave in 1960 is equally relevant today, more than one-half century later. The only difference is that if it were given today, it would have more emphasis on other agents, that is, chemicals, and a growing list of health endpoints in addition to cancer.

Out of the controversy of overestimating or underestimating radiation risks at low levels, the NRC Committee on BEAR emerged (NRC 1959). That committee would soon be renamed the Committee on Biological Effects of Ionizing Radiation (BEIR) and issue its first report in 1972 (NRC 1972). That report included estimates of cancer risk at low doses based on linear extrapolation from cancer mortality at high doses from the studies of the Japanese atomic bomb survivors and other groups. In this same time period, the AEC introduced the concept of *as low as reasonably achievable*, an approach advocated by Edward Lewis in the 1960 Congressional hearing. The concept implies that no threshold exists for radiation-induced disease and that exposures should be held as low as reasonably achievable to minimize any radiation-induced harm.

Parker (1976) later addressed the use of radiation as a prototypical toxic agent for considering the health risks of other agents:

> First, the case could be solved and safety extrapolated to low exposures if a generalized theory of the deleterious actions of the agent could be developed. This must be attempted for any new agent. Then a broader umbrella should be developed for classes of agents, if it exists technically. Short of these unifications, the problems of each new agent might be looked at as follows: Make an early attempt to determine whether the relevant risks have a threshold or not. In doing this, develop measurement systems that are unambiguous and acceptable to all. If animal data are going to be discarded because the only relevant subject is man himself, review early whether animal research is needed at all. If comprehensive theory for the particular agent is compatible with a hazard threshold or even a practical threshold for low exposure (due to latency period inversely related to exposure), there is an acceptable technological standard to be found. If not, the eventual standard involves value judgments. The efforts of the scientific fraternity will never be sufficient in themselves. The key element is to identify the plausible effects as early as possible and to promote informed public discussions as early as possible. (p. 40)

Much of the early radiation health effects research was concerned with developing a scientific basis for setting exposure limits. As Parker noted, the approach shifted over time from *tolerance dose* to *permissible dose* to *acceptable risk*. He appropriately noted that this introduced *value judgments* that go beyond scientific and technical competence. At this juncture, it is important to emphasize that the ICRP and NCRP are voluntary, nongovernmental bodies comprised principally of scientists, including medically trained personnel. The same can be noted for the NRC BEIR Committees. Their competence in evaluating scientific data that informs public policy decisions is above reproach. To be explicit, they can estimate the risks at differing radiation doses; however,

a legitimate question remains as to whether these groups are appropriately constituted to decide for society at large an acceptable level of risk that is associated with a particular radiation dose from a given source or all sources.

In 1977, the ICRP announced its clear shift to a risk-based approach to the establishment of standards for radiation protection (ICRP 1977). The ICRP's approach was to define the concept of acceptable risk from radiation exposure of workers by relating it to the fatal accident rate in so-called safe industries. Later, the NCRP (1987) would adopt a similar approach.

One stimulus to moving to an *acceptable risk* orientation was the need to become quantitative in estimating health risks as noted by Albert (1994). Another stimulus for the development of quantitative estimates of risk was the increasing attention given in the 1960s to the proactive conduct of *consequence studies*. Some of the earliest *consequence studies* were concerned with nuclear war scenarios and nuclear power reactor accidents. Others were a spin-off of studies related to the space program and included the consequences of failure of space systems that utilized nuclear reactors or radionuclide power sources fueled with plutonium or other radionuclides. One prominent consequence study dealt with nuclear power reactors and was conducted under the leadership of Norman Rasmussen of MIT (NRC 1975). Another major consequence study during the 1970s was concerned with the development of a breeder or plutonium recycle reactor (Cuddihy et al. 1977).

While the discussion here focuses on radiation protection guidelines, it is important to recognize that the developments concerning radiation were taking place on a larger stage. The 1950s and 1960s were a time of increasing concern for environmental quality and related impacts on human health. In many ways, Rachael Carson's book, *Silent Spring* (1962), served as a catalyst for public demands for change and regulation. The National Environmental Policy Act (NEPA) of 1969 signed into law by President Richard Nixon on January 1, 1970, in many ways, provided a foundation for a broad range of additional actions, including Nixon's creation of the U.S. Environmental Protection Agency by executive order and passage of the Clean Air and Clean Water Acts. It is noteworthy that the U.S. Environmental Protection Agency charged with administering the Clean Air Act found it useful to draw on the radiation experience in modeling dose–response relationships as it dealt with assessing the cancer risk of exposures to hazardous air pollutants (Albert 1994).

A key element of NEPA was a requirement that all federal agencies prepare environmental assessments and environmental impact statements for proposed major activity, including those involving the use of federal funds and permits issued by federal agencies. As a result, the application of NEPA and the development of environmental assessments and environmental impact statements extended to many state and local projects.

From the foregoing, it is apparent that the need for quantitative estimates of the potency of radiation for causing a range of health effects, especially cancer, was coming from two interrelated activities. The first need was to provide a scientific basis for setting radiation protection standards. The second was the need related to conducting consequence studies such as those required to meet NEPA requirements.

The consequence studies involving nuclear facilities from the very beginning were comprehensive in extending from sources of radiation and radioactivity to the transport and fate of radionuclides in the environment to the exposure of individuals, the internal dose to various tissues, and finally the estimated health consequences. This comprehensive structure is apparent in the schematic rendering presented earlier in Figures 18.1 and 18.3. With radioactive material, the distinction between external exposure and internal dose is obvious, a distinction that has also become apparent for chemical agents. It is fortunate when dealing with radiation and radionuclides that metrics for ionization exist that can be used to describe exposure and dose. Unfortunately, common dose metrics do not exist for describing dose across a diverse array of chemicals. All of the nuclear facility *consequence studies* required as input some estimate of the potency of radiation for producing deleterious effects and especially solid cancers and leukemia. The textbook edited by Till and Grogan (2008) provides a number of examples of *consequence studies* conducted to guide remediation activities at various nuclear sites. Till (2013), in his Lauriston S. Taylor lecture, elaborated on the key elements of the large number of dose reconstruction activities he and his colleagues have participated in as risk assessment evolved over the past six decades.

The NRC BEIR III Committee (1980) issued a report endorsing the use of an LQ model of radiation-induced cancer. An LQ model predicts that the cancer risks of low-level radiation exposures are less than predicted by a strictly linear model extrapolating from high doses. The report noted that developmental effects, a deterministic effect, from irradiation in utero may exhibit a threshold. It indicated that an LNT model provided the best estimate of genetic risk from radiation exposure. The report did note that it was unknown and probably not determinable whether dose rates on the order of 1 mSv per year, on the order of dose rates from background radiation, were detrimental to people. More recently, the NRC BEIR VII Committee (BEIR VII 2006) endorsed the use of a linear, no-threshold model to describe the relationship between radiation dose and excessive cancer risk for brief exposures to whole-body irradiation.

Current Radiation Protection System

Very early in the development of information on the effects of externally delivered radiation exposure, internally deposited radionuclides, and a related system of radiation protection, it became apparent that it would be very difficult to consider separately each type of radiation and radionuclide. An attractive alternative was at hand, taking advantage of the fact that all kinds of radiation and radionuclides produce biological effects by ionizing tissue. The approach that has evolved is to cover exposures, both external irradiation and from internally deposited radionuclides, from all sources in a holistic manner with absorbed tissue dose as the common metric.

Preston (2004) has provided a concise review of the radiobiological concepts that undergive radiation protection. Key elements of the system developed by the ICRP are presented in its reports (ICRP 1966, 1977, 1999, 2007).

A central element of the dose-based radiation protection scheme is the use of W_R, tissue-weighting factor (W_T), and a dose and dose rate effectiveness factor (DDREF) to allow calculation of effective dose expressed as Sv as a critical intermediate step to estimating total detriment from cancer and heritable effects.

The 2007 ICRP recommendations for W_R are shown in Table 18.23. The W_R factors are based on the RBE of the radiation of interest, to the absorbed dose in an organ or tissue in order to derive the equivalent dose. In simple terms, the system assumes that with the same ionizing tissue dose, alpha particles are 20 times as effective as gamma photons. The system uses W_T factors for the principal tissues and organs to calculate effective dose. The ICRP-recommended W_T factors are shown in Table 18.24. The W_T factors represent the relative contribution of each tissue or organ to the total detriment resulting from uniform irradiation of the whole body.

The DDREF is defined as the factor by which cancer risks observed after large acute doses should be reduced when the radiation is delivered at a low dose rate or in a series of small fractions. For stochastic effects, the ICRP recommends a DDREF of 2 for deriving nominal risk coefficients for low doses and dose rates of low-LET radiation. The BEIR VII (BEIR VII 2006) Committee recommended a DDREF of 1.5. Note that the DDREF combines both dose and dose rate. In my opinion, consideration should be given to separately identifying a dose effectiveness factor (DEF) and dose rate effectiveness factor (DREF). Based on the evidence reviewed earlier on the occurrence of cancer associated with exposure to low-LET beta irradiation, a DREF as high as 4 would be appropriate. Raabe (2011) has also emphasized the need for change in considering the effectiveness of low-dose-rate exposures. Brooks et al. (2009) have also commented on the need to separate the DREF from the DDREF for internally deposited radionuclides for which the dose rate is typically low and the dose protracted.

The ICRP system distinguishes between deterministic effects and stochastic effects (recall Figure 18.4). Deterministic effects such as the development of a radiation-induced cataract of the eye are assumed to have a threshold dose below which they are not manifest. Above that dose, the severity of the effect is assumed to increase with increasing dose. Stochastic effects are radiation-induced effects such as cancer and heritable effects that increase in proportion to increasing dose without any change in the severity of the effect. The ICRP retains its fundamental hypothesis that the induction of stochastic effects is a linear function of absorbed dose without a threshold. The current ICRP (ICRP 2007; Wrixon 2008) recommendations for detriment-adjusted nominal risk coefficients for stochastic effects after exposure to radiation at low dose rate (10^{-2} Sv^{-1}) are shown in Table 18.25. The 2007 values are based on cancer incidence weighted for lethality and life impairment, whereas the 1990 values were based upon fatal cancer risk weighted for nonfatal cancer, relative life years lost for fatal cancers, and life impairment for nonfatal cancers. Note that while the cancer risk coefficients changed very little from 1990 to 2007, the risk coefficients for heritable effects were substantially reduced. Wrixon (2008) noted, "The decimal places in the table are not intended to indicate a high level of precision; they are simply the outcome of ICRP calculations." For comparison purposes, the NCRP (1993)-recommended dose limits are also shown in Table 18.25.

The ICRP (2007; Wrixon 2008)-recommended dose limits for planned exposure situations are also shown in Table 18.25. Note that the effective dose, driven by concern for stochastic effects, principally radiation-induced cancer, is different by a factor of 20 for occupational exposures versus population exposures. In contrast, the deterministic effects limits differ by a factor of 10 between occupational exposures versus population exposures. In considering these dose limits, it should be noted that they are provided

TABLE 18.23
Recommended Radiation-Weighting Factors (W_R)[a]

Radiation Type	Radiation-Weighting Factor (WR)
Photons	1
Electrons and muons	1
Protons and charged pions	2
Alpha particles, fission fragments, heavy ions	20
Neutrons	A continuous function of energy

[a] Used to derive the effective dose.

[b] Remainder tissues: adrenals, extrathoracic (ET) region, gall bladder, heart, kidneys, lymphatic nodes, muscle, oral mucosa, pancreas, prostate (♂), small intestine, spleen, thymus, uterus/cervix (♀).

TABLE 18.25
Recommended Dose Limits (mSv in a Year)

Type of Limit	ICRP	NCRP
A. *Occupational exposure*		
Stochastic effects		
Effective dose limit (cumulative)	20 mSv/year averaged over 5 years, not to exceed 50 mSv in any one year	10 mSv × age
Annual	50 mSv/year	50 mSv/year
Deterministic effects		
Dose equivalent limits for tissues and organs (annual)		
Lens of eye	150 mSv/year	150 mSv/year
Skin, hands, and feet	500 mSv/year	500 mSv/year
B. *Embryo/fetus exposure*		
Effective dose limit after pregnancy is declared	0.5 mSv/month	Total of 1 mSv to abdomen surface
C. *Public exposure (annual)*		
Effective dose limit, continuous or frequent exposure	No distinction between frequent and infrequent—1 mSv/year	1 mSv/year 5 mSv/year
Effective dose limits, infrequent exposure		
Dose equivalent limits	15 mSv/year	15 mSv/year
Lens of eye	50 mSv/year	50 mSv/year
Skin and extremities		
D. *Negligible individual dose (annual)*	No statement	0.01 mSv/year

Sources: ICRP (International Commission on Radiological Protection), The 2007 Recommendations of the International Commission on Radiological Protection, ICRP Publication 103, 2007; NCRP (National Council on Radiation Protection and Measurements), Recommendations for limits for exposure to ionizing radiation, NCRP Report No. 116, NCRP, Bethesda, MD, 1993.

within an overarching framework in which the goal is to have doses *as low as reasonably achievable*. The ICRP (2007; Wrixon 2008) has also provided a framework for dose constraints and reference levels (Tables 18.26 and 18.27).

The most significant sources for developing the estimates of radiation potency have been the results periodically reported from follow-up studies of the survivors of the atomic bombings of Hiroshima and Nagasaki, Japan, such as the paper of Ozasa et al. (2012). The data relating cancer or leukemia deaths to absorbed dose have been fit with a number of different mathematical functions, usually including a linear or LQ model of the relationship between low doses of radiation and cancer (Lewis 1957; NRC 1990, 2006; Ozasa et al. 2012). Models with a linear component at the lowest doses have been used, even though at the lowest doses of concern, the presence or absence of a linear relationship between dose and cancer response and the absence of a cancer response above the background cannot be proven

TABLE 18.26
Framework for Dose Constraints and Reference Levels

Bands of Effective Dose, mSv (Acute or Annual)	Characteristics	Requirements	Examples
20–100	Controlled by action on exposure pathway	Consider reducing doses	Reference level for radiological emergency
1–20	Controlled by action or source or exposure pathway	For planned exposure situations, individual dose assessment and training	Constraints for occupational exposure. Constraints for comforters and carers of patients treated with radiopharmaceuticals. Reference level for radon in dwellings
<1	Controlled by action on source	Periodic cheques on exposure pathways	Constraints for public exposures in planned situations

TABLE 18.27
Detriment-Adjusted Nominal Risk Coefficients for Stochastic Effects after Exposure to Radiation at Low Dose Rate (10^{-2} Sv^{-1})

	Cancer		Heritable Effects		Cancer Total Detriment	
Exposed Population	**1990[a]**	**2007[b]**	**1990**	**2007**	**1990**	**2007**
Whole	6.0	5.5	1.3	0.2	7.3	5.7
Adult	4.8	4.1	0.8	0.1	5.6	4.2

[a] 1990 cancer values based upon fatal cancer risk weighted for nonfatal cancer, relative life years lost for fatal cancers, and life impairment for nonfatal cancer.

[b] 2007 cancer values based upon the data on cancer incidence weighted for lethality and life impairment.

as discussed by multiple groups and scientists (NRC 1988, 1990; Hoel and Li 1998; Clarke 2008).

Clarke (2008), who has served as chair of the ICRP, has addressed the uncertainties of estimating effects at low doses using Figure 18.42 to frame the discussion. He has stated that

> Studies on DNA repair and the cellular/molecular processes of radiation tumorigenesis provide no good reason to assume that there will be a low-dose threshold for induction of tumors in general. However, curvilinearity of the dose response in the low-dose region – perhaps associated with biochemical stress responses or changing DNA repair characteristics – cannot be excluded as a general feature. The mechanistic modeling of tumorigenesis is at a relatively early stage of development, but the data available tend to argue against a dose threshold for most tumor types.

In discussing Figure 18.42, he noted, "It is clear that the risk figures apply to the slope of the dose–response curve at the level of background, some few millisieverts per year. However, a strictly linear dose response should not be expected in all circumstances." "It must be recognized that ongoing and future studies in epidemiology and animal science, while remaining of great importance for quantitative risk assessment, will not resolve the uncertainties surrounding the effects in humans of low-dose radiation. Accordingly, there will be an increased need for weight-of-evidence judgments based on largely qualitative data from cellular and molecular studies of the biological mechanisms that underlies health effects; the provision of such judgment demands strong support from biologically validated computational models of risk." He goes on to note, "The development of mechanistic models of radiation risk demands more than a simple improvement in the understanding of cellular or molecular processes."

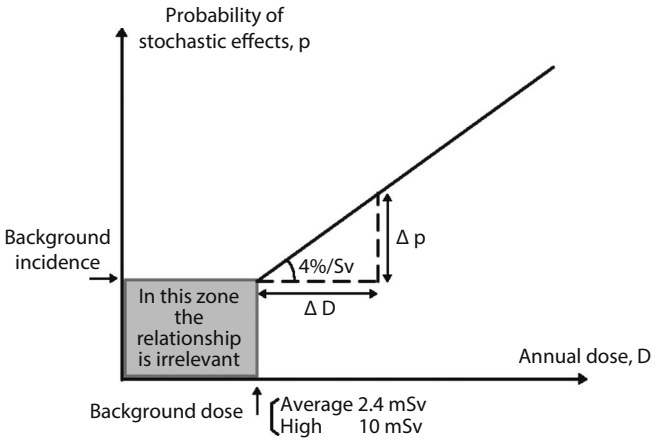

FIGURE 18.42 Region of the dose–response curve when risk factors apply. (From Clarke, R.H., The risks from exposure to ionizing radiation, in: *Radiological Risk Assessment and Environmental Analysis*, eds. J.E. Till and H.A. Grogan, Oxford University Press, New York, pp. 531–550, 2008.)

The concept of population dose and population detriment (NCRP 1960a,b) emerged during the 1940s and 1950s and was reinforced by the consequence studies. This was a natural outgrowth of concern for genetic effects and the use of population dose and detriment as a criterion of integrated injury to the gene pool. However, its use quickly moved beyond concern for genetic effects to cancer risks. It is obvious that the use of linear models of dose–response relationships and population dose and detriment go hand in hand. Using a linear model, it is easy to integrate dose over a population of any size over any time period. Then using a standard coefficient of excess cancer risk per unit dose, one can calculate the excess cancer risk for the population. Some individuals have noted cynically that if the calculated value seems low, then the population size or the duration of exposure can be increased or both population size and duration of exposure can be increased and the population risk recalculated. Unfortunately, many times only the excess cancer risk is presented in the absence of the underlying cancer risk that would have been observed if the added radiation exposure had not occurred. The result is a lack of context for considering the calculated excess radiation-induced risk.

FUTURE RESEARCH

This chapter is grounded in a view that ionizing radiation from external sources and internally deposited radionuclides has been studied more extensively than any other toxic agent. A wide range of adverse health effects have been identified and placed into two broad categories: deterministic effects and stochastic effects. The radiation dose–response relationships for both deterministic and stochastic effects are now very well known. Is it appropriate to ask if major issues can be addressed through further research to enhance our understanding of the effects of external radiation and internally deposited radionuclides? A separate, but important question follows: Is it likely that further scientific advances in understanding ionizing radiation can enhance its use as a diagnostic and therapeutic modality? The answer to that question

is a resounding yes! The issue of research needs related to better understanding the health impacts of exposure to external radiation and internally deposited radionuclides and the use of the knowledge acquired in setting radiation protection standards is a difficult and more complex, multifaceted issue. In the remainder of this section, some of the key issues will be discussed.

Advances in the management of individuals accidentally exposed to high doses of radiation will come from practical experience treating such individuals, as in the past and as is true of other acute toxicants. Let us hope that such situations occur very infrequently. The treatment approach will focus on the individual patient and be driven by symptoms and estimates of absorbed dose. Specific anticipatory research in this area is likely to have limited impact. Positive impacts will come from continuing advances in medical practice.

In my opinion, the prospects for developing pharmaceuticals as radiation-specific countermeasures is quite low based on more than a half century of experience attempting to identify agents that are effective in mitigating radiation-induced effects. The complexity of the radiation injury process defies a *silver bullet* approach. It is obvious that physicians that face the need to treat victims of radiation exposures producing clinical effects would certainly welcome pharmaceuticals developed with a view to a broader application in treating the myriad of pathways involved in ARS. In the absence of specific pharmaceutical agents for treating radiation-induced injury, physicians will use the time-honored approach at treating the clinical signs and symptoms attempting to limit morbidity and mortality.

The most persistent issue concerning the health effects of ionizing radiation relates to concern for the stochastic effects, principally induction of cancer from low-dose-rate, low-dose exposures. Henshaw (1941) and Cantril and Parker (1945) scoped the issue in the World War II era, and in recent reviews, Morgan and Bair (2013) and Coleman (2013) identified some of the issues that underpin the controversy over the extent of radiation-induced effects, if any, associated with low-dose and low-dose-rate radiation exposures. In my opinion, it is unfortunate that neither recent review framed their discussion using the source–exposure–dose–response paradigm (Figure 18.3) strongly advocated in this chapter for integrating the knowledge of radiation-induced effects. I submit that the use of that paradigm has guided the most fruitful research to resolve uncertainties in our understanding of dose–response relationships for radiation effects. Morgan and Bair (2013), as they noted, arbitrarily define a low dose of ionizing radiation as an acute exposure of <100 mGy (mSv). To provide perspective on this dose, it is about 30 times the average annual natural background dose and 30 times the average annual dose from anthropogenic sources.

Another perspective on the issue of understanding potential radiation-induced effects at low doses comes from the analysis of Mettler and Upton (2008). They call attention to the statistical methods discussed earlier by Land (1980) and BEIR VII Committee (2006) and proceed to describe the issue:

> The sample size needed to find or estimate an increased heath risk in a population depends on the size of the risk already present in the population. Thus, to find an excess of an effect that occurs rarely in a population, only a small number of cases may be needed; however, to find a small increase in the incidence of cancer (which occurs spontaneously in 40% of people), a large exposed population is needed. As the additional risk due to any noxious agent becomes smaller, the sample size must increase as the inverse square of the risk to maintain statistical precision and power. For example, if excess risk is truly proportional to dose and if a sample size of 100,000 is necessary to determine the effects of a 0.1 Gy exposure, a sample of approximately 10 million persons will be needed statistically to find the same effect for 0.01 Gy.

Mettler and Upton (2008) noted that a sample size of 1000 is needed to detect a response from 1 Gy. These calculations are fully consistent with the findings to date in the Japanese A-bomb survivors followed very carefully for 58 years (1945–2003) after the bombings. As of 2003, in that population of 86,611, with observations beginning in 1950, there were 10,929 cancer deaths with 527 attributed to radiation exposure and 35,685 noncancer deaths with 353 attributed to radiation exposure (Table 18.15).

It is apparent that most of the deaths attributable to radiation in the Japanese atomic bomb survivors were associated with quite high doses, over 0.1 Gy, that is, the dose Morgan and Bair (2013) arbitrarily suggested as being a low dose and then proceeded to advocate more research at lower doses. In the aggregate, only about 5% of the cancers and 1% of the noncancer deaths in the A-bomb survivors were attributable to radiation with the vast majority of the deaths at doses greater than 0.1 Gy. These statistics should be sobering to epidemiologists, experimental toxicologists, and all those engaged in assessing hazards and risks and those planning experiments on mechanisms of radiation-induced diseases at low doses. As noted by Mettler and Upton (2008), this analysis is relevant to all noxious agents. For the radiobiologists and experimental toxicologists who note that they work with molecular and cellular systems in which more sensitive responses can be characterized, I remind them of the need to place their typical deterministic experimental outcome findings in the context of the statistical framework for stochastic effects discussed earlier. It is clear that cancer occurs as a stochastic disease, and hence, the mechanisms and modes of action that are critical to the occurrence of cancer are of a stochastic nature.

It is obvious that the door should always be open to the conduct of research driven by intellectual curiosity, simply to better understand how humans respond to radiation exposure. However, from a pragmatic viewpoint, it is important to ask if there are key uncertainties in our knowledge of radiation-induced effects, either of a deterministic or stochastic

nature (including hereditable effects or cancer) that limit policy makers in making societal decisions on radiation protection standards, establishing cleanup criteria for radionuclide-contaminated sites or making decisions on the siting of nuclear facilities, including reactors, fuel-reprocessing plants, or nuclear waste storage facilities. In my opinion, the answer is a resounding NO! How the current knowledge is used is a matter of policy, precision estimates of radiation hazards at doses below 0.1 Gy are not the stumbling block to policy decisions, or is it causing potential radiation exposure populations to be inadequately protected.

EPILOGUE: IMPLICATIONS FOR CHEMICAL TOXICITY AND RISK

This textbook focuses on evaluating chemical toxicity, hazards, and risks; thus, it is appropriate to ask what has been learned from the study of radiation and radionuclides that is applicable to chemicals. In my opinion, internally deposited radionuclides and internally deposited chemicals are directly analogous with external radiation exposure being relatively unique. The source–exposure–internal dose–health response paradigm presented in Figure 18.3 is equally relevant to the study of chemicals and internally deposited radionuclides. A clear lesson from the study of internally deposited radionuclides is the importance of absorbed dose in understanding the mechanisms of action and dose–response relationships and comparing the radiation of different qualities delivered at different dose rates.

Absorbed dose is the critical link between exposure and mechanisms of action that lead to alterations in the occurrence of disease in addition to that which would have been observed in the absence of exposure to radiation. While absorbed tissue dose of ionizing radiation is well accepted as a common dose metric for internally deposited radionuclides, a similar unifying metric does not exist at this time for the diverse array of chemicals that are of interest. Perhaps such a metric for chemicals will be devised sometime in the future. In the field of chemical toxicology, there is a rich history of studying the toxicokinetics, the disposition in the body over time, of individual chemicals. However, these studies have not always been well integrated with studies of toxicodynamics and rarely have been linked to studies of late-occurring health effects of either brief or protracted exposures to chemicals within an exposure–dose–response paradigm. Indeed, some scientists and agencies have taken a view that they will first conduct a long-term bioassay using only an exposure metric (i.e., mg of agent/m^3), and if the bioassay is positive, then they will conduct a toxicokinetic study to try to understand the exposure–response outcome. The experience with internally deposited radionuclides suggests that future studies of the toxicity and human health risks of chemicals should be anchored in the exposure–dose–response paradigm to be most fruitful.

Experience with internally deposited radionuclides has given clear evidence that the radiation quality and dose rate at which ionizing radiation is delivered to specific organs and tissues have a major impact on the effectiveness of the absorbed dose for producing either acute or chronic adverse effects over and above the background incidence of disease. Considering first radiation quality, is it possible that a broad class of chemicals operate via mechanisms analogous to alpha-emitting radionuclides, while other classes of chemicals are more analogous to the beta-emitting radionuclides? Recall the alpha-emitting radionuclides were about 10–20 times more potent than the beta-emitting radionuclides in causing cancer. Considering dose rate, is it possible that the influence of exposure rate for chemicals might be better understood if more attention was given to the absorbed dose rate in specific tissues and organs for chemicals? Recall that beta-emitting radionuclides had a factor of 4 differences in cancer-inducing potency related to the rate at which the radiation dose was delivered.

As clearly demonstrated by the data reviewed in this chapter, the health effects of internally deposited radionuclides can be conveniently grouped into deterministic effects with clear threshold dose–response relationships and stochastic effects, such as cancer, that have dose–response relationships best described with linear or LQ models of dose-ERR and an inability to ascertain, because of statistical limitations, if a threshold exists at low doses and low dose rates. The studies of internally deposited radionuclides that have yielded the most useful data for analyzing dose–response relationships have had dose data on individual subjects, irrespective of whether they were human subjects in an epidemiological study or dogs in a controlled exposure study. Some of the most fruitful analyses have used RR models; absolute risk models have not been as informative. Unfortunately, RR models have rarely been used in chronic chemical toxicity studies, especially experimental studies. No doubt this relates to the past focus on using chronic bioassays to identify health hazards including cancer induction rather than to understand exposure–dose–response relationships. Perhaps greater use should be made of chronic studies with chemicals that are specifically designed to understand exposure–dose–response (relative to background incidence) relationships for at least a few purposefully selected specific chemicals. The obvious candidates based on the radiation experience would be to study chemicals for which there is a strong base of exposure–dose–response data for human populations.

As noted repeatedly in this chapter, ionizing radiation is a relatively weak carcinogen. I would argue that most chemicals with the exception of a few purposefully active pharmaceuticals and perhaps a few *legacy* chemicals are likewise not very potent in causing cancer or other effects, and moreover, effects are only observed under conditions of high exposure rates and high cumulative exposures. *Blockbuster* exposures used in many animal and cellular studies are many times higher than likely to be experienced by most potentially exposed human populations. I question whether the mechanisms observed in these kinds of studies designed within the context of deterministic outcomes are relevant to understanding potential stochastic effects in which the ERRs are very small and occur randomly. Perhaps the time has arrived, with new molecular techniques emerging at a rapid pace, to rethink our experimental approach to studying both radiation and chemicals as

to their stochastic effects, such as cancer, which appear as a small excess late in life. Recall within the context of attributable risk the results of the 58-year follow-up of the Japanese A-bomb survivors. Irrespective of how exquisite the methods might have been used to evaluate each and every cancer, only about 5% of the cancers on a statistical basis have been attributed to radiation. The experimentalist studying tissues from deceased individuals is not able to determine which of the cases are radiation induced; they are only known in a statistical sense. I suggest it may be productive to take time out to explore some new approaches to studying both radiation- and chemical-induced excess disease. Indeed, a possible outcome is to conclude that enthusiasm for an agent-oriented focus on attributable disease may be misplaced and that greater benefits to society will be achieved if the focus is redirected to the multifactorial etiology of disease recognizing the complex family of disease in multiple sites and organs (Vogelstein et al. 2013). It is clear that science has not revealed the etiology of most cancers. It has revealed that radiation exposures are a minor etiological factor. In my opinion, the same can be said with confidence for exposure to chemicals.

It is true that life exists in a sea of radiation, radioactivity, and chemicals for most populations. Moreover, all living things consist of chemicals constantly undergoing complex interactions microsecond by microsecond in an elegant and well-controlled manner consistent with population having healthy lives that extend on average over 75 years in most industrialized countries. Fortunately, those well-controlled mechanisms function appropriately most of the time in complex mammalian organisms with only the infrequent occurrence of life-threatening diseases as a result of low-level exposures to radiation, radioactivity, and exogenous chemicals. Thus, these agents make small contributions to the burden of disease in advanced countries. Unfortunately, that reality is absent from the planning of most research, and the subsequent introduction or conclusions of the papers describing the research, the papers usually start by noting concern for exposure to radiation or chemicals. Perhaps the scientific community, when broadly championing the need for more research on these agents, inadvertently contributes to radiation phobia and chemical phobia.

SUMMARY

The goal of this chapter has been to provide the reader with an understanding of the health effects of ionizing radiation within the context of the multiple sources and uses of radiation and radioactivity. The distinction has been made repeatedly between radiation and radioactivity and between irradiation from external sources and internally deposited radionuclides. The chapter began with a review of the remarkable history of ionizing radiation noting key landmark events linked to creating sources of exposure to external radiation and internally deposited radionuclides and elucidating associated health hazards and risks. Roentgen's discovery of x-rays led to the rapid application of radiation in key diagnostic and therapeutic procedures that soon became central to the practice of medicine. Somewhat later, the first major nonmedical usage of radioactive materials began when instrument dials were painted with radium to make them luminous. Unfortunately, the discovery of the injurious effects of external radiation exposure and internally deposited radionuclides, especially their cancer-causing potential, accompanied these beneficial applications of radiation.

The discovery of nuclear fission in 1937 served as a benchmark for another radiation era. This soon led to controlled nuclear fission, the production of ^{239}Pu and ^{235}U as fissile materials, the development of the A-bomb, and its use in bombing two Japanese cities. Out of this tragedy came the remarkable epidemiological data on the A-bomb survivors, data that today serve as a cornerstone of our knowledge of the late-occurring effects, both cancer and noncancer, of brief exposure to external radiation. This data set, its analyses, and interpretations are the foundation of radiation protection standards used around the world. Data on the cancer-causing effects of exposure to radon and its daughter products provide complementary data on a unique radiation risk. Quantitative data on exposure–radiation dose to tissues–health effects acquired principally from LSS conducted in beagle dogs and epidemiological observations on a few key radionuclides are central to today's understanding of the health risks of internally deposited radionuclides.

Without question, ionizing radiation has been studied far more extensively than any other toxic agent. Despite the extraordinary amount of information acquired on radiation-induced disease, especially cancer, uncertainties remain and most of all clamorous debate continues on the precise nature of the dose–response relationship for ionizing radiation at low radiation doses to various organs and especially radiation doses given at very low radiation dose rates similar to background levels. Despite the uncertainties, it is apparent that ionizing radiation is a relatively weak carcinogen and even weaker toxicant in producing noncancer effects at low dose rates and total radiation doses. It is my professional opinion that there is a very low probability that the health risks of low radiation dose rates and total radiation doses have been underestimated using an LNT model, including its use for extrapolation to exposures below 0.1G and above background levels. Unfortunately, this viewpoint is frequently lost in the scientific and policy debates over the setting of radiation protection standards, the conduct of risk assessments, and the frequent call for more research.

The major questions concerning radiation and health risks and the use of nuclear technology relate to policy decisions that should be informed by the already abundant science on radiation-induced disease. Scientific information alone, no matter how precise or elegant, is insufficient for making those policy decisions that are concerned with very low levels of extrapolated risk relative to the inherent everyday risks of life and the central policy question: "What is an acceptable level of risks for a particular agent, action, or technology?" Scientific knowledge can inform the policy decisions at the core of that question, and science *cannot* answer that question!

QUESTIONS

18.1 What are the differences between deterministic and stochastic effects of radiation exposure and the dose–response relationships used to model the two kinds of effects?

18.2 Describe the fundamental differences between dose rate and pattern of total dose accumulation for the thyroid from a brief exposure to x-irradiation versus ^{131}I when the total delivered dose is 100 mSv? For a population of 10-year-old children, discuss the likelihood of either exposure producing an excess of thyroid cancer.

18.3 Which radionuclides, when ingested or inhaled in a soluble form, behave like potassium, calcium, and iodine?

18.4 Describe the evidence supporting the statement that radiation is a weak carcinogen.

18.5 Discuss the concept of hormesis. If you believe that radiation hormesis should be used in setting regulatory standards for radiation exposure, describe your proposed regulatory scheme.

18.6 Brief whole-body exposure to x-irradiation at sufficiently high doses has the potential for causing an increase in the incidence of cancer and heritable effects. Discuss the evidence for both health endpoints being observed in large populations whose total dose was 1 Sv.

18.7 Discuss the agricultural ecosystem pathways for human exposure to accidental releases of ^{90}Sr, ^{131}I, and $^{134,137}Cs$, including potential steps that should be taken to reduce exposures and dose to critical tissues.

18.8 Describe the evidence supporting the statement that the results of studies with beagle dogs exposed briefly to ^{239}Pu are reliable predictors of the effects of human inhalation exposures to ^{239}Pu aerosols.

19 Plant and Animal Toxins

Frederick W. Oehme, Daniel E. Keyler, and A. Wallace Hayes

CONTENTS

TOXINS IN NATURE

Nature is beautiful, but is it always safe? Nature and things natural can be hazardous and risky if individuals are not informed and constantly aware of the dangers lurking in the green foliage, the crystal clear waters, and the bushes and rocks!

Naturally occurring toxins may be grouped into those originating in plants, algae, fungi, bacteria, and various members of the animal kingdom. The natural hazards of bacterial toxins and those from fungal toxins in the category of mycotoxins will be discussed in Chapter 19. This contribution will present the toxic hazards from plants, algae, mushrooms, and toadstools and hazards from animal-origin toxins.

The toxins from such widely diverse naturally occurring organisms can be found throughout our environment. Foliage may have a variety of toxic plants, waters can carry algae, and where moisture is, various hazardous fungi may grow. The dry land may harbor reptiles, amphibians, spiders and insects, and even mammals capable of inflicting injury. Animals found in waters include various invertebrates and vertebrates found in oceans, shellfish, and fish carrying toxins from other sources and such unsuspected bearers of poisons such as sea turtles, polar bears, seals, and walruses.

In short, naturally occurring toxins are everywhere and have continuing potential for intoxication.

Natural toxicants (toxins) are unique in that they exist in the organism's structure, yet are not harmful to that host. They are also special in that individuals potentially affected by these natural toxins may become exposed by consuming the toxin-bearing material, such as when consuming poisonous plants or toxic marine animals, by receiving skin contact and producing durable irritation or traumatic injury, such as occurs from poison ivy or blistering agents in plants or from cactus spines penetrating body surfaces, or most commonly such harmful effects result from animals carrying venoms and producing envenomations (injections) through stings, bites, or other delivery systems. In many cases, these delivery systems are specialized to cause reactions on contact, embed materials that are then released by the victim's biological tissues, or result in direct administration into the victim's body tissues and fluids. As in all areas of toxicology, the amount of exposure or dose delivered to the victim largely determines the resulting clinical effect.

Exposure to toxins present in nature is in many cases accidental, as persons collecting green plants mistake a toxic variety for a similarly appearing green food plant. Individuals may elect to chew and swallow plants because of ignorance. In some cases, the use of native herbal medications produce hazards due to selecting inappropriate natural materials and/or poor approximation of amounts to include in various preparations. In other instances, malicious use of natural toxins may be involved in homicidal or retaliatory actions. One way or another, these natural materials when introduced into the human body are capable of producing mild, moderate, or lethal effects.

Naturally occurring toxins are complex. Unlike synthetic compounds used for therapeutic or specific chemical needs, toxins from plants or animals are mixtures of organic, proteinacious, enzymatic, and even mineral materials that are present in various proportions that fluctuate with the individual plant's or animal's maturity, location, species, and the various life changes that growing and maturing organisms go through. The relative proportion of the numerous components in these toxic *packages* varies sufficiently so that their impact upon biological systems is not only affected by the quantity administered but also by the relative proportion of each of the components in the mixture. At any one time, the dose received from a specific animal envenomation or plant weight will fluctuate significantly—so that an exposure to the same amount of a specific plant will not always produce the same biological effect. This creates significant problems when attempting to identify the toxic components of naturally occurring materials. Fractionation of the *mixed bag* of components in any toxic mixture thus becomes problematic when trying to work specifically with the active component responsible for a specific harmful effect. It also impacts the resulting toxicity since the dynamics of the clinical impact fluctuate with these various factors and often require that evaluation of toxicity be based on potential effects or the observation of the direct impact made by the exposure. A single bite from a known poisonous snake does not always induce toxicity or an expected amount of damage. The ingestion of a known amount of a recognized poisonous plant may not induce toxicity or may indeed cause more life-threatening damage than previously documented.

So why are these toxic and often lethal components present in these organisms? One could make the point that they are there *just because* and are part of the organism's normal body component of compounds needed for appropriate functioning. Their introduction into human systems and their adverse effect is just an unfortunate coincidence! Others might argue that the compounds' present is a defensive mechanism to avoid consumption or destruction by other organisms or predators; essentially providing a *distasteful* menu. Others see the types of chemicals present as weapons to be used by the organism, for example, a rattlesnake, to defend itself against predators or other individuals. *Defensive* then is to discourage attack by or consumption from other individuals. Certainly plant toxins have that coincidental effect by keeping browsing animals from consuming plants that produce illness in that species. Finally, the use of venoms or poisons to immobilize animals or fight off other animals is a view into the real world of nature; securing an appropriate diet or nutritional force involves capturing a victim and consuming it as needed. Interestingly, animals consuming prey that their bites have made available for consumption have little impact upon the consuming animal that has just envenomated the victim. Being able to consume one's own poison seems the ultimate path of self-preservation!

The vast amount of information to be gained from the study of these naturally occurring poisons has evolved into a highly specialized and unique aspect of science. The variety of fractions found in venoms and toxic plant materials has required elaborate instrumentation, knowledge, and expertise to deal with the understanding of how and why these toxic materials exist in nature. This study is *Toxinology* and has a broad scope of interest and impact. The science varies geographically and as widely as the range of toxic plant and animal species. The science has a unique and widely respected journal, *Toxicon* [1], and has wide applicability to not only understanding our own environment but also the components of nature and their potential harmful and more recently important beneficial contributions to the human race.

Toxinology seeks to understand the mechanism by which these widely diverse and selective natural chemicals produce their effect. Isolation of various components and demonstrating their structure and biological effects are exciting activities that keep individual scientists busy with one species of organism over a lifetime. The information is used to apply the individual venom or toxin components to potential treatments and use in biomedical research or treatment of human or animal diseases. The Southeastern pygmy rattlesnake possesses a venom containing eptifibatide that reduces the blood clotting process allowing blood to flow more freely by reducing the number of platelets. The drug (Integrilin) is used to reduce the risk of acute cardiac ischemic events in patients with unstable angina or non-ST-segment-elevation

myocardial infarction both in patients who are to receive nonsurgery medical treatment and those undergoing percutaneous coronary intervention. Understanding venoms and their chemical structure and function allows the production of antivenins through manipulation of animal and biological systems. A presence of such materials can be lifesaving in treatment of human animal bites and serious illnesses. The explosion in the use of *botox* for cosmetic surgery and treatment of various neurological disorders is a special example of how such applicability of natural toxins will evolve in future years. As these biological processes are better understood and the individual venom components become identified, their application and use in human medicine and in therapy for natural intoxications will be exciting and of significant health benefit.

Understanding the toxins from plants, algae, fungi, and animals is the substance of the remainder of this chapter.

TOXINS FROM PLANTS

Ever since the frequency of exposures of humans to toxins has been tallied, plants have ranked among the most frequent causes of exposures to toxic substances. In 2011, plants were the eleventh most common cause of human exposures with 47,561 instances—2.2% of the total exposures—reported in the American Association of Poison Control Centers, Toxic Exposure Surveillance System, Annual Report [2]. At the same time, plants and their chemical composition have been investigated for the potential of providing new medical agents and derivatives to treat illnesses and have been an ever common component of herbal drugs and folk medicines. From previous times and cultures, the herbalist-healer has gathered leaves, roots, blossoms and bark to brew remedies, potions, and elixirs with mixed results. Now, alert clinicians have observed that while some of these herbals seem to work well, and others fail, many at best exert a positive placebo effect… while others induce illness! Plants are a true example of balm or poison. A balance is needed to receive beneficial effects versus life-threatening doses from these tricky poisons.

Only very small amounts of some plant parts (flowers, fruits or berries, leaves, stems, bark, or roots) may be toxic and produce illness or even rather dramatic effects. Some plants are poisonous if they are chewed or swallowed. Others cause poisoning by initiating allergies, dermatitis, or mechanical injury due to spines or needles. Some plants are harmful only if eaten or chewed at certain stages of their growth; others are toxic at all stages of development. Thus both the species of the plant and its stage of growth or the season of the year in which exposure occurs is important in determining the potential toxicity.

Of the many plant varieties, only a relatively small number are truly poisonous and develop life-threatening effects. A few pose a serious threat to life or health, but among those few are some widely cultivated flowers, vegetables, and ornamental plants. Some of them are household plants in which specimens may come from Maine or California. Together with the toxic flora of field and forest, they represent an abnormal potential for poisoning, particularly in small children who are apt to appreciate beauty by chewing on it.

Species of the plant, its stage of growth, and the season of the year are all important factors in evaluating potential plant poisonings. In some cases, the part of the plant that is eaten also matters. For example, all portions of the potato plant…except the actual potato…are poisonous; the leaves of a rhubarb plant are highly dangerous despite the fact that the stalks make delicious pies. The only reliable rule is not to eat anything that you're not absolutely sure is safe! [3]

And while human beings are a major focus of toxicology, animals that are outdoors and those that consume plants as part of their natural dietary intake, are at severe risk for consuming *a salad bar* of potential hazards. Of the approximately 1000 recognized poisonous plants that grow in North America, all are unique in becoming toxic to animals and particularly livestock that managers commit to pastures and ranges for their dietary needs. Each year significant economic loss occurs to these animals. Estimates of specific losses are difficult to ascertain, but estimates of the losses caused by poisonous plants in only the 17 western states are dramatic. One percent of the death loss in cattle is attributed to toxic foliage; one percent of the loss of calves from abortions or illnesses surrounding births is estimated due to plants; 3.5% death loss is estimated produced in sheep by plants; and 1% loss of pregnancy potential and newborn lambs is estimated to occur in sheep from poisonous plants. A total economic loss of over $250 million is the best estimate available for poisonous plant damage produced in our 17 western states [4]. When one appreciates the fact that poisonous plants do not always produce death, but depending upon consumption of varying amounts may produce no clinically observable damage but yet reduce weight gain and economic productivity, the losses estimated may reasonably be expected to be considerably greater.

So what are the types of chemicals involved in potential poisonous plant chemistry and toxicity, and what are the plants that produce poisoning if ingested or placed in contact with the human body?

Although it is unusual to have a natural occurring chemical present in only one plant, so too it is equally unusual for any one toxic substance to be uniquely found in only one plant species. Indeed, it is the common finding that most plants have several toxic components present. It is only the distribution of those materials and their concentration in various parts of the plant and at various stages of growth that present the hazard. Consuming berries at an early stage of development may be highly toxic, while once the berries are ripe and are in full bloom toxicity may be reduced. The concentration of the toxin may have distributed from the unripe berry to the stems or to the roots. Not to be outdone, the plant that previously was highly toxic in the young stage by consuming leaves, may now be innocuous when the leaves are consumed, but when the seeds are digested acute toxicity may occur. In each of these examples, the concentration and the type of poison vary with each environmental circumstance. Hence, as consideration is given to the various

chemicals present in plants, one must recognize the content of more than one toxic factor being present and the likely toxicity is dependent upon which toxin is present in the highest concentration and which portion of the plant is consumed by the potential victim.

Toxic Chemical Principles in Plants

The toxic principles in poisonous plants carry many names, some actually present due to plant biochemistry, while others are present in the soil or water nourishing the plant and have been accumulated in the growing foliage. With such a heterogeneous potential for effects, it is understandable that numerous categories of chemical principles and components have been listed as present in plant poisonings. Most contain numerous derivatives and related compounds. A general listing includes alcohols, various alkaloids, amines, anticholinergics, glycosides and glucosides, mechanical injury vectors and associated chemicals, minerals associated with plant growth and incorporated into plants, oxalates, various compounds capable of producing photodynamic pigments and resulting photosynthetization, polypeptides, various resins and resinoids, saponins, and toxalbumens. Others capable of carrying enzymatic properties, hormones, phenolics, and unusual nitrogen compounds are also potentials present.

Alcohols

Alcohols are organic compounds formed from hydrocarbons and founds in species of golden rod and snake root. Tremetol is a specific alcohol that is passed in milk and induces neurological effects in humans and animals consuming the toxin-containing milk.

Alkaloids

The alkaloids are a widely disseminated group of various chemicals found in numerous plants. Their presence in concentration is only mildly influenced by the climate and availability of water, but varies greatly with the species and variety of plants studied. They are widely distributed throughout the plant's structure and only produce strong physiological reactions in consuming individuals. The toxicity induced varies from neurological through liver to kidney damage, and includes the veratrum alkaloids, those found in *Aconitum* species, nicotine, coniine, and those present in *Crotalaria*, *Senecio*, potatoes and tomatoes, lilies, and the highly toxic Japanese yew (*Taxus*). As continuing studies occur on the chemistry of plants, new alkaloid compounds are being discovered and added to this list.

Amines

Amines are only a small number of the toxins found in plants, but many foods contain pressor amines, which constrict blood vessels and increase blood pressure. Individuals medicated with tranquilizers or antidepressants, which inhibit monoamine oxidases and thus induce clinical problems. Generally, the toxic amines affect skeletal or nervous tissue and are found in sweet peas (*Lathyrus*) and mistletoe (*Phoradendron*). A number of plants exhibit anticholinergic properties through their content of atropine or scopolamine. These principles are commonly found in deadly nightshade (*Atropa belladonna*), Sacred datura (*Datura metaloides*), Jimson weed (*D. stramonium*), Trumpet lily (*D. arborea*), Angel trumpet (*D. candida*, *D. suaveolens*), other *Datura* spp., Henbane (*Hyoscyamus niger*), Matrimony vine (*Lycium barbarum*), and Mandrake (*Mandragora officinarum*). The entire plant is toxic, although the flowers, fruits, and seeds are especially high in the atropine-like principles. Agitation, hallucinations, flushed skin, dry mucous membranes, elevated heart rates, and dilated pupils are common effects. These plants account for many admissions to critical care units and are often associated with patients who have ingested seeds or brewed tea made from the seeds. Although death is rare, serious injuries result from the impaired judgment and functionality present in affected victims.

Glycosides

Naturally occurring glycosides are widely distributed in the plant kingdom as probably the most common and largest group of toxic compounds found in plants. Although many are nontoxic, wide varieties do have toxic effects upon ingestion or other exposure. The amount of a particular glycoside present again depends on the plant genetics, the portion of the plant being sampled, and the plant's age, as well as factors such as climate, soil fertility, and available moisture. Toxicity from this group is a function of the aglycone component or a part of it. Numerous groups of toxic glycosides have been identified: coumarin and vanillin glycosides (sweet clover, laurel, horsechestnut); the cyanogenetic glycosides that contain or liberate each hydrocyanic acid (velvet grass (*Holcus lanatus*), hydrangea (*Hydrangea* spp.), flax (*Linum* spp.), cassava (*Manihot esculenta*), lima bean (*Phasecolus lunatus*), cherries (*Prunus* spp.), apple (*Pyrus malus*), sudan grass, Johnsongrass, etc. (*Sorghum* spp.), poison suckleya (*Suckleya suckleyana*), white clover (*Trifolium repens*), arrowgrass (*Triglochin* spp.), vetch seed (*Vicia sativa*), maize, corn (*Zea mays*)); gloiterogenic glycosides [chard (*Beta vularis*), rape seed or meal (*Brassica napus*), black mustard seed (*Brassica nigra*), kale (*Brassica oleracca* var. *acephala*), Chinese cabbage (*Brassica pekinensis*), turnip root (*Brassica rapa*), soybean (*Glycine max*)); irritant oils derived from mustard oils (horseradish (*Armoracia*), white mustard (*Brassica hirta*), Indian mustard (*Brassica juncea*), wild radish (*Raphanus raphanistrum*), fanweed (*Thlaspi arvense*)), and those containing the volatile, unstable protoanemonin oil released from the glycoside ranunculin (marsh marigold (*Caltha palustris*), buttercups (*Ranunculus* spp.)); the steroid glycosides, which contain the poison category of cardiac toxins capable of stimulating or disrupting cardiac function (dogbane (*Apocynum* spp.), lily-of-the-valley (*Convallaria majalis*), foxglove (*Digitalis purpurea*), oleander (*Nerium oleander*), squill (*Urginea maritima*))—the plants containing grayanotoxins (rhododendrons, azaleas *Rhododendron*, sheep laurel, mountain laurel (Kalmia), and andromeda *Pieris*) are also potent cardiotoxic containing plants but not

from steroid glycosides—and noncardioactive saponin steroid glycosides that are not easily absorbed but have additional toxins that injure the digestive tract to allow entrance into the blood stream (corn cockle (*Agrostemma githago*), English ivy (*Hedera helix*), alfalfa (*Medicago sativa*), pokeweed (*Phytolacca americana*), bouncing bet, cow cockle (*Saponaria* spp.), coffeeweed, rattlebox (*Sesbania* spp.).

Mechanical Injury

Some plants may inflict injury through mechanical processes that then allow additional adverse effects to occur. The nettle (*Urtica chamaedryoides*) is a common example as it bears stinging hairs that contain significant amounts of acetylcholine and histamine that induce serious reactions. Other plants having such mechanisms include anemone (*Anemone patens*), poverty grasses, awns (*Aristida* spp.), squirreltail barley, barbed awns (*Hordeum jabatum*), foxtail grasses (*Setaria lutescens*), needle grasses (*Stipa* spp.), cocklebur (*Xanthium* spp.), and burdock (*Arctium lappa*).

Mineral Toxicities

Plants may become toxic secondarily through accumulation of minerals found in soil at high concentration. Chief among those elements are nitrogen, which is accumulated in those plants as nitrate, and selenium, which has varying amounts in soils depending on geologic formation and rainfall. Plants that frequently contain toxic concentrations of nitrates include pigweeds (*Amaranthus* spp.), bishop's weed (*Ammi majus*), tarweed (*Amsinckia* sp.), pigweed, lamb's quarters (*Chenopodium* spp.), Canada thistle (*Cirsium arvense*), poison hemlock (*Conium maculatum*), bindweed (*Covolvulus* spp.), Jimson weed (*Datura* spp.), fireball (*Kochia scoparia*), sweetclover (*Melilotus officinalis*), smartweeds (*Polygonum* spp.), dock (*Rumex* spp.), Russian thistle (*Salsola pestifier*), annual sage (*Salvia reflexa*), elder (*Sambucus pubens*), nightshades (*Solanum* spp.), goldenrods (*Solidago* spp.), and Johnsongrass (*Sorghum halepense*). In addition, certain crops will also accumulate exceedingly high levels of nitrate depending upon the environmental conditions and the availability of nitrogen. Some of these are oat hay (*Avena sativa*), beet and mangoid (*Beta vulgaris*), broccoli, kale, etc. (*Brassica oleracea*), turnip (*Brassica rapa*), soybean (*Glycine max*), barley (*Hordeum vulgare*), sweet potato vines (*Ipomoea batatas*), alfalfa (*Medicago sativa*), radish (*Raphanus sativus*), sudan grass (*Sorghum vulgare*), wheat (*Triticum aestivum*), and corn (*Zea mays*).

Plants taking up selenium are of significant concern to livestock and also to humans who might utilize these high selenium-containing forages. Crops that may do so include poisonvetches (*Astragalus*), prince's plume (*Stanleya*), goldenweeds (*Oonopsis*), woody asters (*Xylorrhiza*), aster (*Aster* spp.), saltbushes (*Atriplex* spp.), gumweeds (*Grindelia* spp.), snakeweed (*Gutierrezia* spp.), tansy aster (*Machaeranthera* spp.), and beard tongue (*Penstemon* spp.).

Other elements found in soil or the environment may contaminate plants or produce toxicity. Such elements include cadmium taken up from fertilizers in which the metal impurity is present, copper from copper-rich soils or copper-containing pesticide use, fluoride from fluoride-containing soils, rock formations or industrial influence contaminating the soils, lead from surface contamination from smelters or lead-containing mine debris, and molybdenum found in soils abnormally high in this element.

Oxalates

The organic acid oxalates found in plants occur in the form of soluble sodium and potassium salts or insoluble calcium oxalates or acid oxalate. Although small amounts of oxalates are found in many plants, several of them will have increased oxalate content depending on the season and geographic location. Highest oxalate concentrations are in late summer and fall in the leafy stage of plant growth. The resulting toxicity may occur from the soluble oxalate salts that enter the bloodstream and later are precipitated in the kidney, or as firm calcium oxalates or acid oxalates that irritate oral membranes on contact, producing burning and irritation upon chewing. The common plants containing variable amounts of soluble oxalates include beet, mangold (*Beta vulgans*), lamb's quarters (*Chenopodium album*), halogeton (*Halogeton glomeratus*), sorrel, sour sob (*Oxlais* spp.), pokeweed (*Phytolacca americana*), rhubarb (*Rheum rhaponticum*), sorrel, dock (*Rumex* spp.), greasewood (*Sarcobatus vermiculatus*), and spinach (*Spinecia oleracea*). Common plants containing the insoluble oxalates producing irritation on mucous membrane contact are jack-in-the-pulpit (*Arisaema* spp.), caladium (*Caladium* spp.), dumbcane (*Dieffenbachia* spp.), philodendron (*Philodendron* spp.), skunk cabbage (*Symplocarpus foetidus*), and caladium (*Xanthosoma* spp.).

Photosensitivity-Inducing Plants

Photosensitivity from plant substances is an interesting phenomenon in which individuals become hypersensitive to sunlight due to the presence of plant-originating material in the peripheral circulation. This may be produced by plants carrying specific photosynthesizers in themselves that directly produce the hypersensitivity, plants that have additional compounds that by themselves produce liver dysfunction with no photodynamic activity but the damage resulting retards elimination of plant materials and allows them to reach the peripheral circulation thus inducing photosynthetization, or due to congenital metabolic defects that allow the accumulation of photodynamic pigments within the individual circulation. Plants producing these types of photosynthetization risks include buckwheat (*Fagopyrum sagittatum*), St. Johnswort, Klamath weed (*Hypericum perforatum*), lechuguilla (*Agava lechaguilla*), cultivated rape (*Brassica napus*), lantanta (*Lantana* spp.), horsebrush (*Tetradymia* spp.), water bloom (*Species of bluegreen algae*), oats (*Avena sativa*), milk purslane (*Euphorbia maculata*), alfalfa (*Medicago sativa*), smartweeds (*Polygonum* spp.), summer cypress (*Kolchia scoparia*), sudan grass (*Sorghum vulgare* var. *sudanese*), clovers (*Trifolium* spp.), and vetches (*Vicia* spp.).

Phytotoxins

Phytotoxins are large, complex molecules similar to bacterial toxins in structure and reactions. They are antigenic with protein-like characteristics that have resulted in the terminology "toxalbumins" used as a designation for this group of plant toxins. Some of these plants have the highest concentration of the poison present in the seeds, such as in castor bean (*Ricinus communis*) from which commercial castor oil is produced. Such plants include precatory bean, rosary pea (*Abrus precatorius*), castor bean (*Ricinus communis*), and black locust (*Robinia pserudoacacia*). The toxin ricin has been specifically isolated as the toxin in castor bean. The highly potent nature of these phytotoxins has attracted attention from defense groups dealing with potential use by terrorists.

Polypeptides

Only a small number of plants containing poisonous polypeptides are currently known. These include mushrooms, blue-green algae, soybeans, potatoes, lima beans, kidney beans, unripe bananas, mangos, and some legumes. Significant consumption for several days is usually required to induce toxicity.

Resins and Resinoids

This heterogeneous group of compounds has the physical characteristic of being solid or semisolid at room temperature, easily melted or burned, being soluble in organic filaments and not containing nitrogen. They tend to be oily or greasy upon extraction and induce variable degrees of toxicity in both potency and clinical effects. Such compounds are found in milkweed (*Asclepias* spp.), hemp, marijuana (*Cannabis sativa*), water hemlock (*Cicuta* spp.), iris (*Iris versicolor*), laurel (*Kalmia* spp.), Japanese pieris (*Pieris japonica*), pine (*Pinus* spp.), laurel, rhododendron (*Rhododendron* spp.), and Japanese wisteria (*Wisteria floribunda*).

Others

There are various other poisonous principles that produce toxicity in often unique ways specific to that individual plant. Some contain enzymes that induce neurological deficits or cancer (bracken fern (*Pteridium aquilidum*); horsetails (*Equisetum* spp.); male fern (*Dryopteris felix-mas*)). The polyphenolic gossypol is found in the seed of cotton (*Gossypium* spp.) and is responsible for commercial applications in human medicine as well as toxicities in all species. Unusual nitrogen compounds are found in some of the legume family foliages (creeping indigo (*Indigofera spicata*); sweet pea (*Lathyrus*); Koa hade (*Leucaena leucocephela*)) producing specific effects on pregnancy, the nervous system, hair follicles, and general health. Estrogenic factors are found in subterranean clover (*Trofolium subterraneum*). The toxic factor found in the cotyledon stage of cocklebur (*Xanthium strumarium*) produces rapid weakness and even death in consuming individuals.

As clinical observations become more extensive and astute, and as analytical chemistry become more specific, no doubt additional toxic components will be identified and related to the varying illnesses and conditions associated with plant exposure and consumption.

Organ Systems Affected

The complexity and variability of the various compounds present in plants result in most plant varieties being capable of inducing more than a single effect and producing several system-specific adverse changes. Depending upon the toxin's presence and their individual concentrations, such harmful effects may influence every organ system in the body individually or as a complex combination of various systemic effects.

Gastroenteritis-Inducing Plants

The majority of plant intoxications occur from the ingestion of plants containing gastroenteric irritants. Symptoms range from burning in the mouth and throat when chewing the leaves of such common household plants such as the vine growing on a windowsill (*Philodendron* spp.) or the dumbcane (*Dieffenbachia* spp.) in the big pot by the front door to severe vomiting, intestinal cramping, and purging diarrhea from the fresh roots and stems of the pokeweed (*Phytolacca americana*), Wisteria seeds, the berries of the spurge laurel (*Daphne* spp.) or the leaves of buttercups (*Ranunculus* spp.).

The onset of the irritant's response is variable since it depends upon the nature of the toxin, possible requirement for activation of the irritant, and the various mechanisms that may illicit emesis or gastroenteritis, thus modifying the clinical response. Plants that cause minor abdominal discomfort in an adult may provoke profound emesis and diarrhea in a small child. Since dehydration and electrolyte imbalance can develop rapidly, it may be necessary to institute replacement therapy promptly to prevent shock.

Serious intoxications are produced by plants containing toxalbumins, for example, the rosary pea (*Abrus precatorius*) and the castor bean (*Ricinus communis*). Following ingestion of the chewed seeds of either of these plants, there may be considerable delay prior to the onset of effects; this is related to the quantity of material present in the chewed seeds. Typically the latent period is about 2 h, but it may be a day or more. The clinical picture is one of severe hemorrhagic gastroenteritis with persistent nausea, emesis, colic, and profuse diarrhea. Dehydration may result in oliguria and cardiovascular collapse. In nonfatal cases, the period of illness varies from 2 to 10 days.

Rosary pea seed, precatory bean (*Abrus precatorius*), contains a phytotoxins that is related to the botchulinum toxin. It produces nausea, colic, diarrhea, weakness, and trembling with a hemolytic anemia and ultimately uremia in severe cases.

Poinsettia (*Euphorbia pulchenima*) has irritating saps in the leaves and stems that lead to vomiting and delirium in patients who are ill for several days.

Philodendron (*Philodendron* spp.) has calcium oxalate crystals that severely affect kidney function and induce listlessness and potentially uremia in severely intoxicated patients.

Dumbcane (*Diffenbachia* spp.) contains insoluble oxalate crystals that are not absorbed but are a severe contact irritant. Swollen mucous membranes of the mouth and throat result that may induce suffocation from the respiratory tract swelling that occlude airways.

Ivy (*Hedera helix*) contains saponic glycosides in the berries. This plant then induces severe diarrhea and may contribute to excitement and excessive nervousness in poisoned individuals.

Lantana (*Lantana camara*) has an alkaloid in the unripe berries and clippings. It is a commonly available plant that in low doses of intake produces mainly digestive tract irritation with some photosensitization leading to sunburn and dermatosis. If large amounts are consumed, circulatory collapse and muscle weakness develop that borders on life-threat.

Daffodil (*Narcissus*) is a common plant with a prominent bulb-like root. It has a potent alkaloid in high concentrations in the bulb. Ingestion or chewing on this bulb induces repetitive and prominent vomiting and digestive tract irritation.

Rhubarb (*Rheum rhaponticum*) is well known for containing high levels of oxalic acid in the leaf blades. This acid is highly irritating and produces severe abdominal pain that proceeds to vomiting, convulsions, anuria, coma, and death as the oxalate crystals occlude to the tubules, ultimately producing uremia.

Pokeweed (*Phytolacca americana*) has a prominent alkaloid (phytolaccatoxin) in all plant parts. Although the roots are most toxic, the prominent deep purple berries fortunately contain lower concentrations of the alkaloid; however, because of their attractiveness, the berries are most frequently eaten. The alkaloid produces gastrointestinal signs that often extend to inducing spasms and convulsions with respiratory paralysis occasionally developing into anoxia.

Death camas (*Zigadenus* spp.) is another plant with a bulb-like root that resembles an onion. It is frequently collected as a *wild onion* and then incorporated into cooked stews and soups. Unfortunately, the alkaloid is not significantly changed by the heating process and prominent gastrointestinal effects result from consumption. The vomiting and diarrhea it produces is often lifesaving by rapidly removing the alkaloid from the intestinal tract.

Mayapple (*Podophyllum peltatum*) contains a resinoid in high concentrations in the root. The rest of the plant is nontoxic and is the most commonly utilized portion. If the root is used as a food material, violent purgative effects result from the resinoid properties.

Castor bean (*Ricinus communis*) has the prominent phytotoxins ricin in the seeds. This is a plant protein that induces all the effects that protein materials induce: gastrointestinal effects are prominent, yet fever, red-blood cell hemolysis, and with high doses, severe convulsions are induced.

Elderberry (*Sambucus americana*) is prominently known for inducing gastrointestinal involvement, yet the toxic principle has not been specifically identified. Based upon exposures, it is apparently present in all parts of the plant but remains an unknown. Elderberry also contains some cyanide that fortunately is volatilized by heating or through the fermentation process.

Daphnea (*Daphne* spp.) contains irritating glycosides, particularly dihydroxycoumarin, in the berries and bark of the plant. These compounds produce severe gastrointestinal irritation and bloody diarrhea is a common effect from significant ingestion.

Wisteria (*Wisteria sinensis*) is another plant with an unidentified toxin in its seed. What is clear is the gastrointestinal irritation that results from ingestion and the neuromuscular collapse that occasionally follows with initial consumption or frequent repeated exposures.

Black locust (*Robinia seudoccacia*) has a heat labile phytotoxins and glycoside in all plant parts. The seeds and the bark are the most commonly involved source of poisoning, although other less-available plant portions also induce risk. The gastrointestinal signs are complicated by additional incidences of depression and neurological effects.

The ability of different plant chemicals inducing similar digestive tract involvement and then associated various systemic effects highlights the numerous and various types of plant toxins that are capable of inducing similar yet complex toxic syndromes. The clinical effects of plant toxins are not simple and accurate diagnosis and therapy is largely based upon history of exposure so that appropriate management can be pursued. In the absence of a history of specific plant ingestion, general management and nursing care is required to alleviate the clinical effects.

Digitalis-Containing Plants

An important clinical group of plants are those with cardiotoxic properties. Many of these cardiotoxin-containing plants induce fatal toxicity by individuals eating the berries or chewing on leaves or flowers. Occasionally, the consumption of water from vases containing the flowers of digitalis-containing plants has been incriminated in poisonings. The initial syndrome from these ingestions is usually local irritation to the mouth followed by emesis. In contrast to toxicity from pure cardiac glycosides, poisoning from these plants will also be associated with diarrhea and abdominal pain due to the multi-presence of other irritants and saponins.

Mistletoe (*Phoradendron serotinu*) has toxic amines in its berries. There are sudden gastrointestinal effects with cardiovascular collapse similar to that seen from the ingestion of digitalis overdosage.

Lily-of-the-valley (*Convallaria majalis*) has cardioactive glycosides in its leaves and flowers that induce irregular heart rates and vomiting.

Foxglove (*Digitalis purpurea*) has significant concentrations of the digitalis glycosides in its leaves. This is the plant from which digitalis was originally isolated and serves as the template for the cardioactive plant poisons. Following initial gastrointestinal irritation and its effects, poisoned individuals develop headaches, irregular heart rates, and cardiac arrhythmias that often lead to tremors and neurological disturbances.

Oleander (*Nerium oleander*) has a cardioactive glycoside very similar to digitalis in all its plant parts. It is a potent toxin vehicle that has produced poisoning from minimal ingestion. One leaf has been accused of inducing life-threatening toxicity. Initial effects are those of nausea, abdominal pain, and bloody diarrhea that lead rapidly to circulatory irregularities, unconsciousness, and coma with death due to respiratory failure.

The cardioactive plant toxins have served as models for potent forensic situations used for suicide or for murder. The complexity of the plant chemistry has for many years confused identification of the toxic vehicle; however, current instrumentation and available chemical knowledge has now produced the ability to recognize, characterize, and identify the presence of these cardioactive glycosides in suspected cases of intoxication.

Nicotine, Cytisine, and Coniine-Containing Plants

These are neurological alkaloids that all exert similar actions. Numerous fatal poisonings have occurred because wild flora often contained complexes of these plants. Skin rashes often occurs in individuals who harvest tobacco leaves (*Nicotiniana* spp) and much more serious toxicity can occur if the tobacco leaves are consumed. Cytisine poisoning is most commonly resulting from the consumption of seeds from the pea-like pods of the golden chain tree (*Laburnum anagyroides*) while intoxications from Coniine usually occur from nibbling of the parsley-like leaves of poison hemlock (*Conium maculatum*) or from eating the seeds from that same plant. This alkaloid is related to nicotine, and all parts of the poison hemlock plant are toxic. It produces an ascending paralysis of the nervous system and is the plant that is famous in Greek history as the source of the fatal poisoning of Socrates.

The toxicity from these plants is usually initiated by vomiting that most commonly begins within 15 min of ingestion and is accompanied by a profuse salivation. Abdominal cramping and diarrhea are rare, yet the gastrointestinal syndrome is always present within 1 h of ingestion. This is followed by confusion, hyperpyrexia, incoordination, occasional mydriasis, and then tachycardia that can lead to fatalities from respiratory failure. Serious intoxications result from this group of plants.

Atropine-Containing Plants

Although a number of plants contain atropine and its related alkaloids, by far the most common and important poisoning is from jimsonweed (*Datura strammonium*). As an abundantly found wild weed, this plant affects persons who eat the seed or suck the flowers, often when they are attempting to use the plant as a hallucinogen. The early symptoms are mydriasis and dryness of the mouth which chronically presents itself as the poisoned individual indicating excessive thirst. The skin becomes hot and dry with redness and rash-like dermatosis occurring around the head and neck of the victim. In severe intoxications, there is pronounced hyperpyrexia, delirium, and hallucinations. These hallucinations may lead to dangerous behavior and activities that become life-threatening. Convulsions may appear in severe overdoses and ultimately coma can develop.

Atropine poisoning mimics a variety of pathologic states such as encephalitis, meningitis, and uremia. Atropine poisoning produces consistently equal and bilateral dilation of the pupil, a hot dry skin and significantly increased heart rates. Young children are more sensitive to atropine poisoning because of their lower tolerance to elevated body temperatures. Fatalities due to atropine-containing plant toxins are uncommon and recovery is usually complete within 24 h. Other than the much longer persistent papillary dilation, the other clinical effects resolve within 12–24 h.

Jimsonweed (*Datura stramonium*) contains at least three alkaloids (hyoscyanine, atropine, scopolamine) in all its plant parts. There are considerably more poisoning in humans than in animals from this plant due to the frequent and often habitual use of jimsonweed seeds and flowers to induce various hallucinogenic states. Ingestion of the alkaloids induces prominent thirst, delirium, and convulsion and in unfortunate states can lead to coma.

Belladonna (*Atropa belladonna*) contains most prominently the atropine alkaloid. **Potatoes and tomatoes** (*Solanum* spp.) contain the solanine alkaloid in the leaves, in green tomatoes, and in the sprouts of potatoes. In addition to the atropine-like effects, gastrointestinal irritation is usually seen and significant neurological involvement occurs.

The **nightshades**—black nightshade, Jerusalem cherry, bull nettle—(*Solanum* spp.) also have the solanine alkaloid in the berries and fruits. The unripe berries of this group of nightshade plants are deadly and responsible for numerous hospitalizations and near fatalities. In addition to the gastrointestinal signs, neurological effects with hot skin and pupil dilation are prominent. This entire group of atropine-like plants induces similar signs that make their clinical recognition of important medical value.

Plants Producing Convulsion and Changes in Nervous System

The principle groups of plants responsible for producing convulsions as primary toxic manifestations are those of the water hemlocks (*Cicuta* spp.). They are found only in wet, swampy areas, making them very lush and attractive to individuals looking for their carrot-like appearance. Usually within 15 min to 1 h after ingestion, the affected individual experiences nausea, salivation, emesis, and tremors. This is quickly followed by multiple grand mal seizures with death occurring secondarily due to prolonged anoxia encountered during the severe tonic muscular contractions.

Water hemlock (*Cicuta maculata*) is the most common of the *Cicuta* species and the most often involved in toxicity. The plant contains an unsaturated alcohol resinoid that is rapidly absorbed, quickly enters the nervous systems, and induces acute nervous signs, violent spastic convulsions, and death from respiratory depression. This plant produces such violent convulsions that fractures of jaw bones or limb structures are commonly found on post mortem in individuals who have died from this poisoning.

Members of the **heath family** (laurel, *laurus nobilis*; rhododendron, *Rhododendron* spp.; azaleas, *Rhododendron* spp.; pieris, *Pieris japonica*) all contain a hydrocarbon resinoid (andromedotoxin) in all their plant parts. This makes them extremely hazardous to produce the characteristic gastrointestinal irritation, mental and muscular depression, paralysis, lowered blood pressure, and eventual coma.

Crocus (*Colchicum autumnale*) has alkaloids in all parts of the plant. The compound is heat stable and uniquely is excreted in milk but slowly. Vomiting is characteristic as an initial effect followed by nervous signs of tremors and seizures.

White snakeroot (*Eupatorium rugosum*) contains a unique 16 carbon alcohol entitled trematol that has been historically a severe risk in the early days of Midwest settlements in the United States. Cattle grazing pastures that had this plant typically would develop ketosis with neurological signs characterized by muscular trembling. This became a serious human problem when the milk from these animals was consumed by families depending upon the nourishment of this product. Trematol is excreted in the milk in reasonable concentrations and thus induces similar *trembles* in children and adults drinking the milk.

Yew (*Taxus* spp.) is an attractive plant that unfortunately induces acute cardiac and gastrointestinal problems if the leaves are chewed. The highest concentration of the alkaloid is in the foliage with minimal amounts in the attractive red berries. This reduced concentration in the berries is often lifesaving since children are attracted to the colorful fruit and consumption is not uncommon. Following the typical gastrointestinal response of vomiting, individuals rapidly become weak and have cardiac rhythm changes that induce serious life risks, which are followed by convulsions that include depression of the respiratory center. Death within a few hours of consumption of this plant is typical.

Locoweed (*Astragalus* spp.) has been used for centuries by Native American tribes during their ceremonial rituals. The plant has several compounds present, all of which produce mind-altering hallucinogenic states. While minimal amounts are used in the ceremonies, larger consumption may lead to violent behavioral changes that can be life-threatening.

Cyanide-Containing Plants

A number of plants and their fruits contain cyanide or cyanide precursors that release cyanide upon enzymatic digestion either in the digestive tract or under appropriate environmental conditions. These cyanide compounds are usually in highest concentration in the pits or leaves of the respective plants; the cyanide released from seeds or pits require that the seed coat be broken by chewing that allows the enzymatic juices of the intestinal tract to complete the conversion to the highly toxic cyanide. Classical onset is extremely acute, resulting in the rapid onset of rapid respirations, collapse due to cellular anoxia and the development of bright-red blood and terminal seizures leading to death usually within 10–30 min of ingesting of the freely available active toxin. Fortunately a commercial *cyanide* kit is available and present in every emergency room. The treatment with intravenous sodium nitrite and sodium thiosulfate is highly effective, but must be initiated before cardiac function ceases.

Apples (*Malus* spp.) have a cyanogenic glycoside in the seeds; **cherries** (*Prunus* spp.) have the glycoside in pits and leaves; other *Prunis* species (**peaches** and **apricots**) have the cyanogenic glycoside in their pits and less concentrations in the leaves.

Hydrangea (*Hydrangea macrophylla*) is typical of a toxic plant in having a potent cyanogenic glycoside present in combination with irritating chemical principles that aggravate the clinical toxicity.

Plants Producing Dermal Contact Effects

Depending upon the chemical principle or structure involved, adverse effects from the consumption of these plants are rare, but may occur under unique conditions. In general, skin irritation is the effect with blistering or mechanical injury from hairs or spines that penetrate the skin.

Poison ivy (*Toxicodendron radicans*) and **poison sumac** (*Toxicodendron vernix*) are well recognized as having an allergic sap (3-*n*-pentadecylcatechnol) that is famous for the vesicant dermatitis produced. The fact that some individuals do not respond to contact from this plant while others show violent reactions attests to the allergic nature of this compound.

Snow-on-the-Mountain (*Euphoria marginata*) contains an irritating vesicant sap that is highly irritating to the conjunctiva of the eye and locally irritating to the skin and gastrointestinal tract mucosa if consumed.

Nettles (*Urtica* spp.) are clearly irritating from the prickly hairs on the plant's surface that produce an irritant reaction upon skin contact. The hairs also provide mechanical irritations that further accentuates the irritating nature of the toxin by allowing some skin penetration.

All these irritant-containing plants are contact toxicants that allow instantaneous removal of the irritant if abundant soap and water are used within 5–10 min of contact to wash off the toxicant. The instantaneous use of this cleansing will also prevent spread of the toxicant to other areas of the body upon itching and rubbing. Medications are available that will relieve the irritation and discomfort and may be used to prevent further mechanical spread of the compound. Unfortunately, there is no neutralizing material available once the compound has come in contact with the skin, thus strong and abundant washing is the best relief to reduce the effect of the irritating compounds.

Cactus (*Pedilanthus* spp.) has strong spines capable of penetrating skin. The penetration is worsened by any force that drives the thorn-like spines further into the flesh. Rapid removal of the spines is important to avoid ultaneous granulomas from developing. These body reactions are attempted to wall off the irritation from the spine, but often produce ulcers and highly inflamed lesions in several parts of the body that had contact with the cactus spines.

The signs of most plant ingestions are gastrointestinal involvement, with neurological effects, depression, seizures,

and coma as occurring if severe intoxication occurs. The history of consumption of plants or the proximity to plant materials is most helpful in diagnosis and is an important phase of the problem-solving aspects of dealing with plant poisonings. Very few direct antidotes are available for treatment, although the *cyanide* kit is an exception and has historically been lifesaving in numerous cyanide-containing plant exposures. In general, the treatment of most plants is to remove as rapidly as possible the plant material from the digestive tract through inducing emesis or hastening a laxative effect, and the use of intestinal decontamination through binding agents such as activated charcoal to minimize the absorption of the plant's toxicity. In severe cases where prolonged vomiting and diarrhea have been present, the use of fluids and electrolyte infusions are helpful to maintain hydration and often are lifesaving. General symptomatic care to relieve pain and discomfort are also employed and found valuable by the affected victims.

A poisonous plant glossary (Table 19.1) provides the common names, scientific names, and general toxic effect of each of the toxic plants of concern discussed earlier. This table can be useful to identify from all the many plants in the environment those which are a significant hazard and the type of toxicity or adverse effect that each could produce. Note that many of those listed affect more than one organ system.

Laboratory Identification of Plant Toxins

The classification and identification of plant compounds associated with cases of poisoning is often subjective; indeed, in many cases plant chemicals are deemed toxic by association with poisoning episodes. They are often the major compound found in a plant known to be poisonous and associated with related compounds that have been shown to produce similar symptoms of poisoning. Years of analysis of plant toxins and the more recent development of specific and sensitive instrumentation have found that plants contain many chemicals that are potentially harmful.

Some plant constituents are not particularly toxic in the form in which they exist in the plant, but on ingestion, they undergo transformations to more toxic principles. Thus, when investigating the effect of plant toxins in mammalian systems, metabolites of the toxin have often been the only detectable compounds. With some groups, such as alkaloids, there is considerable variability within a species in the level and composition in the toxic fractions, depending on location, stage of growth, and other environmental conditions [5].

Analytical resources available to analyze for plant toxins vary significantly from laboratory to laboratory, yet there are analytical procedures to identify the numerous categories and wide spectrum of potential plant toxins. In addition to the classic analytical techniques used (e.g., thin-layer chromatography, high performance liquid chromatography, gas chromatography), other methodologies are also employed. Solvent extraction techniques, super critical fluid extraction, lead acetate precipitation, droplet counter current chromatography, centrifugal thin-lay chromatography, and reverse-phase low-pressure chromatography columns are also employed. Even more recently, the wide application of mass spectrometry and its various combinations with chromatography methods have allowed for identification of alkaloids and other plant toxins with minimal plant sample available (see Chapter 41). Even more recent advances have suggested that capillary electrophoresis and further combinations with mass spectrometry and specific detector systems will improve the sensitivity and detection of illusive plant toxins.

The range of specific plant toxic chemicals now detectable include the following [5]: pyrrolizidine alkaloids; piperidine alkaloids; pyridine alkaloids; indole, tryptamine, β-carboline and related alkaloids; quinolizidine alkaloids; steroid alkaloids; diterpene alkaloids; indolizidine alkaloids; tropane alkaloids; isoquinoline alkaloids; other alkaloids such as colchicine, sesbanimide, and dioscorine; cyanogenic glycosides; glucosinolates; phenolic glycosides; saponins and cardiac glycosides; nitropropanol glycosides; other glycosides such as azoxyglycosides, naphthalenes, anthracenones, and anthraquinones; lectins or hemagglutinins including abrin, jatrophin, momordin, phoratoxin, and ricin; enzymes such as thiaminase; amino acid analogues, and nonprotein amino acids, such as hypoglycin, β-cyano-L-alanine, and S-methylcysteine sulfoxide; the phenylethylamines, including tyramine, N-methyl-β-phenethylamine, hordenine, β-phenylethylamine, and galegine; selenium compounds usually stored as amino acids (selenocystine, methylselenocysteine, γ-L-glutamyl-Se-methylseleno-L-cysteine; sesquiterpene lactones; diterpenes such as croton oil, ingenol, and tigliane esters, simplexin, and the grayanotins I, II, III, IV, and XIV; terpenes (trematol) and hydrocarbons (tanacetine, malvalic acid, cicutoxin, and crepenynic acid); and the numerous oxalates, nitrates, sulfides, and organofluorine compounds that exist seemingly throughout the plant kingdom as soluble acid salts, insoluble salts of calcium and magnesium, and as numerous disulfide and similar inorganic forms [5]. Such a wide spectrum of organic and inorganic chemicals challenges the analytical chemist and provides continuing excitement for toxicologists.

Plant Toxins Present in Milk [6]

Mammary gland secretions are one of the frequent ways in which chemicals are eliminated from a consuming individual's body. Compounds from plants are particularly suited for excretion via this route since many are organic in nature and have considerable lipid partitioning into the mammary gland secretions. Exposures may occur directly from mothers having recently consumed plant materials and suckling infants receiving the milk. All species may be affected by this route of exposure. In commercial dairy herds, animals pasturing on plants that contain compounds likely to appear in milk offer hazard for the general public purchasing such processed milk and milk products. Fortunately, when the milk from one herd exposed to toxins excreted in milk is mixed with the large volume of milk from nonexposed cows, dilution results

TABLE 19.1
Poisonous Plant Glossary

Common Name	Scientific Name	Toxic Effect
Apple	*Malus* sp.	Cyanide
Apricot	*Prunus* sp.	Cyanide
Azalea	*Rhododendron* sp.	Neurological
Belladonna	*Atropa belladonna*	Atropine-like
Black locust	*Robina pseudoacacia*	Gastrointestinal
Black nightshade	*Solanum nigrum*	Atropine-like
Bull nettle	*Solanum* sp.	Atropine-like
Buttercup	*Ranunculus* sp.	Gastrointestinal
Cactus	*Pedilanthus* sp.	Dermatological
Castor bean	*Ricinus communis*	Gastrointestinal, convulsive, tremors
Cherry	*Prunus* sp.	Cyanide
Crocus	*Colchicum autumnale*	Neurological
Daffodil	*Narcissus* sp.	Gastrointestinal
Daphnea	*Daphne* sp.	Gastrointestinal
Death camas	*Zigadenus* sp.	Gastrointestinal
Dumbcane	*Diffenbachia* sp.	Oxalate
Elderberry	*Sambucus Americana*	Gastrointestinal, cyanide
Fescue	*Festuca prateusis*	Gangrene, hormonal, reproductive
Fireweed	*Kochia scoparia*	Liver
Foxglove	*Digitalis purpurea*	Cardiac, digitalis
Greasewood	*Sarcobatus*	Oxalate
Halogeton	*Halogeton glomeratus*	Oxalate
Hydrangea	*Hydrangea macrophylla*	Cyanide
Ivy	*Hedera helix*	Gastrointestinal
Jerusalem cherry	*Solanum pseudocapiscum*	Atropine-like
Jimsonweed	*Datura stramonium*	Atropine-like
Lamb's quarters	*Chenopodium album*	Oxalate
Lantana	*Lantana camara*	Gastrointestinal, photosensitization, neurological
Laurel	*Laurus nobilis*	Neurological
Locoweed	*Astragalus* sp.	Convulsive, tremors
Lily-of-the-valley	*Convallaria majalis*	Cardiac, digitalis
Lupine	*Lupinus argenteus*	Liver
Marijuana	*Cannabis sativa*	Neurological
Mayapple	*Podophyllum peltatum*	Gastrointestinal
Milkweed	*Asclepias* sp.	Gastrointestinal, neurological
Mistletoe	*Phoradendron serotinum*	Cardiac, digitalis
Mother-in-laws tongue	*Sanseivera* sp.	Oxalate
Mountain laurel	*Kalmia latifolia*	Neurological
Mustards, crucifers	*Brassica kaber*	Gastrointestinal
Nettles	*Urtica* sp.	Dermatological
Oak	*Quercus* sp.	Kidney
Oleander	*Nerium oleander*	Cardiac, digitalis
Peach	*Prunus* sp.	Cyanide
Philodendron	*Philodendron* sp.	Oxalate, kidney
Pieris	*Pieris japonica*	Cyanide
Pigweed	*Ameranthus retroflexus*	Kidney
Poinsetta	*Euphoribia pulchenima*	Gastrointestinal
Poison hemlock	*Conium maculatum*	Neurological
Poison ivy	*Toxicodendron radicans*	Dermatological
Poison sumac	*Toxicodedron vernix*	Dermatological
Pokeweed	*Phytolacca americana*	Gastrointestinal
Potato	*Solanum tuberosum*	Atropine-like
Precatory bean	*Abrus percatorius*	Gastrointestinal
Ragwort	*Senecio* sp.	Cardiac, digitalis

TABLE 19.1 (continued)
Poisonous Plant Glossary

Common Name	Scientific Name	Toxic Effect
Red maple	*Acer rubrum*	Hemolytic
Rhododendron	*Rhododendron* sp.	Neurological
Rhubarb	*Rheum rhaponticum*	Oxalate
Rosary pea seed	*Abrus precatorius*	Gastrointestinal
Senna	*Cassia fasciculata*	Gastrointestinal
Snow-on-the-mountain	*Euphorbia marginata*	Dermatological
Sorghum	*Sorghum* sp.	Cyanide
St Johnswort	*Hypericum perforatum*	Photosensitization
Tobacco	*Nicotiana* sp.	Nicotine-like
Tomato	*Lycopersicon lycopersicum*	Atropine-like
Veratrum	*Veratrum californicum*	Teratology
Water hemlock	*Cicuta maculate*	Convulsive, tremors
White snakeroot	*Eupatorium rugosum*	Neurological
Wild Indigo	*Baptisia* sp.	Gastrointestinal
Wisteria	*Wisteria sinensis*	Gastrointestinal
Yew	*Taxus* sp.	Convulsive, tremors

in considerable protection; however, the potential risk is still there. This is especially true if home-produced dairy products are consumed from individual herds in which dilution of the plant toxins is unlikely. Although excretion of natural toxins via the milk is not considered a major route of excretion, the milk emulsion of lipids in an aqueous solution of proteins may contain mixtures of virtually any toxin or compound that is in solution in the mother's or cow's body. The toxins may be bound to blood proteins, be in solution in the circulating lipids, or be freely circulating in the plasma. All of these forms can cross mammary cell membranes, generally by simple diffusion.

Some poisonous principles can be excreted very readily in milk. These principles are usually those of high fat solubility that are concentrated in the lipid portion of the milk, have long biological half-lives, and are frequently present in milk at high concentrations and for long periods of time. Suckling offspring or consumers of milk from cows excreting such toxins are especially vulnerable for toxicity. White snake root (*Eupatorium rugosum*) and rayless goldenrod (*Haplopappus heterophyllus*) contain trematol, which is probably the best example of a natural plant toxicant transferred via milk. It induces a condition in cattle called *trembles* and in humans causes a serious debilitating disease referred to as *milk sickness*. Two plants notorius for having that toxin present and available for milk contamination are white snake root (*Eupatorium rugosum*) and rayless goldenrod (*Haplopappus heterophyllus*). Both are widely disseminated in the Northeast and Midwest, offering ample opportunity for inclusion of the toxin in milk products.

Pyrrolizidine alkaloids have been shown to be transferred in the milk of cattle grazing on pastures infested with plants containing these toxins. The important species of toxic plants containing pyrrolizidine alkaloids are *Senecio, Crotalaria, Heliotropium, Trichodesma, Amsinckia,* and *Echium*. Of these, the *Senecio* species are the most potentially hazardous, particularly tansy ragwort (*Senecio jacobaea*) and threadleaf groundsel (*Senecio douglasii*). In addition to their contamination of milk, plant toxins from this group also have potent hepatotoxic risks.

Glucosinolates occur in the Cruciferae family and also may appear in milk. The genus *Brassica* includes cabbage, broccoli, kale, rape, mustard, turnips, and other plants. Other glucosinolates-containing plants include meadowfoam (*Limnanthes*), watercress (*Nasturtium*), radish (*Raphanus*), horseradish (*Amoracia*), and stinkweed (*Thlaspi*). Piperidine alkaloids are widely spread and are found in poison-hemlock (*Conium maculatum*) and in many plants of the genera *Nicotiana, Conium, Lobelia, Pinus, Duboisia, Sedum, Withania, Carica, Hydrangea, Dichroa, Cassia, Prosopis, Genista, Amondendron, Lupinus, Liparia,* and *Collidium*. Lupines (*Lupinus* spp.) contain the quinolizidine. Other members of this group include scotch broom (*Cytisus*), golden chain (*Laburnum*), and mountain thermopsis (*Thermopsis*).

Locoweed (*Astragalus lentiginosus*), used in ritualistic ceremonies, contains the indolizidine alkaloid swainsonine that is transferred in milk. *Oxytropis serecia* is another swainsonine-containing plant in the locoweed category. Grasses of the lush green pastures and other plants that have high chlorophyll content are metabolized to indole and 3-methylindole in the rumin of cattle consuming these forages. These metabolites of L-tryptophan are also transferred in milk to individuals consuming such. Colchicine is a poisonous alkaloid in autumn crocus (*Colchicum autumnale*) that is stable after drying, heating, or storage; it is also excreted primarily in lactating animals via the milk. Because of its slow excretion, a cumulative effect is likely from even small doses received daily over time.

Numerous other plants, particularly those on the western ranges of the United States [6a], are capable of accumulating

high levels of selenocompounds that are not only hazardous to consuming animals, but also are excreted in cow's milk and concentrations in direct proportion to the selenium intake. Certain plant species of *Astragalus* and *Stanleya* have this selenium-accumulating capability.

The presence of other compounds in milk may induce a disagreeable taste or odor. Plants of the genus *Allium* include species of onion and garlic that taint the milk produced. The sesquiterpene lactones (*Tenulen*) in sneezeweed and bitterweed impart a bitter flavor to the milk of lactating animals grazing these plants. Bracken fern (*Pteridium aquilinum*) produces milk from cows fed this plant that induces urinary carcinomas.

With increasing concern for food safety, recognition and appreciation of the potential for plant toxins contaminating human milk supplies is timely. The fact that plant alkaloids are frequent in these situations and are quite basic, allows them to accumulate in milk. The combination of the basicity and fat solubility of the chemical produces accumulation of the plant toxins in the milk with reduced excretion by other natural processes. Other factors to be considered in evaluating the human health risk from plant toxins or from the heavy consumption of milk by infants and young children, who are already more susceptible to the toxins, is the consumption of milk produced by lactating mothers who use herbal remedies, the availability of these toxic plants to lactating dairy animals, and the consumption of milk from point sources where free grazing milking animals have access to toxic plants. The fact that few laboratory methods have been developed for monitoring natural toxicants of plant origin in milk and milk products heightens the need to assess and monitor their potential danger to human health and safety.

Some Interesting Plant Toxicoses Observations

Plants are capable of adversely affecting many specific organ system targets. One of the most common is skin, resulting in dermatitis as a result of hypersensitivity to plant toxins or direct contact with irritant saps or spines. Mucus membrane irritation is a close second due to contact or consumption of plants with irritant saps or containing oxalate crystals and/or enzymes. Gastrointestinal reactions are by far the most common adverse effect to ingestion of a plant part. Indeed, it is almost a rarity to observe a true plant poisoning without some form of gastrointestinal irritation, which may be severe and may require aggressive fluid therapy. Several plant groups and individual plant species are capable of causing liver damage, and although it usually results from the long-term use of plants for various purposes, some plant products produce a relatively acute hepatotoxicity. Renal impairment after the plant ingestion is rare and is usually confined to associations with dehydration or profound shock. Some plants, such as rhubarb leaves, are noted to cause kidney failure due to the systemic absorption of soluble oxalate salts. Involvement of the hematopoietic system is not uncommon and often involves intravascular hemolysis, methemoglobinemia formation, and breeding tendencies caused by coumarins in herbal teas or from penny royal oil. Parts of many plants, including pears, peaches, apples, apricots, cherries, certain lima beans, and hydrangea contain the amygdalin glycoside that can release cyanide. These are acute episodes and in some cases have been related to ingestion of health food supplements.

Other common plants contain cardiac glycosides that are responsible for effects and in some cases death include fox glove (*Digitalis purpurea*), oleander (*Oleander nurium*) lily-of-the-valley (*Convallaria majalis*), and red squill (*Urginea maritima*). Other less studied plants are reported as *depressing the heart and slowing the pulse*. These effects may be secondary to other organ effects. The ergot alkaloids used for migraine headache control and other purposes may cause severe arterial vasospasm. The autonomic nervous system effects are well described for anticholinergic toxicity from plant products such as Jimson weed (*Datura* spp.) along with members of the Solanaceae family that includes deadly nightshade (*Atropa belladonna*) and henbane (*Hyoscyamus niger*). Nicotine is present in various members of the *Nicotiana* plant family and causes peripheral ganglionic stimulation with seizures and death possible.

Central nervous system changes, including depression and stimulation, may also be frequent plant effects. Many plants, such as tobacco, coffee, tea, marijuana, cocaine, and others, are actively *harvested* to achieve such central nervous system alterations. More severely neurotoxic plants and their derivatives are water hemlock (*Cicuta maculata*) and poison hemlock (*Conium maculatum*). The former is well recognized to cause immediate seizures after ingestion while poison hemlock causes death through paralysis [7].

Despite the widely recognized concern for problems from plant ingestions, some studies have concluded that most plant and herb exposures are mild and do not need aggressive treatment. This conclusion was reached despite the fact that complications were detected in this study, especially following intentional and/or chronic cases of plant ingestion [8].

The circumstances and resulting acute toxicity from ingestion of water hemlock (*Cicuta birosa*) is evident in the report of two individuals who viewed the plants growing in a marshy area and believing it to be an edible species, such as wild parsnips, artichokes, celery, sweet potatoes, or sweet anise. They ate several bites of the root and 20 min later became nauseous, experienced salivation and stomach cramps, and vomited repeatedly before developing grand mal seizures and convulsions leading to coma. Prompt attention at an emergency center resulted in recovery by the 11th day [9].

The toxicity and high allergenic and anaphylactic response from castor beans (*Ricinus communis*) and their dust presents similar risk to exposed individuals. The acute gastroenteritis, gastrointestinal bleeding, hemolysis, hypoglycemia, and fluid and electrolyte depletion are common effects from exposure to these plant materials. Mortality rates of almost 10% have been reported [10].

Acute atropine poisoning from the ingestion of Jimsonweed (*Datura* spp.) is a significant risk to children from their ingestion. An average of almost 80 admissions per year occurred to hospitals in New Zealand with poisonings

from these plants related to their belladonna, hyoscine, and atropine content. Although clinical poisoning results, fatalities are rare but do occur [11].

Juniper tar (cade oil) is distilled from the branches and wood from *Juniperus oxycedrus* containing etheric oils, triterpene, and phenols. It is a frequent constituent of many folk medicines and is used for various antipruritic, keratolytic, and antimicrobial benefits in human and veterinary dermatology. Significant anti-inflammatory activity is also noted. The tar is ingested as a liquid extract of the tree by individuals in the Mediterranean region, yet has caused fever, severe hypotension, renal failure, hepatotoxicity, and cutaneous burns when applied to the face. Using supportive and symptomatic care, a recent patient improved but required 11 days to return to good health [12].

Similarly, the inclusion of plant materials in a Chinese vegetable entrée at an international buffet was associated with multiple cases of burning and facial edema after lunch in an office cafeteria. Pain and stinging/burning of the oral mucosa and potential airway obstruction due to the severe edema resulted from the presence of plant material containing raphides such as plants of the genera *Dieffenbachia philodendron* and *Brassica* that contain needle-shaped crystals of calcium oxalate in their specialized cells. These raphides are excreted in response to mechanical pressure causing irritation and subsequent injury, which may be life threatening if the respiratory passageways become swollen [13].

Not all such toxicities result from direct plant ingestion. The rhododendron (*Rhododendron ponticum*) grows extensively on the eastern flat sea area of Turkey. This plant species contain toxic diterpenes (*Grayanotoxins*) in their nectar, which is then used by bees in the area to generate honey from which commercial products are developed. Ingestion of the honey derived from this plant cause profound hypotension and bradycardia, allowing it to be known locally as *madhoney* [14]. Although a prominent problem in Turkey and the Mediterranean bordering countries, honey intoxications from grayanotoxin contamination have also been reported as early as 1794 in the Great Smoky Mountain region of the United States and northward, probably associated with mountain laurel (Kalmia latifolia*)* and sheep laurel (Kalmia augustifolia*)* pollination. What may seem to be a regional concern has more global dietary safety potential, and the availability of imported honey further suggests the need for continuing vigilance [15].

The oleanders (pink oleander, *Nerium oleander*; yellow oleander, *Thebetia peruviana*) contain cardenolides that exert positive ionotropic effects on the hearts of consuming animals and humans. Toxic exposures to humans, domestic animals, and wildlife from these oleander toxins occur with regularity throughout the geographic region where these plants grow. Although the human mortality associated with oleander ingestion is generally low due to the purgative action that occurs rapidly following ingestion, small children and domestic livestock consuming reasonable amounts of the plant are at increased risk of oleander poisoning [16]. The wide distribution and the fondness of individuals to decorate their surroundings with this attractive yet toxic plant provides an interesting example that the *one medicine* concept even applies to plant toxicities.

TOXINS FROM ALGAE

Algae produce toxins; their presence in water should alert one to potential hazards. Toxic blue-green algae (cyanobacteria) are commonly found growing in fresh and salt water in temperate areas worldwide. They are commonly found in fresh water lakes, livestock ponds, rivers, streams, canals, and ditches. Under the appropriate warm environmental temperatures, calm weather, and stagnate nutritionally rich conditions, very rapid growth of blue-green algae results in blooms that accumulate on the surface of the water and provide opportunity for neurotoxins or hepatic toxins to be produced. These blooms of blue-green algae often occur in the northern United States in the late summer or early winter, and are associated with hot, calm weather, decreased rainfall, and increased nutrients in the water from fertilization or animal wastes; winds that blow in concentrate the algae along the shorelines allow ample opportunity for exposure. In the southern states, algal blooms occur all year long when the optimal environmental conditions are met. The blue-green algae *Microcystis* and *Nodularia* produce the cyclic peptide hepatotoxins microcystin and nodularin, while the algae *Anabaena, Aphanizomenon,* and *Oscillatoria* produce the potent neurotoxins *Anatoxin-A* and *Anatoxin-A(s)* [17].

The neurotoxin anatoxin-A is a bicyclical secondary amine that causes deep polarization of nicotinic membranes, acting as a potent postsynaptic neuromuscular blocking agent. The deep polarization of neurononicotinic membranes is rapid and persistent and leads to respiratory paralysis. The related neurotoxin anatoxin-A(s) inhibits acetylcholinesterase in the peripheral nervous system. Fortunately, this toxin does not seem to cross the blood brain barrier, but the neurological effects on skeletal muscle dysfunction are obvious. Cyanobacteria ingested with water are rapidly broken down in the gastrointestinal tract environment. In the stomach acids, the organisms are lysed with the resulting release of toxins that, when free, are rapidly absorbed further from the small intestine. The hepatotoxins microcystin and nodularin are transported to the liver hepatocytes through a specific carrier-mediated uptake mechanism. There they inhibit protein phosphatasis, which initiates a cascade of events leading to rapid massive hepatocyte necrosis, intrahepatic hemorrhage, and shock.

Effects of Algal Toxins

When the blue-green algae grow in polluted nutrient-enriched waters or ponds, they can appear and disappear in a matter of days with the varying temperatures and weather conditions. The results can be the rapid development of varying toxins depending upon the algal growth present, and the clinical effects may similarly be varied depending upon the

presence of the select toxin. Generally, all the toxic effects may be grouped into those that relate to nervous effects producing relatively rapid death, or more slow clinical damage that may require several days to weeks to resolve. The underlying feature of the latter group is that liver damage is the target effect, and if the victim survives the early dramatic hepatic injury or if small to moderate exposures occur over a relatively few days, the individual may develop subtle or subclinical hepatotoxicosis that may be health-depriving for several weeks.

Neurotoxins

The two primary groups of algal neurotoxins are the anatoxins produced by filamentous *Anabaena flosaquae* and the aphantoxins from *Aphanizomenon flosaquae*. The anatoxins are potent postsynaptic depolarizing neuromuscular blocking agents that affect the acetylcholine receptors producing staggering, muscle fasciculations, gasping for breath, convulsions, and even opisthotonus. Death is by respiratory arrest, which may occur within minutes or a few hours, depending upon the dosage and the species involved. Victims need only to ingest a few milliliters of the toxic surface bloom-contaminated water to receive a lethal dose. Some victims also demonstrate salivation, laceration, urinary incontinence, and defecation prior to death by respiratory failure.

The aphantoxins neurotoxins inhibit nerve conduction by blocking sodium channels, yet induce very similar clinical damage as the anatoxins.

Hepatotoxins

Microcystin is the fast death factor produced by *Microcystis aeruginosa*, identified as a cyclic heptapeptide. This cyclic peptide structure is transferred to its morphologic appearance in waters where it characteristically shows up as small packets of glistening spheres under the microscope. Its unique microscopic appearance has been valuable for identification by public health officials and biologists in pollution situations.

Another low molecular weight heptapepide hepatotoxin with similar microscopic appearances is cyanoginosin (BE-4 toxin), a product of a unique strain of *Microcystis aeruginosa* WR-70 [18]. Characteristic liver injury is produced either acutely or more subtly with limited dose exposure.

Other hepatotoxic toxins have been found generated by *Nodularia spumigena*, *Cylindrospermopsis raciborskii* (Anabaena raciborskii), and by varieties of *Oscillatoria agardhii*.

All the microcystin hepatotoxins cause death by hypobolemic shock resulting from interstitial hemorrhage into the liver. The rapid and extensive centrilobular necrosis of the liver comes from extensive fragmentation and vesiculation of hepatocyte cell membranes. It has been suggested that instead of destroying the hepatocyte cell membrane directly, the hepatoxins affect a cytoskeletal component, which, depending upon dosage, may result in sudden loss of total organ function or more prolonged effective damage [18].

Other Algatoxins

Scytophycins produced by certain strains of *Scytonema pseudohofmanni* are strongly cytotoxic in cell cultures. *S. hofmanni* produces cyanobacterin that has strong anticyanobacterial activity and is considered an algaecide for cyanobacteria. A cytotoxic alkaloid has been isolated from *Hapalosiphon fontinalis* strain V-3-1 that has broad antialga and antimycotic activity. All these toxins have relatively low lethal toxicity in laboratory studies, but when combined with all the other cyanobacteria that are found in almost all fresh water algal poisoning reports, potent neurotoxic alkaloids, hepatotoxic peptides, and these several less lethal but more selective cytotoxic compounds demonstrate the unique combination of hazardous effects possible from this group of toxins [18].

The individual cyanobacteria with their associated toxins may produce a spectrum of toxicity determined by the specific population of algae present and the concentration of their respective toxins. Acute death may occur with few clinical signs. Other victims may present with muscle tremors, rigidity, lethargy, convulsions, and death from respiratory paralysis within minutes to hours following onset of effects. Another cascade of signs consistent with inhibition of cholinesterase includes salivation, urination, laceration, and defecation, together with tremors, convulsions, and respiratory difficulty; death from respiratory arrest may occur again within a few hours. Finally, a myriad of signs generally related to liver damage may present a cascade of depression, vomiting, diarrhea, gastrointestinal slow down, weakness, and anemia. While death often occurs within several hours, it may be delayed for several days. Individuals who survive the initial toxicosis may develop secondary photosensitization due to the compromised liver function and presence of photodynamic sensitive metabolites being retained.

Public Health Significance

The potential for mass populations of toxin-producing cyanobacteria in natural and controlled water bodies presents a serious public health awareness to avoid such entities, or if circumstances permit their development to respond appropriately with clinical management, chemical detection, and control of human and animal exposure. Toxic cyanobacterial populations have been reported in fresh waters in more than 45 countries and in numerous brackish, coastal, and marine environments. The biological and circumstantial variations that occur in the hazards of natural origin clearly suggest that uncertainties and numerous gaps in knowledge are present. However, the importance of identifying the exposure media of potable and recreational waters, as well as animal and plant foods that may contribute to the human population exposure is paramount. Steps to develop and implement risk management strategies for cyanobacterial toxins in water bodies are recalled with each outbreak of toxicity, and the gradual recognition by public health communities of the collective experience and wisdom is slowly building [19].

Paramount in the health detection for dealing with outbreaks of algaintoxication is the detection of the cyanobacterial agents present. Their wide variety and structure has led to the common practice of reporting the presence of *toxins* as microcystin-LR equivalents, regardless of which hepatotoxic variant is present [20]. The increased availability of high pressure liquid chromatography with online mass spectral analysis has facilitated more accurate detection of toxic variance, but due to several microcystins sharing the same molecular mass, definitive identification may be difficult. A further difficulty is the requirement for sample processing before analysis. Recent new technologies employing recombinant antibodies and molecularly imprinted polymers are now being extroided to develop assays and biosensors for these algatoxins. Their advantages in being highly sensitive, not requiring sample processing, and offering simple and less expensive alternatives to existing analytical techniques is encouraging [20].

An additional hurdle is the identification of some of the diverse groups of cyanobacteria being able to produce a wide range of toxic secondary metabolites. These have been classified as neurotoxins, hepatotoxins, cytotoxins, dermatotoxins, and irritant toxins. Cyanobacterial brooms are particularly hazardous due to this production of secondary metabolites and their endotoxins that may be broadly toxic to humans, animals, and plants. These compounds differ in mechanisms of uptake, affected organs, and molecular mode of action. Investigating and understanding the environment and effects of these toxins on the organisms receiving these, as well as their basic toxic mechanisms, continue the challenges raised by the presence of the cyanobacteria organisms in water supplies [21].

Prevention and Control

The wide extremes in adverse health effects resulting from cyanobacteria contact in humans highlight the importance of public health measures to prevent and control the annual often unexpected development of toxicity scenarios. The neurotoxic effects from the anatoxins that mimic the effects of organophosphate insecticides, the dramatic hepatic and digestive tract injuries produced by the microcystins capable of producing acute death or lingering hepatic failure, and the even more diverse health ravaging protein synthesis inhibition of cytotoxins, the skin and mucus membrane irritation and tissue inflammation from the irritant algatoxins, and the confusing effect of cyanobacteria lipopolysaccharides in inducing a toxic shock like syndrome cries out for measures to prevent and control future episodes induced by these organisms.

To halt nutrification of ponds and lakes in natural wildernesses and agricultural and industrial areas is indeed difficult, and merely placing cautionary notices and signs to prevent human exposure to *blooming* waters is a challenge for the human nature. Education programs to alert rural inhabitants and campers seeking to enjoy the pleasures of nature are a start but still do not avoid the human fragility of oversight. Continuing observation and recognition of circumstances and environmental conditions that spawn the rapid development of the cyanobacteria toxins are currently the most commonly used preventive measure by public health and regulatory agencies.

Individuals who have become intoxicated from organisms through the public water supply or through contaminated waters used in preparing various commercial or medicinal formulations are particularly vulnerable. Recently, three human probiotics, *Lactobacillus rhamnosus* strains GG, *Lactobacillus rhamnosus* strain LC-705, and *Bifidobacterium lactis* strain Bb12, were found to bind the microcystin cyanobacteria peptide found in water solutions. As much as 46% removal occurred and offered the possibility of utilizing incubation of sensitive water materials with these probiotics to markedly reduce potential toxicity [22].

The increasing recognition of cyanobacterial toxins in the drinking water from water treatment plants [23] and the dramatic documentation of a variety of cyanobacteria and microcystin concentrations in public water supply reservoirs [24] sends up red flags to heighten and intensify the control measures in place to prevent and avoid contamination of these human water sources. The finding of six toxic genera of cyanobacteria with a greater than 40% frequency of hepatotoxic strains provides sufficient recognition that the development and application of detection and control measures for the avoiding of widespread consumption of these contaminated waters is necessary.

TOXINS FROM MUSHROOMS AND TOADSTOOLS

If the rapid and reasonably accurate identification of poisonous plants is difficult, the identification of toxic mushrooms through merely visible examination is virtually impossible. The old wives' tales that suggest that if the skin of a mushroom is easily removed over the cap…or of the mushroom will not blacken silver when cooked…or if the mushroom's gills are grey, the mushrooms are nontoxic, are simply not true! Ultimately, there are no hard-and-fast rules to distinguish the delicacy from the deadly.

Mushrooms are the fruits of fungi that are made up of multiple threads called hythae. Mushrooms grow on several different types of materials, such as wood, ground, plant or animal material, or dung. The spores of mushrooms are a valuable identification aide. Spores are used to form *prints* as part of the identification process. Many different shapes are described for the various parts of mushrooms, and when put together, they assist in identification. Putting all these items together requires experience, knowledge, and skill—all of which are necessary for the proper identification of genus and species and the determination of whether safety or toxicity is present.

Although *Aminita* (e.g., *A. muscaria, A. phalloides*) is the most toxic genus of mushrooms, the specific toxic principle varies significantly with the specific species of mushroom

collected and ultimately consumed. These toxic principles produce clinical signs that vary from excitement and hallucinations…to severe gastrointestinal involvement with few fatalities…to jaundice and explosive liver damage…to circulatory failure…to coma and death within hours to days. Clinicians recognize the importance of not relaxing treatment measures until the patient is fully recovered from any one of the varied and complex clinical syndromes produced by ingestion of toxic mushrooms.

Clinical Syndromes

The mushroom so frequently pictured in story books with the red cap covered in polka dot fashion with white spots is *Amanita muscaria*. Mushrooms in this group produce maniac excitement and hallucinations within 2–3 h after ingestion. This is usually preceded after an initial period of drowsiness leading to the more excitable phase. The central nervous system excitement does not usually exceed more than 3–4 h in duration.

There is a specific group of muscarine-containing mushrooms that will produce sweating, salivation, and colic that begins within 15 min of ingesting. Pulmonary edema and moist rales are frequently present. Fortunately, this toxin does not cross the blood-brain barrier in sufficient concentration to produce central nervous system effects.

Another subgroup of toxic mushrooms produces severe gastroenteritis that develops with a rapid onset of action. Whereas wild mushrooms eaten by adults invariably have been cooked, a process that markedly reduces or inactivates several irritants and even some major toxins, this is not the case with children, which may account for some of the pediatric fatalities following the ingestion of uncooked *nontoxic* species.

The most serious mushroom poisoning is that in which there is a latent period of about 12 h prior to the onset of symptoms. These intoxications have a grave prognosis and consume considerable therapeutic resources. The mushrooms involved in this syndrome belong to the *Amanita phalloides* group. They contain two classes of thermostable cyclic polypeptides: the phallotoxins and amatoxins. Each of which has distinct pharmacological properties. The phallotoxins act initially at the end of a brief latent period by producing nausea, vomiting, painful colic, and a watery profuse and sometimes bloody diarrhea. Following an apparent recovery and a symptom-free period of 3–5 days, during which symptoms are relieved, the amatoxins exert their hepatorenal toxicity in very evident fashion. Jaundice develops, abdominal pain and weight loss become obvious, and a severe extension of the initial poisoning occurs. If only a small amount has been ingested, only renal tubular necrosis may occur. Large mushroom ingestions often produce fatal hepatic necrosis even before the kidney damage becomes obvious.

Although both of these clinical syndromes are seen, the hepatorenal effects terminating in liver failure and produced by intermediate dosages of mushrooms are the more commonly accounted phenomena. An especially high mortality is associated with mushroom intoxication in children.

Specific Mushroom Toxins

So what are the various chemicals specifically toxic in mushrooms? There are various categories and types of mushroom toxins, most of which have a characteristic set of signs. Animals as well as humans are poisoned by mushrooms, and the ingestion of one fungal species by an animal does not make it safe for human consumption.

Cyclopeptides [25]

Amanita and *Galerina* species of mushrooms are most commonly involved in producing anatoxins. These toxins inhibit mammalian nuclear RNA polymerase B forms, which are involved in transcription of DNA to messenger RNA, thus causing inhibition of protein synthesis at the ribosome level. Their primary target organs are the gastrointestinal tract, kidney, and liver.

After the ingestion of these toxins, there is usually a latent period during which little happens for several hours. Then vomiting, diarrhea, and intense abdominal pain occur for several hours. This then subsides and the patient appears almost normal for a few days. The toxins gradually produce hepatic and kidney failure, which may occur within a few days if the dose received was high enough. Hepatic liver enzymes are elevated; the patient is jaundiced and anuric. Tachycardia, acidosis, hypotension, dehydration, electrolyte and blood coagulation abnormalities, hypoglycemia, hepatic coma, and shock usually occur. If *Amanita smithiana* is the ingested mushroom, primary renal tubulonecrosis may occur with minimal hepatic damage.

Treatment of cyclopeptide toxic ingestion is one of the few mushroom poisonings in which extensive therapies have been tried. Silymarin, derived from the milk thistle *Silybum marianum,* has offered some hope as a free radical scavenger and inhibitor of the penetration by amatoxins into the liver cells. Therapy is required for 4–5 days at 20–50 mg/kg of body weight per day intravenously or 1.4–4.2 g per day orally. Often Silymarin is used together with penicillin G. Penicillin G at 300,000–40,000,000 units per day seems to be of some benefit in treating this mushroom intoxication if given within a few hours of ingestion. The antibiotic seems to reduce hepatic uptake of the toxin, but unfortunately such early therapy following mushroom ingestion is often not possible because of the several hour latent period following ingestion. Thioctics acid has been recommended in the past, but it is difficult to obtain and has had mixed success.

Fairly classical additional treatments have met with moderate success in mushroom toxicities from cyclopeptides. Decontamination of the gastrointestinal tract within a few hours of ingestion using emesis and/or gastric lavage along with activated charcoal administration is classic. Multiple doses of the charcoal given several hours apart are felt useful due to enterohepatic circulation of the toxin. Crucial is the supportive care required to maintain appropriate organ functioning and to avoid renal failure, hepatic coma, blood coagulation problems, acid–base abnormalities, decreased blood glucose, and dehydration. Because of the prominent

liver damage, liver transplants have been done in humans suffering from this specific mushroom intoxication.

Orelline and Orellanine

Species of *Cortinarius* mushrooms contain the *orrellanine* renal toxin. Since clinical signs may not appear for several days following ingestion. Although with larger doses, the clinical signs appear earlier. Anorexia, gastrointestinal disturbances, oliguria, and renal failure are the usual sequence. Although there is no specific antidote, decontamination methods are useful if ingestion is recognized as occurring within the first few hours after the event. Affected kidneys generally recover slowly if the mushroom dose is insufficient to produce cellular death. Dialysis is very useful during the period of renal failure.

Muscimol and Ibotenic Acid

Dramatic and mind-boggling clinical effects occur within a few hours after ingestion of *Amanita muscaria, Amanita pantherina, Amanita strobiliformus,* or *Tricholoma muscarium* mushrooms. The effects begin with drowsiness followed by giddiness, often a maniac behavior, hallucinations and derangement of senses, and signs that resemble those seen in alcohol intoxication. These neurologic effects are complicated by nausea and vomiting, as well as salivation and diarrhea, which may further complicate the clinical picture. The patient becomes confused, disoriented, delirious, and may experience visual hallucinations, muscle spasms and twitching, and occasional convulsions. The periods of drowsiness and agitation often alternate and enthusiastic exaggerated physical activity may be seen. The effects are usually maximum within 3 h after ingestion, but fortunately mortality is minimal, ranging up to 12%.

These variable effects suggest that the toxin concentrations in the mushrooms are quite variable and have been confirmed by chemical analyses. Muscimol and ibotenic are derivatives of gamma-aminobutyric acid and exert their effects on the central nervous system. They both appear to cross the blood-brain barrier, probably by means of an active transport system. Although clinical effects are usually still present more than 5 h after the peak excretion in urine, existing blood levels do not correlate with the clinical effects on the central nervous system. With no specific antidote available, care is generally symptomatic and supportive to avoid self-inflicted injuries due to abnormal behavior. The extreme drowsiness phase frequently requires observation to avoid lack of attention to dangerous behavior.

Monomethylhydrazine

Several mushroom groups carry this toxin. *Gyromitra gigas, Gyromitra esculenta, Helvella elastica, Verpa bohemica, Piziza badia,* and *Gyromitra infula* contain a monomethylhydrazine precursor that when developed as a metabolite becomes toxic. The clinical signs, which are mostly gastrointestinal, occur several hours after the mushrooms are ingested and may not show up for 2 or more days. Once developed, the clinical syndrome is sudden with a bloated sensation followed by vomiting and prominent watery diarrhea. Abdominal cramping, abdominal pain, headaches, and general depression follow and may last for 2 days. Some individuals may develop jaundice, methemoglobinemia, and hemolysis. In the later stages, the clinical effects may include dizziness, loss of muscle coordination, seizures, and coma.

The prominent gastrointestinal effects produced require that affected patients be monitored for dehydration, electrolyte imbalances, red blood cell destruction, and methemoglobinemia. If ingestion is recognized prior to clinical signs developing, gastric decontamination is highly recommended. Although no directive antidote is available, the range of clinical effects (i.e., central nervous system signs, red blood cell alterations, blood glucose depression) and the mushrooms' effect on several organ systems suggest that hepatic and renal function should be monitored for several days.

Muscarine

Prominent cholinergic effects result from consumption of *Clitocybe dealbata, Clitocybe truncicola, Inocybe lacera, Inocybe Pudica,* and *Entoloma rhodopoilum* mushrooms. These effects occur within 30 min to 2 h after ingestion, although when high concentrations of muscarine are present in the consumed mushrooms, signs may appear in as little as 15–20 min. Affected individuals experience blurred vision, excessive perspiration, salivation and lacromation, decreased heart rates, lowered blood pressure, increase peristalsis, mild hypotension, urinary urgency, nasal discharge, pulmonary congestion, and difficult respirations. The presence of excessive perspiration, salivation, and lacromation are generally only seen with this type of mushroom poisoning. Patients may also exhibit flushing of skin, vomiting, abdominal pain, and watery diarrhea.

The toxin is readily absorbed and binds effectively to acetylcholine receptors, initiating what are well-recognized acetylcholine effects at muscarinic sites: the cells are glands, cardiac muscles, and smooth muscle. The effects are peripheral since muscarine has ionic character, which prevents it from crossing the blood-brain barrier. Emesis should always be performed if ingestion is observed. Activated charcoal may be of some value, but the life-threatening cholinergic signs require that atropine be administered. The atropine dose should be repeated until atropinization is present, since the end point for appropriate reversal is the cessation of secretions such as salivation.

Psilocybin and Psilocin

The mushroom genus of *Psilocybe, Panaeolus, Gymnopilus,* and *Conocybe*, and some *Stropharia* species contain these toxins. Effects often are initiated within minutes after ingestion, but may be delayed for a few hours. The effects last up to 4 h with peak activity occurring about 1 h after consumption. The psychoactive effects from these compounds may last up to 15 h, with other nonpsychological effects such

as mydriasis, hypertension, and drowsiness persisting even longer. These potent neuroactive toxins reduce mood swings from euphoric to apprehensive. Visual hallucinations, sweating, yawning, flushing, tremulous speech, incoordination, paresthesias intensified hearing, and unmotivated compulsive body movements typically occur. Nausea and vomiting are present in only about 20% of ingestions.

From 1 to 20 mushroom caps are required to produce the psychological effects, including flashbacks. Psilocybin and Psilocin are four-substituted tryptamine derivatives, which are active when reaching the brain. The effects of psilocin and LSD on brain serotonin are similar. Both psilocin and psilocybin have serotonergic interactions in the peripheral and central nervous system. Most cases are effectively managed when placed in low-stimulus environments and managed with appropriate supportive care. If panic or hyper reactions develop, diazepam therapy is beneficial. Phenothiazine tranquilizers are counterindicated.

Irritants of the Gastrointestinal Tract

Although few fatalities have been reported from mushrooms that produce gastrointestinal irritation, the presence of nausea, vomiting, abdominal pain, and diarrhea soon after ingestion are dramatic effects. Additionally, weaknesses, dizziness, paresthesias, sweating, and varying degrees of headaches have been associated with the gastrointestinal syndrome. *Agaricus xanthodermus, Amanita volvata, Boleus satanus, Chlorophyllum molybdites, Entoloma lividum, Gomphus floccosus, Lampteromyces japonica, Rhodophyllus rhodopolius,* and *Rhodophyllus sinatus* are the mushroom varieties associated with the gastrointestinal disturbances. In total, the onset of clinical signs may be variable, being as early as 15 min or in a few hours. The actual chemicals involved in this digestive syndrome are diverse. It is unknown what specific contributions each of these compounds make to the gastroenteritis. Fortunately, these effects usually resolve spontaneously within a few hours although some may last 24 h or more. There are no serious aftereffects and general symptomatic care is adequate to ensure recovery.

Hypersensitivity Reactions

Various types of hypersensitizations may occur after exposure to mushrooms. These include gastrointestinal, dermatological, and respiratory effects that may be associated with the actual mushroom, with smuts, rusks, sly moles, or dry rotten fungi. Species of *Agaricus* produce an upset stomach for some individuals. Even *Agaricus bisporus*, the mushroom most commonly found in United States grocery stores, has produced temporary gastrointestinal upset in some people who are particularly sensitive to this mushroom. Respiratory and dermal reactions to fungi and fungal spores are fairly common. Since these are usually short-term effects, no specific treatment except prevention by avoiding future exposure is applied. In rare cases where clinical signs are particularly significant, brief corticosteroid administration may be applied. In instances of hepatic failure from mushroom intoxication, recent advances in liver transplantation have proven successful in restoring liver function in most patients.

Treatments

The diverse nature of these mushrooms often precludes the rapid application of therapy. No specific antidotes are available, but if treatment is sought within a few hours after ingestion, the use of emetics to empty the stomach followed by the administration of activated charcoal is a common practice. The use of atropine is significantly avoided. Additional treatments are symptomatic to relieve the uncomfortable effects of the mushroom ingestions and to support the patient during the recovery or healing process. If neurological effects are present, appropriate seizure or nervous control is applied, and diuretic fluid administration and appropriate electrolyte infusions are used to assist with excretion of the toxins and correction of dehydration and electrolyte imbalance. Careful patient monitoring and awareness of potential liver or kidney after effects are necessary nursing steps to assure a satisfactory prognosis and recovery.

An exceptional effort has been made to identify useful therapy for the ingestion of the cyclopeptide antitoxins commonly found in *Amanita* and *Galerina* species. The application of silymarin, derived from the milk thistle *Silybum marianum*, has been periodically favored as a specific treatment for these cyclopeptide intoxications. The flavanoligans in silymarin have been found protected in animals, and are thought to be free radical scavengers and inhibitors of amnitoxin penetration into liver cells. When used for 4–5 days at 20–50 mg/kg of body weight per day intravenously or 1.4–4.2 g/day orally, often in combination of penicillin G, the combination comes as close as practical to a specific antidotal regimen for mushroom toxicity.

The common sense guideline of "Don't pick the mushrooms yourself—and if unsure of a mushroom's toxicity—don't!" provides often critical clinical-sparing guidance. Paramount in the basic toxicology syndrome is the recognition that dose is still a factor. A little taste might satisfy the yearning, while an abundant appetite may lead to serious consequences.

ANIMAL TOXINS

Toxins are represented by an impressively wide spectrum of compounds in numerous botanical species; however, nature's evolutionary chemistry is equally impressive in its complex synthesis of toxins and their diversity and distribution in the world's animal phyla and taxa. From the oceans and continental landmasses of all geographic regions and climates, toxins have been discovered in an array of aquatic and terrestrial animals. The prominent animal kingdom phyla associated with toxins are the Cnidarins, Platyhelminthes, Echinodermata, Mollusca, Annelida, Arthropoda, and Chordata [26].

What Is an Animal Toxin?

An animal toxin can be a protein, enzymatic protein, a small peptide, or homogeneous in nature and is produced by living cells or organisms. Toxins may derive their chemistry from their environment or diet, while the production of some toxins requires the codependence of associated microorganisms and the host animal. Additionally, the chemical make-up of specific animals' toxins can be influenced by geographic variation, seasonal climatic factors, and the influence of these on the animals' habitat. Toxins, biologically and chemically, range from quite simple to complex compounds. Certain animal species may possess only a single toxin within a specific anatomical site in their body. The effect of a single toxin can be like a biochemical bullet that precisely finds its specific target. However, mixtures of toxins in animals are not uncommon, and each single toxin in the mixture may have its individual specific target. When a toxin is introduced into the tissues of another living organism, an adverse physiological event results from the inhibition, or promotion, of another substance or biochemical reaction. In certain circumstances, once a toxin has been introduced into other organisms' tissues, an immune response is elicited, triggering the induction of neutralizing antibodies or antitoxins.

Venoms and Poisons

Some animals, such as amphibians and reptiles, are known to possess a mixture of different toxins usually associated with, and harbored in, highly evolved toxin delivery systems or glands. These toxin cocktails, collectively, are referred to as venoms or poisons, depending on their origin in the animal species. Thus, venoms and poisons are usually mixtures of toxins. Venoms and poisons can elicit a cascade of adverse pharmacological events in their victim. Venoms, being a mixture of toxins, are biologically manufactured or synthesized de novo in a well-developed secretory gland or organ associated with a venom delivery anatomical structure. A poison is generally considered to be the terminal toxin product of a metabolic process, a toxin product of an organism within the animal due to a symbiotic relationship, or toxin product resulting from the biodegradation of a substance. Thus, toxins not directly synthesized by an animal, but which are present in the animal tissues render the animal poisonous. The differentiation of venomous and poisonous animals is most applicable to creatures in marine ecosystems. Given these simplistic definitions, venomous animals are poisonous, but many poisonous animals are not venomous [27].

Toxin Functions

Toxins, venoms, and poisons function by acting as a single agent or working in concert to repel other organisms or more effectively achieve a desired adverse end effect on another organism. Commonly, toxin functions are loosely related to their effects on a given physiological system, resulting in relative terms such as neurotoxins, myotoxins, cytotoxins, and/or hemorrhagic toxins. Regardless of the physiological system affected, animal toxins appear to primarily exist for two important reasons. First many toxins are useful in subduing prey for food, and secondly, toxins often serve in a role of self-defense for the animal in which they are present. Both of these functions, independently or together, provide for the self-preservation and sustained survival of the animal species. However, there are circumstances where a toxin is present in an animal as a result of being passively taken into the body, causing no apparent adverse effects to the animal, and having no apparent function. It is difficult to know if a mollusk harbors a toxic alga for the purpose of protection from predators or for predation of prey food versus simply being present due to the alga's proximity in the mollusk's environment. Thus, a toxin can enter the food chain without having specific function for the animal harboring the toxin.

Bioaccumulation and Bioamplification of Animal Toxins

Animals can accumulate toxins as they are transferred up the food chain. This can be an active or passive bioamplification process as animals ingest, filter in, or absorb certain toxins or toxin-producing organisms, with the end result being a passively acquired toxicity for the host animal. In turn, these animals may, or may not, become poisonous to larger animals that prey on them [28]. This particular scenario is prominent in marine biology as many species of fish are the top consumers or predators of various toxic marine organisms. For example, a mollusk can filter feed on toxin-producing algae and then itself be eaten by a fish that survives the ingestion without complication. A human then consumes this fish with its burden of bioaccumulated toxin. Whether the mollusks' or fish's not being affected is the result of tolerance to the algal toxin or natural resistance to the toxin's effects is variable depending on the species. When humans or other mammals ingest these toxin-laden fish, severe toxicological medical consequences can occur. Animals may also acquire their toxins from a wide variety of toxin-containing plants on which they feed as part of their diet. A more thorough discussion of toxins in the food chain is discussed in Chapter 14.

Toxin Delivery Systems

Toxin delivery to a specific target can only occur following its introduction onto or into another living organism, and in this respect the animals of the natural world have proven to be quite accomplished, reflecting traits of great creativity. The introduction of a toxin, venom, or poison can occur via absorption onto, or across a barrier, and by injection into, or through a barrier. Usually, this barrier is anatomically dermal in nature and not readily penetrated by most nocuous external environmental substances. Toxin application and penetration processes are achieved by specific mechanical strategies such as superficial mucous secretions, bristles and hairs, glandular skin secretions, barbs, spines, and teeth. Pharmacological or toxicological actions of toxins following

TABLE 19.2
Interrelationships of Animal Phyla, Environment, Toxins, and Toxin Targets

Phylum	Class	Common Names	Toxin	Toxin-Target
Mollusca	Marine	Blue-ringed octopus (*Hapalochlaena lunulata*)		
Chordata		Puffer fish (*fugu* sp.)	Tetrodotoxin	Na^+ ion channel
Chordata	Terrestrial	Rough-skinned newt (*Taricha granulosa*)		
		Neotropical toad (*Atelopus carbonensis*)		
Cnidaria	Marine	Sea anemone (*Aiptasia pallida*)	Phospholipase A_2	Cell membranes
Arthropoda	Terrestrial	Honey bee (*Apis mellifera*)		
Mollusca	Marine	Cone snail (*Conus geographus*)	Omega-conotoxin	Ca^{++} ion channel
Arthropoda	Terrestrial	Funnel web spider (*Agelenopsis aperta*)	Omega-agatoxin	
Mollusca	Marine	Cone snail (*Conus purpurascens*)	*K*-conotoxin	
Cnidaria		Sea anemone (*Bundosoma granulifera*)	BgK	K^+ ion channel
Chordata	Terrestrial	E.African green mamba (*Dendroaspis augusticeps*)	Dendrotoxin	
Arthropoda		Yellow scorpion (*Leiurus quinquestriatus*)	Charbytoxin	
Chordata	Marine	Broad-banded sea snake (*Laticauda semifasciata*)	Erabutoxin	ACh receptor
	Terrestrial	Black-necked cobra (*Naja nigricollis*)	Neurotoxin-alpha	
		E.African green mamba (*Dendroaspis augusticeps*)	Fasciculin 1	ACh-esterase

their topical deposition on body surfaces can cause superficial or severe localized reactions. This topical delivery process can be enhanced, dependent on the chemical properties and pharmacological actions of the toxin, inducing the toxin's transdermal absorption, and result in systemic toxicity. Toxin delivery into the systemic processes of another living organism can cause effects ranging from limited physiologic responses to severe systemic physiological alterations, resulting in the death of the unfortunate toxin recipient. Airborne toxin delivery is a method frequently employed by some insects and is achieved by the spraying of a toxin topically onto dermal or ocular surfaces, or even spraying in the oral cavity of predators. More advanced and direct methods of toxin delivery are achieved by injection via a bite or string. These may be associated with an anatomically sophisticated delivery system such as that present in the fang-venom duct-venom gland complex present in solenoglyphic venomous snakes, or the pulsating stinging apparatus of the common honeybee.

Complementation and Diversification of Animal Toxins

The sharing and interrelationships of phyla, toxins, toxin structures, and toxin functions exist across marine and terrestrial environments. Distinct animal species from different phyla, from widely separated geographic regions and habitats, have developed toxins with a variety of chemical-structural and functional relationships. Combinations of animal phyla, animal toxins, and the associated toxin structure–function relationships has yielded four basic schemes in nature: (1) interphylogenetic species producing a common toxin that acts on a common target, (2) interphylogenetic species producing different toxins with chemically related structures that act on a common target, (3) interphylogenetic species producing toxins with unrelated chemical structures that act on a common target, and (4) intraphylogenetic species producing toxins with similar chemical structures, or toxins with unrelated chemical structures, and acting on the same target, or different targets (Table 19.2). The interrelationship of these factors provides evidence for divergent evolutionary function in toxin-producing animals, between phyla or within a phylum, and for a certain degree of convergent evolutionary function with respect to toxin properties and function.

The K-conotoxin from the cone snail, *Conus purpurascens*, phylum Mollusca, is quite different in its chemical configuration compared to that of charbytoxin from the yellow scorpion, *Leiurus quinquestriatus*, phylum Arthropoda, yet both of these toxins target the potassium ion channel [26]. An alternate path in this relationship is observed between toxins from the same phylum when toxins of similar chemical structure are produced, but the toxins act on separate targets. Toxins such as neurotoxin alpha in the venom of the black-necked cobra (*Naja nigricollis*), and fasciculin 1, from the venom of the east African green mamba, are structurally similar, but neurotoxin alpha acts on the acetylcholine receptor while fasciculin 1 acts on acetycholinestease. Omega-conotoxin from the cone snail, *Conus geographicus*, phylum Mollusca, is similar in chemical configuration-structure to omega-agatoxin from the funnel web spider, *Agelenopsis aperta*, phylum Arthrpoda, and both act on calcium ion channels [29]. These examples are illustrative of the evolutionarily diverse creatures that generate similar

chemically configured toxins, resulting in similar pharmacological actions. Thus, toxins from quite evolutionarily different animals, or evolutionarily similar animals, can exhibit both qualitative and quantitative similarities and differences, in their effect. However, there are also toxins, like tetrodotoxin, which are widespread in the animal kingdom (found in the skin of amphibians, fish organs, and blue-ringed octopus) that have a common chemical structure and common pharmacological site of action [30].

Mechanisms of Animal Toxin Actions

Biodiversity of organisms provides for a diverse spectrum of how animal toxins act pharmacologically to do what is essential for the continued survival of their host animal, whether they are needed for acquiring or digesting food, or providing defense. In certain circumstances, this also includes how toxic effects are exerted in animals that have ingested a toxin-containing organism and inadvertently become victims of poisoning. Whether the toxins effects are neurotoxic, myotoxic, cytotoxic, or coagulopathic, these effects are usually due to toxin proteins, enzymatic proteins, and peptides, acting either singly or collectively, as in the case of some venoms, to create a single action or a cascade of reactions that result in toxicological consequences to a living organism.

Toxicity resulting from the pharmacologic actions of different toxins can reflect both qualitative and quantitative differences. A toxin's ability to elicit a toxic effect by acting at a single target may be quantitative due to the resultant toxicity being dependent on the dose of toxin reaching the target, or reaching subtargets within a target. Receptors may structurally possess a single binding site for a toxin, or more than one binding site for the toxin. The degree of toxin binding may be limited by conformational characteristics of the binding site, but binding to a single site or more than a single site, may still depend on the dose of the toxin. If the dose is low, there may be minimal binding at only one site on the receptor, and this may not result in any measurable toxicity. If the toxin dose is large, increased binding may occur at a single site, or at more binding sites on the receptor, resulting in significant toxicity. Thus, with different animal toxins and their quest for different receptor targets or subtargets, there potentially exists a resonance of flexible stoichiometric relationships. All these factors, in addition to the toxin's own chemical configuration, can affect what binding site a toxin is specific for. Subtle differences in how these factors are related is especially important as slight chemical and structural differences in toxins cannot only provide for a specific toxin's binding the same receptor as another toxin, but also allow for the toxin to bind at different site on the same receptor.

Additionally, there may exist binding sites within a given target, such as a cell membrane, which allow the binding of different toxins. This multiple toxin–multiple target relationship is commonly observed with snake venoms. These multiple toxins found in venoms may also function sequentially via synchronized pharmacologic actions when injected into another organism, with one toxin leading to improved bioavailability of another more potent toxin to its target.

Although toxin dose is an important component in the development of toxicological effects, the inherent affinity of toxins for given targets relating to toxin specificity, is also a factor that influences the potency of a given dose of toxin. Animal toxins can compete as agonists or antagonists with endogenous neurotransmitters in synaptisomal clefts, and may either act presynaptically or postsynaptically. Toxins that target the acetylcholine receptor, or neuromuscular junction, are well-established among the different animal phyla. There also exists a prevalence of toxins that target voltage-gated ion channels, primarily sodium, potassium, and calcium ion channels. Again, nature has provided some unique features of select pharmacological effectiveness of toxin specificity as is observed by the selective binding of toxins such as beta-scorpion toxin versus tetrodotoxin from newts, which bind to different sites on the sodium ion channel.

Toxins may also digest or directly inactivate neurotransmitters. Phospholipase A_2 is an enzymatic protein with wide representation in the animal kingdom, and known to exist in greater than 100 isoforms. Not surprisingly the various forms are capable of exhibiting diverse pharmacologic activities and physiological properties ranging from the destruction of cell membranes to acting as presynaptic neurotoxins [31,32]. Other animal toxins can act on a variety of cell membranes, altering cellular membrane integrity, and inducing secondary toxic effects from a toxin's cytolytic, myotoxic, and coagulopathic effects.

Collectively, toxin effects, whether myotoxic, agonistic, or antagonistic to receptors, ion channel altering, or neurotoxic based on their properties such as affinity and specificity, conformational structure/specificity, or length of amino acid sequences contribute to varying levels of toxicity, diversity of pharmacological function, and the extent of pharmacological function leading to a toxicological end effect. A role of animal toxins in nature that has become confounding has arisen from the increasing interface between humans and animals in all ecosystems. How nature's animals use their toxins has been expanded due to the behavioral nature of humans in pursuing activities that cross all ecosystem barriers. Consequently, animals have been forced to use their toxins and venoms in defensive circumstances far beyond their intended protective use against natural predators. The dynamics of these animal–natural predator, and animal–human, relationships will be further discussed with respect to toxinology: specifically, animal phyla, their specific toxins or venoms, toxin functions in the natural world, and their impact in biomedical research and clinical toxicology.

Marine and Freshwater Ecosystem Animal Toxins

Greater than two thirds of the planet earth is covered in ocean saltwaters that are home to diverse and highly integrated marine communities. The remaining one third of the planet's landmasses is dissected by rivers and scattered with lakes, comprising freshwater aquatic ecosystems that also

contain integrated animal communities of great diversity. Similar to the relationship of venomous versus poisonous animals, all marine animals are aquatic, but not all aquatic animals are marine. In organisms from marine environments alone, the chemical structures of greater than 5000 natural products, as single chemical classes or mixed biosynthetic compounds, have been elucidated [33–35]. This number is probably far less for compounds derived from freshwater species because of the considerably smaller freshwater habitat on earth. These organism-taxonomic and toxin-chemistry relationships are complex, and the biogenetic diversity of animal toxins in these habitats is great, and the quest to dissect out animal communities and the specific sources of animal toxins is a continual and ongoing search for scientists.

Invertebrate Marine and Freshwater Animal Toxins and Venoms

Multiple genera representing 11 different classes, derived from 5 different phyla, comprise the phylogenetic roots for thousands of invertebrate species in marine ecosystems (Table 19.3). Although marine invertebrates are rather simplistic in form, ranging from simple hydrozoan corals to more complex forms such as gastropod cone snails, many possess some form of toxin or venom as a means for acquiring a meal, or as a deterrent against predators. However, in addition to toxin effects on other organisms, a remarkable number of marine invertebrate toxins are also harmful, or even lethal, to humans.

Annelida

Bristle worms and fire worms, class Polychaeta, that possess toxins are reported for several genera (Table 19.3) [36]. Known by a variety of common names they share the common feature of having parapodia, leg-like appendages on each of their body segments, with hollow monofilament-like bristles, called setae, attached. In many cases, the bristles may have a feathery appearance. Despite anatomical likenesses, the different species can display a range of appearances reflected in their common names such as palolo worms, featherduster worms, sea mouse, or lug worms. Some such as *Eunice gigantea* have been reported to grow up to three meters in length [36].

Eurythoe complanata, a species indigenous to the tropical Pacific Ocean and Gulf of Mexico has spiny, barbed bristles that it promptly flares when threatened. If bristle contact occurs by a predatory animal, or human touch, the barbed glassy spines are readily released into tissues of the offender. However, this action results in a mechanical or physical insult causing a localized dermal inflammatory response and paresthesia that may last for weeks, but is not believed to be associated with delivery of a toxin. Embedded bristles may be partially removed by the application of adhesive tape over the affected area. Topical use of a steroid cream and oral or topical antihistamines may be a beneficial symptomatic treatment, and severe cases of secondary infection or even gangrene is possible [37,38].

Importantly, certain species such as *Eunice*- and *Glyceria-species* have jaws associated with a defined venom gland and a fang-like proboscis that delivers a large molecular weight, ion channel forming, alpha-glycerotoxin [39]. Clinical symptoms from the bite show it to be quite painful with blanching around the punctures, followed after several days with persistent itching. However, uneventful recovery generally follows.

The medicinal leech, class Hirudinea, is a freshwater annelid with a quite interesting history, as it has been used by the lay public for self remedies, and by physicians since 200 BC, for a variety of medical purposes, including its use as a

TABLE 19.3
Marine and Freshwater Invertebrate Animals: Venomous or Toxin-Producing

Phylum	Class	Common Names	Genera (Toxin-Producing)
Annelida	Polychaeta	Bistleworms, fireworms	*Chloeia, Glycera, Eunice, Eurythoe, Hermodice*
	Hirudinea	Medicinal leech	*Hirudo*
Cnidaria	Anthozoa	Anemones	*Actinia, Aiptasia, Antheopsis, Condylactis, Entacmaea, Halcuriasp, Heteractis, Stomolphus, Tealia, Urticina*
		Corals (soft, stoney, hard)	*Alcyonaria, Gorgonaria, Heliopora*
	Cubozoa	Box jellyfish	*Chironex, Chiropsalmusa, Carukia, Carybdea, Physalia, Tamoya, Tripedalia*
	Hydrozoa	Fire corals	*Millepora*
		Portuguese man-of-war	*Physalia*
		Sea fans	*Aglaophenia, Halecium, Lytocarpus, Macrorhynchia, Nemalecium, Thecocarpus*
	Schyphozoa	True jellyfish	*Cassiopea*, *Cyanea, Chrysaora, Pelagia, Rhizostoma*
Echinodermata	Echinoidea	Sea urchins	*Asthenosoma, Aerosoma, Diadema, Phormosoma, Tripneustes,Toxopneustes*
	Asteroidea	Starfish (sea stars)	*Acanthaster*
	Holothuroidea	Sea cucumbers	*Bohadschia, Thelonota*
Mollusca	Gastropoda	Cone snails	*Conus* sp.
	Cephalopoda	Blue-ringed Octopus	*Hapalochlaena*
Porifera	Demospongiae	Sponge	*Fibula, Lissodendoryx, Microiona, Neofibularia, Tedania*

postoperative aid in microvascular surgery patients [40,41]. These creatures have two suckers, which lie at the anterior and posterior ends of the head, with the mouth being in the anterior sucker where three jaws of teeth are located. Once attached, to the often unknowing victim, blood is sucked out as the leech uses rhythmic contractions of its pharynx to deliver the blood to its crop for storage until digestion takes place. The leech can ingest a blood volume nearly 10 times its weight, and as much as 15 mL of blood may be removed [42]. The anticoagulant effect of leech venom stems from the toxin hirudin, an antithrombin substance, but the venom also contains hyaluronidase, proteolytic enzymes such as bdellins and elgins, fibrinase, collagenase, and salivary apyrases [43,44].

The most common effects of leech bites are the depletion of blood volume in small animals from which the leech draws its nutrition, and the continued oozing of blood from the bite site following detachment. It has been reported that oozing may continue for up to 24 h after leech removal [45]. Leeches have caused hematuria due to urinary tract invasion, and hemoptysis form upper airway attachment [46].

Treatment of leech bite is not standardized and a myriad of means for leech removal have been proposed. Cocaine has been used to paralyze leeches, resulting in their release from their victim, but would certainly not be recommended in cases of a leech-lodged airway. The use of forceps to hold the leech until it releases has been effective, and one individual required anesthesia with direct visualization for leech retrieval [47]. Regardless of the leech removal method, once removed, it is recommended that the wound be irrigated, pressure applied and gelatin sponge used if bleeding persists, and evaluation for wound infection followed up [45].

Cnidaria

The Cnidaria, also known as Coelenterates, include anemones, corals, jellyfish, and hydrozoans (Table 19.3). This phylum is unique for being the only entirely venomous phylum in the entire animal kingdom. The variety of creatures in these classes appear to be quite different visually, yet they frequently share a commonality in their toxin-delivery mechanism, a process that involves stinging organelles known as nematocysts, sometimes referred to as cnidocysts [48,49]. These microscopic structures are organelles contained within specialized stinging cells, or cnidocytes, which, in the resting stage, appear like a well-inflated balloon with a small spike protruding. The spike continues to the interior as a barbed luminous thread that spirals like a spring within a venom capsule. If a significant osmolar or pressure change occurs, the nematocyst explosively discharges its inverted, barbed filament into the tissue of its victim with a simultaneous injection of venom [50]. The discharged nematocyst then appears, grossly, as a slightly deflated balloon attached to a string [36]. Nematocysts are primarily located on tentacles or along folding anatomical ridges, with thousands of these organelles present, allowing for the delivery of considerable quantities of toxins. Interestingly, some creatures have extended the use of nematocysts and their toxins via an interesting phenomenon in which noncnidarian marine creatures such as the octopus, *Tremoctopus violaceus*, attach fragments of Portuguese man-of-war tentacles to their own tentacles as both offensive and defensive armaments [51].

Toxins that have been identified in cnidarians stem from a variety of peptides and proteins that possess neurotoxic, hemolytic, or cytolytic properties [52]. Although the number of species of Cnidaria has been estimated at 10,000 or greater, the number of species potentially dangerous to humans is not known, but believed to be relatively low [53]. Regardless of the unknown number of species dangerous to human health, the medical problems associated with cnidarian envenoming are global in nature [54].

Anthozoa

Anemones are one of the nature's most beautiful and graceful sea life forms, yet these mostly sedentary cnidarians can readily deploy their paralyzing toxins from nematocysts into potential predators that brush against their tentacles, or into the unknowing prey animal that seeks shelter among their tentacles. However, not all sea anemone toxins have been confirmed to be actually located in tentacle nematocysts, as the contracting, intact body of some anemones will secrete cytolytic toxins with mechanical stimulation [55,56]. Anemones can also retract their tentacles under stress conditions, resulting in the secretion of large quantities of cytolytic or hemolytic toxins in mucus, rather than by nematocyst release, that can induce osmotic cell lysis via pore-forming ion channels in membranes. Interestingly, these toxins that serve to acquire prey, may also aid in the self-preservation of an individual that possesses resistance to its own cytolosins, within an anemone colony by allowing intraspecific spatial competition [57].

An additional complexity concerning this marine life form is the interrelationship between some anemone genera (*Entacmaea* and *Heteractis*) and species of fish in the genera *Amphiprion* and *Premnas* that demonstrates a symbiotic relationship in which anemone toxins provide protection to fish hiding among the nematocyst burdened anemone tentacles [58]. The exact reason fish survive in this symbiotic relationship has not been confirmed to be universal, as some fish species are protected by a mucus coating of their skin while others may have acquired immunity to certain sea anemone toxins [59].

An array of toxins has been discovered in anemones, as lethal cytolytic proteins and peptides have been reported in more than 32 species of sea anemones in the order Actinaria alone [60]. Roughly 30 different pore-forming toxins, known as actinoporins, have been characterized in greater than 20 sea anemone species [61]. However, there are several anemone genera that have been reported to be toxin producing (Table 19.3), and several toxins have been extensively characterized, such as sodium/potassium ion channel blockers [62], crustacean/vertebrate lethal cytolysins, and a cardiostimulatory protein, lacking cytolytic, activity has been isolated from *Urticina piscivora* [63].

Some toxins such as, tealiatoxin produced by *Tealia felina*, exhibit both hemolytic and histaminolytic activities [64].

Although a multitude of toxins have been identified, the medical consequences of most anemone stings to humans are fairly similar. The common symptom is a painful, stinging cutaneous lesion, which is localized to the area of tentacle contact [36]. Severity is proportional to the number of discharged nematocysts in the skin. Nematocysts can be inactivated by, *fixing* with the application of 5% acetic acid (vinegar), or a 70% isopropyl alcohol solution. Removal of remnant tentacles and nematocysts can be accomplished by the unidirectional scraping of the affected area with a knife blade or the edge of a plastic card. The lesion should then be washed with antibacterial soap and generously rinsed with water. Topical steroid cream may be useful in reducing local inflammation [65].

Rare acute envenomations have resulted in symptoms of severe pulmonary edema and cardiac arrest and have been the cause of eight deaths following envenomation by *Stomolphus nomuri* [66]. A species of *Condylactis* is believed to have been responsible for the death of a young male due to rapid hepatocellular failure [67].

Cubozoa

The box jellyfish is probably the most well known of the jellyfishes because of their unique anatomy and the potentially severe toxicity that can result from their painful stings. Although closely related, their distinct anatomy separates them from true jellyfish. They are four-sided, cowbell-shaped, translucent, gelatinous creatures that have muscular pedalia at each corner, where tentacles 10 or more times the height of the bell, and have been reported to be in excess of 60 m, stream in the underwater currents [68]. They inhabit mostly subtropical and tropical waters, and the coasts of Australia are notoriously famous for the presence of dangerous jellyfish. *Carybdea* species have been occasionally found in temperate waters [69]. Cubozoans possess four photosensory structures known as rhopalia, which each contain four simple eyes and two complex eyes. This vision system makes cubozoans exceptionally phototactic as evidenced by their light-sensitive behavior of descending to deeper water during bright sunlight, and moving toward the surface in early morning, late afternoon, and evening.

In contrast to the majority of jellyfish, box jellies do not drift with the underwater currents and are not planktonic in nature. They are strong swimmers and some species such as, *Chionex fleckeri*, the dangerous Australian species commonly referred to as the sea wasp, have been reported to move at 3–6 m/min [70]. The Cuboidal jellyfish from Australian waters is associated with interesting and unique local nomenclature such as the *Irukandji* (*Carukia barnsei*), the *jimble* (*Carybdea rastoni*), and the *morbakka* (*Tamoya* spp.) [71–73].

Cubozoan tentacles are laden with nematocysts of several different types, which collectively form a complement of nematocysts referred to as a cnidome [68]. Differing severity of toxicity between different genera may correlate with the nematocyst concentration present in the tentacles of a given species, which is also related to cubozoan species size [74]. However, studies using antibodies against box jellyfish have shown lack of cross-reactivity with other jellyfish venoms, and clearly suggest toxicity difference is also the result of different toxins in the venoms from different genera [75]. Venom of *Chironex fleckeri* is proteinaceous and possesses dermonecrotic, hemolytic, and myotoxic toxins that can work synergistically to cause lethal cardiorespiratory effects [76,77]. Myotoxins of 150 and 600 kDa have been isolated from *C. fleckeri* and shown to be lethal in animal studies, but characterization of other venom components have been illusive [78]. Commonly, the result of envenomation is a hypercatecholanaemia symptom profile, but this does not hold for all species, as the effects of venom from *Chriopsalmus* sp., a species responsible for many fatalities in the Philippines, does not respond to receptor antagonists, or antibodies, that are effective in reversing *C. fleckeri* venom-induced symptoms [79,80]. In cases of severe envenomation, death has occurred within minutes, and there have been at least 67 documented deaths [76].

In general, Cubozoan envenomations do not result in severe complications, but those inflicted by *Chironex fleckeri* can cause death as evidenced by the numerous fatalities reported in Australian waters [81]. Treatment of cubozoan envenomations, without severe symptoms, is accomplished with the use of acetic acid to retard nematocyst firing, and symptomatic support. However, more severe envenomations have required support with mechanical ventilation, which has still been ineffective in cases of profound cardiotoxicity [82]. Antivenom for *C. fleckeri* envenomation treatment has been developed, but there is only limited documentation as to its effectiveness in humans with severe cardiorespiratory symptoms [83].

Irukandji syndrome is a severe form of toxicity resulting from the sting of the small *Carybdea barnesi* jellyfish. It is a species of undefined geographic origin that has primarily been reported off the coasts in the northern-half of Australia, yet an Irukandji-like syndrome has been reported in Hawaii [84]. Although cardiopulmonary complications are predominant, the exact underlying mechanism is unclear. Victims exhibit distress, generalized pain, nausea, frequently severe hypertension, and pulmonary edema. The clinical profile suggests excess catecholamine [85]. Treatment is generally supportive, requiring analgesics, antihypertensive drugs, ventilation, and pressor drugs, with recovery in several (3–4) days [76].

Hydrozoa

Hydrozoa are primarily colonial benthic cnidarians, with the exception of floating *Physalia*, which are simple marine life forms that, like all other members of cnidaria, possess nematocysts. Four different morphological forms of nematocysts are known to be present in Hydrozoa: atrichous isorhiza, microbasic euryteles, microbasic mastigophores, and stenoles [53]. They differ in the arrangement of spines on the shaft, which may result in varying degrees of anchoring to tissue and venom delivery into the victim [86]. Thus, when contact with these organisms occurs, there is mechanical

injury in addition to toxicological injury. Although the number of species in the class has been estimated at greater than 10,000, the number of species known to be potentially dangerous to humans is small [76].

Fire coral, *Millepora* sp., is a hydrocoral rather that a true coral, and is familiar to many reef divers as it is frequently encountered among colonies of true corals. Antler-like in appearance, the velvety tines are covered with nematocyst-containing hydranths that look like small, segmented hairs with umbrellas at the tip. The venom contains thermolabile, proteinaceous components possessing both dermonecrotic and hemolytic properties. Toxicity studies in small rodents have shown it capable of causing death [87]. When contact with fire coral occurs, there is an immediate burning and stinging sensation that progresses rapidly to a painful pruritus. Wheals develop and the area of contact becomes edematous and erythematous. Pain symptoms generally resolve within an hour or two, while dermatological symptoms may persist for up to a week, with pigmentation lesions persisting for 1–2 months [88]. Amelioration of symptoms usually requires only the application of a skin cream, but, in more severe cases, may require deactivation and removal of nematocysts, followed by the application of hydrocortisone cream. It has been reported that papain-containing *meat tenderizer* may be useful in recovering ingrained nematocysts [65].

Portuguese man-of-war, *Physalia physalis*, is a nondiving, oceanic, jellyfish-like, hrydrozoan with a global geographic distribution. Their gas-filled bladders, actually modified medusae, allow them to drift with wind and surface water currents. Their numerous tentacles may be long, trailing 13 m or more into the depths, and can deliver potent venom from their associated nematocysts [89]. A small, morphological form of this genus, *Physalia utriculus*, commonly called the blue bottle, is indigenous to the Micronesian waters of the Pacific, but lesions resulting from its stings are less extensive than those of *P. physalis* [36]. Venom from *Physalia* has not been fully characterized, but a glycoprotein structured toxin, physaliatoxin, has been isolated and described as possessing strong cytolytic and hemolytic properties [90]. Additionally, enzymatic proteins with cardiotoxic effects have been isolated, and whole venom can elicit rapid histamine release from mast cells [91,92]. Complications to humans from the stings of *Physalia* can range from acute pain in tentacle contact areas, to migratory joint pain, and in rare circumstances death from rapid respiratory failure followed by cardiovascular collapse [93]. Unlike the inhibitory response to firing nematocysts of Chironex with acetic acid, this therapy has been reported to induce further nematocyst discharge in cases of *Physalia* sting [94]. Cold packs may reduce the superficial inflammatory and pain response of stung tissues, and papain solution has been useful for inactivating nematocysts [95]. The use of topical lidocaine preparations may also be beneficial in reducing localized inflammation and pain [96]. Antivenom for treatment *Chionex* stings provides no paraspecific coverage or protection to victims of *Physalia* envenomation, as it is not cross-reactive with *Physalia* venom [97]. Thus, there is no definitive treatment in cases of life-threatening envenomation, and basic cardiopulmonary resuscitation and support measures are essential if recovery is possible.

Sea fans are some of the more elegant appearing hydrozoans with their feathery, fan-leafed ferns look. These benthic hydrozoans are found in shallow Atlantic, Indo-Pacific, and Australian waters. Despite their harmless appearance, their nematocysts can deliver painful stings, associated with erythematous and edematous whealing, when contact occurs [54]. The best-known genera for delivering venomous stings are the *Aglaophenia* and *Lytocarpus*, yet other genera may also cause dermal contact-related problems (Table 19.3). Little is known of sea fan venoms, yet in recent years, the discovery of new venomous species has occurred by accident as case reports of stings find their way into the literature. One such species, *Nemalcium lighti*, was found to be capable of delivering pruritus and burn-sensation inducing stings to an unfortunate snorkel victim that persisted for days [52]. Sea fan envenomations are not life-threatening, but basically an aggravating discomfort, and their superficial symptoms respond to deactivation of nematocysts still in contact with skin, and the application of anti-inflammatory creams [65].

Schyphozoa is the class representing the true jellyfish, which are probably the most frequently encountered jellyfish by beachgoers. They tend to be radially symmetrical with their gelatinous medusal forms swimming in varying currents from the surface waters down to the abyss of the oceans, depending on the species [36]. They have a variety of interesting and descriptive names: upside-down jellyfish (*Cassiopea xamachama*), sea nettle (*Chrysaora quinquecirrha*), hair jelly (*Cyanea* sp.), described by Halstead as *mop hiding under a dinner plate*, and mauve stinger (*Pelagia noctiluca*) [36,98]. Although Schyphozoan nematocysts are capable of delivering irritating stings that may rarely cause muscle cramps and unconsciousness, their venoms are not as dangerous as those of their Cubozoan relatives, as no cases of death are found reported in the literature [99].

Chrysaora quinquecirrha crude venom (CQV) possesses a bioactive hyaluronidase, an enzyme thought to aid in the spread of venom, that is similar to the hyaluronidase found in the venom of the five pace snake (*Agkistodon acutus*), again demonstrating the similarity of toxins across phyla in the animal kingdom. Further studies showed CQV to exhibit hemolytic activity [100]. Animal studies have predominantly supported that fatal reactions to jellyfish envenomation have been the result of cardiac, respiratory, or renal toxicity, but CQV studies also suggest the venom is capable of inducing hepatic lesions, subsequent to lethal cytotoxicity, that may explain fatal reactions as a result of delayed hepatic failure [101].

Cassiopea xamachana, from Puerto Rican coasts, can cause painful stings, and recent research showed their venom (CxTX) contains a low molecular weight, <10 kDa, fraction that binds to acetylcholine muscarinic receptors and demonstrated strong hemolytic activity, in an animal model. Additionally, a phospholipase A_2 (PLA_2) fraction contributed significantly to its paralytic activity and lethality [102]. It is

likely that CxTX toxicity is the result of venom toxins acting synergistically. The degree to which Schyphozoans share similarities in their toxins remains to be elucidated, but toxin effects appear to cause a similar clinical profile in humans who have had an unfortunate contact. The varying severity of envenomation apparently is dependent on the extent of the tentacle contact area, and the duration of contact [36]. Treatment of Schyphozoan envenomation is similar to that recommended for Cubozoan stings, and with good supportive care, a favorable outcome is to be expected.

Echinodermata

The phylum Echinodermata is perhaps most familiar to people of all ages because of the amazing starfish, class Asteroidea. For many years these creatures have been taken from the world's oceans, dried and sold as curios, to be appropriately placed on desktops, library shelves, and used in unthinkable numbers for school *show and tells*. Sea urchins, class Echinodea, are also widely recognized due to the fear of a painful encounter with one of their spines. Many children and amateur snorkelers have paid the price for that tempting moment of curiosity, when the extended finger has tried to gently touch one of these creatures, and been rapidly withdrawn in profound pain, or the unwary wader plants a foot on the needle-like spines. Unlike these better-known Echinoderms, the sea cucumbers (class Holothuroidea) possess a more fragile, large sluggish, appearing form that lacks the mechanical injury-inducing abilities of other Echinoderms. Although these creatures are reported to number approximately 6000 different species, only about 1% is believed to be venomous [103].

Sea urchins, class Echinoidea, represent the majority of venomous echinoderms and are painfully familiar to most people who have spent any time swimming, beach walking, surfing, or diving and snorkeling in subtropical or tropical coastal waters. They have a pincushion appearance with stiff, bristle-like spines that are structurally a calcium carbonate matrix, which may be hollow or solid, blunt or sharp, and may possess a venom-producing gland at the spinal apex [104]. They also may introduce venom via pedicellariae, which are jaw-like structures used to grasp unsuspecting prey. Urchin venoms comprise cholinergic substances, hemolysins, proteases, serotonin, and sterol glycosides [105].

Most urchin species are incapable of effectively injecting venom into humans and the resultant sting is primarily a mechanical injury. However, there are two Indo-Pacific ranging species, the Needle Spined Sea Urchin (*Diadema setosum*) and the Flower Sea Urchin (*Toxopneustes pileolus*), that are known to be capable of inflicting serious envenomation symptoms [89]. The severity of symptoms varies depending on the number of penetrating spines, and the associated pain is greater than that of mechanical injury alone. In rare cases of severe envenoming to humans symptoms of bronchospasm, cranial nerve dysfunction, hepatitis, hypotension, palpitations, and syncope have occurred [104,105]. *Toxopneustes* envenomation has even been reported to have caused deaths in Japan [106]. Treatment of urchin envenomation symptoms is ill-defined, and complicated by the fragile nature of spines frequently broken off in the wound. Methods of extricating spines have been relatively ineffective, and appropriate wound care may involve warm water immersion, analgesic drugs, and the breaking of large embedded spines into smaller fragments so they may be more readily absorbed or extruded [37]. Thus, the mainstay of treatment is symptomatic and supportive as needed.

Starfish, class Astoidea, although comprising many harmless species, has one major species responsible for envenomations to humans, the crown-of-thorns starfish (*Acanthaster planci*) of the Indo-Pacific region [36]. The crown-of-thorns starfish, as its name suggests, is an ornately pigmented, and large starfish that is found among the colorful coral reefs where their feeding on coral polyps can destroy the fragile coral reef structure [107]. Like urchins, it is the spines of this starfish, which may grow to 60 cm in diameter and possess 13–16 rays with spines up to 6 cm in length, that inflict a painful wound [36]. Venom is believed to lie in the epidermal cell layer of the spines where acidophilic glandular cells produce venom, which has been shown to have hemolytic and lethal activities in a rodent model [108]. Crude venom has also been shown to exhibit edema-forming and capillary permeability inducing properties [109]. More recent studies have revealed the venom contains a 15.5 kDa, phospholipase A_2 that can induce skeletal muscle myonecrosis in animals [110]. Their venom has also been reported to contain a basic glycoprotein of 20–25 kDa molecular weight, with lethal properties when injected into mice, and hepatic and hypotensive effects have also been observed in animal experiments [111,112].

The symptoms of crown-of-thorns starfish stings are quite similar to those observed from urchins, but the pain subsequent to venom release from embedded spines has been described as extremely intense with throbbing and burning sensations, which may last for a month [37]. Treatment is also similar to that for urchins with hot water submersion being of benefit in relieving pain initially, with prudent follow-up wound care, observation for secondary infection, and use of steroid creams and antibiotics as indicated by symptoms [37].

Sea cucumbers, class Holothuroidea, in stark contrast to their spiny bodied urchin and starfish relatives, are soft-bodied, blob-like creatures with an amazing array of color patterns that are secretive in nature. They have no true appendages other than small tentacles around their mouth, and internally harbor organs referred to as Organs of Cuvier, also known as Cuvierian tubules [89]. Occasionally, divers and beachgoers will handle sea cucumbers causing them to release a glycoside, known as holothurin [113]. This toxin is a saponin produced in the Cuvierian tubules that are readily deployed from the cloaca when contact is made with the offending organism, has a glue-like consistency and can be most inflammatory to skin and cause conjunctival complications to the eye [114]. To remedy symptoms, victims should decontaminate the areas of contact with gentle and voluminous rinsing and washing with mild detergent, and ocular exposures require normal saline irrigation [113].

Mollusca

The cone snails, class Gastropoda, superfamily Conidea, are the dangerously beautiful, paramount toxin-producing representatives of the phylum Mollusca. As a genus, *Conus* represents the largest genus of living marine invertebrates, and it encompasses more venomous species than any other single genus in the entire animal kingdom, with greater than 500 species that display an array of brilliant color patterns [115]. Their venom components have primarily been associated with modest-sized, disulfide and cysteine-rich, peptides, collectively known as conotoxins [116]. Currently, the number of different conotoxins is believed to be greater than 50, 000, and within this number are a plethora of peptides and proteins, with diverse structures, and toxicological activities that target a wide range of ion channels and receptors [117,118]. Not surprisingly, given their venom diversity, cone snail toxins and their derived peptides have a potential role in the development of therapies for a variety of medical disorders.

Cone snails inhabit tropical waters of the world and are predatory, possessing a hollow, harpoon-like radular tooth within its extensible rostrum that can be rapidly deployed for envenomating prey [103]. Prey is usually engulfed and simultaneously envenomated. They have been roughly divided into three groups depending on their preferred prey: molluscivorous (feeding on gastropods, making them somewhat cannibalistic), piscivorous (feeding on fish), and vermivorous (feeding on polychaete worms). They have also been known to prey on bivalve mollusks, octopus, and hemichordate worms [119].

Cone snail toxins have been classified based on their structure, principally their cysteine framework, which is based on the distribution and number of cysteines in the primary sequence [120]. Two major groups of toxins that have been intensely studied are the conotoxins with multiple disulfide bonds, and the much less prevalent *Conus* peptides that possess only a single, or no disulfide linkages. Superfamilies of these peptide toxins most extensively researched are the A—(alpha-conotoxins, alphaA-conotoxins, and kappa conotoxins), M—(μ-conotoxins and psi-conotoxins), and O—(omega-conotoxins, delta-conotoxins, μO-conotoxins, and kappa-conotoxins) superfamilies. Those in the A-superfamily act as nicotinic acetylcholine receptor antagonists, and voltage-gated potassium channel blockers, while the M-superfamily toxins impair voltage-gated sodium channels and act as noncompetitive nicotinic acetylcholine receptor antagonists. The O-superfamily conotoxins possesses the greatest range of function pharmacologically with actions to block voltage-sensitive calcium channels and the ability to block both sodium and potassium voltage-gated channels. The nondisulfide *Conus* peptides such as conantokins, contalakins, conopressins, exhibit M-methyl-D-aspartate receptor antagonism, neurotensin-like peptides, and vasopressin antagonism, respectively while the pharmacological role of contryphans remains to be determined [117].

Cone snail related fatality to humans was first reported by Rumphius in 1705, and the fatality rate in more recent times has been reported to be 70% [121]. Of all the cone snails, it is the Geography Cone (*Conus geographicus*) that most frequently causes envenomation to humans, and is responsible for most fatalities. However, *C. aulicus, C. gloriamaris, C. marmoreus, C. omaria, C. striatus*, and *C. tulipa* have been reported to cause death in humans [121,122]. Victims of *C. geographicus* and *C. obscurus* envenomation experienced a radiating numbness while contrastingly, victims of *C.aulicus, C. textile*, and *C. tulipa* reported intense pain. Acute envenomation symptoms involve muscular paralysis, respiratory distress, loss of gag reflex and ability to swallow, and blurred or double-vision. Timely treatment involving cardiopulmonary support is essential as no antivenom currently exists [117].

The blue-ringed octopus, class Cephalopoda, is a small octopus species native to shallow coastal and intertidal waters of Australia. Two similar appearing species, *Hapalochlaena maculosa* and *H. lunulata*, are native, and as their common name implies, they have yellowish-gold bodies with dark mottled bands and blue rings, which appear to light-up a brilliant fluorescent blue color when the animal is disturbed or frightened [89]. They have eight arms, are carnivorous, and use their two beak-like jaws to introduce venom via the salivary duct with the inflicted bite, but have been observed to subdue prey by releasing their saliva into water surrounding the prey [123].

The venom of *Hapalochlaena* sp. has had two main toxins identified, hapalotoxin and tetrodotoxin, with tetrodotoxin having a defensive role against predatory fish. Additional venom components such as histamine, serotonin, and tyramine have been found in the salivary glands [124]. Originally, the tetrodotoxin was called maculotoxin, but careful spectral analysis using nuclear magnetic resonance showed that it was identical to tetrodotoxin [125]. The bite of the blue-ringed octopus may not elicit a significant pain response, and it may go unnoticed until symptoms of paresthesia around the face and neck are felt. Envenomation to humans has proven fatal, and death has been reported to occur within 30 min of having been bitten. Since no antivenom is available, the rapid use of standard life support measures, with emphasis on respirator-supported breathing being maintained until spontaneous breathing returns [126].

Interestingly, there is recent documentation indicating that saxitoxin is present in *Abdophus* sp. of octopus from the northern coastline of Western Australia. The source of this curare-like neurotoxin, normally produced by dinoflagellates, in the diet of this octopus is uncertain, but the tentacle toxin concentration is believed to be capable of causing profound paralytic shellfish poisoning [127].

Porifera

Sponges, class Demospongiae, are the simplest multicellular marine life forms, having no defined organ systems. They are sessile creatures with amorphous and radially symmetrical shapes that grow attached to nearly any substrate, and are found from deep ocean bottoms to the shallow coastal

waters. There are four classes of Porifera, but the class, Demospongiae, has been most studied. The exact number of sponge species is still a major question, but at least 7000 species are reported in the literature (far fewer are freshwater species), and it has been speculated that the number may be greater than 15,000 [128].

Some have sharp spicules, but these are not believed to deliver toxin, and it may be that potential toxins are associated with the solid body rather than spicules [129]. Although detailed knowledge of sponge chemistry and pharmacology is in its infancy, the number of pharmacologically active compounds being discovered, such as the antitumor macrolides (spongistatins), is rapidly increasing [130]. Toxins specific to sponges have not been identified, but it is clear that adverse dermal reactions can result when dermal contact occurs.

Skin contact with the Southern Australian toxic sponge, *Neofibularia mordens*, can cause severe dermatitis that may last for months, and does not respond well to symptomatic medication. *Tedania* sp. and *Lissodendoryx* sp. have also been reported to cause an irritating dermatitis, but of shorter symptom duration [89]. Ice packs and cooling solutions, with camphor and menthol, have been reported to ameliorate the irritated skin, and hot water and alcohol are to be avoided as they intensify the agitation [37].

Briefly, freshwater sponges such as the *pipera-coora* (*Ephydatia* sp.) from Australia and the *Spongilla lacustris* from Europe may cause irritation with handling, and undefined substances from both were found to cause diarrhea, respiratory distress, and death in animals [89].

Vertebrate Marine and Freshwater Animal Toxins and Venoms

Marine and freshwater vertebrate animal toxins are present in some of the world's creatures most commonly familiar to humans (Table 19.4). Whether it is a stingray in the sandy beach waters, a catfish caught on the fishing line, or sea snake or sea turtle swimming in the coral reef, these are all descriptions for which we can easily conjure up images. However, these conjured images are linked with the fact that stingrays, venomous fish, and sea snakes are the marine vertebrates most responsible for significant envenomations to humans.

Fish are vertebrates represented by 22,000 species, accounting for half the world's vertebrate population [131], and greater than 200 species are venomous [132]. Interestingly, it has been speculated that the evolution of the venom apparatus in a large number of these fish is a result of their nonmigratory, slow moving habits, and their liking of sheltered shallow water environments [133].

It is these various vertebrate marine forms that necessitated the need for a more distinct differentiation between the terms poisonous and venomous. Marine animals that are considered poisonous generally possess an *acquired* toxicity as a result of their having ingested other toxin-producing organisms while venomous animals manufacture their venoms in a distinctive venom gland primarily from their own endogenously produced toxins, and deliver their venom via barbs, fangs, spines, or teeth that cause trauma in addition to the toxicity associated with venom. The collective toxins that make up of venoms tend to be heat labile, large–molecular-weight

TABLE 19.4
Marine and Freshwater Vertebrate Animals: Venomous or Toxin-Producing

Phylum	Class	Common Names	Genera (Toxin-Producing)
Chordata	Chondrichthyes (cartilaginous fish)	Hornsharks, spiny dogfish	*Heterodontus, Squalus*
		Stingray, bat rays, eagle rays, butterfly rays, river rays, whip rays, skate, stingaree	*Aetobatus, Aetomylaeus, Dasyatis, Gymnura, Mobula, Myliobatis, Potamotrygon, Pteromylaeus,Taeniura, Rhinoptera, Urogymnus, Urolophus*
	Osteichthyes (bony fish)	Boxfish, trunkfish	*Lactophrys, Ostracion*
		catfish	*Aurius, Centrochir, Clarias, Heteropneustes, Ictalurus, Liobagrus, Noturus, Pimelodus, Plotosus*, *Pterodoras*, *Tandanus*
		Scorpionfishes	*Centropogon*, *Dendrochirus, Gymnapistes, Helicolenus, Hypodytes, Inimicus, Neosebastes, Notesthes, Pterois, Scorpaena, Sebastes, Sebastodes*
		Stonefish	*Synanceia* (*Synanceja*)
		Toadfish	*Batrachoides, Thalassophryne*
		Blennies	*Meiacanthus*
		Rabbitfish	*Siganus*
		Stargazer	*Uranoscopus*
		Weeverfish	*Echiichthys, Trachinus*
	Reptilia	Sea kraits	*Laticauda*
		True sea snakes	*Acalyptophis, Aipysurus, Astrotia, Disteria, Emydocephalus, Enhydrina, Ephalophis, Hyderlaps, Hydrophis, Kerilia, Kolpophis, Lapemis, Parahydrophis, Pelamis, Thalassophina, Thalassophis*

proteins. Poisons, in contrast, are primarily low-molecular–weight, heat stable substances, and the poisonous animals involved lack an exacting anatomical venom delivery system [134]. Fish of the genera Batrachoides, Echiichtis, and Syanchceia are commonly considered scorpionfishes but are singled out in Table 19.4 because they are prominent venomous piscine genera.

Sea snakes of the Laticauda genus have periods in their reproductive life cycles requiring brief excursions to coastal beaches for egg laying. All other sea snake genera spend their entire lives in water, including giving birth to live young [135]; thus, sea snakes are truly marine animals and are included along with the bony and cartilaginous fishes for presentation and discussion in this vertebrate marine animal section.

Chordata, Marine and Freshwater Venomous Vertebrates

Chondrichthyes

Sharks from only two genera are known to be venomous (Table 19.4), and they are sometimes described as shark-like fish of the subclass, Elasmobranchii [136]. Although it is likely envenomations by these sharks may be more frequent than reported, literature that documents the consequences of envenomation by either genus is lacking. Envenoming by these sharks usually occurs to fishermen as a result of a dermal penetrating puncture with their venomous spines. They have two sharp spines with luminal venom ducts, and no associated integumentary sheath enclosure, that contain a whitish mass with venom-producing vacuolated cells. A single spine is located immediately in front of the anterior dorsal fin, and immediately in front of the posterior dorsal fin [68]. The Port Jackson Shark (*Heterodontus portusjacksoni*) is native to Australian waters, and their spines inflict rough-edged lesions with venom delivery resulting in muscle weakness of the envneomated appendage [137]. The spiny dogfish, Squalus megalops/cubensis, from Brazil known in the local region as *cacao-bagre* caused significant injury to a fisherman while it was being handled. Immediate and intense pain at the site of spine puncture, followed by erythema, edema, and localized kerotosis that persisted for 14 days resulted [138]. Shark spine injuries have the obvious trauma component that accompanies venom effects, and have been treated with wound irrigation, hot water submersion, and antibiotics [36,134].

Stingrays are elasmobranchs, which have representation by at least one genus in nearly all oceans and seas, and the fresh waters of Central and South America. Their dorsoventrally compressed bodies are the perfect design for their cryptic cover while resting in shallow water. The tail extends from the flattened, tetrahedral-shaped body, making them appear like a kite with an attached balancing tail. The tail may possess a single spine or multiple spines with highly serrated edges. Their body size may range from centimeters to greater than three meters, and their barb-like spines have highly serrated edges [134]. Spine morphology varies considerably between different genera and species. The venom is contained within specialized secretory cells inside an integumental sheath that surrounds the caudal spine.

There is little known about the specific chemical make-up of freshwater or marine stingray venoms, but they are thermolabile [139]. Stingray venoms of the genera, *Patamotrygon* and *Urobatis*, have been reported to cause cardiocirculatory toxicity as a result of direct effects on the myocardium [139,140], and neurotoxic effects have also been reported [141]. Recent studies of freshwater stingray venom from *Potamotrygon falkneri* revealed 18 different venom components by acrylamide gel separation, with molecular weights ranging from 12 to 130 kDa, and exhibiting caseinolytic, gelanolinolytic, and hyaluronidase enzymatic activities [142].

Envenomation occurs via the tail whipping the spine forward and upward into a predator or other unfortunate victim, when the stingray is alarmed, frightened, or stepped on causing the simultaneous rupturing of the sheath and secretory cells to release venom. There may be considerable mechanical tissue trauma at the site of laceration or puncture resulting in severe bleeding, and the venom can add further insult by intensifying severe localized pain, erythema, edema, skin necrosis, and ulceration. Systemic symptoms of dizziness, fever, migraine, myalgia, and vomiting have occurred from freshwater stingray envenomations [142]. Victims of marine stingray envenomation have died of cardiovascular failure [143], and in one case, the reported cause of death was the result of cardiac tamponade and myocardial necrosis, following puncture of the thoracic cavity by the stingray spine [144].

Stingray envenomation routinely is inflicted on the lower extremities of humans, and treatment may include immediate attempt in pain reduction by immersion of the affected area in hot water. The wound area may also be anesthetized with 1% lidocaine and irrigated with povidone-iodine, followed by prophylaxis for infection and tetanus. The wound should be carefully examined to confirm that no residual spine fragments or other debris remain, as the removal of these in a timely fashion greatly reduces pain and secondary complications [142]. Severe cases of envenomation, usually those involving puncture of the upper torso, may require careful radiographic evaluation of the puncture site, and advanced life-support measures [144].

Osteichthyes

Venomous bony fishes are primarily inhabitants of tropical oceans, but also exist in some temperate oceans and seas. Additionally, many species have become quite popular and are maintained by fish hobbyists and in private collections. The venoms of the bony fishes are produced, maintained, and delivered by anatomical structures similar to all species. This involves venom production by specific secretory glands within an integumental sheath, associated with spines that are anatomically located in conjunction with fins of the anal, caudal, dorsal, opercular, pectoral, pelvic, or shoulder areas of a given species. When a spine pierces tissue, the integumental sheath's integrity is disrupted and the venom delivered into the wound [145]. It is notable that the inflicted spine

injury from many species may in itself be more traumatic and damaging than the venom.

Fish venoms of nearly all species are used almost exclusively for self-defense, and as such, there is a great degree of similarity in their chemical and pharmacological properties, and their differences are quantitative [146]. Like the venom of their cartilaginous relatives, bony fish venoms also exhibit labile sensitivities, their stability and activity being easily abolished by fluctuations in temperature, heat, and pH [147]. Venom toxins identified for piscine fish range from 15 kDa [148] to 800 kDa [147]. The pharmacological effects of piscine venoms, collectively, are represented by three major observed toxic effects in vivo: (1) their ability to induce serious cardiovascular toxicity, (2) their neuromuscular activity, and (3) their cytolytic activity. Mechanistically, it is thought that both the cardiovascular and neuromuscular effects are the result of the potent cytolytic property, and that a single toxin in the venom is responsible for expression of all these activities [146].

Not surprisingly, given the pharmacological and toxicity similarities for most piscine fish venoms, the treatment of their envenomations is also similar. Early initiation of treatment is important and involves the immediate irrigation of the wound, removal of any easily retrieved material, and immersion of the wound in hot water (not so hot as to cause burns). Analgesic drugs and the use of local anesthetic at the wound site should be instituted. If specific antivenom is available, it should be administered. Timely follow-up with wound care is important to rule out the possibility of retained solid materials in the wound, and evaluate for secondary infection. Marine wound infections, when they occur, are commonly polymicrobial, and appropriate antibiotic administration should be initiated if symptoms are warranting [149].

A few of the more well-known groups and genera of bony piscine fish will now be discussed in more detail.

Catfish—Catfish are an easily recognizable whiskered fish, and approximately 1000 different species inhabit the fresh and salt waters worldwide. They have dorsal and pectoral fin spines, that may or may not be edged with sharp serrations, and are associated with a venom-containing integumental sheath. These spinal fins are usually kept flush with their body; however, when distressed, the spines become locked in an extended position to inflict their wound [68]. Although there are multiple genera associated with toxic reactions (Table 19.3), the main adverse effect of consequence from their inflicted stings is related to the trauma associated with the puncture of tissue.

In North America, catfish of the genera *Ictalurus* and *Noturus* are responsible for most stings [150]. Venom of the white catfish, *Ictalurus catus*, has been reported to contain two to eight lethal factors, and two dermonecrotic factors that was moderately heat stable [151].

In the Indo-Pacific region, the Arabian Gulf catfish (*Arius thalassinus*) and the striped catfish (*Plotosus lineatus*) are notorious for their ability to inflict extremely painful wounds, and deliver several proteinaceous toxins, known as *crinotoxins*, in the stinging process. Both species have also been shown to contain these toxins in their skin secretions as well. Investigation of the activities of *A. thalassinus* toxins revealed they contained vasoconstrictor components that could induce vasoconstriction in vascular smooth muscle [152], and may be related to muscarinic receptor activity [153]. The skin toxin of *P. lineatus* has yielded a hemolysin, two edema-forming factors, and two lethal factors [154]. Venoms of Indian catfish species, *Hereropneustes fossili* and *Plotosus canius*, contain or cause the release of prostaglandins that induce smooth muscle contractions in experimental models [155], and have caused severe neurotoxic symptoms when injected into mice [156]. A lethal component of *C. canius* venom, toxin-PC, acts presynaptically, blocking neurotransmitter release resulting in neuromuscular blockade [157]. Given the array of catfish venom toxinological effects, it is unfortunate that there is little reporting of envenomation cases that would provide a basis to develop optimal clinical management.

Catfish stings and envenomation most often occur to fishermen who are actively pursuing the capture of fish. Symptoms of bleeding, stinging, throbbing sensation, intense pain, and even peripheral neuropathy may result [158]. Treatment comprises judicious wound care and removal of any residual spine fragments in the wound. Secondary infections are a frequent complication with catfish injuries, and antibiotic therapy may be necessary [159,160].

Scorpionfishes—Scorpionfish is a somewhat vague name that is frequently used to encompass a broad general taxonomical classification when referring to any one of a number of genera of anatomically similar fish (Table 19.3). They are commonly known throughout their wide range, as they are present in all oceans of the earth, but venomous species are most prevalent in tropical waters. Out of this diverse group, approximately 80 species have been reported to possess venom toxins or have caused envenomation to humans [161]. They are easily recognized due to their unique and often ornate appearance, an attribute that also makes them desirable by collectors. Some species, such as the lionfish (*Pterois volitans*) and zebrafish (*Dendrochirus zebra*), of the Indo-West Pacific oceans and Red Sea, are highly sought after by aquarists [162].

Scorpionfish venom glands are associated with spines represented in the configuration of 3 anal spines, 10–15 dorsal spines, and 2 pelvic spines. Venom extracts from lionfish (*P. volitans*) and soldier fish (*Gymnapistes marmoratus*) have been found to increase intracellular Ca++ in cultured neurons possibly as a result of pore formation in cell membranes. The increased Ca++ was associated with increased cell death due to cellular swelling and neurite loss [163]. In support of the calcium ion role in toxicity is the observation of both adrenergic and cholinergic cardiotoxic effects from *P. volitans* [164] and *G. marmoratus* [165] crude venoms in animal tissue and cell culture models. Cardiovascular effects of *Scorpaena guttata* venom in rat hearts are biphasic with early reduction in chronotropic and inotropic effects, later

followed by an increase in these effects. Thus, the venom acts on muscarinic and adrenoreceptors, respectively, and this may be the result of endogenous autocoid release [166]. The venom of the bullrout (*Notesthes robusta*), a species native to eastern Australia, contains a 169.8–174.5 kDa protein (*nocitoxin*) that is capable of pain induction in humans via polymodal nociceptor stimulaton [167]. Collectively, the cardiotoxic and neurotoxic effects suggest that scorpionfish venoms act pre- and postsynaptially to induce cell membrane depolarization, and that this action is dependent on extracellular divalent cations [146]. Future research with scorpionfish venoms should provide a number of pharamacologic toxins useful as research tools and possible medical uses.

Envenomation by scoropionfishes nearly always results in profound pain, a possibility of significant swelling, and systemic effects such as nausea, vomiting, diaphoresis, dyspnea, hypotension, weakness, syncope, and collapse have been reported. Systemic complications are possibly related to the intensity of pain rather than true toxic effects of venom [168,169]. Treatment of envenomation is supportive as described earlier; however, stonefish antivenom has been implicated as potential therapy for lionfish and soldierfish envenomations [170].

Stonefish—Synanceia spp., also taxonomically referred to as *Synanceja* spp., are one of the most researched venomous fish genera, and their venoms have yielded unique toxins with a variety of pharmacological activities [171]. The different *Syanceia* species are native to waters throughout the Indo-Pacific oceans, and are known by a variety of local names, such as dornorn or wary-phoul in Australia, devilfish in Java, gofu in Polynesia, sherova in East Africa, and the U.S. name of stonefish is almost universal [134]. These slightly grotesque, but quite interesting looking, fish are morphologically reminiscent of an algae, moss, or barnacle covered rock, and as such, their looks complement their cryptic behavior. Thus, they lay on the bottom waiting to ambush unsuspecting prey, and may also be accidentally stepped on by the unobservant human wading in the shallow waters they frequent.

Stonefish venom glands are closely associated with the 13 dorsal spines, which appear to be covered with rough, thick skin. Two lateral grooves run the length of the spine and the venom glands reside in the mid-third of the spine shaft. The glands are sheathed in a fibrous, multilayered capsule that is vasculature and has a nerve network. Stonefish will release a milky white dermal secretion, independent of their spine venom, when handled or agitated. Crude, fresh Stonefish venom has been characterized as being opalescent in appearance, heat labile, and has a pH of 6.0 [172].

The venoms of three species, *S. horrida*, *S. trachynis*, and *S. verricosa*, have all been found to contain catecholamines [173], exhibit various enzymatic activities [174], and increase vascular permeability [172]. A lethal substance called *stonustoxin* (SNTX) that comprises two large subunits, alpha = 79.4 kD and beta = 79.3 kDa, has been isolated from Indian stonefish, *S. horrida*, venom [175], and induces cardiovascular hypotensive responses in rats, that are thought to be nitric oxide mediated [176]. SNTX also inhibits muscle cell contraction by acting directly on the myocyte rather than neurotransmission blockade [177]. Estuarine stonefish, *S. trachynis*, venom contains a 158 kDa toxin, *trachynilysin* (TLY), that elicits atrial muscle cell membrane hyperpolarizing actions [178], causes massive neurotransmitter discharge at low concentrations, and both muscle and nerve injury at higher concentrations, in tissue preparations [179]. Interestingly, it has been reported that TLY effect mechanisms are quite similar to those produced by alpha-latrotoxin from the black widow spider (*Latrodectus* spp.) [180]. The venom of the Reef stonefish, *S. verrucosa*, also has its own special toxin, *verrucotoxin* (Vtx), a four subunit toxin comprising two alpha (83 kDa) and two beta (78 kDa) subunits [181]. This toxin can also elicit hypotensive [181] and neurotoxic effects in animals [182]. These different stonefish toxins represent the most bioactive components of their respective crude venoms, account for all the suspected lethal activity, and suggest that their venoms comprise a relatively small number of toxins [164]. Their pharmacological and toxicological effects in various cell and animal models may be useful in biomedical research, but it is difficult to clearly define specific functions that impact human health.

Clinical features of stonefish envenoming in humans involve local tissue trauma with gradually intensifying pain at the spine penetration site. Swelling and erythema may progress for up to 24 h. Systemically, the key serious complications are cardiovascular related, with hypotension, bradycardia, pulmonary edema, arrhythmia, and cardiovascular collapse associated with neurologic symptoms of muscle weakness, paralysis, and convulsions, potentially leading to death [183]. Although death has been reported [184], there may be possible inaccuracies with the documentation, and stonefish sting should not be a terminal life event.

Treatment of stonefish envenomated victims is supportive and symptomatic, and specific antivenom produced in Australia (CSL Limited, Parkville, Victoria, Australia) is effective in reversing many of the severe effects of venom toxicity [185]. This antivenom has been considered to possibly provide paraspecific coverage against the toxic effects of *G. marmoratus* and *P. volitans* venoms based on animal studies, but this has not been tested in humans [170].

Toadfish—Thalassophryne spp. are similar to stonefish in behavior and appearance, inhabiting the bottoms of coastal waters worldwide, and some species can use their swim bladders to *sing* their watery trill. They have two dorsal and two opercular spines connected to venom glands, and their venom is delivered with rupture of the integumentary spinal sheath upon stinging [134]. Venom is composed of heat labile, bioactive toxins, range 18–97 kDa molecular weight, that alter arteriolar and venous microvascular hemodynamics, and cause myonecrosis [186]. Envenomation to humans results in severe pain, dizziness, and edema with a rapidly ensuing tissue necrosis [187]. Treatment consists of immersion of the wound in hot water, analgesics or local anesthetics, and supportive wound care [188].

Weeverfish—Echiichthys or *Trachinus* species, weeverfish, predominantly inhabit the flat sandy bottoms of European coastal waters, the Black and Meditteranian seas, Chile's Pacific coast, and South Africa's [68]. Taxonomical confusion may come from the fact that four species of *Echichthys* were previously listed in the genus, *Trachinus* [30]. Although multiple species have been identified, two European species are well known for their toxic stings, the greater weeverfish (*Echiichthys draco*) and the lesser weeverfish (*Echiichthys vipera*) [68]. As their name implies, the greater weeverfish is fairly large, and may reach a half-meter in length. Weeverfish venom delivery is accomplished with any of the five dorsal, or two opercular, spines that have a thin-walled integumentary sheath near their base, covering the venom gland [134].

Weeverfish toxins are quite heat labile, but have been isolated, intact, from *T. draco*, a 105 kDa polypeptide with hemolytic properties called *dracotoxin* [189], and from *T. vipera*, a 324 kDa compound composed of four subunits called *trachinine* [190]. The crude venom of *T. draco* contains histamine, catacholamines, exhibits cholinesterase activity, and produces hypertension with subsequent sustained hypotension in cats, demonstrating a biphasic effect [191].

Weeverfish stings vary widely in their severity from the usual symptoms of intense pain with local inflammation to extremely rare cases of secondary infections associated with fatality [192]. Generally, symptoms resolve in about a week, and treatment is the same as that used for other Osteichthyes envenomations [149].

Sabre-toothed blenny—Meiacanthus nigrolineatus is briefly mentioned here because it is the only piscine fish known to deliver its venom with its grooved canine teeth, in contrast to other piscine fish that deliver their venom with spines. Their venom gland is located in the lower jaw, and there is no information as to the chemical or pharmacological properties of their venom [193]. Their bite to humans is said to be painful (Keyler, D.E. personal communication, 2005.)

Rabbitfish—Siganus spp. are native to the Indo-Pacific oceans and seas. They have 13 venom-delivering dorsal spines, and the associated venom glands are located within anterolateral grooves that run the length of the spine. The four pelvic spines are similar in structural anatomy. This venom delivery and venom gland arrangement is quite similar to that of the lionfish. Like the sabre-tooth blenny, little is known about their venom, but stings are said to be comparable to those of other similar scorpionfish [134].

Stargazer—Uranoscopus spp. have the descriptive name, stargazers, as their small eyes are located on the flat dorsal aspect of their cuboidal-shaped head, making them appear to be gazing upward toward the water's surface. They have a short, but sharp stubby spine with a poorly defined venom gland that surrounds their base on each side of their body in the region immediately above the pectoral fins. Knowledge concerning chemical composition or pharmacological activity of their venom is lacking, and it is only the reporting of human fatalities caused by the Mediterranean specie, *Uranoscopus scaber*, that supports their being considered venomous [194]. Investigators have tested for toxic effects in animals by injecting crude venom extracts from stargazer venom glands, but were unsuccessful in confirming any toxicity [195]. This lack of toxicity confirmation may have resulted from sensitive chemical and toxin instability of the venom following its removal from the venom gland. Treatment of stargazer envenomation should follow that of other piscine envenomations [196].

Boxfish and *Trunkfish—Lactophrys* and *Ostracion* are two genera to be discussed briefly because they produce toxins in their skin, and secrete them rather than deliver them with a specialized apparatus. They are native to the Indo-Pacific and their toxins are used as a defense against other fish predators, and therefore are ichthyotoxic. By releasing these natural fish killing toxins into their immediate environment, they effectively deter their predatory counterparts and survive to live another day [134]. The primary toxin produced by both these genera is *pahutoxin* (PHN), a choline chloride ester of 3-acetoxypalmitic acid that has phospholipid membrane permeability disruptor and surfactant properties [197]. Thus, dual pharmacologic actions of lipophilic and hydrophilic components appear to function synergistically. The regulatory mechanism of this action stems from two distinct fractions in trunkfish skin secretion, and has been proposed to be receptor mediated [198]. The consequences to humans who make contact with these skin secretions are dermal irritation, and persistent complications would not be expected to follow [30].

Reptiia

Sea snakes navigate coral reefs and oceans in the world's subtropical and tropical regions but have been observed thousands of miles distant to these regions, even in the absence of oceanic currents or foul weather. Thus, they are the most widely dispersed venomous reptiles on the earth [199].

Their morphological appearance and physical body structure, although similar to terrestrial snakes, is usually distinguished by the presence of laterally compressed tails with a paddle-like look. Their physiology allows them to dive to depths of 100 m, and stay submerged for greater than 3 h, but they rely on atmospheric air to survive. There are 17 different genera (Table 19.4), and they average approximately 1 m in length, but some species (*Laticauda colubrine*) approach 3–4 m. Sea snakes usually have short (<4 mm), conical, fixed-position fangs, and the fang length varies according to the prey eaten. The fangs are luminal and interface with ducts that connect the fangs to elongated venom glands lying in the upper jaw on each side of the head. Venom glands are fibrous-encapsulated and attach to adductor muscles that contract to express venom through the venom duct network and into prey [135].

Sea snake venoms are complex toxin blends with varying combinations of protein toxin types, are extremely toxic, and their venoms are the most potent of any vertebrate animal on earth. The venom yield delivered from most sea snake species

ranges from 1 to 10 mg, but species such as *Astrotia stokesii* can deliver greater than 20 mg, and as little as 0.04 mg/kg of *Aipysurus duboisii* is fatal to mice. Venom dose-response studies suggest that the beaked sea snake (*E. shcistosa*) delivers enough venom in its maximum yield to kill approximately 53 humans [135]. Whole sea snake venom possesses several enzymes and comprises acetylcholinesterase, hyaluronidase, leucine aminopeptidase, 5'–nucleotidase, phosphomonoesterase, phosphodiesterase, and phospholipase A [200]. Toxins isolated from venom usually contain 60–62 amino acid residues, and a total of 29 different toxins have been isolated from 9 separate species of sea snakes. Purified toxins maintain their integrity as they have been demonstrated to be heat stable, both acid and base pH tolerant, and are more potent than crude venom based on animal LD50 experimental data [201]. The potency of sea snake venoms is linked to both pre- and postsynaptic neurotoxins. An isolated postsynaptic protein toxin of 6–8 kDa molecular weight, which is highly stabilized by multiple disulfide bridges, is a primary pharmacologically active toxin [201]. The postsynaptic toxin binds to the acetylcholine receptor. Venom from the beaked sea snake (*Enhydrina schistose*) contains a phopholipase, and the venom of *Laticauda semifasciata* contains the curaremimetic toxin, *erabutoxin* [202]. A that has a demonstrated presynaptic toxic effect, plus phospholipase activity [202]. Thus, the net effect of venom, on living animals envenomated by sea snakes, is paralysis resulting from irreversible binding of the postsynaptic toxin at the acetylcholine receptor in the neuromuscular junction [203].

Envenomation by sea snakes to humans is a serious medical concern. Sea snake fangs, being small, do not make deep punctures, and fang marks (may appear as scratches) may not be easily visualized. Additionally, the bite is frequently asymptomatic, not even felt by the victim, and local symptoms are usually absent. Envenomation is manifested by diplopia, dysarthria, dysphagia, muscle fasciculations, muscle pain, shock, trismus, and paralysis [204]. Myoglobinuria, myonecrosis, and nephropathy have also been observed [205]. Neurotoxic symptoms may be deferred for up to 3 h, often causing the victim to delay seeking medical attention. Fatalities usually result from paralysis of the diaphragm progressing to respiratory arrest, and lack of timely treatment. A pressure immobilization method of first aid has been found to be beneficial and may be of major importance when a victim is remote to a medical facility [204]. Cardiopulmonary support is effective therapy, and sea snake antivenom (CSL Limited, Parkville, VIC, Australia) is a definitive therapy. Importantly, the antivenom appears to be effective for envenomation by all sea snake species, and it also demonstrates venom similarities of sea snake species [206].

Terrestrial Animal Toxins

The land dwelling animals of the world are associated with all the continental landmasses of the earth, although the diversity and numbers of different species are the greatest in tropical regions. As the latitudinal distance from the equator becomes greater, the diversity and number of animal species decreases. Thus, an inverse relationship exists between the number of species and distance from tropical climates, a relationship that is paralleled with respect to the diversity and number of animal toxins. In recent centuries, a confounding element in these relationships has been the human being. As humans have increasingly traveled the earth, there has been an associated increase in the dispersal of species to regions beyond their natural ranges. Additionally, as the world's population increases and expands geographically into natural environments there is an ever-increasing interface between humans and terrestrial animal species. This leads to human encounters with animals, and consequent envenomations from insects, centipedes, scorpions, spiders, amphibians, lizards, and snakes. The frequency of encounters with these toxin-producing species is probably greatest in tropical third world countries, where the availability of medical treatment is nonexistent or quite limited. Unfortunately, the consequences of humans living in close proximity to potentially dangerous creatures may also lead to the disappearance of animal species over time, and the loss of knowledge related to their natural toxins. The toxins from stinging, biting, and skin secreting terrestrial species, both invertebrate and vertebrate, have received considerable attention in biomedical research for scientific and medical reasons.

Terrestrial Invertebrate Animal Toxins and Venoms

The terrestrial invertebrates capable of delivering toxins via bites, stings, skin secretion, or bristle and hair contact are members of the largest phylum in the animal kingdom, Arthropoda. These relatively small, often thought of as creepy creatures, are probably responsible for envenomations to humans in numbers exceeding the sum of envenomations from all other animal phyla [132]. Arthropods all have legs, and walk, run, or fly, and there are three main classes of toxin- or venom-producing members (Table 19.5).

Arthropoda, Terrestrial Venomous Invertebrates

Arachnida

Arachnids differ from centipedes and insects by possessing eight legs in contrast to the large number on centipedes and the six on insects. They do not have antennae or wings, but can live in a variety of ecosystem environments. Their toxins represent an amazing pharmacological arsenal capable of subduing a spectrum of prey, and multiple arachnid forms pose significant danger to human health in some regions of the earth.

Scorpions

Scorpions are represented by at least 1500 individual species, from multiple genera (Table 19.5) that live in arid and wet ecosystems, are the largest of the arachnids in size, and may possibly be the oldest living creatures on earth (400 million

TABLE 19.5
Terrestrial Invertebrate Animals: Venomous or Toxin-Producing

Phylum	Class	Common Names	Genera (Toxin-Producing)
Arthropoda	Arachnida	Scorpions	*Androctonus, Botothus, Buthus, Centuroides,Heterometrus, Leiurus, Mesobuthus, Opistophthjalmus, Orothochirus, Palamnieus, Scorpio, Tityus*
		Spiders	*Achaearanea, Aganippe, Agelenopsis, Araneus, Arbantis, Argiope, Artosa, Atrax, Badumna, Bothriocyrtum, Breda, Chiracanthium, Cupiennius, Diallomus, Dolomedes, Drassoides, Dysdrea, Eriophora, Fillistata, Hadronnyche, Harpactirella, Hermeas, Heteropoda, Holoplatys, Isopeda, Ixeuticus, Lampona, Lycosa, Latrodectus, Liocranoides, Loxosceles, Missulena, Misumenoides, Neoscona, Nephila, Olios, Opisthoncus, Peucetia, Phidippus, Selenocosima, Steatoda, Tegenaria, Thiodina, Trechona, Ummidia*
		Bird/Goliath spiders	*Ornithoctonus, Theraphosa*
		Tarantulas	*Acanthoscurria, Avicularia, Brachypelma, Megaphobema, Phoeneutria, Phrixotrichus, Poecilotheria, Stromatopelma*
	Chilopoda	Centipedes	*Cormocephalus, Ethmostigmus, Otostigmus, Rhysida, Scolopendra, Scutigera*

years) [207]. Scorpions appear like a small, earth-tone colored, lobster carrying a thin tail with an inverted hook, arched over its back. Their body comprises three distinct sections, but the head and thorax are joined to form a cephalothorax, which has pincers, or pedipalps, used for restraining prey and feeding themselves. The pincer-like claws are actually a modification of the first set of legs, and the remaining three pairs of legs are used for walking. The body part most humans and prey are familiar with is the stinger, which is attached to the telson, a terminal distal segment that houses venom glands connecting to two orifices in the stinger. Scorpions sting with this apparatus, and deliver their venom into a variety of prey organisms, including other arthropods and humans. Scorpions are fossorial and reclusive in nature, tending to be nocturnally active.

Scorpion venoms have been the focus of ion channel researchers for nearly 25 years since the isolation of, *Noxiustoxin*, a short chain venom peptide, in 1928 [208]. Their venoms are a mixed combination of approximately 50–100, low molecular weight, polypeptide toxins, and it has been estimated that there are greater than 100,000 different peptides among all the scorpion species [207]. Of this large number of species and toxins, only 30 scorpion species and an associated 200 distinct polypeptides have been investigated, and their functional properties reported [209]. Their venoms contain various polypeptides with an array of pharmacological and physiological actions highly specific for crustaceans, insects, and mammals, and have been of interest in bioinsecticidal research and development [210].

All scorpion toxins are constructed with an alpha-helical segment and two to three anti-parallel beta-sheet folds, tightly held by three to four disulfide bridges that maintain the tertiary conformational structure.

Four main families of scorpion ion-channel toxins have been proposed, with their separation based on their effects on membrane ion channels: Na^+ channels [211], K^+ channels [211], Cl^- channels [212], and Ca^{2+} channels [213]. Of these four ion-channel families, two main groups, based on their pharmacological activity and molecular size have been identified. The short-chain toxins comprise 23–47 amino acids that primarily effect K^+ channels [214] and the long-chain peptides possess 59–76 amino acids that target their effects on voltage-gated Na^+ channels [215]. It is also evident that scorpions, of nearly all the toxin-producing genera, possess varying combinations of ion-channel toxins [216].

Scorpion potassium channel toxins are diverse and have been divided into alpha-, beta-, and gamma-scorpion toxin subfamilies based on their biophysical properties [214], and these subfamilies have been further split based on their voltage-gated and ligand-gated K^+ channel actions [217]. Scorpion K^+ channel toxins from representatives of several different genera such as *Androctonus mauretanicus* (Kalitoxin), *Buthus martensi Karch* (BmTX3), *Centuroides noxius* (*Noxiustoxin*), *Leirurus quinquestriatus* (*Charybdotoxin*), *Hterometrus spinnifer* (HsTX), and *Scorpio maurus* (*Maurotoxin*) have been identified [218].

The scorpion sodium ion-channel, long-chain toxins are important in their toxic effects, as 90% lethality is attributed to these toxins binding voltage-sensitive Na^+ channels in muscle and nerve cells of mammals [219]. Scorpion sodium ion-channel toxins are designated as alpha- or beta-toxins depending on their binding, site of action, in the Na^+ ion channel [215]. Some of these toxins have also been found to be potent arthropod-selective in their toxicity toward crickets, crabs, squids, and triatomides (kissing bugs), yet lacking apparent toxicity in mammals. This has been found

to be the case with the Na^+ ion-channel toxin, *ardiscretin*, isolated from *Tityus discrepans* venom [216]. In contrast, alpha-toxins from *Buthus* sp. venoms have significant toxic effects in mammals [220]. Similarly, the Na^+ ion-channel toxin, Lqh-alpha-IT, isolated from *Leirurus quinquestriatus hebraeus* venom contains an insect-specific alpha-toxin, while an alpha-toxin from *Androctonus australis* affects primarily mammals. Thus, despite between genera alpha-toxin similarities, diversity in effect on target organisms suggests that relatively minute differences in structure are responsible for the expression of different functions, and that alpha-insect and alpha-mammal toxins may have been derived from a common genetic ancestor [221].

Scorpion envenomation is a serious public health problem in the countries of India, Mexico, Mediterranean and Middle East, North and South Africa, and South America, but relatively few species, despite the large number of toxin-producing species, are worthy of medical concern. However, in countries like Tunisia where up to 40,000 scorpion stings occur annually, resulting in 20–40 deaths, medical treatment of scorpion envenomation is important and fairly common [222].

Scorpions will sting when laid on, sat on, stepped on, or agitated by squeeze-contact with clothing and shoes and can deliver a painful sting with their arched telson, directing their stinger into the victim. Stings frequently occur in the evening hours when people are walking around in their bare feet. Although adult humans may suffer severe complications with scorpion stings, it is children that suffer the greatest mortality [223,224]. Given the pharmacological properties of scorpion venom, it is not surprising that stings, depending on the genus and species involved, can cause local pain, autonomic and central nervous system complications, seizures, cardiopulmonary dysfunction [224], with shock and pulmonary edema being responsible for most fatalities [225]. It is also important to note that hemolysis frequently develops in severe envenomations, and secondary nephrotoxic effects can occur [205].

Medical management strategies, which vary with different global geographic regions, leading to successful outcomes in envenomated victims, have revolved around treatment being performed in medical intensive care facilities, the use of various pharmacotherapies, and the administration of specific antivenom [224]. The use of antivenoms and their effectiveness have been a great controversy historically, with treatment having involved large antivenom doses and resultant anaphylaxis and delayed serum sickness [225]. Efforts are currently underway to produce more effective antivenoms with reduced adverse-effect profiles using recombinant technology [222].

Spiders

Greater than 38,000 spider species, comprising 3526 genera, are known [226], and they inhabit nearly all ecosystems, ranging from the arid hot deserts to the rain forests, and from the peaking slopes of Mount Everest [227] to life within the underwater world [228]. Spiders are masters of deception, existing in a wide variety of shapes and colors, and exhibiting equally diverse behaviors. They have been documented to mimic different vegetation forms, insects, bird dung, twigs, and gastropods, and some like the crab spiders can even change color morphology to camouflage with their preferred foliage [229]. Their size ranges from the size of a pin head (*Patu marplesi*—Samoan moss spider) up to the 25 cm leg span of the bird spider (*Therophosa blondi*) [230]. Like scorpions, their head and thorax are combined to form a cephalothorax, but their abdomen is differentiated from this anatomical structure by a narrow restricting band, or pedicel, making the abdomen pronounced. Spiders usually have eight eyes, and some like the brown spider, *Loxoscelles* spp., have only six, and some cave-dwelling species are blind. Eyesight is limited in most species, but some hunting spiders such as the jumping spider (*Portia fimbriata*) has markedly acute vision [231].

Almost all species of spiders have venom glands and produce toxins, but their ability to be of harm to humans or large prey is usually limited by the size of their paired fangs, which reside with the chelicerae at the anterior of their mouth. Spiders are predatory by nature and their venom delivery is quite effective for prey immobilization. They do not swallow their prey following their paralytic envenomation, but rather extract prey contents using their siphoning stomachs. The digestive enzymes used in liquefaction of their prey are not venom components. Two infraorders represent most of the spiders humans are familiar with. Mygalomorphae contains the tarantulas, and venomous funnel-web spiders of the *Atrax* and *Hadronyche* genera, which possess large paraxial fangs that move in a vertical up and down fashion. Fangs of these large spiders can puncture a fingernail [230]. The smaller Araneomorphae represent approximately 93% of the earth's spiders, and have smaller diaxial fangs that move in a horizontal fashion side to side [226]. Although Araneomorph spiders are not as large as the Mygalomorphs, it is Araneomorph species that are responsible for most bites to humans, and are truly dangerous to humans. Thus, an inverse relationship with size and toxicity, as the smaller spiders are generally more toxic. The spider genera known to produce toxic bites to humans are listed in Table 19.5.

The chelicerae/fangs are quite small in the majority of spider species, and as such are of no danger to humans.

Spider venoms are heterogeneous toxin mixtures composed of 3–8 kDa polypeptides, with a few greater than 10 kDa in mass, and the black widow (*Latrodectus* sp.) possesses a 100 kDa polypeptide toxin [232]. They share many pharmacological properties similar to scorpion venoms with respect to ion-channel actions. It has been estimated that the total number of diverse spider venom polypeptides may be in excess of 1.9 million [233]. Spider venom components have been generally identified as neurotoxins that affect glutamaterigic transmission, Ca^{2+}, Na^+, K^+, and Cl^- ion-channels, stimulate neurotransmitter release, and block postsynaptic cholinergic receptors [234].

The chemical configurations of several glutamate receptor toxins have been elucidated, and determined to be primarily acylpolyamines and polyamine amides [235]. A few identified

toxins include *Joro spider toxin* (JSTX) from *Nephila calvata*, *Nephila spider toxin* (NSTX) from *Nephila maculata*, *argiopine* from *Argiope lobata*, *curtatotoxins* from Hololena curta, and *PhTX-4 toxins* from *Phoneutria nigriventer* [234].

Ion-channel spider toxins have been extensively studied, and they have significant neuropharmacological properties that affect the release of neurotransmitters. Ca^{2+} ion-channel venom studies led to the discovery of *omega-agatoxins* from *Agelenopsis aperta*, and pioneered the way for the discovery of *omega-grammatoxin* (*Grammostola spatulata*), *atracotoxin* (*Atrax robusta*), and many other omega-toxins. Na^+ ion-channel toxins impair excitable cell membrane function by altering ligand-gated sodium channels such as nicotinic cholinoreceptors and voltage-gated sodium channels that impact neuromuscular function, making them effective paralytic toxins. Spiders in the *Atrax* and *Hadronchye* genera (funnel-web spiders), and the genus *Phoneutria* (wandering spiders) have venoms possessing important Na^+ ion-channel toxins. K^+ ion-channel toxin actions are similar to those reported for scorpions. K^+ ion-channel venom toxins such as *hannatoxin* from the Rose tarantula (*Phrixotrichus spatulata*), *phrixotoxins* from the Chilean fire tarantula (*Phrixotrichus auratus*), and *heteropodotoxins* from *Heteropoda venatoria* are just a few of the many pharmacologically active potassium channel toxins. Cl^- ion-channel spider toxins although not critical in action potential mechanisms, they are involved in transepithelial transport [236], and involved in cellular excitability as receptor components for inhibitory neurotransmitters such as GABA [237].

Spider toxins and venom fractions that affect cholinergic transmission, in both the autonomic and central nervous system, have been isolated from several species of orb weaving spiders in the genus *Argiope* [238].

Enzymes in spider venoms are important components responsible for a number of different pharmacological functions. Collagenase activity in venom fractions from Australian spiders of the genera *Eriophora* and *Nephila* (orb weavers), and *Isopeda* (huntsman spiders) has been identified [239]. Hyaluronidase, believed to enhance venom spread, has been found in the venoms from the genera *Cupiennius, Lycosa, Loxosceles,* and *Phoeneutria* [234], and metalloproteinases with proteolytic activity have been isolated from *Loxoscelles* venom [240]. Phosphodiesterases that cleave cyclic nucleotides have been found in the venoms from *Atrax robusta, Aphonopelma cratus*, and *Latrodectus mactans* [241], and sphingomyelinase D-type, a powerful necrotizing toxin, has been characterized from *Loxosceles reclusa* venom [242].

The effects of spider venoms and toxins in cases of spider bite to humans are surprisingly limited, and although many spider genera contain species that have bitten humans, the majority of bites are relatively innocuous, with only a few species responsible for significant envenomation profiles (Table 19.5) [243]. *Badumna* sp. (black house spiders), *Lycosa carolinensis* (wolf spider), and *Chiracanthium mildei* (sac spider) can cause pain and erythema, and *Tegenaria agrestis* (hobo spider) necrotic lesions, but all these symptoms generally resolve without long-term consequences [244]. Spider bites, in contrast to many insect bites and stings, are not associated with inducing allergic reactions [243].

Spiders of medical importance, capable of causing significant morbidity or mortality, include the Australian genera *Atrax* and *Hadronyche* (funnel web spiders), Brazilian *Phoeneutrea* spp. (wandering spiders), *Loxoscelles* (recluse spiders), and *Latrodectus* and *Steotoda* (widow and comb-footed spiders) [244].

Funnel web spiders of Australia (*Atrax* spp.) are believed to be the most venomous and dangerous spiders on earth, and although bites are uncommon and severe envenomation infrequent, they can cause life-threatening symptoms and deaths have occurred [245,246]. Symptoms associated with severe envenomation include both parasympathetic and sympathetic effects on both neuromuscular and cardiopulmonary systems, with paralysis, coma, and profound hypotension resulting in general systems failure [246,247]. Fortunately, there is a funnel web spider (*Atrax robustus*) venom-specific IgG antivenom that is effective in reversing venom-induced toxicity. This antivenom is polyspecific, and is also effective in treating envenomations caused by other *Atrax* and *Hadronyche* spp. [244].

Armed, wandering, or banana spider (*Phoeneutria* spp.) envenomations in South America can result in significant medical complications, have caused at least one pediatric death and are responsible for 42% of the 2850 spider bites reported per year in Brazil [248]. These spiders occasionally appear in other parts of the world after they have been inadvertently imported on agricultural produce. Less than 1% of victims had severe complications (pulmonary edema), and the common symptoms of envenomation were pain, and edema. Local anesthetics and oral analgesics are of benefit, and an Fab'_2 antiarachnid antivenom has been used in moderate to severe envenomations, but its benefit is unknown [248].

Recluse or brown spiders (*Loxosceles* spp.) are capable of inflicting severe ulcerating and tissue-necrotizing bites, and considered a serious hazard in Central and South America, as well as south-central and southeastern parts of North America. They have also appeared in Europe, Asia, South Africa, and Australia, most likely having been transported into these countries, and little is known of their bites in these settings [244]. Their venoms are known for the 23 kDa enzyme, shingomyelinase D (which has four isoforms), which is the main pharmacologically active venom component responsible for most toxic effects [249]. Unfortunately, many spider bites are attributed to *Loxosceles* species, but rarely are bites confirmed to be true recluse bites, and misdiagnosis follows [250]. Bites frequently go unnoticed, as they are relatively painless, and victims delay in seeking medical attention.

Envenomation by *Loxosceles* may be dichotomous in effect, as it may cause a dermonecrotic profile, or it may appear as a viscerocutaneous form [244]. A necrotic lesion may take up to a week to express itself, and the resulting ulceration is insidious, and may persist for months. Fever and fatigue may also be present. The viscerocutaneous symptoms of Loxosceles envenomation may be fulminant, with

hemolysis, coagulopathy, shock, renal failure, and multiple systems failure leading to death if untreated [251].

The persistent nature of recluse spider bite lesions has led to considerable controversy as to the most effective treatment, but in general good thorough wound care, following an early diagnosis, leads to a favorable outcome [250]. Therapies ranging from hyperbaric oxygen to nitroglycerin patches have been used with varying effectiveness [252]. Life support measures and good intensive care are best in cases of severe systemic envenoming [252], and although antivenom is available in South America, its benefit is questionable [251].

Widow spiders (*Latrodectus* spp.) are found throughout the world, and as many as 40 species are known [244]. Envenomation may cause significant morbidity, and has resulted in death [253,254]. *Latrodectus* venoms, and clinical features following envenomation, are similar and have a common clinical syndrome throughout all geographic regions [244]. Widow venoms contain latrotoxins, >100 kDa proteins, the best known is alpha-latrotoxin, and they stimulate massive neurotransmitter release from a variety of nerves [234]. The tissue around a bite does not react to envenomation, but local pain may be present. Severe skeletal muscle pain in the abdomen, back and chest, diaphoresis, hypertension, and cramping are symptoms requiring medical treatment [253]. Spiders in the genus *Steatoda* have been reported to have symptoms similar to widow spiders, but less severe in effect. Treatment may include parenteral benzodiazepines or opioids, and antivenoms are available in Australia and the United States. Antivenom, given intravenously, is beneficial in cases of severe envenomation [244,253] The Australian redback spider antivenom has also been used in severe cases of *Steotoda* envenomation [243].

Tarantulas, due to their size and reputation, deserve a final word with respect to spiders. There are approximately 860 known species comprising 107 genera, and they are found in semi-tropical, semi-temperate, and tropical regions around the world. They are predators that inhabit many biodiverse ecosystems, and are capable of physically overpowering and mechanically injuring invertebrate and vertebrate prey. Their uniqueness and notoriety has resulted in their becoming an amazingly significant portion of the world's pet trade, and multiple species of several genera have been afforded legal protection. Their large fangs deliver rapid-acting venoms that have irreversible effects on central and peripheral nervous systems, allowing the induction of rapid paralysis, even to higher vertebrates [255]. However, despite the magnitude of their notoriety, and their anatomical and venom pharmacological traits, tarantulas are not particularly dangerous to humans.

Few details are available concerning tarantula venoms. Crude venom studies involving mice and 55 different tarantula species showed that certain specie's venoms can induce massive neurotoxicity leading to death in 3–5 min, while others had similar, but reduced effects, resulting in death after greater than 2 h. The most toxic venoms come from the arboreal genera *Heteroscodra, Poecilotheria*, and *Stomatopelma*, with their venoms causing death in seconds (Escouba and Rash, 2004). The venom of the Chinese bird spider, *Ornithoctonus huwena*, known as *Dilaohu*—the *earth tiger*—in China contains a series of toxins known as *huwentoxins* [256] These are small (3000–5000 Da) neurotoxin peptides with voltage-gated Ca^{2+} and Na^{+} ion-channel activities, which are a significant portion of crude venom that is capable of causing lethality in mice and birds in less than 2 min [257].

Bites to humans usually cause mild to severe pain, burning sensation, edema, erythema, itching, and joint stiffness. Severe envenomations, as seen with arboreal Asian (*Haplopelma* spp.), Sri Lankan and Indian (*Poecilotheria* spp.), and South African (*Stromatopelma* and *Pterinochilus* spp.) tarantulas, have been associated with more severe clinical problems such as intense pain and muscle cramps of weeks duration, temporary paralysis, and coma [258]. South American tarantulas (*Theraphosa* spp.) possess body hairs (setae) capable of eliciting dermal urticaria [259] and ocular injury [260].

Tarantula bite treatment has not been specifically defined, but symptomatic treatment with analgesics, antihistamines, topical steroids, and supportive care as needed have been used with success, even in cases of severe envenomation such as those involving Sri Lankan species [261].

Chilopoda

Centipedes are arthropods familiar to most people, and it is usually an unpleasant familiarity. Perhaps it is the words of arthropod scientist, J.L. Cloudsley-Thompson, "centipedes seem to exert a weird fascination on the morbid appetites of the hysterical and insane," that best characterize human thoughts on centipedes [262]. They are globally distributed being native to the Americas, Africa, Australia, Asia, and Europe. Centipedes are nocturnally active, fast-moving, have segmented bodies with one pair of legs per segment, compound eyes with up to 200 optical units, range from 3 to 250 mm in length, and have an aggressive behavior [262]. They are carnivorous and use their powerful poison claws, which are actually modifications of their first pair of legs, to deliver venom from an internal sac into their prey causing rapid paralysis [263]. Prey items include other small arthropods, including other centipedes, and they have been known to feed on toads, snakes, and small vertebrates [264]. There are approximately 3000 known species, but those of the Scolopendromorpha and Scutigeromorpha orders are most important clinically [265].

Centipede venoms, like snake venoms, are complex protein mixtures and have been found to contain esterases, histamine, 5-hydroxytriptamine, lipids, polysaccharides, proteinases, and other various enzymes. An acidic, heal labile, 60 kDa protein cardiotoxin (*toxin S*) has been isolated from Scolopendra subspinipes and could induce hypertension in cats [266]. In contrast, extract from *Scolopendra moristans* venom caused cardiac asystole in the toad heart [267]. Studies of centipede venom on other arthropod nerve systems, using *Scolpendra* sp. venom fraction (SC1), revealed the fraction possessed muscarinic agonist properties that acted directly

on an insect muscarinic receptor subtype closely homologous to the M1-M3 (muscarin) receptors found in mammals [268].

Envenomation by Scolopendra centipedes frequently results in pain, and occasionally local necrosis, but generally does not cause serious complications [269]. However, rhabdomyolysis [270] and fatality have been reported [268]. A study of Australian centipede confirmed envenomations, involving *Cormocephalus*, *Etmostigmus*, and *Scolopendra* species, showed bites from all three genera could cause significant pain, erythema, swelling, and itching with *Ethmostigmus* and *Scolopendra* symptoms more severe [265].

Ingestion of *Scutigera morpha* by an infant (confirmed by an intact centipede found in the feces) resulted in systemic effects, evidenced by paleness, muscle hypotonia, and vomiting, followed by spontaneous recovery over the 48 h period following the ingestion [271]. Treatment with ice packs, analgesics, and hot water submersion have been effective interventions [265].

Insecta

Insects are the most ubiquitous of all terrestrial animal forms, and inhabit every ecological niche on the planet earth. They are six-legged, or many more in the case of larval forms such as caterpillars, allowing their ambulation on a multitude of substrates. Many possess wings, they have three hinged body parts (head, thorax, abdomen), and they all are covered with a chitinous exoskeleton. Additionally, they possess a variety of biting mouth parts and venom delivery devices. Although a plethora of insect species are vectors for a large number of infectious diseases, few have truly toxic venoms of concern. Those that do possess toxins in their venoms are incapable, as a single entity, of causing fatality to humans. However, single assaults can cause toxic reactions and elicit immune responses in humans, and multiple concurrent insults by some species (i.e., swarms of Africanized bees) can result in human fatality. In fact the venoms of most insects in the order Hymenoptera, including fire ants, honey bees, and vespids, are highly immunogenic due to venom proteins [272]. Venom doses range from <1 μg for fire ants, 10 μg for wasps, and up to 50 μg for bees [272]. Thus, the allergic reactions resulting from insect stings are a more clinically prevalent problem than complications associated with direct venom toxicity.

Ants

Only a few species of ants are of any significance with reference to venom toxinology, and are capable of inflicting significant bites and stings. While formic acid is a common component of substances in venom sprayed for either defensive or prey-acquiring purposes by many genera (*Camponotus, Formica, Lasius, Poyergus*), it is a chemical toxin of little consequence to humans other than causing mild dermal or ocular irritation. In contrast, South American fire ants (*Solenopsis* spp.) [273], Australian/Tasmanian bulldog and *jack jumper* ants (*Myrmecia* spp.), Costa Rican and South American tropical ants (*Pseudomymex triplarins* and *Pachycondyla goeldii*) can potentially inflict severe stings [274]. Unfortunately, these ants have been relocated to geographic regions far removed from their native lands, and fire ants have been present in the United States since the early 1920s [275].

Fire ant (*Solenopsis* spp.) venom contains the alkaloids, 2-methyl-6-alkyl and alkenyl disubstituted piperidines, commonly referred to as *solenopsins*. These toxins possess cytotoxic activity that alters the functional integrity of mast cell membranes, causing intracellular degranulation and the subsequent release of histamine. The allergenic component of venom is due to low molecular weight proteins, and four are present in fire ant venom [276]. Fire ants have an aggressive stinging behavior with envenomation resulting in a wide range of effects including dermal necrosis, edema, sterile pustules (occurring several weeks post envenomation), urticaria, and in extremely rare circumstances anaphylactic shock and fatality [277]. The quantity of venom delivered by fire ants ranges from 10 to 100 ng [278], and severity of envenomation appears to be dose-dependent [279]. Management of fire ant stings is not consistent, but antihistamines, topical corticosteroids, cold compresses, and antibacterials have been used [275].

Jack jumper ant (*Myrmecia* spp.) venom has enzymatic activities due to its phospholipase A_2, phospholipase B, hyaluronidase, acid phosphatase, and alkaline phosphatase fractions [280]. Venom also contains two basic peptides: Pilosulin 1 elicits cytotoxic effects [281], and pilosulin 2 has antihypertensive properties [274]. Envenomation by the jack jumper ant has shown its venom is a strong insect allergen, with it being responsible for greater than 90% ant venom anaphylaxis cases in Australia, and deaths in Tasmania [282]. The allergic problems associated with *re-stings* in victims became so serious that a major effort was made, and accomplished, for effective immunotherapy in preventing sting analphylaxis [282].

One mimicking insect often confused to be an ant is the solitary female wasp in the genus *Dasymutilla* (Table 19.5). These are truly wingless female wasps that have the morphological, look-alike, appearance of a large ant, and are commonly referred to as velvet ants (*Dasymutilla magnifica*). As their name implies, their bodies are covered in dense brightly colored hair, giving them a velvety appearance. Venom of *Dasymutilla* spp. contains phospholipase and hyaluronidase, but is low in other enzymatic activities [283]. Their sting is one of the most painful of all insects, and for one species (*Dasymutilla occidentalis*), the pain is so severe they have been dubbed *cow killers* [284], although in reality, the sting is not strong enough to kill a cow!

Caterpillars

Caterpillars are the insect larval form of butterflies and moths (Lepidoptera). Familiar, captivating, and wondrous to children all over the non-Arctic regions of the earth, caterpillars are not all innocent, fuzzy or colorful, crawly creatures. In many countries, they are often considered a major economic agricultural pest as a result of their defoliating appetites. Many species probably acquire their toxins from the foliage

they feed on such as *Lagoa* spp. that feed on oak leaves, resulting in high tannin content in their spines [285]. Though most species are harmless, there are a few that should be left untouched. The caterpillars of concern have hairs (setae) on their slug-like or tubular-shaped bodies, sometimes making them appear like a brush-like, furry/fuzzy, or glass-haired cucumber. There are multiple caterpillar species known to have hairs that readily break off when handled, and these are generally considered stinging hair caterpillars because of the needle-prick pain, and burning and itching that occurs from hair contact. In some species (*Doratifera* spp.) stinging groups of hairs are paired, and mounted on body protuberances attached to venom glands [89], and American and European species may have hairs containing complex peptides and proteins [286]. Examples of caterpillar species causing these effects are Saddleback Caterpillar (*Sibine stimulea*), Io Moth (*Auomeris io*), Hagmoth (*Phobetron pithecium*), Buck Moth (*Hemileuca maia*), Hickory Tussock Moth (*Lophocampa caryae*), Silver-spotted Tiger Moth (*Halisidota argentata*), and the Stinging Rose Caterpillar (*Parasa indetermina*) [287–289].

Australian caterpillars, especially, *Euproctis edwarsi* (Mistletoe Browntail moth), have been confirmed to be of medical significance as their venom contains kallikrein-like serine proteases [290], while those causing lesser effects are represented by the genera *Doratifera* (Cup Moths), *Theosa* the genus of the *billygoat plum stinging caterpillar*, *Theretra* (Hawk Moths), and many more [89]. Symptoms vary in severity from intense pain (rarely) to commonly mild/moderate pain, slight redness to wheals, and may be up to 48 h in duration [287].

The puss caterpillars, *Lagoa cripata* and *Megalopyge opercularis* of the southern United States and Brazil, respectively, have caused local pain, regional lymphadonopathy, headache, and inflammatory dermatitis. Despite analytical attempts to elucidate venom components from these species, they appear to be lacking in enzymes, or toxins, with only several amino acids found. However, nongastrointestinal body extracts reveal that high tannin content is present, and this is derived from their diet of oak leaves [285].

Lanomia oblique (Saturniidae Moth) is a caterpillar primarily from southern Brazil, and is a species of caterpillar second to none when it comes to envenomation. In addition to the local symptoms that result from hair contact of other caterpillars, *Lanomia* caterpillar envenomation produces profound burning pain, and can induce major hematological complications. Their sets of hard-bristled hairs contain venom with prothrombin activating (LO prothrombin activator protease), factor X activator, a phospholipase A(2)-like activity (*Lonomiatoxin*) [291], and both nociceptive and edematogenic properties [292].

Severe envenomation from bristle contact with Lanomia results in a major hemorrhagic syndrome [293] with decline in prothrombin and accelerated thrombin generation, manifested clinically by ecchymosis, hematuria, with bleeding of the nose, skin, gastrointestinal tract, lungs, vagina, and pulmonary and intracerebral hemorrhage leading to death [294,295]. This syndrome usually occurs from 6 to 72 h post envenomation.

Caterpillar sting treatment from most species is symptomatic and involves removal of hairs using tape, washing of the skin, ice packs, and antihistamines, leading to resolution of symptoms within hours [287]. *Lanomia* envenomation treatment is supportive, and specific antivenom has been developed [296], but antivenom experience in human victims of *Lanomia* envenomation is lacking.

Bees, Bumblebees, Hornets, and Wasps

These are part of nature's air force, and human beings from all parts of the world are familiar with the consequences of their attack. Like the ants, the primary complication from envenomation by these stinging *Hymenopterans* stems not only from limited venom toxicity, but also from venom toxins being hyperallergenic to humans [297]. However, massive numbers of stings to a victim results in a venom body burden capable of resulting in severe venom toxicity, and even death [298]. Thus, victims may die whether or not they are allergic to the venom.

Bumblebees, honeybees, and vespid wasps can all deliver a painful sting. However, bumblebees tend to be less aggressive, while Africanized (killer bees) honeybees (*Apis mellifera scutellata*) and hornets will aggressively swarm victims, and wasps are aggressive solitary attackers. The bees use their venomized stingers for self-defense or the defense of the colony while wasps will additionally use their venom to acquire prey [299]. There are approximately 200 species of bumblebees between Canada, Europe, and the United States, [300], multiple honey bee (*Apis*) and hornet/wasp (*Vespa*) subspecies. The venom delivery system for all these stinging hymenoptera, is actually an anatomical adaptation of the ovipositor in females, with a lengthy venom gland connected to a channel that runs through the barbed stinger, and as such, it is only females that can sting. Following a sting, a wasp can usually remove its stinger and repeatedly sting its victim. In contrast, the honey bee's stinger has a more barbed anatomy and remains in the victim, along with the muscular venom gland reservoir attached, which continues to pulse venom into the victim until it is depleted or removed [30].

The venom of bumblebees and honeybees is cross-reactive, demonstrating similarities in their composition [301]. The injected dose of venom for a single bee is about 50 μg [272]. Bee venom (*Apis* and *Bombus*) components have been isolated and identified as a melittin peptide and it tetramers (a major constituent of bee venom), 39 kDa acid phosphatase, 38 kDa hyaluronidase, 28 kDa protease, 14 kDa phospholipase, apamin, and mast-cell degranulating peptide [300,302]. The anaphylactic effects of bee venoms associated with IgE antibodies are due to phospholipase, hyaluronidase, and to a lesser degree melittin [302].

Hornets, wasps, and yellowjacket venom immunochemical studies have shown that hyaluronidase, phospholipases, and a substance of unknown function called antigen 5, are their major venom components [303]. Studies of Taiwan yellow-legged hornet (*Vespa verutina*) venom yielded the

identification of three toxins designated as, *verutoxins* (V1), (V2a), and (V2b), and all three possess a phospholipase A_1 with hemolytic activity demonstrated to directly kill mice at doses as low as 0.87 mg/kg [304]. Given that an average vespid delivers approximately 10 μg per sting [272], this hornet species harbors potently toxic venom.

Envenomation to humans from either bees or vespids can trigger rapid acute immune reactions leading to vomiting, diarrhea, hypotension, coma, hemaglobinuria and myoglobinuria progressing to renal failure, and rhabdomyolysis [305,306]. Moderate venom reactions are more common and involve pain, dermal rashes, urticaria, and edema [307]. Toxicity, independent of immune system responses, or in victims without allergic reactions, is due primarily to phospholipase activity.

Treatment of bee and vespid envenomated victims is largely symptomatic and supportive, and requires a timely response in the case of anaphylaxis, with epinephrine, antihistamine, steroids, and life support. Effective antivenoms are not available, but this therapeutic strategy has been investigated [297].

A final comment on Africanized bees, as their aggressive geographical spread from South America to North America, and aggressive behavior has led to a large number of fatalities in the process of their northward migration [308]. The severity of envenomation by *Apis mellifera scutellata* relates to the venom dose injected with each individual sting, and the potentially large number of stings a victim sustains. A killer bee, in contrast to other bees, delivers approximately 150 μg of venom per sting, which is threefold greater than that delivered by other bees. This characteristic, amplified by the large number of stings as a result of a strong swarming behavior [309], makes encounters extremely dangerous, as the cumulative dose of venom, rather than anaphylaxis, can lead to irreversible organ system damage, and death [310]. Thus, it is important to terminate victim exposure from bees rapidly and safely as possible, and seek medical attention.

Sawfly

Sawflies (*Arge, Lophyrotoma, and Perreyia* spp.) cause significant problems for the livestock industry and the veterinary profession. Sawfly larvae have been documented as having been responsible for large numbers of cattle and sheep deaths in Australia (*Lophyrotoma interrupta*), cattle, dogs, and sheep in Denmark (*Arge pullata*), and cattle, pigs, and sheep in Uruguay (*Perreyia flavipes*) [311]. Sawflies will infest certain species of trees and grasses, for the larval phase of their metamorphosis, and with a changing of seasons many are found on the ground where livestock graze. As such they are consumed by livestock and a brief period of time lapses between ingestion, symptoms, and death [312]. Necrotizing hepatotoxicity is the primary toxic insult. Symptomatic cattle have been described to be hyper-excitable and aggressive to humans [312]. The toxins, octapeptide *lophyrotomin* and heptadeapeptide *pergidin*, are unique because the larvae synthesize de novo these toxins, rather than bioaccumulating them from their food sources, and this appears to possibly be a species survival strategy [313]. In feeding trial experiments it was found that even dead larvae were toxic to cattle and sheep, and that oven-drying of larvae at 110°C for 24 h did not abolish toxicological activity. Of interest, is the fact that *pergidin* appears to be the first phosphorylated peptide isolated from an animal species [311]. The sawfly larvae, having been found on three different continents, suggest that there is not a common toxin source from animal food roughage, and that each larval species can synthesize the toxic peptides. Further conjecture rests with the possible migration of these peptides to nonvisceral tissues in produce animals, as they are water soluble and nondegradable, and this would likely result in their having long resident-times in animal tissues.

Terrestrial Vertebrate Animal Toxins and Venoms

The terrestrial venomous or poisonous vertebrates have caused the human mind to conjure up the most dark-sided images of nature. Snakes, lizards, frogs, salamanders, toads, newts, all have been used in the *witches' brew*, and associated with the evil that exists in the natural world. The unusual appearances of these fascinating creatures, and the fact that many do possess potent poisons, has resulted in their biological and chemical traits being associated with great mystical powers historically. Importantly, in today's world, the presence of some of these creatures is a growing medical concern to humans in many countries where human and natural communities are converging. Equally intriguing are the terrestrial creatures, such as certain species of birds and mammals, which are not usually thought of as likely sources of toxins and venoms. Modern analytical and technological capabilities allow more comprehensive analysis of animal toxins, and a better understanding of animal systematics. As a result of the interface between these disciplines, our toxinological knowledge, and its value in biological science, conservation, and medicine, continues to grow.

Chordata

Reptilia

The ancient Greek historian Diodorus Siculus, thought that the sands of the Theban desert in Egypt could *spontaneously* generate serpents [314]. For millennia since ancient times, terrestrial poisonous snakes, such as cobras and rattlesnakes, have consistently maintained a prominent place in the hierarchy of many cultures, religions, and the realm of fascination in the human mind, even by those who fear them most. Less well known, from a global perspective, are the venomous lizards, the Beaded Lizard and Gila Monster, as they are only distributed in a small confined arid geographic region of the southwestern United States, Mexico, and Guatemala [315]. While arachnids account for a large number of envenomations to humans, and a considerable number of marine animals inflict envenomations as well, the majority of consequences from these envenomations are associated most frequently with morbidity. As such, snake bite has been reported to be the most significant *toxin-related* disease,

envenomation, on earth because of its quantitative contribution to morbidity and mortality, particularly in the Americas, Africa, and Asia [316].

Historical studies of mortality from snake venom poisoning are limited, and the only global comprehensive review revealed an average of 50,000 deaths annually, based on hospital records from 1945 to 1949 [317]. The current number of venomous snake bite envenomations has been estimated to be 2.5 million, and mortality to be 125,000 deaths [318]. Thus, venomous snake bite is still a medical concern of appreciable significance in the world today.

Although the problem with snake bites is important, it should not overshadow the role venomous snakes have in the balance of the natural world. Venomous snakes, using their venom for its primary biological function, readily consume millions of pests that invade human food supplies in many countries of the world. They not only reduce the loss of food supplies keeping pest numbers in check, by keeping populations from exploding, but may also reduce the spread of disease carried by their prey. The impact of their elimination from world ecosystems would be noticed. Furthermore, venomous snakes synthesize an array of toxins that possess a spectrum of pharmacological properties and act on the physiology of numerous animal species. Their venoms provide the natural templates from which biochemical and biomedical research can generate a plethora of useful therapeutic agents.

Snakes

There are approximately 2900 recognized species of snakes, comprising approximately 420 genera [319]. Venomous snakes are found in arid, subtropical, tropical, and temperate regions, ranging up to polar ecosystems on six of the planet earth's continents, excluding Antarctica [316]. They inhabit arboreal, aquatic, desert, mountain, subterranean, and diverse terrestrial microhabitats. Snakes are the most common predator of other vertebrates, and most venomous snake species feed on other reptiles, amphibians, birds, and mammals, with their venoms being highly selective for a given species' preferred prey [319].

Classification and division of venomous snakes into various groups has been a constantly evolving taxonomical process. Generally, there are four main groups of venomous snakes: Atractaspididae, the advanced snakes of the super family Colubridea, the Viperidae, which is a family divided into vipers and pit vipers, based on the presence of an infrared heat-sensing pit between the eye and nasal opening in some vipers, and the Elapidae (Table 19.6). Sea snakes are unique members of the family, Elapidae, as they spend the majority of their lives in oceanic waters, and therefore, are discussed with the marine vertebrates. However, they are true snakes, and a subfamily of Elapidae, the Hydrophiinae [315].

Venomous snakes have evolved several anatomical features with a variety of functions important to their survival. The structures of importance in venomous snakes are those relating to their venom, and its production and delivery. Biomanufacturing of venom is primarily accomplished via ophidian oral glands of two types, although a variety of subtle modifications exist. A salivary system modification, frequently referred to as the Duvernoy's gland, is the toxin-secreting (venom) structure of colubrid snakes, and is a seromucus cell, secretory structure with a weakly defined lumen-like duct, that in some species produces toxic proteinaceous substances [320]. A quite similar structure is found in elapid snakes [319]. The exception to this similarity is the elongated, compressor muscle enclosed venom gland of the Asian coral snakes [314], and some Burrowing and Night adders, which have a venom gland approaching half their body length [319]. Venom glands in viperid snakes are slightly more sophisticated as the musculature, derived from the jaws, encompasses a well-defined duct that extends to the base of the accessory gland that interfaces with the fang sheath, and terminates at the proximal fang-tissue juncture [27].

Fangs of venomous snakes generally are one of four basic dentition types: (1) Aglyphous (conical fangs with no groove, typical of some colubrids); (2) Opisthoglyphous (enlarged teeth with a groove in the back, commonly in colubrid rear-fanged snakes and atractaspids); (3) Proteroglyphous (large anterior, fixed-position fangs with deep frontal grooves, such as cobras); and (4) Solenoglyphous (large tubular, canaliculated, fangs with a hinge-like action due to their attachment to the highly flexible maxillary bone, such as observed in Gaboon vipers) [319]. Both the production of toxic saliva, or venom, and the delivery systems for these different dentitions are key to the acquisition of prey food, such as centipedes, fish, frogs, birds, mammals, and other snakes, and as a defense for self-preservation from predators.

Snake venoms, make up nature's true biochemical cocktails, and are composed of a greater number of toxins than those of other venomous or toxin-producing species of animals, making them the most complex of all poisons [321]. The venoms of the four major groups of terrestrial snakes (Table 19.6) possess activities that affect several physiologic systems in animals. Venoms primarily affect the central and/or peripheral nervous systems, blood coagulation system, cardiovascular system, musculoskeletal system, and renal system [316]. Some venom components, such as the purine and pyrimidine nucleosides, adenosine, guanosine, and hypoxanthine, seem to be present in nearly all elapid and viperid venoms, and act as multifunctional toxins believed to be important in prey acquisition [322]. The net toxic effect, or effects, may be a result of direct toxin toxicity on a target within a single system, but usually results from a combination of effects caused by different toxins acting directly, or secondarily.

Atractaspididae

Mole vipers, burrowing adders, or sometimes referred to as stiletto snakes, comprise the fourteen genera, and 65 species of the fossorial- and subterranean-inhabiting family, Atractaspidae, and are not actually vipers [319]. They are small, dark, glossy scaled, with virtually no distinction between their head and neck, and have small bead-like eyes. Native to Africa, the Arabian Peninsula, and Israel, they have the appearance of a nonthreatening little snake.

TABLE 19.6
Terrestrial Vertebrate Animals: Venomous Snakes

Phylum	Class	Family		Common Names	Genera
Chordata	Reptilia	Atractaspididae	African	Burrowing, mole, stiletto vipers	*Atractaspis, Macrelaps*
		Colubridae	Americas	Bimini racer, parrot, vinesnakes	*Alsophis, Leptophis, Oxybelis*
				Hognosed, wandering garter snake	*Heterodon, Thamnophis, Philodryas*
			African	Boom slang, twig snake	*Disphlodidus, Thelotornis*
			Asian	Keelback, tree snakes	*Rabdophis, Ahaetulla*
		Elapidae	African	Cobras, nambas	*Naja, Hemachatus, Dendroaspis*
			Americas	Coral snakes	*Micrurus, Micuroides*
			Asian	Cobras, coral snakes,	*Naja, Calliophis, Maticora*
				king cobra, kraits	*Ophiophagus, Bungarus*
			Australian	Black/brown snakes	*Pseudechis, Pseudonaja*
				copperheads, death adder	*Austrelaps, Acanthophis*
				taipans, tiger snakes	*Oxyuranus, Notechis*
		Viperidae		*Crotalinae (pit vipers)*	
			Americas	Bushmaster	*Lachesis*
				Cantils, copperheads, cottonmouth	*Agkistrodon*
				Lanceheads, Fer-de-Lance, urutu	*Porthidium, Bothrops*
				jumping vipers, montane vipers	*Atropoides*, *Cerrophidion*
				Eyelash viper, palm pit vipers	*Bothriechis, Bothriopsos*
				rattlesnakes	*Crotalus, Sustrurus*
			Asian	Bamboo, green tree vipers, habu	*Trimerersurus, Protobothrops*
				Hundred pace snake	*Deinagkistrodon*
				Malayan pit viper, mamushi	*Calloselasma, Agkistrodon*
				Temple pit viper	*Tropidolaemus*
				Viperinae (vipers)	
			African	Bush, saw scale, montane vipers	*Atheris, Echis, Montatheris*
				Desert, horned vipers, night adders	*Macrovipera, Cerastes*
				Puff adder, gaboon, rhinoceros	*Bitis*
			Asian	Fea's, leaf-nosed, Russell's vipers	*Azemiops, Eristicophis, Daboia*
				Desert, false horned vipers	*Macrovipera*, *Pseudocerastes*
			European	Asps, adders, mountain vipers	*Vipera*

However, local names in Africa like, *father of blackness*, and *shroud bearer* reflect its potential danger to humans [319]. When scared, the snake will form a buried-head-coil and release like an unwinding spring to deliver a slashing bite. Strangely, each of the four different dentition patterns is represented by at least one genus in the family. Most species in the family are rear-fanged, but a notable exception is the front-fanged assembly of those in the genus *Atractaspis*. Fangs are usually grooved, connecting to an elongated venom gland, and biting is accomplished with little opening of the mouth, as a single fang will extend laterally outward from the side of the mouth to deliver venom by making a slashing-stab motion. *Atractaspis* venom possesses a high percentage of low molecular weight toxins, but is devoid of cholinesterase and hydrolase activity [323]. The most significant toxins isolated from the venom of this family are the *sarafotoxins*, which are a cysteine-rich group of acidic polypeptides, capable of inducing cardiotoxic effects rapidly by the vasoconstriction of coronary vasculature [324]. As little as 2.5 μg of sarafotoxin, from *A. engaddensis* venom, in a mouse caused 100% fatality [323].

Envenomation from *Atractaspis* can be a serious event, and deaths, although not common, have occurred from bites by *A. irregularis* and *A. microlepidota* [325]. Symptoms of envenomation usually involve pain and swelling, with vomiting, abdominal pain, dyspnea, profuse salivation, and necrosis [326]. There is no specific antivenom, or antivenom that is known to provide paraspecific protection from the effects of envenomation, and treatment is supportive [323].

Colubridae

The colubrid snakes are highly diverse, comprising 290 genera representing 1700 snake species, and those species in the family that produce some form of venom or toxic secretions account for greater than 50% of all colubrid species [319]. The bites of a large number of colubrid snake species can cause varying degrees of toxicity, yet documentation of colubrid envenomation in humans has only been reported for approximately 50 species representing 30 genera [327], and depending on how toxicity is defined, there may be many more [315,328]. However, both colubrids that lack a specific fang structure (Aglyphous), and those with rear-fanged

structures (Opisthoglyphs), have been documented to cause severe envenomation, and even human fatalities have resulted from the bites of the rear-fanged South African *Dispholidus typus* (boomslang) [329], and *Thelotornis capensis* (twig snake) [330], the East Asian *Rhabdophis tigrinis* (yamakagashi), which lacks a venom-injecting mechanism [331], and the Argentine racer (*Phylodryas* sp.) [332].

Given the obvious powerful effects of these colubrid venoms, it is unfortunate that very little is known about their toxins or composition. Early studies of salivary secretions, or venoms, from colubrids, with or without enlarged postmaxillary teeth, revealed the presence of 7–10 proteins [333], while more recent electrophoretic venom analyses revealed 10–20 constituents, of 4–200 kDa molecular weight, with species-specific profiles, suggesting that the oral secretions of some colubrids are equally as complex as many front-fanged species of venomous snakes [334]. Enzymatic properties had not been associated with colubrid venom properties until recent investigations characterizing the venoms and oral secretions of a several colubrids, such as the keeled water snake (*Amphiesma stolata*), brown tree snake (*Boiga irregularis*), and false water cobra (*Hydrodynastes gigas*), showed the presence of proteolytic activity. Phosphodiesterase activity, although slight, exists in the western hognose snake (*Heterodon nasicus nasicus*) and wandering garter snake (*Thamnophis elegans vagrans*), acetylcholinesterase is present in the venom of the brown tree snake (*Boiga irregularis*), and moderate to high levels of phospholipase (PLA_2) activity are present in mangrove snakes (*Boiga dendrophila*) and Lyresnakes (*Trimorphodon biscutatus lambda*), respectively [334].

Neuromuscular activity effects of colubrid venoms on avian skeletal nerve muscle are exhibited via the inhibition of postsynaptic actions by venoms from the dog-toothed cat snake (*Boiga cynodon*), mangrove snake, and other *Boiga* spp. and the Egyptian cat snake (*Telescopus dhara*). Inhibition by *Boiga cynodon* venom was a reversible process, while contrastingly, the venom of *Trimorophodon biscutatus* demonstrated irreversible presynaptic neurotoxic activity [335]. Studies of Rufous beaked snake (*Rhamphiophis oxyrhyncus*), a relatively small South African colubrid of the subfamily psammophiine, venom revealed a high protein fraction with PLA_2 activity and in animal nerve muscle preparations showed postsynaptic neurotoxicity. The venom of this species also could induce hypotension followed by cardiovascular collapse in rodents, which would be effective in subduing its prey such as the Naked mole rat [336]. Collectively, these findings concerning the pharmacological and toxicological activities of colubrid venoms show their diversity, potentially high bioactive potency, and only begin to reveal the potential for their use in biomedical research. The composition of colubrid venoms not only confirms their similarity in make-up to more venomous noncolubrid species, which undoubtedly relates to their effectiveness in acquisition of a preferred prey, but also raises concern as to their potential for severe toxicity to humans in clinical medicine.

The bites of colubrid snakes demonstrate the extremes of toxic effects, with most bites resulting in signs and symptoms confined to the bitten area, and pronounced, life-threatening, coagulopathic effects in only a few [337]. Brief details of envenomation to humans by many species of colubrids are frequently all that is available, and it is impossible to know if the symptoms observed represent a severe bite or those associated with a small amount of venom ineffectively delivered [315]. Thus, many colubrid species may harbor quite toxic venoms, but in cases of envenomation, as with viper bites, the degree of envenomation is not always fully expressed, and the incidence of bites by some species so rare, that the true significance of colubrid venom toxicity in humans is unknown. However, it is believed that at least one species in nearly every colubrid family is capable of envenomation leading to severe medical complications in humans, including the potential for fatality (Bryan Grieg Fry, personal communication, 2005.)

Envenomations by the boomslang, twig snake, and red-necked keelback can be most severe, and are known to have caused severe coagualpathic complications resulting in a delayed onset of extensive and prolonged superficial hemorrhaging, that progressed to death [337]. Their bites do not induce local symptoms of envenomation, fang punctures do not bleed at the time of the bite, and their venoms are defibrinating, and activate prothrombin, making them procoagulant in effect, with anticoagulated blood resulting due to consumption [338–340]. Unfortunately, only a species-specific antivenom exists for treating boomslang envenomations, and despite similarities in blood coagulopathy effects observed with envenomation by other similar species such as *Thelotornis capensis*, there is no antivenom cross-reactivity [338]. As such, supportive care and replacement of blood components may be the only potentially effective therapies available [340].

Not as potentially deadly as the genera previously mentioned, but of interest because of its wide range across the North American continent, frequent exposure to humans, and general commonplaceness, is the genus *Thamnophis*, the aglyphic colubrid snakes commonly known as the garter snakes [341]. In addition to their possessing enlarged, grooved, post-maxillary teeth, the salivary secretions of the common garter snake (*Thamnophis sirtalis*) are elaborated from mandible glands, and serve as evidence of a venom delivery system [342]. Several cases of envenomation have resulted from bites by the garter snake species, *Thamnophis sirtalis* [343] and *Thamnophis elegans vagrans* [344]. The victims of these bites suffered local swelling, edema, hemorrhagic vesicles, and ecchymosis, to the extent that they required hospital admission [343,344]. Systemic symptoms did not occur, but the clinical presentation was likened to that observed with pit viper envenoming [344]. Thus, even colubrid species considered to be totally harmless are capable of causing some degree of toxinological insult.

Colubrid species will continue to be redefined toxinomically, and be of significant importance on the forefront of venom research, as the science of their venoms will play an important role in the understanding of venom evolution in the animal world, and in the laboratories of biomedical and pharmacotherapeutic research [332].

Elapidae

Elapid snakes rank high among animals in the toxin world and are predominantly found on four continents (Table 19.6). This family is represented by 63 genera that contain 272 species, and the cobra, coral snake, mamba, and taipan are names of familiarity and notoriety [319]. Ranging in size from inches to meters, they are present in an abundance of brilliant colors, and color patterns, such as the coral snakes of the *Micrurus* and *Micruroides* genera, and exhibit functional threatening anatomical adaptations, such as hooding in cobras (*Naja* spp.)—an image well known and respected by humans for thousands of years. The most noted of the elapids are the cobras, coral snakes, kraits, mambas, and the Australian elapids where the diversity of the family is greatest (Table 19.6) [345]. All elapids are venomous and possess proteroglyphous dentition [315].

The elapid venom delivery system consists of tubular or grooved front teeth that are usually located on the anterior of the maxilla, followed by conical solid teeth. In general, their fangs are shorter than vipers and the associated venom glands have a lesser storage capacity. Elapid venoms are considered to be primarily neurotoxic in effect as their venoms contain nonenzymatic proteins, some enzymatic proteins, and cytotoxic components [346]. The presynaptic neurotoxins are usually phopholipase A_2 (PLA_2) isoforms that either inhibit or induce transmitter release from the presynaptic myoneural junction [347] while the postsynaptic neurotoxins are either short-chain (60–62 amino acids) or long-chain (66–74 amino acids), with their tertiary structure maintained via four to five disulfide cross-linkages, and competitively block acetylcholine from binding to the receptor forming a nondepolarizing block [26]. Elapid PLA_2 toxins may induce pharmacological effects independent of their enzymatic activity, and independent of other venom components such as is the case with *notexin* from *Notechis* sp. (Tiger snake) venom [347], while other PLA_2s require complexing with other protein factors, forming subunits, to express their pharmacologic actions as in the case of *taipoxin* from *Oxyuranus* sp. (Taipan) venom [348]. The PLA_2 enzymes exist in a wide variety of forms, and each enzyme may be highly specific in its action, as is the case with beta-bungarotoxin from the venom of *Bungarus multicinctus* (many banded Krait) that acts via presynaptic effect on nicotinic acetylcholine transmission, but not on adrenergic transmission [349]. To add to the complexity of PLA_2 enzyme functions is the fact that any number of the PLA_2 isoforms may express identical pharmacological effects, but by different mechanisms. Thus, the generalizing of PLA_2 venom activities for all elapid species would be erroneous [31].

In contrast to neurotoxins, some elapid venoms induce hemotoxic effects by possessing procoagulant properties that enhance the conversion of prothrombin to thrombin. Australian elapid venoms possess toxins with this pharmacologic action. For example, *notecarin* from the Tiger snake (*Notechis scutatus scutatus*), *oscutarin* from the Taipan (*Oxyuranus scutellatus*), and *pseutarin* from the Brown snake (*Pseudonaja textilis*) are all potent procoagulant toxins [340]. These varied venom pharmacological properties make snakes of the family Elapidae some of the most dangerous snakes in the world. The more prominent elapid genera will be briefly discussed.

Cobras, genus *Naja* (including the genera *Boulengerina, Hemachatus*, and *Pseudohaje*), are elapids that can attain a relatively large size (3 m), making their ability to inject large quantities of venom a concern to humans. Their highly toxic venom is frequently used to paralyze other venomous snakes they seek for food [319]. In addition to the traditional envenoming with fangs by biting, some species of cobras (i.e., *N. mossambica, N. nigricollis*, and *N sputatrix*) can spit or spray venom from an orifice in the front of their luminal fangs, for a distance of 2–3 m. All cobras can dorsoventrally compress their necks to form a hood. The king cobra (*Ophiophagus hannah*) is not a true cobra but shares similar anatomy and venom properties to true colors, but a cytotoxic, L-amino acid oxidase (*hannatoxin*) has been isolated from their venom [350], and the king cobra is perhaps the world's largest venomous snake, attaining a length up to 5.7 m [351].

Cobra venoms contain cytotoxins and numerous PLA_2 isoforms. The cytotoxins are basic proteins that can account for up to 40% of the total venom protein, and are membrane-active toxins that alter membrane permeability [346]. The cobra PLA_2 toxins are of the group I type based on their structural similarity to pancreatic secreted PLA_2 and exhibit myotoxic effects [352]. Many of these toxins have been referred to as cardiotoxins and are the most abundant of cobra venom constituents. They are basic proteins that are quite similar in conformation to the neurotoxic components of cobra venom but produce primarily cardiotoxic effects [353].

The combined effects of cobra venom toxins following envenomation yield a painful bite with swelling, and neurological symptoms of respiratory distress and paralysis. Despite the common thought that cobra venoms are not tissue damaging, their cell membrane toxins frequently cause necrosis of the skin and subcutaneous tissues. In particular, the venom of African spitting cobras, *N. mossambica* and *N. nigricollis*, can cause significant tissue damage in addition to neurotoxicity [345]. However, bites by cobra species (*Naja naja philippinensis*) of the Philippines cause minimal tissue damage, and exhibit severe and rapidly developing neurotoxicity [354]. Spitting cobras also defensively eject their venom into the eyes of their predators, including humans, causing profound conjunctivitis, pain, photophobia, blepharitis, and corneal opacification. These oculotoxic effects are believed to be related to the free/unbound cardiotoxins in the venom [355]. Death following cobra envenomation can occur rapidly as a result of respiratory paralysis, which can develop in as little as 15 min. However, neurotoxic symptoms may also be delayed for several hours, causing a delay in seeking medical attention.

Antivenoms are available for treating envenomations by African and Asian species, and adequate dosing of the appropriate antivenom usually neutralizes the medically dangerous symptoms that threaten life [356]. Additionally, the anticholinesterase drugs, edrophonium and neostigmine have been

successfully used in treating Philippine cobra (*Naja naja philippinensis*) [354] and monocellate cobra (*Naja kaouthia)* [357] envenomations, respectively. The treatment of ocular exposure from the venom of spitting cobras has involved irrigation, and the topical application of heparin-tetracycline solution [358].

Coral snakes, genera *Micrurus* and *Micuroides*, are native to the southern United States, Mexico, Central and South America, reaching their greatest diversity near the equatorial belt, and are relatively abundant compared with their Asian relatives (*Calliophis* spp. and *Maticora* spp.). The genus Micrurus is represented with nearly 70 species, with wide range of red, black, white, or yellow, ringed color patterns, and many mimic nonvenomous species [315]. These elapids are considerably smaller than cobras (<50 cm–1.5 m), and their fangs are correspondingly smaller.

Coral snake venoms have pharmacological activities that are capable of inducing cardiotoxicity, hemorrhagic toxicity, myotoxicity, and neurotoxicity, with the majority of *Micrurus* species possessing PLA_2 enzymatic activity capable of exhibiting anticholinesterase and anticoagulant actions. [359]. Neurophysiological effects can result from irreversible neuromuscular blockade, reducing evoked acetylcholine (ACh) release, but increasing spontaneous ACh release [360].

Coral snake envenomation to humans gives rise to a bite with minimal pain, and symptoms of nausea and vomiting, dizziness, generalized weakness, drowsiness, euphoria, followed by muscle fasciculations, diaphoresis, bulbar paralysis, diplopia, and slurred speech. Complete paralysis with the loss of respiratory function can last for several days. The neurological symptoms may not be immediately evident and are often delayed in their presentation for or up to 12 h [361].

Treatment of corals snake envenomation is most effectively accomplished with vigilance of respiratory function, and the use of antivenoms. In the absence of appropriate antivenom, it is possible to maintain life by providing artificial respiration for sustained periods until spontaneous breathing returns [362]. Antivenoms for coral snake species in Central and South America are available and are effective treatment, but many victims in these countries suffer symptoms without relief as they do not have timely access to a medical facility [356].

Mambas, genus *Dendroaspis*, are large (up to 4 m), agile African snakes with extremely toxic venoms. They come in grayish and green color morphologies, the terrestrial-inhabiting black mamba (*Dendroaspis polylepis*) and the arboreal-inhabiting green mamba (*Dendroaspis angusticeps*), with three subspecies of green mamba. The black mamba is named not for its body color, but for the charcoal colored interior of its mouth [363]. They are proteroglyphic with enlarged maxillary front fangs, that are moderately moveable, with no teeth posterior to the fangs, and these are associated with a well-developed venom gland.

Mamba venoms contain *dendrotoxins*, toxins of 57–60 amino acid residues cross-linked with disulfide bridges. These are neurotoxic in effect and stimulate acetycholine release from neuromuscular junctions. They have minimal antiprotease activity, and selectively block certain subtypes of voltage-dependent K^+ channels in neurons, with green (alpha-dendrotoxin) and black (Toxin K) mamba venoms differing in the subtype of K^+ channels pharmacologically affected [364]. Thus, via their blocking action on K^+ channels, they facilitate transmitter release at peripheral synapses, thereby inducing nerve action potentials repetitively. In the central nervous system, dendrotoxin induces seizures when injected into animals [365]. The mamba toxin, *fasciculin*, is an anticholinesterase toxin that is a selective potent inhibitor of acetylcholinesterase. Not surprisingly, mamba venoms also contain cardiotoxins [366] and muscarinic toxins of several types that selectively act on different muscarinic acetycholine receptor subtypes [367]. Their venom is also high in hyaluronidase activity that enhances venom spread. These different toxins, with their respective pharmacologic actions, work synergistically and are likely the explanation for the pronounced cardiovascular problems in victims of mamba envenomation.

Mambas can store from 4 to 8 mL per venom gland/fang, and they will bite repeatedly injecting a significant quantity of venom. There may be only a tingling sensation at the site of the bite, and symptoms can appear rapidly (10 min) or be delayed. Symptoms are progressive, and commonly consist of unconsciousness, diaphoresis, flaccid paralysis, respiratory paralysis, sustained hypotension, and direct cardiotoxicity leading to death [368].

Treatment of mamba envenomation victims with polyvalent antivenom (South African Vaccine Producers, (Pty) Ltd., Sandspringham, South Africa) is effective, and the treatment of choice. Symptomatic and supportive treatment is important and should complement antivenom therapy, but not be in lieu of antivenom use [368].

Taipans are the quintessential venomous snakes of the elapid family, and are native to Australia and Papua New Guinea. These are sizable snakes (2–3.5 m), and similar to mambas in their alert, nervous behavior, being very aware of their environment, and any intruder. There are two forms, the coastal taipan (*Oxyuarnus scutellatus*), and the inland taipan (*Oxyuranus microlepidotus*), sometimes referred to as the Fierce snake, which is believed to be the most venomous terrestrial snake in the world. The inland taipan's average bite delivers enough of its potent venom to kill 62 humans (70 kg body wt.), and that of the coastal taipan 27 humans [363].

Taipan venom contains neurotoxins, a Ca^{2+} complex-specific channel blocker, and a prothrombin activator [369]. The neurotoxin, *taipoxin*, is a trimeric PLA_2 that inhibits the release of acetylcholine form the presynaptic cholinergic nerve terminal, and is perhaps the most clinically important toxin. Postsynaptic PLA neurotoxins have also been found to be present in taipan venom [370].

Envenomation by taipans to humans results in progressive neurotoxicity exhibited by ptosis, opthalmoplegia, trismus, and paralysis of bulbar, peripheral, and respiratory muscles [371]. A pronounced consumptive coagulopathy may also occur [371]. Antivenom is available and effective if given early after the bite, but is less efficacious in ameliorating

neurotoxic symptoms after they are present, and respiratory support may be required [372]. The single most important measure to assure survival of taipan envenomation is rapid presentation to a medical facility with life support equipment.

Viperidae

Vipers and pit vipers, like the elapids, are indigenous to four continents, and represent two subfamilies, comprising 30 genera that radiate to 230 species (Table 19.6). Their various unique anatomical structures and behaviors have given them a reputation as creatures to be *reckoned with*. The viperidae do have a prominent and well-developed venom delivery system, possessing the advanced solenoglyphic dentition interfaced with a highly flexible maxillary bone that is associated with a sizable venom gland. As such, regardless of venom toxicity, they are capable of effectively delivering a large quantity of venom deep into the tissues of their victims. The viperidae are subdivided to two subfamilies based on the presence or absence of infra-red sensory facial pits that are used in sensing and sizing-up their prey. Those without heat sensing pits (*Viperinae*) are Afro-Asian (i.e., Horned vipers, *Cerastes* spp.) and Eurasian genera (i.e., European adders, *Vipera* spp.) that are not found in the Americas or Australia. Viperids with the specialized heat-sensing capability (*Crotalinae*, pit vipers) are found in both the Americas (i.e., Rattlesnakes, *Crotalus* spp.) and Eurasia (i.e., Malayan pit viper, *Callocelasma rhodostoma*), but are absent in Africa and Australia (Table 19.6). Given their multi-continental and latitudinal distribution (69° N to 47° S), they inhabit arboreal, semi-aquatic, and terrestrial ecosystems from tropical to temperate climates [319]. The venoms of crotalinae and viperinae subfamilies, and their toxicological effects, are probably the most extensively studied of all snakes.

Viperidae venoms, although they possess some toxins similar to elapid toxins such as PLA_2s, differ from those of elapids in their clinical pharmacologic effects. Viperidae venoms are complex, with a variety of constituents that are chemically different, and each constituent may exhibit a different pharmacological activity (Figure 19.1). In contrast to neurological complications observed in most cases of elapid envenomation, viperidae venoms exhibit a wide variety of pharmacological mechanisms that primarily lead to venom-induced hemorrhagic effects. Exceptions to this basic concept are the neurological effects caused by venom of South American rattlesnake toxin, *crotoxin (Crotalus durissus*), and Mojave rattlesnake, *mojavetoxin* (*Crotalus scutulatus*) in certain regions of the southwestern United States. For example, Asian viperidae venoms, such as the Malayan pit viper's venom contains a serine protease glycoprotein that cleaves fibrinogen-A from fibrinogen, while the venom of the saw scale viper (*Echis carrinatus*) contains the prothrombin-activating zinc metaloprotein, *Ecarin*, and venom of the Russell's viper (*Daboia russelli*) has protease constituents that activate factor X in the clotting cascade [321]. Viperidae, both viperinae and crotalinae, venoms alter blood coagulation, cause myonecrosis, and possess numerous enzymatic proteins that can impact nearly every organ system [373]. Prothrombotic venom toxins of the viper *Bitis arietans* (Bitiscetin), and the pit-vipers *Bothrops jararaca* (Botrocetin) and *Trimeresurus albolabris* (Alboaggregin), contain C-type lectin and metalloproteinase-disintegrins that promote platelet aggregation. In contrast, similar toxins within these same C-type lectin and metalloproteinase-disintegrin families, from *Trimeresurus flavoviridus* (Flavocetin), *Bitis arietans* (Bitistatin), *Agkistrodon halys blomhoffi* (Mamushigin), and *Crotalus atrox* (Catrocollistatin), have been found to inhibit

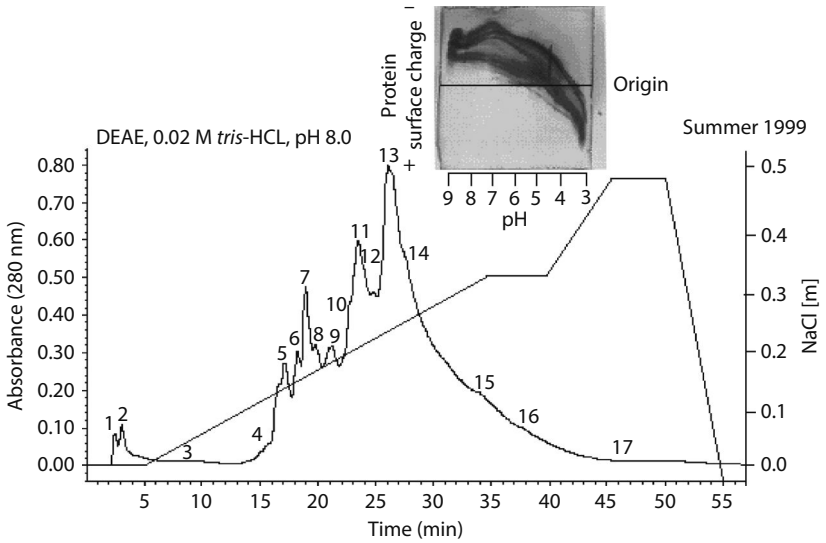

FIGURE 19.1 Profile of *Crotalus horridus* (timber rattlesnake) crude venom obtained by cation exchange high-performance liquid chromatography, illustrating the complexity of snake venom, as each peak represents a different venom fraction possessing its own pharmacologic activity. Inset: electrophoretic profile of venom showing separation of venom components based on pH, acidic or basic venom protein characteristics. (From John Perez, Natural Toxins Research Center, Kingsville, TX.)

platelet function, and demonstrate the commonality of some venom components across genera and across different continents [374]. Some crotalinae and viperinae (*Crotalus adamanteus, Crotalus ruber,* and *Agkistrodon halys blomhoffii*) venoms also contain phosphodiesterases [375]. The timber rattlesnake of the United States, one of the most widely distributed species of crotalinae, has a venom component, *crotalocytin* that causes rapid platelet aggregation [376].

Other venom toxins within the viperidae are the myotoxins, which are expressed as PLA_2 isoforms, with and without enzymatic activities, and in some pit vipers (*Bothrops asper*) these have been shown to change in expression depending on the age of the snake, with juveniles not expressing any PLA_2 isoforms. These are quantitatively important venom constituents that contribute to muscle necrosis and are triggered at the plasma membrane as a result of membrane destabilization with a loss of Ca^{2+} permeability [377]. Within the pit vipers, zinc metaloproteinases have been isolated from western diamondbacked rattlesnake, *Crotalus atrox* (*atrolysins*), and from eastern diamondbacked rattlesnake, *Crotalus adamanteus* (*adamalysins*), and differ from most venom proteases in that they all have hemorrhagic activity. These are known as the SVMPs (Snake venom metalloproteianases) [378]. L-amino acid oxidases are also common to most viperidae venoms and serve as an aid in prey digestion [321].

Envenomation by pit vipers or vipers usually results in complications with blood coagualation, tissue damage, and a redistribution of body fluids due to alterations in vascular permeability. The severity of envenomation can vary considerably depending on how much venom was injected with the bite, and where the bite was sustained. Large quantities delivered intravenously represent a worst-case scenario. Fortunately, most pit viper/viper bites are fairly superficial and large quantities of venom are not injected, and at times no venom is injected [379]. Pronounced pain is almost always present following bites, and edema and ecchymosis common.

Envenomations by pit vipers and vipers can result in profound hypotension, incoaguable blood due to venom anticoagulant effects, or as a result of consumption of blood coagulation components. Red cell membranes may rupture producing hemolysis, and delayed kidney damage. In general, victims may exhibit a DIC-like syndrome (disseminated intravascular coagulopathy). A few species of viperidae (*Crotalus scutulatus, Crotalus durissus terrificus* and *Vipera aspis*) have been studied for their potential therapeutic effects [380,381].

Treatment of viperidae envenomation usually involves the use of monovalent or polyvalent antivenoms, which are effective if administered within a reasonable time frame (Norris and Bush, 2001). Antivenoms are available for most prominent species of pit vipers and vipers [356]. Supportive care and wound care are essential in the treating of viperidae envenomation, and necrotic lesions may be slow to heal. Morbidity from viperidae envenomation frequently occurs when antivenom therapy is unavailable or an inadequate dose of antivenom has been administered [379].

Lizards

Heloderma, the only genus of lizards known to be dangerously venomous in the world, comprises only two species, the beaded lizard (*Heloderma horridum*) and the Gila monster (*Heloderma suspectum*), which are commonly referred to as escorpi'on. These two species further divide into five subspecies, *H. suspectum suspectum, H. s. cinctum, H. horridum horridum, H. h. exasperum,* and *H. h. alvarezi* [382]. The Gila monster is native to the extreme southwestern United States, and northwestern Mexico, while the range of the beaded lizard interfaces with that of *H. suspectum*, at its southern extreme in Mexico, but continues on down along the Pacific coast to Guatemala [315]. They are stout and solidly thick in the body, legs, and tail, and have a beady covering that is thoroughly, and irregularly, blotched with a pink/yellow pattern on a black/brown background. Interestingly, the forked tongue of *H. suspectum* is black, in contrast, to the pink forked tongue of the *H. horridum*. The Gila monster prefers an arid, rocky terrain, and will even dig burrows or use burrows of another animal, while the beaded lizard will inhabit forested areas, and is frequently observed in trees during the rainy season [383]. These lizards range in size from 35 to 70 cm, with the beaded lizard being the lengthier of the two.

Heloderma have short, slightly recurved, sharp, peg-like teeth that are grooved on both the anterior and posterior surfaces, with these grooved teeth anchored to the maxillary and mandible jaw bones. Although these lizards appear sluggish and somewhat uncoordinated when walking, as they appear to be waddling, they can rapidly flex their body and clamp their jaws around a victim. They will frequently chew once attached to a victim, and will not let go making them difficult to remove.

The delivery of venom by *Heloderma* stems from multilobed glands, lacking in musculature, that are located in the anterior portion of the lower jaw, on both sides, with each gland lobe independently having a duct that opens at the base of a tooth. When biting a victim, the muscle contraction of the jaw forces the venom from the ductal openings and channels it along tooth grooves, both upward and downward, with venom conduction via capillary action.

Venom chemistry studies of *Heloderma* have not been comprehensive, but limited studies show the venom of both species to be similar [384]. The venoms are known to possess enzymatic properties, as demonstrated by the presence of hyaluronidase, arginine hydrolase, phospholipase A_2 [385], and kallikrein-like enzymes [384,386]. One of the kallikrein-like enzymes capable of inducing hypotensive effects has been dubbed, *Helodermatine*. Additionally, an acidic protein neurotoxin, *gilatoxin*, a hydrolase toxin, *Horridum toxin*, and a hypothermic toxin, *Helothermine* (toxin from a *Heloderma* with a hypothermic effect), capable of significantly lowering body temperature in animals, have all been identified in beaded lizard venom [387,388]. *Heloderma suspectum* venom appears to be absent of hemolytic, hemorrhagic, and proteolytic properties [389], but vasoactive peptides and a vasodilating venom component have been isolated [387].

Heloderma have few enemies other than man, and it is humans who suffer the consequences of their powerful bite. Although claims and reports of death from *Heloderma* envenomation exist, their legitimacy has been greatly questioned [382]. Envenomation from *Heloderma* is quite painful, and much of the pain is a result of pure mechanical trauma injury. These lizards will hang on when they bite for extended periods of time without lessening their grip. Teeth may even be broken off when human victims are trying to remove the tightly attached lizard. Prominent symptoms, aside from intense pain, are edema, erythema, nausea and vomiting, dizziness, hypotension, leukocytosis, weakness, tachycardia, diaphoresis, and lymphangitis [390]. Arteriospasm, with severe pain, of an envenomated digit may also occur [391]. Hypotension is a major concern and, in some cases, may be related to venom-induced anaphylaxis involving swelling of the tongue [392]. Symptoms may persist for greater than 72 h, and wound care is critical, as broken teeth may need to be removed, and secondary infection may ensue. Treatment of envenomation consists of good supportive care, and may involve fluids, antihistamines, and corticosteroids, with careful cleaning of the wound and antibiotics [390].

Amphibia

In addition to the variety of freshwater and toxic marine animal life forms such as sedentary anemones, swimming catfish, or drifting jellyfish, and the numerous semi-aquatic and terrestrial toxic animal life forms such serpentine-swimming sea snakes, walking lizards, and crawling land snakes, nature has filled another ecological niche with, not only awkwardly walking, but *hopping* amphibians. They may live in water, on the land, or utilize both as adults, but usually have some stage of their life cycle overlapping between these two habitats. Amphibians, possessing toxic properties in their body or skin inhabit subtropical and tropical regions of the earth, but a few are also found in temperate regions. A few of the approximately 2600 amphibia are known in the realm of toxinology for their toxic skin secretions (Table 19.7) [393]. As a group, amphibians commonly are the prey food items of a variety of animal predators, such as birds, fish, snakes, and humans. Thus, given their limited modes of locomotion, making escape from hungry predators difficult, antipredation strategies that would ensure their continued survival often depend on their ability to fend off predators in toxinological ways, making them quite distasteful, or even poisonous. Thus, the ability of some amphibians to secrete skin toxins has been a phenomenon for which toxinological explanations have been sought and one of great interest to medicine and science.

Man's interest in amphibian skin secretions began over two millennia ago in China when powdered frog skins were used as heart stimulants and diuretics [89]. Today, the quest for knowledge concerning amphibian toxins and related biologically active compounds continues as evidenced by the continuing studies of one of the most widely distributed and potent natural toxins, tetrodotoxin (TTX). Present in a spectrum of unrelated taxa, such as bacteria, a flatworm, goby fish, octopus, and puffer fish, TTX is also prevalent in several amphibian genera and species and subspecies [394]. However, of the greater than 5000 amphibian species, categorized to 44 families [395], only 6 appear to contain TTX [396]. First isolated from the puffer fish of oceanic waters, and then from the terrestrial amphibian, the California newt (*Taricha torsa*), TTX continues to be discovered in new species [397].

Amphibian toxins are passively delivered, transdermally, when they are harassed, or actually being engulfed by predators. The skin of amphibians is a complex organ of interrelated biochemical, morphological, and physiological functions utilized for hydration, reproduction, respiration, thermoregulation, antifungal and antimicrobial protection, and antipredator defense and is essential to amphibian survival [398]. Toxins are released from specialized mucous-secreting, or granular, dermal glands distributed throughout the dorsal skin but, in some cases, are also present in specialized anatomical structures, like the bulbous parotoid gland, located in the post maxillary region of some salamanders and toads [89]. These are sites of synthesis for alkaloids, biogenic amines, peptides, proteins, and steroids [398]. The consequence of toxin release is basically a distasteful adverse reaction to predators, but in some instances, death to another creature may occur following ingestion of the toxin-containing amphibian.

Frog, newt, and toad skin secretions, from several species, representing several major amphibian genera, contain the potent, nonprotein neurotoxin, *TTX* [399]. Frogs of the

TABLE 19.7
Terrestrial Vertebrate Animals: Amphibians and Reptilia (Lizards)

Phylum	Class	Common Name		Genera (Toxin-Containing)
Chordata	Amphibia	Frogs, poison dart frogs		*Aetlopus, Brachycephalus, Colosthetus, Dendrobates, Epipedobates, Gastrophryne, Kaloula, Limnonectes, Mantella, Phylobates, Polypedates, Rana*
		Newts		*Cynops, Notophthalmus, Paramesotrition, Taricha, Triturus*
		Salamanders		*Salamandra*
		Toads		*Ansonia, Bombina, Bufo, Leptophryne, Pedostypes*
	Reptilia	Lizards	Beaded lizard Gila monster	*Heloderma*

genera *Brachycephalus, Colosthetus*, and *Polypedates* [397], toads of the genus *Atelopus* [399], and newts of the genera *Cynops* and *Taricha* [400] are all different amphibian genera containing at least one species that possesses TTX in its body. The origin of TTX in amphibians, and all other animals, has been a topic of great interest, and there is considerable evidence that TTX may be of dietary origin, associated with a symbiotic relationship with TTX-producing bacteria, and as such it is bioaccumulated [401]. However, recent studies in rough-skin newts (*Taricha grannulosa*) suggest that TTX has been produced by granular skin glands, in high concentrations, independent of bacteria symbiosis, alluding to the possibility of different TTX origins in different amphibian species [402]. A recently discovered TTX, 11-oxotetrodotoxin (11-oxoTTX), has been isolated from the skin extract of the Brazilian frog, *Brachycephalus ephippium*, and found to be four to five times more toxic than TTX itself, demonstrating possible evolutionary changes in TTX [403]. Further research with two other species of the *Brachycephalus* genus (*B. nodoterga* and *B. pernix*) has confirmed the presence of several new deoxy-TTX and nor-TTX analogues [397].

Toxicity of TTX results from its ability to specifically, and irreversibly block, voltage-gated, Na^+ ion channels, abolishing the action potential at very low concentrations (μg/kg) [404]. The result of this action is varying degrees of paralysis in animals, but some predators like the common garter snake (*Thamnophis sirtalis*) appear to be resistant to TTX toxicity [405]. TTX toxicity to humans results from ingestion of significant quantities of TTX. Human fatality, within 24 h of ingesting a rough-skin newt, that caused cardiopulmonary arrest, has been reported [406]. Although TTX is relatively prevalent in amphibians, there are also other significant toxins of great interest, and potency, present in amphibians.

Frogs and Toads

Frogs and toads of several genera (Table 19.7) from particular bufonid, dendrobatid, mantellid, and myobatrachid anuran lineages, have yielded over 500 lipophilic alkaloid compounds, representing 22 different structural classes [407]. The alkaloids represent several truly unique toxins that appear to be present in dermal secretions, not because of de novo synthesis or genetic factors, but as a result of the arthropod diet of certain frogs. Diet preference for myrmicine ants appears to be a primary source that leads to alkaloid sequestration in several brilliantly colored, Central and South American, dendrobatid poison dart frogs, and these ants have comprised up to 73% of stomach contents of *Dendrobates* spp. [408]. The frogs (poison dart frogs) best known for the more potent alkaloid toxins are those in the genera *Allobates, Dendrobates, Epidobates*, and *Phyllobates*. Toxic alkaloids present in these genera include the voltage-gated Na^+ channel activating *batrachitoxins* (BTXs), noncompetitive nicotinic receptor-gated channel blocking *historonicotoxins* (HTXs), cardiotoxic and myotoxic *pumiliotoxins* (PTXs) and allopumiliotoxins (aPTXs), and the nicotinic receptor agonist, epibatidine with its antinociceptive properties [409]. Additional skin alkaloid toxins include coccinellines, cyclopentaquinolizidines, decahydroquinolines, tricyclic gephrytoxins, indolizidines, piperidines, pseudophrynamines, and pyrrolidines [410]. On the other side of the ocean from these dendrobatid frogs are several varieties of frogs and toads from Thailand that have toxic skin secretions. The ranid frogs, *Rana raniceps*, *R. signata,* and *R. hosei*, along with the rhacophorid frog, *Polypedates leucomystax*, have skin extracts that cause locomotor difficulties and prostration when injected into mice, and a skin extract from *Limmonectes kuhli* contains pumiliotoxin alkaloids. Virtually nothing is known about potential toxic effects of these extracts to humans [411].

Toads of the Americas and Asia are also noted for their noxious secretions. The widely distributed marine toad (*Bufo marinus*), Amazonian (*Bufo aqua*), Asian (*Bufo gargrizans*), European (*Bufo vulgaris*), and North American, Colorado river toad (*Bufo alvarius*) are a few of over 200 toad species, all having paratid glands capable of producing biologically active compounds [412]. The biologically active substance serotonin is found in both humans and toads, but it is a 5-hydroxydimethyltryptamine, that is present in all toad species, and is known as *bufotenine*. When this compound is methylated it becomes bufotenidine, dehydrobufotenidine, and 5-methoxydimethyltryptamine (5-MeO-DMT), a potent bufotenine only known to exist in *Bufo alvarius* [413]. It is the 5-MeO-DMT that is believed to induce hallucinations in humans following licking of toads, or smoking their venom [414]. In addition to bioactive toad venom components there are the bufodienolides (bufogenins and bufotoxins), biosynthesized from cholesterol, that are highly toxic cardioactive steroids that most likely work in concert with epinephrine and norepinephrine, which are also present in toad venom [415].

Toxicity associated with toad venom is similar to that of digoxin [416], with inhibition of the sodium–potassium ATPase pump [417]. Small, companion animals have died as a result of toad ingestion [418]. Chan Su poisoning in humans who ingested dried toad venom as an aphrodisiac and people who *licked* or *mouthed* toads to get high have caused profound cardiotoxicity that has resulted in several fatalities [419]. Successful treatment of cardiotoxic effects has been accomplished with the use of digoxin-specific antibody Fab fragments [419]. Still further demonstrating the diversity of toad toxins has been the isolation of morphine-like toxins from *Bufo marinus* skin extract [420], and a sleep-inducing factor from the extract of the Indian toad, *Bufo melanostictus* [421], in which only males of this species possess a Bidder's organ, located *rhostorventrally* to the kidney, that produces a Bidder's organ-cardiotoxin capable of inducing cardioneuromuscular blockade in animals [422].

Newts and Salamanders

Newts are similar to salamanders in appearance except that their skin has a dryer, less clammy, or slimy feel to it. Toxic species are native to the east and west coasts of the United States and Japan. Their primary toxin is tetrodotoxin and has been discussed earlier.

Salamanders of European terrestrial forested habitats may be bright orange and black bicolored, or solid black, and have a wet sheen appearance to their bodies. They are of the genus *Salamandra*, the European fire salamander (*Salamandra salamandra terrestis*) and the Alpine salamander (*Salamandra atra atra*), and like their dendrobatid amphibian relatives, secrete toxic alkaloids from their skin. Samamandarine and samamanderone are the steroidal alkaloids of prominence, but cycloneosamandione, samamandinine, samanine, samamandaridine, and samandenone may also be present [423]. These are possibly cholesterol-derived steroidal alkaloids, and they are synthesized by the salamanders rather than taken up in the diet or some other form. Detailed pharmacologic actions of these salamander alkaloids are lacking but have been shown to have nerve-blocking activity both peripherally and centrally in the nervous system [424]. Although these toxins may serve as deterrents to predators, their effects in humans are unknown.

Marine Animals: Poisonous, Toxin Bioaccumulated

Poisonous marine animals do not synthesize the toxins they carry in their bodies and organ systems but rather accumulate the toxins from their diet or environment. Thus, the toxins are actually produced by other organisms that live in the surrounding marine environment. A variety of marine animals are seafoods common to the human diet that may potentially become toxin-bearing and cause severe risk to human health and life following their consumption (Table 19.8). For example, the most popularly known seafood poisoning, exhibited as neurotoxic symptoms and cardiopulmonary toxicity, and potentially human death, may result from eating puffer fish. Prepared in gourmet restaurants as a delicacy dish, *fugu*, if improperly prepared may lead to severe tetrodotoxin poisoning in the innocent diner [425].

Marine animals most commonly acquire these toxins from dinoflagellate (toxic microalgae) species such as *Alexandrim* spp., *Gymnodinium catenatum, Pyrodinium bahamense* (all associated with Paralytic shellfish poisoning and Red tides) [426], *Dinophysis* spp. (Diarrhetic shellfish poisoning) [427], *Nitzschia* spp. (Amnesic shellfish poisoning), and *Gymnodinium brevis* (Neurotoxic shellfish poisoning) [428]. Still other toxins, associated with different poisoning symptoms, also come from dinoflagellates, such as *Gabierdiscus toxicus* and *Ostreopsis lenticularis* (Ciguatera poisoning), that contain toxin-producing bacteria [429], while *Pfiesteria* spp. have caused considerable human sickness yet no toxin has been identified [430]. Not surprisingly, the presence of dinoflagellate toxins in marine animals will fluctuate in some species with seasonal climate changes that trigger algal blooms. Additionally, some toxins

TABLE 19.8
Marine Animals: Poisonous and Toxin-Containing

Phylum	Class	Common Names	Genera (Potentially Toxic)	Toxins

Histamine

form, and accumulate, in food fish as a result of spoilage, such as the case in scromboid poisoning [431].

There are no simple antidotes for treating victims of marine food poisoning, and symptomatic and supportive care, including life-support, are essential for successful outcomes.

Animal Toxins and Poisons from Unusual Sources

The amazing thing about animal toxins is that in addition to being present in snakes, poison dart frogs, jellyfish, scorpions, spiders, and other likely *poisonous creatures*, there are toxins and poisons that show up in the most unlikely of creatures (Table 19.9). No one would ever think of poisonous birds from Papua New Guinea with toxins in their feathers to deter predators, and that the toxins are similar to those found in Central and South American poison dart frogs [432], nor would anyone think that the powerful Polar bear could be poisonous and cause serious vitamin A toxicity from ingestion of its liver as a human dietary food [30]. The gracefully swimming sea turtles, like many poisonous fish, may accumulate algal toxins from the oceans, and when their meat is consumed, cause death [89]. The littlest of mammals, the shrews, have salivary toxins capable of inducing hypotension and paralysis [433]. Even the most unusual of mammals, the egg-laying platypus, has a toxin secreting, crural venom gland, connected by a duct to an erectile keratinous spur, just above the webbed foot on each hind leg. The males only possess this venom apparatus, and if skin penetration to a predator occurs, it can cause severe pain, edema, and hyperalgesia [434].

In contrast, to these creatures, one might expect a vampire bat to have a toxin in its saliva that would alter blood coagulation, and such is the case with this flying mammal, as the anticoagulant *draculin* allows the free flow of blood from its dietary victims [435].

Toxins in the animal kingdom, whether used for defense against predation, or for prey acquisition, have been an evolutionary key to the long-term survival of toxin-containing, toxin-producing, and poisonous creatures. The animal phyla, classes, genera, and species that make up nature's living synthesis laboratories will continue to be the true Nobel chemists of the world despite human intellect.

BENEFICIAL USES OF NATURALLY OCCURRING TOXINS

So what does all this massive group of information on the diverse effects of multiple natural toxins come down to? Is there continuity to the available information? Can generalizations be made and extrapolated across species? What can be learned for the betterment of societal health and preventive and therapeutic medicine?

The varying potencies and clinical damage produced by the plants, algae, mushrooms and diverse representations of the animal kingdom clearly indicate the variety and intensity of toxicity resulting from these naturally occurring intoxications. The variety of body systems affected both in animals and in human beings compliments the wide identification of toxic chemical entities identified already from each natural vector. Correlating the presence of specific toxic compounds with their physiological effects allows researchers to consider developing new chemicals derived from these natural products to produce or modify drugs to influence physiological functionings. Such modifications could improve health, could block disease mechanisms, or could offer valuable insight into therapies and new modalities for therapeutic intervention. The abundant reports of individuals being bitten by snakes and treatment-specific antivenom followed by the course of the toxicity offer information on future improved therapies. A young male bitten by a king cobra and treated with massive doses of Thai King Cobra Antivenom within

TABLE 19.9
Animal Toxins and Poisons from Unusual Sources

Phylum	Class	Common Names	Genus	Toxins/Poison
Chordata	Aves	Rubbish birds		
		Blue-capped ifrita	*Ifria*	Batrachitoxin
		Hooded pitohui	*Pitohui*	Homobatrachotoxin
		Quail	*Coturnix*	Coniine, hyoscyamine
				Solanins
Mammalia		Platypus	*Ornithorhyncus*	Enzymatic proteins
				Hyaluronidase
		Polar bear	*Thalarctos*	Retinol (Vit. A)
		Shrew	*Blarina, Neomys*	Kallikrein
			Sorex, Solenodon	
		Vampire bat	*Desmodus*	Draculin
	Reptilia	Sea turtles		
		Green	*Chelonia*	Chelonitoxin
		Hawksbill	*Eretmochelys*	
		Loggerhead	*Caretta*	

an hour of envenomation, and the rapid uneventful recovery with no after effects, provides good clinical experience and insights into the value of such early and massive therapy [436]. This case and others document the efficacy of an efficient emergency medical system and the prompt utilization of intravenous dosing with specific volumes of antivenom.

Components of natural toxins may also be used to attenuate or reverse illnesses in humans, often on an initial empirical basis and later to more recognized efficacy in treating human functional disturbances. Snake venom derived Arginine-Glycine-Aspartic acid containing Disintegrins (Rhodostomin) has been shown to inhibit cell adhesion and particularly the adhesion of breast and prostate carcinoma cells to bone extracellular matrices. Rhodostomin also inhibited migration and invasion of the breast and prostate carcinoma, markedly inhibiting tumor growth and bone destruction. These disintegrins from snake venom strongly inhibit adhesion, migration and invasion of tumor cells as well as tumor growth of human breast cell cancer in bone; they thus have the potential to be developed as alternate therapy for the bone metastasis of cancer cells [437].

Snake venoms have also been used to provide more effective therapy of human and animal problems. Coagulopathy is a significant cause of morbidity and mortality in snake-bitten humans; yet probably prepared fractions of snake antivenoms are effective treatment, more so than standard factory placement therapy and heparin [438]. Understanding the mechanisms of action for such potent benefits serves to advance medical therapeutics and prevent human suffering. The disintegrins and other snake venom proteins have shown extreme promise in the treatment of a range of hemostatic disorders; for example, ancrod from the Malayan Pit Viper (*Calloselasma rhodostoma*) has been effectively used as an anticoagulant for therapeutic defibrination [439]. These and other fractions from naturally occurring toxins offer continuing mechanisms to study modes of action from these molecular structures to benefit human and animal health.

The diverse animal and plant sources for these potentially useful products highlight the numerous opportunities for identifying beneficial fractions from plants and animals that could have wide use in medicine. The recent observation that extra virgin olive oil contains a compound that provides the same pain-relieving effect as the anti-inflammatory compound ibuprofen. Since inflammation is believed to form the basis for a variety of chronic diseases, and current anti-inflammatory compounds have undesirable side effects, this discovery is just another example of the possibilities that chemicals in natural products may offer.

The opportunities are all around us in our plant and animal kingdom, and the experiences gained in nonhuman animals from their continuing exposure to plants and animals living in the wild offer instances of excitement when potent chemical effects are observed from such exposures. The comparative value of animal effects to naturally occurring toxins emphasizes the importance of applying such information to human medicine and to toxicology.

It is true that there is one medicine…and also one toxicology!

QUESTIONS

19.1 What are the differences in the chemical characteristics of a venom and a synthetic chemical?

19.2 What conditions affect the concentration and type of toxin in a poisonous plant? What conditions affect the concentration and type of toxin in the venom of a poisonous animal?

19.3 What body organs are commonly affected by poisonous plants? Give two plants that primarily affect each such organ.

19.4 Discuss the laboratory procedures used to detect the presence of toxins in plants.

19.5 What plant toxins are secreted in breast milk or the milk from lactating animals?

19.6 What are the common toxins that are generated by blue-green algae? What body systems do they each affect?

19.7 Why are blue-green algae of public health significance?

19.8 What are the clinical effects produced by mushroom consumption?

19.9 Through what mechanisms do animal toxins exert their harmful effects?

19.10 What are the five categories (classes) of toxic marine invertebrates?

19.11 Give three toxic marine animals in the Cnidaria group.

19.12 Discuss the potentially beneficial uses of the toxins found in plants and animals.

19.13 What are the five bony fish known to be venomous and hazardous to humans?

19.14 What are the effects of envenomation by sea snakes?

19.15 How might terrestrial invertebrate animals deliver their toxins?

19.16 What are the largest sized arachnoids? What are the oldest living toxic creatures?

19.17 In what parts of the world are scorpion bites serious health problems?

19.18 Give the common names of five different venomous spiders.

19.19 What is the chemical composition of centipede venom?

19.20 What are the common names of five venomous members of the *Insecta* group of animals?

19.21 What is unique about Australian caterpillars?

19.22 What dose of venom is injected by the sting of one bumblebee? What is the dose of venom injected by one hornet sting? What is the dose of venom injected by the sting of one killer bee?

19.23 Name and characterize five venomous reptiles.

19.24 What are the various types of dentition that venomous snakes have?

19.25 Describe the difference in venom activity between colubrid, elapid, and pit viper snakes.

19.26 Discuss the various treatments available for the bites of venomous snakes.

19.27 Name the two venomous lizards in the world and how they deliver their venoms.

19.28 How are amphibian toxins delivered to victims?
19.29 What is the potent nonprotein neurotoxin found in skin secretions from several amphibian genera?
19.30 Discuss the unique toxins in the dermal secretions of frogs and toads.
19.31 What commonly dispensed drug induces similar toxicity to that associated with toad toxicity?
19.32 What is the primary toxin elaborated by newts?
19.33 What are five marine animals that commonly acquire toxins from dinoflagellate species?
19.34 Discuss the animals that are not usually considered to carry toxins, but are capable of inducing poisoning in unsuspecting humans.

20 Humane Care and Use of Laboratory Animals in Toxicology Research

Dale M. Cooper, Lisa Craig, Christopher N. Papagiannis, Duane W. Poage, Gregory W. Ruppert, and David G. Serota

CONTENTS

INTRODUCTION

Procedures for the use of animals in research are heavily driven by regulations, and regulations are heavily driven by public expectations. This chapter is intended to introduce the scientist to these regulations and expectations, as well as the scientific concepts that underlie the regulatory standards. The complexity of these requirements is such that scientists are not expected to be experts in this area. Laboratory animal science and medicine have become their own fields of study with professional associations, training programs, certifications, and even a Board specialization in veterinary medicine.[1] Scientists should cultivate cooperative relationships with the professionals responsible for laboratory animal care and welfare at their institution, or if such professionals do not exist, bring this expertise in-house or utilize available consultants. This can be a challenge, as animal welfare compliance can sometimes conflict with scientific freedom, which entails some risk of developing adversarial relationships between scientists and compliance personnel. It is important for both scientists and compliance staff to remember that each of their roles is critical to the success of the research mission and open communications are critical.

Public Perception of Animal Research

The selection of the best model for risk assessment of new drugs and chemicals is impacted not only by the scientific

merits of the model, but also by public attitudes toward the use of animal models in research. Public attitudes have affected the science of toxicology through subtle effects on model selection due to pressure on institutions from shareholders, public constituents, animal extremist protesters, and through the creation of government regulations and industry standards directly affecting the cost of conducting animal research. Regulations and the associated standards are discussed throughout this chapter to provide the basic framework for all procedures related to the humane care and use of laboratory animals.

Attitudes toward animals and their use in research vary throughout the world based on philosophy, culture, religion, gender, socioeconomic level, species of animal, and the intended research use.[2–5] However, there are several basic concepts underlying animal welfare regulations and standards in existence throughout the world. First, there is the concept that there is intrinsic value to life and in particular, sentient life. The second concept is that sentient animals have the capacity to experience pain or distress and try to avoid pain and distress wherever possible. The third concept is that research animals share common genetic and physiologic attributes, making them useful for biological modeling in humans as well as animal species. Thus, the use of animals in procedures, which have the potential for pain and distress or are terminal, is perceived to represent an ethical cost and should only be performed where there is scientific justification and no suitable alternative.[2,6]

Depending on how individuals value each of these concepts, a spectrum of attitudes can be displayed toward animal use.[4,7] One philosophy is often referred to as animal extremist or animal rights. This is the belief that the rights of animals are equal to those of humans, and the use of animals in research is unethical because animals cannot consent to the research procedures for study. People with these beliefs may express them through lifestyle choices related to the use of animals or animal products for food, fiber, clothing, work, companionship, or sporting use. Others become involved politically in an attempt to influence public policy or corporations, while some protest through media, writing campaigns, and/or publically. Few go to extremes and may harass or induce violence toward people working at research institutions, their customers and investors, infiltrate research operations for the purposes of generating publicity or regulatory investigations, causing property damage and theft, or the release of animals.[4,8]

Animal rights activities have profound effects on the use of animals in research by driving the development of a regulatory infrastructure for the care and use of animals in research. There have been positive effects from this infrastructure as it has led to significant learning about the specific contributions animal models make versus nonanimal models in safety assessment research and the control of variables when using animal models in research. However, there have been negative effects as well. The cost of research and the time required for planning and conduct of research have increased, and most importantly, a significant gap has appeared in communication between biomedical researchers and the public regarding the importance of animal models in the development of medical treatments as well as chemicals for our lifestyle and civilization. Attitudes have continued to support limiting animal research as well as limiting the species of animals available for use. Western Europe, in particular, has seen significant restriction in animal use over the last decade.[2,8] As animal research can be conducted in other countries, it has not affected the overall progress of research, but if this trend encompasses the globe, profound impacts on the progress of biological sciences could occur. On a practical level, institutions using animals need to screen employees for animal extremist activities and maintain internal and external security to protect from incursions. It is also important for all staff to be trained to understand the need for animals in research, but also understand the approval process justifying the use of animals and the extensive care provided to them.

The opposite of animal rights extremism is a lack of value for animal life or recognition of the ability of animals to experience pain or distress.[9] This attitude is somewhat perplexing from a scientific standpoint, as in order for animals to be good models of human biology, they must share similar anatomical, physiological, and neurological capabilities that would logically result in their ability to experience pain or distress in the same way that humans do. Like animal extremism, not valuing animal life can also result in problems within research institutions if it leads to resistance to regulatory compliance. When expressed openly, it may be viewed as insensitive and perpetuates the traditional stereotype of science being cold and uncaring. This can polarize the attitudes of the public as they may react to one extreme viewpoint by adopting the other extreme viewpoint. Staff may require sensitivity training to understand and respect the diversity of viewpoints regarding animals and the importance of complying with both the spirit of animal welfare regulations and the letter of them.

Fortunately, these extreme views are relatively rare. The majority of individuals recognize that there are ethical tradeoffs with many of the decisions humans make. In general, as long as researchers demonstrate they are paying attention to basic principles, such as respect for life, minimizing pain or distress, and using animals only when scientifically justified, the public supports the use of animals in research.[4,7,10] It is important that the public can see that these basic principles are being employed. It is critical for biomedical research institutions and individual researchers to maintain open communications with their communities and constituencies so that the importance of the research performed and the ethical standards that are used to determine when and how animal models are used is also clear. Institutions need to maintain this communication internally as well as externally as scientists and nonscientific staff may also have questions or concern about animal use and need the same information to be comfortable with animal use at their institution. In fact, institutional employees may be one of the most important audiences for this message. If a staff member becomes dissatisfied with an aspect of animal use and does not feel that

they can address it internally, they become a risk for passing information on to an animal extremist group, the media, or a government agency in an attempt to get their issue addressed. Communication with the public creates certain risks of confronting the attitudes of extremists as does talking with the media, who may not have a moral agenda but will modify the tone of their report to maximize the sale of their product. Therefore, external communication must be done carefully. Institutions commonly have policies restricting communications with the media or nonemployees and may have designated leaders and/or trained public relations staff to manage these communications. Outreach programs for schools and the community are also common. Successful programs often have well-prepared presentations, clear messages, and experienced and engaging speakers who know how to present biomedical research in a positive light and are able to respond to questions posed by the public. There are professional organizations that assist research institutions with this task (Table 20.1) and scientists or institutions can become involved with and support these organizations and their missions.

Scientific Justification for Animal Use and Alternatives

To address both public concerns about the use of animals in research and meet compliance needs, one must scientifically

justify when and how animal models are used in the process of developing drugs and chemicals, and explore alternatives to animal use. In order to scientifically justify animal use in research, scientists must document a search for *alternative* models.[11–13] Alternative models include not only a choice between animal and nonanimal models but also alternatives to procedures in animals causing more than momentary or slight pain or distress. This concept, first described in a book by Russell and Burch in 1959, is categorized as the *3 Rs*: *replacement*, *reduction*, and *refinement*.[12,14,15]

Replacement alternatives include the use of nonanimal in vitro and in silico models. Clearly, a nonanimal model cannot experience pain or distress. However, replacement alternatives can also involve the use of less sentient animals, as it is believed by some that less sentient animals have a lower ability to experience pain or distress.[6] Therefore, invertebrate models are preferable since they have a less-developed central nervous system (CNS) in comparison to a vertebrate. Furthermore, the use of a *lower* vertebrate such as a fish or amphibian is also considered preferable to the use of a bird or mammal, and the use of a lower mammal such as a rodent is considered preferable to the use of a higher mammal such as a dog or nonhuman primate. This concept has been questioned based on both biological and ethical grounds since there are some invertebrates like cephalopods with advanced CNSs, and the relative level of sentience of different vertebrates is difficult to measure among different taxa that evolved parallel behaviors.[16,17] In addition, perception of sentience or other *moral value* is affected by religious and cultural norms, as well as personal experience.[6] For example, dogs may be perceived as having higher value than nonhuman primates by some individuals, despite a large body of literature suggesting sentience is higher in nonhuman primates. In the Western world, rodents are often viewed as vermin, and therefore of lower value, but behavioral evaluation of mice and rats shows a high level of cognition and capacity to experience pain or distress.[18]

One potential replacement alternative is the use of human volunteers. This is not classically considered a replacement alternative, and is not consistent with the idea of using a less sentient organism for research. However, humans can freely choose whether to participate in the research procedures and can be educated on the potential for pain or distress from the procedure. The results of the research also directly benefit the humans; therefore, they directly bear any risk from the research for their own benefit. While it could be argued that this alone should drive the use of humans rather than animals for research, regardless of a human's willingness to volunteer, most individuals and cultures have determined that the involuntary use of humans is considered more unethical than the involuntary use of animals, as reflected by laws and religious mores. There is also a scientific case arguing against the routine use of humans for the development of new drugs and medical devices: It is much harder to control variability in human populations due to genetics, lifestyle, and compliance with research procedures. Therefore, the sensitivity of a human bioassay is inherently lower than a well-defined and controlled animal assay, assuming there is good relevance of the animal assay to the human condition.[19]

The appropriate use of replacement alternatives is already incorporated into regulatory guidelines for submission of data for new drug or medical device registration,[20,21] but it is also driven by scientific and economic considerations. Not only does animal use tend to be more expensive compared to nonanimal models, it is generally more difficult to control experimental variables. Nonanimal models are very useful for high-throughput screening of test articles, particularly where there are well-defined mechanisms of disease or toxicity that can be detected by the assays.[22,23] However, because not all of these mechanisms are known, initial screening assays must be supplemented by live animal assays. Live animal data are required prior to gaining approval for testing in humans because the risks associated with new therapies are often greater than most humans will volunteer to take. In addition, scientists will typically choose a rodent model over a nonrodent model due to the lower cost to buy, care for, and use rodents and the ability to control genetic and environmental variables in many rodent models. Regulatory guidelines also require the use of two species of animals prior to human studies, one of which must be a nonrodent due to the higher level of relevance of nonrodent models for certain biological systems.[24]

Reduction alternatives are those that minimize the number of animals used. It is important to evaluate reduction alternatives against the bigger picture of a research program, as simply reducing the number of animals on an experiment can have negative effects for the study including nonmeaningful data, the need for additional animals to be added later, or the need to repeat or conduct additional studies. Therefore, when designing studies to produce valid data, statistical methods are very useful and can help define the appropriate number of animals needed for valid results. For this reason, the animal use review process will typically ask whether statistical methods have been incorporated into the study design.[11–13,15] In some cases, statistics are not utilized for study design, as some assays driven by regulatory requirements mandate a certain number of animals,[24] usually based on industry experience with the assay. When regulatory requirements are not driving the study design, studies should be designed to provide appropriate statistical power to detect biologically relevant differences among groups for the specific endpoints measured. If the statistical difference in mean response considered biologically relevant and level of variability in response among individuals on the study is not known, the use of pilot studies to generate preliminary and/or comparison data should be considered. Pilot studies are also useful for other reasons, as they can help to troubleshoot practical aspects of procedures and can also be used to evaluate refinement alternatives as discussed later.[12]

A final concept in application of reduction alternatives is to remember that the overall goal of alternatives is to reduce pain or distress, not just reduce the number of animals used. In this sense, subjecting the smallest number of animals possible to pain or distress is desirable. Early studies in the

development process typically use fewer animals than those later in the process, and they are not necessarily conducted according to strict regulatory standards that may limit the ability to alter experimental design or procedures in response to the condition of the animals. Therefore, if it is necessary to conduct an experiment resulting in significant pain, distress, or even death of the animal, it is better to perform those studies in the early stages of drug development, and communicate the need for these studies to employees and animal welfare compliance bodies at the institution who may react negatively to these events. By employing methods that ensure significant toxicity is clearly defined and readily measured, subsequent studies using greater numbers of animals can be designed with more humane endpoints, and the overall level of pain or distress involved with the development program will be minimized.

Refinement alternatives reduce the potential for pain or distress of animals that are on study. To justify that a refinement cannot be used, there needs to be scientific evidence that it will interfere with the goals of a study.[11–13] As time has passed since the initial development of animal welfare regulations and standards, expectations regarding compliance have also evolved. At one time, ethical review bodies accepted a justification for an exception if there was a theoretical risk that a refinement procedure would interfere with the goals of a study. However, as evidence has accumulated to show what types of procedures actually do interfere with research goals, and the conditions under which they can do so, the expectation has evolved that exceptions to these procedures be supported by data rather than theory. This is the purpose of the requirement for a literature review for alternatives and with the current availability of electronic databases and publications, the ease of performing this review is greater than it was only a few years ago. However, refinement data may not be available in the literature. Outside of publications specifically focused on alternative models, most publications emphasize the data derived from a model rather than animal welfare aspects of the model. This means that in order to scientifically evaluate whether a particular refinement will interfere with study goals, the scientist may need to generate the data themselves.[12,15]

Collection of data on experimental refinements is not traditionally considered a business goal for research institutions and scientists, therefore, appropriate allocation of time and resources are not always available for this purpose. However, from a legal standpoint, it is a scientist's responsibility to demonstrate that alternatives are not available and institutions have a responsibility to support all aspects of their research program.[11,12] Therefore, strategies must be developed to obtain these data with minimal impact on resources. Pilot studies are often useful for this purpose. Pilot studies are often run in the course of development of new models and methods, and in the early developmental stages for new drugs and devices. Additional data may be collected from these studies for assessment of animal welfare endpoints or to assess the impact of animal welfare procedures on research endpoints.[25] This type of approach may also be applied when training new personnel on standardized models. Ethical review bodies should be willing to approve the use of positive control articles along with these activities, while setting the animal welfare procedure as the independent variable to determine its impact on study data. Likewise, the effects of procedures intended to improve animal welfare can be assessed through assessment of measures of well-being, such as animal behaviors, activity, physiologic state, and endocrine homeostasis that have previously been shown to be associated with pain or distress.[12,26]

Institutional Responsibilities for an Animal Care Program

The myriad requirements for the humane use of animals in research often necessitate the development of an institutional infrastructure and employment of staff whose jobs are dedicated to meeting these requirements. The exact requirements for an animal care program not only vary by country but also by the particular regulatory or oversight body. There can be some flexibility in program requirements, allowing institutions to design a program to best meet their needs; however, most programs are very similar and have several similar characteristics to their structure and the roles and responsibilities of staff. The following sections define the basic structure of an animal care and use program, including management, compliance, veterinary care, research staff, husbandry, and facility management.

Management

Institutions are responsible for ensuring the availability of adequate resources to meet animal welfare requirements, and typically a specific individual at a relatively senior management level is assigned this responsibility. In the United States, this person is termed the institutional official (IO) for the animal care program. There are specific legal requirements for the IO. The IO must be the chief executive officer (CEO) of a company, or she or he may be another leader who can legally commit resources to the animal care program and represent the institution when making commitments to outside agencies or oversight organizations.[11–13] It is also the responsibility of the managers in all departments or business units at the institution for implementing aspects of the animal care program within their areas, not only at the direction of the IO but also in regard to basic animal ethics and welfare practices.

Compliance Oversight

In the United States, emphasis is placed on self-monitoring for compliance with regulatory and animal welfare standards. Therefore, the organizational level and structure of the compliance group, its resources and authority, and strong evidence it can and is doing its job will be a focus of regulatory or other oversight organizations' audits of an animal care program. In the United States, it is the Institutional Animal Care and Use Committee (IACUC) that is responsible for compliance processes such as the review and approval of individual research activities, establishing policies and procedures,

monitoring research activities for compliance, inspecting facilities, investigation concerns about animal welfare, creating corrective and preventative action plans where there are deficiencies, advising management and the IO on resources needed to manage the animal care program, and reporting on the status of the animal care program to regulatory and oversight organizations.[11–13] At some institutions and under some regulatory systems, there is separation between evaluation of animal use for ethical considerations and review of the scientific justification for the work being conducted.

IACUCs are designed to provide diverse inputs on research proposals, as balancing scientific and ethical needs is often a matter of judgment, and it is important to ensure as much bias of judgment as possible is eliminated. The majority of the membership of an IACUC should be scientific staff.[12] An ideal IACUC membership would include representatives from all scientific areas at the institution to provide appropriate scientific expertise when reviewing research proposals. U.S. regulations also require membership to include at least one veterinarian, one nonscientific member, and one person who is not affiliated with the institution to represent the perspective of the general public.[11–13] Controlling for overrepresentation by a single business area at the institution is also required and needed to prevent conflicts of interest when reviewing and approving proposals.[11]

Veterinary Care

Animal care programs are required to have one or more veterinarians with training or experience working with research animals.[11–13] If an institution is not large enough to require a full-time Attending Veterinarian, they may use a consultant on a part-time basis as long as there is regular interaction between the veterinarian and the facility staff. Professional board certification is provided by the American College of Laboratory Animal Medicine (ACLAM) and the European College of Laboratory Animal Medicine (ECLAM). In the United States, generally, it is legal for any veterinarian to serve as the Attending Veterinarian, even if they are not licensed in the state where they work. Research animals are owned by the institution and veterinary care provided to them does not constitute the *practice* of veterinary medicine as regulated by the state. However, unlicensed veterinarians will be limited in the activities they can perform, such as signing health certificates for interstate shipping of animals, and access to prescription drugs and controlled substances, unless they are able to operate under a researcher's license.

Institutions may also employ veterinary technicians or nurses to support the veterinarian. Veterinary technicians may also be certified or licensed by the state or they may be personnel with appropriate training and experience. Professional organizations like the American Association for Laboratory Animal Science (AALAS) provide training and certification for technicians to provide medical care. Veterinary technicians are also not constrained by state veterinary practice acts when they work in a research institution and are able to diagnose and treat animals, and perform surgery without direct oversight by a veterinarian. Thus, there can be operational efficiency by employing several veterinary technicians who are supervised by a veterinarian. It is important to note, however, that animal welfare regulations and standards require evidence of oversight by a veterinarian for all veterinary care provided, for example, through the use of veterinarian-approved standard operating procedures, or receiving veterinary approval for treatment plans.[12]

Research Staff

There are often several levels of research staff in an institution including senior, junior, and technical personnel. The senior scientific staff can be Principal Investigators or study directors, and are primarily responsible for the design of studies, oversight and decision making, interpretation of data, and writing a report or publication on the data. These staff members normally have training in independent research gained through an MS or PhD program, or they may have gained research experience by working in the field for a period of time. Junior-level scientists in training or who have an undergraduate degree may also be employed, but people in this role usually do not perform research independently. Junior scientists often work under the supervision of a senior scientist and perform some of the same roles. They may be more involved with the daily conduct of the study and also perform study procedures, particularly at a smaller laboratory. The final level of research staff is the technical personnel who perform the study procedures. Large institutions may have a dedicated professional technical staff to perform these activities, while smaller laboratories may have relatively few dedicated technicians working for each scientist, with much work conducted by the junior scientific staff or trainees.

Different levels of research staff may require different training and qualifications to perform their jobs and meet animal welfare requirements. Staff involved in study design, decision making, and data interpretation need to be trained on approval requirements for research using animals, on scientific justification for animal use and alternatives, on institutional policies regarding procedures that may or may not be used, or the guidelines under which they can be used, and on humane endpoints. Personnel performing actual study procedures need to know all of these topics as well, but only at a general level of understanding. It is most critical for staff who perform study procedures to be trained and competent to handle animals, perform technical procedures for test article administration, surgery, anesthesia, analgesia, biological sample collection, recognition of pain or distress, and procedures for humane euthanasia.[11–13] Organizations like AALAS provide training and certification for these procedures, but it is common that institutions develop their own training programs to meet the specific needs of the research they perform.

Animal Husbandry

Institutions must also provide daily care to animals in the way of monitoring, provision of feed and water, cleaning, and sanitation.[11–13] Larger institutions often have a centralized service to provide animal husbandry and may charge a

per diem or flat cost to cover these overhead costs. Smaller laboratories may delegate husbandry tasks to the technical research personnel. Training requirements for husbandry personnel are increasing compared with the needs in the past. Although husbandry personnel may not need advanced scientific training to perform their jobs, they must be aware of animal welfare requirements and have technical training for the procedures they perform. The specific nature of animal welfare standards necessitates having personnel who can attend to the details of animal care as well as ensure that they are not adversely impacting the research being conducted. Animal facilities are becoming increasingly more automated and computerized, but attention to animal care and knowledge of animal welfare is still a very important aspect of husbandry. AALAS has training programs for animal husbandry procedure and animal facility management.

Facility Management

Animal facilities have a number of specialized features that are discussed later in this chapter, such as advance heating, ventilation, and air conditioning (HVAC), and containment of hazardous agents. These features necessitate having a dedicated and skilled engineering and maintenance staff who can properly design facilities that meet animal welfare requirements and keep them operating.[12] It may not be practical for a small facility to maintain a full-time maintenance staff, in which case it is critical for outside service providers to be available and appropriately qualified or experienced in the needs of research animal facilities. As expertise in research animal facility management is not always easy to find, experts from related fields, such as the agriculture industry, may need to be consulted.

ANIMAL WELFARE REGULATIONS AND STANDARDS

Resources for animal welfare standards and regulations are summarized in Table 20.2. The emphasis of this chapter is on standards for the United States. The reader should consult regulations and standards for each country in which they work, but the general concepts discussed in this chapter are relevant internationally. Europe has consolidated standards through the European Union,[27] but each country still has its own authority for enforcement with specific procedures.

United States Department of Agriculture

The United States Department of Agriculture (USDA) has authority to regulate animals used in research through the Animal Welfare Act of 1966 and as amended in 1970, 1976,

1985, and 1990. The act is implemented through the Animal Care section of the Animal and Plant Health Inspection Service (APHIS) division of USDA. The USDA animal welfare regulations cover warm-blooded animals used in research but exclude rats of the genus *Rattus*, mice of the genus *Mus*, birds bred for research, and livestock used in research related to food or fiber production. If livestock are used for biomedical research, they are regulated by the USDA. These regulations also cover the breeding of these species for research, as well as some non-research-related activities, such as commercial breeding, transportation, brokering, and exhibition of animals. Institutions performing these activities must be registered or licensed with the USDA and are inspected at least annually by veterinary inspectors from Animal Care–APHIS–USDA for compliance with the regulations. Inspectors can issue citations leading to warning letters, fines, or even suspension of an institution's research registration.[11]

The USDA animal welfare regulations cover many of the same areas as other regulations that are discussed in the section on standards. However, there are some unique aspects to the regulations, such as composition of the IACUC, record keeping, cage space, cleaning and sanitation, and reporting requirements of research institutions. Many of the USDA regulations are very specific, establishing engineering standards for animal welfare requiring relatively rigid compliance. In addition to these regulations, there are a number of administrative *policies* created by the USDA and published on their website that represent interpretation of sections of the regulations that are not specific. Another useful document on the Animal Care website to help research institutions in understanding USDA regulatory requirements is the inspectors' manual that is used as a training guide by Animal Care personnel.

Public Health Service

The U.S. Public Health Service (PHS) has authority for animal research under the Health Research Extension Act of 1985 that created the PHS Policy on the Humane Care and Use of Laboratory Animals. This policy covers all vertebrate animals used in research funded by the PHS (e.g., National Institutes of Health or NIH), and institutions must have an Assurance of Compliance on file with the Office of Laboratory Animal Welfare (OLAW) within the NIH to be eligible for this funding.[13] The PHS Policy primarily details administrative requirements for compliance and refers to two other documents for standards of compliance. The first is the *U.S. Government Principles for the Use of Animals in Research*. This document lists nine basic concepts for research animal use. The second document is the *Guide for the Care and Use of Laboratory Animals*—a more detailed document of standards to be discussed later.[12] Both of these documents establish performance standards for animal use rather than the engineering standard approach reflected in the USDA regulations. Also unlike USDA, OLAW does not routinely inspect research facilities. Instead, there is significant reliance on self-reporting of gaps in compliance with the policy and associated standards. However, if there is continuing or severe noncompliance, OLAW may form a team to inspect an institution and, if the inspection results in findings, may withhold funding for research.

Good Laboratory Practices

The good laboratory practice (GLP) standards created by the Food and Drug Administration (FDA) and Environmental Protection Agency (EPA) primarily establish requirements for the planning, conduct, and reporting of research results used to support registration of drugs, vaccines, medical devices, and chemicals. However, the GLPs impact animal research in several ways. First, for many bioassays, the animal is the test system and all aspects of the care and use of the animals must be defined and documented to ensure data integrity.[21] In many cases, procedures that ensure data integrity are also procedures that support the welfare of the animals and typically this does not result in any conflicts between the different regulating bodies. However, specific compliance procedures and compliance philosophy between GLP inspectors, and animal welfare inspectors or auditors can be different. It may seem that GLP inspectors are more detail oriented and *stricter* than animal welfare auditors, but the primary difference is in the details that are relevant to each set of regulations and standards.

The second area of impact for the GLPs on animal welfare standards is with authority for making decisions. Animal welfare standards focus on the role of the IACUC and the veterinary staff as the primary authorities for decision making around study designs and treatment for animals on study, while the GLPs establish the study director as the single point of control for conduct of a study. Legally, there is not a conflict between these seemingly disparate requirements. The USDA, OLAW, and FDA have established a Memorandum of Understanding between the agencies that they will support the compliance missions of one another.[28] To make this arrangement work in practice, it is important to understand where the responsibilities of these three groups lie. The study director is the point of control for study conduct; however, the study design, procedures, and endpoint must first be approved by the IACUC, and any scientific justifications provided by the study director to deviate from animal welfare standards or regulations need to be evaluated to ensure that they are supported by data. The veterinarian has authority for decision making regarding veterinary care when study animals are experiencing pain or distress that has not been approved by the IACUC. It is the veterinarian's responsibility to interpret what constitutes pain or distress, to discuss with the study director whether there are treatment options that will not interfere with the goals of the study and if there are not, to recommend euthanasia. The study director is responsible for following the veterinarian's recommendations, or applying to the IACUC for a change in the scope of the study. The complexity of this arrangement makes good documentation very important, which is why the IACUC requires a written

description of the goals, procedures, potential for pain or distress, and detailed criteria for veterinary care or euthanasia in order to approve a study.

U.S. Government Research Institutions

Intramural research performed by the federal government using animals as well as research funded by these agencies is regulated in much the same way as with public and private institutions. Federal agencies such as the Department of Defense,[29] the Veterans Administration,[30] the NIH,[31] the National Aeronautics and Space Administration,[32] and the National Science Foundation[33] all have policies and procedures for the humane care and use of research animals but, in all cases, point to the *U.S. Government Principles*, the *Guide for the Care and Use of Laboratory Animals*, and the USDA animal welfare regulations for their standards.

State Regulations

Many U.S. states specifically exempt legitimate research from animal cruelty or humane laws and from Veterinary Practice Acts. However, not all do and facility managers and laboratory animal veterinarians should consult with local laws. Some state regulations are relevant even at research institutions. Requirements designed to control animal diseases requiring certain disease testing, vaccinations, and reporting are normally applicable, as are pharmacy and controlled substances regulations.

AAALAC International

The Association for the Accreditation and Assessment of Laboratory Animal Care, International (AAALAC Int.) is an accreditation organization for research institutions using animals that has evolved from its organization in 1965 as a U.S.-based organization promoting animal care standards to its current status as an international organization providing accreditation of animal care programs. AAALAC Int. is generally recognized as being the industry gold standard even though there is no regulatory requirement for an institution to be accredited. Accreditation, however, may be required by agency or institutional policies, may engender different requirements for periodic inspection or auditing by regulatory agencies or sponsor institutions, and may be perceived as a competitive advantage for commercial institutions or for researchers seeking grants. Institutions pay an annual fee for the cost of accreditation, including administrative fees and site visits. Sites are visited or audited every 3 years.

AAALAC Int. uses the *Guide* as its primary standards document, but also holds compliance with applicable law and regulations as a basic requirement for meeting accreditation standards. AAALAC Int. also maintains a list of policies on its website clarifying the agency's interpretation of certain aspects of the *Guide* and other standards. The AAALAC Int. accreditation requires a written description of the animal care and use program be submitted, followed by an on-site visit from a team of experienced site visitors who are industry peers. The site visit is followed by an exit interview where the visitors present a summary of their observations and the recommendations they will make to the AAALAC Int. Council on Accreditation. The council meets three times a year and the final outcome of the site visit is not determined until after this meeting. Institutions may achieve full accreditation with or without suggestions for improvement of the program. Institutions may also receive Conditional Accreditation, where there are certain mandatory deficiencies to be addressed to achieve full accreditation. It may be possible for AAALAC Int. to determine conditions have been met through a written plan from the institution, or it may be necessary for a follow-up visit to the institution. AAALAC Int. may also withhold accreditation if there are significant gaps between standards and conditions at the institution, or if the council doubts the plan of correction from the institution is likely to succeed in addressing deficiencies.

AAALAC Int. site visitors come from a diverse background, which allows for a strenuous peer review process for accreditation. However, this diversity can also be a challenge for institutions, since AAALAC Int. site visitors bring their collective experiences with them when they evaluate a program and compare what they are seeing with best practices throughout the industry. This creates a high bar for the institution's program and also creates somewhat of a moving target for meeting accreditation standards, due to inherent variability among different site visitors. Subsequent site visits can result in suggestions for improvement in areas previously found to be acceptable even without changes in regulations or standards. In the author's experience, institutions should be open in their communication with AAALAC Int. site visitors to clarify expectations and share ideas on how to achieve those expectations. Sometimes a site visitor's comments are based on a limited view of a situation or comments may be misinterpreted by the institution. These situations can be clarified with additional communication at the time of, or following the visit and the process of clarification can be extremely beneficial for establishing a quality animal care program. By contrast, if issues are not addressed but are commented on and require repeat visits, they are likely to move from a suggestion for improvement to a deficiency, a mandatory requirement for maintenance of accreditation. Addressing a comment by AAALAC Int. Council does not necessarily mean significant changes need to be made to the program. It means that the idea will be objectively evaluated for its applicability to the program. If changes are not made, there is an expectation that the performance standard prompting the original comment or suggestion be fully met by one method or another.

For additional information, refer to www.aaalac.org.

Guide for the Care and Use of Laboratory Animals

The Guide, as it is commonly termed, is a publication of the Institute of Laboratory Animal Research (ILAR) of the National Research Council that provides a comprehensive summary of standards for the care and use of vertebrate

animals used in research.[12] *The Guide*, now in its eighth edition, was originally published by the NIH in 1963 and was revised most recently in 2011. It is written by a committee representing the laboratory animal medicine and biomedical research communities and each revision has incorporated the most current ideas and research on methods for ensuring optimal animal welfare and minimization of variables affecting animal models. As previously indicated, *the Guide* is the standard reference for all regulatory agencies, except the USDA, and is also the standard guideline document for AAALAC Int. Even USDA refers to *the Guide* within their policies to establish standards for procedures not covered by their regulations. The most recent revision of *the Guide* incorporates standards and language to make it more applicable internationally,[12] which reflects the globalization of the field of biomedical research and commerce.

The Guide is written primarily as a set of principles that are supported by citations from the peer-reviewed literature. As such it establishes performance standards for animal welfare that allow institutions a certain amount of flexibility in establishing procedures to meet these standards. As would be expected, the regulated community has evolved a certain *standard of practice* with common policies and procedures, and there is a certain amount of peer pressure from regulatory and oversight organizations to follow these procedures. However, if researchers and institutions are able and willing to evaluate their procedures using the performance standards outlined in *the Guide*, IACUCs may approve modifications to standard procedures that are considered compliant.[12] This is very unlike the USDA animal welfare regulations that tend to create much more rigid standards. There are some standards in *the Guide* that are equally inflexible. The verbiage of the document uses the term *must* to indicate items that are considered mandatory for a good animal care program, whereas the terms *should* and *may* precede most of the standards.[12] It is important for institutions to pay attention to these terms as the nature of the term to a large extent dictates how the issues will be viewed during an inspection or site visit.

Agricultural Guide

The Guide for the Care and Use of Agricultural Animals in Agricultural Research is published by the Federation of Animal Science Societies and is used by most regulatory and oversight organizations to establish standards for common agricultural research involving food or fiber production animal.[34] The *Ag Guide*, as it is normally referred to, may also be referenced when using agricultural animals for biomedical research in agricultural settings. Like the ILAR *Guide*, the *Ag Guide* is also written to describe performance standards, and the information within it can be applied to an animal care program in much the same way as that in *the Guide*.

Animal Transportation

There are a variety of regulations to consider when transporting animals or animal tissues or blood domestically and internationally. *The Guide*, the *Ag Guide*, and the USDA animal welfare regulations all define transportation standards.[11–13] These standards include size and construction of shipping containers, environmental conditions, and care and monitoring of animals during transport. For an international shipment, the International Air Transport Association (IATA) Live Animal Regulations document establishes guidelines for commercial carriers.[35]

Regulation of transportation of nonhuman primates, as well as tissues or blood from these animals for international shipment, is performed by the U.S. Fish and Wildlife Service through the Convention on International Trade in Endangered Species (CITES), an international treaty to prevent illegal trade of endangered species. CITES requires any international shipments of endangered animals, blood, or tissues be accompanied by a CITES permit number.[36] Animal importers typically provide the permit number with animals when they are purchased. If a research institution ships these animals or samples from these animals internationally, a new permit must be obtained, but the original permit information is required to get the new permit. Therefore, institutions need to maintain records on this information and also need to plan ahead prior to shipping samples internationally, as CITES permits take several weeks or more to obtain.

The Centers for Disease Control (CDC) regulates quarantine requirements for the importation of nonhuman primates for the purpose of prevention of introduction of diseases, such as tuberculosis, monkey pox, and filoviruses (e.g., Ebola, Marburg). Quarantine facilities must be approved through the CDC and must meet their requirements for isolation housing, monitoring, and testing.[37]

AVMA Panel on Euthanasia

The American Veterinary Medical Association (AVMA) publishes a set of recommendations on humane methods of euthanasia widely cited by animal welfare regulations and the *Guide*. Methods for euthanasia must not cause pain or distress to animals and must provide a rapid and peaceful death. Methods are classified as *approved*, *conditional*, and *unacceptable*. Approved methods are recommended for routine use, while unacceptable methods should never be used. Conditional methods require scientific justification for use, as pain or distress to the animals may occur if performed improperly, or they may be unaesthetic, and their use is discouraged due to impact on personnel and other animals that may be exposed to the procedure.[38]

Professional Organizations

Many professional associations have established their own position statements or standards for the humane care and use of animals (Table 20.3). For example, the American Society of Mammalogists (ASM) has recommendations for field euthanasia of wildlife not found elsewhere in the literature. In addition, position statements by organizations such as the AVMA, AALAS, and ACLAM provide professional

expectations for laboratory animal veterinarians and research institutions to follow. While most professional association standards closely parallel standards within the *Guide* or the *U.S. Government Principles*, these additional standards can aid and impact the interpretation of *Guide* or government regulations and standards.

Occupational Health and Safety

Historically, worker protection agencies like the Occupational Safety and Health Administration (OSHA) did not specifically address occupational hazard of using animals for research. Therefore, animal welfare regulatory and oversight organizations also established standards for personnel safety. While OSHA currently addresses these issues, OLAW and AAALAC Int. monitor facilities to ensure that the programs are compliant.[12,13] Occupational hazards of research involving animals include risk of allergies, bites, scratches and other injuries, zoonotic diseases, or biological agents and chemical or radiation exposure from test materials administered to the animals.[1] The *Guide for Occupational Health and Safety in Animal Research Facilities* is a good resource for details on methods for assessing risk and preventing exposure to hazards.[39] Institutions may manage these programs through a separate health and safety group or the IACUC may assume these responsibilities. In addition to the previously mentioned resources, for research proposals using infectious agents, toxins, and recombinant DNA, approval is needed from a Biosafety Committee.

Diseases that personnel can contract from research animals are termed *zoonotic*. A list of selected zoonotic diseases is provided in Table 20.4. Animals should be tested for common zoonotic diseases and these should be excluded from the facility whenever possible. If it is not possible to exclude a zoonotic disease, protection should be provided through the use of protective clothing, shoe covers, and other personal protective equipment (PPE), such as gloves, safety glasses, goggles, face shields, masks, and respirators. However, some diseases may require additional procedures following exposure to an animal with the disease. For example, if a staff member is bitten, is scratched, receives a puncture from a needle contaminated with macaque body fluids, or receives a splash of body fluids onto a mucous membrane from a macaque nonhuman primate or from a biological sample collected from a macaque, the person and the animal need to be tested for Cercopithecine herpesvirus-I (herpes B virus).[39] If the animal is still alive when the exposure occurs, blood must be collected from the animal and the mucous membranes swabbed and examined for evidence of infection. The animal may be anesthetized for collections. However, if the animal has been euthanized and the exposure occurs from a biological sample (blood, urine, etc.) from the animal, an additional aliquot of blood may be needed for testing. Some institutions bank a serum sample from each animal for this purpose. Other exposure prevention programs can include vaccinations against tetanus and even rabies.[39]

Another safety issue is laboratory animal allergy. Allergies to animals typically result from exposure to urinary proteins, hair, and dander. However, allergies to other substances in the research environment such as latex, antibiotics, and even feed and bedding products may also be risks. The seriousness of allergies can range from minor to life threatening. Therefore, personnel with a history of allergies should disclose this to the occupational health provider so appropriate prevention measures can be taken, such as additional PPE, regular monitoring, or assignment to tasks with lower risk of exposure.[12,39]

Other common occupational health and safety programs include hazard identification, hazard labeling requirements,

TABLE 20.4
Selected Zoonotic Diseases in Laboratory Animals[39]

Species	Diseases/Organisms
Rodents and rabbits	Bubonic plague, cryptosporidiosis, dermatophytosis, dwarf tapeworm, giardiasis, Hanta virus, leptospirosis, lymphocytic choriomeningitis, rat bite fever, salmonellosis, sporotrichosis, yersiniosis
Dogs and cats	Brucellosis, campylobacteriosis, cat scratch fever, cryptosporidiosis, dermatophytosis, giardiasis, listeriosis, nematodiasis (larval migrans), rabies, salmonellosis, sporotrichosis, toxoplasmosis, yersiniosis
Nonhuman primates	Amebiasis, balantidiasis, campylobacteriosis, Cercopithecine herpesvirus-I (B virus), cryptosporidiosis, giardiasis, nematodiasis, rabies, salmonellosis, shigellosis, simian immunodeficiency virus, tuberculosis, viral hepatitis (A, B, C), yersiniosis
Swine	Balantidiasis, brucellosis, campylobacteriosis, cryptosporidiosis, influenza, leptospirosis, listeriosis, salmonellosis, yersiniosis
Sheep and goats	Brucellosis, campylobacteriosis, contagious ecthyma, cryptosporidiosis, dermatophytosis, leptospirosis, listeriosis, Q fever, sporotrichosis, yersiniosis
Cattle	Brucellosis, campylobacteriosis, cryptosporidiosis, dermatophytosis, leptospirosis, listeriosis, salmonellosis, sporotrichosis, yersiniosis
Amphibians and fish	Mycobacteriosis
Birds	Influenza, Newcastle disease, psittacosis, histoplasmosis, salmonellosis, yersiniosis
Reptiles	Salmonellosis, yersiniosis

material safety data sheet distribution and training, ergonomic programs, slip, trip and fall prevention, and management of eyewash stations and safety showers.[12,39]

Associated with personnel safety is environmental safety. Research facilities create a variety of environmental hazards to address when planning and conducting research. Myriad local, state, and federal regulations impact waste management and disposal through regulations for solid waste streams, chemical waste, sewage disposal, or incineration. In addition, facility construction and management are affected by building and fire code requirements. Animal facility managers need to become familiar with these requirements or engage experts in environmental management.

Emergency Management and Business Continuity

It is a requirement within the animal welfare standards to have a plan for responding to and recovering from emergencies.[12] These plans need to address the ways in which animal husbandry and research activities will be accomplished and veterinary care provided in the event of interruptions of power or water, staffing shortages, or interruptions in supply chain due to equipment failures, severe weather, natural disasters, fires, criminal activity, civil unrest, or epidemic disease. There is emphasis on monitoring and prevention, staff training, drills, tabletop exercises, emergency staffing plans, emergency power supply, reserve sources of feed and water, and plans for emergency care, evacuation, or euthanasia of animals to prevent suffering.[12,40]

COMPLIANCE PROCEDURES

IACUC and Ethical Review Boards

As previously discussed, the IACUC or other ethical review board must review and approve all animal use activities before they occur. There are some useful strategies for managing IACUC review and approval in a drug development environment. First, it is important to understand the difference in approach between animal welfare regulatory and oversight organizations and GLP compliance agencies. As described previously, animal welfare compliance requires the input of multiple parties (scientists, veterinarians, and the IACUC), and, therefore, can require more time than is needed for approval of a study protocol or study amendments. The second major difference is that animal welfare compliance focuses on the animals and not on the integrity of and ability to reconstruct study data as with GLP compliance.

It is critical for institutions to plan for the time required for animal welfare review of proposals, particularly in a toxicology facility where studies may need to be started quickly to meet drug development timelines, and where scientists are accustomed to being the single point of control for all other aspects of study planning and conduct. The general process for review is relatively standardized between oversight bodies within the United States. International regulations may vary in their details, but there are a number of common themes.[41] If the proposed study has the potential to result in pain or distress for the animal, a veterinarian must be consulted on methods to prevent or relieve pain or distress. Concurrent with this review, or subsequent to it, the full IACUC must be given the opportunity to review the proposal at a convened meeting of the committee, where it can be approved by a majority of the quorum of the committee, or alternatively the proposal can be distributed to committee members, and after a period of time established by the committee (if no member has requested review by the entire committee), review and approval can be delegated to an individual committee member.[11–13,40] Standard review times vary by the institution, but a minimum of a week should be expected, and in some institutions, reviews can take months. IACUCs do have the ability to expedite reviews, but because review still requires the entire committee to be involved, expediting protocol reviews is extremely disruptive and its use should be limited to extremely urgent situations.

The focus on animal welfare versus study data manifests itself in a slightly different way. Animal welfare review requires justification for the use of the animal model, the value of the research to society, animal numbers, potential for pain or distress, and the plan for preventing or relieving pain or distress.[11–13,40] As this is an ethical review and not a scientific review, not all reviewers of these proposals have a scientific background. Scientists need to limit their use of jargon and abbreviations, or define them in the text. They cannot assume that the reader understands the inherent benefits of the specific molecule being tested, the limitations of alternative systems, or how a particular study is conducted. It is not usually necessary to provide a high level of detail in the justifications, just to walk the reviewers through these issues in a clear and logical way, addressing the specific questions in the protocol, and referring to literature where appropriate.

The other way in which the focus on the animal is different from the focus on the study is in the level of detail required for review of study procedures. Because IACUC review is looking for impact on the animals, some of the procedural details important for a study protocol are not as important for the IACUC. In fact, many institutions allow a proposal to reference approved policies or guidelines giving ranges for parameters such as dose or blood volumes, fasting times, approved anesthetic or analgesic drugs, and even entire standard operating procedures. The IACUC still needs to understand all proposed procedures to be performed on animals and the timeline for when they will be performed, but if the details of the procedure are within the scope of standards the IACUC has reviewed and approved as being appropriate and incorporating all relevant refinements, additional detail may not be required. This allows institutions to start the more lengthy IACUC review process before all of the study details have been finalized and the protocol signed. As long as any final changes to the study do not diverge from the ranges in the IACUC proposal, additional IACUC review should not be needed. Some institutions have taken this approach to another level by maintaining *blanket* IACUC approvals for standardized study designs and procedures and running multiple individual studies under a single IACUC approval. This can work

well if studies are highly standardized, but there is risk of noncompliance if the IACUC approval is too generic to adequately address the goals of the study, the potential for pain or distress, the justifications for alternatives, and the plan to prevent or relieve pain or distress in the animals.

IACUC review can result in one of three outcomes: (1) approval of the study and procedures, (2) modifications to the proposal may be requested in order to obtain approval, and (3) the IACUC may reject a proposal.[11–13,40] In a well-functioning animal care program, rejection of a proposal is rare. However, in the case the proposal is rejected, the IACUC can work with the scientist to make appropriate modifications to the proposal so that it can be approved. In many cases, changes to the proposed procedures are not needed, but further clarification on justifications, the availability of alternatives, or a plan for veterinary care or euthanasia may be required to secure approval. Likewise, it is uncommon for proposals to be approved without any questions or requests for clarifications for the IACUC to make an appropriate decision. Because ethical review involves application of judgment and opinion and because society's views on animal use continually evolve, it is to be expected questions will arise on particular issues, even if they were not previously questioned.

Personnel Training and Qualifications

As with GLP regulations, animal welfare regulations and standards require documentation of training and qualifications for personnel performing study procedures on animals. In addition, training is required on the content and scope of animal welfare regulations and standards, on IACUC review procedures, on appropriate searches for and use of alternatives, and on veterinary care and humane euthanasia methods.[11–13,40] Facilities in compliance with GLP requirements typically do not have problems meeting animal welfare compliance requirements. The IACUC must simply assure itself that the appropriate training program and documentation are in place and overall responsibility can be delegated to other organizational units already managing these functions. In individual proposals for animal use, the scientist submitting the proposal may reference the institutional training program without providing further detail.

In institutions that do not have the GLP infrastructure, if there is not a comparable program for managing training, the IACUC may have to establish its own procedures. Typically, this will involve establishing training and certification requirements for specific procedures that will be performed, establishing a process for certifying trainers or trainees, or establishing an internal training program to provide appropriate didactic and hands-on training. Training records must be maintained, and the IACUC needs to have a way to link the procedures to be performed by individual staff with documentation of their training when they review an animal use proposal. Training programs can take many forms and further information on establishing a training program is available from other sources.[42,43] Training on animal care and use procedures is also available through professional associations and commercial providers.

Training and qualifications also need to be assessed and maintained for personnel from outside of an institution who provide contract or consulting services, or participate in collaborative research. Institutions may choose to enroll these consulting staff in the institution's training program or accept proof of prior training or qualifications, such as a curriculum vitae.[12]

Inspection, Program Review, and Postapproval Monitoring

IACUCs are required to perform a review of the animal care program and facility inspections at least twice a year.[11–13,40] The program review is a formal process that goes through all of the regulatory requirements and checks for institutional compliance and changes in the program. Inspections need to be performed in all areas of the facility where live animals are taken, as well as direct support areas, such as cage wash and equipment storage areas. Any gaps between regulatory requirements or standards and actual procedures or conditions within the facility need to be identified, and a plan for correction established. Any deficiencies need to be classified as minor or significant, based on whether they represent a direct risk to animal health or welfare, are serious, or are repeat findings. The IACUC submits a report of the results of the semiannual program review and inspections to the IO, along with any recommendations for program improvements or needed resources to ensure compliance.

In addition to semiannual review and inspections, IACUCs are expected to perform postapproval monitoring of studies to ensure compliance with approved procedures.[11–13,40] This monitoring can include review of protocols, data, and visits to the areas of animal use to observe procedures. Noncompliant items are also identified and classified according to impact. If there are serious, ongoing deficiencies identified through inspections, postapproval monitoring, or program review that have not been corrected, IACUCs have the authority to suspend specific research activities or the animal use privileges for a particular scientist.

Animal Welfare Concerns

IACUCs are also required to investigate any reports of concern about animal welfare or noncompliance reported by institutional staff, including those reported anonymously. Staff are protected under federal law from any reprisals by the institution resulting from reporting concerns.[11–13,40]

Reporting

Institutions are required to submit annual reports to regulatory agencies and accreditation organizations in order to provide information on animal usage and any significant changes to the program. There are additional reporting requirements specified by each agency or organization. These typically include requirements for reporting changes in key personnel such as the IO, the Attending Veterinarian,

or the IACUC chair; the addition of new facilities; significant events resulting in animal loss, pain, or distress; or suspension of approved activities by the IACUC. Reporting typically must be performed within a specific amount of time following the identification of an incident. Reports to regulatory agencies can become available to the public through Freedom of Information Act (FOIA) requests.

Documentation

Certain records must be maintained to meet animal welfare compliance requirements. Records typically must be retained for at least 3 years after the final disposition of the animals. Required animal care program records include all IACUC records such as protocols, review and approval documentation, meeting minutes, investigations, inspections, and program reviews and reports. In addition, records of animal receipt, veterinary care, animal disposition, facility monitoring and maintenance, animal husbandry, and room and cage sanitation are also required.[11–13,40] While electronic records are acceptable, records need to be readily available during an inspection, which means an effective business continuity plan for an electronic records system is required.

FACILITIES

Design and Construction

Animal facilities or vivariums need to be designed and built with considerations for access, workflow, and maintenance. Facility access needs to be managed for purposes of security, prevention of animal escape, and to minimize the risk of exposure of personnel to animal diseases, allergens, or hazardous agents used in experiments.[1,11,12,44] Historically, separation between animal areas and office space was not prioritized and many older facilities do not lend themselves to this requirement. Ideally, the vivarium would be completely separated from office or public areas and from other operational areas requiring access by multiple departments, such as laboratories, shipping and receiving, storage, and building maintenance. In addition, laboratories processing animal blood or tissues or preparing test articles for administration to animals should be immediately adjacent to the vivarium to limit the transport of these items through public areas.[1]

For enhanced security, a vivarium should be locked or secured using electronic control mechanisms so only people working in the area and have been properly trained in safety procedures and standards for humane care and use of animals are authorized for entry. The entry should have a place for changing clothing, such as a locker room, or space for donning required PPEs such as laboratory coats, shoe covers, or gloves. There should be appropriate areas for research activities such as procedure rooms, monitoring rooms, surgical areas, necropsy, or imaging within the perimeter of the vivarium so the animals are not transported through public areas to other laboratories.[1,12] It is highly recommended to have dedicated procedural space rather than trying to perform research procedures in animal rooms. Other than basic examinations, dosing, and sample collection, it is not appropriate to perform procedures within an animal room that may cause stress to the animals or to animals observing the procedures. In addition, research equipment maintained in the animal room makes it difficult to maintain the room in a sanitary manner and can contribute to the presence of endemic diseases in animal facilities.[11,12] It can also result in competition for space between different research groups and with husbandry personnel, potentially adversely affecting quality and efficiency.

There may need to be secondary containment within a vivarium to contain hazards associated with particular studies or species of animals.[1,39,44] Nonhuman primates are typically separated from other species of animals because of the extra safety procedures required to work with them. Having a dedicated area with a separate entrance and area for changing clothing or PPE is highly advised. This is required for working with biohazardous agents, and similar separation is also typically required for working with radioisotopes and chemical hazards. It may be necessary to separate studies or animals because of the impact of noise, or because of different environmental or housing conditions required. Surgical facilities also require separation of activities generating possible microbial contamination (animal preparation and recovery) from aseptic areas, including surgery personnel and instrument preparation areas and the operating room itself.[11,12]

Consideration should be given to the amount of flexibility required within a vivarium. It is typically less expensive to design and construct space if the intended use of that space is known and will not change. However, as research programs change and the animals and study types used also change with them, the additional cost of building flexibility into the design of the facility may be less expensive and long term rather than having to completely retrofit an area to accommodate different requirements. Some of these requirements are discussed in the sections on Environmental Conditions, Caging, and Husbandry for different models.

Requirements for regular cleaning and sanitation of animal facilities result in a need for design and construction considerations to support these activities. Particularly when working with larger animals, facilities need to be constructed out of durable materials that can withstand physical damage from heavy equipment and frequent washing with water and disinfectants, and require drains or a method for regular removal of waste. Small animal housing areas may not require as much water washing but still need to be constructed of sanitizable materials and be resistant to physical damage. Other strategies for preventing damage to facilities include having corridors and doorways that are wide enough to allow easy movement of equipment, metal or plastic guards on walls and doors to protect areas commonly struck by caging, and automatic door openers to facilitate movement through corridors.[1,11,12]

Traditional vivarium construction is with concrete block and surfaces are sealed with durable material such as epoxy paint, ceramic, or even metal.[12,45–47] Because of the extremely

high costs of this type of construction and difficulty of modification when facility needs change, new ideas are evolving that utilize nonporous materials like polymers that can be easily set up and modified or repaired with the idea that long-term durability is not as important as flexibility. This concept has been extended to facility infrastructure and supplies of water, power, and supply, and exhaust air may be provided through flexible, semidisposable plastics rather than traditional metal piping and conduits.

Another design issue for a vivarium is the way in which sanitation and waste removal will be performed. Animal cages can be sanitized within an animal room, but this must be done without causing stress or harm to the animals from noise, temperature extremes, or chemical exposure. It is common for daily cleaning and general floor and wall sanitation to be performed with animals in the room, but for the more thorough cleaning of caging and room surfaces, animals are either removed from the room, or clean caging is brought in, animals transferred from soiled caging, and the soiled caging brought to a central area for washing. There are alternative methods for this process that do not necessarily require a centralized washing area but that are scalable for large operations. These can include automated waste removal systems and disposable caging.[12]

Cage washing can be performed by hand using water and disinfectants, but this is very laborious for a large facility. Automated cage washers that use chemicals and hot, pressurized water are an industry standard. Areas for cage washing must be large enough to manage the workload, have high ventilation rates to remove heat and humidity, have supplies of steam or hot water and large drains, and be resistant to the water and chemicals used in the area.[12,46] They are typically divided into a dirty side and clean side. On the dirty side, animal waste may be removed and cages pretreated with chemicals to remove scale. Local area ventilation may be needed to minimize worker's exposure to chemicals, animal allergens, and microorganisms and separate spaces needed to stage soiled cages and to perform preparation activities. On the clean side, there may need to be sufficient space to reassemble caging components, test for complete sanitation, and maintain facility records. Following sanitation, cages may need to be stored before being put into use. Adequate storage space is very important as part of facility design.[12] In the author's experience, this is an area where institutions often cut corners in an attempt to reduce construction costs, but the ongoing labor costs associated with inadequate storage space and the regular need to move equipment around will outweigh the initial savings.

Animal facilities also need to be designed and constructed with redundancy in mind. In the event of equipment failure, there may need to be backup systems for power, ventilation, water supply, and capacity to clean and sanitize if a cage washer unit is inoperable.[12,40]

Because of all of these requirements, the vivarium is often one of the more expensive areas in a research facility. Careful planning is critical. It is important to resist the urge to cut costs by designing inadequate support areas for research procedures, sanitation, and storage as this can cost more money in the long run. Operational efficiency is often overlooked in the design of research facilities but should be considered as labor costs are typically a large expense in any institution's budget and they are ongoing costs, whereas construction costs are eventually depreciated.

Environmental Control and Monitoring

An animal's environment can have significant effects on its physiologic state and thus can represent an important experimental variable. It is important for scientists to understand potential impacts of environmental variables on their study so they can appropriately control and monitor them. In general, the animal species used for toxicology are more tolerant of a range of environmental conditions than are many animals in their natural habitat. They have been selected as models because of their similarity to humans, who are themselves a very tolerant species, and have been further adapted to laboratory conditions through selective breeding.

Lighting

Light can be an extremely important variable for many animal species living in natural environments. It allows them to change their behaviors and physiologic state to adapt to seasonal changes in the weather.[12] In laboratory species, the impact of light is often low because of the species used and the ways in which lighting is typically managed. However, its effects can be profound and it is important to understand when this is the case so it is not overlooked as a variable.[1]

Most research institutions eliminate windows from indoor animal facilities to allow for complete control of light. This also is desirable from the standpoint of security. It is common to set facility lighting to match the convenience of research staff. This means a diurnal cycle with 12–14 h of light and 10–12 h of dark. This cycle mimics a normal spring or summer season for animals that display seasonal variations based on light cycles. This is normally the season in which animals are reproductively and metabolically active. This is the physiologic state that is often desired for a model of the human condition because we are continuously reproductively and metabolically active. Where light cycle can become important is when trying to stimulate a specific physiologic condition that may not occur within this paradigm. For example, breeding performance of some animals is significantly enhanced by extending the light phase of the cycle. Likewise, anestrous conditions can be stimulated with shorter light cycles when it is desirable to minimize hormonal stimuli. Light cycle affects many behaviors and should be considered for neurobiological studies.

Diurnal effects also must be considered. Rodents, which represent the majority of animals used in toxicological testing, are nocturnal species. The daytime light cycle established for the convenience of human staff catches them in the time they are normally inactive behaviorally and metabolically. When monitoring many behaviors, including reproduction, activity,

and food and water consumption, it is important to include dark phase monitoring.[48] This may need to be done without having personnel present as turning on lights during the dark phase will interrupt these behaviors, can affect data interpretation, and can reset the animals' circadian rhythms.[49] It is important for staff to record when they have entered a room, particularly during the dark cycle, so that any data anomalies can be cross-referenced with the presence of personnel and a temporary interruption in the dark cycle. The way in which lighting is turned on and off can have significant, but relatively short-lived effects on some species. Increases in heart rate have been shown to occur when lights are abruptly turned on in nonhuman primate rooms compared to a gradual increase in lighting, simulating a *sunrise*.[50] The presence of light at night can introduce study variability such as decreasing blood pressure,[50] cytokine-induced acceleration of tumor growth,[51] reperfusion arrhythmias,[52] and alterations in adrenal activty.[53]

The characteristics of the light provided can also impact animals. The *Guide* specifies a range of light intensities to allow sufficient light for staff to adequately observe the animals and perform their functions, while minimizing the impact of excessive light. In general, high light intensity has been shown to affect animals more than low light intensity.[12,54–58] Albino strains of animals typically used in research are susceptible to retinal degeneration from excessive light levels.[1] They should not be housed directly under room lights without some type of shelter in or over the cage.[12] There are scant data to show that laboratory animals are adversely affected by low light, although reproduction can be affected in rodents.[1,59] Variability in light levels within a room has not been shown to be an important variable in nonhuman primates.[60] However, because of the extreme variation in light levels that can occur in rodent rooms, it is not uncommon to rotate the position of animals on a rack and even the location of the rack in the room during the course of a toxicology study.[1]

Light spectrum is another area that does not seem to be as important to animals as is sometimes hypothesized. Typically, incandescent or standard fluorescent lights may be used interchangeably for most research applications. Simulated sunlight, sometimes termed *full-spectrum light*, has effects on some nonhuman primates, including changes in affiliative, aggressive, and reproductive behaviors and cortisol.[61]

Ventilation

Facility ventilation rates are specified by animal welfare regulations and the *Guide* and are designed to remove waste gases (CO_2 and ammonia) and control humidity and temperature in the animal's microenvironment.[11,12] Excessive ammonia can cause direct irritation and damage to the respiratory epithelium and increases the risk of respiratory infection.[1] The recommended rate of ventilation is very high compared to normal office or laboratory ventilation rates, with 10–15 room air changes per hour being standard for animal housing areas. In addition, primarily fresh air should be used rather than recirculated air, thus requiring preheating or cooling and adjustment of humidity from outside air, adding considerably to the cost of operating a vivarium. There has been some success with alternative ventilation methods to reduce overall facility airflow needs. Air can be recirculated within a room at up to 50% of the supply if it is appropriately filtered or conditioned to remove waste products and prevent the spread of microorganisms.[12] Modifications to the configuration of supply and exhaust, and caging configurations can increase the efficiency of the airflow at removing waste products and decrease overall airflow needs. Rather than relying on a set rate of airflow, sensors can be installed to monitor for critical parameters of air quality and adjust the airflow to meet animals' needs. Individually ventilated cages, ventilated racks, and isolators are also used to focus ventilation to the areas of greatest need while reducing the overall volume of air being managed.[1,12] Typically, environmental conditions are monitored at the room level and not the cage level. Some cage designs limit airflow into the cage, allowing the room conditions to be adequate but not the cage conditions. It is also possible to provide too much ventilation at the cage level, resulting in noise and thermal stress on the animal, which can adversely affect reproduction and animal health.[12]

Air balance is another aspect of ventilation. Room air can be adjusted so the pressure within the room is higher (positive) than in the adjacent corridor to keep airborne particles, odors, or microorganisms from passively flowing into the room. Positive pressure is typically used for the maintenance of immunodeficient or pathogen-free animals and surgical suites. Negative airflow is the opposite (the pressure in the room is lower than in the adjacent corridor). It is utilized to contain airborne particles and organisms within a room and is useful for general animal housing and biocontainment.[12] Corridors can also be adjusted to provide the same type of biocontainment or bioexclusion resulting in somewhat complicated ventilation systems within a vivarium. To maintain the pressure balance, room and corridor doors need to be kept closed when not in use. Air supply and exhaust may also be filtered to contain or exclude particles and microorganisms.[39]

Ventilation should be monitored regularly.[12] Automated monitoring systems can do this continuously. Otherwise, it is common for a daily assessment to be made by personnel in each room to verify that air balance is correct (through installed manometers or the simple measurement of directional airflow when the door is opened) and the room ventilation is normal (through a general feeling of *stuffiness*, presence of odors, or noise associated with ventilation systems). Airflow and balance should be monitored formally using qualified equipment. Annual ventilation monitoring is common in research facilities.

Temperature

Temperature is directly impacted by humidity and ventilation, necessitating coordination of monitoring and control of all of these conditions. Temperature ranges to prevent hypothermia, hyperthermia, or thermal stress (excessive energy expenditure associated with thermoregulation) are listed in the *Guide* and the animal welfare regulations.[11,12] Like air

balance, if room temperatures are not monitored continuously through automated building systems, they should be monitored at least daily using a thermometer.

For indoor housing, acceptable temperature ranges from the low 60s (°F) to the low 80s (°F).[11,12] In general, smaller animals require and can tolerate higher temperatures and larger animals lower temperatures. In particular, neonates and mice have been shown to require temperatures near the higher end of recommended temperature ranges.[12] Some species such as rabbits and sheep tend to do better at the lower end of the temperature ranges independent of their relative body size. By contrast, swine and nonhuman primates tend to prefer warmer temperatures compared to animals of similar size. This is likely due to inherent physiologic needs stemming from their evolution prior to being raised in captivity.

When managing the diverse temperature requirements for animals in an animal facility, it is important to remember personnel also can experience thermal stress. This is particularly problematic with higher temperature requirements, as personnel may be required to wear PPE that is fluid resistant, inhibiting ventilation. Therefore, an appropriate balance must be made between personnel and animal requirements.

Providing animals with a level of control for other than environmental temperature can be a useful strategy for managing temperature needs in a facility with diverse requirements, and also provides enrichment for the animals. This is most often done by providing nesting or shelter material to animals requiring higher temperatures.[12] For outdoor facilities, the use of fans or water mists is useful for giving animals the ability to cool themselves when ambient temperatures are high.[34]

Animals that are ill or experiencing anesthetic or test article effects that affect thermoregulation may require supplemental heat provided through heat lamps, water blankets or bottles, or heated air units. It is critical to monitor animals directly when these devices are used to prevent burns or hyperthermia. In addition, if animals get wet during cage cleaning or if there are leakages from the water supply, they should be dried or transferred to dry housing with bedding to prevent hypothermia.

High temperatures can also be a problem in research facilities. The heat load produced by animals housed in confinement can cause room temperatures to rise rapidly if there is failure of the ventilation system. This can result in large-scale mortality in animal facilities and is one of the reasons that environmental monitoring, automated alarms, and redundant or backup systems are so critical. Less commonly, hyperthermia can also be seen in animals that are anesthetized if excessive thermal support is provided. Swine can carry a gene making them susceptible to malignant hyperthermia and this can be a problem in susceptible breeds of animals during anesthesia, and if animals are stressed from study or husbandry procedures.

Humidity

Humidity should be maintained in a range of 30%–70% in animal rooms and below 50% in feed storage rooms.[12] Excessive humidity can lead to mold and it exacerbates the effects of high temperatures and ammonia and can affect topical drug absorption.[1] Humidity extremes can also be a risk factor for respiratory diseases[1,62] and *ringtail* in rodents, a type of ischemic necrosis that occurs on the tail.[1,12] Humidity can also be monitored by automatic monitoring systems. Continuous monitoring is less critical for humidity than for temperature and ventilation function, because humidity extremes do not affect animals as quickly as these other factors, but it should be recorded at least daily. Humidity can be monitored at the room level using inexpensive hygrometers. For more precise measurement, such as calibration checks of automated systems, a manual sling hygrometer is commonly used on a periodic basis.

Noise and Vibration

Interpreting the impact of noise in animal facilities is complex. Concerns are hypothesized with loud noises, with certain sound frequencies, particularly those in the ultrasonic range, and with the effects of noise from loud or agonistic species.[1,12] It can be difficult to control noises in animal facilities. Loud noises can be generated by equipment, use of water for cleaning, animals becoming excited when people enter the room or feed them, alarm testing, and ventilation systems. The impact of these noises may be overstated by some, as animals can acclimate to noise.[63] Noise exposure above 85 dB is consistently shown to have adverse effects, such as changes in behaviors, blood pressure, heart rate, gastrointestinal microvascular inflammation, and even seizures.[1,12,64–66] Providing exercise may improve the animals' ability to cope with noise stress.[67] It is important to protect studies involving behavior, measurement of stress hormones, and cardiovascular physiology from excessive noise, or at least to manage facility activities around the study schedule. Otherwise, the primary need is to control noises above the OSHA limit of 90 dB associated with hearing loss in humans.[12,39]

The impact of ultrasonic noise is poorly understood. Rodents can hear into the ultrasonic range and specific frequencies have been associated with stress vocalizations,[12] so it has been hypothesized that something emitting this type of noise will elicit a stress response in rodents.[1] There are currently no solid data to support this hypothesis, but an investigation of the presence of ultrasonic noise may be indicated if there are unexpected findings on studies for which no other explanation can be found.

The only requirement for noise monitoring in animal facilities is for the protection of personnel. Noise should be monitored in high noise areas such as dog and swine animal rooms, and cage wash to determine if hearing protection is required for personnel.[39] However, as more is learned about the impact of noise on animals, particularly ultrasonic noise, requirements for additional monitoring may evolve.

Vibrations in the animal facility have also been shown to be important under some circumstances, but as with noise the critical variables have not been established.[1,12] It is recommended that vibration sources be minimized through

appropriate maintenance of equipment and minimizing animals' exposure to construction and maintenance activities.

Vermin

Unwanted animals and insects need to be excluded from animal facilities to prevent transmission of disease, and damage to food supplies and facility structure.[11,12] Exclusion should be based primarily on physical methods. Doors, walls, ceilings, and floors should not have openings to allow vermin to enter. Drains should have traps installed. Facilities need to be kept clean to eliminate a source of food and a place for vermin to hide. Feed needs to be stored off of the floor and away from walls, and once feed bags are opened, it should be kept in sealed containers. Even with these precautions, vermin may still enter the facility. Vermin monitoring programs should be in place to detect these incursions so appropriate action may be taken. Monitoring traps should be checked regularly, particularly those designed to catch mammals so these animals may be humanely euthanized. When vermin are discovered, in addition to developing a plan to eliminate them, it is important to make an assessment of the risk vermin present to the vivarium. One approach is to test vermin for the presence of diseases to determine the risk of these infecting animal colonies. This information must be interpreted in light of the location the vermin were discovered and the mode of transmission of the particular disease. This approach is most useful with mammalian vermin. With insects, an accurate identification of the species of insect provides more information on the risk of them serving as a disease vector. In the author's experience, insects identified in animal facilities are typically agricultural pests or scavengers. Their presence may reflect a problem with facility exclusion or cleanliness but not a direct risk for disease transmission.

Microbial Control and Sanitation

Control of microorganisms is another important aspect of environmental control.[11,12] It is important to understand the scientific basis for microbial control as it is often misinterpreted with the emphasis placed on creating a sterile environment for the animals. Maintaining a sterile environment is not the goal for microbial control in a toxicology facility, as germ-free or gnotobiotic animals are not normally used. The goal is to maintain an environment that is not conducive to maintenance of pathogens. The primary method of excluding these pathogens is to prevent them from entering, through good control over animal sources and basic PPE requirements. Periodic cleaning and sanitation essentially *break the cycle* of infection in the event an organism does get by this first level of defense. It is not even necessary to completely eliminate all exposure to these organisms, only to keep the number of organisms below the threshold for infection in animals. A sterile environment is typically not provided for an entire toxicology facility because it is not practical with large animals, and even for small animals, it is quite expensive to provide sterile water, food, caging, and air and maintain sterility when performing study procedures. A sterile environment also does not represent a normal physiologic state for animals that are modeling the future application of the test articles in patient populations. On the other hand, there are circumstances under which gnotobiotic and axenic or *germ-free* animals may be used, requiring the maintenance of a higher level of microbial control. Gnotobiotic animals (those having specific microorganisms associated with them or *defined flora* animals) represent a slightly more normal model but still do not represent the real world, and true *germ-free* or axenic animals with no microflora have differences in their immunologic function, gastrointestinal physiology, and behavior compared to normal animals.[68–70] Typically, these types of animals are only used for specialized models in the areas of immunology or infectious disease research; however, there are circumstances under which they may be used in toxicology, and in those cases, it is important to maintain a higher level of microbial control.

The typical level of microbiological control in a toxicology facility is a specific pathogen-free (SPF) health status. This term is often misunderstood to mean animals are free of all pathogens or even free of all microbes. In fact, the term simply means the animals have been tested and shown to be free of a certain organism or set of organisms that the user defines. In Europe, there are standardized recommendations for organisms that should be excluded,[71] and in the United States, commercial vendors tend to exclude a similar battery of organisms. However, it is important to understand that these animals still have commensal microflora and typically also some opportunistic pathogens, that is, organisms that may act as commensals under most circumstances but can become pathogenic under certain conditions that are often poorly understood. Maintenance of SPF animals can be somewhat less stringent than gnotobiotic or axenic animals. By specifying the organisms that will be excluded and understanding the biology of those organisms, a facility can design bioexclusion procedures that specifically exclude the organisms of concern and are more practical or cost-effective than full containment procedures. The relative level of the exclusion of different organisms and effort required to exclude them can vary greatly. To exclude rodent-specific organisms, a facility can maintain a basic level of biosecurity by controlling the source of animals to those that have been screened for the excluded diseases and implement basic PPE, pest control, and sanitation procedures to prevent these diseases from being brought in from the outside. Sterilized food, bedding, water, and caging are typically not required as long as these items are also produced or managed in a way to prevent rodent contamination and receive some basic treatment. In order to control pathogens that can be carried by humans or opportunistic microflora, housing and management conditions may need to be implemented that are equivalent to those needed to maintain gnotobiotic or axenic animals. Scientists and facility managers should look carefully at the organisms they are excluding to ensure that the effort being put into it is equivalent to the value gained. Many of the organisms not specific to rodents only cause disease under conditions of significant immune suppression.[72] To evaluate test articles intended to cause immune suppression, a high

level of microbial control may be warranted, as opportunistic infections are to be expected. However, it may be valid to control infections through the use of antimicrobials rather than environmental control, as this is the same condition under which drugs will be used clinically. For test articles where immune suppression is an unintended effect secondary to toxicity, the appearance of opportunistic infections may be interpreted to represent the maximum tolerated dose (MTD) for the test article and identifying that may in fact be a key goal for the study.

As discussed in the section on facility design and construction, the use of easily sanitized materials greatly facilitates microbial control of the environment. Regular sanitation must be performed. Daily to weekly sanitation of floors and work surfaces is standard in the industry. Animal caging with bedding should normally be sanitized weekly, while caging without bedding must be sanitized at least every 2 weeks.[11,12] Walls and ceilings should be cleaned and sanitized as needed. For *wet* rooms such as those used for larger animals, sanitation of all room surfaces is typically performed every 2 weeks along with cage and equipment sanitation. For *dry* rooms such as those used for rodents and rabbits, full room sanitation may be performed less frequently. Monthly to quarterly frequencies are commonly used in the industry. This may only involve a simple wipe-down of the surfaces with a disinfectant. Full room sanitation using more effective methods may only be performed between room uses, or at annual intervals.

Drinking water systems also require sanitation as microorganisms can grow in the water and form a biofilm on the surfaces of the watering systems.[12] These organisms are not typically pathogenic,[73] but biofilm can provide an environment for pathogens to live in, and the presence of biofilm is representative of the level of sanitation for drinking water lines. There are a variety of methods for maintaining microbial quality of watering systems. If completely sterile water must be provided, this may be done using presterilized water or hydration gel in sterile pouches or bottles or chlorinated or acidified water to control microbial growth.[12,74,75] There are also ultraviolet (UV) treatment systems to eliminate microbes within a recirculating water system; however, it is important to properly maintain the UV lights for these systems as they do lose efficacy over time.[76]

For immunocompetent animals, sterile water is not necessary. Normally, the goal is to minimize microbial levels in water and periodically remove any potential pathogens. A periodic cleaning or sanitation process is appropriate for this purpose. If water bottles are used, they are replaced and sanitized on a weekly basis.[12] For automatic water systems, a common method for cleaning is to flush a large volume of water through the water delivery lines in a room and cage rack.[12] This may be done between one and three times a week, as needed to maintain water quality at a desired standard. When cage racks are sanitized at 2-week intervals, waterlines should also be sanitized at this time. A concentrated disinfectant like chlorine may be run through the lines but it is critical this be rinsed thoroughly before use.[12] Some cage washer units are designed to connect a high-temperature waterline to the cage rack waterline to provide sanitation; however, some facilities have success without this type of treatment, just allowing the waterlines to be heated in the cage washing process. Purging residual water from the lines with compressed air eliminates any residual waterborne microorganisms and waterlines can stay within microbiological standards this way while they are being stored.

In order to assure the goal of sanitation is being met, a monitoring program must be in place.[12] The gold standard for microbiological monitoring is testing for microorganisms directly through culturing a sample from the item being monitored, quantitating the growth of microorganisms, and identifying the particular organisms that grew to determine if they are pathogens. Simple quantitation is normally done through a plate count or replicate organism detection and counting (RODAC) plate that monitors for total number of microorganisms present. Unless the goal of the sanitation is sterilization, a low number of organisms may be acceptable as most of these organisms should be nonpathogenic. It is not practical to try to identify all of the organisms found, so a common strategy is to use a selective growth and identification medium to identify pathogens, such as coliform bacteria. Normally, there should be no coliforms in samples from properly sanitized equipment or water systems.

Because of the time and cost associated with microbiological testing, this has historically only been performed at periodic intervals (monthly or quarterly), and more frequent monitoring is performed on the process or equipment to create the conditions that result in effective sanitation. An example of this is monitoring the temperature of the rinse water in an automatic cage washer to ensure that it is high enough for the expected contact time to inactive vegetative microorganisms. A common standard for this is for the rinse water to reach 180°F, as this will achieve sanitation after only a few seconds of contact. Lower temperatures can be equally effective with longer contact times.[11,12,77,78] Another method would be to monitor the concentration of the disinfectant used. This type of monitoring is often performed at least daily, if not every time the sanitation procedure is performed. With the development of newer technologies for microbiological monitoring, it is practical to perform microbial monitoring more frequently. An example of this is the use of a swab-based ATPase assay employing a fluorescent marker that can be read in a handheld unit. This provides rapid, quantitative data that have been shown to correlate with microbial count data.[12,79,80] There are specialized swabs allowing sampling for specific types of microorganisms, such as coliforms. As the methods for monitoring directly, rapidly, and inexpensively for microorganisms become more accepted within the industry, monitoring sanitation conditions (e.g., temperature or chemical concentration) may become less important. However, at this time many animal welfare compliance auditors still expect to see this type of monitoring performed regularly, even if the more relevant microbiological monitoring is being performed at the same interval.

CAGING

Animal cages (often referred to as *primary enclosures*) must meet a variety of requirements, some of which are conflicting. They need to provide enough usable space to meet the animals' basic physiologic and behavioral needs. They also need to provide an appropriate microenvironment, be easily sanitized, durable, prevent animal escape or injury, allow observation of the animals, and allow research functions to be performed.[11,12] An important trend in animal welfare regulatory and oversight standards is the expectation animals will be housed socially unless there is scientific justification for individual housing.[11,12] This creates some additional requirements for animal housing including being able to separate animals when required, ensuring adequate space for feeding to prevent food competition, and space for animals to obtain privacy when they choose. The space required for multiple animals in a single housing enclosure does not necessarily increase linearly with the number and size of the animals.[12] Because caging is very expensive, it can be tempting to cut corners to cut costs when designing and purchasing caging, but in the author's opinion, the long-term labor savings and the improved study success justify investment in quality design and construction of caging.

Cage space and design standards for most animal species are listed in the USDA animal welfare regulations and in the *Guide*.[11,12] For species not listed, the requirement is to meet a performance standard where the animal is able to perform species-typical behaviors and show no evidence of stress, such as abnormal behaviors, failure to maintain body weight or normal growth, abnormalities in hormone levels or balance, or abnormalities in the complete blood count or immune function. This performance standard is applied to all animals, such that even if a cage is meeting regulatory standards, if the animal is not healthy, it is not compliant. European cage space standards tend to emphasize greater amounts of space and more structure in the cage to allow climbing, perching, nesting, and shelter.[27]

While a wide variety of cage designs are available, there are some standard designs commonly used. Large animal cages tend to be constructed of stainless steel with slated or mesh floors and walls, allowing easy cleaning and good ability to observe animals. Cages for species that climb, such as nonhuman primates, cats, and ferrets, need to be enclosed on the top, but for other species with limited ability to jump or climb, they may be open on the top. Climbing species also may have elevated platforms built into the cage for the animal to perch. Nonhuman primates in particular benefit more from the vertical space in a cage rather than the floor space.[12] Cages are adapted for social housing by having a door or panel that opens between adjacent cages to allow animals to be paired when desired and separated when needed. Some designs allow multiple units to be connected and opened so any number of animals may be maintained in a group. These cages may be free standing on the floor, as with a kennel run, livestock pen, or group primate housing, or also may be mounted on wheels (castors) to allow easy movement for cleaning and room reconfiguration.

Historically, multitiered systems were wall mounted, but this is less common now, as it makes it more difficult to clean rooms and to reconfigure rooms when study needs change. Multitiered caging is still commonly used in the United States, but no longer meets European standards for primate caging[27] and is not favored for dogs. Tiered caging increases room capacity compared to single-tier caging or freestanding kennels, but kennels can be easier for personnel to use and perform daily cleaning. With nonhuman primates, tiered caging has been shown to affect the dominance hierarchy established among animals in different cages within the same room,[60] leading some experts to believe it is not optimal for animal welfare. One challenge with multitiered caging is the risk of injury to animals if they jump out of an upper cage and to personnel who must lift animals in and out of these cages. This can be managed through the use of team lifting, lifting devices, ramps, and weight limits for animals placed in upper cages.

The type of slatted or mesh flooring used in large animal housing can be important. Hoofed animals are susceptible to slipping on mesh floors and injuring themselves.[1] There needs to be enough grip to prevent this from happening. For all species, the space between flooring bars needs to be designed so feet or limbs cannot slip between them and become injured or entrapped. If a large animal pen is used for different species, interchangeable floors may be needed as the mesh size may need to be different for each species. Dogs can be susceptible to the development of interdigital cysts if the flooring is improper.[81] The exact cause of this is not known, but the lowest risk for these lesions seems to be associated with a mesh that is extruded rather than woven, is rubberized, and does not allow pooling of water or accumulation of feces.

Large animals can also be maintained on absorbent bedding if it is cleaned and replaced regularly, as it presents the least risk of foot or limb lesions. However, the logistics of managing the amount of bedding needed for large animal housing results in absorbent bedding being relatively uncommon in a typical laboratory environment. Farm-type facilities, however, often use bedding and it can be useful for certain study types where contact with moisture is undesirable or improved footing is needed for the animals.

Rodent caging has historically been constructed similarly to large animal caging. A common system is a metal unit with solid walls and a wire mesh floor that slides into a multitiered rack. A solid shelf or pan under the cages may contain bedding material or absorbent paper to collect waste. This type of caging is very durable, requires relatively low labor input for cleaning, and provides good ventilation for animals. However, the use of wire-floor caging is discouraged by animal welfare standards in the United States and Europe.[12,27] The concern with wire-floor caging is that animals can develop ulceration on the sole of their feet when housed on wire for prolonged periods of time.[12] This may be related to pressure, as it seems to be more common in larger animals. Aside from the risk of foot lesions, wire-floor caging does not allow rodents to display species-typical behaviors of

burrowing and nesting[12] and may increase energy requirements for thermoregulation.[12,82] Wire-floor caging does not lend itself to studies requiring containment of experimental hazards or exclusion of microorganisms.

Newer caging systems for rodents utilize a solid bottom with a layer of bedding to absorb waste. The cages are typically constructed of polycarbonate or other plastics to allow for visualization of the animals that are durable enough to sustain repeated high-temperature washing and chemicals. Cages are kept on multitiered racks as with the wire-floor cages. In some systems, the cages also slide into runners underneath the rack shelf, which serves as the top to the cage, while other caging types have perforated or wire tops and are simply set on a rack shelf. An advantage of the slide-in caging for toxicology studies is there is less labor involved with daily examination and dosing of animals. A cage can be slid out partway, the animal removed, procedures performed, the animal replaced, and the cage slid back in. For cages with a top, there are several extra steps involved, as it is necessary to place the cage onto a separate work surface, and remove and replace the cage top. The advantage of the latter system is that individual cages may be removed from the room and taken elsewhere as a contained unit, while with slide-in caging systems, the rack is needed to keep the animal contained in the cage. Facilities readily work around this by having a supply of lids for these cages that can be used when it is desired to remove individual cages from the rack. If cages are set on the top of a rack shelf rather than slid underneath, it may be necessary to avoid the use of the top shelf on a rack or provide some type of shield between the top cages and room lights to prevent excessive light exposure to these animals.

Besides the benefits to animal health and welfare, solid-bottom cages also allow for containment of hazards and exclusion of microorganisms. Solid lids with high-efficiency filters can be used to keep chemicals and particles in or out of the cage while still allowing ventilation. These lids do reduce overall ventilation,[12] so systems have been designed to push or pull air through the cages by the use of fans built into the racks or connections to building ventilation systems. This type of housing is more expensive to purchase and operate than more conventional caging designs, but can be very useful for certain types of research. It is important to remember when using this type of containment caging that once the cage is opened, the barrier between the cage and the room environment is broken. Typically, these cages should only be opened in a biosafety cabinet or other containment system to prevent contamination.

Social housing for rodents is typically managed through establishing pairs or groups in the standard cages. This can work well, but is a challenge for species or individuals that are highly territorial. The industry has not addressed this issue well, and in the future rodent housing systems may adopt some of the design features used in large animal cages, such as separate compartments or platforms to help manage social housing with territorial species.

Rabbit housing methods somewhat straddle the housing used for large animals and rodents. It is common to house rabbits in metal cages with slat or mesh floors with waste pans underneath. However, rabbits are also susceptible to foot lesions from mesh,[12] and do well on bedding. The logistics of bedding for rabbits is similar to that of large animals and many facilities housing rabbits for a long term will use mesh flooring but are careful to manage the diet of the animals to prevent them from becoming obese.[12] Facilities have adapted large animal cages or pens for rabbit housing, which can work very well, particularly when trying to house them socially.

ANIMAL MODELS

The use of animals in toxicological research dates back to the second and fourth centuries BC when Aristotle and Erasistratus performed experiments on living animals. Documentation of the use of dogs and nonhuman primates in animal experimentation can be dated to the second century AD when Galen conducted animal experimentation, specifically anatomical dissections, on living animals (vivisection) since dissection of human cadavers was outlawed according to Roman law.[83]

While animal testing has been conducted throughout recorded history, the use of animals was primarily experimental in nature: fundamental biological research, acquiring knowledge, or in training or teaching exercises. The conduct of animal studies for predicting the safety prior to testing in man was not required for new drugs prior to marketing until 1938 when the Federal Food, Drug, and Cosmetic Act (21 U.S.C. 301–392) was passed as a result of the sulfanilamide deaths. The proof of efficacy requirement was not required until the Kefauver–Harris Amendment was introduced in 1962 following the thalidomide tragedy.

While animal models used in research include, but are not limited to, pharmaceutical testing, toxicology testing, efficacy testing, surgical research, and pathophysiological research, the majority of the animals used in research are used for pharmaceutical and toxicology testing, specifically with regard to the nonrodent species.[84] With few exceptions, the regulatory guidelines (U.S. as well as international) require that toxicology studies be conducted in one rodent and one nonrodent species for support of pharmaceutical development. When choosing the nonclinical species, the appropriate model should be selected such that the response desired is most predictive of the human response, whether it is toxicity or efficacy being evaluated. Animal models may be exploratory, explanatory, or predictive in nature.[85] For the purposes of this section of the chapter, models of a predictive nature will be focused on since the majority of preclinical models in research are used in this capacity. This section is general in nature and will cover only an overview of the use of preclinical models used in research. A number of resources are available for selection of the appropriate animal models for specific disease states.[86–88]

The animal model(s) selected for use in safety assessment for support of clinical trials should be one that is the most predictive of human toxicity. In the absence of specific data on species relevance, the most sensitive species should be

selected based on prior experience with the compound class. The means by which the species are selected are dependent on the agent being developed and generally fall into one of two categories: small molecules and biopharmaceuticals (large molecules). For small molecules, the standard means to select the nonclinical species is through the use of in vitro metabolic profiling. Liver microsomes from a full spectrum of species (mouse, rat, dog, nonhuman primate, and human) are incubated with the test material and a profile of metabolic products is obtained. The profile from human is compared to the profile of the other species and the rodent and nonrodent species to be used for the nonclinical studies is based on the species that best covers the human metabolic profile. For most small molecules, history has shown this to be the rat and dog; however, it is not uncommon for one of these *standard* species to have a profile different than human and, therefore, the mouse or nonhuman primate may need to be considered. Minipig is also a species that can be included in the metabolic profiling as another option for the nonrodent species.[89] Should the metabolism data not provide a compelling case in support of a particular species, then attributes such as receptor expression or bioavailability can be used in support for or against a particular species. For biopharmaceuticals, regulatory agencies require the nonclinical studies to be conducted in the *most relevant* species, which is based on the pharmacology of the test material. Species selection for biopharmaceuticals is supported through the use of in vitro assays that demonstrate the ability of the test material to elicit a pharmacological effect in cells from a particular species. Most biopharmaceuticals are designed to be specific for humans; therefore, they may not exert their pharmacology in lower-order species such as the mouse and rat. In these cases, it is possible that the nonhuman primate may be used as the only species for the nonclinical studies.

Rats and Mice

In toxicological research, the two most commonly used rodent species are rats (*Rattus norvegicus*) and mice (*Mus musculus*), which were among the first species to be domesticated for scientific evaluation purposes. In fact, toxicity testing has historically often been conducted in both of these species for many test compounds, from initial range-finding studies to 2-year carcinogenicity studies.

Over a long and fruitful scientific history of nearly a century, the rat has generally become a species of choice in toxicological research because of its metabolic similarities to humans, its small size, generally friendly behavior (albeit with occasional individual animal exceptions), short gestation period (approximately 22 days), large litter size (average of 12), lack of emetic response, and fairly short life span (24–30 months). In addition, its use as a primary research species over the course of many years has led to a very robust historical control database for numerous biological parameters/endpoints, both in-life and pathologically, which further enhances its use as a predictor of human response to a compound. The Wistar Institute in Philadelphia, PA, was a prominent player when early researchers diligently worked to establish breeding programs to minimize animal variability and maintain optimal/desirable animal characteristics for scientific purposes.[90] Thus, many of the rat strains that are commonly used in the industry today (which include the Hannover-Wistar, Sprague-Dawley, and Long-Evans) can be traced back to that Wistar pedigree, while others were developed via a different lineage platform (such as the Fischer-344, which was developed for cancer research by the Crocker Institute of Columbia University in New York, NY).[90] The development of SPF rats, as well as the fine-tuning of animal husbandry practices over the course of time, has generally eliminated most of the disease outbreaks that may have potentially introduced variables into a study. However, the breeding process has typically produced some differences among the various strains that the toxicologist should be aware of and duly consider when selecting a particular strain for a toxicology program, rather than automatically defaulting to the standard or favorite strain utilized by a particular contract research organization (CRO) or internal laboratory that has been chosen to conduct the studies. Historical control data have shown that these physiological differences can affect how a particular rat strain reacts to a compound in terms of toxicity (strain-specific differences). As examples, the increased propensity for spontaneous renal disease that has been observed in the SD rat compared to the CD rat[91] may limit the utility of this particular strain for evaluating nephrotoxic compounds; the Fischer-344 rat is historically prone to higher incidences of interstitial cell tumors in the testes and lower incidences of female mammary gland fibroadenoma[90–93] than other strains; and the Hannover-Wistar rat has historically exhibited higher incidences of adenoma pars distalis of the pituitary gland[90–93] compared to other strains. Such considerations are especially important today, where continuing advances in breeding have made available various additional inbred and outbred strains that may be more geared to certain specific models of disease, or development of certain carcinoma types. In the modern research environment, even a casual perusal of any major animal vendor catalog or website offers myriad choices of rat models to consider, in terms of standard outbred strains such as CD, Long-Evans, SD, Wistar, and Hannover-Wistar rats, and standard inbred strains such as Brown Norway, Copenhagen, Fischer-344, and Lewis rats, along with various disease/translational models (such as immunodeficient, renal, cardiovascular, or oncology). Vendor customer service departments or websites often provide such detailed historical control data for customers to request or directly download. Therefore, the indication and mechanism of action of the particular compound being studied might also be a major driver in identification and selection of the optimal strain to use, with the caveat that newer and less frequently used strains do not necessarily have the robust historical control background of more commonly used strains. Such historical control data are often invaluable in assessing and interpreting incidence and severity across dose groups in a study from a histopathological perspective. Furthermore, the overall compilation and availability of such data over

decades also allow for a level of informational assessment of random genetic drift.[94] A number of what may be considered seminal works nicely address the specifics of the toxicologic pathology of the rat[95–97] in greater depth and informational detail, as this particular topic is one of the most abundant in terms of available literature for the toxicologist to reference.

Strain-specific differences can also be particularly important for carcinogenicity studies in terms of optimal survival levels over the course of a 2-year study period, for which valuable information can also be gleaned from historical control databases. In fact, Europe maintains the Registry of Industrial Toxicology Animal-data (RITA) Database, which is a database founded in 1988 by the Fraunhofer Institute of Toxicology and 13 pharmaceutical and chemical companies from Germany and Switzerland, and which companies from all over Europe now participate in by providing carcinogenicity study data for this computerized and standardized database.[98] Data from sources such as RITA in Europe, as well as the National Toxicology Program (NTP) in the United States, have allowed for comparisons of various strains, most notably the Hannover-Wistar rat (generally favored in Europe) and the Fischer-344 rat (with which the NTP has a long history), and the Charles River Laboratories SD rats (most commonly used in the United States), and Harlan SD rats (more often utilized in Europe). These geographical differences in use of strains, the robust data collected, and a trend toward decreased longevity in the CD and SD rats over time, suggest that the SD rat may eventually lose favorability due to its high background tumor rate, larger size, and lower survival rate, when compared to the Hannover-Wistar rat. The Hannover-Wistar is a leaner rat that exhibits a higher survival rate and a generally lower incidence of background tumors.[99] Its potentially increased future use over other strains, most especially if it becomes as favored in the United States as it is in Europe, would benefit the quality of carcinogenicity assessments in terms of minimizing the early termination of 2-year studies (or particular groups within a study) due to low survival, which impacts optimal statistical power for tumor analysis.

The utilization of the mouse for scientific research has an even longer history than that of the rat, as it spans several hundred years, including pioneering early efforts in the evaluation of animal reproduction, blood circulation, and respiration physiology. As with the rat, the mouse has also become a species of choice due to the many advantages it offers for toxicological research, which include its small size, general ease of handling, short gestation period (19–21 days), short natural life span (ranging from 1.3 to 3 years among varied strains), being more economical to purchase, house, and care for, and the availability of robust historical control data. However, the small size that makes the mouse more cost effective and less wasteful of test article also results in a less hardy animal that has more susceptibility to unexpected environmental deviations or to dehydration resulting from an automatic watering system issue/failure, while also limiting the blood sample volume that can be collected as well as urine output (although mouse urine is more concentrated).

A large number of the inbred and outbred strains of mice being used in research today are classified as Swiss strains, which trace back to an original noninbred stock from Lausanne, Switzerland, from which a set of animals was imported to the United States for cancer research by Dr. Clara Lynch of the Rockefeller Institute in 1926.[100,101] However, as with rats, the breeding process has typically produced some differences among the various strains that the toxicologist should be aware of and duly consider when selecting a particular strain for a toxicology program. The normal or typical body weight of various strains at different ages is one such variable to consider, in addition to the typical strain-specific differences shown in histopathological historical control data. Growth curves maintained by vendors such as Charles River Laboratories have shown that by 56 days of age (8 weeks), which is generally considered maturity, outbred strains generally tend to be larger than inbred strains, with the CD-1 outbred strain reaching the highest mean weight when compared with other outbred strains (such as CF-1 and CFW), various inbred strains (such as C3H, C57BU6, and BALB/c), and the hybrid B6C3F1 strain. Of these six particular strains, the C57BU6 and BALB/c strains are generally the smallest at 56 days of age. Some strains of mice, such as nude or athymic strains, are more sensitive to tumor development than heterozygous strains, and thus may exhibit higher incidences of tumors, as well as shorter latency periods. In addition, among numerous strains of mice, susceptibility to spontaneous lung tumors can exhibit wide variability, a situation where the potential chemical inducibility of a compound in this regard would suggest the use of a particular strain over another.[102] As an additional example, the hybrid B6C3F1 mouse exhibits higher spontaneous neoplastic lesions of the liver (hepatocellular adenoma and carcinoma) and the pituitary gland (adenoma) when compared to the CD-1 outbred mouse.[90]

There are a large and proliferating number of strains of mice available to choose from today (beyond inbred, outbred, hybrid, or immunodeficient), which now also include the advent of various genetically engineered mouse models such as the p53+/– knockout mouse (one or both of the alleles of a gene of interest are knocked out), the Tg.AC transgenic mouse (foreign genetic material is inserted into the genome and retains functionality), and the rasH2 transgenic mouse (human genetic material is inserted so that it carries a human oncogene), which offer even more choices for consideration by the toxicologist. While the p53+/– knockout mouse and the rasH2 transgenic mouse can typically be dosed orally (which is the most common route of administration in carcinogenicity studies), the Tg.AC transgenic mouse is typically dosed topically (skin paint study), which also is a decision factor to consider. The advantages of these genetically engineered mouse models are that a 2-year carcinogenicity study in mice can be reduced to a 6-month study that requires lower exposures, these studies require lesser numbers of animals due to their shorter duration, they may help minimize strain differences evident among other mouse strains, and could even be targeted to a specific mechanism of tumor formation.

Although these mice have specific genetic alterations critical to tumorigenesis, these alterations are in and of themselves insufficient to produce tumors before the end of a 6-month duration, thus exposure of these models to a carcinogenic compound would be expected to result in a rapid induction of compound-specific tumors. The particular three genetically engineered mouse models mentioned earlier have progressed past validation studies and have been utilized as part of submission packages in the United States and/or other countries and may indeed be the wave of the future as potential replacements for the 2-year mouse carcinogenicity study[103,104] as more historical control data are accumulated over the course of time and more such studies are commonly and successfully submitted to regulatory authorities going forward. In fact, the rasH2 transgenic mouse may now be taking the lead as the favored option for such studies, as anecdotal information suggests that approximately 20% of mouse carcinogenicity studies for new drug application in the United States now utilize transgenic models, with most of these typically using the rasH2 model, rather than the other two.

Dogs

The dog (*Canis familiaris*) serves as an experimental model in a variety of areas and disease states, including aging, cardiovascular disease, dermatologic disorders, endocrinologic disorders, hematologic disorders, immunologic diseases, musculoskeletal diseases, neurological disorders, ophthalmological disorders, radiation injury, and gene therapy.[105] The majority of dogs used in research are purpose-bred beagles for toxicology safety testing to support subsequent clinical trials; however, other breeds, including large hounds and mixed breed dogs, have been utilized for specific indications/observations in efficacy evaluations (see Table 20.5). The beagle was likely chosen for use originally due to their relatively small size, mild temperament, and ease of handling while still allowing for repeated sample collections/evaluations. These qualities allow for the repeated collection of samples or data from individual animals with a low risk of harm to the dog or the researcher, thus reducing the need for large number of animals. For example, repeated blood collection can be obtained from a single beagle for clinical pathology monitoring and toxicokinetic evaluations without compromising the health of the dog, resulting in the elimination of satellite groups or an increased number of animals that would be required for smaller species or breeds. The beagle was also made popular as a laboratory model in post–World War II research of biological effects following radiation exposure. In this research, important factors used for model selection included a long life span, genetic uniformity, physiological similarity to humans, economy of procurement and maintenance, availability, and ease of husbandry in a laboratory environment.[106] Because of the long history with the laboratory beagle, a robust historical database has been established in many laboratories, making this breed a logical choice for safety testing. Less than 1% of all animals used in research are dogs, and they represent approximately 7% of the USDA-covered species used in research in the United States in 2007 according to the latest available Animal Care Annual Report of Activities published by the USDA.

Nonhuman Primates

There are over 230 different species of nonhuman primates, of which only about 30 species are used in biomedical and behavioral research. There are three suborders of nonhuman primates: the Prosimii, the Tarsioidea, and the Anthropoidea (see Table 20.6). The nonhuman primates used in biomedical and behavioral research belong to the suborder Anthropoidea, so for the purpose of this discussion, only this suborder will be discussed. The suborder Anthropoidea is divided into two infraorders; the Platyrrhini or new-world monkeys (NWM)

and the Catarrhini or old-world monkeys (OWM). Less than 1% of all animals used in research are nonhuman primates and they represent approximately 6.8% of the USDA-covered species used in research in the United States in 2007 according to the latest available Animal Care Annual Report of Activities published by the USDA.

Nonhuman primates serve as one of the best animal models in predicting human responses with regard to safety and efficacy due to the genetic similarities between humans and the nonhuman primates. These genetic similarities are reflected in anatomical, behavioral, developmental, physiological, endocrinological, and reproductive aspects. Ninety-eight percent of human DNA is found in the genes of chimpanzees, 92% in OWM, and 85% in NWM.[107] As a result of these similarities, the nonhuman primate has played a critical role in biomedical safety, efficacy, and behavioral research (see Table 20.7). These similarities make the nonhuman primate an ideal model for research in AIDS; vaccine development of various diseases; Parkinson's disease; Alzheimer's and other cognitive diseases; reproductive, fertility, and endocrine research; hepatitis; neurologic disorders; behavioral and cognitive disorders; genetic disorders; and xenotransplantation.

Old-World Monkeys

OWM (from Africa and Asia) generally used in research are part of the Cercopithecidae family and include the macaques (cynomolgus and rhesus) from Asia and the baboon (olive and yellow baboons), guenon (African green monkey), and mangabey (sooty mangabeys) of Africa. In addition to the nonhuman primates from the Cercopithecidae family, the chimpanzee (Pongidae family) is also used, although in only a few research settings. The chimpanzee is the only great ape used in biomedical research; however, the use of the chimpanzee in research is being limited to those that meet specific criteria established to assess the use of the chimpanzee in biomedical and behavioral.[108] Ninety percent of nonhuman primate toxicology studies are conducted in macaques (usually cynomolgus or rhesus).[109]

New-World Monkeys

NWM (from Central and South America) generally used in research are part of the Callitrichidae (common marmoset, cotton-top tamarin, and mustached tamarin) and the Cebidae (squirrel, owl, and capuchins monkeys).

Rabbits

Today's domestic rabbits used in research were derived from the European rabbit (*Oryctolagus cuniculus*). Rabbits are a desirable research model due to their manageable size, generally docile nature, and breeding characteristics. The earliest records of captive rabbits date back to third century BC. Classic irritation models such as the domesticated New Zealand white (NZW) breed are still in use today despite the in vitro alternatives. Irritation assessments play an important role in worker safety assessment, labeling, and to some extent for the evaluation of dermal products as they provide comparisons for predicting the concentrations that may be tolerated by humans primarily due to accidental exposure.

TABLE 20.7
Examples of Nonhuman Primate Models Used in Research

Research Emphasis	Species	References
Malaria vaccine development, Creutzfeldt–Jakob disease, biomechanics of labor and delivery, pelvic organ prolapse, and emphysema	Squirrel monkey	[320]
Behavioral, developmental, and reproductive biology, virology, and immunology	Macaques	[321]
Intrauterine, reproductive, and surgical research	Olive baboon	[322]
Epilepsy	Yellow baboon	[323]
Parkinson's disease	African green monkey	[324]
Alzheimer's disease	African green monkey	[325]
AIDS	Sooty mangabeys	[326]
Hepatitis C	Chimpanzee	[327]
Parkinson's disease	Marmoset	[328]
Colitis and colonic carcinoma	Cotton-top tamarin	[329]
Colitis cystica profunda, myocardial fibrosis, and membranoproliferative glomerulonephritis	Moustached tamarins	[330]
Choroidal neovascularization	Squirrel monkey	[331]
Viral diseases and oncologic studies	Owl	[332]
Memory	Capuchins	[333]

Other common uses for the rabbit in research include vaginal, penile, and rectal irritation and/or toxicity studies.[110,111]

In addition to an irritation model, rabbits are used in the production of antibodies, biomedical device testing, pyrogenicity testing, and for developmental (teratology) testing of pharmaceutical compounds. Rabbits are sensitive to teratogens and can provide predictive information relevant to humans. For example, rabbits have a similar developmental response to thalidomide as humans. Rabbits are also an acceptable model for pharmaceutical drugs targeted for ocular delivery such as glaucoma. In cases of melanin-binding compounds, the New Zealand red or Dutch-Belted breeds provide a pigmented alternative to the NZW.[110,111]

Guinea Pigs

Today's domestic guinea pig (*Cavia porcellus* or cavy) is a rodent derived from wild guinea pigs found in South America. The first reports of domestic guinea pigs occurred around 1530. Guinea pigs have structural and physiologic features that make them acceptable models for human correlation. For example, both guinea pigs and humans have a need for vitamin C, have similar immunological sensitization reactions, and a susceptibility to tuberculosis. Tuberculosis was discovered in 1882 using guinea pigs and this has been a useful model in the study of infectious diseases due to similarities to the human immune system. They are docile animals, relatively small in size, inexpensive, and easy to maintain in a research environment.[110,112]

Historically, guinea pigs have been used for skin and delayed-contact hypersensitivity testing. The two most common assays include the Buehler and Magnusson–Kligman test (or maximization test). These assays are still in use although the mouse local lymph node assay is now accepted by the regulatory bodies (FDA, EPA, and the Organisation for Economic Cooperation and Development [OECD]) to provide sensitization information. The general safety test is another common use for these animals. They are a common model for auditory research due to the anatomy and accessibility of the ear. One of the first species to be used for allergic testing, they are still a popular model for this arena. They also have been used as a research model for diseases affecting the airways such as asthma and chronic obstructive pulmonary disease (COPD).[112]

Hamsters

Hamsters arrived late (1930s) to the research arena compared to their rodent relatives. The species most commonly used in research is the Syrian or Golden hamster (*Mesocricetus auratus*). Although they are easily housed and inexpensive, they are much harder to handle and more likely to bite if given sufficient opportunity. Hamsters have a cheek pouch, which provides a good repository for compounds needing mucosal irritation assessment.

Syrian hamsters are also a desirable tumor induction model for carcinogenetic assessments as they are more prone to develop certain types of tumors than mice. For example, induced pancreatic tumors in Syrian hamsters are both morphologically and biologically similar to pancreatic ductal adenocarcinoma in humans. Tumor formation in the cheek pouch addresses another cancer target, oral squamous cell carcinoma. The progression of the cheek pouch tumor formation occurs in a predictable fashion, which allows for various stages of human treatments to be assessed (e.g., early warning stage). Another common use for this model includes the research targeted in metabolic diseases such as diabetes and atherosclerosis.

A common use of Chinese hamsters is in the genetic toxicology arena. One of the attributes that makes these animals so valuable is its large chromosomes and low chromosome number. Chinese hamster's bone marrow has been used for cytogenetic testing, while Chinese hamster's ovary cells are used to identify compounds that may induce chromosomal damage by employing the chromosomal aberration or sister chromatid exchange test.[110]

Minipigs

All domesticated pigs originated from the European boar (*Sus scrofa*). Early records indicate that domestication took place around 9000 years ago. Miniature pigs (including the micro pig) developed as purpose-bred animals as they are a more desirable research model when compared to a farm pig due to the reduced requirements for housing, feeding, and, most importantly, the amount of test compound needed for dosing. In addition, the smaller size made them easier to handle for testing purposes.

The minipig (Göttingen Minipig or Hanford Miniature Swine) has been used for years as the standard nonrodent preclinical model in the development of dermal products due to their nonpigmented skin, sparse hair growth, and similar anatomy to human skin. The minipig also has similar characteristics to humans in their gastrointestinal (GI) tract, cardiovascular system, and urogenital system, making them a desirable nonrodent model in the development of therapeutics delivered by routes other than dermal. GI tract similarities include the stomach and small intestine anatomy (similar pH changes and transit time), and similar gastric cell types. They are an excellent cardiovascular model due to the similarities in the structure of the heart and great vessels, and blood flow in the coronary arterial system is almost identical to that of humans. The anatomy of the kidney is more like that of humans than other common research model and renal cytochrome enzymes have similar activity to their human counterparts.[89] The urinary bladder is also very similar to that of humans and the minipig urinary tract provides a good model to evaluate urinary incontinence and renal hypertension.

In addition to the Göttingen minipig and the Hanford™, other common breeds include the miniature swine, Sinclair™ miniature swine, Yucatan, and micro-Yucatan™ miniature swine.[113] A comparison of the body weight growth of each of the different breeds of minipigs is shown in Figure 20.1.

Minipigs have several distinct advantages over both the dog and the primate in preclinical research. For example, they tolerate nonsteroidal anti-inflammatory drug (NSAID) and antihypertensive drug better than dogs and they are not as prone to exhibit vomitus or emesis as seen with dogs.[114] They are generally friendlier than primates and, thus, are easier to handle and dose. In addition, they are often the nonrodent model of choice among European laboratories due to existing ethical concerns over the use of dogs and primates in those countries.

Nontraditional Species

While the more common animal models discussed earlier are most often used in toxicology studies, a nontraditional animal model may be more appropriate as a predictor of toxicity to humans due to specific anatomical, physiological, pharmacological, or metabolic characteristics. In addition, toxicity data from nontraditional, environmentally relevant test species are used and required to support environmental assessments, safety assessments of chemical products, and the safety of environmental species from the release of treated wastewater effluents. The goal of employing such nontraditional animal models would be to most closely emulate the potential human response to a particular pharmaceutical therapy that targets a certain disease state, or as the surrogate to evaluate against environmental toxicity concerns. The major drawbacks in using nontraditional animal models as a toxicity test species are related to acquisition and husbandry issues, background

Regulatory permits for wastewater	Fathead minnow (*P. promelas*)	[130]
	Daphnid (*C. dubia*)	

knowledge on disease processes in these species, lack of robust historical control data, and the degree of concordance with human pharmacology. Table 20.8 lists the more common of these models. Additional aspects of these animals are described in the following sections.

Chinchilla

The chinchilla (*Chinchilla lanigera*) is a rodent native originally to South America that resembles a squirrel in size and appearance. It has been valued for its fur since the late nineteenth century and is a popular pet species.[115] As a toxicity test species, it has been widely used as an animal model for auditory experiments and in other studies in which the structure and function of the ear are of interest. This is due to its ear structure (cochlea) being similar in size and structure to the human cochlea, and an auditory sensitivity that is also similar to that of humans.[85,116]

Ferret

The ferret (*Mustela putorius furo*) is a small carnivore native to Europe that has a long slender body with predatory instincts, and is a popular pet species. It has similar oropharyngeal, gastric, and lung physiology as humans, and large lungs with a capacity about three times as predicted for their body size.[116,117] As a toxicity test species, it has been used to study emetic response in humans over the last three decades,[118] as well as respiratory diseases such as human influenza, severe acute respiratory syndrome (SARS), H1N1 (swine flu virus), cystic fibrosis, and lung cancer.[119] It has also been used in studies for nutrition research, gastrointestinal disease, cardiovascular disease, virus-induced neoplasms, bacterial infections, and viral diseases.[85,118]

Woodchuck

The eastern woodchuck (*Marmota monax*) or groundhog is native to North America, is a member of the rodent order, and can weigh up to about 30 lbs. As a toxicity test species, it has gained wide acceptance in the study of antiviral agents and immunotherapies, since it is prone to a naturally occurring woodchuck hepatitis virus (WHV) infection that is closely related to the human hepatitis B virus (HBV).[85] Woodchucks infected with WHV develop progressively severe hepatitis and hepatocellular carcinoma and are, thus, valuable animal models for pathogenesis and hepatocarcinogenesis. The response of the woodchuck to certain nucleoside analogs (i.e., fialuridine [FIAU]) appears to be identical to humans.[120] Further understanding was gained from their use after the unanticipated and delayed FIAU liver toxicity observed in a 1993 human clinical trial in which 5 out of 15 patients died. Although it has a low reproductive capacity, breeding colonies have been established and maintained in animal facilities allowing for controlled experiments and significant potential for molecular virology and immunological studies, and nonclinical drug safety assessment in antiviral, immunotherapy, or combination drug therapy.[121]

Armadillo

The nine-banded armadillo (*Dasypus novemcinctus*) is an insectivore found in North, Central, and South America. It is one of the few known nonhuman animals that can contract leprosy due to a low body temperature that favors the growth of leprosy-causing bacterium (*Mycobacterium leprae*). The bacterium cannot be cultured in artificial mediums and the armadillo is useful in propagation of the bacterium and as a primary test species for studying potential therapeutic agents

and vaccines.[122] The armadillo is also useful in reproductive research in which its reproductive system produces polyembryony or genetically identical twin eggs, that later separate into four eggs.[123] The group of four young are genetically identical and are useful in experiments requiring consistent biological and genetic makeup in the test species.

Zebrafish

The zebrafish (*Danio rerio*) is native to the streams of the southeastern Himalayan region.[124] They are popular tropical aquarium fish that can be raised in abundant numbers, and have advantages over traditional mammalian models such as small size, simple husbandry requirements, high fecundity, and transparent embryos, yet maintain many similar vertebrate phylogenetic features to humans.[125] With the use of genetic screening in the 1990s, the zebrafish became a mainstream model in developmental biology that led to its use as a model for human disease and drug discovery.[126] These disease models include congenital and hereditary disease, carcinogenesis, infectious disease, inflammation and wound healing, immunological disease, metabolic disease, endocrine disease, nutritional disease, psychological and behavioral abnormalities, and toxicity and poisoning.[126] The use of zebrafish as disease models also led to its primacy as a whole-animal model for screening lead therapeutic candidates in drug discovery.[126] Increased research in the area of zebrafish genetics is likely to lead to even greater understanding and further uses of this animal model in toxicology, pharmacology, and developmental biology.

Models for Environmental Toxicology

Environmental toxicity testing is a necessary consideration of the statutory risk assessment for drugs, chemicals, and wastewater.[127–130] Should toxicity data be needed to support an environmental assessment for a new human pharmaceutical therapy or animal health product, typical toxicity test species depend on the predicted environmental fate of the drug, but might include aquatic species such as fish (e.g., rainbow trout—*Oncorhynchus mykiss*), invertebrates (e.g., *Daphnia magna*), and plants (e.g., *Selenastrum capricornutum*), or terrestrial species such as microorganisms, earthworms, and plants. The rainbow trout is a representative cold water fish species of the Salmonidae family that is sensitive to many toxicants. The invertebrate, *D. magna*, is a daphnid or water flea that reproduces by cyclic parthenogenesis. The green alga, *S. capricornutum*, is a single-celled, crescent-shaped component of phytoplankton whose sensitivity to toxicants is measured by growth inhibition. Assessing the safety of chemical substances also depends on their predicted movement and fate in the aquatic and/or terrestrial environment, but typical ecotoxicity test species include sediment/soil organisms and microorganisms, aquatic and terrestrial plants, amphibians, fish, daphnids, insects, and birds. The safe release of wastewater from treatment facilities requires regulatory toxicity testing to support compliance for a given permit. In general, aquatic test species include fish (e.g., fathead minnows—*Pimephales promelas*) and invertebrates (*Ceriodaphnia dubia*). The fathead minnow is a warmwater fish species of the cyprinid family in which males guard and tend the eggs with the use of a fatty pad found on the dorsal side of the head region. The daphnid or water flea, *C. dubia*, is a sensitive test species to toxicants that reproduces by cyclic parthenogenesis.

Genetics

Maintaining internal breeding colonies is not recommended unless it is required for the purposes of the study or there is no alternative source of animals, such as with specialized transgenic strains. However, even in these cases, it can be advantageous to outsource to commercial vendors who specialize in transgenic and common purpose model colony breeding and maintenance. Outbred stock colony maintenance can be particularly complex and time consuming. Special breeding protocols must be in place to avoid genetic bottlenecking of the colony while also avoiding overproduction of animals. For information on breeding colony management, the reader is referred to published resources.[131,132]

Even when using commercial vendors for animals, there are certain aspects of genetics that are important for scientists to understand. The genetic makeup or genotype of an animal is a primary determinant of how it will respond to experimental conditions. The two aspects of the genotype are the presence of specific genes or alleles and the relative heterogeneity of these alleles within a population.

Animals can be classified as either *inbred* or *outbred* based on their genetic heterogeneity. A truly inbred animal is one that has at least 98.7% concordance at all genetic loci among all individuals in a population. Typically, the only fully inbred animals used in research are rodents. Inbred strains of rodents have been developed through identification of a desired phenotype of genotype, and then performing brother–sister mating for 20 or more generations.[132] A risk when developing inbred animals is that a phenotype will be found that causes significant health problems or is lethal when maximum homogeneity is achieved at all genetic loci. However, inbred strains of rodents are useful when there is a specific phenotype of animal desired and relatively little variation desired among individual animals. Even with fully inbred animals, there are some differences in phenotype among individuals due to ongoing mutations[132] and due to epigenetic and environmental factors affecting development.[133,134]

In general, inbred strains of animals are not used as commonly in toxicological research as they are in discovery research. The inbred state does not represent the norm in clinical populations, so these animals are more useful for modeling specific disease conditions than in screening for toxicity within a population. However, if specific mechanisms of toxicity are known, inbred models can be useful for screening test articles for these types of toxicity as they are potentially more sensitive than an outbred model due to lower individual animal variability.[135,136] There is the potential to use fewer animals to obtain data with lower exposure levels and shorter study duration.

Institutions should verify that vendors are monitoring inbred strains to ensure genetic homogeneity is maintained. This can be done through phenotypic monitoring of key physiologic characteristics of the strain, biochemical monitoring for key isoenzyme characteristic of the strain, or genetic monitoring for specific DNA sequences using restriction fragment length polymorphism (RFLP) or single-nucleotide polymorphism (SNP) methods.[1,12,137,138] If research institutions perform their own breeding, inbred animals are easier to maintain than outbred animals, as only a small population of breeding animals is required. Some effort must be made to prevent genetic drift of the strain from the original animals as it only takes a few generations for subline divergence to develop, particularly if there is any type of selective pressure placed when selecting breeding stock to maintain the line. This can be achieved through selecting a common parent cage to maintain a full-sib-mated inbred colony every five generations.

Outbred animals are those with heterogeneity at multiple genetic loci. This is generally thought to better represent a clinical population, although this conclusion assumes that the genotype and phenotype of the model are relevant to the clinical population for which the animals are serving as the test system.[135] The term outbred is a relative term as all populations of recognized breeds or stocks of animals have some homogeneity that imbues them with their breed characteristics. This is expressed as an inbreeding coefficient that is calculated from the breeding history or pedigree of the population.[132] When evaluating vendor animals, a review of the breeding system and the method for tracking the pedigree should be performed. Phenotypic characteristics should also be evaluated to monitor and characterize an outbred population. Until recently, there was not a good method for monitoring the genotype of outbred animals because of the large number of genetic loci to be evaluated. Methods for monitoring heterogeneity through SNP analysis have now been developed for this purpose, and are useful for understanding differences between animals of the same breed or stock from different sources.[138]

If institutions need to maintain breeding colonies of outbred animals, they must plan for relatively large populations. In addition to starting with a large genetic pool of animals (25–50 breeding pairs of unrelated animals is recommended), care must be taken to prevent inbreeding when selecting animals to serve as future breeders to maintain the colony. Rotational or sectional breeding schemes have been developed for this purpose.[132] It is also important to select breeders randomly from animals that express normal phenotypic characteristics, as any type of selective pressure will result in changes in allelic frequency that rapidly spread through the population (S. Wildt, Harlan Laboratories, personal communication).

Preventative Medicine

Preventative medicine is particularly important with research animal colonies. The presence of disease creates an experimental variable, and treatment for disease can also be a variable. In addition, whenever large numbers of animals are maintained in close proximity, if a disease enters the facility it can spread quickly throughout colonies. Thus, it is very important to prevent disease from occurring in the first place. Institutions need to evaluate the risk of exposure of animals to specific diseases and the consequences of the disease if it infects the animal colony. Strategies for preventing diseases can include purchasing animals free of the organism, vaccinating, or administering anti-infective agents or chemoprophylactic drugs. Preventative medicine programs for different species are published in the veterinary literature. However, it is important to understand the reservoir of the disease and mode of transmission, as many diseases relevant for animals in nonresearch settings are not relevant to animals maintained indoors in closed colonies. This is particularly true for diseases transmitted by insects and wildlife, and parasitic agents with complex life cycles.

Animals may need to be housed under quarantine conditions when they arrive at the research facility until they are tested and shown to be free of diseases, after which they may be housed with other animals in the facility.[12] However, if animals are purchased from trusted vendors who regularly perform testing for common pathogens, they may be brought in without a quarantine requirement. Even if animals have been tested for pathogens by the vendor, it is common practice to test large animals for intestinal parasites after they have arrived in the facility. Rodents and nonhuman primates may be tested for a variety of viral and bacterial diseases and animals may be administered antiparasitic or antibiotic drugs to eliminate common organisms. Vaccines, on the other hand, are not commonly used in research institutions since animals are usually vaccinated against important diseases by the vendor and revaccination is not usually necessary for animals in a closed research colony. One exception is that dogs and cats are commonly vaccinated against rabies in the research environment. The risk of exposure to rabies is negligible in laboratory-housed animals, but most municipalities require evaluating animals for rabies following a bite if they have not been vaccinated, and the only definitive test for rabies requires submission of a brain sample.[139]

Ongoing testing of nonhuman primates for tuberculosis is standard within the industry. The risk of acquiring new infections while housed in the facility is low, but tuberculosis can often be subclinical in nonhuman primates and animals may be anergic to the organism, which results in a false-negative test result. Therefore, repeated testing has evolved as a strategy for ensuring the disease is excluded from the facility.[140]

Rodent colonies are tested for a number of organisms through the use of sentinel animals. Sentinel testing should be performed at least quarterly, or more often if the risk of disease introduction is high due to multiple sources for animals or the presence of breeding colonies that can support endemic infections. Sentinels are typically provided with soiled bedding from other animal cages in the room every time waste is removed from them. These sentinels may be extra animals purchased when the study was initially set up

so new animals are not introduced into an occupied room, reducing the risk of introducing organisms into the room. However, as sentinels age they are more likely to produce false-positive results due to immunologic cross-reactivity with the assay.[71,141] For long-term studies, the use of new, younger animals for each monitoring interval may be used if care is taken to ensure that the animals introduced into the room are themselves free of disease.

Another aspect of preventative medicine is monitoring animals for problems that develop as they age or are used in multiple studies. Animals may require dental care, trimming of nails or hooves, physical examinations, and clinical pathology evaluations to ensure they are healthy and suitable for study use. This is also important for animals with chronic, indwelling catheters or instrumentation. In addition to the maintenance of instrumentation itself, it can be beneficial to periodically perform a physical examination and selected clinical pathology to assess for the presence of subclinical infection or organ damage.[142]

Husbandry

Feed

Diet has the potential to be an important variable to toxicology studies; however, it typically is not due to the commercial availability of properly formulated, well-controlled diets. These diets are formulated to meet the nutritional requirements for each species, have defined nutritional levels, and can be certified by the manufacturer to be free of contaminants. Facilities typically rely on manufacturer certification and analysis to ensure diet quality, however, contaminations can and do occur in diet production and may not be detected by the periodic analysis performed. Therefore, detecting these incidents is heavily dependent on manufacturer quality control procedures. These procedures should be carefully reviewed when qualifying diet vendors.

Typical dietary contaminants can include vermin, pesticides, mycotoxins, heavy metals, and microorganisms.[1,12] Chemical contaminants are minimized by manufacturers through appropriate screening and selection of raw materials. Diet manufacturing methods often involve heat treatment that effectively minimizes the levels of microorganisms and vermin. Diets can be sterilized through autoclaving or irradiation, if required for immunodeficient models or specialized studies. Sterilization can affect the nutritional level of diets as some vitamins are heat labile. Facilities should ensure that they are using diets formulated for sterilization so deficiencies do not develop.[12,143–145]

Animal nutritional needs change with age and reproductive status,[143–145] and diet manufacturers typically produce *life stage* diets appropriate for different physiologic states including growth, reproduction, and aging. However, this approach is not commonly used in toxicology research. There appears to be a focus on eliminating diet formulation as a variable in studies rather than controlling body condition and energy balance. Facility managers typically select a diet that is a compromise between the higher energy and protein requirements required for growth and lactation and the lower levels needed as animals age. This likely is not an important variable for short-term studies using young animals, but it has been shown to be important as animals age, since excessive energy and protein levels affect the incidence of neoplasia, renal failure, and obesity, with its associated health problems.[146] Obesity also increases the amount of test article needed for an animal, and can introduce variability into drug metabolism and distribution because of the greater body fat compartment.[147]

Methods for managing the effects of excessive energy and protein levels have been developed that involve food restriction.[148,149] This is effective but can be costly because of the involved labor. Use of an appropriate diet for aging should be considered as an appropriate alternative, particularly where vendors can produce a line of diets modifying only selected components to adjust for age and reproductive state while leaving the remaining components fixed.

Most standard diets used in research are natural ingredient diets. That is, they use agricultural products, each of which contributes several dietary components to the final formulation.[144] Diets with purified ingredients providing only a single component are available and may be used for some studies. However, these diets are extremely expensive and relatively unpalatable, so they are not used for most purposes.

The presence of certain nonnutritive dietary constituents in natural ingredient diets can be variables in some studies. Nitrosamines are present in fish meal, which is an additive providing protein and omega fatty acids. Nitrosamines are known to be carcinogenic and should be avoided in diets used for oncogenicity testing.[150] Phytoestrogens are naturally occurring selective estrogen receptor modulators present in agricultural products typically used in diets, including soybean and alfalfa.[151] Scientists should determine whether the effects on reproduction and estrogen-responsive tumors are relevant in their studies and consider diets controlling the natural variability of phytoestrogens in natural ingredient diets, or use diets that restrict the use of these ingredients.

Dietary fiber is very important for proper gastrointestinal function in some species of animals. For rabbits, guinea pigs, and ruminants (sheep, goats, cattle), it is important for motility of the gastrointestinal tract and may prevent stasis and overgrowth of *Clostridium* sp. and other pathogens.[152–154] In nonhuman primates, fiber appears to be important for the management of episodic diarrhea common in these animals.[155] Dietary fiber can be managed to some extent through fiber content in commercial pelleted or biscuit diets. However, there appears to also be a requirement for physical *roughage* that can only be supplied through whole agricultural products such as hay, vegetables, and fruit. While animals can be maintained without this additional source of fiber, the incidence and severity of gastrointestinal problems seem to be higher than in animals that do not receive these items. A common concern with the use of agricultural products for dietary supplement is that they typically are not available commercially in palatable forms with defined nutritional content and certified to be free of contaminants.

Facilities can run their own analyses to define these parameters, but this is expensive and of limited value as there is also no control over the supply chain of these types of items and it is not practical to test *lots* that went through the harvest or preparation process as a unit. While control of nutrition and contaminants is important, if these types of additives are fed in small amounts it is unlikely they significantly impact the overall nutritional status of the animal or contribute to study variability. They are normally sourced from suppliers for human and agricultural animal use and typically are considered safe for consumption. Ultimately, the benefits of maintaining gastrointestinal functions in animals must be weighed against such risks.

Animals may be fed ad libitum or a defined amount of food each day (meal feeding). Ad libitum feeding has the advantage of less labor than meal feeding and allows the animal to eat the amount it desires. There is the risk of the animal becoming obese with ad libitum feeding, particularly if a high-energy diet is used. Another risk of ad libitum feeding is that the food can absorb moisture in a humid environment and mold or spoil in between cage changes. Ad libitum feeding is most commonly used with rodents, younger rabbits, and dogs.

The advantages of meal feeding are essentially the opposite of ad libitum feeding. It is possible to control the amount of food, and prevent food wastage and obesity. Food does not spoil as the feeders are emptied daily. Meal feeding is typically used for livestock, nonhuman primates, and is often required for older rabbits and dogs. With meal feeding, slightly more than the minimum requirement is provided to ensure adequate nourishment. Energy requirements for animals at different life stages have been published.[143–145] Vendors provide information on nutrient and energy levels of commercial diets so that the amount of feed needed can be calculated. This can be adjusted as animals are monitored for food consumption, body condition, and weight loss. While meal feeding is more labor intensive than ad libitum feeding, as discussed previously, the benefits of managing an animal's body condition are often overlooked and may be needed if it cannot be managed through diet selection.

Animals are often fasted prior to oral dose administration to prevent food from interfering with absorption of the test article. Fasting is also commonly performed for the collection of serum chemistry samples to ensure that blood glucose and triglyceride measurements are not affected by a recent meal. Fasting is also performed in many species prior to anesthesia to prevent regurgitation, and prior to necropsy to minimize the amount of ingesta in the gastrointestinal tract. The typical duration of a fast is over night, or approximately 12 h. This is adequate for most purposes and is safe in most species.[156] However, clinical hypoglycemia has occasionally been observed by the author in neonates, small rodents, or nonhuman primates following several hours of fasting. Therefore, the age and metabolic status of animals should be considered when fasting animals, and animals at risk of hypoglycemia should be carefully monitored both clinically and glucose monitoring may be indicated. For larger animals, fasts of up to 24 h are generally safe, and for ruminants, fasting for up to 48 h may be required to prevent regurgitation.[157]

Feed can also be restricted for some behavioral models to encourage them to perform tasks for a food reward. The amount of feed is typically restricted to a percentage of the amount the animal eats when fed ad libitum or food is restricted empirically to achieve a percentage of normal body weight when the animal is fed ad libitum. Protocols vary but approximately 75% is a common percentage used for either method.[1,156]

Water

As with diet, drinking water can potentially contain constituents serving as variables in toxicology studies,[1] but with modern water systems, this rarely occurs. For most purposes, use of municipal water with only minimal additional treatment and testing is appropriate.[12] Municipal water is tested periodically using the EPA drinking water testing standard for contaminants such as minerals, heavy metals, pesticides, total bacterial counts (heterotrophic plate counts or HPC), and coliform bacteria. Animal facility drinking water is typically tested for these contaminants at a certified EPA testing laboratory at quarterly to annual intervals to assure no contaminants have been introduced by the facility water system. This testing is also typically performed when a facility is first qualified for use, after the water system has been shut down for maintenance, or if a part of the facility has been decommissioned and put back into use.

Many facilities will add filtration systems with 1–2 μ efficiency to drinking water systems to remove particles. If the water source is extremely hard (high levels of minerals), water softening may be used to prevent mineral accumulation on caging, in watering systems, and in cage washers. Softening of water does add minimal levels of salt to the water, which typically is not enough to affect cardiovascular or renal physiology in normal animals, but may be important when considering different animal models/species and/or study types. Additional filtration or treatment is not normally necessary for immunocompetent animals. However, some facilities will choose to install additional water purification systems, such as higher efficiency filtration (down to 0.2 μ), reverse osmosis, deionization, or distillation if it is necessary to achieve a higher level of purity.[12] Maintenance of watering systems to prevent bacterial growth is described in the section on sanitation.

There are specialized animal models that require water additives. Hypertension can be induced in Dahl salt-sensitive rats by adding salt to drinking water.[158,159] Animals with pituitary, thyroid, or parathyroid glands removed may require addition of salt, glucose, or calcium to their water.[160] In addition, antibiotics or anticoccidial drugs are sometimes added to drinking water to control microbes for veterinary purposes in immunosuppressed models[161] and tetracycline is used with inducible gene expression systems.[162]

Water is typically provided to animals ad libitum. Some research models limit the amount of water provided to the animal to encourage them to perform tasks. It is important to

monitor animals carefully so they do not become excessively dehydrated when limiting water.[1,156] Water is not typically removed when animals are fasted prior to dosing, anesthesia, or necropsy.

Contact Bedding

Bedding is added to the cage of animals to provide a substrate for nesting, thermoregulation, and absorbance of waste products.[12] Bedding benefits many laboratory animal species,[164] but its use is most emphasized in rodents. The thermoregulatory benefit of bedding is important for smaller animals, and it allows rodents to practice species-specific behaviors of nest building, burrowing, and shelter seeking, reduces alopecia, and elicits positive vocalizations.[12,163,165] For larger animals, the logistics of managing the large volumes of bedding needed often precludes its use except where it is critical to the success of the study. However, it may be specifically indicated, for example, with breeding, or to provide padding and footing to animals recovering from orthopedic surgery.

Bedding is typically made of naturally occurring or processed fibrous materials such as wood shavings, wood pulp, paper, cotton, straw, or hay. As with diet and water, it is important to ensure that bedding products do not introduce contaminants or other factors that can affect animal health or introduce variability to studies.[21,166–168] Animals will consume bedding, and continuous contact with bedding products means that animals can be affected by dermal contact and inhalation of particles or aerosols.[1] Because of this, the dust content of bedding should be minimized. Resinous woods such as pine and cedar should not be used for animal bedding because these resins are known to be inducers of cytochrome P450 enzymes that are a key drug metabolism pathway.[169] The source and preparation of paper products need to be evaluated to ensure that there are no residual chemicals that can have physiologic effects on animals.[167,170,171] Bedding can be certified for contaminants in the same way diet is certified. Many commercial bedding products are heat-treated as part of the drying process, which also minimizes microorganisms. However, bedding can be autoclaved or irradiated to fully sterilize it.

Different products vary in their ability to meet the different requirements of bedding material. Some products have been shown to be more effective at controlling waste products such as ammonia.[172] Others may be better for nest construction and providing shelter.[173,174] It is not uncommon for facilities to use several types of bedding in the same cage to optimize bedding function.

Historically, toxicology studies have tried to minimize the use of bedding in rodent cages because it has been thought to obscure clinical signs of toxicity, such as abnormalities in feces, urine, general behavior, and the integument and to prevent consumption of bedding.[175] However, as the use of solid-bottom caging with bedding has increased within the industry, discovery research environments, and toxicology studies run in European facilities, this concern is not considered as significant as it once was. Bedding in solid-bottom caging does not appear to limit detection of clinical signs,[176] and data are now commonly submitted for drug registration that was developed using animals in solid-bottom caging with contact bedding.

Likewise, the historical concern about maintaining rodents on contact bedding due to the reingestion of feces (coprophagy) affecting exposure levels of test articles has not been supported by data. Coprophagy is a normal behavior of rodents and rabbits, and normally the animals consume the feces as it is being expelled, so the use of mesh floor caging does not completely eliminate the reingestion of feces.[177–179] For complete elimination of coprophagy, use of specialized devices is required.[180] Mesh flooring may reduce coprophagy, as animals are frequently observed eating feces from the cage bottom when housed in solid-bottom cages with bedding. However, if it is assumed that the rate of reingestion is similar among treatment groups, coprophagy is not a true variable. This assumption may not be accurate in all cases, and scientists should be aware of situations where coprophagic behavior can become an important variable. Mesh flooring by itself only controls at most 50% of this source of test article.[177–179] If dose levels between groups are within this range, or if there are other factors that can skew coprophagic behavior, it may be an important variable. For example, if the level of active test article or metabolite in the feces is high, the presence of the test article may actually stimulate fecal consumption behavior (e.g., substance abuse, drug-seeking behavior), and if the difference in dose levels between treatment groups is narrow, it is possible that coprophagic behavior could result in enough variability in test article exposure to result in the loss of the ability to discern important effects between dose levels. These multiple *if* scenarios are the exception rather than the rule in toxicological studies.

Cleaning

Animal cages need to be cleaned regularly to remove waste. Large animal slat floor cages are typically sprayed out with water at least daily to remove feces and urine.[11,12] It is important to coordinate daily cleaning between husbandry and research staff so abnormal feces, urine, or emesis are not removed before these observations can be recorded. Bedding or papers placed in waste pans under wire-floor caging is commonly replaced two to three times a week. If bedded cages are used, they must be checked daily and excessively soiled or wet bedding removed. At least weekly all of the bedding needs to be removed, the floor sanitized, and bedding replaced.[12] Bedding may need to be replaced more frequently to keep cages dry and clean. Larger, older animals and diabetic animals, as well as guinea pigs, often require more frequent bedding changes because of the larger amount of waste these animals produce. There is some evidence that frequent cage changing can be a stressor by itself, and scientists need to consider this as a potential variable.[181] Exceptions to animal welfare standards for cage changing frequency need to be approved by the IACUC based on scientific justification. There would need to be clear data demonstrating that the effects of cage changing directly interferes with study goals such that it is not possible to interpret data by correcting for these effects for such an exception to be considered scientifically justified.

Social Environment

Animal welfare regulations and guidelines require social species be housed socially unless there is scientific justification not to do so.[11,12] Justification for an exception may be based on the need to monitor individual food or water consumption; cage observations such as feces, urine, emesis, or hemorrhage; the effects of social housing on behavioral assays; or cross contamination of test articles. It is important to make these justifications based on data rather than supposition, as some expected challenges with social housing have not been supported by the data.[182,183] For example, the ability to accurately identify clinical observations has not been shown to be adversely affected by social housing in solid-bottom caging.[176] Individual food or water consumption may be of limited value in interpreting toxicologic effects of a test article, because other data such as body weight and body condition of clinical signs of hydration are also collected.

Most species of animals used in toxicology research are social. However, the conditions under which they can be housed socially are not necessarily practical in a research environment. Territoriality and dominance can be a particular problem with male members of species such as rabbits, hamsters, some strains of mice, nonhuman primates, and livestock.[12,34] It is possible to socially house these animals if they were introduced prior to sexual maturity,[12,184] if adequate space is provided, and if animals have physical structure in the cage.[12,185,186] When exceptions to social housing are made on a facility-wide basis based on the inability to provide an appropriate environment to facilitate such housing, this should be approved by the IACUC as part of a social housing policy. Exemptions in social housing policies should be reviewed at least annually. Exceptions to social housing may be approved by a veterinarian on an individual animal basis to provide medical care, or because the animal is not compatible with others. For nonhuman primates, these exceptions need to be reviewed and reapproved at least monthly.[11] There are provisions for documentation of permanent exemptions for individual animals based on health or behavioral needs, however, these cases should still be reviewed periodically, as it may be preferable to remove an animal from a colony and replace it with an animal that can be housed in such a way that housing or social stress is minimized.

Social environment can also include housing of behaviorally compatible species in the same enclosure or area.[12] It is not uncommon to house agricultural animals in the same enclosure in farm settings. Mixing of species in the same enclosure or room is less commonly performed in research settings for a variety of reasons, including disease control and separation of study activities. Mice and rats have historically been considered incompatible, because there is thought to be a predatory effect of rats on mice.[12] However, it appears that animals may be able to acclimate to this effect as cohousing of mice and rats has not been shown to adversely affect reproduction in these species[187] and, in fact, is common practice with commercial rodent breeding facilities.

While there are challenges with social housing of animals, for most situations it has been shown to be compatible with toxicology study designs and provides significant benefits to animals.[188] Rats demonstrate a stress-like response when they are removed from a social environment.[189] Animals may have an improved ability to adapt to stressful situations when housed socially,[190] and social groups are important for environmental control such as thermoregulation.[191] Ad libitum–fed rats are less prone to weight gain than singly housed counterparts.[192] There tends to be reduced levels of abnormal behaviors in socially housed animals.[193,194] Dominance behavior can result in occasional fighting with subsequent skin lesions and excessive allogrooming that affects the hair coat and can result in food exclusion and weight loss of submissive animals. Dominance can also temporarily affect sex hormone production, which could be a variable in some studies.[195] With the exception of extreme aggression that can result in injury or death as with socially housed hamsters or male mice, typically, it is possible to interpret study data in light of these signs and there are numerous examples of regulatory approvals based on data collected in socially housed animals.

Environmental Enrichment

Environmental enrichment is often defined as creating a housing environment that stimulates species-typical behaviors in animals that are thought to reduce stress and enhance the welfare of research animals.[12] Enriched environments have been shown to improve animal learning and reduce cognitive loss with aging.[192,196] Social housing is one strategy for environmental enrichment and appears to be a more significant form of enrichment for social animals than environmental modifications.[189] The use of solid-bottom caging with bedding is another method of environmental enrichment that has been previously discussed. Besides social housing, and providing a substrate for burrowing and nesting, other types of environmental enrichment are listed in Table 20.9. It is not within the scope of this chapter to describe all of the specific examples of enrichment that are used and their relative benefits to the animal. This is a specialty area by itself within laboratory animal science, and the inherent nature of successful environmental enrichment is to provide the animal with variety,[188,197] so facility managers and veterinarians are typically trying different items out on a regular basis. It is common to supply animals with several types of enrichment rather than just a single form. Therefore, it is important that scientists consider the potential for data variability from enrichment items and provide direction through the study protocol on the items that may be used or should be restricted.

Manipulanda or toys are a commonly used form of enrichment.[12] There are relatively few risks of common manipulanda items on study data. Many toys are made of inert materials such as stainless steel or plastic. Plastics can be chewed and consumed by animals so it is important to use

TABLE 20.9
Types of Environmental Enrichment for Laboratory Animals

Category	Behavioral Benefits	Examples
Manipulanda	• Provides variety. • Promotes chewing behavior. • Promotes play behavior. • Promotes noise-making behavior. • Interaction time with items reduces time spent on cage exploration that can result in injury or escape. • Reduces excessive self-grooming.	• Plastic chew toys • Hardwood chew sticks • Balls • Metal cage toys • Puzzles and activity boards • Paint rollers and grooming boards
Visual and auditory stimuli	• Provides variety. • Promotes watching and listening behaviors. • Promotes social interactions when not socially housed. • Provides white noise to reduce reactivity to external stimuli. • Acclimation to human noises. • Provides cues for routine facility activities. • Reduces baseline stress levels. • Reduces reactivity to sudden changes in light levels.	• Room, cage, and toy colors • Music, audio books, and nature sounds • Television and movies • Ability to see and hear other animals • Full-spectrum light • Moonlight • Dawn/dusk lighting control • Fresh produce
Food variety and foraging	• Provides variety of flavor and texture. • Provides fiber. • Stimulates appetite. • Stimulates foraging behavior. • Increases time spent on eating.	• Grass hay and alfalfa • Grains and cereals • Prepared snacks • Certified treats • Frozen items • Puzzle feeders • Foraging mats
Environmental control and shelter	• Control over visual and physical social interactions with other animals. • Control over thermoregulations. • Control over light exposure. • Reduces baseline stress levels.	• Nesting material • Shelters • Opaque cage panels • Separate cage compartments • Perches
Exercise	• Promotes play behavior. • Maintains muscular, cardiovascular, and respiratory health. • Maintains appropriate glucose and fat metabolism and energy balance. • Reduces baselines stress levels.	• Social exercise pens with increased cage space • Climbing swings and perches • Running wheels

materials that have been shown to be safe either through contaminant certification or through historical use, which has shown no association with physiologic effects or toxicity. Rodents and rabbits typically gnaw on these items, and while ingestion of small particles of plastic has not been shown to cause gastrointestinal lesions,[198] this material is visible in excreta or ingesta and must be distinguished from abnormal findings. Dogs and nonhuman primates may not be discriminatory when chewing on plastic items, which can result in accidental ingestion and gastrointestinal trauma.[199] It is important to only use items that are too large for them to fit completely in their mouth and are not excessively worn or cracked so that large pieces cannot be ingested. Some manipulanda can result in entrapment and subsequent injury of animals, particularly if they are suspended from the cage structure.[193,200] In an effort to find manipulanda that animals maintain interest in, there have been some natural product manipulanda that have been used, such as certain types of wood[201] and whole coconuts. These items are not easily sanitized and usually are discarded when they become soiled.

Many animals are stimulated by visual and auditory stimuli. Visual stimuli in the form of television, movies, and colored toys, cage, and room surfaces are often used for nonhuman primates.[193] This type of enrichment is unlikely to cause variability in study data. However, it is important to monitor animal reactions as there are anecdotal reports of particular videos that animals react negatively to, such as those showing predatory behavior or violence. Auditory stimuli in the form of music, human voices, nature sounds, or even white noise are often used to reduce animal responses to common noises in the facility. It is not clear whether this serves only to desensitize animals to other noises, or if there is a positive benefit from auditory enrichment. Music has not been shown to be preferred by nonhuman primates over silence[202] or food enrichment (D. Gauvin, 2012, unpublished data). The type of auditory materials should be reviewed and

approved by facility management, as some types of music, particularly very loud or rhythmical music, seem to increase rather than decrease animal stress responses.[202–215]

Another method for providing environmental enrichment is to provide food variety and foraging opportunities. The animals typically used in research are adapted to seek and consume a variety of food sources to meet their full nutritional needs. Providing a balanced diet in the laboratory environment does not alter the drive to express this behavior. Foraging is a specific activity that does not involve just food variety but instead is the work that animals need to perform to obtain the food.[12,193] Animals with continuously growing incisions (rodents and rabbits) require hard food to chew on, or a hard chew toy to prevent teeth from overgrowing.[216] Food may be mixed in with nonfood substrates to increase the time the animals spend obtaining food. Nonhuman primates and other intelligent animals will utilize puzzles with food hidden in them.[193] The challenge for scientists, facility managers, and veterinarians is to find food enrichment items that meet these behavioral needs without introducing dietary variables to studies. Odors are also important to animals and animals respond to olfactory enrichment in ways both positively and negatively.[217,218] Transfer of soiled objects to clean cages may reduce stress and aggression associated with animals reestablishing territories.[219]

Animals also benefit from being able to exercise control over their environment. This can include providing the animal with the ability to control exposure to temperature, light, elevation, and visibility to other animals.[12] Enrichment items that give the animal control over its environment include bedding and nesting material, shelters, elevated perches or vertical space in cages, opaque panels in cages, and sections of caging that are made of thermoneutral materials or are warmed. These items can be extremely important to animals but their use may be restricted because they can make it more difficult to observe animals, remove them from caging to perform procedures, or make the cages more difficult to clean.

It is important to provide animals with the ability to perform physical activity, particularly activities that are normal behaviors for those animals. Social animals will play with, groom, and nest with others.[12,193] Even some amount of agonistic behavior to establish dominance is normal and should not be interfered with unless it adversely affects the health of the animals.[12] Rodents benefit from bedding because they can burrow in it and build nests.[163,220] The use of running wheels provided in the cage results in certain physiologic changes that are generally considered beneficial to the animal but do represent potential research variables.[221–223] It is required that dogs be provided with sufficient space to allow them to exercise, preferably in groups; enforced activity such as treadmill performance does not meet this standard.[11] Cats and nonhuman primates need to have the ability to perch or climb.[11,12]

Acclimation

Animals experience physiologic stress when they are transported and are placed in a new environment. Therefore, acclimation to the new environment is required after animals are received from a supplier before they are put into a study.[12] The amount of time needed for acclimation varies by study needs and the research procedure as different systems take different amounts of time to stabilize.

Animals typically take several days to adapt to a new diet and source of water.[224] Some institutions will attempt to match the diet they use with that used by the animal vendor to minimize the risk of dietary change. Water, however, cannot normally be matched. It may have different constituents that change the odor or flavor, which can affect palatability. The method of delivery can also differ. Animals that are not adapted to the use of automatic watering systems may have difficulty in adapting and facility managers have found that water bottles, bowls, or gelatin can aid to facilitate this transition. Even if they are adapted to automated systems, differences in water pressure or the pressure needed to actuate the water valve may affect animals' ability or willingness to drink.

Socially housed animals need to establish new dominance hierarchies. This can take as little as 1–2 days.[225–228] However, behavioral adaptation to the environment and all of the activities that are performed on the animals can take longer. Training animals for study procedures can take from 1 to 2 weeks.[229,230] The effects of stress on clinical pathology and physiological parameters can range from several days to nearly 2 weeks after transportation.[231–235] This also makes animals more susceptible to infection during this time and they are at risk of anesthetic complications, particularly within the first few days of transportation (S. Adrian, DVM, personal communication), perhaps due to decreased immune function, or perhaps due to direct effects of transportation.[236]

Research Procedures

Many procedures for creating an animal model, administering test article, and collecting data have the potential to affect the welfare of animals and the quality of the data derived from the model. Methods to control these variables are refinement alternatives. Animal welfare regulations and standards specify some aspects of the conduct of research procedures, but in not nearly the detail that is specified for housing and husbandry requirements. Best practices within the industry have evolved. Some of these have been published, but not all, so each institution has IACUC-approved policies and standard operating procedures (SOPs) for the conduct of these procedures at that institution. If the decisions made to create these procedures are not based on data from controlled experiments, but rather from experience and collective wisdom, this information is unlikely to make it into the peer-reviewed literature. In addition, many journals do not include details of procedural refinements in the Methods sections of articles, except in the few publications dedicated to laboratory animal science and alternatives (Table 20.10). Textbooks and abstracts from professional meetings can be useful references for this type of information. In addition, policies from public institutions tend to be available via the internet and it is common practice for institutions to review these when developing their own policies.

These internal policies essentially represent the refinement alternatives that the institution has identified that are relevant to the majority of work it conducts. Additional refinements may still be needed on a study-by-study basis. Scientists are required to indicate within their Animal Care and Use Protocol the refinement alternatives they have considered and the justification for not incorporating available alternatives into their study design.[11,12]

Physical Restraint

Many research procedures require the animal to be physically immobilized to perform them properly and to prevent injury, pain, or distress to the animals in the process. Chemical restraint can and should be used where appropriate (see section on "Anesthesia and analgesia") but is not scientifically appropriate, practical, or necessary for many situations.

The most basic and commonly used form of physical restraint is manual restraint. Animals are normally removed from their cages, manipulated, and restrained by one or more persons to complete a variety of procedures such as cage changing, examination, body weight collection, dose administration, blood collection, or transfer to other data collection devices. It is essential that personnel are trained in proper methods of handling and manual restraint.[11,12] The reader is referred to published resources for these methods.[1,237–239] For some animals and some methods of restraint, PPE is needed for the handler to avoid injury. Protective gloves are appropriate to protect against bites and scratches. However, they can reduce dexterity, which in some cases has the potential to prevent proper restraint from being provided. In the author's experience, if personnel are initially trained in animal handling with the use of protective gloves, they do not experience the same problems as those who are experienced in performing manual restraint without protective gloves who then try to begin using them.

Most animals require some amount of acclimation to manual restraint. Acclimation to manual restraint may begin with the handler talking quietly to the animal, offering positive reinforcement such as a food treat or stroking the animal when the animal approaches the handler, and then handling the animal for short periods of time while also providing positive reinforcement before proceeding to longer periods of restraint.[12] All animals benefit from this type of acclimation but it is particularly critical for larger animals that are more capable of escaping or injuring the handler.

In addition to manual restraint, there are a variety of restraint devices that can be used to restrain animals for longer procedures such as intravenous (IV) infusion or repeat blood collection. These can include restraint tubes for rodents and rabbits, slings for dogs and swine, and chairs for nonhuman primates.[240–244] Animals require acclimation to restraint devices to prevent excessive stress or risk of injury. Animals need to be monitored while they are in restraint devices to make sure that they are breathing normally and extremities are not entrapped in the device. Waste should be cleaned regularly to prevent animals from becoming soiled. If animals are to be maintained in restraint devices for an extended period of time, they may need to be provided with food or water and it is recommended that they be released for a period of time to allow normal movement. This is a specific requirement for nonhuman primates.[11]

There are methods for facilitating dose administration and data collection that provide relatively free movement of animals such as the use of jackets, wraps, and tethers.[245,246] Animals may need acclimation to these methods as with other restraint devices, and the animals need to be monitored

regularly to ensure that the system is not confining the animal or creating a risk of entrapment or injury.

Dose Administration

Administration of test articles has the potential for complications that can result in pain or distress to animals. Refinements in dosing procedures include controlling the volume administered, the pH, and the osmolarity to prevent tissue damage, hemolysis, pain, or inflammation.[244,247,248,251] Recommendations for dose volume and needle size parameters are listed in Tables 20.11 through 20.13. These factors are interdependent. For example, it is not advisable to administer a test article near either extreme of the pH range at a high volume. IV administration can be used for administration of test articles that are closer to the extreme end of the range for pH (between pH 2 and 11) or osmolarity (between 100 and 900 mOsm/L) compared to other parenteral doing methods because the test article is rapidly diluted into the blood and because the blood has significant buffering capacity. However, blood vessels are relatively fragile and repeated or prolonged administration of irritating test articles intravenously can cause significant inflammation or phlebitis. Intramuscular (IM) and intraperitoneal (IP) dosing routes are more tolerant of irritating test articles than subcutaneous (SQ) routes because blood flow to these tissues is higher, which absorbs the material more quickly to prevent development of inflammation. However, the volume that can be dosed IM or IP is lower and the pain associated with the injections is greater than with the SQ route. Enteral (oral or PO) dosing is relatively tolerant of pH extremes and can accommodate a relatively larger volume compared to parenteral routes. For parenteral routes of administration, the needle needs to be sized appropriately. A smaller needle is less painful to inject than a larger one, but may require longer time to administer the dose, particularly if the dosing material is viscous. Care must be taken to ensure that the parenteral doses are administered aseptically to prevent infection.

Oral dosing can be accomplished by administration of a dry form in a tablet or capsule, or by liquid forms through an orogastric or nasogastric gavage tube. Tablets and capsules are relatively easy to administer to dogs or cats, but are relatively difficult to administer to other species. Gavage is the most common enteral dosing method for rodents, rabbits, and nonhuman primates. A risk of gavage dosing is accidental intratracheal (IT) administration of the test article. This can result in foreign body pneumonia and may change the absorption kinetics of the test article. Perforation of the

esophagus is another risk of gavage dosing that results in localized infection and also alters the absorption of the test article. With enteral routes, selection of the appropriate gavage tube is important. A larger gavage tube will allow the dose to be administered more rapidly, but there is more risk of injury to the animal. Smaller tubes can be safer to use, but they are more flexible and may be harder to insert and guide into the esophagus. This can increase the risk of accidental IT administration. Rigid metal gavage tubes have traditionally been used in rodents, but there may be a greater risk of esophageal perforation when used by inexperienced personnel than newer flexible plastic designs. However, some individuals find it harder to appropriately direct a flexible gavage tube and feel the risk of IT instillation is higher with a flexible tube than a rigid one. It is also possible for flexible tubes to be bitten off by the animal and the cut end needs to be retrieved from the esophagus, possibly with the use of anesthesia.

Test articles may need to be administered into tissues or spaces that are difficult to access, such as the bone marrow, a joint space, the CNS, a region of the heart, or other specific organs or tissues. Often animals must be anesthetized for these procedures, both because of the potential for pain with the method of administration and because of the need for complete immobility of the animal to allow precision placement. They typically also require a greater emphasis on aseptic methods because of the invasiveness of the procedure. Some of these methods benefit from the use of imaging technologies such as fluoroscopy, ultrasonography, and even magnetic resonance imaging to ensure precise delivery of the test article.

For some studies, the test article must be administered very frequently or continuously to achieve and sustain the desired level of systemic exposure. Because frequent dose administration increases the risk of dosing error or injury with each dose, indwelling catheters are indicated for this purpose. Catheters are typically placed intravenously, but they may also be placed into other tissues such as the SQ, intracerebroventricular, intrathecal, osteomedullary, or IP spaces; the gastrointestinal lumen; or intravascular with the tip localized to specific sites. Placement and maintenance of these catheters must be performed with appropriate anesthetic and analgesic protocols using aseptic technique. If indwelling catheters are exteriorized, they have a relatively limited duration of use because infections commonly develop in and around the catheter site. Animals also may not be able to be socially housed when an exteriorized catheter is in place, as there is risk of cage mates damaging the catheter or surgical site. However, the author has observed successful social housing of animals with exteriorized catheters when the animals were provided additional environmental enrichment to divert their attention from the catheter. The use of subcutaneously implanted vascular ports significantly improves the longevity of indwelling catheters. They require routine maintenance and there is still risk of infection, but it is lower than with exteriorized catheters.[249–251]

Vehicle selection is also an important factor in dose administration. Some vehicle components that are used to improve solubility of the test article or improve absorption may have adverse effects when administered.[244] For example, surfactants can result in histamine release.[244] This type of reaction can occur at low dose levels and can be serious when they occur. However, it is relatively easy to treat or prevent through the use of antihistamines. Other risks include tissue inflammation and osmotic damage at the site of administration or hemolysis with IV dosing.[251] A full discussion of vehicles is beyond the scope of this chapter and the reader is referred to publications on this subject.[244,247]

Because of the numerous factors when making decisions around dose administration, institutions should have centralized training resources or institutional policies to collect and share experience with dosing methods to ensure the best outcomes for studies and for animals.

Collection of Biologic Samples

Refinement of procedures for the collection of biological samples is also an important consideration for animal welfare and data quality. Many of the considerations for sample collection are similar to those for dose administration. Typically, blood and other body fluids are accessed through a hypodermic needle using manual restraint. But depending on the fluid space, volume required, and frequency of collection, indwelling catheters may also be used. Both exteriorized catheters and those with vascular access ports are appropriate for body fluid collection.[244] These catheters may require chemical restraint or anesthesia to implant, but then require minimal restraint for subsequent use. Technology for automated blood sample collection now exists that significantly reduces the labor associated with repeat sample collection.[244] Aseptic procedures are important for preventing infections when collecting biological samples by any parenteral route.[244]

There are numerous routes for blood collection, and the preferred method varies by the species, size of the animal, and the parameters being measured.[252] There can be some variability in clinical pathology parameters and test article distribution depending on the site of collection.[253–257] In most cases, these differences do not affect the interpretation of data as long as all samples are collected by the same method. However, it can be problematic when comparing results among samples collected using different methods. It can be done, but there is more intersample variability that reduces sensitivity for detecting significant differences.

Handling, physical restraint, and anesthesia can all affect clinical pathology parameters and other data.[1,258–265] This means that a scientist cannot avoid these effects completely, but must choose the method that has the least significant or variable effect on the parameters being measured. Modifications to standard procedures such as the use of a rapidly acting anesthetic like carbon dioxide inhalation, or a physical method of euthanasia such as decapitation, cervical dislocation, or microwave irradiation, may be needed for some endpoints. Indwelling catheters can be useful for the collection of this type of data as the animal may require minimal to no restraint. However, the effects of anesthesia and surgery on the parameters being measured can persist for up to a week after implantation of these catheters, and more study planning is required when using these methods (A. Aulbauch, Dipl. ACVP, ASVCP, personal communication).

Another source of variability in biological data resulting from the sample collection method is associated with tissue damage or contamination that can occur during collection. Needle collection of samples typically results in the least amount of tissue damage to the sample, but if a collection needle is inappropriately sized or the sample is aspirated too quickly, hemolysis can result, for example, with blood collection.[266,267] Hemolysis can interfere with the instrument reading of some assay results, but can also result in artificial elevation of intracellular constituents such as aspartate amino transferase, glucose, or alkaline phosphatase.[268] Some serum chemistry parameters can also be elevated through muscular injury from physical restraint (e.g., in fractious nonhuman primates) or sampling methods that cause leakage of intracellular fluid such as tail or retroorbital sinus collection.[269,270]

One method of blood collection that has created significant controversy within the laboratory animal field is retro-orbital sinus blood collection in rodents.[1,270] This is a method that was used historically without anesthesia, but in recent years animal welfare oversight bodies view this as a painful procedure that requires anesthesia. However, even with anesthesia, injury can occur to the eye or adjacent structures, which results in pain and distress to the animal, and may require euthanasia. These injuries can be treated with antibiotics and anti-inflammatory drugs, but this may be contraindicated depending on the study requirements. The incidence of these injuries can be reduced with some simple preventative measures, such as the use of appropriate size collection tubes, application of vasoconstrictors and direct pressure placed on the orbit to prevent hemorrhage, and early detection and treatment of any evidence of orbital damage.[271] Nevertheless, many institutions have policies restricting the use of retro-orbital blood collection unless there are no acceptable alternatives. Methods such as submandibular, saphenous, sublingual, or tail vein collection can provide useful samples in most situations.

It is important to manage the volume of blood and other body fluids collected to prevent health problems in animals and adverse impacts on study data. There are limited data to support volume standards for most fluids except blood; however, the considerations are similar. If blood is removed faster than the animal can replace it, anemia, hypoproteinemia, or hypovolemia can result.[252,270,272,273] Typically, these will have adverse effects on data quality before they affect animal health. While up to 40% has been removed in rats without adverse clinical effects,[252] clinical pathology data can be affected by removal of as little as 10% of the blood volume.[270] Variability in serum albumin can have significant effects on drug distribution and effects.[274] If larger volumes are required for assays, isotonic fluids or colloidal fluids may be administered to prevent the acute hypovolemic effects of blood loss.[272] However, this may require waiting for several weeks to allow blood constituents to be replaced before additional samples are taken. If large volumes of blood are required for an assay and it must be obtained from small animals, separate cohorts of animals may be required and the blood collected as a terminal procedure. As a general rule, it is safe to collect a volume of blood equivalent to 1% of an animal's body weight (i.e., 10 mL/kg) at a single time, or as a cumulative volume over a 2–4-week period.[252,275]

There is less information on guidelines for collection of other body fluids than for blood. Approximately 200 µL of joint fluid has been collected from rabbits[276] and 300 µL serially from larger species such as sheep and dogs (S. Adrian, DVM, personal communication). Aqueous and vitreous humor has been collected from swine at volumes of 200 µL.[277] Between 50 and 500 mL of fluid can be instilled and collected in dogs for bronchoalveolar lavage,[278] and a volume of 0.1 mL has been used in rats.[279]

Cerebrospinal fluid (CSF) is commonly collected for the measurement of test article distribution into the CNS and the biological effects of the test article. This procedure is typically performed on an anesthetized animal, particularly when collected from the cisterna magna. Collection from the lumbar region of livestock is sometimes performed on conscious, restrained animals using local anesthesia. At least one dose of postprocedural analgesia is recommended. Repeat collections of CSF may be performed using a percutaneous method, but there is risk of inflammation, infection, injury to the spinal cord, and hemorrhage into the CSF, which is detrimental to sample quality. In the author's experience, between two and four collections in an initial 24 h period are possible, and subsequent collections spaced several days to a week apart can be successful as there is sufficient healing of the collection site to prevent chronic traumatic injury. The risk of repeated anesthetic episodes is at least equal to the risk of direct complications from the procedure. Implantation of indwelling epidural or intrathecal catheters should be considered where frequent collection and uncontaminated samples are needed.

The volume of CSF that can be collected tends to be limited more by the small amount of intrathecal or epidural space and the practical aspects of safely collecting an uncontaminated sample, rather than by the risk of CSF depletion. Single collection volumes of 5–15 µL have been reported in mice[280]; 50–100 µL in guinea pigs and rats[281–283]; 1.5–2 mL in rabbits[1]; and 1 mL in rhesus macaques,[284] and 1 mL/5 kg body weight is recommended as a maximum volume in dogs, cats, and horses.[285] These volumes can generally be repeated within the recommended intervals as CSF production rates have been reported to range between approximately 2 and 13 µL/kg body weight/minute[286,287] in different species, and therefore, it is rapidly replaced. It is possible to exceed this rate of collection through a catheter, but there is little risk with percutaneous collection. One author describes replacement of collected CSF volume with saline.[284] This may be indicated to maintain intracerebral pressure when large volumes are removed, but this may affect the quality of future samples until the infusate is replaced by CSF.

In some cases, solid tissue samples may be required to assess the effects of a test article. Biopsy specimens can be collected as a survival procedure with the appropriate use of anesthesia, analgesia, and aseptic collection methods. Historically, repeated collection of intra-abdominal biopsy specimens, such as liver, was constrained by the potential for pain or distress due to repeat major survival surgery. However, the use of less invasive methods, such as endoscopic surgery or ultrasound-guided percutaneous biopsy, has allowed these samples to be collected in a manner that is consistent with animal welfare standards.[12]

Collection of some biological samples, such as feces and urine, does not directly impact the welfare of animals. However, in order to obtain uncontaminated samples, specialized caging may be required. This caging may not meet all of the regulatory standards for cage size and construction, or animals may require individual housing, therefore, specific approval by the IACUC will be required. Caging or housing that does not meet standards should be used for the minimum time necessary to obtain the needed samples, and animals should be returned to normal caging once the collection is complete.

Physiologic and Behavioral Monitoring

Monitoring animals for physiological or behavioral changes resulting from test article administration can present a challenge if the method of monitoring affects the parameters being measured or results in pain or distress to the animal. For example, cardiovascular and respiratory parameters, body temperature, and electronic activity of the heart, brain, or muscle all require instrumentation that is attached to, or implanted into the body to measure them. With acclimation, animals can be maintained in restraint devices while these parameters are measured. Sedation or anesthesia can be used for some measurements as long as the effects of the anesthetic used are known. However, the development of portable external and implantable telemetry has greatly improved the sensitivity of these measurements.[288] While surgical implantation of telemetry devices is invasive, appropriate postoperative care minimizes animal welfare concerns, and animal welfare is improved for subsequent research as there is no restraint required for data collection. In addition, the enhanced sensitivity of these systems allows safety assessments to be performed using lower dosages of drugs that would be required with a less sensitive system, which also represents an animal welfare refinement and provides data on subclinical effects of the test article.

Monitoring of respiratory parameters may require a device that encloses the head or the entire animal.[289] As these chambers may be restrictive, it is important to acclimatize animals to them and to monitor the animals during use. They must also be cleaned and disinfected appropriately so they do not serve as reservoirs for microorganisms that can cause disease.

Behavioral monitoring does not usually require direct instrumentation of the animal but may require housing that does not meet animal welfare standards.[290,291] This monitoring may need to be performed outside of the housing room due to the monitoring equipment being used or the need to isolate the animal from environmental variables that may be present in a general housing area. These monitoring facilities still need to meet the general requirements for animal housing in which they need to have adequate ventilation and environmental control and be kept clean and be sanitized periodically. However, because the number of animals and the duration of housing in these areas are typically lower than in a general housing space, the infrastructure needed to meet standards may be somewhat less involved. The cage space available in operant conditioning chambers may be less than that required by standards and manual cleaning may be required to prevent damage to the electronics. If a swimming test is used, the water needs to be maintained at a temperature that will prevent hypothermia.[291] Animals may need to be dried or provided heat at the completion of the test. Scientists need to have their veterinary staff and IACUC review these housing areas and monitoring equipment and approve them for use. Periodic inspections are performed in these areas as part of the semiannual facility inspection and program review.

Pain Research and Aversive Stimuli

Some research procedures are performed to assess physiologic mechanisms of pain, pain response, or use aversive stimuli to elicit certain behaviors in animals. Refinement of these procedures to minimize pain or distress is challenging as pain is an expected and necessary outcome. The level of pain created should be limited to that which can be reliably measured and that will respond to clinically relevant exposure levels of the test article. The painful stimulus should also not cause tissue injury unless chronic pain is the goal of the study. A model of chronic pain or inflammation need not cause more than localized clinical signs of pain to be biologically relevant. In fact, if the model is severe enough to result in signs of distress, such as weight loss or decreased activity, it is likely that the model will have more variability than desired because there are systemic effects of the model that are more difficult to control than local effects.[291]

Anesthesia, Analgesia, and Surgery

One of the key requirements of animal welfare regulations and standards is that surgical procedures are performed aseptically using appropriate anesthesia, and that analgesics be used following surgery and any time the animal experiences pain, unless doing so will interfere with the goals of the study.[11,12]

Surgery

Aseptic technique for surgery includes a variety of procedures, all of which work together to minimize the exposure of tissues to microorganisms and prevent postoperative infection.[12] Details of aseptic surgery requirements are provided in other resources but the general approach to asepsis is to prevent organism from the animals' skin, the surgeon, or the environment from entering tissues that are exposed during surgery. This begins with proper surgical facilities, as previously described, to isolate the operating room, sterile instruments, and the surgeon from the animal while it is being prepared. Animal hair needs to be removed and the skin prepared antiseptically to reduce the microorganisms on the skin. The surgeon dons clean clothing, a hair cover, mask, and sterile gloves to minimize exposure of the surgical site to skin bacteria, hair, saliva, and other contaminants.[12,292]

Surgical instruments, supplies, and any implanted devices need to be sterile. Sterilization is normally achieved by autoclaving, or with chemicals such as ethylene oxide, vaporized hydrogen peroxide, glutaraldehyde, or hydrogen peroxide/peracetic acid mixtures. Sufficient exposure time for these sterilization methods is critical to their success and sterility needs to be monitored for each batch and each item or package that is sterilized. Less effective antiseptics or disinfectants, such as alcohols, iodophors, or chlorhexidine, are not sufficient for sterilization of surgical materials because they do not eliminate bacterial spores.[12,292]

Surgical technique is also critical for maintaining asepsis. The surgeon needs to be extremely careful not to touch anything outside of the prepared surgical field. This can be

challenging when using specialized equipment for surgical conduct, monitoring, or data collection. This is not a one-person task. Having assistants to manage anesthesia and surgical equipment is critical. In addition to maintenance of asepsis, surgeons need to be skilled in general surgery techniques as well as the specific procedure being performed. Excessive tissue damage and extended surgical time result in devitalization of tissues, increasing the risk of postoperative infection.[292]

Historically, the application of these methods of surgical asepsis has been applied to nonrodent species without question, but rodent surgical technique has often been abbreviated, perhaps in part to accommodate the relatively high volume of nonrodents that are surgically modified for a typical study. However, rodents are equally susceptible to infection and suffer from the same physiologic consequences as any other species. In fact, they are the standard model for studying surgical site infections. Therefore, aseptic technique is just as important to the success of the model and maintenance of animal welfare with rodents as with nonrodents. The methods for achieving asepsis can be modified slightly and still be effective due to the smaller surgical field and shorter surgical times.[292] However, doing so puts particular emphasis on attention to detail and the skill level of the surgical team. To some extent, application of traditional aseptic technique is more forgiving of error than methods that are developed for production purposes.

Because of all of these requirements, surgical programs benefit greatly from being centralized within an institution rather than having each investigator attempt to establish the required facilities and maintain the equipment and skills needed to meet surgical standards.

Anesthesia and Analgesia

The need for anesthesia during surgery or other painful procedures is well established. Animal welfare standards are specific about the requirement for the use of appropriate anesthetic and additional monitoring when neuromuscular blocking agents are used during anesthesia, due to the risk of providing an insufficient depth of anesthesia and the loss of ability to monitor depth through reflex activity.[11,12]

Historically, there has been more controversy over the requirement for analgesics, particularly when performing surgery in rodents. This is likely because the signs of pain in rodents are not as well recognized as those in nonrodents and perhaps also because the relative moral value ascribed to rodents tends to be lower. However, rodents feel and respond to pain and are a standard model for pain research.[293]

A common argument against the use of analgesics following surgery and when animals are experiencing pain for other reasons is concern that the drugs used will interfere with study data interpretation. However, the consequences of *not* relieving pain are often overlooked. Pain has immediate and long-term effects on neurobiology, behavior, and cardiovascular function, some of which are well defined and some of which are not.[293] By contrast, analgesic drugs have relatively well-defined effects and typically only require administration for a short period of time to prevent or relieve pain in animals.[1,293,294] When used at therapeutic levels, their effects on the research model can be predicted and interpreted along with study data.

It may seem self-evident that analgesic drugs cannot be used with models of pain. However, this is not necessarily true for all models. For example, surgically induced neuropathic pain models may be provided with analgesia in the immediate postoperative period to relieve the acute pain of surgery.[295] The drug will be eliminated before data measurement begins as the condition takes a week to develop following surgery. Also if pain is resulting from an injury or condition that is not a planned part of the model, then the pain represents a variable that can adversely affect the quality of data from the model. Short-term treatment to remove this variable may be necessary for the long-term success of the model.

Veterinary Care and Euthanasia

While considerable effort is put into refinement of study procedures to minimize the potential for pain or distress in research animals, the ultimate goal of toxicology research is to study mechanisms and manifestations of serious adverse events associated with the test article. This means that at some point, many animals on these studies will reach the point where they require veterinary care or even euthanasia to relieve the pain or distress. As discussed previously, there must be scientific justification approved by the IACUC to allow animals to experience pain or distress without providing appropriate relief.[11,12] The approval is for pain or distress specifically related to the study that is inherent with the study goals. If pain or distress results from another reason, such as spontaneous disease, injury, or unexpected adverse events, the original IACUC approval may not include these outcomes as being scientifically justified reasons for withholding veterinary care or euthanasia.

Humane Endpoints

In order to accurately assess the toxicological effects of a test article and compare these effects across studies and different classes of test article, it is necessary to have an endpoint that is measurable and consistent. In the early days of toxicology research, one of the clearest endpoints was the death of the animal, and traditionally, the toxicity of the drug was expressed as a lethal dose. However, the advancement of science and the advancement of animal welfare have gone hand in hand. When it was recognized that microscopic examination of tissues provided important information on the mechanisms of toxicity, it became desirable to euthanize and necropsy animals rather than allow them to die spontaneously and allow tissues to degrade through autolysis. Currently, toxicity is often defined through clinical signs, changes in clinical pathology parameters, gene expression, and other biomarkers of changes at the systemic and cellular levels. These data can often be collected prior to the presentation of significant clinical signs that represent pain or distress in animals. When these types of parameters are used

to define toxicity, it is termed a *humane endpoint* and it represents a significant refinement alternative. Technically, the endpoint is the point at which the study data can be collected. In practical terms for a toxicity study, it usually means the point at which dosing is completed and animals are euthanized. Euthanasia is the ultimate way to prevent pain or distress in animals experiencing toxicity but veterinary care can be provided to relieve pain or distress to get animals past a point of acute toxicity to another study endpoint.

Humane endpoints should be applied whenever possible in toxicity studies and should be discussed in the application to the IACUC, particularly when describing justification for doses selected and the plan for veterinary care or euthanasia. Humane endpoints have been embraced by most scientific and regulatory agencies, and various standards have been published.[296,297] The key to applying humane endpoints is to understand when it is and is not scientifically valid to do so. Definition of an MTD for an investigational new drug (IND) application must take into account a number of considerations that make the clear definition of a safety study endpoint challenging. The initial presentation of toxicity may subside with repeated dose administration.[298,299] Therefore, it may not be appropriate to stop dosing in the face of adverse effects until it is known whether the effects will be sustained. For some test articles, such as antineoplastic drugs, the accepted safety margin is narrow and a certain level of toxicity is expected in animal studies. Animals may be dosed in the face of this toxicity so that underlying, additional toxicological effects can be detected. Another challenge with safety study endpoints is seen when trying to define the mechanism of toxicity but the clinical signs or clinical pathology are not definitive. This is often a problem when toxicity presents peracutely after dosing. Continued dosing may be needed to allow development of signs, physiological changes, or tissue lesions that will provide this information. An additional case that complicates humane endpoint determination is when the high dose on a study is showing significant signs of toxicity, but the mid dose is showing no signs. In this case, it may be necessary to reduce the high dose slightly to identify the dose–response level rather than discontinue dosing or euthanize the animals. The scientist may also choose to stop dosing an animal experiencing significant toxicity, but must determine if the toxicity is reversible and cannot euthanize the animals immediately. A final consideration is that it may be better to allow more severe toxicity to develop during studies that are early in the development of a particular test article so they can be thoroughly characterized, which then allows for better definition of a humane endpoint in later studies. Early stage studies typically use smaller numbers of animals, and are not generally conducted according to GLP standards. There is also some flexibility to allow collection of data that was not originally planned, which improves the mechanistic understanding of the cause of the toxicity.

Clinical Care

In all cases where pain or distress is seen in animals, there should be an attempt to provide veterinary care to relieve pain or distress in animals, but the specific care may be limited so that therapeutic drugs do not directly interact with the test article or obscure assessment of the mechanism of toxicity. Historically, veterinary care for animals on toxicology studies, particularly those run according to GLP standards, was severely limited by concerns about interference with the interpretation of study results. However, this is changing along with the mechanistic approach to characterization of the safety profile of a test article. The effects of standard methods of veterinary care are well understood because they were developed using the same process by which new test articles are evaluated and these data are published and available to help with interpretation of study results in light of the care provided.[300] Veterinary care normally only needs to be provided for a limited period of time to relieve pain or distress. For a longer-term study, the effects of several days of treatment are not likely to interfere with data interpretation. If they are, and if the animal cannot maintain a physiological balance without veterinary care, this is often sufficient to define the MTD for the test article. Finally, veterinary therapeutic drugs are administered at clinical dosages that are magnitudes of order lower than the dosages of the test articles that are causing toxicity. These drugs are not likely to cure the animal of the toxicity, but instead are intended to relieve the most serious effects of the test article and allow the animal to maintain a more normal physiological balance until it reaches the planned study endpoint. Veterinary care is not normally provided for minor clinical signs of toxicity, so the likelihood that it will obscure subtle evidence of toxicity is low. However, therapeutic levels of drugs could be a concern where the data collected are physiological in nature rather than toxicological, as with safety pharmacology, fertility, or combined efficacy/safety studies. However, even in these situations, the physiological effects of untreated disease, pain, or distress on study data must be weighed against the effects of the veterinary care. As previously stated, veterinary drugs are well defined, whereas the effects of unrelieved pain or distress can be extremely variable.[301]

Diagnostic tests may need to be performed to diagnose the nature of a problem an animal is experiencing, determine the prognosis, and develop a veterinary care plan. Diagnostic test results contribute to the study dataset, and therefore, scientists and veterinarians need to discuss this testing to ensure that it is collected in such a way that it can be appropriately interpreted. Some testing equipment may not be validated or results may be needed immediately to aid in the veterinary care plan without time for proper quality control checks. Interpretation of some tests, such as radiography or ultrasonography, is subjective, requiring professional veterinary interpretation that can be difficult to consistently repeat. These data are appropriate for the evaluation of animal health, but if there are findings that might add additional information to the study dataset, these tests may need to be repeated on all animals in the study using appropriately controlled and validated assays or equipment. Veterinary records and standard operating procedures should also be written so that it is clear that veterinary observations and diagnoses are

provisional, based on limited datasets, and that final interpretation is dependent on final collection of all study data and evaluation by the scientist.

The most common type of veterinary care that is provided to animals on toxicity studies is supportive care. This is normally nonpharmacologic nursing care that is provided to assist the animal in maintaining its own physiological functions. A common example of this supportive care is providing food items with greater palatability or enhanced nutritional levels to compensate for decreased food consumption. Food supplementation can, however, interfere with the interpretation of body weight and body condition data, and of course quantitative food consumption.

Animals may become dehydrated when they are not eating, or when there is vomiting, diarrhea, renal toxicity, or blood loss as a consequence of test article toxicity. Supplemental fluids provided subcutaneously, intravenously, orally, or through high water content gels or supplemental food items provide immediate and significant improvement in the animals' condition. Aside from fluid consumption measurement, the primary ways that fluid supplementation will interfere with data interpretation are with the detection of clinical signs of dehydration or changes in clinical pathology associated with hemoconcentration or fluid loss. Subcutaneously administered fluids can be mistaken for tissue edema at necropsy and the necropsy team needs to be aware of any veterinary care provided for this reason. Supplemental heat or nesting material to improve the animals' ability to thermoregulate can also be important for supportive care. This is unlikely to interfere with study data interpretation unless body temperature is the primary data on the study. Thermal burns are a risk with heat supplementation and if this occurs, it needs to be communicated to the pathology team.

Pharmacological veterinary care may be indicated for some conditions and study types. It is not possible to address all of the potential therapeutic protocols that may be used, but some common types of treatment are discussed here. While there are scant data in the literature on the potential effects of veterinary therapeutics on the interpretation of toxicological study data,[1] the mechanism of actions and safety levels of these drugs are well characterized[300] and educated decisions can be made when faced with a decision between providing veterinary care and having to remove the animal from study.

The use of analeptic drugs for animals experiencing seizures is indicated to gain immediate control of the situation and prevent injury or death. A choice needs to be made whether to continue dosing the animal at the same level with the hope that the animal will accommodate to this effect, to reduce the dose, or to stop dosing completely. Typically, a single IV dose of a benzodiazepine drug will control a seizure seen on a safety study. As exposure drops below the peak level, these signs normally resolve. If the effect is prolonged, a second dose of the analeptic drug may be indicated, or a longer acting drug like a barbiturate may be required. In the author's experience, if a seizure persists beyond the duration of a barbiturate, the animal is not likely to recover within the same day and euthanasia is indicated. It is generally not practical or scientifically necessary to provide prolonged intensive care for an animal with significant neurological signs.

Gastrointestinal toxicity and emesis may benefit from veterinary care with supplemental fluids, antiemetics, gastrointestinal protectant drugs, or antidiarrheal drugs. These treatments prevent the animal from becoming dehydrated, malnourished, or developing permanent secondary problems such as gastrointestinal hemorrhage or bacterial translocation and sepsis. These drugs are relatively short acting, and once the animal is stabilized, they may be discontinued and the drugs will be eliminated without persistent effects. Dosing may be continued while these drugs are in use but orally administered test articles need to be given several hours before or after administration of gastrointestinal protectant drugs or absorption will be reduced.

Antihistamines are indicated in the event of an anaphylactoid reaction to a test article or vehicle. Once anaphylactoid reactions have been seen, they will likely continue with each subsequent dose. It is not uncommon for antihistamines to be used prophylactically prior to dosing to prevent these reactions. Antihistamines that are rapid acting and have short half-lives such as diphenhydramine are available. They are used relatively commonly with general safety or immunotoxicology assessments of test articles and their use has not been identified as a significant study variable.

Antibiotics and other anti-infective drugs are often indicated in animals for perioperative surgical care, to treat spontaneous infections, or to prevent sepsis when animals are injured, are experiencing gastrointestinal toxicity, or immunosuppressive effects of a test article. As with other therapeutic drugs, considerable information is available on the pharmacology and pharmacokinetics of antibiotics. In addition, the available drug classes for antibiotics are perhaps wider than with any other type of drug, which allows scientists and laboratory animal veterinarians to work around specific restrictions for the test article that is being evaluated.

Anesthetics, sedatives, and analgesics are another group of drugs that are frequently used to provide veterinary care. There are multiple classes of anesthetics and sedatives available, which also allow them to be used with relatively little risk of interference with study data aside from CNS evaluations. There are fewer options with analgesics, particularly with drugs that have a long duration of action. This is desirable when the analgesics need to be administered to a large number of animals. The two primary classes of analgesic drugs used are opioids and NSAIDs. Opioids will impact the assessment of any test article that acts at the opiate receptor and can affect behavior, pulmonary function, gastrointestinal motility, and the immune system.[1,302] NSAIDs act on both the cyclooxygenase and lipoxygenase branches of the arachidonic acid metabolism pathway. In addition to impacts on test articles with activity on these pathways, NSAIDs affect platelet activity, can cause gastrointestinal mucosal bleeding, and in a dehydrated animal can increase the risk of renal toxicity.[302] Despite these challenges, analgesics are important for the relief of pain and distress in laboratory animals

and there must be clear evidence that the use of analgesics will interfere with data interpretation to scientifically justify withholding their use. It cannot be based on a possibility of interference.

Under some circumstances, a variety of other drugs may be used in laboratory animals. Corticosteroids may be required for dermal conditions, acute inflammation, immunologic reactions, or intracerebral edema. Drugs to treat abnormal cardiac function, blood pressure, pulmonary edema, or respiratory arrest may be indicated in emergency situations. Clearly, these drugs can have a myriad of effects on systems that may be evaluated as part of a safety study. Their use needs to be balanced against the risks of not treating the condition or losing the animal from the study.

Euthanasia

The final decision that typically must be made as part of veterinary care or refinement of a study is euthanasia of an animal that is experiencing pain or distress. Criteria for euthanasia of animals should be detailed in the IACUC-approved protocol or, in the case of unexpected signs of toxicity, generic facility guidelines for endpoints that balance animal welfare and scientific needs.

In some cases, the condition of the animal is such that euthanasia must be performed immediately to prevent the animal from suffering unnecessarily, and to collect viable samples for data analysis. It is important that any final data that need to be collected be clearly detailed in the study protocol or that there is communication between the scientist, veterinary staff, research staff, and necropsy team to determine if specific samples need to be collected before the animal is euthanized. In order to prevent delays in euthanizing animals that are in acute distress, it is important that trained staff are available at all hours to euthanize all species of animals that are being used, and that supplies and processing equipment for the samples that need to be collected are also readily available. If necropsy cannot be performed immediately, the animal should be placed into a refrigerator to preserve tissues until the necropsy team can complete the procedure. Freezing of the animal will damage tissues for microscopic examination. However, if microbiological or DNA samples are important, freezing may be indicated to preserve sample quality.

Methods for euthanasia need to be consistent with guidelines from the AVMA.[38] Euthanasia methods need to cause rapid unconsciousness before death and should not result in distress to other animals that may be present at the time of the procedure. Most euthanasia methods use an overdose of anesthesia to cause rapid depression of CNS function and cardiopulmonary arrest. For some studies, these drugs will interfere with endpoint data that must be collected and a physical method of euthanasia that rapidly disrupts CNS function may be needed (e.g., cervical dislocation, decapitation, or captive bolt). Because physical methods of euthanasia are more difficult to perform properly than an anesthetic overdose, and the inherent aesthetic concerns with them, scientific justification is required for their use, and procedures for training of staff in their use and maintenance of equipment are required.

The effects of exposure of animals to the euthanasia of other animals are controversial. If animals experience distress, pheromones can transmit stress responses to other animals.[1] However, the relative stress response associated with observation of euthanasia may be no more significant than that experienced during normal husbandry activities.[303]

Animal Reuse

Not all studies require euthanasia of animals to collect final data. Animals may be used for more than one study if doing so does not result in additional risk of pain or distress to the animal and if the prior use of the animal does not adversely affect the ability to collect quality data on a subsequent study. Appropriate reuse of animals represents a reduction alternative and is commonly employed with species that are costly or in short supply, as with nonrodents, or models that have specialized training or instrumentation. While reduction of overall animal use is in of itself an important goal, there is a direct trade-off between reduction and refinement, as multiple uses of animals expose them to repeated risks of pain or distress from study procedures and endpoints.[12] Animals are commonly reused for acute toxicity, pharmacokinetics, safety pharmacology, and behavioral studies and for staff training or blood donation for in vivo assay development. In order to minimize the risk of pain or distress that is compounded by reuse, it is important to periodically perform an animal welfare assessment on the animals and assure their suitability for continued use. This assessment should consider clinical signs, examination findings, alterations in organ function or clinical pathology that could result from toxicity in a study, the level of pain or distress experienced by the animal in a prior study, continued function of catheters or instrumentation, or the presence of medical or behavioral problems resulting from, or coincidental to the prior study use.

In order to reuse animals effectively from the standpoint of cost control, it is important to carefully manage these stock colonies. Maintenance of animal colonies is expensive and if the animals are not being used regularly, it may be more cost-effective to use them once and euthanize them rather than maintaining them until the next study. Each facility needs to analyze its own costs to make the determination of the maximum interval between studies that justifies reuse from a cost standpoint, but in the author's experience, animals should not be maintained if they are not being used at least several times in a year. Regular use of animals that are in stock colonies is also important for nonfinancial reasons. Animals that are not handled regularly can develop abnormal behaviors and become unsuitable for study use. It is also possible to overlook health problems in animals that develop in between their scheduled health assessments when they are not handled regularly. Ultimately, if there are animals in stock colonies that are not being used regularly, and they are consistently not meeting study selection criteria, it is preferable to humanely euthanize them rather than maintain them indefinitely. With a carefully managed colony, it is usually possible to find a terminal use for these animals, such

as donation of blood or tissues for in vitro assay use, or to provide staff training.

Some institutions have programs to retire research animals from their colonies without euthanizing them.[304] Options for retirement can include transfer to another institution for which they meet study requirements, and adoption to animal retirement centers or to private owners. Retirement of research animals fulfills an important emotional need in some staff, but retirement options must be carefully evaluated by scientists and veterinarians before being approved. It is not appropriate to allow animals to leave an institution if they have health or behavioral problems, or contain hazardous or proprietary agents that will affect their future use. Time may be equally well spent counseling staff members who have concerns about euthanasia of research animals on the reasons that it is indicated for a specific animal and providing ideas for appropriate redirection of their efforts to provide for the welfare of animals.

CONCLUSIONS

Animal welfare is an important issue for our society that has been expressed in the form of regulations and standards for the humane care and use of animals in research. It is important for research institutions to be able to communicate the benefits of the research being performed and the justifications for the way it is being done and to be able to address any potential concerns by both internal staff and the public. Public perception has direct effects on the ability to perform research using animals through the implementation of regulatory requirements and animal welfare standards.

When managed appropriately, meeting animal welfare standards also assures the quality of the data collected from the animals. The focus of animal welfare standards and regulations is to require that the use of animals be justified scientifically through the consideration of *replacement alternatives*, that the number of animals used be minimized through application of *reduction alternatives*, and that the pain or distress be minimized through the use of *refinement alternatives*. Because pain and distress are themselves a source of variability in study data, refinement of husbandry and study procedures improves the reliability of data derived from research animals. Refinement methods may be withheld only when there is scientific justification that their use will directly interfere with the interpretation of study data. This justification must be based on actual evidence or a clear mechanistic argument to support the justification, rather than just a supposition based on the possibility of unknown effects that could interfere with data interpretation.

Animal models used in the safety assessment of pharmaceuticals should be able to closely predict the potential for off-target effects. Through historical use, specific stocks and strains of rats and mice have been established as the most reliable rodent species for this purpose, and the dogs and nonhuman primates as the most reliable nonrodent species. Swine have been growing in use and offer certain advantages for safety assessment. As the understanding of various disease states and human and animal physiology increases, better animal models including genetically modified rats and mice, and nontraditional animal species such as chinchillas, ferrets, woodchucks, armadillos, and zebrafish are being employed to more accurately assess toxicity and predict safety margins of certain pharmaceuticals in humans. The use of environmental toxicity test species provides regulators with data for appropriate risk management decisions to aid in the protection of environmental species from harmful levels of pharmaceuticals, chemical products, and wastewater.

Because of the complexity of regulatory requirements for humane animal care and use and the considerable knowledge that has been accumulated regarding the needs of animals and the effects of study activities on animal health and welfare, institutions need specialists in these areas. Typically, an institution will require one or more veterinarians trained in laboratory animal medicine and personnel with knowledge of laboratory animal science to manage the compliance process, the facilities, and animal husbandry. While scientists may perform their own research procedures, there are significant advantages to having a technical resource staff to conduct studies and research procedures, and allow scientists to focus on study design and data interpretation.

Standards have been developed for all aspects of the humane care and use of research animals. These are codified in animal welfare regulations and accreditation standards. Standards for animal care and use encompass many areas: animal facility design, construction, operation, environmental control, cleaning, and sanitation; animal model selection, acquisition, and genetic, health, and microbial status; feeding, watering, daily care, and monitoring; and behavioral management, research procedures, veterinary care, and euthanasia. The IACUC at each institution is responsible for reviewing each proposal for the use of animals, standard operating procedures at the facilities, and any exceptions to the standards. These standards are designed to promote animal welfare by maintaining animals in a physiological and behaviorally normal state, which in turn serves to minimize the potential for variability on research results resulting from animal pain or distress. Because husbandry and veterinary care procedures themselves can be study variables, it is important that the relative effects of these procedures on study data be carefully evaluated, and simultaneously considered along with the variability that will occur if animals are exempted from animal welfare standards.

Ultimately, what is important is that all aspects of the animal model, its environment, and scientific needs be balanced to determine what is most appropriate from both humane and scientific perspectives. That is the purpose of a committee process for management of animal care programs and for outside regulatory oversight. There is no one person who can understand the interaction of all of the variables that are present within a typical animal study and all parties have biases that can limit their appreciation for some of these variables. It must be remembered that in our society, the use of animals in research is a privilege and not a right. No matter how important and scientifically appropriate the work is, if it cannot

be adequately communicated to the public and their concerns about animal welfare addressed, this privilege can be revoked, which would have a significant impact on the development of new chemicals, drugs, and medical treatments that improve the quality of life for both humans and animals.

QUESTIONS

20.1 Why is it important for scientists to be aware of public opinions regarding animal use and be able to communicate how and why animals are used for toxicological research?

20.2 Give three examples each of *reduction*, *refinement*, and *replacement* alternatives for animal use.

20.3 What are the two primary agencies that regulate animal research in the United States? What are the three primary documents that contain animal welfare regulations and standards used by these agencies?

20.4 What are the examples of animal welfare requirements for the prevention of disease in research animal facilities?

20.5 What effects do pain and distress have on animals and the data collected from them?

20.6 Describe the roles of the IACUC, the veterinarian, and the scientist in determining whether an animal requires veterinary care or euthanasia if it is experiencing toxicity while on a study.

20.7 List three considerations for selection of a species or strain of animal for use as a model for safety evaluation of both small- and a large-molecule test articles.

20.8 Name five specific animal models used in toxicologic research and reasons why each model would be selected for a particular study.

ACKNOWLEDGMENTS

The authors would like to thank Amy Attivissimo for assistance in preparation of the manuscript and the MPI Office of Animal Care and Operations Training staff for guidelines on standard research procedures.

21 Validation and Regulatory Acceptance of Toxicological Testing Methods and Strategies

William S. Stokes

CONTENTS

INTRODUCTION

Toxicological test methods are necessary to assess the hazard and safety of various substances such as medicines, consumer products, and industrial chemicals. Many of these methods have traditionally used animals as the test system. However, there has been increasing interest in the development of alternative methods that incorporate advances in new science and technology and that utilize knowledge of adverse outcome pathways at the molecular and cellular level [1–3]. New testing methods and strategies are sought that can provide improved accuracy and efficiency compared to existing methods. There are also continuing national and international interests and legislative mandates to develop alternative test methods that can replace animal use, reduce the number of animals required for a test procedure, and refine testing procedures to lessen or eliminate unrelieved pain and distress [4]. For any new or revised test method to be used to meet regulatory testing requirements, including alternative methods, the method must first undergo adequate validation and then be determined to be acceptable by regulatory authorities. This chapter discusses the criteria and processes for validation and regulatory acceptance of new, revised, and alternative methods and testing strategies. In addition,

examples of new alternative test methods and testing strategies that have been accepted by national and international authorities are reviewed.

CONCEPT OF ANIMAL USE ALTERNATIVES IN TOXICOLOGY

The concept of animal use alternatives was first described in 1959 by Rex Burch and William Russell in their book *The Principles of Humane Experimental Technique* [5]. Commonly referred to as the *3Rs of alternatives*, this concept involves *reducing* the number of animals needed for a specific study, *replacing* animals with nonanimal systems and approaches, and *refining* animal use to lessen or avoid unrelieved pain and distress. In the 1980s, animal protection groups began to emphasize the need to identify and use alternative methods for animal testing. Industry responded with various initiatives that included support to establish a Center for Alternatives to Animal Testing (CAAT) at the Johns Hopkins University in 198l. Public concern and increased awareness about animal use contributed to the passage of new laws requiring consideration of alternative methods prior to the use of animals in the United States in 1985 [6,7], and in Europe in 1986 and 2010 [8,9]. Additional laws in 1993 and 2000 directed the National Institutes of Health (NIH) to conduct research on alternative methods, to develop and validate alternative methods for testing, and to establish a formal process for acceptance of proposed alternative testing methods [10,11].

Regulatory Requirements for Consideration of Alternative Methods

In the United States, Animal Welfare Act regulations implemented in 1989 require investigators to consider alternative methods prior to the use of animals for research or testing whenever proposed procedures involve more than slight or momentary pain or distress [12]. Before animals can be used, the investigator must provide evidence of the sources used to determine if alternative methods to procedures that cause more than slight or momentary pain or distress are available. The investigator must document this search, and both the search for alternatives and the proposed animal use must be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC). Institutions using animals for research and testing must register with the U.S. Department of Agriculture (USDA) and are subject to periodic compliance inspections by the Animal Care Unit of the USDA Animal and Plant Health Inspection Service (APHIS).

Investigators subject to the provisions of the Public Health Service (PHS) Policy on the Humane Care and Use of Laboratory Animals must also consider refinement, reduction, and replacement alternatives prior to the use of animals [13]. These include organizations that receive funding from PHS agencies (e.g., NIH, FDA, CDC, ATSDR), as well as organizations that participate in the voluntary animal facility accreditation program of the Association for Assessment and Accreditation of Laboratory Animal Care International (AAALAC). The PHS Policy implements relevant provisions of the Health Research Extension Act of 1985 and requires that studies using animals comply with the U.S. Government Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training (Table 21.1) [13]. These principles effectively require incorporation of refinement, reduction, and replacement alternatives into animal studies to the extent that they are consistent with obtaining testing and research objectives.

Refinement Alternatives

Toxicity testing often involves pain and distress as a result of direct or indirect local or systemic tissue damage from the test article. Additional pain and distress may occur as systemic toxicity progresses toward a lethal outcome as a result of significant disruption of normal homeostatic mechanisms. The goals of refinement alternatives are to minimize or eliminate unrelieved pain and distress and to enhance the well-being of animals used in testing and research [4]. Refinements not only provide for improved animal welfare but also enhance the quality of experiments by reducing or eliminating pain and distress as an experimental variable [4,14–16].

Death has been used historically as an experimental endpoint in toxicity testing; however, considerable pain and distress may precede death, and therefore, the occurrence of spontaneous deaths should be avoided during toxicity studies [16–18]. With recent changes to national and international testing guidelines, death is no longer a required endpoint for toxicity studies conducted for regulatory safety testing purposes. Toxicity testing regulations and guidelines now allow for humane euthanasia of moribund animals, as well as animals that show evidence of severe pain and distress [4,16–18]. These include national and international test guidelines for acute oral toxicity conducted to provide an estimate of the oral LD_{50} [19–22]. International guidance has also been developed for selecting appropriate endpoints for toxicity studies [23].

Refinement can be achieved in toxicity studies by identifying earlier, more humane endpoints that are predictive of traditional study endpoints involving pain and distress [4,16–18]. Clinical signs, physiologic parameters, biochemical measurements, and other parameters can serve as potential earlier biomarkers of humane endpoints. Detailed data should be collected to confirm the validity of the earlier biomarker. When it has been determined that the earlier biomarker provides the same or better accuracy as the traditional biomarker, it can be proposed for acceptance by regulatory authorities.

The local lymph node assay (LLNA) is an example of an alternative test method where the use of an earlier mechanistic endpoint completely eliminates the pain and distress previously involved in the determination of allergic contact dermatitis (ACD) potential of chemicals [4,16,24,25]. In the traditional test method using the Buehler test or guinea pig maximization test (GPMT), the test requires observation for actual elicitation of allergic dermatitis manifested by redness, swelling, and pruritus. In contrast, the LLNA uses an earlier, more sensitive biomarker that avoids the need to evoke the potentially painful elicitation phase. This method is discussed in greater detail later in this chapter.

TABLE 21.1
U.S. Government Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training

The development of knowledge necessary for the improvement of the health and well-being of humans as well as other animals requires in vivo experimentation with a wide variety of animal species. Whenever U.S. government agencies develop requirements for testing, research, or training procedures involving the use of vertebrate animals, the following principles shall be considered, and whenever these agencies actually perform or sponsor such procedures, the responsible institutional official shall ensure that these principles are adhered to:

I. The transportation, care, and use of animals should be in accordance with the Animal Welfare Act (7 U.S.C. 2131 et seq.) and other applicable federal laws, guidelines, and policies.
II. Procedures involving animals should be designed and performed with due consideration of their relevance to human or animal health, the advancement of knowledge, or the good of society.
III. The animals selected for a procedure should be of an appropriate species and quality and the minimum number required to obtain valid results. Methods such as mathematical models, computer simulation, and in vitro biological systems should be considered.
IV. Proper use of animals, including the avoidance or minimization of discomfort, distress, and pain when consistent with sound scientific practices, is imperative. Unless the contrary is established, investigators should consider that procedures that cause pain or distress in human beings might cause pain or distress in other animals.
V. Procedures with animals that may cause more than momentary or slight pain or distress should be performed with appropriate sedation, analgesia, or anesthesia. Surgical or other painful procedures should not be performed on anesthetized animals paralyzed by chemical agents. (For guidance throughout these principles, the reader is referred to *The Guide for the Care and Use of Laboratory Animals* prepared by the Institute for Laboratory Animal Research, National Academy of Sciences.)
VI. Animals that would otherwise suffer severe or chronic pain or distress that cannot be relieved should be painlessly killed at the end of the procedure or, if appropriate, during the procedure.
VII. The living conditions of animals should be appropriate for their species and contribute to their health and comfort. Normally, the housing, feeding, and care of all animals used for biomedical purposes must be directed by a veterinarian or other scientist trained and experienced in the proper care, handling, and use of the species being maintained or studied. In any case, veterinary care shall be provided as indicated.
VIII. Investigators and other personnel shall be appropriately qualified and experienced for conducting procedures on living animals. Adequate arrangements shall be made for their in-service training, including the proper and humane care and use of laboratory animals.
IX. Where exceptions are required in relation to the provisions of these principles, the decisions should not rest with the investigators directly concerned but should be made, with due regard to principle II, by an appropriate review group such as an institutional animal care and use committee. Such exceptions should not be made solely for the purposes of teaching or demonstration.

Reduction Alternatives

Reduction alternatives are approaches and methods that result in attainment of study objectives with fewer animals. For example, minimizing one or more experimental variables can often improve statistical power, allowing for fewer animals per group [4,14,15,26]. Using inbred rodent strains is one way to reduce experimental variation associated with genetic differences found in outbred stocks. Optimal statistical designs of studies will also contribute to ensuring the use of the most appropriate number of animals.

One approach to reduction is to periodically conduct a retrospective review of testing results to determine if the number of animals can be reduced without significantly affecting the outcome of the study. For example, six rabbits were routinely used to conduct an ocular irritation assay; however, a retrospective statistical evaluation determined that the number could be reduced to a maximum of three in most situations [27–29]. Further reductions can be accomplished by testing one animal at a time sequentially and stopping if evidence indicates severe irritation or ocular corrosion in one animal [29].

The up-and-down procedure is an example of how animal use for assessing acute oral toxicity has been drastically reduced by up to 80% by use of an innovative statistical approach and sequential animal testing [4,19,22,30]. The acute toxic class method and the fixed dose procedure also provide for reduced animal use for acute oral toxicity studies [21,22,30].

Replacement Alternatives

Replacement alternatives are those that use nonanimal methods, such as cell, tissue, and organ cultures, or nonsentient phylogenetically lower species such as insects [4,5,15]. Nonanimal alternatives can sometimes be used to reach a regulatory hazard decision without animals for a given endpoint, for certain test results, or for certain defined types of substances commonly referred to as the applicability domain. For example, nonanimal test methods for assessing dermal corrosivity potential have been approved [31–35], and no animal or other further testing is required when the substance is identified as a corrosive.

In vitro test methods are also increasingly being incorporated as components in integrated approaches to assess the safety or potential toxicity of various chemicals, medicines, and products [1,3,36]. Their development has been stimulated by advances in new technologies and an enhanced understanding of the molecular and cellular mechanisms of toxicity. Advances in cell and tissue culture methods and the development of genetically modified stable cell lines have contributed to improved in vitro model systems.

New scientific tools such as toxicogenomics, proteomics, and metabonomics are facilitating the identification of more sensitive and earlier biomarkers of toxicity that will likely be incorporated into future in vitro and animal safety testing methods [1,3]. Efforts are underway to investigate the validation strategies that would be required to adopt such new technologies for regulatory decision-making purposes [1,3,36–38]. The number and diversity of in vitro test systems incorporating sensitive biomarkers will undoubtedly expand greatly in the coming years.

Integrated Testing and Decision Strategies

Integrated testing and decision strategies utilize a systematic assessment process that considers all available information at each stage and determines whether the available information is sufficient for a safety decision or whether additional information is needed in order to make a decision [1,3,39,40]. In cases where there is insufficient certainty to make a decision, the ideal ITDS will provide information on what would be the most value-added next additional test that may provide sufficient information to make a decision regarding a specific toxicity. If, based on a weight-of-evidence evaluation, the information is not sufficient, then testing progresses to provide additional information. Testing progresses until sufficient information is available to make a decision. Utilization of integrated testing and decision strategies can sometimes allow for toxicity hazard classifications to be made with fewer or no animals. Proposals for integrated testing strategies for ocular and dermal irritation and corrosion testing have been incorporated into the Globally Harmonized System (GHS) for chemical hazard classification and labeling and as supplemental guidance for international test guidelines [41,42].

VALIDATION OF NEW AND ALTERNATIVE SAFETY ASSESSMENT METHODS AND TESTING STRATEGIES

Prior to using data from new and alternative methods and testing strategies for regulatory safety assessment decisions, the test methods strategies used to generate such data must be determined to be scientifically valid and acceptable for their proposed use [43–46]. Adequate validation is therefore a prerequisite for test methods to be considered for regulatory acceptance. Demonstration of scientific validity requires evidence of the relevance and reliability of a test method and is necessary to determine the usefulness and limitations of a test method for a specific intended purpose. This requires validation studies to determine their accuracy and reliability compared to currently approved reference tests or strategies, and evaluation of whether their proposed use will provide equivalent or improved hazard identification as the currently used test or strategy. Regulatory acceptance involves reviewing the results of validation studies to determine the extent to which a test method can be used to fulfill specific regulatory needs and requirements. This section reviews established criteria for validation.

Test Method Validation Criteria

Validation is defined as the scientific process by which the relevance and reliability of a test method are determined for a specific purpose [43–47]. *Relevance* is defined as the extent to which a test method correctly measures or predicts a biological or toxic effect of interest. Relevance incorporates consideration of the accuracy of a test method for a specific purpose and consideration of mechanistic and cross species or other test system relationships. *Reliability* is an objective measure of the degree to which a test method can be performed reproducibly within and among laboratories over time. A test method is considered adequately validated when its accuracy and reliability characteristics have been adequately determined for a specific purpose.

Criteria that should be met for a new or revised test method to be considered adequately validated for regulatory risk assessment purposes have been developed by national and international authorities (Table 21.2) [44–46]. These criteria serve as principles that should be followed in the validation of new test methods and provide clarity as to the critical information that should be collected and provided to substantiate the validity of test methods to regulatory authorities. The extent to which these criteria are addressed in validation studies will vary with the test method and its proposed use. Accordingly, there must be flexibility in designing validation studies to ensure that the information generated is appropriate given the intended purpose of the test method and consideration of all existing supporting data. Test methods can be designed and used for different purposes by different organizations and for different categories of substances. Accordingly, the determination by regulatory authorities as to whether a specific test method is adequately validated and useful for a specific purpose will be on a case-by-case basis. Regulatory acceptance of new test methods and testing strategies generally requires a determination that decisions made using results from the test method or testing strategy will provide equivalent or improved hazard identification, dose–response assessment, or risk assessment compared to currently used test methods and strategies. Further guidance on adequately addressing established validation criteria is provided in this section.

Test Method Purpose and Regulatory Rationale

New proposed test methods and testing strategies should have a clearly stated regulatory rationale and a clearly defined specific proposed use. The proposed use should describe how a test method is to be used for decision making in the context of current or anticipated regulatory requirements, regulations, and guidelines. National regulatory authorities and international organizations have developed guidance and numerous standardized test guidelines that can be used to meet regulatory safety and hazard assessment requirements for various toxicity endpoints [44,47,48]. Reference data generated for an appropriate range and number of substances using these standardized test method protocols can serve as the basis for

TABLE 21.2
Test Method Validation Criteria

For a new or revised test method to be considered validated for regulatory risk assessment purposes, it should generally meet the following criteria (the extent to which these criteria are met will vary with the method and its proposed use); however, there must be flexibility in assessing a method given its purpose and the supporting database:

1. The scientific and regulatory rationale for the test method, including a clear statement of its proposed use, should be available.
2. The relationship of the test method's endpoints to the biologic effect of interest must be described. Although the relationship may be mechanistic or correlative, tests with biologic relevance to the toxic process being evaluated are preferred.
3. A detailed protocol for the test method must be available and should include a description of the materials required, a description of what is measured and how it is measured, acceptable test performance criteria (e.g., positive and negative control responses), a description of how data will be analyzed, a list of the species for which the test results are applicable, and a description of the known limitations of the test, including a description of the classes of materials that the test can and cannot accurately assess.
4. The extent of within-test variability and the reproducibility of the test within and among laboratories must have been demonstrated. Data must be provided describing the level of intra- and interlaboratory reproducibility and how it varies over time. The degree to which biological variability affects this test reproducibility should be addressed.
5. The performance of the test method must have been demonstrated using reference chemicals or test agents representative of the types of substances to which the test method will be applied and should include both known positive and known negative agents. Unless it is hazardous to do so, chemicals or test agents should be tested under code to exclude bias.
6. Sufficient data should be provided to permit a comparison of the performance of a proposed substitute test with that of the test it is designed to replace. Performance should be evaluated in relation to existing relevant toxicity testing data and relevant toxicity information from the species of concern. Reference data from the comparable traditional test method should be available and of acceptable quality.
7. The limitations of the method must be described; for example, in vitro or other nonanimal test methods may not replicate all of the metabolic processes relevant to chemical toxicity that occur in vivo.
8. Ideally, all data supporting the validity of a test method should be obtained and reported in accordance with GLPs. Aspects of data collection not performed according to GLPs must be fully described, along with their potential impact.
9. All data supporting the assessment of the validity of the test method must be available for review.
10. Detailed protocols should be readily available and in the public domain.
11. The methods and results should be published or submitted for publication in an independent, peer-reviewed publication.
12. The methodology and results should have been subjected to independent scientific review.
13. Because tests can be designed and used for different purposes by different organizations and for different categories of substances, the determination of whether a specific test method is considered by an agency to be useful for a specific purpose must be made on a case-by-case basis. Validation of a test method is a prerequisite for it to be considered for regulatory acceptance.

comparing the performance of a new test method proposed to evaluate the same toxicity endpoint.

The specific purpose of test methods and testing strategies currently included or proposed for inclusion in regulations and guidelines can vary widely [37,44–46]. For example, many methods serve as definitive test methods that provide sufficient information for regulatory hazard classification and labeling decisions, while others may serve as screening tests, mechanistic adjunct tests, or components of a testing battery or testing strategy. A new test method or testing strategy may be proposed as a complete replacement for all testing situations for an existing test method, or it may be proposed to substitute for an existing test method in certain testing situations for a defined applicability domain, such as the evaluation of test articles for specific well-defined product or chemical classes or those with specific physical or chemical properties.

Definitive test methods are those that provide sufficient data to characterize the specific hazard potential of a substance for hazard classification and labeling purposes without further testing. Examples include specific animal tests for skin irritation, eye irritation, ACD, acute oral toxicity, multigenerational reproductive toxicity, and the rodent carcinogenicity bioassay.

Screening test methods are those that may in some situations allow for hazard decisions in a tiered testing strategy or that may provide information helpful in making decisions on prioritizing chemicals for more definitive testing. As an example, a test method could be proposed as a screening test in a tiered testing strategy where positive results can be used to classify and label the hazard of a substance without further testing, while negative results would undergo further defined testing, or testing using the currently accepted definitive testing procedure. Whenever a test method is proposed to be used as a screening test, the specific decisions that will be made with each possible test result must be clearly defined.

Several in vitro screening tests have been accepted for determining if a substance has the potential to cause dermal corrosion [31–35]. Positive results can be used to classify and label substances as corrosives, while negative results may need to undergo additional testing to identify any false-negative corrosive substances and to determine the dermal irritation potential. The use of information from screening tests to meet regulatory requirements must take into consideration the precautionary principle and the public health need to avoid potential underclassification and inadequate or lack of labeling for hazardous substances.

Mechanistic adjunct test methods are those that provide data that add to or help interpret the results of other assays or that otherwise provide information useful for the hazard assessment process. An example is the estrogen-receptor-binding assay [49]. A positive result in this assay indicates that a substance has the potential to bind to the estrogen receptor in an in vitro system; however, it does not definitively indicate that the substance will be active in vivo because it does not take into account absorption, distribution, metabolism, and excretion (ADME) factors. When considered in conjunction with other testing information, such as a positive rodent uterotrophic bioassay, a positive result in this in vitro assay contributes mechanistic information for a weight-of-evidence decision supporting the likelihood that the in vivo bioassay response resulted from an estrogen-active substance. When an adjunct test method is proposed to generate data for use in a weight-of-evidence decision, it is important to provide data that substantiate and quantitatively characterize the weight, or likelihood, that a toxic effect will be associated with the outcome from the mechanistic test.

A *testing battery* is a series of test methods that are generally performed at the same time or in close proximity to reach a decision on hazard potential. This contrasts with a testing strategy, which typically involves several potential test methods, but incorporates the potential for decisions to be made in some situations with only one or more of the methods. In evaluating the scientific validity of test batteries and testing strategies, it is critical that the component test methods undergo validation as individual test methods. For the individual test methods proposed for inclusion, it is essential that each individual test method validation study use the same reference substances or at least a sufficient number of the same substances to adequately evaluate the usefulness and limitations of the proposed test battery or strategy. This is necessary to allow calculation of the accuracy of each possible combination of component test methods and to identify the most accurate combination for given classes or other categories of substances.

Test methods or testing strategies proposed to replace an existing definitive test method will require evidence from validation studies that the use of the proposed method will provide for a comparable or better level of protection than the currently used test method or strategy. In some cases, there may be limitations of a new test method or strategy with regard to certain types of physical or chemical properties (e.g., solubility in an in vitro system) that do not allow for it to completely replace an existing test. In this case, it may be determined to be an adequate *substitute* for the existing test method for many but not all test substances or testing circumstances.

Test Method Scientific Rationale and Relationship of the Test Method Endpoint to the Biological Effect of Interest

The scientific rationale for a new test method should always be provided [44–46]. This should include the mechanistic basis and relationship of the biological model used in the test system compared to that for the species of interest for which the testing is being performed (e.g., humans for health-related testing). The extent to which the mechanisms and modes of action for the toxicity endpoint of interest are similar or different in the proposed test system compared to that in the species of interest must be considered. Other uncertainties regarding mechanisms and modes of action and their potential impact on the relevance of the test method must be discussed. The potential role and impact of in vivo ADME on the toxicity of interest must also be considered, as well as the extent to which each of these parameters is or is not addressed by the proposed test method. For an in vitro test system, the impact of any ADME limitations of the in vitro test system must be discussed. It is also important to consider what is known or not known about similarities and differences in responses between the target tissues in the species of interest, the surrogate species used in the currently accepted test method, and the cells or tissues of the proposed in vitro test system. The extent to which a critical event in any defined adverse outcome pathway for the toxicity endpoint of interest has been incorporated into the test method should be discussed and explained.

Detailed Test Method Protocol

Protocol

The outcome of a validation study should be a detailed standardized, optimized, and transferable test method protocol that has been adequately evaluated to characterize its accuracy and reliability for a specific defined purpose. The test method protocol should be sufficiently detailed that it can be reproduced in other appropriately equipped laboratories with trained personnel. Because most testing conducted for regulatory purposes must be conducted in accordance with national or international good laboratory practice (GLP) regulations [50–53], the test method protocol should be prepared so it can be used as the basis for a GLP-compliant study protocol in specific laboratories.

The test method protocol should provide a detailed description for all aspects of the proposed test method (Table 21.3) [46], including a description of all materials, equipment, and supplies. Detailed procedures for dose selection for animal studies or concentration selection for in vitro studies should be provided. Where appropriate, this should include procedures for dose-range-finding studies and solubility testing to select appropriate solvents, as appropriate. Criteria should be provided for selection of the highest concentration or dose that should be used. For in vivo studies, this may be a maximum tolerated dose, with carefully defined criteria or a defined upper-limit dose. For in vitro methods, this may be a defined limit concentration (e.g., 1 mM), the highest noncytotoxic concentration, or the highest soluble concentration. The duration and basis for test substance exposure and postexposure incubation for in vitro systems should be provided. The nature of data to be collected and the methods and procedures for data collection must be specified.

TABLE 21.3
Selected In Vitro Test Method Protocol Components

1. Biological systems, materials, equipment, reagents, and supplies
2. Concentration selection procedures: for example, defined limit concentration, range-finding studies, procedures for determining limit of solubility, highest noncytotoxic concentration
3. Test system endpoints measured
4. Duration of test article exposure, postexposure incubation
5. Positive, vehicle, negative, and benchmark control substances; basis for their selection
6. Acceptable response ranges for positive, vehicle, and negative control substances, including historical control data and basis for acceptable ranges
7. Decision criteria for interpreting the outcome of a test result, basis for the decision criteria for classifying a chemical, accuracy characteristics of the selected decision criteria
8. Information and data to be included in the study report
9. Standard data collection and submission forms

Positive, Vehicle, and Negative Controls

Nearly every toxicological test will have untreated controls that serve as the basis for detecting whether cells or animals treated with the test article results in an increased response above the control response. When a vehicle or solvent is used with the test article, a vehicle or solvent control should also be used. In addition, it may also be desirable or necessary to have concurrent positive and negative controls. For in vitro test systems, vehicle and positive controls should be designated and used for every test. For some in vivo tests, it may also be necessary to use positive controls. These are necessary to ensure that the test system is operating properly and capable of providing appropriate positive and negative responses. A positive control substance should normally be selected that is intermediate in the potential dynamic response range of the test system. For in vitro tests, an acceptable positive control response range should be developed for each laboratory. Test results are not normally considered acceptable if the positive control is outside of the established (historical) acceptable positive control range.

Benchmark Controls

In some cases, it may be desirable to include substances for which potential toxicity has previously been established in human, animal, and/or in vitro test systems. These substances, commonly referred to as benchmark controls, could include substances that are in the expected response range of the test articles or that have similar chemical structure or physical–chemical properties as the test articles [37]. Benchmark controls can be helpful in providing information about the relative toxicity of a test article compared to other well-characterized similar substances, and can also be used to ensure that the test system is functioning properly in specific areas of the response range.

Decision Criteria

For test methods that determine the hazard classification category of a test substance, the test method protocol must describe the decision criteria used to determine the classification category based on results from the test system. For methods that provide qualitative assessments of toxicity, these may be the criteria used to determine if the results indicate that a substance is positive, negative, or if the result is inconclusive. For example, in Corrositex®, a test method for determining the corrosivity category of substances, the corrosivity hazard category is based on the time that it takes for the substance to penetrate a biobarrier membrane [34,35]. A formula or algorithm that incorporates the decision criteria for a test outcome is often used to convert test method results into a prediction of the toxic effect [44,46]. Accordingly, decision criteria are sometimes referred to as a *prediction model*. Test method decision criteria should address four elements: (1) a definition of the specific purpose of the test method, (2) specifications of all possible results or outcomes that may be obtained when using the test method, (3) an algorithm that converts each study result or outcome into a prediction of the effect of interest, and (4) specification of the accuracy associated with the selected decision criteria (i.e., sensitivity, specificity, false-positive and false-negative rates) [44–46]. Decision criteria should always be carefully described in the test method protocol. It is important to note that decision criteria and prediction models for the final proposed test method protocol may have to be revised following a validation study in order to obtain a sensitivity and specificity appropriate for the intended regulatory use. Such modifications should seek to minimize false-negative and false-positive rates appropriate for the toxicity endpoint being assessed. The regulatory tolerance for false negatives in a test system will depend on the nature, duration, and severity of the injury or disease that could result from any potential false negatives. False negatives can potentially result in exposure to a hazardous substance because it will either be not labeled or underlabeled with regard to the potential health hazards that it could cause.

Test System Selection and Description

The basis for selection of the test system should be described in the test method protocol and should include a detailed description and specifications for animals, cells, tissues, or other critical components used. Procedures for ensuring the correct identity and critical parameters of animal stocks and strains, cells, and tissues should be provided in the test method protocol, including the basis for determining that the components are of acceptable quality and responsiveness [37,51]. Good cell culture practices have been developed to provide guidance on practices necessary to ensure high-quality in vitro testing using cell cultures [54,55].

Evaluation of Test Method Reliability

Test method reliability involves determining the intralaboratory repeatability and intra- and interlaboratory

reproducibility of a test method [37,44,45]. *Intralaboratory repeatability* of a test method is the closeness of agreement between test results obtained in a single laboratory when the test method is used to evaluate the same substance under identical conditions at the same time. These data provide an estimate of the variation that is inherent in the biological responses of a test system and the study conditions in a single laboratory. *Intralaboratory reproducibility* is the determination of the extent that qualified personnel within the same laboratory can successfully replicate results using a specific test method protocol at different times. Acceptable intralaboratory reproducibility should be achieved before evaluating interlaboratory reproducibility.

Interlaboratory reproducibility is a measure of the extent to which different qualified laboratories using the same test method protocol and the same substances can produce qualitatively and quantitatively similar results. This assessment is necessary to determine if the test method protocol contains sufficient procedural detail that will result in qualified laboratories obtaining similar and consistent results, and indicates the extent to which a test method can be transferred successfully among laboratories. Interlaboratory reproducibility should be assessed using the same or a subset of the reference substances used to assess test method accuracy. Most importantly, reference substances representing the full range of possible test outcomes, chemical and physical properties, and mechanisms of toxicity should be evaluated. This can sometimes be accomplished with a smaller number of reference chemicals than used to characterize accuracy; however, there should be a compelling scientific and statistical rationale for using a reduced number of substances for this determination. Interlaboratory reproducibility has typically been assessed using three qualified laboratories. The impact of the results of test method reliability assessments on laboratory transferability and erroneous results should always be considered. Situations where evidence indicates poor reproducibility, such as for certain chemical classes, physicochemical properties, or specific areas of response, should be identified as potential limitations of the proposed test method.

Reference Substances

Reference substances are those for which the response of the substance is known in the existing reference test method or target species; they are used to characterize the accuracy and reliability of the proposed test method [37,44–46]. Test method reliability and accuracy must be evaluated using reference substances representative of the types of substances to which the test method will be applied and should include both known positive and negative substances. The selection of appropriate reference substances is a critical aspect of validation studies. The ideal reference chemicals are those for which high-quality testing data are available from both the reference test method and from the species of interest (e.g., humans); however, adequate human testing data are rarely available for ethical reasons. Exceptions are for substances and endpoints that do not result in severe or irreversible effects, such as ACD and mild to moderate dermal irritation. However, human studies are usually limited to the premarketing assessment of products that are intended for human contact, such as cosmetics and some mild consumer products. For test methods proposed for predicting human health effects, reference substances for which there are accidental human exposures and toxic effects should also be considered.

The number and types of reference substances selected must adequately characterize the accuracy and reproducibility of a test method for its specific proposed use [37,44–46]. Reference chemicals should represent the range of chemical classes, product classes, and physical and chemical properties (e.g., pH, solubility, color, solids, liquids) for which the test method is expected or proposed to be applicable. Reference chemicals should also represent the range of expected responses proposed for the test method, including negatives and weak to strong positives. Reference chemicals and formulations should ideally be of known purity and composition and should be readily available from commercial sources. Formulations should provide detailed information on the type, purity, and percentage of each ingredient. Unless justified, chemicals should not normally pose an extreme environmental or human health hazard, should not be prohibitively expensive, and should not involve exorbitant disposal costs.

Evaluation of Test Method Accuracy

Accuracy reflects the closeness of agreement between results from a new proposed test method and reference values from a currently accepted test method. A two-by-two table can be used to calculate accuracy and the associated parameters (Table 21.4) [46]. *Sensitivity* is the proportion of all positive substances that are correctly classified as positive by the new test method. *Specificity* is the proportion of all negative substances that are correctly identified as negative substances in the new test method. The *false-positive rate* is the proportion of all negative (inactive) substances that

TABLE 21.4
Two-by-Two (2 × 2) Table: Accuracy Statistics

		New Test Outcome		
		Positive	**Negative**	**Total**
Reference Test Classification	**Positive**	a	c	$a + c$
	Negative	b	d	$b + d$
	Total	$a + b$	$c + d$	$a + b + c + d$

Notes: The 2 × 2 table can be used for calculating accuracy (concordance) $((a + d)/(a + b + c + d))$, negative predictivity $(d/(c + d))$, positive predictivity $(a/(a + b))$, prevalence $((a + c)/(a + b + c + d))$, sensitivity $(a/(a + c))$, specificity $(d/(b + d))$, false-positive rate $(b/(b + d))$, and false-negative rate $(c/(a + c))$.

are falsely identified as positive, and the *false-negative rate* is the proportion of all positive (active) substances that are falsely identified as negative.

Ideally, test methods should be highly accurate, have a high level of sensitivity and specificity, and have negligible false-positive and false-negative rates; however, in toxicity testing, this is rarely achievable. Accordingly, decision criteria for interpreting the outcome of a test method must be adjusted depending on the desired performance characteristics and the impact of an erroneous result; for example, from the perspective of protecting public health, it is most desirable to use decision criteria for a test method that provide for a high level of sensitivity and have no or minimal false negatives. This is because a false-negative result incorrectly indicates a lack of hazard or lower hazard than actually exists for a substance. The real hazard of the substance will subsequently not be indicated on packaging or in worker safety information. Products without a proper warning of their real hazard, such as skin and eye corrosives, could then result in human injury or disease to exposed persons. Conversely, a low level of specificity and high false-positive rate can result in overlabeling the true hazard of a substance. This has economic implications in that some hazards require more expensive packaging and shipping precautions. It is also desirable not to overlabel the hazard of a substance because this could lead to complacency in consumer and worker compliance with recommended exposure precautions if accidental exposures frequently do not result in adverse effects.

Test Method Limitations

The limitations of a test method and test system must be described [44,45]; for example, the extent to which an in vitro test system does not replicate all of the metabolic processes relevant to the in vivo toxicity for a specific toxicity endpoint should be discussed. Similarly, there may be uncertainties or known limitations with regard to cross species differences in ADME for certain substances that must also be considered. Furthermore, limitations may be identified with regard to the ability of the test method to reliably and accurately detect the toxicity or biological activity of specific chemical classes and specific physical or chemical properties.

Quality of Validation Data

Ideally, all data supporting the validity of a test method should be obtained and reported in accordance with national or international GLP regulations and guidelines [44,45,50–53]. Because nearly all safety testing for regulatory purposes must be accomplished in accordance with GLP requirements, it is logical that validation studies for a test method proposed for safety testing should be carried out in accordance with those same GLP requirements. This will provide increased confidence in data quality and documentation as to the extent of laboratory adherence to the test method protocols under evaluation. GLPs provide a formal quality assurance system for data collected in the study. If validation studies are not conducted in accordance with GLPs, then aspects of data collection or auditing not performed according to GLPs should be documented. International guidance for the application of GLPs to in vitro testing is available [51]. In any case, all laboratory notebooks, raw and transformed data, and all other relevant test-related information should be retained and available for audit if requested by the reviewing authorities.

Availability of Validation Data

All data supporting the assessment of the validity of a proposed test method should be made available for review [44,45]. This includes raw data collected from the test system, as well as transformed data that are derived from the raw data. All test method protocols used to generate data must also be available. Ideally, the test method protocols and results from validation studies should be subjected to independent scientific peer review and published or submitted for publication in an independent peer-reviewed publication. Additional information on scientific peer review is provided in the section on the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) [44,46].

EVOLUTION AND VALIDATION OF A TEST METHOD

Validation of a test method is one of many stages involved in the evolution of a test method from concept to regulatory acceptance (Figure 21.1) [44]. These stages may begin with determination of the need for a new test method. New test methods are often sought that provide for improved prediction of adverse effects, that are more humane or do not use animals, or that involve less expense and time to conduct. Additional research may be needed to understand critical mechanisms and critical modes of action for a toxicity endpoint of interest and to identify potential biomarkers that can be included in a test method. The test method development stage involves incorporation and evaluation of one or more promising predictive biomarkers in a test system. This usually involves testing a limited number of substances with well-known toxicity to determine if the critical biomarker is capable of detecting the toxic effect. If so, then a decision may be made to initiate validation of the test system. Validation of a proposed test method is an iterative process that typically evolves through several phases (Table 21.5) [44].

Levels of Validation

When considering validation strategies for new test systems and methods, three progressive levels of validation must be

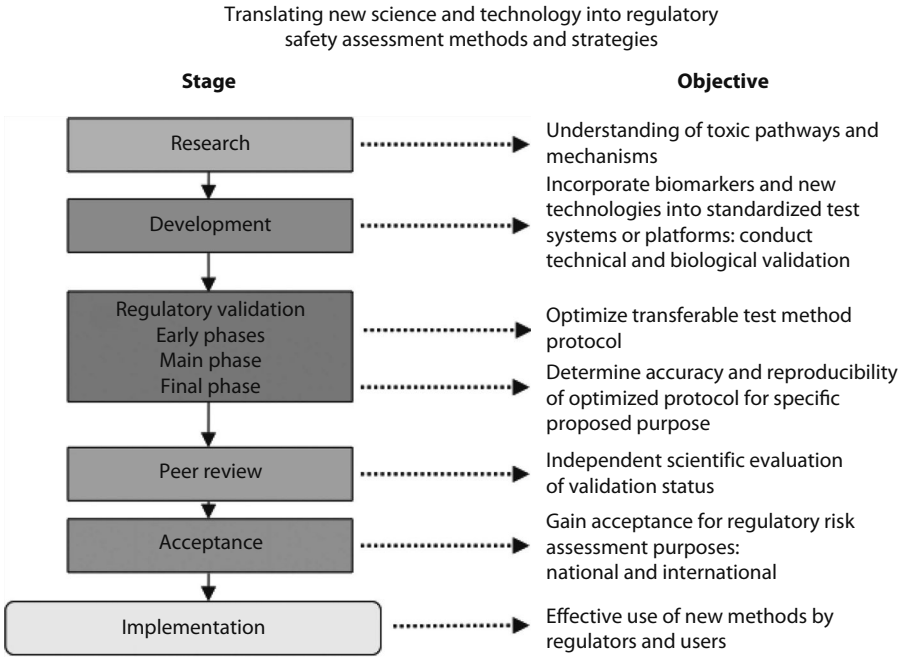

FIGURE 21.1 Test method evolution process. (Adapted from Interagency Coordinating Committee on the Validation of Alternative Methods, Guidelines for the nomination and submission of new, revised, and alternative test methods, NIH Publ. No. 03-4508, National Institute of Environmental Health Sciences, Research Triangle Park, NC, 2003.)

considered [3,56]. First, *technical validation* focuses on the extent that a new technology platform or test system can provide reproducible and reliable results. For example, testing of a limited number of chemicals across a range of responses is repeated to determine if the technology platform provides consistent and reproducible answers. Technical validation occurs early in the test method development process. Test platforms with excessive variation will require modifications to achieve an acceptable range of reproducibility before advancing to biological validation.

Biologic validation evaluates whether the underlying biology of interest is accurately reflected in the outcomes obtained from the new technology platform or test system [3,56]. This determines the extent that the measured qualitative and quantitative responses in the test system are indicative of the true biologic response and whether there are other factors causing unrelated positive, negative, or quantitatively altered responses.

Regulatory validation is often considered following successful technical and biologic validation and when there is potential applicability of test methods using the new technology platform or system to regulatory decision making [3,56]. Regulatory validation determines the extent that the test system generates information useful for regulatory decisions on safety or hazard and the extent that the use of a proposed standardized test method protocol produces similar results in different qualified laboratories. The following sections describe the processes applicable to regulatory validation.

Regulatory Validation: Test Method Standardization, Optimization, and Transferability

Regulatory validation is most efficiently conducted in several phases. The early phases are aimed at test method standardization and optimization of a transferable test method protocol. The first objective is to initially evaluate the standardized test method protocol and then to optimize the test method protocol to maximize accuracy and reliability first within and then across different laboratories. Careful planning is essential prior to the initiation of any validation study. The validation study plan must adequately address established validation criteria [44–46]. The objectives of each phase of the validation study should be clearly defined and a validation study design selected that will adequately address the defined objectives. Test method modifications are often necessary during the early validation phases to reduce sources of intra- and inter-laboratory variation and to optimize the accuracy of the test method to measure or predict the toxicity or biological activity of interest. The goal of the early validation phases is to optimize a test method protocol that is sufficiently accurate and reproducible and that can be used without further modification in the final phase of validation. Because the objective of the formal validation phase is to determine the reproducibility and accuracy of this optimized and standardized test method protocol, no changes should be made to the protocol during the final phase of validation.

TABLE 21.5
Test Method Validation Process

I. Test Development
- A. *Technical validation*
  1. Define the purpose of test.
  2. Assess test system reproducibility and reliability.
- B. *Biological validation*
  1. Determine the extent that test system results accurately reflect the underlying biology of interest.

II. Regulatory Validation
- A. *Preliminary validation study planning*
  1. Establish validation management team; evaluation and oversight procedures.
  2. Define basis and specific purpose of test.
  3. Develop detailed test method protocol for use in all laboratories:
     a. Identify positive and negative control substances.
     b. Establish initial decision criteria.
  4. Design validation study:
     a. Determine number and identity of reference substances for each phase.
     b. Determine number of replicates for each laboratory for each phase.
     c. Determine record-keeping and data submission procedures.
  5. Select participating laboratories; identify experienced lead lab.
  6. Code and distribute chemicals for initial phase.
- B. *Lab training and qualification phase*
  1. Lead laboratory provides training on test system and test method protocol:
     a. Establish initial historical positive control acceptance range for each laboratory.
  2. Labs test replicates of small number of coded chemicals (e.g., 3).
  3. Data reviewed; decision on whether each lab is sufficiently accurate and reproducible, or if not, procedures optimized and retested; repeated until satisfactory results.
- C. *Final protocol optimization phase*
  1. Test selected number of coded chemicals representing range of potency (e.g., 9).
  2. Assess intra- and interlaboratory reproducibility and accuracy.
  3. Further optimize test method protocol to maximize reproducibility and accuracy.
  4. Finalize optimized test method protocol for main validation study.
- D. *Main validation study phase*
  1. Test larger number of coded chemicals representing range of chemistry and potency in all labs, three replicates per lab.
  2. Assess intra- and interlaboratory reproducibility and initial accuracy.
  3. If reproducibility and initial accuracy are satisfactory, progress to final phase.
- E. *Final validation study phase*
  1. Test expanded number of coded chemicals necessary to adequately characterize accuracy of test method protocol in one or more qualified labs.
  2. Assess final accuracy.
  3. Prepare validation study report.
  4. Submit study report to national or international organizations for review.
- F. *Conduct independent scientific peer review*
  1. All data and study results made publicly available.
  2. Peer-review report made publicly available.

III. Recommendations on Test Method and Usefulness and Limitations
1. Test method recommendations supported by validation study provided to regulatory authorities for acceptance decisions.
2. Regulatory authorities announce acceptance decisions.
3. Regulatory testing guidelines updated to incorporate new test methods.

Coding and Distribution of Test Substance

Test substances should normally be coded during all phases of the validation study to exclude bias [37,44,45]. This can be accomplished by the use of a chemical distribution facility not directly associated with the participating laboratories. Each substance should be uniquely coded for each different laboratory so the identity is not readily available to laboratory personnel; however, provisions must be made to ensure that the designated safety officer in each laboratory has the safety data sheets available for each coded substance in case the need arises to access the information. One approach is to provide participating laboratory testing staff with sealed packages containing all relevant health

and safety data, including instructions for accidental exposures or other laboratory accidents. The envelopes can then be returned to the study sponsor at the end of study, with an explanation for any opened envelopes. Laboratories will need to ensure that all environmental, safety, handling, and disposal procedures are in compliance with regulatory requirements.

Selection of Laboratories for Validation Studies

Laboratories selected for validation studies should be adequately equipped and have personnel with appropriate training; for example, validation of an in vitro test method that involves aseptic tissue culture should utilize laboratories that have demonstrated proficiency in successfully conducting tissue culture experiments or testing. The use of three laboratories has generally been found to be adequate for assessing the interlaboratory reproducibility of test methods during validation studies. While there may be a desire to use more laboratories, this can often complicate the management of the study. If more than three laboratories are used, it is vital that all laboratories agree to follow the established protocols and validation study design and to adhere to the quality provisions of the study in order to ensure that high-quality data are generated and to avoid excessive delays. It is helpful to designate the laboratory most experienced with the test method as the *lead laboratory* during early validation studies to serve as a resource for technical issues that develop during the studies.

Phased Validation Studies

In a recent in vitro validation study managed by the National Toxicology Program (NTP) Interagency Center for the Evaluation of Alternative Toxicological Methods (NICEATM), dividing the early validation study into three phases was found to aid in efficiently optimizing the test method protocol [57]. The first phase involved a series of multiple testing in each laboratory with the positive control, with cycles of modifications and additions to the protocol until all laboratories were able to obtain reproducible results. This phase also was used to establish acceptance criteria for the test system, including positive control acceptance values for each laboratory. The second phase tested three coded substances representing three different areas of the response range (low, moderate, and high toxicity) and was again followed by minor protocol revisions to minimize variation within and among the participating laboratories. The third phase tested nine coded substances, again representing the range of responses as well as range of solubility. Additional minor protocol revisions were made after this phase, and an optimized test method protocol was finalized for testing the 60 remaining reference chemicals in the formal validation phase. The test methods and validation study results underwent scientific peer review and were determined to have sufficient reproducibility and accuracy to use in setting initial starting doses for in vivo acute oral toxicity studies [58–60]. Standardized test method protocols and an OECD guidance document incorporating the two test methods were published [61,62].

REGULATORY ACCEPTANCE CRITERIA FOR NEW SAFETY EVALUATION METHODS

After a new test method has been evaluated in a validation study, regulatory authorities do not automatically accept it; rather, the regulatory authorities must determine if there is sufficient evidence that the use of test method will provide for equivalent or improved protection of human health, animal health, or the environment, as defined by the intended purpose of the test method [11,44,60]. Furthermore, although a validated test method can be found to be technically acceptable, the extent that the test method may be useful for specific regulatory bodies is often determined by the nature and type of chemicals and products they each regulate. Regulatory acceptance criteria that should be adequately addressed by a test method proposed for regulatory applications have been developed for the United States (Table 21.6) [44,46], as well as internationally [45]. This section discusses the regulatory acceptance criteria for new test methods.

Independent Scientific Peer Review

The test method should have undergone independent scientific peer review by a group of persons that includes experts in the respective field and includes experts who are knowledgeable about the test model used in the validation study [44–46]. These individuals should not have financial or other conflicts of interest such that they, any family members, or their organizations stand to gain financially or professionally from either a positive or negative outcome of the peer-review process. Transparency of the validation and review process is essential. All data substantiating the scientific validity of the test method should be made available to the public and the public should have the opportunity to comment on the test method, data, and proposed recommendations on the validity of the test method [44,46,60]. The peer-review panel should conduct its deliberations in public session, and the report of the peer-review panel should be made available to the public [44,60]. ICCVAM has implemented a transparent peer-review process that incorporates these features [43,44,60].

Detailed Test Method Protocol

A detailed test method protocol must be provided that includes all relevant standard operating procedures (SOPs), operating characteristics, and decision criteria (e.g., assay acceptance criteria, response criteria) [44–46]. The performance of the test method protocol should be substantiated by appropriate validation studies, and any changes in the protocol from the version used in the validation study should be scientifically

TABLE 21.6
Test Method Regulatory Acceptance Criteria

Validated methods are not automatically accepted by regulatory agencies; they need to fit into the regulatory structure. Flexibility is essential in determining the acceptability of methods to ensure that appropriate scientific information is considered in regulatory risk assessment. A test method proposed for regulatory acceptance generally should be supported by the following attributes:

1. The method should have undergone independent scientific peer review by disinterested persons who are experts in the field, knowledgeable in the method, and financially unencumbered by the outcome of the evaluation.
2. There should be a detailed protocol with SOPs, a list of operating characteristics, and criteria for judging test performance and results.
3. Data generated by the method should adequately measure or predict the endpoint of interest and demonstrate a linkage between either the new test and an existing test or the new test and effects in the target species.
4. There should be adequate test data for chemicals and products representative of those administered by the regulatory program or agency and for which the test is proposed.
5. The method should generate data useful for risk assessment purposes (i.e., for hazard identification, dose–response assessment, and/or exposure assessment). Such methods may be useful alone or as part of a battery or tiered approach.
6. The specific strengths and limitations of the test must be clearly identified and described.
7. The test method must be robust (relatively insensitive to minor changes in protocol) and transferable among properly equipped and staffed laboratories.
8. The method should be time and cost effective.
9. The method should be one that can be harmonized with similar testing requirements of other agencies and international groups.
10. The method should be suitable for international acceptance.
11. The method must provide adequate consideration for the reduction, refinement, and replacement of animal use.

justified. The test method protocol should provide sufficient information to allow for development of laboratory-specific GLP-compliant test protocols.

Adequate Measurement or Prediction of the Endpoint of Interest

Data generated by the test method should adequately measure or predict the endpoint of interest and demonstrate a linkage between either the new test and an existing test, or the new test and effects in the target species of interest [44–46]. Such a determination should ideally include an objective assessment of the accuracy of the existing test for measuring or predicting the toxic effect of interest; however, much of the data generated for an existing test method may be proprietary and therefore not readily available for such an assessment. In such instances, regulatory authorities may not be able to provide the actual data to the public that they use for making regulatory acceptance decisions.

Adequate Test Data

Adequate testing data should be available for the chemicals and products for which the test method is proposed for use [44–46]. In some cases, these data may not adequately represent the complete spectrum of chemicals and products regulated by a specific regulatory agency or program. This lack of data might serve as the basis for nonacceptance by one or more regulatory authorities. However, it is possible for test methods to be found valid and acceptable for some defined chemical classes or physical and chemical properties that may not encompass the entire range of substances regulated by a specific agency. In such cases, acceptance may include specific restrictions on the substances for which the test method may be used.

Usefulness for Risk Assessment

A test method should generate data useful for risk assessment purposes in order to be accepted [44–46]. This will most commonly be for hazard identification purposes but could also include dose–response or exposure assessment purposes. The specific use for which the test method is proposed should be provided, such as whether the test method is proposed as a substitute or complete replacement for an existing test method, whether the test method is proposed as a screening test in a tiered testing strategy, or if the test is proposed as part of a battery of tests using a weight-of evidence approach.

Identification of Strengths and Limitations

The specific strengths and limitations of the test method must be clearly identified and described [44–46]. This description may be in terms of demonstrated usefulness and limitations based on high-quality data, or it may be based on the fact that certain types of substances have not yet been evaluated in the test system. The limitations associated with a test method will necessarily influence its regulatory utility and could restrict its applicability in certain regulatory domains.

Robustness and Transferability

The validation study must have demonstrated that the test method is sufficiently robust and that it is transferable among properly equipped and staffed laboratories [44–46].

There must be sufficient evidence to assure regulatory authorities that similar results will be obtained with the same substance regardless of the geographic area and laboratory where the test method is conducted or the laboratory personnel performing the test.

Time and Cost Effectiveness

The test method should be time and cost effective compared to the test method that it is proposed to substitute or replace [44–46]. Obviously, a test method that takes considerably more time and expense to conduct than an existing test would have to have sufficient other advantages to warrant acceptance by regulatory authorities and use by the regulated industry.

Harmonized for Use by Other Agencies and International Groups

The test method should be capable of being harmonized with similar testing requirements of other agencies and international groups [44–46]. This criterion is especially important in light of the worldwide implementation of the GHS of Classification and Labeling of Chemicals [41]. Accordingly, new test methods should include assessment of the test method accuracy for the GHS hazard classification scheme where appropriate.

Suitability for International Acceptance

New test methods should be suitable for acceptance by international authorities, such as the United Nations (UN), the Organization for Economic Cooperation and Development (OECD), and the International Organization for Standardization (ISO) [44–46]. This is to ensure that the new method can be accepted for use internationally and thereby avoid the need for redundant testing for countries that have not adopted the new test method.

Adequate Consideration of the 3Rs

New test methods must provide for adequate consideration of the reduction, replacement, and refinement (3Rs) of animal use if they involve animals or test system components derived from animals [44–46]. Such consideration is necessary to comply with the United States and European animal welfare regulations, policies, and guidelines [8,9,12,13].

TEST METHOD PERFORMANCE STANDARDS

Many new and alternative test methods are proprietary in nature and are protected by intellectual property laws such as patents, trademarks, and copyrights. Such intellectual protections stimulate innovation by providing financial incentives for companies to develop and market new products, such as in vitro testing methods that may reduce, refine, or replace animal use. U.S. laws, however, require that government regulatory authorities cannot simply endorse or approve proprietary methods until they first convey the basis by which the proprietary methods have been determined to be acceptable for use [46,63,64]. ICCVAM subsequently incorporated procedures to routinely recommend performance standards for all new test methods that it evaluates, regardless of whether they include proprietary components or not. ICCVAM has now developed and recommended performance standards for both in vitro and in vivo test methods, including in vitro corrosivity test methods, the murine LLNA, and in vitro estrogen receptor agonist and antagonist transactivation assays [63–67].

Defining Test Method Performance Standards

Performance standards are defined as the basis by which a proprietary or nonproprietary test method has been determined to have sufficient accuracy and reliability for a specific testing purpose [46,63,64]. Performance standards are based on an adequately validated test method and provide a basis for evaluating the comparability of mechanistically and functionally similar test methods. This process involves first determining that a test method has sufficient accuracy and reliability for a defined specific testing purpose. This information is then used to develop performance standards that can be used as the basis for evaluating the acceptability of proposed test methods based on similar scientific principles and that measure or predict the same biological or toxic effect. If a similar test method adequately addresses and meets these standards, then it would be considered to be comparable, in terms of performance, to the test method used to establish the performance standards. Performance standards can then be used by regulatory authorities to communicate the basis by which they find the original reference test method to be acceptable for specific regulatory testing purposes, as well as to judge the acceptability of subsequent similar methods. ICCVAM now routinely develops and proposes performance standards during test method evaluations for both proprietary and nonproprietary methods that have undergone adequate validation [46,63,64]. The availability and use of test method performance standards can significantly streamline the validation and regulatory acceptance of structurally and functionally similar methods, thus providing more efficient and faster validation [63,64].

Components of Performance Standards

Performance standards consist of three elements: (1) essential test method components, (2) a minimum list of reference chemicals, and (3) accuracy and reliability values [46,63,64]. *Essential test method* components are the requisite structural, functional, and procedural elements of a validated test method that should be included in the protocol of a proposed mechanistically and functionally similar test method. These components include unique characteristics of the test method, critical procedural details, and quality control measures.

If there are deviations from the recommended essential test method components, then a scientific rationale must be provided and any potential impact of the deviations discussed. Incorporation of and adherence to essential test method components will help ensure that a proposed test method is based on the same concepts as the corresponding validated test method.

The *minimum list of reference chemicals* is used to assess the accuracy and reliability of a mechanistically and functionally similar test method that incorporates all of the essential test method components [46,63,64]. These chemicals are a representative subset of those used to demonstrate the reliability and accuracy of the validated reference test method on which the performance standards are based. To the extent possible, these reference chemicals should:

- Represent the range of responses that the validated test method is capable of measuring or predicting (e.g., negative and weak to moderate to strong positives)
- Produce consistent results in the validated test method and in the in vivo reference test method or target species of interest
- Reflect the accuracy of the validated test method
- Have well-defined chemical structures
- Be readily available (i.e., can be purchased from commercial sources)
- Not be associated with excessive hazard or prohibitive disposal costs
- Represent the range of known or suspected mechanisms or modes of action for the toxicity measured or predicted by the test method
- Represent the range of physical and chemical properties for which the test method is proposed to be capable of testing (e.g., solubility, pH, volatility)

These reference chemicals are the minimum number that should be used to evaluate the performance of a proposed mechanistically and functionally similar test method. Reference chemicals should not be used to develop the decision criteria or prediction model for the proposed test method. If any of the recommended reference chemicals are unavailable, other chemicals for which adequate reference data are available could be substituted with adequate scientific justification. To the extent possible, any substituted chemicals should be of the same chemical class and potency activity as the original chemicals. If desired, additional chemicals representing other chemical or product classes and for which adequate reference data are available can be used to more comprehensively evaluate the accuracy of the proposed test method; however, these additional chemicals should not include those used to develop the proposed test method. Table 21.7 provides a list of internationally harmonized performance standards reference chemicals for the LLNA [24,66]. These reference chemicals have now been used to evaluate two new similar versions of the LLNA that were subsequently adopted as OECD test guidelines [68–71].

Accuracy and *reliability* values are the comparable performance that should be achieved by the proposed test method when evaluated using the minimum list of reference chemicals [46,63,64]. Reference chemicals should be designated for performance standards that will result in accuracy and reliability values similar to the overall values determined from the entire validation database for the reference test method.

Process for Developing Performance Standards

The ICCVAM has developed a process for establishing performance standards during the evaluation of proposed new test methods [46,63,64,72]. The process is designed to ensure rigorous scientific review and to provide the opportunity for broad stakeholder and public comment. The ICCVAM process for developing performance standards for new test methods is as follows:

- The NICEATM and the appropriate ICCVAM interagency working group develop proposed performance standards for consideration during the ICCVAM evaluation process. If a sponsor proposes performance standards, these are considered by ICCVAM at this stage. Generally, the proposed performance standards will be based on the information and data provided in the test method submission or on other available applicable data.
- The ICCVAM/NICEATM peer-review panel evaluates the proposed performance standards for completeness and appropriateness during its evaluation of the validation status of the proposed test method. The proposed performance standards are made available with the test method submission to the public for comment prior to and during the peer-review panel meeting.
- The appropriate ICCVAM working group, with the assistance of NICEATM, prepares the final performance standards for ICCVAM approval, taking into consideration the recommendations of the peer-review panel and public comments.
- Performance standards recommended by ICCVAM are incorporated into ICCVAM test method evaluation reports, which are published, provided to federal agencies, and made available to the public. The availability of ICCVAM test method evaluation reports is announced routinely in the *Federal Register*, NTP newsletters, and ICCVAM/NICEATM e-mail LISTSERV groups.
- Regulatory authorities can then reference the performance standards in the ICCVAM report when they communicate their basis for their acceptance of a new test method. In addition, performance standards adopted by regulatory authorities can be provided in guidelines issued for new test methods, which is now done routinely for new OECD test guidelines [34,73].

TABLE 21.7
LLNA Performance Standards: Reference Substances for Validation of Modified LLNA Methods

Substance Name	LLNA	Vehicle	EC3[a]	*N*[b]	Guinea Pig[c]	Human
CMI/MI	+	DMF	0.009	1	+	+
2,4-Dinitrochlorobenzene	+	AOO	0.049	15	+	+
4-Phenylenediamine	+	AOO	0.11	6	+	+
Cobalt chloride	+	DMSO	0.6	2	+	+
Isoeugenol	+	AOO	1.5	47	+	+
2-Mercaptobenzothiazole	+	DMF	1.7	1	+	+
Citral	+	AOO	9.2	6	+	+
Hexyl cinnamic aldehyde	+	AOO	9.7	21	+	+
Eugenol	+	AOO	10.1	11	+	+
Phenyl benzoate	+	AOO	13.6	3	+	+
Cinnamic alcohol	+	AOO	21	1	+	+
Imidazolidinyl urea	+	DMF	24	1	+	+
Methyl methacrylate	+	AOO	90	1	+	+
Chlorobenzene	–	AOO	NC	1	–	–[d]
Isopropanol	–	AOO	NC	1	–	–
Lactic acid	–	DMSO	NC	1	–	–[d]
Methyl salicylate	–	AOO	NC	9	–	–
Salicylic acid	–	AOO	NC	1	–	–
Optional substances to demonstrate improved performance relative to the LLNA						
Sodium lauryl sulfate	+	DMF	8.1	5	–	–
Ethylene glycol dimethacrylate	+	MEK	28	1	–	+
Xylene	+	AOO	95.8	1	NA	–
Nickel chloride	–	DMSO	NC	2	+	+

Abbreviations: AOO, Acetone:olive oil (4:1); CMI/MI, 3:1 5-chloro-2-methyl-4-isothiazolin-3-one/2-methyl-4-isothiazolin-3-one (*KathonCG*); DMF, *N*,*N*-dimethylformamide; DMSO, dimethyl sulfoxide; EC3, estimated concentration needed to produce a SI of 3; LLNA, murine local lymph node assay; MEK, methyl ethyl ketone; NA, not available; NC, not calculated because SI < 3.

[a] Arithmetic means where the number of LLNA studies >1.

[b] Number of LLNA studies from which data were obtained.

[c] Results obtained from GPMT and/or Buehler test.

[d] Presumed to be a nonsensitizer in humans based on the fact that no clinical patch test results were located; it is not included as a patch test kit allergen, and no case reports of human sensitization were located.

Performance Standards for Dermal Corrosivity Test Methods

Performance standards are available for three proprietary—Corrositex, EPISKIN™, and EpiDerm™—and one nonproprietary—rat skin transcutaneous electrical resistance (TER)—in vitro dermal corrosivity test methods [65]. Due to the structural and functional differences of the four methods, three different sets of performance standards were developed [65]. EPISKIN and EpiDerm are structurally and functionally similar; therefore, one set of performance standards was developed for these two methods. The standards were based on EPISKIN, as this method had a larger validation database than EpiDerm (60 vs. 24). In addition to the essential test method components, a minimum list of 24 reference chemicals was selected from the 60 chemicals used for the validation of EPISKIN. This list included 12 corrosives and 12 noncorrosives. All of the selected reference chemicals are commercially available. Accuracy and reliability values for the 24 minimum reference chemicals closely matched the overall performance for the 60 chemicals in the validation database. For the rat skin TER, a minimum list of 24 reference chemicals was selected, which also provided accuracy and reliability values similar to those for the total validation database of 60 chemicals.

Performance standards based on Corrositex were developed for a generic in vitro membrane barrier test system for skin corrosion [34]. This in vitro membrane barrier test system is capable of identifying the three subcategories of corrosivity described by the UN Packing Group (PG) classification system [41]. Accordingly, the validation database contained a larger number of substances (129). The selected minimum list of reference chemicals contained a total of 40 chemicals, including 12 noncorrosive methods and 28 corrosive chemicals [65]. As with the other in vitro methods, the

accuracy and reliability values for the minimum list of reference chemicals were similar to those for the total validation database. These performance standards were subsequently included in the Test Guideline 435 for an in vitro membrane barrier test system for skin corrosion [34].

Using Performance Standards for Validation Studies

The availability of performance standards can significantly expedite the validation and acceptance of new test methods that are structurally and functionally similar to previously accepted methods for which there has been adequate validation [46,63,64]. For example, using performance standards, validation studies on a generic version of Corrositex could potentially be accomplished with 40 substances compared to the over 129 chemicals used for the original validation [29]. Performance standards should also facilitate more efficient and faster validation of improved versions of existing tests. The concept and definition of test method performance standards are now included in international guidance on validation [45].

ICCVAM ROLE IN VALIDATION AND REGULATORY ACCEPTANCE

History

The ICCVAM was first established as an ad hoc interagency committee in 1994 [15,44,60]. It consisted of representatives from 15 federal agencies and programs that require, generate, use, or disseminate toxicological testing information (Table 21.8) [15,44,60]. This committee was created by the National Institute of Environmental Health Sciences (NIEHS) in response to directives in the NIH Revitalization Act of 1993 that charged NIEHS with developing validation and regulatory acceptance criteria and recommending a process for achieving the regulatory acceptance of scientifically valid alternative test methods [10,44,60]. The principles embodied in the validation and regulatory acceptance criteria are based on good science and the need to ensure that the use of new test methods will provide for equivalent or better protection of human health and the environment than previous testing methods or strategies. ICCVAM issued its report in 1997 [44,60].

To implement a process for achieving regulatory acceptance of proposed new, revised, and alternative test methods with regulatory applicability, a standing ICCVAM was established to evaluate the scientific validity of such test methods in 1997 [60]. The NIEHS also established the NICEATM to administer ICCVAM and to provide scientific and operational support for the committee and its activities [60]. The ICCVAM Authorization Act of 2000 established ICCVAM as a permanent interagency committee of the NIEHS under NICEATM [11]. NICEATM collaborates with ICCVAM to carry out scientific peer review and interagency consideration of new test methods of multiagency interest. The center also performs other functions necessary to ensure compliance with provisions of the ICCVAM Authorization Act of 2000 and conducts independent validation studies on promising new test methods [72].

Purposes and Duties

The specific purposes and duties of the ICCVAM prescribed by the ICCVAM Authorization Act of 2000 are provided in Tables 21.9 and 21.10 [11]. In accordance with the ICCVAM Act and its original mandate, ICCVAM also continues to coordinate interagency issues on test method development, validation, regulatory acceptance, and national and international harmonization. The public health goal of NICEATM and ICCVAM is to promote the scientific validation and regulatory acceptance of new toxicity testing methods that are more predictive of human health, animal health, and ecological effects than currently available methods. Methods are emphasized that provide for improved toxicity

TABLE 21.8
Member Agencies of the ICCVAM

The ICCVAM consist of the following 15 federal regulatory and research agencies that require, generate, use, or distribute toxicological testing results:

Agency for Toxic Substances and Disease Registry (ATSDR)
Consumer Product Safety Commission (CPSC)
Department of Agriculture (USDA)
Department of Defense (DOD)
Department of Energy (DOE)
Department of the Interior (DOI)
Department of Transportation (DOT)
Environmental Protection Agency (EPA)
Food and Drug Administration (FDA)
National Institute for Occupational Safety and Health (NIOSH)
National Institutes of Health (NIH), Office of the Director
National Cancer Institute (NCI)
National Institute of Environmental Health Sciences (NIEHS)
National Library of Medicine (NLM)
Occupational Safety and Health Administration (OSHA)

TABLE 21.9
Specific Purposes of the ICCVAM (P.L. 106-545, Section 3(b))

1. Increase the efficiency and effectiveness of federal agency test method review
2. Eliminate unnecessary duplicative efforts and share experiences between federal regulatory agencies
3. Optimize utilization of scientific expertise outside the federal government
4. Ensure that new and revised test methods are validated to meet the needs of federal agencies
5. Reduce, refine, and replace the use of animals in testing, where feasible

Source: 42 U.S.C. §285l-2, ICCVAM Authorization Act of 2000 (P.L. 106-545), 2000.

TABLE 21.10
Duties of the ICCVAM (P.L. 106-545, Section 3(e))

1. Review and evaluate new or revised or alternative test methods, including batteries of tests and test screens, that may be acceptable for specific regulatory uses, including the coordination of technical reviews of proposed new or revised or alternative test methods of interagency interest.
2. Facilitate appropriate interagency and international harmonization of acute or chronic toxicological test protocols that encourage the reduction, refinement, or replacement of animal test methods.
3. Facilitate and provide guidance on the development of validation criteria, validation studies, and processes for new or revised or alternative test methods and help facilitate the acceptance of such scientifically valid test methods and awareness of accepted test methods by federal agencies and other stakeholders.
4. Submit ICCVAM test recommendations for the test method reviewed by the ICCVAM, through expeditious transmittal by the Secretary of Health and Human Services (or the designee of the secretary), to each appropriate federal agency, along with the identification of specific agency guidelines, recommendations, or regulations for a test method, including batteries of tests and test screens, for chemicals or class of chemicals within a regulatory framework that may be appropriate for scientific improvement, while seeking to reduce, refine, or replace animal test methods.
5. Consider for review and evaluation petitions received from the public that
   (A) Identify a specific regulation, recommendation, or guideline regarding a regulatory mandate
   (B) Recommend new or revised or alternative test methods and provide valid scientific evidence of the potential of the test method
6. Make available to the public final ICCVAM test recommendations to appropriate federal agencies and the responses from the agencies regarding such recommendations.
7. Prepare reports to be made available to the public on its progress under this act. The first report shall be completed not later than 12 months after the date of the enactment of this act, and subsequent reports shall be completed biennially thereafter.

TABLE 21.11
ICCVAM Prioritization Criteria

ICCVAM prioritizes proposed test method submissions and nominations based on consideration of the extent to which the proposed test method is:

1. Applicable to regulatory testing needs
2. Applicable to multiple agencies/programs
3. Warranted, based on the extent of expected use or application and impact on human, animal, or ecological health
4. The potential for the proposed test method, compared to current test methods accepted by regulatory agencies, to
   a. *Refine* animal use by decreasing or eliminating pain and distress or enhancing animal well-being
   b. *Reduce* animal use
   c. *Replace* animal use
5. The potential for the proposed test method to provide improved prediction of adverse health or environmental effects, compared to current test methods accepted by regulatory agencies
6. The extent to which the test method provides other advantages (e.g., reduced cost and time to perform) compared to current methods
7. The completeness of the nomination or submission with regard to ICCVAM test method submission guidelines

characterization and savings in time and costs, and that provide for the animal welfare goal of refinement, reduction, and replacement of animal use whenever feasible.

Test Method Nomination and Submission Process

Any organization or individual can submit a test method for which adequate validation studies have been completed to ICCVAM for evaluation [11,46,60]. ICCVAM has published guidelines for the information that should be submitted and has developed an outline to organize the information and data supporting the scientific validity of a proposed test method [46]. Any organization or individual can also nominate test methods for which adequate validation studies have not been completed to the ICCVAM for further study [46]. Nominations are prioritized based on established ICCVAM prioritization criteria (Table 21.11) [46,72]. Specific activities, such as workshops and validation studies, are then conducted for those test methods with the highest priority and for which resources are available [46,72].

ICCVAM Contribution to Regulatory Acceptance of Alternative Test Methods

ICCVAM and NICEATM and their member agencies and international partners have now contributed to the adoption of over 63 in vitro and in vivo alternative test methods by national and international authorities [72,74]. These methods have resulted in significant refinement, reduction, and partial replacement of animal use. Examples of in vitro test methods reviewed and recommended by ICCVAM and adopted by U.S. agencies and the OECD where applicable include

four in vitro methods for identifying dermal corrosives [31–35], two in vitro methods for eye safety testing [75–77], five in vitro pyrogen tests [76], and two in vitro methods for assessing estrogen receptor agonist and antagonist activity of chemicals [49,67,77,78]. Important examples of reduction and refinement alternative methods recommended by ICCVAM and adopted by the OECD include four versions of the LLNA assay for assessing ACD [68–71,73,79,80], the revised up-and-down procedure for determining acute oral toxicity [22,81], and recommendations for the routine use of pain-relieving medications and humane endpoints whenever it is still necessary to use animals for eye safety testing [29,82]. Many other reduction, refinement, and replacement alternative test methods have been evaluated or are currently undergoing evaluation, while still others are being developed for a wide range of human health and ecological testing purposes [72,83].

OTHER ORGANIZATIONS INVOLVED IN VALIDATION

In addition to the United States, several other countries have also established government centers to conduct independent validation studies of new alternative methods. These include, among others, the European Centre for the Validation of Alternative Methods (ECVAM) in the European Union, the Japanese Center for the Validation of Alternative Methods (JaCVAM) in Japan, the National Centre for Documentation and Evaluation of Alternative Methods to Animal Experiments (ZEBET) in Germany, and the Korean Center for the Validation of Alternative Methods (KoCVAM). In 2009, an international memorandum of cooperation was signed by the United States, the European Union, Canada, and Japan to establish the International Cooperation on Alternative Test Methods (ICATM) [84,85]. In 2011, KoCVAM also became a signatory to the ICATM agreement.

International Cooperation on Alternative Test Methods

The ICATM is an agreement to establish and promote international cooperation by national validation centers in the critical areas of validation studies, independent peer review, and development of harmonized test method recommendations for alternative test methods [84,85]. The goal of these cooperation activities is to promote more efficient and more rapid international adoption of scientifically valid alternative methods. The five current national organizations participating in the ICATM are NICEATM/ICCVAM, Health Canada, EURL-ECVAM, JaCVAM, and KoCVAM [85].

EURL-ECVAM

The ECVAM was established by the European Union in 1992 as a component within the European Commission [86]. In 2011, ECVAM was redesignated as the European Reference Laboratory for Alternatives to Animal Testing (EURL-ECVAM) as a result of EU Directive 2010/63/EU [9]. EURL-ECVAM is administratively located within the Institute for Health and Consumer Protection within the European Commission's Joint Research Centre in Ispra, Italy. The duties of the EURL-ECVAM are to promote the development and use of alternative methods in both basic research and applied research and in the regulatory field and to coordinate the process of validation of alternative methods at the European level. EURL-ECVAM has received significant support to assist with the development and validation of in vitro methods to meet EU Parliament deadlines that will prohibit the use of animals for the testing of cosmetic ingredients in 2013 [87]. EU legislation adopted in 2004 already bans the use of animals for testing cosmetic products [88]. ICCVAM and EURL-ECVAM work together on projects and validation studies of common interest to facilitate harmonized methods and to leverage resources [29,89].

JaCVAM

The JaCVAM was officially established in November 2005 [90,91]. The center is a component of the National Institute of Health Sciences, which is part of the Ministry of Health and Welfare, and is located in Tokyo, Japan. The center was established to develop, validate, and review alternative test methods in Japan and interacts closely with the Japanese Society for Alternatives to Animal Experimentation (JSAAE) [90–92]. The JSAAE has provided national leadership in the development and validation of alternative methods in Japan and provides an important scientific network for related in vitro studies in Japan.

ZEBET

The German Centre for the Documentation and Validation of Alternative Methods was established in Germany in 1989 [93]. Since 2002, it has been a component of the Federal Institute for Risk Assessment (BfR) located in Berlin, Germany. ZEBET has been instrumental in the development and validation of several important in vitro alternative methods, including methods for dermal irritation and corrosivity, embryotoxicity, ocular irritation, and photosensitization.

ALLERGIC CONTACT DERMATITIS

The murine LLNA is an example of a reduction and refinement alternative method for assessing the ACD potential of chemicals [4,16,24]. The LLNA was the first alternative test method evaluated and recommended by ICCVAM [25,94–96]. The LLNA uses fewer animals and completely avoids pain and distress compared to the traditional animal tests previously used for ACD testing such as the Buehler test and the GPMT [4,16,24,25,94–98]. The LLNA also provides dose–response information and can be completed in 6 days compared to over 4 weeks for the traditional tests that use guinea pigs [24,25,94]. Based on the results of a comprehensive scientific peer review and technical evaluation, ICCVAM determined that the LLNA was a valid substitute to currently accepted test methods that use guinea pigs and

concluded that the LLNA provides for the refinement and reduction of animal use [25,94]. ICCVAM forwarded test recommendations to agencies for their consideration, and the LLNA was subsequently accepted in 1999 by the U.S. Environmental Protection Agency (EPA), U.S. Food and Drug Administration, Consumer Product Safety Commission, and Occupational Safety and Health Administration. A new internationally harmonized test guideline (Test Guideline 429) on skin sensitization using the LLNA was then adopted in 2002 by the Test Guidelines Programme at the OECD [73].

In 2008 and 2009, ICCVAM evaluated and subsequently recommended several new versions and expanded applications of the LLNA [66,68,69,79,99]. These included an updated version of the LLNA that uses 20% fewer animals and a reduced LLNA (rLLNA) protocol that reduces the number of animals required by an additional 40% [66,79]. The improvements were adopted by U.S. agencies and incorporated in an updated OECD TG429 that also incorporates LLNA performance standards [73]. Finally, two versions of the LLNA that do not use radioactive substances, the LLNA-DA and the LLNA:BrdU-ELISA, were adopted by U.S. regulatory agencies and the OECD in 2011 [70,71]. The LLNA is now commonly used worldwide and is the preferred method to determine the ACD hazard for most types of substances [100,101]. The following sections describe the LLNA test method protocol and recent updates, the rLLNA, the LLNA-DA, and the LLNA:BrdU-ELISA.

Regulatory Rationale for the LLNA

ACD is associated with chemical exposures in the workplace and at home. ACD is a serious public health problem, with over 4000 chemicals and substances known to cause allergic dermatitis in humans [102]. Accordingly, regulatory agencies require testing to determine if substances may have the potential to cause ACD, and require that positive substances must be labeled to warn consumers and workers of the hazard potential for ACD along with appropriate precautions to take to avoid exposures [103–106]. An assessment of the potential for chemicals to cause ACD is therefore an important component of routine chemical and product safety testing. Traditionally, guinea pigs have been used to assess the ACD potential of chemicals, pharmaceuticals, and consumer products [94]. Although these test methods vary, the GPMT and the Buehler assay (BA) have been the most commonly used methods for ACD testing. Both of these tests rely on the induction and elicitation phases of ACD and require about a month to perform. The GPMT also may involve the use of complete Freund's adjuvant, which can be highly irritating to animals. The endpoint measured in the guinea pig methods is a visual assessment of erythema and edema at the challenge location and requires substantial technical expertise [107].

Mechanistic Basis of Allergic Contact Dermatitis

The LLNA is a mechanism-based assay for ACD testing that measures one of the early key biological pathway events that are necessary for the development of chemically induced ACD [108–110]. The sequence of key events that must occur in order to produce ACD are collectively referred to an adverse outcome pathway (Figure 21.2) [110]. The key event measured in the LLNA is the threefold or higher level of lymphocyte proliferation that occurs in the lymph

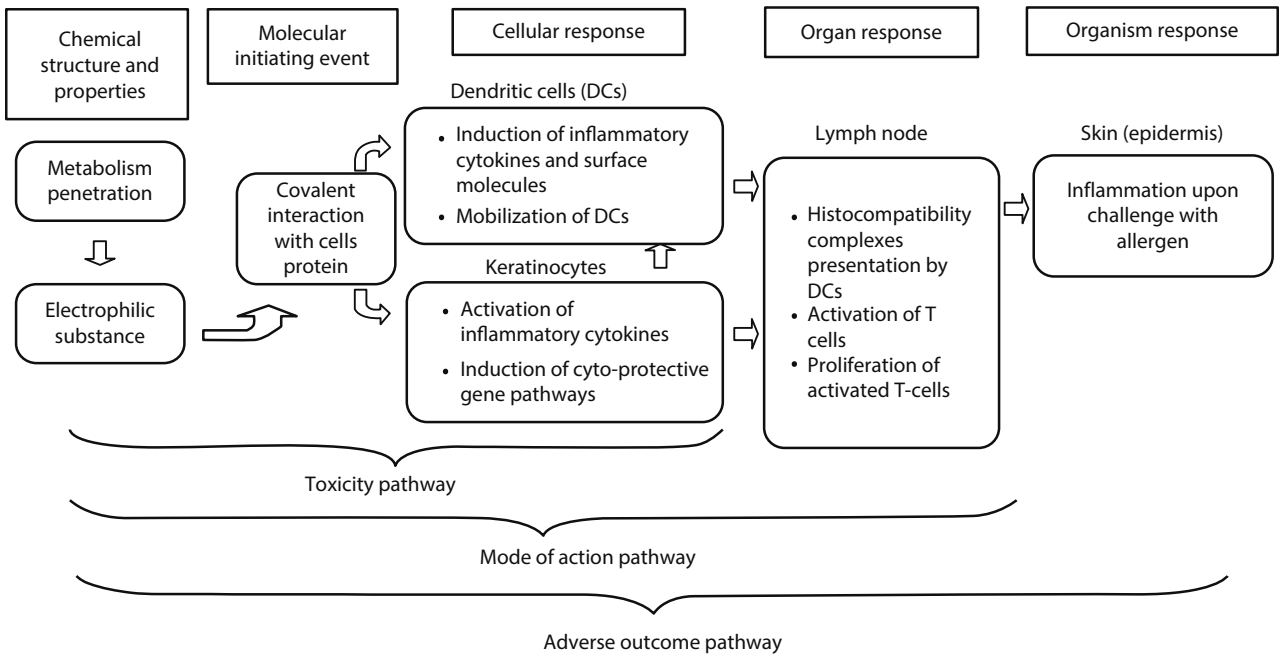

FIGURE 21.2 Adverse outcome pathway for skin sensitization. (From OECD, The adverse outcome pathway for skin sensitization initiated by covalent binding to proteins, Part 1: Scientific evidence, OECD Environment, Health, and Safety Publications: Series on Testing and Assessment No 168, OECD, Paris, France, 2012.)

nodes draining the skin area where a test article is repeatedly applied [94,108,110]. This compares with the assessment in the traditional GP assays of the actual adverse outcome of erythema and edema that occur 24–72 h after a challenge exposure to a sensitizing substance [95].

ACD develops in two phases: an initial induction phase followed by an elicitation phase. The induction phase begins with initial skin contact with a sensitizing agent. Following penetration of the epidermis, reactive electrophilic chemicals undergo covalent bonding to protein in a process called haptenization [110–112]. Allergenic substances that require metabolism in the skin to become reactive are called prohaptens, while substances that require oxidation or other chemical activation to become active are called prehaptens. Biological and chemical assays are now available to assess the peptide reactivity of chemicals, including the direct peptide reactivity assay (DPRA) and a recombinant human keratinocyte cell line with a reporter gene that is activated by electrophilic chemicals [111,113].

Following haptenization, an immediate release of signaling factors and activation of the skin dendritic cells occur. Dendritic cells process the chemical and subsequently mature and migrate to the draining lymph node where they serve as antigen-presenting cells. Lymphocytes within the nodes, upon antigen presentation, undergo cellular proliferation. Lymphocyte proliferation is the mechanistic endpoint assessed in the LLNA and indicates that the induction phase of ACD has taken place [97]. Following proliferation, T-lymphocytes are considered primed, as they have a specific recall for the sensitizing agent. Upon subsequent exposure to the agent, an antigen-specific response occurs, which is referred to as the *elicitation phase*. This second phase occurs only if there is elicitation of specific mediators that cause an inflammatory cell influx to the dermal site. Elicitation is a systemic response that can occur at locations other than the original site of sensitization. The elicitation phase is characterized by erythema and edema and occurs 24–72 h after the challenge exposure. This response is the endpoint assessed in traditional guinea pig tests [110]. Since the LLNA only assesses events that occur during the induction phase of ACD, it therefore avoids the need for later chemical challenge exposures necessary to elicit an allergic response and that can result in pruritus, erythema, and edema for sensitizing chemicals.

Traditional LLNA Procedure

ICCVAM has updated its detailed test method protocol for the LLNA [66] that has been adopted by U.S. regulatory agencies and that serves as the basis for the updated OECD test guideline [73] for the LLNA. The following sections briefly review the LLNA technical procedures in the updated test method protocol, but users should always ensure that they are compliant with the most recent version available and that it is consistent with any additional guidelines from the applicable regulatory authorities for which the test data are being generated. The basic principle underlying the traditional LLNA is that sensitizers induce proliferation of lymphocytes in the lymph node draining the site of chemical application [97,98,108,109]. Generally, this proliferation is proportional to the dose applied and potency of the sensitizer. The test measures cellular proliferations as a function of in vivo radioisotope incorporation into the DNA of dividing lymphocytes in the draining lymph nodes proximal to the application site (Figure 21.3) [72]. The lymphocyte proliferation in the test groups is compared to that in concurrent vehicle-treated controls. A positive control group of animals is included in each assay to indicate whether all biologic and technical aspects of the assay are sufficiently adequate such that the assay is capable of producing a sufficiently positive result for the positive control. If the positive control does not result in a positive test outcome, the test is not considered valid and must be repeated.

Animals

Young adult female CBA/Ca or CBA/J strain mice (nulliparous and not pregnant) 8–12 weeks of age are used for the assay [66,73,94]. Females are used because the existing database is predominantly based on this gender. Other strains and males can be used following evaluation that demonstrates that they can provide equivalent results to the strains and/or gender used in the validation studies. Mice are carefully observed for any clinical signs, including local irritation at the application site and signs indicative of systemic toxicity. Weighing mice prior to treatment and at the time of necropsy will aid in assessing systemic toxicity. All observations are systematically recorded, with records being maintained for each individual mouse.

Test Articles

Solid test substances are dissolved in appropriate solvents or vehicles and diluted, if appropriate, prior to dosing of the animals. Liquid test substances may be dosed directly or diluted prior to dosing. Fresh preparations of the test substance should be prepared daily unless stability data demonstrate the acceptability of storage. The solvent or vehicle should be selected on the basis of maximizing the test concentrations while producing a solution or suspension suitable for application of the test substance. In order of preference, recommended solvents and vehicles are acetone/olive oil (4:1 v/v), *N*,*N*-dimethylformamide (DMF), methyl ethyl ketone (MEK), propylene glycol (PG), and dimethylsulfoxide (DMSO), but others may be used [66,73,94]. Particular care should be taken to ensure that hydrophilic materials are incorporated into a vehicle system that wets the skin and does not immediately run off [99,114,115]. It may be necessary for regulatory purposes to test the chemical in the clinically relevant solvent or product formulation.

Four successfully treated animals are used per dose group, with a minimum of three consecutive concentrations of the test substance plus a solvent or vehicle control and a positive control group. Test substance treatment doses should be based on adopted recommendations and guidelines [66,73]. Doses are selected from the concentration series 100%, 50%, 25%,

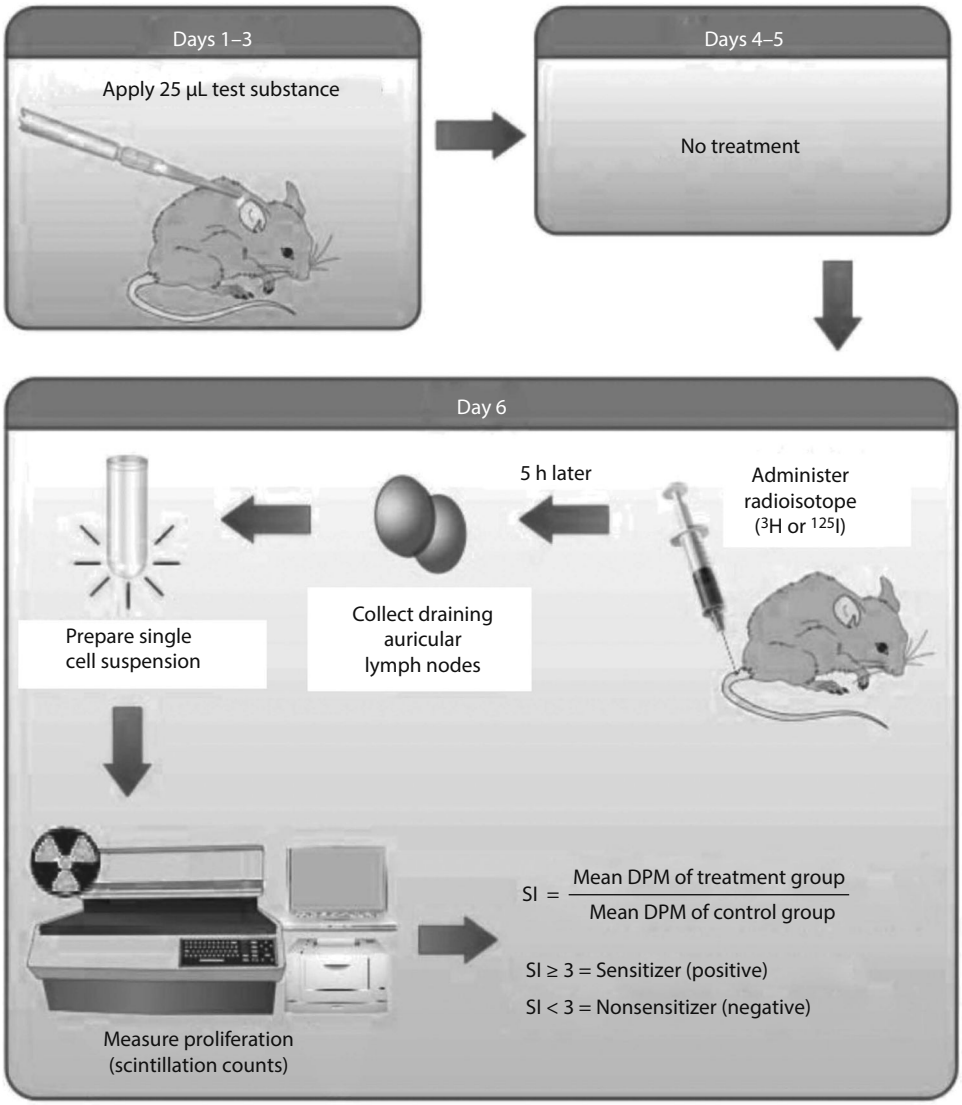

FIGURE 21.3 Testing procedure: traditional murine LLNA. (From Stokes, W.S. and Strickland, J., in Wilhelm, Z. and Maibach, H., eds., *Dermatotoxicology*, 8th edn. Informa Healthcare, London, U.K., 2012, pp. 473–485. With permission.)

10%, 5%, 2.5%, 1%, 0.5%, etc. The maximum concentration tested should be the highest achievable level that does not result in local irritation or overt systemic toxicity. To identify the appropriate maximum test substance dose, an initial toxicity test, conducted under identical experimental conditions except for an assessment of lymph node proliferative activity, may be necessary. To support an ability to identify a dose–response relationship, data must be collected on at least three test substance treatment doses, in addition to the concurrent solvent or vehicle control group. For negative LLNA studies, the concurrent positive control must induce a stimulation index (SI) greater than 3 relative to its vehicle-treated control.

Controls

Concurrent solvent/vehicle and positive controls should be included in each test [66]. In some circumstances, it may be useful to include a naïve control. Except for treatment with the test substance, animals in the control groups should be handled in a manner identical to that for animals of the treatment groups. Inclusion of a positive control group with each test is recommended to ensure that all test protocol procedures are being conducted properly and that all aspects of the test system are working sufficiently adequately that the test is capable of producing a positive response [66]. The positive control should produce a positive LLNA response at an exposure level expected to give an increase in the SI greater than 3 over the negative control group. The positive control dose should be chosen such that the induction is clear but not excessive. Preferred positive control substances are hexyl cinnamic aldehyde (HCA) or mercaptobenzothiazole.

Protocol Schedule

Day 1—Individually identify and record the weight of each mouse prior to dermal applications. Apply 25 µL/ear of the appropriate dilution of the test substance, the positive control, or the vehicle alone to the dorsum of both ears (Figure 21.3).

Days 2 and 3—Repeat the application procedure as carried out on day 1.

Days 4 and 5—No treatment.

Day 6—Record the weight of each mouse. Inject 250 μL of sterile phosphate-buffered saline (PBS) containing 20 μCi of ^{3}H-methyl thymidine (^{3}H-TdR) or 250 μL PBS containing 2μCi of ^{125}I-iododeoxyuridine (^{125}IU) and 10^{-5} M fluorodeoxyuride into each experimental mouse via the tail vein [74,75]. Five hours later, the draining (auricular) lymph node of each ear is excised and pooled in PBS for each animal [51]. Both bilateral draining lymph nodes must be collected.

Lymphocyte Measurements

A single-cell suspension of lymph node cells (LNCs) is prepared for each mouse. The single-cell suspension is prepared in PBS either by gentle mechanical separation through 200-mesh stainless steel gauze or by another acceptable technique for generating a single-cell suspension. LNCs are washed twice with an excess of PBS and the DNA precipitated with 5% trichloroacetic acid (TCA) at 4°C for approximately 18 h. For the ^{3}H-TdR method, pellets are resuspended in 1 mL TCA and transferred to 10 mL of scintillation fluid. Incorporation of tritiated thymidine is measured by β-scintillation counting as disintegrations per minute (dpm) for each mouse and expressed as dpm/mouse. For the ^{125}IU method, the 1 mL TCA pellet is transferred directly into gamma counting tubes. Incorporation of ^{125}IU is determined by gamma counting and also expressed as dpm/mouse.

Calculation of the Stimulation Index

The LLNA measures lymphocyte proliferation in the draining lymph nodes of mice topically exposed to the test article using the incorporation of radioactive thymidine or iododeoxyuridine into DNA. The results are expressed as a ratio, the SI, of the mean number of disintegrations per minute for treated mice as compared to controls. Chemicals with a SI of 3.0 or more are considered positive, and those with a SI less than 3.0 are considered negative. This scoring differs from the scoring in guinea pig assays, where a test substance is classified as positive based on the percentage of animals in a group that are responders (at least 15% in a nonadjuvant assay and at least 8% in an adjuvant test) [70].

Results for each treatment dose group are expressed as the mean SI. The SI is the ratio of the mean dpm/mouse within each test substance treatment group and the positive-control-treated group against the mean dpm/mouse for the solvent- or vehicle-treated control group. The investigator should be alert to possible outlier responses for individual animals within a group that may necessitate the use of an alternative measure of response (e.g., median rather than mean) or elimination of the outlier. Each SI should include an appropriate measure of variability that takes into account the interanimal variability in both the dosed and control groups [51].

In addition to an assessment of the magnitude of the SI, a statistical analysis for the presence and degree of dose–response may be conducted, which is only possible with the use of data from individual animals [66]. Any statistical analysis should include an assessment of the dose–response relationship, as well as suitably adjusted comparisons of test groups (e.g., pairwise dosed group vs. concurrent solvent or vehicle control comparisons) such as by using linear regression analysis to assess dose–response trends or Dunnett's test for pairwise comparisons. When choosing an appropriate method of statistical analysis, the investigator should be aware of possible inequality of variances and other related problems that may necessitate a data transformation or a nonparametric statistical analysis.

Individual mouse disintegrations per minute data should be presented in tabular form, along with the group mean dpm/mouse, its associated error term, and the SI (and associated error term) for each dose group compared against the concurrent solvent or vehicle control group.

Evaluation and Interpretation of Results

In general, when the SI for any single treatment dose group is 3 or greater, the test substance is regarded as a skin sensitizer [66,73,94]; however, the magnitude of the SI should not be the sole factor used to determine the biological significance of a skin sensitization response. A quantitative assessment performed by statistical analysis of individual animal data may provide a more complete evaluation of the test agents. Factors that should be considered in addition to the SI include statistical analyses, the strength of the dose–response relationship, chemical toxicity, solubility, and the consistency of the vehicle and positive control responses. Equivocal results, such as when the SI approaches but does not reach an SI of 3 and there is a positive dose–response relationship, should be clarified by performing statistical analysis and by also considering structural relationships, available toxicity information, and dose selection.

Training and Preparation for Node Identification

There are several methods that can be used to provide color identification of the draining nodes [66,94,95,98]. These techniques may be helpful to provide training for initial identification and should be performed to ensure proper isolation of the appropriate node. Examples of such treatments that can be used for training are listed as follows:

- *Evan's blue dye treatment*—Inject approximately 0.1 mL of 2% Evan's blue dye (prepared in sterile saline) intradermally into the pinnae of an ear. Humanely kill the mouse after several minutes and then proceed with the dissection to remove the auricular lymph nodes.
- *Colloidal carbon and other dye treatments*—Colloidal carbon and India ink are examples of other dye treatments that may be used [78]. For the purpose of node identification during training, a strong sensitizer is recommended. This agent should be applied in the standard acetone–olive oil vehicle (4:1). Suggested sensitizers used for this training exercise include 0.1% oxazolone, 0.1% (w/v)

2,4-dinitrochlorobenzene, and 0.1% (v/v) dinitrofluorobenzene. After treating the ear with a strong sensitizer, the draining node will dramatically increase in size, thus aiding in the identification and location of the node. Due to the exaggerated response produced by the suggested sensitizers for node identification, they are not recommended as positive controls for the assay performance and should only be used for training.

The node draining the ear (auricular) is located distal to the masseter muscle, away from the midline, and near the bifurcation of the jugular vein. Nodes can be distinguished from the glandular and connective tissue in the area by the uniformity of the nodal surface and a shiny translucent appearance. The application of sensitizing agents will cause an enlargement of the node.

Expanded Applicability Domain of the LLNA

Following the 1998 ICCVAM evaluation of the LLNA, the LLNA was not recommended for testing metals, due to some false-negative results, or aqueous substances, because they would not adhere to the skin and allow for sufficient skin contact. There was also no data provided to evaluate the usefulness of the LLNA for formulations. After a number of years of international experience with the LLNA and the accumulation of additional data, ICCVAM reevaluated the potential applicability domain of the LLNA in 2008 [99]. The predictivity of the LLNA was compared to available guinea pig and/or human ACD testing data for a wide range of substance and formulations. Based on this comparison, ICCVAM recommended that the LLNA could be used for testing metal compounds (with the exception of nickel), pesticide formulations, dyes, natural complex substances (i.e., fragrance oil and extracts), and substances tested in aqueous solutions [99]. ICCVAM also recommended that any substance could be tested in the LLNA, unless the substance has unique physicochemical properties that could interfere with identification in the LLNA as a sensitizing substance. U.S. federal agencies concurred with the ICCVAM recommendations on the expanded applicability domain (http://iccvam.niehs.nih.gov/methods/immunotox/llna.htm), and the U.S. EPA updated their policy to accept LLNA data for testing pesticide products [116].

Reduced LLNA Test Method Protocol

The rLLNA is a modified version of the traditional LLNA that reduces animal use by 40% per test [24,73,79,116,117]. The test method protocols for the multidose LLNA and the rLLNA differ only in the number of dose levels tested. In the multidose LLNA, at least three dose levels are tested, while in the rLLNA, only the highest dose of a substance is tested. In either version, it is important that the highest dose is selected based on the maximum soluble concentration that avoids excessive local irritation and/or systemic toxicity [66,79]. The validity of the rLLNA was determined by comparing the outcome of multidose LLNA results to outcomes based only on the highest dose used in the LLNA tests [79]. The validation database included 457 unique substances tested in 471 multidose LLNA studies. Compared to the multidose LLNA, the rLLNA had an accuracy of 98.7% (465/471), a false-positive rate of 0% (0/153), and a false-negative rate of 1.9% (6/318). All six substances that were considered false negative in the rLLNA had an SI < 3 for the highest dose, while multidose LLNA had positive results based on a low- or mid-dose SI ≥ 3. However, the maximum SI in all cases was less than 4, which is considered a weak response. Based on these results, ICCVAM recommended that the rLLNA could be used to distinguish between skin sensitizers and nonsensitizers if dose–response information was not required [79].

ICCVAM also recommended that the rLLNA should be used routinely to determine ACD potential of chemicals and products *before* conducting the traditional LLNA in order to minimize the number of animals used for ACD testing [79]. This is because the majority of products and chemicals are expected to produce negative results. Using the rLLNA results, negative substances can therefore be classified as nonsensitizers and positive substances can be classified as sensitizers with 40% fewer animals. The exceptions to using the rLLNA for the initial test are testing situations where dose–response information is required *and* there is evidence suggesting that the substance is likely to be a sensitizer. In such situations, these substances should therefore be tested initially in the multidose LLNA.

Because of a small possibility of a false-negative result in the rLLNA, negative results should prompt a weight-of-evidence evaluation of all available information [79]. Items that could be considered in such an evaluation include factors that could reduce skin absorption at the high dose, structural relationship to known sensitizers, test results with similar substances, peptide-binding activity, molecular weight, and other in vitro/in silico/in chemico data. The U.S. EPA accepts rLLNA data in situations where dose–response data are not needed, such as when results are expected to be negative [116].

Updates to the LLNA Test Method Protocol

The LLNA test method protocol was updated in 2009 to include several improvements and approaches that could further reduce animal use [66]. The updated OECD test guideline for the LLNA adopted in 2010 incorporates these improvements, as well as the rLLNA, the expanded LLNA applicability domain, and LLNA performance standards [66,73,79,99].

The updated LLNA protocol now uses a minimum of four animals per dose group rather than five. This reduction was based on a retrospective evaluation of data that showed that there was no significant difference in classification outcome when the LLNA was conducted using four animals compared to using five or more animals [79,118].

The updated protocol emphasizes the importance of collecting data from individual animals rather than pooling lymph nodes from all animals in a dose group [66,79].

Pooled data are discouraged because a review of actual data revealed the possibility of low outlier values that could result in false-negative results [66,118]. Outlier analysis is now recommended whenever an unusually high or low value is observed in a dose group [66,73,79]. However, individual animal data must be collected in order to conduct an outlier analysis.

The updated protocol also included more detailed guidance on procedures to select the highest dose used in the LLNA [66,73,79]. In testing situations where there is inadequate basis for selection of the highest dose, then a dose-range finding study is recommended and criteria are provided to select the highest dose that does not cause excessive local irritation or systemic toxicity.

Nonradioisotopic LLNA Test Methods

Two versions of the LLNA are available that do not use radioactive substances: the LLNA:DA and the LLNA:BrdU-ELISA [68,69]. U.S. regulatory agencies and the OECD have adopted both versions [70,71]. These LLNA test methods now allow broader use of the LLNA, as they can be used instead of the traditional guinea pig test methods in laboratories that are not approved to use radioisotopes. These LLNA methods now allow for use of the LLNA for nearly all skin sensitization testing situations, resulting in significantly expanded animal welfare benefits of the LLNA in terms of reduced animal use and avoidance of pain and distress. The nonradioactive LLNA test methods also offer environmental advantages by avoiding the generation of radioactive wastes.

LLNA:DA Test Method

The LLNA:DA (*D* for Daicel Chemical Industries, Ltd., and *A* for ATP) is a nonradioactive LLNA method developed by Idehara and colleagues at Daicel Chemical Industries, Ltd. [24,70,119,120]. The LLNA:DA measures increases in ATP content in the draining auricular lymph nodes removed from treated and control mice. ATP content is quantified using a luciferin–luciferase assay to measure bioluminescence. Because ATP content correlates with living cell number, its measurement serves as an indicator of cell number at the time of sampling. The protocol for the LLNA:DA is similar to that for the LLNA (Figure 21.4). A minimum of four mice

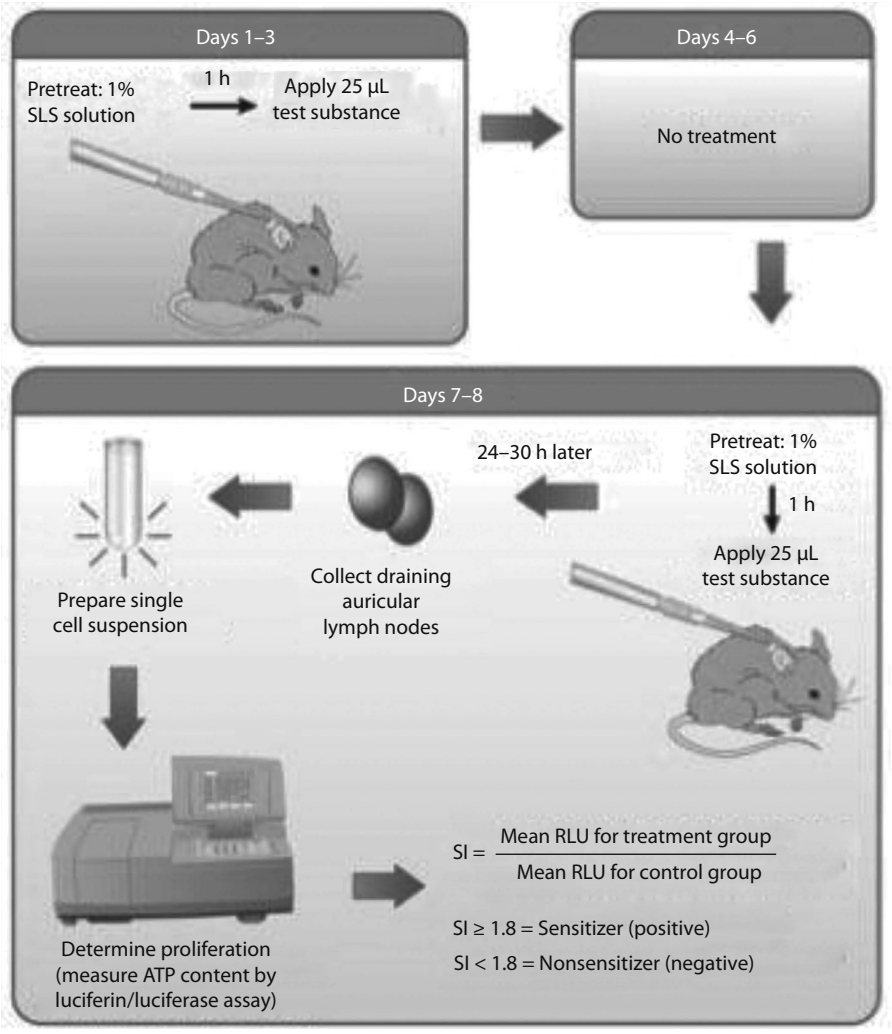

FIGURE 21.4 Testing procedure: murine LLNA:DA. (From Stokes, W.S. and Strickland, J., in Wilhelm, Z. and Maibach, H., eds., *Dermatotoxicology*, 8th edn. Informa Healthcare, London, U.K., 2012, pp. 473–485. With permission.)

are used per dose group, with at least three dose groups and concurrent vehicle and positive control groups [24,68,70].

Test and control substances (25 μL) are applied to the dorsum of each ear on days 1, 2, 3, and 7 one hour after pretreatment with 1% sodium lauryl sulfate (SLS). The SLS increases the absorption of the test substance across the skin. On day 8, the mice are humanely killed, the lymph nodes are excised, and an LNC suspension is prepared for each mouse. ATP content, which is proportional to the light produced by the luciferin–luciferase reaction, is measured using a commercially available kit. An SI value for each treatment group is calculated as the ratio of the mean relative luminescence units for the treatment group compared to the mean relative luminescence units for the control group. The decision criterion for a positive result is an SI ≥ 1.8 [24,70]. A reduced protocol for the LLNA:DA, the rLLNA:DA, should be used in testing situations that do not require dose–response information. The same considerations for using the rLLNA as the initial test for ACD assessments should also be considered in using the rLLNA:DA as the initial test for ACD testing. The applicability domain for the LLNA:DA is the same as the LLNA, unless there are properties associated with a class of materials that may interfere with the test method's accuracy. For example, the use of the LLNA:DA might not be appropriate for testing substances that affect the ATP content of cells (e.g., substances that function as ATP inhibitors) [68].

LLNA:BrdU-ELISA Test Method

The LLNA:BrdU-ELISA (*BrdU* for bromodeoxyuridine and *ELISA* for enzyme-linked immunosorbent assay) is a nonradioactive LLNA method developed by Takeyoshi and colleagues [24,69,121]. The LLNA:BrdU-ELISA assesses lymphocyte proliferation in the draining auricular lymph nodes by measuring the incorporation of the thymidine analog, BrdU, into the DNA of dividing LNCs. The protocol of the LLNA:BrdU-ELISA is similar to that for the LLNA (Figure 21.5). It uses a minimum of four mice for each of three or more dose group and concurrent vehicle and positive control groups. Test and control substances (25 μL) are applied to the dorsum of each ear on days 1, 2, and 3. On day 5, 5 mg BrdU in a volume of 0.5 mL physiological saline is administered via intraperitoneal injection. The mice are

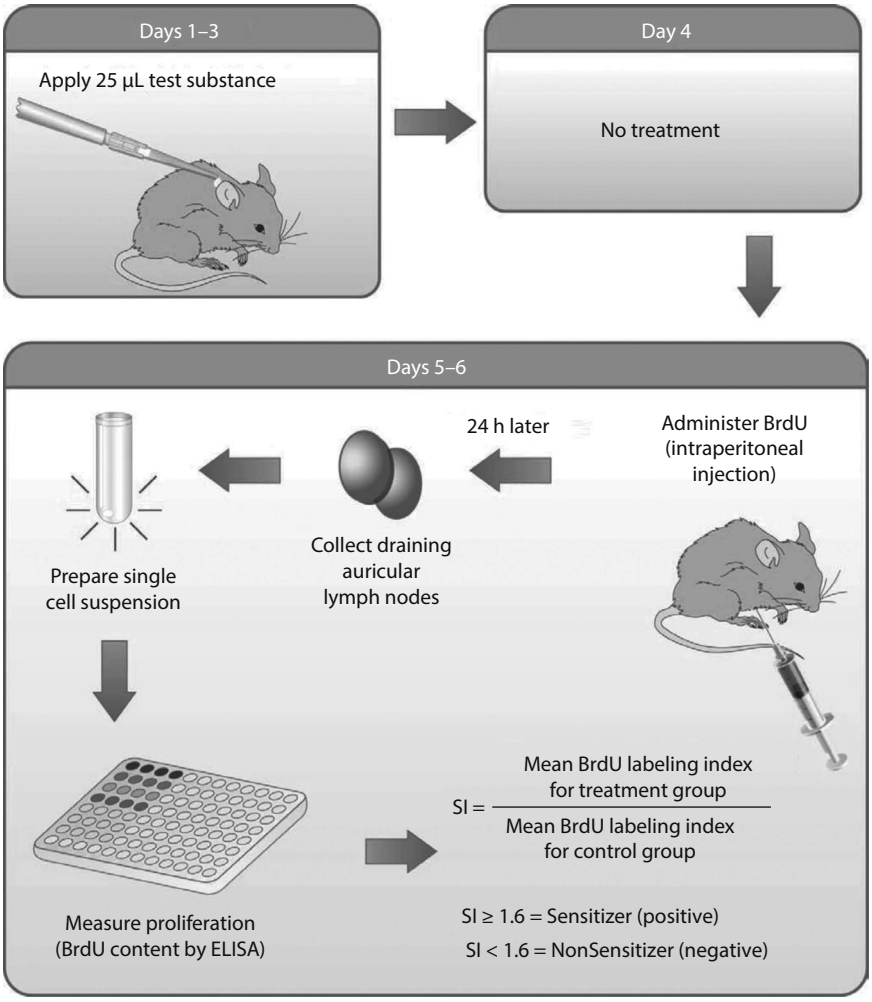

FIGURE 21.5 Testing procedure: Murine LLNA:BrdU-ELISA. (From Stokes, W.S. and Strickland, J., in Wilhelm, Z. and Maibach, H., eds., *Dermatotoxicology*, 8th edn. Informa Healthcare, London, U.K., 2012, pp. 473–485. With permission.)

humanely killed on day 6. The auricular lymph nodes are excised, and an LNC suspension is prepared individually for each mouse. A commercially available ELISA kit is used to assess BrdU incorporation, which is measured spectrophotometrically. An SI value is calculated for each treatment group as the ratio of the mean absorbance for the treatment group to the mean absorbance for the control group. A decision criteria of SI ≥ 1.6 is used to classify positive substances [24,71].

The LLNA:BrdU-ELISA also has a reduced protocol, the rLLNA:BrdU-ELISA, which requires only a single high-dose group, and that reduces the use of animals by 40% [24,69]. The same considerations for using the rLLNA as the initial test for ACD assessments should also be considered in using the rLLNA:BrdU-ELISA as the initial test for ACD testing. The applicability domain for the LLNA:BrdU-ELISA is the same as the LLNA, unless there are properties associated with a class of materials that may interfere with the test method's accuracy. The LLNA:BrdU-ELISA may also be useful in testing nickel compounds based on their correct identification as sensitizers in the validation study [24,69].

ALTERNATIVE METHODS FOR SKIN CORROSION

Four in vitro test methods are available for assessing the dermal corrosivity hazard potentials of chemicals: EPISKIN, EpiDerm (EPI-200), the rat skin TERassay, and Corrositex [31–35]. Based on the available data and performance for each test method, these methods are recommended for use as screening assays for the identification of corrosive substances in a tiered testing strategy, such as that proposed by the OECD (Table 21.12) [42]. In this strategy, positive results can be used to classify and label a substance as a dermal corrosive. Negative results generally require consideration of additional information or testing to properly identify any corrosive substances that may have been falsely identified as noncorrosives and to determine whether the substance is a dermal irritant.

In Vitro Membrane Barrier Test Systems for Skin Corrosion

Validation studies have been completed for an in vitro membrane barrier test system commercially available as Corrositex [35]. Based on its scientific validity, this test method has been recommended for use as part of a tiered testing strategy for assessing the dermal corrosion hazard potential of chemicals, whereby any substance that qualifies for testing can be evaluated [34,35]. In addition, this test method may be used to make decisions on the corrosivity and noncorrosivity of specific classes of chemicals (e.g., organic and inorganic acids, acid derivatives,* and bases) for certain transport testing circumstances. The basis of this test system is that it detects membrane damage caused by corrosive test substances.

The test substance is first evaluated to determine if it is compatible with the test procedure (i.e., if it qualifies for testing). If compatible, the substance is evaluated for the category of acid or base (strong or weak) to determine the appropriate time scale for classifying the potential corrosivity of the test substance. Finally, a compatible substance is applied to the surface of the artificial membrane barrier. The time it takes for the test substance to penetrate through the membrane barrier to an underlying indicator solution determines the corrosivity classification of that test substance. Penetration of the membrane barrier (or breakthrough) is indicated by a color change in a pH indicator dye in the solution below the barrier.

Performance standards have been established for in vitro membrane barrier test systems for corrosivity, as discussed in an earlier part of this chapter [65]. Essential test method components include a description of physical components of the test method (e.g., membrane barrier, categorization solutions, indicator solution), the test substance categorization system, the processes for determining test substance compatibility and test substance categorization, assembly of the physical components of the test method, application of a test substance, the appropriate control substances (solvent controls, positive [corrosive] controls, negative [noncorrosive] controls, benchmark controls), measurement of membrane barrier penetration, interpretation of results, and classification of test substances with regard to corrosivity potential. The test report should include the following information, if relevant to the conduct of the study: test and control substances, justification of the test method and protocol used, test method integrity, criteria for an acceptable test, test conditions, results, description of other effects observed, discussion of the results, and conclusions.

In Vitro Human Skin Cell Culture Systems for Skin Corrosion

The ECVAM conducted validation studies on two in vitro test methods that use cultured human skin cell test systems for assessing skin corrosivity: EpiDerm (MatTek; Ashland, MA) and EPISKIN (EPISKIN SNC; Lyon, France) [122]. These two methods utilize a 3D tissue culture model of human skin composed of a reconstructed epidermis and a functional stratum corneum composed of human keratinocytes. These test methods have been recommended for the testing of all classes of chemicals and for inclusion in tiered testing strategies as part of a tiered or weight-of-evidence evaluation. Neither test method has been validated for categorizing the corrosive properties of chemicals across the three UN PG subcategories of corrosivity, although data are available for differentiating between PG 1 and the two less severe PGs. The methods have been accepted by the European Commission and have been recommended by the ICCVAM for use as screening assays in a tiered testing strategy [31]. An international test guideline is also now available [33].

* *Acid derivative* is a nonspecific class designation and is broadly defined as an acid produced from a chemical substance either directly or by modification or partial substitution. This class includes anhydrides, haloacids, salts, and other types of chemicals.

TABLE 21.12
Testing and Evaluation Strategy for Dermal Irritation/Corrosion

Activity	Finding	Conclusion
1. Review existing human and/or animal data showing effects on skin or mucous membranes.	Corrosive	Apical endpoint—considered corrosive; no testing is necessary.
	Irritating	Apical endpoint—considered an irritant; no testing is necessary.
	Not corrosive/not irritating	Apical endpoint—considered not corrosive or irritating; no testing is necessary.
↓		
No information is available, or available information is not conclusive.		
↓		
2. Perform SAR evaluation for skin corrosion/irritation.	Predict severe damage to skin	Considered corrosive; no testing is necessary.
	Predict irritation to skin	Considered an irritant; no testing is necessary.
↓		
No predictions can be made, or predictions are not conclusive or negative.		
↓		
3. Measure pH (consider buffering capacity, if relevant).	pH ≤ 2 or ≥ 11.5 (with high buffering capacity, if relevant)	Assume corrosivity; no testing is necessary.
↓		
2 < pH < 11.5, or pH ≤ 2.0 or ≥ 11.5 with low or no buffering capacity, if relevant.		
↓		
4. Evaluate systemic toxicity data via dermal route.[a]	Highly toxic	No further testing is necessary.
	Not corrosive or irritating when tested to limit dose of 2000 mg/kg body weight or higher, using rabbits	Assumed not to be corrosive or irritating; no further testing is necessary.
↓		
Such information is not available or is not conclusive.		
↓		
5. Perform validated and accepted in vitro or ex vivo test for skin corrosion.	Corrosive response	Assume corrosivity in vivo; no further testing is necessary.
↓		
Substance is not corrosive, or internationally validated in vitro *and* ex vivo *testing methods for skin corrosion are not yet available.*		
↓		
6. Perform validated and accepted in vitro or ex vivo test for skin irritation.	Irritant response	Assume irritancy in vivo; no further testing is necessary.
↓		
Substance is not an irritant, or internationally validated in vitro *and* ex vivo *testing methods for skin irritation are not yet available.*		
↓		
7. Perform initial in vivo rabbit test using one animal.	Severe damage to skin	Considered corrosive; no further testing is necessary.
↓		
No severe damage.		
↓		
8. Perform confirmatory test using one or two additional animals.	Corrosive or irritating	Considered corrosive or irritating; no further testing is necessary.
	Not corrosive or irritating	Considered not corrosive or irritating; no further testing is necessary.

[a] Can be considered before steps 2 and 3.

The test material is applied topically to a 3D human keratinocyte culture model, composed of at least a reconstructed epidermis with a functional stratum corneum. Corrosive substances are identified by their ability to induce a decrease in cell viability below defined threshold levels at specified exposure periods. The principle of the human skin model assay is based on the premise that corrosive chemicals are able to penetrate the stratum corneum by diffusion or erosion and are cytotoxic to the keratinocytes in the underlying layers. The use of test systems that include human-derived cells or tissue should be in accordance with applicable national and international laws, regulations, and policies.

Investigators using a similar in vitro human skin cell culture model system for skin corrosion must be able to demonstrate that the assay is valid for its intended use. This includes demonstrating that different preparations are consistent in barrier properties (i.e., capable of maintaining a barrier to noncorrosive substances, able to respond appropriately to weak and strong corrosive substances) and that any modification to the existing validated reference test method does not adversely affect its performance characteristics. Performance standards are now available that can be used for this purpose, as described earlier in this chapter [65]. Essential test method components are also available for in vitro human skin model test methods for skin corrosivity [65]. The components are essentially the same as those described for Corrositex with the addition of components unique to in vitro human skin model systems. Human skin models can be obtained commercially (e.g., EPISKIN, EpiDerm [EPI-200]) or they can be developed or constructed in the testing laboratory.

In Vitro Skin Transcutaneous Electrical Resistance Tests for Skin Corrosion

The ECVAM also conducted validation studies on the rat skin TER assay, another in vitro test method for assessing skin corrosivity [122]. The rat skin TER assay measures the extent to which a chemical alters the TER of a skin disc during a defined exposure period. Based on its scientific validity, this test method has been recommended for the testing of all classes of chemicals and for inclusion in tiered testing strategies as part of a tiered or weight-of-evidence evaluation [31,32].

The test substance is applied for up to 24 h to the epidermal surface of skin discs in a two-compartment test system in which the skin discs function as the separation between the compartments. The skin discs are prepared from humanely killed 28- to 30-day-old rats. Corrosive substances are identified by their ability to produce a loss of normal stratum corneum integrity and barrier function, which is measured as a reduction in the TER below a specified level. For rat skin TER, a cutoff value of 5 kΩ has been selected based on extensive data for a wide range of substances where the majority of values were either clearly well above or well below this value. Generally, substances that are noncorrosive in animals but are irritating do not reduce the TER below this cutoff value; however, the use of other skin preparations or other equipment to measure resistance may require the use of a different cutoff value. In such situations, more extensive validation would be required. A dye-binding step is incorporated into the test procedure to confirm positive results. The dye-binding step determines if the increase in ionic permeability is due to physical destruction of the stratum corneum.

Investigators using an in vitro skin TER corrosivity test that is different from the validated test method protocol must be able to demonstrate that the assay is valid for its intended use. This includes demonstrating that different preparations are consistent in barrier properties (i.e., capable of maintaining a barrier to noncorrosive substances, able to respond appropriately to weak and strong corrosive substances) and that any modification to the existing validated reference test method does not adversely affect its performance characteristics. Performance standards are now available to accomplish the necessary validation of test method modifications of the TER [65].

FUTURE PROGRESS

Significant progress and consensus have been made in recent years on the scientific principles and processes for adequate validation of in vitro and other test methods proposed for regulatory applications. Governments, regulatory authorities, and research organizations continue to increase committed resources and personnel to the effort of identifying new and alternative test methods with potential regulatory applicability that are as good as or better than traditionally employed test methods. Regulatory authorities have also communicated the criteria that they will use as the basis for making decisions on the regulatory acceptability of new, revised, and alternative methods. The ICCVAM now provides an efficient process for the interagency evaluation of new, revised, and alternative methods of multiagency interest, thereby limiting or eliminating duplicative efforts by independent agencies. These established criteria and processes will facilitate the validation and regulatory acceptance of proposed test methods that incorporate new science and technology. Similarly, the recently formed International Cooperation on Alternative Methods will continue to provide an efficient means of coordinating international validation studies, reviews, and development of harmonized recommendations that will facilitate more rapid international and global acceptance of alternative test methods. Increased application of new science and technology to safety assessment methods will result in more accurate and efficient tools for the safety assessment process. Future progress in the development, validation, and adoption of improved testing methods based on sound science can be expected to support enhanced protection of public health, animal health, and the environment. Adoption of scientifically valid alternative methods will also support improved animal welfare by reducing, replacing, and providing for more humane use of laboratory animals.

ACKNOWLEDGMENTS

The contributions of the many scientists who contributed to the development and implementation of the test method validation and acceptance criteria and evaluation processes described in this chapter are gratefully acknowledged. The contributions of the scientists who have worked to develop, validate, and review new alternative test methods that have now been adopted are also gratefully acknowledged. A special acknowledgment is extended to those members of the original ad hoc ICCVAM and public stakeholders who developed the original report on validation and acceptance of alternative test methods, including the cochair, Dr. Richard Hill, from the U.S. EPA. The content of this manuscript was supported by the Intramural Research Program of the NIH.

QUESTIONS

21.1 What are the basic requirements for adequate validation of a proposed new test method?

21.2 What are the considerations used by regulatory authorities in determining the acceptability of a new test method?

21.3 What are the three components of test method performance standards, and how can performance standards be used to more efficiently validate new test methods?

21.4 What are the three advantages provided in using the murine LLNA for ACD testing instead of the guinea pig maximization or Buehler test?

22 Acute Toxicity and Eye Irritancy

Ping Kwong (Peter) Chan and A. Wallace Hayes

CONTENTS

The methods and principles of evaluating two categories of hazards, acute systemic toxicity and eye irritation, both resulting from a single or very short-term exposure, are described in this chapter. In recent years, economics and concerns over animal welfare have raised many issues in animal testing. Alternate methods for acute toxicity and eye irritation are being developed and, in some cases, accepted by regulatory agencies for hazard assessment purposes. This chapter describes the classical and/or currently accepted methods for evaluating a test article's potential for acute systemic toxicity and eye irritation, and gives an overview of the current regulatory testing requirements in the United States, European Union, and Japan. Chapter 20 reviews the different nonanimal alternative models for assessing toxicity and irritation in greater detail.

PRINCIPLES OF ACUTE TOXICOLOGY

Acute toxicity testing began nearly a century ago when physicians and pharmacologists were concerned with potent poisons and drugs. In 1927, Trevan [196] introduced the concept of a median lethal dose (LD_{50}) for the standardization of digitalis extracts, insulin, and diphtheria toxin. He recognized that the precision of the LD_{50} value was dependent on many factors such as seasonal variation and the number of animals used in a test. High precision LD_{50} values can only be established with a large number of animals.

The list of extraneous factors that affect the precision of the LD_{50} includes, among other factors, sex, species, strain, age, diet, nutritional status, general health conditions, animal husbandry, experimental procedures, route of administration, stress, dosage formulation (vehicle), and intra- and interlaboratory variations. In spite of the many variables affecting the LD_{50} determination, many governmental agencies still regard the LD_{50} as the sole measurement of the acute toxicity of all materials; however, recent research has resulted in the development and gradual acceptance of alternative methods to assess the acute oral toxicity potential of test materials.

It is important to determine accurately the killing power of highly toxic substances, since a small difference in exposure can distinguish a safe from a lethal exposure. However,

a precise LD_{50} is not necessary when evaluating less toxic materials such as pesticides and consumer products. While the need to evaluate the safety of products with a low-to-moderate toxic potential is still desirable, an approximate measurement of their toxic potential is sufficient for the purposes of hazard and risk and exposure assessment. Furthermore, it may not be scientifically sound to determine a precise LD_{50} value for substances with a low-to-moderate potential for toxicity. This is because extraneous variables, some of which cannot be controlled by the experimenter and errors inherent in the determination of LD_{50} values, can have a significant impact on the study results. Many methods have been developed over the years to calculate the LD_{50} and evaluate the acute toxicity potential of chemicals with a small number of animals. Some of these methods are discussed later in this chapter.

Many scientists have advocated changes in the emphasis of acute toxicity testing. To date, there is a general consensus among toxicologists in academia, industry, and government that the emphasis of acute toxicity testing needs to change [6,16,58,71,110,117,140,184,188]. The value of a precise LD_{50}, except for highly toxic substances, should be de-emphasized and that the focus should be on obtaining as much information as possible on the toxic manifestation and mechanism using the fewest number of animals. Alternative methods for assessing the oral [159–161], dermal [148], and inhalation [149,152] toxic potential of test material have been proposed or adopted by various regulatory agencies. Undoubtedly, such information will be more useful than the LD_{50} to physicians in treating overexposure.

Even though the emphasis of acute toxicity testing is changing, the principles of dose–response and development of signs of toxicity remain the basis of the science of toxicology. It is the objective of this section to refresh the experienced and introduce the novice to these general concepts.

Definition of Acute Toxicity

Toxicity is defined as the harmful effect of a chemical or a drug on a living organism. Various expert groups have defined acute and subchronic toxicities. The Organization for Economic Cooperation and Development (OECD) [157] defines acute toxicity as "the adverse effects occurring within a short time of (oral) administration of a single dose of a substance or multiple doses given within 24 hours." In terms of human exposure, this definition of acute toxicity refers to life-threatening crises such as accidental catastrophes, overdoses, and suicide attempts.

Dose–Response Relationship

Toxicologists often obtain two types of data, quantal and graded. The quantal response is called the *all-or-none* response; it either happens or it does not happen. On the other hand, the graded response can be determined quantitatively and it is continuous. Mortality and incidences of pharmacotoxic signs are examples of quantal data, whereas enzyme activity, protein concentration, body weight, feed consumption, and electrolyte concentration are quantitative parameters. However, many apparently quantal responses are quantitative. If technical measurements permit, they may be graded. For example, the severity of a pharmacotoxic sign can be graded if detection methods are available.

At the molecular level, the graded dose–response relationship often can be explained by the receptor, a relatively old concept but still a valid one. Let "S" be a particular substance that produces a specific response by interacting with a target protein molecule, the receptor (R), in the body to form a substance–receptor (SR) complex. Assuming the reaction is reversible and there is only one binding site on every target receptor molecule, this process can be described by the following expression:

$$S + R \underset{K_2}{\overset{K_1}{\rightleftharpoons}} SR$$

and the mass equation for this reversible process is

$$\frac{k_2}{k_1} = K_d = \frac{[S][R]}{[SR]} \tag{22.1}$$

where

[S], [R], and [SR] are the concentrations of the substance, the receptor, and the SR complex at any particular time, respectively

K_d is the dissociation constant of the process

Let $[R]_0$ be the initial concentration of the receptor, which is usually very small and constant in number when compared with the concentration of the substance. Then

$$[R]_0 = [R] = [SR]$$

thus

$$[R] = [R]_0 - [SR]$$

Substituting the given equation into the mass equation (Equation 22.1) and rearranging

$$[SR]K_d = [S]\left([R]_0 - [SR]\right)$$

or

$$[SR]\left(K_d + [S]\right) = [R]_0[S]$$

which can be rearranged to

$$\frac{[SR]}{[R]_0} = \frac{[S]}{K_d + [S]} \tag{22.2}$$

SR/[R]0 is the fraction of receptor that has reacted with the substance to form the SR complex. If we assume that the response (E) resulting from the interaction of the substance with the receptor is dependent on the fraction of total receptor concentration that has reacted with the substance, then

$$E = \frac{[S]}{K_d + [S]} \tag{22.3}$$

Equation 22.3 is a hyperbolic function; therefore, the response (E) is related to the concentration of the substance in a hyperbolic function relationship. If the concentration of the substance at the receptor site is dependent on the dose, then the response is dependent on the dose administered. This phenomenon is perhaps the simplest version of the receptor kinetic concept relating the dose of the chemical to a biological response. The kinetics of the receptor–substrate interaction may be more complicated, and different dose–response relationships could be drawn based on these complicated kinetics. Readers who are interested in different receptor–substance kinetics are referred to Ferdinard [72].

The quantal dose–response relationship often is difficult to conceptualize based on the receptor theory. However, quantal response also can be viewed as a graded response if the whole population is considered as an individual. This relationship can best be explained in terms of a probability distribution. For a particular response, members of a population, for example, all the rats in the world, respond differently to a particular stimulus such as exposure to a chemical. Some rats will be highly sensitive whereas others will be very resistant. If these different responses are distributed normally within the population (i.e., with most members of the population being neither extremely sensitive nor resistant), the well-known bell-shaped population distribution curve results. If the probability of dose–response is expressed in terms of cumulative response, a sigmoidal curve can be obtained as shown in Figure 22.1. However, most biological response distributions are not exactly normal and tend to be skewed to the higher dose, that is, extreme resistors have a larger *range of dose* to response than the extremely sensitive portion of the population. In general, a logarithmic dose transformation can normalize the distribution (i.e., convert the skewed distribution to a normal distribution; Figure 22.2). After this logarithmic dose transformation, if the probability of the log dose–response is expressed cumulatively, the sigmoidal response curve is obtained (Figure 22.2). How is this lognormal transformation related to a regular dose–response curve? Is there justification or basis for a log dose transformation? To answer these questions, let us again look at Equation 22.3. This equation can be arranged to

$$E = \frac{[S]}{k_2/k_1 + [S]}$$

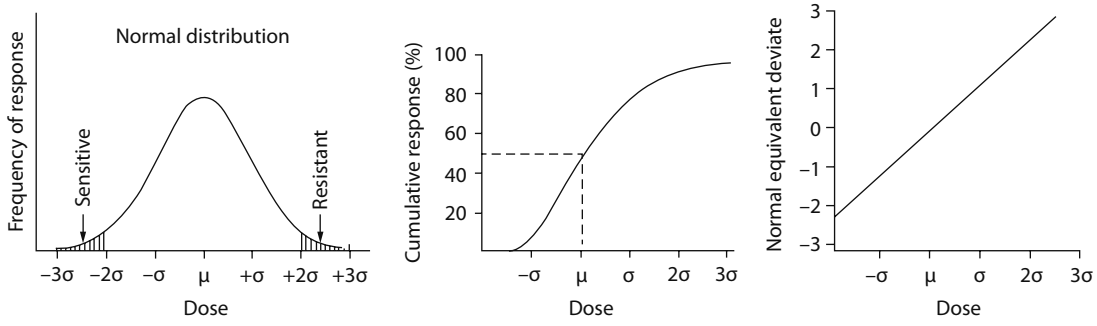

FIGURE 22.1 Normal distribution of dose–response relationships: frequency of response, cumulative response, and cumulative response in terms of NED.

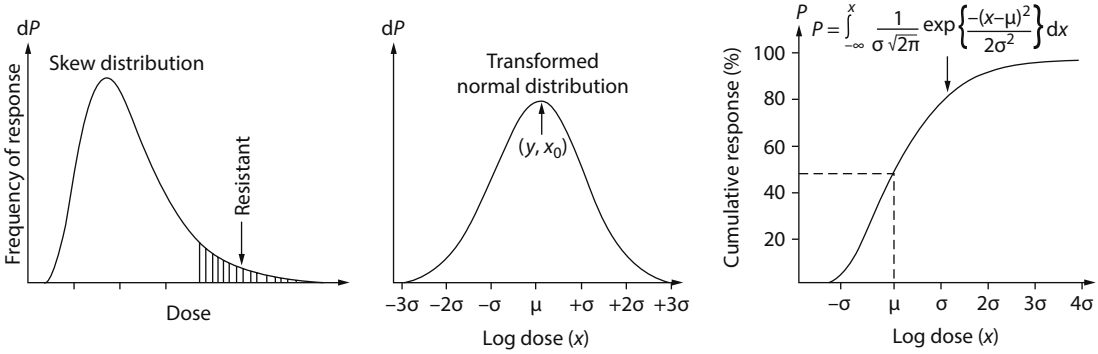

FIGURE 22.2 Skew of dose–response can be normalized by log dose transformation.

which can be rearranged to

$$E = \frac{k_1[S]}{k_2 + k_1[S]} \quad (22.4)$$

Over a certain concentration range, Equation 22.4 will produce a curve very similar to the logarithmic function $E = K_1 \log (k_2 [S] + 1)$ [34]. Therefore, there may be justification for the log transformation besides simply a mathematical convenience.

Since a sigmoidal curve is more difficult to analyze than a straight line, many experts feel that further transformation of the log dose–response hyperbolic function is necessary to obtain a *straight-line* function curve. Perhaps, the most widely used transformation is the normal equivalent deviate (NED) or the similar probit transformation [12,35,38,44,50,75,130]. This technique involves the log dose transformation and the transformation of the cumulative response probability to the NED or probit. After both the probability and the dose are transformed, their transformed values are directly related to each other. A brief derivation of the straight-line direct function relationship between the log dose and NED or probit will be presented later in this chapter.

LD_{50} and Its Determination

Definition

The LD_{50} in its simplest form is the dose of a compound that causes 50% mortality in a population. A more precise definition has been provided by the OECD panel of experts as the "statistically derived single dose of a substance that can be expected to cause death in 50% of the animals" [157].

In other words, an LD_{50} of a compound is not a constant, as it has been treated by many; rather, it is a statistical term designed to describe the lethal response of a compound in a particular population under a discrete set of experimental conditions.

The significance of the LD_{50} has been examined by many scientists [6,58,71,110,117,140,184,188] who have concluded that it is an imprecise value and not a biological constant; furthermore, its importance should be de-emphasized for most types of materials. For most materials, an approximate LD_{50} value is sufficient and that more emphasis should be placed on characterizing the signs of toxicity, identifying the target organs and elucidating the material's mechanism of action.

The numeric value of the LD_{50} has been widely used to classify and compare the toxic potential of chemicals; the importance placed on the LD_{50} and how it is used in a safety evaluation has almost reached a level of abuse. Although determining the LD_{50} under a set of experimental conditions can provide valuable information about the toxicity of a compound, the numeric LD_{50} per se is not equivalent to acute toxicity. It should always be remembered that lethality is only one of many reference points used to characterize acute toxicity. When evaluating the acute toxic potential of a material, the slope (response/dose) of the dose–response curve, time to death, pharmacotoxic signs, and pathological findings all need to be considered, as they are critical endpoints. Therefore, defining acute toxicity based only on the numeric value of an LD_{50} is inappropriate.

As pointed out in a previous paragraph, lethality is a quantal response and the probability of a cumulative response is related to dose in a hyperbolic (sigmoidal) function. The cumulative probability of response is directly related to the standard deviates of a log dose population (Figure 22.1). Therefore, the slope of the log dose–response curve will indicate the relationship between the range of dose and the lethal response. This relationship is more important in risk assessment than the numeric value of the LD_{50} because more insight is available about the intrinsic toxic characteristics of a compound. Sometimes, the slope can give a clue to the mechanism of toxicity. For example, a steep slope may indicate rapid onset of action or faster absorption. A large margin of safety is predicted when a compound has a flat slope, that is, only a small increase in response with a large increase in dose. With the slope, it often is possible to extrapolate the response to a low dose (e.g., LD_0, LD_1) or even to a no-observed-effect level (NOEL). It is especially important to know the slope when comparing a set of compounds. Two compounds may have identical LD_{50} values but different slopes and thus have quite different toxicological characteristics depending on the range of doses. Parallel dose–response curves may indicate a similar mechanism of toxicity, kinetic pattern, and probably similar prognosis. Neither the LD_{50} nor the slope can reveal absolutely a specific mechanism, but with pharmacokinetic and other biochemical studies elucidation of the mechanism of toxicity may begin to be possible.

Determination of LD_{50}

Many methods are available for the determination of the LD_{50}. They can be grouped into two categories, the *normal population assumption* and the *normal population assumption-free* methods. The former usually can be analyzed by graphic procedures.

The *normal population assumption-free* methods are represented by Thompson's moving average interpolation [194] and the *up-and-down* method [19–22,34,46]. The former method is widely accepted, and convenient tables [50,203] are available for estimation of the value of the LD_{50} with confidence limits when either 0% or 100% mortality incidences are observed. However, there are some restrictions on the use of the Thompson method, that is, four doses must be at equal log dose intervals and the number of animals per dose level must be equal. The up-and-down or *pyramid* method is designed to estimate the LD_{50} with a small number of samples. It has an economical advantage because fewer animals are needed, but the test can be time consuming and requires a larger amount of test article. Because it has the advantage of using only a few animals, the up-and-down method is popular when a study has to be conducted in large animals such as cows or sheep or expensive animals such as monkeys. A study comparing LD_{50}'s obtained using the up-and-down method and other methods revealed an excellent

agreement [20]. Two apparent shortcomings of the up-and-down method is that it is not adequate for estimating the incidence of delayed deaths and a dose–response of mortality or signs of toxicity cannot easily be obtained. However, Weil [204] has adapted the up-and-down method to calculate the slope of acute toxicity response.

The *normal population assumption* method is represented by the probit analysis approach, which can be performed either by graphic means [75] or by mathematical calculation [76]. Since the probit analysis is used widely in evaluating acute toxicity data, the principles in performing this analysis will be discussed briefly. This method involves the transformation of both the cumulative response probability and dosage data.

When the dose is transformed into a log dose (x), the frequency of response versus log doses follows a normal distribution (Figure 22.2), which can be expressed mathematically as

$$dP = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(\frac{-(x-u)^2}{2\sigma^2}\right) \tag{22.5}$$

where

- σ^2 and u are the variance and the mean of the population, respectively
- P is the probability corresponding to each value of x (Figure 22.2)

The LD_{50} is defined as the log dose that can produce 50% mortality in a population (i.e., $P = 0.5$ or 50% cumulative response). Let x be the log LD_{50}; then $P = 0.5$ will correspond to the area under the lognormal distribution curve from $-\infty$ to x_o; or $P = 0.5$ will correspond to the integration of Equation 22.5 from $-\infty$ to x_o. That is,

$$P = 0.5 = \int_{-\infty}^{x_o} \frac{1}{\sigma\sqrt{2\pi}} \exp\left(\frac{-(x-u)^2}{2\sigma^2}\right) dx \tag{22.6}$$

The solution of Equation 22.6 is $x = u$, the true mean or the median of the lognormal distribution. One way to solve this equation is by a graphic method. The integration of Equation 22.5 from $x = -\infty$ to $+\infty$ can be represented graphically by a sigmoidal curve as illustrated in Figure 22.2. Analysis of the sigmoidal curve is more difficult than a straight line. One way to transform the sigmoidal curve to a straight line is by NED analysis or similarly by probit analysis. For a detailed description of this analysis, the reader should consult Finney's text [75]. A brief derivation of the straight-line function between log dose and the transformed probability of response is described in the following.

Probability (P) is normally expressed in terms of percentage or with values between 0 and 1; but Gaddum [81] has proposed to measure the probability of response on a transformed scale called the NED, or the standard deviation of a normal distribution, which can be described mathematically by Equation 22.5. In a particular case, the normal distribution of response with mean equal to 0 and the standard deviation equal to 1, Equation 22.5 can be written as

$$dP = \frac{1}{\sqrt{2\pi}} \exp\left(\frac{-x^2}{2}\right) dx$$

Similarly, if this distribution of response is plotted on the y axis (Figure 22.3), then

$$dP = \frac{1}{\sqrt{2\pi}} \exp\left(\frac{-y^2}{2}\right) dx \tag{22.7}$$

The probability in such a case is defined by a value on the y axis of Figure 22.3, that is, the integration of Equation 22.7 from $-\infty$ to y:

$$P = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{y} \exp\frac{-y}{2}\, dy \tag{22.8}$$

In other words, for each value of y (from $-\infty$ to $+\infty$) expressed in terms of the standard deviation of a normal distribution with the mean equal to 0 and the standard deviation equal to 1, there is a corresponding value of probability (P) expressed in terms of percentage or having a value ranging from 0 to 1. Thus, equivalent values on the y axis can be used to define the value of P or vice versa; y and P define each other. This relationship is illustrated in Figure 22.3.

The particular probability of response to a particular log dose value x, as described in Equation 22.6, will be

$$P = \int_{-y}^{-x} \frac{1}{\sigma\sqrt{2\pi}} \exp\left(\frac{-(x-u)^2}{2\sigma^2}\right) dx \tag{22.9}$$

where u and σ are the mean and standard deviation of the log dose, respectively.

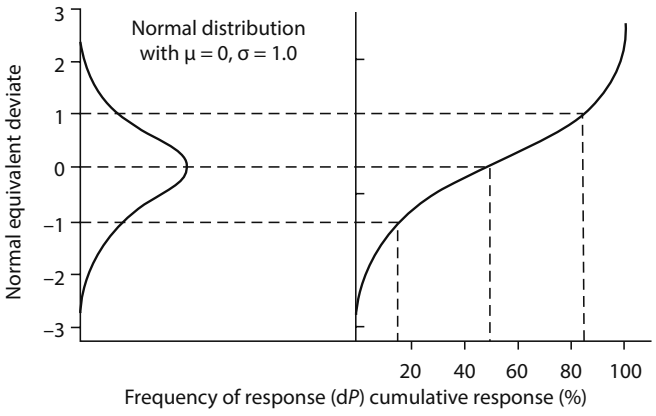

FIGURE 22.3 Probability of response can be expressed in terms of the percentage of population or the NED of a normal distribution with mean = 0 and standard deviation = 1.

If P is expressed by a value of y on the y axis (standard deviations), then

$$P = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{y} \exp\left(\frac{-y^2}{2}\right) dy$$

$$= \int_{-\infty}^{x} \frac{1}{\sigma\sqrt{2\pi}} \exp\left(\frac{-(x-u)^2}{2\sigma^2}\right) dx$$

The solution of this equation is $x = u + \sigma y$ or

$$y = \frac{(x-u)}{\sigma} = \frac{1}{\sigma}x - \frac{u}{\sigma} \qquad (22.10)$$

Therefore, the probability when expressed in terms of y (the NED scale) is related linearly to x, the log dose. If x is plotted against the corresponding y, a straight line with slope = $1/\sigma$ will be obtained. To further facilitate calculation, Bliss [11] suggested a slightly different NED unit called the probit, such that the new y value is equal to $[(x - u)/\sigma] + 5$. This procedure eliminates the negative values of NED when P has a value of less than 50%. Therefore, the probit is equal to the NED plus 5. The linear relationship between probits and log dose is similar to the relationship between NED and log dose. Thus, when $y = 5$, from Equation 22.10

$$5 = \frac{(x-u)}{\sigma} + 5$$

and $x = \mu$ (i.e., the median log dose that has a probability of response of 50%).

Estimation of LD_{50} by Probit Analysis

The basic linear equation for the probit analysis as described in the previous section is

$$y = 5 + \frac{1}{\sigma}(x-u)$$

where y is the probit (σ is the standard deviation of a log-normal distribution with mean u, and x is the log dose). This equation is linear with respect to y and x often can be expressed as a linear equation, for example, $y = \alpha + \beta x$, where $\beta = 1/\sigma$ = slope, and $\alpha = 5 - (u/\sigma)$. When $y = 5$, $(x - u)/\sigma = 0$; thus $x = \mu$ (the median log dose). Furthermore, y is related to P (the probability of response that has a value of 0–1) by the following equation:

$$P = \frac{1}{\sqrt{2\pi}} \int_{-x}^{y} \exp\left(\frac{-y}{2}\right) dy$$

The reader should bear in mind that both the u and x are in log dose scale.

The following steps should be taken for graphic estimation of LD_{50} by probit analysis.

1. Convert response probabilities to probit units by a probit transformation table (see Ref. [45, pp. 54–55]).
2. Convert all doses into log dose units (e.g., $\log_{10}$ dose = x). (Steps 1 and 2 may be eliminated if probit-log graphic paper is available.)
3. Using the probit as the abscissa and $\log_{10}$ dose as the ordinate, plot the response probit units against the $\log_{10}$ dose.
4. Draw a straight line such that the vertical deviations of points (the probits) at each x value are as small as possible. Extreme probits, for example, those outside the range of probits 7 and 1, carry little weight in the fitting of the probit–log dose–response line and thus should be excluded.
5. From the regression of the probit–log dose line, extrapolate the log dose corresponding to probit units of 5, which also correspond to the $P = 0.5$. Thus, this extrapolated dose should be the median lethal *log dose*, and the LD_{50} value would be the *antilog* of this log dose value.
6. Calculate the slope of the probit–log dose line. This slope, $\beta = 1/\sigma$, is defined as the number of increases in probit units for a unit increase in log dose. The slope defined by Litchfield and Wilcoxon [116] is equal to

$$\frac{1}{2}\left(\frac{LD_{84}}{LD_{50}} + \frac{LD_{50}}{LD_{16}}\right) = \sigma$$

   This slope is different but related to the slope described here, thus the larger the slope value, the steeper the probit–log dose response. The opposite is true in the Litchfield and Wilcoxon definition.
7. An χ^2 test should be conducted to determine if the fitted line is adequate. A small value of χ^2 statistic (within the limits of random variation) may indicate satisfactory agreement between the theoretically expected line and the fitted line. A significantly large χ^2 statistic may indicate either that the animals do not respond independently or that the fitted line (probit–log dose) does not adequately describe the dose–response relationship of the test substance. If the latter is true, forms of the dose–response curve other than the probit–log dose linearity may exist, and further transformation may be needed [75]. If the former is the case, then precision of the line is reduced.
8. Determination of precision is by weighting the coefficient. The standard deviation of a binomial distribution is $\sqrt{PQ/n}$, where P and Q are the mean probabilities, P equals $(1 - Q)$, and n is the number of test subjects. Thus the variance is PQ/n, the square of the standard deviation. It is obvious that the variance (i.e., the spread of a distribution) is

inversely related to n. This relationship means that the larger the number of test subjects, the smaller the variance and the better the precision. The reciprocal of the variance is invariance, which measures the weight, nW. Here W (weighting coefficient) = Z^2/PQ, where $Z = (1/\sqrt{2\pi})\exp(-y^2/2)$ and is related to the normal frequency function corresponding to the NED. A table of weighting coefficients (see Ref. [45, p. 55]) corresponding to probits (y) is available [76]. The standard error for the log LD_{50} is given by

$$\frac{\sigma}{\sqrt{\Sigma nW}}$$

if the estimated log LD_{50} does not greatly differ from the true mean log LD_{50}, because this estimation does not take into consideration the error in the estimation of α for the probit–log dose–response line. A better equation for the estimation of the variance of the estimated log LD_{50} is given by

$$V(m) = \sigma^2\left(\frac{1}{\Sigma nW} + \frac{(m-\bar{x})^2}{\Sigma nW(x-\bar{x})^2}\right)$$

where

$V(m)$ is the variance of LD_{50}
$\bar{x}$ is the weighted mean log dose
m is the median log dose
x is the log dose
$1/\sigma = 1/\Sigma nW(x-\bar{x})$

If the χ^2 is large, indicating that the test subjects do not respond independently to the dose, the estimation of variance of log LD_{50} may not apply, and adjustment due to the sampling variation of the slope ($1/\sigma$) of the probit–log dose line may have to be made [75]. For a quick estimation of the LD_{50}, this adjustment may be dropped, and the SE would be the square root of the variance, that is, $\sqrt{V(m)}$.

One must remember that the dose is expressed in log dose; therefore, the estimation of the SE for the LD_{50} in the original dose unit (e.g., mg/kg) is impossible. However, an approximation is given:

$$\text{SE}(LD_{50}) = (10^m)\cdot([\log_e(10)\cdot(S_m)]$$

where S_m (which equals $\sigma/\sqrt{\Sigma nW}$ or $\sqrt{V(m)}$) is the estimated SE for the median log dose m (i.e., m = log LD_{50} or $10^m = LD_{50}$).

A more rapid approximation of the SE of log LD_{50} was given by Litchfield and Wilcoxon [116] as

$$S_m = \frac{S}{N'/2}$$

where

S is the difference between two log doses of expected effects (as indicated by the probiting dose line) that differ by one unit of probit
N' is the total number of animals between the log dose limits, corresponding to the expected probit 4.0–6.0 (i.e., the 16% and 80% responses)

9. *Fiducial limits.* The concept of fiducial limit is similar to the confidence limit. The value of the two may be the same, but they are not always identical. The fiducial probability F (e.g., 95%) can be defined as the situation when the true value of a parameter lies between the calculated upper and lower limits, which would not be contradicted by a significance test at the 1/2 $(1 - F)$ probability level. These higher and lower limits are called the fiducial limits. For rapid analysis, the fiducial limits at the F = 95% level can be estimated by log $LD_{50} \pm 1.96$ (S_m). A more detailed estimation can be obtained by the maximum likelihood estimation [75].

   Another simple approximation of the fiducial limits is given by Litchfield and Wilcoxon [116] as LD_{50}/fLD_{50} and $LD_{50} \times fLD_{50}$ for the lower and upper limits, respectively, where LD_{50} is defined as the LD_{50} factor equal to $(s)\left(2.77/\sqrt{N'}\right)$.

   Here s is the slope, which is defined as

$$\frac{1}{2}\left(\frac{LD_{54}}{LD_{50}} + \frac{LD_{50}}{LD_{16}}\right) = \frac{1}{2}(3.55 + 3.55) = 3.55$$

   In this example, and N' is the total number of animals used between response probabilities 16% and 84% (i.e., probit 4 and 6, equal to 30 in this example). Then fLD_{50} equals 1.896. Therefore, the lower fiducial limit is equal to 8.91/1.896 = 4.70, and the upper fiducial limit is equal to 8.96 × 1.896 = 16.90.

Logistic Transformation

Waud [202] suggested a logistic approach to calculate the LD_{50}. Thus

$$P = \frac{D^E}{(D^E + K^E)}$$

where

P is the probability of response
D is the dose
E and K are scale and location parameters, respectively
K corresponds to the LD_{50}

With the procedure of iteration, K and E can be estimated with a range of confidence. The derivation of this equation is beyond the scope of this chapter, and interested readers are referred to the original article by Waud [202].

Nonlethal Parameters

Although the LD_{50} and the slope of the dose–response curve can provide valuable information on the toxicity of a compound, the LD_{50} *is not equivalent to toxicity.* Chemicals can induce damage to the physiological, biochemical, immunological, neurological, or anatomical systems not characterized by the LD_{50}. Depending on the severity and the extent of the disturbance of the normal biological functions, the animal may survive the toxic response even though some irreversible tissue damage may have occurred. Nonlethal, adverse effects are as undesirable as lethality and certainly should be taken into consideration during the risk assessment of a chemical.

A major problem in analyzing nonlethal responses is that in many cases the data are not quantal. For example, dermal toxicity ranges from slight to severe. These polychotomous data may be handled by RIDIT *analysis*, which was designed to analyze quantal responses with more than two outcomes [1,18,92].

While toxic effects may contribute to lethality, any attempt to correlate a particular nonlethal response to mortality may be irrational [189] unless that response is the only one responsible for the eventual death of the animal. Identification of the response or responses related to mortality is not often a straightforward matter. Nonlethal responses that affect the general well-being of an animal should be considered in the risk assessment of a compound.

If nonlethal responses can be viewed as true quantal data, the *median effective dose* (ED_{50}) and the corresponding dose–response curve may apply. The ED_{50}, which often is used in the standardization of biologically active compounds such as a drug, has a meaning similar to the LD_{50} except that it is designated to examine nonlethal parameters such as pharmacological responses and other nonlethal adverse effects. The ED_{50} is defined as a statistically derived single dose of a substance that can be expected to cause a particular effect to occur in 50% of the animal population. The therapeutic index (TI), defined by the ratio of LD_{50}/ED_{50} or LD_1/ED_{99}, has been applied to establish the safety margin of some biologically active drugs. The higher the index, the greater the margin of safety with the drug, that is, a large difference exists between the amount of compound predicted to kill 50% of the animals and the amount of compound predicted to elicit a particular response in 50% of the animals. The TI gives an even greater estimate of safety when the LD_1 is compared to the ED_{99}.

Reversibility of Nonlethal Parameters

In general, reversible responses are those that diminish with elimination of the chemical from the body. A true reversible response will cause no residual effects when the chemical is completely eliminated from the body. Such responses are commonly seen in drugs used at therapeutic dose levels. As the amount of drug in the body increases, the magnitude of the effect also increases. If it is truly reversible, the effect will wear off when the drug is completely eliminated.

The reversibility of a particular response is dependent on the organ or system involved, intrinsic toxicity of the chemical, length of exposure, total amount of the chemical in the body at a specific time, and the age and general health of the animal. If the amount of chemical in the body is high enough, the intensity of the response may overwhelm a particular organ. Effects indicated through hormonal imbalance such as thyroid effects generally are reversible unless the threshold is surpassed. Damage in rapidly regenerating organs, such as liver, is usually more likely to be reversible than damage in nonregenerating tissues, such as nerves. A good example is the delayed onset of neuropathy caused by many organophosphate insecticides. The chemical may be completely eliminated from the body before the effect manifests itself. Animals with renal or liver diseases are often more susceptible to damage (reversible or irreversible) by a chemical insult because of decreased ability to eliminate the chemical. Exposure to a chemical at an early age may induce irreversible damage more easily than at an older age because of the limited development of the kidneys and/or functional capacity of other organs, such as the liver.

In risk assessment, it is important to know whether a toxic effect is reversible. Irreversible effects seen in animals obviously are weighted more heavily in reaching a conclusion on the toxicity and hazard a chemical may pose for humans.

ACUTE TOXICITY TESTING

The objectives of acute toxicity testing are to define the intrinsic toxicity of the chemical, predict hazard to nontarget species or toxicity to target species, determine the most susceptible species, identify target organs, provide information for risk assessment of acute exposure to the chemical, provide information for the design and selection of dose levels for prolonged studies, and, the most important and practical of all, provide valuable information for clinicians in the prediction, diagnosis, and treatment for acute overexposure (poisoning) to chemicals. Acute studies often are called the "first line of defense" in the absence of data from long-term studies. These data help industrial, governmental, and academic institutions formulate safety measures for their researchers and for limited segments of their worker population during the early stage of the development of a chemical. From a regulatory standpoint, acute toxicity data are essential in the classification, labeling, and transportation of a chemical. From an academic standpoint, a carefully designed acute toxicity study can often provide important clues on the mechanism of toxicity and the structure–activity relationship for a particular class of chemicals.

Many acute toxicity studies have been conducted solely for the purpose of determining the LD_{50} of a chemical. However, the reader is reminded that acute toxicity is not equivalent to the LD_{50}, and that the LD_{50} is not an absolute biological constant to be equated, as some investigators have, with such chemical constants as pH, pK_a, melting point, and solubility. The LD_{50} is only one of many indices used in defining acute toxicity. A well-designed acute toxicity study should include

consideration of the dose–response relationship of both lethal and nonlethal parameters, as discussed earlier. Sometimes, biochemical measurements in an acute test can aid in elucidating the mechanism of toxic actions. Histopathology of organs may be helpful in determining the cause of death and identifying the target organs.

The use of animals in acute toxicity studies has been widely debated for many years. Aside from valid scientific concerns on the usefulness of classic LD_{50} values (e.g., uncertainty in species extrapolation, seldom needed for potent drug standardization), there are broader issues on animal testing, some are political in nature and others economically based. The cost of animal testing has been increasing at a skyrocketing rate over the last decades, and even without animal rights activism, the scientific community will need less costly alternatives to cope with the increasing demand for safety evaluation of a vast number of existing and new chemicals. While reduction in the number of animals used and refinement of existing testing methods to minimize pain and suffering of animals represent the short-term objective, replacement of animal testing with nonanimal-based methods is the ultimate goal. Currently, genuine, validated, and regulatory-accepted nonanimal alternative methods to replace whole animal acute toxicity testing are still more of a goal than a reality, even though the concept has been widely accepted by scientists from industry, professional societies, and certain regulatory bodies [4,128,187,188].

Types of Acute Testing

Since acute toxicity data may provide the first line of defense, a battery of tests under different conditions and exposure routes should be considered. In general, these tests should include oral, dermal, and inhalation toxicities, and skin and eye irritation studies. Other tests such as acute preneonatal and neonatal exposure, dermal contact sensitization, and phototoxicity should also be considered. Depending on sound scientific factors, which may vary from one chemical to another, the number and kind of acute tests needed to establish the initial toxicity database may not be the same. For example, inhalation testing may not be conducted when inhalation exposure is not expected to occur because of the physical properties of the chemical (e.g., respirable particles cannot be generated). Generally, oral, dermal, and inhalation toxicities along with eye irritation tests should be considered as part of an initial acute investigation. These tests are often used for the regulatory purposes of labeling and classifying the hazard potential of a chemical or formulation, although increasing concerns also are placed on skin sensitization studies. This chapter is concerned only with acute oral, dermal, and inhalation toxicities and eye irritation testing.

Acute Oral Toxicity

Classical oral toxicity tests, which use a large number of animals and precisely determine the LD_{50}, continue to be required by some regulatory bodies for the purpose of classification and labeling of chemicals. However, many studies have shown that adequate acute toxicity and lethality information can be obtained by using fewer animals than classical LD_{50} studies require. DePass [42], Lipnick et al. [115], and Gribaldo et al. [87] have reviewed several modified LD_{50} tests. Although the main endpoint remains lethality, these tests generally fulfill the goal of reducing the number and suffering of animals and, in some cases, provide adequate information for hazard classification and labeling.

One example of a modified LD_{50} test is the *approximate lethal dose method*; this method involves sequential dosing until the lowest lethal dose is obtained. Initially an arbitrary dose is given to an animal. If the animal survives, a second animal is given 1.5 times the initial dose; and sequentially several animals are given increasing doses in the same manner until a lethal dose is achieved. The lethal dose is the approximate lethal dose (ALD). In general, only 6–10 animals are required to achieve the ALD. Comparison of classical LD_{50} values and the ALD indicates that the ALD can be used to closely predict the LD_{50} (Table 22.1).

Recently developed alternative methods, such as the limit test [80], the British Society of Toxicology (BST) method [17], the up-and-down method [20–22], fixed-dose procedure [198], and acute toxic class method [177], do reduce the number of animals needed to assess the oral toxic potential of chemicals. A number of these alternative methods have been endorsed by scientific researchers, regulatory authorities, and animal advocates [4,128,187,188], with some having been adopted as regulatory guidelines [159–161]. As use and general acceptance of these alternative methods increases, regulatory bodies will likely need to redefine their approach to how chemicals are classified and labeled.

Classical Method

With regulatory acceptance of the *fixed-dose*, *acute toxic class*, and *up-and-down procedure* methods [153], use of the classical method to assess the toxic potential of chemicals is no longer accepted in the European Union [147].

Principle

The test material, undiluted or diluted with the appropriate solvent or suspending vehicle, is given to several groups of animals by gavage with a feeding needle or by gastric intubation. A vehicle control group is included if needed, but generally this group is not necessary if the toxicity of the vehicle is known. Clinical signs, morbidity, and mortality are observed at specific intervals. Animals that die or become extremely moribund during the study are subjected to necropsies. At the conclusion of the study's observation period, surviving animals are killed and necropsied. Tissues may be saved for histopathological examination to facilitate the understanding of the acute toxicity of the compound. In order to increase the reproducibility of the study, all experimental conditions and procedures should be standardized, and the study should be conducted according to generally recognized good laboratory practices (GLP) outlined by the Environmental Protection Agency (EPA) and the OECD [56,57,162].

TABLE 22.1
Comparison of Acute Oral Toxicity in the Rat Using ALD versus Classical (Conventional) Method

Chemical	Classical Method		Approximate Method	
	n	LD_{50} (mg/kg)	*n*	ALD (mg/kg)[a]
Tetraethyl lead	36	20	5	26
Methomyl	53	40	5	26
Hexachlorophene	46	165	11	90
Adiponitrile	65	301	7	300
Caffeine	40	483	8	450
N-butylhexamethylene diamine	35	536	7	1000
Hexamethylene diamine	92	1127	5	1500
Bromobenzene	35	3591	8	3400
Carbon tetrachloride	105	10,054	5	7500

[a] The lowest dose that caused death.

Animals

Responses elicited by a compound often vary greatly among species. Ideally, toxicity tests should be conducted with an animal that will elicit compound-related toxic responses similar to those that occur in man, that is, an animal that metabolizes the compound identically to man and that has the same susceptible organ system(s). Under such conditions, the animal data may be extrapolated to man. Unfortunately, finding such an ideal animal is a difficult if not impossible task.

A less ideal but more manageable approach is to conduct acute toxicity studies in a variety of animal species under the assumption that if the toxicity of a compound is consistent in all the species tested, and then a greater chance exists that such a response may also occur in man. Even though the response in different species is not consistent, it generally is considered better to err on the safe side with the risk assessment being based on the most sensitive species, unless there is justification that such responses are less likely to occur in humans. An example of when a sensitive species would not be considered would be when it is known there is a dissimilarity in test article metabolism between a more sensitive animal species and man. While these are logical assumptions and generally quite reliable, there is the danger that the results in the animals may underestimate or overestimate the response in humans. Therefore, there is no absolute criterion for selecting a particular animal species. However, priority should be given to species with metabolism or other physiological and biochemical parameters similar to man. Animal species also should be selected on the basis of convenience, economical factors, and the existing database for the animal. Rats, mice, rabbits, and guinea pigs are most commonly chosen for acute toxicity studies.

Acute toxicity, even within a particular species, can vary with health conditions; age; sex; genetic makeup; body weight; differences in absorption, distribution, metabolism, and excretion of the compound; and the influence of hormones [48]. For example, immature animals may lack an effective drug-metabolizing enzyme system; this may contribute to higher toxicity of the compound in an immature animal if the enzyme is responsible for the detoxification of the compound. On the other hand, if the enzyme responsible for generating a toxic metabolite is inactive then it is possible that the toxic potential of the material will be underestimated. Obesity may affect the distribution and storage of a compound, especially if it is highly lipophilic. Sex hormones may be the target, or sex hormones may modify a particular toxic response, which then may account for different toxic responses between sexes. Liver and renal diseases associated with old age may contribute to higher toxicity. Variations in genetic makeup among different strains may alter metabolism or other parameters, which may affect the toxicity of a particular compound. It is therefore important to document all data on animals: age, sex, body weight, strain, general health condition, and source. In general, healthy, young adults should be used.

Number and Sex

The precision of the acute test is dependent to a large extent on the number of animals employed per dose level. Historically, 10 rats (5/sex) have been recommended in most regulatory guidelines [51,61,66,157,186], although more recently modified protocols are acceptable using as few as three animals per dose level [160,161]. The degree of precision needed and in turn the number of animals per dose group needed depend on the purpose of the study. In screening tests or tests designed to define the range of toxicity, fewer animals per dose level or fewer numbers of dose levels may be considered. In rare situations where a fairly precise LD_{50} is needed, the number of dose levels (at least three dose levels) and animals per dose group may need to be increased. Literature surveys have shown that when there are sensitivity differences between the sexes, females, in general, are more sensitive [115].

Grouping, Preparation of Animals, and Randomization

Animals not previously treated with test substances in other studies should be identified individually by coded marks, metal ear tags, or tattoos. The animals then should be quarantined for at least a week prior to dosing to acclimatize them to the conditions of the animal room. The animals should be fasted prior to administration of the test substance if the route of administration is oral. The purpose of fasting the animal is to eliminate feed in the gastrointestinal (GI) tract, which may complicate absorption of the test substance. Rats usually are fasted overnight. Because mice have a higher metabolic rate, withholding feed for 3–4 h may be adequate. Over-fasting small animals with a high metabolic rate may induce undesirable effects. The animals should be randomly assigned to dose groups. Randomization ensures a homogeneous population and can minimize errors due to sampling bias. All animals with body weights and health conditions out of the normal range should be eliminated prior to the randomization procedure.

Dose Levels

In general, the dose levels should be sufficient in number to allow a clear demonstration of a dose–response relationship and to permit an acceptable determination of the LD_{50}, if required. Three dose levels generally are sufficient. The selected dose levels should bracket the expected LD_{50} value with at least one dose level higher than the expected LD_{50} but not causing 100% mortality, and one dose level below the expected LD_{50} value but not causing 0% mortality, when the probit analysis method is applied to estimate the LD_{50}. However, with a method such as the moving average under some specific conditions (at least four dose levels with equal logarithmic intervals between each dose level, and with equal numbers of animals in each dose group), the LD_{50} can be estimated even with 0% mortality at the lower-dose levels and 100% mortality at the two higher dose levels. In any event, three or more dose levels with a wide range of toxicity responses are recommended if no other toxicity data are available.

Dosages

If necessary, the test substance should be dissolved or suspended in a suitable vehicle, preferably in water, saline, or an aqueous suspension such as 0.5% methylcellulose in water. If a test substance cannot be dissolved or suspended in an aqueous medium to form a homogeneous dosage preparation, corn oil or another solvent can be used. If the toxicity of the vehicle is not known, a vehicle control group should be included in the test. The animals in the vehicle control group should receive the same volume of vehicle given to animals in the highest dose group.

The test substance can be administered to animals at a constant concentration across all dose levels (i.e., varying the dose volume) or at a constant dose volume (i.e., varying the dose concentration). However, the investigator should be aware that the toxicity observed by administration in a constant concentration may be different from that observed when given in a constant dose volume. The maximum dose volume in rodents should not exceed 10 mL/kg body weight for nonaqueous vehicles or 20 mL/kg body weight for aqueous solution or suspension. In any event, for scientific and humane reasons the dose volume should be as small as possible.

Observations

The emphasis in acute toxicity studies is on the determination of the dose–response and the onset of toxic signs. The observation period should be flexible depending on the purpose of the study. This period should be based on the onset of signs, the nature of the toxicity, time to death, and the rate of recovery. For most highly toxic substances, the onset of toxic signs and the time to death may be very short, and prolonged observation may not be necessary. The slope of the dose–response curve for such test substances is usually very steep, and the treated animals either die or survive within a very short time. The observation period also should be long enough for the determination of reversibility or the recovery of an adverse effect. Under specific circumstances, the observation period might be longer, but it normally does not exceed 14 days.

Clinical examination, observation, and mortality checks should be made shortly after dosing, at frequent intervals over the next 4 h, and at least once daily thereafter. The intervals and frequency of observation should be flexible enough to determine the onset of signs, onset of recovery, and the time to death. The mortality checks should be frequent enough to minimize unnecessary loss of animals due to autolysis or cannibalism. Cage side observations should include any changes in the skin, fur, eyes, mucus membranes, circulatory system, autonomic and central nervous systems, somatomotor activities, behavior, etc. Any pharmacotoxic signs such as tremor, convulsions, salivation, diarrhea, lethargy, sleepiness, morbidity, fasciculation, mydriasis, miosis, droppings, discharges, or hypotonia should be recorded. The most common pharmacotoxic signs are listed in Tables 22.2 through 22.4. Individual body weights should be determined just prior to dosing, once weekly, and at death or at termination. Necropsies should be performed on animals that are moribund, found dead, and killed at the conclusion of the study. All changes in the size, color, or texture of any organ should be recorded. Any gross change observed at necropsy should be described according to the size, color, and position of the lesion. While a complete microscopic examination of tissues and organs is ideal and would be helpful in defining acute toxicity, economic and time factors may preclude such a study. If the investigator feels that microscopic examination of a lesion is essential, tissues from these lesions should be preserved in an appropriate fixative such as 10% buffered formalin.

Fixed-Dose Procedure (Test Limit)

The traditional test limit for acute oral toxicity was considered to be 5.0 g/kg body weight, but more recently accepted

TABLE 22.2
Common Signs and Observations in Acute Toxicity Tests

Clinical Observation	Observed Signs	Organs, Tissues, or Systems Most Likely to Be Involved
I. Respiratory blockage in the nostril, changes in rate and depth of breathing, changes in color of body surface	A. Dyspnea: difficult or labored breathing, essentially gasping for air, respiration rate usually slow	
	1. Abdominal breathing: breathing by diaphragm, greater deflection of abdomen upon inspiration	Central nervous system (CNS) respiratory center, paralysis of costal muscles, cholinergic
	2. Gasping: deep labored inspiration, accompanied by a wheezing sound	CNS respiratory center, pulmonary edema, secretion accumulation in airways, increased cholinergic
	B. Apnea: a transient cessation of breathing following a forced respiration	CNS respiratory center, pulmonary cardiac insufficiency
	C. Cyanosis: bluish appearance of tail, mouth, foot pads	Pulmonary–cardiac insufficiency, pulmonary edema
	D. Tachypnea: quick and usually shallow respiration	Stimulation of respiratory center, pulmonary–cardiac insufficiency
	E. Nostril discharges: red or colorless	Pulmonary edema, hemorrhage
II. Motor activities: changes in frequency and nature of movements	A. Decrease or increase in spontaneous motor activities, curiosity, preening, or locomotions	Somatomotor, CNS
	B. Somnolence: animal appears drowsy, but can be aroused by prodding and resumes normal activities	CNS sleep center
	C. Loss of righting reflex, loss of reflex to maintain normal upright posture when placed on the back	CNS, sensory, neuromuscular
	D. Anesthesia: loss of righting reflex and pain response (animal will not respond to tail and toe pinch)	CNS, sensory
	E. Catalepsy: animal tends to remain in any position in which it is placed	CNS, sensory, neuromuscular, autonomic
	F. Ataxia: inability to control and coordinate movement while animal is walking with no spasticity, epraxia, paresis, or rigidity	CNS, sensory, autonomic
	G. Unusual locomotion: spastic, toe walking, pedaling, hopping, and low body posture	CNS, sensory, neuromuscular
	H. Prostration: immobile and rests on belly	CNS, sensory, neuromuscular
	I. Tremors: involving trembling and quivering of the limbs or entire body	Neuromuscular, CNS
	J. Fasciculation: involving movements of muscles, seen on the back, shoulders, hind limbs, and digits of the paws	Neuromuscular, CNS, autonomic
III. Convulsion (seizure): marked involuntary contraction or seizures of contraction of voluntary muscle	A. Clonic convulsion: convulsive alternating contraction and relaxation of muscles	CNS, respiratory failure, neuromuscular, autonomic
	B. Tonic convulsion: persistent contraction of muscles, attended by rigid extension of hindlimbs	CNS, respiratory failure, neuromuscular, autonomic
	C. Tonic–clonic convulsion: both types may appear consecutively	CNS, respiratory failure, neuromuscular, autonomic
	D. Asphyxial convulsion: usually of clonic type but accompanied by gasping and cyanosis	CNS, respiratory failure, neuromuscular, autonomic
	E. Opisthotonos: tetanic spasm in which the back is arched and the head is pulled toward the dorsal position	CNS, respiratory failure, neuromuscular, autonomic
IV. Reflexes	A. Corneal eyelid closure: touching of the cornea causes eyelids to close	Sensory, neuromuscular
	B. Primal: twitch of external ear elicited by light stroking of the inside surface of ear	Sensory, neuromuscular
	C. Righting: ability of animal to recover when placed dorsal side down	CNS, sensory, neuromuscular
	D. Myotact: ability of animal to retract its hindlimb when limb is pulled down over the edge of a surface	Sensory, neuromuscular
	E. Light (pupillary): constriction of pupil in the presence of light	Sensory, neuromuscular, autonomic
	F. Startle reflex: response to external stimuli such as touch and noise	Sensory, neuromuscular

TABLE 22.2 (continued)
Common Signs and Observations in Acute Toxicity Tests

Clinical Observation	Observed Signs	Organs, Tissues, or Systems Most Likely to Be Involved
V. Ocular signs	A. Lacrimation: excessive tearing, clear or colored	Autonomic
	B. Miosis: constriction of pupil regardless of the presence or absence of light	Autonomic
	C. Mydriasis: dilation of pupils regardless of the presence or absence of light	Autonomic
	D. Exophthalmos: abnormal protrusion of eye in orbit	Autonomic
	E. Ptosis: dropping of upper eyelids, not reversed by prodding animal	Autonomic
	F. Chromodacryorrhea: red lacrimation	Autonomic, hemorrhage, infection
	G. Relaxation of nictitating membrane	Autonomic
	H. Corneal opacity, iritis, conjunctivitis	Irritation of the eye
VI. Cardiovascular signs	A. Bradycardia: decreased heart rate	Autonomic, pulmonary–cardiac insufficiency
	B. Tachycardia: increased heart rate	Autonomic, pulmonary–cardiac insufficiency
	C. Vasodilation: redness of skin, tail, tongue, ear, foot pad, conjunctivae, and sac, and warm body	Autonomic, CNS, increased cardiac output, hot environment
	D. Vasoconstriction: blanching or whitening of skin, cold body	Autonomic, CNS, decreased cardiac output, cold environment
	E. Arrhythmia: abnormal cardiac rhythm	CNS, autonomic, pulmonary–cardiac insufficiency, myocardiac infarction
VII. Salivation	A. Excessive secretion of saliva: hair around mouth becomes wet	Autonomic
VIII. Piloerection	A. Contraction of erectile tissue of hair follicles resulting in rough hair	Autonomic
IX. Analgesia	A. Decrease in reaction to induce pain (e.g., hot plate)	Sensory, CNS
X. Muscle tone	A. Hypotonia: generalized decrease in muscle tone	Autonomic
	B. Hypertonia: generalized increase in muscle tension	Autonomic
XI. GI signs:		
Droppings (feces)	A. Solid, dried, and scant	Autonomic, constipation, GI motility
	B. Loss of fluid, watery stool	Autonomic, diarrhea, GI motility
Emesis	A. Vomiting and retching	Sensory, CNS, autonomic (in rat, emesis absent)
Diuresis	A. Red urine	Damage in kidney
	B. Involuntary urination	Autonomic sensory
XII. Skin	A. Edema: swelling of tissue filled with fluid	Irritation, renal failure, tissue damage, long-term immobility
	B. Erythema: redness of skin	Irritation, inflammation, sensitization

TABLE 22.3
Autonomic Signs

Sympathomimetic	Piloerection
	Partial mydriasis
Sympathetic block	Ptosis
	Diagnostic if associated with sedation
Parasympathomimetic	Salivation (examined by holding blotting paper)
	Miosis
	Diarrhea
	Chromodacryorrhea in rats
Parasympathomimetic block	Mydriasis (maximal)
	Excessive dryness of mouth (detect with blotting paper)

TABLE 22.4
Toxic Signs of Acetylcholinesterase Inhibition

Muscarinic Effects[a]	Nicotinic Effects[b]	CNS Effects[c]
Bronchoconstriction	Muscular twitching	Giddiness
Increased bronchoconstriction	Fasciculation	Anxiety
Nausea and vomiting (absent in rats)	Cramping	Insomnia
Diarrhea	Muscular weakness	Nightmares
Bradycardia		Headache
Hypotension		Apathy
Miosis		Depression
Urinary incontinence		Drowsiness

[c] Atropine might block early signs.

protocols for acute toxicity [159–161] have a test limit of 2.0 g/kg body weight. Protocol used is a modification of the protocol developed by the BST as described by Van den Heuvel et al. [199]. Basically, this procedure calls for dosing animals in a stepwise fashion using fixed doses of 5, 50, 500, and 2000 mg/kg. The initial dose level selected (discriminating dose) would be a dose expected to produce some signs of toxicity and should be nonlethal, nonpainful, and nonstressful. The dose could be selected by using available information, or by conducting a *sighting study* using three or four animals. If no mortality was observed at the highest dose level, a higher dose level was generally not necessary. The focus of the test should not be limited to mortality (found dead or killed for humane reasons), but should include other toxicity endpoints such as time course of signs of toxicity and necropsy findings. These data and the *discriminating dose* should provide adequate data for hazard assessment, comparative reference, and labeling classification (Table 22.5).

A multinational validation study in 33 laboratories with 20 materials using the fixed-dose approach produced consistent results on the time course of signs of toxicity, which was adequate for acute toxicity risk assessment and acute toxicity classification based on the European Economic Community (EEC) criteria. Compared to the classical method, fewer animals were used and less stress occurred [199]. This test has been adopted by the OECD as an alternative acute oral toxicity method [159].

Acute Toxic Class Method

This method has been described by Roll et al. [177] and is based on the assumption that using a minimum number of animals in a stepwise procedure will provide enough information on the acute toxicity of a substance to allow classification according to the most commonly used classification schemes. Three animals of one sex are used for each step; while normally females are used (considered to be generally slightly more sensitive, see Ref. [115]), either sex can be used. The initial dose is selected from one of the following fixed-dose levels: 5, 50, 300, or 2000 mg/kg body weight and should be chosen to produce some mortality. If existing information suggests that mortality is unlikely at the 2000 mg/kg dose, then a limit test at that level may be conducted with three animals of each sex. If deaths occur, further testing at the lower-dose levels may be necessary. This method was evaluated in national and international validation studies [182,183], and has been adopted by the OECD as an alternative acute oral toxicity method [160]. Like the fixed-dose method (see preceding section), this method will enable a judgment with respect to classifying the test material in one of a series of toxicity classes in accordance with the Globally Harmonized System (GHS) for the classification and labeling of chemicals [154].

Up-and-Down Procedure

The up-and-down procedure [20–22,161], which is one of the more modern methods of estimating the LD_{50}, is based on the maximum likelihood method. Like the *acute toxic class* method animals are dosed following a stepwise procedure. However, animals are dosed one at a time at a minimum of 48 h intervals, with the first animal receiving a dose just below the estimated LD_{50}. If the first animal survives, the next one receives a higher dose. If the first animal dies, the next one receives a lower dose. The spacing of doses generally is adjusted by a factor of 3.2 (default factor corresponding to a dose progression of one half log unit) up or down depending on the outcome of the previous animal. Comparison of classical LD_{50} values to the up-and-down derived LD_{50} shows close agreement (Table 22.6). This test has been adopted by the OECD as an alternative to the more traditional methods of LD_{50} determination [161]. The OECD test guideline also contains the provision for a limit test that uses a maximum

TABLE 22.5
Investigation of Acute Oral Toxicity Using the Fixed-Dose Method of Interpretation of Results

Fixed Dose (mg/kg)	Results	Interpretation
5[a]	Less than 100% survival[b]	Compounds that may be very toxic if swallowed
	100% survival but evident toxicity	Compounds that may be toxic if swallowed
	100% survival; no evident toxicity	Retested at 50 mg/kg if not already tested at that level
50	Less than 100% survival[b]	Compounds that may be toxic or very toxic if swallowed; retested at 5 mg/kg if not already tested at that level
	100% survival but evident toxicity	Compounds that may be harmful if swallowed
	100% survival; no evident toxicity	Retested at 500 mg/kg if not already tested at that level
500	Less than 100% survival[b]	Compounds that may be toxic or harmful if swallowed; retested at 50 mg/kg if not already tested at that level
	100% survival but evident toxicity	Compounds that do not present a significant acute toxic risk if swallowed
	100% survival; no evident toxicity	Retested at 2000 mg/kg if not already tested at that level
2000[c]	Less than 100% survival[b]	Compounds that may be harmful if swallowed; retested at 500 mg/kg if not already tested at that level
	100% survival with or without evident toxicity	Compounds that do not present a significant acute toxic risk if swallowed

[a] Where a dose of 5 mg/kg produces significant mortality, or where a sighting study suggests that mortality will result at that dose level, the substance should be investigated at a lower dose level. The level chosen should be one that is likely to produce evident toxicity but no mortality.

[b] Includes compound-related mortality and humane kills but not accidental deaths.

[c] It should be noted that testing mortality at this dose level is carried out primarily for risk assessment purposes. However, where no evident toxicity is seen at 500 mg/kg its results are relevant to classification if there is greater than 50% mortality (including humane kills).

TABLE 22.6
Comparison of Rat Oral LD_{50} Using the Up-and-Down Method versus Classical (Conventional) Method

	Classical Method		Up-and-Down Method	
Chemical No.	*n*	LD_{50} (g/kg)	*n*	LD_{50} (g/kg)
1	50	0.273	6	0.388
2	40	0.344	9	0.421
3	40	3.490	8	4.120
4	40	3.520	6	4.020
5	40	4.040	6	3.520
6	40	5.560	6	5.700
7	40	9.280	6	8.770
8	20	>10.00	3	>10.10
9	50	10.11	7	11.09
10	10	>20.00	8	22.40

of five animals. This test is used when there is information suggesting that the test material has a low potential to be toxic, in this study a test dose of 2000 mg/kg or, as required, 5000 mg/kg is used. Animals are dosed in a sequential manner with the second animal receiving the dose only if the first animal survives the limit dose.

Data from this method can be analyzed using either SAS [181] or BMDP [47] computer program packages, which are available to many toxicology laboratories. Other examples of programming for the estimation of the LD_{50} with a small computer have been reported [113,178].

Acute Dermal Toxicity

Dermal exposure is an important route of exposure. The objective of conducting an acute dermal toxicity study is the same as an acute oral toxicity study, to assess the adverse effects resulting from a single dermal application of a test substance. The acute dermal test also provides the initial toxicity data for regulatory purposes, labeling, classification, transportation, and subsequent subchronic and chronic dermal toxicity studies. In addition, results from this type of test could provide information on dermal absorption and a test material's potential mode of toxic action. Comparison of acute toxicity by the oral and dermal routes may provide evidence of the relative penetration of a test material.

While the general experimental design and principles of acute dermal toxicity testing are similar to those of acute oral testing, there are differences. These differences include selection of the animal species, the number of animals per dose level, preparation of animals, dosage, and administration of the test substance. Only differences in the acute dermal test are described in this section.

Recently, an OECD test method similar in principle to the acute oral toxicity fixed-dose procedure [198] has

been developed and is currently under review [148]; when approved, this method would reduce the number of animals needed to assess the dermal toxic potential of chemicals. Because this method has not been finalized and formally approved, it will not be discussed here.

Principle

The test material is applied dermally, undiluted or diluted with the appropriate solvent, in graduated doses to several groups of animals. A vehicle control group is included if needed, but generally this group is not necessary if the toxicity of the vehicle is known. Clinical signs, morbidity, and mortality are observed at specific time intervals. Animals that die or become extremely moribund during the study are necropsied. At the conclusion of the study's observation period, surviving animals are killed and necropsied. Tissues may be saved for histopathological examination to facilitate the understanding of the acute toxicity of the compound. In order to increase the reproducibility of the study, all experimental conditions and procedures should be standardized, and the study should be conducted according to generally recognized GLP outlined by the EPA and the OECD [56,57,162].

Animals

The three most commonly used animal species for this type of test are rabbits, rats, and guinea pigs. However, other species can be used for this type of test. At the start of the study, healthy animals between 8 and 12 weeks old with a range of weight variation not exceeding ±20% of the appropriate mean value should be used. Variables, such as species used, age and health of the animal, body weight, sex, and housing environment, can affect the outcome of an acute dermal toxicity test. The animals should be housed individually in a controlled environment. Quarantine, acclimatization, and randomization are as described in earlier text for acute oral toxicity studies. The back of the animal or a band around the trunk should be clipped free of hair. When clipping the hair, care must be taken not to abrade the skin. If abraded skin is called for, a needle may be used, but care must be taken not to damage the dermis. Increasingly, investigators have come to question the value of conducting tests on abraded skin, and many consider such tests to be irrelevant. To date, almost all testing guidelines call for conducting the dermal test only on intact skin [51,62,67,151,157,186]. In contrast to the acute oral toxicity test method, fasting animals overnight is not necessary. Generally, 10 animals per dose level (5/sex) are sufficient to allow for an acceptable estimation of the dermal LD_{50}. However, depending on the nature of the test substance and available safety information, smaller numbers of animals can be used. Females used in the study should be nulliparous and not pregnant.

Dose Levels

Dose selection is similar to the acute oral toxicity test. Higher doses do not need to be tested when a test substance at 2000 mg/kg, considered the limit dose, has not produced test substance-related mortality. This is because administration of additional test substance would only be applied on top of the test substance layer already present. This layering may form a physical barrier to prevent further absorption of the test substance from the application site.

While a control group generally is not needed, a vehicle control group should be included in the study if the toxicity of the vehicle is not known. Its influence on dermal penetration of the test substance should be fully established prior to the study.

Preparation of Dosage and Dosing Procedure

The test substance should be applied uniformly to approximately 10% of the body surface of the animal (e.g., 4 cm × 5 cm for rats, 12 cm × 14 cm for rabbits, 7 cm × 10 cm for guinea pigs). Under certain conditions, the area of application may vary; for example, the area of application for highly toxic substances may be small because a lower volume is applied.

Liquid test substances generally are applied undiluted. If the test substance is a solid, it should be pulverized, weighed, placed on a plastic sheet or porous gauze dressing, moistened so as to form a paste with normal saline (one part test substance for one part saline) or an appropriate solvent, and then spread evenly on the closely clipped skin to ensure uniform contact with the skin. Grinding of the solid test substances may not be needed under some conditions. For example, when a granular formulation is tested, it may be more relevant to test the substance in its formulation state than to destroy the formulation by grinding.

The test substance can be applied under semiocclusive, occlusive, or nonocclusive (open) conditions; choice of the application method depends on what the most likely exposure pattern is in humans. The application method with the highest potential for skin irritation is occlusive, followed by semiocclusive and nonocclusive exposures. It should be noted that skin irritation may not only cause stress to the animal but can also increase dermal penetration of the test substance.

For nonocclusive application, the application site remains uncovered but the volume of liquid test material that can be applied to the skin may be limited depending on the volatility of the liquid. It may be necessary to immobilize the animal or use a device such as an *Elizabethan* collar so as to prevent the animal from ingesting the test material as a result of licking the application site. For occlusive application, the application site is covered with an impervious material such as a plastic sheet. For semiocclusive application the application site is covered with a porous gauze dressing as described in the following paragraph. The volume that can be applied with the occlusive or semiocclusive patch generally is larger than that of the nonocclusive method.

Dosing Procedures for Liquid Test Substances

The dosing procedure for the rabbit is detailed because rabbits are the most widely used species for this type of testing. Rabbits are clipped free of hair with an electric animal hair clipper. The rabbit may have to be restrained by tightening the

hind legs to a secured post and holding the nape of the neck during clipping. When using the occlusive method, a plastic cuff in a cylindrical shape (approximately 12–15 in. long and 10 in. in diameter) open at both ends can be used. The cuff is put onto the trunk of the rabbits, covering the application site. With the help of another investigator, the plastic cuff is folded around the trunk and secured at the thorax and flank of the rabbit with surgical adhesive tapes. Care should be exercised so that the cuff is sufficiently secured but not too tight to affect breathing. Using a long feeding needle, the correct amount of the liquid test substance is drawn into a syringe of appropriate size. The needle then is placed under the cuff and half of the dose is delivered evenly on each side of the vertebral column. After withdrawal of the needle, the test substance is evenly distributed over the application site by gently rubbing the top of the plastic cuff. A piece of cloth of appropriate size is then wrapped around the plastic cuff and taped in place to absorb any test substance that may spill off the cuff. After dosing, the investigator should observe the animal for a moment to see if breathing is affected, prior to putting the animal back into the cage. In the semiocclusive method, a porous gauze dressing replaces the plastic cuff. In nonocclusive exposure, the test substance is applied uniformly over the skin: care must be taken to minimize run off from the skin, especially for aqueous dosing solutions. Applying the test substance in small amounts at a time may help.

Dosing Procedure for Solid Test Substances

If the test substance is a solid, it should be ground with a mortar and pestle unless there is justification not to pulverize. The correct dose of the ground solid is weighed, placed in the center of a plastic sheet of appropriate size, and moistened with sufficient normal saline or another appropriate vehicle. If a vehicle other than saline or water is used, the effect of the vehicle on the skin penetration of the test substance should be considered, and its toxicity should be known. The type of vehicle selected should be based on the expected mode of exposure of the test substance and should be mixed into a paste. The paste then is spread evenly around the center of the plastic sheet. With one person holding the rabbit by grasping it at the back, another person moistens its belly and its back with paper towels soaked with saline. Then the rabbit is placed with its belly on the test substance paste on the plastic sheet, and another investigator wraps the sheet around the trunk of the rabbit. The plastic cuff is secured in place with surgical tape at the thorax and the flank. A piece of cloth of appropriate size then is wrapped around the plastic cuff and secured in place in the same manner. In the semiocclusive method, a porous gauze dressing replaces the plastic sheet.

Dosing Procedures for Rats and Guinea Pigs

Method of dosing rats and guinea pigs is similar to that of the rabbit. Liquid samples should be placed on the back instead of belly or on the lateral trunk. If nonocclusive exposure is called for in rats, the test substance should be applied to the skin as near to the head as possible to prevent ingestion by preening of the application site. A plastic collar may be used to further limit access to the treatment site. Generally, the plastic collar produces more stress in the rat, as indicated by chromodacryorrhea (red stain around the eyes), than in the rabbit. To minimize stress in rats, small collars can be hand made from light cardboard. The collar is lined with cut rubber tubing around the neck area and stapled in place. The cardboard collar is lighter and easier to place on small animals. It can readily be replaced if needed (the collar placed on the neck usually will last about 3 days), and it is more economical than the commercially available plastic collars.

Exposure Period and Removal of Cuff

Almost all testing guidelines [51,61,66,151,157,186] call for 24 h continuous exposure. Upon completion of the exposure, the cuff is removed and the application site is gently wiped with a paper towel soaked with saline, water, or any appropriate solvent to remove residual test substance remaining on the application site.

Observation Period

As in the acute oral toxicity test, the recommended minimum observation period is 14 days. However, the duration and intervals of observation should be flexible enough to establish onset of signs, time to death, and time to recovery, but should be frequent enough such that the loss of animals due to autolysis and cannibalizing is minimal. In addition, skin irritation should be assessed according to a scoring system such as the one described by Draize et al. [49].

Acute Inhalation Toxicity

Inhalation exposure is an important route of exposure. The objective of conducting an acute inhalation toxicity study is to evaluate the toxic potential of a test material that may be inhaled, such as a gas, a volatile substance, or an aerosol. Such testing may provide information on the adverse effects resulting from exposure to inhalation application of a single dose of a test substance. The acute inhalation test provides the initial toxicity data for regulatory purposes, labeling, classification, transportation, and subsequent subchronic and chronic dermal toxicity studies. Comparison of acute toxicity by the oral and inhalation routes may provide evidence of the relative penetration and bioavailability of a test material.

While the general experimental design and principles of acute inhalation toxicity testing are similar to those of acute oral testing, there are differences. These differences include selection of the animal species, the number of animals per dose level, preparation of animals, dosage, and, most importantly, administration of the test substance.

Recently, OECD test methods similar in principle to the acute oral toxicity's fixed-dose [198] and acute toxic class [160] methods have been developed and are currently under review [149,152]; when approved, these methods would reduce the number of animals needed to assess the inhalation toxic potential of chemicals. Because these methods have not been finalized and formally approved they will not be discussed here.

Principle

Several groups of animals are exposed to a fixed concentration of test material by inhalation for a short period of time, one concentration per group. While whole body exposure inhalation data are accepted by regulatory agencies, it is recommended that nose-only or head-only exposure be used as this minimizes oral exposure from animals licking the compound off their fur. When a vehicle is used to help attain an appropriate concentration of test material, a vehicle control group should be included in the study. Clinical signs, morbidity, and mortality are observed at specific time intervals. Animals that die or become extremely moribund during the study are subjected to necropsies. At the conclusion of the study's observation period, surviving animals are killed and necropsied. Tissues may be saved for histopathological examination to facilitate the understanding of the acute toxicity of the compound.

Animals

While several mammalian species have been used, the preferred species is the rat. In selecting a test species, priority should be given to the species with metabolism or other physiological and biochemical parameters similar to man. At the start of the study, healthy animals between 8 and 12 weeks old with a range of weight variation within and between test groups should not exceed ±20% of the mean weight. The animals should be housed individually in a controlled environment. Quarantine, acclimatization, and randomization are as described in earlier text for acute oral toxicity studies.

At least 10 animals (5/sex) per concentration level are recommended in most regulatory guidelines [63,64,68,150,186] giving sufficient numbers to allow for an acceptable estimation of the inhalation LC_{50}. However, depending on the nature of the test substance and available safety information, smaller numbers of animals can be used. Females, if used, should be nulliparous and not pregnant.

Environmental Conditions

Inhalation equipment used should be able to sustain a dynamic airflow of 12–15 air changes per hour, ensure adequate oxygen content of 19% and an evenly distributed exposure atmosphere [63,150]. If a whole body chamber is used, individual housing must be used and the total volume of test animals should not exceed 5% of the volume of the test chamber. Temperature and relative humidity need to be monitored continuously and should be maintained at 22°C ± 2°C and 30%–70%, respectively.

Dose Levels

In general, three concentration levels should be used and spaced to produce a concentration–response curve in order to permit an acceptable determination of the LC_{50}. Animals are usually exposed for a period of 4 h. Dose range–finding studies using single animals may help determine the doses to be used in the main study when the toxic potential of the test material is unknown. In selecting the dose levels to be used, particle size analysis should be performed to determine the consistency of particle size distribution. While not specifically required by OECD, U.S. EPA guidelines recommend that the mass median aerodynamic diameter (MMAD) particle size range should be between 1 and 4 μm (particle size distribution that permits deposition throughout the respiratory tract). When a vehicle is used to attain the desired test material concentration, a vehicle control group should be included in the test.

Observations

The recommended minimum observation period is 14 days. However, the duration and intervals of observation should be flexible enough to establish onset of signs, time to death, and time to recovery, but should be frequent enough such that the loss of animals due to autolysis and cannibalizing is minimal.

Clinical examination, observation, and mortality checks should be made shortly after dosing, at frequent intervals over the next 4 h, and at least once daily thereafter. Cage side observations should include any changes in the skin, fur, eyes, mucus membranes, circulatory system, autonomic and central nervous systems, somatomotor activities, behavior, etc. Individual body weights should be determined just prior to dosing, once weekly, and at death or at termination. Gross necropsies should be performed on animals that are moribund, found dead, and killed at the conclusion of the study with particular attention paid to any changes in the respiratory tract.

Test Limit

If no test substance–related mortality is observed at an exposure of 5 mg/L or the maximum attainable concentration for 4 h, then it is not necessary to conduct a full study [64,150].

ASSESSMENT OF EYE IRRITATION INDUCED BY CHEMICALS

The eye captures visible energy and converts the energy to neurosignals, which are transmitted to the intricate central nervous system where they form neuroimages (vision). The importance of having this ability to perceive the external environment through vision is a giant step in the evolution process. In humans, vision along with hearing is vital for the development of speech, learning, and intelligence. Loss of vision can greatly curtail normal living.

There are three basic components of vision: optics, photoreceptors, and conducting nerves. All three components must function properly to form a clear and sharp neuroimage in the visual cortex. The optics of the eye (cornea, aqueous humor, iris, lens, and vitreous humor) must remain transparent and be able to refract and focus light on the right position on the photoreceptors. The photoreceptors (the cones and rods) of the retina must be able to undergo photolysis and convert light energy to neuropotential impulses. The optic nerves must be able to carry these neuroimpulses to the visual cortex.

Because the eye is constantly exposed to the external environment, the cornea must be protected from drying, dust, and microorganisms. The eyelids, the lacrimal system, and the somatosensory response of the cornea all work together to protect this outermost structure of the eye. Like other organs, the major portion of the eye is nourished by blood vessels.

The retinal, circumcorneal, and uveal vessels also nourish and help maintain the eye. These vessels are so arranged and constructed that they normally do not alter the transparency of the ocular optics. Nutrients reach the transparent tissues of the eye via tears, the aqueous humor, and vitreous fluids.

Normal ocular functions are in delicate balance and are interdependent. Any traumatic insult, chemical or physical, can upset one or many of these ocular functions, thus creating a disturbance in vision. Depending on the extent of the traumatic injury (ranging from drying of the tear film to corneal ulceration or optic nerve damage), partial or complete loss of vision can result. Ocular injury not only can result from accidental physical trauma, but also radiation and chemicals.

Chemicals can cause ocular damage locally by accidental exposure to the eye, or systemically by ingestion of chemicals such as food contaminants and drugs. Because many chemicals can produce ocular damage either locally or systemically [85,95,129,176], it is important to test products for ocular effects before exposing workers during manufacturing and, ultimately, before subjecting consumers to products on the market. Ocular effects resulting from systemic exposure are beyond the scope of this chapter. This section focuses on eye irritation resulting from direct ocular contact.

Conducting ocular tests in humans is not only impractical but also unethical. Consequently, many methods and techniques have been developed over the years for testing ocular effects in animals. This section describes the animal methods for detecting potential eye irritants and discusses their limitations. In recent years, in vitro methods intended to replace eye irritancy tests in animals have evolved; an overview of some of these methods is discussed in Chapter 20.

Testing for potential eye irritancy is required for labeling and classification of chemicals by most regulatory agencies worldwide. The test protocol, interpretation of results, and classification scheme vary among countries. The differences among major industrial countries also are discussed.

Definition of Chemically Induced Eye Irritation and Corrosion

Irritation can be defined as reversible inflammatory changes in the eye and its surrounding mucus membranes following direct exposure to a material on the surface of anterior portion of the eye. Corrosion is irreversible ocular tissue damage following exposure to a material. From a practical point of view, the distinction between reversible and irreversible changes sometimes is limited by the length of the observation period. Therefore, the term *eye corrosion* should be reserved for gross tissue destruction of the eye, which generally occurs rapidly following exposure. When interpreting results from an eye irritation study, one must take into consideration the biological nature and significance of the ocular changes. For example, conjunctival redness is considered a mild ocular effect.

Normal Physiology and Anatomy of the Eye

A brief description of the normal physiology and anatomy of the eye is essential for understanding the development of eye irritation. Details can be found in a variety of textbooks and reviews [74,126,172].

Functionally, the eye can be divided into three basic parts (Figure 22.4). From posterior to anterior, they are as follows.

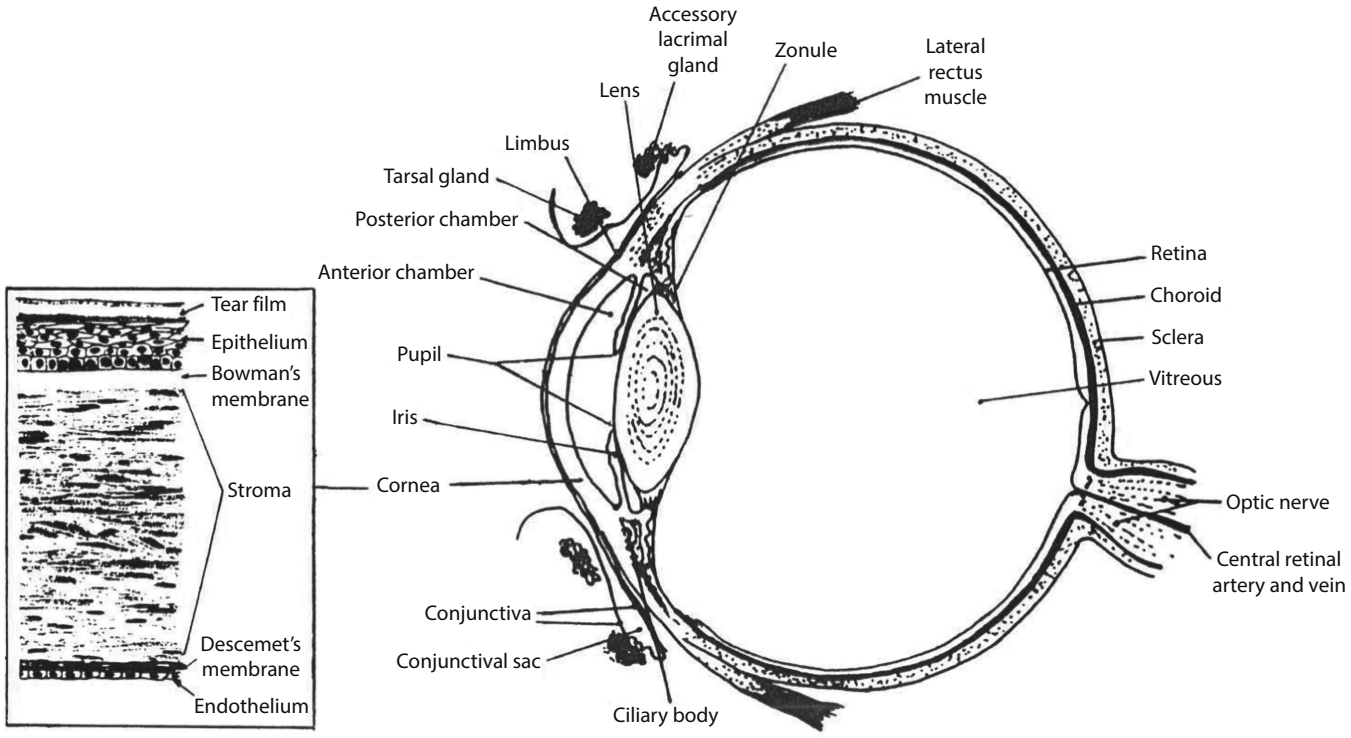

FIGURE 22.4 Schematic illustration of the eye.

Photoreceptors (*retina*): The part of the eye that connects to the central nervous system via the optic nerve.

Optics: Structure that focuses visible light (image) onto the retina; it includes (from anterior to posterior) the cornea, iris, aqueous humor in the anterior chamber, the lens, and its related organelles such as the zonules and ciliary body (muscles), and the vitreous in the posterior chamber.

Protective, lubricating, and nutritional structures: These include the anterior eyelids and conjunctiva and associated secretory glands, the sclera and its outside layer (the fibrous tunic) and inside layer (uvea–vascular), and the ciliary body (secretory).

For chemically induced eye irritation, the main concern is generally on the directly exposed organelles such as the cornea, conjunctiva, and the iris. Effects on these structures can easily be detected by gross observation. If the chemical can penetrate deeper into the eye, other organelles also can be affected. Detection of the effects on these deeper structures requires special aids.

Cornea

The cornea is composed of, from anterior to posterior, the epithelium, Bowman's membrane, stroma, Descemet's membrane, and endothelium. The epithelium is about five cells deep in the transitional zones at the periphery. The basal cells are columnar, the other cells are squamous, and the cells between the two layers are polygonal (wing cells). Bowman's membrane (12 μm) is an acellular layer of collagen and ground substance, which provides a functional interface between the stroma and epithelium. An intact Bowman's membrane and the epithelial basal cell layer are vital to the regeneration of damaged epithelium. Damage to Bowman's membrane may predispose the cornea to fibrosis. The stroma consists of lamellae of collagen fibrils and fibroblasts supported by ground substances. The stroma forms most (nine-tenths) of the cornea and is limited on its inner surface by Descemet's membrane.

In addition to the organization of sheets of fibrils, other unique features such as proper hydration also contribute to corneal transparency. Descemet's membrane (5–10 μm), like Bowman's membrane, is an acellular layer, which is the basement membrane of the endothelium. The endothelium is a single layer of cells, which completely covers the posterior surface of the cornea. The cells are hexagonal with large nuclei. This layer of the cornea is particularly rich in the active transport enzyme adenine triphosphatase (ATPase). The maintenance of proper hydration of the cornea has been attributed to the activity of this enzyme, which catalyzes an active sodium–potassium pump [15,108,118]. The limbus is a transitional region between the cornea and the sclera. This region, rich in vascularization, is the source of fluid and infiltration cells during corneal injury.

The epithelium and the overlying tear film provide the intrinsic protection for the cornea. Other layers have almost no intrinsic resistance to injury. Penetration into deeper layers of the cornea and other structures of the eye is limited by the chemicals' solubility and lipophilicity. Chemicals that are lipophilic and water-soluble penetrate more rapidly and probably deeper into the eye than other chemicals.

The cornea is always covered with a film of tears, which consists of several oily and aqueous layers. Proper tear formation and drainage as well as the stability of the precorneal tear film are important for a normal precorneal optical surface, proper lubrication, nutrition for the cornea, removal of bacteria and debris from the cornea, and activity on the cornea. Reduction of tear formation can lead to a dry eye, mechanical friction, irritation, or infection. A discussion on the assessment of tear film formation, stability, and drainage is available [31].

The cornea is a powerful refractive biological optic. Its refractive power is dependent on its being transparent and on proper hydration. Maintenance of proper transparency and hydration is dependent on many mechanisms, for example, proper tear flow, absence of deposits and blood vessels, proper arrangement of collagen fibrils, unimpaired nutritional supply for the metabolic active pump (Na^+–K^+), and proper intraocular pressure. Decreased transparency or hydration can be a result of corneal scars (decreased corneal thickness) or corneal edema (increased corneal thickness). Corneal edema can be caused by epithelial damage, endothelial damage, increased intraocular pressure, lack of oxygen, or inhibition of the electrolyte balance pump (Na^+–K^+-activated ATPase), which is located mainly in the endothelial membrane, but also is found in the epithelium. Methods for measuring corneal curvature, corneal thickness, intraocular pressure, blood/aqueous humor barrier, and corneal endothelium damages have been reviewed [31].

Conjunctiva

The conjunctiva is part of the eyelid. It is the delicate membrane that lines the eyelid (palpebral conjunctiva) and covers the exposed surface of the eyeball (bulbar conjunctiva). Histologically, the conjunctiva is an aqueous, nonkeratinized epithelium with numerous mucus-secreting cells. Accessory lacrimal glands are present in the conjunctiva, which contribute to the aqueous layer of a precorneal tear film. The Meibomian gland, a specialized sebaceous gland in the eyelid, secretes the outer oily layer of the tear film.

The main function of the eyelid is to protect the eye, especially the cornea, from external trauma through proper blinking reflexes and secretion of tears. Normal secretory and excretory functions of the tear are also important for normal optical function of the eye. The precorneal tear film can form an optically uniform layer over the microscopically irregular surface of the corneal epithelial cells. The tear flow continuously flushes cellular debris or foreign bodies from the eye, lubricates the corneal surface from mechanical friction caused by blinking, provides nutrients to the cornea, and induces antibacterial activities by proteolytic enzymes and immunoglobulin. All of these functions are important to

maintain an optically intact corneal surface. Substances that affect the stability of the precorneal tear film by interfering with the secretory/excretory functions or with the blinking mechanism can cause serious damage to the cornea and may even cause corneal ulceration.

The nictitating membrane or the third eyelid is an important and prominent structure in many species of animals including the rabbit but is not as important in humans and nonhuman primates. It aids in protecting the conjunctiva and the cornea when the eyeball is retracted. The nictitating membrane, like the conjunctiva, also contains lacrimal glands and its secretion contributes to the aqueous layer of the precorneal tear film. In addition, the nictitating membrane helps to support the position of low eyelids and forms the lacrimal lake in the medial canthus. Vascularization in the conjunctiva generally consists of superficial and deep groups, mainly in the bulbar conjunctiva.

Three endpoints generally are associated with irritation in the conjunctiva: redness, chemosis, and discharge. In response to an irritant, the eyelids blink, the tear secretion increases, and the conjunctiva vessels dilate. Blinking and tearing (discharge) aid in removing the irritant from the eye, and tear flow also may reduce the acidity or basicity of the irritant. Vessel dilation may be triggered by histamine, prostaglandins, or other inflammatory mediators, resulting in an apparent increase in vascularity (redness) in the conjunctiva. If irritation is severe, the dilation of the vessel increases and vascular fluid and proteins leak into the conjunctiva resulting in edema (chemosis). If the edema is severe, bulging may hinder normal functioning of the eyelids.

Iris

The iris forms the pupil and functions in regulating the amount of light that may reach the retina. High-intensity light causes constriction of the diameter of the pupil whereas low-intensity light dilates it. It does so by two sets of muscles acting opposite each other to control the diameter of the pupil. These muscles, circulatory and radiating, are innervated by both the autonomic and sympathetic nervous systems. The set of muscles forms the distinct characteristic of iridic furrows of the iris.

The iris is anatomically located posterior to the cornea, and is a very vascular structure made of loose connective tissues, muscle, and pigmented cells. The amount of pigment in the iris varies. Heavily pigmented cells are found in most species except albinos. Only a small amount of pigment is found in the albino rabbit eye. This is an advantage in ocular studies because it allows easier and better examination of the iridal vessels, lens, and retina.

The observation endpoints of local iridic injury are increased vascularity, edema (increased thickness of the stroma/swelling), reaction to light, aqueous flare, and gross destruction of tissue. These are the manifestations of an inflammatory process (iritis) responding to an irritant. Like the conjunctival vessels, the iridic vessels dilate and leak vascular fluid in response to irritants. Dilation of vessels and leakage cause edema and apparent changes in vascularity such as injection of iridic vessels (hyperemia). Aqueous flare is a result of protein leaking from the iridic vessels into the aqueous humor of the anterior chamber. Protein leakage into the anterior chamber alters the refractive index of the aqueous humors. Light beams entering the anterior chamber are scattered, giving the anterior chamber a cloudy appearance which contrasts with a clear appearance in normal eyes as a light beam passes through the pupil and the anterior chamber, for example, during examination with a slit lamp. This is called the aqueous flare or Tyndall phenomena, which is usually not noted during routine gross examination of the eye. In a more severe form of iritis, tissue destruction may result and nerve innervation may be disrupted, causing the pupil to be unresponsive to light. Failure to react to light, from a practical standpoint, is the most reliable observation of a severe iridic reaction since severe iritis is usually accompanied by severe opacity in the cornea, which may obscure the visible detection of changes on the iris.

DRAIZE TEST

The Draize test was developed in 1944 by Draize et al. to study eye irritation [49]. The test was based on the original work of Friedenwald et al. [79]. For years, the Draize test has been used as the animal test to identify human eye irritants. It is a simple and generalized test. It is easy to conduct and requires no special instruments. While simplicity is probably the main reason for its popularity, it is also the limitation of the test per se. Undeniably, the Draize test can adequately identify most of the moderate-to-severe human eye irritants, but the test may fail to detect mild or subtle ocular irritation even with proper modification.

In the original Draize test, a standard 0.1 mL or 0.1 g of test substance is applied to the conjunctival sac of an albino rabbit's eye. The eyelid is held together for a few seconds and then released. The degree or extent of opacity on the cornea, the redness on the iris, and the chemosis and discharge on the conjunctiva are scored subjectively according to an arbitrary scale at preselected intervals (1, 24, 48, and 96 h) after exposure. Scoring is based on the degree of effects caused by the testing substance. More emphasis is placed on the opacity of the cornea, which has a maximum score of 80, whereas emphasis is progressively less with other effects: conjunctival changes (maximum score of 20) and iritis (maximum score of 10) [24,84,121].

The Draize test has been a subject of controversy among animal rights groups [93,179] and even in the scientific community [9,24,84,88,96,121,174,205]. This test has been criticized on the dose volume, use of animals as models, methods of exposure, irrigation, number of animals, observation and scoring including laboratory procedure variability, and interpretation of results, all of which are discussed in the following.

Dose Volume

The 0.1 mL dose volume used in the original test was based on the volume used earlier by Friedenwald et al. [79] to study

the mechanism of acid- and base-induced ocular damage. This dose volume was selected arbitrarily as a standard volume for intraocular injection. Draize et al. [49] adopted it solely for convenience, which unfortunately has set a seemingly unchangeable doctrine for years even though the 0.1 mL dose volume lacks a scientific basis and, in conjunction with the conjunctival dosing method, often over-predicts the eye irritancy of a chemical.

Proponents of the 0.1 mL dose volume argue that this dose is a maximized test for the worst case and that it can better predict human eye irritants. While the purpose of the Draize test is to predict what would happen to human eyes within the expected range of exposure, the 0.1 mL dose is out of the range of human exposure. Even though the intent is to maximize the dose that is applied to the rabbit eye, use of 0.1 mL is excessive when you consider the fact that the maximal volume the cul-de-sac of a rabbit's eye can hold is only 30–50 μL [134]. Thus, because the cul-de-sac will not retain more than 50 μL, the remaining amount of test material will simply fall from the eye. Furthermore, the worst case is not necessarily the best case. Constantly estimating the eye irritation potential of test materials will have a desensitizing effect on consumers' and workers' awareness of potential eye irritation, thereby defeating the purpose of testing for eye irritancy in order to protect consumers and workers.

There are no data to substantiate the argument that the 0.1 mL dose can better predict human eye irritants. On the contrary, in at least one survey, there was little correlation between human accidental exposure experience and data generated by the traditional 0.1 mL maximal dose. The survey did not support the general presumption that rabbit eyes are more sensitive than human eyes [28]. Simply reducing the dose volume has produced data closer to eye irritation experienced in humans. For example, comparison of human eye irritation resulting from accidental exposure to many consumer products has revealed that lower-dose volume (0.01 mL) predicts the eye irritancy potential much better than the 0.1 mL dose volume [78,88]. In one of the studies, the time needed for recovery from eye irritation in humans was compared with animal tests in monkeys and rabbits [78]. Results of this study clearly demonstrated that the modified Draize test (Federal Hazardous Substances Act [FHSA] protocol) with a dose volume of 0.1 mL was the poorest predicting test. While all three animal tests over-predicted the eye irritancy experienced in humans, the low dose volume and monkey tests were better than the standard Draize test.

In 1977, a panel on eye irritancy test of the National Academy of Sciences (NAS), formed at the request of the Consumer Product Safety Commission (CPSC), recommended lowering the dose volume [144]. Subsequently, dose volumes ranging from 0.003 to 0.03 mL were proposed because they appeared to predict human eye irritants accurately, cause less pain to animals, and were able to discriminate slight-to-moderate eye irritants [88,90,210]. Williams et al. [210] showed that direct corneal application in a dose volume of 0.01 mL increased the response on the cornea when compared with the standard 0.1 mL dose but did not change the response on the conjunctiva. These results in the absence of compounding effects of a high-dose volume suggest that the lower-dose volume is just as sensitive a method for eye irritancy testing as the higher-dose volume.

Animal Models

As with other toxicological tests in animals, the primary reason for assessing the ocular irritation potential of test articles in animals is their predictability for humans. Recognizing that there are anatomical, physiological, and biochemical differences between human and animal eyes, researchers are confronted with the difficult task of selecting the appropriate animal model and suitable test conditions to identify potential human eye irritants. The corneal thickness of dogs and rhesus monkeys is similar to that of humans (approximately 0.5 mm) [121,125,135], whereas rabbit corneal thickness is somewhat thinner (0.37 mm) [121]. There is a lack of a recognizable Bowman's membrane in rabbits, but they have a well-developed nictitating membrane (an additional target tissue). Rabbits have thick fur around the eyes, loose eyelids susceptible to mild irritants, an ineffective tear drainage system, and a poorly developed blinking mechanism [144]. There are also species differences in biochemistry (e.g., variation in enzyme content [112]), and different penetration rates of various substances [120].

Even though there are shortcomings and exceptions in predictability, the rabbit has been the preferred species for eye irritancy studies. Advantages of using the rabbit include a large established database, relatively inexpensive animal to use, availability, ease of handling, and large, unpigmented eyes suitable for various ophthalmological examinations. With some exceptions [86,174], the rabbit eye is generally more sensitive to irritating materials than human or monkey eyes [7,25]. Thus there are built-in safety factors for making extrapolation and assessment of hazard to humans.

In addition to rabbits, dogs and primates sometimes are used for ocular testing. Eye irritancy in primates generally is more closely correlated with the exposure experience in humans, although dogs also have been shown to be suitable under certain circumstances [10]. Because they are more expensive and less available, dogs and primates are only used occasionally to assess eye irritancy.

Regardless of which animal is used, the investigator should always have a good understanding of the animal eye being observed. Background ocular findings, if not observed prior to exposure, can be recorded falsely as chemically induced damage.

Methods of Exposure

Basically, there are two ways of administering a test article to the eye: (1) instilling the test material into the cul-de-sac of the conjunctiva or (2) applying it directly onto the cornea. Of these methods, the conjunctival exposure procedure has been more frequently used historically because of the ease of application and has been perceived as an accurate method

of dosing. However, some studies [10,88] have shown that conjunctival instillation of the test article is inappropriate under many circumstances, especially when the test article is a solid powder. The possibility exists that a solid test article can become trapped in the conjunctival sac, producing some undesirable mechanical effects that make it difficult to interpret the observed ocular irritation results. It is also known that a considerable amount of the standard 0.1 mL or 0.1 g dose (especially as a solid powder) either falls or is blinked from the eye once the animal's eyelids are released. Based on this evidence, the claim that conjunctival dosing is more accurate than direct application to the cornea may not be valid.

The corneal exposure method, on the other hand, mimics more closely the actual accidental exposure experience in humans. When assessing the hazard of most chemical accidents, this method should be considered except when the chemical is intended for pharmaceutical use [144]. When applicators that had been developed for the corneal exposure method [7,25] were used, a more uniform corneal lesion was observed, resulting in less observation variability [7]. For a study as specific as corneal wound healing, it is recommended that a corneal applicator be used [139]. However, for hazard assessment, it is desirable to apply the test substance directly onto the cornea while the lids of the test eye are gently held open. Immediately afterwards, the eyelids are closed for a second and then released to allow blinking; this action more closely mimics actual human exposure [88].

Irrigation

Washing the eye is a typical emergency remedy after accidental exposure to chemical substances. In experimental studies, the treated eye usually is irrigated 20–30 s after exposure to the test substance. Water is rapidly but gently squeezed from a plastic bottle to produce a constant gentle stream of water irrigating the entire treated eye. Irrigation should last for at least 1 min.

The effect of irrigation on the interpretation of test results has been the subject of many studies [7–9,14,40,77,86,89,165,185]. While irrigation of the treated eye right after exposure can prevent or minimize eye irritation in rabbits, the effectiveness of irrigation is dependent on the chemical, the concentration, the time lag between exposure and initiation of the irrigation, and the volume of irrigation. Early washing (less than 1 min after test article application) generally is recommended to reduce irritation [40,77,89,185]; however, in some cases, irrigation has been shown to increase ocular irritation [82,185]. In other cases, ocular damage was almost instantaneous if irrigation were not initiated within a few seconds [40].

Number of Animals

As a rule the precision of a study increases with the number of animals used. Sometimes, the desired precision may be offset by animal-to-animal variabilities. Economic considerations also are important in determining the number of animals used in a test group. A balance between economic considerations and reliability of test results should determine the number of animals tested in a study.

For eye irritation studies, a group size of nine rabbits was recommended in the original Draize test, and group sizes of at least six, three, three, and four rabbits have been recommended by the FHSA [73], Interagency Regulatory Liaison Group (IRLG) [101], OECD [158], and NAS [144], respectively. The relationship of variability, classification, and group size is addressed in the literature [8,89,206]. With larger group size, smaller variability has been noted [206], whereas with a decreased group size, lesser differentiation of irritancy has been suggested [8]. Recognizing these facts, Guillot et al. [89] suggested that with three rabbits in an initial study, there was a 96% chance that a positive or negative eye irritation result would be obtained. A similar conclusion was reached in another study in which the ocular irritation potential of 67 petroleum products was evaluated using six rabbits per product [43]. The eye irritation scores for the petroleum products based on all six rabbits were compared statistically with the scores using two, three, four, or five animals. The comparison showed that a subsample size of two, three, four, and five rabbits correctly classified (compared with the original six rabbits/test classification) the chemicals at 88%, 93%, 95%, and 96% accuracy, respectively.

Observations and Scoring

Reversibility and severity are the two major criteria used to measure eye irritancy in the Draize test. Reversibility refers to the time needed for the ocular effects to disappear and for the eye to return to its normal state. To determine this reference time, treated eyes are examined periodically at 24 h intervals, on day 7 after exposure, or at longer intervals if needed to establish reversibility [49]. The observation period varies for different guidelines. For example, the FHSA uses 24, 48, and 72 h time spans [73]; the OECD uses 1, 24, 48, and 72 h, and, if needed, extended observations [158]; and the NAS recommends 1, 3, 7, 14, and 21 days [144]. The observation period should be flexible so that one can confidently assess the persistence of ocular effects and fully characterize the degree of involvement, since the onset and healing of ocular effects often are unpredictable [86].

Assessing the severity of different ocular effects is subjective. This subjective evaluation is the major source of error for intra- and interlaboratory variations [205]. Therefore, to minimize at least the intralaboratory variability in scoring, uniformity in scoring techniques must exist among investigators regardless of which scoring system is followed. Pictorial references such as those prepared by the Food and Drug Administration (FDA) [70] and the CPSC [39] can be extremely helpful in the standardization of scoring eye irritation.

The types of ocular effects observed in the Draize test involve the cornea, iris, nictitating membrane, and

TABLE 22.7
Scale of Weighted Scores for Grading the Severity of Ocular Lesions

Lesion	Score[a]
I. Cornea	
A. Opacity—degree of density (area that is most dense is taken for reading)	
Scattered or diffuse area—details of iris clearly visible	1
Easily discernible translucent areas, details of iris clearly visible	2
Opalescent areas, no details of iris visible, size of pupil barely discernible	3
Opaque, iris invisible	4
B. Area of cornea involved	
One-quarter (or less) but not zero	1
Greater than one-quarter—less than one-half	2
Greater than one-half—less than three-quarters	3
Greater than three-quarters—up to whole area	4
Corneal score equals A × B × 5; total maximum = 80	
II. Iris	
A. Values	
Folds above normal, congestion, swelling, circumcorneal injection (any one or all of these or combination of any thereof), iris still reacting to light (sluggish reaction is positive)	1
No reaction to light; hemorrhage, gross destruction (any one or all of these)	2
Score equals A × 5; total maximum = 10	
III. Conjunctivae	
A. Redness (refers to palpebral conjunctivae only)	
Vessels definitely injected above normal	1
More diffuse, deeper crimson red, individual vessels not easily discernible	2
Diffuse beefy red	3
B. Chemosis	
Any swelling above normal (includes nictitating membrane)	1
Obvious swelling with partial eversion of the lids	2
Swelling with lids about half closed	3
Swelling with lids about half closed to completely closed	4
C. Discharge	
Any amount different from normal (does not include small amounts observed in inner canthus of normal animals)	1
Discharge with moistening of the lids and hairs just adjacent to the lids	2
Discharge with moistening of the lids and considerable area around the eye	3
Score equals (A + B + C) × 2; total maximum = 20

[a] The maximum total score is the sum of all the scores obtained for the cornea, iris, and conjunctivae.

conjunctiva. A system for grading ocular responses (Table 22.7) was originally proposed by Draize et al. [49], subsequently a number of modifications were proposed [39,70,144]. In the Draize system, the intensity and area of involvement on the cornea are graded separately on a scale of 0–4. The product of the two scores is multiplied by 5 to obtain a weighted corneal score. The congestion, swelling, circumcorneal injection, hemorrhage, and iridic failure of reactions to light are graded collectively on a scale of 0–2, and the score is multiplied by 5 to obtain a weighted iridic score. The redness, chemosis, and discharge of the conjunctivae are graded on a scale of 0–3, 0–4, and 0–3, respectively. The sum of the conjunctival scores is then multiplied by 2 to obtain a weighted conjunctival score. Other lesions also are recorded, such as pannus (corneal neovascularization), phlyctena, and rupture of the eyeball.

In the guidelines set forth by the EPA, CPSC, FHSA, OECD, EEC, and Japan's Ministry of Agriculture, Forestry and Food (MAFF) [39,51,61,73,186], only the degree (intensity of cornea damage, iritis, and redness and chemosis [swelling]) of the conjunctivitis is scored (Table 22.8). The area involved on the cornea as well as the discharge of the conjunctiva are not taken into consideration in scoring. Various aids are used at times to facilitate or increase the resolution power of these observations. These aids include fluorescein staining and ophthalmoscopic or slit lamp microscopic examinations. A scoring system has been developed for the slit lamp and fluorescein staining examination [144] (Table 22.9).

TABLE 22.8
Grades for Ocular Lesions

Lesion	Grades
Cornea	
No ulceration or opacity	0
Scattered or diffuse areas of opacity (other than slight dulling of normal luster), details of iris clearly visible	1[a]
Easily discernible translucent areas, details of iris slightly obscured	2
Nacreous areas, no details of iris visible, size of pupil barely discernible	3
Complete corneal opacity, iris not discernible	4
Iris	
Normal	0
Markedly deepened folds, congestion, swelling, moderate circumcorneal injection (any of these separately or combined); iris still reacting to light sluggish reaction is positive	1[a]
No reaction to light, hemorrhage, gross destruction (any or all of these)	2
Conjunctivae	
Redness (refers to palpebral and bulbar conjunctivae excluding cornea and iris)	
Vessels normal	0
Some vessels definitely injected	1
Diffuse, crimson red, individual vessels not easily discernible	2[a]
Diffuse, beefy red	3
Chemosis	
No swelling	0
Any swelling above normal (includes nictitating membrane)	1
Obvious swelling with partial eversion of lids	2[a]
Swelling of lids about half closed	3
Swelling of lids more than half closed	4

[a] The lowest grade considered positive.

Marked	3
Maximal conjunctival score	12

Other scoring systems have been proposed for lacrimation, blepharitis, chemosis, injection of conjunctival blood vessels, iritis, kerectasis, and corneal neovascularization [3].

Interpretation of Results

There are essentially four categories of data generated by the Draize test to be considered when interpreting the results of ocular testing: (1) type of ocular effects, (2) severity, (3) reversibility, and (4) rate of incidence. Weighting the scores in the original Draize test has to some extent take the first category into consideration, yet it biases toward the cornea, one of the most critical ocular tissues. Severity is measured according to a graded scoring system, whereas reversibility is expressed as the time needed for the affected ocular tissue to return to the normal state. Incidence is the number of animals that show some kind of ocular effect during the study. Interpretation of the data is a multiple and factorial undertaking. All four categories of data are somewhat interrelated; the individual scores do not represent an absolute standard for the irritancy of a material [156].

In one study, how the eye irritation was interpreted was not considered to be the major factor contributing to interlaboratory variability [205]. This finding is not surprising, if one assumes that everyone adheres to the same interpretation criteria. However, the question is what are the appropriate criteria for interpreting eye irritation results that would have an impact on placing eye irritants into different categories? The individual tissue scores do not represent an absolute standard for the irritancy of a material [157].

Many classification systems for eye irritants have been proposed. Some have been published in the literature [86,89,107,144] and in various testing guidelines [51,73,186], yet many others are used in individual laboratories. There is general agreement among investigators on how to classify test substances when no irritation is observed or when severe irritation or corrosion is seen, but there is little agreement on how to classify irritancy that falls between these two extremes. The manner in which data are evaluated directly affects the conclusions reached.

Because of the complexity of eye irritancy data and their interdependence, some investigators have chosen to simplify the interpretation to a pass-or-fail approach. For example, in the FHSA guideline [73], if four or more of the six test rabbits show ocular effects within 72 h after a conjunctival sac exposure (0.1 mL or 0.1 g of the test material), the test material is considered to be a positive eye irritant. The ocular effects in consideration are "ulceration of the cornea (other than a fine stippling), corneal opacity (other than a slight deepening of the normal luster), inflammation of the iris (other than deepening of folds), an obvious swelling with partial eversion of the lids, or a diffuse crimson red with individual vessels but not easily discernible." If only one of the six animals tested shows ocular effects within 72 h, the test is considered negative. If two or three of the six animals tested shows ocular effects, the test is repeated. The test substance is considered to be a positive irritant if three or more animals show ocular effects in the repeated test; otherwise, the test is repeated. Any positive ocular effect observed in the third test automatically classifies the test substance as an irritant. A similar approach has been adopted in the IRLG guideline [101], but an option is given that declares a test positive when two or three of six rabbits tested show a positive ocular effect and the test is not repeated. The pass-or-fail interpretation is too simplistic, however, and it does not separate eye irritants, especially those that fall between the two extreme irritancy categories (from nonirritating to severely irritating). Gradation of potential eye irritation is important to denote an anticipated hazard and to convey to consumers or workers that a specific degree of precaution should be exercised whenever a potential exposure to the substance exists.

Green et al. [86] used a different approach in which eye irritancy was classified into four easily recognizable categories based on the most severe responder in a group. The four categories are as follows.

Nonirritation: Exposure of the eye to the test article under the specified conditions causes no significant ocular changes. No tissue staining with fluorescein was observed. Any changes that did occur cleared within 24 h and were no greater than those caused by normal saline under the same conditions.

Irritation: Exposure of the eye to the test article under the specified conditions causes minor, superficial, and transient changes of the cornea, iris, or conjunctiva as determined by external or slit lamp examination with fluorescein staining. The appearance at any grading interval of any of the following changes was sufficient to characterize a response as an irritation: opacity of the cornea (other than a slight dulling of the normal luster), hyperemia of the iris, or swelling of the conjunctiva. Any changes cleared within 7 days.

Harmfulness: Exposure of the eye to the test article under specified conditions causes significant injury to the eye, such as loss of the corneal epithelium, corneal opacity, iritis (other than a slight infection), conjunctivitis, pannus, or bullae. The effect healed or cleared within 21 days.

Corrosion: Exposure of the eye to the test article under specified conditions results in the types of injury described in the previous category and also results in significant tissue destruction (necrosis) or injuries that adversely affect the visual process. Injuries persisted for 21 days or more.

This classification system took into consideration the nature of ocular effects, reversibility of those effects, and, to a certain extent, the qualitative severity, but not the incidence. The NAS committee that revised NAS publication 1138 [144] proposed a system of classification similar to that of Green et al. [86] even though the categories were named differently: inconsequential or complete lack of irritation, moderate irritation, substantial irritation, and severe or

corrosive irritation. The NAS classification was also based on the most severe responder, and incidence was not considered. A provision for repeating the test was given as an option to increase the confidence level in making a judgment in some borderline cases. This eye irritancy classification system has been widely adopted. One shortcoming of the NAS system was that too wide a spectrum was created for moderate irritancy, which may lead to overutilization of the cautionary term *moderate*. Many investigators have experienced problems in interpreting results from fluorescein staining of the cornea when the NAS gradation system is used. The confusion arises mainly from the occasional artifacts inherent in fluorescein staining. Experience and sound scientific judgment are needed to properly interpret the fluorescein staining results (see the discussion on ophthalmological techniques).

Griffith et al. [88] disagreed with using the most severe responder for classification of eye irritancy, claiming that there was no epidemiological evidence to suggest that the most severe rabbit responder would correlate with the worst possible case of human exposure. Instead, these investigators used the median time for recovery for classification according to the same temporal criteria as in the NAS system. The underlying logic is that the incidence of responders is being considered indirectly.

The classification systems of Green et al. [86], Griffith et al. [88], and NAS [144] have not taken into account the severity of irritancy, although there is a perception of a direct relationship between severity and reversibility. Examining the data of Griffith et al. [88] supports the conclusion that there is a direct correlation between median time to recovery and the severity of irritancy.

Kay and Calandra [107] proposed yet another rating system based on the Draize scores, taking into account the extent and persistence of irritation and the overall consistency of the data. The Kay and Calandra system has not been verified for correlation to human exposure experience, nor has it been compared with other classification systems.

Guillot et al. [89] proposed a scoring system in which the greatest mean irritation score within an observation period is identified. On the basis of this score, the test substance is classified into six categories, ranging from nonirritating to maximum or extremely irritating. In order to maintain this initial rating, the data also must meet the arbitrary criteria for reversibility and frequency of occurrence; otherwise, the rating is upgraded one category. Guillot et al. [89] did attempt to compare their rating with the OECD protocol and claimed that one-third of the 56 materials tested could be classified into a lower category by the OECD protocol.

The most current modification of the OECD protocol [158] is an effort to minimize the number of animals used to produce data suitable for hazard classification. In this simplified scheme, a Draize eye test is conducted using one animal if severe effects are expected, or three animals if no severe eye irritation is anticipated. Scoring is based on ocular lesions that occur within 72 h of exposure and results are expressed in terms of the lesions and their reversibility (eye irritation) or irreversibility (eye corrosion). The EPA has revised its health effects test guidelines for acute eye irritation [65] to be more consistent with the OECD protocol. A revised EEC directive, based on the OECD approach, provides hazard classification corresponding to risk phrases (R36—Irritating to eyes and R41—Risk of serious damage to eyes). These risk phrases are assigned to the label of a chemical when two or more of the three animals exhibit scores within certain arbitrary numbers [52].

A summary of the current international classification systems and major features for eye irritancy testing is shown in Table 22.10. Despite such a range of classification schemes, there is little difference in the actual scoring system (basically adhering to the original Draize) [49].

SPECIAL OPHTHALMOLOGICAL TECHNIQUES

The Draize test is a generalized test concentrating on the effects of the material on the cornea, iris, and conjunctiva. Examination usually is performed using a hand light. Accurate observations are limited by the experience and training of the investigator and it is possible for subtle ocular changes to be missed. If subtle ocular changes are to be detected and ambiguous gross observations resolved, or if internal tissues (e.g., the lens and the retina) are to be examined, the investigator must rely on special techniques. Many such techniques have been developed over the years, most of which are more objective than the gross examination itself. A few comments on the fluorescein staining technique and several of the more objective methods are presented.

Fluorescein Staining for Corneal Damage

Fluorescein is a weak organic acid (Figure 22.5) that is only slightly soluble in water, but its sodium salt is moderately soluble in water. It is very efficient in absorbing ultraviolet light and emitting fluorescent light. The maximum absorption of fluorescein is 490 nm (excitation) in the violet region and its maximum emission is 520 nm in the green region of the spectrum. Its nonionized form is less fluorescent than its ionized form. At pH 7.4, fluorescein does not appear to bind to tissue and is nontoxic in animals, making it an ideal marker for an ocular fluid dynamics study. Because fluorescein is a deeply colored and highly fluorescent chemical, it can be detected at very low concentrations in biological tissues or fluid; however, its detection sensitivity often is limited by the background fluorescence of biological tissues.

Because sodium fluorescein is a polar molecule, it can easily diffuse into aqueous medium and does not readily traverse lipophilic membranes. For example, if ulceration occurs on the cornea, the lipophilic membrane barrier is compromised and the fluorescein diffuses freely through the ulcerated area of the cornea and either is dissolved or suspended in the aqueous medium of the stroma. More detailed information

TABLE 22.10
Major Features of Eye Irritation Tests and International Classification Schemes

Methodology	FHSA (CPSC FDA OSHA)	OECD	EPA (Modified OECD)	Canada (Modified OECD)	European Union (EEC)
Initial considerations					
Screen for pH (<2 or >11.5)	NS	Yes	Same as OECD	Same as OECD	Same as OECD
Results from skin irritation	NS	Yes	Same as OECD	Same as OECD	Same as OECD
Number of animals:					
Screen for severe effects	NS	1	Same as OECD	Same as OECD	Same as OECD
Main test	≥6	≥3	Same as OECD	Same as OECD	3
Volume administered	0.1 mL or 100 mg	0.1 mL or ≤100 mg	Same as OECD	Same as OECD	Same as OECD
Scoring times	1, 2, 3 days	1 h, 1, 2, 3 days (may be extended to assess reversibility)	1 h, 1, 2, 3 days (may be extended to assess reversibility ≤21 days)	1 h, 1, 2, 3 days (may be extended to assess reversibility)	1 h; 1, 2, 3 days
Minimal positive response:					
Corneal opacity	1	NS[a]	1	2.0[b]	≥2.0, <3.0[c]
Iritis	1	NS[a]	1	1.0[b]	≥1.0, <1.5[c]
Conjuctival					
Redness	2	NS[a]	2	2.5[b]	≥2.5[c]
Chemosis	2	NS[a]	2	2.5[b]	≥2.0[c]
Positive test	≥4 positive of 6 animals	NS	NS[a]		≥2 positive of 3 animals
Label categories:					
Irritant	Reversible inflammatory effect	Same as FHSA	Same as FHSA	Positive response requires labeling as a poisonous and infectious material	R 36
Severe irritant	NS	NS	NS		R 41
Corrosive	Visible destruction or irreversible alterations	Same as FHSA	Same as FHSA	NS	NS

Note: NS, not specified.
[a] Individual scores do not represent an absolute standard for the irritant properties of a material.
[b] Mean of at least three animals.
[c] Mean of three scoring intervals and scores representing two or more animals.

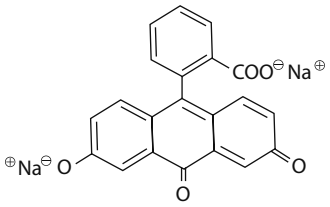

FIGURE 22.5 Structure of fluorescein.

on the chemical and biological properties of fluorescein is provided in two excellent reviews [124,136].

Since its first use in studying the origin of aqueous humor secretion more than a century ago [55], fluorescein has become an important aid in ophthalmology. It has been used as a marker in detecting obstructions in the nasolacrimal drainage systems, for studying changes in the flow dynamics of different ocular fluids, for demonstrating leakage of retinal vessels in angiography, for estimating permeability of the cornea and lens, and for identifying ulcerations on the cornea [124]. Among these uses, fluorescein's ability to detect subtle changes on the corneal epithelium [36,98] has been a routine procedure in animal eye irritation studies.

An intact corneal epithelium is a lipophilic barrier to sodium fluorescein, but when the barrier is damaged and an ulceration or change in membrane structure occurs, some of the fluorescein added to cornea will penetrate into the intercellular aqueous spaces of the stroma. When light is cast on the cornea, fluorescence is detected in the damaged area of the epithelium. Once fluorescein enters the stroma, it eventually passes through Descemet's membrane and the endothelium into the aqueous humor.

Staining is usually performed using either a prepared solution of fluorescein or fluorescein-impregnated paper strips. Commercially available solutions contain 0.25%, 1.0%, or 2.0% fluorescein sodium salt. These solutions will contain preservatives that act to minimize bacterial contamination [29]. A drop of the solution is instilled onto the eye

with excessive fluorescein being flushed immediately with a sufficient amount of water. The eye is then examined under a cobalt-filtered UV light for epithelial defects. Fluorescein-impregnated paper strips [111] are free of contamination and easy to use. Moistened with collyria (medicated eye lotion), a strip is touched lightly to the dorsal bulbar conjunctiva. The small amount of fluorescein should distribute uniformly on the cornea by either diffusion or blinking. Flushing is not usually necessary if the strips are applied properly. Nonetheless, if the strip touches the cornea, it becomes necessary for the cornea to be flushed with water before examination. Better results are obtained with the fluorescein-impregnated strip when examination is by slit lamp microscopy.

Fluorescein staining has two valuable applications in a routine eye irritation test: It can be used to screen eyes prior to the study so as to ensure that only healthy eyes are used and to evaluate the cornea's recovery from grossly observed damage. Slight epithelial effects still can be detected by fluorescein even though they are not visible during gross observation. While most of these subtle effects on the cornea will disappear in a relatively short period of time, prolonged effects detected by fluorescein staining, but not by gross examination, should raise a concern over the healing process. However, when no gross lesions are detected at any time during a study (except for a few incidences of minor fluorescein staining on the cornea), one should not be overly concerned. If there are any effects on the cornea, they must be extremely minimal ones on the superficial epithelium for eye irritation to rate as nonirritating or inconsequential. If the staining is not an artifact, the minimal ocular effects detected under such circumstances should be readily reversible.

Although fluorescein staining can detect very subtle corneal epithelial changes, significant background staining can alter the interpretation of the actual amount of damage present because of an increase in the number of artifacts present. Apparent staining of the cornea can also result from incomplete flushing of excessive fluorescein with water or even from reflected light. A strong jet of water during irrigation can cause mild damage to the cornea. Damage also can occur if the eye is not handled properly during gross examination. These changes are not related to the test article but may be detected with fluorescein staining. Sometimes, fluorescein staining can cause haziness on the cornea even though a clear cornea is seen prior to fluorescein staining. Whether the hazy appearance of the cornea is a reflection of mild change or artifact depends on several factors. If the hazy appearance also is visible under a cobalt filter and is preceded by grossly visible lesions, it generally is considered to be a residual effect of mild severity that will disappear within a short time. However, if the hazy appearance is seen intermittently or is not preceded by ocular effects, it is likely an artifact. Proper training and experience are necessary to recognize artifacts and to obtain reliable, reproducible, and consistent results from fluorescein staining. In general, it is not necessary to stain lesions that are obvious and grossly evident. It is when lesions would otherwise go undetected by gross examination that fluorescein staining is of value.

Slit Lamp Microscopy

The slit lamp biomicroscope is an important instrument for studying ocular tissues, especially the cornea. As its name suggests, a slit lamp consists of a microscope that views optical sections of different layers of the cornea made by an intense light beam acting as a surgical knife or microtome cutting through different layers of the eye. Many lesions that would remain undetected by gross examination can be observed with the slit lamp biomicroscope. Using recent models of slit lamp microscopes, one not only can observe the different layers of the cornea but also can examine other transparent parts of the eye such as the aqueous humor, lens, and vitreous body.

The slit lamp biomicroscope consists of an illuminating light source and a microscope. Both components are movable and adjustable, allowing the eye to be illuminated and observed from different angles and with different width and height adjustments of the slit light beam. An area of the cornea can simultaneously be illuminated and magnified by aligning the incidence of the light beam and the focus of the microscope. The light beam also can be directed at the area from different angles, providing several views of the same area.

Two types of slit images are used for illumination: parallelepiped and optical section [127]. For the parallelepiped slit image, a rectangular light beam (approximately 1–2 mm wide and 5–10 mm high) is projected onto the cornea. The shape of the illuminated area is similar to a parallelepiped prism where the outer and inner surfaces are bent because of the shape of the cornea. For the optical section slit image, the width (20 μm) of the light beam is narrowed to its minimum and is projected onto the cornea, providing a sagittal view that is similar to a thin histological section.

There are several basic illumination techniques (Figure 22.6): diffuse illumination, sclerotic scatter illumination, direct and indirect focal illumination, direct and indirect retroillumination, and specular reflection [135,190].

Diffuse Illumination

In diffuse illumination, a slightly out-of-focus wide beam is used to scan and localize any gross lesions of a large area of the eye. Usually, the first step in examining the eye under a microscope is for gross lesions and their extent of change. This technique is similar to observing the eye with a hand light, except that the observation is made under a microscope (Figure 22.6a).

Sclerotic Scatter Illumination

In sclerotic scatter illumination (Figure 22.6b), a narrow light beam is directed at the temporal limbus, and the microscope is focused centrally on the area of the cornea to be examined. The light reflected from the sclera will transmit within the cornea by total reflection. Under normal conditions nothing will be seen, but if even minor changes are present the reflected light will be obstructed and the damaged area (e.g., mild corneal edema) will be illuminated. This technique is useful for detecting minimal changes in the cornea.

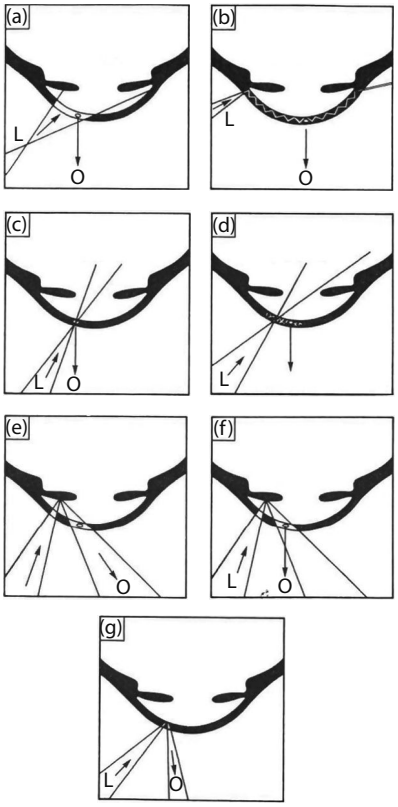

FIGURE 22.6 Seven basic methods of illumination in slit lamp microscopy: (a) diffuse, (b) sclerotic scatter, (c) direct focal, (d) indirect focal, (e) direct retroillumination, (f) indirect retroillumination, and (g) specular reflection. O = observer; L = illuminator light. (Modified from McDonald, T.O. et al., *J. Soc. Cosmet. Chem.*, 24, 163, 1973. With permission.)

Direct Focal Illumination

In direct focal illumination, the light beam and the microscope are focused sharply at the same point of interest in the same plane (Figure 22.6c). If a rectangular slit image is used for illumination and focused on the cornea, three general areas are seen when the parallelepiped is formed on the cornea: the epithelium (anterior bright line), the stroma (central clear marble-like area), and the endothelium (posterior thin bright line). If an optical section slit image is used for illumination, the corneal layers seen from anterior to posterior are a thin bridge layer, a thin dark layer, a granular layer, and another thin bright layer. These correspond to the tear film, the epithelium, the stroma, and the endothelium, respectively. Altering the angle of incidence of the light beam decreases or increases the reflection. This allows for the detection of depth of the lesion. Opacities on the different layers can be detected easily as obstructions of the incident light beam.

Indirect Focal Illumination

Indirect focal illumination (Figure 22.6d) is accomplished by a narrow beam of light directed at an opaque area of the cornea. For example, changes in blood vessels at the cornea adjacent to the opaque area are illuminated and can be detected by focusing the microscope at these areas.

Direct and Indirect Retroillumination

In direct (Figure 22.6e) and indirect (Figure 22.6f) retroillumination, the light beam is directed at tissues behind the cornea, for example, the iris or the fundus. The reflected light illuminates the area of interest of the corneal tissue and can be focused under the microscope. The microscope can be located directly on the path of the reflected light (direct retroillumination), thus permitting subtle changes to be observed against a contrasting background. Any optical obstruction by lesions such as scars, pigment, or vessels located along the reflection light path will appear as darker areas on a brighter background. Lesions such as corneal edema and precipitates that can scatter the reflection light will show up as a brighter area against a darker background. When the microscope is located off the reflection light path (indirect retroillumination), the corneal structure is observed against a dark background such as the pupil or iris. Indirect retroillumination is better for observing opaque structures, whereas direct illumination often is used to detect corneal edema and precipitates.

Specular Reflection Illumination

Specular reflection (Figure 22.6g) is most useful in studying the endothelium and precorneal tear film. This technique makes use of the difference in refractive properties between the corneal surface and the adjacent medium of the posterior and anterior surfaces of the cornea. The microscope is focused on the cornea adjacent to the path of the incident slit light beam. By alternating the angle of incidence, a point can be reached such that a total reflection is obtained on the junction between the aqueous medium and the most posterior corneal surface, thus illuminating endothelial cell patterns and Descemet's membrane. Similar techniques can be performed on the anterior corneal surface to visualize precorneal tear film.

Scoring System for Slit Lamp Examinations

By using slit lamp microscopic techniques, many subtle changes can be observed that would not otherwise be evident from the Draize test. A different scoring system must be developed to reflect such subtle changes. Baldwin et al. [2] proposed a scoring system for the cornea, anterior chamber, iris, and lens. Subsequently, the NAS [144] developed a scoring system for slit lamp examinations that is similar to the Draize system in which an emphasis was placed on changes occurring in the cornea, iris, and conjunctiva. In the NAS system, the intensity and area involved are the two main criteria for scoring. Using this scoring system, the investigator must have a good understanding of the physiology of the normal eye. Like the Draize score, the NAS system is based on corneal effects; total maximal corneal score is 20 as compared with 11 and 15 for iridic and conjunctival scores, respectively. A detailed scoring scale and criteria are listed in Table 22.9.

Corneal Pachymetry

Since corneal transparency is so important to vision (over 70% of the Draize score is derived from assessment of damage to the cornea), objective procedures to quantify corneal effects

are an important element in eliminating intra- and interlaboratory variabilities in assessing the effects of ocular exposure to exogenous agents. Corneal transparency, thickness, and hydration are related in a linear fashion [94]. Therefore, changes in corneal thickness can be used as an indicator of irritant affects, which may impair normal corneal hydration and transparency. When corneal thickness is measured appropriately, it can be used to objectively quantify swelling of the corneal stroma, which is a typical early irritant response. The measurement of corneal thickness is called pachymetry, which comes from the Greek words *pachys* (thick) and *metry* (the process of measuring). One method for measuring corneal thickness uses an optical pachometer attached to a slit lamp microscope. Optical pachometers provide essentially indirect measurements of apparent corneal thickness based on displacement of light beams bouncing off the endothelial and epithelial surfaces of the cornea. The principles of this method have been previously described [31].

Various investigators [27,37,109,138] have reported that corneal thickness is significantly correlated with the Draize corneal score using a variety of substances from different chemical classes. Moreover, Kennah et al. [109] clearly demonstrated a substantial reduction in the coefficient of variation when comparing corneal swelling to the Draize scores for various surfactants, alcohols, ketones, acetates, and aromatic chemicals.

Recent advances in human ophthalmological procedures to correct visual acuity (i.e., radial keratotomy, eximer-laser photorefractive keratectomy) have resulted in the development of improved devices to measure corneal thickness, which both guide the practitioner before and after the procedure, and provide a means to measure the effectiveness of the treatment. The ultrasonic pachymeter is such a device [13,142,193,200] and it may have useful application to in vivo ocular irritation testing.

The ultrasonic pachymeter is an instrument with a handheld probe that emits an ultrasonic signal of fixed velocity. The probe is placed directly on the anterior surface of the cornea and after signal emission; a sensor directly measures the time difference between echoes of signal pulses reflected from the front and back surfaces of the cornea. This time differential is directly proportional to the thickness of the cornea via a function that is computed as the product of the time delay between the two echoes (in seconds) and the velocity of sound in the corneal tissue (in meters/second). Whereas the optical pachometer indirectly equates displacement of incident light to corneal thickness, the ultrasonic pachymeter provides a direct measurement.

Comparative evaluations of the sources of variability in human corneal thickness measurements using optical and ultrasonic [83,97,114,166,180] or between different ultrasonic devices [207] have been reported and discussed. Salz et al. [180] found that sources of variation include intra- and intersession variations, interobserver variation, left/right eye variation, and variations due to alternate settings of ultrasonic sound frequency. They reported that the optical pachymeter had significant intersession variation, significant interobserver variation, and significant differences in left and right eye thickness measurements, whereas the ultrasonic pachymeter demonstrated high reproducibility, no interobserver variation, and no left/right eye variation.

The ultrasonic pachymeter has many desirable features such as relatively low cost, portability, ease of operation, and it requires less operator skill and training than the optical pachometer. When used in humans a topical anesthetic is employed since the tip of the measuring probe must be in contact with the corneal surface before a measurement can be taken. However, it has been reported that because of a lower corneal sensitivity in rabbits [33,131], an anesthetic is not necessary before taking corneal thickness measurements.

Since the velocity of sound can vary in different tissue, accurate readings for absolute corneal thickness require that the ultrasonic sound frequency of the instrument be matched to the tissue of interest. The velocity of sound in human corneal tissue has been variously reported as 1502 m/s [143], 1586 m/s [175], and 1610 m/s [146]. Salz et al. [180] in their human cornea comparison of optical to ultrasonic pachymetry used an approximate velocity of 1590 m/s and found good agreement between the two measurement methods. The velocity of sound in cat [114], rabbit [32], and bovine [164] corneal tissue was found to be 1590, 1580, and 1550 m/s, respectively. Empirical methods to determine the velocity of sound in corneal tissue have been described [114,164].

The utility of ultrasonic pachymetry in measuring corneal thickness changes in rabbits [119,141] and rats [119] after treatment with ocular irritants has been reported. The findings, albeit limited to a small number of chemicals, support the continued pursuit of this method as a relatively inexpensive, objective way to measure corneal irritant effects.

Confocal Microscopy

The confocal microscope is another instrument that can be used to measure corneal thickness, as well as provide high-resolution microscopic images to study the cellular structure within corneal tissue. The first confocal microscope was described by Minsky [132,133] in a 1957 patent application. This device had a pinhole and a lens (objective and condenser) located on either side of the specimen to be viewed. The intent of the design was to eliminate any scattered light that might pass through the specimen, thus concentrating all light at a point source that was the focal point. The term confocal originated because the objective lens and the condenser lens were focused on the same specimen point.

Whereas the image seen in a conventional light microscope includes the in-focus image in the x,y (horizontal) plane and the out-of-focus image above and below in the z (vertical) plane, the confocal microscope only focuses in the x,y plane. Indeed, de-focusing a confocal microscope makes the image totally disappear rather than appear blurred. Reducing the out-of-focus signal above and below the focal plane results in enhanced resolution. In contrast to the light microscope, which is focused by moving the objective, moving the specimen focuses the confocal microscope. This feature provides an

optical sectioning capability that allows thick tissue sections such as the cornea to be viewed in vivo or in vitro in both the horizontal and vertical planes. Because of the point source light illumination, however, scanning the specimen is necessary in order to produce a full field of view with the confocal microscope. Scanned images can be viewed through a video monitor on a real-time basis, imported into a videocassette recorder, or stored as a digital image [168] for later viewing and analysis. For a complete review of the principles and applications of the scanning confocal microscope, see Petroll et al. [169].

By successively scanning the cornea and capturing a series of optical sections, it is possible to reconstruct a three-dimensional (3D) image of the tissue. Methods for 3D imaging of rabbit cornea in vitro [104,122,170] and in vivo [69,104,137,167] have been described. These methods have been used to characterize the changes in area and depth of corneal injury of surfactant-induced eye irritation in the rabbit [123] and to examine the relationship between area and depth of injury to corneal cell death [103].

Mauer et al. [123] used in vivo scanning confocal microscopy to qualitatively and quantitatively characterize the initial changes occurring after treatment with surfactants known to produce slight, mild, moderate, and severe corneal irritation. Materials were applied directly to the corneas of six rabbits per group at a dose of 10 μL with macroscopic (Draize) and microscopic evaluations beginning at 3 h after treatment and continuing periodically through day 35. Microscopic 3D images were obtained from the surface epithelium to the endothelium and measurements were made for surface epithelial cell size, epithelial layer thickness, total corneal thickness, and depth of keratocyte necrosis. The average Draize scores at 3 h for the slight, mild, moderate, and severe irritants were 6.0, 39.3, 48.5, and 68.7, respectively. Confocal microscopic images at 3 h showed that corneal injury with the slight irritant was limited to the epithelium (cell size and thickness 59% and 82% of control). The mild irritant had removed the surface epithelium, increased the corneal thickness to 158% of control, and produced keratocyte necrosis to a depth of 4.3 μm. With the moderate irritant, the epithelium was markedly attenuated, the corneal thickness was 156% of controls, and keratocyte necrosis extended to a depth of 19 μm. For the severe irritant, the epithelium was significantly thinned, the corneal thickness was 166% of controls, and keratocyte necrosis extended to a depth of 391 μm.

The use of confocal microscopy in studies designed to provide semiquantitative information on the nature and depth of injury to the cornea after chemical treatment has the potential to serve as an important link to the development of physiologically relevant and mechanistically based in vitro alternatives to the Draize eye test [123].

LOCAL ANESTHETICS

For humane and scientific reasons, guidelines such as those established by the IRLG [101] and the OECD [158] provide options for using local anesthetics in eye irritation studies. Tetracaine, lidocaine, butacaine, proparacaine, and cocaine have all been tested for their eye irritation, with the results being mixed and inconclusive. While most of these anesthetics can alleviate pain, they also can inhibit or reduce the somatosensory area of the eye and the blinking reflex. Tear flow is reduced causing the test substance to be trapped and remain undiluted on the cornea instead of being blinked from the eye or diluted and flushed away by the tear flow. The blinking and tearing reflexes are important defense mechanisms, especially among higher primates, to accidental exposure to any substance [96]. Some local anesthetics can cause delay in corneal epithelial regeneration and loss of surface cells from the cornea [90]. Some local anesthetics such as procaine, lignocaine, piperocaine, amylocaine, amethocaine, and cinchocaine are cytotoxic to cultured human cells including conjunctival cells [41]. However, at least one study has shown that a 0.5% tetracaine solution apparently had no effect on corneal healing [171]. Further research is needed to reveal the interaction of local anesthetics and chemically induced ocular effects. Local anesthesia is sometimes useful to induce akinesia of the eyelid during eye examination.

Local anesthetics are desirable to alleviate pain, but one must be aware of the potential physical, chemical, physiological, and toxicological incompatibilities before considering the use of local anesthetics.

HISTOLOGICAL APPROACHES

Histological examination of the eyes has been included routinely in subchronic and chronic toxicity studies, but because it is time consuming and costly, it is performed only occasionally in eye irritation studies. Results may be no more informative than those from observations and measurements by other techniques. However, histological examination of ocular tissue can reveal the type of damage, tissues involved, and certain subtle changes in ocular tissue.

Both electron and light microscopic examinations have been used to evaluate local ocular injury [86,105,106,176,192,195,201, see Ref. 95 for review]. Although these methods sometimes can reveal morphological changes of different parts of the cornea, conjunctiva, lens, and retina, as well as visual nerve degeneration, there are shortcomings with electron and light microscopy. Issues with using histological techniques to examine damage include, being able to section the precise lesion, problems in slide preparation and subjective interpretation of observations. Another problem is that histological examination generally is made on dehydrated tissue [26], which makes some lesions, such as corneal edema, difficult to detect. However, histological examination of ocular tissues in local eye irritation studies has been considered an objective method because of its high sensitivity in detecting very mild ocular effects [96].

Protocol Refinement

Since it is generally agreed that in vitro techniques will not replace animal testing immediately, efforts should be made to reduce the number of animals used and to refine the study

design in order to minimize pain. Since precision of an eye irritancy test is a function of the number of animals used, the question arises as to whether it is justified to use a large number of animals to increase precision? The answer is no, since there is seldom an advantage to testing eye irritancy with more than three to six animals. The largest variable in an eye irritancy test is among animals, and the test itself is designed to be a bioassay. Therefore, to use a large number of animals in hope of achieving a higher level of precision is neither realistic nor scientifically sound. A statistical analysis of 155 Draize irritancy studies with six-rabbit scores has shown that reducing the number of animals to five-, four-, three-, or two-animal scores retains a 98%, 96%, 94%, or 91% agreement, respectively, with an irritant classification of these chemicals based on the six-rabbit scores [191]. The correlation coefficients for randomly selected subsets of five, four, three, or two scores were 0.998, 0.996, 0.992, and 0.984, respectively. The results of this study show that sufficient accuracy can be obtained by reducing the number of animals used in the Draize test. A combination of lower test substance dose volume (one-tenth the Draize test dose volume) and fewer animals (three) also has yielded good correlation with the standard Draize test [23].

Another proposal is to test only for skin irritation. If the material causes severe skin irritation, it is presumed to be severely irritating to the eye as well. Thus, the argument concludes, an eye irritation test is not needed. Extrapolation from skin to eye is not always valid. In at least one study of 60 severe skin irritants, only 39 also caused severe eye irritation, 15 caused mild or no ocular effects, and the other 6 caused moderate eye irritation [208,209]. Nonetheless, this approach has been proposed as one element of a tier system to prevent conducting an eye irritancy test when other potentially relevant information is available [102].

Many company guidelines specify that materials with extremely high or low pH do not need to be tested for eye irritancy. This approach is fully justified, especially for highly basic compounds. Alkali compounds generally have a higher potential of causing severe eye irritation than acidic compounds.

ALTERNATIVE ACUTE AND EYE IRRITANCY TESTS

The issue of pain and suffering of animals traditionally used in toxicity tests has long been recognized, and after decades of advocate by animal right organizations, both industry and regulatory authorities around the world have embraced the need for minimizing animal pain and suffering in their strategy for conducting toxicity tests, and regulating chemicals. The general strategy to minimize pain and suffering of animals used for toxicity testing is through (1) using a tier approach to guide the need for, and the way of, conducting animal toxicity studies; (2) refining test protocol and evaluation endpoints to minimize the pain and suffering of animals; (3) reducing the number of animals used in the test to achieve the same testing objectives; and (4) replacing whole animals tests with tests conducted with phylogenetically lower species of animals such as insects, or with nonanimals systems such as cell cultures, reconstructed tissues, or isolated animal or human tissues and organs. To be accepted for regulatory purposes, these alternative approaches and systems must be validated in terms of their scientific rationales, predictability, and consistency. Since the founding of the Fund for Replacement of Animals in Medical Experiments (FRAME) in the United Kingdom in 1969, significant advances have been accomplished toward achieving the "3 Rs" of replacement of animals; reduction in the numbers of animals used; and refinement of techniques to alleviate or minimize potential pain, distress, and/or suffering. Over the last several decades, a number of alternative methods have been validated and implemented by regulatory bodies. These advances have been made through the coordinated efforts of organizations such as the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM), the National Toxicology Program Interagency Center for the Evaluation of Alternative Toxicological Methods (NICEATM), and the Scientific Advisory Committee on Alternative Toxicological Methods (SACATM) in the United States; the European Centre for the Validation of Alternative Methods (ECVAM), the ECVAM Scientific Advisory Committee (ESAC), and the German Center for Documentation and Evaluation of Alternative Methods to Animal Experiments (ZEBET) in Europe; the Japanese Centre for the Validation of Alternative Methods (JaCVAM); the Korean Centre for the Validation of Alternative Methods (KCVAM); and by international consensus-driven bodies such as the OECD, ICH (*International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use*), VICH (International Cooperation on Harmonization of Technical Requirements for Registration of Veterinary Products), and International Cooperation on Alternative Test Methods (ICATM). A list of validated alternative methods for acute toxicity, eye corrosion/irritation, skin sensitization, and phototoxicity is found in Table 22.11.

This section discusses alternative toxicity test methods for acute toxicity and eye irritancy. Readers are referred to Chapter 20 for further discussions on other alternative test methods for other toxicity.

Alternative Test Methods for Acute Toxicity

Traditionally, acute toxicity has been expressed as the LD_{50}, a statistical estimate of the acute lethality of an agent. The objective of conducting such studies, however, should not be limited to establishing an LD_{50} value for the substance. The LD_{50} is a historically chosen reference point for defining the lethal poisoning potential of a substance. More importantly, acute toxicity studies should define the substance's dose–response relationship of all toxicities.

Nonetheless, the LD_{50} value provides a measure of the relative toxicity of an unknown agent compared with other agents administered by the same route to the same species, strain, age, and sex of the animal. The LD_{50} value, an indicator of lethal potency, is frequently the first safety test for a new chemical, the agent being administered via the route by which humans might be exposed, and animal mortality

TABLE 22.11
List of Validated and Regulatory Accepted Alternative Toxicity Tests (1998–2011)

Method/Test	United States	OECD TG/ISO/EU
Acute toxicity		
Up-and-down procedure for acute oral toxicity	OECD TG 425 accepted in 2003	TG 425 (2001)
Fixed-dose procedure for acute oral toxicity	OECD TG 420 accepted in 2001	TG 420 (2001)
Acute toxic class method for acute oral toxicity	OECD TG 423 accepted in 2001	TG 423 (2001)
Acute toxicity in vitro starting dose procedure, 3T3 cells	Accepted in 2008	GD 129 (2010)
Acute toxicity in vitro starting dose procedure, NHK cells	Accepted in 2008	GD 129 (2010)
Inhalation toxicity—acute toxic class method	OECD TG 436 accepted in 2009	TG 436 (2009)
Acute skin irritation/corrosion		
EPISKIN™ in vitro human skin model skin corrosivity test	OECD TG 431 accepted in 2004	TG 431 (2004)
EpiDerm™ in vitro human skin model skin corrosivity test	OECD TG 431 accepted in 2004	TG 431 (2004)
SkinEthic™ in vitro human skin model skin corrosivity test	OECD TG 431 (meets performance standards in 2006)	TG 431 (2004)
Rat transcutaneous electrical resistance (TER) test in vitro skin corrosivity test	OECD TG 430 accepted in 2004	TG 430 (2004)
EST-1000 method for skin corrosivity testing	OECD TG 431 (meets performance standards in 2009)	TG 431 (2004)
EPISKIN™ in vitro human skin model skin irritation test	OECD TG 439 accepted in 2010	TG 439 (2010)
EpiDerm™ in vitro human skin model skin irritation test	OECD TG 439 accepted in 2010	TG 439 (2010)
SkinEthic™ in vitro human skin model skin irritation test	OECD TG 439 accepted in 2010	TG 439 (2010)
Acute eye irritation/corrosion		
BCOP test method to identify severe eye irritants/corrosives	Accepted in 2008	TG 437 (2009)
ICE test method to identify severe eye irritants/corrosives	Accepted in 2008	TG 438 (2009)
Cytosensor Microphysiometer® test method for eye safety testing	Accepted in 2011	New TG public comment (2011)
Use of anesthetics, analgesics, and humane endpoints for in vivo ocular safety testing	Accepted in 2011	New TG public comment (2011)
FL test method for identifying ocular corrosives and severe irritants		New TG public comment (2011)
Skin sensitization test guidelines		
Murine local lymph node assay (LLNA) for skin sensitization	Accepted in 1999; as OECD TG 429 in 2002	TG 429 (2002); ISO (2002)
Updated LLNA protocol (requires 20% fewer animals)	Updated TG 429 accepted in 2010	TG 429 (2010)
Reduced LLNA protocol (requires 40% fewer animals by using only the high-dose group)	Updated TG 429 accepted in 2010	TG 429 (2010)
LLNA: DA for skin sensitization testing (a nonradioisotopic LLNA test method)	OECD TG 442A accepted in 2010	TG 442A (2010)
LLNA: BrdU-ELISA for skin sensitization testing (a nonradioisotopic LLNA test method)	OECD TG 442B accepted in 2010	TG 442B (2010)
Phototoxicity test guideline		
3T3 NRU phototoxicity test for skin photo-irritation	OECD TG 432 accepted in 2004	TG 432 (2004)
3T3 NRU phototoxicity test: application to UV filter chemicals	OECD TG 432 accepted in 2004	TG 432 (2004)

assessed in the 24 h period after treatment. Given that people might acquire the chemical by different routes, it may be necessary to carry out two experiments, choosing two of the three possible routes (ingestion, inhalation, and dermal) of administration in anticipation of quite different values. Although accurate determinations of the lethal potency are no longer required, some insight into the potency, even a rough estimate of the range of acute toxicity, can be important for certain types of ingredients. Regulatory agencies are still concerned about massive spills and the impact of these on the health of local populations. The Bhopal, India incident revealed just how little information was available on the toxicity associated with inhalation, dermal exposure, and ocular exposure to methyl isocyanate.

A properly designed study can yield much more information than just *a number*. While, by definition, 50% of the animals will die, close observation of these animals during the first 12 h period after treatment often reveals clues to possible means by which the toxicant may be causing an effect; clues that are valuable to the clinical toxicologist. Furthermore, 50% of the animals will survive the treatment and these survivors are a repository of biological effects elicited by the test agent. These animals are observed over the next 14-day period to assess the short or long duration of toxicity; the rapid

or slow recovery; the appearance of any additional, delayed, or secondary toxic effects; changes in hematology, serum biochemistry, and urinalysis; and changes in organ/tissue function measured by relatively noninvasive techniques. When the animals are euthanized at 14 days after treatment, organs/tissues are available for detailed microscopic examination to correlate observed untoward effects and/or injury with morphological changes. Thus, animals surviving the toxic insult are a veritable treasure trove of information concerning the mode(s) of the chemical-induced toxicity.

Alternative In Vivo Animal Acute Toxicity Test Methods

Traditional methods for assessing acute toxicity use death of the animals as an endpoint to establish the LD_{50}. Newer approaches avoid using death as the only endpoint, but rely instead on the observation of clear signs of toxicity, or their absence, at one of a series of fixed-dose levels administered to the animal in a stepwise manner. These newer methods have been validated and accepted by regulatory bodies worldwide (Tables 22.11 and 22.12).

The classical acute toxicity protocol, OECD TG 401, has been replaced by three reduction alternatives: the fixed-dose procedure (OECD TG 420), the acute toxic class method (OECD TG 423), and the up-and-down procedure (OECD TG 425). Each uses preset, defined, or hazard class cutoff doses administered to a single or small group of animals, in a stepwise manner. The starting dose is selected on the basis of a small range-finding study, cytotoxicity screen, or existing data. After each stepwise dosing, the animals are monitored for overt toxicological signs until death in the up-and-down procedure, or the absence or presence of signs of toxicity and/or death in the toxic class method, or clear sign of toxicity in the fixed-dose procedure. Details for each of these procedures can be found on the OECD website [163].

Alternative In Vitro Nonanimal Acute Toxicity Test Methods

Over the last couple of decades, researchers have been developing in vitro cytotoxicity data (IC_{50}) to predict the LD_{50} of

chemicals. These researchers have proposed the use of the in vitro toxicity data to predict the starting dose used in many reduction alternative acute toxicity studies, and as part of a tier strategy to eliminate or minimize the need for conducting in vivo animal studies. So far, two in vitro toxicity tests have been validated and accepted in the United States and the European Union for the purpose of predicting the starting dose: the neutral red uptake (NRU) test with rodent cells (3T3 NRU assay), and the NRU test with normal human keratocyte (NHK) cells (OECD Guideline Document 129; Table 22.11).

Alternative Test Methods for Eye Corrosion/Irritation

Damage to the eye is an all too common consequence of an accidental splashing of an industrial chemical, a home or health care product, a pesticide or a solvent, resulting in a painful, and frequently permanent, injury. The Draize eye test has been successfully used since first described in 1944. The thought, however, of placing a highly irritating agent in an animal's eye and causing pain is abhorrent. If the dermal irritancy test is positive, there is little scientific basis for carrying out the eye test, since that agent will almost certainly be positive in the eye. Hence, dermal irritancy tests can be used to screen out strong eye irritants. However, between these highly damaging, strong acids or bases and completely innocuous agents lie a wide variety of seemingly neutral, slightly acidic or basic soaps, detergents, shampoos, cosmetic creams, and lotions, all of which may show minimal effects on the skin but which may still be irritating if accidentally introduced into the eye.

Alternative In Vivo Test Methods: The Animal Eye Test with Reduced Number of Animals

The basic ocular irritation test in the rabbit has been reduced from six animals at each exposure level to two or, at most, three animals per dose without sacrificing much accuracy (Supplement to OCED TG 405). Many test series have shown 88%–91% accuracy with two animals per treatment group. The agent, instilled in the pouch formed by the lower eyelid, is held in place for 1 s and then released. The treated eye is not washed, allowing the animal's own tear secretions to flush out the material. The untreated eye serves as a control. Both eyes are examined at 1, 24, 48, and 72 h after treatment. The irritation (or damage) to the cornea, the conjunctiva, and the iris is scored numerically in a subjective manner. The test is open in that the experiment can be terminated at 72 h if there is no evidence of irritation, but observed effects can be assessed for a longer time period.

Tier Approach for Conducting Animal Eye Corrosion/Irritation Tests

A variety of tier testing strategies have been proposed to reduce the number of animals in eye irritation testing [5,91,99,102]. These strategies usually begin with a weight-of-evidence approach in an effort to review existing information that would allow classification and labeling a material as a severe ocular irritant without animal testing, or to conduct testing with a reduced number of animals. An example of this approach is shown in Table 22.13, a tier testing scheme adopted by the OECD in TG 405 for assessing eye corrosion/irritation. The tier approach ultimately enables conducting confirmatory test using one or two animals only.

Alternative In Vitro Nonanimal Eye Corrosion/Irritation Tests

A number of nonanimal in vitro eye corrosion/irritation test systems have been developed, using a variety of marker endpoints (Tables 22.14 and 22.15). The in vitro eye corrosion/irritation tests fall under four general categories: isolated eye assays, chicken egg membrane assays, reconstituted corneal systems, and acellular synthetic membrane models. The endpoints used include cytotoxicity/viability/proliferation histology/ultrastructure, barrier function, inflammatory mediator release or expression, and cellular metabolism. Some of these tests are briefly described in the following.

The Bovine corneal opacity and permeability (BCOP) assay: This test uses enucleated cow eyes that would otherwise be discarded at slaughterhouses. The cornea is isolated from the rest of the eye and maintained in a holder. A test substance is applied to this isolated cornea for a specified time, then removed and the test substance's effect on the permeability of the cornea to fluorescein dye and on the opacity of the corneal (the degree of transmission of light through the cornea) are determined. Histopathology often is included.

Isolated chicken eye (*ICE*): This test uses enucleated chicken eyes obtained from slaughterhouses. The eyes are placed in a holder, kept moist, and treated with the test substance. Three biological endpoints on the cornea are measured: corneal swelling, corneal opacity, and fluorescein retention. The irritation potential of a substance is calculated from the mean values of these measurements. Histopathology often is included.

EpiOcular assay: "MatTek's EpiOcular™ corneal model is a reconstructed multilayered of stratified, squamous epithelium equivalent to that found in human cornea. The reconstructed corneal epithelium equivalent is derived from normal, human-derived epidermal keratinocytes. EpiOcular has been used in nonanimal in vitro eye corrosion/irritation tests based on a number of biological endpoints including MTT, IL-1a, PGE2, lactate dehydrogenase (LDH), and sodium fluorescein permeability.

HCE-T TEP assay: The epithelial barrier used in this test is a stratified culture of human corneal epithelial cells (HCE-T cell line) similar to the human surface. It measures the transepithelial permeability (TEP) of fluorescein dye to assess the integrity of tight junction of epithelial barrier. The assay's endpoint is the concentration of a test material that causes fluorescein retention by the HCE-T cultures to decrease to 85% relative to the control cultures (FR85). It is possible that the TEP fluorescein permeability in the HCE-T model is not only regulated by the integrity of the tight junction, but it may also affected by other factors such as cell viability and desmosomal junction integrity. Other endpoints that have also been evaluated using the HCE-T model are, for example, lactate release, PGE2 release, various cytokines, and MTT dye uptake.

TABLE 22.13
Tier Strategy for Acute Eye Irritation/Corrosion Test in OECD Test Guideline (TG 405)

Activities	Finding and Conclusions
1.1. Existing human and/or animal data showing effects on eyes.	*Severe damage*: considered corrosive; no testing needed; *irritating*: considered irritant. No testing is needed *Not corrosive/not irritating*: considered noncorrosive and nonirritating; no testing is needed
1.2. Existing human and/or animal data showing corrosive effect on skin.	*Skin corrosive*: assume corrosive to eyes; no testing needed
1.3. Existing human and/or animal data showing severe irritant effects on skin. (*If no information available, or available information not conclusive, go to 2.)*	*Severe skin irritant*: Assume irritating to eyes; no testing needed
2.1. Perform structure activity relationship (SAR) evaluation for eye.	*Predict severe damage to eye*: assume corrosivity to eyes, no testing needed; *predict irritation to eyes*: assume irritating to eyes, no testing needed.
2.2. Perform SAR evaluation for skin. *(If no predictions can be made, or predictions are not conclusive or negative, go to 3.)*	*Predict corrosivity to skin*: assume corrosivity to eyes, no testing needed
3. Measure pH (consider buffering capacity, if relevant). (*If 2 < pH < 11.5, or pH ≤ 2.0 or ≥ 11.5 with low/no buffering capacity, if relevant, go to 4.)*	*pH ≤ 2 or ≥ 11.5* (*with high buffering capacity, if relevant*): assume corrosivity to eyes, no testing is needed
4. Evaluate systemic toxicity data via dermal route. (*If such information is not available or is not highly toxic, go to 5.)*	*Highly toxic at concentrations that would be tested in eye*: substance would be too toxic for testing, no testing needed
5. Perform validated and accepted in vitro or ex vivo test for eye corrosion. (*If substance is not corrosive, or internationally validated in vitro/ex vivo testing methods for eye corrosion are not yet available, go to 6.)*	*Corrosive response*: Assume corrosivity to eyes, no further testing needed
6. Perform validated and accepted in vitro or ex vivo test for eye corrosion. (*If substance is not an irritant, or internationally validated in vitro/ex vivo testing methods for eye irritation are not yet available, go to 7.)*	*Irritant response*: assume irritancy to eyes, no further testing needed
7. Experimentally assess in vivo skin irritation/corrosion potential (see OECD TG 404). (*If substance is not corrosive or severely irritating to skin, go to 8.*)	*Corrosive or severe damage response*: considered corrosive to eye, no further testing needed
8. Perform initial in vivo eye test using one rabbit. *(If no severe damage, or no response, go to 9.)*	*Severe damage to eyes*: considered corrosive to eye, no further testing needed
9. Perform confirmatory test using one or two additional animals.	*Corrosive or irritating*: considered corrosive or irritating to eye, no further testing needed *Not corrosive or irritating*: considered nonirritating and noncorrosive to eyes, no further testing is needed

TABLE 22.14
In Vitro Systems Used for Testing Eye Corrosion/Irritation

Systems	Examples
Isolated eye assays	BCOP; porcine corneal opacity and permeability (PCOP); ICE assay; isolated rabbit eye (IRE); isolated mouse eye; human cornea
Chicken egg membrane assays	Chorioallantoic membrane vascularization assay (CAMVA); hen's egg test—chorioallantoic membrane (HET-CAM) assay
Reconstituted corneal systems	
Cornea models	Human cornea models; rabbit cornea models (3D corneal tissue construct); bovine cornea models (epithelium and stroma)
3D human corneal epithelial cell models	HCE-T human corneal epithelial cell model; SkinEthic™ HCE model; Corneal epithelial cell line (CEPI); coty corneal epithelial model
3D epithelial cell models	EpiOcular; Madin Darby Canine kidney cell line (MDCK) FL
3D conjunctival epithelial cell models	Human conjunctival model
Monolayer epithelial cell	Human corneal epithelial cells; rabbit corneal cells; rabbit corneal cell line; various epithelial and fibroblast cell lines
Acellular models	EYETEX™/irritection; hemoglobin denaturation

TABLE 22.15
Biological Endpoints Used for In Vitro Testing for Eye Corrosion/Irritation

Systems	Examples
Cytotoxicity/viability/proliferation	3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (CAS 298-93-1); Thiazolyl blue tetrazolium bromide (MTT) (tetrazolium salt; mitochondrial dehydrogenase dye reduction); LDH; lactate release
	Dye uptake/exclusion/penetration: neutral red release (NRR); NRU; Akamar blue™; Methylene blue; WST-1 (tetrazolium salt that yields water-soluble cleavage products)
Opacity/histology/ultrastructure	Histology for opacity in BCOP model; transmission electron microscopy (TEM) in cell models
	Chemical-induced damage causing changes in light transmission through the cornea—an increase signifying corneal cell loss and a decrease indicating opacity
Barrier function (cell integrity and membrane damage)	Fluorescein dye uptake assessing cell damage: fluorescein permeability in isolated eye assays (BCOP, etc.); FL/MDCK cells; fluorescein transepithelial permeability (TEP);
	Transepithelial electrical resistance (TER or TEER) and other measures of tight junctions
Inflammatory mediator release or expression	Inflammatory response releasing chemotactic factors and then reacted with neutrophils; inflammatory response releasing specific cytokines mediators (histamine, serotonin, prostaglandins, leukotrienes, thromboxanes) that can be collected in the bath medium and quantitated by chemical assay; Arachidonic acid metabolites
	Fertile chicken egg chorioallantoic membrane (CAM) assay: scoring for vascular changes in the membrane blood vessels with fluorescein dye as well necrotic damage
Cellular metabolism	Lactate release/glucose uptake; pH/Cytosensor Microphysiometer®
Other	Total glutathione content; ATP content; methionine incorporation; cell migration; cell differentiation; cytoskeletal changes

MDCK fluorescein leakage (FL) assay: The FL assay used a monolayer of Madin Darby Canine kidney cell line (MDCK) cells cultured on permeable membrane culture inserts. It measures the rate of fluorescein penetration across the membrane to assess any damage caused by the test substance on the integrity of tight junctions of the MDCK cell layer membrane.

Regulatory Acceptance of Alternative In Vitro Nonanimal Eye Corrosion/Irritation Tests

Four in vitro methods have been validated, and either have been accepted or are in the process of being accepted by the OECD (Table 22.11) as part of a tier strategy to identify strong to moderate irritants and nonirritants, leaving those agents showing suspicious or equivocal results to be tested in animals. The four in vitro eye tests are BCOP test method for identifying ocular corrosives and severe irritants (OECD TG 437); ICE test method for identifying ocular corrosives and severe irritants (OCED TG 437); the Cytosensor Microphysiometer® test method for identifying chemicals not classified as irritants, as well as ocular corrosive and severe irritants (OECD TG draft); and the FL test method for identifying ocular corrosives and severe irritants (OECD TG draft). The draft for the revision of OECD TG 405 has taken into consideration the performance of the validated and accepted in vitro tests as part of testing strategy for eye corrosion/irritation.

BCOP test method for identifying ocular corrosives and severe irritants (*OECD TG 437*): The BCOP test method is an organotypic model that provides short-term maintenance of normal physiological and biochemical functions of the bovine cornea in vitro. In this test method, damage by the test substance is assessed by quantitative measurements of changes in corneal opacity and permeability with an opacitometer and a visible light spectrophotometer, respectively. Both measurements are used to calculate an *in vitro* irritation score (IVIS), which is used to assign an in vitro irritancy hazard classification category for prediction of the in vivo ocular irritation potential of a test substance. The BCOP test method uses isolated corneas from the eyes of freshly slaughtered cattle. Corneal opacity is measured quantitatively as the amount of light transmission through the cornea. Permeability is measured quantitatively as the amount of sodium fluorescein dye that passes across the full thickness of the cornea, as detected in the medium in the posterior chamber. Test substances are applied to the epithelial surface of the cornea by addition to the anterior chamber of the corneal holder.

ICE test method for identifying ocular corrosives and severe irritants (*OECD TG 438*): The ICE test method is an organotypic model that provides short-term maintenance of the chicken eye in vitro. In this test method, damage by the test substance is assessed by determination of corneal swelling, opacity, and fluorescein retention. While the latter two parameters involve a qualitative assessment, analysis of corneal swelling provides for a quantitative assessment. Each measurement is either converted into a quantitative score used to calculate an overall Irritation Index, or assigned a qualitative categorization that is used to assign an in vitro ocular corrosivity and severe irritancy classification. Either of these outcomes can then be used to predict the in vivo ocular corrosivity and severe irritation potential of a test substance.

REGULATORY STATUS

The purpose of conducting safety testing is to obtain information that enables the toxicologist to evaluate the hazard potential of a test material in order to if and how it can be used safely. Information pertaining to a test material's hazard potential is also used by Regulatory Agencies for the purposes of classification and labeling when a *new* or *existing* chemical

is being registered or *notified*. Ultimately, the goal of safety testing is to be able to predict the probability of risk to human health under conditions of intended or accidental exposure. Understanding a chemical's or product's potential for toxicity enables one to manage the risk associated with the use of the material through communication (e.g., labeling, use instructions, material safety data sheets [MSDS]), package design (e.g., use of a child resistant closure), availability (e.g., institutional vs. consumer product), and medical management following an accidental exposure. The following sections will summarize the primary test guidelines; international chemical inventories that require the conduct of acute toxicity and ocular irritation testing; and classification schemes used by regulators in the United States, European Union, and other countries or region, for labeling or other hazard communication purposes.

Chemical Inventories

Since the establishment of the toxic substance inventory by the U.S. EPA under Toxic Substances Control Act (TSCA) in the 1970s, many countries around the world now regulate their chemical substances by establishing similar chemical inventories—lists of chemicals that are allowed to be manufactured, imported, used, and put on the market in that country. The producer, importers, or user of chemical can put the chemical on the list by satisfying the regulatory requirements, sometimes including toxicity testing, and often need to put (or include) a new chemical onto the chemical inventory list through processes such as notification, registration, etc. In general, *existing* chemicals are defined as chemicals that were in use or in the market at the time the legislation creating the inventory went into effect. *New* chemicals are those chemicals that are not included in the inventory list. The legislative differentiation between *existing* and *new* mainly impacts on a chemical's regulatory priority. Many countries place high regulatory priority on the new chemicals, but in European Union and United States, high priorities have also been given to certain categories of *existing* chemicals, for example, PBT (persistent, bioaccumulative, and toxic) chemicals as well as HPVC (high production, volume chemicals); and others under the EU Council Regulation (EEC) No. 793/93 also known as Existing Substances Regulation (ESR).

While notification/registration requirements vary from country to country, most do require, at a minimum, that data from some acute toxicity testing be provided. In some cases, irritation testing (ocular and dermal) is also required. Table 22.16 lists some of the chemical inventories of existing and new chemicals, which require data from acute toxicity and irritation studies. The chemical inventories listed in Table 22.16 include chemicals and chemical mixtures, but exclude agrochemicals, cosmetics, food additives, pesticides, pharmaceuticals, and radionucleotides, which are regulated by separate legislations not discussed here.

Within the last decade, many new legislations around the world, especially in European Union, have been or are being implemented to expand and update existing inventories [30,145], to address an existing data gap [60,155] or to unify multiple databases [173]. The EU Registration, Evaluation, and Authorization of Chemicals (REACH) entered into force on June 1, 2007, and into operation on June 1, 2008. The REACH has a major impact on the regulation of chemicals in the EU Communities as well as other countries and regions; it has replaced the European Inventory of Existing Commercial Chemical Substances (EINECS) and European List of Notified Chemical Substances (ELINCS) chemical inventories in the European Union, with a single system managed by the European Chemicals Agency (ECHA). Because of its far reaching impact on regulating chemicals in European Union as well as other parts of the world, REACH is discussed in more details here.

EU Registration, Evaluation, Authorization, and Restriction of Chemicals

In 2007, the EU REACH came into force and implementation started in 2008. This new EU chemical control legislation is complex and comprehensive, aiming to address many critical issues in controlling the risks associated with the uses of chemicals, their mixtures as well as articles treated with chemicals in European Union. REACH replaces all pervious chemical legislations with patchy goals and inefficient processes; addresses issues of data deficiency on many existing chemicals; shifts the burden of collecting information/data, risk assessment, risk management, and risk communication to the manufacturers and importers; promotes broader involvement in the decision making processes and implementation (manufacturers, importers, downstream users, Member States competent authorities, EU Commission, EU Council, and the public at large); installs mechanisms for random or selected checks for compliance; prioritizes the evaluation of chemicals of high concerns; restricts or bans the uses of chemicals with unreasonable risks to health and environment; rationalizes animal testing; and promotes cost sharing.

The legislation base for EU REACH is Regulation (EC) No. 1907/2006 of the European Parliament and of the Council of December 18, 2006 concerning the REACH; establishing a ECHA; amending Directive 1999/45/EC; and repealing Council Regulation (EEC) No. 793/93 and Commission Regulation (EC) No. 1488/94 as well as Council Directive 76/769/EEC and Commission Directives 91/155/EEC, 93/67/EEC, 93/105/EC, and 2000/21/EC. Because of the inefficiency of older EU legislations to address the vast number of chemicals in use or in the market that have little or no toxicity data on the potential hazards to the human health and the environment, the REACH legislation was enacted to unify all the patchy EU legislation on *existing* and *new* chemicals enacted over the last decades. The primary aim for REACH is, over a period of 11 years, to assess the potential hazards of all the chemicals of high concern or high production volume, and through the regulatory process to either register or restrict the use of these chemicals. To increase the efficiency, one of the main purposes of REACH is to shift the burden of testing and risk assessment of many existing and new chemicals, from regulatory authorities to manufacturers and importers. REACH is a complex, comprehensive legislation covering

TABLE 22.16
Chemical Inventories with an Acute Toxicity Data Requirement

Country	Inventory	Regulatory Authority
Australia	Australian Inventory of Chemical Substances (AICS).	National Occupational Health & Safety Commission (Worksafe Australia).
Canada	Domestic Substances List (DSL). Non-Domestic Substances List (NDSL). New Substances Notification Regulations (NSNR).	Environment Canada.
China	Inventory of Existing Chemical Substances in China (IECSC).	State Environmental Protection Administration.
European Union	ECHA central data base of chemicals registered under REACH. Annexes IV and V: list of chemicals exempted from registration, mainly based on the previous EINECS and ELINCS. Annex XIV: list of substances of high concerns (CMR, accumulative, etc.); once a substances is included on this list, authorization is required for commerce and use, by demonstrating safety and no risk for the specific use. Annex XVII: list of use restrictions for some dangerous substances, mixtures, or articles.	ECHA. *Note*: The EINECS and ELINCS previously managed by European Chemicals Bureau have been transferred to ECHA under REACH. REACH creates a single system for both *existing* and *new* substances; non-phase-in substances (i.e., those not produced or marketed prior to the entry into force of REACH) and phase-in substances (those substances listed in the EINECS, or those that have been manufactured in the Community, but not placed on the Community market, in the last 15 years or the so-called no longer polymers of Directive 67/548).
	Screening Information Data Set (SIDS)	Organization for Economic Cooperation and Development.

Philippines	Philippines Inventory of Chemicals and Chemical Substances (PICCS)	Department of Environment & Natural Resources.
United States	Toxic Substances Control Act (TSCA) High Production Volume (HPV)	EPA.

[a] Since 1995, authority for conducting toxicity reviews has been delegated to the National Institute of Environmental Research (NIER).

all chemicals (single chemical substances, mixtures/preparation and treated articles containing releasable chemical substances, unless they are explicitly exempted). Exemptions from REACH include those chemicals explicitly being regulated under other legislations such as those for drugs, food, pesticides, etc.; low risk substances; naturally occurring substances such as minerals, ores, certain polymers; and those listed in Annex IV and V of REACH. REACH also stipulates specific regulatory processes, priority lists, cost sharing on testing, compensation of use of toxicity data, responsibilities of downstream users, etc.

REACH regulates dangerous substances, their mixtures (preparations), and articles treated with the substances through four major processes: registration, evaluation, authorization, and restriction.

Registration: Under REACH, each manufacturer, importer of a substance (chemical, its mixtures, or articles treated with the chemical), unless it is explicitly exempted, has to register the substance with ECHA before manufacturing or placing on the market. Under REACH, substances are categorized as *phase-in* or *non-phase-in* substance. Phase-in substances are those that have already been manufactured and/or placed in the market before REACH was in force, or those previously exempted polymers that have been reclassified as *no longer polymer*. Non-phase-in substances are those that do not meet the afore mentioned criteria. Upon on-time preregistration, phase-in substances have a longer transitional registration deadline than *non-phase-in* substances. Chemicals for research and development purposes are also exempted from registration for a period of 5 years.

Registration under REACH is based on the principle of one registration for one substance (chemical itself, mixtures containing the chemical, or article treated with the chemical). This means that all manufacturers and importers of an identical substance must submit registration application together sharing costs and information.

Under REACH, registrant(s) of a substance must submit to ECHA a registration dossier (technical dossier and chemical safety report) containing relevant information on the substance itself, hazard identification (and testing proposal if appropriate), risk assessment, as well as information on how the risk can been managed and communicated, including classification, labeling, and packaging (CLP). After the dossier has passed the administrative and technical checks for completeness for meeting all registration requirements, it will be assigned a registration number. All information submitted, except those that can be claimed as confidential, will be published for public involvement in the registration and decision making process.

Evaluation: ECHA and an component authority of a Member State will conduct evaluation of information submitted on some substances on the quality of the registration dossier, testing proposals, as well as whether the substance can pose an unreasonable risk to health and the environment. The outcome

of the evaluation could be the risk associated with the use of the chemical is sufficiently under control and adequate measures in place, thus require no further action; or information submitted is insufficient for the assessment of the risk, thus require submission of further information; or the risk is not sufficiently under control and thus require risk management measures such as harmonized CLP, inclusion on the authorization list (Annex XIV), banning the substance, or imposing/amending restrictions on the uses of the substance (Annex XVII).

Authorization: Once a substance is placed in the authorization list (Annex XIV), manufacturers/importers need to apply for special authorization for specific uses. Granting of authorization will be based on a weight of risk/benefit assessment through two committees, the ECHA's Risk Assessment Committee (RAC) and the Committee for Socio-Economic Analysis (SEAC), public consultation, as well as the availability of lower-risk alternatives.

Restriction: A member state, or EU Commission through ECHA, can initiate the process of imposing restrictions on the use of a substance, or even banning it, if they have a concern that the substance could pose an unreasonable risk to health and the environment. The process of restriction is based on the Committees' opinion and public consultation. After the Commission has made the decision, the restrictions will be imposed (amendment to Annex XVII).

REACH aims for a whole supply chain involvement in controlling the risk associated with the production and uses of chemicals. Downstream users, such as formulators, end users, treated articles producers, refillers, reimporters, etc., also have certain responsibilities under REACH, which include: provide use information to suppliers enabling them to conduct safety assessment, comply to the safety measures and use restrictions provided by suppliers, inform suppliers of any new information on hazard and/or risk on the chemical, as well as prepare and submit their own chemical safety report to ECHA, if needed.

Implementation of REACH started on June 1, 2008. REACH provisions are being phased-in over 11 years for all existing chemicals (phase-in chemicals) in accordance to a priority-based time schedule:

- November 30, 2010—Registration completed for chemicals of high concerns (≥1 metric ton/year of CMR, carcinogens, mutagens, and reproductive toxins; ≥100 metric tons/year of chemicals very toxic to the aquatic environment [PBT/vPvBs—very persistent and very bioaccumulative substances—classified with N: R50-53]; and ≥1000 metric tons/year of other chemicals)
- May 31, 2013—Registration completed for chemicals ≥100–1000 metric tons/year
- May 31, 2018—Registration completed for chemicals ≥1–100 metric tons/year

Data requirement under REACH is based on production or imported volume—the higher the volume, the larger the amount of data required. A technical dossier including a chemical safety report is required for the chemicals with an annual production volume of 10 metric tons or above. Information required includes chemical identity, physic–chemical properties, toxicity, ecotoxicity, environmental fate, exposure, and instructions for appropriate risk management. REACH lists certain higher tier tests required for chemicals with annual production volume of 100 metric tons or more.

Since entering into forces on June 1, 2007, the complexity of implementation of REACH has emerged and some controversial issues have surfaced. The EU Commission on Environment is planning to conduct a comprehensive review on REACH in 2012 with respects to its impact on risk caused by chemicals in 2012 compared to the 2007; its health and environmental benefits; its contribution to the development, commercialization, and uptake of products of emerging technologies; its impact on innovation and functioning of EU chemical industry; and issues related to operation, implementation and enforcement, CLP, technical assistance offered, and registration requirements for 1–10 metric tons substances and polymers; as well as REACH issues concerning nanotechnology.

Test Guidelines

The regulatory status of test methods used to evaluate the acute toxic and ocular irritation potential of test materials is in a state of flux. Most international regulatory agencies are attempting to reduce both the number of animals necessary to assess the acute toxicity potential and ocular hazard and to minimize pain and suffering. The primary acute toxicity and ocular irritation test guidelines that have been adopted by various regulatory agencies are summarized in Table 22.17.

The *International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use* (ICH) is an ongoing effort bringing together regulatory authorities of the United States (FDA), European Medicines Agency (EMA), and Japan and representatives from the pharmaceutical industry with the goal of harmonizing the technical aspects of test method design, data interpretation, and product registration [100]. While acute toxicity testing is a critical first step in the evaluation of a new pharmaceutical compound, the only recommendation pertaining to acute toxicity testing made by ICH is that the LD_{50} determination for pharmaceuticals should be abandoned [100].

Many countries have adopted the OECD toxicity test guidelines for regulatory purposes including notification, registration, and CLP of chemicals. A list of these globally accepted toxicity test guidelines for acute toxicity and irritation tests is given in Table 22.12.

After decades of advocates from animal welfare organizations, alternative toxicity tests have been gradually adopted for regulatory purposes. For example, under the REACH legislation, an increased use of animals in testing is expected, as the hazardous properties of chemicals cannot be sufficiently determined by using currently available in vitro nonanimal test methods, and regulatory action cannot solely rely on these tests. However, REACH encourages adaptation of alternative toxicity tests in favor of animal tests whenever it is possible, and a fast

tracking process (TSAR, Tracking System for Alternative test methods Review, Validation and Approval in the Context of EU Regulations on Chemicals) has been put in place to adopt promising new alternative test methods for regulatory purposes.

Classification Schemes

Two examples of how acute toxicity and ocular irritation data are used for the purposes of classifying and labeling chemicals and products are those detailed in European Council Directive 67/548/EEC Annex VI [53] and U.S. EPA Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) guidelines [59]. While the types of chemicals and products evaluated in the European and U.S. schemes are different, both schemes (as shown in Tables 22.10, 22.18, and 22.19) highlight the manner in which acute toxicity and ocular irritation data are used to define the hazard potential of individual chemicals and products. Chemicals and products evaluated in accordance with criteria defined in Council Directive 67/548/EEC Annex VI [53] are assigned risk or "R" phrases [54]. The choice of R phrases is made on the basis of the classification to ensure that the potential dangers identified in classification are expressed on the label.

However, all the classification and labeling systems will be ultimately replaced by the UN initiative, the GHS. For example, in European Union, from June 1, 2015, all mixture products must be classified and labeled in accordance with Regulation (EC) No. 1272/2008 (GHS); thereafter, Directives 67/548/EEC (on dangerous substances) and Directive 1999/45/EC (on dangerous preparations or mixtures) will no longer have any legal status.

Globally Harmonized System of Classification and Labeling of Chemicals

One practical use of acute toxicity data is for hazard classification and labeling of chemicals. The criteria for classification and labeling vary from country to country, and sometimes from regulatory agency to agency. The variation in classification and labeling has been an obstacle to international trade, and the need for harmonization is long overdue.

The GHS of Classification and Labeling of Chemicals was initiated at the *United Nations Conference on the Environment and Development* in Rio de Janeiro in 1992. It attempts to harmonize the hazard classification and the hazard communication of chemicals (labeling and MSDS), aiming to promote international trade and to set an internationally recognized safety standard of chemicals. The primary components of GHS include definition of hazard endpoints, classification criteria for hazard endpoints, mixture rules, safety data sheets (SDS) or MSDS, label elements, and implementation plans. GHS does not require testing or establishment of test methods; rather, GHS is a self-classification system using relevant data available from all sources. The GHS classification process is designed to be simple and transparent with a clear distinction between hazard classes and categories in order to allow for *self-classification* as far as possible. For many hazard classes, the criteria are semiquantitative or qualitative and expert judgment is required to interpret the data. Decision tree approach is provided in the GHS *Purple Book* [197] for many hazards (e.g., eye irritation) to assist in classification. GHS is a voluntary system to be adopted into local or

national regulations. Each country set its own implementation schedule. Some variations and flexibilities are provided, but ultimately, GHS will replace all CLP legislations and practices worldwide; for example, all current CLP legislations in the European Union will be replaced by GHS by 2015.

GHS harmonizes most classification criteria based on the substance's intrinsic health, physical, and environmental hazards. It uses pictograms, hazard statements, and signal words *danger* and *warning* to communicate hazard information on the labels and MSDS, and is based on the intrinsic hazard of the substance. The GHS allows individual countries or regions to implement building blocks (a set of GHS hazard classification and communication criteria) to meet the needs of their audience and sectors. The building blocks, however, may not be altered. In addition, there is room for Competent Authority Options and special limits for communication of components in mixtures. The GHS is a dynamic system being continuously updated based on implementation experience and the availability of relevant scientific information. The first edition of the GHS was approved by the Committee of Experts at its first session in December 2002 for initial global implementation. Since then, the GHS has been updated several times based on the experience of implementation. The latest update is the fourth edition published in 2011 [197]. The GHS has been implemented in almost in all the major economies, including United States, European Union, China, Japan, Korea, Southeast Asia, etc., for the transportation of dangerous substances. The implementation of GHS in other sectors, supply and use, workplace, etc., varies among countries. Eventually, the GHS is expected to replace all the current classification and labeling systems globally.

GHS is built on 16 physical, 10 health, and 3 environmental hazard classes, and comprises the following communication elements: 9 pictograms, 2 signal words *danger* or *warning*, 72 individual and 17 combined *hazard statements*, and 116 individual and 33 combined precautionary statements.

The 16 physical hazard classes are explosives, flammable gases, flammable aerosols, oxidizing gases, gases under pressure, flammable liquids, flammable solids, self-reactive substances, pyrophoric liquids, pyrophoric solids, self-heating substances, substances which in contact with water emit flammable gases, oxidizing liquids, oxidizing solids, organic peroxides, and corrosive to metals. The 10 health hazard classes are acute toxicity, skin corrosion/irritation, serious eye damage/eye irritation, respiratory or skin sensitization, germ cell mutagenicity, carcinogenicity, reproductive toxicology, target organ systemic toxicity (single exposure, target organ systemic toxicity, and repeated exposure), and

aspiration toxicity. The three classes of environmental hazards are hazardous to the aquatic environment (acute aquatic toxicity and chronic aquatic toxicity), bioaccumulation potential, and rapid degradability. The GHS classification categories for health hazards are summarized in Table 22.20.

The hazard statements are assigned a unique alphanumerical code that consists of one letter and three numbers as follows: the letter "H" (for *hazard statement*); a number designating the type of hazard as follows: "2" for physical hazards, "3" for health hazards, and "4" for environmental hazards; and two numbers corresponding to the sequential numbering of hazards arising from the intrinsic properties of the substance or mixture, such as explosive properties (codes from 200 to 210), flammability (codes from 220 to 230), etc.

The hazard classification criteria of toxicity and irritation of single substance under the GHS are listed in Tables 22.21 through 22.24, whereas the major pictograms used in GHS are listed in Table 22.25.

Classification and labeling of mixtures under GHS: While the classification and labeling of a single toxic substance are relatively straight forward under GHS, the process of classifying a mixture is tiered, and is dependent on the amount of information available for the mixture and its components, that is, (1) available data for the mixture itself, and/or (2) similar mixtures, and/or (3) data for the ingredients of the mixture. The process for the classification of mixtures is based on the following steps: (1) if test data are available for the mixture itself, the classification of the mixture will be based on that data (except carcinogens, mutagens, and reproductive toxicants); (2) if test data are not available for the mixture itself, then the appropriate bridging principles should be used; and (3) if (a) test data are not available for the mixture itself and (b) the bridging principles cannot be applied, then the calculation or cutoff values should be used to classify the mixture. When a mixture has not been tested, but there are sufficient data on the components and/or similar tested mixtures, then these data can be used in accordance with the following six bridging principles: (1) Dilution: If a mixture is diluted with a diluent that has an equivalent or lower toxicity, then the hazards of the new mixture are assumed to be equivalent to the original; (2) Batching: If a batch of a complex substance is produced under a controlled process, then the hazards of the new batch are assumed to be equivalent to the previous batches; (3) Concentration of highly toxic mixtures: If a mixture is severely hazardous, then a concentrated mixture is also assumed to be severely hazardous; (4) Interpolation within one toxic category: Mixtures having component concentrations within a range in which the hazards are known or assumed to have those known hazards; (5) Substantially similar mixtures: Slight changes in

TABLE 22.24
GHS Classification Criteria for Target Organ Toxicity from Single Exposure

Category 1	Category 2	Category 3
Significant toxicity or presumed to have significant toxicity in humans; classified based on:	*Presumed to be harmful to human health; classified base on*:	*Transient target organ effects; classified based on*:
Reliable, good quality human case studies or epidemiological studies	Animal studies with significant toxic effects relevant to humans at generally moderate exposure (guidance)	Narcotic effects
Animal studies with significant and/or severe toxic effects relevant to humans at generally low exposure (guidance)	Human evidence in exceptional cases	Respiratory tract irritation

the concentrations of components are not expected to change the hazards of a mixture and substitutions involving toxicologically similar components are not expected to change the hazards of a mixture; (6) Aerosols: An aerosol form of a mixture is assumed to have the same hazards as the tested, nonaerosolized form of the mixture unless the propellant affects the hazards upon spraying. The basic GHS approach to the classification and labeling of health hazards is summarized in Table 22.25.

For acute toxicity, GHS allows the use of two formulas to calculate the acute toxicity estimate (ATE) for mixtures for classification and labeling purposes [197] as follows:

1. When data available for all ingredients (ignoring acutely nontoxic components, such as water, sugar, etc., and ingredients that fall at the upper threshold of Category 4 from a limit dose test), or where acute toxicity data are unavailable on total concentration of ingredients at <10%, ATEmix is determined using the following formula:

$$\frac{100}{\mathrm{ATE(mix)}} = \sum_{n} \frac{C_i}{\mathrm{ATE}_i}$$

where
C_i is the concentration of ingredient i
n is ingredients
i is running from 1 to n
ATE_i is the acute toxicity estimate of ingredient
ATE(mix) is the acute toxicity estimate of the mixture

TABLE 22.25
Major Hazard Pictogram Used in GHS

Description	Pictogram	Hazard Class and Hazard Category
1. Exploding bomb		Unstable explosives Explosives of Divisions 1.1, 1.2, 1.3, and 1.4 Self-reactive substances and mixtures, Types A and B Organic peroxides, Types A and B
2. Flame		Flammable gases, Category 1 Flammable aerosols, Categories 1 and 2 Flammable liquids, Categories 1, 2, and 3 Flammable solids, Categories 1 and 2 Self-reactive substances and mixtures, Types B, C, D, E, and F Pyrophoric liquids, Category 1 Pyrophoric solids, Category 1 Self-heating substances and mixtures, Categories 1 and 2 Substances and mixtures, which in contact with water, emit flammable gases, Categories 1, 2, and 3 Organic peroxides, Types B, C, D, E, and F
3. Flame over circle		Oxidizing gases, Category 1 Oxidizing liquids, Categories 1, 2, and 3
4. Gas cylinder		Gases under pressure: Compressed gases Liquefied gases Refrigerated liquefied gases Dissolved gases
5. Corrosion		Corrosive to metals, Category 1 Skin corrosion, Categories 1A, 1B, and 1C Serious eye damage, Category 1
6. Skull and crossbones		Acute toxicity (oral, dermal, inhalation), Categories 1, 2, and 3
7. Exclamation mark		Acute toxicity (oral, dermal, inhalation), Category 4 Skin irritation, Category 2 Eye irritation, Category 2 Skin sensitization, Category 1 Specific target organ toxicity—single exposure, Category 3
8. Health hazard		Respiratory sensitization, Category 1 Germ cell mutagenicity, Categories 1A, 1B, and 2 Carcinogenicity, Categories 1A, 1B, and 2 Reproductive toxicity, Categories 1A, 1B, and 2 Specific target organ toxicity—single exposure, Categories 1 and 2 Specific target organ toxicity—Repeated exposure, Categories 1 and 2 Aspiration hazard, Category 1
9. Environment		Hazardous to the aquatic environment Acute hazard, Category1 Chronic hazard, Categories 1 and 2

2. When acute toxicity data are unavailable on total concentration of ingredients at >10%, ATEmix is determined using the following formula:

$$\frac{100-\left(\sum C(\text{unknown})\right)}{\text{ATE(mix)}}=\sum_{n}\frac{C_i}{\text{ATE}_i}$$

where
C_i is the concentration of ingredient i
C (unknown) is the total concentration of ingredients with unknown acute toxicity data
n is ingredients
i is running from 1 to n
ATE_i is the acute toxicity estimate of ingredient
ATE (mix) is the acute toxicity estimate of the mixture

The classification of skin and eye corrosion/irritation of mixtures under GHS generally follows the bridging and additivity principles. When no test data are available for the mixture and bridging principles do not apply, the classification is based on additivity which assumes that each corrosive or irritant component contributes to the overall corrosivity/irritancy of the mixture in proportion to its potency and concentration. Whether the mixture is considered to be an irritant or seriously damaging to the skin or eye is based on cutoff values (Tables 22.26 and 22.28). If additivity approach does not apply as many substances are corrosive or irritant at concentration <1% (e.g., acids and bases, inorganic salts, aldehydes, phenols, and surfactants), then different criteria are used [Tables 22.27 and 22.29]).

TABLE 22.26

Base with pH ≥ 11.5	≥1	Category 1
Other corrosive (Category 1) ingredients for which additivity does not apply	≥1	Category 1
Other irritant (Category 2) ingredients for which additivity does not apply, including acids and bases	≥3	Category 2

QUESTIONS

Q. What is the importance of acute toxicity testing and is a precise LD_{50} value necessary to adequately define acute toxicity?

A. Acute toxicity testing is the way in which we define the intrinsic toxicity of a chemical, identify target organs, provide information for risk assessment of acute exposure, provide information for the design and selection of dose levels for more prolonged studies (i.e., subchronic, chronic), and most importantly, provide information to clinicians for use in treatment of acute chemical poisoning. Information from acute toxicity testing is also used to provide insight into the mechanism of action of a chemical, to formulate safety measures during the early stages in the development of a new chemical, and for categorization and labeling purposes for handling and shipping chemicals. One should not confuse the concept of acute toxicity with the term LD_{50}. The LD_{50} is a statistically defined measure of acute toxicity but is only one of many ways to define acute toxicity. Indeed, a precise LD_{50} is seldom required in acute toxicity testing, and its use is being de-emphasized to reduce the total number of animals and pain and suffering involved in their use. The LD_{50} is being replaced by more modern methods. The up-and-down procedure and the acute toxic class method are alternatives to the LD_{50} test that can be used to estimate the medial lethal dose and to provide hazard classification for labeling, respectively.

Q. Name some of the factors that can influence the results of an acute toxicity study.

A. Physiochemical properties of the test article (lipophilicity, molecular weight, and solubility), species used, age of the animals, route of exposure, and rate of test article metabolism.

Q. The following mortality data were obtained from an acute oral toxicity study.

Dose (mg/kg)	1	2	4	8	16	32
Mortality	0/10	1/10	3/10	4/10	7/10	10/10

Calculate the LD_{50}, the SE of the LD_{50}, the fiducial limits, and the slope of the dose–response curve.

		Probits		Probabilities	Responses		
Log Dose (x)	n	Observed	Expected	Expected (P)	Observed	Expected	χ^2
0.30	10	3.72	3.82	11.9	1	1.19	0.0344
0.60	10	4.48	4.36	26.1	3	2.61	0.0344
0.90	10	4.75	4.75	46.4	4	4.64	0.0789
1.20	10	5.52	4.45	67.4	7	6.74	0.1646
1.50	10	—	—	—	10	—	0.0307
						$\Sigma\chi^2 = 0.386$	
						$df = 2$	

A. Procedure

1. Determine the log dose and probits:

Log dose	0.0	0.3	0.6	0.9	1.2	1.5
Probits	—	3.72	4.48	4.75	5.52	—

2. Plot log dose versus probits (Figure 22.7) and fit the best point(s) to a straight line (see Figure 22.7).
3. From the log dose probits line, extrapolate the log $LD_{50} = 0.95$; then LD_{50} = antilog 0.95 = 8.91 mg/kg body weight.
4. From the same line, calculate the slope as: (numbers of probit units)/unit log dose = 2/11 = 1.818.

Thus, $\sigma = 1/\text{slope} = 0.55$ (Figure 22.7).

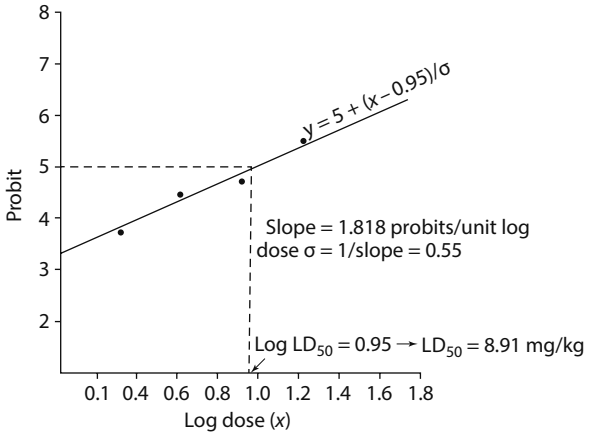

FIGURE 22.7 Example of probit versus log dose plot.

5. χ^2 *test of goodness of fit.* Expected probability is converted from the expected probits. The test is conducted by converting each expected probit (y) back to the expected probability (P) and then to the number of expected responses (E) (i.e., multiply the expected probability P by n). The difference between expected and observed number of responses will be used to calculate the χ^2 statistic, but instead of using $\Sigma[(E-0)^2/E]$, the weighted value will be used, that is, $\Sigma[(E-0)^2/E(1-P)]$. The degree of freedom (df) is $N-2$, where N is the number of dose levels used in the calculation of χ^2. The critical χ^2 for $(4-2)=2$ degrees of freedom is 6.0 at a $P=0.05$, and the calculated $\chi^2=0.386$, which is less than the critical value, indicating that the fitted line is adequate.
6. *Determination of precision of LD_{50} by weighting.* The SE of $\log \mathrm{LD}_{50} = S_m = \sigma / \sqrt{\Sigma mW} = 0.55 / \sqrt{18.5} = 0.129$.

   The approximation of SE (LD_{50}) = $(10^m) \cdot (S_m)$ = 8.91 × 2.302 × 0129 = 2.646. The precision of LD_{50} = 8.91 ± 2.646 mg/kg.

Dose (mg/kg)	2	4	6	16
W	0.277	0.423	0.541	0.564
nW	2.77	4.23	5.41	5.64
ΣnW		18.05		

7. *Fiducial limits.* Using the approximation formula, the fiducial limit calculated at the F = 95% level is given by log LD_{50} ± 1.96 (S_m). Thus the lower log LD_{50} limit = 0.5 − 1.96 × 0.129 = 0.697, and the antilog 0.697 = 4.977. The upper log LD_{50} limit = 0.95 + 1.96 × 0.129 = 1.20 = 15.849. Antilogs of 0.697 and 1.2 give the fiducial LD_{50} limit 4.98–15.85 mg/kg.

Q. What type of distribution provides a precise description of a lethality response to a toxic test article?

A. Lognormal distribution.

Q. Compare and contrast eye irritation and eye corrosion including in the discussion a description of the observation endpoints usually associated with irritancy in the three major tissues of the eye.

A. Eye irritation can be defined as reversible inflammatory changes in the eye and its surrounding mucous membranes following exposure to a material on the surface of the anterior portion of the eye. By contrast, corrosion represents irreversible tissue damage to the eye following exposure to a material. The amount of damage to each of the three major eye tissues, the cornea, the conjunctiva, and the iris, is what differentiates irritancy from corrosion. Gross tissue destruction that follows rapidly after exposure and persists for an extended period in any or all of these tissues is usually an indication of eye corrosion. Irritancy, however, can occur to various degrees. Assessment of injury is based on the presence and severity of cloudiness (opacity) and swelling of the cornea; redness, edema (chemosis), and discharge in the conjunctiva; and increased vascularity, edema, absence of reaction to light, and cloudiness (aqueous flair) in the iris.

Q. A consumer aerosol product contains ingredient A (20%), ingredient B (30%), and water (50%); there are no inhalation data on the product itself, but the acute inhalation LC_{50} (rat, 4 h) is 0.5 mg/L for ingredient A, and 5 mg/L for ingredient B. What is the GHS acute toxicity classification category and pictogram for this product?

A. Use the ATE (mixture) formula to calculate the LC_{50} for the product, ignoring the water component. The calculated LC_{50} (product) = 2.17 mg/L; thus the product is in Category 4 with an exclamation pictogram.

KEYWORDS

Acute toxicity; Eye irritancy; Clinical signs and observation; Oral acute toxicity; Dermal acute toxicity; Inhalation acute toxicity; Eye irritation; Eye corrosion; Lethal medium dose (LD_{50}); Lethal medium concentration (LC_{50}); Probit analysis; Fluorescein staining for corneal damage; Slit lamp microscopy; Corneal pachymetry; Confocal microscopy; Alternative toxicity test methods; Bovine corneal opacity permeability (BCOP) assay; Isolated chicken eye test; EpiOcular assay; HCE-T TEP assay; MDCK PL assay; Tier testing strategy; Driaze's test for eye irritation; EU registration, evaluation, authorization, and restriction of chemicals (REACH); Classification, labeling, and packaging of chemicals (CLP); Globally harmonized system (GHS) of classification and labeling of chemicals

23 Genetic Toxicology

David J. Brusick and Wanda R. Fields

CONTENTS

INTRODUCTION

Genetic toxicology addresses the identification, analysis, and management of agents with toxicity directed toward the hereditary components of living organisms. A large proportion of human disease is either directly or indirectly associated with altered genetic information. Although many agents are capable of indirectly altering DNA functionality at excessively high exposure concentrations, the primary objective of genetic toxicology is to identify and assess genetic

hazard from agents that specifically interact with nucleic acids or are capable of altering the expression of genomic information. Such agents are classified as *genotoxic*.

The term genotoxic is a general descriptor used to distinguish chemicals that directly change normal genomic function from those that do not; however, categorization of a chemical as genotoxic is not a priori an indication of a health hazard.[1]

Genotoxicants are characterized by several properties including those which alter (1) the nucleotide sequence of genes, (2) chromosome structure, (3) chromosome number, or (4) expression of genes. Change in nucleotide sequence is described as *mutation*, structural chromosomal damage is referred to as *clastogenicity*, change in chromosome number is called *aneuploidy*, and change in gene expression in the absence of any alteration in DNA sequence is identified as an *epigenetic* effect. These major classes of genotoxic damage are responsible for an array of human genetic diseases, congenital malformations, and key steps in cancer initiation (Table 23.1).

Genetic toxicology began in the late 1960s with concerns raised regarding potential genetic and reproductive effects arising from man-made chemicals entering the environment. Early objectives of genetic toxicology were focused on the integrity of the human reproductive process and the induction of new transmissible DNA damage. Test methods employed initially were largely in vivo and oriented toward the detection of alterations to germ cells. At the end of the 1960s, reports from Bruce Ames and other investigators were available showing a strong relationship between results in tests for genotoxicity and bioassays for rodent carcinogenicity.[2–4] More recently, attention has been drawn to a class of agents that do not change the primary structure of DNA, but alter phenotypes through environmentally induced alterations in gene expression patterns.[5]

Over the past 40 years, genetic toxicology testing has evolved to a point where it now plays a dual role in safety evaluation programs. One role is the identification and risk assessment of genotoxic agents capable of altering the integrity of the human genome. The second role is the application of genetic toxicology data to achieve a better mechanistic understanding of chemicals that produce somatic cell diseases such as cancer.

BASIC GENETIC CONCEPTS

Gene Structure

DNA is responsible for the hereditary characteristics of all living systems, with the exception of some viruses that use RNA. Even those organisms that store their hereditary information in RNA go through a DNA intermediate during replication. The structure and biochemical characteristics of human DNA has been summarized by Baltimore.[6]

The basic functional unit in a DNA molecule is termed a *gene*. Most of the early knowledge concerning structure and operation of genes was acquired from studies with bacteria or bacteriophages. Advances in understanding the molecular biology of mammalian cells have resulted in equivalent information in eukaryotic cells. The nucleotide composition and the mechanisms by which information encoded in a gene is transformed into gene products are universal. Universality was established through recombinant DNA engineering studies, which demonstrated that genes continue to function properly after having been transplanted from human cells to bacterial cells or from bacterial cells to plant cells.[7,8]

DNA found in prokaryotic (bacteria) and eukaryotic cells (plant and animal cells) differs in a number of ways. In prokaryotic cells, DNA forms a single *chromosome* with little or no substructure along the molecule. DNA in eukaryotic cells, on the other hand, is organized in combination with structural and regulatory proteins (*histones*) into highly differentiated chromosomes. The basic structure of chromosomes is similar across species with most having their genomic DNA distributed across multiple chromosomes. Chromosomes contain genes with functional coding sequences called *exons* separated by nonfunctional, repeat DNA sequences and regions of noncoding DNA called *introns*. The exact role of intron regions is not known, but in the human genome, the numbers of introns and exons are roughly equal.

In eukaryotic cells, the process of gene transcription is controlled by regulatory genes.[9] There are two major types of regulatory regions: promoters and enhancers. Promoters are found immediately adjacent to genes and contain specific DNA sequences (e.g., TATA) that serve as recognition sites for polymerases and other proteins needed to initiate transcription. During *transcription* (reading of the DNA code into mRNA), RNA polymerase transcribes both exons

TABLE 23.1
Examples of Effects from Genotoxic Agents

Mutation Type	Examples of Inherited Effects	Examples of Somatic Effects
Single base changes	Sickle cell disease, Phenylketonuria Hemophelia	Epithelial cancers, activation of ras oncogenes
Small deletions and/or Translocations	Duchenne muscular dystrophy	Lymphomas, leukemias, enhanced activation of Myc, abl oncogenes
Whole chromosome losses or gains	Down's syndrome (trisomy 21) Turners syndrome (monosomy X)	Loss of tumor suppressor genes, retinoblastoma Wilm's tumor, breast cancer

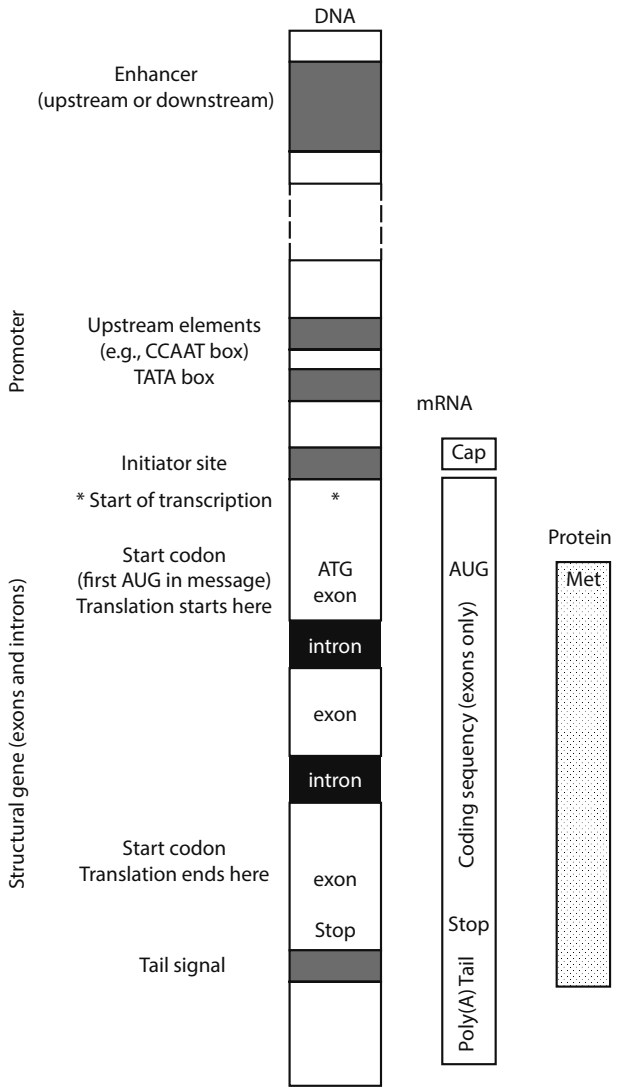

FIGURE 23.1 Gene structure, function, and regulation.

and introns into pre-mRNA. Proteins called spliceosomes located in the nucleus of the cell excise intron regions and splice the coding sequence together. The resulting mature mRNA is then transported to *ribosomes* outside the nucleus for *translation* (reading of the mRNA into polypeptides) (Figure 23.1). In some instances, the resultant polypeptides undergo posttranslational modification (glycosylation, hydroxylation, proteolytic cleavage) depending on their cellular functions. Enhancers are specific DNA sequences that function to enhance transcription but are not necessarily adjacent to the genes they affect. Enhancers may occur on either strand of the DNA and affect genes located hundreds or thousands of bases away.

Somatic and Germ Cell Characteristics

From a genetic perspective, multicellular eukaryotic organisms are composed of two cell types: somatic cells and germ cells. Somatic cells constitute the major portion of the mammalian organism. The adult human body is estimated to be made up of 10^{14} somatic cells. The number of germ cells (ova) is fixed by sexual maturity in females, while males continuously produce male germ cells (sperm) from spermatogonial stem cell populations. The total DNA composition (*the genome*) of most somatic cells is found in the *diploid* (two complete sets of chromosomes) configuration. Virtually all in vitro mammalian cell assays used in genetic toxicology employ somatic cell types. Germ cells, or gametes, constitute a special cell population in multicellular organisms. Germ cells are derived from diploid stem cell, and following meiosis, they are left with a single (*haploid*) set of chromosomes. Their function is to pass genomic information from one generation to the next. Mutations found in germ cells produce a broad array of heritable genetic diseases, congenital malformations, and predisposition to other disorders. Mutations found in somatic cells are generally less damaging unless they result in the initiation of malignant cell transformation.

Mutation and Human Disease

The biological consequences of DNA damage are dependent on which type of cell (somatic or germ) carry the alteration. The mutational basis for many human disorders and anomalies is well documented.[10] The human genome contains preexisting mutations forming what is called the *genetic disease burden*. The extent of the preexisting genetic disease burden is estimated to be as high as 5% (Table 23.2). Diseases associated with this genetic burden contribute significantly to the healthcare costs of most developed countries and the high mortality rates in less well-developed regions. The precise origin of preexisting DNA alterations found in the human gene pool is unknown, but Table 23.3 provides some of the accepted sources for the genetic disease burden. Although human mutagenicity has not been demonstrated in epidemiology investigations, experimentation in animal models amenable to the study of transmissible mutations provides convincing evidence that environmental genotoxicants would be capable of inducing transmissible mutations in human germ cells.[11,12] Genetic changes in somatic cells are associated with a range of dysfunctions, including inherited and induced tumors,[13] teratogenesis,[14] reproductive failure,[15] and atherosclerosis,[16] and appear to be involved in aging.[17]

It is estimated that the human genome consists of approximately 25,000 genes controlling all aspects of an organism's biology and behavior. Our knowledge of the function of these genes remains limited, but research continues to identify functionality at an increasing pace. As of 2008, the *Online Mendelian Inheritance in Man* database established in 1997 by Dr. V.A. McKusick reported 387 genes of known sequence with a known phenotype and 2310 human phenotypes with a known molecular basis.

The deleterious consequences of germ cell alterations vary according to the nature of the alteration. Other than certain DNA alterations (e.g., balanced chromosomal translocations or dicentric chromosomes) that are compatible with cell replication, the vast majority of damage to chromosomes

TABLE 23.2
Composition of the Existing Human Genetic Burden

Type of Genetic Alteration	Incidence per Thousand Newborns (Approximate)	Examples of Diseases Associated with Alteration
Chromosomal abnormalities (e.g., translocations, aneuploidy)	6.9	Down's syndrome (trisomy 21) Klinefelter's syndrome (XXY) Cri du chat (chromosome deletion)
Autosomal dominant mutation	2.5	Familial polyposis (colon cancer) Huntington's disease Retinoblastoma
Autosomal recessive mutation	2.5	Sickle cell disease Phenylketonuria
X-linked recessive mutation	1.7	Duchenne muscular dystrophy Hemophilia
Polygenic or congenital effects	30	Cleft lip Spina bifida
Total	43.6	

TABLE 23.3
Probable Sources of Preexisting Mutations Found in the Human Genome

Spontaneous errors occurring during normal DNA replication and repair
Unavoidable environmental exposures (e.g., food, radiation, products of combustion, mycotoxin, pesticides, manufacturing emissions)
Therapeutic treatments that are directly mutagenic (e.g., radiation or chemotherapy)
Effective treatment of formerly lethal genetic diseases thereby elevating the probability of their contribution to the gene pool
Production of genotoxic by-products of normal oxidative metabolism processes (i.e., reactive oxygen species, lipid peroxidation)

(i.e., breaks or deletions) results in lethality to the respective germ cell or to the embryo derived from that germ cell. Consequently, most genetic damage produced in human germ cells is observed as reproductive failure (e.g., spontaneous abortion). A much smaller proportion of the damage is of a type that is transmissible. Newly generated dominant gene mutations will be expressed in the first generation (F_1). The impact of dominant mutations on the gene pool (*all genes contained in a given population*) is generally limited because the *affected* individuals are aware that they are carrying the mutant form of the gene and are aware that they can transmit the mutant gene to their children. Thus, depending on the severity of the disease or effect, parents can decide, prior to reproducing, if the health risk associated with possible transmission to a child is acceptable.

Unlike dominant mutations, recessive disease mutations will not be expressed unless both alleles of the gene pair are mutant. Two phenotypically normal heterozygous carriers for a recessive mutant allele (on autosomal chromosomes) will theoretically produce offspring that have a 25% incidence of exhibiting a recessive disease. Additionally, 50% of their offspring will be the same phenotypically normal heterozygous carriers as the parents. The frequencies of recessive mutations in the gene pool are maintained by the phenotypically normal heterozygous carriers. An increase in the incidence of new recessive mutations poses the most serious threat to human populations as these mutations are usually not expressed immediately after induction. New recessive mutations tend to accumulate in the gene pool in the heterozygous configuration. Due to the resultant generational latent period, the ultimate expression of a *new* recessive mutation in the population may have no apparent association with the environmental exposure that induced it until several generations later. This situation severely limits the opportunity to use human epidemiological studies to detect human genetic risk.[18,19] Finally, sex-linked recessive mutations are alterations on the X chromosome and appear as dominant mutations when transmitted to male offspring as the Y chromosome has no corresponding alleles to offset the effects of the X-linked mutation.

The discipline of genetic toxicology initially relied upon a set of in vivo tests focused on the detection of DNA damage to germ and somatic cells of rodent species with an intent to extrapolate the results to human hazard and risk assessments.[15,19,20] Early testing approaches employed rodent assays, which detect dominant lethality (implantation failure or early embryonic lethality), heritable translocation induction (semisterility), and specific locus mutation induction in somatic and germ cells.[21] Genetic risk assessment using an extrapolation approach will be discussed later in this chapter; however, the lack of a set of known human mutagens makes the validation of this approach difficult. As a consequence, alternative approaches have been developed for assignment of heritable mutation risks to humans.[22]

In summary, deleterious genes (diseases) are present in the human gene pool with predictable rates. The origin of this genetic disease burden in humans is not completely known, but it is imperative that we, as current caretakers of the human

gene pool, use all precautions to transmit the gene pool to the next generation in no worse shape than it was received.

Carcinogen–Mutagen Relationship

During the late 1960s, a substantial amount of scientific evidence demonstrated that most chemical carcinogens, or their metabolites, had electrophilic properties and would directly bind to DNA.[23] Early studies of carcinogen binding used purified DNA and did not directly demonstrate a relationship between the binding, mutation formation, and cancer initiation. The introduction of a *Salmonella* assay for detecting mutation (Ames test), combined with an in vitro metabolic activation system, appeared to offer a rapid, inexpensive method to identify DNA-reactive/DNA-binding chemicals capable of inducing mutation and cancer.[2,24] The Ames test was the forerunner of a broad array of in vitro submammalian and mammalian cell assays that were later proposed as rapid screens for carcinogens.[3,25]

The relevance of genotoxicity assays as predictors of carcinogenicity was later supported by studies demonstrating that normal, nonmalignant mammalian cells could be transformed into cancer cells by transfecting them with DNA isolated from malignant cells.[26] Ultimately, specific genes were identified in the transfected DNA that, when mutated, were responsible for the transformation.[27] These *cancer* genes (*oncogenes*) are highly conserved genes in most eukaryotic organisms. Oncogenes (e.g., *ras*, *myc*) are activated by nucleotide substitution mutations or chromosome breaks[13,28] in specific exons. The spectra of nucleotide substitutions induced may be characteristic of a particular carcinogen. In vivo experiments with mice documented that nucleotide changes in K-*ras* oncogenes isolated from tumors induced by some chemical carcinogens are agent specific and serve as signatures specific to that chemical.[29] Identification of the signature nucleotide changes in *ras* gene sequences isolated from tumors of humans exposed to the chemical in question are then able to link the human tumor to prior exposures.

Other cancer genes called *tumor suppressor* genes (e.g., p53) have been identified. These genes in their normal configuration produce proteins responsible for suppressing tumor cell development. DNA mutations that result in the inactivation of the suppressor proteins will result in increased tumor development. One specific tumor suppressor gene, the p53 gene, is involved in the process of apoptosis and has been used as the basis of a short-term model of tumorigenesis in transgenic mice made heterozygous for the p53 gene.[30] This model primarily detects mutagenic carcinogens through mutation-induced inactivation of the single normal p53 allele.

Initial optimism that genotoxicity tests might be a shortcut to animal and/or human carcinogen prediction was generated by studies correlating the results of specific genotoxicity tests (or batteries of tests) with rodent bioassay responses for the same chemicals. By 1974, concordance between rodent carcinogenicity and results from the Ames test, alone, appeared to be as high as 90%–95%, and a paper published by Ames et al.[24] was confidently titled *Carcinogens are mutagens: a simple test system combining liver homogenates for activation and bacteria for detection*. However, as more chemicals were added to the database of Ames test results over the next decade, the predictivity declined, and by 1984, the concordance between the Ames test and rodent bioassay results dropped to just over 60%.[31] There are several reasons for the reduction in concordance[32]; however, the factor that had the most influence was an expansion in the sets of chemical classes used in the comparisons. Reports in the early to mid-1970s showing high concordance were based on sets of chemicals highly biased toward inclusion of electrophilic carcinogens. Later studies included a heterogeneous range of animal carcinogens, including those that were not electrophilic. These *epigenetic carcinogens* failed to give the appropriate responses.[33] The initial response to the declining concordance was an expansion in the range of different tests used to evaluate chemicals. This leads to the development of test batteries, which included the Ames test plus other microbial- or cell-based assays.[3] The result of this action was an increase in overall sensitivity (more positive responses for carcinogens) but an even greater decline in concordance specificity (fewer noncarcinogens without a positive response). The analysis of the declining concordance between short-term tests and animal cancer bioassays leads to the conclusion that genotoxicity tests, particularly in vitro ones, were good in identifying carcinogens but were less reliable in predicting noncarcinogenicity. This issue is clearly evident in the result provided in Table 23.4, which shows that test batteries generally improve correlation sensitivity but have too many false positives to be of value in identification of noncarcinogenic chemical. In fact, most chemicals classified as noncarcinogens by agencies such as the National Toxicology Program (NTP) and the International Agency for Research on Cancer (IARC) produced positive responses in one or more tests in a battery of in vitro genetic assays, suggesting that the specificity of

TABLE 23.4
Predictivity Performance of a Battery of Three Common In Vitro Assays

Characteristic	Ames (%)	Mouse Lymphoma (%)	Chromosome Aberrations (%)	All Tests Combined (%)
Sensitivity	58.8	73.1	65.6	84.7
Specificity	73.9	39.0	30.8	22.9
Concordance	62.5	62.9	67.8	—

in vitro tests is too poor to rely upon individual tests or test batteries to predict carcinogenic profiles for new molecules.[31] Addition of in vivo results to the process of predicting carcinogenicity with tests detecting DNA damage (e.g., mouse micronucleus) also failed to improve the overall predictive performance.[33] The Ames test has the best overall combination of sensitivity and specificity and may be the most effective screen for carcinogenic activity. The claim of accurately predicting animal carcinogenicity, and noncarcinogenicity, using in vitro genotoxicity tests has not yet been fulfilled.

A valuable application of genetic toxicology results to cancer risk estimation has been the use of genotoxicity data by regulatory agencies as a key component in determining the mode of action (MOA) for carcinogens.[34,35] Carcinogens with positive effects in genetic tests are considered to have an MOA through direct effects on DNA. Carcinogens that test negative for genotoxicity are presumed to produce tumors through one of several epigenetic MOAs. The U.S. Environmental Protection Agency (EPA) has developed a decision tree approach, which uses genetic test results to aid in the selection of the most appropriate data extrapolation model for cancer risk assessment.[36] A genotoxic mechanism implies a no-threshold mechanism whereas a threshold may exist for epigenetic MOAs.

An important factor affecting an appreciation for the complexity of DNA alterations and accurate carcinogen predictivity is the need to define epigenetic mechanisms and develop tests to detect agents that induce them. Several diseases, including cancer, are associated with aberrant DNA methylation.[37,38] Inclusion of tests for epigenetic effects would increase the predictivity of tests assessing genotoxicity and move short-term testing closer to the goal of carcinogen identification.

MECHANISMS OF GENOTOXICITY

Background and Spontaneous DNA Alterations

DNA synthesis and replication are not flawless processes, and in rare instances, genetic alterations occur spontaneously during regular cell division. In addition, aerobic metabolism produces reactive by-products (e.g., hydroxyl radicals, formaldehyde) capable of damaging DNA. Peroxisomes compartmentalize oxidative metabolism leading to reactive products that would otherwise be detrimental to the cell, although under certain conditions, these products may be released. The vast majority of oxidized DNA base lesions are repaired by DNA repair systems, but in certain situations of excessive toxicity, unrepaired endogenous DNA damage is a cause of background or spontaneous mutation.

Background mutation can also arise from exposure to environmental agents such as radiation (e.g., radon gas, cosmic, solar), chemical pollution (e.g., combustion hydrocarbons), and diet. Perturbation of endogenous DNA damage or disease-related inflammation (e.g., osteoarthritis[39]) will result in increased levels of mutation and chromosome damage. Although DNA damage due to endogenous processes and other natural sources can be minimized, it cannot be totally eliminated.

Classification Scheme for Genotoxic Effects

DNA damage may be classified into several broad categories based on the nature (presumed mechanism) of the DNA effects (Table 23.5).

DNA binding and nucleotide changes are alterations occurring at the nucleotide level. Nucleotide damage generally produces point mutations through base-pair substitution or insertion/deletion. Point or gene mutations are generally induced by agents that specifically target nucleophilic sites on individual bases in nucleic acids. The normal DNA base pairings are shown in Figure 23.2. Adenine and thymine form two hydrogen bonds, and guanine and cytosine form three. Hydrogen bonds are weak electrostatic forces involving oxygen and nitrogen atoms at specific sites on the purine and pyrimidine molecules. When electrophilic chemical species covalently bind (*adduct*) to portions of the DNA bases involved in the formation of hydrogen bonds, the resultant structures (Figure 23.3) can produce electron shifts from the H-bonding sites to areas within the molecules giving rise to opportunities

TABLE 23.5
Major Categories of DNA Damage

Mechanism	Description
Covalent binding	A chemical bond formed when electrons are shared between two atoms. Electrophilic agents form covalent bonds with DNA. Chemicals that form covalent bonds alter the normal electron sharing between DNA base pairs (i.e., G:C) leading to mispairing and gene mutation.
Intercalation	Insertion of an agent between base pairs in double-stranded DNA. This deforms the DNA configuration and adversely affects processes of DNA replication and repair. The typical alteration generated is a frameshift mutation. Intercalation does not involve covalent bonds.
Cross-linking	Agents that can form covalent bonds with multiple sites on the DNA may form interstrand or intrastrand cross-links that prevent normal DNA replication that leads to breaks in the DNA backbone.
DNA strand breakage	SSB or DSB are produced by cross-linking agents as well as reactive oxygen species. DNA breaks can produce chromosome aberrations.
Epigenetic	Agents that alter gene expression without changing the base sequence of DNA are classified as epigenetic genotoxicants. Examples include DNA methylation and histone protein acetylation and deacetylation.

for short-lived mispaired bases (e.g., A:C or G:T). If this aberrant pairing occurs before or during a DNA replication cycle, the result may be the substitution of a new base pair in place of the original one. One cycle of DNA replication is needed to fix the error in daughter DNA strands and to create base-pair substitution mutations. This process is referred to as the *expression period* in mutation assay protocols. Base-pair addition/deletion mutations, also called *frameshift mutations*, result from the addition or deletion of one or a few nucleotide pairs from the nucleotide sequence in an exon or gene. Because the codon sequence reads in one direction and is not punctuated, the loss or gain of a single base pair changes the reading frame of the gene—hence, frameshift mutation. The deletion of base pair shifts the reading frame to the right, and the addition of base pair shifts it to the left. This type of mutagenic mechanism is illustrated in Figure 23.4. Both frameshift and base-pair substitution gene mutations result in alterations in translation of mRNA into the proper amino acid sequence in the gene products producing a mutant cell or organism. Base-pair substitution and frameshift mutations are responsible for both human genetic diseases and cancer initiation in proto-oncogenes and tumor suppressor genes.

Detection of DNA binding or even specific adducts is not equivalent to the detection of mutation.[40,41] When electrophilic

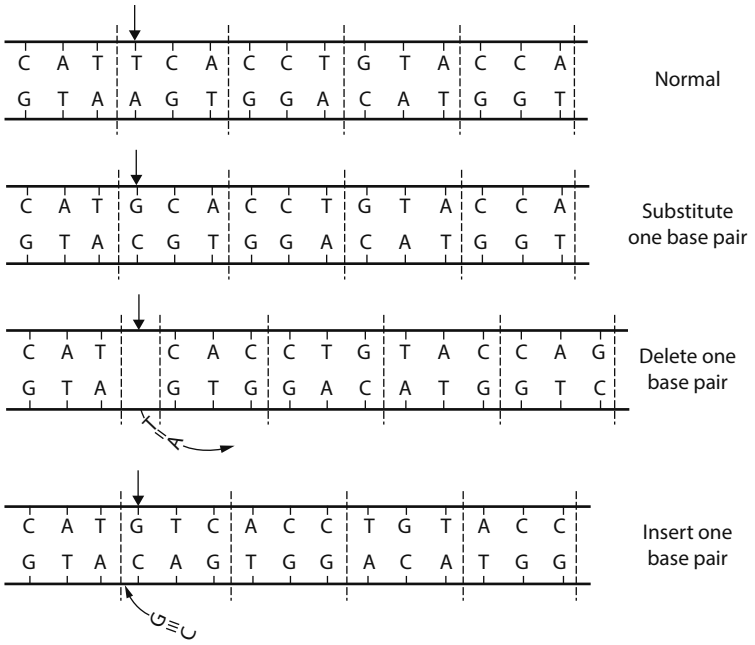

FIGURE 23.4 Base substitution and frameshift mutation mechanisms.

chemicals react with DNA, they form both unstable and stable adducts. Unstable DNA adducts tend to be removed forming abasic sites in the DNA that are generally repaired. Stable adducts can result in mispairing and mutation. The ratio of stable to unstable adducts differs by chemical even among closely related structures. Consequently, adduct levels, per se, are not an accurate indicator of mutagenicity. However, adduct detection in vivo is a sensitive method to demonstrate exposure to electrophilic agents. Unfortunately, not enough is known about adduct processing and repair for this technique to accurately define genetic or cancer risk.[42] At the present time, the qualitative and quantitative relationships between DNA adduct formation and mutation are known for only a small number of agents. It is known that organs and tissues in mammals have different capacities for repairing adducts, and that some adducts, such as the O-alkyl adducts, are repaired less efficiently than N-7 adducts, for example, and are believed to produce most of the mutagenic damage responsible for tumor initiation.[40] In summary, when comparing different carcinogens, no quantitative correlation exists between the level of DNA adduct formation and mutation.

DNA breakage, *chromosome aberrations*, and *abnormal chromosome segregation* involve the structural integrity of chromosomes as well as chromosome number. Clastogenic effects are visible through cytologic analysis of condensed chromosomes. During most of a cell's existence, DNA is packaged in the nucleus of somatic cells as uncondensed chromatin and is not visible except during mitosis when chromatin is condensed. Figure 23.5 illustrates the generalized anatomy of a chromosome at metaphase. The condensed chromosome shows distinctive banding with Giemsa staining. It contains a constricted region known as the centromere. To either side of the centromere are the chromosome arms that terminate in unique sequences called *telomeres*. The darker bands (G+ bands) in the stained chromosome represent condensed DNA (heterochromatic) believed to represent areas of little or no gene expression (transcription). The lighter bands (G− bands) represent relaxed DNA sequences believed to be active genomic areas where gene expression (transcription) is occurring. The telomeric regions at the ends of the chromosome structures are important for chromosome stability and cell longevity.[43] Telomeres consist of repetitive sequence of a small number of nucleotides (TTAGGG) that protect the ends of chromosomes from fusing. During somatic cell replication, telomeres are not completely replicated. They are gradually shortened, and when the telomeres reach a critical threshold, cell division stops in what is called *replicative senescence*.[43,44] The enzyme telomerase (a reverse transcriptase) can replace lost telomeric DNA. Telomerase is almost nonexistent in somatic cells but is found in embryonic stem cells and tumor cells.

Chromosomal effects scored microscopically are the result of damage to the integrity of the DNA molecule producing strand breaks, either single-strand breaks (SSBs) or double-strand breaks (DSBs). DNA strand breakage can be the result of exposure to reactive oxygen species or cross-linking DNA adducts. Chemicals that interfere with DNA synthesis and DNA repair processes may also produce increased levels of DNA strand breaks. In addition to DNA-reactive agents, chromosome alterations are also produced by secondary mechanisms, especially in vitro, by extreme shifts in cellular homeostasis such as high temperature, low pH, or osmotic changes.[45–47]

Damage to chromosomal DNA can be subdivided into changes in chromosome number resulting in aneuploidy (gain or loss of less than a complete set of chromosomes) or

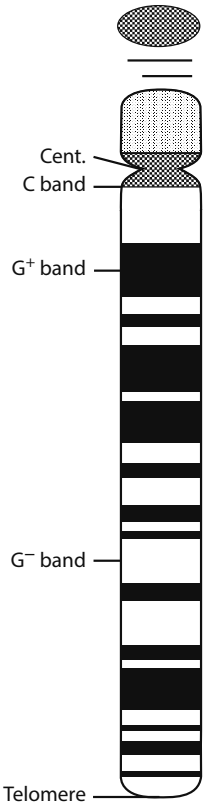

FIGURE 23.5 Diagram of chromosome G⁻ bands are areas of light staining indicating active transcription. G⁺ bands are highly stained areas with minimal transcription.

polyploidy (multiple full sets of chromosomes)[48] or changes in chromosome structure (breaks, deletions, rearrangements). A wide range of in vitro and in vivo genetic test methods are available to assess numerical changes and structural breaks. Since most chromosome breakage of the types scored in aberration analyses results in cell death, the breaks and gaps that are found serve as signals indicating the probable induction of other more stable and, therefore, more relevant chromosome damage such as balanced translocations, dicentric chromosomes, stable deletions, and numerical changes such as aneuploidy. It is these stable aberrations that are associated with human genetic diseases and cancer.

Sister chromatid exchange (SCE) is another type of chromosomal event, which can be visualized in cells by using a specific bromodeoxyuridine staining process; however, SCEs are exchanges between identical DNA chromatid sequences and are not, per se, a DNA alteration resulting in any known adverse outcome. SCEs occur normally but are increased by genotoxic agents and can, in a manner similar to DNA adducts, be used as a dosimeter of exposure, but not as a predictor of mutation or cancer.

DNA changes not altering the primary sequence affect gene expression and, in some cases, such as genetic imprinting, the effects are transmissible. DNA methylation and histone protein acetylation are two epigenetic changes that result in gene expression and contribute to genetic-based diseases.[49–51] Epigenetic phenomena play a key role in regulating gene expression.[49] One of the most widely studied epigenetic modifications is DNA methylation at cytosine residues in gene promoters. Genomic imprinting refers to methylation of genes that results in monoallelic expression depending on the parental origin. This is typically accomplished by methylation of specific genes. An individual normally has one active copy of an imprinted gene. Improper imprinting or aberrant methylation can result in an individual having two active copies or two inactive copies. Although only a minority of human genes are imprinted, unscheduled methylation can lead to altered expression producing severe developmental abnormalities, cancer, and other problems.[39] Some environmental agents (e.g., cadmium, folate, zinc, and nickel) have been shown to alter DNA methylation patterns.[37]

In eukaryotes, genomic DNA is packaged with histones to form chromatin, which in turn condenses to form more compact structures. The condensation of chromatin affects processes requiring access to the DNA, such as transcription, replication, DNA repair, or recombination. A second epigenetic process is associated with acetylation of histone proteins found in chromosomes. Acetylation of chromosomal proteins is produced by two types of enzymes: histone acetyltransferases (HATs) and histone deacetylases (HDACs). HATs acetylate histones, while HDACs deacetylate histones, and together they regulate transcription profiles for specific functions. Acetylation of the lysine residues at the N terminus of histone proteins removes positive charges, thereby reducing the affinity between histones and DNA.[51] This makes RNA polymerase and transcription factors easier to access the promoter region. Therefore, in most cases, histone acetylation enhances transcription, while histone deacetylation represses transcription. Research has demonstrated that histone deacetylation can repress tumor suppressor gene expression increasing cancer risks.[52] Inhibitors of HDAC (HDACI) are highly effective in upregulating tumor suppressor gene expression, reducing tumor growth and inducing programmed cell death in vitro and in cancer patients in phase I and II clinical trials.[53] Some short-chained fatty acids (e.g., valproic acid), benzamides, and ketones are HDACIs and under investigation as possible anticarcinogenic treatments. Studies with one histone deacetylase (HDAC2) have shown that it can be elevated in mice by amyloid beta, which may then result in downregulation of genes responsible for cognition.[54]

Factors Influencing Genotoxic Hazard/Risk

Repair of DNA Damage

The fidelity and integrity of genetic information in organisms are maintained by several types of enzymatic DNA repair. The characteristic of self-repair is unique to DNA and emphasizes importance of the integrity of this molecule to the survival of an organism. Most components of DNA repair operate constitutively in organisms, although a few repair processes are adaptive (inducible) following cellular exposure to genotoxicants.[55,56]

There are more than 20 different oxidative DNA base lesions involved in the estimated 10,000 oxidative hits, which occur per cell per day in the mammalian genome.[57] Constitutive cellular repair capacities are generally adequate to compensate for the typical endogenous background damage; however, recurrent exposures to high concentrations of exogenous genotoxic agents may saturate the DNA repair capacity, leading to mutation and associated chronic diseases such as cancer and aging.

The common feature of repair processes is their ability to detect, remove, and replace damaged segments of DNA.[58] If a DNA lesion (i.e., DNA strand break or adduct) can be repaired prior to mutation fixation, the net effect of the DNA damage to an organism may be nil. This is especially true following intermittent, low-level exposures to genotoxicants where repair enzymes are not fully saturated. DNA adducts are not all recognized or repaired equally by excision repair.[59]

Test systems measuring some parameter of the DNA repair process have been used as screens for detection of primary DNA damage. Normal organisms are capable of some type of DNA repair activity following chemical insult; thus, stimulation or induction of repair activity following chemical treatment at sublethal concentrations is a good indicator that the target organism has experienced DNA-directed toxicity. DNA repair induction (i.e., induction of unscheduled DNA synthesis [UDS]) can be used as a screen for genotoxicity.[60]

Studies of DNA repair kinetics indicate that once premutational lesions have been induced in the DNA, both error-prone and error-free repair processes are activated. Error-prone systems attempt to maintain DNA continuity and, in the process, may actually generate nucleotide mismatches (e.g., A:C or G:T) that result in mutations. Error-free repair replaces the damaged DNA site with a correct nucleotide sequence. The fidelity of repair depends on the degree to which the two different processes are involved. Factors that determine whether error-prone or error-free pathways predominate include (1) the target organism species, (2) the cell type involved, (3) the chemical mutagen, and (4) the specific DNA lesion induced. Some data suggest that the error-free repair pathways predominate at low exposure levels, and error-prone pathways come into play only following saturation of the error-free enzymes.

Some repair processes directly reverse the damage in a single step. Thymidine dimers (covalently linked adjacent thymidine bases) induced by ultraviolet light exposure are reversed by a photolyase enzyme. Alkylating agents form adducts at the guanine-O^6 position and can be reversed by alkylguanine transferase. This enzyme removes the alkyl adduct from DNA transferring it to a cysteine residue in a single step.[61]

The remaining DNA repair processes involve multiple steps with multiple enzymes recruited to the repair sites as a repair complex. Various proteins (i.e., p53, CHEK1, CHEK2) are also involved in preventing damaged cells from entering S-phase to give repair processes time to remove the damage.[62]

Base excision repair (BER) and nucleotide excision repair (NER) are the primary repair mechanisms for chemical damage. The general processes involved in BER and NER are shown in Figure 23.6. BER corrects damaged bases or

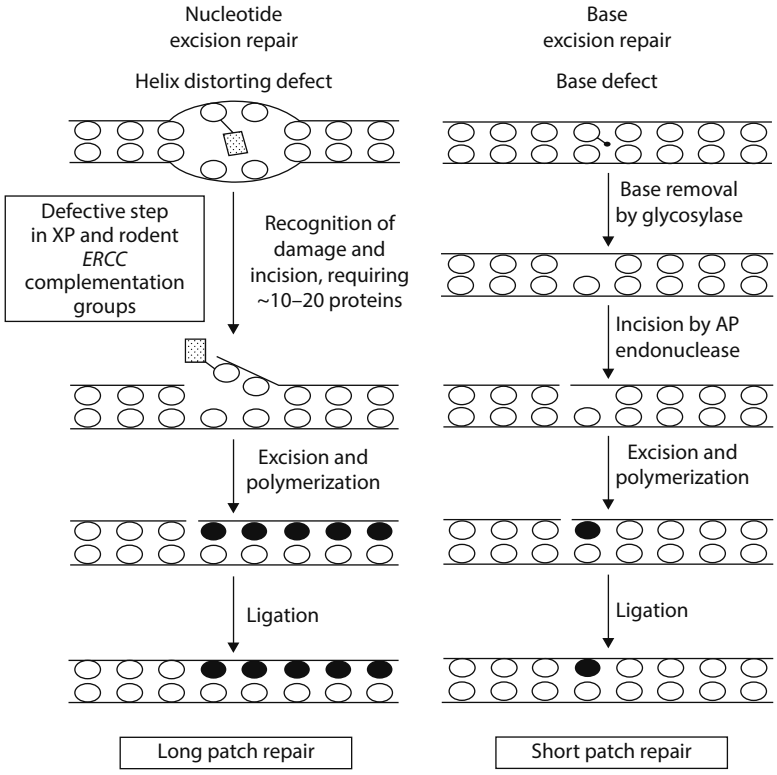

FIGURE 23.6 Diagrams illustrating NER and BER processes.

abasic sites in DNA. In BER, glycosylases also involved in mismatch repair (MMR) catalyze release of the inappropriate or damaged base followed by replacement and ligation.[63] The enzyme complex responsible for NER of bulky adducts requires more than 20 proteins and consists of several steps.[64] An endonuclease cleaves the DNA at the site of the damage, an exonuclease cuts out the damaged region including nucleotides to either side (i.e., 25–30 nucleotides), and new bases are replaced by a DNA polymerase using an editing function to ensure that the correct bases are incorporated into the repair patch. Finally, DNA ligase seals the repair patch. NER serves as the genome on a global basis (scanning the entire length of the DNA for damage) in addition to repair localized around DNA sites actively engaged in transcription where transcribed genes are scanned by translocating RNA polymerases, which sensitively detect DNA damage and initiate transcription-coupled repair (TCR), a subpathway of NER.[65] Occasionally, even in error-free repair, DNA polymerase can incorporate incorrect bases leading to mismatched pairings that do not properly hydrogen bond and escape proofreading. Failure to detect and repair these mismatches leads to general genome-wide increases in gene mutation. A specific repair process identified as mismatch repair (MMR) uses proteins that recognize aberrant DNA pairing caused by replication errors and targets the newly synthesized DNA strand. A short segment of the DNA duplex is excised and filled by the repair polymerase.[66] This is a second-chance repair process that occurs after BER and NER and improves the accuracy of those processes. Deficiencies in MMR proteins are associated with increased cancer risk.

Several less well-studied repair systems have been identified, one of which is specific for sealing (ligase) SSBs after remodeling of the opened ends by poly(adenosine diphosphate [ADP]-ribose)polymerase and another that repair interstrand DNA cross-links that block DNA synthesis at the replication fork. The repair enzymes break the DNA at the site of the cross-link followed by restoration of the replication fork, which removes lesions from the template DNA strands of actively transcribed genes.[67] Table 23.6 summarizes the major DNA repair processes that exist in organisms.

Theoretical assumptions and data from studies of repair in many species support the belief that at background or low exposure levels, an error-free removal of adducts from DNA can be virtually 100% effective, which supports the arguments for thresholds in cancer initiation.[68] Thus, one observes survival shoulders and nonlinear kinetics for mutation induction in repair-proficient cells and the loss of apparent no-effect regions in repair-deficient cells.

Genetic Susceptibility to Genotoxic Damage

Gene polymorphisms affecting traits such as xenobiotic metabolism and DNA repair capacity are likely to influence human susceptibility to genetic damage. Identification of gene polymorphisms that influence the susceptibility of an individual to the pharmacologic and toxic effects of therapeutic agents has developed into a major field of medical genetics. Institutions have assembled alleles from hundreds of polymorphic genes, and large human populations can be screened for single-gene polymorphism with automated high-throughput screening systems employing techniques such as DNA binding and transcription activation. Studies in humans exposed to polycyclic aromatic hydrocarbons (PAHs) documented a genotypic influence on the level of adducts. Polymorphism in GSTMI 2 (glutathione transferase), CYP1A1, and CYP2D6 alleles all affect the formation of DNA adducts found in white blood cells of exposed individuals.[69] Individuals expressing different polymorphic forms of the same genes can vary significantly in their response to a toxic agent. Unlike the genetic uniformity desired in experimental models in toxicology testing, the diversity associated with metabolic and DNA repair kinetics in human populations is sufficient to influence the degree of risk from exposure to genotoxicants.[64,70,71] Studies comparing the DNA repair capacity of humans with that of experimental animals suggest some significant differences, complicating the extrapolation of genotoxic results from mice to humans.[72]

Additional information about repair genes comes from studies of human genetic diseases such as xeroderma pigmentosum (XP). Individuals with XP lack one of the enzymes in the NER repair process, and affected individuals, with as

TABLE 23.6
Major Mechanisms of DNA Repair

Mechanism	Target DNA Lesion	Process
Direct reversal	Thymidine dimers	Photolyase enzyme converts pyrimidine dimers into two adjacent pyrimidines.
	Methylated bases	DNA methyl transferase removes methyl adducts directly from DNA.
BER	Abasic sites and damaged single bases	Glycosylase enzymes remove altered base and fills the gap prior to ligase sealing.
Excision repair	Large and/or bulky DNA adducts	Multistep process involving damaged region containing multiple bases that are removed and replaced using the other DNA strand as template. The most common repair process and is associated with both global and transcription-coupled DNA repair.
MMR	Erroneously matched base pairs (i.e., A:C or G:T)	Mismatched sites are excised and replaced using existing strand as template and polymerase III. Multistep process. Repaired by MutS, MutL, and MutH proteins.
Recombinational or cross-link repair	DNA cross-links	Not well studied but the repair enzymes break the DNA at the site of the cross-link followed by restoration of the damaged region of the DNA replication fork.

little as 1%–2% of the normal repair capacity, usually experience high levels of intrinsic DNA damage.[73] Cancer susceptibility among XP individuals is believed to be a consequence of the genetic damage and can be as much as 1000 times greater than for non-XP individuals. Other human syndromes associated with reduced repair capacity (e.g., ataxia telangiectasia, Bloom's syndrome, Fanconi's anemia) are inherited traits that also exhibit increased cancer risk.[73] Because DNA repair capacities exhibit such a broad range, genetic effects induced in genetically homogenous animal models with uniform repair can only be extrapolated to human risk estimates with large margins of error. The integration of metabolomics information into a genetic profile may eventually be used to direct an individual's lifestyle optimization.

Lifestyle

It is well documented that occupation and lifestyle can influence genetic hazard.[74–76] Tobacco use and alcohol consumption are both associated with genotoxic risk.[77,78] Diet is also a direct and indirect source of mutagens. The average human consumes about 10 tons (dry weight) of food by the age of 50 years,[79] and genetic toxicology studies have demonstrated that a number of common foods contain substances that are mutagenic.[74,80] Genotoxic agents such as aflatoxin B1, acrylamide, furfural, caffeic acid, and formaldehyde can be present in foods at low levels.

Other lifestyle exposures that may represent important risks are less subject to individual control. Exposure to ultraviolet light and ionizing radiation are common. Ambient air in many industrial and urban areas contains silica dust and carbonaceous particles coated with agents (e.g., aromatic amines and hydrocarbons) producing mutagenic responses in a range of assays.[81]

A possible genotoxicity defense process is linked to agents known as antimutagens. Agents that eliminate or reduce the mutagenic activity of a known mutagen when administered prior to mutagen exposure have been labeled antimutagens. Some investigators suggest that consuming certain foods or vitamins can protect an individual from DNA-damaging agents in the environment. For example, antioxidant materials found in plants (e.g., flavonoids) can reduce the mutagenic activity of chemicals such as ethylmethanesulfonate, benzo(*a*)pyrene, and other common mutagens when studied in vitro.[82] Unfortunately, unequivocal evidence of significant antimutagenic activity for these agents at typical use exposures in vivo has been difficult to demonstrate.

GENETIC TOXICOLOGY TESTING

Since 1970, more than 200 tests have been used to identify agents with genotoxic properties. A perspective on the number of tests used and a method for organizing the data produced by the various tests can be obtained from a review of the genetic activity profile (GAP) program of the EPA.[83] This program collected and analyzed genetic testing results from a wide range of in vitro and in vivo tests.

A relatively small number of those tests have continued to be recommended for routine screening and/or research in genetic toxicology. Strategies developed for the detection and assessment of genotoxic hazard include both in vitro and in vivo tests. Test selection and application is generally determined by characteristics of the test agent. Some tests such as microbial mutation tests (e.g., Ames II, green screen) or in vitro cell assays measuring micronucleated cells with flow cytometry can be conducted using semiautomated methods and are useful to evaluate large numbers of agents for basic genotoxicity classification.[84,85] Other tests such as in vivo evaluations for chromosome damage, induction of DNA repair synthesis, or DNA strand breakage provide more detailed information regarding the impact of route of exposure and in vivo metabolism and detoxification on the genotoxic activity of the test agents. The international scientific and regulatory communities have developed guidance documents outlining strategies for the evaluation of new chemicals, pesticides, food additives, and pharmaceutical products.[86]

Testing Strategies and Data Evaluation

A genotoxic compound may be defined as *an agent that produces a positive response in a bioassay measuring any genetic end point* (e.g., mutation, DNA breaks, clastogenicity). Although this definition considers virtually all forms of damage to DNA to classify an agent as genotoxic, that classification should not be interpreted a priori as an indication of hazard or risk. Additional experimental information beyond this initial classification is necessary to resolve concerns of genetic hazard/risk to somatic or germ cells.
