One is also occasionally required to evaluate whether a series of numbers (such as an assignment of animals to test groups) is random. This requires the use of a randomization test, of which there are a large variety. The chi-square test can be used to evaluate the goodness-of-fit to a random assignment. If the result is not critical, a simple sign test will work. For the sign test, we first determine the middle value in the numbers being checked for randomness. We then go through a list of the numbers assigned to each group, scoring each as a "+" (greater than our middle number) or a "–" (less than our middle number). The number of pluses and minuses in each group should be approximately equal.

Transformations

If our initial inspection of a dataset reveals it to have an unusual or undesired set of characteristics (or to lack a desired set of characteristics), we have a choice of three courses of action. We may proceed to select a method or test appropriate to this new set of conditions or abandon the entire exercise or transform the variables under consideration in such a manner that the resulting transformed variates (X' and Y', e.g., as opposed to the original variates X and Y) meet the assumptions or have the characteristics that are desired.

The key to all this is that the scale of measurement of most (if not all) variables is arbitrary. Although we are most familiar with a linear scale of measurement, there is nothing that makes this the correct scale on its own, as opposed to a logarithmic scale (familiar logarithmic measurements are pH values or earthquake intensity [Richter scale]). Transforming a set of data (converting X to X') is really as simple as changing a scale of measurement.

There are at least four good reasons to transform data:

1. Normalize the data, making them suitable for analysis by our most common parametric techniques such as ANOVA. A simple test of whether a selected transformation will yield a distribution of data that satisfies the underlying assumptions for ANOVA is to plot the cumulative distribution of samples on probability paper (commercially available paper that has the probability function scale as one axis). One can then alter the scale of the second axis (i.e., the axis other than the one that is on a probability scale) from linear to any other (logarithmic, reciprocal, square root, etc.) and see if a previously curved line indicating a skewed distribution becomes linear to indicate normality. The slope of the transformed line gives us an estimate of the SD. And if the slopes of the lines of several samples or groups of data are similar, we accordingly know that the variances of the different groups are homogeneous.
2. Linearize the relationship between a paired set of data, such as dose and response. This is the most common use in toxicology for transformations and is demonstrated in the "Probit/Log Transforms and Regression" section.
3. Adjust data for the influence of another variable. This is an alternative in some situations to the more complicated process of ANCOVA. A ready example of this usage is the calculation of organ weight to body weight ratios in in vivo toxicity studies, with the resulting ratios serving as the raw data for an ANOVA performed to identify possible target organs.
4. Make the relationships between variables clearer by removing or adjusting for interactions with third, fourth, etc., uncontrolled variables that influence the pair of variables of interest.

Common transformations are presented in Table 9.9.

Exploratory Data Analysis

Over the past 20 years, an entirely new approach has been developed to get the most information out of the increasingly

TABLE 9.9
Common Data Transformations

Transformation	How Calculated[a]	Example of Use
Arithmetic	$x' = x/y$ or $x' = x + c$	Organ weight/body weight
Reciprocals	$x' = 1/x$	Linearizing data, particularly rate phenomena
Arcsine (also called angular)	$x' = \arcsine\sqrt{x}$	
Logarithmic	$x' = \log x$	pH Values
Probability (probit)	x' = probability x	Percentage responding[b]
Square roots	$x' = \sqrt{x}$	Surface area of animal from body weights
Box Cox	$x' = (x^v - 1)v$ for $v \neq 0$	A family of transforms for use when one has no prior knowledge of the appropriate transformation to use
	$x' = \ln x$ for $v = 0$	
Rank transformations	Depends on the nature of samples	As a bridge between parametric and nonparametric statistics

[a] x and y are original variables; x' and y' transformed values; c stands for a constant.
[b] Plotting a double reciprocal (i.e., $1/x$ vs. $1/y$) will linearize almost any dataset, so will plotting the log transforms of a set of variables.

larger and more complex datasets that scientists are faced with. This approach involves the use of a very diverse set of fairly simple techniques that comprise EDA. As expounded by Tukey [20], there are four major ingredients to EDA:

- *Displays*—These visually reveal the behavior of the data and suggest a framework for analysis. The scatterplot (presented earlier) is an example of this approach.
- *Residuals*—These are what remain of a set of data after a fitted model (such as a linear regression) or some similar level of analysis has been removed.
- *Reexpressions*—These involve questions of what scale would serve to best simplify and improve the analysis of the data. Simple transformations, such as those presented earlier in this chapter, are used to simplify data behavior (e.g., linearizing or normalizing) and clarify analysis.
- *Resistance*—This is a matter of decreasing the sensitivity of analysis and summary of data to misbehavior so the occurrence of a few outliers, for example, will not complicate or invalidate the methods used to analyze the data. For example, in summarizing the location of a set of data, the median (but not the arithmetic mean) is highly resistant.

These four ingredients are utilized in a process falling into two broad phases: an exploratory phase and a confirmatory phase. The exploratory phase isolates patterns in and features of the data and reveals them, allowing an inspection of the data before there is any firm choice of actual hypothesis-testing or modeling methods has been made.

Confirmatory analysis allows evaluation of the reproducibility of the patterns or effects. Its role not only is close to that of classical hypothesis testing but also often includes steps such as (1) incorporating information from an analysis of another closely related set of data and (2) validating a result by assembling and analyzing additional data. These techniques are in general beyond the scope of this text; however, Velleman and Hoaglin [21] and Hoaglin et al. [22] present a clear overview of the more important methods, along with codes for their execution on a microcomputer (they have also now been incorporated into Minitab). A short examination of a single case of the use of these methods, however, is in order.

Toxicology has long recognized that no population—animal or human—is completely uniform in its response to any particular toxicant. Rather, a population is composed of a (presumably normal) distribution of individuals, some resistant to intoxication (hyporesponders), the bulk responding close to a central value (such as an LD_{50}), and some being very sensitive to intoxication (hyperresponders). This population distribution can, in fact, result in additional statistical techniques. The sensitivity of techniques such as ANOVA is reduced markedly by the occurrence of outliers (extreme high or low values, including hyper- and hyporesponders), which, in fact, serve to markedly inflate the variance (SD) associated with a sample. Such variance inflation is particularly common in small groups that are exposed or dosed at just over or under a threshold level, causing a small number of individuals in the sample (who are more sensitive than the other members) to respond markedly. Such a situation is displayed in Figure 9.6, which plots the mean and SDs of methemoglobin levels in a series of groups of animals exposed to successively higher levels of a hemolytic agent.

Though the mean level of methemoglobin in group C is more than double that of the control group (A), no hypothesis test will show this difference to be significant because it has such a large SD associated with it. Yet this inflated variance exists because a single individual has such a marked response. The occurrence of the inflation is certainly an indicator that the data need to be examined closely. Indeed, all tabular data in toxicology should be visually inspected for both trend and variance inflation.

A concept related (but not identical) to resistance and EDA is that of *robustness*. Robustness generally implies insensitivity to departures from assumptions surrounding an

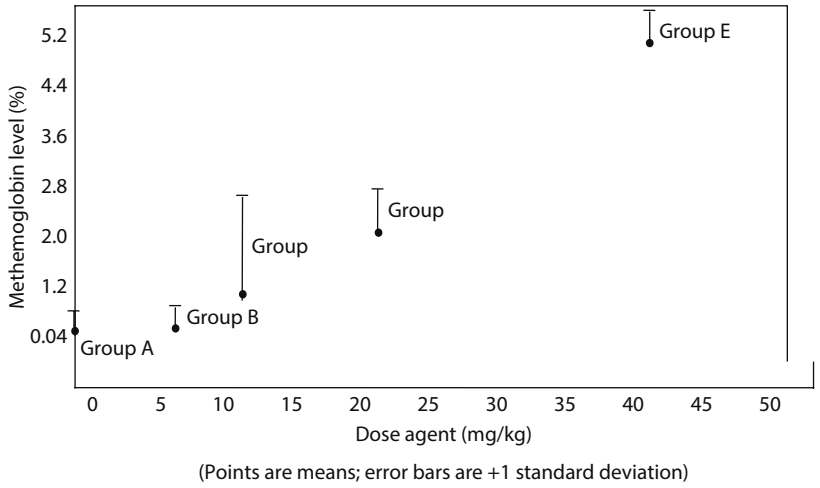

FIGURE 9.6 Variance inflation.

underlying model, such as normality. When summarizing the location of data, the median, though highly resistant, is not extremely robust, but the mean is both nonresistant and nonrobust.

HYPOTHESIS TESTING OF CATEGORICAL AND RANKED DATA

Categorical (or contingency table) presentations of data can contain any single type of data, but generally the contents are collected and arranged so they can be classified as belonging to treatment and control groups, with the members of each of these groups then classified as belonging to one of two or more response categories (such as tumor/no tumor or normal/hyperplastic/neoplastic). For these cases, two forms of analysis are presented: Fisher's exact test (for the 2 × 2 contingency table) and the R × C (R, row; C, column) chi-square test (for large tables). It should be noted, however, that versions of both of these tests permit the analysis of any size of contingency table.

The analysis of rank data—what is generally called *nonparametric statistical analysis*—is an exact parallel of the more traditional (and familiar) parametric methods. There are methods for the single-comparison case (just as Student's *t*-test is used) and for the multiple-comparison case (just as ANOVA is used) with appropriate post hoc tests for exact identification of the significance with a set of groups. Four tests are presented for evaluating statistical significance in rank data: the Wilcoxon rank-sum test, distribution-free multiple comparisons, Mann–Whitney U test, and the Kruskal–Wallis nonparametric ANOVA. For each of these tests, tables of distribution values for the evaluations of results can be found in any of a number of reference volumes [23]. It should be clearly understood that, for data that do not fulfill the necessary assumptions for parametric analysis, these nonparametric methods are either as powerful or, in fact, more powerful than the equivalent parametric test.

Fisher's Exact Test

Fisher's exact test should be used to compare two sets of discontinuous quantal (all or none) data. Small sets of such data can be checked by contingency data tables, such as those of Finney et al. [24]. Larger sets, however, require computation. These include frequency data such as incidences of mortality or certain histopathological findings. Thus, the data can be expressed as ratios. These data do not fit on a continuous scale of measurement but usually involve numbers of responses classified as either negative or positive—that is, a contingency table situation [15].

The analysis is started by setting up a 2 × 2 contingency table to summarize the numbers of positive and negative responses, as well as the totals of these, as follows:

	Positive	Negative	Total
Group I	A	B	$A + B$
Group II	C	D	$C + D$
Totals	$A + C$	$B + D$	$A + B + C + D = N_{total}$

Using the earlier set of symbols, the formula for P appears as follows*:

$$P = \frac{(A+B)!(C+D)!(A+C)!(B+D)!}{N!A!B!C!D!}$$

The exact test produces a probability (P) that is the sum of the earlier calculation repeated for each possible arrangement of the numbers in the earlier cells (i.e., A, B, C, and D) showing an association equal to or stronger than that between the two variables. The P resulting from these computations will be the exact one- or two-tailed probability depending on which of these two approaches is being employed. This value tells us if the groups differ significantly (with a probability less than 0.05, say) and the degree of significance.

* $A!$ is A factorial; for example, for 4!, this would be (4)(3)(2)(1) = 24.

Assumptions and Limitations

- Tables are available that provide individual exact probabilities for small sample size contingency tables (see Zar [25]).
- Fisher's exact test must be used in preference to the chi-square test for small cell sizes.
- The probability resulting from a two-tailed test is exactly double that of a one-tailed test from the same data.
- Ghent [26] has developed and proposed a good (although, if performed by hand, laborious) method extending the calculation of exact probabilities to 2 × 3, 3 × 3, and R × C contingency tables.
- Fisher's probabilities are not necessarily symmetric. Although some analysts will double the one-tailed *p*-value to obtain the two-tailed result, this method is usually overly conservative.

2 × 2 Chi-Square Test

Although Fisher's exact test is preferable for the analysis of most 2 × 2 contingency tables in toxicology, the chi-square test is still widely used and is preferable in a few unusual situations (particularly if cell sizes are large yet only limited computational support is available). The formula is simply

$$\chi^2 = \frac{(O_1 - E_1)^2}{E_1} = \frac{(O_2 - E_2)^2}{E_2}$$

$$= \sum \frac{(O_i - E_i)^2}{E_i}$$

where

*O*s are observed numbers (or counts)
*E*s are expected numbers

The common practice in toxicology is for the observed figures to be test or treatment group counts. The expected figure is calculated as

$$\mathrm{E} = \frac{(\text{column total})(\text{row total})}{\text{grand total}}$$

for each box or cell in a contingency table. Our degrees of freedom are (R − 1)(C − 1) = (2 − 1)(2 − 1) = 1. Looking at a chi-square table for 1 degree of freedom, we see that this is greater than the test statistic at 0.05 (3.84) but less than that at 0.01 (6.64) so $0.05 > p > 0.01$.

Assumptions and Limitations

Assumptions

1. Data are univariate and categorical.
2. Data are from a multinomial population.
3. Data are collected by random, independent sampling.
4. Groups being compared are of approximately same size, particularly for small group sizes.

When to use

1. The data are of a categorical (or frequency) nature.
2. The data fit the earlier assumptions.
3. Goodness-to-fit to a known form of distribution is being tested.
4. Cell sizes are large.

When not to use

1. The data are continuous rather than categorical.
2. Sample sizes are small and very unequal.
3. Sample sizes are too small (e.g., when total *N* is less than 50 or if any expected value is less than 5).
4. Any 2 × 2 comparison is being performed (use Fisher's exact test instead).

R × C Chi-Square Test

The R × C chi-square test can be used to analyze discontinuous (frequency) data as in Fisher's exact test or the 2 × 2 chi-square test; however, in the R × C test, we wish to compare three or more sets of data. An example would be the comparison of the incidence of tumors among mice on three or more oral dosage levels. We can consider the data as positive (tumors) or negative (no tumors). The expected frequency for any box is equal to (row total)(column total)/(N_{total}). As in Fisher's exact test, the initial step is to set up a table (this time an R × C contingency table):

	Positive	Negative	Total
Group I	A_1	B_1	$A_1 + B_1 = N_1$
Group II	A_2	B_2	$A_2 + B_2 = N_2$
	↓	↓	↓
Group R	A_R	B_R	$A_R + B_R = N_R$
Total	N_A	N_B	N_{total}

Using these symbols, the formula for chi-square (χ^2) is

$$\chi^2 = \frac{N_{total}^2}{N_A N_B N_K}\left(\frac{A_1^2}{N_1} + \frac{A_2^2}{N_2} + \cdots + \frac{A_K^2}{N_2} - \frac{N_A^2}{N_{tot}}\right)$$

The resulting χ^2 value is compared to table values [16] according to the number of degrees of freedom, which is equal to (R − 1)(C − 1). If χ^2 is smaller than the table value at the 0.05 probability level, the groups are not significantly different. If the calculated χ^2 is larger, there is some difference among the groups, and 2 × R chi-square or Fisher's exact tests will have to be compared to determine which groups differ from which other groups.

Assumptions and Limitations

1. The test is based on data being organized in a table with *cells* (in the following table, *A*, *B*, *C*, and *D* are cells).
2. None of the expected frequency values is less than 5.0.
3. The chi-square test is always one tailed.
4. Without the use of some form of correction, the test becomes less accurate as the differences between group sizes increase.
5. The results from each additional column (group) are approximately additive. Due to this characteristic, the chi-square test can be readily used for evaluating any R × C combination.
6. The results of the chi-square calculation must be a positive number.
7. The test is weak with either small sample sizes or when the expected frequency in any cell is less than 5 (this latter limitation can be overcome by pooling, or combining, cells).
8. Test results are independent of order of cells, unlike Kolmogorov–Smirnov.
9. The test can be used to test the probability of validity of any distribution.

		Columns (C)		
Rows (R)	**No Effect**	**Control**	**Treated**	**Total**
		A	*B*	*A* + *B*
		C	*D*	*C* + *D*
Total		*A* + *C*	*B* + *D*	*A* + *B* + *C* + *D*

Wilcoxon Rank-Sum Test

The Wilcoxon rank-sum test is commonly used for the comparison of two groups of nonparametric (interval or not normally distributed) data, such as those that are not measured exactly but rather as falling within certain limits (e.g., how many animals died during each hour of an acute study). The test is also used when there is no variability (variance = 0) within one or more of the groups we wish to compare [15].

The data in both groups being compared are initially arranged and listed in the order of increasing value, then each number in the two groups must receive a rank value. Beginning with the smallest number in either group (which is given a rank of 1.0), each number is assigned a rank. If there are duplicate numbers (called *ties*), then each value of equal size will receive the median rank for the entire identically sized group; thus, if the lowest number appears twice, both figures receive a rank of 1.5. This, in turn, means that the ranks of 1.0 and 2.0 have been used and that the next highest number has a rank of 3.0. If the lowest number appears three times, then each is ranked as 2.0, and the next number has a rank of 4.0; thus, each tied number gets a median rank. This process continues until all of the numbers are ranked. Each of the two columns of ranks (one for each group) is totaled, giving the sum of ranks for each group being compared. As a check, we can calculate the value:

$$\frac{(N)(N+1)}{2}$$

where N is the total number of data in both groups. The result should be equal to the sum of ranks for both groups.

The sums of rank values are compared to table values [27] to determine the degree of significant differences, if any. These tables include two limits (an upper and a lower) that are dependent on the probability level. If the number of data is the same in both groups ($N_1 \neq N_2$), then the lesser sum of ranks (smaller N) is compared to the table limits to find the degree of significance. Normally, the comparison of the two groups ends here, and the degree of significant difference can be reported.

Distribution-Free Multiple Comparison

The distribution-free multiple comparison test should be used to compare three or more groups of nonparametric data. These groups are then analyzed two at a time for any significant differences [28]. The test can be used for data similar to those compared by the rank-sum test. We often employ this test for reproduction and mutagenicity studies (such as comparing survival rates of offspring of rats fed various amounts of test materials in the diet).

As shown in Example 9.2, two values must be calculated for each pair of groups: the difference in mean ranks and the probability level value against which the difference will be compared. To determine the difference in mean ranks, we must first arrange the data within each of the groups in the order of increasing values, then we must assign rank values, beginning with the smallest overall figure. Note that this ranking is similar to that in the Wilcoxon test except that it applies to more than two groups. The ranks are then added for each of the groups. As a check, the sum of these values should equal:

$$\frac{(N_{total})(N_{total}+1)}{2}$$

where N_{total} is the total number of figures from all groups. Next, we can find the mean rank (R) for each group by dividing the sum of ranks by the numbers in the data (N) in the group. These mean ranks are then taken in those pairs that we want to compare (usually each test group vs. the control), and the differences are found ($|R_1 - R_2|$). This value is expressed as an absolute figure; that is, it is always a positive number.

The second value for each pair of groups (the probability value) is calculated from the expression:

$$z\left[\frac{a}{K}(K-1)\right]\sqrt{\frac{N_{total}(N_{total}+1)}{12}}\sqrt{\frac{1}{N_1}\frac{1}{N_2}}$$

where

- a is the level of significance for the comparison (usually 0.05, 0.01, 0.001, etc.)
- K is the total number of groups
- z is a figure obtained from a normal probability table and determining the corresponding z-score

The result of the probability value calculation for each pair of groups is compared to the corresponding mean difference $|R_1 - R_2|$. If $|R_1 - R_2|$ is smaller, then there is no significant difference between the groups. If it is larger, then the groups are different, and $|R_1 - R_2|$ must be compared to the calculated probability values for $a = 0.01$ and $a = 0.001$ to find the degree of significance.

Example 9.2

Consider the set of data provided earlier (ranked in increasing order), which could represent the proportion of rats surviving given periods of time during diet inclusion of a test chemical at four dosage levels (survival index).

I		II		III		V	
5.0 mg/kg		2.5 mg/kg		1.25 mg/kg		0.0 mg/kg	
% Value	Rank	% Value	Rank	% Value	Rank	% Value	Rank
40	2.0	40	2.0	50	5.5	60	9.0
40	2.0	50	5.5	50	5.5	60	9.0
50	5.5	80	12.0	60	9.0	80	12.0
100	17.5	80	12.0	100	17.5	90	14.0
		100	17.5	100	17.5	100	17.5
						100	17.5
Sum of ranks	27.0		49.0		55.0		79.0

$N_I = 4$, $N_{II} = 5$, $N_{III} = 5$, $N_{IV} = 6$ $N_{total} = 20$

Check sums of ranks = 210, $(20 \times 21)/2 = 210$
Mean ranks (R)

$$R_1 = \frac{27.0}{4} = 6.75 \qquad R_2 = \frac{49.0}{5} = 9.80$$

$$R_3 = \frac{55.0}{5} = 11.00 \qquad R_4 = \frac{79.0}{6} = 13.17$$

Comparison Groups	R_1–R_2	Probability Test Values
5.0 vs. 0.0	6.42	$\left(\frac{0.05}{4(3)}\right) = Z_{0.00417} = 2.637$
		$\sqrt{\frac{(20)(21)}{12}}\sqrt{\frac{1}{4}+\frac{1}{6}} = 10.07$
2.5 vs. 0.0	3.37	$\left(\frac{0.05}{4(3)}\right) = Z_{0.00417} = 2.637$
		$\sqrt{\frac{(20)(21)}{12}}\sqrt{\frac{1}{5}+\frac{1}{6}} = 9.45$
1.25 vs. 0.0	2.17	$\left(\frac{0.05}{4(3)}\right) = Z_{0.00417} = 2.637$
		$\sqrt{\frac{(20)(21)}{12}}\sqrt{\frac{1}{4}+\frac{1}{6}} = 10.07$

Because each of the $|R_1 - R_2|$ values is smaller than the corresponding probability calculation, the pairs of groups compared are not different at the 0.05 level of significance.

Assumptions and Limitations

1. As with the Wilcoxon rank-sum test, too many tied ranks inflate the false positive.
2. Generally, this test should be used as a post hoc comparison after Kruskal–Wallis.

Mann–Whitney U Test

This is a nonparametric test in which the data in each group are first ordered from lowest to highest values, then the entire set (both control and treated values) is ranked, with the average rank being assigned to tied values. The ranks are then summed for each group, and U is determined according to

$$U_t = n_c n_t + \frac{n_t\left(n_t + 1\right)}{2} - R_t$$

$$U_c = n_c n_t + \frac{n_c\left(n_c + 1\right)}{2} - R_c$$

where

n_c and n_t are the sample sizes for the control and treated groups, respectively

R_c and R_t are the sums of ranks for the control and treated groups, respectively

For the level of significance for a comparison of the two groups, the larger value of U_c or U_t is used. This is compared to critical values as found in tables [29].

With the earlier discussion and methods in mind, we can now examine the actual variables that we encounter in teratology studies. These variables can be readily divided into two groups: measures of lethality and measures of teratogenic effect [30]. Measures of lethality include (1) corpora lutea per pregnant female, (2) implants per pregnant female, (3) live fetuses per pregnant female, (4) percentage of preimplantation loss per pregnant female, (5) percentage of resorptions per pregnant female, and (6) percentage of dead fetuses per pregnant female. Measures of teratogenic effect include (1) percentage of abnormal fetuses per litter, (2) percentage of litters with abnormal fetuses, and (3) fetal weight gain. As demonstrated in Example 9.3, the Mann–Whitney U test is employed for the count data, but which test should be employed for the percentage variables should be decided on the same grounds as described later under reproduction studies.

Example 9.3

In a 2-week study, the levels of serum cholesterol in treatment and control animals are successfully measured and assigned ranks as follows:

Treatment		Control	
Value	**Rank**	**Value**	**Rank**
10	1	19	4
18	3	28	13
26	10.5	29	14.5
31	16	26	10.5
15	2	35	19
24	8	23	7
22	6	29	14.5
33	17	34	18
21	5	38	20
25	9	27	12
Sum of ranks	77.5		132.5

The critical value for one-tailed $p \le 0.05$ is $U \ge 73$. We then calculate

$$U_t = (10)(10) + \frac{10(10+1)}{2} - 77.5$$

$$= 100 + \frac{110}{2} - 77.5 = 77.5$$

$$U_c = (10)(10) + \frac{10(10+1)}{2} - 132.5 = 2.5$$

Because 77.5 is greater than 73, these groups are significantly different at the 0.05 level.

Assumptions and Limitations

1. It does not matter whether the observations are ranked from smallest to largest or vice versa.
2. This test should not be used for paired observations.
3. The test statistics from a Mann–Whitney test are linearly related to those of Wilcoxon. The two tests will always yield the same result. The Mann–Whitney is presented here for historical completeness, as it has been much favored in reproductive and developmental toxicology studies; however, it should be noted that the authors do not include it in the decision tree for method selection (Figure 9.2).

Kruskal–Wallis Nonparametric ANOVA

The Kruskal–Wallis nonparametric one-way ANOVA should be the initial analysis performed when we have three or more groups of data that are by nature nonparametric (not a normally distributed population, data of a discontinuous nature, or all the groups being analyzed not being from the same population) but not of a categorical (or quantal) nature. Commonly, these will be either rank-type evaluation data (such as behavioral toxicity observation scores) or reproduction study data. The analysis is initiated [31] by ranking all the observations from the combined groups to be analyzed. Ties are given the average rank of the tied values (i.e., if two values would tie for 12th rank and therefore are ranked 12th and 13th, then both would be assigned the average rank of 12.5).

The sum of ranks of each group (r_1, r_2, …, r_k) is computed by adding all the rank values for each group. The test value H is then computed as

$$H = \frac{12}{n(n-1)} \sum \frac{r_1^2}{n_1} + \frac{r_2^2}{n_2} + \cdots \frac{r_k^2}{n_k} - 3(n+1)$$

where n_1, n_2, …, n_k are the number of observations in each group. The test statistic is then compared with a table of H values. If the calculated value of H is greater than the table value for the appropriate number of observations in each group, there is significant difference between the groups, but further testing (using the distribution-free multiple comparisons method) is necessary to determine where the difference lies (as demonstrated in Example 9.4).

Example 9.4

As part of a neurobehavioral toxicology study, righting reflex values (whole numbers ranging from 0 to 10) were determined for each of five rats in each of three groups. The values observed and their ranks are as follows:

Control Group		5 mg/kg Group		10 mg/kg Group	
Reflex Score	**Rank**	**Reflex Score**	**Rank**	**Reflex Score**	**Rank**
0	2	1	5	4	11
0	2	2	7.5	4	11
0	2	2	7.5	5	13
1	5	3	9	8	14.5
1	5	4	11	8	14.5
Sum of ranks	16		40		64

From these, the H value is calculated as

$$H = \frac{12}{15(15+1)}\left[\frac{16^2}{5} + \frac{40^2}{5} + \frac{64^2}{5}\right] - 3(15+1)$$

$$= \frac{12}{240}\left[\frac{256 + 1600 + 4096}{5}\right] - 48$$

$$= \frac{1}{20}(1190.4) - 48$$

$$= 59.52 - 48$$

$$= 11.52$$

Consulting a table of values for H, we find that for the case where we have three groups of five observations

each, the test values are 4.56 (for $p = 0.10$), 5.78 ($p = 0.05$), and 7.98 (for $p = 0.01$). As our calculated H is greater than the $p = 0.01$ test value, we have determined that there is a significant difference between the groups at the level of $p < 0.01$ and would now have to continue to a multiple comparisons test to determine where the difference is.

Assumptions and Limitations

1. The test statistic H is used for both small and large samples.
2. When we find a significant difference, we do not know which groups are different. It is not correct to then perform a Mann–Whitney U test on all possible combinations; rather, a multiple comparison method must be used, such as the distribution-free multiple comparisons.
3. Data must be independent for the test to be valid.
4. Too many tied ranks will decrease the power of this test and lead to increased false-positive levels.
5. When $k = 2$, the Kruskal–Wallis chi-square value has 1 degree of freedom. This test is identical to the normal approximation used for the Wilcoxon rank-sum test. As noted in previous sections, a chi-square with 1 degree of freedom can be represented by the square of a standardized normal random variable. In the case of $k = 2$, the H statistic is the square of the Wilcoxon rank-sum z-test (without the continuity correction).
6. The effect of adjusting for tied ranks is to slightly increase the value of the test statistic, H; therefore, omission of this adjustment results in a more conservative test.

Log-Rank Test

The log-rank test is a statistical methodology for comparing the distribution of time until the occurrence of the event in independent groups. In toxicology, the most common event of interest is death or occurrence of a tumor, but it could just as well be liver failure, neurotoxicity, or any other event that occurs only once in an individual. The elapsed time from initial treatment or observation until the *event* is the *event time*, often referred to as *survival time*, even when the event is not death.

The log-rank test provides a method for comparing risk-adjusted event rates, useful when test subjects in a study are subject to varying degrees of opportunity to experience the event. Such situations arise frequently in toxicology studies due to the finite duration of the study, early termination of the animal, or interruption of treatment before the event occurs. Examples where use of the log-rank test might be appropriate include comparing survival times in carcinogenicity bioassay animals that are given a new treatment with those in the control group or comparing times to liver failure for several dose levels of a new NSAID where the animals are treated for 10 weeks or until cured, whichever comes first.

If every animal were followed until the event occurrence, the event times could be compared between two groups using the Wilcoxon rank-sum test; however, some animals may die or complete the study before the event occurs. In such cases, the actual time of the event is unknown because the event does not occur while under study observation. The event times for these animals are based on the last known time of study observation and are referred to as *censored* observations because they represent the lower bound of the true unknown event times. The Wilcoxon rank-sum test can be highly biased in the presence of the censored data.

The null hypothesis tested by the log-rank test is that of equal event time distributions among groups. Equality of the distributions of event times implies similar event rates among groups, not only for the clinical trial as a whole but also for any arbitrary time point during the trial. Rejection of the null hypothesis indicates that the event rates differ among groups at one or more time points during the study.

The idea behind the log-rank test for the comparison of two life tables is simple: If there were no difference between the groups, the total deaths occurring at any time should split between the two groups at that time. So, if the numbers at risk in the first and second groups in, say, the sixth month were 70 and 30, respectively, and 10 deaths occurred in that month, then we would expect

$$10 \times \frac{70}{70+30} = 7$$

of these deaths to have occurred in the first group, and

$$10 \times \frac{30}{70+30} = 3$$

of the deaths to have occurred in the second group.

A similar calculation can be made at each time of death (in either group). By adding together the results of all such calculations for the first group, we obtain a single number, the extent of exposure (E_1), which represents the expected number of deaths in that group if the two groups had the same distribution of survival times. An extent of exposure (E_2) can be obtained for the second group in the same way. Let O_1 and O_2 denote the actual total numbers of deaths in the two groups. A useful arithmetic check is that the total number of deaths ($O_1 + O_2$) must equal the sum of the extents of exposure ($E_1 + E_2$). The discrepancy between the Os and Es can be measured by the quantity

$$x^2 = \frac{\left(|O_1 - E_1| - 1/2\right)^2}{E_1} + \frac{\left(|O_2 - E_2| - 1/2\right)^2}{E_2}$$

For rather obscure reasons, x^2 is known as the log-rank statistic. An approximate significance test of the null hypothesis of identical distributions of survival time in the two groups is obtained by referring x^2 to a chi-square distribution on 1 degree of freedom. This is demonstrated in Example 9.5.

Example 9.5

In a study of the effectiveness of a new monoclonal antibody to treat specific cancer, the times to reoccurrence of the cancer in treated animals in weeks were as follows:

Control Group			Treatment Group		
1	5	11	6	10	22
1	5	12	6	11	23
2	8	12	6	13	25
2	8	15	6	16	32
3	8	17	7	17	32
4	8	22	9	19	34
4	11	23	10	20	35

The table provided later presents the calculations for the log-rank test applied to these times. A chi-square value of 13.6 is significant at the $p < 0.001$ level.

Illustration

$$t = 23, \quad 2\times\frac{6}{7} = 1.7143, \quad 2\times\frac{1}{7} = 0.2857$$

Test of significance

$$x^2 = \frac{\left(|O_1 - E_1| - 1/2\right)^2}{E_1} + \frac{\left(|O_2 - E_2| - 1/2\right)^2}{E_2}$$

$$= \frac{\left(|9 - 19.2| - 1/2\right)^2}{19.2} + \frac{\left(|21 - 10.8| - 1/2\right)^2}{10.8} = 13.6$$

Estimate of relative risk

$$\hat{\theta} = \frac{9/19.2}{21/10.8} = 0.24$$

The log-rank test as presented by Peto et al. [32] uses the product-limit life-table calculations rather than the actuarial estimators shown earlier. The distinction is unlikely to be of practical importance unless the grouping intervals are very coarse.

Peto and Pike [33] suggest that the approximation in treating the null distribution of χ^2 as a chi-square is conservative, as it will tend to understate the degree of statistical significance. In the formula for χ^2, we have used the continuity correction of subtracting 1/2 from $|O_1 - E_1|$ and $|O_2 - E_2|$ before squaring. This is recommended by Peto et al. [32] when, as in nonrandomized studies, the permutational argument does not apply. Peto et al. [32] give further details of the log-rank test and its extension to comparisons of more than two treatment groups and to tests that control for categorical confounding factors.

Assumptions and Limitations

1. The endpoint of concern is, or is defined so it is, right censored; that is, once it happens, it does not recur. Examples are death or a minimum or maximum value of an enzyme or physiologic function (such as respiration rate).
2. The method makes no assumptions on distribution.
3. Many variations of the log-rank test for comparing survival distributions exist. The most common variant has the form

$$x^2 = \frac{\left(O_1 - E_1\right)^2}{E_1} + \frac{\left(O_2 - E_2\right)^2}{E_2}$$

where O_i and E_i are computed for each group, as in the formulas given previously. This statistic also has an approximate chi-square distribution with 1 degree of freedom under H_0. A continuity correction can also be used to reducing the numerators by 1/2 before squaring. Use of such a correction leads to even further conservatism and may be omitted when sample sizes are moderate or large.

Time	At Risk			Relapses			Extent of Exposure		
(*t*)	T	C	Total	T	C	Total	T	C	Total
1	21	21	42	0	2	2	1.0000	1.0000	2
2	21	19	40	0	2	2	1.0500	0.9500	2
3	21	17	38	0	1	1	0.5526	0.4474	1
4	21	16	37	0	2	2	1.1351	0.8649	2
5	21	14	35	0	2	2	1.2000	0.8000	2
6	20.5	12	32.5	3	0	3	1.8923	1.1077	3
7	17	12	29	1	0	1	0.5862	0.4138	1
8	16	12	28	0	4	4	2.2857	1.7143	4
10	14.5	8	22.5	1	0	1	0.6444	0.3556	1
11	12.5	8	20.5	0	2	2	1.2295	0.7705	2
12	12	6	18	0	2	2	1.3333	0.6667	2
13	12	4	16	1	0	1	0.7500	0.2500	1
15	11	4	15	0	1	1	0.7333	0.2667	1
16	11	3	14	1	0	1	0.7857	0.2143	1
17	9.5	3	12.5	0	1	1	0.7600	0.2400	1
22	7	2	9	1	1	2	1.5556	0.4444	2
23	6	1	7	1	1	2	1.7143	0.2857	2
Total				9	21	30	19.2080	10.7920	30
					(O_1)	(O_2)	(E_1)	(E_2)	

4. The Wilcoxon rank-sum test could be used to analyze the event times in the absence of censoring. A generalized Wilcoxon test, sometimes called the *Gehan test*, based on an approximate chi-square distribution, has been developed for use in the presence of censored observations. Both the log-rank and the generalized Wilcoxon tests are nonparametric tests, and they require no assumptions regarding the distribution of event times. When the event rate is greater early in the trial than toward the end, the generalized Wilcoxon test is the more appropriate test because it gives greater weight to the earlier differences.

5. Survival and failure times often follow the exponential distribution. If such a model can be assumed, a more powerful alternative to the log-rank test is the likelihood ratio test. This parametric test assumes that event probabilities are constant over time; that is, the chance that a patient becomes event positive at time t given that he is event negative up to time t does not depend on t. A plot of the negative log of the event times distribution showing a linear trend through the origin is consistent with exponential event times.
6. Life tables can be constructed to provide estimates of the event time distributions. Estimates commonly used are known as the Kaplan–Meier estimates.

HYPOTHESIS TESTING: UNIVARIATE PARAMETRIC TESTS

Univariate case data (where each datum is defined by one treatment and one effect variable) from normally distributed populations generally have a higher information value associated with them, but the traditional hypothesis-testing techniques (which include all the methods described in this chapter) are generally neither resistant nor robust. All the data analyzed by these methods are also, effectively, continuous; that is, at least for practical purposes, the data may be represented by any number, and each such data number has a measurable relationship to other data numbers.

Student's *t*-Test (Unpaired *t*-Test)

Pairs of groups of continuous, randomly distributed data are compared via this test. We can use this test to compare three or more groups of data, but they must be intercompared by examination of two groups taken at time and are preferentially compared by ANOVA. Usually, this means comparison of a test group vs. a control group, although two test groups may be compared as well. To determine which of the three types of *t*-tests described in this chapter should be employed, the *F*-test is usually performed first. This will tell us if the variances of the data are approximately equal, which is a requirement for the use of the parametric methods. If the *F*-test indicates homogeneous variances, and the numbers of data within the groups (N) are equal, then Student's *t*-test is the appropriate procedure [15]. If the *F* is significant (the data are heterogeneous) and the two groups have equal numbers of data, the modified Student's *t*-test is applicable [34].

The value of t for Student's *t*-test is calculated using the following formula:

$$t = \frac{X_1 - X_2}{\sum D_1^2 + \sum D_2^2} \sqrt{\frac{N_1 N_2}{N_1 + N_2}\left(N_1 + N_2 - 2\right)}$$

where

$$\sum D^2 = \frac{N\sum X^2 - \left(\sum X\right)^2}{N}$$

The value of t obtained from the earlier calculations is compared to the values in a *t*-distribution table according to the appropriate number of degrees of freedom (df). If the *F* value is not significant (i.e., variances are homogeneous), the df = $N_1 + N_2 - 2$. If the *F* is significant and $N_1 = N_2$, then the df = $N - 1$. Although this case indicates a nonrandom distribution, the modified *t*-test is still valid. If the calculated value is larger than the table value at $p = 0.05$, it may then be compared to the appropriate other table values in the order of decreasing probability to determine the degree of significance between the two groups. Example 9.6 demonstrates this methodology.

Example 9.6

Suppose we wish to compare two groups (at test and control groups) of dog weights following inhalation of a vapor. First, we would test for homogeneity of variance using the *F*-test. Assuming that this test gave negative (homogeneous) results, we would perform the *t*-test as follows:

	Test Weight		Control Weight	
Dog	X_1 (kg)	X_1^2	X_2 (kg)	X_2^2
1	8.3	68.89	8.4	70.56
2	8.8	77.44	10.2	104.04
3	9.3	86.49	9.6	92.16
4	9.3	86.49	9.4	88.36
Sums	$\sum X_1 = 35.7$	$\sum X_1^2 = 319.31$	$\sum X_2 = 37.6$	$\sum X_2^2 = 355.12$
Means	8.92		9.40	

The difference in means = 9/40 = 8.92 = 0.48.

$$\sum D_1^2 = \frac{4(319.31) - (35.7)^2}{4} = \frac{2.75}{4} = 0.6875$$

$$\sum D_2^2 = \frac{4(355.12) - (37.6)^2}{4} = \frac{6.72}{4} = 1.6800$$

$$t = \frac{0.48}{\sqrt{0.6875 + 1.6800}} \sqrt{\frac{4(4)}{4+4}(4+4)} = 1.08$$

The table value for t at the 0.05 probability level for (4 + 4 – 2), or 6 degrees of freedom, is 2.447; therefore, the dog weights are not significantly different at $p = 0.05$.

Assumptions and Limitations

1. The test assumes that the data are univariate, continuous, and normally distributed.
2. Data are collected by random sampling.
3. The test should be used when the assumptions in 1 and 2 are met and there are only two groups to be compared.
4. Do not use when the data are ranked, when the data are not approximately normally distributed, or when more than two groups are to be compared. Do not use for paired observations.

5. This is the most commonly misused test method, except in those few cases where one is truly comparing only two groups of data and the group sizes are roughly equivalent. It is not valid for multiple comparisons (because of resulting additive errors) or where group sizes are very unequal.
6. The test is robust for moderate departures from normality, and, when N_1 and N_2 are approximately equal, it is robust for moderate departures from homogeneity of variances.
7. The main difference between the *z*-test and the *t*-test is that the *z*-statistic is based on a known SD (σ) while the *t*-statistic uses the sample SD (*s*) as an estimate of σ. With the assumption of normally distributed data, the variance σ^2 is more closely estimated by the sample variance s^2 as *n* gets large. It can be shown that the *t*-test is equivalent to the *z*-test for infinite degrees of freedom. In practice, a large sample is usually considered to be $n \geq 30$.

Cochran *t*-Test

The Cochran test should be used to compare two groups of continuous data when the variances (as indicated by the *F*-test) are heterogeneous and the numbers of data within the groups are not equal ($N_1 \neq N_2$). This is the situation, for example, when the data, although expected to be, are not randomly distributed [3]. Two *t* values are calculated for this test: the observed *t* (t_{obs}) and the expected *t* (t'). The observed *t* is obtained by

$$t_{obs} = \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{W_1 + W_2}}$$

where $W = \text{SEM}^2$ (standard error of the mean squared) = S^2/N, where variance *S* can be calculated from

$$S = \frac{N\sum X^2 - \left(\sum X\right)^2}{\left(N/N-1\right)}$$

The value for t' is obtained from

$$t' = \frac{t'_1 W_1 + t'_2 W_2}{W_1 + W_2}$$

where t'_1 and t'_2 are values for the two groups taken from the *t*-distribution table corresponding to $(N - 1)$ degrees of freedom (for each group) at the 0.05 probability level (or such level as one may select).

The calculated t_{obs} is compared to the calculated t' value (or values, if t' values were prepared for more than one probability level). If t_{obs} is smaller than a t', the groups are not considered to be significantly different at that probability level. This procedure is shown in Example 9.7.

Example 9.7

Using the RBC count comparison from the discussion of the *F*-test (with $N_1 = 5$, $N_2 = 4$), the following results were determined:

$$\bar{X}_1 = \frac{37.60}{5} = 7.52 \quad W_1 = \frac{0.804}{5} = 0.1608$$

$$\bar{X}_2 = \frac{29.62}{4} = 7.52 \quad W_2 = \frac{0.025}{4} = 0.1608$$

(Note that S^2 values of 0.804 and 0.025 are calculated using the formula set forth in the section on "Bartlett's Test for Homogeneity of Variance.")

$$t_{obs} = \frac{7.52 - 7.40}{\sqrt{0.1608 + 0.0062}} = 0.29$$

From the *t*-distribution table, we use $t_1 = 2.776$ (df = 4) and $t_2 = 3.182$ (df = 3) for the 0.05 level of significance; there is no statistical difference at $p = 0.05$ between the two groups.

Assumptions and Limitations

1. The test assumes that the data are univariate, continuous, and normally distributed and that group sizes are unequal.
2. The test is robust for moderate departures from normality and very robust for departures from equality of variances.

F-Test

This is a test of the homogeneity of variances between two groups of data [15]. It is used in two separate cases. The first is when Bartlett's test indicates heterogeneity of variances among three or more groups (i.e., it is used to determine which pairs of groups are heterogeneous). Second, the *F*-test is the initial step in comparing two groups of continuous data that we would expect to be parametric (two groups not usually being compared using ANOVA), the results indicating whether the data are from the same population and whether subsequent parametric comparisons would be valid. The *F* is calculated by dividing the larger variance (S_1^2) by the smaller one (S_2^2). S^2 is calculated as

$$S = \frac{N\sum X^2 - \left(\sum X\right)^2}{\left(N/N-1\right)}$$

where

N is the number of data in the group

X represents the individual values within the group

Frequently, S^2 values may be obtained from ANOVA calculations. Use of this is demonstrated in Example 9.8. The

calculated F value is compared to the appropriate number in an F-value table for the appropriate degrees of freedom ($N - 1$) in the numerator (along the top of the table) and in the denominator (along the side of the table). If the calculated value is smaller, it is not significant, and the variances are considered homogeneous (and Student's t-test would be appropriate for further comparison). If the calculated F value is greater, F is significant and the variances are heterogeneous (and the next test would be a modified Student's t-test if $N_1 = N_2$ or the Cochran t-test if $N_1 \neq N_2$; see Figure 9.2 to review the decision tree).

Example 9.8

If we wished to compare the RBC counts of rats receiving a test material in their diet with the RBC counts of control rats, we might obtain the following results:

Test Weight		Control Weight	
X_1 (kg)	X_1^2	X_2 (kg)	X_2^2
8.3	68.89	8.4	70.56
8.8	77.44	10.2	104.04
9.3	86.49	9.6	92.16
9.3	86.49	9.4	88.36
$\sum X_1 = 35.7$	$\sum X_1^2 = 319.31$	$\sum X_2 = 37.6$	$\sum X_2^2 = 355.12$
8.92		940	
Test RBC		**Control RBC**	
X_1	X_1^2	X_2	X_2^2
8.23	67.73	7.22	52.13
8.59	73.79	7.55	57.00
7.51	56.40	7.53	56.70
6.60	46.56	7.32	53.58
6.67	44.49		
$\hat{A}X_1 = 37.60$	$\hat{A}X_1^2 = 285.97$	$\hat{A}X_2 = 29.62$	$\hat{A}X_2^2 = 219.41$

Variance for X_1

$$S_1^2 = \frac{\left(5(285.97) - (37.60)^2/5\right)}{5-1} = 0.804$$

Variance for X_2

$$S_3^2 = \frac{\left(4(219.41) - (29.62)^2/4\right)}{4-1} = 0.804$$

$$F = \frac{0.804}{0.025} = 32.16$$

From a table for F values, for 4 (numerator) vs. 3 (denominator) degrees of freedom, we read the limit of 9.12 at the 0.05 level. As our calculated value is larger (and, therefore, significant), the variances are heterogeneous and the Cochran t-test would be appropriate for comparison of the two groups of data.

Assumptions and Limitations

1. This test could be considered as a two-group equivalent of Bartlett's test.
2. If the test statistic is close to 1.0, the results are (of course) not significant.
3. The test assumes normality and independence of data.

Analysis of Variance

ANOVA is used for the comparison of three or more groups of continuous data when the variances are homogeneous and the data are independent and normally distributed. A series of calculations are required for ANOVA, starting with the values within each group being added (ΣX) and then these sums being added ($\Sigma\Sigma X$). Each figure within the groups is squared, and these squares are then summed (ΣX^2) and these sums added ($\Sigma\Sigma X^2$). Next the correction factor (CF) can be calculated using the following formula:

$$\mathrm{CF} = \frac{\left(\sum_1^K \sum_1^K X\right)^2}{N_1 + N_2 + \cdots + N_k}$$

where

N is the number of values in each group
K is the number of groups

The total sum of squares (SS_{total}) is then determined as follows:

$$\mathrm{SS}_{total} = \sum_1^K \sum_1^N X^2 - \mathrm{CF}$$

In turn, the sum of squares between groups (SS_{bg}) is found from

$$\mathrm{SS}_{bg} = \frac{\left(\sum X_1\right)^2}{N_1} + \frac{\left(\sum X_2\right)^2}{N_2} + \cdots + \frac{\left(\sum X_k\right)^2}{N_k} - \mathrm{CF}$$

The sum of squares within group (SS_{wg}) is then the difference between the last two figures, or

$$\mathrm{SS}_{wg} = \mathrm{SS}_{total} - \mathrm{SS}_{bg}$$

Now, there are three types of degrees of freedom to determine. The first, total degrees of freedom, is the total number of data within all groups under analysis minus one ($N_1 + N_2 + \ldots + N_k - 1$). The second figure (the degrees of freedom between groups) is the number of groups minus one ($K - 1$). The last figure (the degrees of freedom within groups, or error df) is the difference between the first two figures ($\mathrm{df}_{total} - \mathrm{df}_{bg}$).

The next set of calculations requires the determination of the two mean squares (MSs) (MS_{bg} and MS_{wg}). These are the respective sum of square values divided by the corresponding df figures (MS = SS/df). The final calculation is that of the *F* ratio. For this, the MS between groups is divided by the MS within groups ($F = MS_{bg}/MS_{wg}$). A table of the results of these calculations (using data from Example 9.9 at the end of this section) would appear as follows:

	df	SS	MS	*F*
Between groups	3	0.04075	0.01358	4.94
Within groups	12	0.03305	0.00275	
Total	15	0.07380		

For interpretation, the *F* ratio value obtained in the ANOVA is compared to a table of *F* values. If $F \leq 1.0$, the results are not significant and comparison with the table values is not necessary. The degrees of freedom for the greater MS (MS_{bg}) are indicated along the top of the table. Then read down the side of the table to the line corresponding to the degrees of freedom for the lesser MS (MS_{wg}). The figure shown at the desired significance level (traditionally 0.05) is compared to the calculated *F* value. If the calculated number is smaller, there is no significant difference among the groups being compared. If the calculated value is larger, there is some difference, but further (post hoc) testing will be required before we know which groups differ significantly.

Example 9.9

Suppose we want to compare four groups of dog kidney weights, expressed as percentage of body weights, following an inhalation study. Assuming homogeneity of variance (from Bartlett's test), we could complete the following calculations:

	400 ppm	200 ppm	100 ppm	0 ppm
	0.43	0.49	0.34	0.34
	0.52	0.48	0.40	0.32
	0.43	0.40	0.42	0.33
	0.55	0.34	0.40	0.39
ΣX	1.93	1.71	1.56	1.38

$$\Sigma\Sigma X = 1.93 + 1.71 + 1.56 + 1.38 = 6.58$$

Next, these figures are squared:

	400 ppm	200 ppm	100 ppm	0 ppm
	0.1849	0.2401	0.1156	0.1156
	0.2704	0.2304	0.1600	0.1024
	0.1849	0.1600	0.1764	0.1089
	0.3025	0.1156	0.1600	0.1521
ΣX^2	0.9427	0.7461	0.6120	0.4790

$$\Sigma\Sigma X^2 = 0.9427 + 0.7461 + 0.6120 + 0.4790 = 2.7798$$

$$CF = \frac{(6.58)^2}{4+4+4+4} = 2.7060 = 0.04075$$

$$SS_{total} = 2.7798 - 2.7060 = 0.0738$$

$$SS_{bg} = \frac{(1.93)^2}{4} + \frac{(1.71)^2}{4} + \frac{(1.56)^2}{4} + \frac{(1.38)^2}{4} - 2.7060$$

$$= 0.04075$$

$$SS_{wg} = 0.07380 - 0.04075 = 0.03305$$

The total degrees of freedom (df) = 4 + 4 + 4 + 4 − 1 = 15

$$df_{bg} = 4 - 1 = 3$$

$$df_{bg} = 15 - 3 = 12$$

$$MS_{bg} = \frac{0.4075}{3} = 0.01358$$

$$MS_{wg} = \frac{0.03305}{12} = 0.00275$$

$$F = \frac{0.01358}{0.00275} = 4.94$$

Going to a table of *F* values, we find the 3 df_{bg} (greater MS) and 12 df_{wg} (lesser MS), and the 0.05 value of *F* is 3.49. Because our calculated value is greater, there is a difference among groups at the 0.05 probability level. To determine where the difference is, further comparisons by a post hoc test will be necessary.

Assumptions and Limitations

1. What is presented here is the workhorse of toxicology—the one-way ANOVA. Many other forms exist for more complicated experimental designs.
2. The test is robust for moderate departures from normality if the sample sizes are large enough; unfortunately, this is rarely the case in toxicology.
3. ANOVA is robust for moderate departures from equality of variances (as determined by Bartlett's test) if the sample sizes are approximately equal.
4. It is not appropriate to use a *t*-test (or a two-groups-at-a-time version of ANOVA) to identify where significant differences are within the design group. A multiple-comparison post hoc method must be used.

Post Hoc Tests

There is a wide variety of post hoc tests available to analyze data after finding significant results in an ANOVA. Each of these tests has advantages and disadvantages, proponents, and critics. Four of the tests are commonly used in toxicology and will be presented or previewed here. These are Dunnett's *t*-test and Williams's *t*-test. Two other tests that are available in many statistical packages are Turkey's method and the Student–Newman–Keuls method [25]. If ANOVA reveals no

significance, it is not appropriate to proceed to perform a post hoc test in hopes of finding differences. To do so would only be another form of multiple comparisons, increasing the type I error rate beyond the desired level.

Duncan's Multiple Range Test

Duncan's test [35] is used to compare groups of continuous and randomly distributed data (such as body weights or organ weights). The test normally involves three or more groups taken one pair at a time. It should follow only observation of a significant F value in the ANOVA and can serve to determine which group (or groups) differs significantly from which other group (or groups). There are two alternative methods of calculation. The selection of the proper one is based on whether the number of data (N) is equal or unequal in the groups.

Groups with Equal Numbers of Data ($N_1 = N_2$)

Two sets of calculations must be carried out: (1) the determination of the difference between the means of pairs of groups, and (2) the preparation of a probability rate against which each difference in means is compared (as shown in the first of the two examples in this section). The means (averages) are determined (or taken from the ANOVA calculation) and ranked in either decreasing or increasing order. If two means are the same, they take up two equal positions (thus, for four means, we could have ranks of 1, 2, 2, and 4 rather than 1, 2, 3, and 4). The groups are then taken in pairs, and the differences between the means ($\bar{X}_1 - \bar{X}_2$), expressed as positive numbers, are calculated. Usually, each pair consists of a test group and the control group, although multiple test groups may be compared if so desired. The relative rank of the two groups being compared must be considered. If a test group is ranked 2 and the control group is ranked 1, then we say that there are two places between them; if the test group is ranked 3, then there would be three places between it and the control.

To establish the probability table, the SEM must be calculated as presented earlier or as

$$\sqrt{\frac{\text{Error mean square}}{N}} = \sqrt{\frac{\text{Mean square within group}}{N}}$$

where N is the number of animals or replications per dose level. The MS within groups (MS_{wg}) can be calculated from the information given in the ANOVA procedure (refer to the earlier section on "Analysis of Variance"). The SEM is then multiplied by a series of table values [27,36] to set up a probability table. The table values used for the calculations are chosen according to the probability levels (note that the tables have sections for 0.05, 0.01, and 0.001 levels) and the number of means apart for the groups being compared and the number of error degrees of freedom. The error df is the number of degrees of freedom within the groups. This last figure is determined from the ANOVA calculation and can be taken from ANOVA output. For some values of df, the table values are not given and should thus be interpolated. Example 9.10 demonstrates this case.

Example 9.10

Using the data given in Example 9.9 (four groups of dogs, with four dogs in each group), we can make the following calculations:

	Rank			
	1	**2**	**3**	**4**
Concentration (ppm)	0	100	200	400
Mean kidney weight ($\bar{X}$)	0.345	0.390	0.428	0.482

Groups Compared	$\left(\bar{X}_1 - \bar{X}_2\right)$	**No. of Means Apart**	**Probability**
2 vs. 1 (100 vs. 0 ppm)	0.045	2	$p > 0.05$
3 vs. 1 (200 vs. 0 ppm)	0.083	3	$p > 0.05$
4 vs. 1 (400 vs. 0 ppm)	0.137	4	$0.01 > p > 0.001$
4 vs. 2 (400 vs. 100 ppm)	0.092	3	$0.05 > p > 0.01$

The MS within groups from the ANOVA example was 0.00275; therefore, the SEM = $\sqrt{0.00275}$ = 0.02622. The error df (df_{wg}) was 12, so the following table values are used:

No. of Means Apart	**Probability Levels**		
	0.05	**0.01**	**0.001**
2	3.082	4.320	6.106
3	3.225	4.504	6.340
4	3.313	4.662	6.494

When these are multiplied by the SEM, we get the following probability table:

No. of Means Apart	**Probability Levels**		
	0.05	**0.01**	**0.001**
2	0.0808	0.1133	0.1601
3	0.0846	0.1161	0.1662
4	0.0869	0.1212	0.1703

Groups with Unequal Numbers of Data ($N_1 \neq N_2$)

This procedure is very similar to that discussed earlier. As before, the means are ranked, and the differences between the means are determined ($X_1 - X_2$). Next, weighting values (a_{ij} values) are calculated for the pairs of groups being compared in accordance with

$$a_u = \sqrt{\frac{2N_iN_j}{\left(N_i + N_j\right)}} = \sqrt{\frac{2N_1N_2}{\left(N_1 + N_2\right)}}$$

This weighting value for each pair of groups is multiplied by $(\bar{X}_1 - \bar{X}_2)$ for each value to arrive at a t value. This is the t that will later be compared to a probability table.

The probability table is set up as earlier except that instead of multiplying the appropriate table values by SEM, SEM^2 is used. This is equal to $\sqrt{\text{MS}_{wg}}$.

For the desired comparison of two groups at a time, either $(\bar{X}_1 - \bar{X}_2)$ value (if $N_1 = N_2$) is compared to the appropriate probability table. Each comparison must be made according to the number of places between the means. If the table value is larger at the 0.05 level, the two groups are not considered to be statistically different. If the table value is smaller, the groups are different, and the comparison is repeated at lower levels of significance; thus, the degree of significance may be determined. We might have significant differences at 0.05 but not at 0.01, in which case the probability would be represented at $0.05 > p > 0.01$. Example 9.11 demonstrates this case.

Example 9.11

Suppose that the 400 ppm level from the earlier example had only three dogs, but that the mean for the group and the MS within groups were the same. To continue Duncan's test, we would calculate the weighting factors as follows:

100 ppm vs. 0 ppm

$$200\,\text{ppm vs. } 0\,\text{ppm } N_1 = 4; \quad N_2 = 4a_r = \sqrt{\frac{2(4)(4)}{4+4}} = 2.00$$

$$400\,\text{ppm vs. } 0\,\text{ppm } N_2 = 4; \quad N_4 = 4a_r = \sqrt{\frac{2(3)(4)}{3+4}} = 1.852$$

400 ppm vs. 100 ppm

Using the $(\bar{X}_1 - \bar{X}_2)$ from the earlier example, we can set up the following tables:

Concentration (ppm)	No. of Means Apart	$(\bar{X}_1 - \bar{X}_2)$	a_u	$(\bar{X}_1 - \bar{X}_2)a_u$
100 vs. 0	2	0.045	2.000	2.000(0.045) = 0.090
200 vs. 0	3	0.083	2.000	2.000(0.083) = 0.166
400 vs. 0	4	0.137	1.852	1.852(0.137) = 0.254
400 vs. 100	3	0.092	1.852	1.852(0.092) = 0.170

Next we calculate SEM^2 as being 0.00275 = 0.05244. This is multiplied by the appropriate table values chosen for 11 degrees of freedom (df_{wg} for this example). This gives the following probability table:

No. of Means Apart	Probability Levels 0.05	0.01	0.001
2	0.1632	0.2303	0.3291
3	0.1707	0.2401	0.3417
4	0.1753	0.2463	0.3501

Comparing the t values with the probability table values, we get the following:

Comparison	Probability
100 ppm vs. 0 ppm	$p > 0.05$
200 ppm vs. 0 ppm	$p > 0.05$
400 ppm vs. 0 ppm	$0.01 > p > 0.001$
400 ppm vs. 100 m	$0.05 > p > 0.01$

Assumptions and Limitations

1. Duncan's test assures a set alpha level or type I error rate for all tests when means are separated by no more than ordered step increases. Preserving this alpha level means that the test is less sensitive than some others, such as the Student–Newman–Keuls. The test is inherently conservative and not resistant or robust.

Scheffe's Multiple Comparisons

Scheffe's test is another post hoc comparison method for groups of continuous and randomly distributed data. It also normally involved three or more groups [37,38]. It is widely considered a more powerful significance test than Duncan's test. Each post hoc comparison is tested by comparing an obtained test value (F_{contr}) with the appropriate critical F value at the selected level of significance—the table F value multiplied by $(K - 1)$ for an F with $(K - 1)$ and $(N - K)$ degrees of freedom, where K is the number of groups being compared. F_{contr} is computed as follows:

1. Compute the mean for each sample (group).
2. Denote the residual MS by MS_{wg}.
3. Compute the test statistic as

$$F_{contr} = \frac{\left(C_1\bar{X}_1 + C_2\bar{X}_2 + \cdots + C_k\bar{X}_k^{12}\right)}{(K-1)\text{MS}_{wg}\left(C_1^2/n_1 + \cdots + C_k^2/n_k\right)}$$

where C_k is the comparison number such that the sum of C_1, C_2, …, $C_k = 0$. This is demonstrated in Example 9.12.

Example 9.12

At the end of a short-term feeding study, the following body weight changes were recorded:

	Group 1	Group 2	Group 3
	10.2	12.2	9.2
	8.2	10.6	10.5
	8.9	9.9	9.2
	8.0	13.0	8.7
	8.3	8.1	9.0
	8.0	10.8	
		11.5	
Totals	51.6	76.1	46.6
Means	8.60	10.87	9.32

$MS_{wg} = 1.395$.

To avoid logical inconsistencies with pairwise comparisons, we compare the group having the largest sample mean (group 2) with that having the smallest sample mean (group 1), then with the group having the next smallest sample mean, and so on. As soon as we find a nonsignificant comparison in this process (or no group with a smaller sample mean remains), we replace the group having the largest sample mean with that having the second largest sample mean and repeat the comparison process.

Accordingly, our first comparison is between groups 2 and 1. We set $C_1 = -1$, $C_2 = 1$, and $C_3 = 0$ and calculate our test statistic:

$$F_{contr} = \frac{(10.87 - 8.60)^2}{(3-1)(1.395)(1/6 + 1/7)} = 5.97$$

The critical region for F at $p \le 0.05$ for 2 and 11 degrees of freedom is 3.98; therefore, these groups are significantly different at this level. We next compare groups 2 and 3 using $C_1 = 0$, $C_2 = 1$, and $C_3 = -1$:

$$F_{contr} = \frac{(10.87 - 9.32)^2}{(3-1)(1.395)(1/7 + 1/5)} = 2.51$$

This is less than the critical region value, so these groups are not significantly different.

Assumptions and Limitations

1. The Scheffe procedure is robust to moderate violations of the normality and homogeneity of variance assumptions.
2. It is not formulated on the basis of groups with equal numbers (as one of Duncan's procedures is), and if $N_1 \neq N_2$, there is no separate weighting procedure.
3. It tests all linear contrasts among the population means (the other three methods confine themselves to pairwise comparison, except they use a Bonferroni-type correlation procedure).
4. The Scheffe procedure is powerful because of its robustness, yet it is very conservative. The type I error (the false-positive rate) is held constant at the selected test level for each comparison.

Dunnett's *t*-Test

Dunnett's *t*-test [39,40] has, as its starting point, the assumption that what is desired is a comparison of each of several means with one other mean and only one other mean; in other words, that one wishes to compare each and every treatment group with the control group but not compare treatment groups with each other. The problem here is that, in toxicology, one is frequently interested in comparing treatment groups with other treatment groups. However, if one does want to compare treatment groups with only a control group, then Dunnett's is a useful approach. In a study with K groups (one of them being the control), we will wish to make $(K - 1)$ comparisons. In such a situation, we want to have a P level for the entire set of $(K - 1)$ decisions (not for each individual decision). Dunnett's distribution is predicated on this assumption. The parameters for utilizing a Dunnett's table, such as found in his original article, are K (as earlier) and the number of degrees of freedom for the MS within groups (MS_{wg}). The test value is calculated as

$$t = \frac{|T_j - T_i|}{\sqrt{2MS_{wg/n}}}$$

where

- n is the number of observations in each of the groups; the MS within group (MS_{wg}) value is as we have defined it previously
- T_j is the control group mean
- T_i is the mean of, in order, each successive test group observation

Note that one uses the absolute value of the positive number resulting from subtracting T_i from T_j. This is to ensure a positive number for our final t. Example 9.13 demonstrates this test, again with the data from Example 9.9.

Example 9.13

Assume that the means, N values, and sums for the groups previously presented in Example 9.3 are as follows:

	Control	100 ppm	200 ppm	400 ppm
Sum (ΣX)	1.38	1.56	1.71	1.93
N	4	4	4	4
Mean	0.345	0.39	0.4275	0.4825

The MS_{wg} was 0.00275, and our test t for four groups and 12 degrees of freedom is 2.41. Substituting in the equation, we calculate our t for the control vs. the 400 ppm to be

$$= \frac{|0.345 - 0.4825|}{\sqrt{2(0.00275)/4}} = \frac{0.1375}{\sqrt{0.001375}} = \frac{0.1375}{0.037081} = 3.708$$

which exceeds our test value of 2.41, showing that these two groups are significantly different at $p \le 0.05$. The values for the comparisons of the control vs. the 200 and

100 ppm groups are then found to be 2.225 and 1.214, respectively. Both of these are less than our test value; therefore, the groups are not significantly different.

Assumptions and Limitations

1. Dunnett's test seeks to ensure that the type 1 error rate will be fixed at the desired level by incorporating CFs into the design of the test value table.
2. Treated group sizes must be approximately equal.

Williams's *t*-Test

Williams's *t*-test [41,42] is popular, although its use is quite limited in toxicology. It is designed to detect the highest level (in a set of dose/exposure levels) at which there is no significant effect. It assumes that the response of interest (such as change in body weights) occurs at higher levels but not at lower levels and that the responses are monotonically ordered so $X_0 \le X_1 \ldots \le X_k$. This is, however, frequently not the case. Williams's technique handles the occurrence of such discontinuities in a response series by replacing the offending value and the value immediately preceding it with weighted average values. The test also is adversely affected by any mortality at high dose levels. Such moralities "impose a severe penalty, reducing the power of detecting an effect not only at level K but also at all lower doses" [42, p. 529]. Accordingly, it is not generally applicable in toxicology studies.

Analysis of Covariance

ANCOVA is a method for comparing sets of data that consist of two variables (treatment and effect, with our effect variable being the *variate*), when a third variable (the *covariate*) exists that can be measured but not controlled and which has a definite effect on the variable of interest. In other words, it provides an indirect type of statistical control, allowing us to increase the precision of a study and to remove a potential source of bias. One common example of this is in the analysis of organ weights in toxicity studies. Our true interest here is the effect of our dose or exposure level on the specific organ weights, but most organ weights also increase (in the young, growing animals most commonly used in such studies) in proportion to increases in animal body weight. Here, as we are not interested in the effect of this covariate (body weight), we measure it to allow for adjustment. We must be careful before using ANCOVA, however, to ensure that the underlying nature of the correspondence between the variate and the covariate is such that we can rely on it as a tool for adjustments [43,44].

Calculation is performed in two steps. The first is a type of linear regression between the variate Y and the covariate X. This regression, performed as described under the "Linear Regression" section, gives us the following model:

$$Y = a_1 + BX + e$$

which in turn allows us to define adjusted means (Y and X) such that $Y_{1a} = Y_1 - (X_1 - X^n)$.

If we consider the case where K treatments are being compared such that $K = 1, 2, \ldots, K$ and we let X_{ik} and Y_{ik} represent the predictor and predicted values for each individual i in group k, respectively, we can let X_k and Y_k be the means. Then, we define the between-group (for treatment) sum of squares and cross products as

$$T_{xx} = \sum_{k-1}^{k} n_k \left(\bar{X}_k - \bar{X}\right)^2$$

$$T_{yy} = \sum_{k-1}^{k} n_k \left(\bar{Y}_k - \bar{Y}\right)^2$$

$$T_{xy} = \sum_{k-1}^{k} n_k \left(\bar{X}_k - \bar{X}\right)\left(\bar{Y}_k - \bar{Y}\right)$$

In a like manner, within-group sums of squares and cross products are calculated as

$$\sum xx = \sum_{k=1}^{K} \sum_{i} \left(X_{ik} - X_k\right)^2$$

$$\sum yy = \sum_{k=1}^{K} \sum_{i} \left(Y_{ik} - Y_k\right)^2$$

$$\sum xy = \sum_{k=1}^{K} \sum_{i} \left(X_{ik} - X_k\right)\left(Y_{ik} - Y_k\right)$$

where

i indicates the sum from all the individuals within each group
f is the total number of subjects minus number of groups

Also

$$S_{xx} = T_{xx} + \sum xx$$

$$S_{yy} = T_{yy} + \sum yy$$

$$S_{xy} = T_{xy} + \sum xy$$

With these in hand, we can then calculate the residual MSs of treatments (St^2) and error (Se^2):

$$St^2 = \frac{Tyy - \left(S^2xy/Sxx\right) + \left(\sum {}^2xy \Big/ \sum xx\right)}{lc - 1}$$

$$Se^2 = \frac{\left(\sum yy - \left(\sum {}^2y \Big/ \sum xx\right)\right)}{f - 1}$$

These can be used to calculate an F statistic to test the null hypothesis that all treatment effects are equal:

$$F = \frac{St^2}{Se^2}$$

The estimated regression coefficient of Y or X is

$$B = \frac{\sum xy}{\sum xx}$$

The estimated standard error for the adjusted difference between two groups is given by

$$\text{sd} = \text{se}\frac{1}{n_j} + \frac{1}{n_j} + \frac{\left(X_i - X_j\right)}{\sum xx}$$

where n_i and n_j are the sample sizes of the two groups. A test of the null hypothesis that the adjusted differences between the groups is zero is provided by

$$t = \frac{Y_1 - Y_0 - B\left(X_1 - X_0\right)}{\text{sd}}$$

The test value for t is then obtained from the t-table with $f - 1$ degrees of freedom. Computation is markedly simplified if all the groups are of equal size, as demonstrated in Example 9.14.

Example 9.14

An ionophere was evaluated as a potential blood-pressure-reducing agent. Early studies indicated that there was an adverse effect on blood cholesterol and hemoglobin levels, so a special study was performed to evaluate this specific effect. The hemoglobin (Hgb)-level covariate was measured at the start of the study along with the percent changes in serum triglycerides between the start of the study and at the end of the 13-week study. Was there a difference in effects of the two ionopheres?

Ionophere A		Ionophere B	
Hgb x	Serum Triglyceride (% Change) Y	Hgb x	Serum Triglyceride (% Change) Y
7.0	5	5.1	10
6.0	10	6.0	15
7.1	–5	7.2	–15
8.6	–20	6.4	5
6.3	0	5.5	10
7.5	–15	6.0	–15
6.6	10	5.6	–5
7.4	–10	5.5	–10
5.3	20	6.7	–20
6.5	–15	8.6	–40
6.2	5	6.4	–5
7.8	0	6.0	–10
8.5	–40	9.3	–40
9.2	–25	8.5	–20
5.0	25	7.9	–35
		5.0	0
		6.5	–10

To apply ANCOVA using Hgb as a covariate, we first obtain some summary results from the data as follows:

	Ionophere A (Group 1)	Ionophere B (Group 2)	Combined
Σx	112.00	119.60	231.60
Σx^2	804.14	821.64	1,625.78
Σy	–65.00	–185.00	–250.00
Σy^2	4,575.00	6,475.00	11,050.00
Σxy	–708.50	–1,506.50	–2,215.00
x	7.000	6.6444	6.8118
y	–4.625	–10.2778	–7.3529
n	16	18	34

We compute for the ionophere A group ($i = 1$):

$$S_{xx(1)} = 804.14 - \frac{(112)^2}{16} = 20.140$$

$$S_{yy(1)} = 4575.00 - \frac{(-65)^2}{16} = 4310.938$$

$$S_{xy(1)} = \quad 708.50 - \frac{(112)(-65)}{16} = \quad 253.500$$

Similarly for the ionophere B group ($i = 2$), we obtain the following:

$$S_{xx(2)} = 26.964$$

$$S_{yy(2)} = 4573.611$$

$$S_{xy(2)} = -277.278$$

Finally, for the combined data (ignoring groups), we compute as follows:

$$S_{xx} = 48.175$$

$$S_{yy} = 9211.765$$

$$S_{xy} = -512.059$$

The sums of squares can now be obtained as

$$\text{TOT}(\text{SS}) = 9211.8$$

$$\left(20.140 + 26.964\right)\left(4310.938 + 4573.611\right)$$

$$\text{SSE} = \frac{-\left[-253.5 - 277.28\right]^2}{\left(20.14 + 26.964\right)} = 2903.6$$

$$\text{SSG} = \frac{\left(48.175\right)\left(9211.765\right) - \left(-512.059\right)^2}{48.175} - 2903.6 = 865.4$$

$$\text{SSC} = \left(4310.938 + 473.611\right) - 2903.6 = 5980.9$$

and the ANCOVA summary table can be completed as

Source	df	SS	MS	*F*
Treatment	1	865.4	865.4	9.2[a]
X (Hgb)	1	5980.9	5980.9	63.8
Error	31	2903.7	93.7	
Total	33	9211.8		

[a] Significant ($p < 0.05$); critical *F* value = 4.16.

The *F* statistics are formed as the ratios of effect MS to the MSE (93.7). Each *F* statistic is compared with the critical *F* value with 1 upper and 31 lower degrees of freedom. The critical *F* value for $\alpha = 0.05$ is 4.16. The significant covariate effect ($F = 63.8$) indicates that the triglyceride response has a significant linear relationship with Hgb. The significant *F* value for treatment indicates that the mean triglyceride response adjusted for hemoglobin effect differs between treatment groups.

Assumptions and Limitations

1. The underlying assumptions for ANCOVA are fairly rigid and restrictive. The assumptions include the following:
   a. The slopes of the regression lines of a *Y* and *X* are equal from group to group. This can be examined visually or formally (i.e., by a test). If this condition is not met, ANCOVA cannot be used.
   b. The relationship between *X* and *y* is linear.
   c. The covariate *X* is measured without error. Power of the test declines as error increases.
   d. There are no unmeasured confounding variables.
   e. The errors inherent in each variable are independent of each other. Lack of independence effectively (but to an immeasurable degree) reduces sample size.
   f. The variances of the errors in groups are equivalent between groups.
   g. The measured data that form the groups are normally distributed. ANCOVA is generally robust to departures from normality.
2. Of the seven assumptions provided earlier, the most serious are the first four.

MODELING

The mathematical modeling of biological systems, restricted even to the field of toxicology, is an extremely large and vigorously growing area. Broadly speaking, modeling is the principal conceptual tool by which toxicology seeks to develop as a mechanistic science. In an iterative process, models are developed or proposed, tested by experiment, reformulated, and so on, in a continuous cycle. Such a cycle could also be described as two related types of modeling: *explanatory* (where the concept is formed) and *correlative* (where data are organized and relationships derived). An excellent introduction to the broader field of modeling of biological systems can be found in Gold [45].

In toxicology, modeling is of prime interest in seeking to relate a treatment variable with an effect variable and, from the resulting model, predict effects at exact points where no experiment has been done (but in the range where we have performed experiments, such as determining LD_{50} values) to estimate how good our prediction is, and, occasionally, simply to determine if a pattern of effects is related to a pattern of treatment.

For use in prediction, the techniques of linear regression, probit/logit analysis (a special case of linear regression), moving averages (an efficient approximation method), and nonlinear regression (for doses where data cannot be made to fit a linear pattern) are presented. For evaluating the predictive value of these models, both the correlation coefficient (for parametric data) and Kendall's rank correlation (for nonparametric data) are given. And, finally, the concept of trend analysis is introduced and a method presented.

When we are trying to establish a pattern between several data points (whether this pattern is in the form of a line or a curve), what we are doing is *interpolating*. It is possible for any given set of points to produce an infinite set of lines or curves that pass near (for lines) or through (for curves) the data points. In most cases, we cannot actually know the real pattern, so we apply a basic principle of science: Occam's razor. We use the simplest explanation (or, in this case, model) that fits the facts (or data). A line is, of course, the simplest pattern to deal with and describe, so fitting the best line (linear regression) is the most common form of model in toxicology.

Linear Regression

Foremost among the methods for interpolating within a known data relationship is regression, which involves the fitting of a line or curve to a set of known data points on a graph and interpolating (estimating) this line or curve in areas where we have no data points. The simplest of these regression models is that of linear regression (which is valid when increasing the value of one variable changes the value of the related variable in a linear fashion, either positively or negatively). This is the case we will explore here, using the method of least squares.

Given that we have two sets of variables, *x* (say, mg/kg of test material administered) and *y* (say, percentage of animals so dosed that die), it is necessary to solve for *a* and *b* in the equation $Y_i = a + bx_i$, where the uppercase Y_i is the fitted value of y_i at x_i and we wish to minimize $(y_i - Y_i)^2$. So, we solve the following equations:

$$a = \bar{y} - b\bar{x}$$

$$b = \frac{\sum x_1 y_1 - n\bar{x}\bar{y}}{\sum x_1^2 - n\bar{x}^2}$$

where

a is the *y* intercept
b is the slope of the time
n is the number of data points

Use of this is demonstrated in Example 9.13.

Note that, in actuality, dose–response relationships are often not linear, and instead we must use either a transform (to linearize the data) or a nonlinear regression method [46]. Note also that we can use the correlation test statistic (to be described in the "Correlation Coefficient" section) to determine if the regression is significant (and, therefore, valid at a defined level of certainty). A more specific test for significance would be the linear regression ANOVA [31]. To do so, we start by developing the appropriate ANOVA table and then proceed to perform the linear regression portion of the ANOVA as shown in Example 9.15.

Example 9.15

From a short-term toxicity study, we have the following results:

Dose Administered (mg/kg)	Percent Animals Dead (%)		
x_1	x_1^2	y_1	x_1y_1
1	1	10	10
3	9	20	60
4	16	18	72
5	25	20	100
Sums $x_1 = 13$	$x_1^2 = 51$	$y_1 = 68$	$x_1y_1 = 242$

$$\bar{x} = 3.25 \quad \text{and} \quad \bar{y} = 17$$

$$a = 17 - (2.4)(3.25) = 9.20$$

$$b = \frac{242 - (4)(3.25)(17)}{51 - (4)(10.5625)} = \frac{21}{8.75} = 2.40$$

We therefore see that our fitted line is $Y = 9.2 + 2.4X$. These ANOVA table data are then used as shown in Example 9.12.

Linear Regression ANOVA

Source of Variation (1)	Sum of Squares (2)	Degrees of Freedom (3)	MS (=2/3) (4)
Regression	$b_1^2\left(\sum x_1^2 - n\bar{x}^2\right)$	1	By division
Residual	By difference	$n - 2$	By division
Total	$\sum y_1^2 - n\bar{y}^2$	$n - 1$	

We then calculate $F_{1,n-2}$ = (regression MS)/(residual MS). This is demonstrated in Example 9.16.

Example 9.16

We desire to test the significance of the regression line in Example 9.11:

$$\sum y_1^2 = 10^2 + 20^2 + 18^2 + 20^2$$

$$\text{Regression SS} = (2.4)^2\left[51 - 4(3.25)^2\right] = 50.4$$

$$\text{Total SS} = 1224 - 4\left(17^2\right) = 68$$

$$\text{Residual SS} = 68 - 50.4 = 17.6$$

$$F_{1,2} = \frac{50.4}{8.8} = 5.73$$

This value is not significant at the 0.05 level; therefore, the regression is not significant. A significant F value (as found in an F distribution table for the appropriate degrees of freedom) indicates that the regression line is an accurate prediction of observed values at that confidence level. Note that the portion of the total sum of squares explained by the regression is called the *coefficient of correlation*, which in the earlier example is equal to 0.86^2 (or 0.74). Calculation or the correlation coefficient is described later in this chapter.

Finally, we might wish to determine the CIs for our regression line; that is, given a regression line with calculated values for Y_i given x_i, within what limits may we be certain (with, say, a 95% probability) what the real value of Y_i is? If we denote the residual MS in the ANOVA by s^2, then the 95% confidence limits for a (denoted by A, the notation for the true, as opposed to estimated, value for this parameter) are calculated as

$$t_{n-2} = \frac{a - A}{\sqrt{\dfrac{s^2\left(\sum x^2\right)}{n\sum x_1^2 - n^2\bar{x}^2}}}$$

$$= \frac{9.2 - A}{\sqrt{\dfrac{8.8(51)}{4(51) - (16)(10.562)}}} = \frac{9.2 - A}{\sqrt{\dfrac{448}{35.008}}}$$

$$9.2 - A = -15.405$$

$$= 9.2 - 15.405$$

Assumptions and Limitations

1. All the regression methods are for interpolation, not extrapolation; that is, they are valid only in the range for which we have data—the experimental region—not beyond.
2. The method assumes that the data are independent and normally distributed, and it is sensitive to outliers. The x-axis (or horizontal) component plays an extremely important part in developing the least-squares fit. All points have equal weight in determining the height of a regression line, but extreme x-axis values unduly influence the slope of the line.

3. A good fit between a line and a set of data (i.e., a strong correlation between treatment and response variables) does not imply any causal relationship.
4. It is assumed that the treatment variable can be measured without error, that each data point is independent, that variances are equivalent, and that a linear relationship does not exist between the variables.
5. The many excellent texts on regression, which is a powerful technique, include Draper and Smith [47] and Montgomery et al. [48], which are not overly rigorous mathematically.

Probit/Log Transforms and Regression

As we noted in the preceding section, dose–response problems (among the most common interpolation problems encountered in toxicology) rarely are straightforward enough to make a valid linear regression directly from the raw data. The most common valid interpolation methods are based on probability (probit) and logarithmic (log) value scales, with percentage responses (death, tumor incidence, etc.) being expressed on the probit scale and doses (Y_i) expressed on the log scale. There are two strategies for such an approach. The first is based on transforming the data to these scales, then doing a weighted linear regression on the transformed data. (If one does not have access to a computer or a high-powered programmable calculator, the only practical strategy is not to assign weights.) The second requires the use of algorithms (approximate calculation techniques) for the probit value and regression process and is extremely burdensome to perform manually.

Our approach to the first strategy requires that we construct a table with the pairs of values of x_i and y_i listed in the order of increasing values of Y_i (percentage response). Beside each of these columns, a set of blank columns should be left so the transformed values may be listed. We then simply add the columns described in the linear regression procedure. Log and probit values may be taken from any of a number of sets of tables, and the rest of the table is then developed from these transformed x_i and y_i values (denoted as x_i' and y_i'). A standard linear regression is then performed (see Example 9.17). The second strategy we discussed has been broached by a number of authors [49–52]. All of these methods, however, are computationally cumbersome. It is possible to approximate the necessary iterative process using the algorithms developed by Abramowitz and Stegun [53], but even this merely reduces the complexity to a point where the procedure may be readily programmed on a small computer or programmable calculator.

Example 9.17

(See the following table.) Our interpolated log of the LD_{50} is 1.000539, calculated by using $Y = -0.200591 - 0.240226x$, where x equals 5.000 (the probit of 50%) in the regression equation. When we convert this log value to its linear equivalent, we get an LD_{50} of 10.0 mg/kg. Finally, our calculated correlation coefficient is $r = 0.997$. A goodness-of-fit of the data using chi-square may also be calculated.

Percentage of Animals Killed (x_1)	Probit of $x_1 = x_1'$	Dose of Chemical (mg/kg) (y_1)	Log of $y_1 = y_1'$	$(x_1')^2$	$x_1'y_1'$
2	2.9463	3	0.4771	8.6806	1.40568
10	3.7184	5	0.6990	13.8264	2.59916
42	4.7981	10	1.0000	23.0217	4.79810
90	6.2816	20	1.3010	39.4585	8.17223
98	7.2537	30	1.4771	52.6162	10.4190
	$\sum x_1' =$		$\sum y_1' =$	$\sum (x_1')^2 =$	$\sum x_1'y_1' =$
	24.9981		4.9542	137.6034	27.68974

Assumptions and Limitations

1. The probit distribution is derived from a common error function, with the midpoint (50% point) moved to a score of 5.00.
2. The underlying frequency distribution becomes asymptotic as it approaches the extremes of the range; that is, in the range of 16%–84%, the corresponding probit values change gradually. The curve is relatively linear, but beyond this range, the values change ever more rapidly as they approach either 0% or 100%. In fact, there are no values for either of these numbers.
3. A normally distributed population is assumed, and the results are sensitive to outliers.

Moving Averages

An obvious drawback to the interpolation procedures we have examined to date is that they do take a significant amount of time (although they are simple enough to be done manually), especially if the only result we desire is an LD_{50}, LC_{50}, or LT_{50}. The method of moving averages [54,55] gives a rapid and reasonable accurate estimate of this median effective dose (m) and the estimated SD of its logarithm. Such methodology requires that the same number of animals be used per dosage level and that the spacing between successive dosage exposure levels be geometrically constant (e.g., levels of 1, 2, 4, and 8 mg/kg or 1, 3, 9, and 27 ppm). Given this and access to a table for the computation of moving averages, one can readily calculate the median effective dose with the following formula (illustrated for dose):

$$\log m = \log D + \frac{d(K-1)}{2} + df$$

where

m is the median effective dose or exposure
D is the lowest dose tested
d is the log of the ratio of successive doses/exposures
f is a table value taken from Gad [23] for the proper K (the total number of levels tested minus 1)

Example 9.18 demonstrates the use of this method and the new tables.

Example 9.18

As part of an inhalation study, we exposed four groups of five rats each to levels of 20, 40, 80, and 160 ppm of a chemical vapor. These exposures killed 0, 1, 3, and 5 animals, respectively. From the $N = 5$, $K = 3$ tables on the r value 0, 1, 3, 5 line, we get an f of 0.7 and an α_f^4 of 0.31623. We can then calculate the LC_{50} to be

$$\log LC_{50} = 1.30130 + \frac{0.30103(2)}{2} + 0.30103(0.7)$$

$$= 1.30103 + 0.51175$$

$$= 1.81278$$

$$\therefore LC_{50} = 65.0 \text{ ppm with 95\% CIs of } \pm 2.179\, d\sigma_f$$

or

$$\pm 2.179(0.30103) \times (0.31623) = \pm 0.20743$$

Therefore, the log confidence limits are 1.81278 ± 0.20743 = 1.60535–2.02021; on the linear scale, 40.3–104.8 ppm.

Assumptions and Limitations

1. A common misconception is that the moving-average method cannot be used to determine the slope of the response curve. This is not true. Weil has published a straightforward method for determining slope in conjunction with a moving-average determination of the LD_{50} [56].
2. The method also provides CIs.

Nonlinear Regression

More often than not in toxicology, we find that our data demonstrate a relationship between two variables (such as age and body weight) that is not linear; that is, a change in one variable (e.g., age) does not produce a directly proportional change in the other (e.g., body weight), but some form of relationship between the variables is apparent. If understanding such a relationship and being able to predict unknown points are of value, we have a pair of options available to us. The first, which was discussed and reviewed earlier, is to use one or more transformations to linearize our data and then to make use of linear regression. This approach, although most commonly used, has a number of drawbacks. Not all data can be suitably transformed. Sometimes the transformations necessary to linearize the data require a cumbersome series of calculations, and the resulting linear regression is not always sufficient to account for the differences among sample values; there might be significant deviations around the linear regression line (i.e., a line may still not give us a good fit to the data or do an adequate job of representing the relationship between the data). In such cases, we have a second option available—fitting the data to some nonlinear function such as some form of the curve. This is, in general form, nonlinear regression and may involve fitting data to an infinite number of possible functions, but most often, we are interested in fitting curves to a polynomial function of the general form:

$$Y = a + bx + cx^2 + dx^2 + \cdots$$

where x is the independent variable. As the number of powers of x increases, the curve becomes increasingly complex and will be able to fit a given set of data increasingly well. Generally in toxicology, however, if we plot the log of a response (such as body weight) vs. a linear scale of our dose or stimulus, we get one of four types of nonlinear curves [16]:

- *Exponential growth*, where $\log Y = A(B^x)$, such as the growth curve for the log phase of a bacterial culture
- *Exponential decay*, where $\log Y = A(B^{-x})$, such as a radioactive decay curve
- *Asymptotic regression*, where $\log Y = A - B(p^x)$, such as a first-order reaction curve
- *Logistic growth curve*, where $\log Y = A/(1 + Bp^x)$, such as a population growth curve

In all of these cases, A and B are constants and p is a log transform. These curves are illustrated in Figure 9.7.

All four types of curves are fit by iterative processes; that is, best-guess numbers are initially chosen for each of the constants, and after a fit is attempted, the constants are modified to improve the fit. This process is repeated until an acceptable fit has been generated. ANOVA or ANCOVA can be used to objectively evaluate the acceptability of it. Needless to say, the use of a computer generally accelerates such a curve-fitting process.

Assumptions and Limitations

1. The principle of using least squares may still be applicable in fitting the best curve, if the assumptions of normality, independence, and reasonably error-free measurement of response are valid.
2. Growth curves are best modeled using a nonlinear method.

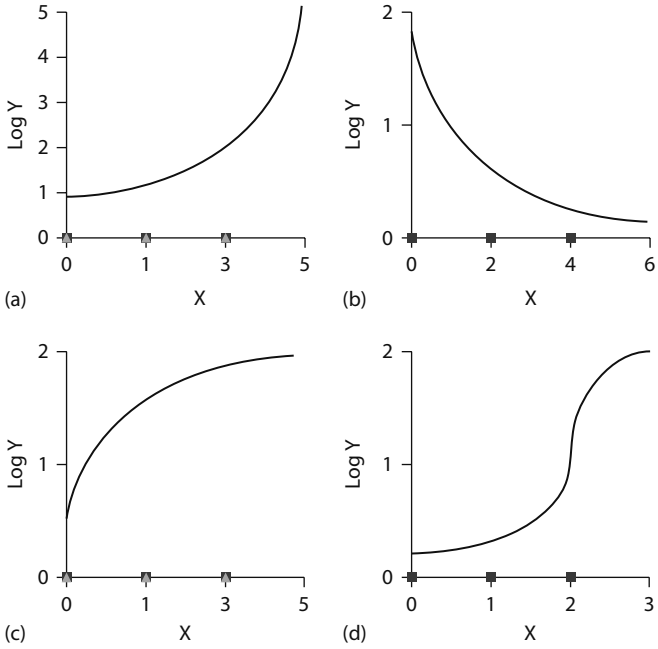

FIGURE 9.7 Common curvilinear curves. (a) Exponential growth law Log Y = A(B^X), (b) exponential decay law Log Y = A(B^{-X}), (c) asymptotic regression Log Y = A – B(ψ^X), (d) logistic growth law Log Y = A/(1 + Bψ^X).

Correlation Coefficient

The correlation procedure is used to determine the degree of linear correlation (direct relationship) between two groups of continuous (and normally distributed) variables; it will indicate whether there is any statistical relationship between the variables in the two groups. For example, we may wish to determine if the liver weights of dogs on a feeding study are correlated with their body weights. Thus, we will record the body and liver weights at the time of sacrifice and then calculate the correlation coefficient between these pairs of values to determine if there is some relationship. A formula for calculating the linear correlation coefficient (r_{xy}) is as follows:

$$r_{xy} = \frac{N\sum XY - \left(\sum X\right)\left(\sum Y\right)}{\sqrt{N\sum X^2 - \left(\sum X\right)^2}\sqrt{N\sum Y^2 - \left(\sum Y\right)^2}}$$

where

- X is each value for one variable (such as the dog body weights in the earlier example)
- Y is the matching value for the second variable (the liver weights)
- N is the number of pairs of X and Y

Once we have obtained r_{xy}, it is possible to calculate t_r, which can be used for more precise examination of the degree of significant linear relationship between the two groups. This value is calculated as follows:

$$t_r = \frac{r_{zy}\sqrt{N-2}}{\sqrt{1-r_{zy}^2}}$$

This calculation is also equivalent to r = sample covariance/(S_xS_y), as was seen earlier under ANCOVA.

The value obtained for r_{xy} can be compared to table values [16] for the number of pairs of data involved minus two. If the r_{xy} is smaller (at the selected test probability level, such as 0.05), the correlation is not significantly different from zero (no correlation). If r_{xy} is larger than the table value, there is a positive statistical relationship between the groups. Comparisons are then made at lower levels of probability to determine the degree of relationship (note that if r_{xy} equals either 1.0 or –1.0, there is complete correlation between the groups). If r_{xy} is a negative number and the absolute value is greater than the table value, there is an inverse relationship between the groups; that is, a change in one group is associated with a change in the opposite direction in the second group of variables. Both computations are demonstrated in Example 9.19.

Because the comparison of r_{xy} with the table values may be considered a somewhat weak test, it is perhaps more meaningful to compare the t_r value with values in a t-distribution table for (N – 2) degrees of freedom (df), as is done for Student's t-test. This will give a more exact determination of the degree of statistical correlation between the two groups. Note that this method examines only possible linear relationships between sets of continuous normally distributed data.

Example 9.19

If we computed the dog body weight vs. dog liver weight for a study, we could obtain the following results:

Dog	Body Weight (kgj) X	X^2	Liver Weight (g) Y	Y^2	XY
1	8.4	70.56	243	59,049	2,041.2
2	8.5	72.25	225	50,625	1,912.5
3	9.3	86.49	241	58,081	2,241.3
4	9.5	90.25	263	69,169	2,498.5
5	10.5	110.25	256	65,536	2,688.0
6	8.6	73.96	266	70,756	2,287.6
Sum	ΣX = 54.8	ΣX^2 = 503.76	ΣY = 1,494	ΣY^2 = 373,216	ΣXY = 13,669.1

$$r_{xy} = \frac{6(13,669.1) - (54.8)(1,494)}{\left(\sqrt{6(503.76) - (54.8)^2}\right)\left(\sqrt{6(373,216) - (1,494)^2}\right)}$$

The table value for six pairs of data (read beside the [$N - 2$] value, or $6 - 2 = 4$) is 0.811 at a 0.05 probability level. Thus, there is a lack of statistical correlation (at $p = 0.05$) between the body weights and liver weights for this group of dogs. The t_r value for these data would be calculated as follows:

$$t_r = \frac{0.381\sqrt{6-2}}{\sqrt{1-(0.381)^2}}$$

The value for the *t*-distribution table for 4 degrees of freedom at the 0.05 level is 2.776; therefore, this again suggests a lack of significant correlation at $p = 0.05$.

Assumptions and Limitations

1. A strong correlation does not imply that a treatment causes an effect.
2. The distances of data points from the regression line are the portions of the data not explained by the model. These are called *residuals*. Poor correlation coefficients imply high residuals, which may be due to many small contributions (variations of data from the regression line) or a few large ones. Extreme values (outliers) greatly reduce correlation.
3. *X* and *Y* are assumed to be independent.
4. Feinstein [57] has provided a fine discussion of the difference between correlation (or association of variables) and causation.

Kendall's Coefficient of Rank Correlation

Kendall's rank correlation, represented by τ (tau), should be used to evaluate the degree of association between two sets of data when the nature of the data is such that the relationship may not be linear. Most commonly, this is when the data are not continuous or normally distributed. An example of such a case is when we are trying to determine if there is a relationship between the length of hydra and their survival time (in hours) in a test medium, as is presented in Example 9.18. Both of our variables here are discontinuous, yet we suspect a relationship exists. Another common use is in comparing the subjective scoring done by two different observers.

Tau is calculated at $\tau = N/n(n-1)$, where n is the sample size and N is the count of ranks, calculated as $N = 4({}^nC_i) - n(n-1)$, with the computing of ${}^nC_i$ being demonstrated in the example. If a second variable Y_2 is exactly correlated with the first variable Y_1, then the variates Y_2 should be in the same order as the Y_1 variates; however, if the correlation is less than exact, the order of the variates Y_2 will not correspond entirely to that of *Y*. The quantity N measures how well the second variable corresponds to the order of the first. It has a maximum value of $n(n-1)$ and a minimum value of $-n(n-1)$.

A table of data is set up with each of the two variables being ranked separately. Tied ranks are assigned as demonstrated earlier under the Kruskal–Wallis test. From this point, disregard the original variates and deal only with the ranks. Place the ranks of one of the two variables in rank order (from lowest to highest), paired with the rank values assigned for the other variable. If one (but not the other) variable has tied ranks, order the pairs by the variables without ties [15]. The most common way to compute a sum of the counts is also demonstrated in Example 9.20. The resulting value of tau will range from –1 to +1, as does the familiar parametric correlation coefficient, *r*.

Example 9.20

During the validation of an in vitro method, it was noticed that larger hydra seem to survive longer in test media than do small individuals. To evaluate this, 15 hydra of random size were measured (mm), then placed in test media. How many hours each individual survives was recorded over a 24 h period. These data are presented in the following text, along with ranks for each variable.

Length	Rank (R_1)	Survival	Rank (R_2)
3	6.5	19	9
4	10	17	7
6	15	11	1
1	1.5	25	15
3	6.5	18	8
3	6.5	22	12
1	1.5	24	14
4	10	16	6
4	10	15	5
2	3.5	21	11
5	13	13	3
5	13	14	4
3	6.5	20	10
2	3.5	23	13
5	13	12	2

We then arrange this based on the order of the rank of survival time (there are no ties here). We then calculate our counts of ranks. The conventional method is to obtain a sum of counts C_i, as follows: examine the first value in the column of ranks paired with the ordered column. In the following case, this is rank 15. Count all ranks subsequent to it that rank greater than 15. There are 14 ranks following the 2 and all of them are less than 15; therefore, we count a score of $C_1 = 0$. We repeat this process for each subsequent rank of R_1, giving us a final score of 1. By this point, it is obvious that our original hypothesis—that larger hydrae live longer in test media than do small individuals—was in error.

R_2	R_1	Following R_2 Ranks Greater than R_1	Counts (C_i)
1	15	—	$C_1 = 0$
2	13	—	$C_2 = 0$
3	13	—	$C_3 = 0$
4	13	—	$C_4 = 0$
5	10	—	$C_5 = 0$
6	6.5	10	$C_6 = 0$
7	10	—	$C_7 = 0$
8	6.5	—	$C_8 = 0$
9	6.5	—	$C_9 = 0$
10	6.5	—	$C_{10} = 0$
11	3.5	6.5	$C_{11} = 0$
12	6.5	—	$C_{12} = 0$
13	3.5	—	$C_{13} = 0$
14	1.5	—	$C_{14} = 0$
15	1.5	—	$C_{15} = 0$
			$C_i = 1$

Our count of ranks (N) is then calculated as follows:

In other words, there is a strong negative correlation between our variables.

$$N = 4(1) - 15(5-1)$$
$$= 4 - 15(14)$$
$$= -206$$

We can then calculate tau as

$$= \frac{-206}{15(15-1)} = \frac{-206}{210} = -0.9810$$

Assumption and Limitation

1. This is a very robust estimator that does not assume normality, linearity, or minimal error of measurement.

Trend Analysis

Trend analysis is a collection of techniques utilized by toxicology since the mid-1970s [58]. The actual methodology dates back to the mid-1950s [59]. Trend analysis methods are a variation on the theme of regression testing. In the broadest sense, the methods are used to determine whether a sequence of observations taken over an ordered range of a variable (most commonly time) exhibits some form of pattern of change (an increase or upward trend) associated with another variable of interest (in toxicology, some form or measure of dosage and/or exposure). Trend corresponds to sustained and/or systematic variations over a long period of time. It is associated with the structural causes of the phenomenon in question—for example, population growth, technological progress, new ways of organization, or capital accumulation.

The identification of trend has always posed a serious statistical problem. The problem is not one of mathematical or analytical complexity but of conceptual complexity. This problem exists because the trend as well as the remaining components of a time series are latent (nonobservables) variables so, therefore, assumptions must be made on their behavioral pattern. The trend is generally thought of as a smooth and slow movement over the long term. The concept of *long* in this connection is relative, and what is identified as a trend for a given series span might well be part of a long cycle once the series is considerably augmented. Often, a long cycle is treated as a trend because the length of the observed time series is shorter than one complete face of this type of cycle. The ways in which data are collected in toxicology studies frequently serve to complicate trend analysis, as the length of time for the phenomena underlying a trend to express themselves is frequently artificially censored.

To avoid the complexity of the problem posed by a statistically vague definition, statisticians have resorted to two simple solutions: one consists of estimating trend and cyclical fluctuations together (the *trend cycle*); the other consists of defining the trend in terms of the series length (the *longest nonperiodic movement*).

Trend Models

Within the large class of models identified for trend, we can distinguish two main categories: deterministic trends and stochastic trends. Deterministic trend models are based on the assumption that the trend of a time series can be approximated closely by simple mathematical functions of time over the entire span of the series. The most common representation of a deterministic trend is by means of polynomials or of transcendental functions. The time series from which the trend is to be identified is assumed to be generated by a nonstationary process where the nonstationarity results from a deterministic trend. A classical model is the regression or error model [66], where the observed series is treated as the sum of a systematic part or trend and a random part or irregular. This model can be written as

$$Z_t = Y_t + U_t'$$

where U_t is a purely random process, that is, $U_t \sim$ i.i.d. $(0, 2/u)$ (independent and identically distributed with expected value 0 and variance $\sigma(2/u)$).

Trend tests are generally described as k-sample tests of the null hypothesis of identical distribution against an alternative of linear order; in other words, if sample I has distribution function F_i, $i = 1$, then the null hypothesis H_0: $F_1 = F_2 - \ldots = F_k$ is tested against the alternative: H_1: $F_1 \geq F_2 \geq \ldots = F_k$ (or its reverse), where at least one of the inequalities is strict. These tests can be thought of as special cases of tests of regression or correlation in which association is sought between the observations and its ordered sample index. They are also related to ANOVA except that the tests are tailored to be powerful against the subset of alternatives H_1 instead of the more general set $\{F_1 \neq F_j$, some $i \neq j\}$.

	Control		Low Doses			High Doses		
Month of Study	Total *X* Animals with Tumors	Change (X_{A-B})	Total *Y* Animals with Tumors	Change (Y_{A-B})	Compared to Control ($Y - X$)	Total *Z* Animals with Tumors	Change (Z_{A-B})	Compared to Control ($Z - X$)
12 (A)	1	NA	0	NA	NA	5	NA	NA
13 (B)	1	0	0	0	0	7	2	(+)2
14 (C)	3	2	1	1	(–)1	11	4	(+)2
15 (D)	3	0	1	0	0	11	0	0
16 (E)	4	1	1	0	(–)1	13	2	(+)1
17 (F)	5	1	3	2	(+)1	14	1	0
18 (G)	5	0	3	0	0	15	1	(+)1
19 (H)	5	0	5	2	(+)2	18	3	(+)3
20 (I)	6	1	6	1	0	19	1	0
21 (J)	8	2	7	1	(–)1	22	3	(+)1
22 (K)	12	4	9	2	(–)2	26	4	0
23 (L)	14	2	12	3	(+)1	28	2	0
24 (M)	18	4	17	5	(+)1	31	3	(–)1
				Sum of signs	4+		Sum of signs	6+
				$Y - X$	4–		$Z - X$	1–
					= 0 (no trend)			= 5

Different tests arise from requiring power against specific elements or subsets of this rather extensive set of alternatives. The most popular trend test in toxicology is currently that presented by Tarone in 1975 [58] because it is the one used by the National Cancer Institute (NCI) in the analysis of carcinogenicity data. A simple, but efficient alternative is the Cox and Stuart test [65], which is a modification of the sign test. For each point at which we have a measure (such as the incidence of animals observed with tumors), we form a pair of observations—one from each of the groups we wish to compare. In a traditional NCI bioassay, this would mean pairing control with low dose and low dose with high dose (to explore a dose-related trend) or each time period observation in a dose group (except the first) with its predecessor (to evaluate a time-related trend). When the second observation in a pair exceeds the earlier observation, we record a plus sign for that pair. When the first observation is greater than the second, we record a minus sign for that pair. A preponderance of plus signs suggests a downward trend, while an excess of minus signs suggests an upward trend. A formal test at a preselected confidence level can then be performed.

More formally put, after having defined what trend we want to test for, we first match pairs as $(X_1 - X_{1+c})$, (X_2, X_{2+c}), …, $(X_{n'-c}, X_{n'})$, where $c = n'/2$ when n' is even and $c = (n' + 1)/2$ when n' is odd (where n' is the number of observations in a set). The hypothesis is then tested by comparing the resulting number of excess positive or negative signs against a sign test table such as are found in Beyer. We can, of course, combine a number of observations to allow ourselves to actively test for a set of trends, such as the existence of a trend of increasing difference between two groups of animals over a period of time. This is demonstrated in Example 9.21.

Example 9.21

In a chronic feeding study in rats, we tested the hypothesis that, in the second year of the study, there was a dose-responsive increase in tumor incidence associated with the test compound. We utilize a Cox–Stuart test for trend to address this question (see the previous table). All groups start the second year with an equal number of animals. Reference to a sign table is not necessary for the low-dose comparison (where there is no trend) but clearly shows the high dose to be significant at the $p \leq 0.5$ level.

Assumptions and Limitations

1. Trend tests seek to evaluate whether there is a monotonic tendency in response to a change in treatment; that is, the dose–response direction is absolute. As the dose goes up, the incidence of tumors increases. Thus, the test loses power rapidly in response to the occurrences of reversals—for example, a low-dose group with a decreased tumor incidence. Methods are available [61] that smooth the bumps of reversals in long data series. In toxicology, however, most data series are short (i.e., there are only a few dose levels).

   Tarone's trend test is most powerful at detecting dose-related trends when tumor onset hazard functions are proportional to each other. For more power against other dose-related group differences, weighted versions of the statistic are also available [62,63]. In 1985, the U.S. *Federal Register* recommended that the analysis of tumor incidence data be carried out with a Cochran–Armitage trend test [64,65]. The test statistic of the Cochran–Armitage test is defined as the term

$$T_{CA} = \sqrt{\frac{N}{(N-r)r}}, \quad \frac{\sum_{i=0}^{k}\left(R_1 - (n_1/N)r\right)d_1}{\sqrt{\sum_{i=0}^{k}(n_i/N)d_1^2\left(\sum_{i=0}^{k}(n_i/N)d_1\right)^2}}$$

with dose scores d_i. Armitage's test statistic is the square of this term (T_{CA}^2). As one-sided tests are carried out for an increase in tumor rates, the square is not considered. Instead, the earlier-mentioned test statistic presented by Portier and Hoel [66] is used. This test statistic is asymptotically standard normal distributed. The Cochran–Armitage test is asymptotically efficient for all monotone alternatives [58], but this result holds only asymptotically. Tumors are rare events, so the binominal proportions are small. In this situation, approximations may become unreliable. As a result, exact tests that can be performed using two different approaches—conditional and unconditional—are considered. In the first case, the total number of tumors r is regarded as fixed; thus, the null distribution of the test statistic is independent of the common probability p. The exact conditional null distribution is a multivariate hypergeometric distribution. The unconditional model treats the sum of all tumors as a random variable, and the exact unconditional null distribution is a multivariate binomial distribution. The distribution depends on the unknown probability.

METHODS FOR THE REDUCTION OF DIMENSIONALITY

Techniques for the reduction of dimensionality are those that simplify the understanding of data, either visually or numerically, while causing only minimal reductions in the amount of information present. These techniques operate primarily by pooling or combining groups of variables into single variables but may also entail the identification and elimination of low-information-content (or irrelevant) variables. Descriptive statistics (calculations of means, SDs, etc.) are the simplest and most familiar form of reduction of dimensionality. Here, we first need to address classification, which provides the general conceptual tools for identifying and quantifying similarities and differences between groups of things that have more than a single linear scale of measurement in common (e.g., which have both been determined to have or lack a number of enzyme activities). We will then consider two collections of methodologies that combine graphic and computational methods: multidimensional/nonmetric scaling and cluster analysis. Multidimensional scaling (MDS) is a set of techniques for quantitatively analyzing similarities, dissimilarities, and distances between data in a display-like manner. Nonmetric scaling is an analogous set of methods for displaying and relating data when measurements are nonquantitative (the data are described by attributes or ranks). Cluster analysis is a collection of graphic and numerical methodologies for classifying things based on the relationships between the values of the variables that they share. The final pair of methods for the reduction of dimensionality that will be tackled in this chapter is Fourier analysis and life-table analysis. Fourier analysis seeks to identify cyclic patterns in data and then either analyze the patterns or the residuals after the patterns are taken out. Life-table analysis techniques are directed toward identifying and quantitating the time course of risks (such as death or the occurrence of tumors).

Classification

Classification is both a basic concept and a collection of techniques that are necessary prerequisites for further analysis of data when the members of a set of data are (or can be) each described by several variables. At least some degree of classification (which is broadly defined as the division of the members of a group into smaller groups in accordance with a set of decision rules) is necessary prior to any data collection. Whether formally or informally, an investigator has to decide which things are similar enough to be counted as the same and develop rules for governing collection procedures. Such rules can be as simple as "measure and record body weights only of live animals on study" or as complex as that demonstrated by the expanded weighting classification presented in Example 9.22. Such a classification also demonstrates that the selection of which variables to measure will determine the final classification of data.

Example 9.22

Is animal of desired species?	Yes/No
Is animal member of study group?	Yes/No
Is animal alive?	Yes/No
Which group does animal belong to?	
Control	
Low dose	
Intermediate dose	
High dose	
What sex is the animal?	Male/Female
Is the measured weight within an acceptable range?	Yes/No

Classifications of data have two purposes [67,68]: *data simplification* (also known as *descriptive function*) and *prediction*. Simplification is necessary because there is a limit to both the volume and the complexity of data that the human mind can comprehend and deal with conceptually. Classification allows us to attach a label (or name) to each group of data, to summarize the data (i.e., assign individual elements of data to groups and to characterize the population of the group) and to define the relationships between groups (i.e., develop a taxonomy).

Prediction, meanwhile, is the use of summaries of data and knowledge of the relationships between groups to develop hypotheses as to what will happen when further data are collected (as when more animals or people are exposed to an agent under defined conditions) and as to the mechanisms that cause such relationships to develop. Indeed, classification is the prime device for the discovery of mechanisms in all of science. A classic example of this was Darwin's realization that there were reasons (the mechanisms of evolution) behind the differences and similarities in species that had caused Linnaeus to earlier develop his initial modern classification scheme (or taxonomy) for animals.

To develop a classification, one first sets bounds wide enough to encompass the entire range of data to be considered but not unnecessarily wide. This is typically done by selecting some global variables (variables every piece of datum has in common) and limiting the range of each so it just encompasses all the cases on hand. Then one

selects a set of local variables (characteristics that only some of the cases have, such as the occurrence of certain tumor types, enzyme activity levels, or dietary preferences) that serves to differentiate between groups. Data are then collected, and a system for measuring differences and similarities is developed. Such measurements are based on some form of measurement of distance between two cases (x and y) in terms of each single variable scale. If the variable is a continuous one, then the simplest measure of distance between two pieces of data is the Euclidean distance, $d(x,y)$, defined as

$$d(x,y) = \sqrt{(x_i - y_i)^2}$$

For categorical or discontinuous data, the simplest distance measure is the matching distance, defined as

$$d(x,y) = \text{Number of times } x_i \neq y_i$$

After we have developed a table of such distance measurements for each of the local variables, some weighting factor is assigned to each variable. A weighting factor seeks to give greater importance to those variables that are believed to have more relevance or predictive value. The weighted variables are then used to assign each piece of data to a group. The actual act of developing numerically based classifications and assigning data members to them is the realm of cluster analysis and will be discussed later in this chapter. Classification of biological data based on qualitative factors has been well discussed; Gordon [68] and Glass [69] do an excellent job of introducing the entire field and mathematical concepts.

Relevant examples of the use of classification techniques range from the simple to the complex. Schaper et al. [70] developed and used a very simple classification of response methodology to identify those airborne chemicals that alter the normal respiratory response induced by CO_2. At the other end of the spectrum, Kowalski and Bender [71] developed a more mathematically based system to classify chemical data (a methodology they termed *pattern recognition*).

Statistical Graphics

The use of graphics in one form or another in statistics is the single most effective and robust statistical tool and, at the same time, one of the most poorly understood and improperly used. Graphs are used in statistics (and in toxicology) for one of four major purposes. Each of the four is a variation on the central theme of making complex data easier to understand and use. These four major functions are exploration, analysis, communication and display of data, and graphical aids. Exploration (which may be simply summarizing data or trying to expose relationships between variables) is determining the characteristics of datasets and deciding on one or more appropriate forms of further analysis, such as the scatterplot. Analysis is the use of graphs to formally evaluate some aspects of the data, such as whether there are outliers present or if an underlying assumption of a population distribution is fulfilled. As long ago as 1960 [72], some 18 graphical methods for analyzing multivariate data relationships had been developed and proposed.

Communication and display of data are the most commonly used functions of statistical graphics in toxicology, whether for internal reports, presentations at meetings, or formal publications in the literature. When communicating data, graphs should not be used to duplicate data that are presented in tables but rather to show important trends or relationships in the data. Although such communication is most commonly of a quantitative compilation of actual data, it can also be used to summarize and present the results of statistical analysis. The fourth and final function of graphics is one that is largely becoming outdated as microcomputers become more widely available. Graphical aids to calculation include nomograms (the classic example in toxicology of a nomogram is that presented by Litchfield and Wilcoxon for determining median effective doses) and extrapolating and interpolating data graphically based on plotted data.

There are many forms of statistical graphics (a partial list, classified by function, is presented in Table 9.10), and a number of these (such as scatterplots and histograms) can be used for each of a number of possible functions. Most of these plots are based on a Cartesian system (i.e., they use a set of rectangular coordinates), and our review of construction and use will focus on these forms of graphs.

Construction of a rectangular graph of any form starts with the selection of the appropriate form of graph followed by the laying out of the coordinates (or axes). Even graphs that are going to encompass multivariate data (i.e., more than two variables) generally have two major coordinates as their starting point. The vertical axis or ordinate (also called the y-axis) is used to present an independent variable. Each of these axes is scaled in the units of measure that will most clearly present the trends of interest in the data. The range covered by the scale of each axis is selected to cover the entire region for which data are presented. The actual demarking of the measurement scale along an axis should allow for easy and accurate assessment of the coordinates of any data point, yet should not be cluttered.

Actual data points should be presented by symbols that present the appropriate indicators of location, and if they represent a summary of data from a normal data population, it would be appropriate to present a symbol for the mean and some indication of the variability (or error) associated with that population, commonly by using error bars, which present the SD (or standard error) from the mean. If, however, the data are not normal or continuous, it would be more appropriate to indicate location by the median and present the range or semiquartile distance for variability estimates. The symbols that are used to present data points can also be used to present a significant amount of additional information. At the simplest level, clearly distinct symbols (circles, triangles, squares, etc.) are very commonly used to provide a third dimension of data (most commonly the treatment group). But by clever use of symbols, all sorts of additional information can be presented. Using a method such as Chernoff's faces [73], in which faces are used as symbols of the data points (and various aspects of the faces present additional data, such as the presence or absence of eyes denoting the presence or absence

TABLE 9.10
Forms of Statistical Graphics (by Function)

Exploration		
Data Summary	**Two Variables**	**Three or More Variables**
Box and whisker plot	Autocorrelation plot	Biplot
Histogram	Cross-correlation plot	Cluster trees
Dot-array diagram	Scatterplot	Labeled scatterplot
Frequency polygon	Sequence plot	Glyphs and metroglyphs
Ogive		Face plots
Stem and leaf diagram		Fourier plots
		Similarity and preference maps
		Multidimensional scaling displays
		Weathervane plot

Analysis		
Distribution Assessment	**Model Evaluation and Assumption Verification**	**Decision Making**
Probability plot	Average vs. standard deviation	Control chart
Q–Q plot	Component-plus-residual plot	Cusum chart
P–P plot	Partial residual plot	Half-normal plot
Hanging histogram	Residual plots	Ridge trace
Rootagram		Youden plot
Poissonness plot		

Communication and Display of Data		
Quantitative Graphics	**Summary of Statistical Analyses**	**Graphical Aids**
Line chart	Means plot	Confidence limits
Pictogram	Sliding reference distribution	Graph paper
Pie chart	Notched box plot	Power curves
Contour plot	Factor space/response	Nomographs
Stereogram	Interaction plot	Sample–size curves
Color map	Contour plot	Trilinear coordinates
Histogram	Predicted response plot	
	Confidence region plot	

of a secondary pathological condition), it is possible to present a large number of different variables on a single graph.

The three other forms of graphs that are commonly used in toxicology are histograms, pie charts, and contour plots. Histograms are graphs of simple frequency distribution. Commonly, the abscissa is the variable of interest (such as lifespan or litter size) and is generally shown as classes or intervals or measurements (such as age ranges of 0–10 and 10–20 weeks). The ordinate, meanwhile, is the incidence or frequency of observations. The result is a set of vertical bars, each of which represents the incidence of a particular set of observations. Measures of error or variability about each incidence are reflected by some form of error bar on top of or in the frequency bars, as shown in Figure 9.8. The size of class intervals may be unequal (in effect, one can combine or pool several small class intervals), but it is proper in such cases to vary the width of the bars to indicate differences in interval size.

Pie charts are the only common form of quantitative graphic technique that is not rectangular; rather, the figure is presented as a circle out of which several slices are delimited. The only major use of the pie chart is in presenting a breakdown of the components of a group. Typically, the entire set of data under consideration (such as total body weight) constitutes the pie, and each slice represents a percentage of the whole (such as the percentages represented by each of several organs). The total number of slices in a pie should be small for the presentation to be effective. Variability or error can be readily presented by having a subslice of each sector shaded and labeled accordingly.

Finally, we have the contour plot, which is used to depict the relationships in a three-variable, continuous data system. That is, a contour plot visually portrays each contour as a locus of the values of two variables associated with a constant value of the third variable. An example would be a relief map that gives both latitude and longitude of constant altitude using contour lines.

The most common misuse of graphs is to either conceal or exaggerate the extent of the difference by using inappropriately scaled or ranged axis. Tufte [74] has identified a statistic for evaluating the appropriateness of scale size, the *lie factor*, defined as

$$\text{Lie factor} = \frac{\text{Size of effect shown in graph}}{\text{Size of effect in data}}$$

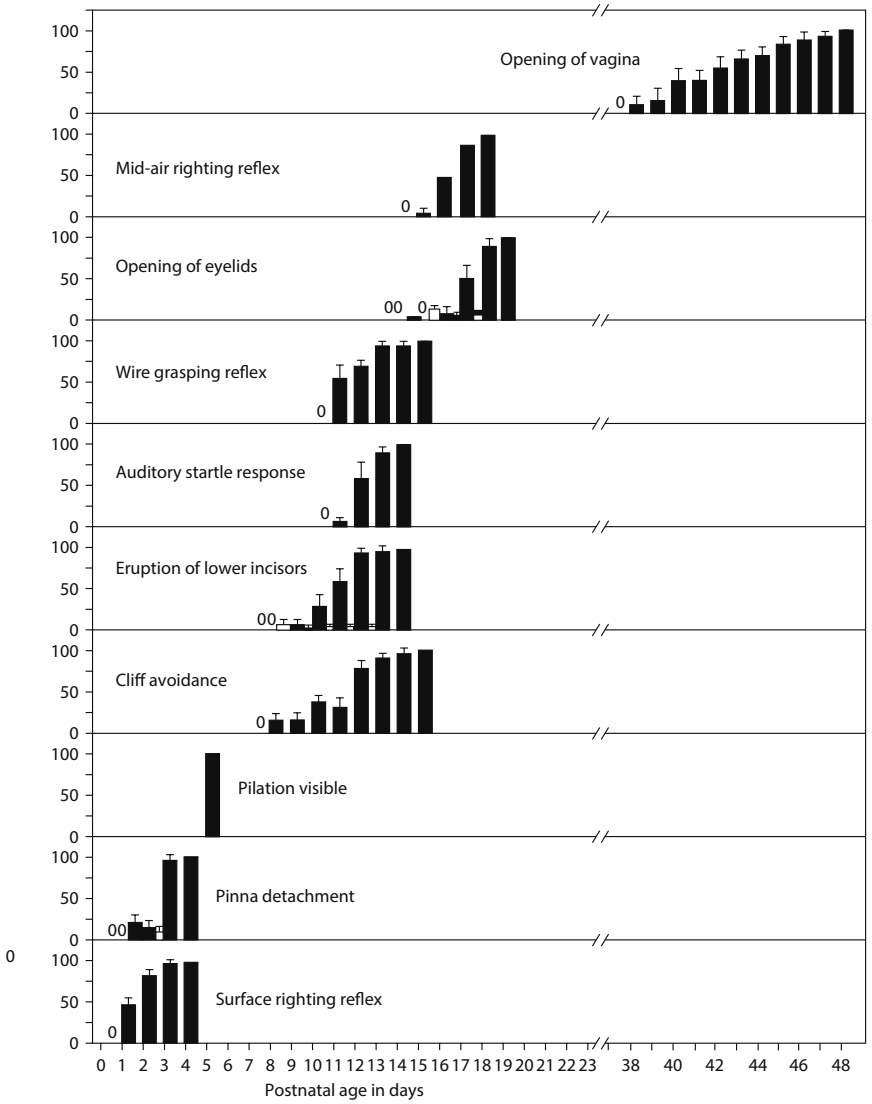

FIGURE 9.8 Acquisitions of postnatal development landmarks in rats.

An acceptable range for the lie factor is from 0.95 to 1.05. Less means the size of an effect is being understated; more means that the effect is being exaggerated. A number of excellent references are available for those who would like to pursue statistical graphics more. Anscombe [10] presents an excellent short overview, while other references [14,74–76] provide a wealth of information.

Multidimensional and Nonmetric Scaling

MDS is a collection of analysis methods for datasets that have three or more variables making up each data point. MDS displays the relationships of three or more dimensional extension of the methods of statistical graphics. MDS presents the structure of a set of objects from data that approximate the distances between pairs of the objects. The data, called *similarities*, *dissimilarities*, *distances*, or *proximities*, must be in such a form that the degree of similarities and differences between the pairs of the objects (each of which represents a real-life data point) can be measured and handled as a distance (remember the discussion of measures of distances under classifications). Similarity is a matter of degree; small differences between objects cause them to be similar (a high degree of similarity), while large differences cause them to be considered dissimilar (a small degree of similarity).

In addition to the traditional human conceptual or subjective judgments or similarity, data can be an objective similarity measure (the difference in weight between a pair of animals) or an index calculated from multivariate data (the proportion of agreement in the results of a number of carcinogenicity studies); however, the data must always represent the degree of similarity of pairs of objects. Each object or data point is represented by a point in a multidimensional space. These plots or projected points are arranged in this space so the distances between pairs of points have the strongest possible relation to the degree of similarity among the pairs of objects. That is, two similar objects are represented by two points that are close together, and two dissimilar objects are

represented by a pair of points that are far apart. The space is usually a two- or three-dimensional Euclidean space, but it may be non-Euclidean and may have more dimensions.

MDS is a general term that includes a number of different types of techniques; however, all seek to allow geometric analysis of multivariate data. The forms of MDS can be classified according to the nature of the similarities in the data [77]. It can be qualitative (nonmetric) or quantitative (metric MDS). The types can also be classified by the number of variables involved and by the nature of the model used; for example, classical MDS (only one data matrix and no weighting factors used on the data), replicated MDS (more than one matrix and no weighting), and weighted MDS (more than one matrix and at least some of the data being weighted). MDS can be used in toxicology to analyze the similarities and differences between effects produced by different agents in an attempt to gain an understanding of the mechanisms underlying the actions of one agent to determine the mechanisms of the other agents. Actual algorithms and a good intermediate-level presentation of MDS can be found in Davison [78].

Nonmetric scaling is a set of graphic techniques closely related to MDS and definitely useful for the reduction of dimensionality. Its major objective is to arrange a set of objects (each object, for our purposes, consisting of a number of related observations) graphically in a few dimensions while retaining the maximum possible fidelity to the original relationships between members (i.e., values that are most different are portrayed as most distant). It is not a linear technique; it does not preserve linear relationships (i.e., *A* is not shown as twice as far from *C* as *B*, even though its value difference may be twice as much). The spacings (interpoint distances) are kept such that, if the distance of the original scale between members *A* and *B* is greater than that between *C* and *D*, then the distances on the model scale will likewise be greater between *A* and *B* than between *C* and *D*. Figure 9.5, presented earlier, uses a form of this technique to add a third dimension by using letters to present degrees of effect on the skin. This technique functions by taking observed measures of similarity or dissimilarity between every pair of *M* objects, then finding a representation of the objects as points in Euclidean space such that the interpoint distances in some sense match the observed similarities or dissimilarities by means of weighting constants.

Cluster Analysis

Cluster analysis is a quantitative form of classification. It serves to help develop decision rules and then use these rules to assign a heterogeneous collection of objects to a series of sets. This is almost entirely an applied methodology (as opposed to theoretical). The final result of cluster analysis is one of several forms of graphic displays and a methodology (set of decision-classifying rules) for the assignment of new members into the classifications. The classification procedures used are based on either density of population or distance between members. These methods can serve to generate a basis for the classification of large numbers of dissimilar variables, such as behavioral observations and compounds with distinct but related structures and mechanisms [79,80], or to separate tumor patterns caused by treatment from those caused by old age [27].

The five types of clustering techniques are [81] as follows:

- Hierarchical techniques—Classes are subclassified into groups, with the process being repeated at several levels to produce a tree that gives sufficient definition to groups.
- Optimizing techniques—Clusters are formed by optimization of a clustering criterion. The resulting classes are mutually exclusive; the objects are clearly partitioned into sets.
- Density or mode-seeking techniques—Clusters are identified and formed by locating regions in a graphic representation that contains concentrations of data points.
- Clumping techniques—These are variations of density-seeking techniques in which assignment to a cluster is weighted on some variables so clusters may overlap in graphic projections.
- Others—These methods do not clearly fall into the other classes.

Romesburg [82] provides an excellent step-by-step guide to cluster analysis.

Fourier or Time Analysis

Fourier analysis [83] is most frequently a univariate method used for either simplifying data (which is the basis for its inclusion in this chapter) or for modeling. It can, however, also be a multivariate technique for data analysis. In a sense, it is like trend analysis; it looks at the relationship of sets of data from a different perspective. In the case of Fourier analysis, the approach is to resolve the time dimension variable in the dataset. At the simplest level, it assumes that many events are periodic in nature, and if we can remove the variation in other variables because of this periodicity (by using Fourier transforms), then we can better analyze the remaining variation from other variables. The complications to this are that (1) there may be several overlying cyclic time–based periodicities and (2) we may be interested in the time-cycle events for their own sake.

Fourier analysis allows one to identify, quantitate, and (if we wish) remove the time-based cycles in data (with their amplitudes, phases, and frequencies) by use of the Fourier transform:

$$nJ_i = x_i \exp\left(-iw_i t\right)$$

where

n is the length
J is the discrete Fourier transform for that case
x is the actual data
i is the increment in the series
w is the frequency
t is the time

A graphic example of the use of Fourier analysis in toxicology is provided in Figure 9.9.

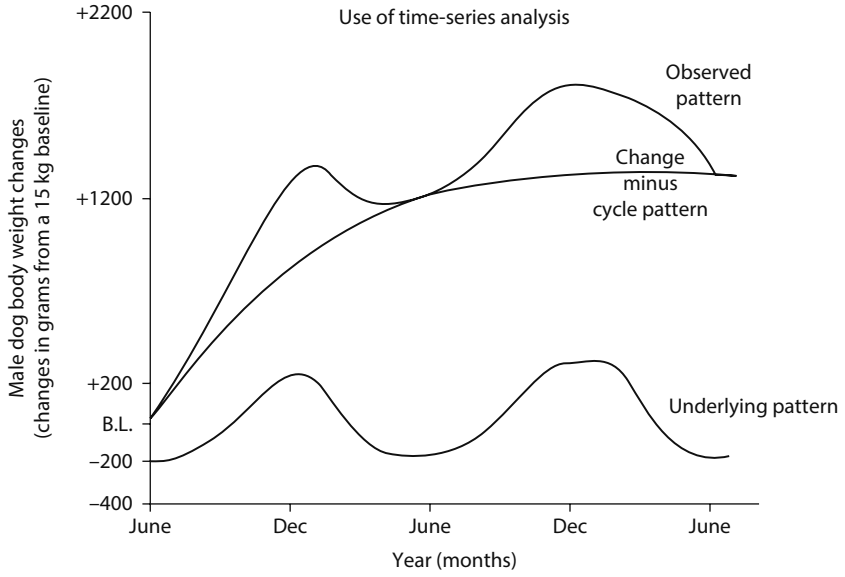

FIGURE 9.9 Use of time-series analysis.

Life Tables

Chronic in vivo toxicity studies are generally the most complex and expensive studies conducted by a toxicologist. Answers to a number of questions are sought in such a study—notably, if a material results in a significant increase in mortality or in the incidence of tumors in those animals exposed to it. But we are also interested in the time course of these adverse effects (or risks). The classic approach to assessing these age-specific hazard rates is the use of life tables (also called *survivorship tables*).

It may readily be seen that during any selected period of time (t_i), we have a number of risks competing to affect an animal. There are risks of natural death, death induced by a direct or indirect action of the test compound, and death due to such occurrences of interest of tumors [84]. Also, we are indeed interested in determining if (and when) the last two of these risks become significantly different than the natural risks (defined as what is seen to happen in the control group). Life-table methods enable us to make such determinations as the duration of survival (or time until tumors develop) and the probability of survival (or of developing a tumor) during any period of time.

We start by deciding the interval length (t_i) we wish to examine within the study. The information we gain becomes more exact as the interval is shortened, but as interval length is decreased, the number of intervals increases and calculations become more cumbersome and less indicative of time-related trends because random fluctuations become more apparent. For a 2-year or lifetime rodent study, an interval length of a month is commonly employed. Some life-table methods, such as the Kaplan–Meyer, have each new event (such as a death) define the start of a new interval.

Having established the interval length, we can tabulate our data [85]. We begin by establishing the following columns in each table, with a separate table being established for each group of animals (i.e., by sex and dose level):

- The interval of time selected (t_i)
- The number of animals in the group that entered that interval of the study alive (l_i)
- The number of animals withdrawn from the study during the interval (such as those taken for an interim sacrifice or that may have been killed by a technician error) (ω_i)
- The number of animals that died during the interval (d_i)
- The number of animals at risk during the interval $l_i = l_i - 1/2\omega_i$, or the number at the start of the interval minus one half the number withdrawn during the interval
- The proportion of animals that died ($D_i = d_i/l_i$)
- The cumulative probability of an animal surviving until the end of that interval of study: $P_i = 1 - D_i$, or 1 minus the number of animals that died during that interval divided by the number of animals at risk
- The number of animals dying until that interval (M_i)
- The number of animals found to have died during the interval (m_i)
- The probability of dying during the interval of the study: $c_i = 1 - (M_i + m_i/l_i)$, or the total number of animals dead until that interval plus the animals discovered to have died during that interval divided by the number of animals at risk through the end of that interval
- The cumulative proportion surviving (p_i) is equivalent to the cumulative product of the interval probabilities of survival (i.e., $p_i = p_1 \cdot p_2 \cdot p_3 \cdot \ldots p_x$)
- The cumulative probability of dying (C_i), equal to the cumulative product of the interval probabilities to that point (i.e., $C_i = c_1 \cdot c_2 \cdot c_3 \cdot \ldots c_x$)

With such tables established for each group in a study (as shown in Example 9.23), we may now proceed to test the hypothesis that each of the treated groups has a significantly

shorter duration of survival or that the treated groups died more quickly (note that plots of total animals dead and total animals surviving will give one an appreciation of the data but can lead to no statistical conclusions).

Now, for these two groups, we wish to determine effective sample size and to compare survival probabilities in the interval months 14–15. For the exposure group, we compute sample size as

$$l_{g14-15} = \frac{0.8400\left(1-0.8400\right)}{\left(0.0367\right)^2} = 99.7854$$

Likewise, we get a sample size of 98.1720 for the control group. The standard error of difference for the two groups here is

$$SD = \sqrt{0.0367^2 + 0.0173^2} = 0.040573$$

The probability of survival differences is $P_D = 0.9697 - 0.8400 = 0.1297$. Our test statistic is then 0.1297/0.040573 = 3.196. From our z value table, we see that the critical values are

$$p \le 0.05 = 1.960$$
$$p \le 0.01 = 2.575$$
$$p \le 0.001 = 3.270$$

As our calculated value is larger than all but the last of these, we find our groups to be significantly different at the 0.01 level ($0.01 > p > 0.001$). A multiplicity of methods is available for testing significance in life tables, with (as is often the case) the power of the tests increasing as does the difficulty of computation [58,86–88].

We begin our method of statistical comparison of survival at any point in the study by determining the standard error of the K interval survival rate as [89]

$$S_K = P_k\sqrt{\sum_1^k\left(\frac{D_i}{1'_x - d_x}\right)}$$

We can also determine the effective sample size (l_1) in accordance with

$$l_1 = \frac{P\left(1-P\right)}{S^2}$$

We can now compute the standard error of difference for any two groups (1 and 2) as

$$S_D = \sqrt{S_1^2 + S_2^2}$$

The difference in survival probabilities for the two groups is then calculated as

$$P_D = P_1 - P_2$$

We can then calculate a test statistic as

$$t' = \frac{P_D}{S_D}$$

This is then compared to the z distribution table. If $t' > z$ at the desired probability level, it is significant at that level.

Example 9.23 illustrates the life-table technique for mortality data. With increasing recognition of the effects of time (both as age and as length of exposure to unmeasured background risks), life-table analysis has become a mainstay in chronic toxicology. An example is the reassessment of the ED_{01} study [90] that radically changed interpretation of the results and understanding of underlying methods when adjustment for time on study was made. The increased importance of, and interest in the, analysis of survival data have not been restricted to toxicology, but rather have encompassed all the life sciences. Those with further interest should consult Lee [91] or Elandt-Johnson and Johnson [92], both general in their approach to the subject.

MULTIVARIATE METHODS

In a chapter of this kind, an in-depth explanation of the available multivariate statistical techniques is an impossibility; however, as the complexity of problems in toxicology increases, we can expect to confront more frequently data that are not univariate but rather multivariate (or multidimensional). For example, a multidimensional study might be one in which the animals are being dosed with two materials that interact. Suppose we measure body weight, tumor incidence, and two clinical chemistry values for test material effects and interaction. Our dimensions—or variables—are now A = dose x; B = dose y; W = body weight; C = tumor incidence; D and E, which are levels of clinical chemistry parameters; and possibly also t (length of dosing).These situations are particularly common in chronic studies [93]. Although we can continue to use multiple sets of univariate techniques as we have in the past, we risk significant losses of power, efficiency, and information when doing so, as well as an increased possibility of error [94].

Here we will also look briefly at the workings and uses of each of the most commonly employed multivariate techniques, together with several examples from the literature of their employment in toxicology and the other biological sciences. We will group the methods according to their primary function: hypothesis testing (are these significant or not?), model fitting (what is the relationship between these variables, or what would happen if a population would be exposed to x?), and reduction of dimensionality (which variables are most meaningful?). It should be noted (and will soon be obvious), however, that most multivariate techniques actually combine several of these functions.

The most fundamental concept in multivariate analysis is that of a multivariate population distribution. At this point, it is assumed that the reader is familiar with the univariate random variable and with such standard distributions as the normal distribution. Here, we extend these to the multivariate normal distribution.

Multivariate data are virtually never processed and analyzed other than by computer. One must first set up an appropriate database file and then enter the data, coding some of them to meet the requirements of the software being utilized; for example, if only numerical data are analyzed, sex may have to be coded as 1 for male and 2 for females. Having recorded the data, it is then essential to review for suspect values and errors of various kinds. There are many different types of suspect values, and it is helpful to distinguish among them:

- *Outliers*—These are defined to be observations that appear to be inconsistent with the rest of the data. They may be caused by gross recording or entering errors, but it is important to realize that an apparent outlier may occasionally be genuine and indicate a nonnormal distribution or valuable data point.
- *Inversions*—A common type of error occurs when two consecutive digits are interchanged at the recording, coding, or entering stage. The error may be trivial if, for example, 56.74 appears as 56.47, but it may generate an outlier if 56.74 appears as 65.74.
- *Repetitions*—At the coding or entering stage, it is quite easy to repeat an entire number in two successive rows or columns of a table, thereby omitting one number completely.
- *Values in the wrong column*—It is also easy to get numbers into the wrong columns.
- *Other errors and suspect values*—Many other types of errors are possible, including misrecording of data of a minor nature.

The general term used to denote procedures for detecting and correcting errors is *data editing*. This includes checks for completeness, consistency, and credibility. Some editing can be done at the end of the data entry stage. In addition, many routine checks can be made by the computer itself, particularly those for gross outliers. An important class of such checks are range tests. For each variable, an allowable range of possible values is specified, and the computer checks that all observed values lie within the given range. Bivariate and multivariate checks are also possible; for example, one may specify an allowable range for some functions of two of more variables. Checks called *if–then* checks are also possible; for example, if both age and date of birth are recorded for each animal, then one can check that the answers are consistent. If the date of birth is given, then one can deduce the corresponding age. In fact, in this example, the age observation is redundant. It is sometimes a good idea to include one or two redundant variables as a check on accuracy. Various other general procedures for detecting outliers are described by Barnett and Lewis [95].

When a questionable value or error is detected, the toxicologist must decide what to do about it. One may be able to go back to the original data source and check the observation. Inversions, repetitions, and values in the wrong column can often be corrected in this way. Outliers are more difficult to handle, particularly when they are impossible to check or have been misrecorded in the first place. It may be sensible to treat them as missing values and try to insert a value guessed in an appropriate way (e.g., by interpolation or by prediction from other variables). Alternatively, the value may have to

be left as unrecorded, and then either all observations for the given individual will have to be discarded or one will have to accept unequal numbers of observations for the different variables. With a univariate set of observations, the analysis usually begins with the calculation of two summary statistics—namely, the mean and SD. In the multivariate case, the analysis usually begins with the calculation of the mean and SD for each variable, and, in addition, the correlation coefficient for each pair of variables is usually calculated. These summary statistics are vital in providing a preliminary look at the data.

The sample mean of the *j*th variable is given by

$$\bar{x}_j = \sum_{r=1}^{n} \frac{x_{rj}}{n}$$

and the sample mean vector, x, is given by $x^T = [x_1, x_2, \ldots, x_n]$. If the observations are a random sample from a population with mean x, then the sample mean vector x is usually the point estimate of x, and this estimate can easily be shown to be unbiased. The SD of the *j*th variable is given by

$$S_j = \sqrt{\left[\sum_{r=1}^{n} \frac{\left(x_{rj} - \bar{x}_j^2\right)}{\left(n-1\right)}\right]}$$

The correlation coefficient of variables i and j is given by

$$r_{ij} = \sum_{r=1}^{n} \frac{\left(x_{ri} - \bar{x}_j\right)\left(x_{rj} - \bar{x}_j\right)}{\left(n-1\right)s_i s_j}$$

These coefficients can be conveniently assembled in the sample correlation matrix (R), which is given by

$$R = \begin{bmatrix} 1 & r_{12} & \cdots & r_{1n} \\ r_{21} & 1 & \cdots & r_{2n} \\ \vdots & & & \\ r_n^1 & r_n^2 & \cdots & 1 \end{bmatrix}$$

Note that the diagonal terms are all unity.

The interpretation of means and SDs is straightforward. It is worth looking to determine if, for example, some variables have much higher scatter than others. It is also worth looking at the form of the distribution of each variable and considering whether any of the variables must be transformed; for example, the logarithmic transformation is often used to reduce positive skewness and produce a distribution that is closer to normal. One may also consider the removal of outliers at this stage.

Three significant multivariate techniques have hypothesis testing as their primary function: *MANOVA*, *MANCOVA*, and *factor analysis*. Multivariate analysis of variance (MANOVA) is the multidimensional extension of the ANOVA process we explored before. It can be shown to have grown out of Hotelling's T^2 [96], which provides a means of testing the overall null hypothesis that two groups do not differ in their means on any of p measures. MANOVA accomplishes its comparison of two (or more) groups by reducing the set of p measures on each group to a simple number applying the linear combining rule $W_i = w_j X_{ij}$ (where w_j is a weighting factor) and then computing a univariate F ratio on the combined variables. New sets of weights (w_j) are selected in turn until the set that maximizes the F ratio is found. The final resulting maximum F ratio (based on the multiple discriminant functions) is then the basis of the significance test. As with ANOVA, MANOVA can be one way or higher order, and MANOVA has as a basic assumption a multivariate normal distribution. When Gray and Laskey [97] used MANOVA to analyze the reproductive effects of manganese in the mouse, it allowed the identification of significant effects at multiple sites. Witten et al. [98] utilized MANOVA to determine the significance of the effects of dose, time, and cell division in the action of abrin on the lymphocytes.

Multivariate analysis of covariance (MANCOVA) is the multivariate analog of ANCOVA. As with MANOVA, it is based on the assumption that the data being analyzed are from a multivariate normal population. The MANCOVA test utilizes the two residual matrices using the statistic and is an extension of ANCOVA with two or more uncontrolled variables (or covariables). A detailed discussion can be found in Tatsuoka [99].

Factor analysis is not just a technique for hypothesis testing; it can also serve a reduction of dimensionality function. It seeks to separate the variance unique to particular sets of values from that common to all members in that variable system and is based on the assumption that the intercorrelations among the n original variables are the result of there being some smaller number of variables (factors) that explain the bulk of variation seen in the variables. All of the several approaches to achieving these end results seek a determination of what percentage of the variance of each variable is explained by each factor (a factor being one variable or a combination of variables). The model in factor analysis is $y = Af + xz$, where y is an n-dimensional vector of observable responses, A is a factor loading, an $n \times q$ matrix of unknown parameters, f is a q-dimensional vector of common factor, and z is an n-dimensional vector of unique factor.

Used for the reduction of dimensionality, factor analysis is said to be a linear technique because it does not change the linear relationships between the variables being examined. Joung et al. [100] used factor analysis to develop a generalized water-quality index that promises suitability across the United States and has appropriate weightings for 10 parameters. Factor analysis promises great utility as a tool for developing models in risk analysis where a number of parameters act and interact.

Now, we move on to two multivariate modeling techniques: *multiple regression* and *discriminant analysis*. Multiple regression and correlation seek to predict one (or a few) variable from several others. It assumes that the available variables can be logically divided into two (or more) sets

and serves to establish maximal linear (or some other scale) relationships among the sets. The linear model for the regression is simply

$$Y = b_0 + b_1X_1 + b_2X_2 + \cdots + b_pX_p$$

where

Y is the predicted value
b values are set to maximize correlations between X and Y and Y and Y (the actual observations)

The Xs are independent of predictor variables, and the Ys are dependent variables or outcome measures. One of the outputs from the process will be the coefficient of multiple correlation, which is simply the multivariate equivalent of the correlation coefficient (r).

Schaeffer et al. [101] have neatly demonstrated the utilization of multiple regression in studying the contribution of two components of a mixture to its toxicological action, using quantitative results from an Ames test as an endpoint. Paintz et al. [102] similarly used multiple regression to model the quantitative structure–activity relationships of a series of 14 1-benzoyl-3-methyl-pyrazole derivatives.

Discriminant analysis has for its main purpose to find linear combinations of variables that maximize the differences between the populations being studied, with the objective of establishing a model to sort objects into their appropriate populations with minimal error. At least four major questions are, in a sense, being asked of the data:

- Are there significant differences among the K groups?
- If the groups do exhibit statistical differences, how do the central masses (or centroids, the multivariate equivalent of means) of the populations differ?
- What are the relative distances among the K groups?
- How are new (or at this point unknown) members allocated to establish groups? How do you predict the set of responses of characteristics of an as yet untried exposure case?

The discriminant functions used to produce the linear combinations are of the form

$$D_I = d_{i1}X_i + d_{i2}Z_2 + \cdots + d_{ip}Z_p$$

where

D_I is the score on the discriminant function I
d values are weighting coefficients
Z values are standardized values of the discriminating variables used in the analysis

It should be noted that discriminant analysis can also be used for the hypothesis-testing function by the expedient of evaluating how well it correctly classifies members into proper groups (say, control, treatment 1, treatment 2, etc.). Taketomo et al. [103] used discriminant analysis in a retrospective study of gentamycin nephrotoxicity to identify patient risk factors (i.e., variables that contributed to a prediction of a patient being at risk).

Finally, we introduce four techniques whose primary function is the reduction of dimensionality: *canonical correlation analysis*, *principal components analysis*, *biplot analysis*, and *correspondence analysis*. Canonical correlation analysis provides the canonical R, an overall measure of the relationship between two sets of variables (one set consisting of several outcome measures, and the other of several predictor variables). The canonical R is calculated on two numbers for each subject:

$$W_i = \sum w_j X_{ij} \quad \text{and} \quad V_i = \sum v_j Y_{ij}$$

where

X values are predictor variables
Y values are outcome measures
W_j and V_j are canonical coefficients

MANOVA can be considered a special case of canonical correlation analysis. Canonical correlation can also be used in hypothesis testing for testing the association of pairs of sets of weights, each with a corresponding coefficient of canonical correlation, each uncorrelated with any of the preceding sets of weights, and each accounting for successively less of the variation shared by the two sets of variables. For example, Young and Matthews [104] used canonical correlation analysis to evaluate the relationship between plant growth and environmental factors at 12 different sites.

The main purpose of principal components analysis is to describe, as economically as possible, the total variance in a sample in a few dimensions; that is, one wishes to reduce the dimensionality of the original data while minimizing the loss of information. It seeks to resolve the total variation of a set of variables into linearly independent composite variables that successively account for the maximum possible variability in the data. The fundamental equation is $Y = AZ$, where A is a matrix of scaled eigenvectors, Z is the original data matrix, and Y represents the principal components. The concentration here, as in factor analysis, is on relationships within a single set of variables. Note that the results of principal components analysis are affected by linear transformations. Cremer and Seville [105] used principal components analysis to compare the difference in blood parameters resulting from each of two separate pyrethroids. Henry and Hidy [106], meanwhile, used principal components analysis to identify the most significant contributors to air quality problems.

The biplot display [107] of multivariate data is a relatively new technique that promises wide applicability to problems in toxicology. It is, in a sense, a form of EDA, used for data summarization and description. The biplot is a graphical display of a matrix Y_{nmx} of N rows and M columns by means of row and column markers. The display carries one marker for each row and each column. The *bi* in biplot refers to the joint display of rows and columns. Such plots are used primarily

for inspection of data and for data diagnostics when such data are in the form of matrices. Shy-Modjeska et al. [108] illustrated this usage in the analysis of aminoglycoside renal data from beagle dogs, allowing the simultaneous display of relationships among different observed variables and presentation of the relationship of both individuals and treatment groups to these variables.

Correspondence analysis is a technique for displaying the rows and columns of a two-way contingency table as points in a corresponding low-dimensional vector space. As such, it is equivalent to simultaneous linear regression (for contingency table data, such as tumor incidences, which is a very common data form in toxicology), and it can be considered a special case of canonical correlation analysis. The data are defined, described, and analyzed in a geometric framework. This is particularly attractive to such sets of observations in toxicology as multiple endpoint behavioral scores and scored multiple tissue lesions.

A number of good surveys of multivariate techniques are available that are not excessively mathematical [109–111]. More rigorous mathematical treatments on an introductory level are also available [112]. Most of the techniques we have described are available in the better computer statistical packages.

META-ANALYSIS

Meta-analysis, meaning *analysis among* (and actually entailing analysis of multiple existing analyses), is being used increasingly in biomedical research to try to obtain a qualitative or quantitative synthesis of the research literature on a particular issue. The technique is usually applied to the synthesis of several separate but comparable studies to yield a single answer. Though dating back to the 1930s [113], only recently has it become popular. The process of systematic reviews and meta-analysis has three main components: (1) systematic review and selection of studies, plus (2) quantitative and (3) qualitative analyses [114–116].

Selection of Studies for Analysis: Systematic Reviews

The issue of study selection is perhaps the most problematic for those investigators doing meta-analysis. The criteria for selection may vary from project to project; however, several factors concerning selection must be addressed before analyses commence. Each choice made by the investigator must be weighed carefully as to the likely effect of selection bias vs. the perceived bias that the selection was designed to remove:

- *Use of gray literature.* The current dogma among many scientists is that only peer-reviewed literature is valuable for inclusion in reviews and, therefore, by inference systematic reviews. Should studies be limited to those that are peer reviewed or published? It is well known that negative studies, or those that report little or no benefit from following a particular course of action, are less likely to be published than positive studies; therefore, the published literature may be biased toward studies with positive results, and a synthesis of these studies would give a biased estimate of the impact of pursuing some courses of action. When a systematic review is planned, a plethora of industrial, academic, and government research papers have often been prepared that deal with the issue under consideration. Unfortunately, access to this gray literature is limited, although search engines are now available that can be used to attempt to discover this unpublished information. These studies may give a less biased report on the topic in question; however, some of these unpublished studies may be of lower quality than peer-reviewed materials. Sometimes poor research methods can produce reported results that underestimate the impact, hence providing an opposite bias to that described earlier.
- *Peer review.* As mentioned earlier, peer review is considered the primary method for quality control in scientific publishing. Should publications in a systematic review and meta-analysis be limited to peer-reviewed articles and, if so, what journals should be included or excluded? The choice of journal may be used as another filter based on the rigor of review and editor latitude given to fill the journal. Some investigators recommend that only those studies that are published in peer-reviewed publications be considered in meta-analysis. Although this may seem an attractive option, it might produce an even more highly biased selection of studies for systematic review.
- *Quality control.* Peer review is not the only method of providing quality control and quality-assured data for meta-analysis. Additional quality control and assurance criteria may be used to select the best and most reliable data during systematic review. A rhetorical question we could ask is "Should studies be limited to those that meet additional quality control criteria?" If investigators, undertaking a systematic review, impose an additional set of criteria before including a study in the meta-analysis, the average quality of the studies used should be improved. Contrary to the quality issue is the concern about selection bias. In fact, by placing specific quality filters on data, the investigators may introduce more bias than created by the poor quality data. Moreover, different investigators may use different criteria for a valid study and therefore select a different group of studies for meta-analysis. The result is a possible conflicting output of the meta-analysis.
- *Study design.* Some investigators insist that systematic reviews be limited to randomized controlled studies. Such a limitation produces a variant of the potential bias described earlier. At one time,

rigid quality standards were more likely to be met by randomized controlled studies than by observational studies, but this is no longer necessarily the case. Observational methods are currently used to evaluate naturally occurring effects, particularly those that are uncommon. It is quite possible that more important issues, such as combining data from studies performed in different laboratories and using different strains of a single animal species, may result in more systematic error than the study design.

- *Methodology.* Different methodologies can cause differing degrees of systematic bias on output data. This begs the question "Should studies selected for use in meta-analysis be limited to those using identical methods?" This limitation would mean using only separately published studies from the same laboratory in a limited time frame for which the methods were comprehensively monitored and determined to be identical. In practice, application of this filter would massively reduce the number of studies that could be used in the meta-analysis whose power would therefore be decreased greatly. Accordingly, the user must understand the inherent differences between studies and exercise caution and judgment in selecting and rejecting them for use.

Pooled (Quantitative) Analysis

The main purpose of meta-analysis is to provide a quantitative assessment of the similarity of responses in a number of studies. The goal is to develop better overall estimates of the degree of benefit achieved by specific exposure and dosing techniques based on the combining, or pooling, of estimates found in the existing studies of the interventions. This type of meta-analysis is sometimes called a *pooled analysis* because the analyst pools the observations of many studies and then calculates parameters such as risk or odds ratios from the pooled data. Because of the many decisions regarding inclusion or exclusion of studies, different meta-analyses might reach very different conclusions on the same topic. Even after the studies are chosen, many other methodological issues are involved in choosing how to combine means and variances (e.g., what weighting methods should be used). Pooled analysis should report relative risks and risk reductions as well as absolute risks and risk reductions.

Methodological (Qualitative) Analysis

Sometimes the question to be answered is not how much toxicity is induced by the use of a particular exposure but whether there is any biologically significant toxicity. In this case, a qualitative meta-analysis may be done, in which the quality of the research is scored according to a list of objective criteria. The analyst then examines the methodologically superior studies to determine whether the question of toxicity is answered consistently by them. This qualitative approach has been referred to as *methodological analysis* or *quality scores analysis*. In some cases, the methodologically strongest studies agree with one another and disagree with the weaker studies. These weaker studies may be consistent with one another.

Bayesian Inference

Sensitivity and specificity of a test are important to characterize and to understand the accuracy and precision of the data generated. Once a researcher decides to use a certain test to diagnose an illness, two important questions require answers. First, if the test results are positive, what is the probability that the researcher has uncovered the condition of interest? Second, if the test results are negative, what is the probability that the patient does not have the disease? Bayes's theorem provides a method to answer these two questions. The English clergyman after whom it is named first described the theorem centuries ago [117]. It is one of the most imposing statistical formulas in the biomedical sciences. Put in symbols more meaningful for researchers such as toxicologists and pathologists [118], the formula is as follows:

$$P(D|T+) = \frac{p(T+|D+)\,p(D+)}{\left[p(T+|D+)\,p(D+)\right] + \left[p(T+|D-)\,p(D-)\right]}$$

where

p denotes probability
$D+$ means that the animal has the effect in question
$D-$ means that the animal does not have the effect
$T+$ means that a certain diagnostic test for the effect is positive
$T-$ means that the test is negative

Vertical line (|) means *conditional upon* what immediately follows

Most researchers, who have to address sensitivity, specificity, and predictive values, often do not wish to use Bayes's theorem; however, this is a useful formula. Closer examination of the equation reveals that Bayes's theorem is merely the formula for the positive predictive value.

The numerator of Bayes's theorem describes cell a, the true-positive results, in a 2 × 2 table. The probability of being in cell a is equal to the prevalence multiplied by the sensitivity, where $p(D+)$ is the prevalence (i.e., the probability of being in the affected column) and $p(T+|D+)$ is the sensitivity (i.e., the probability of being in the top row, given the fact of being in the affected column). The denominator of Bayes's theorem consists of two terms, the first of which again describes cell a, the true-positive results, and the second of which describes cell b, the false-positive error rate. This rate can be represented by $p(T+|D-)$, which is multiplied by the prevalence of unaffected animals or

$p(D-)$. True-positive results (a) divided by true-positive plus false-positive results ($a + b$) gives $a/(a + b)$, the positive predictive value.

In genetics, a simpler formula for Bayes's theorem is sometimes used. The numerator is the same, but the denominator is $p(T+)$. This makes sense because the denominator in $a/(a + b)$ is equal to all of those who have positive test results, whether they are true-positive or false-positive results.

Bayes's Theorem in the Evaluation of Safety Assessment Studies

In a population with a low prevalence of a particular toxicity, most of the positive results in a screening program for that lesion or effect would be falsely positive. Although this does not automatically invalidate a study or assessment program, it does raise some concerns about cost effectiveness, which can be explored using Bayes's theorem.

An example to illustrate Bayes's theorem is a study employing an immunochemical stain–based test to screen tissues for a specific effect. This test uses small amounts of antibody, and the presence of an immunologically bound stain is considered a positive result. If the sensitivity and specificity of the test and the prevalence of biochemical effect are known, Bayes's theorem can be used to predict what proportion of the tissues with positive test results will have true-positive results (i.e., truly showing the effect).

Figure 9.10 shows how the calculations are made. If the test has a sensitivity of 96% and if the true prevalence is 1%, then only 13.9% of tissues predicted showing a positive test result actually will be true positives. Pathologists and toxicologists can quickly develop a table that lists different levels of test sensitivity, test specificity, and effect prevalence and shows how these levels affect the proportion of positive results that are likely to be true-positive results. Although this calculation is fairly straightforward and is extremely useful, it seldom has been used in the early stages of planning for large studies or safety assessment programs.

Bayes's Theorem and Individual Animal Evaluation

Uncertainty concerning the exact cause of death of an animal is a problem that faces most toxicological pathologists. Suppose a toxicological pathologist is uncertain about an animal's cause of death and has a positive test result, such as in the example given earlier.

Even if the toxicological pathologist knows the sensitivity and specificity of the test in question, interpretation is still problematic. In order to calculate the positive predictive value, it is necessary to know the prevalence of the particular true tissue/effect that the test is designed to detect. The prevalence is thought of as the expected prevalence in the population from which the animal comes. The actual prevalence is usually not known, but usually an estimate is attempted.

PART 1 Initial data

Sensitivity of immunological stain = 96% = 0.96
False-negative error rate of the test = 04% = 0.04
Specificity of the test = 94% = 0.94
False-positive error rate of the test = 06% = 0.06
Prevalence of effect in the tissues = 01% = 0.01

PART 2 Use Bayes's theorem

$$P(D+|T+) = \frac{p(T+|D+)p(D+)}{\left[p(T+|D+)p(D+)\right] + \left[p(T+|D-)p(D-)\right]}$$

$$= \frac{(\text{Sensitivity})(\text{Prevalence})}{\left[(\text{Sensitivity})(\text{Prevalence})\right] + (\text{False}-\text{Positive error rate})(1-\text{Prevalence})}$$

$$= \frac{(0.096)(0.01)}{\left[(0.096)(0.01)\right] + \left[(0.06)(0.99)\right]}$$

$$= \frac{0.0096}{0.0096 + 0.0594} = \frac{0.0096}{0.0690} = 0.139 = 13.9\%$$

PART 3 Use of a 2 × 2 table, with numbers based on the assumption that 10,000 tissues are in the study:

True Disease Status

Test Result	Number Affected	Not Affected	Total
Positive	96 (96%)	594 (6%)	690 (7%)
Negative	4 (4%)	9306 (94%)	9,310 (93%)
Total	100 (100%)	9900 (100%)	10,000 (100%)

Positive predictive value = 96/690 = 0.139 = 13.9%.

FIGURE 9.10 Use of Bayes's theorem or a 2 × 2 table to determine the positive predictive value of a hypothetical tuberculin-screening program.

An example of such a situation is when a pathologist evaluates a male primate observed to have fatigue and signs of kidney stones. No other clinical signs of parathyroid disease are detected on physical examination. The toxicological pathologist considers the possibility of hyperparathyroidism and arbitrarily decides that its prevalence is perhaps 2%, reflecting that in 100 such primates, probably only 2 of them would have the disease. This probable disease prevalence is referred to as the *prior probability*, reflecting the fact that it is estimated prior to the performance of laboratory tests.

This probability is based on the estimated prevalence of a particular pathology among primates with similar signs and symptoms. Although the toxicological pathologist believes that the probability of hyperparathyroidism is low, he considers the serum calcium concentrations to rule out the diagnosis. Somewhat to his surprise, the results of the test are positive, with an elevated level of calcium of 12.2 mg/dL. The pathologist could order other tests for parathyroid disease, but some test results may be positive and some negative for a number of reasons.

PART 1 Initial data

Sensitivity of the first test = 90% = 0.90
Specificity of the first test = 95% = 0.95

PART 2 Use Bayes's theorem

$$P(D+|T+) = \frac{p(T+|D+)p(D+)}{\left[p(T+|D+)p(D+)\right] + \left[p(T+|D-)p(D-)\right]}$$

$$= \frac{(0.90)(0.02)}{\left[(0.90)(0.02)\right] + (0.05)(0.98)}$$

$$= \frac{0.018}{0.018 + 0.049} = \frac{0.018}{0.067} = 0.269 = 27\%$$

PART 3 Use of a 2 × 2 table

True Disease Status

Test Result	Number Affected	Not Affected	Total
Positive	18 (90%)	49 (5%)	67 (6.7%)
Negative	2 (10%)	931 (95%)	933 (93.3%)
Total	20 (100%)	980 (100%)	1000 (100.0%)

Positive predictive value = 18/67 = 0.269 = 27%.

FIGURE 9.11 Use of Bayes's theorem or a 2 × 2 table to determine posterior probability and positive predictive values.

Under these circumstances, Bayes's theorem could be used to make a second estimate of probability, referred to as the *posterior probability*, reflecting the fact that this determination is made after the test results are known. Calculation of the posterior probability is based on the sensitivity and specificity of the test that was performed, which in this case was elevated serum calcium, and on the prior probability, which in this case was set at 2%. If the serum calcium test had a 90% sensitivity and a 95% specificity, a false-positive error rate of 5% would be expected. Note that specificity plus the false-positive error rate always equals 100%.

When this information is used in Bayes's equation, as shown in Figure 9.11, the result is a posterior probability of 27%. This means that the animal in question is now within a group of primates with a significant possibility of parathyroid disease. In Figure 9.11, note that the result is the same when a 2 × 2 table is used (i.e., 27%).

This is true because the probability based on Bayes's theorem is identical to the positive predictive value.

In light of the 27% posterior probability, the pathologist decides to order a parathyroid hormone radioimmunoassay, even though this test is expensive. If the radioimmunoassay had a sensitivity of 95% and a specificity of 98% and the results turned out to be positive, Bayes's theorem could again be used to calculate the probability of parathyroid disease. This time, however, the posterior probability for the first test (27%) would be used as the prior probability for the second test. The result of the calculation, as shown in Figure 9.12, gives a new probability of 94%. Thus, the primate in all probability did have hyperparathyroidism.

PART 1 Initial data

Sensitivity of the first test = 95% = 0.95
Specificity of the first test = 98% = 0.94
Prior probability of disease = 27% = 0.27

PART 2 Use Bayes's theorem*

$$P(D+|T+) = \frac{p(T+|D+)p(D+)}{\left[p(T+|D+)p(D+)\right] + \left[p(T+|D-)p(D-)\right]}$$

$$= \frac{(0.95)(0.27)}{\left[(0.95)(0.27)\right] + (0.02)(0.73)}$$

$$= \frac{0.257}{0.257 + 0.049} = \frac{0.257}{0.272} = 0.9449^{a} = 94\%$$

PART 3 Use of a 2 × 2 table

True Disease Status

Test Result	Number Affected	Not Affected	Total
Positive	256 (95%)	15 (2%)	271 (27.1%)
Negative	13 (5%)	716 (98%)	729 (72.9%)
Total	269 (100%)	731 (100%)	1000 (100.0%)

Positive predictive value = 256/271 = 0.9446[a] = 94%.

* The slight difference in the results for the two approaches is due to rounding errors. It is not important biologically.

FIGURE 9.12 Use of Bayes's theorem or a 2 × 2 table to determine second posterior probability and second positive predictive values.

The reader may be wondering why the posterior probability increased so much the second time. One reason was that the prior probability was considerably higher in the second calculation compared to the first (27% vs. 2%) based on the fact that the first test yielded positive results. Another reason was that the specificity of the second test was high (98%), which markedly reduced the false-positive error rate and therefore increased the positive predictive value.

Assumptions and Limitations

1. Test results must be independent of each other. This also means that the population remaining after one test must have the same proportional response to the following tests as the original population did.
2. If the calculations are done on an iterative basis, care must be taken to correct for cumulative round-off errors.

DATA ANALYSIS APPLICATIONS IN TOXICOLOGY

Having reviewed basic principles and provided a set of methods for statistical handling of data, the remainder of this chapter addresses the practical aspects and difficulties encountered in day-to-day toxicological work. As a starting point, we present in Table 9.11 an overview of data types

TABLE 9.11
Classification of Data Commonly Encountered in Toxicology

Type of Data	Examples
Continuous normal	Body weights
	Food consumption
	Organ weights: absolute and relative
	Mouse ear swelling test (MEST) measurements
	Pregnancy rates
	Survival rates
	Crown–rump lengths
	Hematology (some)
	Clinical chemistry (some)
Continuous but not normal	Hematology (some; WBC)
	Clinical chemistry (some)
	Urinalysis
Scalar data	Neurobehavioral signs (some)
	PDI scores
	Histopathology (some)
Count data	Resorption sites
	Implantation sites
	Stillborns
	Hematology (some; reticulocyte counts, Howell-Jolly, WBC differentials)
Categorical data	Clinical signs
	Neurobehavioral signs (some)
	Ocular scores
	GP sensitization scores
	Mouse ear swelling test (MEST) sensitization
	Counts
	Fetal abnormalities
	Dose/mortality data
	Sex ratios
	Histopathology data (most)

actually encountered in toxicology, classified by type (as presented earlier). It should be stressed, however, that this classification is of the most frequent measure of each sort of observation (such as body weight) and will not always be an accurate classification. There are now common practices in the analysis of toxicology data, although they are not necessarily the best. They are discussed in the remainder of this chapter, which seeks to review statistical methods on a use-by-use basis and to provide a foundation for the selection of alternatives in specific situations.

Median Lethal and Effective Doses

For many years, the starting point for evaluating the toxicity of an agent was to determine its LD_{50} or LC_{50}, which are the dose or concentration, respectively, of a material at which half of a population of animals would be expected to die. These figures are analogous to the ED_{50} (effective dose for half a population) used in pharmacologic activities and are derived by the same means. To calculate either of these figures we need, at each of several dosage (or exposure) levels, the number of animals dosed and the number that died. If we seek to establish only the median effective dose in a range-finding test, then four or five animals per dose level, using Thompson's method of moving averages, is the most efficient methodology and will give a sufficiently accurate solution. With two dose levels, if the ratio between the high and low doses is 2 or less, even total or no mortality at these two dose levels will yield an acceptably accurate medial lethal dose, although a partial mortality is desirable. If, however, we wish to estimate a number of toxicity levels (LD_{10}, LD_{90}) and are interested in more precisely establishing the slope of the dose/lethality curve, the use of at least 10 animals per dosage level with the probit/log regression technique is the most common approach. Note that in the equation $Y_i = a + bx_1$, b is the slope of the regression line and that our method already allows us to calculate 95% CIs about any point on this line. The CI at any one point will be different from the interval at other points and must be calculated separately. Additionally, the nature of the probit transform is such that toward the extremes—LD_{10} and LD_{90}, for example—the CIs will balloon. That is, they become very wide. Because the slope of the fitted line in these assays has a very large uncertainty, in relation to the uncertainty of the LD_{50} itself (the midpoint of the distribution), much caution must be used with calculated LD_x values other than LD_{50}. The imprecision of the LD_{35}, a value close to the LD_{50}, is discussed by Weil [119], as is that of the slope of the log dose–probit line [120]. Debanne and Haller [121] recently reviewed the statistical aspects of different methodologies for estimating a median effective dose.

There have been questions for years as to the value of LD_{50} and the efficiency of the current study design (which uses large numbers of animals) in determining it. As long ago as 1953, Weil et al. [122] presented forceful arguments that an estimate having only minimally reduced precision could be made using significantly fewer animals. More recently, the last few years have seen an increased level of concern over the numbers and uses of animals in research and testing and have produced additional arguments against existing methodologies for determining the LD_{50} or even the need to make the determination at all [123]. In response, several suggestions for alternative methodologies have been advanced [124–126].

Body and Organ Weights

Among the sets of data commonly collected in studies where animals are dosed with (or exposed to) a chemical are body weight and the weights of selected organs; in fact, body weight is frequently the most sensitive indication of an adverse effect. How to best analyze this and in what form to analyze the organ weight data (as absolute weights, weight changes, or percentages of body weight) have been the subject of a number of articles [127–130].

Both absolute body weights and rates of body weight change (calculated as changes from a baseline measurement

value that is traditionally the animal's weight immediately prior to the first dosing with or exposure to the test material) are almost universally best analyzed by ANOVA followed, if called for, by a post hoc test. Even if the groups were randomized properly at the beginning of a study (no group being significantly different in mean body weight from any other group and all animals in all groups within two SDs of the overall mean body weight), there is an advantage to performing the computationally slightly more cumbersome (compared to absolute body weights) changes in body weight analysis. The advantage is an increase in sensitivity, because the adjustment of starting points (the setting of initial weights as a zero value) acts to reduce the amount of initial variability. In this case, Bartlett's test is performed first to ensure homogeneity of variance, and the appropriate sequence of analysis follows. With smaller sample sizes, the normality of the data becomes increasingly uncertain, and nonparametric methods such as Kruskal–Wallis may be more appropriate [25].

The analysis of relative (to body weight) organ weights is a valuable tool for identifying possible target organs [125]. How to perform this analysis is still a matter of some disagreement, however. Weil [128] presented evidence that organ weight data expressed as percentages of body weight should be analyzed separately for each sex. Furthermore, because the conclusions from organ weight data of males differed so often from those of females, data from animals of each sex should be used in this measurement. Others [129,131–133] have discussed in detail other factors that influence organ weights and must be taken into account.

The two competing approaches to analyzing relative organ weights call for either of the following [130]:

- Calculate organ weights as a percentage of total body weight (at the time of necropsy) and analyze the results by ANOVA.
- Analyze the results by ANCOVA with body weights as the covariates, as discussed previously.

A number of considerations should be kept in mind when these questions are addressed. First, one must keep a firm grasp on the difference between biological significance and statistical significance. In this particular case, we are especially interested in examining organ weights when an organ weight change is not proportional to changes in whole body weights. Second, we are now required to detect smaller and smaller changes while still retaining a similar sensitivity (i.e., the $p < 0.05$ level). Several devices are available to attain the desired increase in power. One is to use larger and larger sample sizes (number of animals), and the other is to utilize the most powerful test we can; however, the use of even currently employed numbers of animals is being vigorously questioned, and the power of statistical tests must, therefore, now assume an increased importance in our considerations.

The biological rationale behind analyzing both absolute body weight and the ratio of organ weight to body weight (this latter as opposed to a covariance analysis of organ weights) is that, in the majority of cases, except for the brain, the organs of interest in the body change weight (except in extreme cases of obesity or starvation) in proportion to total body weight. We are particularly interested in detecting cases where this is not so. Analysis of actual data from several hundred studies (unpublished data) has shown no significant difference in rates of weight change of target organs (other than the brain) compared to total body weight for healthy animals in those species commonly used for repeated dose studies (rats, mice, rabbits, and dogs). Furthermore, it should be noted that ANCOVA is of questionable validity in analyzing body weight and related organ weight changes, because a primary assumption is the independence of treatment—that the relationship of the two variables is the same for all treatments [134]. Plainly, in toxicology, this is not true.

In cases where the differences between the error MSs are much greater, the ratio of F ratios will diverge in precision from the result of the efficiency of covariance adjustment. These cases are where either sample sizes are much larger or where the differences between means themselves are much larger. This latter case is one that does not occur in the designs under discussion in any manner that would leave ANCOVA as a valid approach, because group means start out being very similar and cannot diverge markedly unless there is a treatment effect. As we have discussed earlier, a treatment effect invalidates a prime underpinning assumption of ANCOVA. Shirley and Newman [135] have argued the case for ANCOVA, but without providing answers to arguments presented earlier.

Clinical Chemistry

Several clinical chemistry parameters are commonly determined from the blood and urine collected from animals in chronic, subchronic, and occasionally acute toxicity studies. In the past (and still, in some places), the accepted practice has been to evaluate these data using univariate–parametric methods (primarily t-tests and/or ANOVA); however, this can be shown not to be the best approach on a number of grounds.

First, such biochemical parameters are rarely independent of each other, and our interest often is not focused on just one of the parameters; rather, there are batteries of the parameters associated with toxic actions at particular target organs. For example, increases in creatinine phosphokinase (CPK), γ-hydroxybutyrate dehydrogenase (γ-HBDH), and lactate dehydrogenase (LDH), occurring together, are strongly indicative of myocardial damage. In such cases, we are not just interested in a significant increase in one of these, but in all three. Table 9.12 gives a brief overview of the association of various parameters with actions at particular target organs. A more detailed coverage of the interpretation of such clinical laboratory tests can be found in other references [136–139].

Similarly, the serum electrolytes (sodium, potassium, and calcium) interact with each other; a decrease in one is frequently tied, for instance, to an increase in one of the others. Furthermore, the nature of the data (in the case of some parameters), either

TABLE 9.12
Association of Changes in Biochemical Parameters with Actions at Particular Target Organs

Parameter	Blood	Heart	Lung	Kidney	Liver	Bone	Intestine	Pancreas	Notes
Albumin				↓	↓				Produced by the liver; very significant reductions indicate extensive liver damage
ALP					↑	↑	↑		Elevations usually associated with cholestasis; bone alkaline phosphatase tends to be higher in young animals
ALT (formerly SGPT)					↑				Elevations usually associated with hepatic damage or disease
AST (formerly SGOT)		↑		↑	↑			↑	Present in skeletal muscle and heart and most commonly associated with damage to these
Beta-2-Microglobulin				↑					
Bilirubin (total)	↑				↑				Usually elevated due to cholestasis, due to either obstruction or hepatopathy
BUN				↑	↓				Estimates blood-filtering capacity of the kidneys; does not become significantly elevated until the kidney function is reduced 60%–75%
Calcium				↑					Can be life threatening and result in acute death
Cholinesterase				↑	↓				Found in plasma, brain, and RBC
CPK		↑							Most often elevated due to skeletal muscle damage but can also be produced by cardiac muscle damage; can be more sensitive than histopathology
Creatinine				↑					Also estimates blood-filtering capacity of kidney as BUN does
Glucose								↑	Alterations other than those associated with stress uncommon and reflect an effect on the pancreatic islets or anorexia
GGT					↑				Elevated in cholestasis; this is a microsomal enzyme, and levels often increase in response to microsomal enzyme induction
HBDH		↑			↑				—
KIM-1				↑					
LDH		↑	↑	↑	↑				Increase usually due to skeletal muscle, cardiac muscle, or liver damage; not very specific
Protein (total)				↓	↓				Absolute alterations usually associated with decreased production (liver) or increased loss (kidney); can see increase in case of muscle wasting (catabolism)
SDH					↑↓				Liver enzyme that can be quite sensitive but is fairly unstable; samples should be processed as soon as possible
Trophonin		↑							

Note: ↑, increase in chemistry values; ↓, decrease in chemistry values; ALP, alkaline phosphatase; BUN, blood urea nitrogen; CPK, creatinine phosphokinase; GGT, gamma glutamyl transferase; HBDH, hydroxybutyric dehydrogenase; LDH, lactic dehydrogenase; RBC, red blood cells; SDH, sorbitol dehydrogenase; SGOT, serum glutamic oxaloacetic transaminase (also called AST [aspartate amino transferase]); SGPT, serum glutamic-pyruvic transaminase (also called ALT [alanine amino transferase]).

because of the biological nature of the parameter or the way in which it is measured, is frequently either not normally distributed (particularly because of being markedly skewed) or not continuous in nature. This can be seen in some of the reference data for experimental animals in Mitruka and Rawnsley [140] or Weil [141] in, for example, creatinine, sodium, potassium, chloride, calcium, and blood.

Hematology

Much of what we said about clinical chemistry parameters is also true for the hematologic measurements made in toxicology studies. Which test to perform should be evaluated by use of a decision tree until one becomes confident as to the most appropriate methods. Keep in mind that sets of values and (in some cases) population distribution vary not only between species but also between the commonly used strains of species, and that control or standard values will drift over the course of only a few years.

Again, the majority of these parameters are interrelated and highly dependent on the method used to determine them. RBC count, platelet counts, and mean corpuscular volume (MCV) may be determined using a device such as a Coulter counter to take direct measurements, and the resulting data are usually stable for parametric methods. The hematocrit, however, may actually be a value calculated from the RBC and MCV values and, if so, is dependent on them. If the hematocrit is measured directly, instead of being calculated

TABLE 9.13
Some Probable Conditions behind Hematological Changes

Parameter	Elevation	Depression	Parameter	Elevation	Depression
Red blood cells	Vascular shock Excessive diuresis Chronic hypoxia Hyperadrenocorticism	Anemias: blood loss, hemolysis, low RBC production	Platelets	—	Bone marrow depression Immune disorder
Hematocrit	Increased RBC Stress Shock: trauma, surgery Polycythemia	Anemias Pregnancy Excessive hydration	Neutrophils	Acute bacterial infections Tissue necrosis Strenuous exercise Convulsions Tachycardia Acute hemorrhage	—
Hemoglobin	Polycythemia (increase in the production of RBC)	Anemias Lead poisonings	Lymphocytes	Leukemia Malnutrition Viral infections	—
Mean cell volume	Anemias B_{12} deficiency	Iron deficiency	Monocytes	Protozoal infections	—
Mean corpuscular hemoglobin	Reticulocytosis	Iron deficiency	Eosinophils	Allergy Irradiation Pernicious anemia Parasitism	—
White blood cells	Bacterial infections Bone marrow stimulation	Bone marrow depression Cancer chemotherapy Chemical intoxication Splenic disorders	Basophils	Lead poisoning	—

from the RBC and MCV, it may be compared by parametric methods (see Table 9.13).

Hemoglobin is directly measured and is an independent and continuous variable. However, and probably because at any one time a number of forms and conformations (oxyhemoglobin, deoxyhemoglobin, methemoglobin, etc.) of hemoglobin are actually present, the distribution seen is not typically a normal one but rather may be a multimodal one. Here, a nonparametric technique such as the Wilcoxon or multiple rank-sum analysis is called for.

Consideration of the WBC and differential counts leads to another problem. The total WBC is, typically, a normal population amenable to parametric analysis, but differential counts are normally determined by counting, manually, one or more sets of 100 cells each.

The resulting relative percentages of neutrophils are then reported as either percentages or are multiplied by the total WBC count with the resulting count being reported as the absolute differential WBC. Such data, particularly in the case of eosinophils (where the distribution does not approach normality), should usually be analyzed by nonparametric methods. It is widely believed that relative (%) differential data should not be reported because they are likely to be misleading.

Finally, it should always be kept in mind that it is rare for a change in any single hematologic parameter to be meaningful. Rather, because these parameters are so interrelated, patterns of changes in parameters should be expected if a real effect is present, and analysis and interpretation of results should focus on such patterns of changes. Classification analysis techniques often provide the basis for a useful approach to such problems.

Histopathological Lesion Incidence

The last 20 years have seen increasing emphasis placed on histopathological examination of tissues collected from animals in subchronic and chronic toxicity studies. It is not true that only those lesions that occur at a statistically significantly increased rate in treated or exposed animals are of concern, for in some cases, a lesion may be of such a rare type that the occurrence of only one or a few such in treated animals raises a red flag. It is true, however, that in most cases, a statistical evaluation is the only way to determine if what we see in treated animals is significantly worse than what has been seen

in control animals [171]. And although cancer is not our only concern, this category of lesions is that of greatest interest.

Typically, comparison of incidences of any one type of lesion between controls and treated animals are made using the multiple 2 × 2 chi-square test or Fisher's exact test with a modification of the numbers of animals as the denominators. Too often, experimenters exclude from consideration all those animals (in both groups) that died prior to the first animals being found with a lesion at that site. The special case of carcinogenicity bioassays will be discussed in detail in the next chapter.

An option that should be kept in mind is that, frequently, a pathologist can not only identify a lesion as present but also grade those present as to severity. This represents a significant increase in the information content of the data that should not be given up by performing an analysis based only on the perceived quantal nature (present/absent) of the data. Quantal data, analyzed by chi-square or Fisher's exact tests, are a subset (the 2 × 2 case) of categorical or contingency table data. In this case, it also becomes ranked (or ordinal) data; the categories are naturally ordered (e.g., no effect < mild lesion < moderate lesion < severe lesion). This gives a $2 \times R$ table if there are only one treatment and one control group or an $N \times R$ (multiway) table if there are three or more groups of animals.

The traditional method of analyzing multiple, cross-classified data has been to collapse the $N \times R$ contingency table over all but two of the variables, following this with the computation of some measure of association between these variables. For an N-dimensional table, this results in $N(N-1)/2$ separate analyses. The result is crude, giving away information and even (by inappropriate pooling of data) yielding a faulty understanding of the meaning of data. Though computationally more laborious, a multiway ($N \times R$ table) analysis should be utilized.

Reproduction

The reproductive implications of the toxic effects of chemicals are being increasingly important. Because of this, reproduction studies, together with other closely related types of studies (such as teratogenesis, dominant lethal, and mutagenesis studies), are now commonly companion to chronic toxicity studies. One point that must be kept in mind with all reproduction-related studies is the nature of the appropriate sampling unit. What is the appropriate N in such a study: the number of individual pups, the number of litters, the number of pregnant females? Fortunately, it is now fairly well accepted that the first case (using the number of offspring as the N) is inappropriate [129]. The real effects in such studies actually occur in the female that was exposed to the chemical or is mated to a male that was exposed. What happens to her and to the development of the litter she is carrying is biologically independent of what happens to every other female or litter in the stud. This cannot be said for each offspring in each litter; for example, the death of one member of a litter can and will be related to what happens to every other member. Also, the effect on all of the offspring might be similar for all of those from one female and different or lacking for those from another.

As defined by Oser and Oser [142], four primary variables are of interest in a reproduction study. First is the fertility index, which may be defined as the percentage of attempted matings (i.e., each female housed with a male) that resulted in pregnancy, pregnancy being determined by a method such as the presence of implantation sites in the female. Second is the gestation index, which is defined as the percentage of mated females, as evidenced by a vaginal plug being dropped or a positive vaginal smear, that deliver viable litters (i.e., litters with at least one live pup). Two related variables that may also be studied are the mean number of pups born per litter and the percentage of total pups per litter that are stillborn. Third is the viability index, which is defined as the percentage of offspring born that survive at least 4 days after birth. The last in this four-variable system is the lactation index, which is the percentage of animals per litter that survive 4 days and also survive to weaning. In rats and mice, this is classically taken to be 21 days after birth. An additional variable that may reasonably be included in such a study is the mean weight gain per pup per litter.

Given that our N is at least 10, we may test each of these variables for significance using a method such as the Wilcoxon–Mann–Whitney U test or the Kruskal–Wallis nonparametric ANOVA. If N is less than 10, we cannot expect the central limit theorem to be operative and should use the Wilcoxon sum of ranks (for two groups) or the Kruskal–Wallis nonparametric ANOVA (for three or more groups) to compare groups.

Developmental Toxicology

When the primary concern of a reproductive/developmental study is the occurrence of birth defects or deformations (terata, either structural or functional) in the offspring of exposed animals, the study is one of developmental toxicology (teratology). In the analysis of the data from such a study, we must consider several points. First is sample size. Earlier, a method to estimate sufficient sample size was presented. The difficulties with applying these methods here revolve around two points: (1) selecting a sufficient level of sensitivity for detecting an effect and (2) factoring in how many animals will be removed from study (without contributing a datum) by either not becoming pregnant or not surviving to a sufficiently late stage of pregnancy. Experience generally dictates that one should attempt to have 20 pregnant animals per study group if a pilot study has provided some confidence that the pregnant test animals will survive the dose levels selected. Again, it is essential to recognize that the litter, not the fetus, is the basic independent unit for each variable.

A more fundamental consideration, alluded to in the section on "Reproduction," is that as we use more animals, the mean of means (each variable will be such in a mathematical sense)

will approach normality in its distribution. This is one of the implications of the central limit theorem; even when the individual data are not normally distributed, their means will approach normality in their distribution. At a sample size of 10 or greater, the approximation of normality is such that we may use a parametric test (such as a *t*-test or ANOVA) to evaluate results. At sample sizes less than 10, a nonparametric test (Wilcoxon rank-sum or Kruskal–Wallis nonparametric ANOVA) is more appropriate. Other methodologies have been suggested [143,144] but do not offer any prospect of widespread usage. One nonparametric method that is widely used is the Mann–Whitney U test, which was described earlier. Williams and Buschbom [145] further discuss some of the available statistical options and their consequences, and Rai and Ryzin [146] have recommended a dose-responsive model.

Dominant Lethal Assay

The dominant lethal study is essentially a reproduction study that seeks to study the endpoint of lethality to the fetuses after implantation and before delivery. The proper identification of the sampling unit (the pregnant female) and the design of an experiment so that a sufficiently large sample is available for analysis are the primary statistical considerations. The question of sampling unit has been adequately addressed in earlier sections. Sample size is of concern here because the hypothesis-testing techniques that are appropriate with small samples are of relatively low power, as the variability about the mean in such cases is relatively large. With sufficient sample size (e.g., from 30 to 50 pregnant females per dose level per week [147]), variability about the mean and the nature of the distribution allow sensitive statistical techniques to be employed.

The variables that are typically recorded and included in analysis are (for each level/week) (1) the number of pregnant females, (2) live fetuses per pregnancy, (3) total implants per pregnancy, (4) early fetal deaths (early resorptions) per pregnancy, and (5) late fetal deaths per pregnancy.

A wide variety of techniques for the analysis of these data have been used. Most common is the use of ANOVA after the data have been transformed by the arc sine transform [148]. Beta binomial [149,150] and Poisson distributions [151] have also been attributed to these data, and transforms and appropriate tests have been proposed for use in each of these cases (in each case with the note that the transforms serve to stabilize the variance of the data). With sufficient sample size, as defined earlier in this section, the Mann–Whitney U test is recommended for use here. Smaller sample sizes necessitate the use of the Wilcoxon rank-sum test.

Diet and Chamber Analysis

Earlier we presented the basic principles and methods for sampling. Sampling is important in many aspects of toxicology, and here we address its application to diet preparation and the analysis of atmospheres from inhalation chambers. In feeding studies, we seek to deliver doses of a material to animals by mixing the material with their diet. Similarly, in an inhalation study, we mix a material with the air the test animals breathe. In both cases, we must then sample the medium (food or atmosphere) and analyze these samples to determine what levels or concentrations of material were actually present and to assure ourselves that the test material is homogeneously distributed. Having an accurate picture of these delivered concentrations, and how they varied over the course of time, is essential on a number of grounds:

1. The regulatory agencies and sound scientific practice require that analyzed diet and mean daily inhalation atmosphere levels be ±10% of the target level.
2. Excessive peak concentrations, because of the overloading of metabolic repair systems, could result in extreme acute effects that would lead to results in a chronic study that are not truly indicative of the chronic low-level effects of the compound but rather of periods of metabolic and physiologic overload. Such results could be misinterpreted if true exposure or diet levels were not maintained at a relatively constant level.

Sampling strategies are a matter not just of numbers (for statistical aspects) but also of geometry, so the contents of a container or the entire atmosphere in a chamber can be truly sampled; it is also a matter of time, with regard to the stability of the test compound. The samples must be both randomly collected and representative of the entire mass of what one is trying to characterize. In the special case of sampling and characterizing the physical properties of aerosols in an inhalation study, some special considerations and terminology apply. Because of the physiologic characteristics of the respiration of humans and of test animals, our concern is very largely limited to those particles or droplets that are of a respirable size. Unfortunately, respirable size is a complex characteristic based on aerodynamic diameter, density, and physiological characteristics. Although particles with an aerodynamic diameter of less than 10 μm are generally agreed to be respirable in humans (i.e., they can be drawn down to the deep portions of the lungs), 3 μm in aerodynamic diameter is a more realistically value. Typically, it then becomes a matter of calculating measures of central tendency and dispersion statistics, with the identification of those values that are beyond acceptable limits [49].

Genotoxicity

In the last 25 years, a wide variety of tests [152] for genotoxicity have been developed and brought into use. These tests give us a quicker and less expensive (although not as conclusive) way of predicting whether a material of interest is a mutagen, and possibly a carcinogen, than do longer-term whole-animal studies. How to analyze the results of the multitude of tests (Ames, DNA repair, micronucleus, chromosome aberration, cell transformation, and sister chromatid exchange, to name

a few) is an extremely important question. Some workers in the field hold that it is not possible (or necessary) to perform statistical analysis and that the tests can simply be judged to be positive or not positive on the basis of whether or not they achieve a particular increase in the incidence of mutations in the test organism. Quantitations of potency are complicated by the fact that we are dealing with a nonlinear phenomenon; although low doses of most genotoxicants produce a linear response curve with increasing dose, the curve will flatten out (and even turn into a declining curve) as the higher doses provoke an acute response.

Several concepts different from those we have previously discussed need to be examined, for our concern has now shifted from how a multicellular organism acts in response to one of a number of complex actions to how a mutational event is expressed, most frequently by a single cell. Given that we can handle much larger numbers of experimental units in systems that use smaller test organisms, we can seek to detect both weak and strong mutagens.

Conducting the appropriate statistical analysis and utilizing the results of such an analysis properly must begin with an understanding of the biological system involved, and from this understanding, the correct model and hypothesis must be developed. We begin such a process by considering each of five interacting factors [153,154]:

1. α, which is the probability of our committing a type I error (saying an agent is mutagenic when it is not, equivalent to our *p* in such earlier considered designs as Fisher's exact test)—false positive
2. β, which is the probability of our committing a type II error (saying an agent is not mutagenic when it is)—false negative
3. Δ, our desired sensitivity in an assay system (such as being able to detect an increase of 10% in mutations in a population)
4. σ, the variability of the biological system and the effects of chance errors
5. *n*, the single necessary sample size to achieve each of these (we can, by our actions, change only this portion of the equation) as *n* is proportional to σ/α, β, and Δ

The implications of this are, therefore, that (1) the greater σ is, the larger *n* must be to achieve the desired levels of α, β, and Δ; (2) the smaller the desired levels of α, β, and/or Δ (if *n* is constant), the larger our σ is.

What are the background mutation level and the variability in our technique? As any good genetic or general toxicologist will acknowledge, matched concurrent control groups are essential. Fortunately, with these test systems, large *n* values are readily attainable, although there are other complications to this problem, which we will consider later. An example of the confusion that would otherwise result is illustrated in the intralaboratory comparisons on some of these methods done to date, such as that reviewed by Weil [155].

New statistical tests based on these assumptions and upon the underlying population distributions have been proposed, along with the necessary computational background to allow one to alter one of the input variables [α, β, or Δ]. A set that shows particular promise is that proposed by Katz [156,157] in his two articles. He described two separate test statistics: Φ, for when we can accurately estimate the number of individuals in both the experimental and control groups, and θ, for when we do not actually estimate the number of surviving individuals in each group and we can assume that the test material is only mildly toxic in terms of killing the test organisms. Each of these two test statistics is also formulated on the basis of only a single exposure of the organisms to the test chemicals. Given this, then we may compute

$$\Phi = \frac{a\left(M_E - 0.5\right) - Kb\left(M_C + 0.5\right)}{\sqrt{Kab\left(M_E + M_C\right)}}$$

where

- *a* and *b* are the number of groups of control (*C*) and experimental (*E*) organisms, respectively
- $K = N_E/N_C$, where N_C and N_E are the numbers of surviving microorganisms
- M_E and M_C are the numbers of mutations in the experimental and control groups
- μ_e and μ_c are the true (but unknown) mutation rates (as μ_c gets smaller, *N* must increase)

We may compute the second case as

$$\theta = \frac{a\left(M_E - 0.5\right) + \left(M_C + 0.5\right)}{ab\left(M_E - M_C\right)}$$

with the same constituents.

In both cases, at a confidence level for *I* of 0.05, we accept that $\mu_c = \mu_e$ if the test statistic (either Φ or θ) is less than 1.64. If it is equal to or greater than 1.64, we may conclude that we have a mutagenic effect (at $\alpha = 0.05$).

In the second case (θ, where we do not have separate estimates of population sizes for the control and experimental groups), if *K* deviates widely from 1.0 (if the material is markedly toxic), we should use more containers of control organisms (tables for the proportions of each to use given different survival frequencies may be found in Katz [157]). If different levels are desired, tables for θ and Φ may be found in Kastenbaum and Bowman [158].

An outgrowth of this is that the mutation rate per surviving cells (μ_c and μ_e) can be determined. It must be remembered that, if the control mutation rate is so high that a reduction in mutation rates can be achieved by the test compound, these test statistics must be adjusted to allow for a two-sided hypothesis [159]. The α levels may likewise be adjusted in each case or tested for, if we want to assure ourselves that a mutagenic effect exists at a certain level of confidence (note that this is different from disproving the null hypothesis).

It should be noted that numerous specific recommendations have been made for statistical methods designed for individual mutagenicity techniques, such as that of Bernstein et al. [160] for the Ames test.

Behavioral Toxicity

A brief review of the types of studies or experiments conducted in the area of behavioral toxicology and the classification of these into groups is in order. Although a small number of studies do not fit into the following classification, the great majority may be fitted into one of the following four groups. Many of these points have been covered in earlier articles [79,161].

Observational score-type studies are based on observing and grading the response of an animal to its normal environment or to a stimulus that is imprecisely controlled. This type of result is generated by one of two major sorts of studies. Open-field studies involve placing an animal in the center of a flat, open area and counting each occurrence of several types of activities (grooming, moving outside a designated central area, rearing, etc.) or timing until the first occurrence of each type of activity. The data generated are scalar of either a continuous or discontinuous nature but frequently are not of a normal distribution. Tilson et al. [162] presented some examples of this sort.

Observational screen studies involve a combination of observing behavior and evoking a response to a simple stimulus, the resulting observation being graded as normal or as deviating from normal on a graded scale. Most of the data so generated are rank in nature, with some portions being quantal or interval. Irwin [163] and Gad [161] have presented schemes for the conduct of such studies that became the basis of the commonly used functional observational battery. Table 9.14 gives an example of the nature (and of one form of statistical analysis) of such data generated after exposure to one material.

The second type of study is one that generates rates of response as data. The studies are based on the number of responses to a discrete controlled stimulus or are free of direct connection to a stimulus. The three most frequently measured parameters are licking of a liquid (milk, sugar water, ethanol, or a psychoactive agent in water), gross locomotor activity (measured by a photocell or electromagnetic device), or level pulling. Examples of such studies have been published by Annau [164] and Norton [165]. The data generated are most often of a discontinuous or continuous scalar nature and are often complicated by underlying patterns of biological rhythm.

The third type of study generates a variety of data classified as error rate. These are studies based on animals learning a response to a stimulus or memorizing a simple task (such as running a maze or a Skinner-box type of shock-avoidance system). These tests or trials are structured so animals can pass or fail on each of a number of successive trials. The resulting data are quantal, although frequently expressed as a percentage.

The final major type of study is one that results in data that are measures of the time to an endpoint. They are based on animals being exposed to or dosed with a toxicant, and the time taken for an effect to be observed is measured. The endpoint is usually failure to continue to be able to perform a task and can, therefore, be death, incapacitation, or the learning of a response to a discrete stimulus. Burt [166] and Johnson et al. [167] present data of this form. The data are always of a censored nature—that is, the period of observation is always artificially limited as in measuring time to incapacitation in combustion toxicology data, where animals are exposed to the thermal decomposition gases to test materials for a period of 30 min. If incapacitation is not observed during these 30 min, it is judged not to occur. The data generated by these studies are continuous, discontinuous, or rank in nature. They are discontinuous because the researcher may check or may be restricted to checking for the occurrence of the endpoint only at certain discrete points in time. On the other hand, they are rank if the periods to check for occurrence of the endpoint are far enough apart, in which

TABLE 9.14
Functional Observational Battery Parameters Showing Significant Differences between Treated and Control Groups

	Rats (18-Crown-6 Animals Given 40 mg/kg i.p.)				
Parameter	Control Sum of Ranks	N_C	18-Crown-6 Treated Sum of Ranks	N_T	Observed Difference in Treated Animals (Compared to Controls)
Twitches	55.0	10	270.0	15	Involuntary muscle twitches
Visual placing	55.0	10	270.0	15	Less aware of visual stimuli
Grip strength	120.0	10	205.0	15	Considerable loss of strength, especially in hind limbs
Respiration	55.0	10	270.0	15	Increased rate of respiration
Tremors	55.0	10	270.0	15	Marked tremors

Note: All parameters provided earlier are significant at $p < 0.05$.

TABLE 9.15
Overview of Statistical Testing in Behavioral Toxicology

Type of Observation	Most Commonly Used Procedures	Suggested Procedures
Observational scores	Student's *t*-test or one-way ANOVA	Kruskal–Wallis nonparametric ANOVA or Wilcoxon rank-sum
Response rates	Student's *t*-test or one-way ANOVA	Kruskal–Wallis ANOVA or one-way ANOVA
Error rates	ANOVA followed by a post hoc test	Fisher's exact, R × C chi-square, or Mann–Whitney U test
Times to endpoint	Student's *t*-test or one-way ANOVA	ANOVA then a post hoc test or Kruskal–Wallis ANOVA
Teratology and reproduction	ANOVA followed by a post hoc test	Fisher's exact test, Kruskal–Wallis ANOVA, or Mann–Whitney U test

Tests commonly used vs. tests most frequently appropriate.

Note: That these are the most commonly used procedures was established by an extensive literature review that is beyond the scope of this chapter. The reader, however, need only look at the example articles cited in the text of this chapter to verify this fact.

case one may actually only know that the endpoint occurred during a broad period of time—but not where in that period.

There is a special class of test that should also be considered at this point—the behavioral teratology or reproduction study. These studies are based on dosing or exposing either parental animals during selected periods in the mating and gestation process or pregnant females at selected periods during gestation. The resulting offspring are then tested for developmental defects of a neurological and behavioral nature. Analysis is complicated by a number of facts:

1. The parental animals are the actual targets for toxic effects, but observations are made on offspring.
2. The toxic effects in the parental generation may alter the performance of the mother in rearing its offspring, which in turn can lead to a confusion of prenatal and postnatal effects.
3. Different capabilities and behaviors develop at different times.

A researcher can, by varying the selection of the animal model (species, strain, sex), modify the nature of the data generated and the degree of dispersion of these data. In behavioral studies particularly, limiting the within-group variability of data is a significant problem and generally should be a highly desirable goal.

Most, if not all, behavioral toxicology studies depend on at least some instrumentation. Very frequently overlooked here (and, indeed, in most research) is that instrumentation, by its operating characteristics and limitations, goes a long way toward determining the nature of the data generated by it. An activity monitor measures motor activity in discrete segments. If it is a *jiggle cage* type of monitor, these segments are restricted so only a distinctly limited number of counts can be achieved in a given period of time and then only if they are of the appropriate magnitude. Likewise, the technique can also readily determine the nature of the data. In measuring response to pain, for example, one could record it as a quantal measure (present or absent), as a rank score (on a scale of 1–5 for decreased to increased responsiveness, with 3 being normal), or as scalar data (by using an analgesia meter that determines either how much pressure or heat is required to evoke a response).

Study design factors are probably the most widely recognized of the factors that influence the type of data resulting from a study. Number of animals used, frequency of measures, and length of period of observation are three obvious design factors that are readily under the control of the researcher and directly help to determine the nature of the data.

Finally, it is appropriate to review each of the types of studies currently utilized in behavioral toxicology according to the classification presented at the beginning of this section, in terms of which statistical methods are used now and what procedures should be recommended for use. The recommendations, of course, should be viewed with a critical eye. They are intended with current experimental design and technique in mind and can claim to be the best only when one is limited to addressing the most common problems from a library of readily and commonly available and understood tests. Table 9.15 summarizes this review and recommendation process.

Carcinogenesis

In the experimental evaluation of substances for carcinogenesis based on experimental results in a nonhuman species at some relatively high dose or exposure level, an attempt is made to predict the occurrence and level of tumorigenesis in humans at much lower levels. An entire chapter could be devoted to examining the assumptions involved in this undertaking and review of the aspects of design and interpretation of animal carcinogenicity studies. Such is beyond the scope of this effort. The reader is referred to Gad [23] for such an examination. The single most important statistical consideration in the design of carcinogenicity bioassays in the past was based on the point of view that what was being observed and evaluated was a simple quantal response (cancer occurred or it did not) and that a sufficient number of animals needed to be used to have reasonable expectations of detecting such an

effect. Though the single fact of whether or not the simple incidence of neoplastic tumors is increased due to an agent of concern is of interest, a much more complex model must now be considered. The time-to-tumor, patterns of tumor incidence, effects on survival rate, and age at first tumor all must now be included in a model.

Bioassay Design

As presented earlier in the section on "Experimental Design," the first step that must be taken is to clearly state the objective of the study to be undertaken. Carcinogenicity bioassays have two possible objectives. The first objective is to detect possible carcinogens. Compounds are evaluated to determine if they can or cannot induce a statistically detectable increase in tumor rates over background levels, and only by happenstance is information generated that is useful in risk assessment. Most older studies have such detection as their objective. Current thought is that at least two species must be used for detection, although the necessity of a second species (the mouse) is increasingly questioned. The second objective for a bioassay is to provide a range of dose–response information (with tumor incidence being the response) so a risk assessment may be performed. Unlike detection, which requires only one treatment group with adequate survival times (to allow the expression of tumors), dose–response requires at least three treatment groups with adequate survival. We will shortly look at the selection of dose levels for this case; however, given that the species is known to be responsive, only one species of animal needs to be used for this objective.

To address either or both of these objectives, three major types of study designs have evolved. First is the classical skin-painting study, usually performed in mice. A single easily detected endpoint (the formation of skin tumors) is evaluated during the course of the study. Although dose–response can be evaluated in such a study (dose usually being varied by using different concentrations of test material in volatile solvent), most often detection is the objective of such a study. Although others have used different frequencies of application of test material to vary dose, there are data to suggest that this serves to introduce only an additional variable [168]. Traditionally, both test and control groups in such a test consist of 50–100 mice of one sex (males being preferred because of their very low spontaneous tumor rate). This design is also used in tumor initiation/promotion studies.

The second common type of design is the original NCI bioassay. The announced objective of these studies was the detection of moderate to strong carcinogens, although the results have also been used in attempts at risk assessment. Both mice and rats were used in parallel studies. Each study used 50 males and 50 females at each of two dose levels (high and low) plus an equal-sized control group. The National Toxicology Program (NTP) has subsequently moved away from this design because of a recognition of its inherent limitations. More animals per group and more dose groups are now used.

Finally, the standard industrial toxicology design uses at least two species (usually rats and mice) in groups of no fewer that 100 males and females each. Each study has three dose groups and at least one control. Frequently, additional numbers of animals are included to allow for interim terminations and histopathological evaluations. In both this and the NCI design, a long list of organs and tissues are collected, processed, and examined microscopically. This design seeks to address both the detection and dose–response objectives with a moderate degree of success.

Selecting the number of animals to use for dose groups in a study requires consideration of both biological (expected survival rates, background tumor rates, etc.) and statistical factors. The prime statistical consideration is reflected in Table 9.16. It can be seen in this table that, if, for example, we were studying a compound that caused liver tumors and were using mice (with a background or control incidence of

TABLE 9.16
Sample Size Required to Obtain a Specified Sensitivity at $p < 0.05$ Treatment Group Incidence

Background Tumor Incidence	P[a]	0.95	0.90	0.80	0.70	0.60	0.50	0.40	0.30	0.20	0.10
0.30	0.90	10	12	18	31	46	102	389	—	—	—
	0.50	6	6	9	12	22	32	123	—	—	—

	0.50	3	3	5	6	7	9	12	19	24	147
0.01	0.90	5	5	7	8	10	13	19	27	46	114
	0.50	3	3	5	5	6	8	10	13	25	56

[a] P is the power for each comparison of treatment group with background tumor incidence.

30%), we would have to use 389 animals per sex per group to be able to demonstrate that an incidence rate of 40% in treatment animals was significant compared to the controls at the $p = 0.05$ level.

Perhaps the most difficult aspect of designing a good carcinogenicity study is the selection of the dose levels to be used. At the start, it is necessary to consider the first underlying assumption in the design and use of animal cancer bioassays—the need to test at the highest possible dose for the longest practical period. The rationale behind this assumption is that, although humans may be exposed at very low levels, detecting the resulting small increase (over background) in the incidence of tumors would require the use of an impractically large number of test animals per group.

This point is illustrated by Table 9.16, where, for example, only 46 animals (per group) are needed to show a 10% increase over a zero background (i.e., a rarely occurring tumor type), but 770,000 animals (per group) would be needed to detect a 0.1% increase above a 5% background. As we increase dose, however, the incidence of tumors (the response) will also increase until it reaches the point where a modest increase (say, 10%) over a reasonably small background level (say 1%) could be detected using an acceptably small-sized group of test animals (in Table 9.17, we see that 51 animals would be needed for this example case). There are, however, at least two real limitations to the highest dose level. First, the test rodent population must have a sufficient survival rate after receiving a lifetime (or 2 years) of regular doses to allow for meaningful statistical analysis. Second, we really want the metabolism and mechanism of action of the chemical at the highest level tested to be the same as at the low levels where human exposure would occur. Unfortunately, toxicologists usually must select the high dose level based only on the information provided by a subchronic or range-finding study (usually 90 days in length), but selection of either too low or too high a dose will make the study invalid for the detection of carcinogenicity and may seriously impair the use of the results for risk assessment.

There are several solutions to this problem. One of these has been the rather simplistic approach of the NTP Bioassay Program, which is to conduct a 3-month range-finding study with sufficient dose levels to establish a level that significantly (10%) decreases the rate of body weight gain. This dose is defined as the maximum tolerated dose (MTD) and is selected as the highest dose. Two other levels, generally one half MTD and one quarter MTD, are selected for testing as the intermediate- and low-dose levels. In many earlier NCI studies, only one other level was used.

The dose range-finding study is necessary in most cases, but the suppression of body weight gain is a scientifically questionable benchmark when dealing with the establishment of safety factors. Physiologic, pharmacologic, or metabolic markers generally serve as better indicators of systemic response than body weight. A series of well-defined acute and subchronic studies designed to determine the chronicity factor and to study the onset of pathology can be more predictive for dose setting than body weight suppression. Also, the NTP's MTD may well be at a level where the metabolic mechanisms for handling a compound at real-life exposure levels have been saturated or overwhelmed, bringing into play entirely artifactual metabolic and physiologic mechanisms [169]. The regulatory response to questioning the appropriateness of the MTD as a high dose level [170] has been to acknowledge that occasionally an excessively high dose is selected but to counter by saying that using lower doses would seriously decrease the sensitivity of detection.

TABLE 9.17
Average Number of Animals Needed to Detect a Significant Increase in the Incidence of an Event (e.g., Tumors, Anomalies) over Background Incidence (Control) at Expected Incidence Levels Using Fisher's Exact Probability Test ($p = 0.05$)

Background Incidence (%)	Expected Increase in Incidence (%)

DATA ANALYSIS APPLICATIONS IN TOXICOLOGICAL PATHOLOGY

Having reviewed basic principles and provided a set of methods for the statistical handling of data, the remainder of this chapter addresses the practical aspects and difficulties encountered in preclinical safety assessment in the field of toxicological pathology. Analyses of pathology data are well defined although they may not necessarily use the best methods available. The use of statistical methodology is discussed in the remainder of this chapter. The aim of this section is to review statistical methods on a use-by-use basis and to provide a foundation for the selection of alternatives in specific situations. Meta-analyses and Bayesian approaches are not addressed in detail but should be kept in mind.

Body and Organ Weights

Body weight and the weights of selected organs are usually collected in studies where animals are dosed with, or exposed to, a chemical. In fact, body weight is frequently the most sensitive indication of an adverse treatment effect. How to analyze these data best and in what form to analyze

the organ weight data, such as absolute weights, weight changes, or percentages of body weight, have been the subject of great discussion.

Both absolute body weights and rates of body weight change are best analyzed by ANOVA followed, if called for, by a post hoc test. Body weight change is usually calculated as changes from a baseline measurement value, which is traditionally the animal's weight immediately prior to the first dosing with or exposure to the test material. To standardize body weight, no group should be significantly different in mean body weight from any other group, and all animals in all groups should lie within two SDs of the overall mean body weight. Even if the groups were randomized properly at the beginning of a study, there is an advantage to performing the computationally slightly more cumbersome changes in body weight analysis. The advantage of this calculation is an increase in sensitivity because the adjustment of starting points (i.e., the setting of initial weights as a zero value) reduces the amount of initial variability. In this case, Bartlett's test is performed first to ensure the homogeneity of variance, and the appropriate sequence of analysis follows.

If sample sizes are small or normality of data is uncertain, nonparametric methods, such as Kruskal–Wallis, may be more appropriate. The analysis of relative organ weights is a valuable tool for identifying possible target organs. How to perform this analysis is still a matter of some disagreement. Organ weight data, expressed as percentages of body weight, should be analyzed separately for each sex. Often, conclusions from organ weight data of males differ from those of females; hence, separating these data by gender should always be done. Other factors, such as the effect of stage of the reproductive cycle on uterine weight, may also influence organ weights. These factors must be taken into account both in the stratification of animals and in the interpretation of results.

The two alternative approaches to analyzing relative organ weights call for either calculating organ weights as a percentage of total body weight at the time of necropsy and analyzing the results by ANOVA or analyzing results by ANCOVA, with body weights as the covariates as discussed previously. A number of considerations should be kept in mind when this choice is made. First, one must recognize the difference between biological significance and statistical significance. By evaluating relative body weight, the significance of a weight change that is not proportional to changes in whole body weights must be determined. Second, the toxicological pathologist now must interpret small changes while still retaining a similar sensitivity (i.e., the $p < 0.05$ level).

Several tools can be used to increase the power of the analysis. One is to increase the sample size by increasing the number of animals, and the other is to utilize the most powerful test available that is appropriate to the data. The number of animals used in the groups is currently under debate with respect to the power of detecting a significant change. The power of statistical tests is important in the consideration of animal numbers.

In the majority of cases, except for the brain, the organs of interest change weight in proportion to total body weight, except in extreme cases of obesity or starvation. This change is the biological rationale behind analyzing both absolute body weight and the ratio of organ weight to body weight. Analyses are designed to detect cases where this relative change does not occur. Analysis of data from several hundred studies has shown no significant difference in rates of weight change of target organs, other than the brain, compared to total body weight for healthy animals in rats, mice, rabbits, and dogs used for repeated dose studies. The ANCOVA is of questionable validity in analyzing body weight and related organ weight changes, as a primary assumption is the independence of treatment. In toxicological pathology, the assumption that the relationship of the two variables is the same for all treatments is not true.

In cases where the differences between the error MSs are much greater during the analysis, the ratio of F ratios will diverge in precision from the result of the efficiency of covariance adjustment. These cases occur where either sample sizes are large or where the differences between means themselves are great. This latter case is one that does not occur in the designs under discussion in any manner that would leave ANCOVA as a valid approach because group means are very similar at the beginning of the experiment and cannot diverge markedly unless there is a treatment effect. As discussed earlier, a treatment effect invalidates a prime underpinning assumption of ANCOVA.

Clinical Chemistry

A number of clinical chemistry parameters are commonly determined on the blood and urine collected from animals in chronic, subchronic, and, occasionally, acute toxicity studies. In the past, and currently in some places, the accepted practice has been to evaluate these data using univariate–parametric methods, primarily t-tests and ANOVA; however, this is not the best approach. First, biochemical parameters are rarely independent of each other, and the focus of inquiry is rarely limited to only one of the parameters. Instead, several parameters can change when toxicity is seen in specific organs. For example, simultaneous elevations of creatinine phosphokinase, γ-hydroxybutyrate dehydrogenase, and lactate dehydrogenase are strongly indicative of myocardial damage. In such a case, the clinical importance of these findings is not limited to a significant elevation in one of these enzymes; all three must be considered together. Detailed coverage of the interpretation of such clinical laboratory tests can be found elsewhere.

Second, interaction occurs among parameters; therefore, each parameter is not independent. For example, serum electrolytes (sodium, potassium, and calcium) interact such that a decrease in one is frequently tied to an increase in one of the others. Finally, either because of the biological nature of the parameter or the way in which it is measured, data are frequently skewed or not continuous. This skewness and discontinuous nature of data can be seen in some of the reference data for experimental animals (e.g., creatinine, sodium, potassium, chloride, calcium, and blood).

Carcinogenesis

Inferences about the potential human carcinogenicity of substances are based on experimental results obtained from a nonhuman species given the substance at a high dose or exposure level. The aim of this procedure is to predict the possibility and probability of occurrence of tumorogenesis in humans at much lower levels. An entire textbook could be devoted to examining the assumptions involved in this undertaking and review of the aspects of design and interpretation of animal carcinogenicity studies. Such detail is beyond the scope of this chapter. The reader is referred to Gad [23] for more detail.

In the past, the single most important statistical consideration in the design of carcinogenicity bioassays was based on a simple quantal response: cancer did or did not occur. Experiments were designed so a sufficient number of animals were used so as to have a reasonable expectation of detecting an effect if one occurred. Although the primary objective was to determine whether the incidence of tumors was increased following exposure to the test article of interest, a much more complex model should now be considered to answer other questions pertinent to the extrapolation of experimental results in animals to make inferences about risks to human health.

The time to tumor, patterns of tumor incidence, effects on survival rate, and age at first tumor can now be evaluated. The rationale for including these factors lies in concerns associated with likely planned or unplanned exposure of humans to xenobiotic and naturally occurring substances, and relatively small increases in the incidence of tumors over background would require the use of an impracticably large number of test animals per group.

To illustrate this point, examine the data provided in Table 9.17. Here, only 46 animals per group are required to show a 10% increase over a zero background, where the background included a rarely occurring tumor type. To detect a 0.1% increase above a 5% background, 770,000 animals per group would be needed! As dose increases the incidence of tumors, the response will also increase. This increase occurs until it reaches the point where a modest increase (e.g., 10%) over a reasonably small background level (e.g., 1%) could be detected using an acceptably small-sized group of test animals. Table 9.17 shows that 51 animals would be needed for such a situation. It can be seen that the number of animals required to demonstrate a 1/100,000 increase above a 25% background incidence would be very large.

At least two potential difficulties often occur in the group given the highest dose. First, mortality can be higher than other groups; a sufficient number of rodents must survive to the end of the study to allow for meaningful statistical analysis. Second, toxicological pathologists must select the high dose level based only on the information provided by a subchronic or range-finding study, usually 90 days in length. To predict carcinogenic effects across species, it is necessary that the metabolism and mechanism of action of the chemical at the highest level tested are the same as at the low levels where human exposure would occur. Unfortunately, selection of a dose that is too low may make the study invalid for the detection of carcinogenicity, and selection of a dose that is too high, where toxicokinetics result in different metabolism, may seriously impair the use of the results for risk assessment.

QUESTIONS

9.1 Given that the complexity and volume of data resulting from toxicology studies continue to increase, what methods serve to make results more readily understood while still maintaining accuracy and without losing precision?

9.2 Why are statistical graphics increasingly important?

9.3 Given that safety evaluations of pharmaceuticals and other regulated products involve multiple studies, how might statistics better serve in performing relative risk assessments (read across reviews)?

9.4 Why does controlling (or reducing) variability within group datasets serve to increase the sensitivity of detecting real differences between groups (significant effects)? And how does this contribute to reducing animal usage?

10 Practice of Exposure Assessment

Dennis J. Paustenbach and Amy K. Madl

CONTENTS

INTRODUCTION

Health risk assessment is the process wherein toxicology data from animal studies and human epidemiology are evaluated, a mathematical formula is applied to predict the response at low doses, and then information about the degree of exposure is used to predict quantitatively the likelihood that a particular adverse response will be seen in a specific human population.[1–3] More simply, risk assessment is a process by which scientists evaluate the potential for adverse health effects from exposure to naturally occurring or synthetic agents.[4] Regulatory agencies have used the risk assessment process for nearly 50 years, most notably the U.S. Food and Drug Administration (USFDA).[5] However, the difference between assessments performed in the 1950s and 1960s and those performed in the 1980s and 1990s and even more currently is that dose-extrapolation models, quantitative exposure assessments, and quantitative descriptions of uncertainty have been added to the process.[6] Because of increased ability to measure and predict exposures and better quantitative methods for estimating the low-dose response (such as physiologically based pharmacokinetic [PBPK] models), risk assessments conducted today provide more accurate risk estimates than in the past.[3,7,8]

Since 1980, most environmental regulations and some occupational health standards have, at least in part, been based on health risk assessments.[3,9,10] They include standards for pesticide residues in crops, drinking water, ambient air, and food additives, as well as exposure limits for contaminants found in indoor air, consumer products, and other media. Risk managers increasingly rely on risk assessment to decide whether a broad array of risks are significant or trivial—an important task since, for example, more than 400 of the about 2000 chemicals routinely used in industry have been labeled carcinogens in various animal studies.[11–13] In theory, the results of risk assessments in the United States should influence virtually all regulatory decisions involving so-called toxic agents.[14–16]

The risk assessment process has four parts: hazard identification, dose–response assessment, exposure assessment, and risk characterization.[11] Although progress has been made over the past 20+ years in how to conduct and interpret toxicology and epidemiology studies (e.g., hazard identification), and scientists believe that they are doing a better job of dose–response extrapolation than in the past, most significant advances in the risk assessment process have occurred in the field of exposure assessment.[17–19]

Since about 1995, an increasing number of environmental scientists have embraced the view that "toxicology data are important, but they do not mean much without quantitative information about human exposure."[20] For this reason, the toxicology community has shown increasing interest in understanding the exposure assessment field.[21,22] Fortunately, a significant amount of research has been conducted to identify better values for many exposure parameters, and major improvements have been made in applying these exposure factors to various scenarios. This chapter is intended to familiarize toxicologists, risk assessors, and others with this evolving field.

BASIC CONCEPTS

Description of Exposure Assessment

Exposure assessment is the step that quantifies the intake of an agent resulting from contact with various environmental media (e.g., air, water, soil, food).[3,8,23,24] Exposure assessments can address past, current, or future exposures, although uncertainties can become significant when attempting to anticipate what might have happened or what will happen.[8,25–31] Researchers have used a variety of methods to approximate historical and future exposures, including using geographic location, job history, historical records, biomonitoring, and estimates from mathematical models, as a proxy for exposure.[32–37]

Exposure assessment in various forms dates back at least to the early twentieth century, and perhaps earlier, particularly in the fields of epidemiology,[38,39] industrial hygiene,[40,41] and health physics.[42] Exposure assessment combines elements of all three disciplines and relies on aspects of biochemical toxicology (to estimate delivered dose), atmospheric sciences, anthropometry, analytical chemistry, food sciences, physiology, environmental modeling, and others.[43]

Fundamentally, an exposure assessment describes the nature and size of the various populations exposed to a chemical agent and the magnitude and duration of their exposures.[44,45] It determines the degree of contact a person has with a chemical and estimates the magnitude of the absorbed dose.[46] Several factors need to be considered when estimating that dose, including characteristics of the contaminated media, exposure duration, route of exposure, chemical bioavailability from the contaminated media (e.g., soil), and, sometimes, the unique characteristics of the tested population (e.g., hairless mice absorb a greater percent of chemical than other mice). By definition, *duration* is the period of time over which the person is exposed. An *acute* exposure generally involves one contact with the chemical, usually for less than a day. An exposure is considered *chronic* when it takes place over a substantial portion of the person's lifetime. Exposures of intermediate duration are usually called *subchronic*.[43]

Knowledge of the chemical concentration in an environmental medium is essential to determine the magnitude of the absorbed dose. This information is usually obtained by analytical measurements of samples of the contaminated medium (air, water, soil, sediment, food, or house dust). Estimates can also be made using mathematical models, such as models relating air concentrations at various distances from a point of release (e.g., a smoke stack) to factors including release rate, weather conditions, distance, and stability of the agent.[47,48] Needless to say, a significant number of factors need to be considered to quantitatively evaluate a typical, complex contaminated site (Figure 10.1).

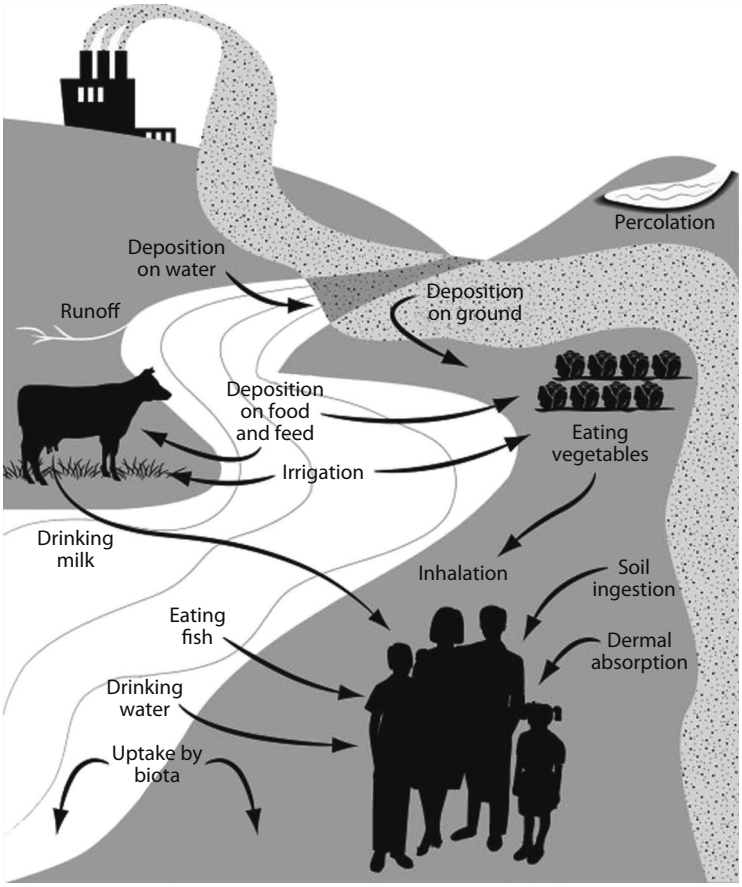

FIGURE 10.1 Illustration of exposure pathways.

In general, exposure assessments have matured to a degree that usually possesses less uncertainty than other steps in the risk assessment. Admittedly, many factors should be considered when estimating exposure; for example, it is a complicated procedure to understand the transport and distribution of a chemical that has been released into the environment.[49] Nonetheless, a number of studies have shown that if the majority of factors are considered, one can do a fairly adequate job of quantifying with confidence the chemical concentrations in various media and the resulting uptake by exposed persons.[8,50,51] No doubt, in the coming years, these estimates will be confirmed or rejected as larger amounts of biomonitoring data become available and are used to relate internal chemical doses to the external environment and the impact on adverse health responses.

The primary routes of human exposure to chemicals in the ambient environment are dust and vapor inhalation, dermal contact with contaminated soils or dusts, and ingestion of contaminated food, water, house dust, or soil. In the workplace, the predominant exposure route usually is inhalation, followed by dermal uptake and, to a lesser extent, dust ingestion due to hand-to-mouth contact.[7] Uncertainty in environmental exposure assessment can be greater than in an occupational exposure assessment. However, in many workplaces, there can be large fluctuations in airborne concentrations, a significant difference in work practices of different persons, and there is real difficulty in measuring dermal uptake and incidental ingestion.[41,52–56]

Scientists in the field of radiological health were the first to quantitatively estimate human uptake of environmental contaminants[57,58]; thus, the published literature in health physics can be a source of valuable information when conducting assessments of chemical contaminants.[59] This work, which was conducted after World War II, provided numerous methodologies for estimating human uptake of environmental contaminants.[59] These have been refined over the past decade.[27,60–62] The availability of information on the degree of exposure associated with various scenarios has increased dramatically in recent years, as evidenced by the recent *EPA Exposure Factors Handbook* and *Child-Specific Exposure Factors Handbook*—documents containing nearly 2000 pages of combined information on exposure assessment.[63,64]

The practice of exposure assessment, at least for regulatory purposes, has changed over time. For example, beginning in the late 1970s, U.S. regulatory policy encouraged or mandated the use of conservative approaches when conducting exposure assessments. This was codified in the Environmental Protection Agency's (EPA) original document entitled *Risk Assessment Guidance for Superfund*, so-called RAGS.[65] At that time, standardization of exposure assessments used to satisfy regulatory agencies was considered prudent because it guaranteed that risks would not be underestimated in order to ensure protection of public health. Beginning in the mid-1980s, concern was expressed that repeated use of conservative exposure factor assumptions was producing unrealistically high estimates of exposure and that the cost of achieving the recommended cleanup levels was becoming enormous.[53,66–73] Thus, to evaluate the accuracy of many of the factors used in these assessments, changes in the process began to occur. Government agencies such as the Office of Management and Budget (OMB) and the U.S. EPA have developed new guidelines and urged risk assessors to do an even better job at eliminating compounding conservatism in their assessments.[74]

Around 1990, risk assessors began to apply Monte Carlo techniques and probabilistic approaches to eliminate the possibility of compounding conservatism and to increase the transparency of the analyses. Application of Monte Carlo techniques to exposure assessment has dramatically improved our understanding of the certainty of exposure estimates thereby altering the field permanently.[37,71,75–87] The EPA and other agencies have now embraced this approach, which is well described in several guidelines as well as the document called RAGS3A (a process for conducting probabilistic risk assessment).[83,88,89]

What Is Exposure?

Over the years, the terminology used in published exposure assessment literature has been inconsistent. Although there is reasonable agreement that human exposure means contact with the chemical or the agent,[24,65,90] there has not yet been widespread agreement as to whether this means contact with (1) the visible exterior of the person (skin and openings in the body, such as mouth and nostrils) or (2) the so-called exchange boundaries where absorption takes place (skin, lungs, gastrointestinal tract).[43] The differing definitions have led to some ambiguity in the use of terms and units for quantifying exposure. For example, the terms dose, uptake, and intake have often been used loosely.

Some scientists find it helpful to think of the human body as having a hypothetical outer boundary that separates the inside of the body from the outside.[43] The outer boundary of the body consists of the skin and openings into the body, such as the mouth, nostrils, or punctures and lesions in the skin. In most exposure assessments, chemical exposure is defined as contact of the chemical with some part of this boundary. An exposure assessment is the quantitative or qualitative evaluation of that contact. It describes the intensity, frequency, and duration of contact, and often quantifies the rate at which the chemical crosses the boundary (chemical intake or uptake rates), the route of the chemical across the boundary (exposure route [e.g., dermal, oral, or respiratory]), the resulting amount of chemical actually crossing the boundary (dose), and the amount of chemical absorbed (internal dose).[24,91] A very workable quantitative definition of exposure is to think of it as "the product of (concentration), (time), and (duration), or rate of transport of toxicant (mg/min)."[52]

Depending on the purpose of the exposure assessment, the numerical output of these analyses may be an estimate of either exposure or dose. If an exposure assessment is being done as part of a risk assessment in support of an epidemiologic study, for example, sometimes only qualitative exposure levels are all that can be provided. In these situations,

categories such as low-, medium-, and high-level exposures may be used (although strongly discouraged by the authors). By contrast, a greater portion of the assessments of environmental or occupational exposure conducted in recent years attempt to quantitatively predict the absorbed dose (mg/kg-day) and, occasionally, the circulating blood level or the concentration of the toxicant in the target organ.[92–98]

Concepts of Exposure, Intake, Uptake, and Dose

The process of a chemical entering the body can be described in two steps—contact (exposure), followed by actual entry (crossing the boundary). Absorption, by crossing the boundary, leads to the availability of an amount of chemical to biologically significant sites within the body (target tissue dose). Although the description of contact with the outer boundary is simple conceptually (e.g., mg benzene/cm^2 skin), estimating the degree to which a chemical crosses this boundary is somewhat more complex.[99]

In the early 1990s, some scientists described the transport of chemicals into the body as involving two separate steps: intake and uptake. Intake involved physically moving the chemical in question through an opening in the outer boundary (usually the mouth or nose), typically via inhalation, eating, or drinking. Normally, the chemical was contained in a medium such as air, food, water, or dust/soil. Here, the key question was the mass inhaled or ingested. Uptake, in contrast to intake, involved absorption of the chemical through the skin or across other barriers.

Today, most scientists tend to lump intake and uptake together, simply calling the amount of chemical entering the body as *intake* or the *absorbed dose*. Some chemicals are absorbed completely, so systemic absorption is the same as that eaten or in contact with the skin. In other cases, the chemical is often contained in a carrier medium, the medium itself typically is not absorbed at the same rate as the *contaminant of interest*, so estimates of the amount of chemical crossing the boundary cannot be made directly. For example, benzene on the surface of a contaminated soil particle will move quickly through the skin, but benzene in the center of the soil particle may never completely reach the surface and, therefore, it is not bioavailable and may never enter the bloodstream. Of course, for many inorganic chemicals such as arsenic or lead in soil, bioavailability can be very low since the chemical is bound to the interstices of the soil particle. Here, absorption can be very low. In short, if a chemical cannot be released, it has no bioavailability and, consequently, since there is no absorbed dose the chemical does not pose a risk.

Dermal absorption is an example of direct uptake across the outer boundary of the body. A chemical uptake rate is the amount of chemical absorbed per unit of time. In this process, mass transfer occurs by diffusion, so uptake will depend on the concentration gradient across the boundary, permeability of the barrier, and other factors.[91,100,101] Chemical uptake rates can be expressed as a function of the exposure concentration, permeability coefficient, and surface area exposed, or as flux.[7]

Bioavailability

The study of the bioavailability of chemicals in various media began around 1980 and continues to be an important area of research.[51,102–120] Most studies are of oral bioavailability, although the dermal and inhalation bioavailabilities of chemicals on various media have also been studied. Bioavailability has been a bit confusing due to the lack of a standard terminology.[121] The review paper by Ruby et al. is probably the most authoritative one on this topic,[102] although the text by Hrudey is also a valuable resource.[121] We suggest that the following definitions be used in future assessments:

Bioavailability: Oral bioavailability is defined as the fraction of an administered dose that reaches the central (blood) compartment from the gastrointestinal tract. Bioavailability defined in this manner is commonly referred to as *absolute bioavailability* and is equal to the oral absorption fraction.

Relative Bioavailability: Relative bioavailability refers to comparative bioavailabilities of different forms of a substance or for different exposure media containing the substance (e.g., bioavailability of a metal from soil relative to its bioavailability from water), expressed in this document as a relative absorption factor (RAF).

Relative Absorption Factor: The RAF describes the ratio of the absorbed fraction of a substance from a particular exposure medium relative to the fraction absorbed from the dosing vehicle used in the toxicity study for that substance (the term relative bioavailability adjustment [RBA] is also used to describe this factor).

Bioaccessibility: The oral bioaccessibility of a substance is the fraction that is soluble in the gastrointestinal environment and is available for absorption. The bioaccessible fraction is not necessarily equal to the RAF (or RBA) but depends on the relation between results from a particular in vitro test system and an appropriate in vivo model.

There are both in vitro and in vivo tests for evaluating bioavailability and many different approaches have been suggested over the past 25 years.[51,102–108,110–125]

As noted by Ruby et al. (1999), a number of in vitro tests have been used to characterize the oral bioavailability of various chemicals in various media.[102] Simple extraction tests have been used for several years to assess the degree of metals dissolution in a simulated gastrointestinal-tract environment. The predecessor of these systems was developed originally to assess the bioavailability of iron from food, for studies of nutrition. In these systems, various metal salts or soils containing metals are incubated in low-pH solution for a period intended to mimic residence time in the stomach. The pH is then increased to near neutral, and incubation continues for a period intended to mimic residence time in the small intestine. Enzymes and organic acids are added to simulate gastric and small-intestinal fluids. The fraction of lead, arsenic, or other metals that dissolve during the stomach and

small-intestinal incubations represents the fraction that is bioaccessible (i.e., is soluble and available for absorption).

A number of in vivo tests have also been used with varying success. For example, gastrointestinal absorption of lead in humans varies with the age, diet, and nutritional status of the subject as well as with the chemical species and the particle size of lead that is administered. Age is a well-established determinant of lead absorption; adults typically absorb 7%–15% of lead ingested from dietary sources, while estimates of lead absorption from dietary sources in infants and children range from 40% to 53%. For the purpose of modeling exposure to lead in soil, the U.S. EPA assumes that the absolute bioavailability of lead in diet and water is 50% and that the absolute bioavailability of lead in soil is 30% for children. This corresponds to a soil RAF of 0.60 (60%) for the bioavailability of soil lead relative to lead in water (i.e., RAF = 0.3/0.5).[102] However, recent findings have revealed that fractional bioaccessibility (bioaccessible compared to total) of lead is only 5%–10% of total lead in urban soils, far lower than the 60% bioavailability of food lead presumed by the U.S. EPA (30% absolute bioavailability used in the integrated exposure uptake biokinetic [IEUBK] model).[126]

The results of bioavailability studies need to be considered in virtually all assessments involving human exposure.[51,102,107,114,116,117,120,121] Often, the effects in uptake will be minor while in other cases, one may find that insignificant quantities of a chemical are absorbed even though the applied dose or exposure is quite high.[122,127]

Applied Dose or Potential Dose

Applied dose has been defined as the amount of chemical available at the absorption barrier (skin, lung, gastrointestinal tract).[43] It is useful to know the applied dose if a relationship can be established between it and the internal dose, a relationship that can sometimes be established experimentally. This can be estimated either through modeling or by direct measurement. For example, years ago, some researchers analyzed phenol concentrations in the blood of volunteers over time after placing their hands in containers of nitrobenzene or benzene in an attempt to quantify the flux rate.[128,129] Usually, it is difficult to measure the applied dose directly, as many of the absorption barriers are internal to the human, and not localized in such a way to make measurement easy. An approximation of applied dose can be made, however, using the concept of potential dose.[43]

Potential dose is simply the amount of chemical that is ingested or inhaled, or the amount of chemical contained in material applied to the skin. It is a useful term or concept in those instances when there is a measurable amount of chemical in a particular medium. The potential dose for ingestion and inhalation is analogous to the administered dose in a dose–response experiment.

For the dermal route, potential dose is the amount of chemical applied or the amount of chemical in the medium applied (e.g., as a small amount of soil deposited on the skin). Note that because all of the chemical in the soil particulate is not contacting the skin, this differs from exposure (the concentration in the particulate times the duration of contact) and applied dose (the amount in the layer actually touching the skin).[43,74,130]

As previously noted, the amount of chemical that reaches the exchange boundaries of the skin, lungs, or gastrointestinal tract may often be less than the potential dose if the material is only partly bioavailable and therefore only partially absorbed. For example, only about 0.001%–1.0% of dioxins or polycyclic aromatic hydrocarbons (PAHs) on fly ash in contact with the skin are likely to penetrate.[125] When bioavailability data are available, adjustments to the potential dose should be made to convert it to the absorbed or internal dose.[121,125]

Internal Dose

The amount of chemical that has been absorbed and is available for interaction with biologically significant receptors (e.g., target organs) is called the internal dose. Estimating internal dose can be difficult but it is one of the primary objectives of a good exposure assessment.[131,132]

Transport models are available to assist in this process.[133] Once absorbed, the chemical can be metabolized, stored, excreted, or transported within the body. The amount transported to an individual organ, tissue, or fluid of interest is termed the delivered dose.[98,134,135] The dose delivered to the target organ may be only a small part of the total internal dose but, by definition, it is the most relevant. For example, although 1 mg of polychlorinated biphenyl (PCB) may be absorbed into the body, at any given time, the amount in the liver (the target organ) may only be 0.001 mg. The time course over which that 0.001 mg is delivered is often equally important to understand. Work to refine the techniques used to estimate delivered dose has been among the most exciting areas of exposure assessment research in recent years. Currently, the best approach to estimate delivered dose is to measure blood or to use PBPK models.[98,132,136–140] Recent research efforts have involved the use of PBPK models and data on polymorphisms in metabolic enzymes to understand the disposition of environmental toxicants in potentially susceptible human populations.[135]

The biologically effective dose (BED), or the amount that actually reaches cells, sites, or membranes where adverse effects occur,[141] may represent only a fraction of the delivered dose, but it is obviously the best one for predicting adverse effects. Understanding the BED is the ultimate goal of exposure assessment. Regrettably, thus far, toxicologists have rarely been able to estimate BED or measure it for most chemicals.[43]

Currently, most risk assessments dealing with environmental chemicals (as opposed to pharmaceutical assessments) rely on dose–response relationships based on the potential (administered) dose or the internal dose, because our understanding of how to estimate the delivered dose or the BED is insufficient for most chemicals. In general, the best method currently available for estimating the dose to the target organ is to use PBPK models. These have been developed for nearly 100 high-volume industrial chemicals (Table 10.1).[142]

Often, it is more convenient in risk assessment to refer to dose rates, or the amount of a chemical dose (applied or

TABLE 10.1
Examples of PBPK Models for Toxic Materials

Benzene	Lead
Benzo[a]pyrene	Methanol
Butoxyethanol	Methoxyethanol (2-ME)
Butoxyethanol	Methyl ethyl ketone (MEK, #1205)
Carbon tetrachloride	Nickel
Chlorfenvinphos	Nicotine
Chloroform	Parathion
Chloropentafluorobenzene	Physostigmine
cis-Dichlorodiammine platinum	PBB
Dichloroethane	PCBs
Dichloromethane	Styrene
Dieldrin	Toluene
Diisopropylfluorophosphate	TCDF
Dimethyloxazolidine dione	TCDD (dioxin)
Dioxane	Tetrachloroethylene
Ethylene oxide	Trichloroethane
Ethyoxy ethanol (2-EE)	Trichloroethylene
Formaldehyde	Trichlorotribluoroethane
Hexane	Vinyl chloride
Hexavalent chromium	Vinylidene fluoride
Kepone	Xylene

Note: This table is an expansion of one presented in a paper by Leung and Paustenbach (1995).[142]

internal) per unit time (e.g., mg/day), or as dose rates on a per-unit-body-weight basis (e.g., mg/kg-day). Most exposure data found in the various editions of EPA's *Exposure Factors Handbook* and *Child-Specific Exposure Factors Handbook* and other guidance documents are presented as dose rates (e.g., grams of fish consumed each day) rather than as absorbed dose.[63,64,143–145]

Exposure and Dose Relationships

Depending on the purpose of the exposure assessment, and the mechanism of action of the chemical, different estimates of exposure and dose may need to be calculated. Often, estimates of uptake will be presented in units so that the dose metric will be the same as that used in the toxicology study, which may not be useful for exposure calculations. When risk is a function of time of exposure, exposure or dose profiles can be very useful. In these profiles, the exposure concentration or dose is plotted as a function of time.[146] Concentration and time are used to depict exposure, while amount and time characterize dose. Such profiles are important for use in risk assessment where the severity of the effect depends on the pattern by which the exposure occurs, rather than on the total (integrated) exposure. For example, a developmental toxicant may only produce effects if exposure occurs during a particular stage of development.[147–149] As shown in Figure 10.2, during the time above a certain dose rate (the shaded portion), there was an increased risk to the fetus of certain birth defects. Similarly, a single acute exposure to very high contaminant

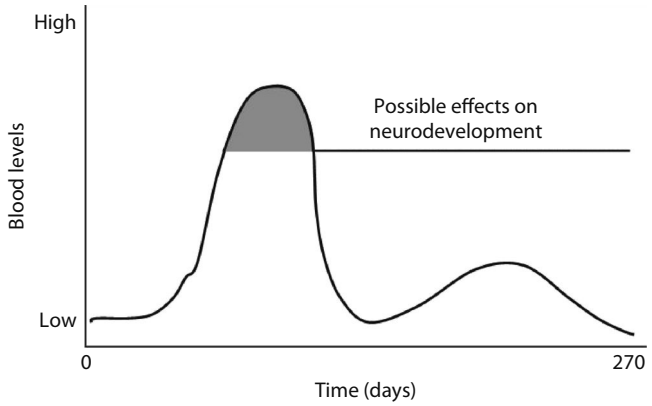

FIGURE 10.2 Time course of exposure to a developmental toxicant. Note that the shaded portion represents the blood concentration of toxicant that is necessary to offer some probability that an inverse effect might occur.

levels may induce adverse effects, even if the average exposure is much lower than apparent no-effect levels. In order to understand hazards posed by most chemicals, it is important to consider its pharmacokinetics. For example, for a chemical that has a long biologic half-life, internal exposure continues long after the chemical is ingested because blood levels remain high until the substance is metabolized and/or eliminated. Conversely, for others, the chemical is inhaled, absorbed, metabolized, and excreted in less than an hour after exposure.

In general, there is a need to consider the time elements of exposure assessment relative to the risk posed by the exposure. Standard approaches to time averaging to estimate long-term daily exposure concentration, in some cases, result in substantial underprediction of short-term variations in exposure. Similarly, the use of short-term measurements may overpredict long-term exposures.[150,151] It is useful to understand the relationship between the biological half-lives of toxicants and the subsequent critical time element of the exposure. Indeed, the appropriate consideration of these elements should dictate the *ATs* for both the exposure limits and exposure assessment.[54,55,152–154]

If a material causes its biological damage quickly and is gone from the body in a short time, then how we test its toxicity is critical. For example, consider a material with a half-life of a few minutes in the body. If we were to test it by spreading or apportioning the daily dose of this material over 24 h using inhalation, it will give very different results than if the animal absorbed the same quantity in a couple of 1 h inhalation exposures. The same dose of this quick-acting material would do much more damage amassed in a bolus dose administered over a few minutes or even an hour or two than if absorbed over 24 h.

Thus, dosing times in animal studies should be commensurate with the biological half-life. We often need to measure the exposure over an appropriately short period of time in which the worst-case exposure may occur. The same logic also holds for the dermal (topically applied) and oral (normally ingested) exposures in that they appear to occur in time frames that are comparable to what we would expect in use. Bolus dosing by

gavage or injection would, of course, be the worst case. Thus, if a material causes its biological damage and is gone from the body in a relatively short period of time, then a long-term measure of exposure will generally be unnecessary.

On the other hand, if the biological half-life of the compound is longer than a few days, then relatively high spikes of exposure over a day or two are not particularly significant from a health impact perspective. What is important from a chronic toxicity perspective for these types of compounds is, of course, the weighted average over a significantly long time period. As such, it would only seem appropriate to use an annual average exposure when you are dealing with a compound with a very long (greater than 90 days) half-life in the body and no evidence of acute toxicity at high short-term dose rate.[153,155,156]

Integrated or aggregate exposure is the sum total of exposure to a chemical via all routes of exposure (and all media). It is now commonplace to add as many as 6–10 different exposure sources per route (e.g., dichlorodiphenyltrichloroethane [DDT] in different fruits and vegetables) and three exposure routes (e.g., DDT via food, air, and dermal contact).[157–160] Modeling software that characterize doses from exposure to multiple chemicals, by multiple routes, and from multiple sources are available.[159] The units of aggregate exposure are concentration times duration. Aggregate exposure has been considered in complex assessments of the past 10 years, for example, incinerators, but it came to the fore with the passage of the Food Quality Protection Act (FQPA) in 1996. An increasing number of guidance documents from regulatory agencies and examples from researchers of how to perform these assessments have been published over the last 5 years.[61,159,161] Some research has been devoted to understanding aggregate environmental exposures, and there have been many attempts to determine the source contribution for different chemicals. These efforts have been the underpinning for studies such as the National Human Exposure Assessment Survey (NHEXAS), Children's Total Exposure to Persistent Pesticides and Other Persistent Organic Pollutants (CTEPP), Center for Health Assessment of Mothers and Children of Salinas (CHAMACOS), and Minnesota Children's Pesticides Exposure Study (MNCPES).[162–170]

Integrated exposure is the total *area under the curve* (AUC) of the exposure profile. An exposure profile (a picture of the exposure concentration over time) is particularly useful when trying to understand occupational exposure because it contains more information than a numerical estimate of the integrated exposure, including the duration and periodicity of exposure, the peak exposure, and the shape of the area under the time–concentration curve. The risk posed by most systemic toxicants with chronic effects is best understood by evaluating the blood concentration versus time relationship.

A common way to characterize exposure is the time-weighted average (TWA). This is particularly relevant when conducting an assessment of a carcinogenic chemical in the workplace. In cancer risk assessments, the time over which exposure is integrated is usually 70 years.[43,171] A TWA dose rate is the total dose divided by the time period of dosing, usually expressed in units of mass per unit time, or mass/time normalized to body weight (e.g., mg/kg-day). TWA dose rates, such as the lifetime average daily dose (LADD), are used in dose–response equations to estimate lifetime risk.

Measures of Dose

For risk assessment purposes, dose estimates should be expressed in a manner that can be compared with available dose–response data from animal or human studies. For example, if data on human exposure are in milligram of lead per deciliter of blood (mg/dL), it would be best to use the blood concentrations in an animal study to predict the risk to humans. Frequently, dose–response relationships are based on potential dose (called administered dose in animal studies), although dose–response relationships are sometimes based on internal dose. These differences need to be accounted for. The measure of dose selected should be based on the mode of action of the adverse effect.[74,146,171–175] For example, to assess a nasal irritant, the airborne concentration of the chemical is a relevant dose and an even better dose metric would be milligram of chemical contacting a square centimeter of nasal mucosa.

Doses may be expressed in several different ways. Solving Equation 10.1, for example, gives the dose rate over the time period of interest. The dose per unit time is the dose rate, which has units of mass/time. The most common dose measure is average daily dose (ADD), which is used to predict or assess the noncarcinogenic effects of a chemical:

$$\mathrm{ADD} = \frac{[\mathrm{C} \cdot \mathrm{IR} \cdot \mathrm{B}]}{[\mathrm{BW} \cdot \mathrm{AT}]} \tag{10.1}$$

where

ADD is the potential average daily dose
BW is the body weight
B is the bioavailability
AT is the time period over which the dose is averaged (days)
C is the mean exposure concentration
IR is the ingestion rate

A typical calculation follows.

Example Calculation 1: Determining the ADD

A typical American eats a certain amount of lettuce over a lifetime (about 2000 kg). Assume that on any given week, the maximum quantity ingested is 0.5 kg, and the maximum on any one day is 0.04 kg/day. Assume that the typical aldrin residue is 4 mg/kg on all lettuce ingested over the person's lifetime. What is the ADD of aldrin for the maximum week? Assume that the oral bioavailability of aldrin in lettuce is 90%.

Given

$$\mathrm{C} = 4 \text{ mg/kg (aldrin)}$$

$$\mathrm{BW} = 70 \text{ kg}$$

$$\mathrm{AT} = 7 \text{ days}$$

$$\mathrm{IR} = 0.5 \text{ kg}$$

$$\mathrm{B} = 0.9$$

Therefore,

$$\text{ADD} = \frac{\left[\text{C} \cdot \text{IR} \cdot \text{B}\right]}{\left[\text{BW} \cdot \text{AT}\right]}$$

$$\text{ADD} = \frac{[4\ \text{mg/kg}] \cdot [0.5\ \text{kg}] \cdot [0.9]}{[70\ \text{kg}] \cdot [7\ \text{days}]}$$

$$\text{ADD} = 0.004\ \text{mg/kg-day}$$

When the primary health risk posed by a chemical is cancer or another chronic effect, then the biological response is usually described in terms of lifetime probabilities (e.g., the increased risk of developing cancer during a 70-year lifetime is 2 in 100,000). In these circumstances, even though exposure does not occur over the entire lifetime, doses are usually presented as LADDs.[43] The LADD takes the form of Equation 10.2, with lifetime (LT) replacing the averaging time (AT):

$$\text{LADD}_{\text{pot}} = \frac{[\text{C} \cdot \text{IR} \cdot \text{B}]}{[\text{BW} \cdot \text{LT}]} \qquad (10.2)$$

Example Calculation 2: Determining the LADD

What is the LADD in Example Calculation 1 involving aldrin in lettuce? Assume that the maximum reasonable lifetime uptake of lettuce (99% person) is 14,000 kg.

Given

$$\text{C} = 4\ \text{mg/kg (aldrin in lettuce)}$$

$$\text{IR} = 14{,}000\ \text{kg}$$

$$\text{B} = 0.9$$

$$\text{BW} = 70\ \text{kg}$$

$$\text{LT} = 70\ \text{years} = 25{,}550\ \text{days}$$

where

$$\text{LADD} = \frac{\left[\overline{\text{C}} \cdot \overline{\text{IR}} \cdot \overline{\text{B}}\right]}{\left[\text{BW} \cdot \text{LT}\right]}$$

Then

$$\text{LADD} = \frac{[4] \cdot [14{,}000] \cdot [0.9]}{[70] \cdot [25{,}550]}$$

$$\text{LADD} = 0.028\ \text{mg/kg-day}$$

Although other measures of chronic dose may be more appropriate for predicting the hazard posed by specific chronic toxicants, such as an area-under-the-blood-concentration (AUC) curve or the peak target tissue concentration, the LADD is the most common dose metric used in carcinogen risk assessment (Figure 10.3).

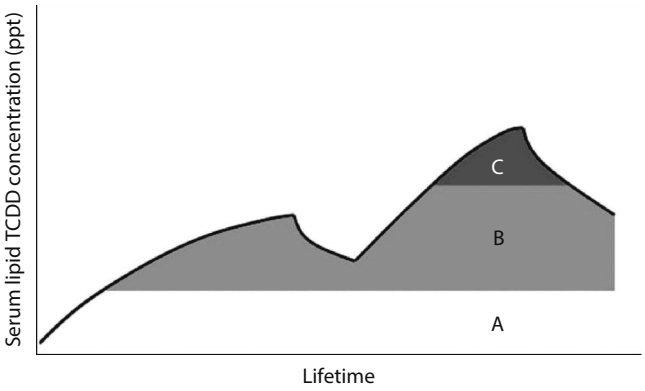

FIGURE 10.3 Theoretical concentration vs. time curve for TCDD illustrating one possible relationship between AUC and response. This figure illustrates the possible combination of AUC and thresholds for production of various responses: area A, no effect; area B, enzyme induction occurs; area C, significant increased cell proliferations. (From Aylward, L.L. et al., *Environ. Sci. Technol.*, 30, 3534, 1996. With permission.)

CONCEPTUAL APPROACHES TO EXPOSURE ASSESSMENT

Quantifying Exposure

Certain methods, such as environmental sensors and geographic information system (GIS), can be used to derive information about external environmental exposures and the personal activity patterns that influence the magnitude, frequency, duration, and pathways of exposure. Other methods, such as biologic sensors, toxicogenomics, and body burden assays, are more frequently being used to derive measurements of internal biologic exposure.[176–179] Although exposure assessments are conducted for a variety of reasons, the process of estimating exposure can be generally approached using one of the following three methods[43]:

1. Direct measurement: The exposure can be measured at the point of contact (the outer boundary of the body) while it is taking place, measuring the exposure concentration and time of contact and integrating them (point-of-contact measurement). An example is the measurement of the amount of contaminated soil on an exposed hand of someone digging a hole to plant a tree. The relevant exposure information would be contaminant concentration in soil (μg/g), surface area of the hand in contact with the soil (100 m^2), and time of exposure (2 h).
2. Exposure scenario: Sometimes one is concerned about an exposure that may or may not occur so a hypothetical exposure scenario is developed. In these assessments, specific data cannot actually be collected, but relevant information can be found. For example, if an incinerator were built, it would not be known today how much of each chemical in the airborne emissions would reach the various compartments in the environment (food, soil,

sediment, surface water), but one can describe what would likely occur (a scenario).

3. Biomonitoring: Sometimes historical exposure can be estimated based on the amount of chemical in the body or being eliminated in breath, urine, or feces. In recent years, doses have been reconstructed through internal indicators (biomarkers, body burden, excretion levels) for persistent organics and several metals. Among the most common historical examples are lead in blood, urinary mercury, volatile hydrocarbons in the breath, and dioxins in blood fat.

These three approaches to exposure quantification (or dose) are independent because each is based on different assumptions and/or data. The fact that they are independent measures is useful in verifying or validating the results of the various approaches. Each of these three has strengths and weaknesses; using them in combination can considerably strengthen the credibility of an exposure assessment.[12,24,180] For example, results of the exposure assessment would be validated if one could mathematically predict the absorbed dose per day of a chemical, estimate the resulting blood concentrations, and confirm these estimates by sampling the blood of the exposed population.[51]

Estimates Based on Direct Measurement

Point-of-contact or direct exposure assessment evaluates the exposure as it occurs. By measuring chemical concentrations at the interface between the person and the environment as a function of time, this yields an exposure profile. The best-known example of point-of-contact measurement is the radiation dosimeter. This small badge-like device measures radiation exposure as it occurs, and provides an integrated exposure estimate for the period of time over which the measurement has been taken.[43] The Total Exposure Assessment Methodology (TEAM) studies conducted by EPA also made use of direct measurements.[181] In the TEAM studies, a small pump with a collector and an absorbent was attached to a person's clothing to measure his or her exposure to airborne solvents or other pollutants as it occurred, just as has been done in industrial hygiene studies of the past 60 years.[182] In both of these examples, the measurements were collected at the interface between the person and the environment while exposure was occurring.

The area of exposure assessment known as agricultural hygiene has developed very sophisticated techniques for estimating the uptake (absorption) of chemicals during the mixing and application of pesticides.[183–185] Macroscale technologies such as laser-based and infrared radiation–based sensors are currently being used for assessing population exposures to sulfur and nitric oxides in industrial-stack effluents. Other microscale sensors, including personal dosimeters, are being used to monitor levels of carbon dioxide, carbon monoxide, volatile organic compounds (VOCs), pesticides, and PAHs in the workplace, household, and personal environment.[176] Recent efforts have focused on automated *lab-on-a-chip* sensing devices for detection environmental agents.[176,186]

A common limitation in exposure assessment is the lack of information about patterns of physical activity and behavior that affect the likelihood of exposure, the frequency and duration of exposure, and the uptake and distribution of environmental agents in the body.[176] GIS approaches have been used for developing individual metrics for exposure to pesticides, drinking water contaminants, and air pollutants, such as nitric oxide, sulfur dioxide, and particulates.[176,187–189] Only recently, researchers have used GIS to derive personal exposure estimates by linking information about personal activity and behavioral patterns with environmental data.[176,189–191] Interestingly, personal dosimetry devices are able to measure individual variables related to activity, such as motion, temperature, pressure, energy use, respiratory function, and heart rate.[176,192–199]

Providing that the measurement devices are accurate, the direct measurement method likely gives the most accurate exposure value for the period of time over which the measurement was taken. It is often expensive, however, to use these techniques to evaluate persons in the community, and measurement devices and techniques do not currently exist for all chemicals (at least at ambient concentrations).

Estimates Based on Exposure Scenarios

Using the exposure scenario approach, the assessor attempts to estimate or predict chemical concentrations in a medium or location, and link this information with the time that individuals or populations are in contact with the chemical. An exposure scenario is the set of assumptions describing how this contact takes place. This is, by far, the most common approach to exposure assessment, and such an approach is necessary when trying to predict the impact of events that may occur in the future, such as building a new manufacturing facility or introducing a new pesticide.[28,200–202]

The first step to building a scenario is to determine the concentration of the contaminated media. This is typically accomplished indirectly by measuring, modeling, or using existing data on concentrations in the media of concern, rather than at the point of contact (e.g., pesticide residues on food or metal emissions on residential soils). Often, we assume that the concentration in the bulk medium is the same as the concentration at the point of exposure. This can be a source of potential error and should be discussed in the uncertainty analysis. For example, over the past 20 years, most assessments of the hazard posed by contaminated soil was based on soil samples collected in the top 6 in. of soil, even though most persons were exposed routinely to the surface soil (usually the top 2.5 in.). Arguments can be made in either direction about the appropriateness of this assumption.

The next step in conducting an exposure scenario is to estimate the contact time, identify who is likely to be exposed, and then develop estimates of the exposure frequency and duration. Like chemical concentration characterization, this is usually done indirectly using demographic data, survey statistics, behavior observation, activity diaries, activity models or, in the absence of more substantive information, assumptions about behavior.[63,64,145]

Chemical concentration and population characterizations are ultimately combined in an exposure scenario. One of the major problems in evaluating dose equations is that the limiting assumptions used to derive them (e.g., steady-state assumptions) do not always hold true. Two approaches to this problem are available: (1) to evaluate the exposure or dose equation under conditions when the limiting assumptions do hold true, or (2) to build a dynamic model that accounts for both accumulation and degradation. The microenvironment method, which is typically used to evaluate air exposures, is an example of the first approach. This method evaluates segments of time and location when the assumption of constant concentration is approximately true, and then sums the time segments to determine the total exposure for the respiratory route, effectively removing some of the uncertainty.[203] In occupational hygiene, this is done by combining time-motion data with short-term air concentration data.[204] While estimates of exposure concentration and time of contact may be estimated in some situations, the concentration and time-of-contact estimates can be measured for each microenvironment. This avoids much of the error due to summing average values in cases where concentration and time of contact vary widely.

In the second approach, a computer model can efficiently predict dose if enough data are available.[39,48,205] When conducting modeling, there are various tools used to describe uncertainty caused by parameter variation, such as Monte Carlo analysis, and these may be necessary in some assessments.[88] Monte Carlo techniques should rarely be helpful when assessing individuals or small populations since actual *by person* data will often be available.

Estimating Exposure Using Biological Monitoring

Exposure can often be estimated after it has taken place. One important factor is whether the biological half-life of the chemical is sufficiently long to allow for accurate measurement. If a total dose is known or can be reconstructed, and information about intake and uptake rates is available, an average past exposure rate can be estimated.[146,206–210] Dose reconstruction relies on measuring biological fluids or other samples (blood, urine, hair, nails, or feces) after exposure and, if intake and uptake have already occurred, these measurements can be used to back-calculate dose.[146] However, data on body burden levels or biomarkers cannot be used directly unless a relationship can be established between these levels (or biomarker indications) and internal dose.

Biological monitoring can be used to evaluate the amount of a chemical in the body by measuring one or more parameters (Table 10.2). In general, if these measurements can be made and the biologic half-life is acceptable, then past

TABLE 10.2
Examples of Types of Measurements to Characterize Exposure-Related Media and Parameters

Type of Measurement (Sample)	Usual Attempts to Characterize (Whole)	Examples	Typical Information Needed to Characterize Exposure
1. Breath	Total internal dose for individuals or population (usually indicative of relatively recent exposures).	Measurement of VOCs, alcohol (usually limited to volatile compounds)	1. Relationship between individuals and population, exposure history (i.e., steady state or not) pharmacokinetics (chemical half-life), possible storage reservoirs within the body 2. Relationship between breath content and body burden
2. Blood	Total internal dose for individuals or population (may be indicative of either relatively recent exposures to fat-soluble organics or long-term body burden for metals).	Lead studies, pesticides, heavy metals (usually best for soluble compounds, although blood lipid analysis may reveal lipophilic compounds)	1. Same as earlier 2. Relationship between blood content and body burden
3. Adipose	Total internal dose for individuals or population (usually indicative of long-term averages for fat-soluble organics).	National Health and Aging Trends Study (NHATS), dioxin studies, PCBs (usually limited to lipophilic compounds)	1. Same as earlier 2. Relationship between adipose content and body burden
4. Nails and hair	Total internal dose for individuals or population (usually indicative of past exposure in weeks to months range; can sometimes be used to evaluate exposure patterns).	Heavy metal studies (usually limited to metals)	1. Same as earlier 2. Relationship between nails, hair content, and body burden
5. Urine	Total internal dose for individuals or population (usually indicative of elimination rates); time from exposure to appearance in urine may vary, depending on chemical.	Studies of tetrachloroethylene and trichloroethylene	1. Same as earlier 2. Relationship between urine content and body burden

exposure estimates can be reasonably accurate. Not all of these can be measured for every chemical and is dependent on several variables[43]:

- The concentration of the chemical itself in biological tissues or sera (blood, urine, breath, hair, adipose tissue, etc.)
- The concentration of the chemical's metabolite(s)
- The biological effect that occurs as a result of human exposure to the chemical (e.g., alkylated hemoglobin [Hb] or changes in enzyme induction)
- The amount of a chemical or its metabolites bound to target molecules

The results of biomonitoring can be used to estimate chemical uptake during a specific interval, if background levels do not mask the marker and the relationship between uptake and the selected marker is known.[211] The sampling time for biomarkers is often critical. Establishing a correlation between exposure and measurement of the marker, including pharmacokinetics, is necessary to properly back-calculate historical exposure.[43,177,178]

The strengths of this method are that it demonstrates exposure and absorption of the chemical that have actually taken place, and theoretically, it can give a good indication of past exposure. The drawbacks are as follows: It will not work for every chemical because of interferences or the reactive nature of the chemical, or because the biological half-life of the agent is too short; the approach has been applied to only a few chemicals; data relating internal dose to exposure are needed; and it may be expensive.

For those chemicals to which biological monitoring can be used to estimate past exposure, the information obtained can be invaluable for conducting retrospective exposure assessments that can be used in epidemiology studies. Some examples of chemicals for which past exposure can reliably be estimated include several metals as well as numerous large organic chemicals (e.g., DDT, chlordane, dioxin, polybrominated biphenyls [PBB], PCB).[146] A more detailed discussion about the current uses and emerging applications of biomonitoring for environmental exposure science is discussed later in this chapter.

INFORMATION UPON WHICH EXPOSURE ASSESSMENTS ARE BASED

Comprehensive exposure assessment of a complex scenario may require several hundred exposure factors to estimate the various chemical concentrations in one of several dozen different media. Among the most complex exposure assessments are those that address the risks posed by airborne emissions from combustors (Figure 10.4).[60,203,212] In order to estimate the concentration, numerous dispersion models, as well as fate and transport models, may be required. In addition, the assessor may need to search the literature to identify relevant studies from as many as 10 related fields of research. Sometimes, hundreds of published papers and government guidance documents need to be evaluated, used, and cited. In short, the exercise can be formidable, especially for assessments involving food chain contamination. Equally difficult and highly complex exposure assessments are those that attempt to estimate the uptake of fish by various members of the angling public.[79]

Obtaining Data on Intake and Uptake

The numerous editions of the *Exposure Factors Handbook* and *Child-Specific Exposure Factors Handbook* present statistical data on many of the factors used to assess exposure, including intake rates, and these provide citations for primary references.[63,64] Today, this series of publications represents the most comprehensive, single source of exposure

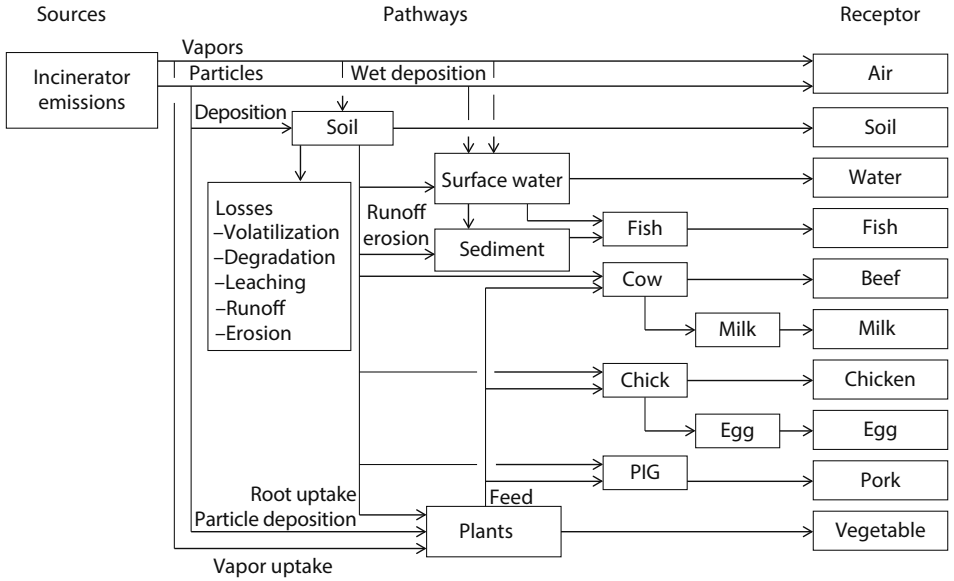

FIGURE 10.4 EPA's conceptual approach to dealing with direct and indirect exposure pathways as illustrated by assessments of incinerator emissions.

assessment information. Some of the many intake factors in the various volumes include the following:

- Drinking water consumption rates
- Breast milk ingestion rates for infants
- Consumption rates for homegrown fruits, vegetables, beef, and dairy products
- Consumption rates for recreationally caught fish and shellfish
- Rates of hand-to-mouth and object-to-mouth activities for children
- Incidental soil ingestion rates
- Pulmonary ventilation rates
- Surface area of various parts of the human body
- Body weight for various age groups
- Duration and frequency in different locations and microenvironments
- Duration and use of consumer product use
- Duration of lifetime

Table 10.3 presents examples of some of the standard or default exposure factors used in risk assessment.

TABLE 10.3
Selected Standard Default Assumptions Used in Exposure Assessment

Variable	Age Category	Mean or Central Tendency	95th Percentile
Drinking Water (mL/day)	1 to <2 years	271	837
	2 to <3 years	317	877
	3 to <6 years	327	959
	6 to <11 years	414	1316
	≥21 years	1043	2958
Soil (ingestion) (mg/day)	1 to <6 years	50	
	6 to 21 years	50	
	Adult	20	
Total Food (g/day)	1 to <2 years	1039	1756
	2 to <3 years	1024	1649
	3 to <6 years	1066	1746
	6 to <11 years	1118	1825
	21 to <40 years	1100	2110
Inhalation Rate (m^3/day)	1 to <2 years	8	12.8
	2 to <3 years	8.9	13.7
	3 to <6 years	10.1	13.8
	6 to <11 years	12	16.6
	11 to <16 years	15.2	21.9
	16 to <21 years	16.3	24.6
	21 to <31 years	15.7	21.3
	31 to <41 years	16	21.4
	41 to <51 years	16	21.2
	51 to <61 years	15.7	21.3
	61 to <71 years	14.2	18.1
	71 to <81 years	12.9	16.6
	≥81 years	12.2	15.7
Body Weight (kg)	1 to <2 years	11.4	14
	3 to <6 years	18.6	26.2
	11 to <16 years	56.8	88.8
	Adult	80	
Lifespan (years)	Male	75	
	Female	80	
Exposed Skin Area (%)	Adult gardening cold months	8	33
	Adult gardening warm months	33	69
Showering (min/day)	1 to <2 years	20	
	2 to <3 years	22	44
	3 to <6 years	17	34
	6 to <11 years	18	41
	≥18 years	17	
Residence Time (years)		13	46

The *Exposure Factors Handbook* is updated routinely to include new research data on previously discussed factors. It also provides default parameter values, which can be used when site-specific data are not available. Obviously, general default values should not be used in place of known, valid data that are more relevant to the assessment being conducted. The *Exposure Factors Handbook*, though substantial, may not contain all available information on exposure factors or relevant studies, so a supplemental literature search should be conducted to ensure that pertinent literature has been identified. As will be discussed later, if a probabilistic or Monte Carlo assessment is to be conducted, the documents titled *Risk Assessment Guidance for Probabilistic Assessment* (2001) and *Options for Development of Parametric Probability Distributions for Exposure Factors* (2000) should be consulted.[88,89]

Concentration Measurements in Environmental Media

Sometimes, the published data are inadequate to conduct a proper site-specific assessment. In these cases, concentration data can be gathered by conducting a new field study, or by evaluating data from past field studies and using them to estimate concentrations. Media measurements taken close to the point of contact are preferable to measurements far removed geographically or temporally. As the distance from the point of contact increases, the certainty of the data at the point of contact usually decreases, and the obligation for the assessor to show relevance of the data to the assessment at hand becomes greater. For example, an outdoor air measurement, no matter how close it is taken to the point of contact, cannot by itself adequately characterize indoor exposure.[213]

Concentrations often vary considerably from place to place, seasonally, and over time due to changing emission and use patterns.[47,53,214] This needs to be considered not only when designing studies to collect new data but also when evaluating the applicability of existing measurements as estimates of exposure concentrations in a new assessment. It is of particular concern when the measurement data will be used to extrapolate to long time periods, such as lifetimes. Transport and dispersion models are frequently used to help answer these questions.[205]

The exposure assessor is likely to encounter several different types of measurements. One type often used to understand concentration trends is outdoor fixed-location monitoring. This measurement is used by EPA and other groups to provide a record of pollutant concentration at one place over time. Nationwide air and water monitoring programs have been established so that baseline values in these environmental media can be documented. Although it is not practical to set up a national monitoring network to gather data for a particular exposure assessment, data from existing networks can be evaluated for relevance to an exposure assessment. These data are often far removed from the point of contact. Adapting data from previous studies usually presents specific challenges.

Indoor air contaminant concentrations can vary as much or more than those in outdoor air.[17,215–219] Consequently, indoor exposure is best represented by measurements taken at the point of contact. However, because pollutants, such as carbon monoxide, can exhibit substantial penetration to the indoor environment, indoor exposure estimates should consider potential outdoor, as well as indoor, sources of the contaminant(s) under evaluation.[22,43,220–222]

Contaminant concentrations in food and drinking water measurements can also be measured. General characterization of these media, such as market basket studies (where representative diets are characterized), shelf studies (where foodstuffs are taken from store shelves and analyzed), or drinking water quality surveys, is usually far removed from the point of contact for an individual but may be useful in evaluating exposure concentrations for a large population. Measurements of tap water or foodstuffs in a home and how they are used are closer to the point of contact. In evaluating the relevance of data from previous studies, variation in the distribution systems must be considered, as well as the space-time proximity.[43]

Consumer or industrial product analysis is sometimes done in order to characterize the chemical concentrations in products. Product formulations can change substantially over time, similar products do not necessarily have similar formulations, and regional differences in product formulation can also occur. These should be considered when determining the relevance of extant data and when setting up sampling plans to gather new data.[43]

Another type of concentration measurement is the microenvironmental measurement. Rather than using measurements to characterize the entire medium, this approach defines specific zones in which the concentration in the medium of interest is thought to be relatively homogeneous and then characterizes the concentration in that zone.[24,223] Typical microenvironments include the home or parts of the home, office, automobile, or other indoor settings. Microenvironments can also be divided into time segments (e.g., kitchen during the day, kitchen during the night). This approach can produce measurements that are closely linked with the point of contact, both in location and time, especially when new data are generated for a particular exposure assessment. The more specific the microenvironment, however, the greater the burden on the exposure assessor to establish that the measurements are representative of the population of interest.

The concentration measurement that provides the closest link to the actual point of contact is personal monitoring. In virtually all cases, if available, this information should be the basis of exposure assessments of individuals. An obvious exception is the work environment where lapel sampling is conducted while the person is wearing a respirator; thus, in this case personal sampling would not reflect genuine exposure.

Models and Their Role

Often the most critical assessment element is estimating pollutant concentrations at exposure points. This is usually

carried out by combining field data and modeling results. In the absence of field data, this process often relies on the results of mathematical models of aerial dispersion, such as Industrial Source Complex Long-Term (ISCLT), or of water movement, such as Modular Three-Dimensional Finite-Difference Groundwater Flow Model (MODFLOW).[224–228] EPA's Science Advisory Board and others have recommended that modeling ideally should be linked with monitoring data in regulatory assessments, although this is not always possible.

A modeling strategy has several aspects, including setting objectives, model selection, obtaining and installing the code, calibrating and running the computer model, and validation and verification. Many of these aspects are analogous to the quality assurance and quality control measures applied to measurements.

Regardless of whether models are extensively used in an assessment or whether a formal modeling strategy is documented in the exposure assessment plan, when computer simulation models, such as fate and transport models, and exposure models are used in exposure assessments, the assessor must be aware of the performance characteristics of the model and state how the exposure assessment requirements are satisfied by the model.[205]

The site must be characterized if models are to be used to simulate pollutant behavior at a specific site. Site characterization for any modeling study includes examining all data on the site, such as source characterization, dimensions and topography of the site, location of receptor populations, meteorology, soils, geohydrology, and ranges and distributions of chemical concentrations. For exposure models that simulate both chemical concentration and time of exposure (through behavior patterns), data on these two parameters must be evaluated.[24,28,229] Criteria are provided by EPA for selecting surface water models and groundwater models, respectively; the reader is referred to these documents for details.[230,231] Similar selection criteria exist for air dispersion models.[232]

A primary consideration in selecting a model is whether to perform a screening study or a detailed evaluation. A screening study makes a preliminary evaluation of a site or a general comparison between several sites. It may be generic to a type of site (i.e., an industrial segment or a climatic region) or may pertain to a specific site for which sufficient data are not available to properly characterize the site. Screening studies can help direct data collection at the site by, for example, providing an indication of the level of detection and quantification that would be required and the distances and directions from a point of release where chemical concentrations might be expected to be highest. An example of a screening-level modeling effort would be to estimate the amount of lead deposited by an incinerator onto local crops using a basic air dispersion model, without considering local geographical or weather conditions. The next level of complexity would consider the presence of mountains, their proximity to the stack, the local weather patterns, and the number of atmospheric inversions per year. A higher level of analysis could incorporate yet other, more subtle factors.

The value of the screening-level analysis is that it is simple to perform and may indicate that no significant contamination exists. Screening-level models are frequently used to get a first approximation of the concentrations that may be present. Often these models use very conservative assumptions; that is, they tend to overpredict concentrations or exposures. If the results of the conservative screening procedure predict concentrations or exposures at less than a predetermined no-concern level, then more detailed analysis is probably not necessary. If the screening estimates are above that level, refinement of the assumptions or a more sophisticated model is necessary to generate a more realistic estimate.[43]

Screening-level models also help the user conceptualize the physical system, identify important processes, and locate available data. The assumptions used in the preliminary analysis should represent conservative conditions, such that the predicted results overestimate potential conditions, limiting false negatives. If the limited field measurements or screening analyses indicate that a contamination problem may exist, then a detailed modeling study may be useful.

By contrast, the purpose of the detailed evaluation is to use the best data available to make the best estimate of spatial and temporal chemical distributions of a specific site. Detailed studies typically require higher-quality data and more sophisticated models.

Accounting for Background Concentrations

Background exposure to xenobiotics, especially environmentally persistent ones, can occur due to natural or anthropogenic sources.[233] In most exposure assessments, background soil concentrations are the focus of attention, but the same issue can be relevant when evaluating sediments, ambient air, groundwater, and vegetation (food stuffs). At some sites, it is important that these so-called *background* concentrations be accounted for because removing the quantity of toxicant due to humans may, in fact, not appreciably change the concentrations or be sufficient to reduce the risk to acceptable levels. For example, naturally occurring concentrations of lead, arsenic, and cadmium, in some locations, may be higher than cleanup levels established by various regulatory agencies.[232,234] The exposure assessor should try to determine local background concentrations by gathering data from nearby locations clearly unaffected by the site under investigation, or by referring to published works that have assessed this issue.[235]

Description of Background Levels

When assessing soils, background levels can be viewed in at least four different ways[224]:

- *Pristine* levels—Some would like to equate background levels with those associated with the *pristine* state, that is, soils or landscapes unaffected by human activity. This rather idealistic situation probably no longer exists; even in Antarctica, mercury

and dioxin concentrations can be detected in some media. Toxic elements mainly associated with the solid phase of some natural material (such as soil dust, plant or volcanic ash, vegetable matter) are relatively mobile in a global sense. For example, Nriagu (1979) has suggested that about 40 million tons of heavy metals have been dispersed atmospherically over the many centuries of human activity.[236]

Increases in pollutant metal concentrations have been measured up to 60 km from smelters, and automotive lead (fine particles) has been measured in soils and rainfall up to about 50 km downwind from major cities. Soil contamination up to 50–100 m from highways by automotive lead (coarser particles) is an example of short-range transport and contrasts with transport of toxic metals on a continental or global scale (e.g., contamination of the Greenland ice sheets from the northern United States, mercury in the Florida Everglades due to aerial releases in South America, the snows of the New Zealand Alps by soil dust from inland Australia).[224]

- *Normal* levels—The question could be asked—are soils contaminated at farms in the higher rainfall areas of the Appalachians, which used to receive automotive exhaust particulates from the New York metropolitan area 200 km away? These soils are not pristine, but the chemical concentrations are perfectly safe for growing food, raising farm animals, and residential living. Soils from such areas would have a range of what is often called *normal* background values. To most exposure assessors, this mosaic of normal soils, which is only affected by the minor pollution of everyday activities associated with modern rural and urban life, should be the basis for defining background values. Statistically, this range of normal background values would constitute a single lognormally distributed population. Obviously, one needs to exclude the outliers or *hot* spots due to a geochemical anomaly, or localized pollution arising from either industrial emissions, disposal of waste products, or intensive (excessive) use of farm chemicals.[224]
- Historically polluted regions—Local community and regulatory policies often affect what are defined as background levels. A community with highly developed environmental consciousness may insist on very low, possibly unreasonable, reference values. Some densely populated areas with historically derived pollution, perhaps from former mining activities, may sustain apparently healthy populations that pragmatically must accept higher *background*-level values. The cities of Philadelphia, Baltimore, and New York, and parts of Japan, for example, may fit in this category.
- Geochemical variation—Background levels of some potentially toxic elements may vary among geographical regions because of differences in soil type. The resulting concentrations are often called naturally occurring levels. An important factor is the composition of rocks and sediments that weather from soils. Some extreme examples are high concentrations of nickel, cobalt, and chromium in igneous rocks such as basalts that cover extensive areas in western Victoria and Tasmania, Australia, and high concentrations of boron in soils on marine sediments in the Riverina, Mallee, and Wimmera districts of South Australia and Victoria, Eyre Peninsula, and parts of western Australia.

Some regulatory agencies have provided written guidance describing how to select soil or sediment cleanup values that account for background chemical concentrations. These have varied significantly, but within the past 5 years, there appears to be some convergence regarding the definition of background, how to measure it, and how it should affect exposure assessment calculations.

ESTIMATING UPTAKE VIA THE SKIN

When attempting to predict chemical risks in the environmental or occupational setting, the dermal exposure route should nearly always be assessed. In most evaluations of hazardous waste sites and ambient air or water contaminants, this is not a major route of exposure. Although the uptake of chemicals via the skin has generally been overlooked in most workplace exposure assessments, it probably represents a substantial portion of the exposure for many occupations. Even though gloves are more frequently used than in years past and training has increased on the possible hazards of dermal exposure, there is still ample evidence to indicate that, in order to conduct a complete exposure assessment, this route deserves attention.[91,92,130,237–240]

In addition to the risks associated with systemic toxicity due to uptake via the skin, it is sometimes necessary to evaluate the allergic contact dermatitis (ACD) hazard. In recent years, techniques have been developed to quantitatively predict the likelihood of elicitation and induction of ACD.[241,242] Some regulatory agencies are concerned with ACD and have developed cleanup standards based on this health endpoint. More recently in the arena of product development, significant improvements have been included in dermal sensitization risk assessments for products such as fragrance ingredients.[243,244] For evaluations of contact sensitization as a critical health endpoint, there is now considerable support for using quantity per unit area of skin (above a minimum application area) rather than other dose metrics such as concentration applied to the skin.[245–251] This dose metric concept has been incorporated in the quantitative risk assessment approach for the global fragrance industry in assessing the risks of dermal sensitizers in fragrance ingredients.[243]

In the workplace, a worker's skin frequently comes into contact with solvents or chemicals mixed in water (aqueous materials). In most environmental settings where persons can be exposed to contaminated soil, dust, or water, dermal uptake must be assessed. Fortunately, a good deal of research

has been conducted to understand the rate at which chemicals pass through the skin. Percutaneous absorption of neat chemicals (e.g., the pure liquid) was often studied in humans until the late 1970s.[129,252–258] Because of the potential toxicity of many chemicals and improved laboratory techniques, in vivo human studies have been largely supplanted by experiments with laboratory animals, in vitro studies, or athymic rodents grafted with human skin.[259] Historical research has shown that, in general, chemical penetration of the human skin is similar to that of a pig or monkey, and much slower than that of the rat and rabbit.[260] Thus, for many chemicals, there is some level of confidence that the rate of dermal uptake of a chemical by humans can be inferred from animal data.

Starting in the 1980s, in vitro studies using human skin began to be conducted on a more routine basis. In these studies, a piece of excised skin is attached to a diffusion apparatus with a top chamber to hold the applied chemical and a temperature-controlled bottom chamber containing saline or other fluids (plus a sampling port to withdraw fractions for analysis).[261] Although human forearm skin is optimal, it is difficult to obtain, so abdominal or breast skin is commonly used. In general, a properly conducted in vitro test can be a reasonably good predictor of the absorption rate in vivo.[262,263] However, due to the fragile nature of the technique, these studies must be carefully interpreted.[264] Often, depending on the conditions of the test, the results are not applicable to humans.

Aside from neat liquids and exposure to contaminated water, dermal exposures can also occur through contact with dust or dirt on surfaces and by way of contact with soil- or dust-bound contaminants.[213] Surface-to-skin transfer of contaminants is a complex process. For example, a pesticide can be transferred to skin during contact with any contaminated exposure medium. Once on the skin, pesticide residues and contaminated particles can be transferred back to the contaminated surface during subsequent contact, loss by dislodgement or washing, or transferred into the body by percutaneous absorption or hand-to-mouth activity.[265] Few studies have directly estimated soil loading on human skin, or measured dermal contact of contaminated equipment by workers.[266–275] However, recent efforts using a fluorescent tracer as a surrogate for pesticide residues and house dust particles have proved informative in understanding the parameters that affect residue transfer from surface to skin, skin to other objects, and skin to mouth.[265,276] In these studies, controlled transfer experiments were conducted by varying contact parameters with each trial. The mass of a tracer transferred was measured and the contact surface area estimated using video imaging techniques. Parameters evaluated included surface type, surface loading, contact motion, pressure, duration, and skin condition. Results have shown that surface loading and skin condition are among the important parameters for characterizing residue transfers.[265]

The available studies probably provide sufficient data to generate point estimates of soil adherence and, perhaps, can provide a reasonable probability density function (PDF) for most persons exposed to contaminated soils. The degree of representativeness of the data to the general population is difficult to assess.[277] Recently, a couple of studies measured the adherence of soil to multiple skin surfaces (hands, forearms, lower legs, faces, and feet) under ambient and recreational conditions.[268,270] Dermal loading on the hands was found to vary over five orders of magnitude and to be dependent on the type of activity. Differences between pre- and postactivity adherence demonstrated the episodic nature of dermal contact with soil. However, because of the activity-dependent nature of soil exposure, data from these studies must be interpreted for their relevance to the type of activity, frequency, duration, and otherwise site-specific nature of exposure. The various studies involving contaminated soil are informative for providing an estimate of exposure; however, they are probably a couple orders of magnitude greater than what might be expected in a chemical plant. Nonetheless, this work is a *starting point* for bracketing potential exposure to dusts in the workplace.

Recently, there has been a reasonable level of research investigating exposure to house dust. The basis for this concern has been increasing evidence that controlling exposure to house dust, especially in homes located near sites with considerable surface soil contamination, is more important for reducing the health hazard than remediating the soil.[213,278–282] Numerous papers in recent years have shown that in-house exposure to toxics is much greater than that encountered due to ambient (so-called environmental) contamination.[22,217,283,284] In household dust studies, the source of the dust sample can provide a historical, as well as recent collection of potential exposures from dust inside the home. Undisturbed surfaces (e.g., top of a refrigerator, attic dust) can be indicative of materials deposited over a long period of time, whereas frequently cleaned surfaces (e.g., kitchen countertops) will be indicative of the most recent deposits.[285]

Along these lines, and of particular interest to those who study indoor exposure, is the recent work to develop standardized approaches for collecting wipe samples and estimating the amount of dust loading on the palm of the hand.[286,287] Using fluorescein-tagged Arizona test dust as a possible surrogate for house dust, particle transfers to both wet and dry skin were quantified for contact events with stainless steel, vinyl, and carpeted surfaces that had been preloaded with the taggest test dust.[276] With these tests, researchers found that (1) only about one-third of the projected hand surface typically came into contact with the smooth test surfaces; (2) the fraction of particles transferred to the skin decreased as the surface roughness increased, with carpeting transfer coefficients averaging only one-tenth those of stainless steel; (3) hand dampness significantly increased the particle mass transfer; and (4) consecutive presses decreased the particle transfer by a factor of three as the skin surface became loaded, requiring about 100 presses to reach an equilibrium transfer rate.[276] Although dermal absorption of toxicants in house dust will almost always pose a relatively low dermal uptake hazard, the uptake of toxicants due to hand-to-mouth contact can be substantial.[213]

Quantitative Description of Dermal Absorption

For the purposes of risk assessment, percutaneous absorption is defined as transport of externally applied chemicals through cutaneous structures and the extracellular medium to the bloodstream.[24,130] In many settings, such as the agricultural workers, platers, mechanics, and others, dermal uptake is the primary route of exposure. The simplest way to describe the rate of skin absorption is to apply Fick's first law of diffusion at steady state[288,289]:

$$J = \frac{dQ}{dt} = \frac{D \cdot k\nabla C}{e} \approx K_p \cdot C \qquad (10.3)$$

where

- J (=dQ/dt) is the chemical flux or rate of chemical absorbed (mg/cm^2-h)
- D is the diffusivity in the stratum corneum (cm^2/h)
- k is the stratum corneum/vehicle partition coefficient of the chemical (unitless)
- ∇C is the concentration gradient (mg/cm^3)
- e is the thickness of the stratum corneum (cm)
- K_p is the permeability coefficient (cm/h)
- C is the applied chemical concentration (mg/cm^3)

The concentration gradient is equal to the difference between the concentrations above and below the stratum corneum. Because the concentration below is small compared to the concentration above, ∇C can be approximated as equal to the applied chemical concentration. From Equation 10.3, it can be seen that the rate of absorption is directly proportional to the applied concentration. The diffusivity represents the rate of migration of the chemical through the stratum corneum. Since the stratum corneum has a nonnegligible thickness, there is a period of transient diffusion (lag time), during which the transfer rate rises to reach a steady state. In these studies, the steady state is maintained indefinitely, provided the system remains constant. Depending on the type of chemical, the lag time can range from minutes to days.[91] From an exposure assessment standpoint, if the exposure duration is shorter than the lag time, it is unlikely that there will be any significant systemic absorption.[288,290]

The partition coefficient (K_p) is one of the key parameters that influences the degree to which a chemical penetrates the skin.[288,290–293] Fatty chemicals tend to accumulate in the stratum corneum. Conversely, the stratum corneum is an effective barrier for hydrophilic substances, which tend to have low skin absorption rates. Because stratum corneum/vehicle partition coefficients are difficult to measure, the three parameters (D, k, and e) are combined to give an overall permeability coefficient (K_p). It is noteworthy that Equation 10.3 only approximates most in vivo exposure situations in which true steady-state conditions are rarely attained. In spite of its limitations, this equation has yielded reasonable estimations of the actual absorption rates of chemicals for many situations (Table 10.4).

Dermal absorption is often reported in experimental studies as fractional absorption; however, this is generally not

independent of loading conditions. Some studies have suggested that relative dermal absorption of certain chemicals decreases with increasing dermal loading (i.e., amount of substance per unit area of skin).[294,295] Therefore, a calculated internal dose when extrapolating from experimental conditions to an exposure setting of interest, without accounting for dermal loading, may underestimate or overestimate actual risks.[240] This is particularly important when evaluating dermal toxicity studies because if the area of dosing is so small that no effect is observed (even if it is saturated), the apparent chemical toxicity can be artificially reduced by loading more chemical onto the same target area.[296] In a quantitative assessment of dermal absorption experiments, the relationship between dermal loading and relative absorption was compared across 138 different studies and 98 substances.[240] In the majority of cases (63%), an inverse relationship between relative dermal absorption and dermal loading was observed with relative absorption varying by more than factor of a 100 within a dermal loading range that is relevant for occupational scenarios. A likely explanation offered for this trend is the saturation of the absorption capacity of the skin, particularly for the slow rate of absorption of poorly water-soluble substances through the water film of the skin or its saturation at higher dermal loading ranges.[240]

Pharmacokinetic Models for Estimating the Uptake of Chemicals in Aqueous Solution

Pharmacokinetic models predict the uptake of a chemical through the skin based on fundamental thermodynamics. Several different models have been proposed. For example, a four-compartment pharmacokinetic model was developed in 1982.[293] This model, which uses first-order rate constants, describes chemical movement through the compartments representing the various skin structures. It has been used successfully to predict the chemical disposition in the skin and plasma as a function of their physicochemical properties, and when an input rate constant to the skin surface is added to the model, it can be used to assess vehicle effects. A similar model that treats the barrier membrane as a series of spaces filled with immiscible liquids has also been developed[291]; its advantage is that it allows examination of non-steady-state conditions in which Fick's law does not apply.

Under an infinite-dose situation in which the amount of a chemical lost by penetration is too small to alter the applied concentration (e.g., where one is swimming), the rate of absorption is essentially linear once steady state has been reached. In the finite-dose system, however, the chemical solution is applied as a thin film and the concentration decreases as penetration proceeds (e.g., a splash). All other model parameters being the same, penetration is reduced under finite-dose conditions. This is because the chemical concentration is continuously reduced over time, resulting in a decrease in the gradient across the stratum corneum. These modeling results indicate that the mechanism by which fluxes are affected must be considered when extrapolating to non-steady-state conditions.

Although classic pharmacokinetic modeling like that described by Guy et al. (1982) can provide a good mathematical description of the disposition of chemicals,[290] it does not depict exactly the biological processes in the intact animal. Fortunately, pharmacokinetic methods based on physiological principles are feasible alternatives for analysis of in vivo skin penetration studies. PBPK models realistically describe the disposition of the chemical in the intact animal in terms of rates of blood flow, permeability of membranes, and partitioning of chemicals in tissues.[291,297] Characterizing dermal absorption in terms of actual anatomical, physiological, and biochemical parameters facilitates extrapolations to the real species of interest, humans.

PBPK models were developed to describe the percutaneous absorption of volatile organic contaminants in dilute aqueous solutions.[298] The exposure scenario modeled was either hand or full-body immersion into a vessel of solute-contaminated water. Modeling results suggested that chemical uptake in aqueous solutions is most markedly influenced by epidermal blood flow rates, followed by epidermal thickness and lipid content of the stratum corneum. In general, thicker and fattier skin provides a better barrier to dermal penetration of chemicals. These are precisely the principles under which barrier creams offer their protection for increasing the effective thickness and lipophilicity of the skin. This model also predicted that the dose of some volatile organic chemicals in water absorbed through the skin during a 20 min bath may be equivalent to the amount inhaled.[298]

Among the most complex and best validated of the various models for dermal uptake of liquids is that developed by McDougal et al.[100,299–312] These authors have successfully predicted dermal uptake rates of humans for more than a dozen chemicals based on animal data. One advantage of dermal PBPK models over traditional in vivo methods is their ability to accurately describe nonlinear biochemical and physical processes. For example, describing skin penetration based on blood concentrations or excretion rates as *percent absorbed* assumes that all processes have a simple linear relationship with the exposure concentration. This is often not the case. The kinetics become nonlinear when the absorption, distribution, metabolism, or elimination of a chemical is saturated

at high exposure concentrations. This model and other models developed since then are generally reliable methods for estimating dermal uptake for certain classes of chemicals.

Factors Used to Estimate Dermal Uptake

Many factors need to be quantitatively accounted for in order to estimate the likely systemic uptake of a chemical that comes into contact with the skin, either as a liquid or when present in soil or dust.[7,130,313]

Dermal Bioavailability

The typical media of concern for assessing cutaneous contact to environmental chemicals, in contrast to occupational exposure, are house dust, soil, fly ash, and sediment. In the workplace, dermal uptake is due to direct contact with liquids and contact with surfaces contaminated with dirt or liquids. A number of parameters can influence the degree of cutaneous bioavailability of chemicals in complex matrices. These may include aging (time following contamination), soil type (e.g., silt, clay, and sand), type and concentration of co-contaminants (e.g., oil and other organics), and the concentration of the chemical contaminant in the media.[125] The bioavailability of a chemical in soil will usually be affected by its physicochemical properties. Chemicals with high molecular weights tend to bind to soil/dust and be less water soluble, while smaller molecules will frequently be water soluble, less tightly bound, and relatively bioavailable.[101,121] The cutaneous bioavailability of perhaps 20–30 chemicals in soils has been determined in animals.[51,106,115,118,120–122,125,314–317] These studies show that different media and different chemicals can yield dramatically different cutaneous bioavailabilities. The results of these studies, for example, produce values of bioavailability for different chemicals that range from 0.001% to 3% for chemicals in soil. Dioxin and lead are considered classic case studies since there are many human populations that have been exposed to these chemicals in dust or soil yet the blood levels can be very high or very low depending on the bioavailability.

Skin Surface Area

There is an abundance of information about the surface area of different portions of the body. One simple approach is to use the *rule of nines* for estimating the surface area of the human body[318]: the head and neck are 9%, upper limbs are each 9%, lower limbs are each 18%, and the front or back of the trunk is 18%.[69] EPA has estimated an exposed surface area (arms, hands, legs, and feet) of 2900 cm^2 for children 0–2 years old; 3400 cm^2 for children 2–6 years old; and 2940 cm^2 for adults (an adult is assumed to wear pants, an open-neck short-sleeve shirt, shoes, and no hat or gloves).[43] When assessing chemical exposure in the ambient environment, most of the necessary surface area information can be found in EPA's *Exposure Factors Handbook* and *Child-Specific Exposure Factors Handbook*.[63,64] Table 10.5 presents the skin surface areas commonly used when conducting exposure assessments.[63,64,318] A distribution plot of skin area versus body weight has been developed.[319]

TABLE 10.5
Representative Mean Surface Areas of the Human Body (Adult Male 21 years and Older)

Body Portion	Area (cm^2)
Whole body	20,600
Head	1,360
Trunk (includes neck)	8,270
Upper extremities	3,930
Arms	3,140
Upper arms	1,720
Forearms	1,480
Hands	1,070
Lower extremities	8,020
Legs	6,820
Thighs	4,120
Lower legs	2,680
Feet	1,370

Soil Loading on the Skin

A key factor to consider when estimating dermal uptake is the soil-to-skin adherence rate. Values of 0.5–0.6 and 0.2–2.8 mg/cm^2 have been reported for adults and children, respectively, although it is important to carefully consider site-specific information when conducting these assessments.[53,266,272,320] Work by Finley et al. (1994), Kissel et al. (1996), and Holmes et al. (1996) have built on prior studies to show that dermal loading can vary significantly among different activities and different people.[267,268,270] The *Exposure Factors Handbook* and *Child-Specific Exposure Factors Handbook* give considerable attention to this topic.[63,64] One approach to improving dermal uptake calculations is to use area-weighted adherence factors. When assessing the risk to large populations, Monte Carlo techniques are often useful in characterizing distributions of exposure.[37]

Interpreting Wipe Samples

In some workplaces, wipe sampling has been conducted historically to assess the degree of surface contamination. Hospitals were among the first occupational settings, as long ago as 1940, to rely on this method to determine microbial levels in operating rooms. In pharmaceutical manufacturing, wipe sampling has been used as an indicator of hygienic conditions since the 1960s. The health physics profession has utilized wipe samples extensively as an indicator of the need for better housekeeping and decontamination; this group performed most of the early work in quantifying the relationship of wipe sample concentrations to dermal and oral uptakes.

Over the years, few papers have discussed on how to collect and interpret wipe samples.[270,321–325] When the primary effect of a chemical is skin discoloration, ACD, or chloracne, wipe sampling was nearly always the preferred approach for assessing the acceptability of the workplace (rather than relying on air samples). Beginning in the 1980s, a substantial number of wipe samples were collected in office buildings contaminated

with dioxins and furans after electrical transformer fires to estimate the potential human exposure.[326] This approach was recently used to assess exposures to dust generated from the September 11, 2001, terrorist attacks,[285,327–329] as well as household dust in homes surrounding dioxin-contaminated sites in Midland, Michigan.[279–282] Some of the most interesting investigations of surface dust are the use of chemical tracers or signatures to identify sources of contaminated surface dust, such as in the case to evaluate buildings impacted from the World Trade Center dust or to characterize chemical air dispersion and personal exposures in urban environments.[330,331]

Although wipe sampling data have generally been used as an indicator of cleanliness,[321] these data can also be used to estimate systemic uptake of a contaminant if the degree of skin contact with the contaminated surfaces and the bioavailability of the chemical (in that medium) are known. While historical wipe sampling methods were rather imprecise, they were useful for obtaining a rough estimate of the possible exposure, which could be refined later by other means, such as biological monitoring. Based on estimates of the contribution of dust to overall intake of persistent chemicals (e.g., polybrominated diphenyl ethers, polychlorinated biphenyls, and polyaromatic hydrocarbons), it has been suggested that residential dust measurements could be useful in augmenting or replacing questionnaire-based assessments of human exposure in epidemiologic studies.[332]

If one knows that wipe sampling results are representative of what comes into contact with the hands (i.e., actually able to be absorbed), then the procedures for converting wipe sample data to estimates of systemic uptake are straightforward.[333] For example, if one knows the number of times a surface (e.g., valve handle, instrument controller, or drum) is touched, the surface area of the hand touching these items (usually the palm), and the percutaneous chemical absorption rate, then the uptake can be estimated using wipe sample information. The best wipe sampling data were those collected in a reliable and consistent manner, with a focus on the mass per unit area. Hand wash or hand wipe sampling is often more representative of the true hazard than surface wipe samples.[334] The bulk of what is known about how to best evaluate this matter comes from the relatively robust studies of agricultural workers that have been conducted over the past 20 years by hygienists, who specialized in this area (e.g., Kissel, Poppendorf, Spears, Knarr, Knack, and Fenske).

Until recently, no standardized approaches existed for conducting wipe sampling. Although surface sampling has been utilized as a metric to evaluate human health under a variety of settings,[335–338] a number of factors can influence the amount of substance collected and measured. These factors include differences in (1) methodology (wet/dry wipe, collection media, microvacuum), (2) human factors (operator differences in sampling technique), (3) surface characteristics (physical shape, porosity, roughness), and (4) residue characteristics (particle size, dust loading).[339,340] Differences in the use of wetting agent (acetone, methylene chloride, water, saline, isopropanol, and ethanol) and sampling media (paper, cotton, and synthetic fibers) produced drastically different results. In some procedures, especially those that used methylene chloride (in which the paint was concurrently stripped by the solvent), the chemical in the paint matrix was assumed to be bioavailable (a completely unreasonable assumption). Much of the previous work, which measured the amount of chemical released following aggressive scrubbing of the contaminated surfaces with detergent or solvent, did not reflect a realistic exposure scenario. Thus, there has been a need for standard techniques that attempt to mimic the conditions in which a hand comes into contact with a contaminated surface.[325] Some of the techniques have been developed by hygienists involved in agricultural exposure assessment.[184,341–343]

In an attempt to fill this need, fairly sophisticated work to standardize these procedures has been conducted by researchers at Rutgers University. A couple of their wipe sampling procedures and devices have been patented.[286] They have also developed a dry contact sampling device that offers promise for understanding the hazard from surface dusts.[287] The implications from recent wipe sampling research are that (1) a minimum number of samples are needed to have statistical confidence, (2) the pressure applied to the cloth during sample collection should be standardized, (3) neat solvent should not be used as a collection medium, (4) the size of the sample area needs to be sufficient to collect enough contaminant for quantification, and (5) the technique should be validated by using glove analyses. More research will be devoted to this topic in the coming years as it has become quite clear that *in-home* versus outdoor exposures are generally much better predictors of risk since such a large fraction of the day is spent indoors (and because rugs, upholstery, drapes, toys, and other objects tend to accumulate toxicants over time).[344–346]

Estimating the Dermal Uptake of Chemicals in Soil

One of the most frequently occurring exposure scenarios involving environmental exposures is that of contaminated soil.[53] Unfortunately, dermal uptake of chemicals found in soil has infrequently been evaluated experimentally.[91,347] Dermal absorption of chemicals from soil is influenced by a number of chemical and physical factors, including layering (extent and pattern of soil particles across the skin surface), particle size distribution, sorption capacity, soil–chemical contact time (*aging*), and contaminated soil–skin contact time (exposure).[347] There are several key aspects of chemical absorption from soil particles that are important to consider.[347] First, as chemicals have water solubility limits, the capacity of chemicals to sorb to soil particles is finite. Thus, it is important to keep in mind that experimental data representing absorption of the free chemical correspond to the neat chemical and not absorption from soil. Second, sorption of chemicals by soil particles is not instantaneous and depending on the properties of the chemical, some compounds require long periods (e.g., months) to reach equilibrium. Third, compounds move from soil to skin through two primary mechanisms: contact transfer and diffusion. The transfer of contaminants as a result of soil particles directly contacting the skin may occur quickly, whereas diffusion may occur slowly but may

ultimately account for a larger percentage of total absorption.[347] In effort to encourage standardization of methods on soil dermal absorption research, Spalt and colleagues (2009) offered five primary criteria to improve interpretation of investigations on this topic. These criteria include reporting of results in the context of possible layering effects, soil saturation, particle size selection, soil–agent contact time, and assurance of continuous soil–skin contact.[347]

A model to estimate the amount of a chemical in soil that crosses the stratum corneum into the underlying tissue layer has been developed.[101] In order to differentiate this absorptive process from bioavailability, which also includes transport into blood, McKone (1990) refers to the percentage of available chemical as an uptake fraction. The approach is based on the fugacity concept, which measures the tendency of a chemical to move from one phase to another. Because the skin has a fat content of about 10% and soil has an organic carbon content of 1%–4%, a chemical in soil placed on the skin will move from the soil to the underlying adipose layers of the skin. However, this transfer depends on the period of time between deposition on the skin and removal by evaporative processes. The mass-transfer coefficients of the soil-to-skin layer and the soil-to-air layer define the rate at which these competing processes occur.

Results of this model suggest that the chemical uptake fraction in soil varies with the exposure duration, soil deposition rate, and physical properties of the chemical, and is particularly sensitive to the values of the K_{ow}, as well as the mass or depth of soil deposited on the skin. When the amount of soil on the skin is low (<1 mg/cm^2), a high uptake fraction, approaching unity in some cases, is predicted. With higher soil loading (20 mg/cm^2), an uptake of only 0.5% is predicted. Because of the diverse variations of the uptake fraction with soil loading, results obtained from experiments with a single soil loading should be applied with caution to human soil-exposure scenarios.

The dermal uptake of chemicals in soil is a complex process, but its behavior is predictable if the controlling factors are accounted for and quantified.[91,101] In situations involving a relatively thin layer of a chemical on the skin, a few generalizations can be made. First, for chemicals with a high K_{ow} and a low air/water partition coefficient, it is reasonable to assume 100% uptake in 12 h. Second, for chemicals with an air/water partition coefficient greater than 0.01, the uptake fraction is unlikely to exceed 40% in 12 h. Third, for chemicals with an air/water partition coefficient greater than 0.1, one can expect less than 3% uptake in 12 h. In most occupational settings, contaminated soil will rarely be in contact with the skin for greater than 4 h before it is washed off. Consequently, this should be accounted for when attempting to predict systemic uptake.

Dermal Uptake of Contaminants in Soil

In order to estimate chemical uptake, one needs to know the percutaneous absorption rate, the exposed skin area, the chemical concentration, and the exposure duration.[348] One scenario would be a thin film of chemical on the skin. For this finite-dose scenario, the following equation is useful:

$$\text{Uptake (mg)} = (C)(A)(x)(f)(t) \quad (10.4)$$

where
- C is the concentration of the chemical (mg/cm^2)
- A is the skin surface area (cm^2)
- x is the thickness of the film layer (cm)
- f is the absorption rate (%/h)
- t is the duration of exposure (h)

Another scenario would be an excess amount of a chemical on the skin (i.e., infinite dose). In this case, the thickness of the chemical layer is not calculated and steady-state kinetics are assumed. For a chemical in an aqueous or gaseous media,

$$\text{Uptake (mg)} = (C)(A)(K_p)(t)(d) \quad (10.5)$$

where d is the distribution factor. For a neat liquid chemical,

$$\text{Uptake (mg)} = (A)(J)(t) \quad (10.6)$$

where
- K_p is the permeability coefficient (cm/h)
- J is the flux of chemical (mg/cm^2/h)

EPA has suggested using the following equation for estimating percutaneous absorption of chemicals in soil[313]:

$$\text{Uptake (mg)} = (C)(A)(r)(B) \quad (10.7)$$

where
- C is the concentration of the chemical in soil (mg/g)
- A is the skin surface area (cm^2)
- r is the soil-to-skin adherence rate (g/cm^2)
- B is the cutaneous bioavailability (unitless)

Example Calculation 3: Skin Uptake of a Chemical in Soil

A person gardens with soil contaminated on average with 250 ng dioxin per gram of soil (250 ppb). Assuming that the person's hands and lower arms are in contact with the soil, the soil loading is equal to 0.2 mg/cm^2, and the cutaneous bioavailability of dioxin in soil is 1%,[125] what is the plausible uptake of dioxin by this person (using Equation 10.7)? Assume that the person washes his or her hands every 4 h and the exposed area of skin is 1800 cm^2.

$$\text{Uptake (ng)} = (C)(A)(r)(B)$$

where

$$C = 250 \text{ ng/g}$$

$$A = 1800 \text{ cm}^2$$

$$r = 0.2 \text{ mg/cm}^2$$

$$B = 0.01$$

By substitution,

$$\text{Uptake} = \left(\frac{250\text{ ng TCDD}}{1\text{ g soil}}\right)\left(\frac{0.2\text{ mg soil}}{\text{cm}^2\text{ skin}}\right)\left(\frac{1\text{ g}}{10^3\text{ mg}}\right) \times \left(1800\text{ cm}^2\text{ skin}\right)\left(0.01\right) = 0.9\text{ ng TCDD}$$

Note: A preferred method for performing this calculation, if data are available, is to use a flux rate (ng/cm^2-h) for the chemical. Assume that the rate is 500 ng/cm^2-h:

$$\text{Uptake (ng)} = (C)(J)(A)(t)$$

where

$$J = 500\text{ ng/cm}^2\text{-h}$$

$$t = 4\text{ h}$$

By substitution,

$$\text{Uptake} = \left(\frac{250\text{ ng TCDD}}{1\text{ g soil}}\right)\left(\frac{1\text{ g}}{10^9\text{ ng}}\right)\left(1800\text{ cm}^2\text{ skin}\right) \times \left(4\text{ h}\right)\left(500\text{ ng/cm}^2\text{ h}\right) = 0.9\text{ ng TCDD}$$

Uptake of Chemicals in an Aqueous Matrix

Published estimates of dermal uptake of chemicals in water have generally focused on evaluating workplace or environmental exposure. A number of different scenarios have been evaluated.[76,349–353] For example, the possible uptake of a chemical present in water, the amount of chlordane absorbed through the skin by a man swimming for 4 h in water containing 1 ppb chloroform has been estimated.[350,351] Likewise, the amount of chloroform absorbed by a boy swimming for 3 h in water has been calculated.[343] However, about 10 years ago, it was recognized that in the indoor environment, dermal exposure to volatile chemicals present in drinking water will rarely represent the vast majority of the hazard. Specifically, it was found that inhalation exposure due to the release of vapors from liquids to which people were in close contact was a greater contributor to the dose.[354] For example, comparisons have been made of the chloroform concentration in exhaled breath after a shower to that after an inhalation-only exposure.[60,350,351,355–361]

Example Calculation 4: Skin Uptake of a Chemical from Water

A person has filled his swimming pool with shallow well water contaminated with 0.002 mg/mL (2 ppb) toluene. What is the plausible dermal uptake of toluene while swimming in the contaminated water for half an hour? Assume that 18,000 cm^2 of skin is exposed and the K_p is 1.01 cm/h. From Equation 10.5,

$$\text{Uptake} = (C)(A)(K_p)(t)(d)$$

where

$$C = 0.002\text{ mg/mL}$$

$$A = 18{,}000\text{ cm}^2$$

$$K_p = 1.01\text{ cm/h}$$

$$t = 0.5\text{ h}$$

d = distribution factor (1 mL of water covers 1 cm^3).

By substitution,

$$\text{Uptake} = (0.002\text{ mg/mL})\ (18{,}000\text{ cm}^2)\ (1.01\text{ cm/h}) \times (0.5\text{ h})\ (1\text{ mL water/1 cm}^3)$$

$$\text{Uptake} = 18\text{ mg}$$

Percutaneous Absorption of Liquid Solvents

While the percutaneous absorption of chemical solutes generally proceeds by simple diffusion, the skin uptake of neat chemical liquids is not necessarily exclusively governed by Fick's law. Consequently, the uptake of neat liquid through the skin needs to be estimated using direct in vivo skin contact techniques. Table 10.6 presents the percutaneous absorption rates of some neat industrial liquid solvents that have been determined in human volunteer studies.

TABLE 10.6
Absorption Rates of Some Neat Industrial Liquid Chemicals in Human Skin In Vivo

Chemical	Absorption Rate (mg/cm^2-h)
Aniline	0.2–0.7
Benzene	0.24–0.4
2-Butoxyethanol	0.05–0.68
2-(2-Butoxyethoxy)ethanol	0.035
Carbon disulfide	9.7
Dimethylformamide	9.4
Ethylbenzene	22–23
2-Ethoxyethanol	0.796
2-(2-Ethyoxyethoxy)ethanol	0.125
Methanol	11.5
2-Methoxyethanol	2.82
2-(2-Methoxyethoxy)ethanol	0.206
Methyl butyl ketone	0.25–0.48
Nitrobenzene	2
Styrene	9–15
Toluene	14–23
Xylene (mixed)	4.5–9.6
m-Xylene	0.12–0.15

Example Calculation 5: Skin Uptake of a Neat Liquid Chemical

Due to carelessness or a leak, the inside of a glove becomes contaminated with 2-methoxyethanol. How much can be absorbed if a worker wears the contaminated glove on one hand for half an hour? Assume that the surface area of exposed skin is 360 cm^2 and the flux rate is 2.82 mg/cm^2-h. From Equation 10.6,

$$\text{Uptake} = (A)(J)(t)$$

where

$$A = 360\ cm^2$$

$$J = 2.82\ mg/cm^2\text{-h}$$

$$t = 0.5\ h$$

By substitution,

$$\text{Uptake} = (360\ cm^2)\ (2.82\ mg/cm^2\text{-h})\ (0.5\ h)$$

$$\text{Uptake} = 508\ mg$$

In order to understand the relative hazard from skin exposure versus inhalation exposure, the quantity of 2-methoxyethanol absorbed by the same worker via inhalation for 8 h (10 m^3 of air inhaled), assuming a threshold limit value (TLV®) of 16 mg/cm^3, can be estimated and compared to the dose due to inhalation exposure. Assume an 80% inhalation uptake efficiency.

$$\text{Inhalation uptake} = (16\ mg/m^3)(10\ m^3)(0.8)$$

$$= 128\ mg$$

Thus, the uptake of 2-methoxyethanol following 30 min of skin exposure of a single hand can be as much as four times that from inhalation for 8 h at the TLV concentration, a presumably safe level of exposure. From this example, it is clear that the cutaneous route of entry can, in some situations, significantly contribute to the total absorbed dose, especially in the occupational setting.

Percutaneous Absorption of Chemicals in the Vapor Phase

Until the 1990s, it was generally assumed that the plausible dose resulting from vapors absorbed through the skin was too low to pose a hazard. Only a few studies have examined this issue.[255,352,362] A few clinical reports have encouraged some limited in vivo research to evaluate the absorption of several chemicals in the gaseous phase through the human skin (Table 10.7). A chamber system to measure the whole-body percutaneous absorption of chemical vapors in rats has been described by McDougal et al.,[100] and this approach has produced some interesting results.[304] In this system, chemical flux across the skin is determined from the chemical concentration in blood during exposure by using a PBPK model. In most cases, vapor absorption through the skin amounts to less than 10% of the total dose received from a combined skin and inhalation exposure. While there is good agreement between the rat and human in the relative ranking of the permeability coefficients among the chemicals studied, for an individual chemical the rat skin appears to be two to four times more permeable than the human skin. These observations are consistent with previously reported data.[125,129,257,262,264]

TABLE 10.7
Percutaneous Absorption Rates for Chemical Vapors In Vivo

Chemical	Skin Update in Combined Exposure (%)[a]	Permeability Coefficient K_p (cm/h)	
		Rat	Human
Styrene	9.4	1.75	0.35–1.42
m-Xylene	3.9	0.72	0.24–0.26
Toluene	3.7	0.72	0.18
Perchloroethylene	3.5	0.67	0.17
Benzene	0.8	0.15	0.08
Halothane	0.2	0.05	
Hexane	0.1	0.03	
Isoflurane	0.1	0.03	
Methylene chloride		0.28	
Dibromomethane		1.32	
Bromochloromethane		0.79	
Phenol			15.74–17.59
Nitrobenzene			11.1
1,1,1-Trichloroethane			0.01

[a] In combined exposure, rats are simultaneously absorbing chemical vapors by inhalation and by whole-body absorption through the skin.

It is generally not necessary to account for the contribution from percutaneous uptake of vapors when the occupational exposure limit (OEL) is used as a guideline for acceptable exposure, because uptake via this route is usually inherent in the data; that is, the studies of animals or humans from which data were collected were usually exposed via inhalation (whole body) so dermal uptake of the vapor occurred. While good work practices and the law require that persons not be placed in life-threatening atmospheres, sometimes, in emergency situations, airline (supplied air) respirators or self-contained breathing apparatus (SCBA) are worn in environments containing chemical concentrations 10- to 1000-fold greater than the TLV. In these cases, it is can be useful to account for vapor uptake through either exposed or covered skin.

Although nearly all data on vapor absorption involve bare skin, the role of clothing in preventing skin uptake has occasionally been evaluated. For example, a study of workers wearing denim clothing indicated no decreased uptake of phenol vapors[257] but found a 20% and 40% reduction in uptake of nitrobenzene and aniline vapor,[128,252] respectively. Although standard clothing may slightly decrease the amount

of a chemical transferred from air through the skin, it can be a significant source of continuous exposure if the clothing has been contaminated.

Example Calculation 6: Skin Uptake of a Chemical Vapor

Assume that a person needs to repair a leaking pump, so he enters a room wearing an airline respirator. Assume that the room contains 500 mg/m^3 nitrobenzene (100 times the current TLV) and it takes 30 min to repair the pump. How much nitrobenzene might be absorbed through the skin?

The head, neck, and upper limbs are assumed to be exposed (surface area = 4860 cm^2), and the rest of the body (surface area = 13,140 cm^2) is covered with clothing. Assume that the percutaneous K_p of nitrobenzene is 11.1 cm/h and that the clothing has reduced the skin uptake rate of vapors by about 20%.[128]

$$\text{Uptake} = (C)(A)(K_p)(t)$$

$$\begin{aligned}\text{Uptake through exposed skin} &= (500\ \text{mg/m}^3)(4860\ \text{cm}^2) \\ &\quad \times (11.1\ \text{cm/h})\ (0.5\ \text{h}) \\ &\quad \times (1\ \text{m}^3/10^6\ \text{cm}^3) \\ &= 13.5\ \text{mg}\end{aligned}$$

$$\begin{aligned}\text{Uptake through clothing} &= (500\ \text{mg/m}^3)(13{,}140\ \text{cm}^2) \\ &\quad \times (11.1\ \text{cm/h})(0.8)(0.5\ \text{h}) \\ &\quad \times (1\ \text{m}^3/10^6\ \text{cm}^3) \\ &= 29\ \text{mg}\end{aligned}$$

$$\text{Total uptake} = 13.5 + 29 = 42.5\ \text{mg}$$

From this example, it is clear that if one enters an environment containing a high concentration of an airborne contaminant, even if a supplied air respirator is worn, the degree of skin uptake of the vapor may be worthy of evaluation to ensure that the worker is protected. In this example, uptake following 1 day of inhalation exposure at the TLV (5 mg/m^3) results in 50 mg uptake [(10 m^3)(5 mg/m^3)]. These kinds of calculations sometimes have to be conducted in difficult work environments that are in a state of alert (e.g., submarines, chemical plants during emergency situations).

ESTIMATING INTAKE VIA INGESTION

If the appropriate information is available, estimating the intake of various chemicals due to ingestion is a relatively straightforward exercise. In general, one is concerned with the ingestion of the following media: drinking water, other liquids, food, soil, and house dust. Drinking water contamination may occur due to soil contamination from leaking underground storage tanks, landfills, or hazardous waste sites, as well as discharges from contaminated streams or water transport systems. Nearly all foods in Western society contain a number of intentional and unintentional chemicals, including pesticide residues, naturally occurring chemicals, and food additives that serve as preservatives or enhancers of taste or visual appeal. Soils are ingested as a result of eating incompletely washed vegetables, hand-to-mouth contact, and through direct ingestion by children. Soils are also ingested when particles too large to reach the lower respiratory tract are inhaled (and then are swallowed). House dust contaminated with a number of chemicals can be ingested due to contact with foods, toys, upholstery, carpet, and hand-to-mouth activities.[213,363]

Estimating Intake of Chemicals in Drinking Water

Estimating the magnitude of the potential dose of toxics from drinking water requires knowledge of the amount of water ingested, the chemical concentrations in the water, and the chemical bioavailability in the gastrointestinal tract. The amount of water ingested per day varies with each person and is usually related to the amount of physical activity. A good deal of literature has addressed the amount of water ingested by persons engaged in different kinds of activities. Numerous studies cited in EPA's *Exposure Factors Handbook* and *Child-Specific Exposure Factors Handbook* have generated data on drinking water intake rates.[63,64] Many of the studies have reported fluid intake rates for both total fluids and tap water. Total fluid intake is defined as consumption of all types of fluids including tap water, milk, soft drinks, alcoholic beverages, and water intrinsic to purchased foods. Total tap water is defined as water consumed directly from the tap as a beverage or used to prepare foods and beverages (i.e., coffee, tea, frozen juices, soups). Data for both consumption categories are presented in numerous publications. Table 10.8 presents typical information reported from these studies.[63,64,99]

All currently available studies on drinking water intake are based on short-term survey data. Although short-term data may be suitable for obtaining mean intake values that are representative of both short- and long-term consumption patterns, upper-percentile values may be different for short- and long-term data because there is generally more variability in short-term surveys. Most of the currently available drinking water surveys are based on recall, which may be a source of uncertainty in the estimated intake rates because of the subjective nature of this type of survey technique.[63,64,99]

TABLE 10.8
Summary of Tap-Water Intake by Age

	Intake (mL/day)		Intake (mL/kg-day)	
Age Group	Mean	10th–90th Percentiles	Mean	10th–90th Percentiles
Infants (<1year)	302	0–649	43.5	0–100
Children (1–10 years)	736	286–1,294	35.5	12.5–64.4
Teens (11–19 years)	965	353–1,701	18.2	6.5–32.3
Adults (20–64 years)	1,366	559–2,268	19.9	8.0–33.7
Adults (65+ years)	1,459	751–2,287	21.8	10.9–34.7
All ages	1,193	423–2,092	22.6	8.2–39.8

However, recently researchers have looked for ways to better characterize exposures that persons might have experienced as a result of ingestion of contaminated drinking water. These efforts have included the use of GIS software to integrate fate and transport modeling of chemicals in groundwater with the geocoded study population, develop input data for the simulation model, and assign individual exposures to chemicals of interest by linking results of the model to the census block group of residence.[189,364]

To estimate the intake of toxics via direct ingestion of drinking water, the calculation is straightforward:

$$\text{Intake} = (V)\,(C)\,(B)$$

where

V is the volume of water (L/day)
C is the concentration of chemical in water (μg/L)
B is the bioavailability (unitless)

One of the more interesting observations of the past 20 years is that ingestion of contaminated drinking water is sometimes not the primary route of exposure to the toxicant in drinking water. Uptake of volatile chemicals via inhalation can be nearly as great in some homes as ingestion, which is the result of the presence of these chemicals in air due to showering, off-gases from the dishwasher, and other opportunities for volatilization of the chemical.[350,351,354]

Importance of Soil Ingestion When Estimating Human Exposure

Between 1980 and 1995, predicted risks associated with the ingestion of contaminated soil were the primary drivers for remediating many (if not most) hazardous waste sites. As discussed by Paustenbach et al.,[53] there was no better example than the site in Times Beach, Missouri. Billions of dollars can be needed to clean up these kinds of sites to levels that would not pose a significant risk if children actually ate significant quantities of contaminated soil. Because of the expense of remediation, a good deal of research has been conducted over the past 20 years to attempt to quantitatively understand this route of exposure.

Clearly, the ingestion of soil and house dust is a potential source of human exposure to toxicants.[17,279–281,365,366] The potential for contaminant exposure via this source is greater for children because they are more likely to ingest greater quantities of soil than adults. Inadvertent soil ingestion among children may occur through the mouthing of objects or hands, whereas soil ingestion in adults can be driven by occupational contact with soil.[64,367] Mouthing behavior is considered to be a normal phase of childhood development. Adults may also ingest soil or dust particles that adhere to food, cigarettes, or their hands. Deliberate soil ingestion is defined as pica and is considered to be relatively uncommon.[64] Because normal, inadvertent soil ingestion is more prevalent and data for individuals with pica behavior are limited, the focus of most exposure assessments is on normal levels of soil ingestion that occur as a result of mouthing or unintentional hand-to-mouth activity.[43,53,71,368]

Mouthing activities by children, which are generally accepted as normal and commonplace (e.g., Barltrop [1966] estimated that almost 80% of all children at age 1 year exhibited mouthing tendencies),[369] are potential exposure routes to trace amounts of soil and/or dust adhering to fingers, hands, and objects placed in the mouth. The available data indicate that soil exposure occurs through several indirect routes:

1. Soil contributes to house dust (e.g., by local dust deposition and mud and dirt carried in by shoes and pets).
2. House dust (fine particles) adheres to objects and to children's hands.
3. Children ingest dust particles when sucking and mouthing objects and fingers.

Obviously in some situations, exposure may be direct (a child playing outdoors may eat dirt directly). In other situations, oral exposure may occur via contamination of domestic water supplies or contamination of vegetable produce grown onsite. However, the content and concentration of dusts in the indoor environment, which may represent the most important source of indirect exposure to soil, need to be better understood.[213,224] Considerable efforts have been made through large-scale studies, such as the National Children's Study, NHEXAS, and MNCPES, to better characterize indoor exposures to chemicals adhered to household dust, particularly pesticide, lead, and allergen exposures to chlidren.[162,370–372] Several researchers have concluded that the hazard posed by the majority of household pesticides is better detected by dust sampling than by air sampling.[363,366,373–375] Studies designed to characterize children's exposure to pesticides indicate that the largest number of pesticides and the highest concentrations are found in household dust compared to air, soil, and food.[376,377] Other recent research efforts have involved better characterization of personal activities using questionnaire, videotaping, wireless-coupled infrared technologies, and personal digital assistant (PDA) techniques to quantify dermal and ingestion exposures of microactivities, such as hand-to-mouth and object-to-mouth activities.[165,167,170,378,379] Overall, recent studies have shown that children's behavioral and activity patterns that may lead to ingestion through hand-to-mouth activities are better characterized through video assessment rather than questionnaires.[380–382] This has been further confirmed through biomonitoring that there is a direct relationship between chemical body burden (e.g., blood lead levels), mouthing behaviors, and contact with surfaces.[382]

Many studies have been conducted to estimate the amount of soil ingested by children. Most of the early studies attempted to quantify the amount of soil ingested by measuring the amount of dirt present on children's hands and making generalizations based on behavior. Soil intake studies have been conducted using a methodology that measures

trace elements in feces. These measurements are used to estimate the amount of soil ingested over a specified period of time.

Studies of Soil Ingestion

In light of the importance of soil ingestion for estimating human exposure to contaminated soil, several literature surveys have been undertaken to identify the typical amount of soil consumed by children and adults.[53,63,64,99,224,368] Research evaluating lead uptake by children from ingestion of contaminated soil, paint chips, dust, and plaster provides the best source of information. Walter et al.[383] estimated that a normal child typically ingests very small quantities of dust or dirt between the ages of 0 and 2 years, the largest quantities between 2 and 7 years, and nearly insignificant amounts thereafter. In the classic text by Cooper,[384] it was noted that the desire of children to eat dirt or place inedible objects in their mouths becomes established in the second year of life and disappears more or less spontaneously by the age of 4–5 years. A study by Charney et al.[385] also indicated that mouthing tends to begin at about 18 months and continues through 72 months, depending on several factors such as nutritional and economic status, as well as race. Work by Sayre et al.[386] indicated that ages 2–6 years are the important years, but that "intensive mouthing diminishes after 2 to 3 years of age."

An important distinction that is often blurred is the difference between the ingestion of very small quantities of dirt due to mouthing tendencies and the disease known as pica. Children who intentionally eat large quantities of dirt, plaster, or paint chips (1–10 g/day), and consequently are at greater risk of developing health problems, can be said to suffer from the disease known as pica. This disease is known as geophasia if the craving is for dirt alone. Geophasia, rather than pica, is generally of greatest concern in areas with contaminated soil.

Duggan and Williams[387] have summarized the literature on the amount of lead ingested through dust and dirt. In their opinion, a quantity of 50 μg of lead was the best estimate for daily ingestion of dust by children. Assuming, on the high side, an average lead concentration of 1000 ppm would indicate a soil and dust ingestion rate of 50 mg/day. Lepow et al.[388] estimated an ingestion rate equal to 100–250 mg/day (specifically, 10 mg ingested 10–25 times a day). Barltrop[369] and Barltrop et al.[389] also estimated that the potential uptake of soils and dusts by a toddler is about 100 mg/day. In a Dutch study, the amount of lead on hands ranged from 4 to 12 ng. By assuming maximum lead concentrations of 500 ng/g (concentrations were typically lower) and complete ingestion of the contents adsorbed to a child's hand on 10 separate occasions, the amount of ingested dirt would equal 240 mg. Thus, in order to eat 10,000 mg of soil per day, the rate suggested by the Centers for Disease Control and Prevention, children would have to place their hands into their mouths 410 times a day, a rate that seems improbable.[390,391]

A report by the National Research Council[390] addressing the hazards of lead suggested a soil/dust ingestion rate of 40 mg/day. Day et al.[392] measured the amount of dirt transferred from children's hands (age range from 1 to 3 years) to a sticky sweet and estimated that a daily intake of 2–20 sweets would lead to dirt intake of 10–1000 mg/day. Bryce-Smith[393] estimated 33 mg/day. In its document addressing lead in air, EPA assumed that children ate 50 mg/day of household dust, 40 mg/day of street dust, and 10 mg/day of dust derived from their parents' clothing (i.e., a total of 100 mg/day).

Kimbrough et al.[368] estimated the ingestions of soil at Times Beach, Missouri, based on unpublished observations about children's behavior and hand-to-mouth activity. A few years later, Kimbrough noted that their estimate of up to 10,000 mg/day was clearly not close to reality and her personal estimate would be nearer 50 mg/day.[224] LaGoy[394] based his soil ingestion estimates on a review of the literature, in particular using empirical data derived by Binder et al.[395] and Van Wijnen et al.[396] Similarly, Paustenbach based his estimates on a review of the literature,[229] including the mass-balance quantitative study conducted by Calabrese et al. in 1989.[397]

De Silva[398,399] adopted a different approach that may overcome some of the uncertainties inherent in the assumptions of the indirect studies mentioned in earlier text by applying a *slope factor* increase of 0.6 μg/dL in children's blood lead levels for each 1000 ppm increase in soil lead (this factor was developed by Barltrop et al.[389] following his work on blood lead levels in children from villages on old mining sites). De Silva then deduced that an increase of 0.6 μg/dL in blood indicates an extra oral intake of 3.75 μg lead/day, based on an EPA calculation that an increase of 1.0 μg lead/day in children's diets produces an increase of 0.16 in the blood lead level. With a soil lead value of 1000 ppm, 3.75 mg of soil would contain 3.75 μg of lead, suggesting that 3.75 mg/day (say 4 mg) of soil was ingested by the children. However, the slope factor used here may not be the most appropriate, since mining soil wastes typically have larger-sized particles, which tend to decrease lead bioavailability compared with soil contaminated by lead smelter activity and therefore reduce the slope factor.

A major step forward beyond estimating soil ingestion using indirect measurements was the attempt to study tracer elements found in soil with elements measured in the urine and feces of children. Several studies have been conducted thus far that have used this approach.[355,356,395,397–403] One early tracer study evaluated the amount of soil eaten by 24 hospitalized and nursery school children by analyzing the amount of aluminum, titanium, and acid-soluble residue in the feces of children aged 2–4 years.[396] They found an average of 105 mg/day of soil in the feces of nursery children, and 49 mg/day in hospitalized children. Even with the limited number of children in the study, the difference between the two groups was significant ($p < 0.01$). If the value for the hospitalized children is assumed to be the background level because these substances are taken in from nonsoil sources (e.g., diet and toothpastes), the estimated average amount of soil ingested by the nursery school children would be 56 mg/day. This value is

in the lower range of estimates in the literature and supports the use of 100 mg/day as a reasonable daily average uptake of soil by toddlers (ages 2–4 years or 1.5–3.5 years).

There have been two major studies completed by Calabrese et al.[355,356,397,400,401,404] In the first, they quantitatively evaluated six different tracer elements in the stools of 65 school children aged 2–4 years. They attempted to evaluate children from diverse socioeconomic backgrounds. This study was more definitive than prior investigations because they analyzed the children's diets, assayed for the presence of tracers in the diapers, assayed house dust and surrounding soil, and corrected for the pharmacokinetics of the tracer materials.

In the second study, soil ingestion estimates were obtained from a stratified, simple random sample of 64 children aged 1–4 years residing on a superfund site in Montana.[405] The study was conducted during the month of September for 7 consecutive days. Soil ingestion was estimated by each soil tracer via traditional methods as well as by an improved approach using five trace elements (Al, Si, Ti, Y, and Zr), called the best tracer method (BTM), which corrects for error due to misalignment of trace input and output, as well as error occurring from ingestion of tracers from nonfood, nonsoil sources, while being insensitive to the particle size of the soil/dust ingested. According to the BTM, the median soil ingestion was less than 1 mg/day while the upper 95% was 160 mg/day. No significant age- (1 year vs. 2 years vs. 3 years) or sex-related differences in soil ingestion were observed. These estimates are lower than the estimates observed in the first study, which was conducted in New England during September and October.

Based on the series of early papers by Calabrese et al.,[355,356,397–401] a few generalizations can be made. The first two studies were difficult to conduct and interpret. Only children from a single climate were studied, and it can be expected that rates vary with the amount of time spent indoors and outdoors. In addition, only a handful of children have been studied (less than 500), so it is not possible to characterize the percentage of children who might tend to ingest large quantities of soil or house dust. The relevant amount of soil or house dust ingested indoors versus outdoors is not known yet. In most cases, the contaminant concentrations in dust can be quite different when found in a carpet versus the yard.[213] This was demonstrated in a more recent study that involved evaluation of aggregate daily exposures, contributions of specific pathways of exposure, and temporal variation in exposure to chlorpyrifos from a collection of indoor air, carpet dust, exterior soil, and duplicate diet samples.[170] Chlorpyrifos concentrations in each medium and self-reported rates of time spent inside at home, time and frequency of contact with carpet, frequency of contact with soil, and weights of the duplicate diet samples were used to derive exposure to chlorpyrifos from each medium, as well as average daily aggregate exposure. While it was found that inhalation of indoor air and ingestion of solid food accounted for almost all (97.9%) exposure to chlorpyrifos on average, the authors did report significant differences in average chlorpyrifos concentrations in exterior soil and carpet dust.[170] Specifically, a chlorpyrifos concentration of 204 ng/kg was reported for exterior soil, whereas carpet dust showed a pesticide concentration of 2380 ng/kg.[170] Overall, although there is some degree of uncertainty in the results of the various studies, it appears that the best estimate of soil intake for most children resides in the area of 10–25 mg/day. It appears that perhaps 1%–5% of the children may ingest much larger amounts during certain days or weeks (e.g., 2000 mg/day), but these tendencies do not occur on a chronic basis.

The issue of how much soil and house dust children eat, as well as the percent of children who are engaged in these activities, remains an active area of research.[396–398,402–404,406,407] Work by Calabrese and Stanek[408] suggests that prior work yielded reasonable results for purposes of risk assessment. Most of the values discussed here are presented in Table 10.9. As discussed previously, another area of research impacting exposure assessments of contaminated soil, which has been and continues to be actively pursued, is the bioavailability of the contaminant in the soil matrix.[51,103,104,106,110,111,115,118–121,317,409,410]

TABLE 10.9
Recommended Values for Childhood and Adult Soil and Dust Ingestion Rates Used in Health Risk Assessments

		Soil or (Dust) Intake (mg/day)	
Author	**Age Group**	**CT**	**Upper Percentile**
U.S. EPA[63,64]	6 weeks to <1 year	30 (30)	
	1 to <6 years	50 (60)	
	3 to <6 years		200 (100)
	6 to <21 years	50 (60)	
	Adults	20 (30)	
Barltrop et al. [389]	2–6	100	
Lepow et al.[388]	2–6	100–250	
Day et al.[392]	2–6	10–1,000	
Kimbrough et al.[368]	0–9 months	0	
	9–18 months	1,000	
	1.5–3.5	10,000	
	3.5–5	1,000	
	5+	100	
Hawley[724]	0–2	Negligible	
	2–6	90	
	6–18	21	
	18–70	57	
La Goy[394]	1–6	500 (max)

		9–16	
Paustenbach[69]	2–4	25–50	
	Adults	2–5	
De Silva[399]	Children	~4	
Calabrese and Stanek[408]	Children	30–60	

What Is the Significance of Pica?

There appears to be some confusion in the literature over what constitutes *pica*. Pica can be defined as "the habitual ingestion of substances not normally regarded as edible," but some authors have included mouthing and sucking activities in their definitions.[411] Others appear to assume that all children with pica necessarily must be habitual soil eaters. In fact, pica behavior may be generalized to the ingestion of many different (nonfood) substances, or may be specific to one substance such as paper, soap, or earth. It is likely that repetitive pica behavior specifically for dirt, or habitual *geophagia*, rarely occurs in the general population in most industrialized countries.[412,413]

Pica should, therefore, be considered a *normal* temporary phenomenon in some children. In the general population, the prevalence of both mouthing and pica, and the range of articles ingested, has been shown to decrease with age.[369] In the 1-year-old age group, 78% of children mouthed objects and 35% ingested them; this behavior decreased at the age of 4 years, when 33% were mouthing and only 6% had pica. It is also relevant to note that in certain circumstances, pica for soil may be culturally determined (such as eating clay, high in silicon and aluminum, for its medical properties in the relief of stomach discomfort and diarrhea by some Aborigines; or the custom of eating earth during pregnancy in certain cultures).[224] For example, some women in the southern portions of the United States have a craving for and eat certain clays during pregnancy. Pica may be associated with physical disorders, including iron deficiency. However, it has been debated whether pica represents a cause or an effect of these deficiencies. Pica can also be associated with mental illness. It has also been reported that 25% of institutionalized mentally handicapped adults indulged in pica of one kind or another (including bizarre objects ranging from rags and string to rocks, insects, and feces).[412]

Calabrese and Stanek[408] have indicated that in their studies, they have observed great variability in soil ingestion by children. They have noted, for example, that some children are highly variable in their soil ingestion activities, displaying little propensity for soil ingestion on one day while ingesting copious amounts the next day. While there has not been any concerted focus on the soil pica child, the available data indicate that some children ingest over 50 g of soil on particular days. They note that while it is true that some children will ingest large amounts of soil, it is far from certain whether soil pica is a behavior that only a small subgroup displays over a limited number of years (e.g., 1–6) or whether most children, on occasion, display this behavior or some combination of both behavioral patterns. Clearly, additional work is needed to understand this topic.

Soil Ingestion by Adults

For most persons beyond the ages of 5–6 years, the daily uptake of dirt due to intentional ingestion is generally thought to be quite low. With the exception of some lower-income persons who eat clays due to tradition or mineral deficiency, adults will not usually intentionally ingest dirt or soil. However, there are two other important ways in which adults eat dirt—incidental hand-to-mouth contact and through dust on vegetables. It has been shown that most soil ingested from crops comes from leafy vegetables. Interestingly, investigations at nuclear weapons trials have shown that particles exceeding 45 μm are seldom retained on leaves. Furthermore, superficial contamination by smaller particles is readily lost from leaves, usually by mechanical processes or rain and certainly by washing.[414] As a result, unless the soil contaminant is absorbed into the plant, superficial contamination of plants by dirt will rarely present a health hazard.[53,415]

The estimated deposition rate of dust from ambient air in rural environments is about 0.012 μg/cm^2-day, assuming that rural dust contains about 300 μg/g of lead (the substance for which these data were obtained). EPA has estimated that even at relatively high air concentrations (0.45 mg/m^3 total dust), it is unlikely that surface deposition alone can account for more than 0.6–1.5 μg lettuce/g dust (2–5 μg/g lead) on the surface of lettuce during a 21-day growing period.[53] These data suggest that daily ingestion of dirt and dust by adults due to eating vegetables is unlikely to exceed about 0–5 mg/day even if all of the 137 g of leafy and root vegetables, sweet corn, and potatoes consumed by adult males each day were replaced by family garden products.

With respect to the second route—unwashed vegetables—only a very limited amount of work has been conducted. It has been suggested that the primary route of uptake will be through accidental ingestion of dirt on the hands, which may be of special concern to smokers who tend to have more frequent hand-to-mouth contact. It is true that before the importance of this route of entry was recognized, persons who worked in lead factories between 1890 and 1920 probably received a large portion of their body burden of lead due to poor hygiene; however, such conditions are now rare in the United States and most developed countries.

Some persons have evaluated the exposure experience of agricultural workers who apply or work with pesticide dusts. Because of the frequency and degree of pesticide exposure during its manufacture or application, these data do not appear to be appropriate surrogates for estimating soil uptake from the hands of persons who live on or near sites having contaminated soil. In addition, most of the published studies on pesticides involve liquids such as the organophosphates, rather than *soil-like* particles. Exposure studies of persons who apply granular pesticides might be more useful for defining upper-bound estimates of dermal exposure than estimates based on dusty workplaces.[326,416]

At least one study has been conducted to specifically address soil uptake by adults involved in remediating waste sites.[202,406,408,417] The results suggest that the amount of soil eaten by these workers is much less than the default value of 100 mg/day suggested by EPA in a number of guidance documents or risk assessments.

Estimating the Intake of Chemicals via Food

Without question, the information necessary to accurately estimate the ingestion of xenobiotics via foods is one of the most complex of all exposure calculations. The hundreds of different possible foods and dozens of different chemicals that can be present as a pesticide residue and background concentrations of various chemicals in soil make this a formidable task. The methodology for estimating uptake via ingestion must account for the quantity of food ingested each day, the concentration of contaminant in the ingested material, and the bioavailability of the contaminant in the media. Over the past 20 years, a significant amount of work has been directed at understanding these exposure factors.[63,64]

The approach to estimating uptake via foods was first applied in the late 1940s by the FDA and had not changed appreciably through 2000.[418] However, because of the passage of the FQPA of 1996, which significantly amended the U.S. laws that regulate pesticides (e.g., Federal Insecticide, Fungicide, and Rodenticide Act [FIFRA] and the Federal Food, Drug, and Cosmetic Act), the methodology for estimating uptake of chemicals from foods has changed dramatically.[419] Specifically, the FQPA established a stringent health-based standard (*a reasonable certainty of no harm*) for pesticide residues in foods to assure protection from unacceptable pesticide exposure and to strengthen health protections from pesticide risks for sensitive populations. In addition, the FQPA required the U.S. EPA to consider the cumulative effects on human health that may result from exposure to mixtures of pesticides.[419] In response, the U.S. EPA Office of Pesticide Programs (OPP), in consultation with the FIFRA scientific advisory panel, has developed guidelines for the cumulative risk assessment of pesticides that share a common mechanism of toxicity.[175,420] The approach is conceptually similar to methods developed by the U.S. EPA for estimating exposure to mixtures of dioxins and dibenzofurans using toxicity equivalence factors to normalize the toxicity (i.e., binding to the aryl hydrocarbon receptor) of each member of the group with respect to that of a single chemical.[421] Specifically, the FQPA requires that all pesticide residues from foods be added together, in a prescribed manner based on target organ, with the goal of understanding the total daily dose of all residual pesticides in the diet.[160,175,420] Then, if necessary, the pesticide manufacturers are expected to calculate the necessary residue level that their chemical may have in a particular food so that the total dose does not exceed a fraction of the acceptable daily intake (ADI).

Ingestion of contaminated fruits and vegetables is a potential pathway of human exposure to toxic chemicals. Fruits and vegetables may become contaminated with toxic chemicals by several different pathways. Ambient air pollutants may be deposited on or absorbed by plants, or dissolved in rainfall or irrigation waters that contact the plants. Plant roots may also absorb pollutants from contaminated soil and groundwater. The addition of pesticides, soil additives, and fertilizers may also result in food contamination. Formulas are available to predict the concentration of chemicals from the soil, which have deposited from the air, and remain after treatment with a pesticide.

The primary information source on consumption rates of fruits and vegetables among the U.S. population is the U.S. Department of Agriculture's (USDA) Nationwide Food Consumption Survey (NFCS) and the USDA Continuing Survey of Food Intakes by Individuals (CSFII).[418,422–426] Data from the NFCS have been used in various studies to generate consumer-only and per-capita intake rates for individual fruits and vegetables, as well as total fruits and total vegetables. CSFII data have been analyzed by EPA to generate per-capita intake rates for various food items and food groups.[63,64,425,426]

Consumer-only intake is defined as the quantity of fruits and vegetables consumed by individuals who ate these food items during the survey period. Per-capita intake rates are generated by averaging consumer-only intakes over the entire population of users and nonusers. In general, per-capita intake rates are appropriate for use in exposure assessment for which average dose estimates for the general population are of interest, because they represent both individuals who ate the foods during the survey period and individuals who may eat the food items at some time, but did not consume them during the survey period. Total fruit intake refers to the sum of all fruits consumed in a day, including canned, dried, frozen, and fresh fruits. Likewise, total vegetable intake refers to the sum of all vegetables consumed in a day, including canned, dried, frozen, and fresh vegetables.

Intake rates may be presented on either an as-consumed or dry-weight basis. As-consumed intake rates (g/day) are based on the weight of food in the form in which it is consumed. By contrast, dry-weight intake rates are based on the weight of food consumed after the moisture content has been removed. Therefore, when calculating exposures based on ingestion, the unit of weight used to measure the contaminant concentration in the produce needs to be understood. Intake data from the individual NFCS and CSFII components are based on *as eaten* (i.e., cooked or prepared) forms of the food items or groups. Thus, no corrections are required to account for changes in portion sizes from cooking losses.[425–427]

Estimating source-specific exposures to toxic chemicals in fruits and vegetables may also require information on the amount of fruits and vegetables exposed to or protected from contamination as a result of cultivation practices, the physical nature of the food product itself (i.e., those having protective coverings that are removed before eating would be considered protected), or the amount grown beneath the soil (i.e., most root crops such as potatoes). The percentages of foods grown above and below ground will be useful when the contaminant concentrations in foods are estimated from concentrations in soil, water, and air. For example, vegetables grown below ground would more likely be contaminated by soil pollutants, but leafy aboveground vegetables would more likely be contaminated by deposition of air pollutants on plant surfaces. Some examples of various exposure factors and confidence ratings for liquids and food are presented in Table 10.10.[428]

TABLE 10.10
Selected Default Exposure Factor Recommendations Involving Food Intake for Citizens of the United States

Variable	Age or Geography Category	Mean	95th Percentile
Total Food (g/day)	3 to <6 years	1066	1746
	6 to <11 years	1118	1825
	21 to <40 years	1100	2110
Meats (g/kg-day)	3 to <6 years	3.9	8.5
	6 to <11 years	2.8	6.4
	21 to <50 years	1.8	4.1
Dairy (g/kg-day)	3 to <6 years	24	51.1
	6 to <11 years	12.9	31.8
	21 to <50 years	3.5	10.3
Breast Milk (mL/day)	Birth–<1 month	510	950
	1 to <3 months	690	980
	3 to <6 months	770	1000
	6 to <12 months	620	1000
Fruits (g/kg-day)	3 to <6 years	4.6	14.9
	6 to <11 years	2.3	8.7
	21 to <50 years	0.9	3.7
Vegetables (g/kg-day)	3 to <6 years	5.4	13.4
	6 to <11 years	3.7	10.4
	21 to <50 years	2.5	5.9
Grains (g/kg-day)	3 to <6 years	6.2	11.1
	6 to <11 years	4.4	8.2
	21 to <50 years	2.2	4.6
Finfish (g/kg-day)	3 to <6 years	0.19	1.4
	6 to <11 years	0.16	1.1
	21 to <50 years	0.15	1
Shellfish (g/kg-day)	3 to <6 years	0.05	0
	6 to <11 years	0.05	0.2
	21 to <50 years	0.08	0.5
Fish Intake—Recreational Anglers (g/day)	Adult (≥18 years)		
	Marine—Atlantic	5.6	18
	Marine—Gulf	7.2	26
	Marine—Pacific	2	6.8
	Rivers	20–70	
	Lakes	5–10	

Individual average daily intake rates calculated from NFCS and CSFII data are based on averages of reported individual intakes over 1 day or 3 consecutive days. Such short-term data are suitable for estimating mean average daily intake rates representative of both short- and long-term consumptions. However, the *distribution* of average daily intake rates generated using short-term data (e.g., 3 days) does not necessarily reflect the long-term *distribution* of average daily intake rates. The distributions generated from short- and long-term data will differ to the extent that each individual's intake varies from day to day; the distributions will be similar to the extent that individuals' intakes are constant from day to day.[63,64]

The variation in day-to-day intake rates among individuals will be greatest for food items or groups that are highly seasonal, and for items or groups that are eaten year-around but are not typically eaten every day. For these foods, the intake distribution generated from short-term data will not reflect long-term distribution. On the other hand, for broad categories of foods (e.g., vegetables), which are eaten on a daily basis throughout the year with minimal seasonality, the short-term distribution may be a reasonable approximation of the true long-term distribution, although it will show somewhat more variability.

The EPA's OPP uses three primary models to evaluate cumulative risk for chemicals that share a common mechanism of toxicity and involve concurrent exposure by all relevant pathways and routes of exposure. These models include (1) Dietary Exposure Evaluation Model (DEEM)/Calendex, (2) Lifeline (assesses exposure, risk, and benefits to elements of people's diets and living environment), and (3) Cumulative and Aggregate Risk Evaluation System (CARES). Each of these models uses food and drinking water consumption data from USDA's CSFII (1994–1996, 1998) and user-entered

residue data to estimate dietary exposure using probabilistic techniques. OPP sets tolerances for specific pesticides on raw agricultural commodities based on estimates of dietary risk. These estimates are calculated using pesticide residue data for the food item of concern and relevant consumption data.

The USDA has also conducted a study entitled *Food and Nutrient Intakes of Individuals in One Day in the U.S.*[422,428,429] USDA calculated mean intake rates for total fruits and total vegetables using NFCS data from 1977 to 1978 and 1987 to 1988, and CSFII data from 1994 to 1995.[422,428,429] Mean per-capita total intake rates are based on intake data for 1 day from the 1977–1978 and 1987–1988 USDA and NFCS, respectively. Data from both surveys are presented in the *Exposure Factors Handbook* to demonstrate that although the 1987–1988 survey had fewer respondents, the mean per-capita intake rates for all individuals agree with the earlier survey. Also, slightly different age classifications were used in the two surveys, providing a wider range of age categories from which exposure assessors may select appropriate intake rates. The age groups used in this dataset are the same as those used in the 1987–1988 NFCS. Information for per-capita intake rates and consumer-only intake rates for various ages of individuals is also available. Intake rates for consumers only were calculated by dividing the per-capita consumption rate by the fraction of the population using vegetables or fruits in a day.[63,64] The advantages of using these data are that they provide intake estimates for all fruits, all vegetables, or all fats combined. Again, these estimates are based on 1-day dietary data that may not reflect usual consumption patterns.[63,64]

Children's exposure from food ingestion may differ from that of adults because of differences in the type and amounts of food eaten and intake per unit body weight.[64] Recent information on consumption rates of foods among children is available from the USDA's NFCS and the USDA's CSFII. Data from the 1989–1991 and 1994–1996 CSFIIs have been used in various studies to generate children's per-capita intake rates for both individual foods and the major food groups. The Supplemental Children's Survey to the 1994–1996 CSFII (1998) was conducted in response to the FQPA of 1996,[425,426] which required the USDA to provide data from a larger sample of children for use by the EPA in estimating exposure to pesticide residues in the diets of children. The 1998 survey adds intake data from 5559 children from birth through 9 years of age to the intake data collected from 4253 children of the same age who participated in the 1994–1996 CSFII.[425,426]

Intake of Fish and Shellfish

Contaminated finfish and shellfish are potential sources of human exposure to toxic chemicals. Pollutants are not only carried in surface waters but also may be stored and accumulated in sediments as a result of complex physical and chemical processes. Consequently, various aquatic species can be exposed to pollutants and may become sources of contaminated food.[63,64]

Accurately estimating exposure to various chemicals in a population that consumes fish from a polluted water body requires an estimation of caught-fish intake rates by fishermen and their families. Commercially caught fish are marketed widely, making the prediction of an individual's consumption from a particular commercial source difficult. Because the catch of recreational and subsistence fishermen is generally not diluted in this way, these individuals and their families represent the population that is most vulnerable to exposure by intake of contaminated fish from a specific location.[63,64]

Over the years, fish consumption survey data have been collected using a number of different approaches that need to be considered when interpreting the survey results.[430] In general, surveys are either *creel* studies in which fishermen are interviewed while fishing or broader population surveys using mailed questionnaires or phone interviews. Both data types can be useful for exposure assessment purposes, but somewhat different applications and interpretations are needed. In fact, creel study results have often been misinterpreted because of inadequate knowledge of survey principles.[63,64,431,432]

The typical survey seeks to draw inferences about a larger population from a smaller sample of that population. The larger population from which the survey sample is taken and to which the survey results are generalized denotes the target population of the survey. In order to generalize from the sample to the target population, the probability of being sampled must be known for each member of the target population. This probability is reflected in weights assigned to each survey respondent, with weights being inversely proportional to sampling probability. When all members of the target population have the same probability of being sampled, all weights can be set to one and essentially ignored.[433,434]

In a mail or phone study of licensed anglers, the target population generally involves all licensed anglers in a particular area, and in these studies, the sampling probability is essentially equal for all target population members. In a creel study, the target population is anyone who fishes at the locations being studied; generally in a creel study, the probability of being sampled is not the same for all members of the target population. For instance, if the survey is conducted for 1 day at a site, then it will include all persons who fish there daily, but only about one-seventh of the people who fish there weekly, one-thirtieth of the people who fish there monthly, etc. In this example, the probability of being sampled (or inverse weight) is seen to be proportional to the frequency of fishing. However, if the survey involves interviewers who revisit the same site on multiple days, and persons who are only interviewed once for the survey, then the probability of being in the survey is not proportional to frequency; in fact, it increases less proportionally with greater frequency of fishing. If the same site is surveyed every day of the survey period with no reinterviewing, all members of the target population would have the same probability of being sampled, regardless of fishing frequency, implying that the survey weights should all equal 1.[433,435]

On the other hand, if the survey protocol calls for individuals to be interviewed each time an interviewer encounters them (i.e., without regard to whether they were previously interviewed), then the inverse weights will again be proportional to fishing frequency, no matter how many times interviewers revisit the same site. Note that when individuals can be interviewed

multiple times, the results of each interview are included as separate records in the database, and the survey weights should be inversely proportional to the expected number of times that an individual's interviews are included in the database.[63,64,433,435]

Fish and shellfish exposure assessments are among the most complicated of all assessments.[436] A significant portion of the *Exposure Factors Handbook* addresses this topic.[63,64] Recently, fairly complex methods, including Monte Carlo modeling, have been applied to resolve many of the difficulties estimating exposure of anglers and their families.[79,430]

Aggregate Exposure and FQPA

Pesticides are regulated under the FIFRA and the Federal Food, Drug and Cosmetics Act (FFDCA). In 1996, Congress passed the FQPA that amended both FIFRA and FFDCA.[419] These laws mandated EPA to register pesticides and set tolerances based on a safety determination, a reasonable certainty that use of a given pesticide or consumption of raw agricultural commodity or processed foods that contain the pesticide and its residues will cause no reasonable harm to human health or the environment. EPA evaluates risks posed by the use and usage of each pesticide to make a determination of safety. Based on this determination, EPA regulates pesticides to ensure that use of the chemical is not unsafe.

In the past, EPA evaluated safety of pesticides based on a single chemical, single exposure pathway scenario. However, FQPA requires that the Agency consider aggregate exposure in its decision-making process. Section 408(a)(4)(b)(2)(ii) of FFDCA specifies with respect to a tolerance that there must be a determination "that there is a reasonable certainty that no harm will result from aggregate exposure to the pesticide chemical residue, including all anticipated dietary exposures and all other exposures for which there is reliable information." Section (b)(2)(C)(ii)(I) states that "there is a reasonable certainty that no harm will result to infants and children from aggregate exposure to the pesticide chemical residues …." *Aggregate dose* is defined as the amount of a single substance available for interaction with metabolic processes or biologically significant receptors from multiple routes of exposure. *Aggregate risk* is defined as the likelihood of the occurrence of an adverse health effect resulting from all routes of exposure to a single substance. Conversely, *cumulative risk* is defined as the likelihood of the occurrence of an adverse health effect resulting from all routes of exposure to a group of substances sharing a common mechanism of toxicity.

As shown in Figures 10.4 and 10.5, the most basic concept underlying all aggregate exposure assessments is that exposure occurs to an individual. The integrity of the data concerning this exposed individual must be maintained throughout the aggregate exposure assessment. In other words, each of the individual *subassessments* must be linked back to the same person.[175] Because exposures are based on that received by a single individual, aggregate exposure assessments must agree in time, place, and demographic characteristics. Time–microenvironment–activity (TMA) studies have become an integral part of exposure assessment and risk management and play a key role in explaining exposure variation.[437] The individual's temporal, spatial, and demographic characteristics are then used to develop a distribution of total exposure to (many) individuals in a population of interest.[175]

Each of these parameters has imbedded attributes that must be matched to create a reasonable assessment. Some of these imbedded attributes include

- Time (duration, daily, seasonally)
- Place (location and type of home, urbanization, watersheds, region)
- Demographics (age, gender, reproductive status, ethnicity, personal preference)

Exposures to pesticides do not occur as single events, but rather as a series of sequential or simultaneous events that are linked in time and place. By performing aggregate assessment (single chemical, multiple pathway/routes), exposure and risk assessments are expected to move closer to describing the pattern of exposure actually encountered by people in the real world.[175] Developing realistic aggregate exposure and risk assessments requires that the appropriate temporal, spatial, demographic exposure factors be correctly assigned. Examples of some of these factors include sex- and age-specific body weights, regional-specific drinking water concentrations of the pesticide being considered, seasonally based pesticide residues in food, and frequency of residential pest control representative of housing type. Exposure factor information, such as that presented in the *CSFII* (1992) and *Exposure Factors Handbook*,[63,64] takes into account seasonal-, age-, and ethnic-related differences. Both documents are critical resources for aggregate exposure and risk assessments. Once an aggregate exposure and risk assessment is completed for one individual, population and subpopulation distributions of exposures and risk may be constructed by probabilistic techniques.[61]

An aggregate exposure and risk assessment is distinct from a cumulative risk assessment. Cumulative risk is defined as "the measure or estimate of distributions of exposures (doses) for a set of chemicals that act by a common mechanism of toxicity."[10,438,439] Cumulative risk assessment evaluates risks from multiple chemicals via all routes and pathways of exposure. The cumulative risk assessment considers the combined toxicological effect of a group of chemicals with a common mechanism of toxicity. The definition of a common mechanism of toxicity is defined as

> Two or more pesticide chemicals that produce an adverse effect(s) to human health by the same, or essentially the same, sequence of major biochemical events. The underlying basis of the toxicity is the same, or essentially the same, for each chemical.[10]

Specific guidance concerning conducting a cumulative aggregate risk assessment has been developed.[61,160,420]

When studying environmental health risks from chemical and nonchemical stressors, multiple levels of analyses are often considered to understand the causal pathway from combined exposures to adverse health outcomes.[439] These levels involve understanding the macro level (e.g., government policies,

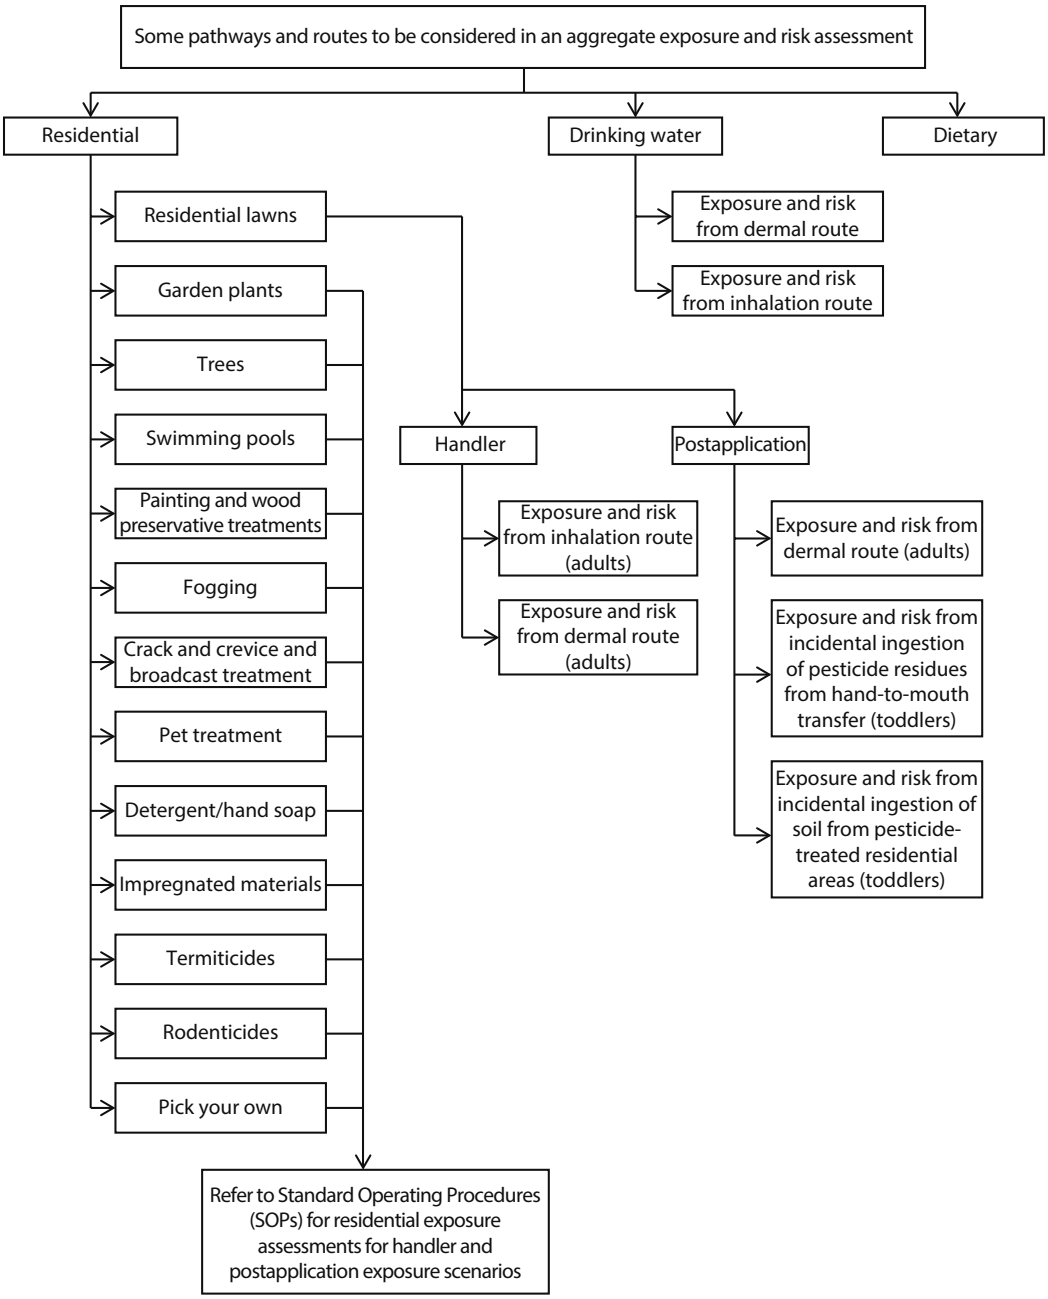

FIGURE 10.5 Factors to consider in an aggregate exposure assessment. (From U.S. Environmental Protection Agency, General principles for performing aggregate exposure and risk assessment, U.S. Environmental Protection Agency (USEPA), Office of Pesticide Programs, Washington, DC, November 28, 2001.)

regulation, market forces), the meso level (e.g., neighborhood pollution levels, social environments, community resources), and the micro level (e.g., personal exposures, body burden, health status, psychological factors, activities and behaviors, socioeconomics, physical and demographic characteristics).[439] These conceptual approaches have been applied in recent models, such as the Cumulative Environmental Hazard Inequality Index (CEHII), the World Health Organization (WHO) Urban Health Equity Assessment and Response Tool (Urban Heart), and EPA's Community-Focused Exposure and Risk Screening Tool (C-FERST).[439] In addition, the U.S. EPA Office of Research and Development along with the National Exposure Research Laboratory (NERL) in their *Cumulative Communities Research Program* is developing and applying tools to enhance cumulative risk assessments to address key questions about (1) identifying and prioritizing key chemical stressors within a given community, (2) developing estimates of exposure from multiple stressors for epidemiologic studies, and (3) tracking effectiveness of risk reduction strategies.[440] A recent paper by Barzyk et al.[438] summarizes over 70 tools available to aid in gathering information and assessing environmental issues related to community-based cumulative risk assessments. In addition, Young and colleagues have compared the use of four different probabilistic models to two deterministic models to

estimate aggregate residential exposure to pesticides within different application scenarios.[441]

Understanding aggregate exposures is a critical component of exposure and risk assessment of chemicals under the new European Union (EU) legislation of chemical management, called Registration, Evaluation, and Authorisation of Chemicals (REACH). In brief, REACH requires companies that manufacture or import more than 1 ton of a substance per year to register the substance at the new EU Chemicals Agency. The aim of REACH is to control and demonstrate the safe use of chemicals for consumers, workers, and the environment. Core to the REACH process is the development of exposure scenarios that relate to how a substance is manufactured or used during its life cycle and how the manufacturer or importer controls or recommends to downstream users to control exposures of humans and the environment.[442,443] Under this new legislation, REACH requires aggregation of exposure from all relevant identified sources, which no doubt will necessitate the use of probabilistic approaches and comprehensive databases on populations' habits, practices, and behaviors.[444]

Breast Milk

Breast milk is a potential source of exposure to toxic substances for nursing infants. Lipid-soluble chemical compounds accumulate in body fat and may be transferred to breast-fed infants in the lipid portion of breast milk. Because nursing infants obtain most (if not all) of their dietary intake from breast milk, they are especially vulnerable to exposures to these compounds. In fact, the peak body burdens of certain chemicals (such as dioxin) can reach their lifetime peak (μg/kg) on the last day of nursing at age 12–24 months. Estimating the magnitude of the potential dose to infants from breast milk requires information on the quantity of breast milk consumed per day and the duration (months) over which breast-feeding occurs.

Several studies have generated data on the ingestion of breast milk.[445–447] Typically, breast milk intake has been measured over a 24 h period by weighing the infant before and after each feeding without changing its clothing (test weighing). The sum of the difference between the measured weights over the 24 h period is assumed to be equivalent to the amount of breast milk consumed daily. Intakes measured, using this procedure, are often corrected for evaporative water losses (insensible water losses) between infant weighings.[64,448] Neville et al. (1988) evaluated the validity of the test-weight approach among bottle-fed infants by comparing the weight of milk taken from bottles with the difference between the before and after feeding weights of infants.[446] Once corrected for insensible water loss, test-weight data were not significantly different from bottle weights. Conversions between weight and volume of breast milk consumed are made using the density of human milk (approximately 1.03 g/mL).[64,448] Techniques for measuring breast milk intake using stable isotopes have been developed; however, little data based on this new technique have been published.[64,448]

Factors associated with breast milk intake include the frequency of breast-feeding sessions per day, the duration of breast-feeding per event, the duration of breast-feeding during childhood, and the magnitude and nature of the population that breast-feeds.[64] Infant birth weight and nursing frequency have been shown to influence the rate of intake. Infants who are larger at birth and/or nurse more frequently have been shown to have higher intake rates.[64,448] Also, breast milk production among nursing mothers has been reported to be somewhat higher than the amount actually consumed by the infant.[428,449] A portion of EPA's *Exposure Factors Handbook* and *Child-Specific Exposure Factors Handbook* addresses this topic, and a few published papers have offered some novel approaches.[63,64] Some examples of breast milk intake rates are presented in Table 10.11.

Information on the fat content of breast milk is also needed for estimating dose from breast milk residue concentrations that have been indexed to lipid content.[63,64,447,450] Environmental chemicals with high lipid solubility are likely to be found in breast milk. These chemicals include polyhalogenated compounds, organochlorine insecticides, and polybrominated diphenylethers. For many long-lived environmental chemicals in lactating women, breast milk may be a major route of elimination.[451] These fat-soluble chemicals are incorporated into the milk as it is synthesized and they must be measured in accordance with the fat content of the milk to allow for meaningful comparisons within an individual and among populations.[452]

The lipid content of breast milk varies according to the length of time that an infant nurses, and it increases from the beginning to the end of a single nursing session. The lipid portion accounts for approximately 4% of human breast milk (39 ± 4.0 g/L).[63,64,450] Most studies in evaluating chemical exposures through breast milk have not accounted for the fact that women's stores of lipophilic chemicals in adipose tissue and breast milk are depleted over the duration of lactation.[453] There are a number of factors that affect contaminant levels in breast milk, including the health of the mother during pregnancy and during the lactation period, the presence and levels of other xenobiotics that may alter metabolism, change in body mass index (BMI) during pregnancy and lactation, diet, other factors that may mobilize fat, parity and length of previous lactation, the number of children being breast-fed at one time, maternal age, and maternal BMI.[452] In addition, variation in the time of breast milk sampling (including time postpartum and time of day), the age of the mother, and the number of previously breast-fed children can also influence measured levels.[453]

While the study of prescription drugs has provided a basis for understanding the governing principles behind transfer of chemicals through breast milk,[454] the research of environmental chemical exposure through breast milk has increased dramatically over the last few decades. One of the earliest reports of the measurement of an environmental chemical in breast milk was by Laug and colleagues in 1951, who reported that the breast milk from 32 women from the general population of Washington, District of Columbia contained DDT (1,1,1-trichloro-1, 2-bis(4-chlorophenyl)ethane) at an average concentration of 0.13 ppm.[455] Since then, a number of studies have evaluated trends of exposure to environmental chemicals through breast milk. Studies have measured chlordane, dieldrin/aldrin, heptachlor, hexachlorobenzene, hexachlorocyclohexane, dioxins and furans, polychlorinated biphenyls, polybrominated diphenyl ethers, and metals in breast milk. The data that exist suggest that bans and restrictions in recent decades on the use of many of the persistent organic pollutants have led to a dramatic decline in the levels of many of these chemicals in breast milk.[456]

ESTIMATING UPTAKE VIA INHALATION

Estimating intake via inhalation depends on only a few exposure factors, for example, inhalation rate, airborne chemical concentration, bioavailability, and, if it is a particle, particle size. In general, uncertainty in estimates of intake via inhalation is among the smallest of all exposure calculations. Inhalation rates are known to vary directly with the amount of physical activity of the persons being evaluated. Airborne chemical concentrations are obtained through either direct measurement or modeling. The form of the chemicals in the air will be a gas (includes vapors) or particles (dusts or fumes). In general, it is assumed that virtually all of the vapors or gases will be absorbed if inhaled.[43,74,255,457] This may not be the case for volatile chemicals, if the concentration in the blood is approaching steady state. In those cases, a significant fraction of the inhaled vapors will be present in the exhaled breath and, therefore, not absorbed.[129] In addition, it is usually assumed that if particles enter the lower respiratory tract, they will eventually be absorbed unless the chemical is highly insoluble. In general, it is assumed that particles less than 150 μm are inhalable, but virtually all particles greater than 10 μm (by weight) will be captured in the upper respiratory tract (nose and throat) and then ingested. It has often been assumed that particles less than 10 μm will be captured in the lower respiratory tract and nearly 100% of these will eventually be absorbed.

Exposure Science in Air Pollution Research

The field of exposure assessment in studying the effects of ambient particulate air pollution has shown some exciting new developments in the last 10–20 years. Tools such as forensic chemical mapping of sources, source apportionment, and tracer analysis for outdoor–indoor contributions of personal exposures have been coupled with health outcome data. Over the last decade, over 100 studies of more than 35 different cities have investigated the acute effects of ambient particulate matter (PM) showing increased hospital admissions and deaths from cardiopulmonary disease (e.g., asthma, chronic obstructive pulmonary disease, arrhythmia, heart attack).[458–460] The effects appear to best correlate with $PM_{2.5}$, with an increased mortality of 0.5%–1.5% for every incremental concentration increase of 5 $\mu g/m^3$.[459] While the mechanisms by which ambient PM causes increased morbidity and mortality due to respiratory and cardiovascular disease are not well understood, investigators have proposed that the ultrafine fraction of ambient PM may be responsible for, or at least contribute to, these effects. The study of these very-fine-sized particles (e.g., $PM_{2.5}$, PM with a median mass aerodynamic diameter less than 2.5 μm) as well as those much smaller (ultrafine or nanosized particles, $PM_{0.1}$, PM with a median mass aerodynamic less than 0.1 μm) has probably been among the most exciting areas of research in the environmental sciences over the past 20 years.[461–464]

The great majority of the epidemiologic literature with respect to the effects of ambient air particulate pollution on morbidity and mortality from cardiopulmonary disease has focused on the combined fine and ultrafine fraction of airborne PM ($PM_{2.5}$). Only recently have human population studies begun to separately characterize the fine and ultrafine fraction of particulate pollution episodes.[465–469] Although

changes in ST-segment depressions, blood pressure, and heart rate variability as in the case of panel-based population studies, or increased hospital admissions for cardiovascular or respiratory disease or increased stroke mortality, have been specifically associated with increases in nanosized particulate pollution, there have also been correlations reported for other constituents (e.g., nitrogen dioxide, carbon monoxide) that often accompany PM from combustion sources. In a study of eight Canadian cities to examine the association between acute exposure to ambient air pollutants and mortality, it was observed that the PM mass only explained 28% of the total health effect of the mixture, with the remaining effects accounted for by the gases.[470] Thus, differentiating the effects of nanosized particulate pollution from other copollutants will continue to pose a challenge. An increasingly greater number of studies, however, are comparing the effects of more traditionally characterized particle size fractions (PM_{10}, $PM_{2.5}$) to that within the ultrafine or nanosized range. The few studies that have made these comparisons, however, have reported varying correlations with the nanosized particles showing greater associations in some cases (e.g., heart rate variability, blood cells, platelet activation markers [CD40 ligand]) or a complete lack of association (e.g., shortness of breath, chest pain) with health effects as compared to the fine-sized particulate fraction.[471–473]

A number of studies have focused on various techniques for source apportionment of ambient PM with the hope that if PM toxicity could be determined by source types, then the regulation of PM may be more effectively implemented. While few studies have conducted such analyses, there is suggestive evidence that PM from certain combustion sources (i.e., secondary aerosols and traffic) and not other sources (e.g., soil) is associated with mortality.[474] These studies are highly complex and it can be difficult to discern trends associated with health effects due to variability of chemical speciation caused by regional, spatial, seasonal, and temporal changes, as well as overlapping chemistries of different emission sources.[474–479]

Within the last 5 years, there has also been greater recognition that exposures within the home, workplace, or other microenvironments have a greater contribution to the total personal exposure to PM than what is represented by outdoor stationary PM monitoring.[480,481] A recent study to characterize indoor sources of ultrafine PM found that outdoor ultrafine PM had difficulty penetrating the home and, based on sample measurements, estimated that for a typical suburban nonsmoker lifestyle, indoor sources provide about 47% and outdoor sources about 36% of the total daily ultrafine PM exposure and in-vehicle exposures add the remainder (17%).[480] Interestingly, cooking on gas or electric stoves and electric toaster ovens was the major source of ultrafine PM in the home with other common sources being cigarettes, vented gas clothes dryers, air popcorn poppers, candles, and electric mixers, toasters, hair dryers, curling irons, and steam irons.[480]

To better understand the health impacts of ambient PM in light of personal exposures to PM in microenvironments, researchers have developed various modeling efforts, sought to identify tracer elements to track ambient PM, and conducted large personal sampling regimens to develop infiltration rates and attenuation factors for ambient PM entering the home and contributing to person exposures.[482–487] In the conceptual framework, linking air pollution exposure to disease requires identification of individuals with increased exposures and tools to determine how and whether the exposures increased the likelihood of disease. Factors that complicate identifying this association include time–activity allocations and mobility (e.g., commuting), microenvironmental and building infiltration factors, age-specific factors (children, working parents, immobile elderly), and spatial and temporal differences in sources and concentrations of air pollutants.[488] Recent data have shown mixed results on the association between peak personal exposures to $PM_{2.5}$ from indoor versus outdoor sources and changes in heart rate variability.[489,490] Differentiating the health impacts of ambient air pollution versus microenvironmental personal exposures will certainly continue to be an active area of research given recent questions about the applicability of air pollutions measurements from a single location and the mobility of the population, as well as the contributions of consumer products and other sources to chemical exposures in the indoor environment.[488,491]

Various Inhalation Rates

A significant amount of research has been conducted to correlate various inhalation rates with different tasks and body weights. Most studies on this subject have been summarized in the most recent *EPA Exposure Factors Handbook*.[63] Data are available for dozens of different levels of physical activity and the distributions for several populations are presented.

A number of equations have been proposed for predicting the inhalation rate based on body weight.[63] The *Exposure Factors Handbook* and other sources provide a number of tables that relate physical activity with inhalation rate (see Table 10.12).

Bioavailability of Airborne Chemicals

Because the mass of chemicals inhaled is usually quite small, and because most particles less than 10 μm in diameter are thought to be fairly easily absorbed, it is generally

TABLE 10.12
Daily Inhalation Rates Estimated from Daily Activities

	Inhalation Rate (IR)		
Subject	Resting (m^3/h)	Light Activity (m^3/h)	Daily Inhalation Rate (DIR) (m^3/day)
Adult man	0.45	1.2	22.8
Adult woman	0.36	1.14	21.1
Child (10 years)	0.29	0.78	14.8
Infant (1 year)	0.09	0.25	3.76
Newborn	0.03	0.09	0.78

assumed that particles are 100% bioavailable after they are trapped in the lower lung. Likewise, it is generally assumed that most vapors and gases are completely absorbed (100% bioavailable) if they reach the lower respiratory tract. Both are conservative assumptions that should be reassessed on a case-by-case basis.

ROLE OF UNCERTAINTY ANALYSIS

Exposure assessment uses a wide array of information sources and techniques. Even when actual exposure-related measurements exist, assumptions or inferences will still be required. Most likely, data will not be available for all aspects of the exposure assessment and these data may be of questionable or unknown quality. In these situations, the exposure assessor will have to rely on a combination of professional judgment, inferences based on analogy with similar chemicals and conditions, and estimation techniques. The net result is that the exposure assessment will be based on a number of assumptions with varying degrees of uncertainty.[43]

The decision analysis literature has focused on the importance of explicitly incorporating and quantifying scientific uncertainty in risk assessments.[435,436] Reasons for addressing uncertainties in exposure assessments include the following[43]:

- Uncertainty information from different sources and of different quality must be combined.
- A decision must be made about whether and how to expend resources to acquire additional information (e.g., production, use, and emissions data; environmental fate information; monitoring data; population data) to reduce the uncertainty.
- So much empirical evidence exists that biases may occur, resulting in so-called best estimates that are not very accurate. Even when all that is needed is a best-estimate answer, the quality of the answer may be improved by incorporating a frank discussion of uncertainty into the analysis.
- Exposure assessment is an iterative process. The search for an adequate and robust methodology to handle the problem at hand may proceed more effectively, and to a more certain conclusion, if the associated uncertainty is explicitly included and it can be used as a guide in the process of refinement.
- A decision is rarely made on the basis of a single piece of analysis. Furthermore, it is rare for there to be one discrete decision; a process of multiple decisions spread over time is the more common occurrence. Chemicals of concern may go through several levels of risk assessment before a final decision is made. During this process, decisions may be made based on exposure considerations. An exposure analysis that attempts to characterize the associated uncertainty allows the user or decision-maker to do a better evaluation in the context of the other factors being considered.
- Exposure assessors have a responsibility to present not just numbers, but also a clear and explicit explanation of the implications and limitations of their analyses. Uncertainty characterization helps to achieve this.

Essentially, constructing scientifically sound exposure assessments and analyzing uncertainty go hand in hand. The reward for analyzing uncertainties is knowing that the results have integrity or that significant gaps exist in available information that can make decision-making a tenuous process.

Variability versus Uncertainty

While some authors treat variability as a specific component of uncertainty, EPA and others advise risk assessors (and, by analogy, the exposure assessor) to distinguish between variability and uncertainty.[12,492] Specifically, uncertainty represents a lack of knowledge about factors affecting exposure or risk, whereas variability arises from true heterogeneity across people, places, or time. In other words, uncertainty can lead to inaccurate or biased estimates, whereas variability can affect the precision of the estimates and the degree to which they can be generalized.

Variability and uncertainty can complement or confound one another. National Research Council[12] has drawn an instructive analogy based on estimating the distance between the earth and the moon. Prior to fairly recent technological developments, it was difficult to accurately measure this distance, resulting in measurement uncertainty. Because the moon's orbit is elliptical, the distance is a variable quantity. If only a few measurements were taken without knowledge of the elliptical pattern, then either of the following incorrect conclusions might be reached:

- The measurements were faulty, thereby ascribing to uncertainty what was actually caused by variability.
- The moon's orbit was random, thereby not allowing uncertainty to shed light on seemingly unexplainable differences that are in fact variable and predictable.

A more fundamental error in the earlier situation might be to incorrectly estimate the true distance and assume that a few observations were sufficient. This latter pitfall—treating a highly variable quantity as if it were invariant or only uncertain—is most relevant to the exposure or risk assessor.[43]

Now consider a situation that relates to exposure, such as estimating the ADD by one exposure route—ingestion of contaminated drinking water. Suppose that it is possible to measure an individual's daily water consumption (and concentration of the contaminant) exactly, thereby eliminating uncertainty in the measured daily dose. The daily dose still has an inherent day-to-day variability, however, because of changes in the individual's daily water intake or concentration of the contaminant in the water.[43]

Clearly, it is impractical to measure the individual's dose every day. For this reason, the exposure assessor may estimate

the ADD based on a finite number of measurements, in an attempt to *average out* the day-to-day variability. The individual has a true (but unknown) ADD, which has now been estimated based on a sample of measurements. Because the individual's true average is unknown, it is uncertain how close the estimate is to the true value. Thus, the variability across daily doses has been translated into uncertainty in the ADD. Although the individual's true ADD has no variability, the estimate of the ADD has some uncertainty.[43]

The preceding discussion pertains to the ADD for one person. Now consider a distribution of ADDs across individuals in a defined population (e.g., the general U.S. population). In this case, variability refers to the range and distribution of ADDs across individuals in the population. By comparison, uncertainty refers to the exposure assessor's state of knowledge about that distribution, or about parameters describing the distribution (e.g., mean, standard deviation, general shape, various percentiles).[43]

As noted by the National Research Council,[12] the realms of variability and uncertainty have fundamentally different ramifications for science and judgment. For example, uncertainty may force decision-makers to judge how probable it is that exposures have been overestimated or underestimated for every member of the exposed population, whereas variability forces them to cope with the certainty that different individuals are subject to exposures both above and below any of the exposure levels chosen as a reference point.[43]

Types of Variability

Variability in exposure is related to an individual's location, activity, and behavior or preferences at a particular point in time, as well as pollutant emission rates and physical/chemical processes that affect concentrations in various media (e.g., air, soil, food, and water). The variations in pollutant-specific emissions or processes, and in individual locations, activities, or behaviors are not necessarily independent of one another. For example, both personal activities and pollutant concentrations at a specific location might vary in response to weather conditions, or between weekdays and weekends.[43]

At a more fundamental level, three types of variability can be distinguished:

1. Variability across locations (spatial variability)
2. Variability over time (temporal variability)
3. Variability among individuals (interindividual variability)

Spatial variability can occur both at regional (macroscale) and local (microscale) levels. For example, fish intake rates can vary depending on the region of the country. Higher consumption may occur among populations located near large bodies of water such as the Great Lakes or coastal areas. As another example, outdoor pollutant levels can be affected at the regional level by industrial activities and at the local level by activities of individuals. In general, higher exposures tend to be associated with closer proximity to the pollutant source, whether it is an industrial plant or related to a personal activity such as showering or gardening. In the context of exposure to airborne pollutants, the concept of a *microenvironment* has been introduced to denote a specific locality (e.g., a residential lot or a room in a specific building) where the airborne concentration can be treated as homogeneous (i.e., invariant) at a particular point in time.

Temporal variability refers to variations over time, whether long or short term. Seasonal fluctuations in weather, pesticide applications, use of woodburning appliances, and fraction of time spent outdoors are examples of longer-term variability. Examples of shorter-term variability are differences in industrial or personal activities on weekdays versus weekends or at different times of the day.

Interindividual variability can be either of two types: (1) human characteristics such as age or body weight and (2) human behaviors such as location and activity patterns. Each of these variabilities, in turn, may be related to several underlying phenomena that vary. For example, the natural variability in human weight is due to a combination of genetic, nutritional, and other lifestyle or environmental factors. Variability arising from independent factors that combine multiplicatively generally will lead to an approximately lognormal distribution across the population or across spatial/temporal dimensions.[31,43,493]

Monte Carlo Analysis

Among the most significant advances in exposure assessment of the past 20 years is the application of Monte Carlo or other probabilistic analyses to environmental health issues.[25,83,88,494] Monte Carlo analysis has existed as an engineering analytical tool for many years, but the development of specialized computer software (e.g., Crystal Ball [Decisioneering, Boulder, Colorado], @RISK [Palisades Corp., Newfield, New York]) has allowed its application to new areas. As discussed previously, one criticism of many exposure assessments has been a reliance on overly conservative assumptions about exposure, as well as the problem of how to properly account for the highly exposed (but usually small) populations that do exist.[75,445] The Monte Carlo technique offers an approach to addressing this issue.

The probabilistic or Monte Carlo model accounts for the uncertainty in select parameters evaluating the range and probability of plausible exposure levels. Instead of specifying input parameters as single values, this model allows for consideration of the probability distributions. The Monte Carlo statistical simulation is a statistical model in which the input parameters to an equation are varied simultaneously. The values are chosen from the parameter distributions, with the frequency of a particular value being equal to the relative frequency of the parameter in the distribution. The simulation involves the following three steps:

1. The probability distribution of each equation parameter (input parameter) is characterized, and the distribution is specified for the Monte Carlo simulation. If the data cannot be fit to a distribution, the

data are *bootstrapped* into the simulation, meaning that the input values are randomly selected from the actual dataset without a specified distribution.
2. For each iteration of the simulation, one value is randomly selected from each parameter distribution, and the equation is run. Many iterations are performed, such that the random selections for each parameter approximate the distribution of the parameter. Five thousand iterations are typically performed for each dose equation.
3. Each iteration of the equation is evaluated and saved; hence, a probability distribution of the equation output (possible doses) is generated.

This technique generates distributions that describe the uncertainty associated with the risk estimate (resultant doses). The predicted dose for every 50th percentile to the 95th percentile of the exposed population and the true mean are calculated. Using these models, the assessor is not forced to rely solely on a single exposure parameter or the repeated use of conservative assumptions to identify the plausible dose and risk estimates. Instead, the full range of possible values and their likelihood of occurrence is incorporated into the analysis to produce the range and probability of expected exposure levels.[25,37,80–82,144,495]

The methodology is illustrated in the following examples. The first example is to understand the time needed to go shopping. Time spent shopping each month (minutes) is estimated by the product of two parameters: the number of trips per month and the total time spent in the store (minutes). Total time spent in the store is the sum of time spent shopping and time spent waiting in line. Using Monte Carlo techniques, a distribution of likely values is associated with each of these parameters. These distributions depend on the detail of information available to characterize each parameter. For example, the distribution compares all of the information, such as those days when the line at the checkout counter is short, as well as those when the line is long. It is noteworthy that each parameter has a different distribution: lognormal, Gaussian, and square. Total time spent shopping is then calculated repeatedly by combining parameter values that are randomly selected from these distributions. The result is a distribution of likely time spent shopping each month. Using this technique, information concerning each parameter is carried along to the final estimate.

The second example, which directly applies to toxicologists, is to build a distribution that describes the various soil ingestion rates for children. As shown in Figure 10.6, the three pertinent distributions are the basis for constructing the overall exposure distribution. Most of the variables used in an exposure assessment actually exist as ranges, rather than single point values. For instance, the common assumption that adult body weight is 70 kg will be replaced in a Monte Carlo analysis by the appropriate distribution (i.e., normal)

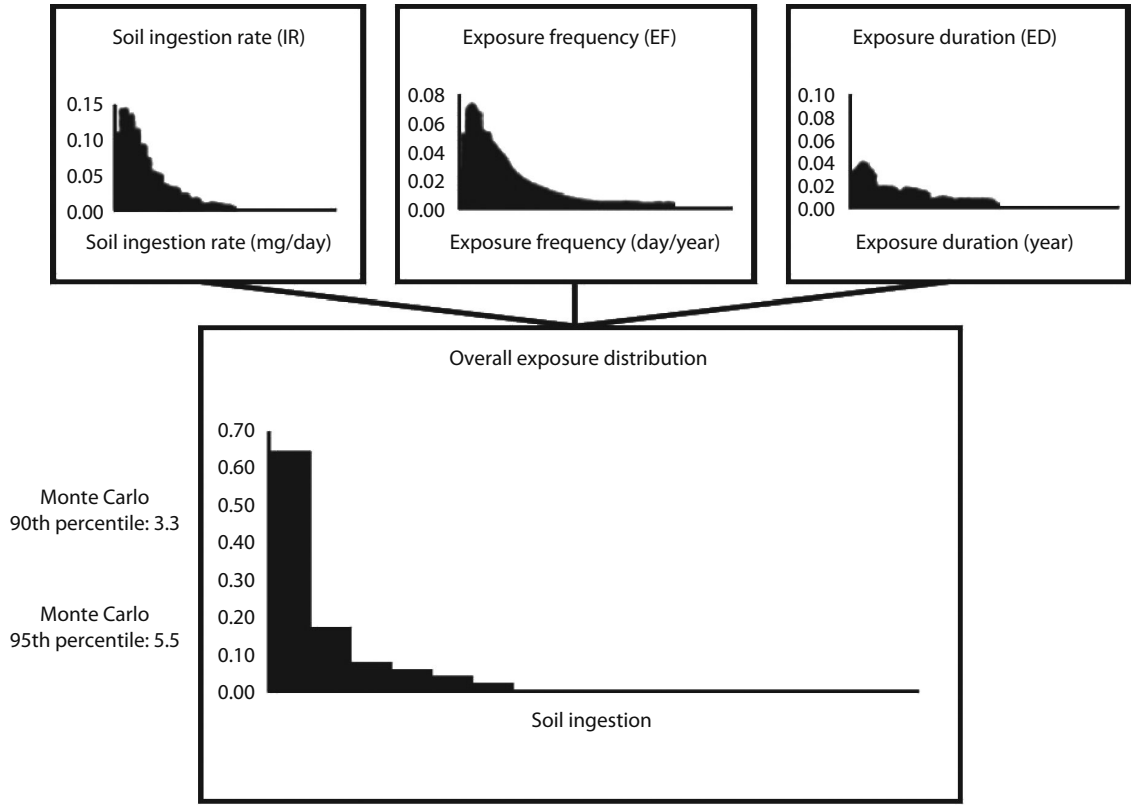

FIGURE 10.6 Example of how probability density functions (distributions) for three different related exposure factors are combined to form a distribution for the amount of soil ingested by a population of children. The Monte Carlo technique allows the risk assessor to account for the variability in many exposure parameters within a population and then produce a distribution that characterizes the entire population.

TABLE 10.13
U.S. EPA Guiding Principles for Monte Carlo Analysis

1. Conduct preliminary sensitivity analyses to identify important contributors to the assessment endpoint and its variability and uncertainty.
2. Based on the results of the sensitivity analyses, include probabilistic assessments only for the important pathways and parameters.
3. Use the entire database of information when selecting input distributions.
4. When using surrogate data, identify sources of uncertainty, and whenever possible, validate the use of these data by collecting site-/case-specific data.
5. If empirical data are collected for use in the assessment, use collection methods that improve the representativeness and quality of these data (especially at the tails of the distribution).
6. Identify when expert judgment, rather than hard data, is used in the assessment.
7. Separate uncertainty and variability during the analysis.
8. Use appropriate methods to address uncertainly and variability, e.g., 2D Monte Carlo.
9. Discuss the numerical stability of estimates at the tails of the distribution.
10. Identify which sources of uncertainty are addressed by the assessment and which are not.
11. Provide a detailed description of all models used.
12. Provide a detailed description of the input distributions, including a distinction between variability and uncertainty in these distributions, and a graphical representation of the probability density and cumulative distribution functions.
13. Provide a graphical representation of the probability density and cumulative distribution functions of each output distribution.
14. Consider the potential covariance between important parameters. If the covariance cannot be determined, evaluate the impact of a range of potential covariances on the output distributions.
15. Present point estimates and identify where they fall on the exposure distribution. If there are large differences between point estimates and Monte Carlo estimates, explain if the differences are due to changes in the data or models used.
16. Present results in a tiered approach.

of body weights (including maximum, minimum, mean, and standard deviation). Using this approach, virtually every exposure variable, whether physiological, behavioral, environmental, or chronological, can be replaced with a probability distribution.[37,77,78,80–82,144,267,434,495–504] Since no population (or individual) is exposed to a single concentration; breathes, eats, or drinks at a single rate; or is exposed for the same length of time, it is not appropriate to assess them as such. To be protective, high values are employed, resulting in the problems of compounding conservatisms mentioned previously.[66,67,75,505,506]

The probabilistic analysis addresses the main deficiencies of the point estimate approach because it imparts more information to risk managers and the public, and uses all of the available data.[507,508] The range of values (i.e., the distribution) for all the variables used in an exposure assessment is determined (e.g., normal, lognormal, uniform, triangular) and combined into a *distribution of distributions*. Because of the extrapolations involved and the assumptions made, the area of single greatest uncertainty in risk assessment is associated with the dose–response evaluations.

It should also be clear that, in addition to exposure variables, data forming the basis of the toxicological criteria (carcinogenic potency factors [CPFs] and reference doses [RfDs]) are also amenable to Monte Carlo–style analysis in which a robust database exists.[509–521] As with exposure variables, the advantage to this approach is that it allows all data to be used (and weighted appropriately, where necessary), thus avoiding reliance on a single experiment or endpoint.

Probabilistic analyses have in recent years been recognized in regulatory guidance,[63,83,88] and EPA's Risk Assessment Forum has published a document of principles for conducting Monte Carlo analyses (Table 10.13).[511] EPA and a number of states (and other countries) have published a comprehensive guidance document on how to conduct Monte Carlo assessments.[83,88]

Like traditional exposure analysis, one challenge to performing a Monte Carlo analysis properly is having appropriate distributions for use in the analysis. Numerous studies on individual variables have been published in the risk assessment literature,[71,76,83,319,403,406,507,522–526] and the impact on the distributions employed on the outcome has also been discussed.[31,527–531] It should be noted that these techniques can be combined with other advanced risk assessment methods (i.e., PBPK modeling) to further reduce uncertainty in risk estimates.[84,532] Two-dimensional Monte Carlo analyses and probabilistic approaches, in general, have been developed that take into account both variability and uncertainty and have been utilized as a method to quantify uncertainty in sensitivity analyses.[86,533–537] Information appropriate to probabilistic analyses can often be found in published papers in fields quite distant from the environmental sciences.

Case Study Using Monte Carlo Technique

An example might be useful.[524] Assume that persons are likely to be exposed to contaminated drinking water at the maximum contaminate level (MCL). Concern has

been raised that these regulatory limits are not sufficiently protective and that certain federal and state regulatory programs (i.e., Resource Conservation and Recovery Act) are justified in requiring groundwater remediation to levels below that of drinking water standards. In order to test this supposition, it is necessary to evaluate the possible incremental cancer risk of exposure via tap-water ingestion, dermal contact with water while showering, inhalation of indoor vapors, and ingestion of produce irrigated with groundwater, using a probabilistic approach. PDFs for each exposure variable (e.g., water ingestion, skin surface area, fraction of exposed skin, showering time, inhalation rate, air exchange and water use rates, exposure time) are then identified and used in the appropriate exposure equation to calculate dose and risk. A commercially available software package (i.e., @RISK) could be used to conduct the Monte Carlo analysis.[504]

Some have suggested that the Latin Hypercube (LHC) approach offers some advantages to traditional approaches for identifying the correct number of iterations. Often, one can reach convergence sooner with LHC than the Monte Carlo option in @RISK/Crystal Ball. In addition, LHC is more reproducible (to the hundredth decimal place). The Monte Carlo option needs more iterations to reach convergence.

The results of such an analysis are presented in Table 10.14.[524] The risk associated with exposure to water at the current MCL for four different contaminants, as well as the 50th and 95th percentiles of exposure as determined by the probabilistic analysis, is shown. At the 50th percentile level (*the best estimate*), the risk ranges from 6×10^{-7} (tetrachloroethylene) to 9×10^{-6} (chloroform), while at the 95th percentile (*the upper-bound risk*), these risks range from 4×10^{-6} (tetrachloroethylene) to 1.5×10^{-4} (chloroform). These values can be compared to the point estimate risks calculated for the MCLs, which range from 7×10^{-6} (tetrachloroethylene) to 5.4×10^{-5} (vinyl chloride). For the 50th percentile (average) person, all calculated risks are within the range of *acceptable* risks adopted by regulatory authorities for Superfund sites (1×10^{-4} to 1×10^{-7}). For the 95th percentile person (upper bound), the risks are still mostly below the 1×10^{-4} benchmark risk level generally used to separate acceptable from unacceptable risks. For tetrachloroethylene, these results are 30 (50th percentile) to 3 (risk at the MCL) times below the reasonable maximum exposure risk of 2×10^{-5} developed by combining the 95th percentile values for each exposure variable using standard EPA risk assessment methodologies. This point estimate is greater than the 99th percentile of risk and is consistent with statements regarding the conservatism of the reasonable maximum exposure (RME) approach. These results suggest that chemical residues in drinking water at the MCLs will be health protective and that remedial goals based on de minimis requirements (1×10^{-6}) might be unnecessarily low.[524]

TABLE 10.14
Risks Calculated for Exposure to Four Halogenated Solvents in Water Using Probabilistic Analysis at the MCL and for the 50th and 95th Percentile Exposures

Chemical	50th Percentile Risk	95th Percentile Risk	MCL Risk
Tetrachloroethylene	0	0.000005	0.000007
Chloroform	0.000009	0.00014	0.000017
Bromoform	0.000002	0.000016	0.000023
Vinyl chloride	0.000005	0.000029	0.000054

In terms of estimates for the reasonably maximally exposed (RME) individual, which often serve as the basis for regulatory decisions, several observations on the utility of probabilistic assessment can be made. First, exposure assessments that incorporate two to three direct exposure pathways usually show that the 95th percentile probabilistic estimates are three to five times below the traditional RME estimates. Second, for multipathway assessments that contain several indirect exposure pathways, the 95th percentile probabilistic estimates can be as much as an order of magnitude below the RME estimates. Third, when the number of distributions used in the exposure assessment is 10 or more, the difference between the 50th- and 95th-percentile estimates may be between 5 and 10. Finally, in such assessments, the difference between the RME estimates and the 95th percentile probabilistic estimates can be as high as 100. In the probabilistic approach to estimating exposure and risk, the complete range of potential risks can be illustrated along with the likelihood estimates and estimates of uncertainty associated with such risks. While the availability and confidence of distributions for exposure variables differ, risk assessors ought to take advantage of this and similar approaches in their risk assessments to advance and improve the process. In addition, since the highest degree of uncertainty in risk assessment tends to be the CPFs, attention ought to be directed to applying probabilistic analysis to the development of toxicity criteria in a similar manner.[514,521]

Sensitivity Analysis

In addition to establishing exposure and risk distributions, probabilistic analysis can also identify variables with the greatest impact on the estimates and illuminate uncertainties associated with exposure variables through sensitivity analysis.[538–543] Sensitivity analysis is the study of how the uncertainty in the output of a model (numerical or otherwise) can be apportioned to different sources of uncertainty in the model input. The sensitivity analysis is hence considered by some as a prerequisite for model building in any setting and in any field where models are used.[537] Sensitivity analysis can help in identifying critical control points, prioritizing additional data collection, and verifying and validating a model.[534] This provides some insight into the confidence that resides in exposure and risk estimates, and has two important results. First, it identifies the inputs that would benefit most from additional research to reduce uncertainty and improve risk estimates. Second, assuming that a thorough assessment

has been conducted, it is possible to phrase the results in more accessible terms, such as

> The risk assessment of PCBs in smallmouth bass is based on a large amount of high-quality reliable data, and we have high confidence in the risk estimates derived. The analysis has determined that 90 percent of the increased cancer risk could be eliminated through a ban on carp and catfish, but there is no appreciable reduction in risk from extending such a ban to bass and trout.[520]

Such a description provides all stakeholders with considerably more information than a simple point estimate of risk based on a traditional exposure and risk assessment.[142]

If the most *sensitive* exposure variables are based on limited or uncertain data, confidence in these estimates will be poor. Robust datasets, on the other hand, lead to increased confidence in the resulting estimates. In the example mentioned in the earlier text involving smallmouth bass, sensitivity is defined as the ratio of the relative change in risk produced by a unit relative to change in the exposure variables used. A Gaussian approximation (the product of the normalized sensitivity and the standard deviation of the distribution) of intake was used to allow both sensitivity and uncertainty to be gauged. In this case, the true mean of each distribution was chosen as the baseline point value, and the differential value for each variable was calculated by increasing this value by 10%. For each variable, the differential value was substituted, the risks recalculated, and the baseline value replaced.[524] Sensitivity was calculated using the following formula:

$$\text{Sensitivity} = \frac{|\text{Risk}_{\text{baseline}} - \text{Risk}_{10\%}|}{|\text{X}_{\text{baseline}} - \text{X}_{10\%}|} \times [\sigma]$$

where

$X_{baseline}$ and $X_{10\%}$ are the baseline and differential values for the variable X, respectively

σ is the standard deviation for the distribution of variable X

The sensitivity of each variable relative to one another is assessed by summing the unitless sensitivity values and determining the relative percent that each variable contributes to the total.

Table 10.15 identifies the most important variables in the probabilistic analysis for tetrachloroethylene. In this case, the most sensitive exposure variables in household exposure to tap water are exposure time in shower and exposure duration. Relatively small changes in these variables will result in relatively large changes in the risk estimates. Since these estimates are based on actual time-use studies and census information, this suggests a high level of confidence can be placed on this estimate, particularly if site-specific data are being used. If the critical variables (in terms of sensitivity) were not based on robust data, this would suggest that the risk assessment could be improved by additional research on these exposure variables. It is interesting that the form of the distribution chosen for the variables is less important than the validity of the data.[72] When the empirical distribution of the tap-water ingestion rate was substituted with a lognormal distribution,[544,545] the resultant change in the risk estimates was less than 1%.[504]

TABLE 10.15
Results of Sensitivity Analysis for Tetrachloroethylene Exposure in Household Water

Exposure Variable	Sensitivity (Unitless)	Percentage Rank (%)
Shower exposure time	0.000004	55.0
Exposure duration	0.000001	20.0
Plant–soil partition factor	0	8.4
Water ingestion rate	0	4.6
Surface area of exposed skin	0	4.4
Body weight	0	3.8
Dermal permeability constant	0	1.8
Skin fraction contacting water	0	1.5

In this case, the value of the sensitivity analysis is that it allows input variables to be ranked in order of importance and confidence in the output to be established to a higher degree than previously possible. As pointed out by EPA,

> [W]here possible, exposure assessors should report variability in exposures as numerical distributions and should characterize uncertainty as probability distributions. They need to identify clearly where they are using point estimates for "bounding" potential exposure variables or estimates; these point estimates should not be misconstrued to represent, for example, the upper 95th percentile when information on the actual distribution is lacking.[520]

As noted by EPA, such explicit presentation of the data reduces the temptation to use the exposure assessment process for veiling policy judgments.[546]

EVOLVING RESEARCH IN EXPOSURE ASSESSMENT

The field of exposure assessment will continue to benefit from ongoing research efforts. The following are some fruitful areas of ongoing research.

Bioavailability

Areas of applied research that will improve the practice of exposure assessment include bioavailability, speciation, chemical fate, and the role of biological monitoring. For over 20 years, consideration of the bioavailability of a chemical in a various media has become an increasingly important aspect of the exposure assessment process.[51,102,118,120,121,547] Alexander (1995) has shown that a variety of organic chemicals in soil lose the ability to interact with biological receptors over time,[548] despite the fact that the chemical concentration

in soil remains largely the same. The alteration in bioavailability extends across the various routes of exposure as well.[106–108,111–113,115,119,122,125,314–316,547,549,550] Inorganic compounds, even those posing a potentially significant degrees of hazard (i.e., cyanide), react similarly.[551–554] These losses in hazard potential are presumably due to irreversible chemical interactions with soil constituents. Table 10.16 indicates that the bioavailability of lead added to soil is immediately halved and that it is further reduced over time.[555] This would suggest that an assumption of 100% bioavailability of this compound (and many others) from soil is erroneous. It is also clear that the environmental media in which the compound occurs will influence its uptake into the body.[549] EPA recognized this fact when it developed an RfD for manganese and acknowledged that the bioavailability and resultant dose of manganese can drastically differ depending on whether the chemical exists in solid matrices (e.g., food, soil) or water.[10] One simple method to improve bioavailability estimates is to conduct extractions under more biologically relevant conditions.

Bench-scale extraction experiments in simulated gastric fluids or sweat can be used to inexpensively and accurately measure how readily environmental residues can be released from the media in which they occur.[102,124,556] As with inhalation or ingestion of vapors or solutions, both the release and absorption rates of agents from an environmental matrix (i.e., soil) across biological membranes need to be incorporated into the risk assessment when such data are available, and generated when absent. This need is particularly of issue for assessing dermal exposure. The problem for materials in aqueous solutions is less problematic than from solid matrices.[91] For liquids, permeability constants expressed in terms of agent weight per unit area per time (mg/cm^2/min) have been developed for a number of agents, and in vivo and in vitro techniques or mathematical models exist to develop similar flux rates if needed.[260,261,264,288,290,298,316,550,557–560] From soil, however, the typical approach in many risk assessments has been to assume a constant percent absorbed from soil adhered to skin as a default. For volatiles, an absorption rate of 25% has been used. For semivolatiles and inorganics, absorption rates of 10% and 1% have been used, respectively.

Some experimental data for absorption are available for a few agents (e.g., PCBs, DDT, dioxin, benzo[a]pyrene), suggesting that the simple assumption of a constant percentage absorbed may overestimate or underestimate the dose depending on the agent, co-contaminants, soil type, exposure duration, and similar considerations.[125,314,316,410,550] The impact of this default approach results in an instantaneous dermal dose being assumed, regardless of whether the soil remains in contact with the skin for 1 min or 1 day. This assumption, together with the questionable route-to-route adjustment of toxicity criteria from oral to dermal previously discussed, results in the dermal absorption of agents from soil, which arguably should present a minor exposure and risk in most cases, being a major driver in the risk assessment of soil-bound contaminants.

TABLE 10.16
Effect of Matrix and Aging on the Bioavailability of Lead from Soil

Treatment			
Lead Acetate (ppm Diet)	Soil Lead (ppm)	Tibial Lead (Standard Deviation)	Relative Lead Absorption
—	—	0.3 (0.3)	—
—	11.3	0	—
50	—	247 (10)	100
50	11.3	130 (30)	53
—	706	40 (6)	16
—	9,95	108 (26)	44
—	1,080	37 (7.3)	15
—	1,260	53.6 (7)	22
—	10,420	173 (22)	70

Chemical Fate

Risk assessors ought to incorporate information on the fate of chemicals in the environment in their exposure estimates, whenever possible.[552] Many organic compounds tend to degrade over time, and may disappear from exposed surfaces relatively quickly or otherwise change.[69,561] As suggested earlier, inorganic compounds may also undergo changes in the environment over time that affect their fates.[554,555] Influencing factors include degradation by sunlight, soil and water microbes, evaporation, and chemical interactions. The resultant changes can dramatically alter the outcome of exposure assessments.[51,551] For instance, most criticism of incinerators has focused on the inhalation risk of dioxin emitted from the stacks. As it turns out, the environmental half-life of dioxin (as a vapor) is only 90 min because of photolytic degradation. By contrast, the half-life of dioxin in soil or fly ash is 50–500 years. The focus of concern is often not the main risk issue when environmental fate is considered because levels and availability change over time.[7] Incorporation of half-life data into risk assessments can have substantial benefits for improving understanding of the potential exposures and risks associated with a specific situation.[2,562] In a similar manner, the risk from persistent contaminants (i.e., DDT) in fish has usually been assessed using results from the analysis of raw fish fillets in combination with assumptions about the size and number of fish meals. The effects of cleaning and cooking on these residues are not typically considered, but have been shown to be reduced substantially in many cases (i.e., 50% or greater).[563,564] Since many of these risk assessments form the basis of fish advisories or bans with potentially significant economic repercussions, there is obviously an important reason to make these exposure estimates as accurate as possible. In addition, since there are known health benefits to fish consumption, making recommendations against eating fish based on theoretical risk needs to be rigorously defended.[565]

Biomarkers and Biomonitoring

There is general agreement among the scientific community that diseases that contribute the greatest public health burden to society result from complex interaction between genetic and environmental factors, such as chemical pollutants, nutrition, lifestyle, infectious agents, and stress.[176,566–568] The field of epidemiology is a critical field for understanding these interactions. The cornerstone of exposure assessment in epidemiologic studies is the development of the exposure metric, the estimate of exposure for each individual of the study population.[176]

The past two decades have witnessed a dramatic increase in the level of research activity, derivation of theoretical constructs, and development of practical applications for the direct measurement of biological events or responses that result from human exposure to xenobiotics.[211,569] These measurements, conveniently grouped under the descriptor *biological markers* or *biomarkers*, reflect molecular and/or cellular alterations that occur along the temporal and mechanistic pathways connecting ambient exposure to a toxicant and eventual disease. As such, an almost limitless array of biomarkers is theoretically available for assessment, and only a minute fraction of these has been recognized and investigated to date.[569–571]

The term biomarker is a general term for specific measurements of an interaction between a biological system and an environmental agent.[166,572] Biomarkers can be broadly grouped into several categories: biomarkers of internal exposure, biomarkers of early biological effects, susceptibility biomarkers, genomic biomarkers, and biomarkers of health risk.[573] The International Programme on Chemical Safety defines three classes of biomarkers: biomarker of exposure, effect, and susceptibility:[572]

1. Biomarker of exposure is defined as an exogenous substance or its metabolite or the product of an interaction between a xenobiotic agent and some target molecule or cell that is measured in a compartment within an organism.
2. Biomarker of effect is a measurable biochemical, physiological, behavioral, or other alteration within an organism that, depending on the magnitude, can be recognized as associated with an established or possible health impairment or disease.
3. Biomarker of susceptibility is an indicator of an inherent or acquired ability of an organism to respond to the challenge of exposure to a specific xenobiotic substance.

Some events that can technically be classified as biomarkers of chemical exposure (e.g., hematological changes following high levels of exposure to lead or benzene, acetylcholinesterase inhibition by organophosphates) have been measured for decades. However, the recent surge of interest in this field has been driven by technical advances in analytical chemistry and molecular genetic techniques and by the recognition that *classical* toxicology and epidemiology may not be able to alone resolve critical questions regarding causation of environmentally induced disease.[211]

Epidemiology relies on inference of associations between exposure and response variables. Typically, the measurements of response in epidemiologic studies reflect late-stage endpoints of morbidity, mortality, body weight decrease, tumor development, and tissue pathology.[176,574,575] Defining risk at a late stage in the disease process provides little opportunity to intervene and redirect the outcome. It is clearly more desirable to identify early changes in biologic processes that can serve as predictive markers of exposure, of early effect, or of susceptibility.[176,576]

Important early applications of biomarkers to characterize environmental and occupational exposures have also been explored by several groups in the United States and abroad. Biomarkers of internal dose reflect the absorbed fraction of a xenobiotic, that is, the amount of material that has successfully crossed physiological barriers to enter the organism.[577] Consequently, the magnitude of the biomarker accounts for bioavailability and is influenced by numerous parameters such as route of exposure, physiological characteristics of the receptor, and chemical characteristics of the xenobiotic. In general, simple measurement of xenobiotic levels in biological media (blood, tissue, urine) can provide data on internal dose, and this is called biomonitoring.[578–580] As employed in most studies, biomonitoring indicates the presence of the substance or marker in the body at a single point in time, corresponding to when the specimen was taken, but such data alone provide no information on the source, pathway, the magnitude, the frequency or the duration of exposure.[581,582] Biomonitoring of exposure involves the measurement of the concentration of a chemical in a given biologic matrix during or after absorption, distribution, metabolism, and elimination (ADME), and its concentration level depends on the amount of the chemical that has been absorbed into the body, the pharmacokinetics (ADME) of the chemical, and the exposure scenario, including the time sequence of exposure and time since last exposure.[583,584] Ideally, in order to link the dose with adverse health outcomes, measurements of the BED, the dose at the target site that causes an adverse health effect, are preferred.[582,583]

Biomarkers reflect internal dose (in terms of proximity to downstream events in the sequence) and could include the measurement of a metabolite in selected biological media, particularly if such metabolite is active or critical to the toxic effects seen.[211] Ideally, a biomarker should be biologically relevant, sensitive, and specific (i.e., valid) and should be readily accessible, inexpensive, and technically feasible. Analytical, metabolic, and source specificities are important aspects to consider when identifying an appropriate biomarker, where the analytical specificity refers to the capability of the analytical method to exclusively measure the chemical (parent or metabolite) of interest, metabolic specificity means that the chemical measured is derived exclusively from the parent chemical of interest, and source specificity indicates the source of the chemical in the body.[585] This combination of requirements is rarely achieved, and some trade-off

TABLE 10.17
Biomarkers Examined for Selected Occupational and Environmental Chemicals

	Biomarker		
Chemical	**Exposure**	**Effect**	**Susceptibility**
PAH	DNA adducts[a]	*hprt* mutation	GST-M1
	Hb adducts	*gpa* mutation	NAT-2
	Serum albumin (SA) adducts	*fes* oncogene activation	CYP1A1
	Urinary 1-HP[a]	*ras* p21 level	CYP2A2
	Sister chromatid exchange (SCE)	DNA single-strand breaks	
	SCE (high-frequency cells)	Chromosomal aberrations	
		Micronuclei	
1,3-Butadiene	Hb adducts[a]	*hprt* mutation	
	SCE	Chromosomal aberrations	
	Urinary metabolites	Micronuclei	
		ras oncogene activation	
Acrylamide	Hb adducts[a]		
	Urinary metabolites		

[a] Biomarkers for which cumulative data indicate the best correlation with ambient exposure.

is inevitable in order to obtain useful biomarker data in a timely manner. A few promising examples are presented in Table 10.17. The validation process for a biomarker involves determining the relationship between the biological parameter measured and both upstream and downstream events in the continuum, that is, the dose–response curve must be characterized.[211]

For the majority of chemicals of interest, occupational or environmental sources may not be the only source of exposure. The identification of the exposure depends on the concentration difference in the *exposed* individual or group, in comparison to the general population.[585] Over the last decade, the U.S. Centers for Disease Control and Prevention (CDC) has expanded its biomonitoring efforts in order to better characterize potential trends in chemical exposures to the general population.[166] In its recent National Health and Nutrition Examination Survey (NHANES) reflecting biomonitoring data between 2007 and 2010, the CDC applied a new sampling methodology, in which all Hispanics, not just Mexican Americans, were evaluated and race/ethnicity domains were combined (12–15 and 16–19 years of age) or split (40–49 and 50–59 years of age) to increase the number of participants aged 40+ and decrease 12- to 19-year-olds from previous cycles. The CDC released the National Report on Human Exposure to Environmental Chemicals, which provided a cumulative analysis (containing all the results from previous reports) and new data, including that for 75 new environmental chemicals for years 2003–2004.[586] The Fourth National Report on Human Exposure to Environmental Chemicals represents exposure information and separate analyses by age, sex, and race/ethnicity on 212 environmental chemicals in people who had blood and urine samples since 1999.[586] In addition, the most recent Fourth National Report on Human Exposure to Environmental Chemicals, Updated Tables,[587] provides new data since the release of the fourth report, including updated tables for 119 chemicals in the fourth report[586] and tables for 34 new chemicals. The national exposure information identifies which chemicals are within Americans in measurable quantities; determines whether exposure levels are higher among population subgroups; determines how many Americans have levels of chemicals above recognized health threshold levels; establishes reference ranges that define general population exposure so unusual exposures can be recognized; assesses the effectiveness of public health efforts to reduce population exposure to selected chemicals; and tracks over time trends in U.S. population exposure.[588]

These data have been proven to be very useful in understanding national trends of chemical exposure, as well as the effectiveness of laws intended to restrict environmental emissions. Biomonitoring of lead and persistent organic pollutants are probably the two best examples of how biomonitoring can confirm the reduction of human exposures as a result of restrictions of environmental emissions. Blood lead measurements in the population were important in identifying lead in gasoline as a significant source of human lead exposure and documenting the reduction in blood lead levels in the population as a result of removing lead from gasoline and other products in the United States.[588] In the United States, the mean lead blood concentration in children during the consecutive phases of NHANES II, III, and IV in 1976–1980, 1988–1991, and 1991–1994 were 150, 36, and 27 μg/L, respectively.[166,589] Serum cotinine levels in the early 1990s found more widespread exposure to environmental tobacco smoke (ETS) in the United States than previously thought and additional measurements in 1999 and 2000 documented major declines in exposure to ETS as a result of public health

actions in the 1990s.[588] The results of biological monitoring for evaluating the background contamination or the trends regarding contamination have also been used to compare internal exposure to organochlorine compounds or the trends in the concentration of dioxins in breast milk.[166,590–592]

With the increased analytical sensitivity to detect chemicals in various biological media and the increasing use of biomonitoring data in an integrated approach for epidemiologic studies, there is a substantial need to design and interpret such data that would support environmental health decision- and policy-making and provide informative risk communication to the public. Improved methods to provide quantitative links between biomonitoring information and the potential for adverse health risk would certainly assist with human health risk evaluations. Several organizations have offered guidance to enhance the application of biomonitoring data in these kinds of assessments.[593] The National Research Council (NRC) committee on Human Biomonitoring for Environmental Toxicants in the report *Human Biomonitoring for Environmental Chemicals* provides guidance on designing and conducting studies as well as research to enable interpretation and reporting of biomonitoring results to the individuals measured and the public.[594] The European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC) published a report, *Guidance for the Interpretation of Biomonitoring Data*, which includes a framework for interpreting human biomonitoring data. In addition, the International Life Science Institute's Health and Sciences Institute (ILSI/HESI) biomonitoring committee seeks to identify and refine effective biomonitoring tools and data to characterize exposures to chemicals.[593] More recently, the International Council of Chemical Associations' Long-Range Research Initiative (ICCA-LRI) sponsored a workshop, *Twenty-First Century Approaches to Toxicity Testing, Biomonitoring, and Risk Assessment*, and identified research needs to close the gap between interpretation and understanding of emerging biological data and rapid technology advancements.[595] As noted by the National Academy of Sciences (NAS), a critical prerequisite for meaningful use of data from new technologies will be to distinguish between the changes representing perturbations in cells or tissues that may resolve themselves through normal homeostatic mechanisms and those changes that represent a true activation of toxicity pathways that lead to disease.[596] Biomonitoring assay methods have incredible sensitivity to detect chemicals and metabolites in biological media in the parts per billion and even parts per trillion. An important question that arises with these enhanced detection limits are whether and how the measurable levels potentially link to predictions of adverse health outcomes and the relevance for characterizing true population exposures.[595]

Biomonitoring in Environmental Science and Health Risk Assessment

Biomonitoring data can be used to identify early indicators of a biological effect for assessing health risk and contributors of exposures, which can support rational health risk management planning. Biomonitoring has been used as a tool to validate other exposure assessment techniques. For example, in a review of 14 different concurrent or consecutive passive dosimetry-biomonitoring studies of agricultural workers, it was shown that the total absorbed dose estimated using passive dosimetry, human kinetics, and dermal absorption data for eight different active pesticide ingredients was similar to measurements of human urinary biomonitoring data.[597] In addition, biomonitoring data have been used to examine the validity of parental questionnaire responses of child touching and mouthing behaviors during outdoor play in comparison to data derived from video assessments.[382] Through biomonitoring of blood lead levels, it was confirmed that hand-to-mouth activities as determined by video monitoring were directly correlated to child blood lead levels and parental questionnaire responses did not accurately reflect children's oral behaviors, play habits, or play environment.[382] It has been suggested that biological monitoring for exposure assessment may also be a useful tool following chemical incidents.[598] Such application of biological monitoring has proved successful following chemical incidents involving mercury, methylmercury, PCBs, and dioxins,[599–605] as well as other relatively long lifespan biomarkers including sulfur mustard,[606] ethylene oxide,[607] dichlorvos,[608] and acrylonitrile.[609]

More recently, a novel screening tool, termed biomonitoring equivalents (BEs), has been proposed as a means to assist in the interpretation of biomonitoring data for public health risk assessment.[610–612] BE is the concentration or range of concentrations of a biomarker of exposure consistent with existing exposure guidance values and is analogous to biological exposure indices (BEIs) developed by the American Conference of Governmental Industrial Hygienists (ACGIH). More specifically, BEs are the concentrations of a chemical in the body that are equivalent to guidance values (e.g., RfDs, minimum risk levels [MRLs], tolerable daily intakes [TDIs], and their underlying toxicological points of departure) and are calculated using chemical pharmacokinetic properties that dictate the relationship between external and internal exposures.[610–612] The BE approach has also been suggested as an opportunity to use chemical-specific information and the relationship between the biomarker and critical dose metric to refine uses of default uncertainty assumptions in the risk assessment process.[610] The first application of the BE approach involved 2,4-dichlorophenoxyacetic (2,4-D) in which pharmacokinetic data and models were applied to existing health-based exposure guidance values from the U.S. EPA to estimate corresponding BE values for 2,4-D in plasma and urine.[613,614] Although these approaches can provide useful insights relating biomarker levels to regulatory requirements under the simplified assumption of chronic, steady-state exposures, these techniques are not applicable to reconstructing real-world exposure scenarios, because such scenarios often involve nonsteady, transient exposures with variable frequencies, durations, and intensities.

Recent Applications of Biomonitoring in Exposure Science

Research over the last decade has expanded the use of biomarkers in applying human biological monitoring data of exposure to individual disease and susceptibility information.[211,615,616] The advancement in analytical methods has allowed researchers to measure markers in a variety of biological specimens, including serum, cord blood, urine, feces, hair, bone, teeth, breast milk, saliva, and exhaled breath.[583,590,617–620] In addition, recent technical advances have also allowed researchers to use biomarkers to address questions about the effectiveness of personal protection equipment and engineering controls in preventing exposures in the workplace,[618] contribution of different exposure pathways on biomarker patterns,[574] effect of genetic polymorphisms on biomarkers of mutagenicity,[616,621] impact of personal activities on individual exposure,[164,590] and correlation of biomarkers of exposure and disease risk.[620,622]

Research efforts, such as the NHEXAS,[623] the CTEPP,[624] and other U.S. EPA programs, have focused on developing databases of exposures of human populations to a wide range of pollutants in air, water, food, soil, and indoor/residential environments, over a wide range of space and time scales. For example, the University of California, Berkeley, CHAMACOS collected biomarkers in farming communities for pesticides and other important pollutants from mothers and their newborn children from conception through early childhood.[163] Data from NHEXAS have been used to understand lead, phenanthrene, naphthol, and chlorpyrifos environmental concentrations in outdoor air, soil, indoor air, dust, dermal, water, beverages, and diet solids in relation to urine and blood concentrations.[164] In particular, these data were used to evaluate how personal activities and lifestyle factors (e.g., seasonal differences, ventilation [window, central air/heat], home environment [paint, cement, carpet, fireplace], pesticide use, garden care, smoking, gas grill use, vacuuming method, schedule [work at home], and personal hygiene) may contribute to exposure to the specific chemicals within the home environment.[164] Georgopoulos and colleagues summarized and assessed the feasibility of applying exposure reconstruction approaches to some of the most comprehensive national databases that include complementary exposure and biomarker data.[625]

The measurement of chemicals and biomarkers has revolutionalized the field of exposure assessment. Current challenges with the increasing analytical sensitivity of detecting chemicals in various biological media and the more widespread application of these tools in population-based studies involve the interpretation of these data for minimizing exposure and health risks, as well as effectively communicating the risk trade-offs to the general public. The University of Michigan Dioxin Exposure Study (UMDES) is one study or series of studies that will likely serve as a model for future research integrating questions about complex environmental exposure pathways by which chemicals in soils, sediments, fish and game, homegrown produce, and household dust lead to increased body burdens.[279–282,626–628] This study was undertaken in response to concerns that discharge of dioxin-like compounds from the Dow Chemical Company facilities in Midland, Michigan resulted in contaminated soils in the Tittabawassee floodplain and areas of the city of Midland, and potentially led to an increase in residents' body burdens of polychlorinated dibenzodioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs).[281] Environmental contamination was believed to result from an aerosol plume from historic incinerators that deposited PCDDs on surface soils downwind of the plant and through releases into the Tittabawassee River downstream of the plant from chloralkali operations during World War I. In addition to measuring soil, household dust, and serum dioxin concentrations, other parameters potentially influencing exposures and dioxin body burdens were assessed, including demographic factors (i.e., age, BMI, breast-feeding history, race, smoking), residence factors (i.e., location, use, time), work history, water activities, fish and meat consumption, and hunting activities. A principal focus of the study was to evaluate activities that involve contact with contaminated soils, river sediments, and household dust. These included living on contaminated soil, living with contaminated household dust, and pursuing activities in the contaminated water bodies and floodplain (boating, swimming, picnicking, hiking). Little evidence was found that these activities were associated with increased serum dioxins.[279] The study also demonstrated that direct environmental exposures cannot be properly assessed without careful control of age, sex, BMI, smoking, and breast-feeding; these demographic factors largely accounted for the variation in serum dioxin concentrations with little apparent contributions from environmental exposures.[279] Despite this, small but statistically significant differences in serum dioxin concentrations were detected in populations living in the Tittabawassee River floodplain and within the city of Midland.[280]

While the researchers cautioned that the study results of the UMDES could not be extended to assess the potential health risks to children living in areas of dioxin-contaminated soil, recent data on the pharmacokinetic characteristics of dioxins in children from the Seveso, Yucheng, and Yusho experiences offered some insights on this topic.[604,629–632] Using the internal dose model of dietary and soil PCDD/F exposures in young children developed by Kerger et al.,[629] the possible impact of oral and dermal uptakes from the contaminated soils and house dust on the serum lipid toxicity equivalents (TEQ) concentrations of children was evaluated.[632] Consistent with the reported findings of the UMDES for soil/dust and serum lipid TEQ in adults,[279] the internal dose model predicts that child residents exposed to 10–1000 pg/g TEQ using the 50th percentile uptake factor are not likely to show measurably increased TEQ body burdens from soil/dust ingestion and dermal contact.[279] This evaluation also supported the well-established contention that background dietary concentrations of PCDD/Fs are far more substantial contributors to child TEQ body burdens compared to soil and house dust ingestion.[53,213,633]

Biomonitoring Data for Forward and Inverse Analyses

Biomonitoring data have been applied in a *forward* mode of analysis, whereby biological doses and effects are assessed using exposure measurements and, more recently, in an *inverse* mode of analysis, in which biomarkers are used to estimate or reconstruct external exposures. The forward analysis utilizes direct application of environmental exposure, toxicokinetic and toxicodynamic models either empirical or mechanistic (i.e., physically and biological based), where as the reconstruction analysis requires application of numerical model inversion techniques in conjunction with toxicokinetic and/or toxicodynamic models.[625]

PBPK models are broadly applicable as tools for relating dose biomarkers to measures of population exposure and health risk.[168] This approach was evaluated in the EPA dioxin reassessment, in which PBPK models were used to evaluate the reasonableness of their earlier estimated cumulative dietary intake of dioxin compounds.[634,635] Wallace and Pellizzari[637] and Wallace[636] assessed the utility of using exhaled breath for estimating exposure and body burden for VOC based on PBPK models. Chinnery and Gleason[638] and McKone[559] used PBPK models of chloroform applied to breathe samples reported by Jo et al.[351] to determine the relative contribution of inhalation and dermal exposure routes for adults showering with water containing residual chloroform from disinfection.[350] More recently, measurements of serum lipid 2,3,7,8-tetrachlorodibenzodioxin (TCDD) concentrations in adults and/or children from Seveso, Italy; Vienna, Austria; and Yucheng and Yusho, China have been used to model the distribution and elimination of dioxins.[604,629,631,639–641]

Several factors can influence the feasibility of reconstructing exposures from biomarkers. These factors include the specificity and sensitivity of the biomarker in relation to the exposure event(s); biochemical properties and biological factors (e.g., genetic polymorphisms) that impact the absorption, distribution, metabolism, and elimination; and various exposure characteristics (e.g., frequency, magnitude, duration, pathway), as well as supplemental exposure information (e.g., behavior, activities, macro- and microenvironment source locations, personal monitoring). Inherent in the use of biomonitoring data in these frameworks is the assumption that the relative magnitude and variation of the biomarker in the biological media are representative of the external chemical exposure. With this general assumption, reverse dosimetry methods have been used to estimate daily intakes of chemicals (i.e., phthalates, bisphenol-A, pesticides) to the corresponding biomarker concentrations in population surveys.[642–644]

While all of these factors are considered, the applicability and adequacy of the forward model (e.g., toxicokinetic/toxicodynamic model) and the efficacy of the computational inversion technique for reconstruction are the two most important factors for use of biomonitoring data for exposure reconstruction.[625] Reverse dosimetry or exposure reconstruction from biomonitoring data was recently used to demonstrate the application of PBPK modeling in estimating population exposures to trihalomethanes from biomonitoring results.[645] However, even with detailed information from national studies, such as the NHEXAS and the NHANES, it is not necessarily enough for detailed reconstruction of exposures under various conditions. For example, information about the last urinary void time associated with urinary biomarker samples can significantly improve interpretation of urinary biomarker data.[625]

Many compounds have short half-lives relative to the intervals between exposures and significant intraindividual, and within-day biomarker variability can exist due to fast chemical absorption and elimination. Reverse dosimetry may not be appropriate if the time frame of exposure characterization is not appropriately matched to the health outcomes of interest. For example, if the health outcome of interest is a chronic disease, a single measurement of a transient biomarker is not likely to provide accurate characterization of an individual's exposure leading up to the disease.[646] However, pilot studies to examine serial biomarker performance in relation to exposure patterns can help determine biomarker variability and timing to inform exposure characterization strategies and sample size requirements.[647] Incorporating such information in future biomonitoring study designs would be beneficial for these types of reverse analysis.

Other Emerging Applications of Biomarkers

Biomarkers are an important component of the emerging discipline of molecular epidemiology, which seeks to expand the capabilities and overcomes the limitations of classical epidemiology by incorporating biological measurements collected in exposed humans.[211,648] Biomarkers have also recently been suggested as an important potential tool in the emerging science of characterizing the *exposome*, which represents the totality of exposures received by a person during life and offers the potential to investigate environmental causes of chronic diseases.[649] Early efforts at utilizing biomarkers to make quantitative estimates of exposure and to predict human cancer risk were made by Ehrenberg and Osterman-Golkar.[650] Using ethylene oxide as a model xenobiotic, these investigators explored the use of macromolecular reaction products (i.e., Hb adducts) as internal dosimeters. By employing Hb adduction data, they predicted the level of ambient ethylene oxide that would correspond to a tumorigenic dose of γ-radiation, which they termed the *rad-equivalent dose*. Seminal work in the area of biomarkers as applied to the molecular epidemiology of cancer was performed by Perera and Weinstein,[651] who proposed the use of such techniques to identify environmental contributors to human cancer incidence.

Persistent and nonpersistent chemicals can react with biomolecules such as DNA, Hb, or fatty acids to form biomolecular adducts. By using these adducts as a surrogate for exposure, a greater length of time (dependent on the life of the adducts) can pass after exposure before measurements are collected.[583] Biomarkers with half-lives of 7 days or longer exhibit physiologic dampening of fluctuations in external

contaminant levels and can offer advantages when compared to short-lived biomarkers or exposures assessed by air monitoring.[652] Ehrenberg and Osterman-Golkar first proposed using Hb adducts to monitor the internal dose of alkenes and epoxides such as ethylene oxide over two decades ago.[650] This methodology has since evolved into a widely used and highly sensitive technique for quantitating N-terminal Hb adducts of a variety of xenobiotic metabolites in human blood. Hb adducts have been employed as internal exposure biomarkers for aromatic amines, nitrosamines, PAHs, and other compounds.[211]

Toxicogenomics-based methods have recently been used in laboratory settings to develop biomarkers of exposure, early biologic response, and susceptibility.[176] Toxicogenomics is a broad field that seeks to define, on a global basis, the levels, activities, regulation and interaction of genes, mRNA transcripts (transcriptomics), proteins (proteomics), and metabolites (metabolomics) in a biologic sample or system.[176] The approaches have been used for classifying exposures to a variety of chemicals and drugs, for example, hydrazine, 2-bromoethanamine, lead, acetate, cadmium, and acetaminophen based on mechanism of action and dose; they have been used for classifying health outcomes for cardiovascular disease and cancer based on disease status and severity.[176,653–666] The primary basis of classification and discovery in these studies is the molecular signature. Once the discriminating elements of the molecular signature are identified, biologic function can be inferred by mapping components to known biologic pathways and verifying functionality in follow-up studies.[176] However, some of the greatest challenges with this technology is that background levels of expression and variability for mRNA transcripts, proteins, and metabolites in human tissues are currently not known, but must be defined if toxicogenomic methods are to be used to assess personal exposures in epidemiologic studies. Expression levels are expected to vary widely because of differences in diet, lifestyle, health status, and genetic predisposition.[176] Despite the enormous promise of toxicogenomics for advancing our understanding of the relationship between environmental exposure and disease, the challenge has been, and will continue to be, the development of genetic and biologic markers that are predictive of adverse health outcomes in both experimental and human studies.[176]

One such area of active research with respect to biological markers for environmental contributions to disease is that of epigenetics.[667–671] Epigenetics refers to any change in gene expression that is stable between cell divisions but does not involve changes in the DNA sequence of the organism. Mechanisms involved with epigenetic changes include methylation of cytosine residues in the DNA, remodeling of chromatin structure, regulatory processes mediated by small RNA molecules, and other gene silencing pathways.[670] However, one of the most significant challenges with this area of research is understanding the *normal* epigenome in regard to the distinction between adaptive and adverse epigenetic changes. Without detailed characterization of the epigenome, including stable and variable methylation sites, it is not possible to evaluate whether an epigenetic alteration is an adverse effect from exposure to an exogenous agent or is part of the normal epigenetic variability.[668] As described in a workshop by the National Academy of Sciences' Standing Committee on Use of Emerging Science for Environmental Health Decisions *Use of Emerging Science and Technologies to Explore Epigenetic Mechanisms Underlying the Developmental Basis for Disease*, epigenetic testing is not yet sufficiently validated for the regulatory process because (1) no single test is ideal for epigenetic effects, (2) normal methylation patterns and long-term effects are not well understood, and (3) standardized tiered screening scheme to prioritize chemicals is lacking.[668]

Statistical and Analytical Issues

Despite the use of precise and reproducible analytical methods, we often do not have enough data of chemical concentrations to estimate exposure with great certainty. Because of resource availability, over the past 20 years, it has often been the case that a single round of analytical results or samples collected for other purposes serves as input and the surrogate for long-term or lifetime exposure.[672] As noted previously, chemical concentrations vary over both time and space, which makes the task of dose estimation all the more difficult.[563] For instance, using the (estimated) average dose to predict the typical lifetime dose may seriously overestimate or underestimate the actual dose. In addition, the average dose may be less important in the biological scheme of things than peak exposures or exposures at specific times (i.e., developmental effects) and ought to be considered as such in the evaluation of exposure.[174] Techniques do exist for estimating long-term exposure from short-term data,[673–675] but the reliability of these estimates is uncertain. Similarly, a variety of mathematical or bench-scale models exist that have been used to estimate exposure in the absence of measurements or long-term monitoring data.[676] As has been noted on several occasions, "all models are wrong, but some are useful," and risk assessors should carefully evaluate mesoscale and microscale models, as well as model outputs, for relevance and accuracy. Often, field measurements can serve as useful and relatively inexpensive *reality checks* on model results.

Equally important in exposure assessment are the statistics used to analyze field data. Environmental data are most often lognormally distributed. Under such conditions, a geometric average is generally assumed to be a better measure of the central tendency of data than the arithmetic mean.[677] Despite this, the arithmetic mean (and the 95% upper confidence limit of the arithmetic mean) is typically used to identify environmental concentrations for use in exposure assessment. Since the advances in analytical chemistry have improved our ability to measure trace amounts of chemicals in different media and identify potential sources in some situations, less reliance should be placed on the use of mathematical models to predict the distribution of chemical and physical agents in the environment, and actual field data should be collected.

Another important issue in exposure assessment is how the analytical limit of detection (LOD) is handled in calculations. An agent reported as a nondetect may be treated as a numerical zero, or occurring at the LOD or some fraction of the LOD, typically one-half of the LOD or the LOD divided by the square root of two, for purposes of calculating statistics. The manner in which censured data are assessed may affect the outcome of the risk assessment process.[678–685] For instance, analysis of highly contaminated samples or samples containing interfering substances may result in high LODs. Under such conditions and in the absence of additional analysis, assuming that nondetects are present at one-half the LOD could result in the exposure assessment and subsequent risk assessment being driven by compounds that are not truly present in the environmental media. When such an approach is used on a site that may be only 2%–10% contaminated (based on surface area), the predicted severity of the level of contamination will be much higher than what actually exists.[677] In these cases, it is often appropriate to insert a value lower than one-half the LOD when conducting exposure assessment calculations.

The practical result of these decisions can be illustrated by considering the following 11 data points resulting from analysis of field samples: Nondetect (ND), ND, ND, ND, ND, 5, 6, 6, 8, 55, and 500 ppm. The results are lognormally distributed as expected. The detection limit is 0.05 ppm, and nondetects are assumed to be present at one-half the detection limit (0.025 ppm). Using these assumptions, the arithmetic mean of the dataset is 52.7 ppm, while the geometric mean is 1.3 ppm. The practical consequence of choosing one descriptor over the other may be to misidentify or mischaracterize the dose and ultimately the risk, and will influence regulatory decisions involving remediation and regulation.

CLOSING THOUGHTS

The field of exposure assessment has evolved significantly over the past 20 years. We have learned a great deal about where people are exposed to xenobiotics and the relative degree of exposure. Not that long ago, most of our concerns were about industrial chemicals in our water, ambient air, and the soil. Today, we know that indoor exposure to particles, vapors, and gases in the home (influenced by smoking) often represents the predominant source of exposure for most persons. Aggregate exposure assessment and biomonitoring have changed the field of exposure assessment tremendously and are moving research to look at more complex and less obvious sources and pathways of exposure. A greater portion of our work in the future will undoubtedly focus on better understanding the individual contribution that environmental and indoor sources have to personal exposures,[176,220,222] differential exposures among susceptible populations (e.g., children, elderly, disease compromised),[686] and biological markers that identify biologic events early in the exposure-disease continuum.

Of the four portions of a risk assessment, exposure assessment has made the biggest improvement in quality over the 30-year history of health risk assessment. Often, exposure assessments will contain less uncertainty than other steps in a risk assessment, especially the dose–response portion. Admittedly, there are a large number of factors to consider when estimating exposure and it is a complicated procedure to understand the transport and distribution of a chemical that has been released into the environment. Nonetheless, the available data indicate that scientists can do an adequate job of quantifying the concentration of the chemicals in the various media and the resulting uptake by exposed persons if they account for all the factors that should be considered.

There are at least 11 significant lessons we have learned about conducting exposure assessments in recent years. Had we not had to learn through experience, avoiding these lessons could potentially have saved the United States hundreds of millions of dollars and thousands of person-years of work.

First, experience has shown that in our attempts to be prudent, we placed too much emphasis on the so-called maximally exposed individual (MEI).[68,70,71,76] Often, the results of those analyses were misinterpreted by the public and/or misrepresented by some scientists or lawyers. Often, as a result, poor decisions were made by risk decision-makers.

Second, as we have learned how to accurately characterize the risks of exposure for about 95% of the population, more emphasis has been placed on evaluating the various special groups (e.g., Eskimos, subsistence fishermen, dairy farmers)[79,359,451,590,687–690] and potentially susceptible populations (e.g., children, fetuses, elderly).[162,165,169,370,374,376–379,583,686,691–702] Although the risk for these populations needs to be understood, the typical levels of exposure for the majority of the population should be the initial focus of the assessment. Risk managers need to understand the size of the exposed populations and the risks.

The third lesson is a variation of the second—do not allow the repeated use of conservative assumptions to dictate the results of the assessment. In recent years, many investigators have addressed this issue and have demonstrated its importance. Monte Carlo techniques can generally be successful in addressing this problem.

Fourth, we have learned that risk managers and the public want to understand the statistical confidence in our estimates of risk. Sensitivity analyses can yield important information about the critical exposure variables.[534–537,678,679,684,703] Furthermore, most risk assessments can benefit from analyses of both variability and uncertainty. Without these, risk managers are not fully informed.

Fifth, we have improved our techniques for statistically handling samples that have no detectable amount of a contaminant. Frequently, regulatory agencies have used the LOD of the analysis or one-half the LOD in the exposure calculations

relying on the premise that the contaminant might be present at that level. We learned that when such an approach is used (without reflection) on a site that may only be 2%–10% contaminated (based on surface area), the impact of a few samples on the results could lead us to improper conclusions about the level of risk to persons who live there or nearby.

Sixth, we have gained a significant degree of confidence in our ability to estimate historical exposures, so-called dose-reconstruction or retrospective risk assessments. Over the past 20 years, these assessments have been used in epidemiology studies to understand the likely exposure to workers and/or those in the community nearly 40–50 years ago based on estimated chemical usage and emission data, measured data, and models.[29,30,37,204,209,210,237,704–709]

Seventh, we now understand the need to quantitatively account for indirect pathways of exposure. For example, the uptake of a contaminant in water by humans due to ingestion is obvious (and direct), but the uptake of the same contaminant by garden vegetables due to watering or uptake via the inhalation of volatile contaminants from the water while showering are indirect pathways that had not always been evaluated in assessments. Perhaps the most important indirect route of exposure, which had not been considered before 1986 when regulating airborne nonvolatile chemicals, is the ingestion of particulate emissions that have deposited onto soil and plants and are subsequently eaten by grazing animals.[60,212]

Eighth, we have learned that children and their exposure patterns are unlike those of adults.[162,165,169,370,374,376–379,583,686,691–702] As some have said, in more ways than one, children are not miniature adults! Their intake of certain foods, percentage of time outdoors, proximity to carpets, and inhalation rates per body weight are all different.

The ninth lesson learned is to use biological monitoring to validate or confirm the predicted degree of human exposure. Over the past 20 years, analytical chemists have increased their ability to detect very small quantities of dozens of chemicals in blood, urine, hair, feces, breath, and fat.[164,166,168,452,453,573,581,583,585,588,590,615–622,639,652,690,710–714] For many chemicals, these data represent a direct indicator of recent exposure and, in some cases (such as PCBs and dioxins), chronic exposure. Validation of our exposure assessments should be one of the major areas of study during the next few decades (both through biomonitoring and molecular epidemiology).

Tenth, it has become clear that in most cases, the most significant risks due to exposure to chemicals occur in the workplace. Even though great strides have been made in industrial hygiene over the past 50 years, the doses to which persons can legally be exposed are much greater (often by a factor of 100) than those to which most persons not in those occupations will ever be exposed.

Eleventh, and perhaps most important, we have learned that (for most persons) exposures to chemicals and bacteria in the home pose a greater risk than to those in the ambient air or through the ingestion of water. Many fine studies conducted in the 1970s through the current day continue to show that in-home exposures to most chemicals are 2–20 times greater than that present in the ambient environment.[22,217,219,222,283,357,363,366,457,504,715–723]

We have come a long way in a short time. Several professional societies including the International Society of Exposure Science (ISES), Society for Risk Analysis (SRA), American Industrial Hygiene Association (AIHA), Air and Waste Management Association (AWMA), American Chemical Society (ACS), Society of Toxicology (SOT), International Society for Regulatory Toxicology and Pharmacology (ISRTP), and others have all placed an emphasis on improving the practice of exposure assessment. All indications are that the information we have gained has significantly improved the quality of recent risk assessments and it can be expected that due to better exposure assessments, future decisions by risk managers will be much better informed.

QUESTIONS

10.1 Describe ways in which biomonitoring data are being used to understand exposure and environmental health risk.

10.2 In case study, several pesticides were detected in soil surrounding a residence. Describe the various media and pathways in which a family may be exposed to these pesticides, as well as the different factors that would need to be considered to conduct a quantitative exposure assessment of this particular family. Include topics related to interpretation of environmental and biological sampling, behavioral and susceptibility factors, and pesticide contamination within various media besides soil.

10.3 Name five emerging areas involved with different aspects of exposure science.

10.4 What factors influence the uptake of chemicals from soil particles through the skin, and what are some of the important criteria for assessing experimental dermal absorption studies?

10.5 What methods have researchers used to quantify soil ingestion in children?

10.6 Name at least four different national databases that are available to identify activity and behavioral patterns and/or biomonitoring data for different demographics within the general population.

11 Epidemiology for Toxicologists

Geary W. Olsen, John L. Butenhoff, and Ralph R. Cook

CONTENTS

INTRODUCTION

It is not by accident that a chapter on epidemiology has been included in a text on toxicology (Figure 11.1).

An important role of toxicology is to provide a basis from which to infer causation of an association of exposure to a chemical agent with adverse health outcomes as may be observed in epidemiological studies. The limitations of epidemiological studies include such factors as uncertainty in exposure classification, numerous factors that may confound interpretation, and potential exposures to multiple agents. Although toxicological studies can be carried out in a

"And it was so typically brilliant of you to have invited an epidemiologist."

FIGURE 11.1 And it was so typically brilliant of you to have invited an epidemiologist. (From William Hamilton, The New Yorker Collection, www.cartoonbank.com.)

controlled manner that limits potential confounding and lessens uncertainty regarding exposure, limitations do exist and include use of surrogate species or in vitro test systems, limited statistical power, and, typically, potentially higher exposures than those occurring in the human populations studied in epidemiological investigations. In evaluating the potential for adverse effects of xenobiotics and natural toxins on human health, there has been a long historical interaction between the fields of epidemiology and toxicology [1]. Often, associations of adverse human health outcomes with exposures to xenobiotic or natural toxins have been demonstrated to be causal based on the results of toxicological investigation. Conversely, observations of effects in toxicological studies have led to identification of those effects in exposed human populations based on epidemiological investigations. Just as toxicological data have traditionally held a principal role in the human health risk assessment process, the value and potential supremacy of epidemiological data have gained increasing recognition. Therefore, it is important if not necessary for toxicologists to have an understanding of the manner in which epidemiological studies are undertaken and interpreted and how the data from epidemiological investigations may be used in the processes of hazard evaluation and risk assessment.

Although it cannot be overemphasized that an understanding of basic epidemiological principles has always been of value to the practicing toxicologist, the consideration and use of epidemiological data in a regulatory context has gained significant ground in recent years. For example, two recent regulations, the 2007 European Union Regulation on Registration, Evaluation, Authorization and Restriction of Chemicals (REACH) and the U.S. Occupational Safety and Health Administration (OSHA) 2012 updated final rule for hazard communication standard (HCS), both emphasize the use of human data in establishing effect levels and in classifying chemicals for hazard communication, respectively.

REACH Guidance on Epidemiology Data

REACH guidance on information requirements and chemical safety assessment identifies human data as a valuable source of hazard information [44]. The guidance cites the advantages of human data as being the direct application to the human species; obtained, in most cases, from relevant exposure conditions; and often derived from a more heterogeneous population when compared to toxicological data. Epidemiological studies are noted as a major source of human data for hazard assessment under REACH. Despite the potential uncertainties inherent in evaluation of epidemiological data, such human data are recognized under REACH as the most relevant in assessing potential health hazard and risk to human populations. However, it is emphasized that any interpretation of epidemiological data be accomplished in consultation with experts in the methodology used in epidemiological studies as well as experts in the clinical aspects of the data under consideration. The REACH guidance illustrates the processes used for integrating human data into the derivation of critical derived no effect level (DNEL) and derived minimal effect level (DMEL) values.

Ensuring the quality of human data used in human health hazard assessment is necessary under REACH. REACH regulation relates specifically to evaluation of human information. Six adequacy criteria are provided for assessing

adequacy of human data. These are the following: (1) the proper selection and characterization of the exposed and control groups, (2) adequate characterization of exposure, (3) sufficient length of follow-up for disease occurrence, (4) valid method for observing an effect, (5) proper consideration of bias and confounding factors, and (6) a reasonable statistical reliability to justify the conclusion.

OSHA Guidance on Epidemiology Data

In 2012, OSHA modified the HCS to comply with the United Nations Economic Commission on Globally Harmonized System of Classification and Labelling of Chemicals (GHS) (http://www.unece.org/trans/danger/publi/ghs/ghs_rev04/04files_e.html). The GHS states that "In addition to animal data and valid in vitro testing, human experience, epidemiological data, and clinical testing provide important information that should be considered in application of the GHS." In the OSHA HCS, it is stated that "epidemiological data and experience on the effects of chemicals on humans (e.g., occupational data, data from accident databases) shall be taken into account in the evaluation of human health hazards of a chemical." Further, the final rule states that

> Where evidence is available from both humans and animals and there is a conflict between the findings, the quality and reliability of the evidence from both sources shall be evaluated in order to resolve the question of classification. Reliable, good quality human data shall generally have precedence over other data. However, even well-designed and conducted epidemiological studies may lack a sufficient number of subjects to detect relatively rare but still significant effects, or to assess potentially confounding factors. Therefore, positive results from well-conducted animal studies are not necessarily negated by the lack of positive human experience but require an assessment of the robustness, quality and statistical power of both the human and animal data.

The OSHA HCS recognizes that epidemiological data are often key in evaluating the potential human relevance of effects observed in nonhuman studies:

> Route of exposure, mechanistic information, and metabolism studies are pertinent to determining the relevance of an effect in humans. When such information raises doubt about relevance in humans, a lower classification may be warranted. When there is scientific evidence demonstrating that the mechanism or mode of action is not relevant to humans, the chemical should not be classified.

Search for Scientific *Truth* Regarding Human Disease Etiology

The search for scientific *truth* regarding the causes of human disease (also referred to as causal inference) is a laborious multistep process, a winnowing of a large number of postulated hypotheses down to the few that can be supported with data derived from testing and observation. Success depends on the replication of results, coherence of evidence from many different fields, and, ultimately, an understanding of the underlying biological mechanisms of action. In evaluating the potential human health effects of chemical exposures, three major sources of scientific information are used by the courts, various government agencies, and the larger scientific community: experimental laboratory research, controlled clinical investigations, and observational epidemiology studies. These three are not mutually exclusive in method or thought; nonetheless, each makes a unique contribution toward understanding the etiologies of human disease and each has certain inherent limitations. Ultimately, the determination of causation depends on the demonstration of a meaningful elevated risk for the disease among those with the *exposure* and a biological explanation for the excess. The former can only be obtained via epidemiology studies; the latter usually comes from an interplay of information derived from experimental laboratory research and controlled clinical investigations.

Toxicology has become stylized to the extent that the format of research results can be both predictable and quantitative. This made it convenient for information derived from toxicology studies to be used in quantitative risk assessments and related regulations. This convenience facilitated a major concern regarding extrapolation beyond the data to make inferences about health effects for levels of exposure that were not administered (i.e., the much lower exposures observed in humans). The 2007 U.S. National Research Council report (*Toxicity Testing in the 21st Century: A Vision and a Strategy*) proposed relying on less animal studies and more in vitro methods using human cells in a high-throughput context in order to identify biological *toxicity* pathways that would be sufficiently perturbed to lead to adverse health outcomes [96]. Risk assessments would then shift from high-dose observations to identifying the doses below which an exposure would not likely result in pathology [6]. Furthermore, in vitro methods do not take into account detoxification processes that may occur in vivo. Therefore, epidemiology studies of human exposure (low) levels would become much more relevant in the risk assessment process.

Clinical investigators also administer measured doses according to a predetermined schedule, to humans, thereby eliminating the need to extrapolate between species. Other technical biases, at least in theory, are minimized by randomly assigning potential study participants to either the exposed group or the unexposed controls; however, humans are not passive participants in health research. At the very least, they must consent to be studied. Some do not, and key characteristics of those who do and those who do not may be markedly different, quite possibly to the extent of compromising the utility of the initial randomization. Furthermore, specific subgroups (e.g., only men or only those who are patients of a single clinician) may be eligible for inclusion in the research. For all of these reasons, *controlled* clinical trials are, at best, quasi-experimental research. This means that care must be exercised in extrapolating their findings too broadly.

The two major strengths of observational epidemiology research are that one, it studies humans and, two, it deals

with the effects of real exposures—actual levels, durations, and patterns of exposure to individual agents and to mixtures. If epidemiology studies are well done, they furnish results that reasonably can be extended to larger populations. Unfortunately, epidemiologists often handle exposure as a qualitative variable (either as a yes/no or some variation of high, medium, and low). This can limit the utility of the research results for those who require quantitative information. Even when afforded an opportunity to analyze a continuous exposure variable (e.g., serum concentrations of a low-level environmental contaminant), whose measurement is not inexpensive, epidemiologists are prone to analyze the data in qualitative (categorical) terms with cut points that may just be a few nanograms per milliliter (ng/mL). Occasionally, both qualitative and quantitative estimates are provided. In addition, because the research is observational in the sense that the investigators simply observe natural experiments and do not exercise control over the key variables, epidemiologists routinely must grapple with a number of technical biases that are largely transparent to those in the other two fields. If these biases (in particular, selection, information bias [misclassification], and confounding) are not adequately addressed during the study design or data analysis, the study results may be unduly imprecise and important associations missed (i.e., false negative) or conversely the biases result in overestimates of risk (false positive). Alternatively, the results may be relatively precise but precisely inaccurate, thereby also leading to interpretations that are incorrect. Some of these problems can be exacerbated if the epidemiologist utilizes secondary sources of data (data originally gathered for purposes other than the specific research project, possibly even for reasons unrelated to research), especially if the methods for the original data collection process were poorly documented.

One other point differentiates epidemiology from toxicology and clinical medicine research. To call oneself an epidemiologist does not require any specific set of educational requirements, testing, or state or national licensure. Avenues exist to obtain formal training through doctoral and postdoctoral graduate degree programs in epidemiology, but this does not prevent someone with minimum training to declare himself or herself an epidemiologist. Toxicologists have various board certification processes such as the American Board of Toxicology (Diplomate, American Board of Toxicology) or the American College of Veterinary Toxicology (board certification) that certify a measure of competency. Medical professionals (e.g., MD, DVM, DDS) have their respective examination processes for state licenses and board certification requirements. Beyond graduation with a degree in epidemiology (MPH, MS, PhD), the closest *approval* process within the U.S. epidemiology community is voluntary membership in the American College of Epidemiology (ACE) that assigns a committee to review membership applicants based on their curriculum vitae to determine whether they can be credentialed as *members* or *fellows*. Only a handful of epidemiologists ever took the ACE examination that was discontinued in the late 1980s. A selective American Epidemiology Society exists for senior level epidemiologists. Other societies may have different requirements but not require examination. Epidemiologists have different strengths based on their experiences. Some enter the field with strong statistical skills; others have extensive training in human biology. Others arrive from the social and behavioral sciences. The formal graduate degree programs in epidemiology require a proficiency in both biology and statistics, but individuals with any level of education can gather a dataset, analyze it, report the results, and call their effort epidemiology research. The rule of thumb for the consumer of epidemiology results therefore, especially if a report appears in other than the peer-reviewed literature, is *caveat emptor*. Furthermore, peer review should not necessarily be viewed as a process that leads to epidemiologic research excellence either. Nor should a journal's impact factor [70]. The ultimate peer reviewer is the reader of an epidemiology paper. *Caveat emptor* indeed.

Historically, epidemiology has been defined as the study of the distribution and determinants of disease in humans [85]. Although commonly used, this definition is incomplete. Epidemiologists certainly search for the factors associated with human disease but they also attempt to identify both interventions that likely will benefit those who are at risk for getting the condition (perhaps because of unique patterns of exposure to combinations of putative agents or a genetic predisposition for reacting adversely to such exposures) and treatments that will help control or cure any significant pathology once it occurs. They also, implicitly or explicitly, try to determine which agents do not cause a specific disease, which interventions will not be successful, and which treatments are not effective.

As with toxicology and clinical research, epidemiology practice is an amalgam of subject-specific knowledge and methods. And just as clinical specialties and areas of expertise in toxicology have evolved with the growing complexities of each of those two fields, epidemiology is divided into a number of overlapping subgroups: occupational, environmental, reproductive, cardiovascular, cancer, infectious disease, molecular, genetic, nutritional, medical device, clinical, etc. Some of these are subdivided still further; for example, AIDS is a subcategory of viral, which, in turn, is a subset of infectious disease. Although certain knowledge and techniques may be unique to a subgroup, many concepts are common across the disciplines. As practiced today, epidemiology research sometimes involves multidisciplinary teams (e.g., epidemiologists, statisticians, physicians, geneticists, industrial hygienists, sociologists) as research studies have increased in population sizes and scientific complexities. Very large multi-institutional studies are not uncommon.

Primary Objective of Chapter

The primary objective of this chapter is to introduce those concepts that span epidemiology so toxicologists might become better consumers of the epidemiology literature. The topics include measures of disease frequency, measures of risk and association, study methods, and issues. All of

these are interrelated so the order of presentation is somewhat arbitrary, but the first three set the stage for the last one, in particular the key issues impacting validity—selection, information bias (misclassification), and confounding. Each of these in turn is presented to show how it can bias the measures of association. The intent is to make the readers more sensitive to possible biases so they might determine for themselves how well the investigators recognized a potential problem and addressed it during study design, data collection, and data analysis—and during data interpretation.

Several of the major points are illustrated with examples from the epidemiology literature or, to a lesser extent, with toxicology or clinical references. In part, this was done to emphasize the point that all science—experimental, quasi-experimental, and observational—is based on assumptions that may not be correct. Some of these assumptions are relatively innocuous. Conversely, some are so important that, if violated, the process is severely biased and any policies based on that science also are likely flawed. Those are the two poles of a continuum, but validity is not a dichotomous variable like pregnancy. Evaluating epidemiology research very rarely leads to *black or white* conclusions but rather varying shades of gray. The challenge for the consumer of scientific reports is to determine which data provide useful information, which data do not, and which data lie somewhere in between—intriguing enough to warrant additional research but not strong enough to merit intervention. This winnowing equates to first identifying potential problems that may have compromised the validity of the research; second, determining the probability to which the problems occurred; and, third, estimating the impact, if any, they had upon the results.

This chapter is by design a very limited overview. For those who wish to have a more detailed presentation of epidemiology, the list of references includes a number of published textbooks [31,55,115,116,124]. Note that, throughout this chapter, key *terms of art* are highlighted. Most can be found in Last's *Dictionary of Epidemiology*, an invaluable resource to any technical library [84]. Additionally, found in Appendix A at the end of this chapter is the Strengthening the Reporting of Observational Epidemiology Research (STROBE) statement, which provides an outline that can be used for critiquing epidemiology reports [134,136]. Found in Appendix B are five examples from the scientific literature that illustrate, in more detail, some of the epidemiologic concepts presented in this chapter. Three of these examples are based on the authors' epidemiology experience.

MEASURES OF DISEASE FREQUENCY

Data, information, and knowledge are related but not equivalent terms. Data are gathered by the investigator during the course of an investigation. Information is analyzed data. Knowledge is meaningful information that can be used to predict or solve problems. By way of analogy, data are bricks, information the wall, and knowledge the building. Just as good bricks can be put together poorly to build an unstable wall, so can data be valid but aggregated in a fashion that produces useless information. Pseudoknowledge may be a function of either bad data or useless information, just as a structurally unsound building may result from poor-quality bricks or an unstable wall. When information is biased (with error), the term information bias will be used in this chapter. Misclassification occurs as a result of the biased information.

Prevalence and Incidence

For the epidemiologist, the two general types of data are *prevalence* and *incidence*. Prevalence is what is observed at a single point, a snapshot of what is prevalent, what exists, at a specific point in chronological or biological time. For example, the number of toxicologists currently employed by the federal regulatory agencies is prevalence data. Incidence is the number of incidents, of new events, that develop over time. Because it represents a delta (a change), incidence data have to be gathered at two or more points in time. In a sense, if prevalence is a snapshot, incidence is a movie. The number of toxicologists hired by the federal agencies in any given year is an example of incidence data. They did not work for the agencies at the start of the year (observation point one), but they did work for the government later in the year (observation points two or more).

Parenthetically, when epidemiologists speak of prevalence data, they are usually referring to *point prevalence*, but they may mean *period prevalence*. Period prevalence is a combination of what exists at the beginning as well as what occurs during a specified period. The number of toxicologists who were employed by the federal agencies at any time during a given year is period prevalence data. It includes those who were working at the beginning of the year (point prevalence data) and those who were hired during the year (incidence data). Period prevalence may or may not be the same as the number of those who were employed at the end of the year (more point prevalence data) because some toxicologists may have left government employment during the period of observation.

Whether data are period prevalence or incidence can sometimes be difficult to discern because both refer to events occurring during a span of time. The key is whether the data represent a combination of existing and new events (period prevalence) or just new events (incidence). Unless otherwise noted, the term *prevalence* is used in this chapter as a synonym for *point prevalence*.

The difference between prevalence and incidence data is important for at least three reasons. One, incidence data can be used to evaluate cause and effect; prevalence data usually cannot, at least not without additional assumptions. However, unlike incidence data, prevalence is used to measure the disease burden in a population. Two, because prevalence data can be gathered at a single point in time, it is much easier to obtain; therefore, many reports in the medical literature are based on prevalence data. Three, the medical literature can incorrectly use the two terms interchangeably; as a consequence, reports that use valid prevalence data to develop nonsense information about cause and effect appear in even the most prestigious journals.

Although the two terms are different, they are related [64]. Under steady-state conditions (i.e., incidence rates and disease duration are stable over time), prevalence (P) is a function of both the incidence (I) and the duration (D) of the disease where $P/(1 - P) = I \times D_{average}$. The quantity $P/1 - P$ is the prevalence odds. For small prevalence where $1 - P$ approximates 1 (e.g., $P < 0.1$), the equation could be rewritten as $P = I \times D_{average}$. For any prevalence proportion, $P = I \times D_{average}/1 + I \times D_{average}$.

What this means is that a chemical may not cause a disease, may not increase the incidence of the disease, but it may still be associated with a higher prevalence of the condition. Whether that is good news or bad depends on the circumstances; for example, the incidence of diabetes may be quite stable in a population, but if that population is given access to a chemical called insulin, then the prevalence of the condition likely will increase dramatically. It will increase because the insulin extends the duration of the disease by allowing more of the afflicted to live longer.

Conversely, the prevalence of minor birth defects (prevalence because the events are measured at a single point in biological time: birth) could be lower among live children born to women exposed to some agent, not because the agent prevents the development of minor defects in utero but because the agent causes major malformations, including some among those fetuses who happen to have minor defects. If the major malformations lead to early spontaneous abortions, the *incidence* of minor defects might be quite stable, but the duration in utero of those with both types of congenital defects would be shortened and fewer newborns with minor problems would be observed at birth. The *prevalence* of minor defects among live births would be lower.

Figures 11.2 and 11.3 illustrate these points. In both figures, a group of six patients (A through F) is observed for 2 years. In Figure 11.2, the condition is time limited; it spontaneously resolves, it is cured through some treatment, or the patient dies. The point prevalence at the initial baseline observation (year 0) is one (patient A). Two additional cases subsequently occur (patients C and F) and all three resolve before year's end. At the end of year 1, the point prevalence is zero, the incidence is two, and the period prevalence is three. During the following year, two more cases develop (patients B and D) and one patient dies (patient D) of an unrelated cause before the end of the year. At year's end, therefore, the point prevalence is zero, the incidence is two, and the period prevalence is also two.

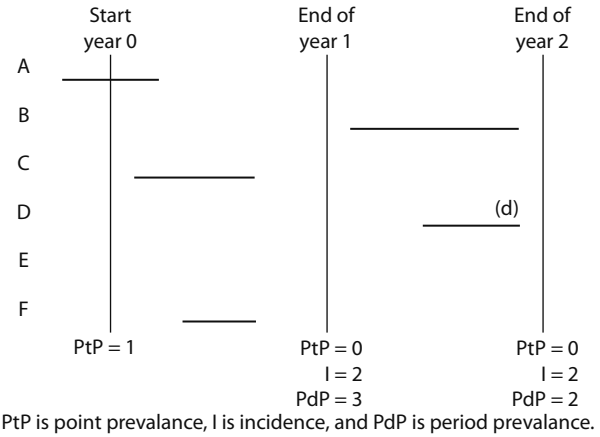

FIGURE 11.2 Prevalence versus incidence (time-limited condition).

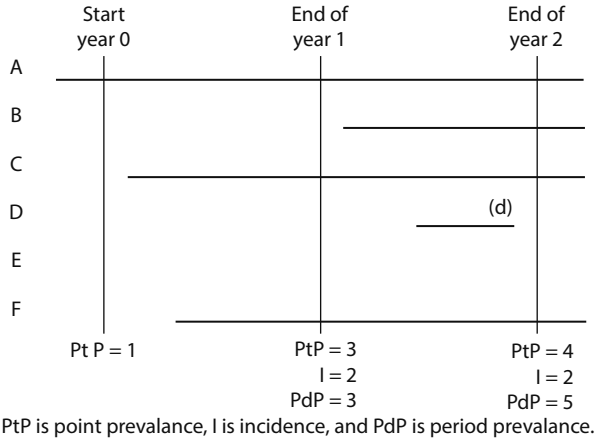

FIGURE 11.3 Prevalence versus incidence (condition chronic).

In Figure 11.3, the condition is chronic, perhaps because, like diabetes, it has been extended through treatment. Note that the incidence is exactly the same as in the previous example. It is two in each year; however, the extended duration has impacted both measures of prevalence. The point prevalence at the time of the three observations (baseline, year 1, year 2) is, respectively, one (patient A), three (patients A, C, and F), and four (patients A, B, C, and F). The period prevalence for the first year is three. For the second, it is five even though patient D died before year's end. Each of these three measures of disease provides valuable information, but using either type of prevalence data for interpretations about cause and effect depends on assumptions about *incidence time* (i.e., when the health event actually occurred) and disease duration that are often untestable or incorrect.

Rates

Technically, incidence and prevalence refer to numerator data; however, in both the epidemiology and medical literature, these terms often are used interchangeably with, respectively, *incidence rate* and *prevalence rate*. An incidence rate is the number of new events of a disease in a defined population that occur during some specified period of time. A prevalence rate is the number of cases of disease observed in a defined population at a point in time. In both, the numerator is a subset of the denominator. Obviously, errors of count in either the numerator or the denominator can impact the accuracy of a rate; nonetheless, in some technical reports, the former may not be a subset of the latter, and the description as to how either was compiled may be less than clear.

Rather than presenting a rate as the actual numerator (the exact number of new events observed) in comparison to the actual denominator (the precise count of the group under study)

at or during the period of observation, for convenience, a rate is usually given as the number of cases per 100 or per 1,000 or per 10,000. For example, if the study group had 486 persons and 5 new events occurred during a 12-month period of observation, then the incidence rate might be presented 1.0 per 100 per year (5 divided by 486 times 100) or, alternatively, as 10.3 per 1000 per year.

As opposed to toxicology, in epidemiology the study groups can be either *fixed* or *open* (sometimes referred to as *dynamic*). In a fixed study group, those included are defined at the start and followed over time. If no losses occur during the period of study, the group may be called a *closed population*. In this situation, when the population size is fixed, the rate becomes the proportion of people who become cases among those in the population at the start of the interval. This is referred to as an *incidence proportion* and it is dimensionless. In an open study group, individuals may be added or lost during the time of study. Just the events that occur and just the time that passes during the period each individual was under observation are counted. This so-called person-time experience assumes that observing 10 people for 1 year is the same as observing 1 person for 10 years. In some situations, the assumption is appropriate; in others, it may not be. The determination of which is which depends on the underlying biological model. Occupational epidemiologic studies are almost always open as each employee followed has his or her own hire date, termination date (quit, retired, lost to follow-up), and perhaps end-of-follow-up date (lost to follow-up, deceased, followed to end of study).

MEASURES OF EFFECT AND ASSOCIATION

To the general population, the concept of risk can seem straightforward. It is interpreted as a probability. *Risk* is defined as the probability that a disease develops in a person within a specified time interval. However, it can be easily misunderstood since it may be used without a clear time reference. To say a man over 65 years of age has an 8% risk of dying from cardiovascular disease does not place such risk in a time period. Is it within the next week, month, year, or remaining lifetime? The following measures of risk and association provide epidemiologic perspective.

Absolute Risk

It is an immutable fact of life that we are all going to get ill at some time and ultimately we are all going to die. On a personal level, the questions for each of us are by what disease and when? Epidemiologists are also interested in those questions, but they are particularly interested in whether the disease occurs more frequently or more severely in association with some type of exposure. In other words, when it comes to identifying the causes of disease, what is at issue is whether the *absolute risk* for a specific disease among the exposed is greater than the absolute risk of that same disease in the unexposed.

Relative Risk

Epidemiologists speak of the *counterfactual ideal*, which is comparing the same exposed person with his unexposed counterfactual experience [65]. That is, compare the experience of a person with exposure to the same exact experience during the same time period but without the exposure. Of course, this is not possible as time cannot be duplicated but it implies the person has the same experience twice, once with the exposure and once without the exposure. Likewise, this counterfactual ideal experience could be considered with a population.

Although the counterfactual experience is not possible to obtain whether on an individual or population basis, epidemiologists attempt to mirror it by comparing a population with exposure to a different population without exposure assuming the two populations have comparable risk for disease except for the exposure. *Absolute effect measures* are differences in occurrence measures and are not dimensionless. The *effect* of exposure can be measured as the risk difference (RD) (*incidence proportion* exposed minus *incidence proportion* unexposed) or the *incidence rate difference* (*incidence rate* exposed minus *incidence rate* unexposed).

Relative effect measures are ratios of occurrence measures and are dimensionless. A *relative measure of effect* for risk is determined by the RD divided by the risk in the unexposed:

$$\text{Relative effect} = \frac{\text{RD}}{R_{\text{unexposed}}} = \frac{R_{\text{exposed}} - R_{\text{unexposed}}}{R_{\text{unexposed}}} = \text{Risk ratio} - 1$$

$$\text{where Risk ratio} = \frac{R_{\text{exposed}}}{R_{\text{unexposed}}}$$

Epidemiologists ignore subtracting the 1 (since this is a baseline value) resulting in the *risk ratio* (RR) having the numerical range from zero to infinity.

In a similar manner, incidence rate data can result in a *rate ratio*:

$$\text{Relative effect} = \frac{\text{ID}}{I_{\text{unexposed}}} = \frac{I_{\text{exposed}} - I_{\text{unexposed}}}{I_{\text{unexposed}}} = \text{Risk ratio} - 1$$

$$\text{where Risk ratio} = \frac{I_{\text{exposed}}}{I_{\text{unexposed}}}$$

It is important to remember that risks are not directly comparable to rates because of different units. The risk ratio and rate ratio are often called *relative risks*. An risk ratio is proportionate to a rate ratio based on the time (T) at risk:

$$\text{Risk ratio} = \frac{R_{\text{exposed}}}{R_{\text{unexposed}}} = \left(\frac{I_{\text{exposed}}}{I_{\text{unexposed}}}\right)\left(\frac{T_{\text{exposed}}}{T_{\text{unexposed}}}\right)$$

A risk ratio and a *rate ratio* (*relative risks*) are key measures of association between exposure and disease. If the relative risk is appreciably greater than 1 among those with a particular

exposure, it is possible that the agent may be causing the disease. Maybe. Conversely, if the relative risk is below 1, the agent may be protecting against the disease. Maybe. And, if the relative risk approximates 1, there may be no meaningful association between the two variables. Once again, may be. *Maybe* is an important caveat in all three situations because how well the *apparent relative risk* (the number derived as the result of a particular investigation) corresponds to the *true relative risk* (the actual underlying biological truth) depends not only on the statistical stability of the estimate of relative risk but also on how well the potential technical biases of selection, information bias (misclassification), and confounding were controlled in the study design, during data collection, and by data analyses.

Recall now that a measure of effect was based on the underlying counterfactual principle of what happens to one population under two entirely distinct conditions for which only one can occur. A measure of association refers to what happens in two distinct populations. It is possible that the two populations may be the same population studied under two different time periods. For example, measure the incidence of a specific cancer in a community before and after application of an aerial insecticide.

Standardized Mortality Ratio

In occupational cohort mortality studies, the measure of association may be provided as a *standardized mortality ratio* (SMR). Toxicologists often encounter occupational epidemiology study results in their review of specific chemical hazards; thus, an extended description is provided herein. The SMR is the ratio of the number of deaths observed in the study group to the number that would have been expected to occur in the absence of exposure if the exposure did not affect the distribution of person-time. Occasionally, the SMR is presented as a ratio of *observed to expected* (O/E) deaths and may be more easily understood in communication meetings to workers or the public when expressed as an SMR. The interpretation of an SMR parallels that of a relative risk. Historically, the O/E ratio was multiplied by 100 where an SMR = 100 was equivalent to observed deaths equal expected deaths. Over the past 20+ years the multiplication by 100 has gained disfavor such that an SMR of 1.0 is analogous to a relative risk of 1.0. Because the observed number of deaths occurs in discrete increments and the number of expected deaths is a continuous variable (i.e., the expected deaths might be a biologically impossible number such as 1.27365…), by convention, many epidemiologists will not calculate an SMR if the number of observed deaths is less than 2 [31]. They may simply provide the two numbers (the observed and the expected) or just offer a confidence interval. Sometimes, they will do neither and merely indicate that the numbers were too small to be meaningful.

The expected number of deaths in an occupational population is obtained by multiplying the stratum-specific mortality rates in the reference population times the corresponding number of person-years in the study population and then summing across all strata. At a minimum, these stratum-specific rates will be age, sex, race, and calendar-year specific. For many occupational studies, the mortality experience of a national white male population is used as a reference, even if a small number of those in the occupational cohort are of a different race or ethnic group. The assumption is that the calculations of expected deaths will be adequate. Sex-, race-, and disease-specific mortality rates are available for most general populations. Essentially, the mortality rates of the general population are assumed to be the desired counterfactual rates. However, there will be other important differences between the exposed population and the general population besides their basic demographic distributions. Using an SMR approach also means that the investigator is assuming that no one in the reference population was exposed to the same degree as the study population. If the exposure is relatively rare among those in the reference population, the assumption is probably reasonable because the mortality experience of those few who were exposed would have had very minimum impact on the population statistics. On the other hand, if the exposure is relatively common (e.g., something like chlorinated drinking water), then the assumption may be unreasonable and another type of study would have to be done to obtain valid information. The occupational study population may be different than the reference population with other habits including smoking, dietary preferences, access to medical care, socioeconomic status, etc.

Another important caveat of an SMR analysis is if subgroups of the occupationally exposed group have different distributions such as age or calendar-year. This comparison is often done to assess a dose–response trend. Because each subgroup's SMR is weighted by the person-time experience, there can be residual confounding if such person-time is substantively different. When the subgroups have little differences in person-time across the strata, then residual confounding is less likely.

Choice of the referent population usually encompasses both national and regional (e.g., state, multicounty) mortality rates. It is conceivable that SMR associations may be quite different based on the referent populations used. There are many examples in the literature when this occurrence happens. For example, Olsen et al. reported the lung cancer mortality experience of a large population of male chemical workers in Freeport, Texas [100]. Using the U.S. mortality rates, the SMR was 1.14 (95% CI 1.04–1.25). Using Texas mortality rates, the SMR was 1.13 (95% CI 1.03–1.23). However, using the regional five county mortality rates, the SMR was 0.92 (95% CI 0.83–1.00). This example illustrates the point that regional rates are generally preferred in the interpretation of occupational data.

Instead of using mortality data, similar calculations can be performed for a *standardized incidence ratio* (*SIR*). Instead of death being the outcome of interest, it is illness, oftentimes cancer, but the calculations and the resultant interpretations are basically the same. So, too, are the underlying assumptions. SIRs are often calculated when the observed cancer incidence of the cohort is determined through record linkage

with regional cancer registries and expected numbers are calculated using cancer incidence rates from the reference population, which is that covered by the regional cancer registry. Currently in the United States, every state has a functional statewide cancer registry system although their longevity differs greatly between states.

Proportional Mortality Ratio

On increasingly rare occasions, it may not be possible to define a cohort, but information exists on those in the group who have died. Company and union records have been used to conduct such analyses. The *proportional mortality* (or *morbidity*) *ratio* (PMR) is a measure of the relative importance of an individual category of disease *among those with any disease* to the corresponding proportions among a reference population. As such, both numbers in the ratio are numerator data. Although it is a convenient measure to obtain, it must be used with caution in etiologic research because it compares proportions and not rates. It makes the assumption that a higher proportion of a particular disease is the same as an increased frequency of that disease. Because a PMR calculation works like a teeter-totter, that assumption may be invalid. Although a higher proportion of a disease may be due to an increased incidence, it also may simply be a function of a lower frequency (and therefore a lower proportion) of some other condition, disease B. For example, a higher PMR for cancer among an occupational group with a certain exposure may mean that more of those with the exposure were developing (and dying) from cancer than those in the reference population, but it is also consistent with the interpretation that those with the exposure were *not* dying more often from cancer; they were just dying less often from noncancer events. In other words, in a PMR analysis, an apparently *adverse* finding may be spurious (e.g., solely a function of the *healthy worker effect*) [89].

Attributable Fraction

As previously defined, the relative measure of effect was defined as the RD between the exposed and unexposed groups divided by the risk in the unexposed group. The attributable fraction is defined as the RD between the exposed and unexposed groups divided by the risk in the exposed group [65]:

$$\text{Attributable fraction} = \frac{\left(R_{\text{exposed}} - R_{\text{unexposed}}\right)}{R_{\text{exposed}}}$$

The attributable fraction can be understood as the proportion of disease in an exposed group that may be caused by the exposure if there were no biases in the determination of the risk. For example, if the risk in the exposed group was 0.15 and the unexposed 0.12, then the attributable fraction = 0.20, which is 20% of the risk among the exposed. A second calculation is required when applied to the target population from which the exposed group originated. The overall attributable fraction needs to take into account the proportion of all cases in the source population that is exposed. For example, if the proportion of cases in the population that is exposed is 8%, then the overall attributable fraction for the population is the attributable fraction among the exposed (0.20) multiplied by the proportion of exposed cases in the population (0.08). This equals 0.016, or 1.6% of all cases in the population are attributable to the exposure. In other words, among all cases in the population, 1.6% are attributable to the exposure. A major caveat to the interpretation of an attributable fraction is the fact that although the calculation is straightforward, the term *attributable* is dependent upon knowing causation is certain. In most instances, this is not the situation and thus any calculation needs to clarify this point. To further confuse the picture, different terms are used in the epidemiology literature. The aforementioned attributable fraction has also been called an attributable risk, attributable risk percent, and attributable proportion. Attributable risk has also been defined as the RD or the rate difference. It is always best for the definition to be clearly defined and understood. Because of this confusion, Rothman et al. recommend the term attributable risk not be used [65].

With two incidence rates, the rate difference also provides a measure of the excess burden of disease that an exposed population might expect to experience as a result of the exposure if there is a causal relationship. It represents the amount of the disease that would have never occurred if the exposure had been prevented. Note that the two measures—the rate ratio and the rate difference—provide very different information. The higher the *relative risk*, that is, above one, the greater the likelihood that a true cause-and-effect relationship exists, but a high *relative risk* for a very rare disease among a few individuals with a unique exposure may be of de minimis concern from a public health perspective, whereas a lower *relative risk* for a relatively common condition might equate to an enormous number of cases. By way of example, it is generally accepted that excess exposures to vinyl chloride monomer cause angiosarcoma of the liver. The *relative risk* for this association is quite high, but the total number of excess cases, worldwide, approximates 100. By way of contrast, the *relative risk* for heart disease among cigarette smokers is only about 1.5, but the rate difference equates to a large number of cases—many, many orders of magnitude more than 100. This is because both the disease and the exposure are relatively common. From a public health perspective, it is much more important to control the excess risk of disease related to smoking than it is the risk associated with vinyl chloride monomer. Yet, for the purpose of establishing a cause for the disease, it took many fewer epidemiology studies to establish an etiologic association between vinyl chloride monomer and liver angiosarcomas than it did for cigarettes and cardiovascular problems.

Rate ratios and rate differences are derived from research in which two groups are defined based on exposure status, and the disease patterns of each are followed forward in time. On occasion, it is easier to get groups based on whether they do or do not have a specific disease and then collect data on previous exposures. For example, it may be more convenient to identify all those who developed lung cancer during some

period, possibly via the use of data from a tumor registry, and identify a comparable group of healthy individuals from the general population. Of course, how this control selection is done is not an easy undertaking if biased selection is to be avoided. Gathering data on previous exposures from those in each group (or from their next of kin) would allow the calculation of an *odds ratio* (OR), the odds of having been exposed to a particular agent given one had the disease versus the odds of having been exposed to that same agent among the healthy controls. If a study is done properly, the OR will approximate the *relative risk*; for example, if the *relative risk* for getting lung cancer among cigarette smokers is 10, the OR of having been a cigarette smoker among those with lung cancer also will be about 10. For simplicity, the rest of the text will focus predominately on two measures of association: the relative risk and the OR.

METHODS

Cohort

Over the years, epidemiologists have developed a variety of methods to evaluate cause and effect. The most intuitively obvious, and the most analogous to the approach used in toxicology, is the *cohort* study. A cohort is simply a group with some common characteristic (e.g., gender, ethnic background, health behavior, or exposure to a particular chemical or medicine). In a cohort study, the incidence disease experience of two cohorts are compared, one with an exposure and one without. Construction and follow-up of cohorts, however, is anything but simplistic. Ideally, multiple cohorts, each with a different level of exposure, are identified with different levels of exposure that are assessed either quantitatively or qualitatively(e.g., low, medium, high). Irrespective of the number of groups, conceptually, exposure status is determined first, and health data—on subsequent mortality, morbidity, clinical measurements, etc.—are then gathered forward in time. Depending upon the time period spent in the cohort, an individual's exposure experience may vary considerably and only some of this exposure may have relevance to the disease in question. The induction period is defined as period of time from causal action until disease initiation. How much exposure is required to initiate the causal action? Is the risk of exposure effects best described by an average intensity exposure, cumulative exposure, or peak exposure? What is the amount of time necessary for any of these exposures to initiate the disease process? Oftentimes, the investigator does not know the induction period. Exposures that occur during the induction period may not be relevant to the initiation of the disease. Epidemiologists often lag exposures to minimize recent exposures that occurred near the time of diagnosis of a chronic disease since the disease process had already begun prior to the exposure. Apportioning person-time to the correct exposure category is paramount. For example, if a person worked 40 years at a manufacturing plant and began his exposure to a specific chemical in year 11, then considering his first 10 years of employment related to this exposure would be invalid. Occupational cohort definitions generally require a minimum time spent employed before entry into the cohort (e.g., 1 month, 6 months, 1 year). Counting this period as eligible time at risk is also invalid since all cohort members had to survive through this time period to enter the cohort. This is referred to as immortal person-time and should be excluded from incidence analyses. Inclusion of immortal time would bias estimated disease rates downward.

Cohort studies can be defined as to when the exposure information is collected in relation to the disease in question. If the exposure status is determined in the present and the health data are then gathered into the future, the term *prospective cohort study* has been used. Prospective cohort studies, for all of their advantages, may not be the method of choice in preliminary investigations of the causes of disease, especially if the disease has a long latency. As opposed to toxicologists who dose animals of species with relatively short life spans (a standard chronic feeding study of mice takes 2 years), epidemiologists examine a long-lived species, humans; therefore, if they only did prospective cohort studies of chronic disease, they likely would complete very few projects during their professional careers. To overcome this problem, epidemiologists will often use historical records—personnel files, medical archives, industrial hygiene reports, etc.—to define their exposed and unexposed study groups at some arbitrary date in the past. They will then gather health data on each individual in the study groups from that point up to the present. These are sometimes called *retrospective cohort studies*. Irrespective of whether the starting point for a cohort study is at the present or in the past, the results are based on incidence data presented as relative risks (and, if appropriate, RDs).

Figure 11.4 illustrates how this is done. Two groups of healthy individuals are identified at a point in time. One group is selected because they have (or had) a known or presumptive exposure to a specific agent; the second because they don't have (and ideally never had) the exposure. The health experience of those in each group is then compiled in an equivalent fashion over some defined period of time. This health experience is converted into incidence rates and the rates compared by means of a relative risk. It is possible to calculate relative risks for all health events combined (e.g., total causes of mortality) or for any number of distinct outcomes (e.g., just deaths due to angiosarcoma of the liver). When the cohort approach is used in exploratory data analysis, it can be considered an exposure in search of a disease, a hypothesis-generating exercise. If it targets just one or a limited number of specific associations of a priori concern, it is akin to hypothesis testing. Many epidemiology studies are a combination of both, and it may be difficult for the reader to discern which associations were of concern at the beginning of the research and which were simply serendipitous findings [7].

In the example, each group at the start of the study had 10,000 individuals; therefore, the marginals for the 2×2 table are both 10,000. During the period of study, X individuals in the exposed group were observed to have developed the disease (cell a), while the remainder ($10{,}000 - X$) did not (cell b). The

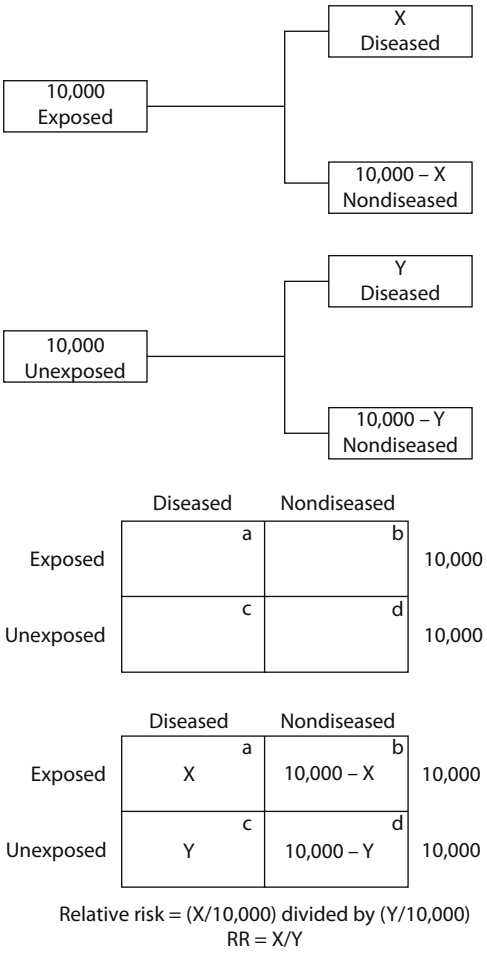

FIGURE 11.4 Illustration of the cohort method.

incidence rate for the exposed is *X* divided by 10,000 (10,000 being the total of those in cells *a* and *b*). Among the unexposed, *Y* developed the same disease (cell *c*) and 10,000 − *Y* did not (cell *d*). The incidence rate among the unexposed is therefore *Y* divided by 10,000. Dividing *X* over 10,000 by *Y* over 10,000 gives the relative risk. Because both groups had the same denominator, this particular *relative risk* simplifies to *X*/*Y*. In real life, that seldom happens. Furthermore, the denominator is not people but person-time (i.e., sum of all individuals' times each person's follow-up time in the study).

Hypothetically, the investigators might have found that 50 individuals among the exposed developed the disease and only 10 among the unexposed (Figure 11.5). After inputting these numbers into the table, the resultant calculations would produce an *relative risk* of 5. The exposed had five times the risk of developing the disease as did the unexposed, assuming there was no selection, misclassification, or confounding bias and the finding was not a chance occurrence.

In a cohort study, those in both groups must be free of the condition at the start of the investigation. This implies that no one in either the exposed or the unexposed group is eligible until they are first examined and determined to be disease free. In other words, the first step of any prospective incidence study is, conceptually, a *cross-sectional* or

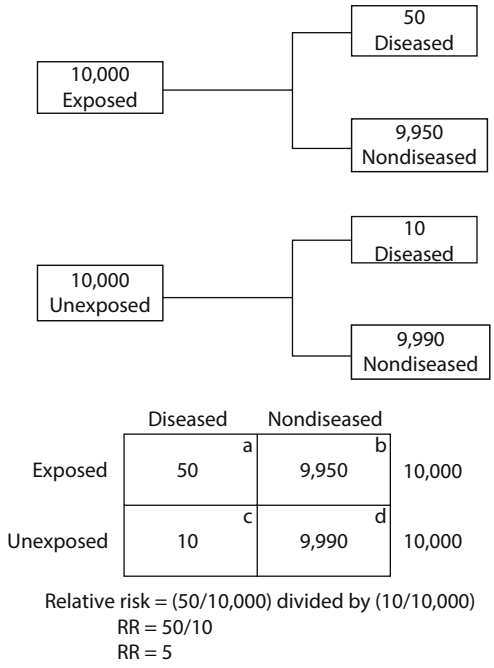

FIGURE 11.5 Illustration of the cohort method; RR = 5.

prevalence study. The data from this cross-sectional study, even though they are collected on two or more cohorts, cannot be used to make interpretations concerning etiology. They are prevalence data.

A cohort study can be a very labor-intensive process. The cohort has to be identified. Exposure histories have to be compiled and validated. Study subjects (or their next of kin) may have to be traced and contacted and data obtained on personal habits, hobbies, and a host of other variables. Medical records must then be collected and coded. Many things can complicate the process. All of this results in a study that is very expensive to conduct. Therefore, once a cohort is established, the study investigators, and their successors, try to follow the cohort for long periods of time. This is especially true when the incidence of disease is relatively infrequent. The use of disease registries (e.g., regional cancer registries) has assisted with disease identification through record linkage. However, most diseases are not found in registry systems. The amount of medical information can vary from person to person simply because of differences in healthcare-seeking behavior. The study subjects may have many different physicians, each providing a different level of care, possessing diverse diagnostic skills, and having office records with unique formats. Many states and municipalities have disparate rules governing access to government records such as death certificates. In addition, litigation and regulations may delay the process of data collection [8,10,38].

Case–Control

Cohort studies are not ideally suitable for the study of rare diseases. In the hypothetical example, 20,000 individuals were tracked to identify the 60 who actually got the disease.

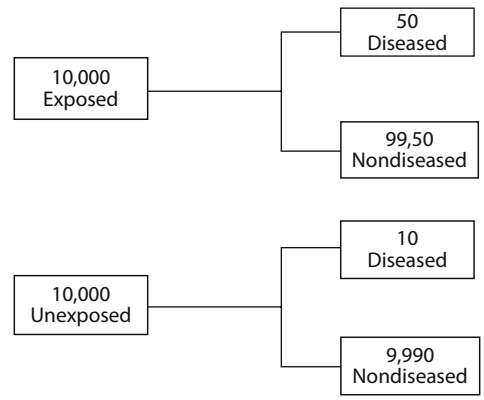
To overcome this and other inefficiencies of cohort studies, epidemiologists developed the *case–control* method. With case–control studies, the past exposures of those with some disease are compared to the past exposures of those who do not have the disease; for example, smoking histories might be compared between men who do and do not have lung cancer. Cases in the case–control approach could be the same as those included in the cohort design. Controls would be a sample from the source population from which the cases originated. If cases are a sample (e.g., 100% or a random sample) and controls are a random sample from the source population, then the case–control study is considered to be population based. This is considered the most ideal type of case–control study. Two important considerations for control selection are as follows: (1) controls need to be selected from the same source population that gave rise to the cases and (2) controls should be selected independently of their exposure status. Of course, the latter is also true for cases. Density sampling refers to the longitudinal sampling of controls based on the amount of person-time that a person is at risk of disease in the source population. In this regard, a case could be eligible to be a control up until the case's diagnosis.

If the cases originate from a medical database, for example, then the source population can be less clear and is defined as a secondary base. For example, an investigator could select cases and controls from the admission practices of a large hospital but the potential for biased selection of cases and controls becomes increasingly problematic. These are referred to as hospital- or clinic-based controls. Other types of control selections that may occur, when the source population is not defined, may include neighborhood and friend controls. It has been shown when cases are deceased, it remains preferable to use living, rather than dead, controls as the latter would not represent the exposure distribution in the general population.

Special types of case–control studies include nested case–control, case–cohort, and case–crossover studies. Briefly, a nested case–control study occurs within a cohort study, which allows for random sampling of both cases and controls. A case–cohort case–control study occurs when everyone within the cohort has an equal chance of being included in the study as a control regardless of person-time in the cohort. This design is often employed with several different types of cases using the same set of controls from the source population. A case–crossover study involves one or more pre- or postdisease time periods selected as the matched control period for the case. Since the case and control are the same individual, age, sex, and birthdates are automatically matched.

Because the study participants for a case–control investigation are first determined in the disease axis of the 2 × 2 table and data are then gathered on exposure status to fill in each of the four cells, the odds of past exposure are calculated, respectively, for the disease group and for the nondiseased control group. These odds are then compared to develop an OR. Because the magnitude of the OR in well-done case–control research closely approximates that of the underlying RR, it allows the interpretations of a case–control study to parallel those of the cohort method: An OR appreciably above 1 suggests a causal association between the disease and the exposure, an OR appreciably below 1 suggests protection, and a ratio near 1, plus or minus, suggests no association between the exposure and the disease.

If we go back to the hypothetical example, there were 60 new cases of disease in this closed population (Figure 11.6). Knowing the age, gender, race, and perhaps other key characteristics of the diseased, 60 nondiseased individuals could be randomly selected from the remainder of the 20,000. These 120 would constitute the bottom marginals of the 2 × 2 table, 60 in each column. Data could then be collected on past exposure. In this particular example, 50 of the diseased group would end up in cell *a* and 10 in cell *c*. Among the nondiseased, approximately 30 would end up in cell *b* and another 30 in cell *d*. Parenthetically, the nondiseased in each exposure category were approximately the same, 9,950 and 9,990; therefore, random sampling of 60 from the aggregate 19,940, should select equal numbers from each group: 30 and 30. With data in all four cells, the odds of exposure among



Odds ratio = odds of exposure among the diseased vs. the odds of exposure among the nondisease
Odds ratio = 50/10 divided by 30/30
OR = 5
The cross-product ratio is *ad* divided by *bc*
OR = 50 × 30 divided by 30 × 10
OR = 5

FIGURE 11.6 Illustration of the case–control method; OR = 5.

the patients would be 50–10 (5–1) and the odds of exposure among the controls would be 30–30 (1–1), giving an OR of 5. Conveniently, the calculations for case–control studies often simplify to a *cross product ratio* (*ad* divided by *bc*). In the example, 50 times 30 divided by 30 times 10 simplifies to 5.

All too frequently, it has become common practice by epidemiologists (and others) in reviewing the literature to describe ORs greater than one simply as a *positive association*—regardless of their magnitude or statistical significance. In part, this is done because the OR is dimensionless (as is the relative risk and the SMR). However, in reality, it must be remembered that the OR represents the odds for disease given a certain degree of exposure compared to the odds of disease for a lesser amount of exposure. With the advent of biomonitoring of low levels (parts per billion or lower) of environmental chemicals in humans, it is not uncommon to see ORs reported for quartile ranges of biomonitoring serum levels in the general population where such quartile concentration ranges are only a few parts per billion (ng/mL) or less. See Example 11.B.5 for such an instance related to subfecundity and perfluorochemicals. This practice ignores the actual comparison of two different odds based on an exposure level as well as the considerably much higher concentrations necessary to observe an adverse effect in toxicological studies. Thus, the sole use of the term *positive association* (or negative association) in the epidemiologic literature should be curtailed. By itself, this terminology poorly describes epidemiologic study findings and is therefore invariably misleading.

For this case–control study in Figure 11.6, an evaluation of just 120 individuals provided the same information as a study of 20,000. In the context of the time, effort, and cost, gathering data on such a limited number of study subjects can be a tremendous advantage. Paradoxically, the small size of the study can also be a problem because seemingly minor amounts of bias can have a dramatic impact on the OR.

Avoiding inadvertent bias can be more difficult in case–control studies because the health outcome has already occurred. If the investigators or the study subjects are not properly blinded, this knowledge can impact both who participates in the research and what data they provide. Social forces still may influence the results; for example, those with disease may be more inclined to participate in the research because they have a greater need to understand why they became ill. Also, the cases who selectively participate may expend greater effort toward trying to remember their past exposures and thereby provide more comprehensive or more valid data than the controls. This is called *recall bias*. It is a type of *information bias (differential misclassification)* that when present often leads to overestimates of risk.

Another methodological issue with a case–control study is that it may utilize a combination of prevalence and incidence data instead of just incidence data and thereby limit its utility for etiologic interpretations. Even with its limitations, a case–control approach can be very attractive. Because the two groups are initially defined on disease status, data on any number of exposures can be collected. As a consequence, a large number of different associations can be evaluated simultaneously and rapidly reduced to just a few that deserve further study. For that reason, an exploratory case–control study can be considered a disease in search of an exposure, the mirror image of the hypothesis-generating exercise done in a cohort mode.

A case–control study also can focus in depth on just one disease exposure association, testing a hypothesis derived from case reports or other types of research with much greater sophistication than might be feasible in a cohort study. In certain situations, it can be advantageous to use the cohort and the case–control approach in series to generate a relatively small and well-defined number of hypotheses. Such a *nested case–control study* can combine the strengths of both methods; for example, the cohort approach could be used to identify a cluster of disease within a broadly defined group, perhaps all those ever employed at a multiple-chemical-manufacturing facility, and a case–control study could then be implemented within the larger cohort not only to narrow the focus to those few agents that appear to be most important for that particular disease but also to do so with proper adjustments for confounding. This integrated approach, therefore, can achieve both efficiency and rigor.

Cohort and case–control studies are sometimes referred to as *analytic* research, in contrast to other types of epidemiology investigations that are simply *descriptive* of time, place, and person. In theory, the term *analytic* should be restricted to those studies designed to test a priori hypotheses, but in practice, it is often used more broadly to refer to any cohort or case–control research, regardless of whether it generates or tests hypotheses. That is unfortunate, because it blurs the distinction between these two important stages of discovery and the role each plays in the search for the causes of human disease.

Cross-Sectional

A study that ascertains its individual study subjects without regard to disease or exposure status is a cross-sectional study. These are relatively inexpensive endeavors compared to cohort and case–control endeavors and the study findings can be quickly ascertained and reported. The cross-sectional study examines prevalent cases since there is no longitudinal component to a cross-sectional study. Because disease and exposure information are obtained at the same time, it is not possible to examine an exposure response temporal relationship. Be aware that all too frequently investigators pay brief homage to this critical limitation in the discussion of their cross-sectional study but ignore it as they try to make etiological inferences from associations generated from other temporally challenged cross-sectional studies. Another important consideration is that in cross-sectional studies, the cases tend to be selected from individuals with longer duration of disease. Cases with shorter duration are less likely to be sampled at any point in time. This is called *length-biased sampling*. Should exposure influence the duration of the disease, then erroneous inferences are a logical consequence.

Ecologic

An ecologic study is when the unit of analysis for the exposure is generally described as an index of exposure for a group and the disease outcome is a mortality or incidence rate for that group or population [92]. The unit of analysis is not the individual. A classic example of an ecologic study relates national or regional mortality and incidence rates with per capita consumption of dietary food groups that show *western diets* are either associated or not associated with specific types of disease. Ecologic measures may be classified into three types: (1) aggregate measures of observations derived from individuals in each group, (2) environmental measures that are physical characteristics of the place in which members of each group live or work, and (3) global measures that are attributes of groups for which there is no similarity at the individual level. Ecologic studies can be an important study design used by environmental epidemiologists who may utilize geographic information system (GIS) in their analyses. The ecologic fallacy is the well-known bias that can arise from ecologic studies. An association observed between variables at a group level does not necessarily reflect the biologic effect at the individual level [92]. The lack of knowledge regarding heterogeneity of exposures and covariates within groups is also problematic. As a result, analyses at a group level may result in vastly different conclusions than analyses performed by individuals within the group.

Case Studies or Case Series

Hypotheses for analytic epidemiology may originate from toxicology studies or from epidemiology investigations, but many evolve from clinical observations and are published in the form of *case studies* or *case series*. Although based a great deal on intuition, a case study is a time-honored way for a clinician (e.g., physician, veterinarian, dentist) to develop new theories about the causes of human disease. It has been said with some justification that every human carcinogen was first identified by an astute clinician who published his or her findings in the form of a case study or case series. Nonetheless, that does not mean case studies can be used to unerringly identify new etiologic associations. Although the theories derived from case studies are not always wrong, history teaches that they are seldom right [11,40,112]. Determining which is which depends on data developed by others using experimental, quasi-experimental, and observational research. If we go back to the 2 × 2 table, we can see why.

To test a hypothesis about a new cause for human disease (to identify an elevated risk in analytic epidemiology research), data are needed in all four cells of the 2 × 2 table—data that are properly defined on both variables. Case studies tend to focus just on those in one of the four cells: cell *a*, the exposed with disease. Very little if any data are gathered by the clinician on those in each of the other three cells. Furthermore, those from whom data are gathered are a *convenience sample*. They probably are not a representative sample of any well-defined group, especially not a representative sample of the source population from which they arose—irrespective of their exposure history. They are not because physicians tend to direct their efforts toward diagnosing and treating those with medical problems.

In Figure 11.7 examples a through c, the three 2 × 2 tables represent the three possible types of association. In the first, the 50 in cell *a* translates to an RR of 5; in the second, the 30 to an RR of 1; and in the third, the 20 to an RR of 0.5. The three relative risks have very different meanings. Although it is conceivable that any clinician practicing in a community might become suspicious if a cluster of 3 or so patients came to him or her with the same rare disease and all had a similar exposure history, based on the information available, the clinician would not be able to determine whether the cluster was a subset of those in cell *a* from Figure 11.7a, b, or c. Most clusters, however provocative, yield few scientific insights [113]. Furthermore, additional case reports do not satisfy the need for replication and confirmation. Once a testable hypothesis has been formulated, additional case reports proposing the same hypothesis contribute nothing. The fact that cluster investigations offer few scientific insights does not mean, however, that some type of interaction with the concerned public should be ignored. As Bender and colleagues [11] aptly stated, an appropriate public health response to a cluster inquiry from the public should be *responsibly responsive*.

By way of example, in the silicone breast implant controversy, it was originally hypothesized that women who received this medical device were at increased risk for

Example a. Relative risk is 5

	Diseased	Nondiseased	
Exposed	50	9,950	10,000
Unexposed	10	9,990	10,000
	60	19,940	20,000

Example b. Relative risk is 1

	Diseased	Nondiseased	
Exposed	30	9,950	10,000
Unexposed	30	9,990	10,000
	60	19,940	20,000

Example c. Relative risk is 0.5

	Diseased	Nondiseased	
Exposed	20	9,950	10,000
Unexposed	40	9,990	10,000
	60	19,940	20,000

A physician sees three patients with the condition and all three were exposed to the same chemical, leading him to conclude that the disease in all three was caused by the chemical exposure. Is he correct?

FIGURE 11.7 Case studies and case series.

breast cancer. The theory was based on clinical observations, and concern was increased because of an animal toxicology study that demonstrated an Oppenheimer effect, the tumorigenic properties of foreign bodies as observed in rodents [20,52,91]. As a result of subsequent research, both experimental and observational, something between Figure 11.7b and c is now thought to most closely approximate the association between silicone breast implants and human breast cancer. It is being theorized that these medical devices or the materials from which they were constructed offer some type of protective effect against breast cancer [23,127]. The current data-based theory is in exact opposition to the hypothesis originally derived from the case reports.

Interestingly, no action has been taken on this information. Why? Probably because even though the epidemiology study results have been reasonably consistent and demonstrate coherence with the findings of the experimental animal research and the public health implications of such an association could be profound considering both the frequency and the life-threatening characteristics of the cancer, the underlying biological mechanisms of protection have not been identified.

ISSUES

The objective of an epidemiologic study is to produce a valid and precise estimate of the effect of an exposure on the occurrence of disease in the studied source population [66]. Validity refers to the accuracy of the estimate of an effect. Accuracy reflects two sources of error: random and systematic. Random error reflects the precision of the estimate of effect. A larger sample size (study population) results in a lower amount of random error and therefore higher precision. Systematic error reflects the biases incurred by the study design, study conduct, and data analyses. Systematic errors affect validity regardless of the study sample size. Fewer systematic biases generally reflect the greater the validity of the estimate of effect but the magnitude of error from different systematic biases should not be viewed as equal. Internal validity refers to that within the source population. External validity (generalizability) refers to the inferences considered outside the source population to another target population. There are three categories of violations to internal validity: selection bias, information bias, and confounding. Information bias is a function of nonrandom measurement error and is oftentimes referred to as misclassification.

Everything in the scientific literature must be read with a degree of healthy skepticism [107]. This can be difficult enough within a single field, but it is truly a daunting task when a scientist tries to evaluate the merit of work from a different discipline yet alone with epidemiology, which often encompasses multidisciplinary teams of researchers. If a toxicologist understands the basics of data, measures of disease frequency, measures of association, and methods, the epidemiology literature can be screened using the mantra of *selection*, *information bias (misclassification)*, *confounding*, *chance*, and *causation*.

The order of this mantra is important. If obvious systematic errors (biases) are related to selection, information, or confounding, it may make very little sense to spend time trying to evaluate the merit of the investigators' statistical analyses, much less to assume the findings have any biological meaning. It is no accident that the scientific literature has a highly stylized format: some variation of abstract, introduction, methods and materials, results, discussion, and conclusion. This format allows the reader to rapidly focus on the key components of the work. If the authors provide a one-sided presentation of the topic in the introduction, supply insufficient detail regarding their methods and materials, or do not critique their own work in the discussion—pointing out the potential biases of selection, information, and confounding and how they were addressed—the reader should exercise considerable caution before accepting either the results or the conclusions, even as provisional truth. A guide (see Appendix A) was written, entitled Strengthening the Reporting of Observational Epidemiology (STROBE), whose objective is to allow for better clarity of epidemiology research findings (as written by the author) and understanding of epidemiology reports (as read by the consumer) [134,136].

Selection

In epidemiology, *bias* is used to denote a deviation from the truth but not necessarily to imply that the deviation was intentional [7,132]. *Selection bias* refers to errors that are related to systematic differences between those who are and are not selected in a study. Even if the data gathered are valid for those who are examined, it may be inappropriate to use any information derived from the data for purposes of extrapolation to a larger population; for example, the results of a study of hormone replacement therapy among women cannot logically be extended to men. In epidemiology research, various types of selection bias can be introduced by the study subjects, the investigators, or even traditional medical practice and other social forces.

Self-selection occurs in both clinical research and some epidemiology studies. It is well recognized that those who participate in controlled clinical investigations, that is, those who actually sign informed consents, may not be representative of the general population; therefore, even with randomization of treatment, care must be taken before extending the study results too broadly. A similar problem occurs in observational studies in which some type of active participation, some type of action on the part of the study subjects, is required. For example, informed consent is required for any epidemiology study in which biological samples are collected. Usually, the more invasive the procedure, the more disinclined are the potential subjects to participate and the greater the potential for bias; however, in other situations, this bias may be less obvious or, paradoxically, so obvious that it is largely overlooked. As an example, how many times have you received a questionnaire in the mail and, rather

than responding, tossed it away? By doing so, you introduced a potential *participation bias* into that investigator's work, the potential for which may not be acknowledged in the final report.

In certain types of observational research, self-selection is not a problem. Projects that can be conducted without the active cooperation of the subjects often are able to achieve close to 100% follow-up; for example, occupational cohort mortality studies that utilize personnel records and industrial hygiene reports to identify the exposed and death certificates to document the cause of death can be conducted with little or no self-selection [98]. However, whether the information provided has relevancy is a different question. Using death certificates to study conditions that have high survivorship lacks scientific justification.

The same arguably holds for some studies that utilize medical records, but only if the medical records relate to the total health experience of a well-defined population. Such is the case in certain countries with socialized medicine in which all the hospital and clinic records are available for the entire citizenry. The Scandinavian countries are well known for their record linkage systems that are founded on a personal identification number at birth that is used throughout life to link to numerous computerized health care, income, work history, education, and residential databases.

Either intentionally or not, investigators can introduce selection bias when they decide who to study, especially if they make a greater effort to obtain participation among the exposed more than the unexposed, or the diseased than the healthy. Figure 11.8 is an advertisement that appeared in a Kansas paper in the late 1980s. It apparently was placed by investigators who wished to identify more subjects for a research project and thereby improve its statistical power. What they presumptively did not recognize was that by recruiting simultaneously on both health outcome (non-Hodgkin's lymphoma [NHL]) and exposure (2,4-dichlorophenoxyacetic acid [2,4-D]), they would introduce a significant selection bias into their work, one potentially so severe as to possibly invalidate any of their findings.

A spuriously elevated relative risk can be predictably found in any research in which the study subjects are selected on the joint characteristics of the condition of interest and the putative agent of concern. This is also referred to as Berkson's bias [12]. People with multiple diseases will be overrepresented in a hospital population compared to the general population according to the laws of probability. A spurious association can then be obtained because of the different probabilities of admission to a hospital for those with the disease, without the disease, and with the characteristic of interest.

WANTED
Kansas farmers suffering from non-Hodgkins lymphoma especially those exposed to herbicides such as 2,4-D. Needed to interview for research article. Please send name, address, and phone number to Box P7629 Classified Dept., The Star, 1729 Grand, K.C., MO 64108.

FIGURE 11.8 Recruitment of study subjects.

Figure 11.9 illustrates the dynamic that leads to *Berkson's bias*, a particular type of selection bias that occurs as a result of the patterns of referral, either self-referral or physician referral [57]. Although there is some merit in asserting that the 250 individuals who initially consulted a physician represent those with the more definitive illness among the 1000 in the population at risk and thus are legitimate subjects for etiologic research, it is less likely that the same thing can be said about the 5 referred to a specialist or the 1 who finally ended up at a university center. Patients seen by specialists or at tertiary referral centers include a disproportionate number whose disease is complicated, obscure, or atypical. A spuriously elevated relative risk will predictably be found in any research in which the study subjects are selected on the joint characteristics of the condition of interest and the putative agent of concern.

Even if no formal study is conducted, the specialist may develop a marked suspicion concerning the presumptive cause for the condition and then act on that presumption. Once it becomes known in the community that a physician or a referral center is interested in patients with a particular condition, especially when it occurs in conjunction with exposure to a specific agent, additional referrals or self-referrals further compromise the value of the sample for etiologic research [125]. Ironically, the more caring the physician in the sense of being more willing to provide therapy to those who have been unsuccessfully treated or refused treatment by others, the more that physician becomes a magnet for these patients.

In evaluating the literature, the reader needs to ask two questions related to selection bias: Was the sample that the investigators were attempting to study truly representative of some larger group? Were the researchers successful in getting participation from all or a large majority of those they sought to study? An individual epidemiology report probably will have little or no value if the answer to either question is *no*. The operative term in the previous sentence is *probably*. It is important to note that not every potential selection bias is real; therefore, studies with less than 100% participation should clearly not be dismissed as meaningless. The question is how does one determine whether or not a study with less than optimal participation provides relatively unbiased results? Usually, one cannot make that determination from the single study. The question can be addressed in the context of the larger body of literature. If the results of the potentially flawed study are comparable with those of other work in which selection bias is a lesser concern, the consistency suggests a cross validation of findings. On the other hand, if the results of

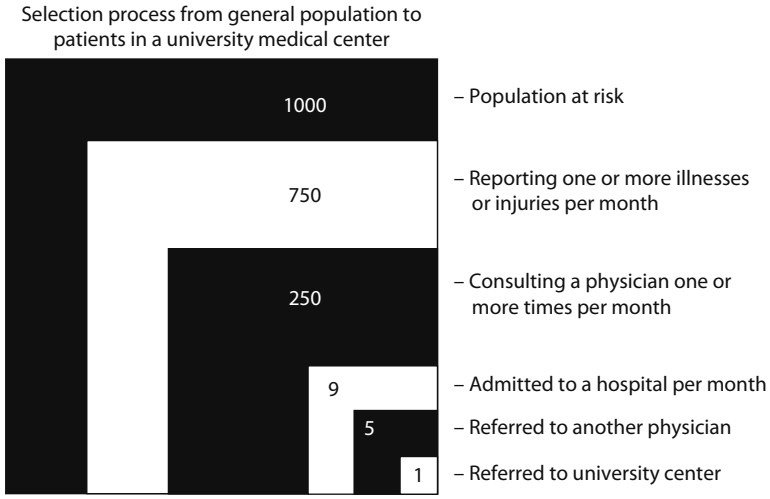


FIGURE 11.9 Berkson's bias: potential selection bias by referral. (From Gehlbach, S.H., *Interpreting the Medical Literature*, McGraw-Hill, New York, 1993. With permission.)

multiple studies are markedly different, it raises concern that the findings of one or more of the reports are biased.

Information Bias

Information bias, also known as *measurement* or *misclassification bias*, is a systematic error arising from the inaccurate measurement or inappropriate classification of subjects on the study variables—either exposure (to the putative agent or confounder) or health outcome. At some level, all measurement or classification is inaccurate. The errors may be large or small, and, in turn, depending on the use to which the data are put, these errors may be important or meaningless. As an example, in measuring blood pressure, some physicians routinely round up to the next increment of 5 (e.g., 140 mmHg systolic and 90 diastolic or 145 and 95), others round down, and still others record to the closet unit of 2. The experienced clinician tends to make these measurements consistently on the same two of the five Korotkoff sounds, but which two may vary from physician to physician [54]. These variations from the true blood pressure probably have very little importance in the clinical setting if the patient is consistently measured and treated by the same physician, but they could be very important if treatment is provided by multiple physicians. They also could be important if the clinical data were used to judge the relative efficacy of a variety of treatments as administered by different physicians.

Epidemiologists are concerned whether the misclassified information is the consequence of the disease or exposure [66]. In the most basic 2 × 2 terminology, a variable is misclassified on a dichotomous exposure (yes/no) or disease (yes/no) level. Classification error that depends on the actual values of other variables is referred to as differential misclassification. Classification error that does not depend on the actual values of other variables is called nondifferential misclassification. Misclassification can occur within exposure or disease. For example, individuals classified as exposed may not be exposed and individuals classified as nonexposed may be exposed.

Nondifferential misclassification of a dichotomous exposure will always bias an effect toward the null value (i.e., toward a relative risk = 1.0). If there are several categories of exposure, the nondifferential misclassification, however, may be biased toward or away from the null value depending on the categories to which individuals were misclassified. Differential misclassification of exposure could either increase or decrease an apparent effect. It is not readily predictable without further investigation. Nondifferential misclassification is the more prevalent condition. Be wary of epidemiologic studies whose investigators confuse the lack of knowledge of differential misclassification (due to lack of any investigation of it within the study) as reason to believe the measures of effect reported had to be biased toward the null due to the more likely presence of nondifferential misclassification. A lack of data to investigate differential misclassification is an inadequate excuse to noncritically accept as fait accompli nondifferential misclassification in any epidemiologic study.

One of the most common types of information bias is *recall bias* that occurs in case–control studies. Cases and controls may recall past exposures differently due to their disease and nondiseased conditions. Because of their disease, cases may spend considerable time pondering why they were diagnosed with their condition. Independent of any research study, the cases may question their immediate and distant past history for suspected possible (exposure) causes. In this Internet age, ready access to global search engines makes information and opinions readily available to cases and their relatives from medical professionals, patients, consumers, and advocates. Controls, on the other hand, would unlikely go through the same recall experience until questioned in a research setting. The time and energy spent on such recall by a control is likely to be considerably less than the case.

Example 11.B.2 reviews recall bias through the differential recall by type of respondents for the agricultural use of the phenoxy herbicide 2,4-D. This recall was dependent on the type of respondent for cases of NHL in a series of case–control studies conducted by the National Cancer Institute (NCI) [27,28,73,143]. Interviews conducted of the next of kin of NHL cases recalled greater 2,4-D exposure use than interviews of living NHL cases. The controls were interviewed directly as they were not deceased; thus, differential misclassification of exposure occurred likely due to recall bias by the type of respondent.

An epidemiologist might use various techniques to avoid or reduce the potential misreporting. Concealing the intent of the research from the study subjects is one, but such blinding of subjects is increasingly difficult to use in a climate of mandated informed consent and almost instantaneous dissemination of news about the latest health controversy. Another approach is to add a dummy health variable whose association with the exposure is biologically implausible; for example, a query about dental caries could be incorporated into a study evaluating the effects of exercise on angina. If a strong correlation exists between the frequency with which the study subjects reported the dummy variable and the health outcome of concern, one should suspect a misreporting problem. In such a situation, it may be necessary to validate the reports—perhaps, if feasible, by examining a subset of the respondents or via review of medical records that predate the controversy or by use of a biological marker such as saliva cotinine for cigarette smoking [83,111,137].

At a minimum, the processes by which the data were collected should be well defined. Even then, there could be problems. It is well recognized by the seasoned researcher that mechanical or electronic instruments of assessment periodically must be calibrated to ensure a consistency of measurement over time. To achieve validity, they must be calibrated to an external standard. The application of other data collection tools such as questionnaires may be less than rigorous. With survey instruments, the order in which the questions are posed can be important. Even if the questionnaire is not open-ended, the words themselves may have alternative connotations for different ethnic or racial groups. To the extent possible, epidemiology research should use tools whose strengths and limitations are well recognized or should incorporate a validation pilot into the research project.

Diagnostic bias, a type of observer bias, occurs when a physician's diagnosis is influenced by his or her knowledge of certain exposures or surrogates of such exposures. In a study of eosinophilia–myalgia syndrome, Wagner et al. [138] found up to a sixfold increase in diagnosing the condition when physicians were told the patients had ingested L-tryptophan even though use of this dietary supplement was not part of the definition for the condition.

Similar biases occur in toxicology research, both nondifferential and differential. The traditional acceptance of tumors, benign and malignant, as a surrogate for cancer is one form of misclassification. In well-conducted studies, it probably is nondifferential, but any time the methods for disease determination differ between the exposed animals and the controls, it could be differential. For example, if more histopathological slides are made or read for the exposed animals than the controls, it is more likely that small occult tumors will be found among the exposed. This is differential misclassification, one that would introduce an overestimate of risk.

Sensitivity and Specificity

Consistency (i.e., precision) of measurement, although important, does not ensure the absence of measurement bias, whatever its underlying cause. As illustrated in Figure 11.10,

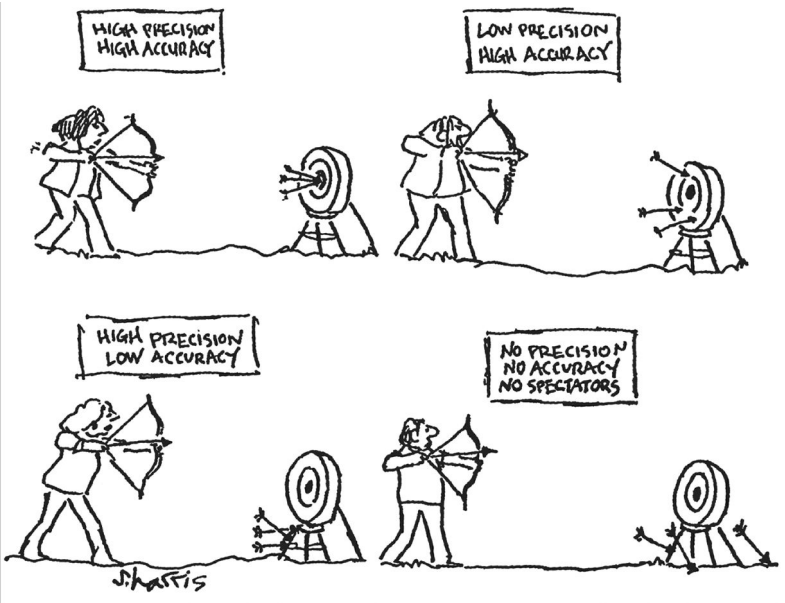

FIGURE 11.10 Precision and accuracy.

it is possible to be precise and precisely incorrect. What is more important is accuracy (i.e., the validity of the data). The key measures of validity are *sensitivity* and *specificity*. Sensitivity is a measure of how well the test identifies a true condition (disease or exposure). Specificity is a measure of how well it documents a true noncondition (the absence of disease or exposure).

It is actually more complicated than that. A number of tests used in medicine, such as blood cholesterol or antinuclear antibody status, do not clearly separate the normal individuals from those who are abnormal [124,128]. The distribution of values in each group overlap (Figure 11.11). In such situations, the operational diagnostic break point between the two can be somewhat arbitrary. It can be set to identify all the true abnormals (point a; all the true positives) but only by accepting a certain number of false positives—incorrectly labeling some normal individuals as abnormal. Or the break point could be moved to correctly identify all the true normals (point b), but only at the expense of getting more false negatives—misclassifying some of the abnormal patients. In other words, where the break point is set can impact the sensitivity and specificity of a test, and if sensitivity is improved, it may mean the specificity has been compromised and vice versa. For example, one could arbitrarily declare all chemicals human carcinogens. Such an error on the side of caution would certainly correctly label all the true carcinogens and would guarantee a sensitivity of 100%, but the specificity of such a strategy would be abysmal because the number of false positives would be huge.

Note that to determine the sensitivity and specificity of a test, its results must be compared to those of a *gold standard*, an accepted test or procedure that reliably determines the presence or absence of the condition. Why then is it necessary to have the new test? Why not just use the gold standard? The new test may be needed because the gold standard is not as useful a tool in the clinical setting. It might be more expensive, inconvenient, invasive, or dangerous.

Paradoxically, data gathered by means of a gold standard actually might have little utility for etiologic research in and by itself but still may be important for the development of tools that can be used in such investigations. For example, explantation (the surgical removal of a medical device such as a breast implant) is considered the gold standard for implant rupture; however, for both technical and ethical

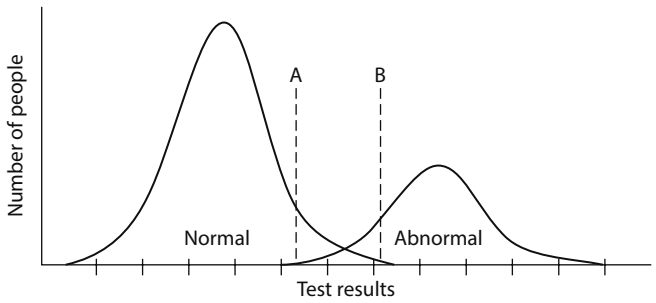

FIGURE 11.11 Sensitivity versus specificity.

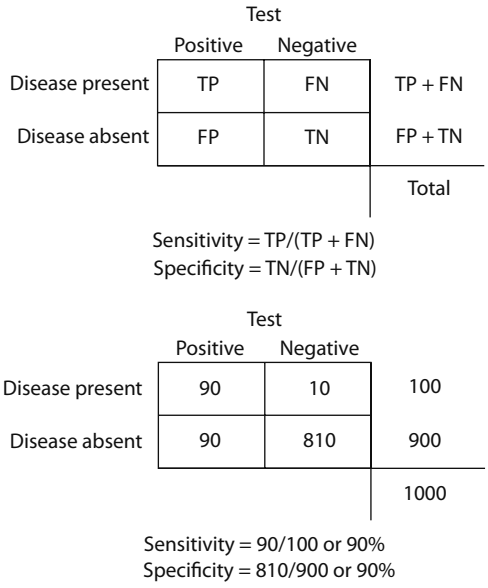

FIGURE 11.12 Sensitivity and specificity.

reasons, it can only be used to collect prevalence data. Other noninvasive techniques such as mammography, ultrasound, and magnetic resonance imaging (MRI) can collect incidence data and at lesser risk to the patient, but the relative validity of each can only be established via the gold standard of explantation.

Given that there is a suitable gold standard, Figure 11.12 shows how these measures are calculated. In the figure, TP is true positive, FN is false negative, FP is false positive, and TN is true negative. Sensitivity is obtained by dividing TP by (TP + FN) and specificity by dividing TN by (FP + TN). For this particular example, the sensitivity and specificity are both 90%, quite good for most clinical tests [112]. Sensitivity reflects how well, given that the condition is actually present, the test detects the condition. Conversely, specificity is a measure of how well, given that the condition is really absent, the test does not erroneously document its presence.

Predictive Value Positive and Predictive Value Negative

In real life, whether or not the condition is actually present is unknown before the test is performed. That is the reason for doing the test! For most investigations, what is of greatest interest is the predictive capabilities of a test: how well, given the test result is positive or negative, it respectively predicts the presence or absence of the condition. These measures, *predictive value positive* (PV+) and *predictive value negative* (PV–), can be obtained by making calculations in the vertical axis of the 2 × 2 table (Figure 11.12). In this example, the PV+ is 50% and the PV– is 98.8%. What this indicates is that among those who are diagnosed as having an illness on the basis of an abnormal test result, only 50% of them are truly diseased, but among those whose test result was in the normal range, 98.8% are actually healthy.

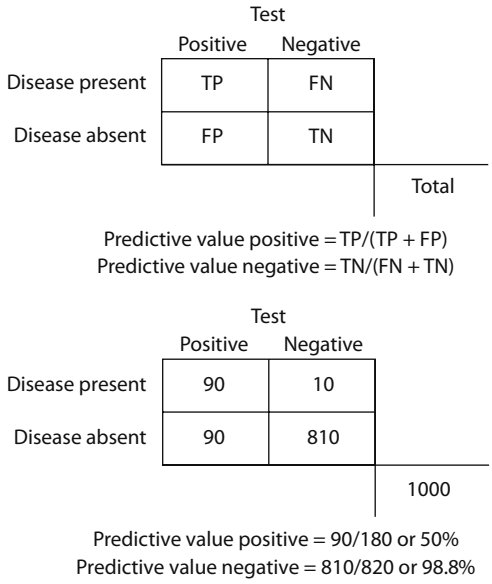

FIGURE 11.13 PV+ and PV–.

The two sets of measures are related but not equivalent. Although the sensitivity and specificity are relatively stable attributes of a test, the predictive values vary widely as a function of the background frequency of the condition being studied. Figure 11.13 illustrates this point. For a given test, the less frequent the condition, the lower the PV+ and the higher the PV–. When the disease frequency drops to 1 in a 1000, the PV+ is less than 1%. In other words, if used as a screening tool the test would label patients as abnormal incorrectly more than 99 times out of 100. This interplay between the underlying validity of a test and the relative frequency of the condition being studied not only impacts epidemiology, but it also has important implications for medical surveillance (and the government regulations that mandate, fund, or otherwise support such procedures) as well as toxicology, in particular as it impacts risk assessment.

A blue-ribbon panel of experts, for example, recommended that routine mammography screening be restricted to women over 50 or those in high-risk groups. In both, the frequency of breast cancer is orders of magnitude higher than it is in the general population of younger-aged women. This recommendation ignited a fire storm of controversy, and the panel, in part apparently due to pressure from congress, subsequently modified its recommendation to include younger women [48]. This may prove to be a mistake. Predictably, what will happen is that the medical system will be flooded with false positives [46] (Figure 11.14).

Given:
Sensitivity = 90%
Specificity = 90%

Disease frequency	PV+	PV–
1 in 10	50%	98.8%
1 in 100	8.3%	99.9%
1 in 1000	0.9%	99.99%

FIGURE 11.14 Predictive values as a function of disease frequency.

False-positive breast cancer screening tests among younger women have a number of downsides. One, a false-positive test can severely frighten patients, and many among those subsequently told the test was incorrect will retain a lingering anxiety at the very least. Two, an abnormal mammogram is often checked by means of a biopsy; this surgical procedure is associated with a certain small but predictable risk of infection, bleeding, loss of sensation, and adverse reactions to anesthesia, and for women without breast cancer, it is an unnecessary risk. Three, false positives put a strain on our medical care delivery system and misdirect limited resources. Four, procedures that produce false results cost money, a financial burden that must be borne by the individual patient in the form of direct payments and by society at large in the form of increased insurance premiums and higher taxes. Five, and arguably of greatest importance, some young women after one, two, or more false-positive reports may lose confidence in the procedure. A certain number of these will drop out of the mammography program and never reenroll. This means that they will not get the screening test later when they would benefit from it most.

The results of toxicology studies are not immune to this problem, in part because their results are routinely extrapolated to humans. If a high dose of an agent is found to cause tumors among rodents, it is current policy to assume that it will cause some form of cancer in humans at lower levels of exposure. Unfortunately, although the sensitivity of toxicology research is quite high (but not perfect), its PV+ for extrapolations between different species of rodents is low, on the order of 50% in a study of various chemicals purposefully selected because of their presumed carcinogenicity [75]. Arguably, its PV+ is even lower for humans, especially for chemicals being tested simply to satisfy a mandated protocol.

Descriptive epidemiology research, such as that done by Robinson et al. [109], focuses on a single group. Nonetheless, misclassification obviously can produce erroneous information. In analytic epidemiology, the problem is compounded because data are gathered on and compared between two or more groups. This can lead to errors that are either *nondifferential* or *differential* (Figure 11.15).

Given:
True relative risk = 1 (i.e., background incidence rate is equivalent in the exposed and the unexposed)
Differential misclassification fixed
Sensitivity and specificity among the exposed: 95% and 90%, respectively
Sensitivity and specificity among the unexposed: 90% and 95%, respectively

Background incidence rate	Apparent relative risk
10 per 100 per year	1.9
1 per 100 per year	5.5
1 per 1000 per year	9.2

FIGURE 11.15 Risk estimates in the presence of differential misclassification.

Confounding

Confounders are the extraneous factors that explain or produce all or some of the difference between the measure of association and the measure of effect that would be obtained with a counterfactual ideal [65]. In a research study, this difference may be an overestimation or underestimation of the measure of effect in disease frequency between the exposed and unexposed.

A confounder has three necessary characteristics:

1. A confounding factor must be an extraneous risk factor for the disease.
2. A confounding factor must be associated with the exposure under study in the source population.
3. A confounding factor must not be affected by the exposure or the disease. It cannot be an intermediate step in the causal path between the exposure and the disease.

Confounders can either be directly measured or a surrogate for a confounding factor. Age, for example, is a surrogate for a constellation of biological, environmental, and social factors that individually and in aggregate are associated with increased risks to certain diseases. The same can be said for race and ethnic background. Different confounding factors have different effects. None is a universal confounder.

In addition to being an alternative cause, the second necessary characteristic requires a confounding factor to be associated with the exposure under study in the source population. As with the biases related to selection and misclassification, the degree of differential distribution of the confounder between exposed and unexposed determines the direction and magnitude of the error. In addition, the relative potency of the confounder can also, to a greater or lesser extent, influence the apparent relative risk or OR. Cigarette smoking, for example, is one of the major determinants of lung cancer. An epidemiology study investigating the carcinogenic potential of a particular exposure vis-à-vis lung cancer has to take smoking into consideration as a possible confounder.

Smoking is also associated with mortality due to cardiovascular disease, but not to the degree to which it causes lung cancer. In other words, equivalent amounts of unequal distribution between the two study groups may not have the same impact on the measures of risk for different conditions because the potency, the biological activity of a confounder, varies from disease to disease. With lung cancer, smoking equates to a relative risk of perhaps 10, whereas for cardiovascular mortality, the relative risk lies closer to 1.5; for still other diseases, it has an RR that approximates 1 (no effect).

Very few diseases have only one etiology. Even a rare malignancy such as angiosarcoma of the liver has a number of alternative causes aside from vinyl chloride monomer [49]. Agents with high potency are relatively easy to discern. It is those with lesser biological activity that are more difficult to identify. An indeterminate number of the latter undoubtedly have not yet been discovered. Theoretically, because all of the causes for the various diseases are unknown, some level of confounding may occur in any epidemiology study (and any toxicology study for that matter). In addition, it is highly likely that there are synergistic and antagonistic actions between various agents, both exogenous and endogenous, further complicating the picture.

The third necessary factor of a confounder, it must not be an intermediate step between exposure and disease, is met if the confounder precedes exposure and disease. However, this may not be readily discernable.

A confounder is not the same as an *effect modifier*, although an agent, depending on the study, can be one, both, or neither. Effect measure modification produces a nonuniformity of effect across various levels of the effect modifier [65]; for example, the consequences of exposure to pathogenic organisms vary by immunization status. Under the assumption that study biases have been adequately controlled, analyzing for statistical interactions is considered a method for analyzing effect-measure modification. However, statistical interactions are not straightforward as interactions observed in additive models (linear regression) would not necessarily be apparent in multiplicative models (e.g., logistic regression). Because statistical interactions are a result of measure or scale and the model chosen, they should not be confused with biological interactions, which refer to a mechanistic action.

As with exposure and disease, confounders can be misclassified. Nondifferential misclassification of a dichotomous confounder causes a bias in the direction of the confounding variable. The result will be between the unadjusted association and the association that would have been obtained if the confounder had not been misclassified. This is referred to as residual confounding and occurs when the stratum of a confounder is overly broad and/or open-ended (e.g., age ≥65). Confounding can occur within the stratum. Therefore, more narrowly defined strata reduce residual confounding. Differential misclassification of confounders also occur with less predictable results—similar to differential misclassification of exposure and/or disease. The differential misclassification of a confounder may result in adjusted associations that are not even within the range of an unadjusted and correctly adjusted association.

Confounding can be addressed through study design or data analysis, or a combination of both. The former may be accomplished by randomization, restriction, or matching. Randomization can only be performed in experimental studies (e.g., clinical trials). As an example of restriction, if smoking is a confounder for a particular disease (i.e., those who smoke get the disease more frequently than those who do not smoke, but those who do not smoke still get the disease), confounding by smoking can be dealt with by restricting the study subjects (both those exposed to the putative agent and the controls) to just those who never smoked. This design strategy simplifies the analysis and interpretation of the data, but it also restricts how broadly the results can be extrapolated. If only nonsmokers are studied, the results derived from the sample usually only apply to the

larger population of nonsmokers. Comparable information about smokers must come from another study restricted to exposed and unexposed individuals, all of whom smoked. *Matching* of potential confounders (e.g., age, race, gender, smoking) is an intuitively attractive way of addressing confounding that combines elements of both study design and data analysis; however, it is not a panacea [114]. Not only may it be difficult to do properly, but it also places certain constraints on the types of information that can be developed. Also, it may lead to overmatching (i.e., to matching on surrogates of exposure or health outcome) [57]. Matching may be accomplished by individual subjects or by frequency of groups.

Alternatively, if a certain number of subjects is being evaluated and it is known that a proportion of those in the exposed and unexposed groups were smokers, controlling for confounding could be attempted at the data analysis stage of the research, possibly by means of a *stratified data analysis* whereby different strata of smokers are analyzed and the results combined across strata. The other statistical technique would be through the appropriate regression analyses based on study design.

No matter what method is used to prevent or control confounding (e.g., stratification, covariate adjustment, matching), decisions about which specific potential confounders might be important must be made at the stage of protocol development, if for no other reason than to ensure that adequate data are collected. Obviously, it would be impossible to adjust for smoking during the analysis stage of the research if no data concerning cigarette smoking had been collected. Therein lies an excellent reason to draw a causal diagram as part of the protocol development (see section on *Causal Inference*). In experimental studies, the number of variables is purposefully kept to a minimum and ostensibly all of them are under the control of the investigators. Those who conduct observational studies of humans do not have the same advantages. The number of variables is limited only by life itself. Each participant in an epidemiology study has his or her own unique genetic makeup and own unique pattern of extraneous exposures (e.g., diet, medications, personal habits). Although either or both may be only weak confounders for a particular health outcome under investigation, they may be one reason why epidemiology research, especially any single study, has difficulty in reliably identifying putative agents with lesser biological potency, with true relative risks less than 3 or so. This is because even in the absence of selection and misclassification biases, the signal may be swamped by the noise of uncontrolled confounding. In epidemiology, the signal-to-noise ratio is improved via more research, especially more targeted research. As the exposure–disease associations become more focused, the relative risks should increase in size. If they do not, be suspicious of claims of causation. Also, be suspicious of etiologic interpretations based on one study unless supporting evidence is available.

Confounding is not restricted to epidemiology research. It also occurs in toxicology; for example, Hart and associates [68] have explored the impact of feed intake in laboratory animals. They noted that animals fed ad libitum have poorer health and longevity than those whose diet has been restricted. The total caloric load appears to play a role, but trace contaminants may also be important. As reported recently by Paolini and colleagues [101], most standardized diet formulations used by cancer research laboratories worldwide "contain the well-known mutagenic carcinogenic element manganese at the same level and, in some cases, at an even higher level (up to ninefold) compared to that used to study the carcinogenicity of manganese itself." Obviously, the more animals they eat, the higher their caloric load and the higher their dose of this carcinogen; however, the amount ingested could be an unintended consequence of the experiment (e.g., ever larger amounts of the test chemical mixed with the feed may make the feed less and less palatable). For those experiments in which ingestion varied by dose level of the experimental agent, it is quite possible that the results reflect a measure of confounding and perhaps effect modification. Paolini et al. [101] also summarized a number of problems using historical controls; for example, "$B6C3F_1$ mice have a higher natural incidence of tumors than humans, and this incidence has also changed over time, increasing in excess of 50% over a period of just 10 years."

Although it is impossible to consider all possible confounders in any single study, the reader of epidemiology reports should determine whether attempts were made to control for those factors that likely would have had the greatest impact on the results. As with other types of potential bias, a paper can offer a number of clues as to how well this issue was or was not properly managed. If confounding was ignored or obviously inadequately addressed, be skeptical of the information. Look for confirmation in other work that did try to minimize confounding.

Chance

Within the mantra of selection, information bias (misclassification), confounding, chance, and causation, the rubric *chance* covers all things mathematical and statistical and some that are methodological. For example, did the investigators add, subtract, multiply, and divide properly? Were the numbers of subjects consistently the same in the abstract, results, discussion, and tables? With much more complex statistical procedures, it is possible for even the most seasoned epidemiologist to inadvertently ignore a key assumption and thereby produce erroneous results. If numbers are inconsistent within a report, do the authors explain why? And, if they do, does the explanation seem appropriate? If the answer to either question is no, then look for confirmation of the results elsewhere. Or look for a correction published as an errata in a subsequent issue of the journal.

Also, determine how the data were aggregated for analysis. Does it make sense, in particular, biological sense? By way of example, in 2001, investigators affiliated with the Food and Drug Administration published a study entitled *Silicone gel breast implant rupture, extracapsular silicone, and health status in a population of women* [25]. This paper has been represented as demonstrating a causal association between *leaking silicone gel implants* and fibromyalgia (FM) [144]. The original article, its conclusions, and subsequent interpretations have been severely criticized for a variety of reasons [19,45].

For the purposes of this discussion, the point of interest is how the investigators chose to make their key comparison. Through the use of explant surgery, they determined the prevalence of implant status among women with breast implants (no women without implants were included in the research). Three categories of exposure were defined: extracapsular rupture (obvious silicone adjacent to or remote from the outside of the tissue capsule that surrounds every implant), intracapsular rupture (silicone outside the medical device but apparently confined inside the tissue capsule), and intact implants. The authors reported a statistically significant excess (OR, 2.8; 95% CI, 1.2–6.3) of self-reported symptoms consistent with FM, but only when they compared the complaints of women who had extracapsular rupture with those in the aggregate group who either had intracapsular rupture *or* intact implants.

It was pointed out in subsequent letters to the editor that the strategy made no biological sense. As one critic noted, "…if an association exists between implant status and FM, one would hypothesize … the true gradient would be: intact < intracapsular rupture < extracapsular rupture." Reformatting the data presented in the paper so that ORs not reported in the published paper could be calculated, he noted that the OR between FM and ruptured status reached statistical significance largely as a consequence of the way the comparison group was structured [19]:

> The OR between FM and extracapsular rupture (compared to intact devices) is 1.88 and not statistically significant. The OR between FM and intracapsular rupture (compared to intact devices) is 0.50 and also not statistically significant. The OR for any rupture versus intact devices is 0.87 … the largest difference in FM risk is between extracapsular and intracapsular rupture. If a gradient in risk exists, these data seem to suggest a gradient for FM that is: intracapsular rupture < intact < extracapsular rupture … suggesting that intracapsular rupture may protect women against FM!

p Values, Confidence Intervals, and *p*-Value Functions

A major difference between toxicology and epidemiology is in the use of *p* values to describe research findings. Unlike toxicology journals, epidemiology journals often inform its contributors that *p* values are not to be used except in certain circumstances (e.g., tests for trend). Whereas toxicologists will almost always offer measures of variation (e.g., standard deviation) to accompany their point estimates (e.g., arithmetic means), epidemiologists prefer the use of *confidence intervals* for their point estimates (e.g., relative risks, ORs). Why such differences between the two disciplines? A satisfactory explanation requires understanding random error—assuming the biases of systematic error have been controlled—a large assumption indeed.

By definition, a *p* value is the statistic obtained from hypothesis testing. It is the probability, *assuming the null hypothesis is true*, that the obtained study data are as far (or farther) from the null hypothesis than that observed. In experimental studies, the hypotheses that are tested are primarily formulated a priori. The *p* value is conditional on the null hypothesis, which is usually the following: there is no relation between exposure (treatment) and disease. Small *p* values are consistent with the rejection of the null hypothesis. *p* values of 0.05 or 0.01 are often (arbitrarily) used to reject the null hypothesis; however, the null hypothesis could still be true, despite the low *p* value. If the *p* value is above this arbitrary value, the null hypothesis is not rejected; however, the null hypothesis could still be false, despite the higher *p* value. Under either circumstance, the *p* value does not offer an estimate of the random error in the point estimate.

A confidence interval, still set at an arbitrary level usually 95% or 90%, provides precision around a point estimate. A 95% confidence interval of a point estimate (e.g., OR) implies that if the study (data) could be hypothetically obtained many more times, the interval within the confidence limits should include the *true value* 95% of the time. Assumptions include that the only difference in the repeated studies is chance in the collection of data and systematic biases are not present. Although in observational epidemiologic research such assumptions are impossible to fulfill, the confidence interval still provides an estimate of the precision of the data. Wide confidence intervals indicate imprecise point estimates. Narrow confidence intervals indicate the opposite. Neither though prove the validity, or lack thereof, of the data. Some epidemiologists use an informal statistical hypothesis test by stating that if the null hypothesis (e.g., OR = 1.0) is not included in the confidence interval, then the findings are *statistically significant*. However, this is essentially no different than a test of the null hypothesis but at least the width of the confidence interval is still provided to examine precision.

Ideally, a *p*-value function (or confidence interval function) could be offered for important point estimates [104]. Unfortunately, available journal space per article prevents this practice although technical reports could offer it. A *p*-value function plots various *p* values (*y*-axis) for a range of hypotheses with the estimates of effect (*x*-axis) (e.g., relative risk, OR). The shape of the curve results in a visual of the strength of the association and precision. Nested confidence intervals can then be read from the curve; therefore, the reader could better understand a range (indeed an infinite range) of confidence intervals, not just an arbitrary one (e.g., 95%).

As noted previously, a study result may have a wide confidence interval and still be valid. A result from a small study relatively unbiased by selection, misclassification, and confounding

may be more valid than the result from a larger study that has a narrower confidence interval. Although the former may have limited utility in and by itself to support or refute causation as a consequence of its low power, when combined with the results of other studies of comparable quality, it may prove to be very valuable. This is the rationale underlying *meta-analysis.*

Exploratory Data Analysis and Multiple Comparisons

Scientific discovery is not a destination. It is a journey with many side trips along the way. It starts with a hypothesis, a theory whose genesis may be any number of things ranging from the subjective (clinical observations that seem unusual for intuitive reasons) to the super quantitative (statistically significant findings derived during *exploratory data analysis* of a large medical dataset, such as the health claim files of a private insurance company or of Medicare/Medicaid). Before these findings can be accepted as even provisional truth, they have to be confirmed by additional research, preferably well-focused hypothesis-testing research.

In both hypothesis-generating and hypothesis-testing exercises, the same statistical tools and the same levels of statistical significance may be used; yet the findings of the former do not carry the same interpretive weight as those from the latter. That's because the former, in addition to uncontrolled confounding, are subject to a *multiple comparisons bias* [129]. Exploratory statistical analyses of large and diverse datasets that may selectively report only those results that support their own theories are viewed as post hoc reasoning [90,120,129]. Because few comparisons are presented, the reader is given the erroneous impression that only those few were considered and therefore they must have been of some a priori concern. Investigators who are guilty of post hoc reasoning are sometimes derisively called *Texas sharpshooters*. In most target shooting, one shoots at a preexisting bull's eye. The Texas sharpshooter first shoots at the side of the barn (perhaps from very close to the building) and then draws the bull's eye around the holes.

The statistical tests used in health research factor in both a type I and a type II error. A type I is the error of rejecting a null hypothesis, of concluding that a difference exists when, in truth, it does not. By convention, the alpha level (the probability of a type I error) is usually set at 0.05 (which equates to a 95% CI). This means that a certain predictable number of statistically significant findings are incorrect, about 1 in 20. The greater the number of comparisons, the greater is the number of spurious associations that may be found (i.e., the larger is the multiple comparisons bias). Various techniques have been developed to address this bias, the simplest perhaps being the *Bonferroni correction* in which the putative alpha is divided by the total number of comparisons and the *corrected alpha* is used to determine the presence or absence of statistical significance [88]. For example, if the study alpha level was preset at 0.05 and 10 comparisons were made, a Bonferroni-corrected 95% CI would, in essence, be a 99.5% CI. This method has many detractors who argue that much more suitable methods are available to address multiple comparisons especially those incorporating Bayesian statistics where specifying a *prior* is required in the analytical computation of the posterior distribution [63]. Besides the *prior* input parameters, the other input is a function that shows the probability of the observed data for any given set of parameter values (i.e., the likelihood function). In other words, assign a level of probability to the premise of the prior argument. The *posterior* probability will depend on what was used as the *prior* probabilities. A range of disparate *priors* will eventually converge into similar *posterior* probabilities in the face of consistent data. Toxicologists should expect to see more Bayesian analyses presented in the epidemiology literature in the future.

In summary, even the most precise results may be wrong, a consequence of simple mathematical errors, technical bias, or less innocent intent. Although exploratory data analysis is a valuable tool, more is not always better. This maxim applies equally well to epidemiology, toxicology, and clinical medicine (Figure 11.16). To be interpreted properly, the results of tests must be put in the context of the size of the dataset, the number of tests that were performed, the body of knowledge that is already available, and, if possible, the mind-set of the investigators at the inception of the research.

You seem to be in fine health but let's run a few tests.
I'm sure we can find something wrong with you.

FIGURE 11.16 Multiple comparisons bias in clinical medicine.

The latter may be obvious from the introduction of the paper or from the protocol, but sometimes, it can only be surmised.

Meta-Analysis

Meta-analysis refers to the use of statistical tools to combine the results of different studies. Originally, it was confined to randomized controlled clinical trials, to combining results of multiple small studies of the equivalent design (i.e., those with identical dosing regimens and comparable, well-defined outcomes). It is increasingly being used to aggregate the findings of multiple epidemiology studies, even when their results were derived by means of disparate methods (e.g., cohort and case–control studies), the sample sizes varied by orders of magnitude, the categories of exposure differed, and the disease outcomes were similar but not equivalent [14]. Although some decry the use of meta-analysis for this purpose, others view it as an important adjunct to the traditional, more subjective literature review. Essentially, is the primary purpose of meta-analysis to produce a combined estimate of effect that, when done properly, has a narrower confidence interval than each individual study or is the primary purpose of meta-analysis to identify the heterogeneity in study results? The more insightful answer is that understanding the reasons for the heterogeneity of the estimates of effect is indispensable to understanding the literature, regardless of whether a meta-analysis estimate of effect is calculated.

Meta-analysis is not the same as *data pooling*. Whereas meta-analysis depends on the research results as obtained from epidemiology reports, pooling refers to the aggregation of the actual raw data from many different studies and the subsequent analysis of this larger, single dataset. Conceptually, pooling has some advantages over meta-analysis, but in practice, it also has a number of disadvantages, a major one being access to the data. Unlike meta-analysis, where the results have been distributed publicly via the scientific journals, data are not as readily available. In part, this is because of concerns related to protecting the privacy of individual study subjects and the confidentiality of their data [9].

The validity of a meta-analysis is dependent on the validity of the studies included in the exercise. To address this problem, some have suggested that a priori rules must be established with respect to which studies to include or exclude. Unfortunately, these rules may reflect the personal biases of the one doing the meta-analysis. For that reason, a type of sensitivity analysis is arguably a better approach [102]. In this type of analysis, the results of all available studies are first evaluated together and then various combinations are used to better understand how the different methods, number of study subjects, classifications of exposure, or definitions of health outcome may have influenced the calculations. It can even be used to compare and contrast the results of different studies that may have different types of bias and to explore whether potential bias is a likely explanation for why one or just a few of the studies seem to be outliers. If a comprehensive sensitivity analysis is conducted and the results published, readers also have the opportunity to make their own interpretations, something that can be difficult to do with the traditional literature review or even with pooling.

One particular type of bias to which both literature reviews and meta-analyses are particularly susceptible is *publication bias*. Publication bias is a type of selection bias. It refers to the tendency of authors to submit and editors preferentially to accept studies with provocative positive findings [7,42,77]. This has also been referred to as *positive results* bias. Should these results ultimately be shown to not be causal, the findings are considered to be false-positive results. Example 11.B.4 recaps the simmering debate within epidemiology circles regarding false-positive and false-negative results and their role in publication bias. A number of different approaches can be used to assess the possibility of publication bias, but the best way to avoid it is to aggressively search for pertinent research reports, including those in the form of dissertations, abstracts, and publications in obscure journals [107]. The use of funnel plots allows the meta-analyst to visually examine for symmetry of the available studies [126]. In a meta-analysis, the funnel plot is a graph of the estimates of risk for every study with their corresponding precision (standard error). Publication bias may lead to an asymmetrical graph if smaller studies that lack effects are not included in the meta-analysis.

Causation

Understanding disease etiology depends on a complex, iterative course of inquiry called the *scientific method* [131]. To quote Hazen [69], "The scientific method is an elegant process for learning about the natural world, but it is neither intuitive nor obvious." This method can be idealized as a cycle of observation (data collection), synthesis (data analyses), hypothesis (reasoned conjecture based on the interpretations of patterns derived during the data analyses, often as interpreted in the context of other information), and prediction. The prediction then has to be tested (sometimes referred to as the hypothesis-testing stage of scientific inquiry) with a new round of observation and synthesis, providing results that, given they replicate the original findings, reinforce the initial hypothesis. Alternatively, the results might not support the hypothesis, in whole or in part; therefore, the original hypothesis might be dismissed outright or modified and retested by means of a new round of prediction, observation, and synthesis. This goes on until there is some level of consensus that a provisional truth has been identified. As a rule of thumb, the more provocative the association, the more imperative the need to replicate the findings.

It is important to recognize that the prediction must be constructed in a form that is both unambiguous and refutable; therefore, although the hypothesis may be stated as "exposure to agent *X* is associated with an increased risk to disease *Y*," the prediction has to be stated in the null (i.e., exposure to agent *X* will not be followed by an increased risk of disease *Y*) and the null refuted. Refuting the null lends support for the hypothesis, but in science, the default is always the null; consequently, a theory of cause and effect may be disproved by an unfulfilled

prediction, but it can never be completely proved—thus the caveat about *provisional truth*. Alternatively, an anomaly (an exception to a prediction) may lead to new insights; for example, it may suggest a prediction that restricts causal actions of agent *X* to higher levels of exposure.

It is also important to recognize that at the core of any scientific inquiry is the prevailing expectation about the workings of the natural world. For example, the current paradigm regarding dose–response for carcinogens is (1) linear and (2) nonthreshold. This paradigm is now being challenged. For example, Calabrese [26] has shown that for a large number of chemicals, both attributes of the current paradigm are wrong, particularly at lower ranges of exposure. This indicates a necessary reevaluation of the current paradigm in risk assessment and risk management.

Causal Inference

A causal mechanism has many component causes [117]. For example, a concussion incurred by someone hitting his forehead against the car windshield could have the following components: (1) driving too fast, (2) not wearing a seatbelt, (3) talking on the cell phone, (4) distraction by a passenger, (5) oncoming car not dimming their lights, (6) alcohol, (7) turning the radio to a different station, (8) poor brake pads, (9) driver not wearing corrective lenses, and (10) inexperience at driving a motor vehicle. Both genetic and environmental (nongenetic) components may apply. On a population basis, some of these component causes are more strongly associated with the adverse event, whereas some are weaker causes. Some of these components are likely to have interacted such as driving too fast and poor brake pads resulting in a longer distance required to stop. Because of these interactions, the sum of component causes attributable to an effect (disease) is greater than 100%. Bottom line: diseases have multifactorial etiologies. A sufficient cause is defined as those minimum components necessary for the effect (disease) to occur.

The induction period is defined as the period of time beginning at the first component cause and ending when the final component cause acts and the disease (concussion) occurs. Although it appears in the aforementioned example that most component causes occurred simultaneously, the poor eyesight occurred well before this accident and is likely genetic. Thus, induction period is not readily known for many diseases including cancers. The latent period is defined as the time frame from disease occurrence until its detection. In the instance given earlier, the concussion might have occurred immediately but was not detected for a few hours or days. In the case of cancer, component causes result in the initiation and promotion of cancer. The cancer may not be detected, however, until there are marked clinical symptoms (abdominal pain). Or the cancer is detected much earlier via a colonoscopy. Epidemiologists often combine these two time periods in their data analyses (induction–latency period) since they may not be individually well defined.

It is beyond the scope of this brief review to discuss causal inference theory. Scientific philosophies have revolved around inductivism, refutation, consensus, and Bayesianism [117]. As important as understanding causal theory, the toxicologist should familiarize himself with the use of causal diagrams. To draw a causal diagram, it is critically important to distinguish causal relations from associations. Causal diagrams allow nonmathematicians to graph causal relations among the exposure, outcomes, and covariates. Example 11.B.5 shows how researchers determined, through the use of a causal diagram, that an association between concentrations of serum perfluoroalkyls measured during pregnancy and time to pregnancy (TTP) (i.e., subfecundity) was, in fact, the likely result of the interpregnancy interval (which included TTP) affecting the serum perfluoroalkyl concentrations and not vice versa as proposed by the original investigators, otherwise referred to as *reverse causation*.

Establishing causal inference, the weight of evidence inferring that exposure to a substance can cause an effect in humans, is a common goal of epidemiology and toxicology. Adami et al. [1] noted that a principle underlying the philosophy of science is that causality cannot be *proven*; it can only be inferred with different degrees of certainty. Hill introduced a list of nine aspects of associations that should be considered before inferring causation [72]. Often erroneously referred to as the Bradford Hill criteria (guidelines is a more appropriate descriptor as stated by Hill), several of these aspects benefit from evidence that may be collected in toxicological investigations (Table 11.1).

Even when selection, information bias (misclassification), and confounding are minimal, identification of the causes of human disease is not simply an exercise of calculating which exposure–disease associations are statistically significant. Sir Bradford Hill, a British statistician/epidemiologist, presented his guidelines for subjectively considering causation in the mid-1960s [69]. They are still in wide use although with increasing reservations. In interpreting data, he noted that an investigator must deal with two basic problems: *significance* (the statistical reliability of a finding) and *inference* (the interpretations one might make from such a finding). With the former, he cautioned against either over- or underinterpreting the importance of statistical significance—noting that, if absent, *chance is not an unlikely reason* for an apparent difference, for an apparent association, or for an apparent elevated relative risk, but, if present, *chance is still a possible, though unlikely, explanation*. He also advised that conclusions related to a new

Reasoning by analogy

finding have to be *more guarded* and stress the *limitations* of the data (size of the sample, potential for bias, etc.). As for inference, he offered nine criteria for differentiating between *causation or merely association* when faced *with a clear and significant association between some form of sickness and some feature of the environment* (Table 11.1).

Despite the widespread use of these guidelines, the nine points have been criticized as misguided and epidemiologists have not agreed on a set of causal criteria [116]. Nor are they likely to do so. For example, scientific refutation of causal hypotheses (inferences) could be considered a more meaningful approach [116]. Nevertheless, these nine points offered by Hill are popular and often cited in review papers. Therefore, a brief explanation is in order despite the sound reservations offered by others. *Strength of the association* refers to the size of the relative risk or OR. *Consistency* refers to the finding of similar relative risks for the same condition and exposure in different epidemiology studies conducted by different investigators on different groups of participants. *Specificity* suggests that elevated risks should be to a single or small number of well-defined health problems. *Temporal relationship* means exposure precedes disease. If the disease occurs before the exposure, it cannot have been caused by the exposure. *Biological gradient* refers to dose–response. *Biological plausibility* depends on the biological knowledge of the day. Some consider this necessary to prove causation; others do not. They are satisfied if a meaningful association is found for a risk factor even if the exact causal agent and the process by which it works are unknown. *Coherence of the evidence* is the amalgamation of what is known concerning the natural history and biology of the disease, the presumptive actions of the etiologic agent, the results of experimental research on animals, and the contributions of other types of information. The evidence can come from within a single study or across studies from many different disciplines. The next attribute was *experiment*, but not necessarily in the context of a laboratory experiment. He also considered the removal of the presumptive etiologic agent a type of experiment. *Reasoning by analogy* refers to the situation where if agent *X* can cause disease *Y*, perhaps a material similar to *X* can cause a disease comparable to *Y*.

From a toxicological perspective, Hill's second viewpoint, consistency of the association, while referring primarily to epidemiological associations, can be strengthened if observations from toxicological studies support the causality assumption. The fourth aspect, temporality, must be achieved and can be strengthened by toxicological investigation, which, by its nature, is prospective and designed to evaluate cause and effect. Biological gradient, or dose–response, is Hill's fifth aspect, and dose–response data from toxicological studies can strengthen the interpretation of exposure–response from epidemiological studies, where quantitation of exposures may be more uncertain. Hill's sixth, seventh, and eighth aspects, respectively referring to biological plausibility, coherence with *generally known facts of the natural history and biology of the disease*, and experimental evidence, all may benefit from the results of toxicological experimentation. With respect to experimental evidence, Hill stated that "Here the strongest support for the causation hypothesis may be revealed." Thus, toxicological evidence can make a strong contribution to the process of inferring causation from associations observed in epidemiological studies.

Inferring causation is an uncertain process, and the degree of uncertainty can be reduced by considering the results of both epidemiological and toxicological investigation. Serving a purpose similar to Bradford Hill's viewpoints, from a toxicological perspective, frameworks have been developed to consider human relevance of toxicological observations, and the REACH guidelines have provided a framework for assessing health hazards and derived no effect levels (DNELs) and derived minimal effect levels (DMELs) based on *animal* and human data. These previous frameworks have been valuable in structuring the manner in which experimental observations are placed in perspective for the risk assessment process. However, a process that consciously aims to integrate the observations from epidemiology and toxicology has been lacking until recently.

Building upon previous work [18,33,80,81,121], Adami et al. [1] have provided a framework for integrating toxicological and epidemiological data in evaluating potential causal inference. Their five-step process, called *Epid-Tox*, includes (1) collection of all data, (2) assessment of data quality, (3) evaluation of the weight of evidence, (4) assignment of a scalable conclusion, and (5) placement on a causal inference grid. This process, leading to the casual inference grid and one of four descriptors for potential causality, is best visualized from their paper, reproduced here as Figure 11.17. The grid itself from Adami et al. [1], reproduced herein as Figure 11.18, includes an *x*-axis on which to place causal inference evidence from epidemiological investigation, from *against* to *for* going from left to right, as well as *y*-axis on which to place biological plausibility based on experimental data, from *low* to *high* going from bottom to top. The grid is divided into four quadrants, with an area allocated to *insufficient information* for placement occurring in the center. The four potential causality conclusions corresponding to the four quadrants are *likely*, *uncertain* (based on strength of the epidemiological association but lack of biological plausibility), *uncertain* (based on plausibility from toxicological studies but lack of evidence in epidemiological investigation), and *unlikely* (both epidemiological and toxicological evidence infer a lack of effect). Adami et al. provide several examples of the application of the Epid-Tox process, and the reader is encouraged to consult these examples.

Any process used to infer causality based on the integration of epidemiological and toxicological data should be considered iterative in time. It is important to remember the observation provided by Hill [72] at the end of his article:

> All scientific work is incomplete - whether it be observational or experimental. All scientific work is liable to be upset or modified by advancing knowledge. That does not confer upon us a freedom to ignore the knowledge we already have, or to postpone the action that it appears to demand at a given time.

Legal Causation

At one time, courts tended to disregard epidemiology as simply a statistical exercise that provided information of little probative value; however, within the last 20 years, it has become key to the legal theory of causation as used in the particular type of litigation that deals with tort or product liability [13]. Epidemiology research helps establish not only whether an agent is causally associated with a particular disease but also whether the association supports a finding of *more likely than not*. This equates to an attributable risk percent (AR%) of greater than 50% and, with knowledge of the relative risk (RR), can be calculated with the following formula: AR% = (RR − 1)/RR. For example, a relative risk of 3 would equate to an attributable risk percent of 67%.

As mentioned earlier, the various calculations regarding attributable risk have no meaning until causation for human disease is established—however, that is temporarily accomplished. In theory, therefore, an exposure–disease association has four characteristics that must be demonstrated before a claim of causation logically can be accepted in legal deliberations: (1) The putative agent must be a known cause of the disease, (2) the causal relationship must be more likely than not, (3) the plaintiff must have been exposed to the agent in adequate quantity and for sufficient duration, and (4) the plaintiff must have developed the appropriate disease after the exposure. The first two deal with *general causation*. The last two pertain to *specific causation*. In tort liability cases, the plaintiff has the burden to prove all four, at least in theory. Trials are emotional events and jury deliberations can sometimes be more influenced by the subjective than the objective.

Prior to the 1993 Daubert decision, juries were the triers of fact and judges basically functioned as the umpires of the proceedings [39,53,106]. They made rulings regarding process but few about content. The Daubert case changed that [39]. After a series of appeals that went all the way to the supreme court, judges were given the additional responsibility of serving as *gatekeepers*. Juries retained the role of triers of fact, but judges were charged with determining which body of facts were relevant and reliable versus which were simply junk science—which testimony would assist the jury in their deliberations and "whether the 'probative value' of the testimony substantially outweighed the risks of prejudice, confusion or wasted time" [74]. In practice, this means federal judges now must decide which expert witnesses can and cannot testify and what opinions they will be permitted to convey to the jury. Many state courts are also moving toward a process based on the Daubert principles.

Some courts have done an impressive job in rendering judgments that have included sophisticated legal arguments well infused with scientific principles. Others have accomplished the same result with the help of outside experts employed directly by the court, an option acknowledged in the Daubert decision. Still others at the state level have yet to apply the Daubert principles, in part because some judges feel uncomfortable with their new role and in part because the new rules technically pertain to just the federal judiciary [43].

Lawyers and judges, even at the federal level, are still exploring the limits of the gatekeeper function and how certain statistical and epidemiologic thought might be translated into legal concepts. As an example, statistical significance means that a finding has a lower confidence limit above 1; that is, there is some assurance that the estimate of risk is different than 1. The legal notion of *more likely than not* requires a relative risk above 2, but it is unclear whether the key finding, to be admissible, has to be statistically significantly different than 1 or statistically significantly different than 2. When there is just one or a limited number of epidemiology studies, the latter makes more sense; however, the former is not inconsistent with epidemiology opinion when a large number of reasonably valid studies have similar results.

Clinical Causation

Neither epidemiology causation (what Sir Bradford Hill called *medical causation*) nor legal causation should be confused with *clinical causation*. The primary goal of clinical medicine is diagnosis and treatment. In a sense, the major reason for a diagnosis is to predict which treatment will most successfully reverse, eliminate, or control a patient's troublesome symptoms or signs of pathology. If the diagnosis is correct, the resulting treatment works and the patient is well served. If not, the patient likely gets no better, possibly gets worse, or even may develop additional adverse outcomes as a result of the inappropriate therapy.

Experienced clinicians are adept at the technique of *differential diagnosis*. Through the use of various signs, symptoms, and test results, and factoring in the risks inherent to alternative treatments, they identify the most probable diagnoses, weigh the merits of each, and use the resultant information to help select a treatment that likely will be most successful. If that particular treatment does not work, they move on to the next most likely diagnosis and a different treatment and, if that does not work, to still another, continually balancing benefit and risk.

When clinicians speak of searching for the *cause* of a patient's problems, they usually are referring to identifying the most likely diagnosis, quite possibly one whose underlying mechanisms of action are unknown. Arguably, knowledge regarding the underlying cause of a particular disease is only important in the clinical setting if it materially impacts treatment decisions—for example, if a specific type of bacterial pneumonia is more efficaciously treated by a particular antibiotic—and the underlying causes are not initially discovered by the process of differential diagnosis. Such knowledge is derived from experimental animal research, controlled clinical investigations, and observational epidemiology studies. Contrary to what some clinicians have asserted, differential diagnosis, no matter how sophisticated, does not obviate the need for etiologic research [5,58,62,108]. As the many programs of the National Institutes of Health demonstrate, research regarding cause and effect and that related to diagnosis and treatment are complementary but not equivalent.

Parenthetically, proper diagnoses are made by means of pattern recognition, by what Margolis has called *habits of the mind* [87]. Within the context of clinical causation, this has a number of implications. One, the more extensive a physician's training and experience, the larger the number of mental templates he or she acquires against which he can compare the next patient's combination of signs, symptoms, and test results; thus, even if the underlying etiology for a condition is unknown (i.e., the condition is idiopathic), a physician may develop successful strategies for treating the syndrome. Two, this knowledge, no matter how prodigious, is always finite. Physicians recognize this. They specialize so they might concentrate their energy on developing in-depth knowledge within one sector of medical practice, and even within that specialty they refer patients to their peers, a tacit acknowledgment that another physician may be better suited to diagnose and treat a particular individual. Three, because the number of templates increases as a direct result of experience, the more seasoned the clinician, the greater the clinician's ability to diagnose and, paradoxically, the greater the potential for a multiple comparisons bias. The latter is reflected in case reports.

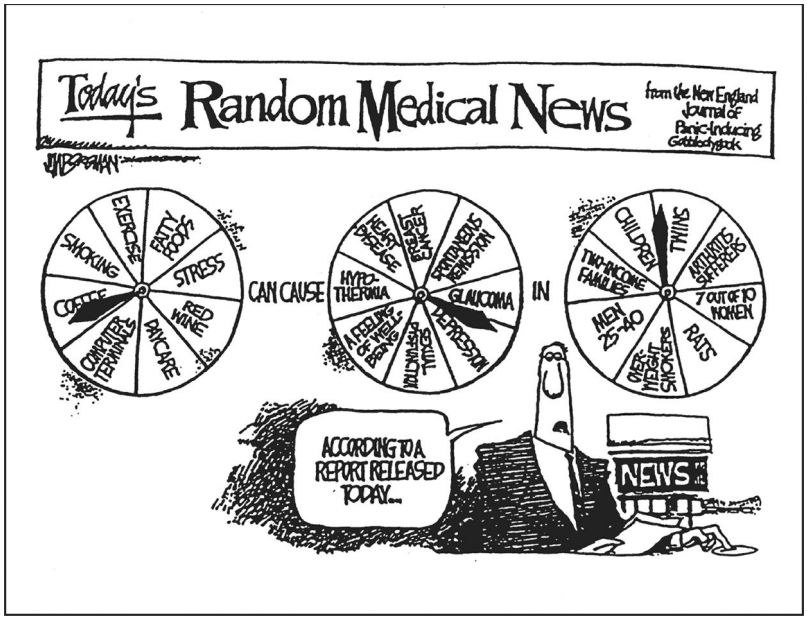
CONCLUSION

As de Grasse Tyson noted in his essay, *Certain Uncertainties*, "The frontier of science is a messy place" [41]. As a consequence, to the uninitiated, science appears to provide contradictory and therefore unreliable findings, regardless of whether the research is experimental, quasi-experimental, or observational, but perhaps more so for the latter (Figure 11.19). Part of the reason for the apparent inconsistencies is related to technical bias (selection, information, and confounding), but part is due to overinterpretation of the findings of any single study, either by the study investigators or by the consumers of research reports.

One of the primary goals of any scientist should be the elimination of bias from his or her research. The first step is to acknowledge that various types of bias exist, the second is to understand how they occur, and the third is to develop methods and procedures to avoid, minimize, or control bias. Over the years, well-trained epidemiologists have found ways to address potential error and improve the validity of their research. The same can be said for toxicologists and clinical investigators. The scientific method has been core to all of these endeavors.

The scientific method is one of the major discoveries in human history [24,133]. It has allowed mankind to gain a more objective view of the universe, to better understand the workings of the atom, and to successfully identify the causes of disease and with that understanding to treat, control, and even eliminate some of the major scourges that once were endemic worldwide. Unfortunately, the scientific method can be laborious, inconvenient, time consuming, and expensive. The temptation to take shortcuts can be great, but history teaches that shortcuts often just lead to further confusion [119]. Identifying the truth can be difficult enough even in the best of circumstances, but it is impossible with biased data, inappropriate methods, or muddled logic. Without a doubt, the scientific method does not lend itself to today's instantaneous news cycle with 30 s sound bites.

One of the responsibilities of the technical journals is to screen research papers and determine which have sufficient rigor in data, methods, and interpretation to warrant publication; however, scientific investigation is a human endeavor and peer review an imperfect process, so biased studies still



By Jim Borgman

FIGURE 11.19 Today's random medical news. (Copyright 1997, The Cincinnati Enquirer, Cincinnati, OH. Reprinted with permission of King Features Syndicate.)

get published, even in the best of journals. And what is the *best* journal? One that has high *impact factor* that is an inherently flawed statistic unto itself [70,71]? For that reason, in epidemiology research, no matter where it is published, the ultimate judgment regarding the value of any single report or group of reports will have to be made by the consumer: the epidemiologist, toxicologist, physician, lawyer, judge, newspaper reporter, or other member of the general public less well versed in the scientific method. This chapter provides a conceptual framework whereby basic understanding of epidemiologic findings might be critically understood by the toxicologist. Within a basic understanding of epidemiology data, measures of association, and methods, this critical assessment is based on the mantra of selection, information, confounding, chance, and causal inference. All are important in determining the validity of epidemiologic studies.

QUESTIONS

11.1 What is the difference between prevalence and incidence?
11.2 Describe two methods used in epidemiology.
11.3 What is literature bias?
11.4 Define sensitivity and specificity.
11.5 What are the three necessary characteristics of a confounder?
11.6 What can be learned from a meta-analysis?
11.7 Are the Hill guidelines for causation universally accepted?

ACKNOWLEDGMENT

The authors gratefully acknowledge the assistance of Gail Olsen in the preparation of this document.

APPENDIX A

STRENGTHENING THE REPORTING OF OBSERVATIONAL STUDIES IN EPIDEMIOLOGY (STROBE) STATEMENT

The Consolidated Standards of Reporting Trials (CONSORT) statement was originally designed to improve the quality of reports of randomized trials [134,136]. Subsequent types of initiatives followed including guidance on how to report data from observational research. To accomplish the latter, an initial workshop was held in 2004 that ultimately produced, 3 years later, the published document *Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) Statement*. Initial financial support for this initiative was obtained from the European Science Foundation.

The STROBE statement should be viewed as a guideline to assist authors when writing reports of analytical observational studies, to support editors and reviewers when reviewing such manuscripts for publication, and to assist the reader when critically reading published papers [136]. The STROBE statement focused on three study designs: cohort, case–control, and cross-sectional. The STROBE statement is a checklist of 22 items that were considered necessary for the reporting of observational studies. The items relate to the article's title (item 1), the introduction (items 2 and 3), methods (items 4–12), results (items 13–17), discussion (items 18–21), and funding (item 22). A total of 18 items are common to all three study designs, while four items (6, 12, 14, and 15) are design-specific items. Accompanying the published STROBE statement checklist is a lengthy explanation and elaboration intended to enhance its understanding.

It is equally important to emphasize what the STROBE statement is not. The STROBE statement is not to be viewed as a prescription for designing or conducting observational research nor mandating requirements for the uniformity of presentations [134]. The STROBE statement should not be interpreted as a means to assess the quality of published observational research.

As with most epidemiological initiatives and studies, the STROBE statement has received its share of criticism. Guidelines for reporting should not evolve into an instrument for judging the quality of observational studies. The STROBE statement does not adequately emphasize the importance of defining study hypotheses, specifying biologic rationale for such hypotheses, testing the hypothesis, and, in particular, requiring careful consideration of biological plausibility [82]. As epidemiology remains a relatively young science whose creativity lies in the development of new methods, the STROBE statement should be time limited with a specific expiration date [118]. Criticism of the STROBE statements also surrounded its affirmative statements on statistical significance testing at the expense of reporting point estimates, confidence intervals, and the need to conduct power analyses on only an a priori basis. And finally, such guidelines should be at the forefront of the design, conduct, and analysis of all studies and not to be considered only at the time of reporting. Poorly conducted studies may be inappropriately triaged to address what should have been done rather than what was done, leading to a less transparent reporting environment, which, of course, is contrary to the founding principle of the STROBE statement [86].

Despite these expressed concerns of some epidemiologists, the STROBE statement can serve as useful guidance to toxicologists to remind them of what data should be reported in epidemiologic studies. The quality of the study, however, remains to be elucidated through the critical evaluation of the study's hypothesis, methods, results, and discussion.

EXAMPLE 11.B.1 SELECTION BIAS

The 1995 publication by Robinson and colleagues entitled *Analysis of explanted silicone implants: A report of 300 patients* illustrates a number of potential selection biases [110]. Among the 300 women who Dr. Robinson explanted

TABLE 11.A.1
STROBE Checklist

Item	Recommendation
Title and Abstract	
1. Information	(a) Indicate the study's design with a commonly used term in the title or abstract.
	(b) Provide in the abstract an informative and balanced summary of what was done and what was found.
Introduction	
2. Background	(a) Explain the scientific background and rationale for the investigation being reported.
3. Objectives	(b) State specific objectives, including any prespecified hypotheses.
Methods	
4. Study design	Present key elements of study design early in paper.
5. Setting	Describe the setting, locations, and relevant dates, including periods of recruitment, exposure, follow-up, and data collection.
6. Participants	(a) *Cohort study*—Give the eligibility criteria and the sources and methods of selection of participants. Describe methods of follow-up.
	(b) *Case–control study*—Give the eligibility criteria and the sources and methods of case ascertainment and control selection. Give the rationale for the choice of cases and controls.
	(c) *Cross-sectional study*—Give the eligibility criteria and the sources and methods of selection of participants.
7. Variables	Clearly define all outcomes, exposures, predictors, potential confounders, and effect modifiers. Give diagnostic criteria, if applicable.
8. Data sources/ measurement	For each variable of interest, give sources of data and details of methods of assessment (measurement). Describe comparability of assessment methods if there is more than one group.
9. Bias	Describe any efforts to address potential sources of bias.
10. Study size	Explain how the study size was arrived at.
11. Quantitative variables	Explain how quantitative variables were handled in the analyses. If applicable, describe which groupings were chosen, and why.
12. Statistical methods	(a) Describe all statistical methods, including those used to control for confounding.
	(b) Describe any methods used to examine subgroups and interactions.
	(c) Explain how missing data were addressed.
	(d) *Cohort study*—If applicable, explain how loss to follow-up was addressed.
	(e) *Case–control study*—If applicable, explain how matching of cases and controls was addressed.
	(f) *Cross-sectional study*—If applicable, describe analytical methods taking account of sampling strategy.
Results	
13. Participants	(a) Report the numbers of individuals at each stage of the study—e.g., number potentially eligible, examined for eligibility, confirmed eligible, included in the study, completing follow-up, and analyzed.
	(b) Give reasons for nonparticipation at each stage.
	(c) Consider use of a flow diagram.
14. Descriptive data	(a) Give characteristics of study participants (e.g., demographic, clinical, social) and information on exposures and potential confounders.
	(b) Indicate the number of participants with missing data for each variable of interest.
	(c) *Cohort study*—Summarize follow-up time (e.g., average and total amount). Report numbers.
15. Outcome data	(a) *Cohort study*—Report numbers of outcome events or summary measures over time.
	(b) *Case–control study*—Report numbers in each exposure category or summary measures of exposure.
	(c) *Cross-sectional study*—Report numbers of outcome events or summary measures.
16. Main results	(a) Give unadjusted estimates and, if applicable, confounder-adjusted estimates and their precision (95% confidence intervals). Make clear which confounders were adjusted for and why they were included.
	(b) Report category boundaries when continuous variables were categorized.
	(c) If relevant, consider translating estimates of relative risk into absolute risk for a meaningful time period.
17. Other analyses	Report other analyses done—e.g., analyses of subgroups and interactions and sensitivity analyses.
Discussion	
18. Key results	Summarize key results with reference to study objectives.
19. Limitations	Discuss limitations of the study, taking into account sources of potential bias or imprecision. Discuss both direction and magnitude of potential bias.
20. Interpretation	Give a cautious overall interpretation of results considering objectives, limitations, multiplicity of analyses, results from similar studies, and other relevant evidence.
21. Generalizability	Discuss the generalizability (external validity) of the study results.
Other information	
22. Funding	Give the source of funding and the role of the funders for the present study and, if applicable, for the original study on which the present article is based.

over the course of 3 years, 214 (71.3%) reportedly had *disruption* (defined as frank rupture of an implant or severe silicone bleed). Interestingly, these authors noted that there was "virtually no difference in the disruption rates between those patients relating symptoms to their implants and those who did not (71.8% vs. 70.9%)," suggesting that health complaints were not a consequence of implant status. Nonetheless, they extrapolated from this sample to predict that most implants will lose their integrity somewhere between 8 and 14 years and recommended that all gel-filled implants be removed, *preferably before 8 years from implantation*.

Robinson et al. based their rates and their interpretations and formulated a policy of explantation on data from a denominator of 300, but that was not the group they actually studied (Figure 11.20). According to the paper, Dr. Robinson saw 495 women who would have been eligible for this investigation, 101 who had been implanted by other surgeons and 394 of his own patients. The 300 were drawn from the 495, but note that, even if he had studied all 495, he still would not have been able to develop rates that were free of potential selection bias. Even with 100% participation of his sample, he would not have been able to develop rates that meaningfully could be extrapolated back to a larger group. That's because the 495 were a convenience sample, an ill-defined and likely highly biased sample of the larger population from whence they came. The larger population included all of Dr. Robinson's implant patients and, by implication, all the breast implant patients of the other 15–20 plastic surgeons who practiced concurrently in the same community. Court records indicate that Dr. Robinson implanted approximately 4000 women and it is quite possible that at least some of the surgeons in his community implanted comparable numbers [109].

So what can we make of the Robinson information? The data collected for this report were prevalence data. Although gathered over a 3-year period, for the individual study subjects they were obtained at a single point in biological time—the time of surgical explantation. Because they had prevalence data, the researchers could not differentiate between events that occurred at the time of surgical implantation, during the period the implant was within the body, or at explantation. Their interpretation, therefore, that implant failure is a function of the aging of the device, presumptively

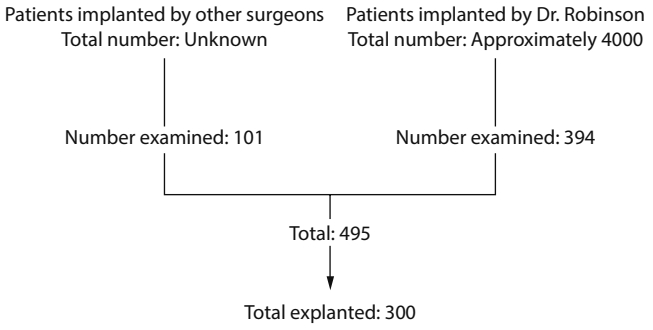

FIGURE 11.20 Convenience sample. (From Robinson, O.G. et al., *Ann. Plast. Surg.*, 34, 1, 1995. With permission.)

related to biological degradation of the silicone elastomer shell, required assumptions (e.g., the incidence time of rupture was just before explantation) that were not adequately addressed in this research.

Based on the work of others, at least some of those assumptions appear to be incorrect. Rapaport et al. [105] found that an appreciable number of implant ruptures occur secondary to micropunctures caused by needles or other medical devices used during the implant procedure. Others have done work that expands on this observation [21]. Brandon and colleagues [22], using lot-matched controls, reported that the material properties of the silicone shell are not affected by implantation for time periods up to 21 years and concluded "that the silicone elastomer undergoes little or no change during implantation." Robinson et al. [110] noted that approximately 25% of the implant ruptures they observed occurred during the explant procedure. At least two other mechanisms contribute to implant ruptures in vivo: closed capsulotomies (manual compression of the breast to rupture the tissue capsule surrounding the medical device) and the so-called fold flaws (disruption of the elastomer by excessive flexing at the site of folds in the shell). Both involve mechanical trauma. Obviously, different approaches might better be used to prevent, control, or otherwise address implant ruptures caused by different mechanisms.

Setting aside the questions of the validity of the data and the causes of implant rupture, if the 300 who were explanted are a representative sample of the ever implanted, then it is quite possible that a high proportion of implanted women have *disrupted* implants. Further, if *disruption* equates to implant rupture, either overt or occult, it suggests that there may be a high rupture rate for these medical devices, at least for those brands and models favored by Dr. Robinson and his colleagues [34]. On the other hand, if the 214 with disrupted implants are the majority of those in the numerator of a true rate, especially if disruption does not equate to rupture, then it is likely that the actual rupture rate is quite low, quite possibly a single-digit phenomenon. Of course, if neither scenario is correct, then the information is invalid and has no utility at all. Furthermore—and in spite of the question about rupture rates—if these authors are correct in their observation that there is a lack of association between implant integrity and health outcome, a conclusion reached independently by others, then is it good public health policy to expose all implanted women to the predictable risks of explant surgery [26,142]? Probably not.

A number of lessons can be learned from this report: One, not understanding the difference between prevalence and incidence data can lead to flawed interpretations [35–37,59–61]. Two, selection bias can occur even when 100% of those selected for the study participate because the selection process itself may be flawed. Three, anytime there is less than 100% participation among those originally selected, even in a descriptive study of just the exposed group, the results are susceptible to an additional selection bias. Particularly troublesome are those situations in which the participation rates differ between the groups (i.e., among

the exposed and the unexposed for a cohort study or the diseased and the healthy in a case–control study) because this suggests that the reasons for participation may not have been equivalent and therefore there may have been a spurious correlation between health outcome and exposure among one group or the other. The consequence of selection bias is an incorrect measure of association, possibly an underestimate of risk but often an overestimate. Complicating the situation still further, the dynamics of selection bias can change over time as a result of a well-publicized environmental controversy, a lawsuit, a provocative news program, or any number of other things; thus, different types of selection bias can wax and wane. Four, biased studies can lead to flawed policies, policies that ironically may put those whom they are designed to protect at greater risk.

EXAMPLE 11.B.2 INFORMATION BIAS

2,4-D is a commonly used herbicide applied in agricultural fields, on golf courses, right-of-ways, and residential lawns for the control of a variety of weeds. It has been extensively researched from a toxicological, epidemiological, exposure assessment, and environmental standpoint. Several scientific reviews have been written over the past 20 years of this literature including a panel hearing report issued by the U.S. Scientific Advisory Board (SAB). After a 17-year deliberative process, 2,4-D was reregistered for use by the U.S. Environmental Protection Agency in 2005 [29,30,47,56,94].

The purpose of this case example is to show data from three NCI case–control studies that suggested the epidemiologic associations reported between 2,4-D and NHL were likely the result of information bias, that is, recall bias by the type of respondent. That is, proxies of cases tended to report more exposure than the direct informants. Proxies were not used with controls. The NCI case–control studies were designed subsequent to Swedish epidemiologic studies that suggested associations between soft-tissue sarcoma, Hodgkin's disease, and NHL with exposure to phenoxyacetic acid herbicides. However, these Swedish studies had their own methodological limitations.

The first NCI case–control study was conducted in Kansas by Hoar et al. [73]. It was a population-based case–control study of male cases of soft-tissue sarcoma, Hodgkin's disease, and NHL. Controls were white men selected from the general population of Kansas. Exposure information, including use of herbicides and insecticides in farming practices, were obtained by a telephone interview. ORs were reported for NHL in relation to *duration, frequency, and latency of 2,4-D use*. Statistically significant trends were reported for all three analyses. In particular, the OR for NHL for frequency of use (days/year) ≥21 days was 7.6 (95% confidence interval 1.8–32.3) compared to having never farmed. Limitations of the study were discussed and the authors suggested the evidence introduced would "likely be similar for cases and controls. This random misclassification of exposure would tend to dilute risk estimates, rather than produce spurious association." However, the questionnaire was not specific for 2,4-D despite the inference otherwise and therefore a correction was issued to clarify this error in the tabular data presented in the original paper. The questionnaire inquired only about herbicide use in general. There appeared to be no difference in ORs based on the vital status of the cases. Information was obtained from next of kin for those cases who were deceased. The authors concluded that since phenoxyacetic acid herbicides were widely used on U.S. farmlands, it meant the carcinogenic effects suggested by this study may have important public health implications.

The second NCI investigation was a population-based case–control study that involved cases of Hodgkin's disease, multiple myeloma, chronic lymphocytic leukemia, and NHL among white men and women in 66 counties of eastern Nebraska [143]. Controls were selected from the same source population that gave rise to the cases. In this study, the questionnaire specifically asked questions about 2,4-D use (not just herbicides in general). Days of application and years of use were inquired. An OR of 3.3 (95% CI 0.5–22.1) was reported for mixing or applying 2,4-D 21 or more days per year. The investigators reported the risk of NHL associated with personal handling of 2,4-D was higher among proxy interviews (1–5 days per year: OR = 2.2; 6–20 days OR = 2.2; 21+ days OR = 2.4) than among self-respondents (1–5 days per year OR = 1.0; 6–20 days OR = 1.6; 21+ days OR = 1.4). Upon finishing their review of other epidemiologic and experimental evidence, the authors concluded, "we believe that the weight of evidence indicates that the user of 2,4-D in an agricultural setting increases the risk of NHL among persons handling the chemical frequently."

The third investigation was the Iowa–Minnesota case–control study [27]. Again, this was a population-based case–control study and was the largest of the three NCI case–control investigations. Questions pertained to *ever handled* various herbicides or insecticides but not about the frequency of handling 2,4-D or any other herbicide (or insecticide). Subsequent to the completion of the study, the investigators reinterviewed a subsample of cases and controls for this information. In a letter to the editor, Cantor et al. reported [28] ORs of 1.3, 1.0, and 0.9 for 1–4, 5–9, and 10+ days per use of 2,4-D (compared to no use) from a resurvey of Iowa farmers from this study. The authors concluded, "The time delay, different method of data collection, and participation of more proxies likely introduced substantial exposure misclassification that is likely to mask exposure response gradients. We therefore consider these findings to be very weak evidence either for or against the possibility of a causal association with any single pesticide exposure." However, the authors only adjusted for type of interview by using its main effect. An interaction term was not included in the model. This was subsequently done by Olsen and Bodner [97] who showed there were differences based on the type of respondent. Among direct informants, the ORs for the three frequency categories of 2,4-D use were 0.5 (95% CI 0.2–1.2), 0.2 (95% CI 0.1–0.8), and 0.7 (95% CI 0.3–1.9), respectively, suggesting recall bias.

For proxy respondents, the ORs were 0.8 (95% CI 0.2–2.7), 1.0 (95% CI 0.3–3.4), and 2.5 (95% CI 0.8–8.0), respectively. Similar differences in magnitudes of association, higher for proxy respondents, were also observed for other herbicides. Olsen and Bodner concluded "if direct informant data are considered more valid than proxy data, which we believe is a reasonable assumption, then the Nebraska study and the Iowa resurvey, using the comparable frequency of use categorizations for 2,4-D among direct informants do not suggest an association between frequency of 2,4-D use and NHL."

Because of the controversy surrounding the use of proxy interviews to obtain information about herbicide usage among cases, Johnson et al. [79] conducted a methodological study of obtaining information about pesticide exposures and the need to assess the reliability and validity of such data. Their study was particularly insightful as it was designed to demonstrate the effect on the OR if there was exposure misclassification. They compared data obtained from direct informants from the original Iowa–Minnesota study to information collected 8–10 years later from proxy respondents of direct informants who died or became incompetent since the initial interview. Their overall findings indicated that both nondifferential and differential misclassification can occur when proxy respondents provide pesticide exposure data and thus misclassification may not always be biased toward the null value. The differential misclassification occurred in approximately 1/3 of the estimates. Pesatori et al. [103] from NCI interpreted these results by saying "on balance, nondifferential misclassification appears to be a greater problem than differential misclassification." Olsen and Bodner, however, disagreed with this conclusion as it quickly dismissed the much greater threat to validity caused by differential misclassification despite it occurring *only* 1/3 of the time in the Johnson et al. methodological study. Olsen and Bodner agreed with the advice offered by Morrison et al. [93] who concluded, after their review of the herbicide and cancer literature, that agricultural pesticide data obtained from case–control studies should be reported stratified by the type of respondent.

The Kansas [73], Nebraska [143], and Iowa-Minnesota [27] NHL case-control studies findings provided some impetus for the NCI's decision to create the Agricultural Health Study (AHS) [135]. The AHS is sponsored by the NCI, U.S. Enviromnetal Proection Agency (EPA), and the National Institute of Environmental Health Sciences (NIEHS). It is a prospective cohort study of pesticide (farming and commercial) applicators in Iowa and North Carolina and began follow-up in 1996 [2]. AHS investigators have yet to publish a peer-reviewed paper on the cohort's experience between NHL and exposure to 2,4-D [3]. However, an abstract presented at the 2013 International Epidemiology Conference in Occupational Health (see Freeman et al. abstract #458) reported no association between NHL and 2,4-D in this prospective study. See Example 11.B.4 for further insights regarding the reporting of false positive, false negative, and publication bias in the epidemiology literature.

EXAMPLE 11.B.3 OCCUPATIONAL CANCER CLUSTER AND EXPOSURE ANALYSIS

More than two decades ago, the U.S. Centers for Disease Control and Prevention published *Guidelines for Investigating Clusters of Health Events* (113). These guidelines primarily focused on *cancer clusters*. A four-stage process was recommended when inquiries of excess cancers were reported to health departments: (1) an initial response to gather information, (2) an assessment of the occurrence of the health event, (3) a feasibility study, and (4) an epidemiologic investigation. Despite numerous efforts to investigate clusters of cancer occurrence in communities, few underlying causes have ever been elucidated. Reasons have included: (1) disease clusters are too small, (2) vague definition of the disease(s), (3) selection of the population studied is flawed by a posteriori reasoning, (4) exposures are poorly defined, (5) difficult data collection due to publicity generated about the cluster, and (6) perhaps the most likely explanation, the fact that identification of cancer clusters is *unexpectedly expected* statistical events. Unlike community clusters of cancer, occupational clusters are more well defined both in terms of location (a specific plant, production process, exposure(s)) and time, although the latter can still be affected from a post priori reasoning. The following case example demonstrates the quality of exposure reconstruction in a complicated environment—that of a research laboratory at a major chemical company. It further shows the difficulty of attributing a specific cause to a well-described excess of cancer (brain) in this research laboratory workplace—despite the rigorous effort put forth with historic exposure reconstruction. A brief review of this exposure reconstruction is illuminating unto itself.

Near the turn of this century several young chemists were diagnosed with brain cancer at the Rohm and Haas Company's research and developmental facility located in Spring House, Pennsylvania. An epidemiologic investigation ensued, which determined between 1963 and 2007 among 5284 workers that there were 14 males who died from brain cancer compared to 5.6 expected based on Pennsylvania mortality rates (SMR 2.39, 95% CI 1.30–4.01) [4]. There were 0 female deaths from brain cancer compared to 1.1 expected. Excluding the brain cancer, this population demonstrated the healthy worker effect. Altogether there were 486 observed deaths versus 952.9 expected (SMR 0.51, 95% CI 0.47–0.56) with statistically significant deficits for all cancer, cardiovascular disease, and diabetes. The histologic types determined for the brain cancers were four astrocytomas, five glioblastomas, one glioma not otherwise specified, one oligodendroglioma, two primary brain cancers histology not provided, and one case with no primary confirmed.

A nested case–control study was conducted with five controls selected for every case based on incidence density sampling. Controls were selected from risk sets of cohort members who were eligible for follow-up, alive at the time of death of the index case, and born within a 5-year birth interval.

Prior to the conduct of the epidemiologic component of the study, a tiered exposure assessment process was developed. Acknowledging the potential for *tens of thousands* of chemical exposures that could have occurred in this workplace, Chen et al. designed a strategy of reconstructing cumulative historical exposures for multiple chemicals and chemical groups [32]. Chemicals of interest were selected on the basis of the plausibility of penetrating the blood–brain barrier and the uniqueness of the chemical's biological activity. Briefly, the strategy was as follows. Employment records were obtained that identified job title, department, and dates of employment that were then used to classify workers into similar exposed groups (SEGs). To create SEGs, Chen et al. [32] categorized jobs to 10 functions: three primary functions involved either synthesis of new chemicals, formulating new chemicals, or handling chemicals and custom tailoring them for customers (tech services). Seven additional functions included administrative, analytical services, applications, synthesis and/or applications, synthesis, and/or formulation, maintenance, and toxicology services. Next, the numerous chemicals used in the research laboratory were narrowed by four decision criteria: (1) physical and chemical properties that focused on chemicals likely to cross the blood–brain barrier, (2) chemicals cited in the literature with central nervous system effects, (3) chemicals that had not been extensively studied in other settings, and (4) advice from technical staff and stakeholders. Using these criteria, five chemical groups were identified: acrylates, bis-chloromethyl ether (BCME), chloromethyl methyl ether (CMME), isothiazolones, and nitrosamines. Common solvents known to affect the CNS were excluded since their use in other industry sectors was more prevalent. Sources of exposure for these five major exposure groups included exposure monitoring data obtained by industrial hygienists, general ventilation data, and procurement data by department.

A Bayesian framework for quantitative exposure reconstruction was used for acrylates, BCME, and CMME. Historical monitoring, exposure modeling, and professional judgment data provided an industrial panel the information to reconstruct the likelihood exposures for acrylates, BCME, and CMME for each SEG over the time periods of interest. Where monitoring data were available, reconstructed exposures for a SEG were based on the terms of the probabilities of the arithmetic mean exposure lying within each of four categories of exposure relative to reference concentrations. For instances when monitoring data were unavailable and exposure modeling was performed, a simple general ventilation model was used. When information was unavailable, professional judgments by current and former industrial hygienists were used that provided a probability analysis of the category of exposures where the arithmetic mean of the SEG most likely belonged and the degree of confidence surrounding this decision. Relative exposures for each SEG were developed by considering information from an employee panel that considered six general determinants of exposure: general ventilation status, hood ventilation status, use of gloves, use of safety glasses, use of personal protective equipment (e.g., respirators, protective equipment), and general health, safety, and cleanliness. Only hood ventilation status and use of gloves had significant changes over time. In addition, relative exposures for all SEGs were estimated by using formaldehyde as an inhalation exposure surrogate. Formaldehyde was chosen due to its ability to cross the blood–brain barrier, CNS toxicity, extensive use at the research facilities, and large amount of monitoring data available. Information obtained allowed for the construct of exposure modifiers for the five chemical exposures. The final job exposure matrix was created by combining the SEGs with the corresponding quantitative or semiquantitative exposure estimates for the five chemical groups. For each employee, the person's cumulative exposure is weighted by the employment history and duration at the research facility with the exposure for each time period of the SEG.

Despite incorporation of this rigorous reconstruction of this exposure matrix, analyses from the nested case–control study were unable to explain the brain cancer cases [4]. Few brain cancer cases were associated with any specific SEG.

This example demonstrates that under the best of circumstances for reconstructing exposure histories for the purpose of disease cluster analysis, it is a difficult undertaking that may still yield minimum etiologic insights. Because of this inability to often provide answers, the source population for any cancer cluster should be provided a reasonable understanding of the likelihood of identifying etiological factors [11].

EXAMPLE 11.B.4 FALSE POSITIVES, FALSE NEGATIVES, AND PUBLICATION BIAS

In 1995, Taubes [130] wrote a highly controversial (within epidemiology) news article published in science that questioned whether epidemiology was facing its limits of being able to identify true positive findings at low effects. The article featured quotes from several prominent epidemiologists and journal editors. One was from Sander Greenland (UCLA) who said, "Remember, there is nothing sinful about going out and getting evidence, like asking people how much do you drink and checking breast cancer records. There's nothing sinful about seeing if that evidence correlates. There's nothing sinful about checking for confounding variables. The sin comes in believing a causal hypothesis is true because your study came up with a positive result, or believing the opposite because your study was negative."

The article by Taubes unleashed currents of support and criticism, internal and external to the discipline of epidemiology. In particular, this quote by Greenland, which was the last statement made in the Taubes article, highlighted the issue of false-positive and false-negative findings. During the past 15 years, this controversy has been a focus of reflection in the epidemiology literature. Some of this discussion is highlighted in the succeeding text.

In 2005, Ioannidis [78] provided a quantitative analysis why he thought most published research findings were

false positives. In other words, once a research result has been established as statistically significant, the poststudy probability that it is true is the positive predictive value (PPV) where PPV = $(1 - \beta)R/(R - \beta R + \alpha)$ where R = the ratio of the number of *true relationships* to *no relationships* among those tested in the field, α = type I error, and β = type II error. Because most investigators rely on $\alpha = 0.05$, this equation results in the inference that a research finding is more likely true than false if $(1 - \beta)R > 0.05$. This relationship, of course, holds assuming no study bias. In the increasing presence of bias (μ), however, Ioannidis shows that PPV = $([1 - \beta]R + \mu\beta R)/(R + \alpha - \beta R + \mu - \mu\alpha + \mu\beta R)$ such that PPV decreases with increasing μ unless $1 - C \leq 0.05$. Thus, with increasing bias, the chances that a research finding is a true positive diminish considerably. Ioannidis offered six corollaries about the probability that a research finding is true:

Corollary 1. The smaller the studies conducted in a scientific field, the less likely the research findings are to be true. Explanation: Small sample size means smaller power. PPV for a true research finding decreases as power decreases toward $1 - \beta = 0.05$.

Corollary 2. The smaller the effect sizes in a scientific field, the less likely the research findings are to be true. Explanation: Modern epidemiology is increasingly obliged to target smaller effect sizes. Consequently, the percentage of true research results is expected to decrease.

Corollary 3. The greater the number and the lesser the selection of tested relationships in a scientific field, the less likely the research findings are to be true. Explanation: Because PPV depends on R (prestudy odds), then research findings are more likely true in confirmatory designs than in hypothesis-generating analyses.

Corollary 4. The greater the flexibility in designs, definitions, outcomes, and analytical modes in a scientific field, the less likely the research findings are to be true. Explanation: Flexibility increases the potential for transforming what would be negative results into positive results as a consequence of increasing bias.

Corollary 5. The greater the financial and other interests and prejudices in a scientific field, the less likely the research findings are to be true. Explanation: Financial and nonfinancial conflicts of interest may lead to distorted reported results and interpretations. Epidemiologists may be prejudiced purely because of their belief in a scientific theory or commitment to their own findings.

Corollary 6. The hotter a scientific field (with more scientific teams involved), the less likely the research findings are to be true. Explanation: Extreme opposite findings are often reported early in any research area. The PPV of isolated findings decreases when many investigator teams are involved. "Positive" results are prioritized as most important to publish. "Negative" results become attractive for dissemination after a positive association has been report. This rapid change from 'positive' to 'negative' research findings has been termed the *Proteus phenomenon*.

In 2009, Boffetta et al. [17] issued a plea for *epistemological modesty* when it came to the false-positive reporting of results in cancer epidemiology studies. They cited two specific examples, one each from environmental and occupational epidemiology, and performed a cumulative meta-analysis of the initial study and subsequent published studies. The two initial papers were on 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene (DDE) and breast cancer and acrylonitrile and lung cancer. In the DDE and breast cancer cumulative meta-analysis, the initial study by Wolf et al. [141] published in 1993 reported a relative risk of 3.7 (95% CI 1.0–13.5) for the highest to lowest 20% of the DDE distribution in serum. By 7 years later, with the addition of eight more research studies, the cumulative meta-analysis relative risk approximated 1.0. The cumulative meta-analysis for acrylonitrile and lung cancer began with the initial study published in 1978 that showed a relative risk of 4.0 (95% CI 1.7–7.9). Twenty-one years later with the addition of nine more published studies, the final pooled meta-analysis relative risk was 1.1 (95% CI 0.9–1.4). Boffetta concluded there are multiple reasons for positive results, particularly initial results, to be false. These included absence of a specific a priori hypothesis, small magnitude of associations, absence of dose effects, systematic biases including selection, information and confounding biases, and failure to consider multiple comparisons. They also discuss preferential publication bias of studies with positive findings—especially with initially new associations. They criticized the tendency by authors to hype new findings citing a few examples. They stressed the need for journals to require authors to discuss the limitations, as well as results, in the summary and abstract of published papers. They proposed that a *note box* of the study limitations become standard practice.

Blair et al. [15] provided their own commentary on the *rhetoric* of false positives published in a different journal. They were highly critical of the position taken by Boffetta et al. They argued that Boffetta et al. only provided a few examples of false positives in the literature, and thus if they (false positives) were "such a widespread and serious problem in epidemiologic research, one would expect that it would be relatively easy to provide many more examples." Blair et al. didn't acknowledge the potential limitations of word length in journal articles as a likely reason why Boffetta et al. limited their paper to a few examples. Blair et al. argued that multiple comparisons are more than just the number of comparisons but on how hypotheses and priori probability of associations are developed and that the lack of subsequent support after initial leads demonstrates how the early phase of this process may be *set aside after further investigation*. Blair et al. felt a rigid a priori listing of hypotheses would be particularly restrictive

and counter the use of long-term prospective studies to evaluate risk factors or outcomes that were not initially specified in the original protocols.

Blair et al. argued that biases from selection and information are more likely to result in false-negative than false-positive associations and thus tend to diminish the association due to nondifferential misclassification. Exposure categorizations that are binary would only result in nondifferential misclassification and diminish the relative risk. When more than two levels of exposure are evaluated, nondifferential misclassification could result in an increase in relative risks for exposure categories other than the highest. Blair et al. suggested that although the potential of uncontrolled confoundings exist, among occupation and lung cancer studies, smoking has been found to be a relatively infrequent confounder despite the well-known association between smoking and lung cancer. Blair et al. agreed that the media may *hype* study findings but criticized Boffetta et al. as they did not provide indication of when scientists' interpretations of their results are *hyped* or simply legitimate disagreements. They felt Boffetta et al. provided only anecdotal evidence of *hyping* and countered it by stating that the cited examples by Boffetta et al. did not provide *obvious evidence of hype*. Using the example regarding DDT and breast cancer [141], Blair et al. quoted an accompanying editorial on the DDT breast cancer paper by Hunter and Kelsey [76]. Hunter and Kelsey wrote, "These data [141] although limited, do suggest the plausibility of an association between organochlorines and increased risk of breast cancer. However, at this stage these mechanisms are incompletely understood, and they will require considerable additional refinement before becoming truly compelling." Blair et al. surmised that this quote and editorial placed the Wolff et al. results in the appropriate context. Blair et al., however, failed to mention the title of the accompanying editorial by Hunter and Kelsey [76] of the Wolff et al. [141] paper. The editorial was entitled, "Pesticide residues and breast cancer: The harvest of a silent spring?" Is this title hyping the findings by Wolf et al. [141]? A counterpoint offered by Blair et al. of the Boffetta paper was their suggestion that Boffetta and colleagues failed to offer no more than few examples of publication bias. Although Blair et al. suggested publication bias may exist, its frequency was unknown. Blair et al. wrote, "We would note that today researchers are highly motivated to publish even negative results because of the expense of conducting studies and the intense public debate that surrounds health issues." This opinion, however, does not necessarily support the fact the NCI has offered only one abstract through 2013 (International Epidemiology in Occupational Health Conference 2013 meeting; see Freeman et al. abstract #458), that has provided results of the Agricultural Health Study (AHS) pertaining to NHL and 2,4-D use. The NCI's initial NHL case-control studies related to 2,4-D [72, 143, 27] were published a quarter of century earlier (see Example 11.B.2 regarding Information Bias). The AHS was a prospective study of a large cohort of pesticide applicators (farmers and commercial applicators) in Iowa and North Carolina. Results? Overall, 78% of the 52,324 applicators provided information on 2,4-D use. There was no association with NHL and 2,4-D use overall (p-trend = 0.84) or any sub-type of NHL with intensity-weighted lifetime days suggesting the earlier case-controls findings were likely false positive results. The lesson for the toxicologist is that consensus based on epidemiologic research is likely to take many years, if not decades.

Another example of potential publication bias was criticism [16,140] leveled at Danish researchers [122] who chose not to report 15 years of government-funded sperm count data that they had collected that appeared not to support their original hypotheses of declining sperm counts? Interestingly in their defense, Skaekaeaek et al. [15] wrote the following, "In 2008, we tried to publish an article containing a figure similar to the one Bonde et al. [16] have now included in their commentary, showing stable sperm counts in Denmark, contrasting with a downward trend in sperm counts in Finland. However, our paper was rejected by 2 leading journals in the field. One referee said frankly: "Most results reported in this new article are not very original and are confirming previous data." As part of the Danish material had been published before, we cut the Danish data out of the manuscript and the Finnish data were subsequently published separately. But now Bonde et al. and Wilcox are attacking our scientific integrity by raising suspicions that we have disingenuously published the decreasing Finnish trend, and have withheld the data showing the unchanged Danish sperm count." Have they? Is this, or is this not, publication bias? If so, by whom? By the investigators for not continuing to try to publish their (nonpositive) Danish results and only publish the positive Finnish findings? By the journal's reviewer by judging the need to publish a paper by the originality of the data? By the editor by not supporting the investigators decision to publish the data despite the reviewer's comment? By all parties?

In conclusion, hyped or not, false-positive and false-negative associations, along with publication bias, are important points of contention within the epidemiology community. The authors do not anticipate a consensus anytime soon, if ever.

EXAMPLE 11.B.5 APPLICATION OF A CAUSAL DIAGRAM

Fei et al. [50] reported maternal levels of perfluorooctanesulfonate (PFOS) and perfluorooctanoate (PFOA), measured at 4–14 weeks of pregnancy, were associated with subfecundity in an analysis of 1240 women from the Danish National Birth Cohort (DNBC). The DNBC was an open cohort selected between 1996 and 2002 and was established by recruitment through general practitioners inviting their pregnant patients to participate in the study. Approximately 50% of general practitioners participated and 60% of invitees participated. Two blood samples were provided during pregnancy with the first taken at weeks 4–14 of pregnancy. Any woman who identified her pregnancy as planned or partly planned was asked how long did she try to get pregnant before becoming pregnant.

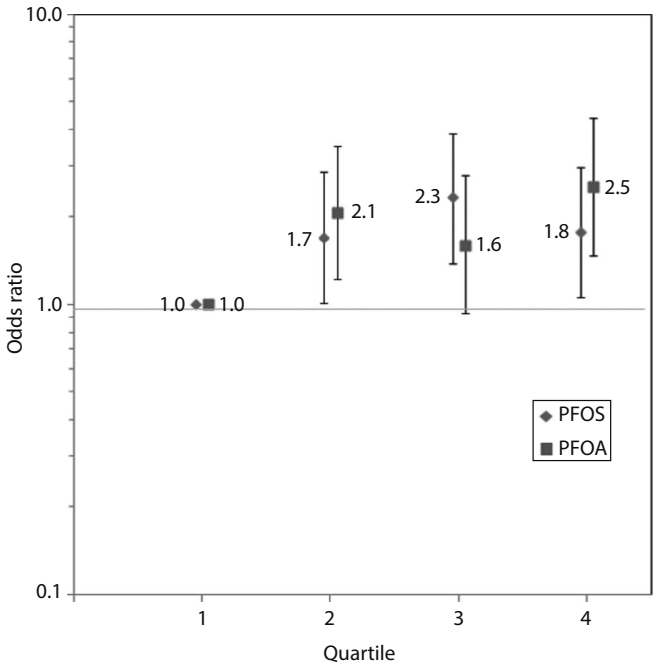

FIGURE 11.21 OR for subfecundity (TTP > 12 months) by PFOA or PFOS quartile. (From Fei, C. et al., *Human Reprod*., 24, 1200, 2009.)

Infertility was defined as having a TTP of >12 months or infertility to establish the current pregnancy. Plasma PFOA and PFOS were measured using high performance liquid chromatography mass spectrometry methods. Potential confounders included maternal age at delivery, parity, prepregnancy body mass index, maternal socio-occupational status, paternal education, paternal age, and alcohol consumption before pregnancy. Provided in Figure 11.21 are ORs for four quartiles of PFOS and PFOA concentrations for TTP (quartile 1 = reference). Trends were significant for PFOS ($p = 0.025$) and PFOA ($p = 0.006$). Fei et al. concluded that general population plasma levels of PFOS and PFOA may increase TTP and could explain some of the fertility differences observed among different populations in developed countries. This study received considerable news media attention at the time of its publication.

As part of their review of the epidemiology literature related to perfluoroalkyls, Olsen et al. [99] questioned the interpretation of the data analyses put forth by Fei et al. Using a causal diagram, Olsen et al. suggested there was no causal association between perfluoroalkyls (PFOA and PFOS) and TTP but rather a *backward* association generally referred to as reverse causation. As shown in Figure 11.22, indicated by the directional lines (follow the arrows), parity is both an outcome of fecundity and a cause of perfluoroalkyl concentrations. This induces a cyclic chain that violates the conditions of causal inference because under the reasonable assumption that perfluoroalkyl levels will be lower after a pregnancy (some placental transfer), a longer interval between births would result in more time for a woman to reaccumulate PFOA and PFOS that would replace the loss incurred from the birth. Assuming two women who begin with comparable perfluoroalkyl concentrations and equal parity, they will have different perfluoroalkyl concentrations at their next birth based on the interpregnancy interval of time. Women with longer time to pregnancies would likely have longer interpregnancy intervals and so may have higher PFOA and PFOS levels prior to the next pregnancy. This would result in longer TTP associated with higher perfluoroalkyl levels but the direction of the causality is backward. The longer time between births (including the TTP) results in the higher PFOA and PFOS concentrations. Unfortunately, Fei et al. did not stratify their analyses by parity to determine whether such an association exists.

Whitworth et al. [139] tested the hypothesis offered by Olsen et al. by analyzing TTP in parous and nulliparous

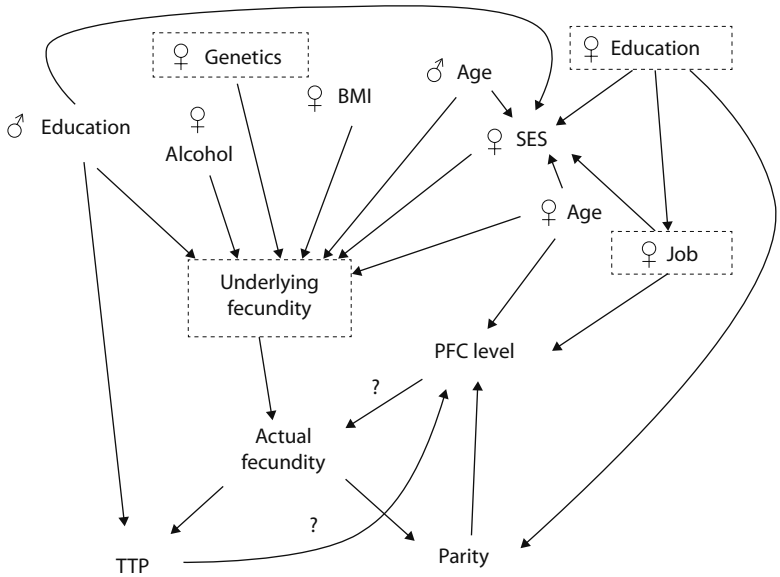

FIGURE 11.22 Causal diagram of maternal perfluorochemical concentrations and TTP. (From Olsen, G.W. et al., *Reprod. Toxicol.*, 27, 212, 2009.)

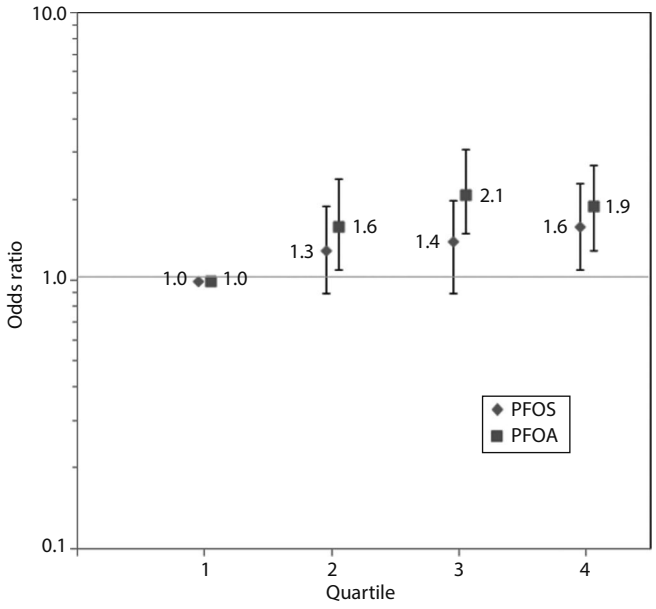

FIGURE 11.23 OR for subfecundity (TTP > 12 months) by PFOA or PFOS quartile. (From Whitworth, K.W. et al., *Epidemiology*, 23, 257, 2012.)

women. If the causal model was likely, then the association between longer TTP and perfluoroalkyl levels would be seen among parous but not nulliparous women since the latter did not have an interpregnancy interval of time. An association observed among nulliparous women would support a subfecundity inference. Whitworth et al. conducted a case–control analysis of 910 women enrolled in the Norwegian Mother and Child Cohort Study. A total of 416 women were cases who self-reported a TTP >12 months. Blood collection for the cohort occurred at approximately 17 weeks gestation. Plasma PFOA and PFOS concentrations were measured by HPLC-MS for cases and controls. Not stratifying for parity resulted in analyses (Figure 11.23) similar to those reported by Fei et al. (Figure 11.21) with perfluoroalkyl levels associated with subfecundity. Stratifying for parity, however, resulted in this association being observed only among the parous women (Figure 11.24), indicating their increased perfluoroalkyl levels may be due to a long interpregnancy interval rather than the cause of long TTP. The results among nulliparous women did not support an association with subfecundity with either PFOA or PFOS.

Upon publication of the Whitworth et al. findings, Fei et al. [51] acknowledged that perfluoroalkyl concentrations can be potentially influenced by the interpregnancy interval for parous women through accumulation of PFOA and PFOS. Adjusting for parity in their original model [50] did not adequately control for it. Upon stratifying their analyses for parity as done by Whitworth et al. [139], Fei et al. [51] reported among nulliparous women a diminished TTP association with PFOA, but not PFOS (Figure 11.25). Fei et al. concluded that there was *limited* evidence for reverse causation based on their reanalysis and welcomed additional studies in populations with elevated and variable levels of PFOA and PFOS exposure.

In summary, the cited example illustrates how the construction of a causal diagram (referred to as directed acyclic graphs) can be very insightful for the epidemiologist, toxicologist, and clinician to more fully understand the role of confounding and bias as they relate to the calculation of an estimate of effect for an exposure on an outcome of interest.

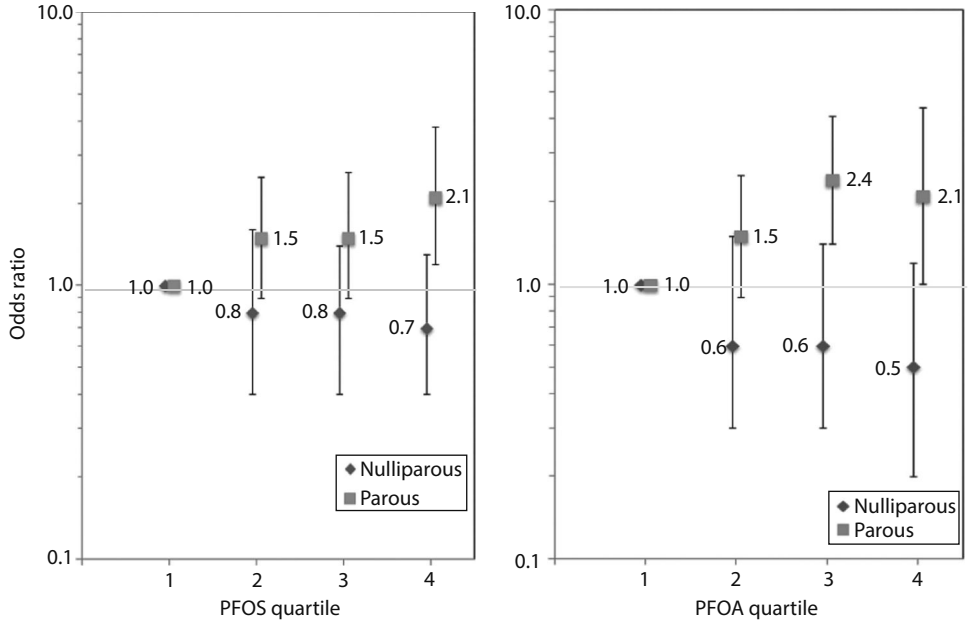

FIGURE 11.24 OR subfecundity (TTP > 12 months) stratified by parity by PFOA or PFOS quartile (95% CI). (From Whitworth, K.W. et al., *Epidemiology*, 23, 257, 2012.)

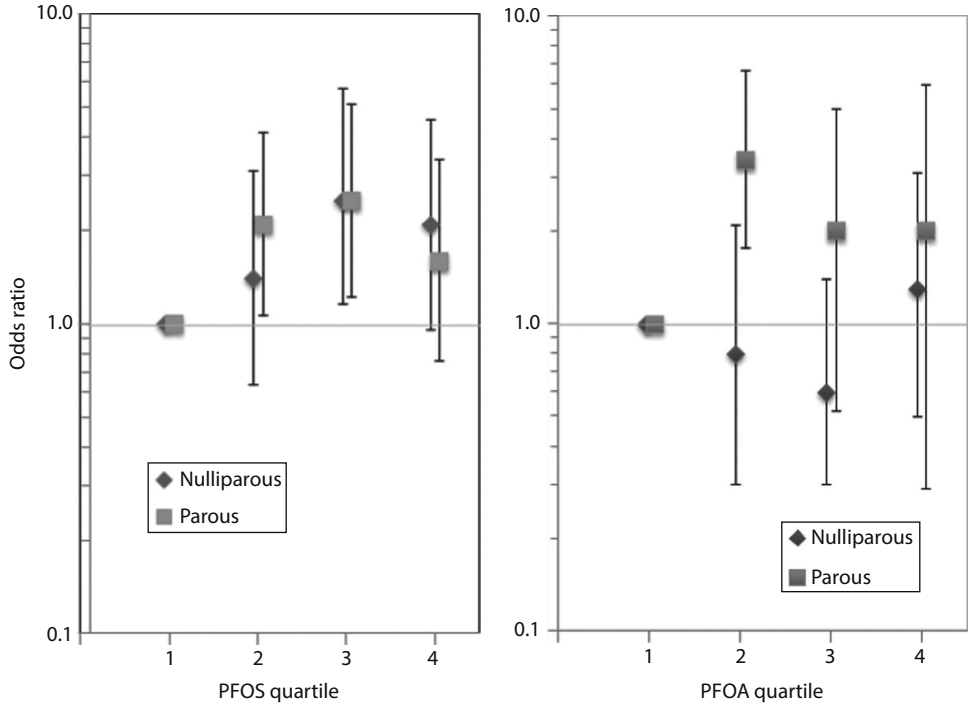

FIGURE 11.25 OR for subfecundity (TTP > 12 months) stratified by parity by PFOA or PFOS quartile (95% CI). (From Fei, C. et al., *Epidemiology*, 23, 264, 2012.)

12 Principles of Pathology for Toxicology Studies

Steven R. Frame, Peter C. Mann, and Jessica M. Caverly Rae

CONTENTS

INTRODUCTION

Anatomical pathology findings often define the critical outcomes of the hazard identification process, including primary target organ effects, no-observed-effect levels (NOELs), adversity of exposure, and interspecies relevance of exposure. As such, the anatomical pathology evaluation is essential to the identification and characterization of target organ toxicity.

Pathology is defined as "the medical science, and specialty practice, concerned with all aspects of disease, but with special reference to the essential nature, causes, and development of abnormal conditions, as well as the structural and functional changes that result from the disease processes" [1]. This definition encompasses the traditional role of the pathologist in identifying morphological changes in tissues at the gross and microscopic levels. It also describes the more comprehensive and often more complex aspects of pathology. These include identifying and characterizing the nature (e.g., inflammatory, degenerative, or disturbances of growth) of abnormal findings, as well as their cause and development (pathogenesis).

Toxicologic pathology is the science that integrates the disciplines of pathology and toxicology and is concerned with the effects of potentially noxious substances [2,3]. The Society of Toxicologic Pathology (STP) defines a toxicologic pathologist as follows: "Any person who is a toxicologic pathologist by virtue of training, experience, and/or scientific contributions to the field, and is actively involved in safety assessment, teaching, or research in toxicologic pathology or the administration of these activities" [4]. The role of toxicologic pathologists is to identify pathological changes, to determine the etiology and significance of those changes, and to clearly and accurately report their conclusions to other scientists. This role requires not only an understanding of normal and abnormal tissue morphology but also a sound understanding of general (*whole animal*) physiology, clinical medicine, and the cellular and molecular processes underlying normal and disease states. This understanding necessarily contains a comparative component, as the pathology evaluation usually encompasses multiple laboratory animal species and is typically used as one component of human risk or safety assessment. Accurate interpretation of the significance of the multiple components of a toxicological study demands that the pathologist draw from a broad spectrum of disciplines in the biological and medical sciences.

The gold standard of the pathology evaluation in toxicity studies has been the examination of paraffin-embedded, hematoxylin- and eosin-stained tissue sections. These standardized methods are time tested, and accurate diagnosis and reporting of findings derived from such routinely prepared specimens will continue to play a critical role in the hazard identification process. In addition, the pathology assessment must integrate other relevant data, such as in-life study parameters (e.g., clinical signs, body weight changes), clinical pathology findings, and metabolism and pharmacokinetic data. Added to these more traditional parameters are a wide array of new technologies that are continually arising from advances in computer technology and molecular biology. Examples include the various *-omics* (genomics, proteinomics, metabolomics), genetically modified animal models, molecular assays, and special microscopy (e.g., digital, laser capture, confocal). Many of these technologies are, or will become, critical tools in drug discovery and development, as well as in the hazard identification and risk assessment of xenobiotics; however, accurate morphological diagnoses using standard pathology methods will likely remain important guideposts directing the practical application of these newer technologies.

This chapter provides (1) an overview of standard pathology procedures commonly used in toxicity studies; (2) a discussion of important considerations in the evaluation, interpretation, and reporting of pathology findings; and (3) a discussion of quality assurance practices in pathology, including pathology peer review and pathology working groups (PWGs). Comprehensive discussions of general pathology and organ-specific toxicologic pathology are beyond the scope of this chapter and are provided in a number of standard texts devoted to these subjects [5–9].

PATHOLOGY PROCEDURES

The primary goals of the pathology examination are to identify and collect all gross lesions, to collect all tissues listed in the study protocol, to trim and process all required tissues for microscopic evaluation, and to diagnose and report all lesions accurately. All of these procedures must be done in a consistent manner and in accordance with standardized procedures.

Necropsy

Necropsy refers to the examination of a body after death [10]. Although the necropsy is often one of the shortest phases in a toxicology study, it is one of the most critical. Procedures typically performed during the necropsy for toxicology bioassays include the gross examination, determination of organ weights, and collection of tissues for microscopic examination. Other procedures that commonly occur at necropsy include terminal blood and urine collection, preparation of bone marrow smears, and collection of samples for biochemical or molecular biology procedures.

The necropsy represents the beginning of data generation in the postmortem phase of the study and is the link between in-life findings and histopathological findings [11]. Necropsy observations often provide the first evidence of target organ effects, including carcinogenicity and cause of death. In addition, intercurrent disease or procedural factors that could complicate study interpretation may also be discovered at necropsy. Improper or incomplete necropsy examination can negatively impact an entire study, and because most aspects of the necropsy are not reproducible events within a study, errors occurring during this phase of the study generally cannot be corrected retrospectively. It is therefore essential that the necropsy be performed by highly trained technicians operating under the supervision of a qualified pathologist [12]. Also, for careful planning and conduct of the necropsy,

the necropsy team must have the following documents available for review prior to and during the necropsy [11,12]:

- *Study protocol*, including amendments
- Standard operating procedures (SOPs)
- Clinical records

The study protocol sets forth the study objectives and study-specific procedures and takes precedence over other documents. SOPs provide study personnel with information on the conduct of specific procedures described in the study protocol that may be performed during the necropsy. The clinical records for each animal must be available to the necropsy technician to ensure that any unusual findings observed in life are identified and collected for microscopic evaluation. In addition, every animal presented for necropsy should have an individual necropsy record for recording body and organ weights, gross findings, and tissues collected. Euthanasia date, time, and method and signature lines for all personnel involved in the necropsy of the animal should also be included [13].

The procedures documented in SOPs are followed universally within an institution for every toxicology study in order to standardize necropsy technique. These SOPs are required by regulatory agencies and contribute to an efficient and comprehensive necropsy [3]. Technicians should be knowledgeable about the procedures documented in the SOPs prior to beginning the necropsy and should be able to consult the SOPs during the necropsy if questions arise. Inconsistencies in the performance of procedures, including those for euthanasia; tissue dissection, retrieval, and weighing; use of descriptive terminology for gross findings; and tissue fixation at necropsy can introduce variables that may significantly complicate subsequent evaluation of organ weight data and may produce tissue artifacts that confound the subsequent histopathological evaluation. Sources of artifact are many, but some common ones include freezing rather than refrigerating animals that die on study, autolysis resulting from prolonged intervals between death and tissue fixation, and inadequate tissue fixation, such as occurs with immersion fixation of tissues that are too large or from the use of improper or compromised fixative.

Euthanasia Procedures

Methods of euthanasia should adhere to the recommendations of the American Veterinary Medical Association *Guidelines on Euthanasia* [14] and the *Guide for Care and Use of Laboratory Animals* [15]. The euthanasia procedure should seek to minimize pain and distress, should be easy to perform consistently, and should minimize tissue artifacts. The selection of specific agents and methods for euthanasia will depend on the species involved and the objectives of the study. Some common methods of euthanasia are given in Table 12.1. Generally, inhalant or non-inhalant chemical agents are preferable to physical methods such as decapitation [15]. Although the selection of specific agents and methods may be species and protocol dependent, all methods of euthanasia should be reviewed and approved by the Institutional Animal Care and Use Committee (IACUC).

TABLE 12.1
Methods of Euthanasia

Asphyxiation
Carbon dioxide
Anesthesia
Isoflurane
Sodium pentobarbital
Methoxyflurane
Halothane
Cervical dislocation
Decapitation (guillotine)

A number of pathology parameters may be influenced by the method of euthanasia and the choice of euthanasia agent. For example, barbiturate euthanasia agents are known to cause pooling of blood in the spleen, resulting in gross enlargement (splenomegaly) and congestion of the spleen in dogs. If the spleen were anticipated to be a primary or secondary target of a test compound, the use of an alternative method of euthanasia should be considered, or at least the known effects of the barbiturate on the spleen would have to be considered in interpreting the gross and organ weight data. The choice of euthanasia procedure may also produce specific histopathological changes that should not be confused with treatment-related changes. For example, carbon dioxide asphyxiation may produce focal, acute alveolar hemorrhage in the lung (Figure 12.1).

To limit postmortem autolysis and the potential introduction of confounding artifacts, the interval between death and necropsy should be minimized. Prolonged intervals between euthanasia and necropsy may produce significant alterations in organ weights and histology. For example, increased liver weights (both absolute and relative to body weight) and microscopic vacuolation of the liver may occur with a

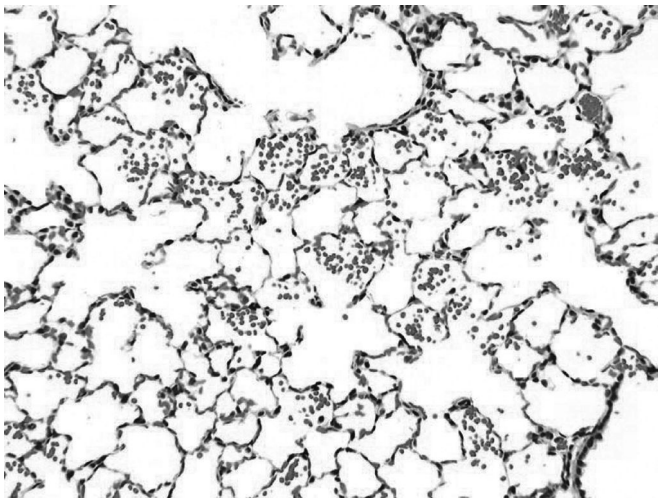

FIGURE 12.1 Focal acute alveolar hemorrhage in the lung of a rat euthanized by CO_2 anesthesia and exsanguination.

delay of only 25 min between euthanasia and necropsy [16]. Dissection should begin no longer than 5 min after euthanasia, and dissection time should not exceed 20 min.

Dissection and Gross Examination

Necropsy personnel performing the gross evaluation should be trained in the anatomy of the test species and in postmortem dissection procedures. Guidelines for the necropsy of laboratory animals have been published [17,18] and should be consulted if needed. During the postmortem examination, the prosector must handle unfixed tissues carefully. Excessive tissue manipulation, including excessive digital pressure or crushing or puncturing tissues with dissection instruments, may create artifacts that could complicate the microscopic examination. Normal saline should be used when rinsing tissue or to keep tissue moist; hypotonic tap water may produce tissue artifacts [12]. To avoid critical and irreversible errors in organ retrieval, the protocol should be strictly followed and consulted as necessary with regard to the tissues and organs that are to be collected. Table 12.2 provides a list of tissues recommended by the STP for subchronic and chronic toxicity studies [19]. This list is a minimum core list for all types of repeat-dose studies. Additional tissue may be added based on exposure route, species or strain of test animal, or known targets. To ensure tissue accountability, the individual necropsy record should include a list of all protocol (and nonprotocol) tissues to be collected and each tissue should be checked-off as it is placed in fixative.

The detection and an accurate description of gross lesions are essential aspects of the necropsy examination, as the gross examination guides subsequent tissue trimming and histopathology. Gross identification and retrieval of lesions is particularly important for nonprotocol tissue, which would otherwise not be examined microscopically. To ensure consistency between prosectors, both within and across studies, gross observations should be identified according to standard descriptive terms. Abnormal gross findings should generally be described using some or all of the following criteria: location, number, size, color, consistency, distribution, and any special features that characterize the lesion. A list of selected terms that can be used in the gross description is given in Table 12.3. The gross descriptions of tissue changes should be concise and descriptive (rather than diagnostic), with special attention given to consistency throughout the necropsy. An example of a gross description is given in Figure 12.2.

TABLE 12.2
STP-Recommended Core List of Tissues to Be Examined Histopathologically in Repeat-Dose Toxicity Studies (for All Species where Applicable)

Adrenal gland	Peripheral nerve
Aorta	Pituitary
Bone with bone marrow[a]	Prostate
Brain	Salivary gland
Cecum	Seminal vesicle
Colon	Skeletal muscle
Duodenum	Skin
Epididymis	Spinal cord
Esophagus	Spleen
Eye	Stomach
Gallbladder	Testis
Harderian gland	Thymus
Heart	Thyroid gland
Ileum	Trachea
Jejunum	Urinary bladder
Kidney	Uterus
Liver	Vagina
Lung	Gross lesions
Lymph node(s)	Tissue masses
Mammary gland[b]	Tissues relevant to route of exposure[c]
Ovary	Tissues unique to the species or strain
Pancreas	Known target tissues
Parathyroid gland

Organ Weight Determinations

As with other end points collected during the necropsy, organ weights cannot be reproduced at a later date, so consistency and accuracy are critical to generating meaningful organ weight data [20]. Organ weight changes can be sensitive indicators of target organ toxicity, and significant changes in organ weights may occur in the absence of changes in other pathology parameters [21]. For example, increased liver weight associated with hepatic cytochrome P450 induction is a common finding in toxicology studies, and liver weight increases of up to 20% relative to controls may occur without microscopic evidence of hepatocellular hypertrophy or changes in serum chemistries [22]. Similarly, modest dose-related changes in kidney weight commonly occur in toxicology studies without histopathological evidence of cellular alteration and may indicate test substance effect [23]. However, while changes in organ weight parameters may be useful indicators of test substance-related effects, a change in organ weight as the sole indicator of target organ toxicity is uncommon, and organ weight changes must be interpreted in an integrated fashion with other study parameters including gross pathology, clinical pathology, and histopathology. Detectable organ weight changes occurring absent correlative changes in these other parameters may not necessarily be indicative of treatment-related or adverse findings and should be interpreted with caution [20].

Given the importance organ weight data may play in the overall interpretation of pathology findings, standardized methods for organ collection and weighing should be in place to ensure consistency and avoid artifactual weight changes. The animal necropsy order should be randomized or appropriately rotated to prevent bias, as organ weights may change

TABLE 12.3
Gross Lesion Description

General Location	Number	Consistency	Special Characteristics
Cutaneous	Single	Brittle	Area
Subcutaneous	Two	Caseous	Adhesion
Peritoneal	Four	Fibrinous	Circumscribed
Abdominal	Greater than *x*	Firm	Depressed
Thoracic	Multiple	Friable	Distended
Cranial	Size	Fluctuant	Flat
Sacral	Small	Gelatinous	Irregular
Lumbar	Enlarged	Granular	Layered
Cervical	Increased in size	Greasy	Linear
Axillary	Decreased in size	Gritty	Lobulated
Inguinal	Exact measurement	Hard	Macule
		Mucoid	Mass
Specific Location	**Color**	Oily	Nodule
Ventral	Black	Rough	Oval
Dorsal	Blue	Rubbery	Papillary
Lateral	Brown	Scaly	Papule
Medial	Clear	Soft	Pedunculated
Distal	Cloudy	Thin	Perforated
Proximal	Dark	Viscous	Pitted
Deep	Green	Watery	Plaque
Hilus	Gray		Polypoid
Wall	Mottled	**Distribution**	Prominent
Lumen	Opaque	Focal	Umbilicated
Mucosa	Pale	Multifocal	Raised
Superficial	Pink	Diffuse	Round
Serosa	Purple	Patchy	Spherical
Cortex	Red	Bilateral	
Medulla	Tan	Symmetrical	
Parenchyma	Transparent	Confluent	
Peripheral	Translucent	Unilateral	
Margin/Edge	White	All lobes	
Anterior	Yellow	Random

throughout the day, particularly in fasted rodents. Similarly, prosector assignments should be rotated to ensure that one prosector does not disproportionately necropsy animals from one dose group, as differences in organ removal and trimming techniques might impact results [20]. More consistent results for organ weight determinations can be attained if the animal is bled out prior to weighing organs [12]. At weighing, care should be taken to remove extraneous tissue and blood clots and to prevent tissue dehydration. For some small tissues, such as rodent thyroid glands or pituitary glands, weighing tissue after fixation may help minimize artifacts associated with the handling of fresh tissue [3,20]. Interpretation of organ weight findings requires evaluation of

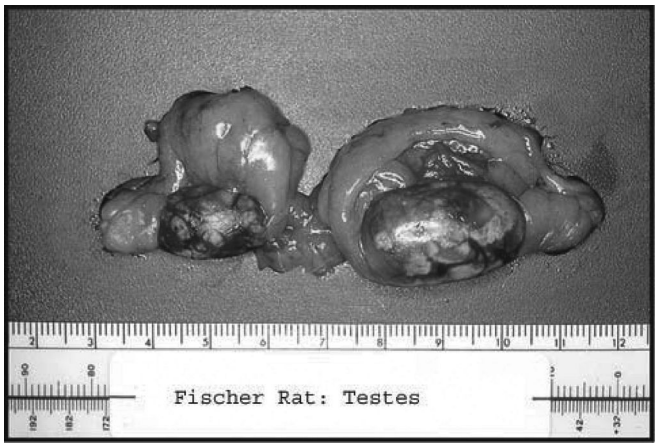

FIGURE 12.2 Gross description: testes. Masses, bilateral, multiple, firm, tan, 0.2–0.5 cm in diameter.

individual animal values, as well as group means for absolute organ weights and organ-to-body and/or organ-to-brain weight ratios. To minimize weighing errors during necropsy, a range of expected normal weights for each organ (matched to the species, strain, sex, and age of the test animal) should be available. Any weights that are outside this range should be verified before recording.

Terminal body weights collected at necropsy should be used to calculate organ-to-body ratios to control for potential variations that may be induced by stressful handling, diurnal fluctuations, or fasting. Organ-to-brain weight ratios may also be useful in some circumstances and can be calculated routinely or can be requested on a case-by-case basis. As noted below (see Primary versus Secondary Effects), understanding the effect of body weight changes on the organ weight for a given organ is important in the overall assessment of organ weight changes, as changes in body weight may lead to increases, decreases, or no change in organ-to-body weight ratios, depending on the organ affected.

The STP has provided recommendations for organs to weigh in repeated-dose toxicity studies of 1-week to 1-year duration (Table 12.4). In addition to those organs listed in Table 12.4, additional organs may be weighed on a case-by-case basis. These organs include uterus, ovary, lung, lymph nodes, gastrointestinal tract, pancreas (nonrodent species), seminal vesicles, salivary glands, and thymus (rodent species). Weighing lymph nodes is not recommended due to marked intra- and interanimal variability and because these tissues may be difficult to isolate from adjacent fat [20]. Organ weight determinations are not recommended for carcinogenicity studies, including those using alternative mouse models, as aging changes and intercurrent disease contribute to greater interanimal variability that can confound interpretation of organ weight changes. Similarly, due to confounding factors such as changes in nutritional status, lack of exsanguination, and absence of matched control, organs from animals that die or are euthanized prior to the scheduled termination should generally not be weighed. Organ weights are also considered to be of limited value in single-dose (acute) studies or in dose escalation studies [20].

TABLE 12.4
Recommended Organs for Weighing[a] in Multidose Toxicology Studies with Study Durations of 7 Days to 1 Year

Organ	Species	Comment
Adrenal glands	Rat, mouse, nonrodent	
Brain	Rat, mouse, nonrodent	
Epididymides		• Weighed in nonrodents and mice on a case-by-case basis. • Weight more valuable when assessed in mature animals.
Heart	Rat, mouse, nonrodent	
Kidneys	Rat, mouse, nonrodent	
Liver	Rat, mouse, nonrodent	
Lungs		
Pituitary gland	Rat, nonrodent	• Optional in mice, as the collection/weighing process may produce artifacts that can complicate microscopic assessment. • In rodents, fixation prior to weighing may provide more accurate weight measurements and improve morphology.
Prostate gland	Rat	• Weighed in nonrodents and mice on a case-by-case basis. • Weight more valuable when assessed in mature animals.
Spleen	Rat, mouse	• Weighed in nonrodents on a case-by-case basis. • Weight may be influenced by method of euthanasia and consistency of exsanguination.
Testes	Rat, mouse, nonrodent	• Weight more valuable when assessed in mature animals.
Thymus	Rat, mouse	• Weighed in nonrodents on a case-by-case basis.
Thyroid/parathyroid glands	Rat, nonrodent	• Optional in mice, as the collection/weighing process may produce artifacts that can complicate microscopic assessment. • In rodents, fixation prior to weighing may provide accurate weight measurements and improve morphology.

[a] Paired organs should be weighed together.

Tissue Fixation

A wide array of fixatives and fixation procedures is available and no universal fixative exists because no one fixative is perfect for all applications. The specific fixation procedure should be determined by the study objectives and study protocol. However, the most common fixation method is immersion fixation in neutral-buffered formalin. Prior to immersion fixation, tissues should be trimmed to approximately 0.5 cm thickness. They are then placed in formalin for at least 24–48 h at a 10:1 volume ratio of fixative to tissue; however, ratios as low as 3:1 are adequate if tissues are properly prepared for fixation. Formalin provides relatively rapid fixation, is easy to use, and is inexpensive, but formalin is potentially toxic and thus requires proper ventilation and disposal. Also, tissue artifacts, such as retinal detachment, may occur secondary to tissue shrinkage. Nevertheless, for most routine studies and for most tissues, 10% neutral-buffered formalin is typically the fixative of choice. Other fixatives and fixation methods may be used for specific tissues or procedures. A common example is the use of modified Davidson's fixative for fixation of the eye and testes [24]. Glutaraldehyde-based fixatives are often employed for ultrastructural studies. Inflation is the preferred method for fixation of the lung and may also be used for hollow organs, including the urinary bladder, stomach, and intestines [12], and involves gentle instillation of fixative into the organ prior to immersion into fixative. Perfusion may be used in special target organ toxicity studies. For example, whole body intravascular perfusion with Karnovsky fixative is commonly employed in neurotoxicity studies [25].

Histology

All changes to tissue that occur after fixation are, in effect, artifact. The goal in processing slides for microscopic (or ultrastructural) examination is to control the artifactual change so it is consistent across organs and across animals [13]. As noted for the necropsy, clearly written SOPs for histology procedures and strict adherence to these SOPs are essential for consistency in histological slide preparation. It is also important that each batch of tissues processed includes tissues from animals in all study groups to avoid apparent compound effects that are actually the result of variation in processing, embedding, or staining. Artifacts may be introduced at any stage in the preparation of tissue for microscopic evaluation including tissue dissection, weighing, and fixation; tissue processing for paraffin embedding; and microtomy, mounting of tissue sections onto glass slides, slide staining, and coverslipping [26,27].

Tissue Trimming

The first step in processing tissues for microscopic evaluation is tissue trimming. Trimming should be performed by

trained technicians with knowledge of gross anatomy and medical terminology and an understanding of the meaning of gross observations made during necropsy. The technician should have the study protocol, as well as the gross findings, available prior to trimming. Tissue trimming is yet another procedure where inconsistencies may result in biased sampling and poor comparability across different groups within a study or across many different studies. Thus, for each organ, SOPs should be available that outline standard trimming procedures to be followed, including the plane of trim (e.g., transverse or longitudinal), and, for larger organs such as the liver or lung, the number of sections and the specific areas to be trimmed. Guides for tissue trimming in rodents have been published in an attempt to standardize tissue trimming across laboratories [28–30]. Tissues should be trimmed to a maximum thickness of 0.3 cm for processing. Smaller tissues can be embedded intact. When trimming masses, adjacent normal tissue should be included where possible, and multiple sections should be taken from masses that are large or variable in appearance.

Tissue Processing, Embedding, and Staining

Following fixation and trimming, the tissue is most commonly processed and embedded in paraffin for microscopic evaluation. The steps involved in tissue processing and paraffin embedding are given in Figure 12.3. Although paraffin embedding is suitable for most forms of light microscopy, embedding media composed of acrylic or epoxy resins are commonly used for high-resolution light microscopy and electron microscopy. Further information on these advanced techniques can be found in other textbooks [31].

Paraffin-embedded tissue blocks are routinely cut with a microtome to produce sections with a thickness of about 4–6 μm (microns). Paraffin tissue sections are most commonly stained with the hematoxylin and eosin stain; however, other histochemical and immunohistochemical stains may also be used to identify specific properties of cells, intracellular structures, or microorganisms [31,32]. Examples of some histochemical special stains used to identify specific structures or materials are given in Table 12.5.

HISTOPATHOLOGY EXAMINATION

Overview

Histopathology is the study of morphological changes in tissues at the light microscopic level [33]. Histopathological findings frequently form the basis of the no-observed-adverse-effect level (NOAEL) in toxicology studies and are a critical part of hazard identification and risk assessment of pharmaceuticals, chemicals, biologics, and medical devices. The STP has published best practices guideline for toxicologic histopathology [33], which is aimed at identifying and defining the fundamental elements of the histopathological examination and appropriate techniques to minimize observer bias. Some of the recommendations given in this guideline are summarized in Table 12.6, and selected topics are discussed in more detail as follows.

Qualifications and Responsibilities of the Pathologist

The histopathological evaluation is the responsibility of the pathologist who must clearly communicate the results of that evaluation not only to other pathologists but also to

Dehydration

- Necessary because paraffin is not miscible with water
- Graded alcohols most commonly used

↓

Clearing

- Clearing reagents must be miscible with both the dehydrant (alcohol) and paraffin
- Commonly used reagents: xylene, toluene, D-limonene
- As the alcohol is removed, the tissue clears
- Must be carefully regulated to avoid excess hardening of the tissue

↓

Impregnation

- Complete removal of clearing reagents by substitution with paraffin
- Temperature of paraffin baths is critical; temperatures >5°C above the melting point of 56°C–58°C will cause excessive hardening of the tissue
- Vacuum removes air, gases, and remaining clearing reagent and draws paraffin into all areas of the tissue

↓

Embedding

- Orientation of tissue in melted paraffin
- Provides a firm medium for tissue sectioning
- Orientation and location of tissue in paraffin block must be consistent across animals

FIGURE 12.3 Procedures for tissue processing and embedding in paraffin.

TABLE 12.5
Selected Histochemical Stains Used in the Histopathological Evaluation

Stain	Uses
Hematoxylin and eosin (HE)	Most commonly used stain for routine histopathology
	Stains nucleus basophilic (blue) and cytoplasm eosinophilic (pink to red)
Periodic acid–Schiff (PAS)	Stains PAS positive structures (magenta); examples include
	Glycogen and mucin
	Basement membranes
	Microorganisms, including some fungi and protozoa
Masson's trichrome	Stains collagen (blue) and muscle (red)
Oil red O	Stains lipids (red); requires fresh smears or cryostat sections
Perl's iron stain	Stains iron (hemosiderin) (blue)
Luxol fast blue	Stains myelinated nerve fibers (blue)
Von Kossa's	Stains calcium (deep purple)
Toluidine blue	Stains mast cell granules (violet)

toxicologists and other scientists. Unlike the approach used in classic diagnostic pathology, which is characterized by lengthy detailed descriptions of each morphological abnormality, toxicologic pathologists must record their findings in a manner that allows for meaningful tabular summaries of the data. A comparison of the diagnostic and descriptive approaches used in classic and toxicologic pathology is given in Figure 12.4. The pathologist should then use the pathology narrative to place the tabulated microscopic findings in proper perspective relative to treatment-related effects and their biological significance; thus, histopathology is interpretive as well as descriptive [33,34].

A uniform accreditation standard for toxicologic pathologists does not exist, and the basic requirements to qualify as a toxicologic pathologist vary by country; however, a general consensus is that practicing toxicologic pathology requires formal training in a biomedical field and postgraduate training in toxicologic pathology. A review of the regional standards for the training and accreditation of toxicologic pathologists has been conducted by the International Federation of Societies of Toxicologic Pathologists [4].

One of the most challenging aspects of the histopathological evaluation in toxicologic pathology is achieving consistency among pathologists both within and across studies, as well as over time. Bucci [3] noted that, other than inaccuracy, inconsistency was the most undesirable characteristic of toxicology data. Histopathological diagnoses typically include some degree of subjectivity; therefore, although the diagnostic terms used by different pathologists for the same lesion should be comparable, they are not expected to always be identical [33,35]. Nevertheless, even though no two pathologists can be expected to produce identical findings (diagnoses, lesion grades) across all tissues examined in a study, qualified pathologists should be able to identify the same treatment-related lesions and the NOAEL for those lesions.

TABLE 12.6
Some Fundamental Elements of the Histopathological Evaluation

Information that should be available to the pathologist prior to the microscopic evaluation

The nature of the test substance and the class of compounds to which it belongs
Results of previous studies with the test compound in the same or different species, including target organ effects
All details of the experimental design (study protocol)
In-life data, including clinical signs, body weight, and nutritional data
Clinical pathology data (hematology, clinical chemistries, urinalysis), as well as hormone and enzyme induction data
Gross findings and organ weight data for individual animals

The process of histopathological evaluation

Assess specimen quality (reflects adequacy of tissue collection, fixation, trimming, processing, and staining)
Ensure that appropriate sections of tissues or organs are present on the slide and request recuts if necessary
Use concise, standardized diagnostic nomenclature and diagnostic criteria for tabular summaries
Use detailed free text as needed to better define complex lesions
Evaluate tissues either animal by animal (allows a more comprehensive assessment of animal's health) or organ by organ (provides a more focused examination of changes and greater consistency in severity grading)
Use a severity grading system that is definable, reproducible, and meaningful
In carcinogenicity studies,
- Distinguish hyperplasia, dysplasia, and neoplasia
- Classify neoplasms as benign or malignant and as primary or metastatic
- Provide evaluation of cause of death

Procedures that may be used to enhance accuracy and consistency of the histopathology evaluation

Informal reevaluation of specific changes in specific tissues; may be conducted using masking techniques
Peer review by a second pathologist of defined subsets of animals and tissues, as well as study conclusions
Review by a PWG consisting of experts for the target tissues of interest

Procedures for the Histopathological Examination

In most circumstances, best results are achieved when all tissues from a study are evaluated by one pathologist [33]; however, in some circumstances, such as large studies or critical studies with short time lines, it may be necessary for two or more pathologists to read different subsets of tissues. Most commonly this involves different pathologists evaluating tissue from males and females. Peer review by a single pathologist is important in achieving consistency in studies where more than one pathologist has evaluated a study. The order of slide review among study groups may vary based

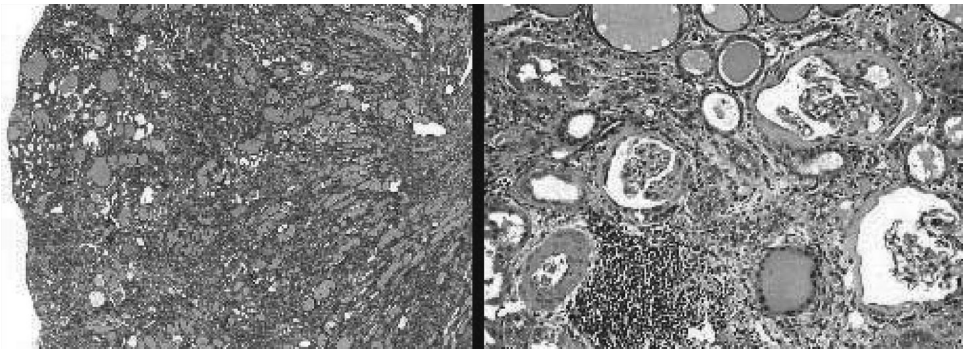

FIGURE 12.4 Morphological diagnoses in classic and toxicologic pathology. Morphological diagnoses based on classic descriptive pathology: Kidney, nephropathy, progressive, chronic, characterized by basement membrane thickening, tubular degeneration and regeneration, tubular dilatation, proteinaceous casts, mixed interstitial inflammatory infiltrate, interstitial fibrosis, mesangial proliferation, dilatation of Bowman's space, proliferation of parietal cells, glomerular adhesions, and sclerotic glomeruli. Morphological diagnosis for tabular summaries: Nephropathy, chronic, progressive, severe.

on study type and personal preference of the pathologist. For some studies, especially those with small group sizes, all controls may be evaluated first to establish the spectrum of *normal*. This is followed by the evaluation of high- and intermediate-dose groups as required by the protocol. Alternatively, the histopathological evaluation may proceed through alternating subsets of animals from each group.

Coded (Blinded, Masked) Histopathology Evaluations

The practice of conducting the initial histopathological evaluation with the pathologist having no knowledge of treatment status of individual animals is a controversial and much debated issue [36,37]. The controversy exists primarily between pathologists and nonpathologists, as most practicing toxicologic pathologists do not endorse coded evaluations for the *initial* slide review [36,38]. The position of the STP on coded evaluations is as follows [39]:

> The Society of Toxicologic Pathologists unequivocally supports open or non-blinded microscopic evaluation of tissues from experimental animals obtained from toxicology studies. The Society supports the long-standing diagnostic pathology practice that a pathologist, when making a microscopic evaluation of tissues, must have access to all available information about the animals from which the tissues were derived. Over the years, this method has been proven as an efficient and effective way of generating accurate data in a setting where time, costs, and productivity must all be considered.

Similarly, the American College of Veterinary Pathologists (ACVP) stated the following position [40]:

> In the opinion of the ACVP, such procedure [coded initial evaluation] is not appropriate for the routine evaluation of slides from toxicology studies.

The foremost objection to a coded slide evaluation concerns the initial histopathological examination of slides in a study. Coded examination will result in a loss of knowledge of the range of normal that exists in known controls. The pathologist uses the concurrent controls to establish a baseline for what is expected in a particular study for a given species, strain, sex, and age of animal. Without this baseline, subtle differences between treated and control groups may be difficult to detect. Another objection to coded examination is that knowledge of the treatment groups during the initial slide review allows the pathologist to assess the spectrum of related morphological changes and determine the most appropriate diagnostic terminology, including combining related diagnoses when indicated, to more accurately describe an observed treatment-related effect. The use of multiple diagnoses for a single disease process may obscure treatment-related effects by introducing unnecessary and confusing detail to the tabular summaries. In addition to these considerations, the additional procedures required to code and decode data and the additional effort necessary for the pathologist to record essentially all observations (including those well within *normal*) would increase study costs and timing; thus, the disadvantages of coded evaluations for the initial slide evaluation are both scientific and economic [38,40].

Although coded evaluations are not recommended for the initial slide review, a coded reexamination of selected target organs is commonly undertaken by toxicologic pathologists to confirm subtle changes or to clarify slight treatment-related effects on the incidence or severity of common background lesions. Thus, the histopathological evaluation has been described as a two-stage process, the components of which are the *identification stage* and the *confirmation stage*. In the identification stage, potential treatment-related findings are initially discovered, and in the confirmation stage, treatment-related associations are validated. The identification stage, as discussed earlier, is traditionally performed as an uncoded examination to minimize the chance that subtle, treatment-related findings will be missed. The confirmation stage is conducted in a coded or masked manner and is used as an informal *check* by the pathologist to guard against the possibility of reporting false-positive or

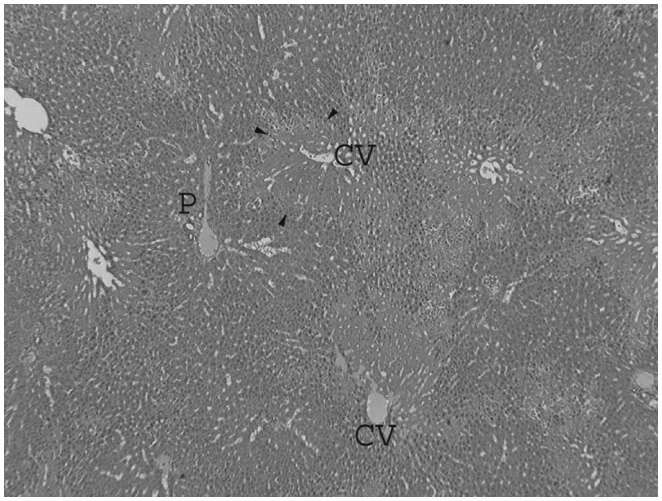
false-negative results. The confirmation stage may not be required in all cases, such as when there are no findings that are potentially treatment-related (negative studies), or for studies in which the evidence of treatment-relatedness is obvious. However, confirmation steps are necessary when, for example, causality for a finding is uncertain, when criteria used for severity grading are especially nuanced, or when determining a NOEL at the lower, less conclusive end of the dose–response for the histopathological finding [41].

Diagnostic Nomenclature

The histopathological diagnosis is the primary means of communicating the results of the microscopic evaluation. The goal of the microscopic examination is to identify test article effects through a comparison of treated animals with control animals. It is important that microscopic observations be recorded in a consistent, objective manner that readily allows tabulation and comparison of group effects. Different grading scales, whether a change should be graded or only noted as present, and the use of modifiers and thresholds all provide opportunities for variation between pathologists. Therefore, standardized terminology should be chosen that clearly communicates the important aspects of tissue changes. Internationally recognized standards for diagnostic nomenclature have been developed with the aim of harmonizing nomenclature and diagnostic criteria in toxicologic pathology [42]. These include th*e Standardized System of Nomenclature and Diagnostic Criteria (SSNDC): Guides for Toxicologic Pathology* [43] and, more recently, the International Harmonization of Nomenclature and Diagnostic Criteria for Lesions in Rats and Mice (INHAND) [44]. A number of toxicologic pathology reference texts also provide guidance on diagnoses and diagnostic criteria [7–9,45].

The construction of a morphological diagnosis is typically hierarchical and includes the topography or site (organ or tissue), the major pathological process, and qualifiers. Qualifiers may specify subsites within the organ, distribution, duration, character, and severity [12,35,46]. An example is given in Figure 12.5. Qualifiers are used as needed to make distinctions that are toxicologically relevant. Except for the severity grade, different terminology for topography, process, or qualifiers defines a separate and distinct diagnosis; thus, the hierarchical approach is highly flexible and allows for an almost unlimited number of diagnoses. Overuse of this flexibility, however, by selecting different combinations of diagnostic terms to describe similar lesions can potentially obscure a treatment-related effect or create the appearances of an effect where none is present. In Figure 12.5, for example, some possible diagnoses might include the following:

- Liver. Necrosis, acute, centrilobular, moderate
- Liver. Necrosis, moderate (no duration or distribution qualifier)
- Liver. Necrosis, acute, coagulative, centrilobular, moderate (character qualifier added)



Organ/Tissue	Primary Pathological Process	Qualifiers		
		Duration	Distribution	Severity
Liver	Necrosis	Acute	Centrilobular	Moderate

FIGURE 12.5 Liver from a Sprague–Dawley rat. Acute coagulative necrosis of hepatocytes (arrowheads) is centered about central veins (CV); hepatocytes in portal areas (P) are unaffected.

Although describing the same primary process, each of these diagnoses as constructed would be summarized and tabulated separately when, instead, a single diagnosis would be more appropriate; however, liver necrosis with a distinctly different distribution may be indicative of a different pathogenesis for the necrosis and thus should be diagnosed separately from the centrilobular lesion presented in Figure 12.5. As an example, subcapsular, rather than centrilobular, necrosis of the liver has been reported to occur following drug-induced liver microsomal enzyme induction with associated hepatomegaly and compression of hepatocytes subjacent to the liver capsule [22]. It is the responsibility of the pathologist to appropriately group lesions of similar morphology, location, and pathogenesis under a single diagnosis that best allows for the detection of treatment-related changes.

Neoplasia has been defined as an abnormal mass of tissue, the growth of which exceeds and is uncoordinated with that of normal tissue and persists in the same excessive manner after cessation of the stimulus that evoked the change [47]. For neoplastic lesions, the diagnosis should indicate whether the neoplasm is benign or malignant and whether it is primary to the tissue being examined or is metastatic. Tumor multiplicity and their bilateral or unilateral presence in paired organs may also be noted. Lesions occurring secondary to the neoplasm, such as inflammation and necrosis, are generally not recorded, as these secondary changes seldom provide useful information.

Although there are exceptions, most neoplasms are classified as to their predicted biological behavior and their cell

of origin. To designate biological behavior, the suffix *-oma* typically indicates that the lesion is benign, while *carcinoma* and *sarcoma* indicate malignant neoplasms of epithelial or mesenchymal origin, respectively. For histiogenesis, prefixes such as *adeno-* (glandular tissue) and *fibro-* (fibrous or connective tissue) are used to designate the cell or tissue of origin. Thus, mammary gland adenocarcinoma refers to a malignant neoplasm of glandular tissue, specifically of the mammary gland. Selected examples of taxonomy of neoplasms are given in Table 12.7 [48].

TABLE 12.7
Selected Taxonomy of Neoplasia

Tissue	Benign Neoplasia	Malignant Neoplasia
Epithelium		
Squamous	Squamous cell papilloma	Squamous cell carcinoma
Transitional	Transitional cell papilloma	Transitional cell carcinoma
Glandular	Adenoma	Adenocarcinoma
Liver cell	Hepatocellular adenoma	Hepatocellular carcinoma
Connective tissue		
Fibrous	Fibroma	Fibrosarcoma
Embryonic fibrous	Myxoma	Myxosarcoma
Cartilage	Chondroma	Chondrosarcoma
Bone	Osteoma	Osteosarcoma
Fat	Lipoma	Liposarcoma
Muscle		
Smooth muscle	Leiomyoma	Leiomyosarcoma
Skeletal muscle	Rhabdomyoma	Rhabdomyosarcoma
Endothelium		
Lymph vessels	Lymphangioma	Lymphangiosarcoma
Blood vessels	Hemangioma	Hemangiosarcoma
Hemolymphatic		
Lymphoid cells	Not recognized	Lymphoma (malignant)
Hematopoietic cells	Not recognized	Leukemia (granulocytic, erythroid)
Neural tissue		
Schwann cells	Schwannoma, benign	Schwannoma, malignant
Oligodendrocytes	Not recognized[a]	Oligodendroglioma, malignant (low or high grade)
Astrocytes	Not recognized[a]	Astrocytoma, malignant (low or high grade)
Embryonic cells	Not recognized	Neuroblastoma

Source: Modified from Haschek, W.M. and Rousseaux, C.G., Chemical carcinogenesis, in *Fundamentals of Toxicologic Pathology*, Haschek, W.M. and Rousseaux, C.G., eds., Elsevier, Amsterdam, the Netherlands, chapter 2, Section II, 2010.

[a] Well-differentiated lesions may be designated *malignant, low grade* rather than benign.

The classification of proliferative lesions as hyperplasia, benign neoplasia, or malignant neoplasia is based on *predictive* biological behavior. This prediction is based on historical correlation of certain microscopic features of neoplasms to clinical behavior. For example, neoplasms are diagnosed as malignant if there is evidence of invasion or metastasis or if histological features of the neoplasm have been shown historically to correlate with invasion or metastasis. It is important to remember, however, that these are operational terms based on evaluation at one point in time, and the future progression of the lesion cannot be definitively predicted unless metastasis has already occurred. Furthermore, the morphological distinction between hyperplasia and neoplasia or benign and malignant neoplasia is not always clear; thus, although the designations hyperplasia, benign neoplasia, or malignant neoplasia have practical utility, they do represent simplifications of a complex process [47].

In toxicologic pathology, diagnostic criteria for proliferative lesions that are relatively objective and reasonably predictive of biological behavior are ideal. At some points along the morphological continuum for some proliferative lesions, however, clear features that differentiate, for example, hyperplasia from adenoma are difficult to identify. In these cases, the size of the lesion may be the central (albeit not the only) criterion used to differentiate hyperplasia from adenoma. Although size should not be the only diagnostic criterion, the use of size as a central feature for some lesions adds consistency to the application of diagnostic terms and thus facilitates comparisons across studies and with historical incidence data. It is important to recognize that in these cases, size may not be a reliable predictor of biological behavior. For example, for proliferative lesions of pancreatic acinar cells, the 2D size of the lesion has been proposed as an important criterion, with lesions less than 5 mm in diameter considered hyperplasia and those greater than 5 mm considered benign neoplasms [44]. The use of size as one of the main criteria in this instance facilitates consistency in diagnosis across studies and laboratories, and some relationship between size and biological behavior for proliferative pancreatic acinar cell lesions has been suggested [49]. However, the differential diagnosis between hyperplastic acinar cell lesions approaching 5 mm in diameter and adenomas slightly greater than 5 mm in diameter is somewhat arbitrary and not necessarily reflective of meaningful differences between the respective lesions.

Severity Grading of Lesions

Severity grading is the semiquantitative application of a defined severity score to specific lesions [35,50]. Although a wide array of morphometric methods is available to quantitate changes in tissue, semiquantitative rating systems, if adequately defined and consistently applied, are fully capable of detecting treatment-related changes. Comparisons of results from quantitative and semiquantitative methods often show no relevant difference between the two methods in identifying a treatment-related effect or determining the NOEL for

that effect; thus, the routine histopathological evaluation is typically conducted using semiquantitative methods [12,50].

Severity grading is used as a diagnosis qualifier, primarily for nonneoplastic lesions, and is especially useful in identifying treatment-related effects that are not clearly incidence based; for example, a treatment-related effect may manifest only as increased severity of a common spontaneous lesion, such as chronic nephropathy. Severity grading is subjective, and systems for grading may vary among pathologists; therefore, reproducibility of results from severity grading requires that the grading scheme be clearly defined. Clear definitions not only provide the reviewer with an image of the spectrum of changes observed for a particular lesion but also aid in the peer review process, which should include an evaluation of the consistency of grading within the study by the peer review pathologist. As long as severity grades are consistently applied across a study, a one-point difference of opinion regarding severity is acceptable, given the semiquantitative nature of severity scoring [42]. For some lesions where severity grading adds no useful information, pathologists may not assign a severity grade. In such cases, changes are typically recorded as present (P), rather than having a severity grade assigned. Examples include neoplasms, cyst(s), autolysis, and congenital anomalies.

There are no standardized guidelines for lesion grading; however, grading schemes most commonly use four or five severity grades, designated by descriptive terms or numerical grade, to denote the extent of tissue involvement and/or the degree of tissue damage. Some commonly used grading schemes are given in Table 12.8.

TABLE 12.8
Some Commonly Used Severity Grading Schemes

Grading Scheme I

0 = Not present
1 = Minimal (<1%)
2 = Slight (1%–25%)
3 = Moderate (26%–50%)
4 = Moderately severe/high (51%–75%)
5 = Severe/high (76%–100%)

Grading Scheme II	**A**	**B**
Grade 1 = Minimal	(<10%)	(0%–25%)
Grade 2 = Mild	(10%–39%)	(26%–50%)
Grade 3 = Moderate	(40%–79%)	(51%–75%)
Grade 4 = Marked	(80%–100%)	(76%–100%)

Grading Scheme III

Grade 1 = Minimal
Grade 2 = Slight (same as mild)
Grade 3 = Moderate
Grade 4 = Marked (same as severe)
Grade 5 = Massive (same as very severe)

Diagnostic Thresholds

In addition to recording treatment-related alterations and notable spontaneous lesions, the pathologist must determine whether or not to document minor variations in normal tissue morphology. Thresholding refers to the practice of determining which variations in normal morphology will be recorded and which variations are below a threshold and will not be recorded. These variations may result from minor age-related changes or they may represent normal anatomic variability within a population of animals. Some degree of thresholding of these common subtle variations in tissue morphology is needed to provide a meaningful compilation of microscopic pathology data. However, care must be taken in determining thresholds for common spontaneous changes, as the potential for a treatment-related effect on the incidence or severity of those changes may be more difficult to determine if they are not recorded. Nonetheless, setting an appropriate threshold can aid in streamlining the number of diagnoses produced in a study, so that treatment-related changes are clear [42].

Diagnostic Drift

Diagnostic drift refers to gradual changes in nomenclature or application of severity grading scales that may occur in a single study group or across several groups in a single study or when several studies are compared. The use of multiple terms or many different qualifiers to diagnose different morphological changes that are essentially the same is one source of diagnostic drift. Terminology and severity grading may also change over the course of evaluating the study as the pathologist becomes better aware of the full spectrum of treatment-related effects. Diagnostic drift cannot be appreciated by observing a single event but rather requires numerous data points separated by time. It is more commonly a problem in large studies containing large numbers of animals and tissues that must be evaluated over a relatively long period of time. Diagnostic drift is a source of variation that, if severe enough, may falsely create or mask treatment-related changes or may complicate determination of the NOEL. A slide evaluation method used to minimize diagnostic drift is to evaluate replicates of animals across all groups—for example, five controls, five high-dose, five low-dose, five mid-dose, and so on. If diagnostic drift is clearly identified in a study, the tissue affected should be reevaluated. In these circumstances, a coded evaluation of the specific tissue and lesion in question may be beneficial [12,33,35].

EVALUATION OF PATHOLOGY DATA

The interpretation of pathology findings requires a comprehensive assessment of gross, organ weight, and histopathological data, as well as in-life and clinical pathology findings. As noted previously, careful attention to the quality and consistency of the processes used to generate pathology data will minimize confounding factors, such as tissue sampling bias or tissue artifacts, that may mimic histopathological lesions.

The pathology findings must, in turn, be considered in the context of other study factors such as study design (dose, duration, route of exposure, postexposure recovery), test animal (species, strain, age, sex, mode of death), and animal husbandry (group vs. individual housing, ad libitum vs. diet optimization, caging, bedding) [51].

As with other data generated in toxicology studies, the evaluation of pathology data is primarily concerned with identifying changes that are due to treatment and determining if those changes are adverse. Although the focus of routine bioassays typically involves comparison of end points across distinct treatment groups, the evaluation of factors such as statistically significant differences between group means, or percent change of a treated group mean from control, should not occur at the expense of a careful examination of individual animal data. This is especially important in shorter-term studies, which typically have group sizes of 10 or fewer animals, and for end points whose measurements are inherently imprecise. Outlined in the following are some of the issues that frequently must be addressed in the evaluation of pathology findings in routine toxicology studies.

Assessing Cause–Effect and Adversity of Pathology Findings

A number of factors should be considered when assessing whether differences between treated and control groups are due to chance or represent an effect of the test article and if treatment-related effects are adverse. Lewis et al. [52] have proposed a list of factors that can be considered for such determinations. These are summarized in Table 12.9. However, none of the factors listed in Table 12.9 should be considered in isolation. Rather, in assessing cause–effect or adversity, these general factors should be considered in combination with specific information for a given study, such as study design and known effects of the test article from previous studies (weight-of-evidence approach). For example, as for other end points in a study, dose–response is an important factor in determining if differences observed in pathology end points between controls and treated groups are likely to represent true effects or are due to chance. An otherwise expected dose–response may not occur in some circumstances even when the response observed is treatment related. For example, test article effects at lower doses may be obscured or absent at higher doses due to overt toxicity, including lethality. Or, dose-dependent mechanisms of action, wherein different (even opposite) mechanisms of action may exist for a compound depending on dose, may also alter an expected dose–response [52]. And while consistency between sexes of potential test substance-related effects may be supportive of a causal association, gender differences in the pharmacokinetic or pharmacodynamic response to a test substance may result in gender-specific target organ effects or severity of effects.

Outliers are extreme deviations in an individual finding from the group norm, as well as from historical values [52]. In the context of assessing test article-related versus chance effects, the term *outlier* also assumes the deviation from norm is not due to the test article. Outliers that are determined to be due to technical errors or that occur secondary to disease states unrelated to test article administration do not reflect a group effect of the test article and should be removed from the analysis. Statistical outliers, however, may represent low-incidence occurrences of compound-related effects; therefore, as previously noted, a weight-of-evidence approach must be taken when determining whether to include or exclude putative outliers.

Although concurrent study controls are the first and best reference for comparison to treated groups, historical data can be a valuable tool in assessing causality (or adversity) of apparent treatment-related effects in a study. A robust historical control dataset for a given parameter may provide better insight into the true incidence and variability of a lesion within an untreated population. As noted by Lewis et al. [52], however, the use of historical data "should not be seen as a convenient device for discounting unwanted or difficult findings." The fact that an altered value for a given parameter falls within historical values would not, in isolation, indicate a chance finding but instead may be more indicative of nonadversity of the effect. For assessing causality, historical data may be helpful in identifying aberrant values within concurrent controls or in assessing potential compound-related

TABLE 12.9
Discriminating Factors for Assessing Cause–Effect Relationships and Adversity of Pathology Findings

Discriminating factors for assessing cause–effect relationship
There is no obvious dose–response.
The group change is due to an outlier in one or more animals.
The measurement of the end point is inherently imprecise.
The change is within normal biological variation (historical control or reference values).
There is a lack of biological plausibility (e.g., the difference is inconsistent with class effects, mode of action, or what is known or expected of the test material).
Discriminating factors for assessing adversity
The effect causes no alteration in the general function of the test organism or of the organs/tissues affected.
The effect is adaptive.
The effect is transient (i.e., resolves in the course of treatment vs. reversibility, which refers to resolution with cessation of treatment).
The severity of the effect is limited (below threshold of concern).
The effect is isolated and independent. Changes in other parameters usually associated with the effect of concern are not observed.
The effect is not a precursor (i.e., not part of a continuum of changes known to progress with time to an established adverse effect).
The effect is secondary to other adverse effects.
The effect is a consequence of the experimental model (e.g., stress associated with restraint or reactions to physical properties of the test substance, such as taste or odor).

Source: Adapted from Lewis, R.W. et al., *Toxicol. Pathol.*, 30, 66, 2002.

effects whose incidence within the control population is very low or very high and variable [52]. The use of historical control data (HCD) in carcinogenicity studies is discussed in more detail below (see Use of Historical Control Data in Carcinogenicity Studies).

Several definitions of adversity have been proposed [52–54]. Based on a review of the literature addressing the question of adverse versus adaptive responses, the following definitions for an adverse effect and for an adaptive response were proposed [55]:

Adverse Effect: A change in morphology, physiology, growth, development, reproduction, or life span of a cell or organism, system, or (sub)population that results in an impairment of functional capacity, an impairment of the capacity to compensate for additional stress, or an increase in susceptibility to other influences.

Adaptive Response: In the context of toxicology, the process whereby a cell or organism responds to a xenobiotic so that the cell or organism will survive in the new environment that contains the xenobiotic without impairment of function.

Evaluating the adversity of an effect that has been determined to be due to exposure to a test article is complicated by a number of factors. First, the terminology associated with adverse effects is varied, with words and terms such as *adverse*, *toxicologically significant* (or *relevant*), and *biologically significant* (or *relevant*) used interchangeably by some or having distinct meanings by others. In addition, most definitions of adversity are not accompanied by criteria for determining adversity. Finally, determining the adversity of effects usually requires case-by-case expert judgment that often precludes rote approaches, but some of the factors given in Table 12.9 may be considered in a weight-of-evidence approach to determining adversity. The NOAEL for a study must be determined within the context of the particular study, and not be based on knowledge of possible compound effects or results of future studies.

Primary versus Secondary Effects

Some changes in organs or tissues that are observed following exposure to a test compound may be the result of primary target effects on some other organ or tissue or due to general systemic toxicity. These secondary effects are generally not considered adverse (Table 12.9); however, in some cases, such as massive iron accumulation in the spleen secondary to hemolysis, the secondary response may produce adverse effects in the affected organ.

As noted previously, changes in some organ weight parameters occurring in association with a decrease in body weight are commonly encountered as secondary effects in toxicology studies. Failure to consider the relationship between an organ weight and the associated decrease in body weight may lead to misinterpretation of organ weight findings. A common example is failure to consider the effects of body weight decrements on the organ weight/body weight ratio. The absolute organ weight of some organs, such as brain and testes, is relatively unaffected by modest decrements in body weight. In these cases, because the numerator (organ weight) is constant but the denominator (body weight) is decreased, the organ weight relative to body weight for these organs is increased in association with treatment-related decreases in body weight. Absent other evidence of primary effects, this increase in organ weight relative to body weight should not be interpreted as a primary pathological change in the affected organ. In contrast, many organs, most notably the liver, decrease in weight with decreased body weight, so the ratio of liver weight to body weight may remain normal relative to controls under conditions of decreased body weight. An increase in the liver weight relative to body weight, even in association with decrements in body weight, may indicate a primary weight increase in the liver [56,57].

Bailey et al. [21] investigated the effects of body weight changes on organ weights and ratios of organ weight to body or brain weight. Organ weight relative to body weight was the most appropriate parameter to evaluate organ weight effects in liver and thyroid gland, and the organ/brain weight ratio was most appropriate for adrenal gland and ovary. For other organs, alternative methods, such as analysis of covariance, were recommended. Whereas these results focused on the rat, the body and organ weight correlations observed were considered to be generally applicable to other species [21].

Many histopathological changes may also occur secondary to severe systemic toxicity, and these may complicate the interpretation of compound-related effects; for example, atrophy and weight decrements in lymphoid organs, especially the thymus, may occur in response to general stress, which may be produced at high doses in routine bioassays. Differentiating primary immunomodulating effects from a high-dose generalized response to stress may be problematic; however, careful examination of the dose–response for lymphoid organ changes may help in the evaluation. Immunosuppressive drugs often produce dose-related effects on lymphoid organs at doses not associated with other significant effects. In contrast, lymphoid changes occurring secondary to stress are expected to be limited to high doses and to occur in association with other signs of toxicity such as weight loss or general clinical suppression [58].

Another common secondary microscopic observation is atrophy of female reproductive organs due to nonspecific general toxicity associated with stress or reduced feed intake, which in turn result in reduced gonadotropin secretion [59]. This may make it difficult to distinguish some primary effects in female reproductive organs from nonspecific secondary effects at doses of a compound that produce severe stress or body weight effects. Nevertheless, making such distinction between primary and secondary effects on reproductive organs can have important implications for reproductive hazard classification. As discussed previously, the significance of

organ weight or histopathological changes must be considered in the context of other study findings, as well as any other information known about the test compound or its class.

Effects Associated with Extreme Doses or Severe Cytotoxicity

Some histopathological changes, including neoplasia, may occur only at high doses of a test compound that overwhelm normal physiological defense mechanisms or that produce severe cytotoxicity with resultant regenerative hyperplasia. Although these effects certainly represent adverse findings to the test species, their relevance to the hazard identification process is questionable, and it is important for the pathologist to fully characterize and contrast these findings with those observed at lower, more relevant doses.

One example of histopathological changes due to excessive doses is the constellation of lung lesions that have been reported to occur in rats following chronic exposure to very high concentrations of particulates that are poorly soluble and of low inherent toxicity (*lung overload*) [60,61]. Microscopically, lung changes are characterized by marked accumulation of particle-laden macrophages in alveolar spaces, interstitial inflammation, hyperplasia of type II pneumocytes, and bronchiolarization and squamous metaplasia of alveolar ducts. With increased duration of exposure, squamous metaplasia and the formation of large cystic, keratinizing squamous lesions or squamous neoplasms may occur in the lung (Figure 12.6). The pathogenesis of these lesions is thought to involve alteration in macrophage clearance and persistent inflammation due to the large surface dose of dust in the lungs. At lower dust concentrations that are not associated with marked inflammatory and adaptive responses, proliferative squamous lesions are not observed. This finding underscores the role of high dust concentrations or surface dose and the associated inflammatory and proliferative changes in the pathogenesis of the lesions.

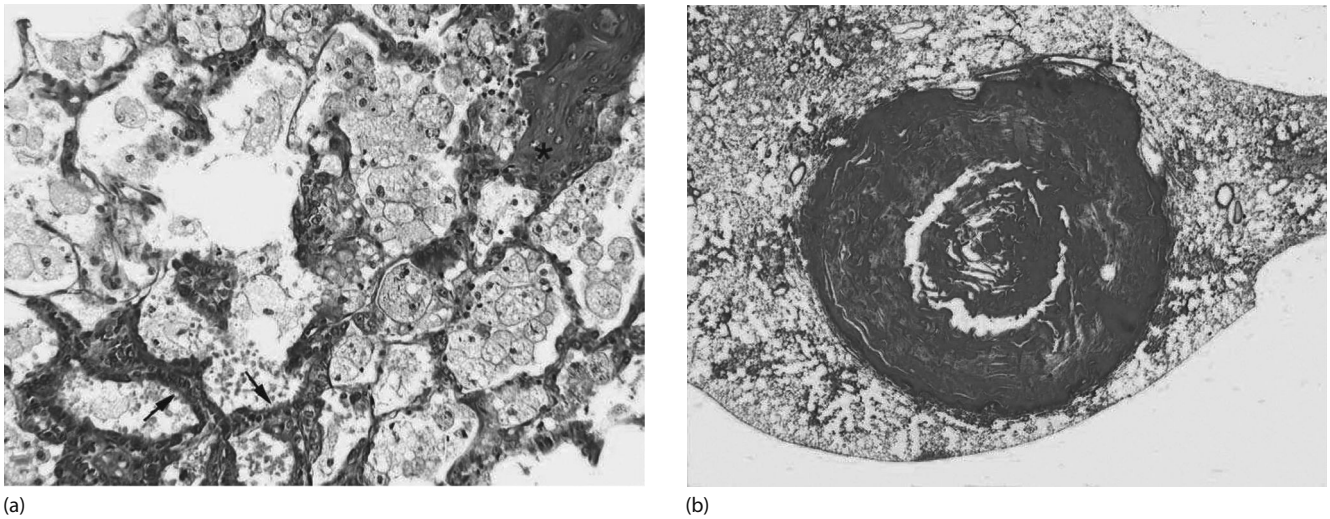
It is important to determine if proliferative lesions such as hyperplasia or neoplasia are due to a direct effect of the compound or are a response to a primary degenerative or necrotic event leading to regenerative hyperplasia. If hyperplasia can be clearly associated with tissue toxicity, then exposures that do not produce the primary toxic event are unlikely to produce cancer in the affected tissue [62].

Selected Data Evaluation Considerations in Rodent Carcinogenicity Studies

Some additional issues that are most commonly encountered in carcinogenicity studies are discussed in Chapters 24 and 25 and in several reviews on the subject. These include general texts and reviews on design and interpretation of long-term studies [63,64] and application of statistics [65–67]. An overview of other selected issues that may be encountered when assessing the result of rodent carcinogenicity studies are discussed in the following.

Combining Neoplasms in Rodent Carcinogenicity Studies

Many of the more common neoplastic processes observed in rodent carcinogenicity studies likely occur through progression from hyperplasia through benign lesions to malignant lesions. In evaluating potential treatment-induced proliferative responses occurring along a morphological spectrum, it may be appropriate in some cases to combine the incidence of neoplasms in the same organ or tissue or in different



(a) (b)

FIGURE 12.6 Lung from a Sprague–Dawley rat exposed by inhalation to high concentrations of a dust. (a) Lesions are characterized by marked accumulation of dust-laden macrophages in alveolar ducts and alveoli, with interstitial inflammation, hyperplasia of type II pneumocytes, and bronchiolarization (arrows) and focal squamous metaplasia (*) of alveolar ducts. (b) With chronic exposure, proliferative keratinizing squamous lesions, including proliferative keratin cysts, may develop.

organs or tissues in which the morphology of the tumors is comparable [68,69]. Brix et al. [69] proposed the following criteria for combining neoplasms:

1. Substantial evidence exists for progression of benign to malignant neoplasms of the same histomorphogenic type. Progression is considered more important if demonstrated within the study in question than if comparisons must be made with past experience (although this knowledge is valuable).
2. The occurrence of hyperplasia may be used as supporting evidence alone, but more so when the criteria for differentiating hyperplasia from benign neoplasia are not clear (i.e., borderline lesions) or when they are arbitrary and do not reflect the biological potential of a given lesion.
3. Most neoplasms of the same histomorphogenic type are combined even if they occur in different anatomic sites.
4. Neoplasms of different morphological classification may be combined when their histomorphogenesis is comparable.

Guidelines for combining neoplasms based on a specific organ or tissue are given in Table 12.10. In addition, neoplasms of the same histomorphogenic type from different but related anatomic sites are generally combined for evaluation, although there are exceptions. For example, neoplasms of larynx, trachea, and major bronchi may be combined while those in the peripheral lung (bronchiolar–alveolar neoplasms) would be analyzed separately. Similarly, neoplasms of the nasal mucosa would not normally be combined with those found in other regions of the respiratory tract. In the alimentary tract, squamous cell neoplasms of the tongue, esophagus, and forestomach (nonglandular) are often combined for evaluation, as are epithelial neoplasms from various regions of the small or large intestine. Morphologically similar neoplasms occurring in both the small and large intestines may also be combined to evaluate the intestinal tract as a whole. However, neoplasms of the glandular stomach are usually evaluated independently. Smooth muscle neoplasms are generally combined for all sites of the body except the gastrointestinal and reproductive tracts, where they are evaluated independently. Systemic neoplasms that have a common histogenesis but may arise in various tissues may also be combined for evaluation of carcinogenicity. Examples of systemic neoplasms include all blood cell neoplasms, including histiocytic sarcoma, as well as neoplasms in which the cell type is present in many different organs, such as hemangiosarcomas and malignant mesotheliomas [69].

Other combinations of neoplasms for comparison between groups may be considered on a case-by-case basis. However, one comparison that is not appropriate is the total number of tumor-bearing animals across groups—without regard to specific morphological tumor types or whether the tumor is benign or malignant. Since most groups of rats and mice (control as well as treated) in 2-year studies will have a very high incidence of neoplasms, the usefulness of such a nondiscriminate grouping would not be additive to the evaluation of carcinogenicity.

Assessment of Hyperplastic Lesions in Rodent Carcinogenicity Studies

Evaluation of a potential neoplastic response in a rodent carcinogenicity study should also include an assessment of hyperplastic changes as they relate to neoplasia since, as noted previously, exposure to chemicals may result in a spectrum of proliferative changes ranging from hyperplasia to neoplasia. Evaluation of the relationship between hyperplastic and neoplastic changes must be done with careful consideration of the multiple factors that impact such a correlation. Some questions to consider when assessing the relevance of hyperplastic lesions to a coexisting neoplastic process are given in Table 12.11. The foremost consideration is that hyperplasia must be viewed within the context of the specific study (and compound) under consideration. Many factors that contribute to an accurate weight-of-evidence assessment of the relevance of hyperplasia to a coexisting neoplastic process are often study-specific. For example, it is important to determine if hyperplastic lesions are a direct effect of compound action or occur secondary to a primary degenerative or necrotic change, with associated reparative (regenerative) hyperplasia. Focal hyperplasia that appears morphologically similar to neoplasia in a given tissue, but occurs without evidence of concurrent tissue injury, may be indicative of a potential direct treatment-related neoplastic response. In contrast, hyperplasia and cancer in a tissue with compound-induced inflammation or degeneration/regeneration suggest that the proliferative lesions are occurring secondary to chronic tissue injury. Even when evidence suggests that hyperplastic lesions are a primary effect of the test article, there are different implications depending on the type of change (e.g., diffuse or focal, with or without cellular atypia or dysplasia), the biochemical mechanism(s) underlying cellular proliferation, the nature of any associated concurrent lesions, the tissue(s) involved, and the type of neoplastic findings [62].

Use of Historical Control Data in Carcinogenicity Studies

HCD for proliferative lesions are useful in the interpretation of long-term rodent carcinogenicity bioassays, especially in the interpretation of rare tumors, tumors that occur spontaneously in high incidences or in highly variable incidences, and in studies where only a marginal increase in tumor incidence in a treated group relative to concurrent controls occurs. HCD are also useful in the interpretation of unexpected increases or decreases in tumor incidences in study control animals or when there is a need for quality control of intercurrent factors that may have compromised the survival of the control or treated animals. The major prerequisites to compare HCD with a specific study under evaluation are the validity and consistency of the respective databases to be compared [70–72].

TABLE 12.10
Guidelines for Combining Neoplasms in the Rat and the Mouse

Organ/Tissue	Combine	Do Not Combine
Adrenal gland	Cortical adenomas and cortical carcinomas	Cortical neoplasms and subscapular neoplasms (mouse)
	Pheochromocytomas and malignant pheochromocytomas	Cortical neoplasms and medullary neoplasms
		Subscapular neoplasms and medullary neoplasms (mouse)
Cardiovascular system	Hemangiomas and hemangiosarcomas	
Intestines, small and large	Adenomatous polyps, adenomas, and adenocarcinomas	Benign mesenchymal neoplasms—various types
	Benign and malignant mesenchymal neoplasms of the same type (if a continuum is observed in a given study)	Malignant mesenchymal neoplasms—various types
Hematopoietic system—mouse	Malignant lymphomas—all types	Malignant lymphomas—all types—and histiocytic sarcomas
	Malignant lymphomas—all types—and lymphocytic leukemia	Leukemias—all types
Hematopoietic system—rat	Large granular lymphoma (mononuclear cell leukemia) and leukemia—other types	Malignant lymphomas—all types—and histiocytic sarcomas
	Malignant lymphomas—all types	
	Large granular lymphoma (mononuclear cell leukemia) and malignant lymphomas—all types	
Kidneys	Tubular cell adenomas and tubular cell carcinomas	Tubular cell neoplasms and transitional cell neoplasms
	Transitional cell adenomas and transitional cell carcinomas	Mesenchymal neoplasms and epithelial neoplasms
Liver	Hepatocellular adenomas, hepatocellular carcinomas, and hepatoblastomas	Bile duct neoplasms and hepatocellular neoplasms
		Hepatocellular neoplasms and vascular endothelial neoplasms
Lung	Bronchioalveolar adenomas and bronchioalveolar carcinomas	Squamous cell neoplasms and bronchioalveolar neoplasms
Mammary gland	Carcinomas—various types	Adenomas and fibroadenomas (but an adenoma or carcinoma arising from a fibroadenoma should be combined with other mammary gland adenomas and carcinomas)
	Adenoma, adenocarcinoma, and carcinoma (if a continuum is observed in a given study)	
	Mammary gland fibroadenomas and fibromas/fibrosarcomas of the subcutis (when the fibroma/fibrosarcoma arises in the mammary gland region)	
Nervous system	Gliomas—various types	Gliomas and medulloblastomas
		Granular cell neoplasms and gliomas
		Nerve cell neoplasms and gliomas
		Meningiomas (all types) and other central nervous system neoplasms
Nose	Squamous cell papillomas and squamous cell carcinomas (if a continuum is observed in a given study)	Squamous cell neoplasms and glandular cell neoplasms
		Esthesioneural epithelial neoplasms and other neoplasms
Oral cavity (and esophagus)	Squamous cell papillomas and squamous cell carcinomas	
Ovary	Germ cell neoplasms—all types	Germ cell neoplasms and stromal neoplasms
	Stromal neoplasms—all types	
Pituitary gland	Adenomas and carcinomas	
Pancreas	Islet cell adenomas and carcinomas	
	Acinar cell adenomas and acinar cell carcinomas	
Prostate	Adenomas and carcinomas	
Skeletal system	Bone neoplasms and cartilage neoplasms (if a continuum is observed in a given study)	
Skin/subcutis	Basal cell neoplasms—all types	Benign mesenchymal neoplasms—various types
	Squamous cell papillomas and squamous cell carcinomas	Malignant mesenchymal neoplasms—various types
	Squamous cell neoplasms and keratoacanthomas	
	Squamous cell neoplasms and adnexal neoplasms (if a continuum is observed in a given study)	
	Benign and malignant mesenchymal neoplasms of the same type (if a continuum is observed in a given study)	

(*continued*)

TABLE 12.10 (continued)
Guidelines for Combining Neoplasms in the Rat and the Mouse

Organ/Tissue	Combine	Do Not Combine
Stomach	Glandular stomach adenomas and adenocarcinomas	
	Forestomach squamous cell papillomas and squamous cell carcinomas	
Testis	Germ cell neoplasms—all types	
	Stromal neoplasms—all types	
Thyroid gland	Follicular cell adenomas and follicular cell carcinomas	Follicular cell neoplasms and C-cell neoplasms
	C-cell adenomas and C-cell carcinomas	
Urinary bladder	Transitional cell papillomas and transitional cell carcinomas	
Uterus (and cervix)	Glandular adenomas and glandular carcinomas	Stromal neoplasms and glandular neoplasms
	Stromal polyps and stromal sarcomas	
Zymbal's gland (and clitoral and preputial glands)	Adenomas—various types	
	Carcinomas—various types	
	Adenomas and carcinomas	

Source: Modified from Brix, A.E. et al., Combining neoplasms for evaluation of rodent carcinogenesis studies, in *Cancer Risk Assessment*, Stedeford, T. and Hsu, C.H., eds., John Wiley & Sons, Inc., Hoboken, NJ, chapter 28, 2010.

TABLE 12.11
Questions to Consider When Assessing the Relevance of Hyperplasia to a Coexisting Neoplastic Process

- Is there a common cell of origin for hyperplastic and neoplastic processes?
- Is there a morphological continuum between hyperplasia and neoplasia within the study?
- Are the hyperplastic and neoplastic lesions histologically similar?
- What is the incidence and severity of spontaneous chronic diseases that may influence development of hyperplastic and neoplastic lesions?
- What are the incidences of hyperplasia and neoplasia?
- Is there other evidence for treatment-related toxicity?

HCD may be limited by variability and drift over time in animal- and study-related factors. These include such factors as animal genetics, the experimental environment, and the macroscopic and microscopic pathological interpretations. Progress has been made in recent years by various groups to reduce some of the sources of variability through international efforts to improve harmonization and standardization of terminology, trimming procedures, and study designs. Guidance has been provided from a variety of regulatory agencies on the use of HCD in carcinogenicity studies [70]. Best practices recommendations of the STP for use of HCD of proliferative rodent lesions are given in Table 12.12.

HCD is just one of many considerations in a weight-of-evidence approach to assessing the potential carcinogenic effect of a compound. Other data to consider include the incidences of other lesions of similar cell lineage, body weight effects, survival, time of tumor onset, concordance of the tumor response across both sexes or different species, and the presence of a positive dose-related response [72].

Assessing Cause of Death

Determining the cause of death in individual animals may be an important consideration in some toxicity studies. The pathologist is responsible for determining the cause of death or morbidity in animals that die prior to the scheduled necropsy and should attempt to identify a cause of death whenever possible. The pathologist should also determine if overall mortality and differences in mortality among groups are the results of the test compound. A review of the assigned causes of death should be included as part of the pathology peer review [73].

Determining the cause of death requires a thorough knowledge of the systemic pathology of the test species and professional judgment. The pathologist should have all study data for the individual animal available, including clinical observations and clinical pathology, as well as pathology data, to make this judgment [73,74]. The cause of death for each animal should be based on the primary disease process judged to have led to morbidity or mortality. The World Health Organization defines cause of death as "the disease or injury which initiated the train of events leading directly to death, or the circumstances of accident or violence which produced fatal injury [75]." If there are several potential causes of death, the one judged to have most likely led to mortality should be chosen. Not all animals have a clear cause of death; if the cause of death cannot be determined from the information available, it should be recorded as undetermined [73].

REPORTING PATHOLOGY FINDINGS

The pathologist's findings and conclusions must be accurately and completely reflected in the study report. The pathology findings must also be integrated with other study data to provide a comprehensive discussion of study findings including

TABLE 12.12
Recommendation for Use of Historical Control Data for Proliferative Rodent Lesions

- The concurrent control group is the most relevant point of comparison for determining treatment-related effects in a study.
- HCD may be useful in the interpretation of the following:
  - Rare tumors
  - Marginally greater incidences (and/or severity) of proliferative changes in treated groups compared to controls
  - Unexpected increases or decreases of tumor incidences in study control animals
  - Disparate findings in dual concurrent control groups
  - Trends in tumor biology and behavior that may evolve over time in rodent models
- HCD should be considered as one of many sources of information that add to the weight-of-evidence approach when assessing the potential carcinogenic effect of a compound.
- HCD from the laboratory that conducted the study under review will likely be more comparable than that compiled from several laboratories.
- Study design parameters should be considered when selecting the appropriate studies for the HCD. These include laboratory, species/strain, route of administration, vehicle, feed, feeding practices, study duration, and housing.
- HCD is more valuable if pathology practices, including necropsy and trimming procedures and application of diagnostic criteria, are standardized.
- HCD from peer-reviewed studies are generally more reliable than those not peer reviewed.
- Published HCD may provide guidance in evaluating data but should be reviewed carefully, as there may be difficulties in assessing the quality of published data.
- HCD may be presented as a range of incidences or percentages and as a mean and standard deviation for a given proliferative lesion. Reporting of incidences per study allows assessment of potential influences of outlier populations.
- The collection of HCD within a limited time span of 2–7 years has been proposed in many guidance documents, but wider intervals may be appropriate if tumor types are stable over a longer period.

TABLE 12.13
Best Practices for Pathology Report Generation

Study Protocol and Accountability

- The study pathologist(s) should contribute to generation of the study protocol.
- The study pathologist should have access to the study protocol and all protocol amendments.
- Individual accountability and responsibility of all study personnel including the study pathologist(s) should be clearly defined in the study protocol and/or final report.
- The study pathologist(s) should have primary responsibility for interpretation of assigned pathology data, including necropsy findings, microscopic findings, and ultrastructural findings (and usually clinical pathology and organ weight findings).

Data Accessibility and Data Review

- The study pathologist should have access to all study data including
  - The intended pharmacologic target and mechanism of action
  - In-life study data
  - Clinical pathology data
  - Organ weight data
  - Necropsy findings
  - Toxicokinetic information data from previous studies with the same test article
- The study pathologist should review all pathology individual and summary data tables.

Study Report and Pathology Report

- Either an integrated study report containing the pathology narrative and tables or a separate pathology report can provide appropriate accountability and integration of all study data.
- The study pathologist should assist the study director in writing and/or reviewing the final study report, including the summary, discussion, and conclusion.
- The study pathologist must sign a separate pathology report or an integrated study report.

relationship of any toxicity findings to exposure to the test substance and the significance of those findings (e.g., adverse or adaptive).

Toxicology laboratories generally issue either an integrated final study report or a separate pathology report that is appended to the final study report. Regardless of the reporting format, the study pathologist and other contributing scientists should provide an integrated assessment of significant study findings including clinical findings, clinical pathology information, organ weight data, anatomic pathology findings, and pharmacokinetic data. The pathology report should include the necessary individual animal data tables, the summary data tables, and the pathology narrative containing integration of pathology findings with all other study data. The pathology report should also clearly note accountability for the primary evaluation and interpretation of pathology data. It is also important that the main study report preserve the integrity of the interpretation of pathology findings [76]. Some recommended best practices for pathology report generation are given in Table 12.13 [76].

QUALITY ASSURANCE AND THE PATHOLOGY PEER REVIEW

Because pathology data often provide important information used in making regulatory decisions on the health hazard and risk to humans of many drugs, industrial chemicals, and pesticides, clearly defined procedures must be in place to ensure the accuracy of pathology data, including the generation, interpretation, and reporting of the data. These quality review procedures usually include a quantitative pathology data review (data audit or pathology materials review) and a pathology peer review. In addition, review of pathology findings for some studies may include a PWG review [12,77,78]. These aspects of the pathology quality assurance are discussed in more detail as follows.

Pathology Data Review

The purpose of the pathology data review is to ensure the quality of the materials and procedures used to generate histopathological data, as well as other pathology data. The data review is most commonly conducted by a quality assurance unit. The pathology materials reviewed include individual animal necropsy records, histology laboratory worksheets, fixed tissues, blocks, and microscopic slides. A complete (100%) inventory of slides, blocks, and bags of remaining wet tissue should be conducted to ensure proper identification and labeling, and all slides and blocks should be matched. A random subset of slides should be examined macroscopically and microscopically to evaluate slide quality, including cover slipping, tissue placement, staining, and presence or absence of artifacts. A random subset of residual wet tissues should also be examined to verify the animal identification number. In addition, residual wet tissue may also be examined by a pathologist to ensure that no additional gross lesions are present that were either not identified at necropsy or not trimmed. Items that may be discovered in the data review include untrimmed lesions, incorrectly identified animals, and slides that do not correspond to their respective blocks [12,77].

Pathology Peer Review

Pathology peer review is a procedure whereby a second pathologist reviews a subset of tissues and other data from the initial pathology evaluation. The primary purpose of the peer review is to verify the accuracy of toxicologically significant microscopic findings; however, it is not intended to corroborate every detail of every microscopic finding in a study [79]. A pathology peer review serves to ensure the integrity of the pathology evaluation, encourages consistency in the application of diagnostic criteria and terminology, and provides a method of continuing education for participants [77,80]. Documented histopathology peer reviews also increase the confidence of regulatory agencies in the pathology portion of the report [81]. Pathology peer review is recommended when important risk assessment or business decisions may be based on pathology interpretations in toxicity studies, including GLP toxicity and carcinogenicity studies. Pathology peer review may also be valuable for non-GLP studies that inform compound development decisions or dose selection for future studies [82].

The histopathology peer review may be informal (undocumented consultations) or formal, and the formal peer review may be prospective or retrospective. The prospective peer review is conducted prior to finalization of the study and is conducted by an informed reviewer, its procedures are included in the protocol, and the results of the peer review are documented in the final report. A retrospective peer review, such as that conducted by a PWG, generally occurs after the data are finalized. The results of a retrospective peer review should be documented in a separate report [77].

A formal peer review is conducted by an independent pathologist whose objectives are to ensure that diagnoses are accurate, that lesions are diagnosed consistently across animals and groups, and that generally accepted diagnostic criteria and nomenclature are followed [77]. Approaches may vary between study types and study objectives as to the sampling size to be evaluated by the reviewing pathologist, but the review typically includes subsets from high-dose and control groups of both sexes, as well as all neoplasms and all target organs. Recommendations for peer review tissue examination protocols are given in Tables 12.14 and 12.15 for toxicity and carcinogenicity studies, respectively [82]. The reviewing pathologist should confirm all treatment-related findings, including NOAELs. At the end of the review, the final diagnosis should represent the consensus of the study pathologist and the reviewing pathologist. The formal peer review should be fully documented to include the tissues examined, the diagnosis of both the study and peer review pathologists, and the actions taken to resolve any differences [77,79]. Worksheets containing the detailed findings of the primary and review

TABLE 12.14
Recommendations for Pathology Peer Review in Toxicity Studies

Rodent Studies

- Protocol tissue
  - *High-dose group*: Examine all protocol organs in at least 30% of high-dose animals of each sex in the treatment phase.
  - *Controls*: Examination of all protocol organs from a subset of control animals may be performed at the discretion of the peer review pathologist.
- Target organs
  - *Controls*: Examine target organs in all animals (in the affected sex) in the control group.
  - *NOAEL groups*: Examine target organs in all animals at the NOAEL (i.e., in the highest-dose group lacking the finding).
  - *Affected groups*: Examine target organs in a sufficient number of animals (50% or more) in affected groups to characterize the finding.
  - *Recovery groups*: Examine all target organs in all control recovery animals and all target organs in all treated recovery animals in the dose groups and sexes in which the finding was observed at the end of the treatment period.

Nonrodent Studies

- Protocol tissue
  - *High-dose group*: Examine all protocol organs in at least 50% (minimum of two) of high-dose animals of each sex in the treatment phase.
  - *Controls*: Examination of all protocol organs from a subset of control animals may be performed at the discretion of the peer review pathologist.
- Target organs
  - *Controls, NOAEL group, and affected group*: Examine target organs in all animals in the affected sex.
  - *Recovery groups*: Examine all target organs in all control recovery animals and in all treated recovery animals in the dose groups and sexes in which the finding was observed at the end of the treatment period.

TABLE 12.15
Recommendations for Pathology Peer Review in Carcinogenicity Studies

- Protocol tissue
  - *High-dose group*:
    - Two-year studies: Examine all protocol organs in at least 10% of high-dose animals of each sex.
    - Six-month alternative carcinogenicity studies: Examine all organs from five high-dose animals per sex.
  - *Controls*: Examination of all protocol organs from a subset of control animals may be performed at the discretion of the peer review pathologist.
- Neoplasms: Examine all neoplasms in all animals
- Target organs
  - *Neoplastic target organs*: Examine all neoplastic target organs (or suspected target organs) from all animals in all groups. Each sex should be considered separately.
  - *Nonneoplastic target organs*: Examine target organs with nonneoplastic findings from
    - All control animals
    - All animals of the highest-dose group lacking the finding
    - Sufficient animals (at least 30%) in affected groups and sexes to verify the finding

pathologist need not be retained, as these are the equivalent of *pathology work files* and are not raw data [79].

Pathology Working Group

A PWG is a panel of expert pathologists assembled to review a specific question concerning study results. A PWG review is typically conducted for finalized studies and may be convened to review certain pivotal or controversial studies that raise regulatory concern or studies that have critical effects for which diagnostic criteria and terminology have changed since the original review; also, they allow comparison of the results of multiple studies that may have been conducted and evaluated by different laboratories or pathologists. The PWG may also be used to address differences between a study and reviewing pathologist that could not be resolved during the peer review process. Sources of disagreement may include unfamiliarity with a lesion, use of different criteria for tumor classification, use of different thresholds for diagnosis of lesions (especially nonneoplastic aging lesions), use of different terminology for the same lesion, diagnostic drift, and varying pathology reporting system data input and reporting requirements. The technical aspects of the PWG have been reviewed by Mann [77] and are summarized in Table 12.16. The U.S. Environmental Protection Agency has also outlined the procedures and documentation necessary for the results of a PWG to be considered in place of the original reading (Table 12.17) [83].

TABLE 12.16
Pathology Working Group: Technical Approach

Composition

Three to five experienced toxicologic pathologists
A chairperson, usually nonvoting,
- Organizes and presents material so as to resolve issues in an unbiased and scientifically sound manner
- Anticipates and seeks resolution of potential problems with the data that might affect interpretation of the study

The study pathologist and reviewing pathologist may attend as panel members

Procedures

The PWG slide review is coded; members have no knowledge of treatment group or previous diagnosis.
PWG reviews representative slides of the target tissue containing the potential treatment-related changes in question.
PWG reviews all slides for which different diagnoses were recorded between the peer review and study pathologists.
PWG provides a consensus diagnosis for each slide examined:
Consensus diagnosis is based on majority vote.
Discussion and reexamination may be required.
The final consensus diagnosis is recorded by the chairperson.
No changes are made to the consensus diagnosis once the slides are uncoded.
After examination and uncoding of slides, the PWG members may be asked to utilize their expertise to discuss the biological significance of their findings.

PWG Report

The report is assembled by the PWG chairperson.
The PWG narrative summary includes the following:
- Incidence tables
- Comments on the diagnostic terminology used
- Morphological descriptions of the lesions examined
- An evaluation of the study pathologist's report
- Comments on the quality of the histological preparations and tissue availability
- The opinions of the PWG

Histopathology Data Collection and Audit Trail

The definition of raw data varies in different regulatory jurisdictions. Raw data have been defined in the U.S. Code of Federal Regulations (21 CFR Part 58; Good Laboratory Practices) as any record (laboratory worksheet, memoranda, or note) that results from an original observation or activity in a nonclinical laboratory study that is necessary for the reconstruction and evaluation of the report of that study. Histopathology observations are based on examination of histopathology slides that are durable and can be reevaluated during the conduct of the study and into the future. Also, in developing the final interpretation and diagnoses, the pathologist must consider a number of dynamic factors during the course of the histopathological evaluation such as histopathology observations in other tissues and in other animals, as well as other types of data from the study. Therefore, the initial histopathology observations, based on evaluation of the tissue(s) present on single glass histopathology slides,

TABLE 12.17
Pathology Working Group Procedures Required by the U.S. Environmental Protection Agency

For any target tissue reevaluated, all slides containing that tissue in all dose groups, as well as the controls, must be reread by the peer review pathologist. This is to include the following:

- Slides previously classified by the study pathologist as within normal limits.
- Slides having tumors, hyperplasia, hypertrophy, foci of cellular alteration, or other nonneoplastic lesions.
- The pathology reports from both the study and peer review pathologists and the original slides are to be submitted to a PWG.
- The PWG will review, as a minimum, all slides about which there were significantly differing diagnoses between the study and peer review pathologists.

A detailed pathology report should be provided that presents the following:

- The PWG findings, including the original diagnosis and the new diagnosis for each slide read.
- A comment column to note any discrepancies, missing slides, etc.

Source: Adapted from USEPA, Requests for reconsiderations of carcinogenicity peer review decisions based on changes in pathology diagnoses, PR Notice 94-5, U.S. Environmental Protection Agency, Washington, DC, 1994.

represent *working interim notes*, and these interim notes are not necessary for reconstruction and evaluation of the report and thus do not represent raw data [84]. Consistent with these considerations, the preamble to the GLP Regulations (http://www.ovpr.uga.edu/qau/resources/glps/fda/preamble) states the following:

> Although the notes taken by a pathologist during histopathological examination of slides are indeed the result of original observations, these notes are not necessary for the reconstruction and evaluation of the final report. The final report is evaluated by an analysis of the pathology syndrome as described in the pathologist's report, which is required under Section 58.185(a)(12). Further, because Section 58.190(a) requires histopathological blocks, tissues, and slides to be retained as specimens, the final report can be reconstructed by verification of the pathology findings by, e.g., a second pathologist or by a team of pathologists.

Based on these considerations, the preamble further notes that

> The pathologists interim notes, therefore, which are subject to frequent changes as the pathologist refines the diagnosis, are not raw data because they do not contribute to study reconstruction. Accordingly, only the signed and dated final report of the pathologist comprises raw data respecting the histopathological evaluation of tissue specimens.

GLP-compliant electronic histopathology data collection computer systems have security measures incorporated into them to protect the integrity of the data throughout the entire data collection and reporting processes. When the histopathology database is locked/completed, an audit trail is activated to track any subsequent changes made. Since the initial histopathology observations/interim notes are not raw data, are not required for study reconstruction and evaluation of the final report, and are not required to be retained, no audit trail is required to track changes to these interim histopathology notes prior to locking the database. Also, for a pathology peer review conducted before a study is completed, the audit trail for the microscopic pathology data should not be initiated until after any changes to the original microscopic observations and interpretations resulting from pathology peer review have been made [76]. Once the histopathology database is locked, a full audit trail entry (who, when, what, and why) is required for each change to the database [84].

TOXICOLOGIC PATHOLOGY IN THE *OMICS* ERA

Advances in genome sequencing and the development of platforms to assess gene and protein expression have made *omics* technologies increasingly important tools in toxicological research [85]. Important areas of impact for toxicogenomics include understanding biological mechanisms, identification of biomarker candidates, and identifying species differences in toxicological responses [86]. Effective application of technologies such as toxicogenomics requires a broad range of skill sets, including molecular biology, biochemistry, pathology, toxicology, bioinformatics, statistics, and mathematics. As such, the interpretation of changes, for example, at the level of the transcriptome should always be undertaken in light of other available study information, such as hematology and clinical chemistry data, histopathology findings, and organ weight changes [87]. In addition, much of the current understanding of adverse effects is linked to apical phenotypic effects such as histological changes. Therefore, phenotypic anchoring of changes in gene or protein expression, or other in vitro end points, is important in determining, for example, whether such changes represent adverse or adaptive effects [55].

As would be expected, many of the factors that may contribute to variability in traditional pathology end points may also be sources of variability in toxicogenomics studies. Thus, gender, fasting, strain, and organ section—important consideration when assessing histopathological changes—are among the most reproducibly prominent biological factors associated with gene expression variance among control animals [88]. As such, established principles of pathology are important considerations in the design and interpretation of toxicogenomic studies. For example, tissues and organs are not uniform in their morphology or function, so gene expression patterns are expected to be different when sampling whole kidney versus renal cortex or renal medulla following exposure to a renal toxin. Therefore, consideration should be given as to what tissues and what portions of tissues need to be collected for gene analysis [85].

The characterization of the morphological changes in a tissue can play an important role in the interpretation of gene expression data. For example, the liver changes following

exposure to a hepatotoxicant may include not only a spectrum of normal, degenerating, and dead cells but also inflammatory cell infiltrates, all of which will be reflected in the RNA from exposed animals. Furthermore, the pattern of changes in gene expression can be expected to vary as the lesions progress from the acute to more chronic phases. And since gene expression in an organ such as the liver may actually reflect primary changes in other targets, such as the red blood cell or intestines, a complete necropsy with histopathologic evaluation of key organ systems can provide an important morphological anchor and corroboration of specific gene expression changes. Other tools of traditional toxicologic pathology, such as electron microscopy and immunohistochemistry, can also provide more detailed information on cellular changes and may provide additional perspective on changes in gene expression. As a discipline based on pattern recognition and requiring familiarity with the dynamics of disease processes and interactions between organs, tissues, and cell populations, toxicologic pathology will be an important contributor to the field of toxicogenomics, from experimental design to data interpretation [89].

QUESTIONS

12.1 What documents should be available to the necropsy team prior to and during the necropsy, and what information is provided in each of these documents?

12.2 What are the disadvantages of coded or blinded histopathological evaluations, and what are some circumstances where a blinded evaluation would be indicated?

12.3 What is diagnostic drift, what are some factors that may cause diagnostic drift, and how can it be minimized?

12.4 What are some discriminating factors to consider in a weight-of-evidence approach to determine if effects are treatment related and if they are adverse?

12.5 What are some scenarios under which HCD might be useful in a carcinogenicity study? Are there any other situations in which HCD can be used and what are they?

12.6 What are the primary purpose and key elements of the pathology peer review?

12.7 Explain phenotypic anchoring and why it is necessary.

13 The Information Infrastructure of Toxicology

Philip Wexler, Fred Berman, Patricia Nance, Ann Parker, and Jacqueline Patterson

CONTENTS

SCOPE OF TOXICOLOGY

The U.S. Society of Toxicology's (SOT) *Definition of Toxicology Task Force* developed the following consensus definition of toxicology in 2005:

> Toxicology is the study of the adverse effects of chemical, physical or biological agents on living organisms and the ecosystem, including the prevention and amelioration of such adverse effects.

This definition was further elaborated by a consensus discussion:

> Toxicity is the adverse end product of a series of events that is initiated by exposure to chemical, physical or biological agents. Toxicity can manifest itself in a wide array of forms, from mild biochemical malfunctions to serious organ damage and death. These events, any of which may be reversible or irreversible, include absorption, transport, metabolism to more or less toxic metabolites, excretion, interaction with cellular macromolecules and other modes of toxic action. Toxicology integrates the study of all of these events, at all levels of biological organization, from molecules to complex ecosystems. The broad scope of toxicology, from the study of fundamental mechanisms to the measurement of exposure, including toxicity testing and risk analysis, requires an extensively interdisciplinary approach. This approach utilizes the principles and methods of other disciplines, including molecular biology, chemistry (analytical, organic, inorganic and biochemistry), physiology, medicine (veterinary and human), computer science and informatics.

This definition reflects the broad multidisciplinary nature of toxicology. Toxicology encompasses research studies on animals, humans, and the environment. Furthermore, it consists of an important medical component via the practice of clinical toxicology. Translational science that seeks for ways to translate bench science to bedside clinical practice is helping to bridge the gap in toxicology between research and patient care.

One can consider toxicology from a variety of perspectives. What are the substances involved?—Chemicals (both singly and in mixtures and formulations; as nanoparticles and otherwise; in food, drugs, industrial applications, products, etc.), physical (such as noise and radiation), and biological (such as animal venoms and plant toxins) or consider effects of various target sites—liver, kidney, skin, nervous system, etc. In addition to the agent, one needs to consider the subject and particular susceptibilities due to gender, age, genetics, state of health, etc. Both acute and chronic exposures or effects need to be taken into account. Occupational toxicology puts the science in a new setting and poses unique problems. Regulatory and safety evaluation and the legal framework present toxicology with a host of additional challenges.

While animal experimentation continues to be widespread, it is expensive, and labor and time intensive, and alternative testing approaches are increasingly being employed. Understanding how to map the molecular pathways of toxicity in cells will play a major role in enhancing our understanding of what makes a substance toxic. Furthermore, toxicology has embraced the *omics* revolution. Bioinformatics and computational toxicology are offering new ways to evaluate and assess toxicity.

SCOPE OF INFORMATION RESOURCES AND THE ROLE OF THE WEB

The use of existing, and generation of new, information has always been an essential part of science. Information science and its progenitor, library science, have traditionally been concerned with the collection, organization, classification, archiving, and dissemination of information. As more and more computer processing power and technological innovations have become available, the lines between the sciences, including toxicology, and information science have intersected. The term *informatics* has been increasingly used to represent an academic discipline utilizing a variety of techniques to process, manage, and retrieve data and other forms of information.

Toxicology data and information can be distributed via an array of resources and media, including paper (yes, still), electronic journals and books, databases and portals, websites, professional societies, trade associations, and government and nongovernmental organizations (NGOs). Data are generated from laboratory animal or in vitro studies (e.g., cell culture), or via in silico methods (i.e., using computer programs to estimate the toxicity of chemicals), with increasing reliance upon high-throughput screening and other alternatives to animal testing. In addition, ethically conducted human studies can provide toxicology and safety information.

Finding the best ways to keep current with the vast amount of literature and other information associated with the many aspects of toxicology is both a challenge and an opportunity. Significant advances have been made in recent years in ease of access to toxicological information, with 24 h–a-day access readily available. The vast array of websites, in addition to Internet mailing lists and social media, provides numerous opportunities for training and information sharing.

Information in toxicology is widespread and often diffusely scattered across scientific disciplines despite continuing efforts to integrate, coordinate, and consolidate. Moreover, the information is presented in many forms, including raw data and study reports, texts and monographs, statutes and regulations, journal articles, and more, which presents a significant challenge for those attempting to find and retrieve information relevant to their interests. In the predigital era, information was either oral or written and on a physical support such as paper, clay tablets, parchment, or vellum. Oral information referred largely to the collegial network—colleagues communicating with each other in face-to-face discussions or via telephone calls as a means of diffusing knowledge. Written information took on a discrete number of forms—textbooks and other monographs, technical journals, newsletters, dissertations, abstracting and indexing services, etc. Over time, the task of storing, maintaining, and retrieving this ever-expanding knowledge base became more complicated and labor intensive. Fortunately, with the advent of computers and, particularly, computer databases, the nature of information began to change, and revolutionized the way we store, retrieve, and share toxicological data. Now, with the establishment and unprecedented expansion of the web, information and its infrastructure have taken on a level of complexity hardly dreamt of even by those already conversant with an earlier era of database searching.

Over the years, toxicology has moved from a descriptive science to one that is largely data driven. Beginning in the late twentieth century, quantitative structure–activity relationship (QSAR), high throughput screening, in silico methodologies, computational approaches for predictive toxicology, the -omics revolution, and systems biology have all been responsible for a groundswell of new data. All these, combined with more recently introduced mobile technologies and electronic social networks, plus standard journal articles, books, Internet databases, and collegial networks, now constitute the broader informatics framework. These loosely connected informational tools, known in the aggregate as toxicoinformatics, have become essential to the practice of toxicology. Toxicologists would do well to embrace its capabilities in order to make the best use of existing toxicological information and to plan for as yet undefined, but unstoppable, future developments.

Today, the lines demarcating one kind of information from another are increasingly blurring, as more and more packaged and synthesized information, not to mention raw data, and the invariable unsubstantiated musings of would-be experts are democratically finding their way onto the web. This presents a challenge to those seeking scientifically

credible toxicology and health information, inasmuch as there is no governing body to ensure that information on the web is accurate or true. Therefore, it is becoming ever more important for information seekers to apply critical and skeptical thinking when viewing web-based toxicology and health information. Guidelines for evaluating the reliability of health (and toxicology) information on the web can be found at the following National Library of Medicine (NLM) website: http://www.nlm.nih.gov/medlineplus/evaluatinghealthinformation.html.

Although bibliographic information and summaries of standard technical documentation in books and journals already have a robust history of online access, the goal of *full*-text digital availability is only now being realized. Most scientific journals now offer direct access to full-text articles online for their subscribers. Elsevier's Science Direct (http://www.sciencedirect.com) is one such collection of full-text literature. MEDLINE®, Thomson Reuters' *Web of Knowledge*, and CAS's *SciFinder* and *SciFinder Scholar* also offer full-text access to subscribers for articles retrieved in bibliographic searches.

Online libraries are in our future, and authors seem to be increasingly accepting of the concept of online publication.[10] Project Gutenberg (http://www.gutenberg.org/), begun in 1971, offers over 100,000 free electronic books on the Internet, directly or through their partners and affiliates. It consists largely of older literary works in the public domain in the United States and elsewhere, but a scientific counterpart is inevitable. The issue of who will ultimately pay for this, and how, remains to be resolved and will be explored a bit more at the end of this chapter. More recently, in 2004, the company that created the web search engine Google™ announced that it is working with libraries at the University of Michigan, Harvard University, Stanford University, Oxford University, and the New York Public Library to digitize books in their collections and make them accessible online. The list of libraries has since expanded. This massive scanning project has brought millions of volumes of printed books into the Google Print database (http://print.google.com/) for around-the-clock and around-the-world access. Both free (public domain) and pay-for-access books, including toxicology texts, are available. Interestingly, the European Union (EU) is moving forward with a similar complementary effort to put European literature online (http://www.europeana.eu/portal/).

Virtually every organization of relevance to toxicology, as reflected here, has a web presence. Activities that would once have required reams of paper to describe and would have resulted in a distribution nightmare are usually consolidated on websites where the user comes to the information instead of vice versa. Consider government agencies such as the U.S. Environmental Protection Agency (EPA) and the U.S. Food and Drug Administration (FDA), whose extensive websites are dense with information. Other notable agencies in this regard include the National Institute for Occupational Safety and Health (NIOSH), the National Institutes of Health (NIH), and the U.S. Centers for Disease Control (CDC). The challenge here, if anything, is how to manage and efficiently navigate (and then digest) the large amount of information and data. Utilization of new *push technologies*, as well as mobile devices and applications, along with social media, all of which will be discussed later, offers alternative approaches to delivering information.

The formerly strict lines between multimedia and computerized representation have long been erased. Digital audio or video transmissions via the Internet (i.e., streaming media) are commonplace, and quality continues to improve as bandwidth increases. Computer technologies used for entertainment hold great potential for educational applications. Indeed, many websites provide audio and video access to live meetings, and instructional videos are increasingly incorporating tools such as Flash™ and ActionScript™ to visually enhance the learning process.

Monographs

This section provides a selective list of books in six areas dealing with toxicology, as well as an *other* category. The six main areas considered are general toxicology, clinical toxicology, analytical toxicology, industrial/occupational toxicology, environmental toxicology, and risk assessment. The *other* category is comprised of books on a variety of topics, such as risk communication, forensic toxicology, and more. The following list offers mostly recent books published since 2000 but also includes older books that are considered classics in the field.

General Toxicology

Ballantyne, B., Marrs, T., and Syversen, T. (2009): *General and Applied Toxicology*, 3rd edn., Macmillan, London, U.K.

Brunton, L., Chabner, B., and Knollman, B. (2010): *Goodman & Gilman's the Pharmacological Basis of Therapeutics*, 12th edn., McGraw-Hill, New York.

Derelanko, M. J. and Hollinger, M. A. (2002): *Handbook of Toxicology*, 2nd edn., CRC Press, Boca Raton, FL.

Duffus, J. H. and Worth, H. G. (eds.) (2006): *Fundamental Toxicology*, Royal Society of Chemistry, Cambridge, U.K.

Gilbert, S. G. (2004): *A Small Dose of Toxicology: The Health Effects of Common Chemicals*, CRC Press, Boca Raton, FL.

Hayes, A. W. (2008): *Principles and Methods of Toxicology*, 5th edn., Taylor & Francis Group, Boca Raton, FL.

Hodgson, E. and Smart, R. C. (eds.) (2008): *Molecular and Biochemical Toxicology*, 4th edn., Wiley, Hoboken, NJ.

Illing, P. (2001): *Toxicity and Risk*, CRC Press, Boca Raton, FL.

Kent, C. (1998): *Basics of Toxicology*, Wiley, New York.

Klaassen, C. D. (2007): *Casarett & Doull's Toxicology: The Basic Science of Poisons*, 7th edn., McGraw-Hill, New York (8th edn. in process).

Klaassen, C. D. (2010): *Casarett & Doull's Essentials of Toxicology*, 2nd edn., McGraw-Hill, New York.

Krishnan, K. and Andersen, M. (2010): *Quantitative Modeling in Toxicology*, John Wiley & Sons.

Lewis, R. A. (1998): *Lewis' Dictionary of Toxicology*, CRC Press, Boca Raton, FL.

Lu, F. C. and Kacew, S. (2009): *Lu's Basic Toxicology: Fundamentals, Target Organs and Risk Assessment*, 5th edn., Informa Healthcare USA, Inc., New York.

McQueen, C. A. (ed.) (2010): *Comprehensive Toxicology*, 2nd edn., (14 vols.). Elsevier, Amsterdam, the Netherlands.
Rose, V. E. and Cohrssen, B. (2010): *Patty's Industrial Hygiene and Toxicology*, 6th edn., Wiley, New York.
Saura, C., Casciano, D., Ballantyne, B., Marrs, T., and Syversen, T. (eds.) (2011): *General, Applied and Systems Toxicology*, Wiley, Chichester, U.K.
Timbrell, J. A. (2001): *Introduction to Toxicology*, 3rd edn., CRC Press, Boca Raton, FL.
Vettorazzi, G. and Anadon, A. (2001): *The ITIC International Dictionary of Toxicology*, ITIC Press, San Sebastián, Spain.
Wexler, P. (2005): *Encyclopedia of Toxicology*, 2nd edn., Elsevier, Oxford, U.K. (3rd edn. in preparation, scheduled for 2013 publication).
Wexler, P., Hakkinen, P. J., Mohapatra, A., and Gilbert, S. G. (2009): *Information Resources in Toxicology*, 4th edn., Academic Press, San Diego, CA.
Williams, P. L. and Burson, J. L. (2000): *Principles of Toxicology: Environmental and Industrial Applications*, 2nd edn., Wiley, New York.
Woolley, A. (2003): *A Guide to Practical Toxicology: Evaluation, Prediction, and Risk*, Taylor & Francis Group, London, U.K.

Clinical Toxicology

Barceloux, D. G. (2008): *Medical Toxicology of Natural Substances: Foods, Fungi, Medicinal Herbs, Plants, and Venomous Animals*, 1st edn., John Wiley & Sons, Hoboken, NJ.
Barile, F. A. (2010): *Clinical Toxicology: Principles and Mechanisms*, Informa Healthcare USA, Inc., New York.
Brunton, L. L., Chabner, B., and Knollman, B. (2011): *Goodman & Gilman's the Pharmacological Basis of Therapeutics*, 12th edn., McGraw-Hill, New York.
Dart, R. C. (2003): *Medical Toxicology*, 3rd edn., Lippincott Williams & Wilkins, Philadelphia, PA.
Delaney, K. A., Ling, L. J., Erickson, T., and Ford, M. D. (2000): *Clinical Toxicology*, W.B. Saunders, Philadelphia, PA.

Woodruff, T. J. (2010): *Environmental Impacts on Reproductive Health and Fertility*, Cambridge University Press, New York.

Journals and Newsletters

Great strides have been made in the early twenty-first century to provide more immediate and easy access to scientific journals. Journals covering many areas of toxicology and related disciplines that affect toxicological research are published by various groups, including commercial publishers, societies, and government agencies. Traditional print journals are giving way to electronic format, which is speeding the transfer of new research and findings to scientists around the world. Free online journals and publishing services go even further to share results with an even wider audience.

Scientific journals covering research and other topics in toxicology have been with us since at least the mid-nineteenth century. Among the successors to key early journals begun in the 1930s and 1940s are *Archives of Toxicology*, *Pharmacology and Toxicology*, *Toxicology and Applied Pharmacology*, and *Eksperimentalnaia i Klinicheskaia Farmakologiia*.

Today, dozens of journals focus on *Toxicology*, either broadly or on special subareas, such as *Biomarkers*, *Carcinogenesis*, and *Metabolism*. In addition, many others focus on applications of toxicology in drug development or in settings such as the ambient environment or the workplace. Other journals cover research and analysis that cross multiple disciplines and address issues—for example, in environmental or public health.

The most significant advancement in the last decade has been the proliferation of access via the Internet and other electronic media. Many journals now provide subscribers and others with early notification of publications (tables of contents). These services alert readers to the latest research quickly and can often be tailored to the user's particular interests. Some journals provide direct access to abstracts online for paid subscribers and the general public, and many now provide full-text online for subscribers or for single article purchase. Further innovations in access to journal literature are described later in this chapter.

Many journals now encourage authors to submit their articles electronically to facilitate faster peer review and acceptance. Journal peer reviews are often handled through e-mail or the Internet, and the use of these technologies has shortened review time considerably. Some journals release accepted papers in manuscript form almost immediately upon acceptance. These papers have not yet been copyedited or formatted for publication and are eventually replaced with the official publication version; however, they are considered published and are citable.

To keep current with available journals is difficult. Names change, as do publishers. New journals are born and others cease publication. The Internet is the easiest way to find a journal of interest, as most publishers have websites for their journals, where one can find information on contents, subscriptions, submissions, and sometimes access to abstracts and full text of articles. *New-Jour* is a comprehensive and free listing of electronic journals and newsletters on the Internet

and is updated frequently (http://gort.ucsd.edu/newjour/NewJourWel.html). In addition, one can access *PubList* (http://www.publist.com/), a free service that provides searches of a database of over 150,000 magazines, journals, newsletters, and other periodicals from around the world; *Ulrich's Periodicals Directory*, a bibliographic database with information on more than 260,000 print and electronic periodicals (http://www.bowker.com/brands/ulrichs.htm); and the U.S. Library of Congress, which has online catalogs of its extensive holdings, including journals (http://www.loc.gov/).

Table 13.1 provides some key toxicology journals, largely those in English. These journals cover toxicology and the related areas of occupational and environmental health, ecotoxicology, risk analysis, and medicine. Readers can easily locate current websites for these journals or their publishers via a standard web search engine, such as Google. It should be emphasized that this is a selective list of journals. Compared to journals, newsletters offer a generally less formal but sometimes more compelling means of keeping up-to-date in a subject. A few of the more prominent online toxicology newsletters are listed in Table 13.2.

Organizations

An extensive listing of toxicology-related organizations, as well as many other resources, appeared in Wexler et al.'s *Information Resources in Toxicology* (2009).[1] Many different types of organizations are associated with toxicology. These include professional societies, trade associations, government organizations, NGOs, centers or departments of universities, and companies. Key examples of these types of organizations are described later in this chapter, together with noteworthy publications and websites providing compilations of this type of information. The reader is urged to exercise caution when considering data and advice from the web, and should carefully consider the source. The authors of this chapter are not responsible for the information provided by the organizations noted, including the content of their sites. Furthermore, the authors do not necessarily endorse any products or services mentioned by the organizations.

Professional Societies

Professional societies associated with toxicology have been reviewed by Kehrer and Mirsalis[2] and Patterson et al.[3]

American College of Toxicology

The mission of the American College of Toxicology (ACT; http://www.actox.org) is to educate and lead professionals in industry, government, and related areas of toxicology by actively promoting the exchange of information and perspectives on the current status of safety assessment and the applications of new developments in toxicology. ACT maintains an outstanding collection of toxicology-related links in its website. The ACT newsletter is available on the website, as are announcements of upcoming meetings. ACT publishes the *International Journal of Toxicology*.

Xenobiotica

International Association of Forensic Toxicologists

The aims of International Association of Forensic Toxicologists (TIAFTnet; http://www.tiaft.org/) are to promote cooperation and coordination of efforts among members and to encourage research in forensic toxicology and related areas of analytical toxicology. The website contains information on systematic toxicological analysis (STA) and the STA Committee for the identification of toxic compounds and metabolites in biological samples.

International Society of Exposure Sciences

The International Society of Exposure Sciences (ISES; http://www.isesweb.org/), formerly the International Society of Exposure Analysis—ISEA, promotes "the use of exposure in the fields of public, occupational, and environmental health." The ISEA was established in 1989 to foster and advance the science of exposure analysis related to environmental contaminants, both for human populations and ecosystems. The membership promotes communication among all disciplines involved in exposure analysis, recommends exposure analysis approaches to address substantive or methodological concerns, and works to strengthen the impact of exposure assessment on environmental policy. ISES publishes *The Journal of Exposure Science and Environmental Epidemiology (JESEE).*

International Union of Toxicology

The International Union of Toxicology (IUTOX; http://www.iutox.org/) members include SOT and over other societies around the world. IUTOX now has over 50 national/regional society members representing over 20,000 toxicologists from industry, academia, and government as members. Its purpose is to foster international scientific cooperation among national and other groups of toxicologists and promote worldwide acquisition, dissemination, and utilization of toxicology knowledge. The IUTOX website provides links to the sites of all available member societies (http://www.iutox.org/members.asp).

Society for Risk Analysis

The Society for Risk Analysis (SRA; http://www.sra.org) is a multidisciplinary and international society addressing all

Society for Risk Analysis (SRA) Risk Newsletter	http://www.sra.org/newsletter.php
Society of Toxicology (SOT) Communiqué Newsletter	http://www.toxicology.org/ms/communique.asp
Trends in Risk Science and Application	http://www.gradientcorp.com/publications/trends.php

areas of risk analysis related to human health and the environment, including risk assessment, risk characterization, risk communication, risk management, and policy relating to risk. SRA publishes a peer-reviewed journal, *Risk Analysis*, which provides a focal point for new developments in risk analysis for scientists from a wide range of disciplines. The journal covers health risks; engineering, mathematical, and theoretical aspects of risks; and social and psychological aspects of risk such as risk perception, acceptability, economics, and ethics. The society's newsletter and annual meeting abstracts are available from its website.

Society of Environmental Toxicology and Chemistry

The Society of Environmental Toxicology and Chemistry (SETAC; http://www.setac.org/) is a worldwide professional society that promotes the advancement and application of scientific research related to contaminants and other stressors in the environment. SETAC publishes two journals: *Environmental Toxicology and Chemistry* and *Integrated Environmental Assessment and Management* and several newsletters. Its website provides access to education materials such as topical webinars, a career center, workshop reports, and technical issue papers.

Society of Forensic Toxicologists

The Society of Forensic Toxicologists (SOFT; http://www.soft-tox.org/) is a member organization of practicing forensic toxicologists and others organized to promote and develop forensic toxicology. Forensic toxicologists analyze biological fluids and tissues for drugs and/or poisons and interpret the analytical results in a judicial context. SOFT sponsors a certification program for its members and its website contains annual meeting information, education and training, research, employment opportunities, publications, and related links.

Society of Toxicology

The SOT (http://www.toxicology.org/) is perhaps the best-known professional society associated with toxicology and has a global, albeit mostly U.S., membership. SOT is an organization of scientists who practice toxicology in many areas. The society holds annual meetings, publishes a journal and a member newsletter, and sponsors continuing education courses. The society addresses toxicological issues through several of its specialty sections. It maintains an excellent collection of toxicology-related websites of various organizations, along with other sites of interest for toxicologists and for people considering a career in, or just seeking information about, toxicology (http://www.toxicology.org/AI/CRAD/careerguide.asp).

Trade Associations

Many trade associations are active in toxicology efforts and evaluations. Listed in the following are a number of broad chemical trade associations. There are many other more specialized groups that represent specific areas.

American Chemistry Council

The American Chemistry Council (ACC; http://www.americanchemistry.com/), formerly the Chemical Manufacturers' Association, is the voice of the U.S. chemical industry. The ACC represents the chemical industry on public policy issues; coordinates the industry's research and testing programs (e.g., the Long-Range Research Initiative [LRI]); and administers the industry's environmental, health, and safety performance improvement initiative, known as Responsible Care®. Members include corporations in the chemical and chemical-using (e.g., consumer product) industries.

British Industrial Biological Research Association

The members of British Industrial Biological Research Association (BIBRA; http://www.bibra-information.co.uk) include British chemical manufacturers. Its activities include the development of summaries (toxicology profiles) of the data for numerous chemicals.

European Chemical Industry Council

The European Chemical Industry Council (Cefic; http://www.cefic.org/) is both the forum and the voice of the European chemical industry. It represents, directly or indirectly, chemical companies that account for nearly a third of the world chemical production. It has numerous working groups related to chemical safety and the regulation of chemicals, and sponsors research related to toxicology and risk assessment. Cefic has developed guidance documents and tools to assist companies in implementing compliance with the European chemicals legislation, Registration, Evaluation, Authorization and Restriction of Chemical Substances (REACH), and makes these available free of charge on the website.

European Centre for Ecotoxicology and Toxicology of Chemicals

The focus of European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC; http://www.ecetoc.org/) includes the manufacture, processing, handling, and use of chemicals. ECETOC also cooperates with governmental agencies and other organizations concerned with the effects of chemicals on health and the environment.

International Council of Chemical Associations

The International Council of Chemical Associations (ICCA; http://www.icca-chem.org/) is the global voice of the chemical industry, representing chemical manufacturers and producers. It accounts for more than 75% of chemical manufacturing operations. ICCA promotes and coordinates Responsible Care® and other voluntary chemical industry initiatives and has a central role in the exchange of information within the international industry and in the development of position statements on matters of policy. It is also the main channel of communication between the industry and various international organizations that are concerned with health, environment, and trade-related issues.

Government Organizations

Government organizations serving as toxicology information resources are numerous and include federal, state/provisional, and local government agencies, as well as international bodies representing or aiding multiple countries. Relevant toxicological resources are widespread.[4]

Environment Canada and Health Canada

The Canadian Environmental Protection Act (CEPA) of 1999 requires the establishment of a Priority Substances List (PSL) to identify substances that are of priority for assessing whether environmental exposure to them poses a risk to the health of Canadians or to the environment. Over 60 priority substances have been evaluated, and some of the assessment documents containing tolerable intakes, tolerable concentrations, and tumorigenic doses and concentrations for these substances are available through their website (http://www.ec.gc.ca/lcpe-cepa/default.asp?lang=En&n=C6C230D5-1). Health Canada also maintains a Domestic Substances List (DSL), which contains over 23,000 chemical substances that are used, imported, or manufactured in Canada for commercial purposes at quantities greater than 100 kg per year (http://www.hc-sc.gc.ca/ewh-semt/contaminants/existsub/index-eng.php).

European Union, European Commission, Joint Research Centre, European Chemicals Agency

European Chemicals Agency (ECHA) is the driving force among European regulatory authorities in implementing the EU's REACH, which was implemented in 2007. REACH's primary aim is "to ensure a high level of protection of human health and the environment." REACH places the burden of proof on industry, which has to collect or generate the data necessary to ensure the safe use of chemicals. ECHA helps companies to comply with the legislation, advances the safe use of chemicals, provides information on chemicals, and addresses chemicals of concern. Chemical information is publicly available through ECHA's central database (http://www.echa.europa.eu/), which houses the International Uniform Chemical Information Database (IUCLID).

The European Commission's Joint Research Centre also includes the Institute for Health and Consumer Protection (IHCP). The mission of the IHCP is to "provide scientific and technical support in the areas of food, consumer products, chemicals and public health" (http://ihcp.jrc.ec.europa.eu/home). IHCP houses the European Union System for the Evaluation of Substances (EUSES), an integrated modeling system that uses a single framework for comparing the potential risks of different substances released to multiple environmental media (water, soil, and air) and multiple human exposure pathways (inhalation, ingestion, and dermal). EUSES can be used for indirect human exposures and for consumer product and worker exposures. IHCP maintains a number of databases, including the European Indoor Air Monitoring and Exposure Assessment Project (AIRMEX), European Chemical Substances Information System (ESIS), and the European Database of EXport and IMport of certain dangerous chemicals (EDEXIM). IHCP also houses the European Centre for the Validation of Alternative Methods (ECVAM). ECVAM is "the reference centre, at an international level, for the development, scientific and regulatory acceptance of alternative testing methods aimed at replacing, reducing or refining the use of laboratory animals and to be applied in different fields in the biomedical sciences."

National Institute of Public Health and the Environment, the Netherlands

The knowledge and expertise of National Institute of Public Health and the Environment (RIVM; http://www.rivm.nl/en/) in the fields of health, nutrition, and environmental protection (including the conduct of research, monitoring, modeling, and risk assessment) are used primarily for advising the Dutch government. As an example of its efforts, RIVM develops human toxicological risk limits (maximum permissible risks or MPRs). Reports for a variety of chemicals based on chemical assessments are compiled in the framework of the Dutch governmental program on risks in relation to soil quality. These MPR values are published in RIVM reports, many of which can be downloaded from the Publications section of this site.

U.S. Centers for Disease Control and Prevention, Department of Health and Human Services

The Agency for Toxic Substances and Disease Registry (ATSDR; http://www.atsdr.cdc.gov) is an agency within the CDC. Its functions include public health assessments of waste sites, health consultations concerning specific hazardous substances, health surveillance and registries, response to emergency releases of hazardous substances, applied research in support of public health assessments, information development and dissemination, and education and training concerning hazardous substances. ATSDR develops toxicological profiles (http://www.atsdr.cdc.gov/toxprofiles/index.asp) for hazardous substances found at National Priority List sites and for the Department of Defense and the Department of Energy (DOE) for substances related to federal sites. Within these documents, ATSDR develops minimal risk values (MRLs; see http://www.atsdr.cdc.gov/mrls/index.asp). Also available is ATSDR's Tox-FAQs™ (http://www.atsdr.cdc.gov/toxfaqs/index.asp), a series of summaries about hazardous substances and their health effects. Information for this series is excerpted from the ATSDR Toxicological Profiles and Public Health Statements.

The NIOSH (http://www.cdc.gov/niosh/) is another part of the CDC and is the federal agency responsible for conducting research and making recommendations for the prevention of work-related injury and illness. Its objectives include the conduct of research to reduce work-related illnesses and injuries, the promotion of safe and healthy workplaces through interventions, recommendations and capacity building, and the enhancement of global workplace safety and health through international collaborations. The NIOSH website provides

access to information on numerous workplace health and safety topics, including chemicals, hazards and exposures, emergency preparedness and response, safety and prevention, and on emerging issues such as nanotechnology.

U.S. Consumer Product Safety Commission

The Consumer Product Safety Commission (CPSC; http://www.cpsc.gov/) protects the U.S. public against risk of injury or harm from consumer products. Among its efforts, the CPSC evaluates and develops standards and guidelines for safety issues and regulations for labeling and packaging. It has also performed exposure-related research as part of the development of risk assessments for exposures to various chemicals in consumer products.

U.S. Department of Energy

The DOE's Risk Assessment Information System (RAIS; http:/rais.ornl.gov/) is a website developed to provide a service-oriented environmental risk assessment expert system. RAIS provides tools for performing basic risk assessment activities, such as preliminary remediation goals, toxicity values and profiles (including the EPA's Integrated Risk Information System [IRIS] and HEAST), federal and state guidelines, human health risk models, and ecological benchmarks.

U.S. Environmental Protection Agency

The mission of the EPA, founded in 1970, is to protect human health and the environment. Several of its components are of particular relevance to toxicology. The National Center for Environmental Assessment (NCEA; http://www.epa.gov/ncea/), for example, serves as the EPA national resource center for the overall process of human health and ecological risk assessments, including the integration of hazard, dose–response, and exposure data and models to produce risk characterizations. The Office of Pollution Prevention and Toxics (OPPT; http://www.epa.gov/oppt/) promotes pollution prevention, safer chemicals, risk reduction, and public understanding of risks. Its Office of Research and Development (ORD; http://www.epa.gov/ord/) is the scientific research arm of EPA. ORD's research helps provide the solid underpinning of science and technology for EPA.

Numerous databases accessible through the EPA's website present a wealth of relevant and reliable data.[5] The IRIS (http://www.epa.gov/iris) is the EPA's consensus database of information on human health effects that may result from exposure to various chemicals found in the environment, including values such as oral reference doses (RfDs) and inhalation reference concentrations (RfCs) for noncarcinogenic health effects, as well as oral slope factors and oral and inhalation unit risks for carcinogenic effects. The Toxics Release Inventory (TRI; http://www.epa.gov/tri) is a database containing information focused on the estimated numbers of pounds of certain toxic chemicals released into the environment, augmented by source reduction and recycling data. Both IRIS and TRI are accessible via the EPA's website and the NLM's toxicology data network (TOXNET®) system (http://toxnet.nlm.nih.gov). Recent informatics efforts in genomics at EPA and National Institute of Environmental Health Sciences (NIEHS) are discussed further later in this chapter.

U.S. Food and Drug Administration

The FDA (http://www.fda.gov/) is an agency consisting of a number of centers within the Department of Health and Human Services with the mission of protecting the public health of Americans by helping safe and effective products reach the market in a timely way, monitoring products for continued safety after they are in use, and helping the public get accurate, science-based information. The Center for Biologics Evaluation and Research (CBER; http://www.fda.gov/BiologicsBloodVaccines/) regulates biological products for disease prevention and treatment. The Center for Devices and Radiological Health (CDRH; http://www.fda.gov/Radiation-EmittingProducts/) ensures that new medical devices are safe and effective before they are marketed; monitors devices throughout the product life cycle, including a nationwide postmarket surveillance system; and ensures that radiation-emitting products (e.g., microwave ovens, television sets, cell phones, and laser products) meet radiation safety standards. The Center for Drug Evaluation and Research (CDER; http://www.fda.gov/ForIndustry/FDAeSubmitter/ucm274477.htm) evaluates all new prescription and over-the-counter drugs before they are sold and serves as a consumer watchdog for marketed drugs to be sure that they continue to meet the highest standards. The Center for Food Safety and Applied Nutrition (CFSAN; http://www.fda.gov/Food/) is responsible for the safety of the entire food supply, except for meat, poultry, and some egg products that are regulated by the U.S. Department of Agriculture. In addition, CFSAN has developed rapid methods for the detection of microbial and viral food contaminants and works closely with public and private sector partners to operate systems for rapid identification and control of outbreaks of foodborne diseases. The Center for Veterinary Medicine (CVM; http://www.fda.gov/AnimalVeterinary/) helps ensure that animal feed products are safe and evaluates the safety and effectiveness of drugs used to treat companion animals (e.g., dogs, cats, and horses). The mission of the National Center for Toxicological Research (NCTR; http://www.fda.gov/AboutFDA/CentersOffices/OC/OfficeofScientificandMedicalPrograms/NCTR/) is to conduct peer-reviewed scientific research that supports and anticipates the FDA's current and future regulatory needs. This involves fundamental and applied research specifically designed to define biological mechanisms of action underlying the toxicity of products regulated by the FDA. This research is aimed at understanding critical biological events in the expression of toxicity and at developing methods to improve the assessment of human exposure, susceptibility, and risk.

U.S. National Institutes of Health

The major information component of the NIH is the NLM. The TOXNET system (http://toxnet.nlm.nih.gov) is a group of databases managed by the NLM's Toxicology

and Environmental Health Information Program (TEHIP), situated within its Specialized Information Services (SIS) Division. The data banks and bibliographic files are built, maintained, and funded by several federal agencies. Its databases are described later in this chapter. Furthermore, the SIS Division of NLM provides online toxicology training via its Toxicology Tutor I, II, and III (http://sis.nlm.nih.gov/enviro/toxtutor.html) and provides extensive information about resources related to toxicology and environmental health education (http://sis.nlm.nih.gov/enviro/envirohealthlinks.html), including academic program directories, continuing education and tutorials, distance learning, etc.

Another NIH institute particularly relevant to toxicology is the NIEHS (http://www.niehs.nih.gov). Its website links to resources from the National Toxicology Program (NTP). The NTP consists of the relevant toxicology activities of the NIEHS, NIOSH, and NCTR. The goals of the NTP are to provide toxicological evaluations on substances of public health concern; develop and validate test methods; develop approaches and generate data that strengthen the scientific basis for risk assessments; and communicate program plans and results to all stakeholders including governmental agencies, the medical and scientific communities, and the public. The NTP website also provides access to NTP testing information and study results, the NTP Report on Carcinogens (RoC), chemical health and safety information, special reports, and announcements, as well as links to the websites for the NTP Center for the Evaluation of Alternative Toxicological Methods (NICEATM) and the Children's Environmental Health Network (CEHN).

Other Organizations

Readers should take note that, as with all the lists in this chapter, the compilation of organizations is highly selective with regard to a number of variables, including geography. There are important toxicology-related groups and activities (e.g., in Asia, Africa, and Latin America) that, because of space limitations, could not be included here.

University-Affiliated Organizations

Extension Toxicology Network

Extension Toxicology Network (EXTOXNET; http://ace.orst.edu/info/extoxnet) is an effort of the University of California at Davis, Oregon State University, Michigan State University, Cornell University, and the University of Idaho. EXTOXNET provides information on pesticides, discussion of concepts in toxicology and environmental chemistry, and fact sheets. This information has been developed by toxicologists and chemists within the Extension Service of these universities with the goal of developing unbiased information in a format understandable by the nonexpert.

Harvard Center for Risk Analysis

The Harvard Center for Risk Analysis (HCRA; http://www.hcra.harvard.edu) attempts to provide a big-picture overview of public health by comparing and ranking a wide range of hazards; analyzing the results of dealing with those hazards in various ways; and developing sound scientific data identifying policy choices that are most likely to achieve the greatest health, safety, and environmental benefits with the most efficient use of finite resources. The center's current research programs focus on the areas of risk characterization and prioritization, improving exposure assessment, understanding dose–response relationships, and valuing risk reductions. The center has a newsletter entitled *Risk in Perspective*, which discusses results of research projects.

National Pesticide Information Center

The National Pesticide Information Center (NPIC; http://npic.orst.edu), a cooperative agreement between Oregon State University and the U.S. EPA, provides objective, science-based information about pesticides and pesticide-related topics to enable people to make informed decisions about pesticides and their use. NPIC operates a toll-free, bilingual telephone service to the public and professionals in the United States, Puerto Rico and the Virgin Islands, and maintains an informational website. NPIC analyzes trends for pesticide misuse, labeling issues, and risks to humans, animals, and the environment, and reports its findings back to EPA.

The Johns Hopkins University

Altweb (http://altweb.jhsph.edu/) is composed of a diverse group of organizations and individuals, many of whom serve in the Altweb Project Team and are interested in alternatives to animal testing. A number of these organizations maintain their own websites that provide key links from and to Altweb. The website is management by The Johns Hopkins University Center for Alternatives to Animal Testing (CAAT). The intent of Altweb is to be the online clearinghouse for resources, information, and news about alternatives to animal testing and to serve as the most comprehensive resource on animal alternatives for scientists, educators, veterinarians, and individuals throughout the world. This effort is designed to bring together government agencies, the academic community, animal protection groups, and private industry to encourage the use of alternative methods.

International Organizations

International Agency for Research on Cancer

The International Agency for Research on Cancer (IARC; http://www.iarc.fr/) is part of the World Health Organization, and its mission is to coordinate and conduct research on the causes of human cancer and the mechanisms of carcinogenesis, as well as to develop scientific strategies for cancer control. IARC is involved in both epidemiological and laboratory research and disseminates information through publications, meetings, courses, and fellowships. Cancer databases and other resources at IARC include the Monographs Database (a complete list of agents, mixtures, and exposures, all evaluated with their classifications) and the Cancer Epidemiology Database among others.

International Consumer Products Health and Safety Organization

The International Consumer Products Health and Safety Organization (ICPHSO; http://www.icphso.org/) is dedicated to health and safety issues related to consumer products manufactured and marketed in the global marketplace. ICPHSO includes a broad range of health and safety professionals and interested consumers, and sponsors workshops to inform and educate manufacturers, importers, distributors, retailers, and others of their product safety responsibilities.

International Labour Organization

The International Labour Organization (ILO; http://www.ilo.org/), an agency of the United Nations (UN), is the international organization responsible for drawing up and overseeing international labor standards. Its main aims are to promote rights at work, encourage decent employment opportunities, enhance social protection, and strengthen dialog on work-related issues. Of particular interest to toxicologists is its International Occupational Safety and Health Information Centre (CIS), the knowledge management hub of its Programme on Safety and Health at Work and the Environment (SafeWork; http://www.ilo.org/safework/lang--en/index.htm). The CIS compiles occupational safety and health-related information and ensures worldwide access to it, creates and disseminates ILO publications (including the ILO Encyclopedia and related products), and maintains an international network of national and international occupational safety and health institutions.

International Programme on Chemical Safety

The International Programme on Chemical Safety (IPCS; http://www.who.int/ipcs/en/) works to establish the scientific basis for the sound management of chemicals, and to strengthen national capabilities and capacities for chemical safety. IPCS aims at promoting the development, harmonization, and use of generally acceptable, scientifically sound methodologies for the evaluation of risks to human health and the environment from exposure to chemicals. The results of such work enhance mutual acceptance of risk assessment products. It publishes a variety of high-quality, peer-reviewed monographs, such as the Environmental Health Criteria (EHC) documents. The IPCS and Organization for Economic Cooperation and Development (OECD) have developed a framework for cooperation in the field of risk assessment methodologies, which ensures complementarity, mutual support and mutual involvement in the projects conducted by each organization.

The IPCS Harmonization Project tries to harmonize approaches to the assessment of risk from exposure to chemicals by increasing understanding and developing basic principles and guidance on specific chemical risk assessment issues. Harmonization enables efficient use of resources and consistency among assessments.

IPCS INCHEM (http://www.inchem.org) provides rapid access to internationally peer-reviewed information on chemicals commonly used throughout the world, which may also occur as contaminants in the environment and food. It consolidates information from a number of intergovernmental organizations whose goal is to assist in the sound management of chemicals. Among the documents offered are the Concise International Chemical Assessment Documents (CICADs), the International Chemical Safety Cards, and Poisons Information Monographs.

Organization for Economic Cooperation and Development

The mission of the OECD, simply put, is to promote policies that will improve the economic and social well-being of people around the world. Its program on chemical safety and biosafety, falling under the OECD's environment initiatives, is to protect human health and the environment through improving chemical safety; to make chemical control policies more transparent and save resources for government and industry; and to prevent unnecessary distortions in the trade of chemicals and chemical products. It also addresses pesticides, biocides, chemical accidents, and biotechnology.

Strategic Approach to International Chemicals Management

The Strategic Approach to International Chemicals Management (SAICM; http://www.chem.unep.ch/saicm), adopted by the International Conference on Chemicals Management (ICCM) in 2006 in Dubai, is a policy framework to foster the sound management of chemicals. It supports the goal agreed upon at the 2002 Johannesburg World Summit on Sustainable Development of ensuring that, by the year 2020, chemicals are produced and used in ways that minimize significant adverse impacts on the environment and human health. ICCM2 was held in 2009 in Geneva and ICCM3 in 2012 in Nairobi. SAICM's Quick Start Programme (QSP) includes a voluntary, time-limited trust fund, administered by the UN Environment Programme, and multilateral, bilateral, and other forms of cooperation.

Nongovernmental Organizations

The Hamner Institute

The Hamner Institute for Health Sciences (http://www.thehamner.org/about-the-hamner/) is an independent, nonprofit organization whose vision is "to be a global leader in translational life sciences research, innovation, and training." The Hamner is located in Research Triangle Park, North Carolina, USA focusing on translational biomedical research using a collaborative and cross-disciplinary approach. The Hamner scientists partner with academic institutions, industries, and governments from around the world to perform innovative research and development in environmental health and chemical risk assessment as well as biopharmaceutical safety, oncology, and nanotoxicology.

Health Effects Institute

The Health Effects Institute (HEI; http://www.healtheffects.org/) is an independent, nonprofit corporation chartered in

1980 to provide high-quality, impartial, and relevant science on the health effects of pollutants from motor vehicles and from other sources in the environment. Primarily supported by the U.S. EPA and the motor vehicle industry, HEI has funded hundreds of studies and published over 100 research reports and several special reports that provide important research findings on the health effects of a variety of pollutants, including carbon monoxide, methanol and aldehydes, nitrogen oxides, diesel exhaust, ozone, particulate matter, and air toxics.

International Life Sciences Institute

The International Life Sciences Institute (ILSI; http://rsi.ilsi.org/) is a nonprofit, worldwide scientific research foundation seeking to improve the well-being of the general public through the pursuit of sound and balanced science. Its goal is to further the understanding of scientific issues relating to nutrition, food safety, toxicology, risk assessment, and the environment.

Toxicology Excellence for Risk Assessment

Toxicology Excellence for Risk Assessment (TERA; http://www.tera.org) is an independent nonprofit research and education organization dedicated to the best use of toxicity data in risk assessment. TERA develops risk values; improves methods for human health risk assessment through their research program; sponsors expert review of risk assessments, risk values, methods, and research through their independent peer review and peer consultation programs; provides technical support, training courses, and risk communication to diverse groups through their education program; and compiles and distributes peer-reviewed risk values to the international user community through the International Toxicity Estimates for Risk (ITER) database, described later in this chapter.

Databases and Websites

The Internet plays a vital role in the provision of information resources. We have access to sources, including full-text journal articles, online that in the past were only available by physically visiting a library. The following websites and databases are intended to serve as a selective list and do not approach the scope of a comprehensive compilation.

Aggregated Computational Toxicology Online Resource

(http://actor.epa.gov/actor/faces/ACToRHome.jsp)—Aggregated Computational Toxicology Online Resource (ACToR) is the U.S. EPA's online warehouse of publicly available chemical toxicity data. ACToR collects data from over 650 public sources on over 500,000 chemicals.[6] The database can be searched by chemical name, registry number, and chemical structure. Queries in the ACToR database also include other U.S. EPA databases such as ToxRefDB (animal toxicity testing results), DSSTox (public forum for chemical structure files), ToxCastDB (ToxCast chemical testing results), and ExpoCastDB (exposure data summaries) in the search strategy.

CAL/EPA–OEHHA Toxicity Criteria Database

(http://www.oehha.ca.gov/risk/chemicaldb)—This toxicity criteria database is maintained by the California Office of Environmental Health Hazard Assessment (OEHHA). The database provides California public health goals (PHGs), acute and chronic reference exposure levels (RELs), cancer classification, cancer potency values, and Proposition 65 No Significant Risk Levels (NSRLs) and Maximum Allowable Daily Level (MADL).

Canadian Centre for Occupational Health and Safety

(http://www.ccohs.ca/)—The Canadian Centre for Occupational Health and Safety (CCOHS) promotes a safe and healthy working environment by providing e-courses, publications, fact sheets, pocket guides, Workplace Hazardous Materials Information System (WHMIS) criteria, and web information service databases. The Web databases include Registry of Toxic Effects of Chemical Substances (RTECS®), MSDS plus CHEMINFO, CHEMpendium, and Occupational Safety and Health (OSH) references and legislation regulations. Some of the databases are restricted to subscribers.

Chemical Effects in Biological Systems

(http://www.niehs.nih.gov/research/resources/databases/cebs)—Chemical Effects in Biological Systems (CEBS) is an integrated public repository for toxicogenomics data, including the study design and timeline, clinical chemistry and histopathology findings, and microarray and proteomics data. CEBS contains data derived from studies of chemicals and of genetic alterations, and is compatible with clinical and environmental studies.[7]

ProQuest Dialog™

(http://www.dialog.com)—Dialog is a vast database collection in science, engineering, business, and intellectual property with full-text access to most of the search results. The database offers comprehensive, global coverage of biomedical research, chemicals, computer science, energy and environment, health industry, mechanical and civil engineering, medical practice, medical devices, pharmaceuticals, food science, software, therapy and treatment breakthroughs, drug interactions, and toxicology, as well as many subject areas. Dialog database content is available in a desktop version through Telnet and Windows® software or through several web browser formats. Dialog is available by subscription or by transactional fees with an access fee through the DialogWeb browser. The following are examples of a few of the databases that can be searched within Dialog:

- *BIOSIS Previews*® is a database that constitutes the major English-language service providing comprehensive worldwide coverage of research in the biological and biomedical sciences. This database includes journal articles, indexes, monographs, meetings, reviews, book chapters, and some patents and is also a key resource for bioengineering and biotechnology researchers.

- *EMBASE*® is bibliographic database that provides comprehensive coverage of the literature on human medicine and related disciplines. The database emphasizes the pharmacological effects of drugs and chemicals.
- *SciSearch*®, a cited reference science database, is an international, multidisciplinary index to the literature of science, technology, biomedicine, and related disciplines produced by Thomson Reuters. It contains all of the records published in the *Science Citation Index* (SCI®), plus additional records in engineering technology, physical sciences, agriculture, biology, environmental sciences, clinical medicine, and life sciences.
- *MEDLINE* is a bibliographic database produced by the U.S. NLM. This database covers the field of medicine including dentistry, veterinary medicine, and medical psychology. It also covers other related fields such as clinical and preclinical medicine, anatomy, pharmacology, toxicology, genetics, microbiology, pathology, environmental health, occupational medicine, psychology, biomedical technology, health planning and administration, and space life science.

eChemPortal

(http://www.echemportal.org/echemportal/index?pageID=0&request_locale=en)—The eChemPortal database is maintained and updated by the OECD. This free database is a global portal to information on chemical substances including physical–chemical properties, ecotoxicity, environmental fate and behavior, and toxicity. Users can search 20+ different databases by these properties or by chemical identity. eChemPortal evolved from the EXICHEM database, which is no longer updated.

European Chemical Substances Information System

(http://esis.jrc.ec.europa.eu/)—This database is a wealth of information for European chemical information. The following areas can be searched: European Inventory of Existing Commercial Substances (EINECS), which contains general chemical information such as CAS Registry Numbers, EINECS numbers, substance names, chemical formulas, structure, classification, and labeling (risk and safety phrases, danger, etc.); European List of Notified Chemical Substances (ELINCS); high production volume chemicals (HPVCs) and low production volume chemicals (LPVCs), including EU producer/importer lists; IUCLID Chemical Data Sheets (in Adobe and OECD format); classification and labeling in accordance with the Globally Harmonized System (CLP/GHS); priority lists; and risk assessment processes and tracking systems in relation to Council Regulation (EEC) 793/93, also known as Online EUropean Risk Assessment Tracking System (ORATS).

ExPub

(http://www.expub.com/Default.aspx)—ExPub consists of more than 130 databases geared toward environmental health and safety professionals and others who need to understand the human health hazards associated with chronic and acute exposures to chemicals. ExPub provides users with access to over 2 million documents covering over 400,000 chemicals. It contains a blend of licensed content, public domain content, and gray literature with links to full-text documents when available. ExPub also includes domestic and international regulatory lists. The ExPub database is only available by subscription from Expert Publishing.

Haz-Map®

(http://hazmap.nlm.nih.gov/)—This occupational toxicology database is designed primarily for health and safety professionals but also for consumers seeking information about the health effects of exposure to chemicals at work. It contains approximately 1000 chemicals or biological agents and links jobs and hazardous tasks with occupational diseases and their symptoms. This association indicates an increased risk for significant exposure and subsequent disease.

ILPI–MSDS (Finding Material Safety Data Sheets on the Internet)

(http://www.ilpi.com/msds/index.html)—This website is a comprehensive MSDS resource maintained by Interactive Learning Paradigms, Inc. (ILPI). The website includes everything from links to material safety data sheets to OSHA regulations and interpretations.

INCHEM

(http://www.inchem.org/)—INCHEM is a website with search capabilities to provide easy access to international chemical safety information from various organizations. The website is housed by the IPCS in cooperation with CCOHS. CICADs, EHC Monographs, IARC Summaries, Joint Expert Committee on Food Additives (JECFA)—Monographs and Evaluations, Joint Meeting on Pesticide Residues (JMPR), and Screening Information Data Set (SIDS) for HPVCs are all searchable from this website.

National Service Center for Environmental Publications

(http://www.epa.gov/ncepihom/index.htm)—The National Service Center for Environmental Publications (NSCEP) maintains and distributes EPA publications in hardcopy, CD-ROM, and other multimedia formats. The current publication inventory includes over 7,000 titles in hardcopy and 35,000 digital titles that are free to all requestors.

NIOSH Databases and Information Resources

(http://www.cdc.gov/niosh/database.html)—The NIOSH website contains a vast array of occupational health and safety resources. The most popular databases include the International Chemical Safety Cards (ICSC), NIOSH Pocket Guide to Chemical Hazards, Immediately Dangerous to Life and Health (IDLH) values, the Emergency Response Safety and Health Database (ERSH-DB), and NIOSHTIC-2 (a bibliographic database of occupational safety and health publications).

Pesticide Action Network Pesticide Database

(http://www.pesticideinfo.org)—The Pesticide Action Network (PAN) Pesticide Database is a project of Pesticide Action Network North America (PANNA) and has been supported by grants from the EPA and a number of foundations. This database is a diverse array of information on pesticides from many different sources that provides human toxicity (chronic and acute), ecotoxicity, and regulatory information for about 5400 pesticide active ingredients and their transformation products, as well as adjuvants and solvents used in pesticide products. References to data sources are provided.

Quertle

(http://www.quertle.info/)—Quertle is a relationship-driven biomedical searchable database. When using more than one search term, all the terms in the query must be found together in a meaningful way, not just scattered throughout the document. This database makes use of Quertle predefined Power Terms™ to search for categories of objects. Search results can be imported into reference management software.

Regional Screening Levels

(http://www.epa.gov/region09/waste/sfund/prg/index.html)—Regional Screening Levels (RSLs; formerly known as Preliminary Remediation Goals or PRGs) are tools for evaluating and cleaning up contaminated sites in the U.S. Superfund and the Resource Conservation and Recovery Act programs. They are risk-based concentrations derived by using risk assessment guidance from the EPA Superfund program, and are intended to assist risk assessors and others in initial screening-level evaluations of environmental measurements. The former PRGs (U.S. EPA Region 9) were harmonized with similar risk-based levels from U.S. EPA Regions 3 and 6 to create a single table of RSLs. The RSL tables can be downloaded in Excel® or PDF. RSLs are generic; they are calculated without site-specific information, however. The website has an online calculator to recalculate the RSL using site-specific data.

PubMed®

(http://pubmed.gov)—PubMed, a service of the NLM, includes over 15 million citations for biomedical articles back to the 1950s. These citations are from MEDLINE and additional life science journals. PubMed includes links to many sites providing full-text articles and other related resources. PubMed can be searched using medical subject heading (MeSH) terms, author names, title words, text words or phrases, journal names, or any combination of these. PubMed has the ability to instantly find related articles for any citation and search results can be imported into reference manager software.

Registry of Toxic Effects of Chemical Substances

(http://accelrys.com/products/databases/bioactivity/rtecs.html and http://ccinfoweb.ccohs.ca/rtecs/search.html)—The RTECS helps users find critical toxicological information by providing citations on over 169,000 chemical substances from more than 2,500 sources. The RTECS database covers several categories of toxicity data: acute toxicity, tumorigenicity, mutagenicity, skin and eye irritation, reproductive effects, and multiple dose effects. The RTECS® database was previously maintained by the NIOSH and is now licensed through Accelrys, Inc. The database is available from Accelrys as an ASCII text file for in-house use (does not include chemical structures) or through value-added resellers such as CCOHS, Chemical Abstracts Service, Dialog, and SiteHawk.

ScienceDirect

(http://www.sciencedirect.com/)—Since its launch in 1997, ScienceDirect has evolved from a web database of Elsevier journals to one of the world's largest providers of scientific, technical, and medical literature. Elsevier has digitized a remarkable amount of the pre-1995 content as possible, going back to the first volume/issue for many journals. Access to full-text articles is available to subscribers or on a pay-per-view basis, and some university libraries have electronic access. ScienceDirect is also available from SciVerse, a platform to search and access content from all Elsevier databases, including beta applications using one login.

Science.gov

(http://www.science.gov/index.html)—Science.gov is a search engine for government science information and research results. One-click search provides results from 50 databases and 200 million pages of government science information from 14 federal science agencies including but not limited to the Departments of Defense, Energy, Health and Human Services, the EPA, the National Aeronautics and Space Administration (NASA), and the National Science Foundation. Science.gov allows clustering or grouping of results by topic, year, or author, and includes Wikipedia topics and EurekAlert items related to the search. Search results can be imported into reference management software or e-mailed to colleagues.

Scirus

(http://www.scirus.com/srsapp/)—Scirus is a comprehensive science-specific Internet search engine. Driven by the latest search engine technology, Scirus searches over 460 million science-specific web pages.

Scopus

(http://www.scopus.com/)—Scopus is a navigation tool covering the world's largest collection of abstracts, references, and indexes of scientific, technical, and medical literature. Updated daily, it includes the abstracts and cited references of over 19,500 titles from more than 5,000 international publishers, and includes 4.6 million conference papers. Seamless links to full-text articles and other library resources make Scopus quick, easy, and comprehensive. Access is only available through subscribing libraries or institutions. Scopus is also available from SciVerse, a platform to search and access content from all Elsevier databases, including beta applications using one login.

Scorecard

(http://www.scorecard.org/)—Scorecard is an Internet service that provides information about chemical releases in the United States. It provides information about local air pollution, including interactive maps that can be accessed by Zip Code, information on toxic chemicals released by manufacturing facilities, and information about the health risks of air pollution. Scorecard ranks and compares pollution in areas across the United States and profiles 11,200 chemicals and shows locations in which they are used, as well as their hazards. Scorecard integrates over 400 scientific and governmental databases to generate its profiles. Environmental Defense transferred ownership of Scorecard to Green Media Toolshed in 2005.

Toxicology Data Network

(http://toxnet.nlm.nih.gov; as a link on http://sis.nlm.nih.gov)—TOXNET® is a group of databases covering toxicology, hazardous chemicals, environmental health, and related areas. It is managed by the TEHIP in the SIS Division of the NLM. Many TOXNET databases are available in mobile versions. TOXNET provides free access and easy searching of many databases, including:

- Carcinogenic Potency Database (CPDB)—CPDB reports standardized analyses of animal cancer tests on more than 1500 chemicals for the results of 6540 chronic, long-term animal cancer tests that have been conducted since the 1950s and reported in the general published literature or by the National Cancer Institute (NCI) and the NTP. The CPDB was developed at the University of California, Berkeley, and Lawrence Berkeley Laboratory.
- Chemical Carcinogenesis Research Information System (CCRIS)—A scientifically evaluated and fully referenced data bank developed by the NCI but no longer being updated, CCRIS contains some 9500 chemical records with carcinogenicity, mutagenicity, tumor promotion, and tumor inhibition test results. Data are derived from studies cited in primary journals, current awareness tools, NCI reports, and other special sources. Test results have been reviewed by experts in carcinogenesis and mutagenesis.
- ChemIDplus—A database providing access to structure and nomenclature authority databases used for the identification of chemical substances cited in NLM databases, ChemIDplus contains over 384,000 chemical records, of which over 300,000 include chemical structures. ChemIDplus is searchable by name, synonym, CAS Registry Number, molecular formula, classification code, locator code, and structure.
- Comparative Toxicogenomics Database (CTD)©—The CTD is a compilation of manually curated data describing chemical–gene/protein interactions and chemical–disease and gene–disease relationships. The results help elucidate the molecular mechanisms underlying variable susceptibility and environmentally influenced diseases. The CTD was developed by North Carolina State University (NCSU) scientists located at NCSU and Mount Desert Island Biological Laboratory.
- Developmental and Reproductive Toxicology/Environmental Teratology Information Center (DART®/ETIC)—A bibliographic database covering literature on reproductive and developmental toxicology. DART/ETIC is no longer funded by the government agencies that created it but is still searchable as a distinct entity as well as a part of TOXLINE®.
- GENE-TOX (Genetic Toxicology)—This legacy toxicology database was created by the EPA and contains genetic toxicology test results on over 3000 chemicals. Selected literature was reviewed by scientific experts for each of the test systems under evaluation.
- Hazardous Substances Data Bank (HSDB®)—This factual database focuses on the toxicology of over 5000 potentially hazardous chemicals, but provides information in the areas of emergency handling procedures, industrial hygiene, environmental fate, human exposure, detection methods, and regulatory requirements. The data are fully referenced and peer reviewed by a scientific review panel composed of expert scientists.
- IRIS; also at http://www.epa.gov/iris—This database is managed by the NCEA of the EPA and contains carcinogenic and noncarcinogenic health-risk information on over 550 chemicals. These chemical files contain descriptive and quantitative information about oral RfDs and inhalation RfCs for chronic noncarcinogenic health effects and hazard identification, as well as oral slope factors and oral and inhalation unit risks for carcinogenic effects. IRIS risk assessment data have been scientifically reviewed by EPA scientists and represent EPA consensus. IRIS is widely used in the EPA for risk-based decision making.
- ITER; also at http://www.tera.org/iter—This database contains human health risk values and cancer classifications for over 680 chemicals of environmental concern from multiple organizations worldwide in support of human health risk assessments. It is compiled by TERA and provides a comparison of international risk assessment information in a side-by-side tabular format. ITER explains differences in risk values derived by different organizations and contains links to the source documentation. It is the only database that includes risk information from independent parties whose risk values have undergone peer review through TERA's ITER Peer Review Program. TERA also helped develop a companion database called RiskIE, available through

the Alliance for Risk Assessment (http://www.allianceforrisk.org/RiskIE.htm), which contains notifications about a variety of human health risk assessment projects that are underway or recently completed.
- LactMed (Drugs and Lactation Database)—Containing over 500 records, LactMed is a peer-reviewed and fully referenced database of drugs, including complementary and alternative medicines, to which breastfeeding mothers may be exposed. Among the data included are maternal and infant levels of drugs, possible effects on breastfed infants and on lactation, and alternative drugs to consider. A mobile device application is now available for the iphone/ipod or android systems.
- TRI—This series of databases describes the releases of toxic chemicals into the environment annually from 1987 to the most recently compiled reporting year. TRI is mandated by the Emergency Planning and Community Right-to-Know Act and is based on data submitted to the EPA from industrial facilities throughout the United States. Information is included on over 600 chemicals and chemical categories. Pollution prevention data are also reported by each facility for each chemical.
- TOXLINE®—A bibliographic database providing comprehensive coverage of biochemical, pharmacological, physiological, and toxicological effects of drugs and other chemicals. Its subfiles include literature from PubMed/MEDLINE, DART, the International Labour Office (CIS) and more. TOXLINE contains over 4 million citations, almost all with abstracts and/or index terms and CAS Registry Numbers.

The TOXNET *Multi-Database* option allows for simultaneous searching of HSDB, IRIS, ITER, CCRIS, GENETOX, CTD, and LactMed.

Other Resources

The NLM's Environmental Health and Toxicology pages (http://sis.nlm.nih.gov/enviro.html) contain links to additional relevant databases in areas such as occupational safety and health, household products, and dietary supplements. LiverTox and PillBox are two additional databases relevant to toxicology. The former provides up-to-date, accurate, and easily accessed information on the diagnosis, cause, frequency, patterns, and management of liver injury attributable to prescription and nonprescription medications, herbals, and dietary supplements. PillBox enables rapid identification of unknown solid-dosage medications (tablets/capsules) based on physical characteristics and high-resolution images. ToxLearn is the successor to ToxTutor, an online tutorial that trains users in the basic principles of toxicology. The toxicology glossary of International Union of Pure and Applied Chemistry (IUPAC) is also made available by NLM, as are programs geared toward the public and schoolchildren (e.g., ToxTown®, ToxMystery).

Toxic Substance Control Act Test Submission Database

(http://www.syrres.com/esc/tscats.htm; Also available as a subfile in NLM's TOXLINE database)—Toxic Substance Control Act Test Submission (TSCATS) Database was developed by Syracuse Research Corporation (SRC) for the EPA in 1985. It is a central system for the collection, maintenance, and dissemination of information on unpublished technical reports submitted by industry to the EPA under the Toxic Substances Control Act (TSCA). Studies on over 8000 chemicals are categorized into three broad subject areas (health effects, environmental effects, and environmental fate).

Other Tools

- *ChemBioFinder* (http://www.chemfinder.com/chembiofinder/Forms/Home/ContentArea/Home.aspx) is a compilation of free and subscription databases for chemical information including chemical structures, physical properties, and hyperlinks.
- *Merck Index* (http://themerckindex.chemfinder.com/TheMerckIndex/Forms/Home/ContentArea/Home.aspx) is an encyclopedia of chemicals, drugs, and biologicals that contains more than 10,000 monographs.
- *General search engines* include http://www.altavista.com; http://www.aol.com; http://www.ask.com; http://www.bing.com; http://www.google.com; http://www.lycos.com; http://www.msn.com; and http://www.yahoo.com.
- *Meta-search engines* include http://www.dogpile.com; http://www.info.com; http://www.monstercrawler.com; http://www.webcrawler.com;andhttp://www.yippy.com.

CONDUCTING A LITERATURE SEARCH

An effective literature review is often necessary at the beginning of a research project or thesis. The literature review should convey the available knowledge and ideas that have been established on the topic including the strengths and weaknesses of the knowledge.[8] It should be more than a descriptive list of the available studies or a set of study summaries. One should begin the literature review with a literature search defined by a guiding concept (e.g., the research objective, problem, issue, or thesis topic). After selecting the topic, one must determine the appropriate keywords and databases to use in the search (see the Databases and Websites section). The keywords should be a diverse set of related terms; often a librarian can provide assistance. The search results should be reviewed to determine if the search were wide enough to capture all the relevant material but still narrow enough to exclude most irrelevant material, and the number of results are appropriate for the topic. If there is a problem with any of these areas (i.e., too little data for a common topic, too much data for an obscure topic), the keywords for the search should be revised and the search conducted again until the results are satisfactory. Once the literature search results are adequate, they should be reviewed to

identify relevant literature. All relevant literature should be retrieved, read, and analyzed; additional relevant literature may be identified through the citations of reviewed literature. Organize the literature into sections that present themes or trends rather than list a summary of each study. By organizing the literature, one can critically analyze the data to synthesize and evaluate it in relation to the guiding concept (e.g., the research objective, problem, issue, or thesis topic).

New Developments and Recent Issues

One might think there is no more room for new technologies to expand the scope and power of information organization and retrieval, but it would be a flawed assumption. Periodically, new ways of managing information overload are developed. Some, inevitably, fall by the wayside, but others offer us opportunities to reconsider the way we have been processing and displaying information all along.

Open Access Publishing

It used to be understood, and was rarely questioned, that the fruits of scientific research, in the form of original data and information, were for sale; however, as a crisis evolved in the pricing of serials, globally networked computers became commonplace, and users began particularly to question the ethics of requiring paid subscriptions to access to data generated by taxpayer dollars, a movement to open access to literature began to take hold, despite continued resistance by some publishers.[6] The 2003 Bethesda Statement on Open Access Publishing (http://www.earlham.edu/~peters/fos/bethesda.htm) has defined open access publishing and formulated the following two conditions that must be met for a publication to be considered open access:

1. The author(s) and copyright holder(s) grant(s) to all users a free, irrevocable, worldwide, perpetual right of access to, and a license to copy, use, distribute, transmit, and display the work publicly and to make and distribute derivative works, in any digital medium for any responsible purpose, subject to proper attribution of authorship, as well as the right to make small numbers of printed copies for their personal use.
2. A complete version of the work and all supplemental materials, including a copy of the permission as stated previously, in a suitable standard electronic format is deposited immediately upon initial publication in at least one online repository that is supported by an academic institution, scholarly society, government agency, or other well-established organization that seeks to enable open access, unrestricted distribution, interoperability, and long-term archiving (for the biomedical sciences, PubMed Central [PMC] is such a repository).

Note that (1) open access is a property of individual works, not necessarily journals or publishers and (2) community standards, rather than copyright law, will continue to provide the mechanism for enforcement of proper attribution and responsible use of the published work, as they do now.

BioMed Central

Covering over 236 journals as of May 2012, BioMed Central (http://www.biomedcentral.com/) serves as an independent publishing house supporting free, immediate, and permanent open access to peer-reviewed biomedical research. Some of the journals require a subscription to view additional content, such as reviews. Among the journals relevant to toxicology are *Environmental Health* (http://www.ehjournal.net/), *Particle and Fibre Toxicology* (http://www.particleandfibretoxicology.com/), and *Tobacco Induced Diseases* (http://www.tobaccoinduceddiseases.com).

Public Library of Science

The Public Library of Science (http://www.plos.org) is a nonprofit publisher and advocacy organization and another publication outlet for peer-reviewed open access technical literature. As of May 2012, they have published online and in print, PLoS series in biology, medicine, genetics, computational biology, pathogens, neglected tropical diseases, and *PLoS ONE*, which publishes across the full range of life and health sciences. PLos Currents, an online publication platform for new scientific research, includes sections in disasters, evidence on genomic tests, Huntington Disease, influenza, muscular dystrophy, and Tree of Life.

Open Access Journals (A Small Sampling)

Many important journals are increasingly *free*. See http://freemedicaljournals.com.

Environmental Health Perspectives (EHP; http://ehp03.niehs.nih.gov/home.action) is a highly regarded monthly journal of peer-reviewed research and news, published by the NIEHS and was one of the very first in toxicology to be made available free online.

The Open Toxicology Journal (http://www.benthamscience.com/open/totoxij/index.htm) publishes research articles, reviews, letters, and guest-edited single topic issues in all areas of cellular, molecular, and biochemical toxicology.

ISRN Toxicology (http://www.isrn.com/journals/toxicology/) is a peer-reviewed, open access journal that publishes original research articles, review articles, and clinical studies in all areas of toxicology.

NIH Policy

The U.S. NIH has been an innovator in the implementation of public access. Its policy is designed to accelerate the public's access to published articles resulting from NIH-funded research. It calls on scientists to submit final peer-reviewed journal manuscripts arising from research funded by NIH to PMC upon acceptance for publication. These papers are then accessible to the public on PMC no later than 12 months after publication. PMC, launched in 2000 (http://www.ncbi.nlm.nih.gov/pmc), is a free full-text archive of biomedical and life sciences journal literature at NIH's NLM. Toxicology is

firmly within its scope. In keeping with NLM's legislative mandate to collect and preserve the biomedical literature, PMC serves as a digital counterpart to NLM's extensive print journal collection. As of May 1, 2012, 2.4 million articles were archived in PMC and 1049 journals fully participated in the process.

Global Initiatives

Open access is, by no means, limited to the United States. The UK's Wellcome Trust, for example, is a major source of support for researchers in biomedical research and the medical humanities. They seek to maximize the distribution of papers by these researchers by providing free, online access and require that electronic copies be made available as soon as possible through PMC and UK PubMed Central (UKPMC) and require that it be within 6 months of the journal publisher's official date of final publication.

Mapping and Other Visualizations

The old saw, "A picture is worth a thousand words," still holds true today. Although certain pictures cannot capture the complexity that requires a verbal explanation and need for an additional *thousand words* to be fully understood, pictures, in addition to presenting a visual image of the thing itself, are useful in enhancing or crystallizing concepts that words and numbers alone cannot. TOXMAP, for example, is a tool developed by the NLM to go hand in hand with the EPA's TRI, a database accessible via the NLM's TOXNET system (http://toxnet.nlm.nih.gov). TOXMAP helps users create maps showing where chemicals are released into the air, water, and ground. It identifies the releasing facilities, color-codes release amounts for a single year, and provides multiple-year chemical release trends.

One area in which visual aids have found increasing use is in online toxicology education. Examples from the NLM include ToxMystery (http://toxmystery.nlm.nih.gov), an interactive tutorial that teaches users about common hazards found in the home, and ToxTown (http://toxtown.nlm.nih.gov), which teaches about hazards found in the larger community. Another is the NLM Toxicology Tutorials (http://sis.nlm.nih.gov/enviro/toxtutor.html), in which users can learn about basic toxicologic principles, toxicokinetics, and cellular toxicology. A final example is ToxLearn (http://toxlearn.nlm.gov), a joint project of the NLM's TEHIP and the U.S. SOT. ToxLearn offers a multi-modular toxicology tutorial that is enhanced by a variety of helpful visual graphics.

The area of chemical structure and activity has benefited from the use of visualizations as well. The PubChem database (http://pubchem.ncbi.nlm.nih.gov), from the National Center for Biotechnology Information (NCBI), is a prime example. PubChem provides information on the biological activities of small molecules, and is organized as three linked databases, the PubChem Substance, PubChem Compound, and PubChem BioAssay, which includes the NCBI's protein 3D structure resource.

Chemical regulation is another area in which visual graphics can benefit comprehension of the various reference values that have been developed by federal, state, and professional organizations. For example, the U.S. EPA has responded to a need by federal, state, and international agencies for graphical arrays that compare human inhalation health effect reference values for specific chemicals, allowing comparisons across exposure durations, populations, and intended use. The result is a document titled *Graphical Arrays of Chemical-Specific Health Effect Reference Values for Inhalation Exposures* (http://cfpub.epa.gov/ncea/cfm/recordisplay.cfm?deid=211003#Download). This review document is organized in two major sections. Section 1 provides background information on the various reference value systems, purposes, and limitations of the derived health effect reference values, and additional chemical-specific information. Section 2 provides summaries on the available inhalation health effect reference values on a chemical-by-chemical basis, also providing the details of the derivation of these reference values. The key element of each summary is a graphical array that compares the available reference values for each chemical.

Although there are scattered image files of toxicological photomicrographs, poisonous plants and animals, intact organisms with toxic damage, etc., no consolidated online library of toxicological images exists yet, although this would be a very useful project. One already available website of images is Clinical Toxinology Resources (http://www.toxinology.com), which is a searchable database of over 6000 images designed to meet the needs of anyone seeking information on venomous and poisonous organisms and poisonous plants throughout the world. This website was developed by the Toxinology Department of the Women's and Children's Hospital, Adelaide, and the Department of Paediatrics at the University of Adelaide.

Computational Toxicology and Toxicoinformatics

The advent of the *omics* disciplines (genomics, proteomics, and metabolomics) has given a boost to toxicology, and they offer new and still evolving approaches to understand the risks posed by many chemicals to human health and the environment. These new biological disciplines, when in the service of toxicology, have been collectively referred to as *toxicogenomics*. Developing mathematical and computer models to predict toxic outcomes and better understand mechanisms of action is known as *computational toxicology* or, sometimes, *toxicoinformatics*.[9–11]

Several major efforts within U.S. government agencies have been advanced to utilize these technologies. The NIEHS developed and sponsors the Toxicogenomics Research Consortium Cooperative Research Program (www.niehs.nih.gov/research/supported/centers/trc/coop/), as well as Environmental Genomics, Comparative Genomics, and Human Metabolism Groups. The EPA has established a National Center for Computational Toxicology (http://www.epa.gov/comptox/), which is part of a broader Chemical Safety for Sustainability Research Program, and the FDA's NCTR now offers a whole suite of bioinformatics tools for the analysis and integration of

genomics, transcriptomics, proteomics, and metabolomics data (www.fda.gov/ScienceResearch/BioinformaticsTools/).

In addition to the NCTR's suite of bioinformatics tools, there are other tools being developed to make sense of the enormous amounts of toxicology data being generated. The EPA's Distributed Structure-Searchable Toxicity (DSSTox) Database Network (http://www.epa.gov/NHEERL/dsstox/), for example, provides a community forum for publishing standard format, structure-annotated chemical toxicity data files for open public access. One of its goals is to facilitate development of improved models for predicting toxicity based on chemical structure.

Another relevant and evolving database is the CEBS Knowledge Base (http://www.niehs.nih.gov/research/resources/databases/cebs/) from the NIEHS. The stated goals of the CEBS are to

- Create a reference toxicogenomic information system of studies on environmental chemicals/stressors and their effects.
- Develop relational and descriptive compendia on toxicologically important genes, groups of genes, SNPs, mutants, and their functional phenotypes that are relevant to human health and environmental disease.
- Create a toxicogenomics knowledge base to support hypothesis-driven research.

Socialization of Push Technology

In the late 1990s, a new concept of information exchange was introduced, *push* technology. Push technology is a style of Internet-based communication in which the consumer initiates a request for information that is set to be delivered directly as the information becomes available. The first application of this was with the Blackberry and the ability to access e-mail directly on a handheld device. Other sources of push technology followed with such applications as listserv, e-subscriptions to newsletter or journals. More recently, the term *push technology* has been merged with *social media*. This merge has created a vast array of technologies such as RSS feeds, Facebook, Twitter, Wikipedia, podcasts, webcasts, blogs, widgets, and mobile device applications (Apps). It is now possible to receive information anywhere in almost any format desired.

The majority of the newer technologies utilized in social media have been viewed as personal resources, but many organizations have utilized these technologies to better communicate with others outside their organization whether it be colleagues or the general public. Social allows for the bidirectional flow of information among potentially millions of people in real time. Until recently, scientific information was generally provided by a few acknowledged experts in the field, was unidirectional in nature and relatively static.

Today, many professional societies, such as SRA and SOT, are utilizing social media. The SRA recently added social media subcommittee to manage all of its social media outlets, including Twitter and LinkedIn. They are utilizing these venues to communicate news to its members. The SOT utilizes various e-newsletters and an RSS feed for communicating the latest society news and research.

Here are examples of organizations that provide useful toxicology and other health-related information via social media, along with URLs that connect to their social media outlets or specific mobile applications:

National Library of Medicine (NLM):
http://www.nlm.nih.gov/socialmedia/index.html
http://toxnet.nlm.nih.gov/pda/
http://druginfo.nlm.nih.gov/m.drugportal
http://hazmap.nlm.nih.gov/index.php

U.S. Environmental Protection Agency (EPA):
http://www.epa.gov/epahome/socialmedia.html
http://www.epa.gov/greenversations/
http://www.epa.gov/epahome/podcasts.htm
http://www.epa.gov/widgets/

Society of Toxicology (SOT):
http://www.toxicology.org/main/news_feed.asp

When utilizing information from social media venues, it must be evaluated to determine the quality of the information provided. Fortunately, for most science-based information utilizing data from well-known organizations, such as U.S. government agencies or well-known reputable private organizations. Certain social media venues, for example, those of U.S. government agencies, such as the CDC and EPA, are closely vetted for the accuracy of information presented. Others, such as Wikipedia, are self-regulated to some extent, inasmuch as contributors serve as *peer reviewers*, limiting the amount of erroneous information that is posted. However, most social media outlets do not monitor their sites to ensure that the information presented is accurate or complete. Therefore, it is important for those seeking toxicology and other science-based information to have the tools to evaluate each resource as regards the quality of information content.

International Policy and Information Coordination

In addition to SAICM, mentioned earlier, under international organizations, a number of major multinational and international conventions seek to address issues of chemical safety. These include the EU's REACH, the GHS of Classification and Labeling of Chemicals, the

Stockholm Convention on Persistent Organic Pollutants, the Rotterdam Convention on Prior Informed Consent, and the Basel Convention on the Transboundary Movements of Hazardous and Other Wastes. The inevitable forward march of globalization requires interaction between toxicologists at an international level. The IUTOX, the voice of toxicology on the global stage, has been aware of this for some time.[12] Its over 50 affiliated societies represent six continents and over 20,000 toxicologists.

The World Library of Toxicology, Chemical Safety, and Environmental Health (http://www.worldtox.org), initiated by the NLM, and hosted by Toxipedia, is being designed as a portal to sources of information from specific countries and international groups and is intended to foster cooperation and collaboration in research and other activities and to minimize duplication of effort. Country Correspondents utilize Wiki technology to build this network. Additional sponsors and organizations are being sought to enhance this important resource that is still in its infancy and has much potential.

CONCLUSION

Information and data generated by advances in the toxicological sciences, in line with that of other scientific disciplines, continue to grow at a phenomenal rate. The increasing complexity derives from the interdisciplinary nature of toxicology and the societal manifestations of the science. Fortunately, the advent of computers and development and expansion of the web have allowed unprecedented access to and utilization of the vast toxicological information base as it continues to expand. Moreover, innovation in technology and software applications have greatly expanded and diversified the ways in which toxicological information is presented, distributed, and shared.

QUESTIONS

13.1 Identify some of the key web-based databases in toxicology, environmental health, and risk assessment.

13.2 What organizations consider toxicology from a global perspective?

13.3 Discuss such issues as mapping and computational toxicology with regard to the future direction of toxicological information; and entertain pluses and minuses and possible outcomes for information controversies, such as open access publishing.

13.4 How has the development of mobile devices, new applications, and social media changed the way in which toxicological information is disseminated? What are some advantages as well as potential pitfalls to the way in which toxicological information is now shared?

13.5 What is the purpose of a literature review and what should be included in the write-up?

14 Food Safety and Foodborne Toxicants

Claire L. Kruger, Chada S. Reddy, Dietrich B. Conze, and A. Wallace Hayes

CONTENTS

DEFINITION OF FOOD

Food is defined in section 201(f) of the Food, Drug, and Cosmetic (FD&C) Act as "(1) articles used for food or drink for man or other animals, (2) chewing gum, and (3) articles used for components of any such article." Examples of food include

- Dietary supplements and dietary ingredients
- Infant formula
- Beverages (including alcoholic beverages and bottled water)
- Fruits and vegetables
- Fish and seafood
- Dairy products and shell eggs
- Raw agricultural commodities for use as food or components of food
- Canned and frozen foods

- Bakery goods, snack food, and candy (including chewing gum)
- Live food animals
- Animal feeds and pet food

Food is presumed to be safe (sections 201(f) and 402(a)(1) of the FD&C Act). However, as with any substance, safety is not absolute and the regulatory paradigms, safety standard, risk assessment process, and ultimate responsibility and authority for ensuring the safety of foods and food ingredients have evolved over time.

The original 1906 Food and Drugs Act forbid the marketing of any food containing "any added poisonous or deleterious substance which may render it injurious to health." Premarket approval was not required; the Food and Drug Administration (FDA) had the burden of proving that a food was adulterated. The 1938 FD&C Act was a watershed in the U.S. food policy (http://www.fda.gov/AboutFDA/WhatWeDo/History/ProductRegulation/ucm132818.htm). It pioneered policies designed to protect the pocketbooks of consumers, and food standards were enacted to ensure the *value expected* by consumers. Criteria for adulteration, mislabeled, or harmful food were described. The 1938 Act eliminated the *distinctive name proviso* and required instead that the label of a food *bear its common or usual name*. Food is determined to be misbranded if it is represented as a standardized food unless it conforms to that standard. The law provides for three kinds of food standards: (1) standards (definitions) of identity, (2) standards of quality, and (3) standards regulating the fill of container. The FD&C Act requires manufacturers to prove the safety of any product that would be marketed over state lines.

As defined in the FD&C Act, a food is considered to be adulterated if it contains any poisonous or deleterious substance that may *render it injurious to health*. Adulteration is defined as a food that bears or contains any added poisonous or added deleterious substance (other than a substance that is a pesticide chemical residue in or on a raw agricultural commodity or processed food, a food additive, a color additive, or a new animal drug); or if it bears or contains a pesticide chemical residue, a food additive, or a new animal drug that is unsafe; or if it consists of or is contaminated by any other substance that makes it unfit for food or renders it injurious to health; or if its container is composed of any poisonous or deleterious substance that may render the contents injurious to health; or if it has been intentionally subjected to radiation, unless the use of the radiation conforms with regulation. The act distinguishes, however, between substances naturally present and substances that have been added to the food. If the substance is something that has not been added to the food, the food is not to be considered adulterated under this clause if the quantity of this substance does not *ordinarily render it injurious to health*.

STANDARDS OF SAFETY FOR FOOD ADDITIVES, COLOR ADDITIVES, GRAS INGREDIENTS, AND NEW DIETARY INGREDIENTS (DIETARY SUPPLEMENTS)

The regulation of a substance in the food supply depends upon the intended use and the claims made for the product (Figure 14.1). Food is consumed for taste, aroma, and nutritive value. A new product may be regulated as a food additive or generally recognized as safe (GRAS) ingredient if the intent is for it to become a component of or affect the characteristics of a food. A food additive that is capable of and is intended to impart color when added or applied to a food must be regulated as a color additive. If a dietary substance(s) is intended to be used by people to supplement the diet by increasing the total dietary intake, then the substance is regulated as a dietary ingredient. Importantly, the supplement in which the dietary ingredient is contained must not be represented for use as a conventional food or as a sole item of a meal or the diet. A product that makes a statement that claims to diagnose, mitigate, treat, cure, or prevent disease is a drug claim and thus would be regulated as a drug. Regulation of drugs will not be discussed in this chapter.

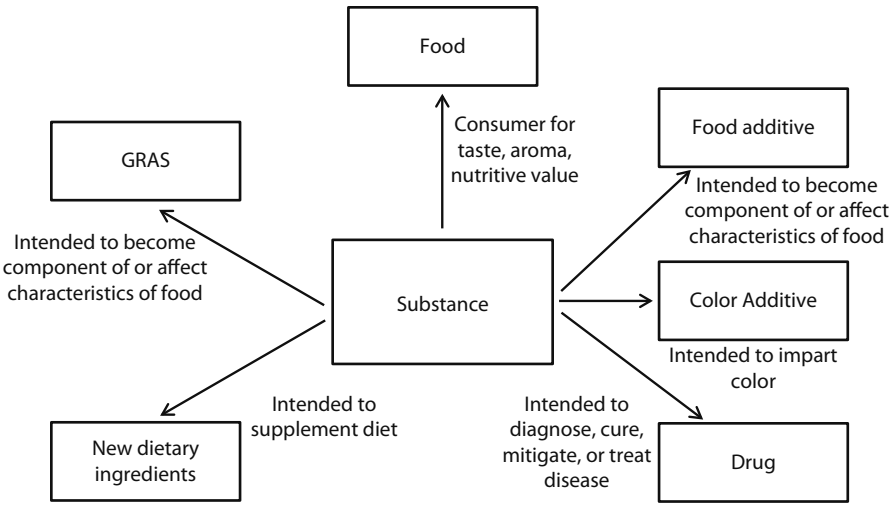

FIGURE 14.1 U.S. regulatory paths for new products.

The implications for the safety evaluation and risk assessment process needed to ensure compliance with applicable regulations for food and color additives, GRAS ingredients, and new dietary ingredients (NDIs) (dietary supplements) will be discussed further in this chapter. A decision tree (Figure 14.2) developed by the FDA utilizes information on intended use and existing authorizations to determine the regulatory path appropriate for a food ingredient (http://www.fda.gov/Food/IngredientsPackagingLabeling/FoodAdditivesIngredients/ucm228269.htm). It is the responsibility of the manufacturer of any food to ensure that all ingredients used are of food-grade purity and comply with specifications and limitations in all applicable authorizations. The overall regulatory status of a food is affected by the regulatory status of each individual food ingredient. To determine compliance, each authorization must consider three elements: identity of the substance, specifications including purity and physical properties, and limitations on the conditions of use.

Food Additives

Any substance that is reasonably expected to become a component of food is a food additive that is subject to premarket approval by the FDA, unless the substance is GRAS among experts qualified by scientific training and experience to evaluate its safety under the conditions of its intended use or meets one of the other exclusions from the food additive definition in section 201(s) of the Federal Food, Drug, and Cosmetic Act (FD&C). Any food additive that is intended to have a technical effect in the food is deemed unsafe unless it conforms either to the terms of a regulation prescribing its use or to an exemption for investigational use. Otherwise, in accordance with section 409 of the act, the substance is deemed an unsafe food additive. Any food that contains an unsafe food additive is adulterated under section 402(a)(2)(C) of the FD&C.

The Food Additives Amendment of 1958 requires premarket approval of new food additives by the FDA before they can be marketed, and the responsibility for proving their safety is placed on the petitioner. The safety standard is defined as reasonable certainty in the minds of competent scientists that a substance is not harmful under its intended conditions of use. Food additives are subject to the provisions of the Delaney clause. The Delaney clause was enacted in 1958 as part of the Food Additives Amendment. A food additive must be found *safe* before the FDA may approve its use, and this clause stipulates that the finding of safety may not be made for a food additive that has been shown to induce cancer in humans or in experimental animals. This is based on the judgment by the U.S. Congress that no food additive is likely to offer benefits sufficient to outweigh any risk of cancer.

The FDA's *Redbook II* provides guidelines for the safety testing of direct food additives. The extent of testing necessary for these additives is based on a concern level approach that takes into account the extent of exposure to the additive as well as the structural class of the compound. Safety evaluation for a direct food additive or color additive used in food involves assigning the additive to a concern level (i.e., low [I], intermediate [II], or high [III]) based on information on the additive's toxicological potential predicted from its chemical structure (i.e., low [A], intermediate [B], or high [C]) and an estimation of cumulative human exposure (Table 14.1) (http://www.fda.gov/Food/GuidanceRegulation/GuidanceDocumentsRegulatoryInformation/IngredientsAdditivesGRASPackaging/ucm054658.htm).

Frequently, exposure information has more weight than structure alert information in assigning additives to a concern level. However, if available, other information may be considered when setting the concern level for a food additive, and final safety decisions are made on a case-by-case basis.

The basic elements of a food additive petition (FAP) submitted to the FDA are the following (http://www.fda.gov/Food/GuidanceRegulation/GuidanceDocumentsRegulatoryInformation/IngredientsAdditivesGRASPackaging/ucm253328.htm):

- The identity and composition of the additive
- Proposed use
- Use level
- Data establishing the intended effect
- Quantitative detection methods in the food
- Estimated exposure from the proposed use (in food, drugs, cosmetics, or devices, as appropriate)
- Full reports of all safety studies
- Proposed tolerances (if needed)
- Environmental information (as required by the National Environmental Policy Act [NEPA], as revised [62 FR 40570; July 29, 1997])
- Ensure that consistent information is presented throughout all sections of the petition, including those pertaining to
  - Chemistry
  - Toxicology
  - Environmental science
  - Any other pertinent studies (e.g., microbiology)

An acceptable daily intake (ADI) is derived utilizing the results from appropriate toxicology studies, considering the significance of differences between treated and control groups with respect to dose-related trends, reproducibility, related findings, the magnitude and types of differences, and occurrence in both sexes. The ADI is compared to the estimated daily intake (EDI) (discussed later in this chapter). If the EDI is less than or approximates the ADI, the food additive is determined to be safe under the proposed conditions of use.

Color Additives

Any substance that is added to food and imparts color to the food is a color additive (see color additive definition in section 201(t) of the FD&C and 21 CFR 70.3(f) and the FDA's implementing regulations in 21 Code of Federal

Regulations (CFR) Part 70). Under section 201(t)(1) and 21 CFR 70.3(f), the term color additive means a material that is a dye, pigment, or other substance made by a process of synthesis or similar artifice, or extracted, isolated, or otherwise derived from a vegetable, animal, mineral, or other source, and that is capable (alone or through reaction with another substance) of imparting color when added or applied to a food, except that such term does not include any material that the secretary, by regulation, determines is used (or intended to be used) solely for a purpose or purposes other than coloring. Under 21 CFR 70.3(g), a material that otherwise meets the definition of color additive can be exempted from that definition on the basis that it is used or intended to be used solely for a purpose or purposes other than coloring, as long as the material is used in a way that any color imparted is clearly unimportant insofar as the appearance, value, marketability, or consumer acceptability is concerned. Any color additive in food is deemed unsafe unless its use is either permitted by regulation or exempted by regulation. Unlike the definition for food additive, there is no GRAS exemption for color additives. Any food that contains an unsafe color additive is adulterated under section 402(c) of the FD&C.

Following the passage of the Color Additive Amendment of 1960, 20 natural colors (comprising preparations such as dried algae meal, annatto extract, beet powder, grape skin extract, fruit juice, paprika, caramel, carrot oil, cochineal extract, ferrous gluconate, iron oxide, turmeric) were exempted from certification, whereas all the synthetic colors were required to be retested if questions regarding their safety arose. A provisional certification was given to those in use that required further testing. Currently, there are seven certified synthetic colors (FD&C colors blue no. 1, red no. 3, red no. 40, and yellow no. 5 are permanently listed, whereas FD&C blue no. 2, green no. 3, and yellow no. 6 are provisionally listed) with unlimited uses; one permanently listed color (citrus red no. 2) is used only for coloring skins of oranges at 2 ppm, and several colors including green 1, green 2, orange B, red 2, red 4, and violet 1 were delisted due to concerns of their carcinogenicity and other chronic toxic effects. A controversy linking food colors to allergies and hyperkinesis in children remains unresolved.

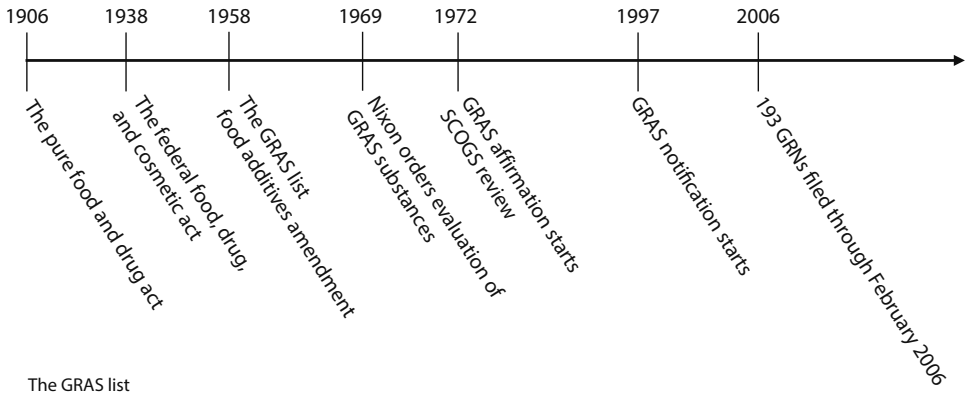
GRAS Ingredients

Congress has amended the FD&C Act many times; the most important of these amendments was the 1958 Food Additives Amendment. This amendment specifically regulates food additives and requires safety to be demonstrated prior to marketing. The critical standard of safety for approval of food additives is reasonable certainty of no harm. Congress did, however, in addition to giving FDA premarket approval of food additives, exclude a class of food ingredients in this amendment that are considered GRAS by qualified experts as having been adequately shown to be safe under the conditions of its intended use (21 CFR section 170.30). GRAS ingredients have no FDA premarket approval requirement nor is there a requirement for advance notice of marketing. The regulatory history of the GRAS process is illustrated in Figure 14.3.

- Under sections 201(s) and 409 of the act and the FDA's implementing regulations in 21 CFR 170.3 and 21 CFR 170.30, a determination of GRAS requires both technical evidence of safety and a basis to conclude that this evidence is generally known and accepted. The technical evidence of safety may be based on either scientific procedures or common use in food prior to January 1, 1958. Safety means that there is a reasonable certainty in the minds of competent scientists that the substance is not harmful under the intended conditions of use [21 CFR section 170.3(i)]. Under 21 CFR 170.30(b), general recognition of safety through scientific procedures requires the same quantity and quality of scientific evidence as is required to obtain approval of the substance as a food additive and ordinarily is based upon published studies, which may be corroborated by unpublished studies and other data and information. Under 21 CFR 170.30(c) and 170.3(f), general recognition of safety through experience based on common use in foods requires a substantial history of consumption for food use by a significant number of consumers.

Therefore, the distinction between a GRAS substance and a food additive is that for a GRAS substance, there is common knowledge of safety within the expert community of the GRAS substance for its intended use. There is no distinction on the basis of the substance or the type of data and information necessary to support safety. For a determination of safety, this means that the scientific standard to which a GRAS substance is held is comparable to that of a food additive. GRAS is a rigorous process that relies on common knowledge and expert consensus about the safety of the substance for its intended use (Kruger et al., 2011).

As noted in the GRAS timeline (Figure 14.3), the GRAS status of a compound is established by recognition of safety among qualified experts, not premarket FDA approval. In 1972, the FDA conducted rulemaking to establish procedures used for a GRAS affirmation petition process for sponsors, at their discretion, to petition the FDA to review the GRAS status of substances. On April 17, 1997, however, the FDA released a proposed rule to replace the GRAS petition process with a GRAS notification procedure. Although the agency's 1997 policy with regard to GRAS notifications is embodied only in a proposed rule, the FDA has, in a de facto manner, already implemented the policy and will no longer accept GRAS affirmation petitions. Notification is not mandatory but is available to the sponsor of the product if it wishes to inform the FDA of its GRAS determination. The FDA does not make its own determination as to the GRAS status of a food ingredient,



The GRAS list
- 1958 food additives amendment: Congress recognized that many food substances would not require a formal premarket review by FDA to assure their safety
- Food additives excludes substances that are recognized, among qualified experts, as having been adequately shown through scientific procedures (or, in the case of a substance used in food prior to January 1, 1958, through experience based on common use in food) to be safe under the conditions of their intended use.
- December 9, 1958: FDA published a list of GRAS substances and incorporated the list in Title 21 of the Code of Federal Regulations. The current list appears in 21 CFR Parts 182, 184, and 186.

Opinion letters
- Many manufacturers wrote to FDA and requested an opinion letter in which an FDA official would render an informal opinion on the GRAS status of use of the substance
- Revoked in 1970 (21 CFR 170.6; 35 FR 5810; April 9, 1970)

Comprehensive review
- October 30, 1969: President Nixon directed FDA to make a critical evaluation of the safety of GRAS food substances.
- March 28, 1972: Life Sciences Research Office (LSRO) of the Federation of American Societies for Experimental Biology (FASEB) began to summarize the available scientific literature and to recommend what restrictions, if any, on the use of the substances would be needed to ensure their safe use in food.

GRAS affirmation
- 1972: FDA conducted rulemaking to establish the procedures (21 CFR 170.35) that it would use to affirm the GRAS status of substances that were the subject of the GRAS review. That rulemaking included a mechanism (the GRAS affirmation petition process) whereby an individual could petition FDA to review the GRAS status of substances not being considered as part of the agency's GRAS review.
- 1973–1997: GRAS Affirmation Petition Process

GRAS notification
- April 17, 1997: FDA proposed to establish a anotification procedure whereby a person may inform FDA of a determination that the use of a substance is GRAS (62 FR 18938; April 17, 1997).
- Industry submits GRAS notice
- FDA is evaluating whether each submitted notice provides a sufficient basis for a GRAS determination and whether information in the notice or otherwise available to FDA raises issues that lead the agency to question whether use of the substance is GRAS

FIGURE 14.3 A GRAS timeline. (From Gaynor, P.M., Bonnette, R., Garcia, Jr. E., Kahl, L.S., Valerio, Jr. L.G., FDA's Approach to the GRAS Provision: A History of Processes, Excerpted from Poster Presention at the FDA Science Forum, April 2006, http://www.fda.gov/Food/IngredientsPackagingLabeling/GRAS/ucm094040.htm.)

and consequently, new GRAS ingredients will no longer be listed in the CFR.

In general, the FDA's response to a notification has been in one of three categories:

- The agency does not question the basis for the notifier's GRAS determination.
- The agency concludes that the notice does not provide a sufficient basis for a GRAS determination (e.g., because the notice does not include appropriate data and information or because the available data and information raise questions about the safety of the notified substance).
- The response letter states that the agency has, at the notifier's request, ceased to evaluate the GRAS notice.

Safety Evaluation of a GRAS Ingredient

The following information is pivotal to the assessment of safety of a GRAS substance:

- *Description of the GRAS substance*
  - Included in this section is a review of the physical and chemical characteristics of the GRAS substance including chemical name(s) (and synonyms), CAS registry number(s), and chemical structure(s) and a description of final product characteristics including established food-grade specifications for the principal components, related substances, by-products, impurities and contaminants, and batch analysis results showing compliance with established food-grade specifications

- *Production Process*
  - Documentation of current good agricultural practice/current good manufacturing practice
  - A process flow diagram with detailed description for each step of the production process and operation parameters
  - A list of raw materials and processing aids with food-grade and regulatory compliance documentation
  - Critical control steps involved in the quality control process
  - Description of potential impurities to be carried over to the final product
- Documentation of stability and shelf life of the product
- *Historical Use, Regulatory Status, and Consumer Exposure*: A review of the history of use and/or natural occurrence of the ingredient in other foods, with a determination of the consequent intake or exposure estimate. An overview of current regulatory status if applicable. A description of the proposed use and use levels utilized to calculate an EDI of the GRAS substance.
- *Intended Effect*: Characterization of the intended function of the GRAS substance in the food.
- *Analytical Methodology*: Method for determining the quantity of the substance in or on food, and any substance formed in or on food, because of its use.
- *Review of Safety Data*: Evaluation of the actual use of the product and issues that may contribute to the safety of the product are included. An identification and critical review from the animal toxicology and clinical literature for safety information on primary components, related substances, secondary metabolites, impurities, and contaminants using relevant data for occurrence and/or levels present, estimated background intake, metabolic fate, toxicological activity, and pharmacological activity is included. Pivotal safety information must be published.
- *Safety Assessment and GRAS Determination*: Evaluation of the safety of consumption of the substance under its intended conditions of use including determination of an ADI for the substance as well as other components or contaminants (if present) and comparison of this ADI to the EDI of the substance from existing and proposed uses. As long as the EDI is less than (or approximates) the ADI, the substance can be considered safe under its intended conditions of use.

Examples of Approaches for GRAS Determination for Specific Types of Food Products

Foods Produced by Genetic Modification

Existing conventional food crops and the products made from them are recognized to be safe. Genetic modification, or the alteration in the genetic makeup of these crop plants for the purpose of developing new varieties, is traditionally done through conventional breeding and selection techniques. Genetic engineering, a more recent technique, is the process of removing a gene from one organism or plant and transferring it to a different organism or plant variety. The advantage is that this technique allows plant breeders to achieve, with great precision, desirable agronomic or quality improvements in food crops, such as resistance to pests and/or enhanced nutritional value (U.S. FDA, 1999). The new DNA introduced by genetic engineering produces a new protein and the safety of that protein is evaluated as part of the risk assessment process. The substances intentionally added to food via biotechnology to date have been well-characterized proteins, fats, and carbohydrates and are functionally very similar to other proteins, fats, and carbohydrates that are commonly and safely consumed in the diet and so will be presumptively GRAS. The safety of a genetically engineered food crop or a product made from that crop is evaluated by comparing the nutritional and toxicological equivalence of the product to its conventional counterpart. Guidance for safety testing of genetically engineered products to assure that no unintended changes in the composition of the food could adversely affect human health has been published by authoritative scientific and regulatory agencies (Codex Alimentarius Commission, 2003; EFSA, 2006a,b; FSANZ, 2007; Health Canada, 2006; ICMR, 2008; U.S. FDA, 1992). Any differences between the conventional and bioengineered product are identified and the safety of the introduced change is determined (U.S. FDA, 1992).

The FDA provided guidance on the information that should be included in the safety and nutritional assessment (http://www.fda.gov/NewsEvents/Testimony/ucm115032.htm). Some examples of this information would include the following:

- The name of the food and the crop from which it is derived
- The uses of the food, including both human food and animal feed uses
- The sources, identities, and functions of introduced genetic material
- The purpose or intended technical effect of the modification and its expected effect on the composition or characteristic properties of the food or feed
- The identity and function of any new products encoded by the introduced genetic material, including an estimate of its concentration
- Comparison of the composition or characteristics of the bioengineered food to that of food derived from the parental variety or other commonly consumed varieties with special emphasis on important nutrients, antinutrients, and toxicants that occur naturally in the food
- Information on whether the genetic modification altered the potential for the bioengineered food to induce an allergic response
- Other information relevant to the safety and nutritional assessment of the bioengineered food

If a bioengineered food included a new protein derived from an allergenic source and consumers would not expect it to be present based on the name of the food, the presence of that allergen must be disclosed on the label (U.S. FDA, 2001). All labeling requirements, including allergen labeling, that apply to conventional foods also apply to bioengineered foods. However, the FDA has not established mandatory labeling requirements to identify foods that have been derived from genetically engineered sources. The reason for this, as articulated in their policy (U.S. FDA, 1992), is that there is no basis to conclude that foods developed by genetic engineering present any different or greater safety concern than foods developed by traditional plant breeding. This is borne out by the conclusions of many risk assessments that have been conducted on bioengineered foods and found no evidence of harm, including allergic reactions (EFSA, 2003, 2004a,b, 2006a,b, 2007, 2008a,b, 2009a–d, 2010a,b, 2011a–e, 2012a–d). Furthermore, to date, there is no documented proof that any approved, commercially grown genetically engineered crop has caused allergic reactions because of the transgenically introduced protein (Goodman et al., 2008).

Food Ingredients Derived from Chemically Complex Extracts

Safe level of ingestion through scientific procedures can be derived by applying a UF to a no observed adverse effect level (NOAEL) derived from a well-conducted toxicology study to derive an ADI. However, when the level of addition of the ingredient to the feed in the animal study exceeds 5% (w/w), untoward physiological effects due to dietary imbalance alone may manifest in such studies (Hayes, 2008; Klaassen, 2008; Kruger and Mann, 2003; Office of Food Additive Safety, 2000). This limitation enters into consideration in the case of natural products, for example, crude extracts, which are composed of a mixture of tens or hundreds of compounds. Many of these compounds are present at such low concentrations that it is impracticable to concentrate the overall extract to such an extent that derivation of an ADI utilizing traditional UFs applied to NOAELs could be generated on each of the minor constituents. Additionally, these matrix molecules may exert an effect on the bioavailability of the active compounds that are present in the natural product (IFT, 2009). It is also important to note that the concept of the 100-fold UF is not appropriate for physiologically active substances. In these cases, the effects seen in animal studies may be due to the physiologic or pharmacologic activity of the active principle and not a classic toxicological response (Booth et al., 2012).

As discussed in a publication authored by members of the U.S. FDA and National Institute of Environmental Health Sciences (NIEHS), the safety assessment of botanical substances is complicated by various factors:

> Compositional diversity is a key factor because botanicals are complex mixtures, for which the identity of all the individual components is not known and the proportion of individual components varies with the source. There are various other factors, among which are the lack of standardization of the botanical (in terms of both materials and analytical methods), lack of identity of the active ingredients, and the use of different formulations of the botanical in the article of commerce when compared with the test substance. The paucity of data on the toxicology of whole extracts or the individual components of botanicals makes it very challenging to determine the safety of botanical substances for use in conventional food. As such, the review of botanical substances for safe use in conventional food must be approached with some skepticism, an open mind and utilization of the full arsenal of scientific tools available to assess the safety of such substances. There is no set formula for dealing with the safety evaluation of such materials or combination of materials. Each new submission must be dealt with on a case-by-case basis.
>
> **(Abdel-Rahman et al., 2011)**

Traditionally, safety determination of a complex natural product has relied on animal toxicology testing to compensate in many instances for the inability to assess safety due to poorly characterized extracts. An approach to determine the safety of natural products involves (1) review and analysis of the existing phytochemical and botanical literature, (2) establishing chemical composition of the raw material and the commercial product, (3) determination of health-based levels of exposure for the identified compounds or compound, and (4) utilization of published toxicology studies to establish safety of exposure to the extract through evaluation of the components/compound classes. A safety paradigm utilizing a thorough analytical elucidation of the composition of the complex natural product may allow a literature-based assessment of safety for the individual components/classes of compounds comprising the botanical extract.

Estimated Daily Intake

Estimates of dietary intake support the documentation of the safety of substances introduced into food either intentionally to accomplish a technical effect, adventitiously as a component of an added substance, or inadvertently through contamination resulting from processing or other sources.

The U.S. FDA's premarket approval processes for food and color additives require an estimate of the probable consumer intake of the additive to determine whether its use or presence in a food at a given concentration is safe. The key determinant in the safety evaluation of a substance found in or added to the diet is the relation of its probable human intake to the level at which adverse effects are observed in toxicological studies. Simply, *the dose makes the poison* (http://www.fda.gov/Food/GuidanceRegulation/GuidanceDocumentsRegulatoryInformation/IngredientsAdditivesGRASPackaging/ucm074725.htm).

In dietary intake assessments, the concentration of an ingredient or chemical constituent in food can be obtained from the intended use levels of the substance in target foods (typical, recommended, or maximum use level); the measured concentration in food as consumed, accounting for processing and storage losses of ingredient; the limit of detection (LOD)

or limit of quantification (LOQ) of the analytical method, as appropriate, if the concentration in the food is nondetectable or nonquantifiable at the LOD or LOQ; established limits for the substance (e.g., specifications in the CFR or the Food Chemical Codex [FCC]) for undesirable impurities and contaminants in food ingredients; or maximum levels for contaminants in foods adopted by a recognized standards-setting body, such as the Codex Alimentarius Commission.

The FDA typically uses the maximum intended use levels proposed to calculate a *worst case* level of intake. For estimating intake of constituents in food ingredients, specification limits (e.g., for appropriate heavy metals, such as lead, arsenic, and mercury) are used to estimate the potential intake of a constituent from the intended use of the ingredient.

There are a number of sources of data available for use in estimating intake of substances in the diet including the following:

- Food consumption surveys
- Food/ingredient disappearance figures
- Total diet study
- Body burden/excretion measurements: *biomarkers*

Each source has advantages and limitations. For a number of reasons, including cost and availability, breadth of data, and ease of data manipulation, the FDA relies primarily on data taken from food consumption surveys.

Food Consumption Surveys

Food consumption data may be collected at the national, household, or individual level. The FDA regularly uses food consumption surveys conducted nationwide at the individual level to estimate the dietary intake of substances. Consumption surveys at the level of the individual provide information on mean food intakes and the distribution of food intakes within subpopulations of individuals defined by demographic factors (e.g., age, gender) and health status (e.g., pregnancy, lactation). These surveys measure food intake by one or more methods, that is, food records or diaries, 24 h recalls, food frequency questionnaires (FFQ), and diet history. In the first two methods, participants record or recall (with a trained interviewer) the amounts and types of each food eaten during the day, both at home and away from home. For the food frequency methods, participants record or recall only the number of occasions each food was consumed over a specified period of time that may vary from 1 day to more than 1 year. These eating-occasion frequencies are multiplied by an appropriate food portion size (based on age–sex considerations) to obtain semiquantitative estimates of the daily food intake.

The U.S. Department of Agriculture (USDA) has collected national food consumption data for more than 70 years. Initially designed to help people achieve economical and nutritious diets, USDA's food consumption surveys gradually broadened in scope and purpose. Nationwide surveys were conducted in 1965–1966, 1977–1978, 1985–1986, 1987–1988, 1989–1991, 1994–1996, and 1998. The more recent surveys, called the Continuing Survey of Food Intakes by Individuals (CSFII) and conducted in 1989–1991, 1994–1996, and 1998, were combined with USDA's Diet and Health Knowledge Survey (DHKS), a telephone survey designed to measure knowledge and attitudes about diet and health. In 1971, the U.S. Department of Health and Human Services (HHS) added a nutrition component to its National Health Examination Survey (NHES), and the survey's name was changed to the National Health and Nutrition Examination Survey (NHANES). Between 1971 and 1994, three NHANES collected dietary data along with health data (1971–1975, 1976–1980, 1988–1994). In 1982–1984, Hispanic HANES was conducted to collect nutrition and health data on Mexican Americans, Cuban Americans, and Puerto Ricans. Since 1999, NHANES has been a continuous, annual survey program.

Continuing Survey of Food Intake by Individuals

The 1994–1996 and 1998 CSFII are the most recent in a series of USDA surveys; intake data from this survey have been released in two database forms: (1) food consumption expressed as food and nutrient intakes and (2) food consumption expressed in equivalent amounts of basic food commodities. The USDA's food coding database is linked to food commodities and nutrient values to convert the survey data (reported food consumption) into relevant outputs for the respective databases.

In each of the 3 survey years of the 1994–1996 CSFII, a nationally representative sample of approximately 5000 noninstitutionalized individuals residing in the United States provided, through in-person interviewing using a 1-day dietary intake questionnaire, food intakes on two nonconsecutive days (3–10 days apart) and health-related information. Additionally, there is a CSFII 1998 Supplemental Children's Survey with 2-day food and nutrient intake data for approximately 5300 children under the age of 10.

National Health and Nutrition Examination Survey

The National Center for Health Statistics' (NCHS) NHANES studies link information on food intake with respondent health information obtained by a physical examination, anthropometric measures, and laboratory analyses of various blood and urine parameters. Three NHANES studies were conducted between 1971 and 1994 (NHANES I–III). Information on vitamin, mineral, and dietary supplement use was collected in those surveys. The food intake data for NHANES were previously based on one 24 h recall that was supplemented with portion size information obtained using detailed measurement guides. NHANES sampled a larger number of individuals than CSFII (approximately 30,000 respondents in NHANES III) and included information on the monthly frequency of dietary supplement use by respondents. NHANES nutrient intake data have been used to a limited extent by the Office of Food Additive Safety (OFAS) but are a valuable source of information on the distribution of usual intakes of nutrients in the U.S. diet.

NHANES became a continuous program in 1999, with approximately 5000 individuals surveyed each year. NCHS released data sets to the public in 2-year cycles (NCHS, 1999–2000, 2001–2002). These dietary data are released in two files: a total nutrient intakes file and an individual food file (with detailed records of gram weights and nutrient values).

Integrated CSFII/NHANES

The CSFII and NHANES surveys were combined by Agricultural Research Service (ARS) and NCHS into a single, continuous, population-based national nutrition survey beginning in January 2002. While NHANES studies have historically included a 1-day recall, beginning in 2002, a second nonconsecutive 24 h recall was added.

The most recent CSFII/NHANES examination surveys for the years 2009–2010 are available for public use: http://wwwn.cdc.gov/nchs/nhanes/search/nhanes09_10.aspx. In 2009–2010, approximately 10,000 people across the United States completed the health examination component of the survey. Any combination of consecutive years of data collection is a nationally representative sample of the U.S. population. It is well established that the length of a dietary survey affects the estimated consumption of individual users and that short-term surveys, such as the typical 1-day dietary survey, overestimate consumption over longer time periods (Gregory et al., 1995). Because two 24 h dietary recalls administered on two nonconsecutive days (day 1 and day 2) are available from the NHANES (NCHS, 2009–2010) survey, these data can be used to generate estimates of intake.

The NHANES provides the most appropriate data for evaluating food-use and food consumption patterns in the United States, containing two years of data on individuals selected via stratified multistage probability sample of civilian noninstitutionalized population of the United States. NHANES (NCHS, 2009–2010) survey data were collected from individuals and households via 24 h dietary recalls administered on two nonconsecutive days (day 1 and day 2) throughout all four seasons of the year. Day 1 data were collected in person in the mobile examination center (MEC), and day 2 data were collected by telephone in the following 3–10 days, on different days of the week, to achieve the desired degree of statistical independence. The data were collected by first selecting primary sampling units (PSUs), which were counties throughout the United States. Small counties were combined to attain a minimum population size. These PSUs were segmented and households were chosen within each segment. One or more participants within a household were interviewed. Fifteen PSUs are visited each year. For the 2009–2010 NHANES, there were 13,272 persons selected; of these, 10,253 were considered respondents to the MEC examination and data collection; 9,754 of the MEC respondents provided complete dietary intakes for day 1, and of those providing the day 1 data, 8,405 provided complete dietary intakes for day 2.

In addition to collecting information on the types and quantities of foods being consumed, NHANES (NCHS, 2009–2010) collected socioeconomic, physiological, and demographic information from individual participants in the survey, such as sex, age, height and weight, and other variables useful in characterizing consumption. The inclusion of this information allows for further assessment of food intake based on consumption by specific population groups of interest within the total population. Among those who completed the food intake survey on both day 1 and day 2, 8301 respondents also provided physiological information including age, sex, and weight; of these, 7738 were 2 years and older.

Sample weights were incorporated with NHANES (NCHS, 2009–2010) to compensate for the potential underrepresentation of intakes from specific population groups as a result of sample variability due to survey design, differential nonresponse rates, or other factors, such as deficiencies in the sampling frame (CDC, 2006; USDA, 2012).

Statistical Methods

Consumption data from individual dietary records, detailing food items ingested by each survey participant, are used to generate estimates for the intake of an ingredient by the U.S. population. Estimates for the daily intake of ingredient represent projected 2-day averages for each individual from day 1 and day 2 of NHANES (NCHS, 2009–2010) data; these average amounts comprised the distribution from which mean and percentile intake estimates were produced. Mean and percentile estimates were generated incorporating sample weights in order to provide representative intakes for the entire U.S. population. *All-person* intake refers to the estimated intake averaged over all individuals surveyed, regardless of whether they consumed food products containing the ingredient, and therefore includes *zero* consumers (those who reported no intake of food products containing the ingredient during the two survey days). *All-user* intake refers to the estimated intake by those individuals consuming food products containing the ingredient, hence the *all-user* designation. Individuals are considered users if they consumed one or more food products containing the ingredient on either day 1 or day 2 of the survey.

Food Usage Data

The individual proposed food uses, default serving sizes, and the corresponding maximum use levels for specific foods as identified by food codes representative of each proposed use are chosen from the Food and Nutrition Database for Dietary Studies (FNDDS). In FNDDS, the primary (usually generic) description of a given food is assigned a unique eight-digit food code (CDC, 2006; USDA, 2012).

Food Survey Results

The estimated *all-person* and *all-user* total intakes of ingredient from all proposed food uses in the United States by population group is summarized to generate the EDI by gender and age group, as appropriate for comparison with the ADI to generate the safety assessment for the ingredient.

Dietary Supplements

The Dietary Supplement Health and Education Act of 1994 (DSHEA) created a new framework for the regulation of

dietary supplements. DSHEA signaled a major departure from the well-established *food* versus *drug* dichotomy that guided the FDA policy. The act reaffirmed the status of dietary supplements as foods. The legislation created a new category of food by specifically defining dietary supplements to include the following dietary ingredients: vitamins, minerals, herbs or other botanicals, amino acids, or other "dietary substance[s] for use by man to supplement the diet by increasing the total dietary intake." Moreover, concentrates, metabolites, constituents, extracts, or any combination of the dietary ingredients set forth earlier are also included in this definition. The second foundation of the dietary supplement definition addresses the form of the supplement. The product must be one "intended for ingestion in tablet, capsule, powder, softgel, gelcap or liquid form." A dietary supplement must not be "represented for use as a conventional food or as a sole item of a meal or the diet."

The DSHEA of 1994 (Public Law 103-417) defined the terms *dietary supplement* (section 201(ff) of the act [21 USC 321(ff)]) and *new dietary ingredient* (NDI) (section 413(c) of the act [21 USC 350b(c)]). A dietary supplement means a product (other than tobacco) intended to supplement the diet that bears or contains one or more of the following dietary ingredients: vitamin, mineral, herb or other botanical, and amino acid; a dietary substance for use by man to supplement the diet by increasing the total dietary intake; or a concentrate, metabolite, constituent, extract, or combination of any of the previously listed ingredients. An *NDI* is one that meets the aforementioned definition for a *dietary ingredient* and was not sold in the United States in a dietary supplement before October 15, 1994. Dietary supplements can be found in many forms such as tablets, capsules, softgels, gelcaps, liquids, or powders. They can also be in other forms, such as a bar; but if they are, information on their label must not represent the product as a conventional food or a sole item of a meal or diet. Whatever their form may be, DSHEA places dietary supplements in a special category under the general umbrella of *foods*, not drugs, and requires that every supplement be labeled a dietary supplement. An NDI is one that meets the aforementioned definition for a *dietary ingredient* and was not sold in the United States in a dietary supplement before October 15, 1994.

A key regulatory feature of this class of foods is that, unlike food additives, there is no requirement for premarket approval. New dietary supplements (one first marketed on or after October 15, 1994) are required only to provide advance notice of new ingredient marketing. For a dietary supplement, a premarket notification must include the "information, including any citation to published articles, which is the basis on which the manufacturer or distributor has concluded that a dietary supplement containing such dietary ingredient will reasonably be expected to be safe" under the conditions of use in the labeling.

As a food, dietary supplements are subject to the standard of adulterated food 21 CFR section 342(f) and are considered to be adulterated if either the dietary supplement or the dietary ingredient contained in the supplement presents a significant or unreasonable risk of illness or injury under conditions of use recommended or suggested in labeling, or if no conditions of use are suggested or recommended in the labeling, under ordinary conditions of use. Additionally, it is considered to be adulterated, if it is an NDI for which there is inadequate information to provide reasonable assurance that this ingredient does not present a significant or unreasonable risk of illness or injury. The United States bears the burden of proof to show that a dietary supplement is adulterated.

A dietary supplement is considered adulterated if it has been prepared, packed, or held under conditions that do not meet current good manufacturing practice regulations final ruling (https://www.federalregister.gov/articles/2007/06/25/07-3039/current-good-manufacturing-practice-in-manufacturing-packaging-labeling-or-holding-operations-for).

DSHEA also provided that a dietary supplement containing an NDI is adulterated unless it meets the requirements set forth in section 413 of the act, which requires premarket notification for certain NDIs. Under section 413(a) of the act, a dietary supplement that contains an NDI is deemed adulterated unless it meets one of two statutory requirements. One is that the dietary supplement contains only dietary ingredients that "have been present in the food supply as an article used for food in a form in which the food has not been chemically altered" (section 413(a)(1) of the act). The alternative requirement is (section 413(a)(2) of the act) that there be a history of use or other evidence of safety establishing that the dietary ingredient when used under the conditions recommended or suggested in the labeling of the dietary supplement will reasonably be expected to be safe. In addition, at least 75 days before being introduced or delivered for introduction into interstate commerce, the manufacturer or distributor must provide the FDA with information, including any citation to published articles, which is the basis on which the manufacturer or distributor has concluded that a dietary supplement containing such dietary ingredient will reasonably be expected to be safe. The FDA has issued a regulation section 190.6 (21 CFR 190.6) establishing the procedure by which a manufacturer or distributor of a dietary supplement that contains an NDI must submit the information required by section 413(a)(2) of the act.

A dietary supplement containing an NDI may be considered adulterated if there is inadequate information to provide reasonable assurance that the ingredient will not present a significant or unreasonable risk of illness or injury (http://www.fda.gov/Food/DietarySupplements/ucm109764.htm). It has been suggested that the wording of the statute has contributed to a lowering of the standard for safety compared with food additives or GRAS ingredients. Other provisions of the act that contribute to a sense that the assurance of safety is lowered are the following: (1) not requiring endorsement either by the agency or by experts qualified by scientific training and experience to evaluate safety; (2) by placing the burden of proof on the government to demonstrate a substance is unsafe; and (3) acceptance of *grandfathering* without stipulating consensus among experts or criteria for safety as the agency had already in place for GRAS substances (Burdock, 2000). The FDA has issued draft guidance to provide additional clarity on their current thinking and to assist industry in complying with DSHEA (Draft Guidance for Industry: Dietary Supplements: New Dietary Ingredient Notifications

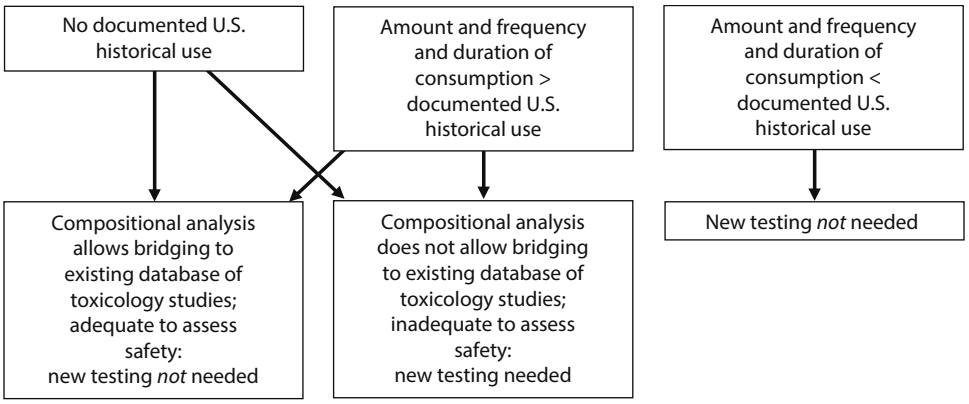


FIGURE 14.4 Decision tree approach for new toxicology testing NDI.

and Related Issues, July 2011). Pivotal to the application of the guidance as it pertains to the safety evaluation of an NDI, the FDA opined that

> the NDI safety standard is different than the standard for food additives, drugs, pesticides, and other FDA-regulated products. Recommendations in guidance documents that are tailored to the safety assessment needs of other FDA-regulated products may not always be appropriate for dietary ingredients and dietary supplements.

The FDA further indicated that

> You should use your own best judgment in compiling scientific evidence that provides a basis to conclude that the NDI that is the subject of your notification will reasonably be expected to be safe when used under the conditions recommended or suggested in the labeling of the dietary supplement described in the notification.

The guidance specifies that a change in the use of a dietary ingredient, by increasing the amount, frequency, or duration of intake compared to traditional use, triggers the classification as an NDI and, subsequently, the need for additional testing in order to complete the safety evaluation. The data needed may be derived from de novo toxicology testing, or as discussed in the section *Food Ingredients Derived from Chemically Complex Extracts*, data to evaluate safety may be available from the literature for the chemical classes that comprise the extract. A decision tree approach that summarizes the toxicology testing recommendations is found in Figure 14.4.

SUMMARY OF REGULATORY PATHS FOR GRAS SUBSTANCES, FOOD ADDITIVES, AND DIETARY SUPPLEMENTS

See Table 14.2.

FOOD CONTACT SUBSTANCES

In 1997, the Food and Drug Administration Modernization Act (FDAMA) amended the FD&C Act to include a notification process for food contact substances (FCSs). The act defined an FCS as "any substance intended for use as a component of materials used in manufacturing, packing, packaging, transporting, or holding food if such use is not intended to have a technical effect in such food" (U.S. FDA, 1998). Examples of FCSs include polymers (plastic packaging materials), pigments and antioxidants used in polymers, can coatings, adhesives, materials used during the manufacture of paper and paperboard, slimicides and biocides (antimicrobial agents), and sealants for lids and caps.

The term *safe*, as it refers to food additives and ingredients (including FCSs), is defined in 21 CFR 170.3(i) as a "reasonable certainty in the minds of competent scientists that a substance is not harmful under the intended conditions of use."

To obtain approval for a new FCS, a food contact notification (FCN) should be submitted to the OFAS at least 120 days prior to the marketing of the FCS. The level of data required to support the safety of an FCS depends on the EDI of the FCS and any impurities it may contain. The FCN should include detailed toxicological, chemical, and environmental information about the FCS and its impurities and should address the potential mutagenicity and carcinogenicity of the FCS and its impurities (www.cfsan.fda.gov/~dms/opa2pmnt.html).

For an FCS or impurity with an incremental dietary exposure ≤1.5 μg of the FCS per person per day (1.5 μg/p/day), toxicity studies are not ordinarily recommended. However, any available information on the mutagenic or carcinogenic potential of the FCS and its impurities should be provided in the notification. For an FCS or impurity with an incremental exposure between 1.5 and 150 μg/p/day, the FDA recommends a battery of short-term genetic toxicity tests: (1) a test for the induction of gene mutations in *Salmonella typhimurium* (the Ames test) and *Escherichia coli* and (2) a test for the induction of gene mutations or chromosome aberrations in mammalian cells in culture such as the mouse lymphoma assay.

For an FCS or impurity with an incremental exposure between 150 and 3000 μg/p/day, OFAS recommends other studies be conducted in addition to the previously mentioned genotoxicity assays. One such study is an in vivo chromosome aberration study, such as the micronucleus test in rodents. OFAS also recommends two subchronic toxicity studies, typically of 90-day duration, one in a rodent species

TABLE 14.2
Comparison of Regulatory Paths

Food Additive	GRAS	Dietary Supplement
FFDC 1938.	Exemption to food additives: Food Additives Amendment 1958. Notification process promulgated 1997.	DSHEA 1994. Draft Guidance for Industry 2011.
FAP	General recognition of safety by expert panel: GRAS dossier (self-GRAS or notification).	Pre-1994: no FDA notification. Post-1994: NDI notification to FDA.
Information and data may be unpublished.	Pivotal information and data must be published.	Information and data may be unpublished.
Assumes lifetime exposure.	Assumes lifetime exposure.	Duration and frequency of exposure dictated on label.
Cannot exclude subpopulations.	Cannot exclude subpopulations.	Can target and exclude subpopulations on the label.
EDI based on specific food uses and levels calculated using databases to derive mean and 90th percentile consumption.	EDI based on specific food uses and levels calculated using databases to derive mean and 90th percentile consumption.	EDI based on recommended use and levels as defined in the labeling.
Reasonable certainty of no harm *specific to use/intake* Delaney clause applies.	Reasonable certainty of no harm *specific to use/intake.*	Reasonably expected to be safe under the conditions of use defined in the labeling.
The FDA makes the determination of safety based on data provided by submitter.	General recognition of safety based on publicly available data and consensus of expert panel opinion.	Burden is on the submitter to establish safety for NDI under the conditions of use defined in the labeling.
FDA premarket approval required.	No FDA premarket approval.	No FDA premarket approval.
Published in 21 CFR.	Record of the voluntary notification and outcome on the FDA website.	Record of the mandatory premarket notification and outcome on the FDA website.

and one in a nonrodent species. These studies should provide adequate toxicological information to determine an ADI for the FCS and/or its constituents.

Depending on the results, these tests may indicate a need for further, more specialized toxicological testing to ensure consumer safety. Specialized testing may include evaluation of neurotoxicity (toxicity effects on the nervous system), immunotoxicity (toxicity effects on the immune system), teratogenicity (toxicity effects on embryos and fetuses), and reproductive toxicity (toxicity effects on the reproductive organs and functions). Depending on the results, the use of the chemical may be judged to be safe, additional tests may be requested to clarify questions raised by the current data, or OFAS may determine that a proposed exposure represents an unacceptable risk and object to the FCN.

For a dietary intake above 3000 μg/p/day, OFAS recommends that the notifier discuss the specific details of the submission with the FDA to determine if the submission of a FAP is more appropriate than submission of an FCN.

FOOD ALLERGY

Introduction

Food allergy, as defined by the World Health Organization in 2003, is the condition where an individual experiences an adverse immunological reaction to a particular type of food (Johansson et al., 2004). The eight most common foods that elicit allergic reactions are eggs, milk, fish, crustacean shellfish (e.g., crab, lobster, shrimp), tree nuts (e.g., almonds, walnuts, and pecans), peanuts, wheat, and soybeans, although reactions to many other foods can occur as well. Food-induced anaphylactic reactions are possible, but the more prevalent adverse immunological reactions include eczema, urticaria, angioedema, nausea, vomiting, diarrhea, rhinoconjunctivitis, and asthma. Recent estimates indicate that food allergies are on the rise, currently affecting approximately 5% of young children and 3%–4% of adults in westernized countries (Branum and Lukacs, 2009; Rona et al., 2007). Thus, there is increasing concern about the safety of food products both from the perspective of the consumer and the food manufacturer.

Currently, avoiding the eliciting allergen is the most successful means of preventing food allergic reactions. Although this strategy is manageable for consumers with appropriate labeling, it presents a major hurdle for the food industry because eliminating allergens from food is nearly impossible and product labeling can negatively impact product sales. To circumvent this, manufacturing facilities typically dedicate single production lines to manufacturing allergen-free products and/or clean their equipment meticulously between manufacturing runs of different foods. Nevertheless, the Food Allergen Labeling and Consumer Protection Act (FALCPA) of 2004 requires that food labels clearly identify the food source names of all ingredient that are or contain any protein derived from the eight most common food allergens.

It is now known that allergic individuals have *thresholds*, a dose at or below which an adverse effect is not seen in an experimental setting (Taylor et al., 2002), which indicates that manufactures may be able to allow minute amounts of allergic substances in food without posing a risk to the consumer.

Unfortunately, defining such thresholds has presented major challenges to physicians and food producers because the allergen sensitivities vary greatly and accumulating enough data to confidently identify the lowest tolerated dose of a particular allergen has been difficult. The concept of identifying safe levels of food allergens, however, is intriguing, and a considerable amount of resources is being invested in the development of validated diagnostic methods to determine the lowest tolerated doses and assessing the risks associated with the consumption of foods containing small amounts of allergenic substances.

The following sections review the immunopathophysiological mechanisms involved in food allergic reactions, tests used to diagnose food allergies, the concept of threshold doses, and allergenic determinants.

Oral Tolerance and Food Allergy

To understand food allergy, one must first appreciate the complexity of the immune system and its ability to respond to foreign substances (see Chapter 37). Briefly, the purpose of the immune system is to defend the host against invading pathogens and potentially dangerous substances. And to do so, it relies on a variety of cells and secreted factors to coordinate and execute the detection and eradication of the invading pathogen or dangerous substance. Implicit in this response, however, is its ability to discriminate foreign substances (nonself antigens) from those of the body (self antigens) and to respond to only nonself antigens (Janeway et al., 2005). The *absence* of self-reactivity is known as *natural* or *self*-tolerance. Importantly, if the immune system mistakenly reacts to self or becomes intolerant to self, an immune response develops, and a chronic inflammatory disease state, known as autoimmunity, results because the causative self antigen is in endless supply.

In the gastrointestinal (GI) tract, the concept of tolerance is vastly different. Every day, millions of foreign antigens are ingested, and moreover, the GI tract is home to a wide variety of commensal bacteria. So, why do the large majority of people not mount an immune response to food and commensal bacteria? Oral tolerance appears to be the answer. Unlike self-tolerance, oral tolerance is believed to be an active state of immune suppression whereby the immune response to the millions of foreign antigens ingested each day and normal gut flora is prevented (reviewed in Strobel and Mowat [1998]). The mechanisms that promote oral tolerance in humans are largely unknown, but studies in animal models suggest that they may involve a combination of neutralizing of foreign antigens with secreted IgA and inducing T-cell anergy, clonal deletion, and the suppressive activities of T regulatory cells.

Food allergies, like all allergies, result from an abnormal and misguided immune response to a substance that is otherwise harmless. Initially, the individual is exposed, reacts, and is asymptomatic, but when they reencounter the sensitizing antigen, the pathologies develop. Unfortunately, the reasons why one person is hypersensitive to the particular antigen as opposed to another are unclear, but it is currently thought to result from a failure to develop and/or the breakdown of oral tolerance. Furthermore, studies in animals suggest that genetics, age, dose and timing of antigen exposure, commensal gut flora, intestinal permeability, and properties of the antigen itself may contribute to the breakdown of oral tolerance (reviewed in Mayer et al. [2001]).

IgE- and Non-IgE-Mediated Hypersensitivity Reactions

Food allergies can be categorized into IgE-mediated and non-IgE-mediated reactions, which are not mutually exclusive. IgE-mediated reactions are true *allergic* responses, also known as type 1 hypersensitivity responses, that typically affect the cutaneous, respiratory, GI, and cardiovascular systems (Wang and Sampson, 2009). These involve IgE antibodies, which are produced by B cells, occur within 2 h of exposure, and can result in anaphylaxis. Mechanistically, they result when an antigen induces the abnormal skewing of CD4+ T cells to Th2 cells and activates B cells. Then, with the help of the abnormally skewed Th2 cell, the B cells undergo class-switching and produce antigen-specific IgE antibodies. The IgE antibodies bind Fc receptors expressed on the surface of mast cells and basophils, and when the antibodies bind the sensitizing antigen, the cells degranulate, releasing histamine and leukotrienes into the extracellular matrix. This leads to capillary venule dilation, endothelium activation, and increased vascular permeability, causing redness and swelling. If the antigen is systemic or rapidly absorbed, histamine and leukotriene release is widespread and can result in anaphylaxis and potentially death.

Non-IgE-mediated responses are less frequent and occur in the absence of detectable food-specific IgE antibodies in the serum or skin. Although the pathophysiological mechanisms that contribute to non-IgE-mediated responses are not well defined, they occur at least 2 h after exposure and appear to be the result of acute or chronic inflammation in the GI tract. From a more global immunological perspective, three types of non-IgE-mediated hypersensitivity reactions exist, that is, type 2 (cytotoxic responses), type 3 (immune complex reactions), and type 4 (delayed-type hypersensitivity [DTH] reactions), and all may contribute to the development of non-IgE-mediated food hypersensitivity responses. Cytotoxic reactions are triggered when antigen-specific IgM or IgG antibodies bind their cognate antigens bound to or found on the surface of cells. This activates a cascade of protein factors known as the complement cascade, which in turn releases the inflammatory mediator C5a, and results in the recognition and lysis of the antibody/complement-bound cell by macrophages. Immune complex reactions are similar, but are triggered when antibodies encounter soluble antigen. Aggregates of the antibody and antigen then form, are deposited in tissues, and cause complement activation and Fc receptor-mediated leukocyte activation. DTH reactions are unlike allergic, immune complex, and cytotoxic response, because they are antibody independent and are the product of an aberrant Th1 or cell-mediated immune response. DTH reactions are triggered when antigen-specific T cells reencounter the sensitizing antigen. The activated T cells in turn produce cytokines, which

promote inflammation. Examples of non-IgE-mediated food hypersensitivity reactions are food-protein-induced enterocolitis and proctocolitis, and examples of reactions that include both IgE- and non-IgE-mediated reactions are atopic dermatitis and eosinophilic gastroenteropathies (Wang and Sampson, 2009).

Diagnosing Food Allergy

Diagnosing food allergy presents a major challenge because it not only requires that the provoking allergen be identified, but also it also demands that the amount of the eliciting allergen and the type of response provoked by the allergen be determined. The primary tools used to diagnose food allergy are a detailed history including a diet record, physical examination, skin prick tests (SPTs), serum tests for food-specific IgE antibodies, trial elimination diets, and oral food challenges (OFCs) (reviewed in Chapman et al. [2006]).

The first steps to diagnosing food allergy are documenting a history of the patient's response and performing a physical exam. These analyses help identify whether or not food is the causative agent, the type of food that is causing the reaction, the amount of food needed to elicit the reaction, and whether or not the reaction is IgE-mediated and provide some insight into the type, timing, and duration of the clinical manifestations.

The next steps include SPTs, serum tests, trial elimination diets, and graded OFCs. SPTs detect the presence of allergen-specific IgE bound to mast cells and are performed by injecting minute amounts of potential food antigens into the epidermal layer of the skin and measuring the extent of redness and swelling, also known as the wheal-and-flare reaction that results from IgE cross-linking and mast cell degranulation. Wheals are generally considered to be significant when the diameter is 3 mm or greater than the wheal induced by the vehicle or negative control (Hill et al., 2004). Intracutaneous/intradermal testing (injecting a small amount of antigen in the dermis) is also performed; however, this is generally used as a follow-up if results from skin prick testing are negative and clinical suspicion still remains high (Carr and Saltoun, 2012). Serum IgE tests involve harvesting blood, collecting the serum, and analyzing it for the presence of antigen-specific IgE antibodies. Although both of these tests are very sensitive, they can produce false-positives, and moreover, their results do not always correlate with the pathophysiological responses to the suspected food. Furthermore, the quality of SPTs and serum IgE tests have been found to be dramatically affected by characteristics of the patient and the quality and characteristics of the reagents and techniques used to perform the assays (Guerin and Tioulong, 1979; Hurst et al., 2002). Thus, although positive results do not unambiguously rule in a particular food as a causative agent, negative results from SPTs and serum IgE test are very helpful in ruling out IgE-mediated responses.

Trial elimination diets involve removing suspected eliciting foods from the diet and monitoring the patient's pathophysiological response (Bock et al., 1988; Sicherer and Sampson, 1999). Because avoiding the eliciting allergen is the most effective way to prevent an allergic reaction, elimination diets may be an effective method for narrowing the search for the eliciting allergen. However, elimination of a potentially eliciting allergen may be difficult and the duration of the trial may not be long enough for the pathology to resolve. As a result, positive results cannot not be used to definitively diagnose food allergy unless other supporting data such as a clearly defined history, responses to SPTs, IgE serum tests, and graded food challenges are also known (Chapman et al., 2006).

OFCs are the most ideal tests for diagnosing food allergy because they directly replicate the route of exposure and define the lowest tolerated dose of the eliciting allergen. However, they can cause anaphylaxis, worsening of atopic dermatitis, and emotional distress. Therefore, OFCs should be performed in settings where medical assistance can be delivered immediately. Furthermore, if an individual presents with a clinical history that suggests a food allergy and has a positive SPT that indicates an IgE-mediated response, an OFC may not be necessary. However, if the history is unclear and the individual has positive SPT, then OFCs may be performed for diagnosis, and a previous episode of anaphylaxis to a food may exclude the use of an OFC (Peters et al., 2012). Graded OFCs are performed by gradually feeding increasing amounts of the suspected eliciting food to the patient and evaluating his or her response over the course of days to determine whether or not any component of the patient's response is non-IgE-mediated. They can also be performed as open, single-blinded, or double-blinded placebo-controlled challenges. The gold standard is the double-blind placebo-controlled food challenge (DBPCFC), which entails feeding test foods and placebos that have been randomly prepared by a third party to the patient (Bock et al., 1988; Nowak-Wegrzyn et al., 2009; Sicherer, 1999). Once the challenge is over, the contents of the test foods are disclosed, the contents are compared to the patient's response, and a diagnosis is made. Importantly, DBPCFC minimizes bias and subjective results, which are typically associated with open and single-blinded oral challenges. However, they do require a significant amount of planning, time, and resources and are primarily reserved for research studies and selected clinical cases.

Threshold Doses

Threshold as defined by the Oxford English Dictionary (9th edn.) is the limit below which a stimulus causes no reaction. In toxicology, it is defined as the dose at or below which a response is not seen in an experimental setting and falls between the NOAEL and lowest observed adverse effect level (LOAEL). For allergens, thresholds exist for both the sensitizing and eliciting phases of the reaction, but, because sensitization occurs asymptomatically, not much is known about the thresholds for the sensitizing phase of the response (Taylor et al., 2008). Thresholds are also specific to individuals, but with enough evidence, they can be determined for a population. For individuals, they are determined at an allergy

clinic by graded DBPCFCs. For populations, they are determined for a group of individuals with a specific type of food allergy, but as with any experimental data, the more individual thresholds obtained for a particular allergen, the greater confidence there is in establishing the *population* threshold. Lastly, thresholds vary from person to person and from allergen to allergen. For peanuts, for example, controlled clinical challenges have found that individual thresholds range from approximately 0.1 mg to 8 g of whole peanut (Taylor et al., 2009, 2010) and that peanut thresholds are, in general, much lower than those for soybeans (Ballmer-Weber et al., 2007; Taylor et al., 2009, 2010). The remainder of this section discusses the different types of thresholds and the approaches used for deriving population thresholds for the eliciting phase of the allergic reaction.

In 2006, the Center for Food Safety and Applied Nutrition at the FDA formed the Threshold Working Group to gather data on the exposure of allergic subjects to allergens and evaluate the possible approaches to establishing food allergen thresholds (The Threshold Working Group, 2008). They identified four general approaches, analytical methods based, safety assessment based, risk assessment based, and statutorily derived, that could be used to establish thresholds.

The analytical methods-based approach relies on the limits of detection for analytical methods used to verify compliance. So, in effect, they establish a *regulatory threshold*. For example, X food contains 10 ppm or greater of ingredient Y, based on the LOD for the method used to determine the concentration of Y. Importantly, this type of threshold is not correlated to biological effects, and thus, allergic reactions can still be provoked in sensitive populations even though the food contains allergenic substances at undetectable levels. Moreover, thresholds will be continually questioned with the development of more sensitive methods of detection.

The safety assessment-based approach relies on data from animal, human, and epidemiological studies that provide an exposure level for which there is no apparent or adverse effect or identify an LOAEL or NOAEL. Then, one or more uncertainty factors (UFs) are applied to account for interspecies and interindividual differences and other uncertainties in the data. The end result is an ADI or for an allergen, a threshold (Lehman and Fitzhugh, 1954). Crump (1984) introduced the benchmark dose (BMD)/margin of exposure (MoE) concept, which refined the classical safety assessment-based approach by fitting a curve to the data and then extrapolating to the dose that corresponds to a 10% response rate. Although both of these methods are routinely used for determining ADIs, it is important to note that they are *deterministic* in nature, relying on actual data points that do not account for the inherent variability in the population. As a result, they are limited to what is known and, because they are intended to ensure that even the most sensitive part of the population is protected under all conditions, generally overestimate health risk and can result in thresholds that are below those that could be reasonably obtained for food manufacturers (Spanjersberg et al., 2007). Furthermore, animal models do not accurately recapitulate allergic reactions in humans. The number and breadth of doses tested in both experimental and clinical study may not allow for an accurate determination of the threshold dose, and in the case of the BMD/MoE technique, the farther away one extrapolates from the actual data points, the greater the amount of the error.

The risk assessment-based approach relies on systematically examining scientific data of known or potential adverse health effects resulting from human exposure to a hazard. It involves identifying the hazard, establishing a dose–response relationship between a hazard's biological effects and the amount consumed, determining the nature and extent of an exposure, and integrating all of these components into an overall estimation of the potential risks to the population. Risk assessments can also be quantitative or qualitative: Quantitative risk assessments provide numerical estimates of the chance of illness or death after exposure to a specific hazard; qualitative risk assessments use verbal descriptors of the risk and uncertainties and often involve expert opinions. Both account for the cumulative probabilities of certain events happening and the uncertainties associated with those events; however, only the quantitative risk assessment-based approach provides insight into both the level of protection and the degree of uncertainty associated with an exposure level. Quantitative risk assessments also require that the entire dose–response curve be determined and validated mathematical procedures that account for population variability be applied. Currently, it is unclear whether or not enough DBPCFC data exist to develop dose–response curves for all the food allergens, yet probabilistic modeling appears to be the most effective mathematical method for quantifying thresholds (Kruizinga et al., 2008; Madsen et al., 2009; Spanjersberg et al., 2007; The Threshold Working Group, 2008).

The statutorily derived approach establishes a threshold by extrapolating from an exemption established by congress for another purpose. For example, FALCPA requires that food products containing an ingredient that contains protein derived from milk, fish, egg, crustacean shellfish, tree nuts, wheat, peanuts, and soybeans be labeled as containing food allergens except for highly refined oils. Thus, if consumption of another food containing levels of protein results in an exposure level that is equal to or less than the level in a typical serving of highly refined oil, it should not be associated with allergic reaction and a threshold can be established. Although this approach is derived from the law, it is not based on a rigorous and systematic evaluation of available scientific data. Furthermore, the data on the amount of protein in refined oils are lacking, and thresholds for all food allergens would be based primarily on the protein levels in highly refined soy and peanut oil.

In conclusion, the Threshold Working Group established that "the quantitative risk assessment approach provides the strongest, most transparent scientific analyses to establish thresholds for the major food allergens." However, because new data and diagnostic tools are being continuously produced, they recommend that thresholds established by any of the four approaches be periodically reevaluated.

Allergenic Determinants

Allergens, by definition, are antigens that are recognized by IgE antibodies and provoke IgE-mediated hypersensitivity responses (Aalberse, 2000). Not all allergens are created equal, however. Some are capable of inducing the primary immune response, which elicits the IgE antibodies that make people sensitive, whereas others only engage preformed IgE antibodies and provoke secondary/hypersensitivity responses. Those that induce the primary responses are considered strong immunogens and are called *complete* allergens. Those that induce only secondary reactions, likely due to their binding cross-reacting IgE antibodies, are weak immunogens and therefore called *incomplete* allergens. Examples of complete antigens include Ara h 2 of peanut and Bet v 1 of birch pollen (Burks et al., 1995; Ipsen and Lowenstein, 1983). An incomplete allergen is Mal d 1 from apples, which provokes IgE-mediated hypersensitivity responses in birch pollen-sensitized individuals because of the homology between Mal d 1 and Bet v 1 and cross-reacting anti-Bet v 1 antibodies (Bjorksten et al., 1980; Holm et al., 2001; Lahti et al., 1980).

Although there have been a few reports of allergic reactions to carbohydrates (Chiang et al., 2012; Commins et al., 2009; Franck et al., 2005), most allergens are proteins or glycoproteins, clustering in less than 2% of all sequence-based protein families (Radauer et al., 2008; Sicherer and Sampson, 1999). Importantly, allergens are heterogeneous, and although they are all capable of binding IgE antibodies, efforts in defining the structural and biochemical determinants that would make an antigen allergenic have been unfruitful.

COMMON FOODBORNE TOXICANTS

Pesticide Residues

A crop protection chemical or pesticide is any substance or mixture of substances intended to control or destroy pests including insecticides, herbicides, fungicides, rodenticides, repellents, and fumigants (http://www.epa.gov/opp00001/regulating/registering/).

In the European Union, a crop protection dossier must comply with the data requirements in Regulations EU 543/2011 and 544/2011 and be submitted to a member state who will act as the *rapporteur member state*. In the United States, pesticides must be registered or exempted by the Environmental Protection Agency's (EPA) Office of Pesticide Programs before they can be sold or distributed in the United States. Once registered, a pesticide may not legally be used unless the use is consistent with the approved directions for use on the label. As part of the registration process, the EPA examines the ingredients of a pesticide; the site or crop on which it is to be used; the amount, frequency, and timing of its use; and storage and disposal practices.

The EPA sets limits on how much of a pesticide residue (maximum residue limits (MRLs) or tolerances) can remain in or on each treated food commodity. Tolerances are set to protect the consumer from potential harmful concentrations of pesticides. The tolerance is the residue level that triggers enforcement actions; if residues are above that level, the commodity is subject to seizure. In setting the tolerance, the EPA must make a safety finding that the pesticide can be used with *reasonable certainty of no harm* to humans, the environment, and nontarget species. The tolerance applies to food imported into this country, as well as to food grown in the United States. In August 1996, the FD&C was amended to include the Food Quality Protection Act (FQPA). This act required the EPA to reassess all of the pesticide tolerances that were in place to ensure that they met current safety standards and were supported by up-to-date scientific data.

The USDA enforces tolerances established for meat, poultry, and some egg products, while the FDA enforces tolerances established for other foods in interstate commerce to ensure that these limits are not exceeded. The International Maximum Residue Limit Database contains MRLs or tolerances for U.S. specialty crops. This database is maintained by the Foreign Agricultural Service, Horticultural and Tropical Products Division of the USDA (http://www.fas.usda.gov/htp/MRL.asp). It can be searched by crop or pesticide and contains information for the United States and 70 other countries.

Heavy Metals

A heavy metal is a member of a loosely defined subset of elements that exhibit metallic properties. Many definitions have been proposed—some based on density, some on atomic number or atomic weight, and some on chemical properties or toxicity (see Chapter 17). Examples of toxic metals include arsenic, cadmium, chromium, lead, mercury, and thallium. Some trace elements (copper, selenium, zinc) are essential to maintain the metabolism of the human body; however, at higher concentrations, these trace elements can be toxic. Poisoning typically results from drinking-water contamination, high ambient air concentrations, or intake via the food chain. The potential danger of heavy metals is increased because these metals tend to bioaccumulate in the body. Refer to Chapter 17 for details regarding the toxicity of these materials.

For food-grade standards, foods and food ingredients and additives conform to specification limits for heavy metals that are promulgated by authoritative agencies such as Food Chemicals Codex (foodchemicalscodex.org/), Joint Food and Agricultural Organization (FAO)/WHO Expert Committee on Food Additives, European Food Safety Authority, and the U.S. FDA. Specifications for heavy metals are based on health-based standards (FCC, 2003). With the exception of methyl mercury in fish, the U.S. FDA has not set regulatory standards for the other heavy metals in foods.

Bacteria and Viruses

Bacterial Infections and Intoxications

Foods contaminated with microbial agents are a major source of human disease, estimated to afflict tens of millions of people and to cost 22 billion dollars annually in

the United States. With few exceptions, most of these outbreaks can be prevented by adequate washing and cooking along with proper cooling, storage, and reheating of cooked foods in clean containers. Bacterial foodborne diseases may result from the consumption, in food, either of bacteria (e.g., *Salmonella* sp. and *Clostridium perfringens*) that can cause disease by multiplying in the intestinal mucosa where they may elaborate toxins (enterotoxins) or from preformed microbial toxins (staphylococcal enterotoxins and botulinum toxins). In addition to these well-known etiologies, genetic changes in bacteria that increase virulence, changes in eating habits, altered food production and distribution systems, increased number of immunocompromised food consumers, and improved detection systems have led to identification of other pathogens such as *E. coli*, *Listeria* sp., and *Yersinia* sp. causing foodborne illness.

C. perfringens frequently causes foodborne illness. Due to the ubiquitous distribution of the organism in soil and in the GI tract of man and animals, prevention is difficult. The enterotoxin, released during sporulation in the large intestine, causes fluid accumulation in the intestines. Among the five distinct types of *C. perfringens* (type A–E), type A is almost always involved in foodborne gastroenteritis and associated signs in humans. The α-toxin produced by certain types of *C. perfringens* possesses lethal, necrotizing, and hemolytic activities. Only meat and fish products provide all the amino acids and growth factors required for growth of *C. perfringens*. Roast beef, beef stew, gravy, and meat pies for type A and pork, other meats, and fish for type C are frequently involved (Bryan, 1979). Typically, foods involved are cooked at or below 100°C for less than an hour and are subsequently kept warm or slowly cooled. Spores that survive the heat shock multiply faster than those not subjected to heat treatment and elaborate the enterotoxin in the gut once the contaminated food has been consumed. The enterotoxin appears to form ion-permeable channels in the cell membrane leading to movement of extracellular calcium and water into the cells resulting in cell death (Osuntokun, 1973). Entry of the toxin into blood stream will lead to release of potassium from hepatocyte, hyperkalemic cardiac failure, and eventually death (Sugimoto et al., 1996). Multiplication and toxin production can be inhibited by heating food to a proper temperature (165°F–212°F), by prompt and effective cooling, and by avoiding prolonged reheating before consumption.

Staphylococcus aureus is probably the leading cause of foodborne illness worldwide. The organisms are gram-positive, nonmotile, and non-spore-forming cocci and occur ubiquitously in the environment. Although man is the leading source of food contamination by way of nasal discharge and infected cuts and wounds, the organism can be present in milk derived from mastitic cows and meat derived from arthritic poultry (Miller et al., 1998). Baked ham, poultry, fish and shellfish, meat and potato salads, cream-filled bakery goods, and high-protein leftover foods are frequently involved in such intoxication (Bryan, 1979). Multiplication of *S. aureus* in raw food products can be inhibited by other spoilage organisms. As a result, mostly cooked products subsequently contaminated by infected handlers and stored at warm temperatures for several hours before consumption are capable of causing intoxication. The causative agent is one of more than six immunologically distinct heat-stable enterotoxic proteins (MW 26,000–34,000) whose secretion is regulated by chromosomes during growth (A, D, and E) or by plasmids (B and C). In addition, *S. aureus* also produces many other substances such as coagulase, DNase, hemolysins, lipases, fibrinolysin, and hyaluronidase that are toxic to one or more animal species. Although all strains of *S. aureus* are potentially pathogenic, enterotoxin production is closely related to the presence of coagulase and DNase. Signs and symptoms begin 1–6 h after consumption of contaminated food and include nausea, salivation, vomiting, retching, occasional diarrhea, abdominal cramps, sweating, dehydration, and weakness followed by recovery in 1–3 days. Severe cases may show fever, chills, drop in blood pressure, and prostration (Miller et al., 1998). Preventive measures effective against *S. aureus* food intoxication include education of food handlers regarding hygienic practices to reduce postcooking contamination of high-protein foods and eliminating prolonged storage of cooked foods at room temperature.

Botulism is a neurotoxic syndrome caused by consumption of improperly cooked and stored foods containing one of seven (A–G) heat-labile neurotoxins produced by *Clostridium botulinum*. It is a ubiquitous, anaerobic, gram-positive, and motile rod capable of forming heat-resistant spores. High moisture, a pH above 4.6, and prolonged anaerobic storage are required for sufficient toxin production (Miller et al., 1998). Common foods involved are home canned fruits and vegetables such as beans, corn, leafy vegetables, and especially peppers, all of which contain toxins A and B. Nonpoultry meats contain toxin B, whereas cheese and other dairy products contain toxin A. Toxin E is isolated mostly from fish products (Miller et al., 1998). Types C and D, causing botulism in animals and birds, do not affect humans. Outbreaks, however, are often from more unusual sources such as chili peppers, tomatoes, and improperly handled baked potatoes wrapped in aluminum foil. Although the FDA approved purified botulinum toxin type A for treatment of eye muscle disorders, cervical dystonia (a neurological movement disorder causing severe neck and shoulder contractions), and frown lines between the eyebrows, because of its fatal effects in aerosolized form and its use in weapons by rogue states, it also is considered a potential agent of bioterrorism.

Botulinum toxins are stable in the acid pH of the stomach where it is protected from the gastric juice and pepsin by a nontoxic component of the toxin molecule. Once in the duodenum, it is activated by trypsin with no change in molecular size and subsequently absorbed into lymphatics. The toxin irreversibly binds to the myoneural junction and acting as a Zn endopeptidase degrades peptides involved in the release of acetylcholine (ACh) thus inhibiting its release at the peripheral cholinergic nerve endings (Miller et al., 1998). Signs and symptoms of botulism usually appear 12–24 h (range:

2 h–6 days) following consumption of the toxin-containing food. Initial signs of nausea, vomiting, and diarrhea are followed by predominantly neurologic signs including headache, dizziness, blurred and/or double vision, loss of light reflex, weakness of facial muscles, and pharyngeal paralysis (difficulty in speech and swallowing). Fever is absent. Sensory reflexes and mental alertness are intact. Paralysis of the respiratory muscles leads to failure of respiration and death, usually in 3–10 days (Smith 1977). Foodborne botulism can be prevented by proper canning technique, boiling vegetables for at least 3 min before serving, and discarding all swollen and damaged canned products after boiling. Control of cases of botulism involves the use of monovalent (E), bivalent (A and B), or polyvalent (A, B, and E) antitoxin, recall of all involved commercial products, proper reporting, and epidemiologic investigation. Boiling for 3 min or heating at 80°C for 30 min destroys the preformed toxin, whereas the use of salt, the antimicrobial compound nisin, polyphosphates, smoke, spices, lactic acid, and nitrite can inhibit the growth of *C. botulinum* and thus prevent toxin formation (Miller et al., 1998). If the nitrite content of cured meats and fish as well as fermented sausages is reduced from current levels as a means of decreasing the level of carcinogenic dietary nitrosamines, it is conceivable that the incidence of botulism from the consumption of such foods will increase unless suitable replacements for the nitrite are found.

Bacillus cereus–associated foodborne disease outbreaks have occurred in Northern and Eastern Europe. A diarrheal illness involving a wide variety of meats and vegetables, various desserts, fish, pasta, milk, and ice cream (similar to that of *C. perfringens*) and a vomiting illness involving flour-based foods such as cereals and fried rice served in Chinese restaurants (similar to that of *S. aureus*) are both apparently caused by this organism (Miller et al., 1998). At least seven toxins including the heat-stable (121°C for 90 min) emetic toxin, cereulide, and the enterotoxins, hemolysin BL and its nonhemolytic homologue, contribute to the syndrome (Miller et al., 1998; Schoeni and Wong, 2005). Enterotoxin appears to disrupt cell membranes leading to increased permeability, whereas the mechanism of emetic toxin is unknown.

Salmonella sp. consists of over 2200 serotypes possessing somatic O, flagellar H, and capsular Vi antigens, of which 50 serotypes commonly occur. *Salmonella typhi, Salmonella paratyphi, and Salmonella sendai* are adapted to human hosts, which serve as sole carriers for those organisms. *S. typhimurium* and *Salmonella enteritidis* are the two most common disease-causing agents in the United States. Feces of infected humans, domestic and wild animals, and birds serve as sources of contamination in a variety of meat and milk products and more recently raw fruits and vegetables. Severe GI signs along with fever, septicemia, shock, and sequelae of embolism including pneumonia, meningitis, and abortion can occur following consumption of contaminated foods. Mortality is rare but occurs in the very young and the very old and in immunocompromised patients. Some individuals develop a chronic condition called Reiter's syndrome manifesting painful joints, irritated eyes, and painful urination. Enteritis can result both from bacterial multiplication within the mucosa and from enterotoxins secreted by some serotypes. Thorough cooking of meats; pasteurization of milk and dairy and egg products; prevention of cross-contamination between cooked and raw products; and finally testing, isolation, and treatment of carrier animals and food handling personnel are all extremely important in controlling the incidence of this most common foodborne disease (Ekperigen and Nagaraja, 1998). In this regard, evidence of emergence of antibiotic-resistant strains such as *S. typhimurium* DT104 in the United Kingdom and United States suggests that future research must be directed at understanding mechanisms of microbial adaptation to stresses if we are to better control such infections. Vaccination allows *Salmonella*-free birds; however, these birds should be housed in a *Salmonella*-free environment and fed *Salmonella*-free pelleted feed.

Shigella spp., especially *Shigella dysenteriae, Shigella flexneri, Shigella boydii*, and *Shigella sonnei*, cause an estimated 165 million cases of *Shigella* diarrhea (acute bacillary dysentery) annually, 99% of which occur in developing countries and 69% in children under 5 years of age resulting in 1.1 million deaths annually (Niyogi, 2005). Young children in day-care and custodial institutions are more susceptible. *Shigella enteritis* is characterized by fever, mucohemorrhagic diarrhea, abdominal cramps, and tenesmus. *Sh. flexneri* can lead to Reiter's syndrome (see *Salmonella*) and eventually to chronic arthritis. *Sh. dysenteriae* type 1 produces shiga toxin and can lead to life-threatening hemolytic uremic syndrome (HUS), the same complication that develops in some cases of infection with enterohemorrhagic *E. coli* (EHEC). Shigellosis is highly contagious producing a large number of secondary cases in each outbreak involving persons in contact with infected patients. Contamination of food by unhygienic food handlers and consumption of raw vegetables raised in contaminated soils are two main contributors to the incidence of *Shigella* diarrhea. Therapy with antibiotics and fluids and prevention through thorough hand washing are effective strategies against the spread of such infections.

Campylobacter jejuni and others in this genus (*Campylobacter sputorum*, *Campylobacter coli*, etc.) are the leading cause of bacterial diarrhea accounting for up to 2.4 million cases in the United States and up to 14% of diarrheal illness worldwide. Many aspects of the illness, including the symptoms that rarely require treatment, are similar to those of salmonellosis (Altekruse et al., 1998). Reactive arthritis, inflammation of urethra and conjunctiva, and Guillain–Barré syndrome (paralysis of limbs and weakness of respiratory muscles) have been described as sequelae in occasional cases (Altekruse et al., 1998).

E. coli, a close relative of the genus *Shigella*, has recently raised concern as a fatal foodborne disease agent. More than 160 serotypes (based on O, H, or capsular K antigen) of which 43 can induce gastroenteritis sometimes associated with life-threatening HUS in humans exist (Riemann and Oliver, 1998). In North America, HUS is the most common cause of acute kidney failure in children, who are

particularly prone to this complication. Pneumonia, meningitis, thrombotic and thrombocytopenic purpura, bladder and kidney infections, and septicemia may also result from *E. coli* infections. Based on virulence factors (which bestow the organism with the ability to attack, invade, and produce toxin in the host cells) located in the plasmids, five virotypes have been identified as pathogenic. These are enterotoxigenic *E. coli* (ETEC), enteroaggregative *E. coli* (Eagg EC), enteropathogenic *E. coli* (EPEC), EHEC, and enteroinvasive *E. coli* (EIEC). Serogroup O 157:H7 belongs to the EHEC group. This organism produces a shiga-like toxin, which may be the most common serotype causing nausea, vomiting, watery, and/or bloody diarrhea. HUS is mainly traceable to consumption of contaminated beef products (Riemann and Oliver, 1998). Less frequently, unpasteurized milk and juices; ham, turkey, salami, and cheese sandwiches; dry fermented sausage; salad; and nonchlorinated water have been involved. The genome of *E. coli* O157:H7 is about 70% homologous with and 30% larger than that of the harmless serotype K12, suggesting that further study of differences between serotypes could lead to a better understanding of the virulence and pathogenicity and tissue predilection of *E. coli* O157:H7. Once in the intestines, *E. coli* produce shiga-like toxins SL1 and SL2 that act, similar to cholera toxin (CT) and ricin, by receptor binding and entry into a vesicular pathway, followed by release and translocation of the enzymatic A1 domain of the A subunit into the target cell cytosol, where covalent modification of intracellular targets leads to activation of adenylate cyclase and a sequence of events culminating in ion fluxes, secretion of serotonin and prostaglandins, and alteration in the expression of genes leading to intestinal cell death and life-threatening diarrheal disease (De Haan and Hirst, 2004; Riemann and Oliver, 1998).

Cronobacter sakazakii (*Enterobacter sakazakii*), found in human and animal gut and in the environment, has been implicated in outbreaks causing meningitis or enteritis, especially in infants where 20% to greater than 50% mortality has occurred. *Cr. sakazakii* has been detected in a variety of foods, but only powdered infant formula has been linked to disease outbreaks (Drudy et al., 2006). Survivors can have long-lasting neurological complications. The outcome in adults seems to be significantly milder.

The FAO/WHO Codex Alimentarius Commission sets international standards for food. Current codex microbiological specifications for powdered infant formula limit the amount of coliforms, which includes *Cr. sakazakii*. While this limit probably helps to prevent a number of outbreaks, it does not confer a sufficient level of safety as evidenced by outbreaks caused by powdered formula meeting the current specifications. Given new information on this emerging problem, the recent expert meeting recommended that codex revise the international standard to better address the microbiological risks of powdered infant formula, including establishing a microbial specification for *Cr. sakazakii* (www.codexalimentarius.org/input/download/standards/…/CXP_066e.pdf; http://www.who.int/foodsafety/publications/micro/mra10.pdf).

Vibrio cholerae, especially the serogroups O1 and O139, have been responsible for large epidemics of cholera worldwide. CT is structurally and mechanistically similar to the heat-labile *E. coli* enterotoxin (De Haan and Hirst, 2004). Although consumption of sewage-contaminated drinking water is the predominant source of major epidemics, foodborne vibriosis can result from the consumption of fecal contaminated foods such as vegetables, fish, and pork products. Consumption of raw vegetables fertilized with untreated sewage and of shellfish harvested from sewage-contaminated estuaries is also a common source. Symptoms of intoxication are severe diarrhea characterized by watery stool (often referred to as rice–water–stool), associated with muscle cramps, hypovolemia, hypotension, shock, and metabolic acidosis due to loss of bicarbonate and poor tissue perfusion. Therapy mainly involves oral or intravenous (in extremely severe cases) rehydration therapy.

Listeriosis, in addition to being transmitted by other routes, is an emerging foodborne disease resulting from the consumption of *Listeria monocytogenes*–contaminated soft cheeses, milk and other milk products, poultry, meat (especially deli meats and frankfurters), and other products (salads, coleslaw, etc.) derived from contaminated vegetables. Food products are contaminated by contact with soil, feces, discharges, and urine from infected animals and humans. The clinical foodborne disease, occurring mostly in pregnant women, neonates, and older and immunocompromised populations, is characterized by GI or flu-like symptoms within 12 h of exposure followed by bacteremia leading to abortions, stillbirths, or premature births in pregnant women; meningitis, respiratory distress, and skin nodules in the neonates; and meningitis-related signs in adults (Cooper and Walker, 1998). The disease can be treated with antibiotics and other supportive measures. Prevention involves improvement of sanitation of the environment and equipment and education to identify and avoid contaminated food products.

Farm-to-fork hygienic measures implemented in Europe seem to be paying off in that the incidence of salmonellosis and certain parasitic diseases shows a decreasing trend in parallel with those in animals (no authors, 2012). Increased use of x-ray irradiation and other microbial reduction strategies on perishable heat-sensitive products such as lettuce, spinach, tomatoes, and almonds is likely to contribute to this decline (Moosekian et al., 2012). Increased reports of antibiotic resistance of the foodborne microbes including *Ca. jejuni*, *Salmonella* spp., and verotoxigenic *E. coli* (VTEC) globally, however, and a lack of public health impact of a total European ban on nonmedical uses of antibiotics indicate that bacterial foodborne disease is a long-term human condition (Koluman and Dikisi, 2013). Impending climate change is likely to add to the burden of waterborne and foodborne disease in humans further.

Viral Foodborne Illnesses

In the United States, as in all industrialized countries, nearly every person will have viral gastroenteritis at least once with

610,000 hospitalizations and more than 4,000 deaths annually. The advent of polymerase chain reaction (PCR), microarray, and proteomic virus detection techniques is beginning to allow the realization that most of the foodborne diarrheal illnesses that failed detection in the past are likely of viral origin. Viruses can neither grow nor produce toxins in foods but can induce foodborne illness by their mere presence in fresh produce or in processed food contaminated by fecal material. As reviewed (Clark and McKendrick, 2004; Leach, 2004), noroviruses, hepatitis virus A and E, rotaviruses, and astroviruses are the major culprits contributing up to two-thirds of all foodborne microbial illnesses. Their highly infectious nature and survival in pH and temperature extremes renders prevention by education, hygiene, and immunization (such as for hepatitis A) especially important in the protection against these illnesses:

Norovirus, due to its ability to be shed by asymptomatic individuals and its environmental stability, is considered the etiological agent responsible for most cases of foodborne gastroenteritis in the United States and worldwide accounting from 60% to 93% of all viral gastroenteritis cases. Infections occur following ingestion of airborne or foodborne (shellfish, water) viral particles without breaks occurring mostly in hospitals, nursing homes, and cruise ships. Expression of carbohydrates belonging to the ABH histo-blood group antigens that allow intestinal cell attachment by noroviruses renders the individuals more susceptible to virus infection. Generally mild clinical features of acute infection include fever, nausea, vomiting, diarrhea, abdominal cramps, headache, and myalgia with more severe and sometimes a fatal course in patients with immunosuppression (cancer or posttransplantation chemotherapy) and a chronic course in normal but stressed individuals. Secondary attacks occur at a high rate, resulting in high rates of transmission and large outbreaks. The high level of norovirus genetic variability in response to changing environment will likely pose considerable challenges to disease control by vaccination akin to the situation with influenza virus.

Rotavirus is the foremost cause of severe gastroenteritis of young children under 5, resulting in over 2 million hospitalizations and up to 600,000 deaths per year worldwide. Fever, nausea, vomiting, diarrhea, abdominal cramps, headache, and myalgia are also common features with the severity increasing in immunocompromised individuals (e.g., HIV, solid organ transplantation, bone marrow transplantation). Rotavirus diarrhea results from a combination of cell-damage-induced malabsorptive, viral enterotoxic peptide–mediated secretory, and enteric nervous system–mediated hypermotility components. Rotavirus enters extraintestinal sites including the blood, central nervous system (CNS), liver, spleen, and kidney. Whether this explains the occasionally reported sudden death, convulsions, and biliary atresia in children remains an investigation.

Hepatitis A and E induce foodborne illness at a rate of 3.77 cases/100,000 population with young adult men (age 25–39 years) at highest risk. Hepatitis A is transmitted primarily by the fecal–oral route and through contaminated food or drinks, especially uncooked fruits and vegetables and shellfish collected from contaminated habitats. After ingestion and absorption, the virus replicates in the liver and is excreted in bile, reaching the highest concentrations in the stool within 2 weeks at which time the risk of transmission is highest. Twenty percent of children age <3 years and 75% of adolescents and adults show symptoms of fever, malaise, abdominal pain, and jaundice lasting for 2 months or longer culminating in fulminant liver failure with the highest case-fatality rates occurring in adults >50 years. No specific therapy is available. Good hand hygiene, effective public water sanitation, and food hygiene are important. Immunoglobulin (from pooled plasma) and two inactivated hepatitis A vaccines offer a high degree of short-term and long-term protection, respectively (Leach, 2004). These measures appear to be paying off as evidenced by steadily declining cases each year. Hepatitis E outbreaks are rare in the United States and are related to consumption of contaminated drinking water during travel to endemic areas such as South Asia and North Africa where mortality rate, especially in pregnant patients, can be high (15%–25%).

Other foodborne microbial agents that contribute significantly to gastroenteritis toll around the world with increasing severity and duration in children, elderly, and immunocompromised individuals include the following: *Yersinia* sp. resulting from consumption of improperly cooked chitterlings (porcine large intestines) by people of African origin during major holidays; *Cryptosporidium* sp. from contaminated water and unpasteurized apple cider; *Cyclospora* infection from contaminated water and fresh berries; *Brucella* sp. from unpasteurized milk and meats from infected cattle, sheep, goats, and their products; and *viruses* such as astroviruses, enteric adenovirus, severe-acute-respiratory-syndrome-inducing coronavirus (SARS-CoV), toroviruses, human parechovirus, picobirnaviruses, cytomegalovirus, and herpes simplex virus.

Mycotoxins

From the standpoint of human and animal health, toxigenic molds belonging to the genera *Aspergillus*, *Fusarium*, and *Penicillium* have received the most attention owing to their frequent occurrence in food and feed commodities (Reddy

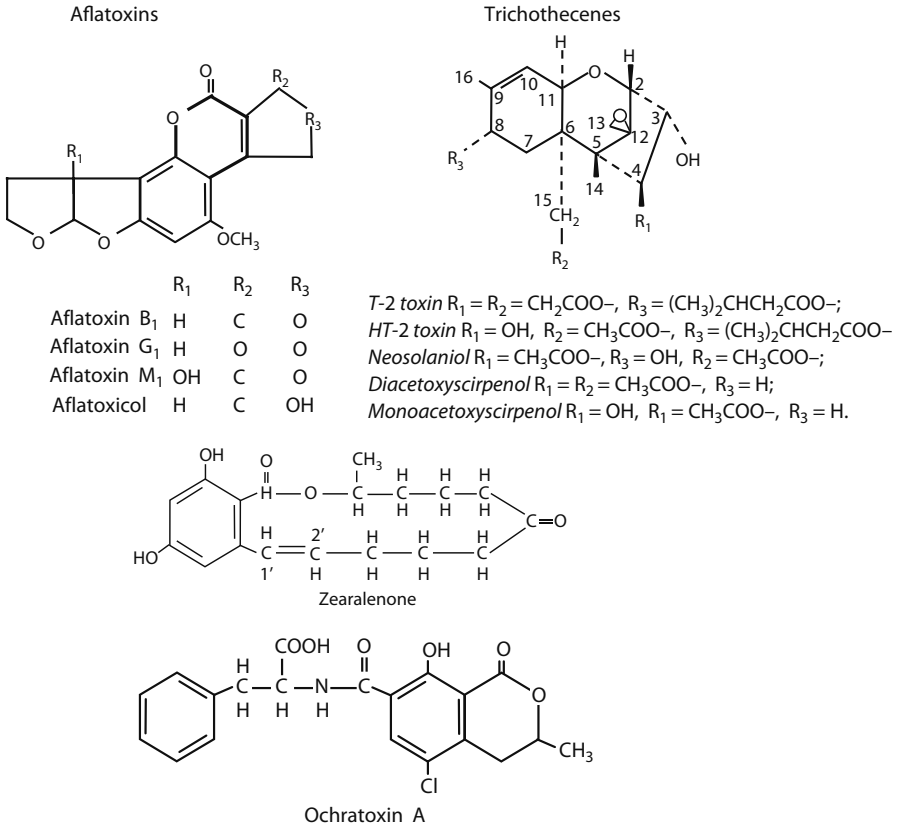

FIGURE 14.5 The structure of the mycotoxins, aflatoxins, trichothecenes, OTA, and zearalenone.

and Hayes, 2008). Unfavorable conditions such as drought and damage to seeds by insects or mechanical harvesting can enhance fungal toxin (mycotoxin) production during both growth and storage thus making mycotoxicoses a problem of both developing as well as developed countries. Although more than a hundred mycotoxins have been identified, the following discussion is limited to those with known public health significance. This subject has been recently reviewed (Bennett and Klich, 2003).

Aflatoxins are a group of highly substituted coumarins containing a fused dihydrofuran moiety (Figure 14.5) and are produced by *Aspergillus flavus* and *Aspergillus parasiticus*. Four major aflatoxins designated B1, B2, G1, and G2 (based on blue or green fluorescence under ultraviolet [UV] light) are produced in varying quantities in a variety of produce including peanuts, various other nuts, cottonseed, corn, cereal grains, and figs that have not been adequately dried at harvest and stored at relatively high temperatures (Busby and Wogan, 1981a,b). Human exposure can also occur from consumption of products containing the aforementioned contaminated food materials as well as from tissues and milk (AFM_1, a hydroxylated metabolite) of food animals that have consumed mold-infested feed.

Aflatoxin B_1 (AFB_1), the most potent and the most commonly occurring aflatoxin, is acutely toxic (LD50 0.3–0.9 mg/kg) to all species of animals, birds, and fishes (Coulombe, 1991). The sensitivity of the animals varies based on the balance between metabolic activation (cytochrome P450) and protection (glutathione [GSH] synthesis) mechanisms with the mouse being very resistant to the carcinogenic effects of AFB_1. Effects of AFB_1 in animals are predominantly on liver and include death without signs, or signs of anorexia, depression, ataxia, dyspnea, anemia, and hemorrhages from body orifices acutely. In subchronic cases icterus, hypoprothrombinemia, hematomas, and gastroenteritis are common. Chronic aflatoxicosis, characterized by bile duct proliferation, periportal fibrosis, icterus, and cirrhosis of liver and associated with loss of weight and reduced resistance to disease (immune suppression), is more prevalent in domestic animals and is also likely to occur in humans (Osweiler et al., 1985). Prolonged exposure to low levels of AFB_1 in animals also leads to hepatoma, cholangiocarcinoma, or hepatocellular carcinoma, and other tumors (Busby and Wogan, 1981a,b). Based on a review of various epidemiological studies, the U.S. National Research Council (NRC, 1996) concluded that the risk of primary hepatocellular carcinoma from AFB_1 exposure may be one in 10,000 in the United States. However, in populations infected with hepatitis B, the risk may be 10–100 times higher. AFB_1 is mutagenic following metabolic activation in many systems including HeLa cells, *Bacillus subtilis, Neurospora crassa, and S. typhimurium* (Busby and Wogan, 1981a,b). AFB_1 is partly metabolized by the cytochrome P450 system in the liver into a variety of reactive products (e.g., AFB_1 8, 9-epoxide) and forms adducts with protein and DNA (Hsieh, 1986). The DNA lesions lead to inactivation of the tumor suppressor

gene ρ53 due to G > T transversions of codon 249 and can explain a high proportion of liver cancer in high-aflatoxin-exposure areas (Guerin and Tioulong, 1979). Such effect biomarkers as well as exposure biomarkers such as AFB_1–DNA or AFB_1–albumin adducts can be used to assess the effectiveness of preventive strategies (Ellenhorn and Barceloux, 1988). By way of protein adducts, AFB_1 inhibits many enzymes involved in DNA synthesis, including DNA-dependent RNA polymerase activity, messenger RNA synthesis, and protein synthesis (Hsieh, 1986), which may be related to several lesions and signs of aflatoxicosis including fatty liver (failure to mobilize fats from the liver), coagulopathy (inhibition of prothrombin synthesis), and reduced immune function.

Other less widespread human clinical syndromes in which aflatoxins have been implicated include childhood cirrhosis in India, possibly Reye's syndrome in many parts of the world, and acute hepatitis (aflatoxicosis) in India, Taiwan, and certain countries in Africa (Shank, 1981).

Widespread concern regarding the toxic effects of aflatoxins in humans and animals and the possible transfer of residues from animal tissues and milk to humans has led to regulatory actions governing the interstate as well as global transport and consumption of aflatoxin-contaminated food and feed commodities. Action levels for total aflatoxins in corn and other feed commodities used to feed mature nonlactating animals range from 100 to 300 ppb. For milk, the action level is 0.5 ppb. For other commodities destined for human consumption and interstate and potential global commerce, the action limit is 20 ppb (FDA Compliance Policy Guides 7106.10, 7120.26, 7126.23):

Ergot alkaloids cause a condition known as ergotism, which is now rare. In the midsixteenth century, the condition was first associated with the consumption of scabrous (ergotized) grain (rye, oats, wheat) subsequently found to be contaminated with *Claviceps purpurea*. Lysergic acid derivatives, the peptides and the amine alkaloids of ergot, were identified as the causative agents of the gangrenous and nervous forms of the disease. The gangrenous form, resulting from a predominance of alkaloids with α-adrenergic (ergotoxine) and vasopressor (ergotamine) action (Kunkel and Jallo, 1990), is typically manifested as prickly and intense heat and cold sensations in the limbs and swollen, inflamed, necrotic and gangrenous extremities that eventually sloughed off. Convulsive ergotism, characterized by CNS signs, numbness, cramps, severe convulsions, and death and abortions in animals, results from the antiserotonin or adrenergic effects in the CNS as well as the uterotonic effects of many of these alkaloids when combined (Kunkel and Jallo, 1990).

Fumonisins, produced by *Fusarium moniliforme Sheldon*, are common fungal contaminants of cereals, especially corn, around the world. Contamination of corn by *F. moniliforme* as well as its major metabolites, fumonisins B_1 and B_2, can induce one of several human and animal diseases among which are leukoencephalomalacia (LEM) in horses; pulmonary edema in swine; renal and hepatotoxicosis in horses, swine, and rats; and hepatocarcinogenic effect in rats (Dutton, 1996). Recent evidence suggests that FB_1 increases chromosomal aberrations in primary rat hepatocytes (Knasmuller et al., 1997) and developmental effects in the offspring secondary to hepatotoxicity in pregnant mice (Reddy et al., 1996). Consumption of high levels of fumonisins in homegrown corn has been associated with higher incidence of human esophageal cancer in certain regions of South Africa and China, northern Italy, and the United States (Charleston, SC). Fumonisins induce neural tube defects in animals, and their presence in corn products is potentially linked to a cluster of anencephaly and spina bifida cases in Texas (Bennett and Klich, 2003; Marasas, 1995). Although the mechanisms of toxic and carcinogenic effects are not clearly understood, inhibition of sphingolipid biosynthesis (Voss et al., 1995), enhancement of lipid peroxidation (Abado-Becognee et al., 1998), elevated secretion of tumor necrosis factor-alpha (Duffy et al., 1997), depletion of GSH levels (Kang and Alexander, 1996), elevated nitric oxide synthesis (Rotter and Oh, 1996), induction of protein kinase C translocation via its action on phorbol ester binding site (Yeung et al., 1996), and inhibition of protein serine/threonine phosphatases (Fukuda et al., 1996) are among the effects that can explain some or all of the effects of FB_1.

Ochratoxins, a group of seven isocoumarin derivatives linked with phenylalanine by an amide bond, are produced by *Aspergillus ochraceus* and *Penicillium verrucosum* (among others) in barley, corn, wheat, oats, rye, green coffee beans, peanuts, wine, cocoa, dried fruits, certain grape wines, and tissues (e.g., pork) and blood from contaminated animals (Bennett and Klich, 2003; Scudamore, 1998). In experimental animals, ochratoxin A (OTA) produces predominantly renal proximal tubular lesions and liver degeneration. The oral LD50 of OTA ranges between 0.2 mg/kg for the dog and 59 mg/kg in mice. Association between consumption of high-level OTA in the diet and nephropathy in humans and swine in the Balkan countries and swine in Denmark and the United States has been clearly established (Krogh et al., 1977; Lloyd et al., 1985). Signs include lassitude, fatigue, anorexia, abdominal (epigastric or diffuse) pain, and severe anemia followed by signs of renal damage. Reduced concentrating ability, reduced renal plasma flow, and decreased glomerular filtration occur sequentially accompanied by gross and microscopic renal changes including necrosis, fibrosis with some tubular regeneration, glomerular hyalinization, and interstitial sclerosis. Death results from uremia. Ochratoxins are

teratogens and probable (International Agency for Research on Cancer (IARC) class 2B) carcinogens (Scudamore, 1998) inducing hepatomas and renal adenomas secondary to genotoxic effects in mice (Kanisawa and Suzuki, 1978).

Relevant cellular effects that mediate the effects of OTA include alteration in enzymes involved in glucose metabolism, ATP synthesis, anion transport, lipid peroxidation, prostaglandins, and extracellular signal-regulated kinases (Creppy et al., 1995; Kuramochi et al., 1997; Meisner and Cimbala, 1985; Schramek et al., 1997).

Psoralens are furocoumarin compounds that have been used in repigmenting achromatic skin lesions in an acquired disease called vitiligo, in some suntan lotions, and in drugs used to treat psoriasis (Busby and Wogan, 1981a,b). Abuse of such compounds can result in dermatitis following exposure to the sun along with nausea, vomiting, vertigo, and mental excitation. A phototoxic dermatitis in celery pickers has also been linked to the presence of psoralens (8-methoxypsoralen, 5-methoxypsoralen, and trimethylpsoralen) in stalks infected with *Sclerotinia sclerotiorum* (pink rot), *Sclerotium rolfsii, Rhizoctonia solani*, or *Erwinia aroideae*, or in celery stalks soaked in 5% NaCl (NAS, 1977). Fig, parsley, parsnip, lime, and clove also contain psoralens. 8-Methoxypsoralen appears to undergo epoxidation of the furan ring similar to aflatoxins and may thus react with DNA in a similar fashion. Treatment with 8-methoxypsoralen and UV led to squamous cell carcinomas of the ear in mice (Busby and Wogan, 1981a,b).

Unlike other photosensitizing agents, psoralens seem to act by photoreacting with DNA and to a lesser extent with RNA. The mechanism of psoralen photosensitivity appears to involve intercalation and cross-linking of psoralen in the DNA, which occurs in three steps: (a) reversible intercalation of psoralen between two pyrimidines on opposing sides of the helix; (b) formation of a monoadduct with the 5,6 double bond of the pyrimidine following absorption of one quantum of UV light; and (c) cross-link formation by absorption of a second quantum of UV light and linking of the monoadduct to the 5,6 double bond of thymidine (Scott et al., 1976). In general, there is an excellent correlation between photoadduct formation and photosensitization of psoralens.

Trichothecenes are a group of 12,13-epoxy trichothecenes produced by Fusarium poae, Fusarium tricinctum, Fusarium graminearum, Fusarium nivale, Fusarium solani, Myrothecium roridum, and Stachybotrys atra, among others, in cereal grains including wheat. The group of macrocyclic trichothecenes including satratoxins, verrucarins, and roridins is produced mainly by Stachybotrys sp. in hay. Although more toxic, this group does not pose significant human health threat due to lack of prevalence. Group A trichothecenes (T-2 toxin, diacetoxyscirpenol) contain a side chain and are relatively less polar compared to group B (nivalenol, deoxynivalenol [DON], fusarenon). A two-volume treatise of trichothecene toxins and their role in human and animal health is available (Beasley, 1989).

Most trichothecenes of health significance are produced by *Fusarium* sp. Characteristic signs of alimentary toxic aleukia (ATA), caused by T-2 toxin and related trichothecenes, including radiometric damage such as irritation and necrosis of skin and mucous membranes, hemorrhage, destruction of thymus and bone marrow, and hematologic changes; nervous disturbances; necrotic angina; and shock are common to all toxic syndromes (Beasley, 1989). Feed refusal, vomiting, and immune suppression are common problems caused by DON-contaminated wheat and corn in farm animals, especially swine and dogs, and possibly humans (Osweiler et al., 1985; Pestka and Smolinski, 2005). Paradoxically, nivalenol and DON exposure for prolonged duration induced autoimmune-like effects similar to human IgA nephropathy (Rotter et al., 1996). Trichothecenes (T-2 toxin) can cause fetal death, abortions, and teratogenic effects (Beasley, 1989). Although several trichothecenes are genotoxic in bacterial, yeast, and cell culture systems (Knasmuller et al., 1997; Tsuda et al., 1998), they exhibit no initiator or promoter effect in whole animal systems (Lambert et al., 1995).

Metabolism of trichothecenes occurs rapidly through deacetylation and hydroxylation and subsequent glucuronidation in the liver and kidneys (Beasley, 1989; Rotter et al., 1996) thus posing little problem of residues in meats from contaminated animals. At the molecular level, DON and other trichothecenes disrupt normal cell function by inhibiting protein synthesis via binding to the ribosome and by activating critical cellular kinases involved in signal transduction related to proliferation, differentiation, and apoptosis (Pestka and Smolinski, 2005). In addition, they also effect serotonergic pathways in the brain and induce expression of a number of cytokines (Rotter et al., 1996). Recently, the European Commission Scientific Committee on Food (SCF) and the Joint FAO/WHO Expert Committee on Food Additives (JECFA) established tolerable daily intakes of 1, 0.7, and 0.06 μg/kg body weight for DON, nivalenol, and the sum of T-2 and HT-2, respectively (Schlatter, 2004).

Zearalenone and zearalenol are nonsteroidal estrogenic contaminants (produced by *Fusarium roseum)* in grains such as corn, wheat, sorghum, barley, and oats. Zearalenone induces effects consistent with those produced by excessive steroidal estrogens, that is, anabolic and uterotropic activities and regulation of serum gonadotropins. Although

swine appear to be the most sensitive and exhibit signs of hyperestrogenic syndrome, that is, changes in serum luteinizing hormone, swollen and edematous vulva, hypertrophic myometrium, vaginal cornification and prolapse (in extreme cases), and infertility (Osweiler et al., 1985), human exposure to zearalenone and its metabolites by way of cereal products can also be significant. High frequency of premature menarche in Puerto Rico is suspected to be a result of high levels of zearalenone and similar compounds in the diet. Recommended safe daily human consumption of zearalenone appears to be 0.05 μg/kg body weight (Bennett and Klich, 2003).

Mode of action of zearalenone involves interaction with estrogen receptors, translocation of receptor–zearalenone complex to the nucleus, combination with chromatin receptors, selective RNA transcription leading to biochemical effects including increased water and lowered lipid content in muscle, and increased permeability of uterus to glucose, RNA, and protein precursors (Gentry, 1986). Available evidence indicates that rapid conversion of zearalenone and zearalanol to conjugated metabolites to be excreted in urine and feces makes consumption of meat and milk from animals receiving Ralgro an insignificant risk to humans.

Zearalenone is genotoxic in bacterial systems (Ghedira-Chekir et al., 1998), forms DNA adducts in female mouse tissues, and induces hepatocellular adenomas in female mice (Pfohl-Leszkowicz et al., 1995). Carcinogenic risk to humans and whether potentiative interaction exists between the adverse effects of zearalenone and those of dietary or endogenous estrogens as well as the xenoestrogens in the environment are unknown at the present time.

Other mycotoxins that have been identified either as contaminants in foods destined for human consumption or as metabolites of fungi isolated from human foods (Busby and Wogan, 1979) are summarized in Table 14.3. Although some of these have been associated with outbreaks of domestic animal diseases, the link between human consumption and disease is either emerging or nonexistent. Others have been shown to induce toxic and lethal effects in laboratory animals with no association between consumption of these toxins by animals or humans and a disease syndrome. Several of these, for example, cytochalasins and secalonic acid D (Reddy, 2005), have been used as research tools to expand our understanding of normal as well as abnormal cellular responses to xenobiotics.

Although it is difficult to assess the total significance of consumption of mycotoxins in human foods, it is easy to conceive that such a task requires extensive research into hundreds of known and potentially large number of as yet unknown mycotoxins. In spite of the vast number of toxic metabolites, reduction in mycotoxin levels in foods and feeds and the prevention of mycotoxicoses in humans and animals can be achieved for the most part by avoiding (1) stress in crops and (2) damage to seeds by pests and/or by mechanical harvesting. Rapid postharvest drying and avoiding conditions that promote mold growth during storage are equally important.

PREVENTION AND CONTROL OF MICROBIAL FOOD HAZARDS

The U.S. national animal health monitoring system has stepped up efforts to monitor food animal and poultry health on the farm and thus develop strategies to deal with potential increases in existing as well as emerging foodborne disease threats. The Food Safety Inspection Service (FSIS) of the USDA began implementing a hazard analysis and critical control point system (HACCP) for pathogen reduction in 1996 for all slaughter and processing operations. The HACCP directs each processing unit to (1) conduct a hazard analysis, (2) identify critical control points at which a safety hazard can be prevented, (3) establish limits at each point, (4) develop monitoring procedures and corrective action when limits are exceeded, and (5) implement record keeping that will allow subsequent verification by FSIS for compliance (Hogue et al., 1998). Data for *E. coli* and *Salmonella* burden of carcasses are used as evidence of fecal and enteric pathogen reduction. These two programs together with recent advances in the establishment of microbial genomic sequences and the development of PCR, DNA microarray, and proteomic methods will provide means for the rapid detection and identification of contaminating organisms and help minimize the incidence of foodborne disease from animal foods in the human populations. The recent approval by the FDA of low-dose irradiation of red meats to control pathogens coupled with previously approved irradiation of poultry for pathogen reduction; pork for control of trichinae; fruits, vegetables, and grains for insect control; and spices, seasonings, and dry enzymes used in food processing for microbial reduction (Andrews et al., 1998) should not only contribute to the reduction and potential prevention of foodborne disease caused by microbial pathogens but also help in increasing shelf life of such products without undesirable organoleptic, toxicological, or nutritional changes. Irradiation is yet to be approved for pathogen control of seafood products and is unsuitable for dairy products because of development of off-flavors and discoloration. In the final analysis, however, the keys to minimize the microbial foodborne illness is at the food preparer/consumer level in the form of hygienic processing, canning, and packaging; choosing reliable and clean food sources, water, and processing aids; cooking at the right temperature; avoiding cross-contamination (of cooked foods with raw); hygienic service (exclusion of infected food handlers from work); and/or prompt and appropriate storage and reheating. The Centers for Disease Control and Prevention (CDC) reports a significant decrease in foodborne disease burden in the last 10 years as a result of the existing regulatory and educational campaigns. It is hoped that the recently

TABLE 14.3
Miscellaneous Mycotoxins

Mycotoxin	Major Producing Organisms	Source of Fungi	Principal Toxic Effects
Alternariol and alternariol methyl ether	*Alternaria* sp.	Sorghum, peanuts, wheat	Highly teratogenic to mice; cytotoxic to HeLa cells; lethal to mice
Altenuene, altenuisol	*Alternaria* sp.	Peanuts	Cytotoxic to HeLa cells
Altertoxin I	*Alternaria* sp.	Sorghum, peanuts, wheat	Cytotoxic to HeLa cells; lethal to mice
Ascladiol	*Aspergillus clavatus*	Wheat flour	Lethal to mice
Austamide and congeners	*Aspergillus ustus*	Stored foodstuffs	Toxic to ducklings
Austadiol	*A. ustus*	Stored foodstuffs	Toxic to ducklings
Austin	*A. ustus*	Peas	Lethal to chicks
Austocystins	*A. ustus*	Stored foodstuffs	Toxic to ducklings; cytotoxic to monkey kidney epithelial cells
Chaetoglobosins	*Penicillium aurantiovirens, Chaetomium globosum*	Pecans	Toxic to chicks; cytotoxic to HeLa cells
Citreoviridin	*Penicillium citreoviride*	Rice	Neurotoxic, producing convulsions in mice
Citrinin	*Penicillium viridicatum, Penicillium citrinum*	Corn, barley	Nephrotoxic, swine
Cyclopiazonic acid	*Penicillium cyclopium*	Ground nuts, meat products	Nephrotoxic, enterotoxic
Cytochalasins	*A. clavatus* *Phoma* sp. *Phomopsis* sp. *Hormiscium* sp. *Metarhizium anisopliae*	Rice, potatoes, kodo millet, pecans, tomatoes	Cytotoxic to HeLa cells, teratogenic to mice and chickens
Diplodiatoxin	*Diplodia maydis*	Corn	Nephrotoxic and enterotoxic to cattle and sheep
Emodin	*Aspergillus wentii*	Chestnuts	Lethal to chicks
Fumigaclavines	*Aspergillus fumigatus*	Silage	Enterotoxic to chicks
Kojic acid	*A. flavus*	Squash, spices	Lethal to mice
Malformins	*Aspergillus niger*	Onions, rice	Lethal to rats
Maltoryzine	*Aspergillus oryzae*	Malted barley	Hepatotoxic and causes paralysis
Moniliformin	*F. moniliforme*	Corn	Cardiotoxic in rodents
Oosporein (chaetomidin)	*Chaetomium trilaterale*	Peanuts	Lethal to chicks
Paspalamines	*Claviceps paspali*	Dallisgrass	Neurotoxic to cattle and horses; causes paspalum staggers
Patulin	*Penicillium urticae*	Apple juice	Lethal to mice; mutagenic; teratogenic to chicks; pulmonary effects in dog; carcinogenic to rats
Penicillic acid	*Penicillium* sp.	Corn, dried beans	Lethal to mice; mutagenic; carcinogenic to rats
PR toxin	*Penicillium roqueforti*	Mixed grains	Hepatotoxic and nephrotoxic to rats; abortion in cattle
Roseotoxin B	*Trichothecium roseum*	Corn	Toxic to mice and ducklings
Rubratoxins	*Penicillium rubrum*	Corn	Causes hemorrhage in animals; hepatoxic to cattle
Secalonic acids	*Aspergillus aculeatus* *Penicillium oxalicum*	Rice, corn	Lethal, cardiotoxic, lung irritant, and teratogenic to mice
Slaframine	*Rhizoctonia leguminicola*	Red clover	Salivation and lacrimation in horses and cattle
Sporidesmins	*Pithomyces chartarum*	Pasture grasses	Hepatotoxic, causes photosensitization in ruminants
Sterigmatocystin	*A. flavus*	Mammals	Mutagen, carcinogen, and hepatotoxic to mammals
Tenuazonic acid	*Alternaria* sp.	Grains, nuts	Lethal to mice
Terphenyllins	*Aspergillus candidus*	Wheat flour	Hepatoxic to mice; cytotoxic to HeLa cells
Tremorgenic mycotoxins			
Fumitremorgens A and B	*A. fumigatus*	Rice	Neurotoxic (prolonged tremors and convulsions)
Paxilline	*Penicillium paxilli*	Pecans	Neurotoxic (prolonged tremors and convulsions)
Penitrems A, B, and C	*P. cyclopium*	Peanuts, meat products, cheese	Neurotoxic (prolonged tremors and convulsions) to cattle, sheep, dogs, and horses

(*continued*)

TABLE 14.3 (continued)
Miscellaneous Mycotoxins

Mycotoxin	Major Producing Organisms	Source of Fungi	Principal Toxic Effects
Tryptoquivalines	*A. clavatus*	Rice	Neurotoxic (prolonged tremors and convulsions)
Verruculogen (TR-1)	*Penicillium verruculosum*	Peanuts	Neurotoxic (prolonged tremors and convulsions)
Unidentified toxin(s)	*Aspergillus terreus* *Balansia epichloe* *Epichloe typhina* *F. tricinctum* and others	Fescue grass	Gangrene (fescue foot); summer slump syndrome; fat necrosis and agalactia in cattle
Xanthoascin	*A. candidus*	Wheat flour	Hepatotoxic and cardiotoxic to mice

Source: Condensed and modified from Busby, W.F. Jr. and Wogan, G.N., Foodborne mycotoxins and alimentary mycotoxicoses, in *Foodborne Infections and Intoxications*, 2nd edn., Riemann, H. and Bryan, F.L., eds., Academic Press, New York, pp. 519–610, 1979.

passed Food Safety Modernization Act of 2011, which imposes a broader range of food industry responsibilities for safer manufacture of food products and allows for a broader authority for federal enforcement, will make even greater strides in the prevention of such problems.

Potential person-to-person spread of microbial diseases via the medium of food and the modern day global nature of human travel and movement of food necessitates global harmonization of efforts in the prevention of the spread of foodborne disease agents. A recent collaborative effort between WHO, FAO, and the World Organisation for Animal Health resulted in agreement (1) to develop reporting and surveillance methods of the incidence of the diseases at the national and international level; (2) to develop international animal health standards for foodborne disease agents that do not cause clinical disease in animals; (3) to study farm ecology (environmental survival, multiplication, and spread and colonization in the animal) of foodborne pathogens; (4) to harmonize foodborne disease investigation and diagnostic methodology and quality control; and (5) to develop uniform application of risk-based farm-to-table approach when developing food safety standards (Magnuson et al., 2011).

NATURAL OCCURRING TOXINS IN THE FOOD SUPPLY

Mushroom Peptides

Cultivated mushrooms are, for the most part, safe. However, among the approximately 5000 species of mushrooms that exist in nature, at least 300 have been shown to be safely edible, while ingestion of up to 200 (generally collected from the wild) has been reported to be toxic and occasionally lethal (12 known) (Puschner and Wegenast, 2012) with 90% of the poisonings occurring in individuals under 19 years of age. One or more of the following classes of compound, cyclopeptide, orellanine, monomethylhydrazine, disulfiram-like, hallucinogenic indoles, muscarinic, isoxazole, GI-specific irritant toxins, are often involved in mushroom poisonings (Table 14.4).

Cyclopeptide toxicants are thermostable and are comprised of *amatoxin* (Figure 14.6), *phallotoxin*, *and verotoxin* groups, the latter two producing effects only at high doses. Approximately one-half of a mature cap of *Amanita verna* (destroying angel common in the United States) or *Amanita phalloides* (green death cap in Europe), containing amanitin, can be lethal in an adult (McPartland et al., 1997). Clinical effects that begin to appear after a 12 h latency period include epigastric tenderness, intense and cramping abdominal pain, nausea, vomiting, and severe secretory diarrhea (possibly bloody) and hepatomegaly with secondary acid–base disturbances, electrolyte abnormalities, hypoglycemia, dehydration, and hypotension. This is followed by elevation of liver enzymes (AST and ALT) and bilirubin, coagulopathy, hypoglycemia, acidosis, hepatic encephalopathy, hepatorenal syndrome, multiorgan failure (including pancreas, adrenal, and testes), disseminated intravascular coagulation, mesenteric thrombosis, convulsions, and death 6–16 days postingestion (Berger and Guss, 2005a). Fatalities are common (10%–30%) even following intensive symptomatic care, which includes fluid replacement, activated charcoal hemoperfusion, and forced diuresis. Penicillin therapy (by an unknown mechanism) and, in countries other than France and the United States, the use of silibinin (from the milk thistle plant, *Silybum marianum*) that prevents hepatocyte uptake of amatoxins have produced beneficial effects in direct relationship with the speed of onset of therapy (McPartland et al., 1997; Vetter, 1998). A return toward normal glucose, factor V, and fibrinogen is prognostic of recovery (McPartland et al., 1997) and may take several weeks to months. Amatoxins act by binding to and inhibiting RNA polymerase II and thus mRNA and protein synthesis leading to cell necrosis (Berger and Guss, 2005a; Vetter, 1998).

The other two groups of polypeptide toxins, the *phallotoxins and virotoxins*, are capable of causing toxic effects only at relatively high doses. The effects of phallotoxins include swelling of the liver due to engorgement of hepatic sinusoids with blood and depletion of blood in the peripheral circulation leading to shock. Reduction of cellular G-actin concentration by a combined effect of stimulated G-actin polymerization into F-actin and inhibition of F-actin depolymerization leading to a loss of membrane elasticity and thus to cell surface vesiculation leads to hepatocyte damage (Stob, 1983).

TABLE 14.4
Mushroom-Induced Syndromes

Syndrome	Mushroom Species	Toxic Compound(s)	Effects	Mechanism	Prevention/Treatment
Rapid onset:					
Gastrointestinal	*Chlorophyllum molybdites* *Entoloma lividum* *Omphalotus olearius* *Paxillus involutus* *Tricholoma pardinum*	Many unknown	Emesis, diarrhea	Unknown	Cooking/fluid replacement
Parasympathetic	*Inocyte* sp. *Clitocybe* sp. *Omphalotus illudens* *Amanita* sp.	Muscarine and related	Increased salivation, lacrimation, and urination; diarrhea; dyspnea; sweating; bradycardia; tremors, etc.	Parasympathetic stimulation	Avoid/atropine
CNS syndrome	*Psilocybe* sp. *Panaeolus* sp. *Copelandia* sp. *Gymnopilus* sp.	Psilocybin Psilocin	Hallucinations involving all sensations; hyperthermia, convulsions, coma, and death	Serotonin agonist	Avoid/diazepam and cooling
	Am. pantherina	Ibotenic acid, muscinol, stizolobic, and stizolobinic acid	Alternating depression and neuromuscular stimulation	Stimulation of bicuculline-reactive postsynaptic receptors	Avoid/diazepam and respiration
	Am. muscaria				
Alcohol sensitization	*Coprinus* sp. *Clitocybe clavipes* *Boletus luridus* *Verpa bohemica*	Coprine and others	Nausea, vomiting, headache, hypotension, tingling, palpitations, tachycardia, testicular damage, etc.	Inhibit acetaldehyde dehydrogenase	Avoid mushroom and alcohol/ supportive
Delayed onset:					
Headache	*G. esculenta* (false morel) *Gyromitra* sp.	Gyromitrin, monomethylhydrazine, etc.	Fatigue, head- and body ache, vomiting, liver damage, death, carcinogenic	Interfere with pyridoxine	Cook or dry, don't inhale vapors
Nephropathy	*Cortinarius* sp.	Orellanine Cortinarin	Polydypsia, oliguria, nausea, head and body aches, chills, etc. Renal tubular and liver necrosis, death	Membrane damage from oxygen-derived free radicals (similar to paraquat)	Hemodialysis
Carcinogenic	*Agaricus bisporus* (edible)	Agaritine, hydrazines	Lung tumors	Genotoxic	Cooking
Hepatotoxic	*Am. phalloides* (Europe) *Amanita virosa* (the United States) *Galerina* sp. *Lepiota* sp.	Amatoxins, phallotoxins, and virotoxins	Emesis and diarrhea, increase in serum enzymes, decrease in glucose and clotting factors, hepatic and renal damage, jaundice, coma, and death	1. Inhibit RNA polymerase 2. Enhance G-actin polymerization into F-actin 3. Inhibit F-actin depolymerization	1. Correct glucose and clotting effects 2. Decontaminate 3. Penicillin and silibinin 4. Supportive 5. Transplant liver

	R_1	R_2	R_3	R_4
α-Amanitin	OH	OH	NH_2	OH
β-Amanitin	OH	OH	OH	OH
γ-Amanitin	CH	H	NH_2	OH
ε-Amanitin	OH	H	OH	OH
Amanin	OH	OH	OH	H
Amanullin	H	H	NH_2	OH
Amaninamide	OH	OH	NH_2	H

FIGURE 14.6 The structures of amatoxins.

The following toxic syndromes produced by other (some nonpeptide) classes of mushroom toxins are summarized in Table 14.4 and discussed in detail (Berger and Guss, 2005b).

Certain degree of initial gastritis (vomiting) and/or enteritis (diarrhea) is a common feature of most mushroom poisonings. Delayed (for up to 3 weeks) acute *renal failure* (interstitial fibrosis and acute tubular necrosis manifesting as polyuria followed by oliguria) is caused by heat-stable bipyridyl orellanine, 2,2′ bipyridine-3,3′,4,4′-tetrol-1,1′-dioxide, or 3,3′,4,4′-tetrahydroxy-2,2′-bipyridine-N,N′-dioxide present in *Cortinarius orellanus, Cortinarius speciosissimus, Cortinarius splendens*, and *Cortinarius gentilis (in Europe) or Amanita smithiana* (*in the Pacific Northwest United States*). Toxicosis begins as weakness, lassitude, and headache and, in severe cases, hepatic failure developing over several days, resulting in hypoglycemia, delirium, and seizures progressing to coma and death, and is caused, especially in isoniazid-sensitive individuals, by a hydrolysis product (N-monomethylhydrazine) of the volatile nonpeptide toxin gyromitrin present in false morels represented by *Gyromitra* species, particularly *Gyromitra esculenta* in Europe. Renal failure can occur a few weeks after ingestion. Inhibition of gamma amino butyric acid (GABA) synthesis and/or induction of pyridoxine deficiency appears to be the contributory mechanism. *Am. smithiana* mushroom, easily mistaken for the matsutake or pine mushroom by overconfident collectors, poisoning presents within 6 h of ingestion with GI toxicity and develops delayed onset of renal insufficiency over the first 1–4 days. Mild elevation of hepatic transaminases peaks 24 h after the ingestion followed by renal injury by 3–5 days postingestion, earlier than with other orellanine-containing mushroom ingestion. Recovery can be expected with aggressive support requiring hemodialysis that may be discontinued after several weeks when creatinine returns to normal and urine output returns. This pattern of delayed-onset renal toxic mushroom ingestion is emerging among mushroom ingestions in Western North America (West et al., 2009).

A *disulfiram (Antabuse)-like* syndrome characterized by headache, paresthesias of the hands and feet, metallic taste, facial flushing, palpitations, tachycardia, orthostatic hypotension, chest pain, nausea, vomiting, and diaphoresis occurs if alcohol is consumed within 72 h after consumption of otherwise safe mushrooms, *Coprinus atramentarius* (common lawn mushroom) and *Clitocybe clavipes*. The syndrome lasts for up to 2 days and is induced by the amino acid coprine [N^5-(1-hydroxycyclopropyl)–L-glutamine]. 1-Aminocyclopropanol hydrochloride is a hydrolytic product of coprine that inhibits aldehyde dehydrogenase leading to accumulation of acetaldehyde from alcohol metabolism (Puschner and Wegenast, 2012).

A *cholinergic syndrome* characterized by salivation, lacrimation, abdominal pain, diarrhea, emesis, perspiration, and occasionally, miosis, rhinorrhea, flushed skin, bradycardia, and hypotension is induced by a heat-stable parasympathomimetic compound, muscarine, present in several lawn and park mushrooms of the genera *Inocybe* or *Clitocybe*. Muscarine activates ACh receptors on the heart, apocrine glands, and

smooth muscle. Nicotinic receptors are not affected unlike with insecticides that inhibit acetylcholinesterase. Because the toxin is not degraded by enzymes such as acetylcholinesterase, the binding to and stimulation of cholinergic receptors is indiscriminate (Puschner and Wegenast, 2012).

Psilocybin (O-phosphoryl-4-hydroxy-N,N-dimethyltryptamine), present in at least 75 mushrooms belonging to *Psilocybe* and *Panaeolus* and *Conocybe*, *Gymnopilus*, and *Stropharia* species, also called *funny* or *magic* mushrooms, alters brain catecholamine levels, especially serotonin, leading to lysergic acid diethylamide (LSD)-like signs including visual and auditory hallucinations, confusion, disorientation, inappropriate behavior, and mydriasis. Rarely, cardiotoxicity manifests as myocardial infarction and serious supraventricular tachycardia.

Beautifully colored mushrooms, *Amanita muscaria* and *Amanita pantherina*, contain isoxazoles (ibotenic acid and muscimol) whose thermostable metabolites stimulate N-methyl-D-aspartate (NMDA) and GABA receptors inducing a syndrome in which symptoms oscillate between various degrees of depression and hyperactivity associated with unrealistic and bizarre behavior.

Although *gastroenteritis* induced by most common mushrooms is mild, that induced by *Chlorophyllum molybdites* (found in lawns, fields, and open woods in southern and Midwestern United States) can be severe requiring immediate medical attention.

Other identified human conditions associated with mushroom production, commerce, and consumption are hypersensitivity to edible mushrooms in certain populations; hypersensitive allergic alveolitis and other pulmonary allergic changes in mushroom workers from spores of certain edible mushrooms (mushroom worker's lung); hemolytic reactions following consumption of mushrooms belonging to genera *Gyromitra*, *Boletus*, and *Paxillus*; and dermatitis (allergic) from contact with one or more species of the genera *Boletus*, *Lactarius*, *Calvaria*, and *Agaricus*. Treatment of such mushroom poisoning is mostly supportive.

Extracts and isolated metabolites from mushrooms can either enhance or suppress innate and acquired immunity leading to beneficial effects such as increased disease resistance, anticancer activity, suppression of autoimmune (T[H]1 type T-cell-mediated) and allergic (T[H]2 type T-cell-mediated) diseases. Mechanistically, low-molecular-weight (MW) metabolites affect apoptosis-, angiogenesis-, metastasis-, cell cycle-related signaling, and high-MW components (polysaccharides or polysaccharide–protein complexes) enhance innate and cell-mediated immune responses leading to altered mitogenic response, T-cell differentiation, and activation of immune effector cells such as lymphocytes, macrophages, and natural killer cells (Lull et al., 2005). Additional beneficial effects of mushrooms include inhibition of clotting and reductions in blood cholesterol and pressure (Berger and Guss, 2005b).

Toxicants in Food of Plant Origin

Foods of plant origin account for most (>70%) of the world's supply of protein. Although plants with obvious toxic effects have been excluded from human diet by trial and error, deleterious (toxic as well as antinutritive) effects from the following groups of compounds are deemed significant for human health.

Alkaloids are nitrogenous heterocyclic organic compounds that protect plants against herbivorous consumption and attack by insects, parasites, and competitors. Major alkaloid groups of concern from the standpoint of human consumption include pyrrolizidines, xanthines, and solanines. Others including piperidines from *Conium* and tobacco; quinolizidines from *Lupinus*. Indolizidines from *Astragalus*, *Swainsona*, and red clover are mainly consumed by grazing animals and can be potentially transferred to humans through milk.

Pyrrolizidine alkaloids (PAs) are a group of more than 300 plant metabolites, including the more toxic acyclic diesters and macrocyclic diesters such as retronecine, senecionine, and petasitenine, posing major threat to human and animal health by their ubiquitous presence in plants such as *Senecio*, *Crotalaria*, and *Heliotropium*. Human exposure and possible health effects result from the wide use of coltsfoot (*Tussilago*), comfrey (*Symphytum*), and petasites (*Petasites*) as herbal remedies, foods (salads), and tea; contamination of food grains with seeds from PA-containing plants; honey derived from pansy ragwort (*Senecio* sp.) and Patterson's curse (*Echium* sp.); and/or through milk from animals grazing alkaloid-containing plants mentioned earlier (Stegelmeier, 2011).

Highly reactive pyrrole derivatives of PA and/or their hydrolysis products formed by the action of mixed function oxidases are considered to be responsible for the toxic effects of PA. Many PAs and their pyrrole metabolites are bifunctional alkylating agents that cross-link to macromolecules including DNA, protein, amino acids, and GSH to produce adducts that inactivate these biomolecules. Typically, high mortality associated with endothelial proliferation and medial hypertrophy that causes occlusion of small branches of hepatic vein leading to liver dysfunction. Centrilobular hepatocyte necrosis and fibrosis (cirrhosis) with ascites/edema is more severe in children and experimental animals. Signs of liver damage include elevations of serum enzymes (AST, ALT, and others) and bilirubin, photosensitivity, and icterus (Stegelmeier, 2011). Simultaneous exposure of rats to bacterial endotoxin synergized the hepatotoxicity of monocrotaline (Yee et al., 2000). Occlusions in the renal and pulmonary arterioles can lead to renal disease with reduced urinary output, pulmonary hypertension, right ventricular hypertrophy, and ultimately to right heart congestive failure. PAs are developmentally toxic inducing lower jaw hypoplasia, musculoskeletal defects involving ribs, and general growth retardation in animals (Hirono, 1987) and hepatomegaly and ascites in humans (Rasenack et al., 2003).

PAs are mutagenic and are carcinogenic in experimental animals having been shown to induce one or more of the following types of cancer: leukemia, hepatic carcinoma, hemangioendothelial sarcoma in the liver, liver cell adenoma, cholangiosarcoma, astrocytoma, squamous cell carcinoma of

the skin, pulmonary adenoma, adenocarcinoma of the small intestines, adenomyoma of the ileum, and rhabdomyosarcoma in animals (Chen et al., 2010; NTP, 2011). Alterations in hepatocyte/endothelial vascular endothelial growth factor (VEGF), in KDR/flk-1 activation, and/or in other oncogenes and tumor suppressor genes such as *K-ras*, *beta-catenin*, and *p53* have been proposed as mechanisms leading to sustained endothelial cell proliferation and thus to hemangiosarcoma. Although no human data exist, riddelliine, a prototype genotoxic PA, is considered by the U.S. national toxicology programme (NTP) as a reasonably anticipated human carcinogen (NTP, 2011).

Solanum alkaloids including solanine, chaconine, and tomatine are found predominantly in potato, eggplant, and tomato (species of *Solanum* genus).

Potatoes, especially the sprouted, greened, blighted, injured, or spoiled, can contain greater than the USDA guideline of 20 mg/100 g of tuber. Exposure to light, immature tubers, wounding of potatoes, and stresses such as fungal attack can increase the content of *solanum alkaloids* severalfold (Beier, 1990) and may have contributed to intoxication in hundreds of cases of human poisonings (Morris and Lee, 1984). Signs of intoxication, some of which may be related to the irritant, estrogenic and cholinesterase-inhibiting activity of the alkaloids, in humans appear at >20 mg alkaloid/100 g of tuber and include headache, vomiting, diarrhea, neurological signs, debilitation, and even death. Recent studies suggest that these alkaloids may sensitize individuals to inflammatory bowel disease (Iablokov et al., 2010); may induce GI distress, dizziness, slurred speech, cranial nerve deficits, and ataxia (Smith et al., 2008); and may cause diabetes insipidus (Friedman et al., 2003). Prolonged exposure at lower doses of these alkaloids can cause increased liver to body weight ratios (Friedman et al., 2003) and antiandrogenic effects (Gupta and Dixit, 2002) in experimental animals. A combination of anticholinergic and antagonistic actions against TNFalpha-induced elevation of $[Ca^{2+}]i$ and plasminogen activator inhibitor likely accounts for these actions.

Exposure of pregnant rats to certain alkaloids including solanine, solasodine, choconine, and cytochalasins B, D, and E resulted in minor skeletal to major facial and CNS abnormalities in the offspring, whereas that of others such as tomatidine were without effects (Schardein, 1985). Baking, boiling, or microwaving does not destroy these alkaloids. Protection of tubers from sunlight, γ-irradiation, soaking in water under controlled conditions, dipping damaged potatoes in emulsified water, treating potatoes with sprout inhibitors during storage, waxing and heating, dipping in oils (corn, olive, or mineral), spraying tubers with lecithin (such as PAM), or simply spray rinsing tubers with an aqueous solution of an edible surfactant (Tween 85) appear to be some simple methods to prevent glycoalkaloid formation during storage (Sharma and Salunkhe, 1989).

The xanthine alkaloids, caffeine, theobromine, and theophylline, are found as major components of coffee (*Coffee arabica*), cocoa (*Theobroma cacao*), and tea (*Thea sinensis*), respectively. Caffeine, in addition, is added to many beverages, foods, and medications (Ellenhorn and Barceloux, 1988). Caffeine-related adverse effects begin when 0.5–1.0 g of caffeine (10 cups of coffee) is ingested by an adult with possible fatalities at 5 g in children and 5–10 g in adults (Daly, 1993; Ellenhorn and Barceloux, 1988). Caffeine and other methylxanthines enhance the release of catecholamines, inhibit phosphodiesterase leading to intracellular accumulation of cyclic AMP, block adenosine receptors, and cause increased release of Ca^{2+} from the terminal cisternae of the sarcoplasmic reticulum (Daly, 1993). Major effects of xanthines involve CNS stimulation (hyperesthesia to convulsions), emesis, cardiovascular effects (cardiac stimulation to arrhythmias), diuresis, and smooth muscle effects leading to decreased vascular resistance and bronchodilation (Daly, 1993). In addition, caffeine enhances gastric secretion of acid and pepsin. In habitual coffee drinkers, cessation of caffeine consumption often results in a withdrawal syndrome characterized by headache, fatigue, drowsiness, depression, difficulty concentrating, irritability, and lack of clarity in thinking among other symptoms (Juliano and Griffiths, 2004). Caffeine increases serum homocysteine, a risk factor for cardiovascular disease (Verhoef et al., 2002), and induces bone loss in postmenopausal women (Rapuri et al., 2001). Caffeine and theobromine are mutagenic in bacterial systems and can potentiate DNA damage caused by other genotoxicants but are neither directly carcinogenic in animals nor associated with human cancer (Ames, 1983; Daly, 1993). Caffeine actually appears to protect against certain cancers, type II diabetes, preeclampsia of pregnancy, and development of parkinsonism (Ascherio et al., 2001; Khoury et al., 2004; Salazar-Martinez et al., 2004). Caffeine is teratogenic in experimental animals causing mostly limb and facial defects (Schardein 1985). Although high caffeine consumption during pregnancy may increase the risk of spontaneous abortion and low birth-weight babies, no correlation exists between caffeine consumption and birth defects in humans (Khoury et al., 2004; Spencer et al., 1987). Greater danger, however, appears to be associated with combined consumption of caffeine with other vasoactive herbal ingredients and medications. Oral exposure to caffeine (30 mg/kg) along with ephedrine (25 mg/kg) in rats (1.4- and 12-fold, respectively, above average human exposure) resulted in death of rats within 4–5 h accompanied by massive interstitial hemorrhage and degeneration and necrosis of myofibers in the myocardium of the left ventricle and interventricular septum (Nyska et al., 2005). The Canadian government (Nawrot et al., 2003) issued guidelines to limit daily caffeine consumption to 400 mg (~eight cups of coffee) in healthy adults, 300 mg (~six cups of coffee) in women of reproductive age, and 2.5 mg/kg in children, as did the U.S. FDA for pregnant women (Daly, 1993).

Cyanogenic glycosides that release highly toxic hydrocyanic acid upon hydrolysis are derived not only from plants (more than 2000) but also from fungi, bacteria, and even members of the animal kingdom (Montgomery, 1980). Although cassava, sweet potatoes, yam, maize, millets, bamboo, sugarcane, peas, beans, almond kernel, lemon,

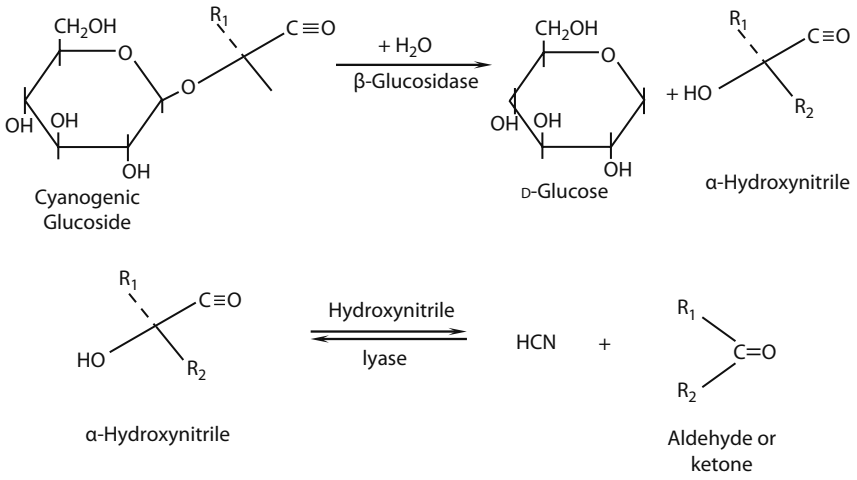

FIGURE 14.7 Enzymatic hydrolysis of cyanogenic glycosides.

lime, apple, pear, cherry, apricot, prune, and plum constitute sources for humans, poisonings are mainly associated with the consumption of improperly processed cassava in Africa, Asia, and Latin America (Barceloux, 2009). Among more than 20 glycosides identified, only four (i.e., prunasin, amygdalin, dhurrin, linamarin, and lotaustralin) appear to be of toxicologic importance (Barceloux, 2009). Cyanogenic lipids, although of unknown toxicological significance, are also present in plants and yield carbonyl compound and HCN upon hydrolysis (Deshpande and Sathe, 1991).

The hydrolysis of the glycoside is triggered by physical disruption (mastication, trampling, etc.) or stress (drought, cooking, frost, etc.) and is catalyzed by β-glucosidase and hydroxynitrile lyase, which are present within the plant or in bacteria in the GI tract of man and animals (Poulton, 1983). The scheme of breakdown leading to the formation of glucose and hydroxynitrile from the glycoside followed by breakdown of hydroxynitrile into carbonyl compounds and HCN is presented in Figure 14.7. Mitochondrial rhodanese catalyzes the conversion of HCN to thiocyanate in the presence of thiosulfate (Poulton, 1983).

Initially, the glycoside is hydrolyzed by a β-glucosidase releasing glucose and α-hydroxynitrile. The hydroxynitrile dissociates either enzymatically or nonenzymatically to yield HCN and the corresponding aldehyde or ketone.

Animals have often been acutely poisoned by young sorghum and arrow grass. Young bamboo shoots and tea made from peach leaves are examples of dietary sources of HCN poisoning in children. The minimal lethal dose of HCN in man and animals is 0.5–3.5 and 2–10 mg/kg, respectively. The acute effects of HCN result from its affinity toward metalloporphyrin-containing enzymes, more specifically cytochrome oxidase. Cyanide concentration of only 33 μM can completely block electron transfer through the mitochondrial electron transport chain and thus prevent O_2 utilization (Poulton, 1983). Death results from generalized cytotoxic anoxia. Signs of acute cyanide poisoning in humans are hyperventilation, headache, nausea and vomiting, generalized weakness, coma, and death due to respiratory depression and failure. Treatment of acute cyanide intoxication involves, in addition to artificial respiration, the conversion of hemoglobin in the blood to methemoglobin with nitrites (sodium or amyl). Methemoglobin competes with cytochrome oxidase for HCN and forms cyanmethemoglobin. Coadministration of sodium thiosulfate will convert free cyanide present in the blood to thiocyanate, which is eliminated in the urine. As free cyanide in the blood decreases, additional cyanide dissociates from the cyanmethemoglobin and is subsequently eliminated (Chen and Rose, 1952).

Tropical ataxic neuropathy (TAN), characterized by myelopathy, bilateral optical atrophy, deafness, and polyneuropathy (konzo), is an irreversible upper motoneuron paralytic disease (Banea-Muyambu et al., 1997) of women and children. Goiter, epigastric burning pain, dizziness, and abdominal distension/vomiting (Abuye et al., 1998) have been linked to longer-term consumption of cassava diets in Africa and other tropical countries (Osuntokun, 1973). These diets were also poor in protein and sulfur-containing amino acids that can detoxify HCN to thiocyanoalanine and subsequently to inert 2-amino-4-thiazolidine carboxylic acid (Poulton, 1983). Although the chronic effects of cyanogen exposure were earlier thought to be due to thiocyanates, recent evidence suggests that both linamarin and cyanide directly interact with methionine and cysteine making them unavailable for GSH synthesis and thus lead to GSH depletion leading to konzo in humans and animals (Banea-Muyambu et al., 1997; Nunn et al., 2011; Soto-Blanco et al., 2002). The recent introduction of a transgenic cassava (Biocassava+) with improved nutritional quality and longer shelf life, reduced glycoside content, and resistance to viral diseases is expected to reduce the incidence of konzo (Sayre et al., 2011).

Cycads, the palmlike plants adapted for adverse climatic conditions of the tropical and subtropical areas of the world, are still used (seeds and stem) as a source of starch in Guam, Kenya, Amami Oshima, Miyako Island, and southern Japan by small groups of people (Matsumoto, 1983). Adverse effects result from incomplete extraction of toxicants, including cycasin and β-N-methylamino-L-alanine (BMAA), during

preparation of the flour. Several neurologic conditions including a paralytic disease (amyotrophic lateral sclerosis [ALS]) and Parkinsonism–dementia (PD) have been reported among the native Chamorro in Guam resulting from the consumption of cycad. Gait disturbances, motor weakness, and paralysis have also been reported in cattle grazing on cycads. Parkinsonian features and degenerative changes in CNS motor neurons in monkeys and, very importantly, Alzheimer's dementia (AD) in human appear to be related to cycad toxicants, especially BMAA (Matsumoto, 1983; Murch et al., 2004; Spencer et al., 1987). In this regard, it is important to note that BMAA has been shown to be produced by potentially all Cyanobacteria (Cox et al., 2005) in many parts of the ecosystem including the root tissues of cycad trees. BMAA also accumulates in cycad seeds and is biomagnified by seed-eating flying foxes that, in turn, are consumed by the Chamorros.

BMAA has been found in the brains of Chamorros that died of neurodegenerative ALS/PD syndrome and in Canadians with AD (Murch et al., 2004), suggesting the possible involvement of Cyanobacteria as an etiological factor for AD. However, the inability to reproduce these findings (Montine et al., 2005) and the failure to produce lesions of AD in experimental animals fed with BMAA question this hypothesis. Mechanistically, attenuation of the cycad-induced neurotoxic syndrome by AP7 and MK801, two selective antagonists of the NMDA receptor and its associated ion channel, suggests a role of the excitatory neurotransmitters in the causation of ALS–PD, other motor-system diseases (Huntington's chorea, Parkinson's disease, and olivopontocerebellar atrophy), and possibly Alzheimer's disease (Spencer et al., 1987). Other effects of cycasin, its aglycone, or cycad flour include hepatic necrosis; subserosal hemorrhages; accumulation of yellow fluid in serosal cavities; benign and malignant tumors in the liver, kidney, lungs, and GI tract (mainly colon); neuroteratologic effects in offspring; death in experimental animals; and mutagenic effects in a variety of in vitro and in vivo systems.

Interestingly, cycasin is neither toxic nor carcinogenic when given parenterally to conventional rats or when given either orally or parenterally to germ-free rats, suggesting that the intestinal flora mediates cycasin toxicity. Bacterial β-glucosidase hydrolyses cycasin to the active carcinogen, methylazoxymethanol (MAM), which produces hepatomas in rats. MAM spontaneously breaks down to methyldiazonium hydroxide, which methylates hepatic DNA, RNA, and some enzymes (Matsumoto, 1983). Certain cycad glycosides inhibit aromatase and may be useful in the treatment of estrogen-dependent cancer (Kowalska et al., 1995).

Enzyme inhibitors present in plant and animal foods can inhibit the action of proteases, amylases, and lipases. However, only the inhibitors of proteases pose some hazard to human health. Although most of protease inhibitors (PIs) are active against serine and cysteine proteases (serpins and cystatins), PIs active against aspartic proteases and carboxypeptidases have also been identified. Pancreatic lipase inhibitors from a variety of plants are being exploited for their antiobesity effects, whereas the PIs appear to have anticancer effects (Clemente et al., 2011; de la Garza et al., 2011).

Kunitz inhibitor and the lower-MW Bowman–Birk inhibitor are the major PIs found in soybeans. They are acid and heat labile and capable of inhibiting trypsin- and chymotrypsin-like proteases involved in carcinogenesis. The fact that significant amounts of these inhibitors reach the large intestines may explain their protective effect against colorectal cancers (Clemente et al., 2011; Kassell, 1970). Egg white, milk, beans, peas, cereal grains, alfalfa, sunflower, and potatoes also have been shown to contain one or more PIs (Janssen, 1997).

The potential adverse effects of PIs include hypertrophy, adenomas and nodular hyperplasia of pancreas, growth depression, and allergic reactions in atopic children (Friedman and Brandon, 2001; Liener, 1980). Pancreatic hypertrophy is likely from constant pancreatic hypersecretion necessitated by release of a humoral agent cholecystokinin pancreozymin in the upper small intestine in response to a deficit in free digestive enzymes (Gallaher and Schneeman, 1984). Although any single source such as soybeans is unlikely to be consumed by humans in quantities of toxicological significance, consumption of multiple sources of PIs may increase the risk of pancreatic hypertrophy and cancer. Ironically, soybean and other trypsin inhibitors are gaining attention for their preventive and inhibitory effects on initiation, promotion, as well as metastasis of cancer induced by many agents in multiple tissues (DeClerk and Inven, 1994; Friedman and Brandon, 2001). Recent studies suggest that Bowman–Birk inhibitor–induced specific proteasomal inhibition leads to alterations in cell cycle proteins and to cell cycle arrest and thus accounts for anticancer effects of these agents (Chen et al., 2005). The contribution of other mechanisms such as inhibition of enzymes involved in oxygen-free radical formation and induction of amino acid deprivation in cancer cells by protease inhibition is yet to be investigated.

Estrogens in plants (phytoestrogens) include flavonoids, isoflavonoids, chalcons, coumestans, stilbenes, lignans, ginsenosides, and other saponins, as well as the recently discovered tetrahydrofurandiols (Lorand et al., 2010). Hundreds of species of plants contain plant sterols and estrogenic isoflavonoids (e.g., genistein, glycetein, daidzein) and/or their glycosides (genistin, glycetin, daidzin), coumestans (e.g., coumestrol, 4-O-methylcoumestrol), and lignans (Adams, 1989; Stob, 1983). Phytoestrogens, although capable of causing infertility in animals grazing heavily on estrogen(coumestan)-containing forages (subterranean clover, alfalfa), have not been proven to cause human health problems. The fungal estrogens, zearalenone and zearalenol, are two major resorcylic acid lactone estrogens produced in corn in response to infection by toxigenic strains of the fungus *F. roseum* and are discussed in the section dealing with the mycotoxins.

Xenoestrogens including dichloro diphenyl trichloroethane (DDT) and its metabolites, bisphenols, alkylphenols, dichlorophenols, methoxychlor, chlordecone, polychlorinated biphenyls (PCBs), and dioxins act via estrogen receptors alpha and beta, nuclear or membrane-bound receptors, receptor-independent mechanisms, or by interference with

the production and metabolism of ovarian estrogens. A mass balance of dietary levels of industrial and natural estrogens, coupled with their estimated estrogenic potencies, indicates that the dietary contribution of estrogenic industrial compounds is 0.0000025% of the daily intake of estrogenic flavonoids in the diet (Safe, 1995). These xenoestrogens are not covered in this chapter.

The average human adult is exposed to 102 μg dietary estrogenic equivalents (reflecting both potency and exposure) daily compared to 3.35 mg/day from estrogen replacement therapy and/or 16.7 mg/day from oral contraceptives (Safe, 1995). The exposure of consumers, especially infants, to high soy content is likely to be significant. Human infants can be exposed to 4 mg/kg body weight or more of isoflavones from soy-based formulas (Aldridge and Tahourdin, 1998). A recent study (Behr et al., 2011), however, estimated the dietary intake of phytoestrogens to be lower than previously estimated (27.5 and 34.0 ng EEQ/day for adults and 1.46 ng EEQ/day for infants). Although phytoestrogens bind to multiple steroid (estrogen, progesterone, and androgen) receptors, they are considered to be selective estrogen receptor β-modulators (SERM). Due to their lower potency (500–10,000 times) compared to estradiol, phytoestrogens can actually impede the action of endogenous estrogen and at higher doses can induce antigonadotropic effects at the hypothalamic, pituitary, and gonadal levels in both sexes (Aldridge and Tahourdin, 1998). Their multiple inputs into cellular signaling begin processes that eventually integrate at the level of mitogen-activated protein kinase activities to coordinately regulate broad cellular destinies, such as proliferation, apoptosis, or differentiation, which may account for their typical nonmonotonic dose–response behavior (Watson et al., 2010).

Effects of phytoestrogens reported in feed animals include infertility in sheep fed with subterranean clover and cattle consuming alfalfa (Altekruse et al., 1998). Feminization of males following developmental exposure has also been reported (Clarkson, 1995). Recent reports of detrimental effects of high levels of phytoestrogens in soy-based products on learning, memory, and anxiety behaviors in male, but not female, rats (Lephart et al., 2004) suggest the need for caution in soy-formula feeding of male infants. Although phytoestrogens appear to be noncarcinogenic when given orally (Verdeal et al., 1980), some (genistein, coumestrol, quercetin, zearalenone, resveratrol, and some metabolites of daidzein) are genotoxic and all exhibit proapoptotic effects in vitro (Bartholomew and Ryan, 1980; Stopper et al., 2005). In humans, reversible changes in menstrual cycle and follicle-stimulating hormone (FSH) and luteinizing hormone (LH) surges in premenopausal women appear to result from soy consumption, but no developmental or infertility problems were noted in populations consuming large quantities of phytoestrogen (Aldridge and Tahourdin, 1998). Phytoestrogens may actually exert antioxidant activity and may protect humans against coronary heart disease; cancer of the breast, prostate, and colon; obesity; and postmenopausal osteoporosis (Adlercreutz, 1995; Beck et al., 2005; Lephart et al., 2004). The results of a study of 939 postmenopausal women participating in the Framingham Offspring Study revealed that a higher intake of phytoestrogens was associated with a favorable metabolic cardiovascular risk profile (de Kleijn et al., 2002).

Phytosterols (campesterol and sitosterol and their 5α-saturated stanols) are normal dietary components (200–300 mg/day) that chemically resemble and thus potentially interfere with absorption of dietary cholesterol and together reportedly decrease the incidence of coronary heart disease by 20%–25% (Gylling and Miettinen, 2005). Paradoxically, high levels of plasma phytosterols alone may be associated with increased coincidence of coronary heart disease. Because plant stanol esters reduce absorption and serum concentrations of both cholesterol and plant sterols, beneficial supplementation of human diets over the long term may be better accomplished with the use of plant stanols alone.

Glucosinolates (GS) are a group of more than 100 flavor-imparting thioglucoside compounds found at up to 60 mg/g in crucifers such as broccoli, cabbage, Brussels sprouts, cauliflower, calabrese, turnip, radish, horseradish, mustard, and rapeseed and related plants. Common names of some important GS include sinigrin, progoitrin, epiprogoitrin, glucobrassicin, neoglucobrassicin, and glucoraphanin. The parent GS as well as their products of plant and human digestive tract bacterial myrosinase (thioglucosidase) hydrolysis (isothiocyanates, nitriles, oxazolidinethione [OZT], thiocyanate ions, and more notably sulforaphene) have been reported to produce biological effects (Verkerk et al., 1998).

Although evidence is lacking in humans, thiocyanate ion inhibits the uptake of iodine by the thyroid leading to iodine-reversible hyperplasia and hypertrophy of the thyroid (cabbage and legume goiter) and growth suppression in animals. OZT also inhibits thyroxin synthesis and induces goiter (brassica seed goiter) in rats by inhibiting the incorporation of iodine into precursors of thyroxin (Matsumoto et al., 1968). This condition is not reversible by iodine supplementation. In addition to goiter, epiprogoitrin and progoitrin also induce liver and kidney enlargement and death at 2.6% in the diet via their nitrile metabolites (Van Etten and Tookey, 1983). Bile duct hyperplasia, hepatocyte necrosis, and megalocytosis of renal tubular epithelium were also seen in these animals (Tookey et al., 1980).

Isothiocyanates are embryocidal and cause fetal weight reduction (Beier, 1990). Isothiocyanates and certain GS (e.g., sinigrin) are mutagenic in the Ames assay, and certain desulfo precursors of GS may be carcinogenic, whereas thiocyanates are not (Beier, 1990; Weil et al., 2004). Moderate intake of cruciferous vegetables in man and animals, however, may exert anticarcinogenic effects attributable to the formation of isothiocyanates (at least 7), indoles, indole-3-carbinol, 3-indoleacetonitrile, and 3,3′-diindolylmethane (Verkerk et al., 1998). The chemoprotective effects of GS appear to result from a variety of distinct but interconnected signaling pathways involving detoxification, inflammation, apoptosis, and cell cycle and epigenetic regulation, among others (Navarro et al., 2011). A recent qualitative comparison of the

benefit and risk of broccoli consumption shows that the benefit from intake in modest quantities and in processed form outweighs potential risks (Latte et al., 2011).

Lectins (phytohemagglutinins) are high-MW (100,000–150,000) heat-labile proteins, lipoproteins, or glycoproteins (up to >10% of total seed protein) detected in over 800 edible plant species of which 600 belong to the Leguminosae (beans, peas) and in animals such as sponges, crustaceans, mollusks, fish blood, amphibian eggs, and even mammalian tissue. They possess the ability to agglutinate erythrocytes with known carbohydrate specificity since they have at least one noncatalytic domain that binds reversibly to specific monosaccharides or oligosaccharides. Animal lectins are usually present in low levels compared with the yields of plant lectins such as legume lectins and manifest a diversity of beneficial activities including antibacterial, antinematode, antitumor, immunomodulatory, antifungal, HIV-1 reverse transcriptase inhibitory, and anti-insect activities (Deshpande and Sathe, 1991; Lam and Ng, 2011).

Interactions of animal lectins such as annexin and galectin with animal cell proteins such as bcl2 and synexin and subsequent triggering of signaling cascades bestow them with an ability to regulate various endogenous functions involving glycoprotein and cell (normal and tumor) recognition, adhesion, and clearance; signal transduction; extracellular glycoprotein trafficking; and mitogenesis, apoptosis, and immune function (Mody et al., 1995; Van Damme et al., 2004).

Upon ingestion, plant lectins such as *concanavalin A* and *phytohemagglutinins* survive digestion by the GI enzymes and bind to membrane glycosyl groups of the cells lining the digestive tract. This leads to nonspecific inhibition of digestion and active and passive absorption of many nutrients (amino acids, fats, vitamins, minerals, thyroxin, etc.) across the intestinal mucosa, alters the bacterial flora, modulates the immune status of the digestive tract, damages the luminal membranes of the epithelium, and induces necrosis of intestinal epithelial cells (King et al., 1980; Vasconcelos and Oliveira, 2004). These effects account for the immediate effects including nausea, vomiting, and diarrhea as well as growth suppression and possibly goiter after long-term oral exposure to high levels (Janssen et al., 1997; Vandenborre et al., 2011). Mortality following acute systemic lectin exposure is associated with damage to the liver (Ikeguonu and Bassir, 1977) and other organs. The most toxic lectin, ricin from castor bean (lethal dose in humans of 1–10 μg/kg body weight), can cause severe intestinal epithelial cell necrosis and death from multiorgan damage (Van Genderen, 1997). Recent evidence suggests that lipid peroxidation mediated by reactive oxygen species may be involved in ricin-induced thyroid damage (Sandani et al., 1997). The lectin portion (B chain) of the ricin dipeptide binds the galactosyl residues on the surface of intestinal epithelial cells and facilitates the intracellular uptake of the enzymatic (RNA-specific N-glycosidase) A chain via clathrin-dependent as well as clathrin-independent endocytosis. The A chain then enters the golgi and ER, inhibits protein synthesis, and causes cell death (Sandvig and Van Deurs, 1997; Van Genderen, 1997). Less toxic lectins may act by the same mechanism to stimulate protein synthesis, mitogen activation, and immune stimulation.

Although ricin has been suggested as a potential warfare/terror agent via contamination of water/food, a substantial mass of the pure powder is required. In addition, the potential for success is low due to variables such as reticulation management, chlorination, mixing, and bacterial and UV light degradation. Injection is not a realistic option for large populations. Dermal absorption of ricin has not been demonstrated. Ricin, administered by inhalation, can be lethal from progressive and diffuse pulmonary edema with associated inflammation and necrosis of the alveolar pneumocytes; however, the technical and logistical skills required to achieve the ideal aerodynamic equivalent diameter for entry into the lungs are generally beyond the ability of most terrorists. These challenges make ricin generally unsuitable as an agent of bioterrorism (Schep et al., 2009).

Although *lipids* are essential for normal development, growth, and cellular function, their overconsumption has been associated with weight gain, obesity, cardiovascular disease, and metabolic syndrome, which, in addition to the aforementioned, is characterized by increased propensity for type 2 (insulin-resistant) diabetes. Factors such as a departure from established food use patterns, the use of new lipids in the human diet, or inborn errors of metabolism (due to polymorphism) act in concert with lipid overconsumption to induce hyperlipidemia and cardiovascular disease including hypertension and obesity. Recent evidence implicates a positive feedback circuit between high dietary fat and increase in brain galanin (GAL), a feeding stimulant peptide, in the onset of human overeating syndrome and obesity (Leibowitz, 2005). Mechanistically, circulating lipids interact directly (as fatty acids) or indirectly (via biosynthetic intermediates such as prostaglandins and leukotrienes or via the interaction of lipids and their derivatives such as diacylglycerol) with a variety of signal transduction pathways and transcription factors such as peroxisome-proliferator-activated receptor, liver X receptor, hepatocyte nuclear factor 4, carbohydrate-response-element-binding protein, farnesoid X receptor, sterol-regulatory-element-binding protein (SREBP) (Roche, 2004). These interactions lead to alterations in the expression of genes (such as adipocytokines) that mediate cellular responses involved in inflammation, a prerequisite to insulin resistance and diabetes. Paradoxically, dietary supplementation with monounsaturated fatty acids (oleic and omega- or alpha-3 fatty acids) and conjugated linoleic acids can prevent and/or reverse the onset of insulin resistance/metabolic syndrome by altering membrane fluidity and signaling and reducing adipose tissue TNFα and subsequent alterations in SREBP (Riccardi et al., 2004; Roche, 2004).

Erucic acid (*cis*-13-docosanoic acid) is predominantly a component of rape- (*Brassica napus* and *Brassica campestris*) and mustard (*Brassica hirta* and *Brassica juncea*) seeds. Canada, Argentina, Mexico, China, India, Pakistan, Japan, and several European countries are the major producers and users of these oils. Growth suppression, myocardial fatty infiltration, mononuclear cell infiltration, and fibrosis

were observed in weanling rats fed with erucic acid at levels supplying greater than 20% of the dietary calories. In addition, ducklings showed hydropericardium and cirrhosis, and guinea pigs developed splenomegaly and hemolytic anemia (Mattson, 1973). Organ-specific inhibition of glutamate oxidation and adenosine triphosphate (ATP) synthesis in cardiac mitochondria (Houtsmuller et al., 1970) could be mechanistically involved in the pathogenesis of these lesions. In humans, however, although the long-term use of Lorenzo's oil (oleic acid and erucic acid) in the treatment of adrenoleukodystrophy or adrenomyeloneuropathy leads to thrombocytopenia and lymphopenia (Unkrig et al., 1994), adverse effects from dietary consumption of erucic acid have not been reported.

Refsum disease is a genetic peroxisomal fatty acid oxidase and catalase deficiency resulting in an inability of the affected individuals to convert phytanic acid (3, 7, 11, 15-tetramethylhexadecanoic acid, a product of chlorophyll metabolism in the rumen) from dairy products and ruminant fats to α-hydroxyphytanic acid in preparation for further oxidation. This results in accumulation of lipids containing phytanic acid in many tissues and a disorder characterized by poor physical and mental growth, blindness, deafness, and other neurologic signs (Chow et al., 1992). Elimination of dairy and ruminant fats from the diet of these individuals results in partial remission.

Cyclopropene fatty acids such as sterculic acid (C19) and malvalic acid (C18) are natural components of oils from plants of the order Malvales, most important of which are cotton and kapok seeds. Cyclopropene fatty acids have been incriminated in the pink discoloration of egg whites and reduced egg production in cottonseed-fed laying hens, growth suppression and impaired female reproduction in rats, and increased saturated fatty acids (possibly cause atherosclerosis) in the tissues of pigs and other animals (Mattson, 1973). Cyclopropene fatty acids are carcinogens and markedly increased the carcinogenicity of aflatoxin in trout (Ames, 1983).

Increase in consumption of polyunsaturated fatty acids in the diet in order to lower blood cholesterol, although beneficial in decreasing the incidence of coronary disease, has raised concern for adverse effects such as increasing the total triglyceride levels and induction of vitamin E deficiency (Mattson, 1973; Riccardi et al., 2004). A study (Carrol, 1982) demonstrated a strong correlation between dietary fat and age-adjusted mortality rate from breast and intestinal cancer. Pancreatic cancer was found to be enhanced by a diet containing 20% corn oil but not by one containing 18% hydrogenated coconut oil and 2% corn oil (Roebuck et al., 1981). Unsaturated fatty acids are easily oxidized during cooking to a variety of mutagens, enals and other aldehydes, and alkoxy and hydroperoxy radicals (Ames, 1983). Lipid oxidation products alter signal transduction pathways (Suzuki et al., 1997) and thus enhance cell proliferation and potentially promote carcinogenesis. Lipid-induced inhibition of immune responses and enhanced formation of some of the known tumor promoters such as prostaglandins and bile acids also have been reported (Carrol, 1982). Interestingly, another study (Hayatsu et al., 1981) showed that oleic and linoleic acids may, in fact, be antimutagenic. The overall effect of dietary fats may depend on the ratio of beneficial fatty acids to those of the causative fatty acids for each effect.

Until a clear understanding of the role of dietary fat in human disease is obtained, prevention of weight gain, obesity, type 2 diabetes, and cardiovascular disease appears to be best achieved by a diet low in fat and sugars and high in fiber and protein.

Oxalates are present in large quantities (0.2%–2.0% on a fresh weight basis) in certain plants including spinach, rhubarb, beet leaves, tea, and cocoa. Cattle and sheep have been poisoned following ingestion of the toxic plants *Halogeton* and *Sarcobatus* (grease wood). Toxic signs result from binding of the oxalic acid to serum calcium leading to hypocalcemia, coagulation defects, and tetany. Degeneration and necrosis of kidneys and vasculature from Ca^{++} oxalate deposition may result in severe cases. However, a subpopulation of urinary stone-forming patients are *hyperabsorbers* of oxalates, absorbing more than the normal 3%–8% of the 150–250 mg/day of dietary oxalate intake, and may benefit from reduction of dietary oxalate intake (Massey, 2003). The possibility that antibiotic therapy–induced loss/reduction of the intestinal oxalate metabolizer, *Oxalobacter formigenes*, may contribute to elevated body and urinary oxalate, increasing the risk of recurrent calcium oxalate kidney stone formation (Stewart et al., 2004). Either directly or via their increased production of reactive oxygen species, oxalates alter lipid signaling pathways leading to changes in renal membrane characteristics and damage that promotes oxalate crystal enucleation and growth into stones (Scheid et al., 2004). Chronic oxalate consumption interferes with absorption of calcium, iron, magnesium, and copper and inhibits succinate dehydrogenase and carbohydrate metabolism (Osweiler et al., 1985). Approximately 2.5 kg of tomato or 0.5 kg of spinach leaves need to be consumed to approach a lethal dose (5 g or more) of oxalates.

Phytic acid, the hexaphosphoric ester of myo-inositol (IP6), is present at high levels (up to 1.5 g%) in the bran and germ of wheat with lesser amounts in other cereals, nuts, seeds, spices, and legumes (EFSA, 2011a). Phytates bind di- and trivalent metals in the following order: $Cu^{++} > Zn^{++} > Co^{++} > Mn^{++} > Fe^{+++} > Ca^{++}$, causing mineral deficiencies (especially of Ca^{++} and Fe^{+++}) in people in developing countries that are heavily reliant on cereals as the exclusive source of protein. Inclusion of phytase, an enzyme that releases phosphate from plant phytic acid, in animal feeds ensures phosphate utilization and reduces environmental phosphate pollution from animal production. By altering inositol second messenger pathways, phytates (especially in combination with inositol) inhibit cell cycle, increase malignant cell differentiation and reversion to normal cells, and are anticarcinogenic in animals and human beings against prostate and possibly breast, colon, liver, leukemia, prostate, sarcomas, and skin cancer (Singh and Agarwal, 2005). Supplementation with minerals and vitamin D can antagonize most effects of oxalates and phytates (Janssen et al., 1997).

Plant phenolics comprise a group of several thousand substituted phenolic compounds occurring in trace amounts as esters or glycoconjugates and play essential roles in plant growth and development, defense, symbiosis, pollen development and male fertility, polar auxin transport, protection against UV radiation, and cell cycle regulation. They are widespread constituents of fruits, vegetables, cereals, dry legumes, chocolate, and beverages such as tea, coffee, or wine. Acute human and animal poisonings are mostly caused by phenolics that are either uncommon or those present as contaminants in human food and include coumarins, aflatoxins, and gossypol. Phenolics common in human foods belong to three general classes, that is, nonflavonoids (gallic, syringic, caffeic, and other acids); flavonoids (flavones such as tangeritin; flavonols such as kaempferol and quercetin; isoflavones such as coumestrol, aurones, chalcones; and anthocyanin pigments); and polyphenols (tannins and lignin). Common human foods rich in flavonoids include coffee, chocolates, tea extract, green and black tea, pomegranate juice, grape juice/extracts, virgin olive oil, red wine, and soy proteins.

Polyphenols are widely distributed and present in relatively larger amounts in cereals, millets, legumes, and fruits. Deleterious effects of long-term exposure of both hydrolyzable (polyphenolic acid) and condensed (polyflavonoid) tannins include reductions in the digestibility of foods and feeds, protein utilization and body weight gain, damage to and sloughing of the mucosal lining of the GI tract, and cancer of the mouth and esophagus (Hirono, 1987; Reed, 1995). In contrast to mild acute effects in humans, livestock losses can exceed $10 million annually, attributable to the toxic effects of hydrolyzable oak tannins consumed when other forages are unavailable (Singleton and Kratzer, 1973). Epidemiological correlation exists between high consumption of condensed tannins (sorghums and dark beer prepared from them, tea, red wines, and areca nuts) and high rates of oral and esophageal cancer (Deshpande and Sathe, 1991). Parenteral exposure to tannins reportedly has led to high incidence of liver and other tumors in rodents (Hirono, 1987). On the other hand, negative association between tea drinking and stomach cancer (Stocks, 1970) and coffee consumption and kidney cancer (Jacobsen and Bjelke, 1982) also exists. Polyphenols, however, are not directly damaging to the DNA (Cheeke, 1989), and experimental evidence of anticarcinogenic effects of penta-O-gallyl-beta-D-glucose and epigallocatechin gallate, two green tea tannins (Fujiki et al., 1992), exists.

Flavonoids and nonflavonoids exert no less than 40 different physiologic and pharmacologic actions accounting for their therapeutic and extensive health food use. These include antiandrogenic, anticoagulant, antihistaminic, antihypercholesterolemic, anti-inflammatory, antinutritional (inhibit protein digestibility and nonheme iron absorption leading to iron deficiency), antioxidant, antiproliferative, antipruritic, antipyretic, antirheumatic, antiseptic, antithrombogenic, antithyroid, antitumor, apoptotic, estrogenic, and vasoactive effects. In addition, polyphenols alter the bioavailability and thus the biologic effects of certain drugs including benzodiazepines, terfenidine, and cyclosporine. Many if not all of these actions are based on their UV-absorbing, chelating, oxidative phosphorylation uncoupling and/or oxidant/antioxidant properties. In addition, induction of P450-mediated enzymes and alteration of other enzymes (phospholipases, ATPases, cycloxygenases, lipoxygenases, protein kinases) plus effects on oncogenes and other signaling components critical for cell survival and proliferation (Cheeke, 1989; Formica and Regelson, 1995) contribute to an array of opposing effects in many systems. Although human consumption of flavonoids can be greater than 1 g/day (Janssen et al., 1997), the toxicological implications of exposure to flavonoids and other simple phenolics arise from lifetime and not acute exposure. High intake of flavonoid supplements in humans and/or experimental feeding of high dietary levels have caused acute renal failure possibly due to hemolysis and liver failure as well as contact dermatitis and anemia (Lin et al., 1997; Mennen et al., 2005).

Endocrine disruption involving inhibition of thyroid peroxidase and thyroid hormone (TH) biosynthesis by flavonoids can lead to increased thyroid weight (goiter) and decreased plasma levels of THs. These alterations are of particular concern for babies exposed to high doses of isoflavones in soy-based infant formula. The estrogenic (at moderate doses) and antiandrogenic (at higher levels) activities of the flavonoids are of limited concern in adults at normal dietary intake (0.2–5 mg/day from Western diet and 20–120 mg/day of isoflavones from Asian diet). However, their antiluteinizing hormone effect at levels present in soy-based infant formula can have adverse effects on sexual maturation of male infants, who normally exhibit luteinizing hormone secretion between birth and 6 months of age.

Many flavonoids including quercetin, kaempferol, myricetin, hesperetin, naringenin, wogonin, and norwogonin as well as their glycosides were mutagenic in bacterial and/or mammalian systems (Hirono, 1987; MacGregor, 1984). Although polyphenols such as caffeic acid, quercetin, and green tea catechins are known to induce tumors in the forestomach, colon, kidney, and highly oxidative tissues in rats and mice, reports of their carcinogenic effects in humans are scanty, likely due to the efficient repair of quercetin quinone methide–DNA adducts in humans (Barotto et al., 1998; Dunnick and Hailey, 1992; Mennen et al., 2005). Preponderance of evidence from animal and in vitro systems, however, points to the preventive effects of flavonoids/polyphenols against cardiovascular diseases, cancers, neurodegenerative diseases, diabetes, and osteoporosis (Scalbert et al., 2005). Clinical studies on biomarkers of oxidative stress, cardiovascular disease risk factors, and tumor or bone resorption biomarkers, however, have often led to contradictory results, likely due to differences in types and levels of phenolics consumed. For example, phenolics are known to exert antioxidant effects at low doses and prooxidant effect at higher doses (Yamanaka et al., 1997). A recent study associated increasing intake of flavones and flavonols, but not other flavonoids, with decreased incidence of breast cancer (Bosetti et al., 2005). Anticarcinogenic

effects of phenolics in animals appear to involve both initiation and progression phases of cancer and a combination of mechanisms including inhibition of metabolic enzymes leading to reduced levels of reactive intermediates, induction of detoxifying enzymes such as GSH-s-transferase, reduced formation of oxidation products, alteration of the activity of protein kinases and oncogenes that stimulate cell proliferation, increase apoptosis, reduced expression of matrix metalloproteinases involved in metastasis, and inhibition of angiogenesis (Balasubramanian and Govindaswamy, 1996; Cheeke, 1989; Hirono, 1987; Kanadaswami et al., 2005; Lin and Ho, 1994; Williamson et al., 1998). Protective effects of flavonoids on the cardiovascular system have been shown more consistently in both animals and human beings. The mechanisms for such effects appear to involve reduction of low-density lipoprotein oxidation (antiatherogenic effect) and platelet aggregation (antithrombotic), vasodilation, relaxation of cardiovascular smooth muscle and their anti-inflammatory and antihypercholesterolemic (decrease in LDL and/or increase in HDL) effects among others (Formica and Regelson, 1995; Howard and Kritchevsky, 1996; Manach et al., 2005).

Gossypol (1,1,6,6,7,7-hexahydroxy-5,5-diisopropyl-3,3-dimethyl [2,2-binaphthalene]-8,8-dicarboxaldehyde), a yellow phenolic pigment in cottonseed, can bind to proteins and minerals and reduce the biological availability of iron and lysine (Janssen, 1997). Similar to other phenolics, free gossypol (>60 ppm) inhibits oxidative phosphorylation and causes a myriad of other effects leading to acute toxicity in animals on a high cottonseed diet. In general, higher doses cause cardiac failure associated with liver and lung (pulmonary edema) damage, whereas chronic exposure leads to general malnutrition and reproductive effects (Cheeke, 1989). Signs of gossypol toxicity include loss of appetite and body weight; rough hair coat; edematous fluid in body cavities, lungs, and pericardium giving rise to gasping; hemorrhagic degenerative changes in liver; and necrosis of cardiac myocytes (Zelski et al., 1995). Changes in plasma K^{++} (increase in calves and decrease in humans) may be responsible for gossypol toxicity. Olive discoloration of yolk and decreased egg hatchability occur in poultry (Cheeke, 1989). Male antifertility effects of gossypol in mammals are only partially reversible and include reduced sperm production as well as motility during the late stages of spermatogenesis likely caused by mitochondrial damage (Randel et al., 1992) or inhibition of protein kinases (Teng, 1995). Gossypol is not mutagenic in the Ames test (Cheeke, 1989) but appears to induce genetic damage (dominant lethal mutations) in rats and may be both an initiator and promoter of carcinogenesis (Ames, 1983). In rat lymphocytes, gossypol induced DNA breaks secondary to cytotoxicity (Quintana et al., 2000).

Gossypol and polyphenol (tannin) toxicity can be prevented by the addition of iron, supplemental protein, vitamins E and K, and alkalinizing agents such as sodium hydroxide. In addition, nonionic detergents such as Tween 80, methyl donors such as choline and methionine, and dehulling and peeling of grains and fruits have also been shown to counteract the toxic effects of tannins (Deshpande, 2002; Singleton and Kratzer, 1973). Although having the potential to eliminate gossypol toxicity, a glandless (gossypol-free) variety of cottonseed appears to be more susceptible to insect attack and has yet to gain popularity.

Proteins, peptides, and amino acids, in an average American diet, should supply about 15% of total calories. Long-term consumption of high level of protein, especially animal derived and in amounts that supply >45% of daily caloric needs, has been associated with weakness, nausea, diarrhea, diabetes, renal glomerular sclerosis, Crohn's disease, and osteoporosis (Barzel and Massey, 1998; Cordain et al., 2000; Shoda et al., 1996; Wolever et al., 1997). A study (Huang et al., 2005) showed that soybean proteins, extracted with 20% ethanol, can inhibit TH receptor (TR) binding to TR element in TH-regulated genes and hypothesized that soy protein rather than other components may account for its hypocholesterolemic and hypolipidemic and thus cardioprotective effects of soybeans. Feeding of high level of soy protein, however, markedly increased pancreatic weights and reduced spleen weights in both male and female rats possibly due to the presence of active residual trypsin inhibitors (known to induce hypertrophy and hyperplasia of the acinar cells) and soy fiber, respectively. Products such as D-amino acids and lysinoalanine formed during alkaline/heat treatment of proteins such as casein, lactalbumin, soy protein isolate, or wheat proteins can reduce the digestibility of other dietary proteins (Gilani et al., 2005).

Protein toxicants such as the allergen hemagglutinins (lectins) and enzyme inhibitors have been discussed elsewhere in this chapter. Toxic peptides from mushrooms are discussed in the succeeding text.

Certain microbial protein toxins are discussed in subsequent sections. Adverse effects from amino acids (Garlick, 2004) appear to be restricted to very high parenteral doses and/or diets with low protein levels. An increase in the consumption of amino acid dietary supplements, flavorings (glutamate as monosodium glutamate [MSG] and aspartate and phenylalanine in aspartame), health promoters, performance enhancers, and behavior modifiers calls for increased vigilance for potential adverse effects associated with such uses. Some examples include hyperlipidemia, hypercholesterolemia, enlarged liver and reduced plasma copper (all reversed by copper supplementation in rats), and increases in urinary zinc, headache, weakness, drowsiness, nausea, anorexia, painful eyes, changed visual acuity, mental confusion, poor memory, and depression in overweight human subjects given 24–64 g/day of histidine. Excessive intake of methionine induces hyperhomocystinemia with or without cardiac disease in both rats and human subjects, among other effects, from excess methionine. Ocular lesions/visual disturbances secondary to accumulation of tyrosine crystals and behavioral/perceptual and performance/intellectual deficits in neonates and animals appear following in utero and/or neonatal exposure to high-tyrosine diets/formulas. Therapeutic use of greater than 10 times the required dose of amino acids, when given on an empty stomach, can lead to adverse effects including gastric distress (essential amino acids); nausea,

febrile reaction, and/or headaches (methionine, isoleucine, and threonine); and disorientation (methionine and tryptophan) in mental patients treated with monoamine oxidase (MAO) inhibitors (Harper, 1973).

Hypoglycin A (β-methylene cyclopropyl alanine) and its γ-glutamyl conjugate, hypoglycin B, are components of the fruit of the plant, *Blighia sapida* (ackee in Jamaica and is in Nigeria). Consumption of this fruit in the unripened stage has been associated with hypoglycemia resulting from inhibition of gluconeogenesis involving inhibition of fatty acyl-CoA dehydrogenases and thus β-oxidation of fatty acids by cyclopropylacetyl CoA (a metabolite of hypoglycin A). Signs of intoxication include vomiting, convulsions, hypothermia, coma, and even death. Pretreatment with clofibrate (stimulator of peroxisomal fatty acid oxidases) prevented many but not all signs, lesions, and biochemical effects (Van Hoff et al., 1985).

Koa haole (*Leucaena leucocephala*), a legume found in Hawaii, and other legume species belonging to Mimosidae family have potentially high nutritive value for animals and humans (NAS, 1997). However, use of these legumes is precluded in ruminants by the goitrogenic effect of the metabolite (3,4-dihydroxypyridine) of an unusual amino acid, mimosine [3-N-(3-hydroxypyridone-4)-2-aminopropionic acid], present in this plant. Mimosine also causes reversible destruction of hair follicle matrix (loss of hair), reduced bone strength and mineral composition in poultry, and growth depression in both ruminants and nonruminants. The ability of mimosine to chelate Zn and Mg, reduce plasma thyroid and other hormone levels (Puchala et al., 1996), and inhibit a large number of enzymes leading to DNA synthesis inhibition and cell cycle arrest (Kalejta and Hamlin, 1997; Liener, 1980) explains many of the effects.

Djenkolic acid, which is an amino acid that is structurally similar to cystine, is present in the djenkol bean (*Pithecellobium lobatum*) in Sumatra and Java. It can neither substitute for cystine nor can it be totally metabolized but can crystallize in the kidney causing hematuria and crystalluria (Liener, 1980).

Favism, a hemolytic disease (accompanied by jaundice and hemoglobinuria) in persons genetically deficient in glucose-6-phosphate dehydrogenase (G6PD) and thus in NADPH and reduced GSH content, results from the consumption of the amino acid 3,4-dihydroxyphenylalanine and the pyrimidine aglycones (divicine and isouramil) of glycosides, vicine and convicine, in broad beans (*Vicia faba*) mainly in the Mediterranean region and in the Middle East (Chevion et al., 1983).

The etiology of the neurologic disease characterized by posterior sensory ataxia in cattle consuming cycads may be an amino acid, BMAA. Certain seleno-amino acids such as methylselenocysteine, selenocystathionine, selenocysteine, and selenomethionine in plants that grow on high Se soils (Liener, 1980), when incorporated into structural animal proteins, may produce defective hair and hooves that are eventually lost during longer-term exposure in livestock. In human beings, a syndrome characterized by abdominal distress, nausea, vomiting, diarrhea, and loss of scalp and body hair had been reported following consumption of coco de momo (*Lecythis ollaria*) nuts containing high levels of selenocystathionine (Aronow and Kerdel-Vegas, 1965).

The amino acids L-2,4-diaminobutyric acid (DABA), 3-N-oxalyl-L-2,3-diaminopropionic acid (ODAP), 3-cyanoalanine, 4-glutamylcyanoalanine, and related homologues, present in seeds of several species of Lathyrus and *Vicia sativa* in the Indian subcontinent, have been implicated in the pathogenesis of neurolathyrism, a syndrome characterized by muscular rigidity, weakness, paralysis of leg muscles, and death following long-term high-level consumption of *Lathyrus sativus* seeds (Van Genderen, 1997). The mechanism of action appears to involve irreversible binding of ODAP to the glutamate receptor and enhanced release/reduced reuptake of glutamine at relevant nerve terminals leading to vascular degeneration and necrosis of neurons (Padmanaban, 1980). In certain individuals, amino acids such as β-aminopropionitrile and the dipeptide (N-γ-glutamyl) aminopropionitrile as well as certain urides, hydrazides and hydrazines, from the green parts of *Lathyrus* and other plants lead to osteolathyrism characterized by bone deformities and reduction in the tensile strength of the aorta (Haque et al., 1997) resulting from the irreversible inhibition of lysyl oxidase and interference with cross-linking of collagen (Wilmarth and Froines, 1992). More recent observational and experimental findings relating to the vascular and systemic effects of molecular pathways implicated in the phenomenon of animal and human lathyrism suggest that vascular adhesion factor seems to be involved in the molecular and developmental pathways of the genetically triggered thoracic aortic diseases and thus could be a potential therapeutic target for these conditions (Sherif, 2010).

Creeping indigo (*Indigofera endecapylla*), a tropical forage, contains a nitric oxide synthase inhibitor, indospicine, which causes liver damage in sheep, rats, and mice by inhibiting the incorporation of arginine, the amino acid it resembles, into protein (Liener, 1980).

Saponins are bitter-tasting steroidal (C27) or mono-, di-, tri-, and sesquiterpenoid (C30) glycosides from plants, fish, and sponges capable of reducing surface tension, hemolyzing red blood cells, and causing toxic effects in cold-blooded animals. Their occurrence, biological effects, and relevance to food, agriculture, and medicine are reviewed by Walker and Yamazaki (1996a,b). D-*Limonene* and several other chemicals from citrus oils such as ginseng saponins, medicagenic acid, and hederosides in alfalfa and *Hedera helix*, respectively, and oleanolic and ursolic acid in a variety of food, medicinal, and other plants as well as their aglycones (sapogenins) have been studied. Their analgesic, antiatherosclerotic, anticarcinogenic, anticholinergic, antihypercholesterolemic, antihyperglycemic, anti-inflammatory, antitubercular, cardioprotective, diuretic, and hepatoprotective effects are likely to encourage increased dietary, supplemental, and medicinal utilization of saponin-containing plants such as ginseng (Malinow et al., 1982; Rao and Sung, 1995; Xu et al.,

1996). Mechanisms of protection involve Ca^{++}-antagonistic and vasodilatory/venoconstrictive; immune-modulatory, bile acid-binding, antiproliferative, and membrane permeabilizing; and antioxidant and anticytochrome P_{450} effects (Rao and Sung, 1995). Feeding high levels of saponin from a variety of sources, however, resulted in lower growth rate; increased serum lactate dehydrogenase (LDH) and glutamic oxaloacetic transaminase (GOT) associated with hepatocellular necrosis; and increased blood urea nitrogen (BUN), hematuria, and proteinuria associated with renal tubular necrosis (Kobayashi et al., 1993; Nakhla et al., 1991) in animals. Several steroidal and nonsteroidal saponins from pasture weeds such as *Hypericum perforatum* and *Narthecium ossifragum*, vines such as *Tribulus terrestris*, and tropical grasses such as *Brachiaria* and *Panicum* spp. cause primary or hepatogenic photosensitization (Cheeke, 1996). Alphahederin, a saponin that induces metallothionein in maternal tissues, appears to induce visceral and skeletal defects in offspring born to exposed mothers by possibly reducing Zn availability to the fetus (Duffy et al., 1997). Similar to the effects of phenolics, the beneficial effects of saponins can be derived from daily doses present in a balanced diet.

Vaso- and psychoactive substances are present at high levels in cheese, yeast products, fermented foods, beer, wine, pickled herring, snails, chicken liver, coffee, broad beans, chocolate, cream products, and plants such as pineapple, banana, plantain, and avocado. Chemically, they are predominantly amines such as tyramine and its methyl derivatives octopamine, dopamine, epinephrine, norepinephrine, histamine, and serotonin (Lovenberg, 1973). Moderate amounts of cheese and yeast products commonly contain the needed dose of 10 mg of tyramine to cause severe hypertensive crisis in individuals treated with nonselective MAO inhibitors for disorders of mood (Baldessarini, 1985). Inhibition of MAO leads to a combined vasopressor effect of unmetabolized biogenic as well as dietary amines. In addition, tyramine enhances release of catecholamines that are present in supranormal amounts in the adrenal medulla (Baldessarini, 1985). Palpitations, migraine headaches, and in some instances intracranial bleeding and death may ensue. Use of selective (MAO-A or MAO-B) inhibitors for therapy appears not to sensitize individuals to dietary tyramine (Matsumoto et al., 1968). Herbs containing toxic psychoactive agents include California poppy, catnip, cinnamon, hops, hydrangea, juniper, kola nut, nutmeg, periwinkle, thorn apple, and wild lettuce (Beier, 1990).

Miscellaneous Plant Toxicants

A common human intoxication called *milk sickness* was one of the most dreaded diseases from the Colonial times to the early nineteenth century in an area extending from North Carolina to Virginia and to the Midwestern United States (Lewis and Elvin-Lewis, 1977). The disease manifested as weakness, nausea and vomiting, constipation, tremors, prostration, delirium, and even death and resulted from the consumption of dairy products made from milk derived from cows (even healthy ones) grazing on white snakeroot (*Eupatorium rugosum*) or rayless goldenrod (*Haplopappus heterophyllus*). The causative agent appears to be trematol, an unsaturated alcohol, in combination with a resin acid (Lewis and Elvin-Lewis, 1977). Other plant toxins excreted through milk that pose toxic hazards for children and nursing animals include pyrrolizidine, piperidine, and quinolizidine alkaloids; sesquiterpene lactones of bitterweed and rubberweed; and GS (Panter and James, 1990). Animals grazing on high Se forages may excrete high levels of Se in milk and contribute to chronic Se toxicosis in the offspring (Panter and James, 1990). Current processing methods have kept these conditions in check for the most part. In cattle, consumption of 5–10 lb of snakeroot causes weakness and trembling of various groups of muscles, labored respiration, and death.

Marine Toxins

Of the many marine organisms capable of containing toxins (>1200 species), only a few are involved in food poisoning. Modern transportation and recent increase in frequency and intensity of toxic algal blooms have led to an increase in the incidence as well as the spread of seafood poisoning. Toxicants may be produced by the fish itself, by the marine plankton or algae consumed by the fish with or without the aid of certain marine bacteria. A detailed discussion of the toxicology of fish-borne toxins can be found in several studies (Brett, 2003; Leftley and Hannah, 1998; Russell and Dart, 1991).

Shellfish poisoning is one of several (amnesic, digestive, neurotoxic–paralytic) disease entities resulting from the consumption of shellfish (clams, crustaceans, lobsters, mussels, oysters, scallops, etc.) that have ingested toxic marine algae, especially certain dinoflagellates. The shellfish are toxic during seasons of heavy algal bloom (such as red tide) containing 200 organisms/mL or more. Toxicity increases in proportion to the concentration of algae and disappears within 2 weeks after the toxic plankton has disappeared from the waters (Russell, 1986).

Saxitoxin (STX), *neosaxitoxin*, and *gonyautoxins* are the most potent of the more than 20 toxins present in the *paralytic shellfish poison*, produced by the dinoflagellates belonging to *Alexandrium*, *Gymnodinium*, *Gonyaulax*, and *Pyrodinium* spp. STX blocks the action potential in nerves and muscles by preferential blockade of inward flow of sodium ions with no effect on the flow of potassium or chloride ions (Kao, 1967). STX also binds to calcium and potassium channels, neuronal nitric oxide synthase, metabolizing enzymes, and transferrin-like family of proteins (Llewellyn, 2006). Consumption of 1 mg of the toxin (in 1–5 mussels or clams weighing 150 g each) can be mildly toxic, whereas 4 mg can be fatal if not treated vigorously. Toxic signs/symptoms begin as numbness of the lips, tongue, and fingertips within minutes after eating. Numbness then extends to the legs, arms, and neck and is followed by general muscular incoordination, which progresses to respiratory paralysis and death. Decreased heart rate and contractile force, headache, dizziness, increased sweating, and thirst may also be noted. Boiling in bicarbonate-treated

water and discarding the broth is suggested as a means of preventing shellfish poisoning (Halstead, 1978).

Diarrheic shellfish poisoning occurs globally from consumption of shellfish (mussels, cockles, scallops, oysters, cockles, whelks, and green crabs) contaminated by one of several species of Dinophysis and contain a combination of okadaic acid (OA), dinophysis toxins (DPT), pectenotoxins, and yessotoxins (Brett, 2003). Both OA and DPT are powerful inhibitors of protein phosphatases and potent tumor promoters (Korn et al., 1996). Whether protein phosphatase inhibition leads to the observed increase in the permeability of intestinal epithelial cells exposed to OA, its diarrheic effect is unknown.

Neurotoxic shellfish poisoning is characterized by nausea, vomiting, diarrhea, chills, headache, muscle weakness and pain, eye and nasal irritation, and, in severe cases paresthesia, difficulty in breathing, double vision, dysphonea, and dysphagia, tachycardia, and convulsions. It has been reported along the Gulf of Mexico, the eastern coast of Florida, and New Zealand following consumption of shellfish (mussels, oysters, and whelks) or inhalation of airborne blooms containing a heavy load of *Gymnodinium breve* and/or similar organisms. The lipophilic polyether toxin, the brevitoxin, promotes Na^+ influx and thus depolarization by its action on site-5 of the voltage-dependent Na^+ channels (Brett, 2003; Leftley and Hannah, 1998).

Amnetic shellfish poisoning, characterized by short-term and sometimes permanent memory loss associated with GI signs and a hallucinatory state, has been reported mostly from the coastal areas in North America, Canada, France, Portugal, and the United Kingdom. Neuronal degeneration and necrosis in the hippocampus, coma, and death may result in severe cases. A water-soluble acidic nonprotein amino acid, domoic acid (and its isomers), is produced by the diatom *Pseudo-nitzschia* sp. in king scallops with lower levels in blue mussels, queen scallops, crab, razor fish, anchovies, sardines, mackerel, jack smelt, albacore, sand dabs, krill, and humpback whales. Domoic acid is a competitive glutamate antagonist and has been ascribed the etiological role in amnetic shellfish poisoning (Brett, 2003; Leftley and Hannah, 1998).

Azaspiracids, a relatively new class of rapidly acting algal toxins potentially produced in mussels and other shellfish throughout northern Europe by *Protoperidinium* sp., act by unknown mechanism(s) to induce GI symptoms including nausea, vomiting, severe diarrhea, and stomach cramps. Necrosis in the lamina propria of the small intestine, thymus, and spleen; fatty changes in the liver; chronic interstitial pneumonia; and lung tumors were also observed (Brett, 2003). The amount of cyclic imines in shellfish is not regulated and these substances have not been categorically linked to human intoxication (Otero et al., 2011).

Ciguatoxins are present in 300–400 tropical reef and semipelagic species of edible marine animals, including barracudas, groupers, sea basses, snappers, surgeon fishes, parrot fishes, jacks, wrasses, eels, and certain gastropods. These species accumulate, in their liver and other viscera, toxins capable of causing ciguatera poisoning, at an estimated 20,000–50,000 cases/year worldwide (Brett, 2003; Lipp and Rose, 1997). The intoxication, common in the South Pacific and the Caribbean, appears to follow the spatial and temporal pattern of the distribution of a photosynthetic dinoflagellate *Gambierdiscus toxicus*, which is consumed by the smaller herbivorous fish and in turn by the ciguatoxic fish (Russell, 1986). Ciguatoxins, a group of 23 colorless and heat-stable lipophilic polyethers (MW of 1100), appear to play a major role in intoxication with some contribution from the water-soluble maitotoxin (Leftley and Hannah, 1998). Ciguatoxins increase membrane permeability to sodium ions causing depolarization of nerves. In addition, ciguatoxin inhibits subsequent inactivation of open Na^+ channels and possesses anticholinesterase activity in experimental animals (Leftley and Hannah, 1998; Russell, 1986). Maitotoxin, on the other hand, inactivates voltage-dependent and receptor-mediated Ca^{++} channels leading to high intracellular Ca^{++} and cell death (Leftley and Hannah, 1998). Ciguatoxicosis is the most common marine toxicosis in humans manifesting as tingling of the lips, tongue, and throat followed by numbness, nausea, vomiting, abdominal pain, diarrhea, pruritus, bradycardia, dizziness, muscle and joint pain, and ataxia. Severe cases exhibit paresis of the legs and infrequently death due to cardiovascular and/or respiratory failure (Leftley and Hannah, 1998; Russell, 1986). Prevention of ciguatera poisoning is difficult, although extensive evisceration of fish may help.

Puffer fish (fugu fish) poisoning, known to occur as far back as 2000–3000 BC in China and Japan, results from consumption of tetrodotoxin (TTx) present in the liver and ovaries of puffer fish, ocean sunfishes, porcupine fishes, blue-ringed octopus, and certain amphibians of the family Salamandridae (Kao, 1966; Russell, 1986). Toxin accumulation is greatest just prior to spawning in the spring. TTx, with a cyclic hemilactal structure, is highly lethal (LD_{50}, 10 mg/kg) to all vertebrates and is active after boiling for 1 h but is inactivated under alkaline conditions. TTx prevents the increase in the early Na^+ permeability in both motor and sensory neuronal membranes similar to that of STX (Russell, 1986). In humans, numbness of the lips, tongue, fingers, and arms, muscular paralysis and ataxia, hypotension, and respiratory paralysis leading to death progress rapidly beginning 30–60 min after consumption of 1–2 mg of TTx (1–10 g of roe or liver). Training of personnel in proper evisceration techniques and licensing of fugu restaurants are of the essence.

Scombroid poisoning is the most widespread fish-borne intoxication resulting from the consumption of inadequately preserved abalone, amberjack, bluefish, tuna, mackerel, mahi-mahi, and sardines in which histamine and saurine are produced as a result of bacterial scombrotoxic action (Lipp and Rose, 1997). Scombroid fish apparently has a sharp or peppery taste. Signs of intoxication include nausea, vomiting, diarrhea, epigastric distress, flushing of the face, throbbing headache, and burning of the throat followed by numbness and urticaria. Severe cases may lead to cyanosis and respiratory distress and, rarely, to death. These signs appear within

2 h of the meal and disappear in 16 h (Russell, 1986). The disease readily responds to antihistamine treatment.

Other marine toxins such as prorocentrolides, pinnatoxins, and spirolides are thought to activate calcium channels, and some were implicated in over 2500 cases of illness in Japan following consumption of the bivalve *Pinna pectinata*. Certain other compounds from algae including amphidinolides and carbenolides with cytotoxic activity against tumor cells, zooxanthellotoxins with vasoconstrictor activity, and gambierdic acids and goniodomin with antifungal properties may be of therapeutic potential (Cheeke, 1989). Due to their actions on a variety of channels and receptors, small amounts of toxin required to produce effects, their heat-stable nature, and the rapidity with which the effects are produced, marine toxins such as STX, TTx, and OA have become internationally regulated chemical weapons.

Foodborne Bioterrorism

Attacks with biological agents are appealing to organizations with limited resources such as terrorist and radical groups, with intent to scare the masses rather than inflict mass casualties. Biological/toxic agents can be grown inexpensively but are difficult to weaponize for aerosol dispersal making large-scale bioterrorist attack unlikely for most radical groups. Bioterrorism involving food and water supplies is a more practical alternative. CDC (Rotz et al., 2002) groups biological warfare agents into (1) category A (easily disseminated/transmitted from person to person, capable of high mortality rates, with the greatest impact on the public health system and civilian psyche, e.g., variola [smallpox], *Bacillus anthracis* [anthrax], *Yersinia pestis* [plague], *C. botulinum* [botulism], *Francisella tularensis* [tularemia], and filo- and arenaviruses [viral hemorrhagic fever]); (2) category B (moderate dissemination and morbidity and lower mortality rates, e.g., *Coxiella burnetii* [Q fever], *Brucella* [brucellosis], *Burkholderia mallei* [glanders], *Burkholderia pseudomallei* [melioidosis], alphaviruses [encephalitis], *Rickettsia prowazekii* [typhus], toxins [toxicoses], *Chlamydophila psittaci* [psittacosis], food safety threats [*Salmonella*, *E. coli,* etc.], and water safety threats [vibrio, cryptosporidium, etc.]); and (3) category C (emerging pathogens currently limited by availability and difficulty in production, e.g., Nipah virus [encephalitis], Hantavirus [pulmonary syndrome], tickborne hemorrhagic fever virus, yellow fever, multidrug-resistant tuberculosis). Although most biological agents are unstable in the environment; are destroyed by public water treatment methods, boiling of water and cooking of food; cause only short-term vomiting and diarrhea; or would require large amounts to overcome dilution, many steps along the centralized food processing and rapid and wide distribution of foods still present a window of vulnerability for intentional introduction of biological agents (organisms and toxins, most likely including botulinum toxin, *Salmonella*, *Shigella*, *E. coli*, and *V. cholerae*) into food products. Recent reviews of bioterrorism agents include those of Karwa et al. (2005) and Meinhardt (2005).

Compared to conventional chemical weapons, toxins are generally difficult to produce in large quantities, nonvolatile, more toxic by weight, dermally inactive, odorless and tasteless, immunogenic, and slow acting (Karwa et al., 2005). Among the toxins used as aerosols, agents that are highly toxic but hard to produce may be more of a threat in a closed space delivery system, while those that are stable and easily produced and delivered are likely used as open-air weapons. Some toxins are also effective when ingested and others are dermally active. Food bioterrorism, similar to those of a nonterroristic foodborne disease, involves large numbers of people within a geographical area consuming the same contaminated food product(s) exhibiting signs characteristic of the agent involved within a short time frame (hours for toxins and up to 72 h for microorganisms) after consumption. Following the September 11, 2001, terrorist attack on the World Trade Center in New York in preparation for dealing with foodborne terrorism events, under the authority of the Public Health Security and Bioterrorism Preparedness and Response Act passed in June 2002, the FDA developed new regulations that addressed registration of all (domestic and foreign) food facilities: (1) prior notification of importation of food shipments, (2) establishment and maintenance of records of receipts and shipments by all processors, and (3) administrative detention of suspect food. More recently, the FDA added Food Security Preventive Measures Guidance (U.S. FDA, 2003) listing security and testing measures to ensure the physical and chemical safety of milk and food products.

Table 14.5 lists toxicants that could potentially be employed as foodborne/waterborne terrorism agents. Of these, the marine toxins (STX and TTx) are difficult to produce and are considered only remote threats. As discussed in the succeeding text, botulinum toxin, staphylococcal enterotoxin B, ricin, and trichothecene mycotoxins have been stockpiled and/or allegedly used in warfare/terrorism in the past and are most likely to be used in future bioterrorism.

Botulinum toxin, produced by the bacterium *C. botulinum*, in addition to its well-known involvement as a foodborne toxin and its approved therapeutic/cosmetic uses, was once stockpiled, experimented, and/or used by the United States, Russia, Iraq, and the Aum Shinrikyo sect in Japan (Karwa et al., 2005). Its absorption via lung renders is a potential threat by aerosol dispersion (particle size 0.1–0.3 μm). Although aerosolization was thought to be a more efficient means of attack leading to the potential death of 1.5 million people with 1 kg of toxin, recent estimates (Wein and Liu, 2005) suggest that less than 1 g of botulinum toxin introduced into the milk supply at some point along the processing (between milking on the farm and bottling in the processing plant) could result in 100,000 casualties in the absence of testing/detection, suggesting that direct contamination of the food supply may be an even more effective means of releasing the toxin. Other products such as juices and other beverages, subject only to pasteurization temperatures before consumption, are also candidates for such attack. Signs, as described earlier, mainly include vision

TABLE 14.5
Toxins with Potential for Use in Foodborne Terrorism

Toxin Type	Examples	Source	Syndrome
Bacterial	Botulinum toxins	*C. botulinum*	Inhalation: Neurologic (descending paralysis)
	C. perfringens toxins and	*C. perfringens*	Ingestion: gastroenteritis
		S. aureus	Ingestion: gastroenteritis
	Staphylococcal enterotoxin B		Inhalation: toxic shock and pulmonary edema
Fungal	Aflatoxin	*A. flavus*	Inhalation: pulmonary edema and hemorrhage Ingestion: hemorrhagic gastroenteritis
	T-2 toxin	*Fusarium* spp.	Dermal: blistering Inhalation: tracheobronchitis and hemoptysis
Algal	Anatoxin A	Blue-green algae	Ingestion: paralysis
	Microcystin	Blue-green algae	Ingestion: paralysis and liver damage
Marine	STX TTx	Dinoflagellate	Ingestion: neurotoxin
		Puffer fish	Ingestion: neurotoxin
Plant	Ricin	Castor bean	Inhalation: respiratory distress Ingestion: gastroenteritis and shock
	Abrin	Precatory bean	Similar to ricin

Sources: Data extracted from Meinhardt, P.L., *Ann. Rev. Pub. Health*, 26, 213, 2005; Karwa, M. et al., *Crit. Care Med.*, 33(supp), S75, 2005.

disturbances, dysphagia, and dysphonia initially followed by descending paralysis, hypotension, and respiratory failure as early as 24 h after exposure. Treatment involves activated charcoal, respiratory support, and administration of the antitoxin. Early symptomatic detection avoids up to two-thirds of the casualties, whereas rapid ELISA testing to detect the toxin at each point in the sequence of events between milking and bottling would prevent nearly all cases. Thus, employment of security measures and testing at each point of production, collection, processing, and transport of foods such as those proposed by the Food Security Preventive Measures Guidance for milk and other food products (U.S. FDA, 2003) are the best safeguards against terrorism involving food products.

Ricin, a lectin from castor bean (*Ricinus communis*), has a significant bioterror history and potential (Audi et al., 2005). Its recent discovery at a South Carolina post office, a White House mail center, and a U.S. senator's office and the still unknown origin are of concern. Ease of production and high toxic potency by oral, inhalation, or parenteral exposure makes ricin highly attractive for bioterrorists, especially when inhaled. The most likely scenarios of ricin use include aerosol release into the environment or adulteration of food and beverages. Ingestion of ricin leads to nausea, vomiting, diarrhea, and abdominal pain beginning within 12 h and progressing to hypotension, liver failure, renal dysfunction, and death due to multiorgan failure or cardiovascular collapse. Inhalational exposure produces cough, dyspnea, arthralgias, and fever and may progress to respiratory distress and death. Ricin analysis at federal laboratories and supportive measures are the best aids to diagnosis and treatment, respectively.

Staphylococcal enterotoxin B, a common foodborne toxin, is an enterotoxin that can be mass produced from cultures of *S. aureus*. It is stable as an aerosol. Inhalation exposure results in binding of the toxin to the major histocompatibility complex that stimulates T cells leading to massive release of cytokines. This leads to interstitial pulmonary edema including fever, myalgia, cough, chest tightness, dyspnea, headache, and vomiting (Karwa et al., 2005). Signs of toxic shock syndrome (hypotension, shock) also occur. The need for large amounts of the toxin necessary to produce effects makes this toxin less desirable compared to some of the other toxins.

The trichothecene toxins (T-2 toxin) may represent the most promising of the mycotoxins as a bioagent because of its ability (1) to induce effects immediately upon contact, (2) to produce lethality at only a few milligrams, (3) to be easily and inexpensively produced, (4) to remain stable as an aerosol, and (5) to spread readily from person to person (Karwa et al., 2005; Stark, 2005). There is no known antidote or vaccine. Allegations of their use as a bioagent either by the United States against North Korea and China in 1952 or by the Soviet Union to attack Hmong tribesmen in Laos and Kampuchia (as *yellow rain*) in 1981 and later in Afghanistan either remain unsubstantiated or have been disproved. Victims, in the yellow rain incident, appear to have exhibited signs similar to those expected from trichothecene intoxication (blistering of the skin, corneal injury, wheezing, cough, tracheobronchitis, and hemoptysis), and leaf samples from the area contained traces of trichothecenes. Subsequently, these allegations were negated by reports that the material in the so-called yellow rain is likely a mass defecation by swarms of Asian honeybees and the trace levels of trichothecenes likely reflected natural production in this area. The U.S. military still considers these agents as serious bioweapons as evidenced by clearance of a reactive skin decontamination lotion by the FDA in March 2003 for use by the military to remove or neutralize chemical warfare agents and T-2 fungal toxin from the skin. Additional information

on history of bioweapon use, mechanism of action, and signs of intoxication of trichothecenes can be found in Karwa et al. (2005) and Stark (2008).

V. cholerae causes the most severe seasonal diarrheal disease epidemics mostly in Asia, Africa, and Latin America. Its main mode of transmission is via contaminated water and food. The same media could be used by terrorists (Meinhardt, 2005) and apparently was used by the Japanese in World War II in China (Karwa et al., 2005). Serogroup O1 (with two main serotypes, Inaba and Ogawa, and biotypes, classical and El Tor) and the recently identified serogroup 0139 Bengal have caused the most severe disease natural outbreaks. The CT is similar to the heat-labile enterotoxin secreted by *E. coli* and causes diarrhea by the same mechanism: excessive net secretion of electrolytes and water from the upper fifth of the small intestine. Details of the factors that trigger, and the mechanisms involved in, the secretion of CT, its mode of action, and the immunology of the disease have been reviewed by Sanchez and Holmgren (2005). Interestingly, the presence of lytic cholera phages in environmental waters appears to reduce the presence of *V. cholerae*, thus providing a mechanism whereby the emergence and duration of cholera epidemics can be naturally controlled. Recently developed mixed serotype and biotype inactivated *V. cholerae* O1 and attenuated classical *V. cholerae* O1 Inaba vaccines appear to be superior to the earlier vaccines due to improved local (gut) immunity. However, immunity only lasts for 6 months.

For details on disease caused by ETEC and *Shigella* spp., please refer to the discussion on *Foodborne Bacterial Diseases* section in this chapter.

Although contamination of foods with conventional chemical weapons including nerve agents (tabun, sarin, soman, and especially VX), cyanide, incapacitating agents (BZ and agent 15), vesicants (mustards, phosgene, and lewisite), and choking agents (phosgene, chlorine, and bromine), or with radionuclides is possible, the volatile nature of the former (with the exception of VX) and the restricted availability of the latter make threats involving foods less likely. The FDA-approved antidote treatment nerve agent autoinjector (ATNAA) (atropine/pralidoxime) autoinjector to treat nerve gas intoxication and new dosage forms of AtroPen (atropine) autoinjectors for use in children and adolescents to deal with nerve agents; ThyroSafe (potassium iodide) tablets to protect the thyroid from general radiation exposures; Prussian blue to inhibit absorption of radioactive cesium and thallium; and pentetate calcium trisodium (Ca-DTPA) and pentetate zinc sodium (Zn-DTPA) to increase elimination of internal contamination with plutonium, americium, or curium, found in the fallout from nuclear detonation and waste from nuclear power plants, are examples of approaches available to respond to and to treat individuals in such emergencies (Meadows, 2004).

Much progress has occurred in our identification and management of foodborne hazards. According to CDC estimates, annual foodborne disease burden has fallen from 76 million cases, 5,000 deaths, and 325,000 hospitalizations in 1999 to approximately 48 million cases, 3,000 deaths, and 128,000 hospitalizations in 2012. Large gaps in our knowledge, however, exist in the areas of mechanisms of pathogenesis of known human intoxications associated with foods; interactions between multiple toxicants present simultaneously, between toxicants and nutritional components, and between toxicants and antitoxicants (including antimutagens and anticarcinogens) in foods; methods of realistic human health risk extrapolation from animal data; and the development of safer plant varieties and processing, cooking, and storage methodologies that minimize toxic hazards to consumers. Considering the facts that natural dietary toxicants are, at least, as toxic as synthetic additives and that their exposure is generally much greater in quantity and consistency than synthetic toxicants, U.S. and worldwide research resources should be shifted to achieve a more realistic balance, in the study of health hazards, toward the natural components in the food supply. Others have advocated this approach as well (Borchers et al., 2010; Pascal, 2009). This task will be difficult because of the vastly variable composition of individual food ingredients as well as the total human diet.

Increased globalization of the food industry, especially fresh produce, requires implementation of improved food safety programs, with a special emphasis on imported foods. Mandatory rules for food protection and safety need to be developed by the FDA and the food industry to prevent future outbreaks, such as the 1996 outbreak of *Cyclospora cayetanensis* from Guatemalan raspberries and the S. enterica Serotype Newport from Brazilian mangoes. Timely recognition of outbreaks and epidemiologic investigations are also critical to identify new infectious agents, vehicles of transmission, and modes of contamination and to institute corrective measures for prevention. The application of newer molecular methodologies to fingerprint the causative organisms (e.g., CDC's *pulsenet*) to identify patterns of intoxication from bacterial and other biotoxins and intensified activities of the national animal health monitoring system combined with more rigorous application of HACCP or similar control methodologies will lead to significant reduction in currently widespread incidences of microbial diseases from food sources.

Just as important is consumer education. Such consumer education is needed to minimize dietary risks using practicable methods and to shatter the myth that *natural is healthy but man-made is toxic*. An educated populace is less likely to be unduly alarmed and is more likely to accept prudent regulatory actions resulting from realistic scenarios of risk estimation.

15 Solvents and Industrial Hygiene

David L. Dahlstrom and John E. Snawder

CONTENTS

Industry and the general public use a wide range of organic solvents to develop, synthesize, modify, and improve many of today's most useful chemical products and manufacturing applications. On a global basis, chemical manufacturers produce billions of pounds of organic solvents annually. Common solvent uses include degreasing agents, paint thinners and removers, dry-cleaning agents, chemical intermediates, extractants, and carrier vehicles for paints, varnishes, and industrial coatings. Many of the organic solvents find applications within the chemical industry in the production of waxes, paints, varnishes, lacquers, pharmaceuticals, plastics, pesticides, rubber goods, synthetic textiles, adhesives, shoe polish, floor cleaners, and many other outstanding products in everyday use.

Many organic solvents can prove to be environmental and occupational toxicants when used without proper and adequate administrative and engineering controls. Broad or singular statements to describe adverse health effects associated with solvent exposure are difficult to make. Such adverse effects will differ depending upon the physical and chemical properties associated with each solvent, class, or composition of a mixture of solvents; the physiological route the solvent enters the body; the nature of the environment in which the solvent is being used; how the solvent/mixture is being used (e.g., liquid or vapor, aerosolized or hand-wiped, hot or cold), the variability of the exposure over time, and even the relative health, gender, or age of the individual exposed. The overriding issue for the industrial hygienist and occupational health specialist is not so much identifying that a potential exposure hazard to an individual solvent or mixture exists, but determining at what concentration, frequency, duration, and route(s) of entry (oral, inhalation, skin, and eye contact) a dose of the solvent or solvent mixture will result in a harmful effect (e.g., dermatitis, systemic injury, irritation, narcosis, neuropathy, carcinogenicity).

CHEMICAL CLASSIFICATION FOR SOLVENTS

In general practice, organic solvents are categorized on the basis of their respective structure and composition into one of 11 chemical classes. Figure 15.1 depicts the general chemical structures for each class and examples of common solvents in each group [128,172]. The 2012 American Conference of Government Industrial Hygienists (ACGIHs) 8 h time weighted average (TWA) threshold limit values (TLVs®) and respective U.S. Department of Labor—Occupational Safety and Health Administration's (OSHA) Permissible Exposure Limit (PEL) for each example is provided.

PROPERTIES OF SOLVENTS

To understand the hazards that organic solvents may present, industrial hygienists (IHs) and other health, safety, and environmental (HS&E) professionals need to know about the basic physical, chemical, and toxicological properties, workplace conditions, proximity of use to other chemical use, the nature or the work activity, and the behavior characteristics of the organic solvents and mixtures being used. The following description of key chemical and physical properties of organic solvents should be considered when attempting to evaluate and control the various risks (defined by both the nature of the hazard and toxicity of the material) that can result when working with organic solvents. Additionally, the industrial hygienist must recognize that most technical-grade solvents used in the workplace often contain small amounts of impurities and that these impurities can affect the properties inherent in the pure solvent.

Boiling Point

The temperature at which the vapor pressure of a liquid becomes equal to the pressure of the surrounding atmosphere is the liquid's *boiling point*. In typical use, a pressure of 1 atm (760 mmHg or 14.7 psi) is considered standard atmospheric pressure at sea level. This atmospheric pressure will vary, however, depending on elevation above or below sea level and should be taken into account when estimating boiling temperatures [21,22].

Vapor Pressure

Like many liquids, most organic solvents begin to evaporate at temperatures below their boiling point. As the temperature of the liquid increases, the volume of vapor evolving will likewise increase. The *vapor pressure* of a liquid is the amount of pressure exerted by the saturated vapor above the surface of the liquid within a closed container [120]. Units of vapor pressure are usually expressed in millimeters of mercury, or mmHg at 20°C (68°F). In principle, vapor pressure is inversely related to boiling point in that the lower the boiling point of the solvent, the higher the relative vapor pressure will be, allowing the solvent to more readily volatilize into the surrounding air. In short, the higher the vapor pressure of the liquid, the greater the propensity to evaporate [21,22,64].

The vapor pressure of a liquid will increase as the temperature of the liquid is increased. Therefore, the amount of vapor above the surface of the solvent entering an open

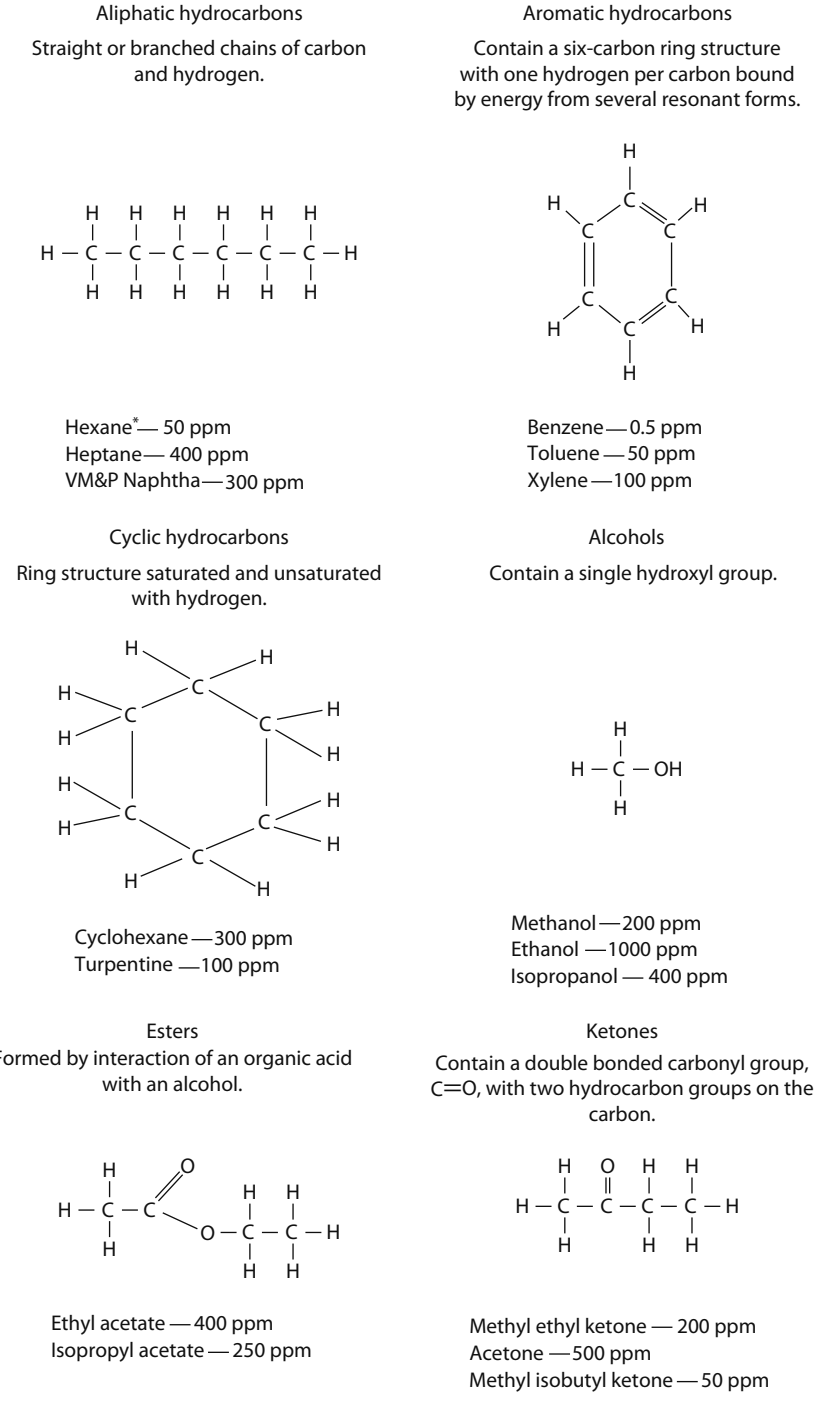

FIGURE 15.1 Classes of organic solvents.

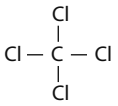
Halogenated hydrocarbon

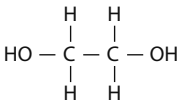
A halogen atom has replaced one or more hydrogen atoms on the hydrocarbon.



Carbon tetrachloride—5 ppm
Methyl chloroform—350 ppm
Chloroform—10 ppm

Glycols

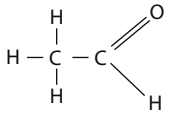
Contain double hydroxyl groups.



Ethylene glycol—100 mg/m^3 (ceiling)
Hexylene glycol— 25 ppm (ceiling)

Aldehydes

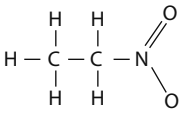
Contain the double-bonded carbonyl group, C=O, with only one hydrocarbon group on the carbon.



Acetaldehyde—25 ppm (ceiling)
Formaldehyde—0.3 ppm (ceiling)

Nitro-hydrocarbons

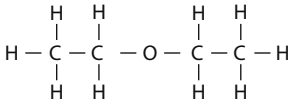
Contain an NO_2 group.



Nitroethane —100 ppm
Nitromethane —20 ppm

Ethers

Contain the C —O —C linkage.



Ethyl ether— 400 ppm
Isopropyl ether—250 ppm

FIGURE 15.1 (continued) Classes of organic solvents.

environment is dependent on the surface area of the liquid, the temperature of the solvent, and the atmospheric pressure.

The IH/HS&E professional is able to use the vapor pressure of a solvent to calculate what the concentration of the solvent vapor in parts per million (ppm) will be at the point of saturation or equilibrium within a given environment. This is performed by dividing the vapor pressure of the solvent by the total atmospheric barometric pressure and then multiplying by 1,000,000:

$$\frac{\text{Vapor pressure of the liquid}}{760\,\text{mmHg}} \times 1{,}000{,}000 = \text{X ppm of vapor}$$

Volatility

Volatility is the ability of a solvent to evaporate. The term *volatile* is commonly used to mean that a material evaporates easily. Volatility is directly related to a substance's vapor pressure. At a given temperature, the substance with higher vapor pressure volatilizes more readily than a substance with a lower vapor pressure. Solvents, or products containing volatile solvents, often present a need for general and/or local exhaust ventilation and other precautions to control vapor concentrations below established exposure and flammability limits [41].

Evaporation Rate

The rate by which liquid evaporates is dependent on a number of intrinsic properties of the liquid and various external factors; the *evaporation rate* is a measure of how quickly the material sublimes to a vapor at normal room temperature. Usually, the evaporation rate is given in comparison to a reference liquid or solvent, such as *n*-butyl acetate or ethyl ether, which evaporates fairly quickly at the same temperature and atmospheric pressure. Because the reference solvent is given an evaporation rate of 1.0, those solvents with an evaporation rate of less than 1.0 evaporate more quickly than the referent and those whose evaporation rate is greater than 1.0 evaporate more slowly [21,22,41]. Often, in many chemical references (i.e., Chemical Safety Data Sheets), the evaporation rate is given only as greater or less than 1, which means the solvent evaporates faster or slower than the reference chemical.

Flash Point

The flash point is the lowest temperature at which a liquid or solid gives off enough vapor to form a flammable air–vapor mixture near its surface. The lower the flash point, the greater the fire hazard. The flash point is an approximate value and should not be taken as a sharp dividing line between safe and hazardous conditions [188]. The flash point of a liquid is often empirically determined by a variety of test methods; each method provides different results. Two types of methods most commonly used are open cup (OC) and closed cup (CC). The flash point is determined based on the temperature at which a solvent within an OC or CC instrument—creates enough vapor sufficient to flash when an ignition source is introduced. Flash point can be used, in part, as a criterion to define under what temperature a solvent may be safely stored in open containers and used. However, solvents introduced into the atmosphere as sprays or mists can be ignited below the flash point of the solvent [21,22,41].

Flammable (Explosive) Range

The range of concentrations of a gas or vapor that, when mixed with air and exposed to an ignition source (spark or flame), will ignite or rapidly combust (explode) is recognized as the *flammability* (explosivity) range for the particular gas or vapor. The flammability (explosivity) range is inclusive of all concentration levels of a gas or vapor from the lowest concentration (lower flammability limit [LFL] or lower explosive limit [LEL]) to the highest concentration (upper flammability limit [UFL] or upper explosive limit [UEL]) a vapor or gas can be made to combust. The range of concentrations between the LFL/LEL and the UFL/UEL is commonly reported in percent concentration (by volume) of the vapor in the air and is typically based on an ambient temperature of 68°F. When considering the LFL/LEL and UFL/UEL of a gas or vapor in conditions other than that of an ambient temperature of 68°F and 1 standard atmosphere, one should recognize that the general effect of increasing the temperature or pressure is to decrease the lower limits and increase the upper limits. Conversely, a lowering of the temperature or pressure will serve to raise the lower limits and lower the upper limit [11,12]. Figure 15.2 provides a graphical depiction of the relationships among flammable/explosive limits, vapor pressure, and flash points [21,22,41].

Specific Gravity

The ratio of the weight of a given volume of a substance (e.g., solvent) at a given temperature (usually given as 75°F) and atmospheric pressure to the weight of an equal volume of water at the same temperature, and atmospheric pressure is known as the *specific gravity* (Sp. Gr.) of the substance. The density of water is about 1 g/cm^3 or g/cc. If the specific gravity of a solvent is less than 1, it will float on top of water; if it is greater than 1, it will tend to sink, depending on its solubility. Therefore, in situations where a solvent is spilled into a water body, it is imperative to determine whether the solvent sinks (Sp. Gr. > 1) or floats (Sp. Gr. < 1) with regard to its ability to catch fire should it reach an ignition source.

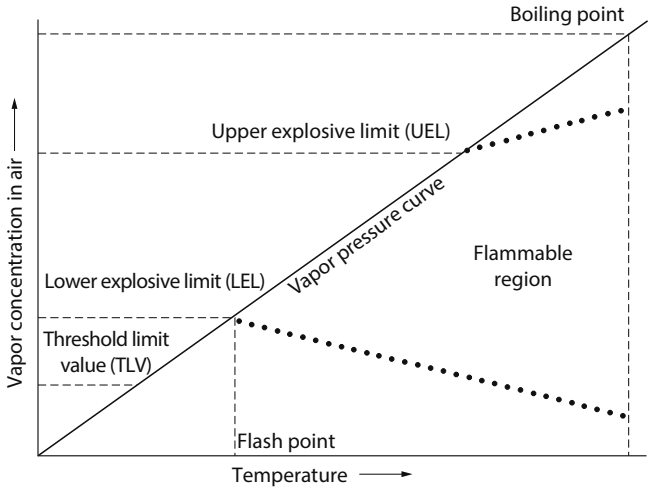


FIGURE 15.2 Diagram of vapor pressure vs. temperature depicts the relationships among upper and lower flammable (explosive) limits, flammable and nonflammable regions, threshold limit value, boiling point, flash point, and vapor pressure curve. This diagram shows what happens to a vapor/air mixture as concentrations and temperature vary. *, TLV®, American Conference of Governmental Industrial Hygienists (ACGIH) Threshold Limit Value (TLV-TWA), 1998.

Vapor Density

The ratio of the weight of a given volume of vapor or gas to the weight of an equal volume of air at the same temperature and atmospheric pressure defines the *vapor density* of that vapor or gas. Vapors or gases with a vapor density less than 1 (lighter than air) will rise into the air, whereas those with a vapor density greater than 1 (heavier than air) will tend to sink to the lowest point in the immediate surroundings. The vapor density of a solvent can be roughly estimated by dividing the molecular weight of the solvent by the molecular weight of air (MW ~ 29). This value is important when considering the potential for oxygen displacement or fire/explosion should an ignition source be in low-lying areas when a solvent is spilled. Conversely, the likelihood of vapors rising and representing an acute respiratory hazard when the vapor density is less than 1 is equally worthy of consideration [21,22,41].

Partition Coefficient

The *partition coefficient* (P) also called the coefficient of oil/water distribution is the ratio of the solubility of a solvent in an oil to its solubility in water. The P value is typically presented as a logarithm of P (log P). The partition coefficient indicates how easily a chemical can be absorbed into or stored within the fatty tissues of the body [74,157]. The P value is also helpful in predicting the fate of the chemical in the environment through its tendency to partition into the water, soil, and living organisms [41,66,171].

WORKPLACE EXPOSURE LIMITS

Occupational exposure limits (OELs) are developed by various organizations for the purpose of protecting the health of workers who may be exposed to specific hazardous substances during their work. Published OELs typically represent consensus standards at the time and are formulated by qualified experts like toxicologists, occupational physicians, industry experts, and epidemiologists. Such experts utilize the most reliable scientific knowledge available at that time to construct a recommended (i.e., National Institute for Occupational Safety and Health (NIOSH)—Recommended Exposure Limit (REL), ACGIH Threshold Limit Value) or enforceable (i.e., OSHA PEL) maximum airborne concentration (incorporating a safety factor to account for uncertainties) over some specified time period for a specific workplace contaminant. Therefore, these OELs are presented as representative of an airborne concentration of a particular chemical that is deemed an acceptable risk to life and health for the general worker population [193]. It is important to recognize that these OELs do not provide a bright line between what concentration is safe and not safe due to recognized uncertainties, variations of effects due to age, health status, gender, work activity level, or workplace environmental conditions, to name a few considerations.

In the United States, the Occupational Safety and Health Administration (OSHA) is empowered to establish and enforce Permissible Exposure Limits (PEL), likewise the Mine Safety and Health Administration (MSHA) also may develop legally enforced OELs specific to mining. Other federal agencies that publish occupational exposure limits include the National Institute for Occupational Safety and Health (NIOSH) Recommended Exposure Limits (REL), the Environmental Protection Agency's (EPA) New Chemical Exposure Limits (NCELs) and voluntary Acceptable Exposure Limits (AELs), the Department of Energy's (DOE) established personnel radiation dose limits, and finally the Department of Defense's establishment of specific OELs for military personnel. Nongovernmental organizations, such as the American Conference of Government Industrial Hygienists before (ACGIH), develop and present an annual compilation of Threshold Limit Value (TLV®) and Biological Exposure Indices (BEIs®) or American Industrial Hygiene Association's (AIHA) Workplace Environmental Exposure Limits (WEELs). Additionally, many states may develop their own specific workplace- or community-focused exposure regulations. Many manufacturers may establish OELs for their own products or processes. In Canada, OELs are established by each province. Similarly, the Control of Substances Hazardous to Health (COSHH) regulations within the United Kingdom regulate workplace exposure levels by specifying maximum exposure limits (MELs) and occupational exposure standards (OESs). German workforce exposures are regulated by the Deutsche Forschungsgemeinschaft (DFG) maximum concentration values in the workplace (MAKs). Once again, it is important to recognize that many of these established OELs will vary from organization-to-organization that creates them as well as over time as scientific knowledge evolves.

The establishment of new OELs is a complex matter. In general, the process involves the review of reliably established toxicity data from a number of relevant sources to identify critical studies, health effects, and toxic endpoints. After the application of safety and uncertainty factors to the critical data, an OEL value may be derived. Each step of the process requires considerable professional judgment in the selection of the appropriate critical studies, health effects, and derived toxic endpoints, as well as in the application of appropriate safety and uncertainty factors. Because of differences in individual perspective, institutional criteria, and political realities, large differences in final OEL value recommendations can and often do occur.

There are four different types of occupational exposure limits in common use:

1. A TWA exposure limit (i.e., OSHA-PEL or ACGIH-TLV) is the TWA concentration of a chemical in air typically averaged over a normal 8 h work day and 40 h work week to which, it is thought, nearly all workers may be exposed day after day without harmful effects. TWA means that the material's average airborne concentration has been calculated using the duration of exposure to variable concentrations of the chemical over a specific time period. In this way, higher and lower exposures are averaged over the work period, day, or week.
2. A short-term exposure limit (STEL) is generally defined as the average concentration to which workers can be exposed for a short period (usually 15 min) without experiencing irritation, long-term or irreversible tissue damage, or reduced alertness. The number of times the concentration reaches the STEL and the amount of time between these occurrences can also be restricted.
3. A ceiling (C) exposure limit is the concentration of the chemical in air, which should not be exceeded at any time.
4. The Immediately Dangerous to Life and Health (IDLH) designation observed for many chemicals refers to an extremely hazardous, life-threatening concentration of the chemical. It is the estimated maximum concentration of an airborne contaminant from which a worker can escape (e.g., after failure of respiratory protection) without loss of life or suffering permanent health impairment within a specified period of time. A chemical's IDLH is defined by U.S. law as "An atmospheric concentration of any toxic, corrosive, or asphyxiant substance that poses an immediate threat to life or would cause irreversible or delayed adverse health effects or would interfere with an individual's ability to escape from a dangerous atmosphere. [29 CFR* 1910.120]" Workers who enter into an IDLH atmosphere are required to wear the highest form of respiratory protection (positive-pressure, self-contained, or airline breathing apparatus) and usually fully protective clothing ensemble. The purpose of establishing an IDLH value is (1) to

> ensure that the worker can escape from a given contaminated environment in the event of failure of the respiratory protection equipment and (2) is considered a maximum level above which only a highly reliable breathing apparatus providing maximum worker protection is permitted [146].

Regardless of the source or legal standing, OELs should not be taken as sharp dividing lines between safe and unsafe exposures. It is possible for a chemical to cause health effects, in some people, at concentrations lower than the recommended OEL while others may not suffer the health effects expected.

Permissible Exposure Limits

The U.S. Department of Labor's OSHA, publishes a list of regulated PELs as TWAs annually in the Code of Federal Regulations (CFRs), Titles 1910, 1915 and 1926. These regulatory PELs establish the averaged airborne concentrations of over 400 chemicals to which the majority of workers may be exposed over an 8 h day, 40 h a week, over a working lifetime (40–45 years) without suffering adverse impact on health. Likewise, the MSHA regulates miner exposures to specified airborne contaminants during an 8 h day and 40 h work week by a similar list of PELs as applied to various types of mining operations (e.g., coal, metallic, and nonmetallic mining). OSHA PELs are incorporated by law as federal OSHA standards in Section 1910.1000 of Title 29 of the CFRs, Tables Z-1 through Z-3, with particular standards for recognized carcinogens provided in sections 1001 through 1048. These PELs were originally derived from the 1968 ACGIH TLVs® and certain air-quality standards recognized as maximum allowable concentrations (MACs) of the American National Standards Institute. The PELs represent the legal allowable concentrations of airborne contaminants within workplaces regulated by OSHA. Although the PELs remain as created unless changes are made in the law, a number of revisions and additions have been made to the PEL list since 1970. The PELs identify chemical TWAs, ceiling values, and skin notations.

Recommended Exposure Limits

The NIOSH RELs are expressed as TWAs, as ceiling limits, or both. These recommended limits are published as chemical-specific criteria documents and are revised periodically as new research information regarding the particular chemical becomes available. The RELs are applicable to worker exposure assessments for up to a 10 h day and are intended to provide the maximum possible health protection for all workers against acute and chronic effects of exposure. Likewise, the RELs provide skin notations for specific chemicals, where applicable. NIOSH publishes and periodically updates its compendium of chemical exposure information for specific chemicals in its NIOSH Pocket Guide to Chemical Hazards (NPG). The NPG is intended as a source of general industrial hygiene information on several hundred chemicals/classes for workers, employers, and occupational health professionals. The NPG presents key information and data in abbreviated or tabular form for chemicals that are found in the work environment. The information found in the NPG includes: Chemical names, synonyms, trade names, Chemical Abstract Number (CAS), Registry of Toxic Effects of Chemical Substances (RTECS) number, Department of Transportation (DOT) Chemical Identification and Guide numbers, Chemical structure/formula, conversion factors, NIOSH RELs, OSHA PELs, NIOSH IDLH values, Physical description and chemical and physical properties of each chemical, suggested measurement methods, personal protection recommendations, sanitation recommendations, respiratory protection selection recommendations, listed chemical incompatibilities and reactivity agents, exposure routes, potential symptoms, target organs potentially effected, and first aid information [143].

Threshold Limit Values

TLVs® and BEIs® are exposure guidelines developed by the ACGIH. Updates of the TLVs® and BEIs® are published by ACGIH each year. Voluntary committees of experts from a variety of disciplines and industries work collectively, using the best available information using industrial experience, animal and human studies to ensure that the TLVs® and BEIs® represent the opinion of the scientific community, based on the respective review of existing published and peer-reviewed literature in various scientific disciplines (e.g., industrial hygiene, toxicology, occupational medicine, and epidemiology). TLVs® and BEIs® are based solely on health factors, and unlike PELs and RELs, there is no consideration given to economic or technical feasibility. A chemical's TLV®–TWA is the airborne concentration to which the average worker may be exposed during an 8 h workday and 40 h work week without suffering adverse effects over a working lifetime. Most TLVs® are presented as TWA values and allow for periodic short-term exposures above the limit, providing there are compensating equivalent exposures that are below the limit during the workday [4]. BEIs®, as provided in the ACGIH's annual publication of TLVs® and BEIs® are a useful measure to evaluate biological monitoring data from workers. The BEIs® provide levels of the specific chemical or its metabolites as measured from exhaled air, blood, and/or urine of workers exposed to the airborne contaminant. Most BEIs® are directly related to the TLV and reflect internal dose for a worker with inhalation exposure to the same chemical at the TLV®. BEIs® are a measure of the amount of chemical or its metabolites in the body and may be useful when evaluating the possibility of skin absorption, effectiveness of personal protective equipment (PPE), or nonoccupational exposure. BEIs are strictly related to 8 h exposures, 40 h a week, and to the specified timing for the collection of the sample [4].

Workplace Environmental Exposure Limits

The AIHA WEEL Committee develops workplace environment exposure limits (WEELs) for chemical agents in common use in the workplace that have no other current OEL

guidelines established by other organizations [10]. WEELs are expressed as an average concentration measured over a time period, as different time periods of exposure measurement are specified, depending on the properties of the particular chemical. The skin notation for a WEEL is used in the same manner as the ACGIH TLV® [4].

USE OF OCCUPATIONAL EXPOSURE LIMITS IN THE WORKPLACE

Time Weighted Average Calculation

The industrial hygienist and other HS&E professionals regularly rely on reference OEL guidelines when assessing exposure to chemical and physical hazards within the workplace. To illustrate the TWA concept, consider a worker who is degreasing metal parts at two different workstations using trichloroethylene (50 ppm TLV®). The employee spends 240 min at Station 1 with an average exposure of 30 ppm, followed by 45 min with no exposure (lunch), then 195 min at Station 2 with an exposure of 60 ppm. Using the formula

$$\frac{\left(C_1T_1\right)+\left(C_2T_2\right)+\left(C_3T_3\right)+\cdots\left(C_nT_n\right)}{480\,\text{min}\left(8\,\text{h}\right)}=\text{X ppm},$$

where

C denotes the concentration of the chemical
T refers to the respective time period of use of that chemical

For the 8 h scenario above the TWA can be calculated as follows [6]:

$$\frac{(30\,\text{ppm}\times 240\,\text{min})+(0\,\text{ppm}\times 45\,\text{min})+(60\,\text{ppm}\times 195\,\text{min})}{480\,\text{min}\left(8\,\text{h}\right)}$$

$$=39.4\,\text{ppm}$$

In this example, the TLV®–TWA of 50 ppm for trichloroethylene exposure has not been exceeded. However, one may want to evaluate the employee's work practices to consider whether the chemical in use can also be absorbed through the skin or eyes, as well as other aspects of the operation (e.g., provision of local exhaust ventilation) to reduce the exposure as much as possible (refer to the sections on exposure controls and PPE).

Today's workplaces are becoming more and more complex. More and varied chemicals of different compositions, structure, size/dimension, and physical state are being incorporated into manufacturing processes, to create new or modified products for the consumer. Simply consider, for example, the workplace processes associated with the development and use of engineered nanomaterials (ENMs), genetically modified (GM) or chemically treated seeds, or the variety of chemicals used and produced in refineries, chemical manufacturing facilities, or even the average fabrication shop. In all of these environments, the average worker can encounter widely fluctuating levels of exposures to chemical mixtures in the workplace environment over the course of the work day, week, year, and career. How does the industrial hygienist evaluate the potential for adverse health impacts on workers in such workplaces where multiple chemicals and their byproducts of production occur?

Provided the components of a mixture have similar toxicological effects, and the workplace air is analyzed for each component, the TLV® for a mixture of airborne chemicals can be calculated by using the formula [2]

$$\frac{C_1}{T_1}+\frac{C_2}{T_2}+\frac{C_3}{T_3}+\cdots\frac{C_n}{T_n}=X$$

where the letters C and T represent the concentration and TLV® of each chemical, respectively. If the calculated results indicate a value greater than 1, then the TLV® of the mixture measured has been exceeded. As an example, suppose a worker was exposed to a mixture of 25 ppm *n*-hexane (TLV® = 50 ppm) and 200 ppm VM&P naphtha (TLV® = 300 ppm) during the shift. The calculated TLV® would be

$$\frac{25\,\text{ppm}}{50\,\text{ppm}}+\frac{200\,\text{ppm}}{300\,\text{ppm}}=0.5+0.67=1.17.$$

The threshold limit has been exceeded, and action should be taken to reduce this exposure. For other examples of TLV®s for mixtures, refer to the most current annual version of the ACGIH TLV® handbook [4].

Adjusting Occupational Exposure Limits for Extended Work Shifts

The evaluation of potential adverse effects upon workers that may result from chemical exposures during extended work shifts (e.g., 10 h or 12 h days) is likewise a point of focus for the industrial hygienist when characterizing job safety within each workplace. To better evaluate job exposures during extended work periods and to compensate for the potential for higher accumulated doses and shorter daily-recovery times, adjustments of the OELs must be made. A review of the approaches to adjusting occupational exposure limits for unusual work schedules is provided in Patty's Industrial Hygiene [155]. The ACGIH, in the TLV®s and BEIs® documentation, refers to many different methods to adapt existing TLV®s to extended work shifts or workweeks [4]. The Brief and Scala model [37] presents one of the simpler guidelines for industrial hygienist dealing with extended work shifts. The Brief and Scala model does not consider health effects, toxic action, or pharmacokinetics. The model simply adjusts the respective exposure limits according to a reduction factor calculated for a single work day by the formula

$$\text{Adjusted TLV}^{\circledR}=\text{TLV}^{\circledR}\times\left[\frac{8}{\text{h}}\times\frac{\left(24-\text{h}\right)}{16}\right]$$

where h = # of hours worked per day or for a work week

$$\text{Adjusted TLV}^{®} = \text{TLV}^{®} \times \left[\left(\frac{40}{\text{h}} \right) \times \frac{(168 - \text{h})}{128} \right]$$

where h = # of hours worked per week

As an example, suppose a worker assigned to a 12 h shift works on a process using methanol. The TLV® for methanol is 200 ppm. Applying the single day formula, the adjusted TLV® to be utilized to assess worker exposure/overexposure over the extended work period would be

$$200 \text{ ppm} \times \left[\frac{8}{12} \times \frac{(24 - 12)}{16} \right] = 200 \times \left[0.667 \times 0.75 \right] = 100 \text{ ppm}$$

INDUSTRIAL HYGIENE SAMPLING METHODOLOGY

The industrial hygienist can utilize a variety of different sampling techniques, instruments, and analytical methods to identify and measure the concentration of a workplace contaminant (chemical, biological, radiological, or physical hazard) in the workplace. In the case of airborne hazards, the concentration in the workplace is evaluated from the perspective of either the general work environment where the work is performed or by measuring the concentration of the contaminants in the air directly breathed by specific worker by sampling within the personal breathing zone (PBZ), an area approximately one foot in radius around the worker's nose.

There are a number of methods available to estimate the identity and/or concentration of contaminants within the workplace. The primary methods of industrial hygiene sampling include active sample collection (typically utilizing a calibrated sampling pump and specific sampling media), direct reading instrumentation, or passive dosimetry. The respective qualitative and quantitative value of the measurement obtained from each of these sampling methods is dependent on the level of accuracy required, the urgency in obtaining results, the cost of sample collection and analysis, and the level of difficulty for collecting the samples.

As chemical detection capabilities and instrument sensitivities improve, the trend in evaluating workplace environments has moved toward the use of direct-reading instruments (e.g., colorimetric detector tubes and handheld instruments) and passive dosimetry (e.g., organic vapor badges). This is due, in large part, to the desire for immediate feedback and ease-of-use associated with these methods. For additional information on industrial hygiene sampling, refer to the ACGIH text, *Air Sampling Instruments* [1]. NIOSH [144,145], OSHA [150,151], and MSHA [118,119] publish methods and guidelines for sampling specific chemicals in the workplace. The United States EPA also publishes many methods that are useful in monitoring workplace contaminants [60]. The NPG [143] includes information on sampling and analytical methods as described in the NIOSH Manual of Analytical Methods [144] or the OSHA numbered methods [150]. In addition, many manufacturers and commercial laboratories provide chemical sampling guides by chemical name and agency method.

Active Sampling

Active sampling involves the use of a powered sampling pump to draw a measured volume of air from the general work environment (general area sample) or an individual worker's PBZ onto a suitable collection media over a defined time period. The sampling media is then analyzed in the laboratory by prescribed analytical procedure to accurately qualify or quantify the amount of material collected. The sampling pump requires field or laboratory calibration with a primary standard to ensure that it is drawing air through the collection media at the desired flow rate. The collection media is an integral part of the sampling train, being connected to the sampling pump via tubing. The complete sampling train is then positioned in the immediate area of the process (point of generation) or is attached within the PBZ of the worker being monitored with the sampling pump on the hip and collection medium located in the worker's breathing zone (typically the shirt collar). When the sampling process for industrial hygiene purposes is completed, the flow rate calibration of the sampling pump is checked against the initial calibration and the associated collection media sent to an AIHA-accredited analytical laboratory for extraction and analysis. Various types of collection media are available for solvents, depending on such factors as the polarity and complexity of the chemical being evaluated. Examples of the variety of sorbent media include

1. Activated charcoal for sampling solvents such as chlorinated hydrocarbons, gasoline, many alcohols, and ketones
2. Silica gel for amines, methanol, phenols, and aldehydes
3. Chemically treated media, including filters for toluene diisocyanates, naphthylamines, and toluidines

Another active sampling method that is becoming more prevalent is the use of evacuated containers. In this instance, a specific volume of air to be sampled is collected by drawing it through a calibrated orifice at a specific flow rate to provide for either rapid inflow (grab sampling) or over time (1–24 h) into a specially prepared evacuated canister. The air within the canister can then be analyzed in the laboratory, after being first pressurized with nitrogen, aliquots of the air sample withdrawn, cryofocused, and analyzed by gas chromatography/mass spectrometry to determine the concentration of the various chemicals/mixtures present [61,152].

Direct-Reading Instrument Methods

Direct-reading instrument methods allow airborne concentrations of solvents (or other contaminants) to be measured with nearly instantaneous results. Direct-reading instrument methods are particularly useful in a number of applications,

including identifying potential process leak locations, determining peak exposure areas and occurrences, evaluating the effectiveness of engineering controls, or for continuous monitoring applications [7]. A wide variety of direct-reading devices and instruments is available for measuring solvent concentrations. The measurement methods generally incorporate the use of colorimetric detector (or indicator) tubes and badges or direct-reading instruments [11–13,62].

Colorimetric detector tubes and badges contain reagent-containing media that react with airborne solvent vapor (categorically or specifically) to produce a color change. The intensity of color change or the length of stain is compared with a calibration scale to determine the concentration (generally within ±25%) of the solvent vapor. The use of these tubes generally incorporate the use of a calibrated bellows-type or battery-powered pump. Such pumps are easy to use, relatively inexpensive, and may be used for short (minutes) or long (hours) sampling intervals. Disadvantages include possible interfering compounds, lower accuracy, and some subjectivity in the readings. Many of these methods are referred to as *grab samples* providing data regarding the presence and general concentration of the air contaminant only at that location and point in time. The results are considered semiquantitative or semiqualitative, due to larger accepted standard error and method limitations [14].

Direct-reading instruments are preferred over detector tubes when multiple readings are desired. Types of direct-reading instruments suitable for measuring solvents include analyzers with flame ionization (FID) and infrared (IR) detectors, combustible gas/vapor meters, photoionization detectors (PIDs), and portable gas chromatographs [5]. Direct-reading instruments can be either handheld (for portability) or fixed (for continuous area monitoring) [137]. The FID and PID are portable, rapid responding, and sensitive instruments but are nonspecific. They are particularly suitable for monitoring many solvents into the part per billion range. Infrared instruments are often capable of both qualitative and quantitative analysis of workplace contaminants but often lack portability and may generally provide slower response times. Combustible gas/vapor monitors are useful from a safety standpoint (detecting flammable/explosive atmospheres); however, for many solvents, the toxicity hazard may be at a lower concentration than the lower flammability/explosive limit [6]. Portable gas chromatographs are often as accurate as laboratory instruments in both qualitative and quantitative analysis of workplace contaminants. Shortcomings include power requirements, the need for specialized compressed carrier gas and sample collection; however, technological advances are providing solutions to many of these issues [144,147].

Passive Dosimetry

General area or PBZ sampling with passive dosimeters (e.g., organic vapor monitors) relies on the principle of molecular diffusion into the collection media rather than actively pulling the air through a sampling train. This detection and measurement technology is particularly well suited for personal sampling because these devices [29]

1. Are lightweight
2. Are unobtrusive
3. Require no external power source
4. Require no calibration
5. Can be used to obtain short-term or full-shift exposures

Organic vapor monitors are accurate (within a specified standard error and limitations) and can be used to sample for many industrial solvents. Analysis generally involves chemical desorption and gas chromatographic methods.

EXPOSURE CONTROLS

Worker overexposure to solvents may be avoided through the selection and implementation of proper administrative policies and practices, management programs (e.g., employee training, education, housekeeping, waste disposal, job safety analysis, medical surveillance), workplace planning (e.g., process design and location, equipment design, materials storage, chemicals used), and the use of engineering controls (e.g., general supply and local exhaust ventilation), where necessary. The selection of appropriate exposure control methods will depend on the nature of the hazard, how the potential hazard enters the work space, and the anticipated exposure pathway (inhalation, dermal, ingestion). Specific exposure-control methods may be mandated by federal health and safety regulations (as in the case of benzene and vinyl chloride) or when exposure levels exceed established OELs (e.g., PELs and TLV®s).

The preferred approaches to controlling workplace exposures to solvents are through the use of administrative or engineering controls. Types of controls (in order of preference): chemical or engineering process changes to eliminate/reduce solvent usage, substitution with a less hazardous solvent (Green Chemistry), isolation of the process to minimize worker exposures, local exhaust ventilation to reduce the concentration at the source in the work environment. The choice of using appropriate PPE to defray worker exposures should be viewed as a control method of last resort when no other practical means are available to control worker exposure. Recognize that the control of solvent exposures within the workplace is generally not resolved by a single control measure but is most often achieved by the application of a combination of these methods [9].

Administrative and Management Control

The first line of defense in the management of worker health and safety is the implementation and management commitment to effective workplace policies and procedures. These policies and procedures set the expectations for personnel practices, workplace behavior, product quality, and supervisor commitment. It is the measure of management

commitment and adherence to established policies and procedures that defines the level of success in workplace safety. Typical management programs that serve to enhance workplace safety and employee well-being include

1. Employee education (hazard communications, hazard awareness, emergency procedures, frequent safety meetings, proper use of PPE)
2. Employee training (e.g., process procedures, materials use, equipment operation and maintenance, standard operating procedures, safe work practices)
3. Community outreach programs (e.g., community right-to-know practices) [15]

Engineering Controls

Engineering controls play a key role in the design and use of production equipment, the general workplace environment, and employee well-being. To maintain safe and healthful work environments, significant consideration must be given to the design and integration of applicable engineering controls in workplace layout, selection and use of production equipment, chemical and material usage, process design, operating procedures, ventilation system configuration, fire suppression, utilities, etc.

Engineering controls should figure prominently in the design of process operations, including the use of solvents and other chemical hazards. In this regard, useful engineering controls can include practices to the following:

1. Eliminate use of the solvent in the process.
2. Substitute a less toxic solvent in the process.
3. Isolate the process from surrounding operations.
4. Enclose the process to minimize worker exposure.
5. Revise processes to minimize or eliminate process hazards by changing from manual to mechanical systems, wet methods from dry methods, water-based cleaners from organic solvent-based ones, etc.
6. Use effective local exhaust or dilution ventilation to eliminate or minimize hazardous levels of solvent vapors from the worker's breathing zone.

Elimination

Recent and ongoing developments in the field of Green Chemistry demonstrate that organic solvent-based processes can often be redesigned to eliminate the use of particular solvents/chemicals in the operation. Eliminating the solvent/chemical is considered the best approach to controlling worker exposure. From a cost perspective, available options should be evaluated during the initial design of the process, but can be instituted whenever safer process methods arise. The practice of process solvent/chemical elimination has been utilized in various organic solvent-based processes such as metals degreasing, cleaning, printing, painting, and treatment. These initiatives are the result of a combination of health and safety awareness, materials cost control, good business practice, and government regulation. Industry has recognized that the elimination of organic solvents may have additional benefits as well, including the reduction of hazardous air pollutant emissions into the ambient environment, the cost savings associated with decreases in waste treatment and disposal costs, and significant reductions in PPE purchases. Examples of organic solvent elimination include replacing chlorinated solvent degreasers with water-based detergent or subcritical carbon dioxide systems (discussed later); replacing solvent-based paints with water-based paints; improving flux application systems in circuit-board manufacturing to eliminate the need for cleaning with chlorinated compounds; and using water-based or vegetable oil-based inks to eliminate solvent-based inks.

Substitution

When the elimination of solvents from a process is not practical, it is often possible to replace the more toxic solvent with another of lower toxicity or less hazardous physical properties (e.g., higher flash point, lower vapor pressure). Often, substitutions may be made within a chemical series by retaining the active group; for example, substitution of butyl cellosolve for methyl cellosolve. In many cases, it may be possible to retain the general chemical group, such as in the substitution of aromatic naphtha for toluene or toluene for benzene. Substituting a solvent with similar polar characteristics but different toxicity, such as ethanol for methanol, may also be possible. Other examples include replacing perchloroethylene with citrus-based products in metal degreasing, substituting isocyanate-containing coatings with toluene-based materials, and replacing formaldehyde used in preserving laboratory specimens with glycol-based compounds.

Isolation and Enclosure

A process can sometimes be enclosed or automated to isolate the worker from the hazards of operation. When total enclosure of a solvent-based process is not possible, the operation can be separated from adjacent areas to minimize the number of workers potentially exposed to the vapor. The isolation by enclosure of a solvent-based process usually requires the introduction of local exhaust or dilution ventilation (see following text) to prevent or minimize the accumulation of toxic concentrations of vapors within the workspace or process enclosure (fire/explosion hazard). Examples of isolation are found in most manufacturing environments; for example, manual painting in automotive assembly plants and manual metal-plating operations have been replaced with robotic systems. These automated processes often can be operated and monitored from remote locations.

Process Revision

The revision of production processes is also a viable engineering control. Often, an engineering cost–benefit analysis that includes consideration of potential decreases in

employee health costs, medical surveillance testing, the use of PPE, and the return on investment for new equipment will determine the practicality of the option whenever newer techniques and production equipment become available. Two examples of process revision related to the potential for exposure to solvents in industrial practice are seen in the spray-painting practice, such as replacing spray-painting with paint dipping and replacing compressed air spray painting with electrostatic methods, resulting in a decrease in the volume of paint overspray into the workplace.

Workplace Ventilation

When the engineering control methods discussed earlier are not feasible or available, the incorporation of mechanical ventilation methods for the control of worker exposure to airborne contaminants such as solvent vapors is appropriate. Within the occupational workplace setting, this involves the balanced delivery of a sufficient supply of uncontaminated air into the work area (dilution ventilation) or direct removal of contaminated air by both general and local exhaust ventilation methods.

Dilution Ventilation

Mechanical ventilation in the workplace to manage worker exposures to airborne contaminants can, in some situations, be accomplished by the introduction of sufficient fresh air in specific work locations to dilute vapors to acceptable levels. Typical applications for dilution ventilation are controlling heat exposures (as in foundries) or regulating humidity and odor. If dilution ventilation is to be used to reduce the concentration of solvent vapors in the ambient air, at least four conditions must be met [3]:

1. The concentrations of solvent vapor generated must be relatively low or the air volume necessary for dilution will become so costly and inefficient as to be impractical.
2. The worker must be positioned a sufficient distance from the immediate source of solvent vapor generation to ensure that the established PEL, TLV®–TWA, STEL, and ceiling limit are not exceeded.
3. The solvent must have a relatively low toxicity rating.
4. The solvent vapor must be released into the work environment at a uniform rate.

Local Exhaust Ventilation

In contrast to dilution ventilation, *local exhaust ventilation* (LEV) functions to remove the solvent vapors (air contaminant) at their point of generation. In most instances, the use of local exhaust ventilation proves to be more effective in protecting the worker from exposure and less expensive to operate because lower air volumes and smaller fans are required. LEV systems can consist of a canopy hood or slotted capture collection system (depending on the vapor density of the solvent), duct work, a suction fan, and an optional filtration system for contaminant removal prior to discharge to the outside environment. Figure 15.3 shows a typical local exhaust ventilation system [9]. The decision of whether or not to install LEV for solvent exposure control is based on a number of factors, including

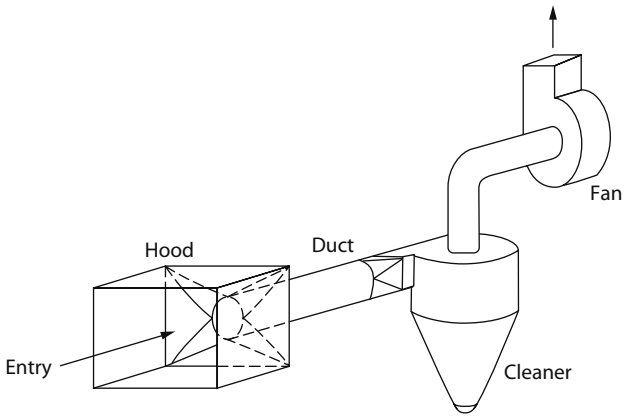

FIGURE 15.3 Typical local exhaust system components. (From DiNardi, S.R., ed., *The Occupational Environment: Its Evaluation and Control*, AIHA Press, Fairfax, VA, 2003. With permission of the American Industrial Hygiene Association.)

1. Lack of more cost-effective controls
2. Volume and toxicity rating of the solvent vapor generated
3. Regulatory requirements
4. Good management practice

In LEV systems, the contaminated air is exhausted to the outside ambient environment either directly or by passing the air stream through some variety of contaminant collection or filtration system. The three types of LEV hood designs for solvent vapor control are *enclosing*, *exterior* (or capture), and *receiving*. Figure 15.4 provides an illustration of each [9].

Enclosing hoods partially or completely enclose the process so the point of contaminant generation is located inside the capture area of the hood. Enclosing the process as much as possible increases the effectiveness and efficiency of LEV systems. Examples of enclosing systems include laboratory chemical fume hoods and spray-paint booths. Exterior hoods, also called *capture* or *slotted hoods*, are located near the point of contaminant generation but do not enclose it. Examples of exterior hoods are slot-type hoods used on vapor degreasing processes and flexible hoods used to exhaust solvent-based

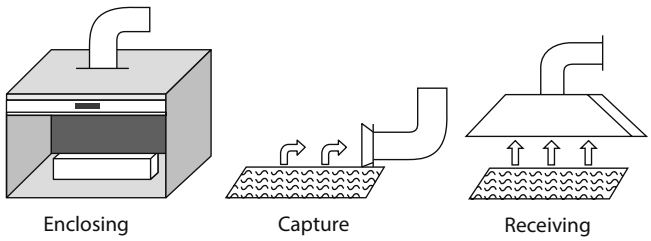

FIGURE 15.4 Three types of local exhaust ventilation hoods.

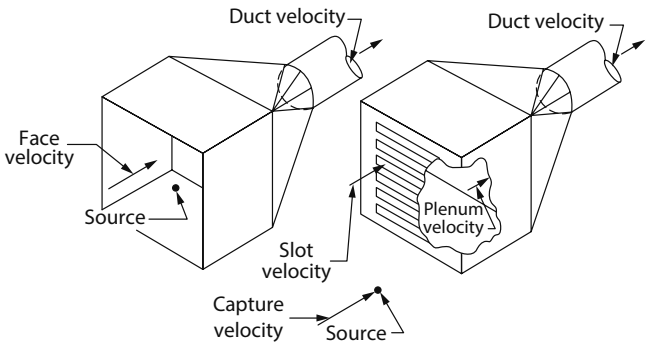

FIGURE 15.5 Principles of exhaust hoods. (From ACGIH, *Industrial Ventilation: A Manual of Recommended Practice*, 23rd edn., American Conference of Governmental Industrial Hygienists, Cincinnati, OH, 2007. With permission.)

mixing processes. Receiving hoods are typically canopy-type hoods used for exhausting hot processes (e.g., ovens and detergent baths). They are generally less suitable for solvent operations such as metal cleaning and degreasing.

Careful evaluation of the specific industrial process should be performed by qualified professionals prior to selection and installation of a LEV system. Input should be obtained from various disciplines, including engineering, planning, industrial hygiene, and ergonomics, and from employees who will be involved with the process operation. In addition to calculating the correct air flow rates and capture velocities, ventilation designers must ensure that the arrangement of the hood and ductwork does not interfere with the work or other aspects of the facility's operation. In general, designers of LEV systems should take into account the flammability limits (e.g., use of approved wiring and motors), vapor density and toxicity of the solvent, the anticipated concentration and volume of vapor generated, possible interfering air currents in the room, whether access to the work area is needed, and, the amount of airflow or capture velocity required to adequately exhaust the contaminant [9].

Capture velocity is the air velocity at any point in front of the hood or at the hood opening that is necessary to overcome surrounding air currents to capture the contaminated air at the point of generation by causing it to flow into the hood. Recommended capture velocities for solvents vary between 50 and 500 ft/min depending on the nature of the operation, toxicity of the vapor, and conditions of solvent dispersion into the air [3].

Figures 15.5 through 15.7 provide design detail principles of local exhaust ventilation, including hood nomenclature and design considerations. For further reading on local exhaust ventilation systems, refer to the fundamental text *Industrial Ventilation: A Manual of Recommended Practice*, published by the ACGIH [3].

Personal Protective Equipment

When engineering or administrative controls are not feasible or do not provide adequate protection, PPE must be used to minimize exposures. PPE should always be considered a last

resort and managed carefully by qualified individuals. This is due to a number of limiting factors associated with PPE, including the following:

a. PPE does not eliminate the hazard. When PPE (e.g., air purifying respirator and elastomeric gloves) is used to control solvent (workplace) exposures, the PPE functions as a barrier that separates the worker from the airborne and liquid hazards present. Should this PPE be compromised, either by tearing or degradation, the worker will be directly exposed to the hazard.
b. The selection and use of the correct PPE are relative to its effectiveness. Because no single respirator type, filtration cartridge or canister, or glove/barrier clothing elastomer is effective in all conditions of solvent use, it is mandatory that the worker and the industrial hygienist/OHS specialist work together to ensure that the PPE selected remains effective against the hazards it is intended to protect against. It is therefore recommended that the employer select only that PPE that is approved by NIOSH whenever possible.
c. The safe use and care of the PPE selected for protection of the worker require proper worker training and are mandated by federal OSHA regulations, as specified in Title 29 CFR 1910 (General Industry), 1915 (Shipyards), 1917 (Marine Terminals), 1918 (Longshoring), and 1926 (Construction). It is therefore incumbent upon management to ensure that proper PPE use programs and procedures are written and available to the respective employees and that the employees are sufficiently trained to know when and how to properly use the PPE available to them. Likewise, it is incumbent upon each employee to participate in such training programs and to use the PPE made available to them in the proper and intended way.
d. The use of PPE may provide a false sense of security to the user. Depending on the frequency of use and the level of training the worker receives, the PPE user may believe that the PPE selected will provide complete protection under all circumstances, leading them to enter into circumstances for which the PPE is not intended or effective. This type of mistake is most commonly evident in chemical spill or emergency incident situations when the volume and concentration of solvent (chemical) vapors and liquid are sufficient to quickly compromise the effectiveness of the standard workplace PPE.

The type and variety of PPE used within the workplace are numerous, making the proper selection and use of this equipment a necessary and sometimes difficult task for management and the worker alike. The PPE selected for use in a particular job setting should match the following:

- The level and type of hazard to be confronted, including the chemical and physical properties of the solvents in use, the workers' level of direct contact with the hazard [solvent], and the nature of the work to be performed)
- The worker's activity, vision, and dexterity needs while wearing the PPE

Often, the worker must confront a combination of hazards/chemical mixtures during job performance, making PPE selection and use decisions complex. Consequently, it is not only advisable for management to consult with respective PPE manufacturers regarding the intended use of PPE but also for the worker to be ever vigilant while using PPE to ensure that the integrity of the PPE remains protective against the hazards encountered. The primary categories of PPE in common use within the workplace include respirators, clothing (suits, gloves, foot coverings, sleeves, and aprons), eye, and face protection. The combined use of PPE representing these categories is dependent on the nature of the hazard, the frequency and duration of exposure, and the nature of the work to be performed. The NPG provides information on exposure hazards and appropriate PPE for over 400 chemicals [143].

Respirators

Respiratory protection is used to provide the wearer with clean breathing air while working in the presence of potentially harmful concentrations of airborne contaminants. Often, the use of respirators in the workplace are employed to protect the worker from intermittent exposures that can occur during process operations or during emergency repair and maintenance. However, respirators may also be the only feasible method of protection for exposures that may occur during normal work operations.

When workplace engineering (e.g., local exhaust or dilution ventilation) or other control methods are not feasible, the employer should implement an effective respiratory protection program, including worker training and medical surveillance (as applicable), and provide workers with respiratory protection appropriate to the hazard. The goal is to ensure that the appropriate type of respiratory protection is selected and used correctly. OSHA's Respiratory Protection Standard for General Industry, as established in 29 CFR 1910.134, specifies the employer and employee responsibilities when respiratory equipment is to be used within the workplace. This standard mandates that the employer develop and implement a written respiratory protection program that describes when respiratory equipment is to be used, what respiratory equipment is to be used, which employees are qualified to use the respiratory protection specified, and how the respiratory equipment is to be used and maintained. OSHA provides guidance documents with basic information to workers and employers who may find themselves using respiratory protection for the first time. The guidance provides information on what respirators are, how they work, and what is needed for a respirator to provide protection [153]. Elements of the program include respirator selection, user training and fit testing, medical approval, and specific instructions for cleaning and maintenance (refer to the 2005 updated standard). Only NIOSH-approved respirators should be selected for use.

NIOSH approval program requirements are specified in 42 CFR Part 84. OSHA and NIOSH also provide information and guidance for the proper selection of respirators [146,154].

The two major categories of respirators are air-purifying and atmosphere-supplying/supplied air. Air-purifying respirators for chemical and particulate (e.g., solvents) exposure provide protection to the user by removing the hazardous contaminant from the stream of the air prior to its inhalation by the user. This air-cleaning process is accomplished by drawing the contaminated air through specially prepared cartridges or canisters containing various filtering or sorbent materials (e.g., activated charcoal). Air-purifying respirators are available in various face-piece configurations, including quarter-, half-, and full-face mounts, with or without eye protection. They are designed to be disposable or reusable and are either operated by negative pressure (user inhales) or battery-powered. It is important to recognize that air-purifying respirators do not provide an independent source of breathing air and should not be used in environments that are oxygen deficient or when the airborne contaminants present do not have good warning properties (e.g., noticeable taste, odor, minor irritating effects below the established occupational exposure limit) to indicate cartridge or canister overloading, improper face-piece fit, or damage to the respirator. Air-purifying respirators should never be worn for protection against airborne chemicals with poor warning properties [6]. Because people vary greatly in their ability to detect odors, other methods such as cartridge replacement schedules or visible end-of-service-life indicators are being developed by various groups to ensure greater safety when air-purifying equipment is used. It is also important to recognize that, because people have different facial configurations, no one make or model of respirator will provide a sufficient face-to-face-piece seal for all users, therefore fit-testing is an integral part of ensuring worker protection. Respirator users need to be trained to check their respirator for proper fit each time they are donned to ensure they provide adequate protection.

Atmosphere-supplying/supplied air respirators provide the user with an independent source of clean breathing air separate from the local environment. Examples of atmosphere-supplying respirators include air-line devices and self-contained breathing apparatus (SCBA). Whereas air-line devices are designed to provide the user with an independent source of air for extended periods of time, the SCBA is designed to provide the user with an independent source of breathing air ranging from 5 min (emergency escape only) to 60 min, depending on user activity and equipment configuration.

Other factors that must be considered when selecting respiratory protection are the nature of the hazard, including oxygen deficiency, concentration of the airborne contaminant, and adequacy of warning properties. The expertise of the industrial hygienist is necessary for proper identification and assessment of the airborne contaminant levels, flammable limit status, and ambient oxygen concentration; evaluating the configuration and location of the work area in relation to an available area of clean air; implementing appropriate and periodic workplace and user monitoring procedures during respirator use; and determining the proper respiratory equipment for use.

Protective Clothing

Protective clothing is used to protect the user from dermal contact and exposure to chemicals by forming a barrier between the skin and the hazard (e.g., solvent). The proper use of protective equipment, including clothing, eye, face, hand, and foot protection, is mandated by OSHA standards found in 29 CFR 1910 Subpart I and should be referred to by employer and employee alike.

Protective clothing includes gloves, laboratory coats, rubber aprons, chemical resistant suits, and boots. Various configurations of chemical-resistant clothing can be selected, depending on the nature and concentration of the solvent (hazard) of concern, the kind of work activity and time period to be performed, and the level of protection required. Chemical-resistant elastomers used as barrier coatings for protective clothing include neoprene, nitrile, natural, or butyl rubber; polyvinyl chloride or polyvinyl alcohol; and Viton™. Some operations may require only partial protection (such as a protective apron, sleeves, or leggings), while others may require the use of full-body enclosures (such as those used by emergency response workers). It must be recognized that the type of protective clothing configuration, barrier material, and level of protection chosen can significantly affect the mobility, vision, and manual dexterity of the worker. Depending on the characteristics of the work environment, the use of protective clothing, especially encapsulating suits, can present potential heat stress hazards and may therefore require the close monitoring of workers and workplace conditions.

The degree of protection afforded by a given type of chemical-protective clothing is related to three primary performance factors: permeation, degradation, and penetration. Permeation is the ability of a chemical to pass through the molecular configuration of a protective barrier (e.g., the clothing or glove) and is defined on the basis of the permeation rate for the particular material being challenged. Degradation of a material results from a reduction in one or more of the physical properties of protective clothing or gloves due to direct contact with a chemical and is defined by the degradation rate for the material with respect to the specific chemical challenge. Penetration is measured as the rate of flow of a chemical through physical aspects of the clothing or glove, such as zippers, seams, pores, or imperfections in the material. Manufacturers of protective clothing determine product-specific performance data via laboratory tests conducted in accordance with methods established by the American Society for Testing and Materials (ASTM). All three factors should be considered when choosing protective clothing, because data for some but not all of these factors may not correlate with a given type of clothing and target chemical; for example, a glove may have acceptable degradation ratings for use with a specific chemical, but the chemical

may readily permeate the material. No single glove or type of protective clothing provides adequate protection against every hazard. Furthermore, a glove type from one manufacturer often has different performance data from the same glove type produced by another manufacturer. Another general source of information is Chemical Protective Clothing, published by the AIHA [8]. This two-volume set provides the data required to select and use chemical protective clothing. Included in the document is a discussion of permeation theory, testing methods, and available vendors.

Eye and Face Protection

Eye and face protection is used to prevent injuries that may occur while handling or transporting solvents and other chemical liquids, vapors, fumes, or particulates. Two types of protective eyewear in common use to prevent exposure are chemical splash goggles and face shields. Chemical splash goggles are designed to completely enclose the eyes (as opposed to safety glasses, which are designed to prevent physical injuries that may result from an object striking the eye). Some goggles may also prevent vapor exposure to the eye in addition to contact with the liquid. Face shields are often worn in conjunction with goggles to protect the face and neck. Face shields and goggles that meet recognized safety standards bear the engraving of ANSI Z-87, which indicates that the device has passed safety performance tests conducted by the American National Standards Institute. OSHA regulates the safe use of eye and face protection within the workplace as described in 29 CFR Part 133.

ABSORPTION OF SOLVENTS AND INHALATION EXPOSURE

Inhalation is the easiest and fastest means of exposure to solvents because solvent vapors in the atmosphere are readily accessible to the respiratory tract when one breathes contaminated air. The respiratory tract has a large surface area and the lining of the respiratory tract is NOT effective in preventing absorption of toxic substances into the body. The respiratory tract consists of the nasal passages, trachea (windpipe), larynx (voice box), and the lungs. The following factors affect inhalation of solvents:

1. Concentration of toxic substance in the air
2. Solubility of substance in the blood and tissue
3. Respiration rate
4. Length of exposure
5. Condition of respiratory tract

A key factor in determining how a solvent enters the body is the solubility of that chemical into blood and tissues. When considering solvent exposure via the inhalation route, the rate of solvent uptake and the subsequent equilibrium concentration in tissues are also dependent on individual activity, breathing rate, and the minute volume of blood flow through the lung and other organs.

Solvents that are highly soluble in water-based systems, such as blood and tissues, are absorbed very readily into the system by the inhalation route, causing blood concentrations to rise rapidly. The driving force is the difference in concentration of the solvent between inspired air and blood. The amount of solvent diffusing through the alveolar capillaries is dependent on the air–blood partition coefficient. Tissue equilibrium concentrations with solvents such as xylene, styrene, and acetone, which are highly soluble in blood and tissues, are not limited by pulmonary ventilation because the tissues act as a sink for the inhaled solvent. As pulmonary ventilation is increased, the blood and tissue concentrations continue to rise. The limiting factor in attaining the tissue equilibrium concentration is the blood flow through the tissues and the blood–tissue partition coefficient [66].

Solvents such as methyl chloroform, methylene chloride, trichloroethylene, and toluene, which have lower solubility in blood and tissues, reach equilibrium rapidly because of low solubility or low blood–air partition coefficients [171]. Tissue concentrations also will reach equilibrium rapidly because of low tissue–blood partition coefficients. In this case, the limiting factor in tissue concentration is the solubility of the solvent in the tissue and the individual's pulmonary ventilation rate [157]. To achieve a higher concentration in tissues and blood, pulmonary ventilation must increase, allowing more solvent to enter the blood and a new blood–tissue equilibrium to be reached [23,24].

DERMAL UPTAKE OF SOLVENTS

The opportunity for solvents to enter the body via contact with the skin is enhanced, in part, due to the large surface area of the skin (18 ft^2). Fortunately, the barrier properties of the skin associated with filamentous proteins and lipids of the stratum corneum naturally inhibit penetration by harmful non-lipid-soluble substances. Disruption of this barrier, however, by injury, illness, or removal of lipids, can facilitate passage of these materials; for example, treatment of the skin with polar organic solvents, detergents, and some surfactants can remove the lipids, thereby increasing the skin's permeability.

Penetration of the skin by a solvent depends on a number of other factors such as the thickness of the skin layers, the integrity of the skin, the concentration gradient of solvent on either side of the epithelium, and a number of physical constants. In addition, the degree to which the skin hydrates can increase absorption by affecting its permeability. Movement of water-soluble compounds may be impeded, however, when the stratum corneum is highly hydrated. Although hair follicles and sweat glands comprise only a small proportion of the skin's surface area, they, too, provide pathways for solvent penetration.

Solvents can denature the lipids in the skin, resulting in drying and irritating effects, cellular hyperplasia, and swelling; for example, the careless use of solvents without the use of barrier creams or proper hand and arm protection frequently leads to cases of dermatitis in the workplace. In studies on the effect of solvents on the lipid barrier in the skin,

the ability of a solvent to penetrate the skin is dependent on the polarity of the solvent and the surface charge of the skin. Results comparing penetration or removal of skin lipids by several solvents indicate that ethanol, the solvent with the greatest polarity, extracts the most lipids, followed by acetone and ether [27]. Treatment of the skin with solvents can also enhance the penetration rate of other compounds. In a study using excised human skin, the effect of several solvents, including dimethyl sulfoxide (DMSO), dimethylacetamide, formamide, and diethyl formamide, on the penetration rate of sarin was examined [121]. The results of this study demonstrate that solvent pretreatment of the skin increases the rate of sarin transport across the skin barrier by a factor of 10–100 over that of sarin alone on control skin.

In studies using toluene, xylene, and styrene vapors to assess the rate of skin penetration of these aromatic solvents in human volunteers, human volunteers were exposed to 300 ppm or 600 ppm concentrations of the solvent vapors for 3.5 h in a dynamic exposure situation. The subjects wore full-face respirators to prevent pulmonary absorption of the solvents via the inhalation route. Each subject exercised for a 10 min period, sufficient to make the subjects perspire and to raise the skin temperature about 0.5°C. Perspiration and warm skin temperature enhance the hydration of the skin and subsequent percutaneous absorption. After termination of exposure, these solvents displayed biphasic elimination from the blood into exhaled air with a short half-life of about 1 h and a much longer half-life of approximately 10 h. Xylene and styrene showed a slight delay in excretion in exhaled air after percutaneous exposure when compared with similar exposure via the inhalation route. Delayed excretion after dermal exposure may be accounted for by a slow release from the skin after termination of exposure.

Overall percutaneous absorption of the xylene, toluene, and styrene concentrations corresponded to only about 0.1% of the amount estimated to be absorbed by the pulmonary route. This observation indicates a very small absorption potential for these solvents by the percutaneous route. When the percutaneous absorption of xylene vapor is compared to earlier work with xylene liquid, the vapor displays an approximate 10-fold greater efficiency in penetrating the skin than does the liquid. According to Riihimäki and Pfäffli [168], it is not uncommon to observe greater penetration with vapor exposure because liquid solvents remove the lipids from the stratum corneum and thus interfere with absorption. Additionally, exercise promoted the absorption of solvents because of the warm hydrated skin. In general, percutaneous absorption of solvent vapors would not contribute significantly to the total blood concentrations of these solvents.

Chemical Interactions Effecting Toxicity

It is not unusual for a toxic chemical to enter the body and interact with another toxic substance or with a medical drug. The result of this interaction of chemical agents, drugs, etc., can be mediated in several ways through effects on absorption, protein binding, biotransformation, or excretion of the drugs or chemicals. The possible results of chemical interactions within the body are listed as follows:

1. *Additive effect* (e.g., 2 + 2 = 4): The effect observed when the combination of two chemicals having independent toxicities results in a combined toxic effect equal to the addition of the two. Example: Two organophosphates simultaneously used as pesticides will depress cholinesterase levels equal to the additive concentrations of each agent.
2. *Synergistic effect* (e.g., 2 + 1 = 20): The toxicological effect that occurs when chemicals having independent toxicity produce a toxic response significantly greater in effect than the additive sum of the two substances observed individually. Example: The hepatotoxicity of carbon tetrachloride is significantly increased in the presence of ethyl alcohol.
3. *Potentiation* (e.g., 2 + 0 = 10): The effect that is observed when one substance acts as a catalyst in the presence of another substance to enhance the toxicity of the second substance. Example: A steady diet of corn oil potentiates the effect of incomplete carcinogens.
4. *Antagonism* (e.g., 2 + 2 = 1): A substance recognized as an antagonist is one whose effect tends to decrease the adverse effect of a second substance. There are various types of antagonist actions. *Functional antagonism* occurs when two chemicals produce opposing physiological effects and result in an overall no net-effect exposure. *Chemical antagonism* occurs when the interaction of the two chemicals results in an interference with the normal chemical transformation of the chemicals so less toxic agent is available. *Dispositional antagonism* occurs when absorption, distribution, or excretion of the chemical is altered; therefore, less of the chemical mixture reaches the target tissue. *Receptor antagonism* occurs when competition for the same receptor results in less of either chemical reaching the receptor. Example: Many of the principles of antagonism are used in the design of antidotes in clinical toxicology or for the poisoning of humans.

TOXICOLOGY OF SELECTED SOLVENTS

This section provides insight into various solvents of occupational concern due to their propensity to produce neurotoxic, reproductive, or carcinogenic effects in humans. Examples are provided for these, as well as less toxic, alternative solvents. Generally speaking, acute exposure to high levels of solvents can result in temporary or long-term alterations of central nervous system (CNS) function.

Effects of Acute Solvent Exposure on the Central Nervous System

Although varying widely in chemical structure and physical properties, organic solvents produce a rather stereotypical

set of toxicological manifestations upon acute exposure [20], the significance of which is dependent on dose concentration, duration, and frequency. Most commonly, acute exposure is evidenced by a varied level of CNS dysfunction and, if exposure is sufficiently severe, narcosis. The systemic toxicity of solvents is observable either throughout the body or in an organ with selective vulnerability distant from the point of entry of the chemical, as with solvents and peripheral neuropathies. Exposure to certain solvents can be associated with some temporary alteration of cognitive and psychomotor function following short-term exposures at or near the TLV® Exposure to greater concentrations may provoke such symptoms as headache, dizziness, ataxia, euphoria, drowsiness, lightheadedness, disorientation, confusion, tremors, and nausea. Exposure to potentially lethal (IDLH) levels of solvents can result in stupor, loss of consciousness, coma, respiratory depression, and abnormal cardiac function.

Toxic Effects of Solvent Exposure on the Peripheral Nervous System

Exposure to solvents at concentrations too low to induce many of the acute symptoms cited earlier is of special concern with regard to neurotoxicity. This concern that results from the capacity of nerve tissue for post-toxicity regeneration is limited and repeated insults may lead to cumulative damage. The more subtle symptoms of chronic solvent exposure include relatively mild alterations of mood and behavior not accompanied by quantifiable evidence of dysfunction on neurobehavioral tests [28,84]. Although dose–response and causal relationships have been difficult to study in the absence of animal models, symptoms of chronic solvent exposure can include

- Increased irritability
- Decreased span of attention
- Loss of interest in daily activities

More severe damage to the nervous system, both central and peripheral, occurs upon repeated exposure to certain solvents such as carbon disulfide and *n*-hexane, as discussed later in this chapter.

Numerous neurobehavioral and functional tests have been used to detect such changes in both clinical and experimental settings [97,163]. Whether the acute effects of solvents play a role in determining the pathogenesis of toxic lesions observed after chronic exposure to the same solvents is uncertain. However, current thought is that the acute effects on the nervous system are mediated through nonspecific interactions of solvents with the cell membrane by increasing membrane fluidity or functional alteration of cell surface receptors, while the effects of chronic exposure are mediated by specific biochemical actions of solvents.

It is well known that neurotoxic chemicals can have a negative impact on sensory function. Often, the symptoms reported following chemical exposure to such chemicals are related to effects observed among the five senses [70]. Toluene, xylene, styrene, trichloroethylene, and carbon disulfide are examples of solvents associated with adverse effects on the auditory system, for example [135]. In the industrial environment, workers are often exposed to solvents as well as high levels of noise, which is known to damage the inner ear and result in hearing loss. Evidence from workplace studies and animal experimentation indicates that the combined effects of noise and ototoxic solvents may increase individual susceptibility to hearing loss [96,135]. In one animal study, rats were exposed to toluene, to noise, or to toluene followed by noise followed by direct testing of their auditory functions. The study results demonstrated that rats exposed to toluene followed by noise exhibited a decrease in auditory sensitivity greater than the sum of the effects of toluene and noise alone [135]. The risk for hearing loss may be increased by factors other than noise, such as drugs or other chemicals, and can also be influenced by heredity and aging [135]. It is important to take all of these factors into account when evaluating hearing loss in the workplace.

Toxic Effects of Solvents on Organ Systems

Organs that receive a high percentage of the cardiac output are exposed to greater doses of absorbed toxicants than poorly perfused tissues. A major determinant of target organ selectivity for the toxicity of solvents is xenobiotic metabolism. While pharmacokinetics define the quantity of solvent reaching a particular organ or tissue after absorption, metabolism may yield products with increased toxic potential relative to the parent chemical. Thus, well-perfused organs with high capacities for specific types of biotransformation reactions, mainly those catalyzed by the cytochrome P450, are common targets for solvent-induced toxicity. In particular, the liver is vulnerable to the toxicity of many solvents, owing to its high capacity for xenobiotic metabolism. Many common hepatotoxic solvents yield toxic intermediates or end-products upon biotransformation. Such hepatotoxic solvents include carbon tetrachloride [164], chloroform [160], and trichloroethylene [26]. However, some solvents, such as ethanol, may exert their hepatotoxic effects indirectly by altering cellular reduction–oxidation balance during metabolism and thereby deranging normal liver function and structure [169].

The kidney, as a filtering and concentrating organ of excretion, receives not only untransformed solvents but also the products of hepatic metabolism of solvents. These biotransformation products—for example, conjugates of trichloroethylene—may be more toxic than the parent chemical and produce renal-specific toxicity [114]. The ion transport and solute concentrating functions of renal tubules also contribute to the vulnerability of the kidney to certain chemical toxicants [115]. In addition, biochemical peculiarities of certain species and genders may play a major role in bringing about solvent-induced renal toxicity. A notable example is the susceptibility of the male rat to renal toxicity caused by 1,4-dichlorobenzene, Stoddard solvent, VM & P naphtha, and other hydrocarbon solvents. This has been attributed to the male rat-specific abundance of the low molecular weight

protein 2μ-globulin, which acts as a carrier for lipophilic molecules [180]. 2μ-Globulin is normally degraded in renal tubule lysosomes and binding to a solvent ligand slows degradation of the protein so that the 2μ-globulin-hydrocarbon complex is sequestered by lysosomes [109]. The sequestered protein apparently disrupts lysosomal function and cytotoxicity results when large amounts of 2μ-globulin accumulate [173]. There is apparently no counterpart to this type of nephrotoxicity in species other than the rat [16].

Organs that catalyze relatively few types of chemical biotransformation reactions or have low rates of xenobiotic metabolism, such as lung, nasal mucosa, and testes, may also be target organs for the toxicity of some solvents. For example, ethylene glycol monomethyl ether and related glycol ethers are testicular toxicants [85,132] as are hexane and the hexane metabolite 2,5-hexanedione [32]. Special attention to the potential susceptibility of the tissues lining the upper airways and nasal mucosa to solvent-induced toxicity is evidenced in recent studies. These tissues have high levels of certain xenobiotic-metabolizing enzymes and, in addition, are exposed to high solvent concentrations relative to the lung and other organs. In particular, esters such as propylene glycol monomethyl ether acetate, dimethylphthalate, and dimethyl succinate are enzymatically transformed by carboxylesterase in the nasal area to yield acidic products that may accumulate to toxic levels in the nasal mucosa [132,178,180,185]. Certain solvents need no metabolism to adversely affect the tissues of the upper respiratory tract; vapors or aerosols of aldehydes cause local tissue damage to the nasal epithelium [134], presumably due to the activity of these solvents in forming protein–protein and protein–DNA crosslinks [88].

Solvent Mixtures

Humans are often exposed to multiple chemicals at work or home. An example reported by Worksafe Australia (the Australian National Occupational Health and Safety Commission), involves solvent exposure and health effects observed in spray-paint apprentices [197]. This study identified 32 different solvents contained in 20 thinner products used by the painters. Within this group, six different categories of solvents were represented: alcohols, aromatic hydrocarbons, esters, glycol ethers, ketones, and mixtures. Of significance was the fact that the workers commonly perceived these 20 thinners to be equivalent products and consequently equally safe to use. This common, but mistaken perspective underscores the need for chemical hazard communication programs to adequately inform workers of the inherent and potential hazards of working with solvent mixtures and chemicals.

As noted previously, exposure to multiple solvents and other chemicals, either simultaneously or sequentially, may alter the toxicological impact of the individual chemicals upon the body. Thus, a combination of certain chemicals may affect (positively, negatively, or not at all) the absorption, distribution, metabolism, and excretion of the chemical mixture within the body of the worker [103]. The study of chemical interactions has evolved most extensively in the area of therapeutic drugs.

Although some information exists on interactions of industrial chemicals, most research on chemical toxicity to date has dealt with single, pure chemicals. These single chemical studies are important because they allow researchers to gather fundamental knowledge about the mechanisms of toxicity under conditions that are well controlled. However, further research is required in the evaluation of potential health effects associated with exposures to multiple chemical compounds [202]. Occupational Exposure Limits (OELs) for defined chemical mixtures may be calculated for many organic solvent mixtures by a procedure called the Reciprocal Calculation Procedure (RCP). The RCP, first published in Appendix H of the ACGIH, 2009 *Threshold Limit Values and Biological Exposure Indices* [2] provides for the calculation of an OEL for a mixture of refined hydrocarbon solvents containing saturated aliphatic, cycloaliphatic, and/or aromatic hydrocarbons consisting of 5–15 carbon atoms and having boiling points in the range of approximately 35°C–330°C.

Glycol Ethers

Glycol ethers represent an important category of solvents that are widely used in mixtures for industrial and consumer applications. They are grouped as ethylene glycol, propylene glycol, or butylene glycol with the ether component of the molecule containing methyl, ethyl, propyl, butyl, or higher molecular weight moieties [76]. Additional members of this class of compounds are the corresponding acetate esters. The miscibility of glycol ethers with water and many organic compounds make them ideally suited as solvents in oil–water compositions. Production capacity of the ethylene-based ethers in 2010 exceeded 3 billion pounds, with the coatings (paint) industry being the major consumer [76,160]. In addition to coatings, glycol ethers are found in many household goods such as brake fluids, waxes, cleaners, dyes, detergents, degreasers, and inks. In particular, 2-butoxyethanol has been formulated into hundreds of consumer products [38].

The current ACGIH TLV®–TWAs and German MAKs for three widely used glycol ethers—2-methoxyethanol (ME), 2-ethoxyethanol (EE), and 2-butoxyethanol (BE)—are 5, 5, and 20 ppm, respectively. The NIOSH RELs for ME, EE, and BE are significantly lower at 0.1, 0.5, and 5.0 ppm, respectively. All have skin notations. ACGIH bases their limit for ME on possible blood, reproductive, and CNS effects. For EE and BE, effects on reproduction and the blood are considered, respectively. The TLV® and REL for propylene glycol monomethyl ether (PGME) are both 100 ppm and are based on potential irritation and CNS effects [2,4,143].

The commonly encountered glycol ethers are colorless liquids with mild odors. The primary routes of exposure in the industrial environment are inhalation and skin absorption [76]. Outside of the workplace, some cases of accidental or intentional ingestion of products containing glycol ethers by children and adults are reported [38]. In general, the ethylene glycol ethers exhibit low acute oral toxicity [76]. Experiments

in rats have shown that the methyl, ethyl, and butyl ethers are readily absorbed through the skin [170]. As the molecular weights of the glycol ethers increase, the potential for inhalation exposure and skin absorption decreases. Because the methyl and ethyl ethers of ethylene glycol and their acetates have demonstrated adverse reproductive, embryotoxic, teratogenic, and developmental effects in animal studies [85–87,141,142], their use in consumer products has declined [76].

Metabolically, the monoalkyl ethers of ethylene glycol are converted to their respective alkoxyacetic acids via the actions of alcohol dehydrogenase [38]. Many of the observed adverse effects caused by ethylene glycol ethers in animals, such as hematotoxicity (e.g., 2-butoxyethanol) and testicular toxicity, are attributed to these toxic metabolites. Whereas rat erythrocytes have demonstrated vulnerability to the hemolytic effects of 2-butoxyacetic acid (from BE), human erythrocytes have been shown to be much less susceptible to these effects [38]. PGME and its acetate (PGMEA) are relatively innocuous compounds when compared to the ethylene glycol ethers discussed earlier. Overexposure to PGME has been associated only with increased liver weight and CNS depression. Studies have shown that EE and PGME are metabolized by different routes and the types of metabolites produced are responsible for the marked differences in toxicity; for example, methoxyacetic acid is the primary metabolite of EE, and propylene glycol is the main biotransformation product of PGME and PGMEA [131,133].

Investigators have studied the potential interaction of ethanol and EE due to the recognition of similar metabolic pathways and the likelihood of concomitant exposure to ethanol due to personal behaviors in some individuals [142]. When dose levels of EE are presented to rats alone or in combination with ethanol, researchers have noted an apparent increase in the duration of pregnancy. Exposure to dose levels of EE during gestational days 7–13 resulted in observation of a decrease in certain behavioral tests such as rotorod performance; however, when test animals were exposed to dose levels of EE and also consumed ethanol, the behavioral deficits observed were diminished. When dose levels of EE were administered alone during late gestation, the motor activity levels of pups were depressed and performance during avoidance conditioning trials was retarded. Observers note that the combined administration of EE and ethanol appears to generate a synergistic effect on the behavioral deficits induced by EE and to depress both activity and learning. Also, it has been observed that ethanol during late gestation altered the neurochemical effects of EE.

In summary, concomitant exposure to ethanol and EE can have differential effects depending on the stage of gestation. Ethanol administration during the early period of gestation tended to improve both the behavioral and neurochemical effects of EE to approximately 50% of the response produced by EE alone. In the late stage of gestation, however, the combination of ethanol with EE exaggerated the effects of EE alone. These scientific observations indicate that the possibility exists for ethanol-induced exaggeration of the potential toxic effects of EE exposure in pregnant workers.

Retrospective epidemiological studies of workers exposed to ME and EE report evidence of adverse effects on the male reproductive system, with increased frequency of reduced sperm counts [199]. Evaluations of sperm production in humans and several other animal species indicate that the output of human sperm is about one fourth that of other mammals when compared on a per-gram tissue basis. This finding suggests that humans may be more susceptible to occupational toxicants than predicted by laboratory animals [182]. As is the case with many widely used chemicals with potentially harmful effects, substitutes are being considered. PGMEA and ethyl-3-propionate have been identified as useful and less-toxic alternatives to ethylene glycol ether solvents [33].

Benzene

Benzene is utilized extensively as a raw material in the manufacture of polymers, detergents, pesticides, dyes, plastics, and resins and as a solvent for waxes, oils, natural rubber, and other compounds [93,123]. In addition, benzene is a component of gasoline, cigarette smoke, and some foods and is generally present at low levels throughout the ambient environment [91]. Exposure to benzene in the workplace is primarily through inhalation, although skin absorption may also contribute to the overall body burden. OSHA regulates benzene specifically by standards established in 29 CFR 1910.1028 and recognizes benzene as an occupational carcinogen [148]. The OSHA PEL for benzene is 1 ppm and the STEL is 5 ppm [148]. The 2005 ACGIH TLV®–TWA and STEL for benzene are 0.5 and 2.5 ppm (skin notation), respectively. The ACGIH designates benzene as a confirmed human carcinogen [2,4]. The NIOSH REL and STEL for benzene are 0.1 and 1 ppm, respectively. NIOSH identifies benzene as an occupational carcinogen [2,4,143]. The ACGIH BEI for benzene is 25 pg (pictograms) of the metabolite *S*-phenylmercapturic acid per gram of creatinine in urine, as measured at the end of the work shift [4].

Due to its high lipid solubility, acute exposure to benzene can depress the CNS to the point of narcosis. Headache, dizziness, nausea, and vomiting are all features of benzene overexposure. Exposure to benzene at high concentrations can lead to blurring of vision, unconsciousness, convulsions, ventricular irregularities, and respiratory failure. Death as a result of exposure to extremely high concentrations of benzene may occur because of respiratory failure or cardiac arrhythmias [175,198]. Concomitant exposure to benzene and high concentrations of catecholamines can sensitize the heart and lead to ventricular fibrillation.

Benzene is hemato toxic [174] and carcinogenic following repeated exposure to high concentrations [126]. A cross-sectional study that compared peripheral blood cell counts of 250 Chinese workers exposed to benzene to 140 age and sex-matched controls found that that total white blood cells, granulocytes, lymphocytes, B cells, and platelets significantly declined with increasing benzene exposure. The researchers found that benzene exposure decreased colony formation

from myeloid progenitor cells, and that these progenitors were more sensitive to benzene toxicity than were mature WBCs. Genetic variation in myeloperoxidase (MPO) and NAD(P)H:quinone oxidoreductase (NQO1) conferred susceptibility to benzene-induced lowering of WBC counts [105].

Numerous rodent studies demonstrate that benzene can also cause cytogenetic damage in vivo [91]. In addition, examination of the chromosomes of humans exposed to high levels of benzene reveals an elevated rate of chromosomal aberrations that persist after cessation of exposure [69]. Chronic exposure to benzene leads to a progressive depression of bone marrow function [116]. Epidemiological studies demonstrate that blood dyscrasias such as pancytopenia, aplastic anemia, and acute myelogenous leukemia can develop in humans as a result of this exposure [126,175]. Furthermore, some clinical investigations indicate that it may take several years after the termination of exposure for benzene-induced leukemia to appear [192].

Enzymes linked to the metabolic activation of benzene and its metabolites are the cytochrome P450 monooxygenases and myeloperoxidase [126]. The major metabolic pathway for benzene appears to be oxidation to a phenol, which is then converted to a sulfate conjugate and excreted in urine. Other hydroxylated metabolites include hydroquinone and catechol. Benzene metabolism can be affected by interactions of benzene with its metabolites or other compounds. As an example, experiments in mice suggest that benzene can inhibit the oxidation of phenol. Furthermore, animal and human studies have demonstrated that co-exposure to toluene may significantly alter the formation of benzene metabolites. Finally, treatment with ethanol induces benzene and phenol metabolism in the liver, resulting in higher levels of active metabolites [126].

The actual mechanism of benzene-induced leukemia is not known. Potential mechanisms for benzene-induced bone marrow disease include metabolism of the parent compound to phenols and other metabolites, in particular, quinone-type metabolites such as catechol, quinol, and pyrogallol, which could react with chromosomes and interfere with mitosis. Another possibility is the depletion of sulfur available for glutathione detoxification, thereby leading to interaction of toxic intermediates with critical elements of the bone marrow. Another suggested mechanism involves transfer of benzene metabolites from the liver to the bone marrow [175]. Researchers have investigated the metabolism and binding of radioisotope-labeled benzene in the isolated hind limb of rats in which benzene was administered directly into the bone marrow space. Metabolites of benzene were found covalently bound to macromolecules in the bone marrow, indicating that the bone marrow has the potential of metabolizing benzene to reactive intermediates [95]. The fact that benzene or benzene metabolites have been shown to inhibit the multiplication of erythrocyte precursor cells in the bone marrow may imply an additional mode of action [106]. The potential for benzene to induce leukemia in experimental animals has been difficult to demonstrate. In a 2-year carcinogenicity study, rats and mice fed benzene in corn oil developed dose-related leukopenia and tumors in multiple organs, but the study failed to show benzene-associated leukemia [91].

Toluene

Toluene is a flammable, aromatic solvent used extensively in the chemical, rubber, paint, and drug industries. It is also useful as a solvent for paints, inks, lacquers, dyes, and other compounds and as an additive for gasoline. Sources of toluene in the ambient environment include manufacturing plants, automobile emissions, gasoline evaporation, and cigarette smoke [44,129]. Various exposure limits and biological indicators of exposure apply to toluene. The ACGIH TLV®–TWA and German MAK for toluene are 50 ppm (skin notation) and 50 ppm, respectively. The NIOSH REL is 100 ppm as a time-weighted average and the STEL is 150 ppm. The established IDLH for toluene is 500 ppm. The current OSHA PEL is 200 ppm, with a 300 ppm ceiling limit as a 10 min peak per 8 h work shift [2,4]. The ACGIH BEIs are 0.05 mg of toluene per liter of venous blood, collected before the last shift of the work week; 1.6 g of hippuric acid per gram of creatinine in the urine, collected at the end of the shift; and, 0.5 mg of o-cresol per liter of urine, collected at the end of the shift [2,4,143]. Toluene in expired air has also been evaluated to determine its usefulness as an indicator of exposure [25]. Analysis of expired air in toluene-exposed workers revealed that the toluene concentration was correlated to the exposure environment, representing approximately 15%–20% of the environmental concentration [39].

The principal toxic effect of toluene is injury to the nervous system. Toluene is most rapidly absorbed by inhalation, followed by ingestion and skin contact. A substantial amount of inhaled toluene is retained in the body. The toxicity of toluene is similar to that of benzene except that it does not exhibit the hematopoietic effects characteristic of benzene. Toluene is an eye and skin irritant, and animal studies indicate that its acute oral toxicity is less than that of other alkyl benzenes [44]. In humans, acute effects of toluene exposure can resemble alcoholic intoxication by first stimulating and later depressing the CNS.

Exposure to high concentrations of toluene, as seen in cases of solvent abuse (e.g., glue sniffing), may cause death by sensitizing the myocardium [167,198]. In chronic abusers of toluene, irreversible neurological toxicity and reversible renal damage have also been reported [181,196]. Symptoms associated with the intentional inhalation of high concentrations of toluene include euphoria, mild tremors, unsteady gait, and changes in behavior. Encephalographic examination of these individuals has shown abnormalities indicative of cerebellar atrophy [100]. Toluene is a lipid-soluble compound that readily crosses the placenta and, as such, may pose a teratogenic risk in cases of high exposure, as with intentional abuse. A pattern of teratogenicity, like that of fetal alcohol syndrome (described in the section on ethanol), is prevalent in human studies relating to excessive in utero exposure to toluene. Simultaneous abuse of alcohol and toluene may heighten the risks [196].

Toluene is metabolized to benzoic acid, which is subsequently conjugated with glycine or glucuronic acid to form hippuric acid or benzoyl glucuronates, respectively. These conjugates, as well as another metabolite, o-cresol, are excreted in the urine [104]. In human studies, ethanol has been shown to inhibit the metabolism of toluene at blood ethanol concentrations of 21 mmol/L [58]. Test results indicate that the concentration of toluene in the alveolar air of the toluene/ethanol-exposed group can be significantly higher than that of the toluene control group. In these studies, hippuric acid and o-cresol excretion is significantly reduced as compared to controls. Additionally, during the 24 h following the last exposure, excretion of both hippuric acid and o-cresol was about 40% to 50% of that excreted by subjects who received only toluene. These results suggest that ethanol may alter the metabolism of inhaled toluene and prolong its elimination from the body; therefore, the possibility of ethanol consumption should be considered during biological monitoring, as ethanol intake could lead to an underestimation of the actual toluene exposure [58].

In contrast to the earlier observations, pretreatment of rats with phenobarbital (PB) indicates that the metabolism of toluene can be enhanced to form benzoic acid. The pretreatment did not, however, appear to effect the rate of conjugation of benzoic acid with glycine to form hippuric acid. The hippuric acid concentration in the urine of PB pretreated rats was about three times that of rats receiving toluene only. In addition, the toluene concentration in the blood of the PB pretreated group was only about half that in the toluene-exposed rats. Not only did the phenobarbital pretreatment enhance metabolism of toluene to benzoic acid (with subsequent conversion to hippuric acid), but it also reduced the blood concentration of toluene, thus shortening the sleeping time induced by the narcotic effect of toluene [94].

At present, the mechanisms of the neurotoxic effect of toluene are not well understood. Some experimental work with rats indicate that exposure to 30,000 ppm of toluene for a few minutes reduced the concentration of tryptophan and tyrosine in plasma by about 50%–20%, respectively, compared to controls. Tryptophan and tyrosine are known to be precursors of the neurotransmitters noradrenaline, dopamine, and 5-hydroxytryptamine. The reason for the decrease in the precursors is unknown, but it is speculated to be an alteration in the hepatic uptake or utilization of these amino acids [195]. A potential factor in toluene-induced neurotoxicity is the production of reactive oxygen species that can result in cell damage. Experiments using rats suggest that benzaldehyde, a metabolite of toluene, accelerates the production of these reactive oxygen species within the nervous system and may also contribute to the overall neurotoxicity [123].

N-Hexane

N-Hexane is a flammable liquid and one of the most toxic of the alkanes. It is an excellent organic solvent that has been used in industrial applications such as printing, low-temperature thermometers, adhesives, extractions, and cleaning processes [43,89]. The primary routes of exposure in the industrial setting are by inhalation and skin contact. The ACGIH TLV®–TWA, NIOSH REL, and German MAK are all 50 ppm. ACGIH and the German MAK recognize *n*-hexane with a skin notation. NIOSH recognizes the IDLH concentration for *n*-hexane as 1100 ppm (10% of the LEL). ACGIH set the TLV® based on possible neuropathy, CNS effects, and irritation [2,4,143]. Acute toxic responses after accidental ingestion include nausea, gastrointestinal irritation, and CNS effects. Inhalation overexposure leads to dizziness, a sense of euphoria, and numbness of the extremities. Exposure to high concentrations causes vertigo and a marked anesthetic effect. Hexane is also an irritant to the skin upon dermal exposure [43].

Many cases of polyneuropathy in workers exposed to *n*-hexane have been noted, with the earliest occurring in Japan [201]. The severity of symptoms in the Japanese workers varied directly with degree and duration of exposure, and in some cases, there was incomplete recovery [89]. Polyneuropathy has also been reported in cases of solvent abuse [43]. The neurotoxic effect of *n*-hexane has characteristically been a progressive motor or sensorimotor neuropathy with symptoms usually reported after several months of exposure [89]. In cases from occupational exposure, symptoms have often been sensory, with numbness and paresthesia in the distal extremities, most notably the feet or hands. Improvement of symptoms is noted after cessation of exposure, and mild cases can recover completely.

Hexane is readily absorbed in laboratory animals and has an affinity for tissues high in lipid content [34]. It is rapidly metabolized to hydroxylated compounds prior to being converted to a keto-form [101,117]. 2,5-Hexanedione and methyl *n*-butyl ketone are the metabolites suspected of being responsible for the production of neurotoxicity.

The mechanism of 2,5-hexanedione-induced neuropathy is not known but several hypotheses have been presented [53,54]. These include a reduction in energy production in the axon resulting in disruption of axonal transport, alteration of protein structure, and inadequate proteolysis of neurofilaments in the nerve terminal. 2,5-Hexanedione has been shown to interact with glyceraldehyde-3,5-dehydrogenase and phosphofructokinase, inhibiting their glycolytic properties and resulting in decreased energy production and possible disruption of axonal flow. Reaction of 2,5-hexanedione with lysine amine moieties to form pyrrole adducts and modification of neurofilament or axonal skeletal proteins is also an attractive hypothesis [40]. Modification of the proteins may lead to cross-linking of the neurofilaments, which could cause difficulty in neurofilament passage through narrow regions of the axon, such as the node of Ranvier, and therefore an accumulation of proteins at the site of constriction. Possible biophysical membrane changes as a result of 2,5-hexanedione may influence the degeneration of the axon. 2,5-Hexanedione binding and inactivation of calcium-dependent proteases that are important for degradation of neurofilament proteins are the last mechanisms mentioned that might lead to accumulation of neurofilaments. Although

none of the mechanisms mentioned fully answers all of the questions concerning *n*-hexane-induced neurotoxicity, these hypotheses offer some contributions to the understanding of the toxic response. It may be that several mechanisms act in parallel to produce the neurotoxic effects.

Repeated exposure of rats to *n*-hexane not only produces the characteristic pattern of neurotoxicity but also results in testicular lesions [200]. The testicular effects are linked to disruption of the cytoskeleton of Sertoli cells. Secondary effects, caused by a loss in functional spermatogonial cells, are seen in affected tubules. Acute exposure led to reversible effects but inhalation or oral exposures of 2–5 weeks led to irreversible effects. Although the neurotoxic effect of *n*-hexane is observed in humans, the testicular effect seen in rats has not been well documented in humans.

Methyl *N*-Butyl Ketone

Industrial uses of methyl *n*-butyl ketone (2-hexanone, MBK) as a solvent or co-solvent (e.g., with methyl ethyl ketone) include the manufacture of adhesives, lacquers, vinyl coatings, printing inks, oils, varnish removers, and other materials [35,102]. Occupationally, the principal routes of exposure to MBK are via inhalation and skin contact with the liquid. The OSHA PEL for MBK is 100 ppm. Since 1998, the ACGIH has identified the TLV®–TWA for MBK at 5 ppm (skin notation) to protect against possible neuropathy. The German MAK is also 5 ppm. The NIOSH REL and IDLH for MBK are 1 ppm and 1600 ppm, respectively [2,4,143].

Methyl *n*-butyl ketone has low acute oral toxicity. The inhalation of high vapor concentrations of MBK can result in eye and respiratory tract irritation followed by CNS depression and narcosis [183]. MBK easily penetrates the skin, and inhalation exposure yields approximately 80%–85% pulmonary retention. In addition, MBK is widely distributed in the tissues, the highest concentrations being found in the blood and the liver [35]. Chronic exposure to low doses may produce degenerative axonal changes, primarily in the peripheral nerves and long spinal cord tracts [176,177,183]. Depending on the route of administration, a number of metabolites in varying amounts can be detected in the blood. The primary neurotoxic metabolite, as with *n*-hexane, is 2,5-hexanedione. Other metabolites identified following oral, intraperitoneal, or respiratory exposures include 2-hexanol and 5-hydroxy-2-hexanediol [35].

Since the 1970s, MBK has been considered a neurotoxic agent after instances of neurotoxicity were reported in the printing and painting industries [18,127]. Inhalation appears to be the primary route of exposure, with the severity of the toxicity being proportional to the extent of exposure. The characteristic disorder associated with methyl *n*-butyl ketone exposure begins several months after chronic exposure commences. Symptoms include weight loss and distal sensory neuropathy marked by a tingling sensation in the hands or feet. The muscular weakness that develops usually involves the hands and feet, but in severe cases may extend to the legs and thighs. The sensory loss is symmetrical and a moderate reduction of nerve conduction velocity is found in peripheral nerves [17,18].

When volunteers were given MBK by inhalation, orally, or by dermal application, 2,5-hexanedione was detected in the serum. Radioactivity associated with the radiolabeled MBK was found to be excreted slowly, indicating that repeated exposures to high concentrations of methyl *n*-butyl ketone may lead to prolonged exposure to its neurotoxic metabolites [57]. The relative neurotoxicity of methyl *n*-butyl ketone, *n*-hexane, and their metabolites was investigated in rats. Potency was estimated by the time required to produce evidence of severe hind limb weakness or paralysis. Results showed 2,5-hexanedione to be most toxic followed by 5-hydroxy-2-hexanone, 2,5-hexanediol, methyl *n*-butyl ketone, 2-hexanol, and *n*-hexane. An examination of the data showed that the neurotoxic potency was related to the amount of 2,5-hexanedione metabolically produced [102].

Carbon Disulfide

Carbon disulfide (CS_2) is a toxic and highly flammable solvent in extensive use in the manufacture of rayon, soil disinfectants, carbon tetrachloride, and electronic vacuum tubes. It is commonly used as a solvent in industrial hygiene analytical procedures. Other applications include its use as a fumigant for grain and a corrosion inhibitor [31,129]. Inhalation and skin contact are the main routes of occupational exposure. Because the sense of smell is quickly fatigued and sensitized to carbon disulfide's characteristic rotten-egg odor, this warning property is not useful in judging exposure. The ACGIH TLV®–TWA exposure limit is 10 ppm with skin notation. The NIOSH REL is 1 ppm with a STEL/ceiling limit of 10 ppm and skin notation. The OSHA PEL–TWA is 20 ppm with a ceiling limit of 30 ppm as a 30 min peak over an 8 h work shift [2,4,143]. The ACGIH TLV®–TWA was set to protect against cardiovascular, CNS, and neuropathic effects. NIOSH has established an IDLH value of 500 ppm [143]. In addition to these levels, proposals in the literature have suggested lowering the occupational exposure limit to 4 ppm to prevent neurological sequelae [90]. The BEI recommended by the ACGIH is 0.5 mg of the metabolite 2-thiothiazolidine-4-carboxylic acid (TEA) per gram of creatinine in urine, measured at the end of the work shift [4].

Acute exposure to high concentrations of carbon disulfide can result in restlessness, euphoria, nausea, vomiting, headache, mucous membrane irritation, unconsciousness, and fatal convulsions. Chronic exposure can lead to abnormalities such as irritability, hallucinations, auditory and visual disturbances, and weight loss [31,79,110,129,191]. Distal sensorimotor neuropathy is the most common chronic effect associated with CS_2 exposure. This has been confirmed in experimental animals as a neurofilamentous axonopathy that affects long axons in the CNS and peripheral nervous system [50,78]. Peripheral neuropathy takes place only after frequent and prolonged exposures to CS_2 and is characterized by a loss of distal sensory and motor function. The condition can progress more proximally with continued exposure.

Chronic exposure to CS_2, as well as hexane, 2-hexanone, and their metabolite 2,5-hexanedione, results in large swellings of the distal axons, which are filled with neuron filaments. Continued exposure causes axonal degeneration distal to the axonal swellings [48,78]. In addition to these effects, encephalopathy, detected by neurological examination and neuropsychological testing, has been reported. Evidence suggests that exposure to CS_2 accelerates the rate of atherosclerosis [78]. In addition, an investigation to determine a possible association between CS_2 exposure and ischemic heart disease mortality found that the relationship is meaningful only for workers exposed to high levels for many years. Price has suggested a safe level of between 15 and 20 ppm [162]. Approximately 70%–90% of absorbed CS_2 is metabolized and excreted in the urine. The remaining 10%–30% is exhaled in the breath unchanged. In addition to TTCA, mentioned earlier, other metabolites found in workers' urine include 2-mercapto-2-thiazolin-5-one and thiocarbamide [90,158,159,189,190].

In a study of rayon production workers with long-term exposure to CS_2 at concentrations well above the TLV®, evidence of neuropathy was observed in a significant number of workers and consisted of distal sensory loss, altered tendon reflexes, reduced muscle power, and reduction in nerve conduction velocity. These abnormalities persisted for up to 10 years after removal from exposure and were considered to be permanent impairments in nervous system physiology [49].

Methanol

Synthetic methanol (or methyl alcohol, wood alcohol) production exceeded 1 billion pounds in 2005. The largest use of methanol was in the production of methyl *t*-butyl ether (MTBE), an additive in gasoline. However, beginning in 2005 because of concerns with ground water contamination from MTBE, its use in reformulated gasoline has declined significantly. It is also utilized as a denaturant for ethanol, a raw material in the production of numerous other chemicals such as formaldehyde and acetic acid, and as a solvent or antifreeze in paints and strippers, cleaners, and windshield washer compounds [55,59].

The major routes of exposure to methanol in the industrial environment are through inhalation and dermal contact. The ACGIH TLV®–TWA of 200 ppm (250 ppm STEL) is based on potential ocular toxicity and CNS effects. The OSHA PEL, German MAK, and NIOSH REL are all set at 200 ppm. NIOSH has further established an IDLH value of 6000 ppm for methanol, and the ACGIH and NIOSH have added skin notations as indications that skin absorption can be a contributor to the overall body burden. The ACGIH BEI is 15 mg methanol per liter of urine, collected at the end of the work shift [2,4,143].

Most information regarding methanol toxicity in humans is gathered from acute exposures, primarily from ingestion, but adverse health effects from inhalation and dermal exposures have been reported [112]. In one NIOSH study, teachers' aides reported headaches, blurred vision, and other symptoms following inhalation exposure to methanol used in duplicating machines. Concentrations at the site were about 2–15 times the current REL. Adverse effects have also been reported following skin applications of methanol for various purposes, although inhalation may have also contributed to these exposures [112].

Methanol is readily absorbed following oral, inhalation, or dermal exposure and is distributed throughout the body according to the water content of the tissues [112]. Ingestion of as little as 2 teaspoonfuls may cause toxicity, whereas the fatal dose in humans is between 2 and 8 oz [77]. In the absence of medical treatment, a dose of between 4 and 10 mL of methanol taken internally can lead to blindness [165], and, depending on the amount of methanol ingested, mild to severe CNS depression can occur. A latent period, commonly 12–24 h, usually ensues followed by severe abdominal pain, difficult breathing, blurred vision, and pain in the eyes, among other symptoms. Visual impairment or total blindness can occur within days depending on individual susceptibility and the time when treatment began [112]. Metabolic acidosis due to formic acid production is thought to be the cause of the delayed symptoms and ocular toxicity [165].

Metabolism of methanol in the liver accounts for a high percentage of absorbed methanol in both nonhuman primates and rats. Lesser amounts are excreted unchanged in the urine and breath. Metabolism is important not because of its primary role in clearance but because of the connection between its metabolites and the acute toxic effects mentioned earlier. Methanol is oxidized by the catalase–peroxidative system in rats, rabbits, and guinea pigs and an alcohol dehydrogenase system in humans and primates. The metabolic sequence proceeds from methanol to formaldehyde to formic acid (formate) and finally to carbon dioxide and water. Formic acid is metabolized in both rats and primates via a folate-dependent pathway. Rats are able to utilize this pathway more efficiently than primates, allowing for a more rapid conversion to carbon dioxide. Because the process is slower in humans and primates, high doses of methanol cause a buildup of formate in tissues, including the eye, resulting in the observed toxicity [165]. Administration of ethanol has been used in treating methanol poisoning because ethanol inhibits the oxidation of methanol by competing for the same metabolic pathway. Prompt hemodialysis to remove both methanol and formate, coupled with concurrent administration of ethanol and bicarbonate, is a successful treatment in many poisoning cases [77]. Fomepizole, a potent inhibitor of alcohol dehydrogenase that does not cause inebriation and is simpler to deliver intravenously than ethanol, is approved by the U.S. Food and Drug Administration for treatment of methanol intoxication.

Ethanol

Ethanol (ethyl alcohol, grain alcohol) is produced in large quantities and is utilized extensively as a solvent in industry, in numerous consumer preparations, and as an additive to up to 95% of all gasoline sold in the United States. Ethanol–gasoline blends are sold as blends ranging from 10% (E10) to

85% (E85) ethanol to gasoline [56]. It is used industrially as a raw material in the production of pharmaceuticals, plastics, perfumes, cosmetics, and other compounds. Other applications include products such as hairsprays, mouthwashes, cleaning products, and drug formulations [77,112]. Denaturants (e.g., methanol) are added to the alcohol in a number of these products to discourage ingestion. The majority of industrial ethanol is synthesized by the acid-catalyzed hydration of ethylene and represents the largest source of ethanol; however, significant amounts are made from the fermentation of natural materials, particularly starchy grains [56,112].

Human exposure to ethanol is primarily through ingestion of alcoholic beverages and inhalation of ethanol vapors from industrial processes and consumer products. Percutaneous absorption appears to be much less important [112]. OSHA, ACGIH, and NIOSH have established the exposure limit of 1000 ppm for ethanol [2,4]. The German MAK is 500 ppm. The NIOSH IDLH of 3300 ppm is set because of safety concerns (10% of the LEL) rather than toxicological considerations [143].

Although there is no clear evidence that ethanol is carcinogenic in animals, it has been shown to be a tumor promoter. Additionally, the International Agency for Research on Cancer (IARC) has classified alcoholic beverages as a Group 1 carcinogen based on the occurrence of a variety of tumors in humans that have been causally related to ingestion of these beverages [112]. An unfortunate occurrence associated with chronic maternal consumption of large amounts of alcohol is a pattern of congenital abnormalities commonly called fetal alcohol syndrome. Effects may include growth retardation, microcephaly, mental deficiency, facial abnormalities, and poor coordination. Children who have been affected may display a few or many of the features characteristic of the syndrome [47,112,161].

Ethanol is a CNS depressant that is capable of inducing all stages of anesthesia. It is readily absorbed by the gastrointestinal tract and the lungs and is distributed throughout the body water [77]. Absorption can be delayed, however, by food in the stomach. Subjects exposed to 5000–10,000 ppm of ethanol vapor experienced eye irritation and coughing [165]. Individuals with tolerance to alcohol experienced headache, drowsiness, and stupor when exposed to concentrations of 9400–13,200 mg/m^3 (5000–7000 ppm) for a period of 110 min [165]. Ingestion of approximately 1 L of an alcoholic beverage (45%–55% ethanol) within several minutes can result in death [77]. Individuals with blood alcohol levels of approximately 0.05%–0.15% (50–150 mg/dL) may exhibit decreased inhibitions, poor coordination, blurred vision, and slowed reaction time. Increasing blood levels to 0.15%–0.30% can result in slurred speech, visual impairment, hypoglycemia, and staggering. At 0.3%–0.5% blood alcohol content (severe intoxication), symptoms can include poor muscular coordination, hypothermia, vomiting and nausea, and convulsions. In adults, coma and death are typically associated with levels exceeding 0.5% [112,165]. The wide ranges reported earlier reflect the differences in tolerance and susceptibility of individuals to the effects of alcohol.

Like methanol, ethanol is metabolized primarily (about 90%) by the liver. Elimination from the body by urinary excretion and pulmonary exhalation is minimal [112]. Oxidation of ethanol to acetaldehyde occurs via alcohol dehydrogenase within the cytosol. Acetaldehyde is then converted to acetic acid by the action of aldehyde dehydrogenase. Both enzymes utilize oxidized nicotinamide adenine dinucleotide (NAD) as a cofactor [77]. Following release to the blood, acetic acid is metabolized to carbon dioxide and water in the peripheral tissues [112]. Alternative, but less active, metabolic pathways have been demonstrated in humans and other species. These include catalase and microsomal ethanol-oxidizing systems [36,111]. Adults metabolize ethanol at a rate of about 7–10 g/h. This rate remains essentially constant for each individual within a wide range of exposure. Metabolic rates are higher for chronic alcoholics and children [112,165].

The interaction of ethanol with other hepatotoxicants is well known. Ethanol pretreatment has been shown to increase the toxicity of carbon tetrachloride, chloroform, trichloroethylene, dimethyl-nitrosamine, chlorpromazine, and other compounds [179]. The induction of cytochrome P450 isozymes may be responsible for their metabolic effects [112].

Methylene Chloride

Methylene chloride (dichloromethane) is widely used in a number of diverse applications, including the manufacture of polyurethane foams, pharmaceuticals production, boat building, paint stripping, vapor degreasing, extraction of caffeine from coffee and tea, and in various consumer products. Its high volatility; good solvent properties for fats, oils, and other compounds; and relatively good water solubility compared to other chlorinated compounds have made it quite valuable [149,184].

Due to the high vapor pressure of methylene chloride, the primary route of human exposure is through inhalation; however, dermal contact can be significant, depending on the method of use. The ACGIH TLV®–TWA of 50 ppm was set to protect against CNS effects and anoxia. In addition, the ACGIH has designated methylene chloride as a confirmed animal carcinogen but also states that available epidemiological studies do not confirm an increased risk of cancer in exposed humans [4]. NIOSH recommends that methylene chloride be regarded as a potential occupational carcinogen [143]. OSHA regulates methylene chloride in the workplace under 29 CFR 1910.1052 [149]. OSHA considers methylene chloride a potential human carcinogen and has reduced the PEL for methylene chloride from 500 to 25 ppm, with a STEL of 125 ppm (15 min) and an action level of 12.5 ppm that triggers certain requirements [149]. The current German MAK is 100 ppm [2].

The primary acute hazards associated with exposure to methylene chloride are due to its narcotic effect and can result in CNS depression and eye, skin, and respiratory tract irritation. In addition, one of the products of methylene chloride metabolism is carbon monoxide, which can impair health in a manner similar to direct exposure to carbon monoxide.

The resulting carboxyhemoglobin levels reduce the supply of oxygen to the heart and may aggravate preexisting heart disease [149].

Metabolism of methylene chloride can proceed via two pathways, one by a route involving cytochrome P450 monoxygenases (CYP) and the other by a route utilizing glutathione *S*-transferase (GST). Carbon dioxide is an end-product in both systems, but carbon monoxide is only produced via the MFO route. At low concentrations, the CYP enzymes appear to dominate, but at higher concentrations (above 300–500 ppm), the glutathione pathway increases in a disproportionate manner [184].

Methylene chloride was shown in a 1986 National Toxicology Program inhalation study to produce lung and liver tumors in male and female mice and benign mammary tumors in male and female rats [80]. Recent research has suggested that mice may be uniquely sensitive at high exposures to methylene-chloride-induced lung and liver cancer [80]. The tumors appear to be caused by a genotoxic mechanism involving metabolites of the GST pathway. The particular metabolites responsible are not found in high concentrations in lung or liver tissue in humans or rats.

In a study to determine the effects of alcohols and toluene upon methylene chloride-induced carboxyhemoglobin in the rat and monkey, it was shown that ethanol, methanol, isopropanol, and toluene inhibited the formation of carboxyhemoglobin. In addition, neither the rat nor the monkey demonstrated the methanol potentiation of carboxyhemoglobin that has been reported to occur in humans [46].

A study of the pharmacokinetics of [14C]-methylene chloride in rats at 50, 500, and 1500 ppm for 6 h showed that metabolic processes were saturated above the 50 ppm exposure concentration. At 48 h after exposure, approximately 95% of the body burden attributable to the 50 ppm exposure was metabolized, in contrast to 69% and 45% at 500 and 1500 ppm, respectively [125]. In addition, the production of carboxyhemoglobin reached a steady-state range of 10%–13% regardless of the exposure concentration, suggesting that the CO metabolic pathway was saturated.

Tetrachloroethylene (perchloroethylene) is another solvent in which patterns of elimination are altered when metabolic pathways become saturated [156]. In a study comparing oral and inhalation exposure of rats to [14C]-tetrachloroethylene, it was found that, with increasing dose, metabolism was saturated, resulting in more of the parent compound being eliminated unchanged at 72 h after exposure [156]. These results with methylene chloride and tetrachloroethylene indicate that simply increasing the exposure concentration does not always increase the body burden in a linear manner. Such information may be useful for safety evaluations to avoid the overestimation of body burden.

1-Bromopropane

1-Bromopropane (*n*-propyl bromide, 1-BP) is a colorless to pale yellow liquid with a strong, characteristic odor. The boiling point is 71°C and the vapor pressure is 110.8 mmHg at 20°C [130,186]. 1-Bromopropane is less flammable than many other halogenated alkanes at room temperature [81,186]. In 2006, worldwide annual production capacity of 1-bromopropane was estimated at greater than 20,000 metric tons (44 million pounds/year), of which 5000 metric tons were thought to be used as a pharmaceutical intermediate or process agent. The United States production was estimated at approximately 5000 metric tons (11 million pounds/year) and growing at a rate of 15%–20% per year [187]. Because 1-bromopropane has a relatively short atmospheric half-life (16 days), it is considered to have a relatively low ozone depletion potential and was marketed as a replacement for ozone-depleting refrigerants (e.g., chlorofluorohydrocarbons and hydrochlorofluorocarbons) [65].

Prior to the late 1990s, 1-BP was primarily used in enclosed processes as an intermediate in the production of pesticides, quaternary ammonium compounds, flavors and fragrances, pharmaceuticals, and other chemicals [82]. Beginning in the later part of the decade, 1-BP was introduced as a presumed less toxic replacement for methylene chloride degreasing operations and critical cleaning of electronics and metals. Because it is relatively nonflammable, 1-BP can be used safely in metal cleaning processes where heating is required. 1-Bromopropane was also introduced as a nonflammable, nontoxic, fast-drying, and inexpensive solvent for adhesive resins. Aerosol-applied adhesives containing 1-BP were used extensively by foam fabricating companies [82]. As usage of 1-BP became more prevalent, case reports of adverse events and toxic effects of 1-BP began to increase [93].

1-Bromopropane is absorbed in animals by all exposure routes and occupational exposures to humans can occur by both inhalation [139] and dermal routes [71]. Metabolism studies in rats and mice, have shown 1-BP can directly conjugate with glutathione forming *N*-acetyl-*S*-propylcysteine, or may be oxidized by P450 enzymes, primarily CYP2E1, to reactive intermediates that can also be further oxidized by other P450 enzymes and/or conjugated with glutathione. Potential biological markers of 1-BP exposure to workers that have been investigated include measurements of bromide ion $Br^{(-)}$, *N*-acetyl-*S*-(*n*-propyl)-L-cysteine (AcPrCys), and 1-BP in urine, and serum bromide level [45,82,83,122].

Although no study was identified that defined the absorption, metabolism, and disposition of 1-BP in animals and humans, it is possible to make some general assumptions based on the previously described reports. Exposure to 1-BP can occur by inhalation, oral, and dermal routes with 1-BP being rapidly distributed through the body tissues. Depending on species and activity levels, 30%–70% of the absorbed dose is eliminated unchanged in exhaled breath. Of the retained 1-BP, it may be eliminated by conjugation with glutathione GSH directly or by GST enzymes, or undergo oxidative biotransformation by the CYP450 monooxygenases. Animal studies strongly suggest that toxicity of 1-BP is dependent on the metabolic pathway of the compound. GSH-dependent metabolic pathways are integral to toxic actions, but it is not likely that the GSH-1-BP-conjugates are the source of toxicity. Instead, a stronger case can be made that toxicity of 1-BP

is dependent on the generation of reactive oxidative metabolites of 1-BP by CYP450 monooxygenases that are conjugated with GSH for elimination. Toxicity of 1-BP likely results when GSH levels are depleted from neutralizing reactive metabolites; as free GSH is utilized, GSH-1-BP-conjugates increase until GSH is consumed. At this point critical cellular components can be damaged, and toxicity results. The strongest support for a mechanism such as this is derived from experiments using sensitive species or strains or more elegantly, genetically engineered animal models that are missing the key step in the toxic pathway [75,113].

1-Bromopropane has been found to be neurotoxic, a developmental and reproductive toxicant, immune-toxic, and hepatotoxic in rodents and has produced neurological and possible reproductive effects in humans [107,108,138,139]. In a 2-year inhalation study by the National Toxicology Program (NTP), nonneoplastic lesions increased in 1-bromopropane-exposed rats (nose, larynx, and trachea) and mice (nose, larynx, trachea, and lung). In addition, predominantly in the nose and skin of exposed rats, there was an exposure-related increase in inflammatory lesions containing Splendore-Hoeppli material, indicative of immunosuppression [136,139]. 1-Bromopropane was shown to be immunosuppressive in rats and mice after whole-body inhalation exposure [19].

Currently, neither NIOSH nor OSHA have established a REL or PEL for workplace 1-BP. ACGIH in the 2005 TLV®s and BEIs recommended an 8 h TWA of 10 ppm as protection against the potential for neurotoxicity, hepatotoxicity, and reproductive and developmental toxicity in 1-BP exposed workers. A Notice of Intended Change (NIC) has been proposed to lower the TLV® to 0.1 ppm (8 h TWA). Other professional organizations and manufacturers have RELs ranging from 20 to 100 ppm. The U.S. EPA stated in May 2007 that exposures within or below the range of 17–30 ppm are anticipated to be protective against reproductive effects in men and women. The only, legally enforceable, occupational standard for regulating 1-bromopropane in the United States is a California OSHA PEL of 5 ppm [40]. Other professional organizations and manufacturers have RELs ranging from 20 to 100 ppm. In 2007, EPA, in response to adverse health findings, proposed to limit uses of 1-BP to metal cleaning and degreasing with appropriate controls; uses as aerosol solvents and adhesives were found to be unacceptable.

NONTRADITIONAL SOLVENTS

Given the negative health and environmental impacts created by some of the more widely used solvents, a great deal of effort has gone into finding suitable replacements. The following compounds are examples of nontraditional materials that show promise as replacement solvents.

D-Limonene

D-Limonene is a naturally occurring monocyclic terpene found in citrus peel oils, spices, evergreens, and human milk [194]. It is considered to have low acute toxicity and is listed as generally recognized as safe (GRAS) as a food additive by the U.S. Food and Drug Administration (21 CFR 182.60). It has found wide application as a solvent in numerous cleaning and degreasing applications, replacing more toxic and environmentally undesirable chlorinated solvents, glycol ethers, xylene, and chlorofluorocarbons (CFCs) [68]. Skin contact with D-limonene may cause irritation and sensitization (attributed to the oxidation product D-limonene oxide) [194]. D-Limonene has been shown to produce hyaline droplet nephropathy and renal tubular tumors in male rats; however, these effects are attributed to the unique presence of α2μ-globulin in the male rat and are not deemed relevant to other species, including humans [67]. Among the attributes of D-limonene are its antimicrobial, antiviral, antifungal, and antilarval properties [42]. D-Limonene and related monoterpenes have also demonstrated chemopreventive and chemotherapeutic efficacy in experimental cancer-therapy models [51]. Based on similar metabolic pathways in rats and humans and the therapeutic successes in rodents, it has been suggested that D-limonene may be an efficacious chemotherapeutic agent for human malignancies [51].

Vegetable Oil–Based Solvents

Vegetable oils and their derivatives (oleo-chemicals) have many industrial uses. They are used as solvents for printing inks, in the production of paints and coatings, as lubricants and fuels, and as feed stocks for many products that are historically manufactured from petroleum hydrocarbons [63]. Fatty acid methyl esters (FAMEs) derived from vegetable oils have been used for fuels (biodiesel), cleaning and degreasing agents, and concrete and asphalt release and cleaning agents [99]. These products emit little or no VOCs, and are less toxic than many organic solvents. However, they can be irritating to the skin with prolonged contact, and mists and vapors are irritating to the eyes and respiratory system. No OELs have been set by NIOSH or OSHA for exposure to workplace levels of FAME compounds. FAME compounds are not on the ACGIH list of TLV®s and BEIs. The OSHA PEL of 5 mg/m^3 for oil mists may apply to some operations (spraying), with products containing FAMEs. Because of the growing use of oleo-chemicals as fuels and solvent substitutes, methyl soyate, a FAME made from soybeans and used extensively as a biodiesel fuel, was nominated for the National Toxicology Program for further testing. Initial tests looking at micronuclei formation in male B6C3F1 mice were negative as were Salmonella tests for mutagenicity [140].

Carbon Dioxide

Carbon dioxide (CO_2) is a gas under standard temperature and pressure conditions. It can be converted, however, to the liquid and supercritical phases by increasing pressure and temperature. The critical point of carbon dioxide is 31°C and 73 atm. Below this point, CO_2 can be maintained in a liquid state (e.g., 65 atm and 25°C), whereas above 31°C no amount of pressure can be applied to liquefy it

(supercritical phase) [92]. In either of these dense phases, CO_2 exhibits good solvent properties.

Beneficial characteristics include liquid-like density, gas-like diffusivity, and low surface tension. In particular, liquid CO_2 acts like a hydrocarbon solvent, it has good homogenizing properties (immiscible liquids form a single phase when mixed with CO_2), and it is a good solvent for many aliphatic hydrocarbons and most small aromatic hydrocarbons. Other chemical groups such as halocarbons, esters, ketones, and low-molecular-weight alcohols also exhibit good solvency in CO_2 [92]. Since the mid-1970s, supercritical CO_2 technology has been employed in the food, beverage, pharmaceutical, and perfume industries. Applications include the production of spice extracts, natural dyes, decaffeinated coffee and tea, plant extracts, active substances from drugs, and volatile oils [30,52,124]. It has also been used in wastewater treatment, chemical analysis, and at times as an aerosol propellant. More recently, liquid CO_2 has found favor as an alternative for metal parts degreasing and as a solvent for dry-cleaning clothes [52,98].

One such CO_2 degreasing system is being used in a pen manufacturing operation to replace perchloroethylene. It consists primarily of two separate systems: a hot oil pretreatment process and an automated system that employs liquid carbon dioxide in a pressure vessel. The application is to degrease and remove chips from ball points after machining. The hot oil unit is used to displace fatty esters contained in machining oil and to remove chips in the point cavity. The automated unit then removes oil from the points using liquid carbon dioxide. The carbon dioxide and oil are separated in a recycling system, and the carbon dioxide is used again during the next cleaning cycle.

Advantages of CO_2 usage over conventional solvents are numerous. Carbon dioxide is nonflammable, noncorrosive, nonreactive, nontoxic, inexpensive, and plentiful. Products obtained are solvent free. Selective separations are possible. Finally, environmental problems are eliminated, because the gas is recovered for future use. One of the disadvantages of CO_2 systems involves the relatively high start-up costs for equipment; however, these may be recouped through improved productivity and reduced costs for waste disposal, for example.

Ionic Liquids

Ionic systems, which are made up of salts that are liquid at room temperature, are finding applications in a number of chemical processes. Ionic liquids have good solvent properties for many inorganic, organic, and, polymeric materials and, in some cases, these compounds can serve as both catalyst and solvent [72]. Research has indicated that partitioning of organic solvents between an ionic liquid and water corresponds closely with that found for molecular organic solvents and water; thus, ionic liquids have the potential to replace the toxic, flammable, and volatile organic compounds currently used in liquid–liquid separations [73]. The room-temperature ionic compounds, such as 1-butyl-3-methylimidazolium hexafluorophosphate and 1-butylpyridinium nitrate, consist of nitrogen-containing organic cations and inorganic anions. Their physical and chemical properties can be altered according to the choice of ions. Advantages compared to conventional organic solvents include low volatility and relative ease of recycling [73]. Other potential uses include removal of organic contaminants from wastewater, soil cleanup, replacement of corrosive mineral acids in refinery processes, and spent nuclear fuel treatment [72]. The safety and toxicological profiles of these compounds have yet to be thoroughly developed; therefore, caution must be exercised before they are put into general use.

OPPORTUNITIES IN THE TOXICOLOGICAL EVALUATION OF SOLVENTS

Human exposure to solvents is quite common in today's society. These exposures frequently involve multiple chemicals that are found in numerous products such as cleaning agents, paint thinners, and fuels. Although most toxicological research to date has dealt with single chemicals, questions remain about the long-term health effects associated with low-level exposures to multiple chemicals and the sensitivity of the toxicological endpoints that are currently being relied upon. Development of innovative experimental protocols and new quantitative mechanistic approaches to the study of chemical interactions may be beneficial in this regard [103,202]. Economic concerns and the desire for less toxic and more environmentally friendly chemicals have resulted in the introduction of numerous alternative compounds into the marketplace. In some cases, little may be known about the health and environmental impacts of these materials; examples include the ionic liquids discussed earlier. It is therefore essential that sufficient toxicological and environmental data be gathered before replacements are introduced on a wide scale. Research has shown that many neurotoxic chemicals are capable of adversely affecting the sensory function. Minor changes in vision or hearing, for example, can dramatically alter job performance and the overall quality of life. While most reports to date have dealt with changes in the visual system, additional investigations into the effects of solvents on hearing, taste, and smell would provide important new information on this subject [70].

QUESTIONS

15.1 Which of the following Occupational Exposure Limits are legally enforceable by statute?
   a. Threshold Limit Values
   b. Recommended Exposure Limits
   c. Workplace Environmental Exposure Limits
   d. Permissible Exposure limits
   e. New Chemical Exposure Limits

15.2 You are a toxicologist with industrial hygiene responsibilities in a large manufacturing company. Your boss has just told you that the solvent the factory is using to degrease metal parts will be banned by the EPA within the next

6 months. Your job is to lead a team of employees, who have a vested interest in the current solvent, in coming up with a suitable alternative material. What are your considerations in recommending a replacement? Explain.

15.3 Assume that the solvent chosen earlier will be used in six locations in the factory. You surmise that some sort of ventilation will be required to protect the employees. What factors must you take into account in recommending the proper system?

15.4 One of your employees has begun using a solvent mixture containing xylene and toluene. To ensure the safety of the worker, you have conducted personal air monitoring throughout the day and have come up with the following sampling times and monitoring results: 0800–1000, 60 ppm xylene and 25 ppm toluene; 1000–1200, 92 ppm xylene and 45 ppm toluene; 1200–1300, no exposure because employee left for lunch; 1300–1600, 110 ppm xylene and 47 ppm toluene. Calculate the TWA exposure for each chemical. Assume that there is no dermal exposure and that the toxic effects contributed by each solvent are additive. Has the TLV®–TWA been exceeded? Toluene TLV® = 20 ppm, Xylene TLV® = 100 ppm.

15.5 Which of the following represents the level of a biomarker of exposure that is most likely to be observed in specimens collected from healthy workers who have been exposed to a specific chemical to the same extent as workers with inhalation exposure at the Threshold Limit Value (TLV®):

a. Biological Exposure Index (BEI®)
b. Biological Limit Value (BLV®)
c. Biological Exposure Limit (BEL®)
d. Biological Benchmark Dose (BMD®)
e. Biological Recommended Limit (BRL®)

15.6 Match each solvent or metabolite with the appropriate fact listed as follows:

Solvent/Metabolite	Fact
1. D-Limonene	a. Antidotal in methanol poisonings
2. Carbon disulfide	b. Associated with bone marrow disease in humans
3. 2,5-Hexanedione	c. Potentially useful in cancer therapy
4. Toluene	d. Teratogen and embryotoxic
5. Methanol	e. Metabolism produces carboxyhemoglobin
6. 2-Butoxyacetic acid	f. Frequently—sniffed to obtain euphoric effect
7. Ethylene glycol monomethyl ether	g. Used in rayon production
8. Benzene	h. A few milliliters can lead to blindness
9. Ethanol	i. Primary causative agent in polyneuropathy
10. Methylene chloride	j. Produces hemolytic effects in rats

ACKNOWLEDGMENTS

The authors wish to thank Amy L. Roe for her assistance in editing/revising the chapter. The authors also gratefully acknowledge the significant contributions of the previous writers, Paul H. Ayres, W. David Taylor, Michael J. Olson, Robert C. Spiker, Jr., Gary B. Morris, and support from Margaret Buckalew.

16 Crop Protection Chemicals
Mechanism of Action and Hazard Profiles

James T. Stevens, Trent D. Stevens, and Charles B. Breckenridge

CONTENTS

INTRODUCTION

The use of chemicals to control pests dates back more than 3000 years to the Chinese, who discovered that sulfur was effective as a fumigant, and then in the sixteenth century, they discovered that arsenic could be used as an insecticide.[1] Tobacco leaf (nicotine) and the seed of *Strychnos nux vomica* (strychnine) were used as rodenticides in the eighteenth century,[2] and the insecticidal active botanicals, including rotenone derived from the root of *Derris elliptica* and pyrethrum from the flowers of chrysanthemums, were used as insecticides in the mid-1800s. Bordeaux mixture (copper sulfate, lime, calcium hydroxide, and water) was introduced in France for mildew control in grapes in 1880.[1] Paris green (copper arsenite) and calcium arsenite were used extensively by the turn of the twentieth century to control the Colorado potato beetle.[2]

The era of modern agricultural production, which began after World War II, depended on (1) the introduction of highly mechanized farming practices; (2) the use of fertilizers, as production was diverted from a large munitions manufacturing capacity that had developed during the war; (3) the use of pesticides aimed at controlling pests; and (4) optimizing yield, especially in monoculture staple crops, such as corn, soybeans, rice, and wheat. The discovery of more efficacious (e.g., low use rate) and selective pesticides (e.g., tolerance to beneficial plants, insects, and animals) has largely been based on the use of screening methods, and more recently, combinatorial chemistry coupled to high-throughput screening techniques to discover new classes of biologically active ingredients. The drive to discover new pesticides comes from the following business imperatives: (1) cost-effectiveness, which confers competitive advantage; (2) societal pressure for improved safety; and (3)

the development of pest resistance (e.g., pests evolve over generations by the selection of polymorphic forms that have developed a tolerance to the pesticide). The incorporation of genes that confer pesticide tolerance to relatively inexpensive, and comparatively safe, nonselective herbicides in key crops is a recent development. More recent still is the insertion of genes into plants to produce an insecticidal protein, delta-endotoxin derived from *Bacillus thuringiensis*, which is thought to create a lytic pore 1–2 nm in diameter in the midgut of the insect.[3] On the immediate horizon is the use of genetic engineering, perhaps combined with chemical-induced changes in plant metabolism, to create functional food and fiber, which exhibit traits that have enhanced nutritional value, facilitate processing, or have other desirable attributes.

In this chapter, the hazard of pesticides is presented for agents that have either significant economic value or are representative of a group of active ingredients with a specific biochemical mode of action (MOA) in targeted species. The MOA, where known, and the hazard profile of organic pesticides, such as those described in the first paragraph or others that have subsequently been discovered, have been included for the sake of comparison with those of synthetic pesticides, because of increased interest in organically grown food and in natural pesticide usage.[4]

Pesticides are grouped according to their MOA in targeted species. This method of classifying fungicides,[5] herbicides,[6] and insecticides[7] was developed by agronomists to assist growers in preventing the development of resistance in targeted species (see Table 16.70). Grouping pesticides according to their MOA is more indicative of potential biological outcomes, and in some instances, this provides data that are directly relevant to toxicologists, because the MOA in the pest species may be more or less conserved in mammals. This is also relevant to pesticide registration, because in 1996, the U.S. Environmental Protection Agency (EPA) was directed by Congress to conduct cumulative risk assessments on chemicals that share a common *mechanism of action* in mammals. In the guidance developed by EPA,[8] they considered an initial grouping of chemicals based upon one of the following four criteria: structural similarity, the mechanism underlying the pesticide effect on target species, the general mechanism of mammalian toxicity, or a specific toxic effect in mammals.

This chapter organizes chemicals by their mechanism of action in the targeted species of fungi, insects, or plants. Chemical structures are provided, but structure–activity relationships are not discussed extensively. Hazard profiles for members of a pest-based *common mechanism class* have the potential to reveal whether there should be an animal-based *common mechanism group,* although such judgments are usually based upon MOA studies in animals. Even if it is established that a group of chemicals belong to a *common mechanism class*, this still leaves unaddressed the important question as to whether the MOA elaborated in the target species or in animal models are relevant to man, and if so, how doses should be scaled between species.

HAZARD CHARACTERIZATION OF PESTICIDES

Federal Insecticide, Fungicide, and Rodenticide Act

The Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) was passed by the U.S. Congress in 1947.[9] The legislation was administered by the U.S. Department of Agriculture (USDA) and remained primarily a labeling requirement for many years. FIFRA has been amended several times and its registration provisions strengthened.[10] Pesticide use in the United States is also regulated under the Federal Food, Drug, and Cosmetic Act (FFDCA). FFDCA was amended in 1954 (Section 408; Miller Amendment) to require the establishment of pesticide tolerances on food.[11] An additional amendment in 1958 (Section 409) created the requirement to establish tolerances for food additives present in processed foods.[11] Section 409 of FFDCA contains the Delaney Clause, which prohibited the use of carcinogens as food additives. The EPA applied this Section 409 of FFDCA to those circumstances when pesticide residues found in processed food were greater than those found in the raw agricultural commodity. Under such circumstances, food additive tolerances are also required, and such additives must not be carcinogenic.

Food Quality Protection Act of 1996

In 1996, the Food Quality Protection Act (FQPA) reauthorized FIFRA provisions, and this act requires tolerances to be reassessed as part of reregistrations.[12] FQPA amendments to the FFDCA[11] and FIFRA[9] directed the EPA to consider a number of factors in assessing risk as part of the tolerance-setting procedure.[12] FQPA provides for a single health-based standard and eliminated the problem posed by having different standards for pesticide concentrations in raw and processed foods. FQPA required that in the process of setting tolerances for pesticide residues in food, the EPA must evaluate the aggregate risk arising from exposure to pesticides from all routes of exposure, including oral, dermal, or inhalation exposure. Occupational exposure assessment, however, remained outside the jurisdiction of FQPA.

FQPA also directed the EPA to consider pesticides having a common mechanism of toxicity and to evaluate the cumulative effect of exposure to pesticides sharing a common mechanism. Finally, the agency was charged with developing techniques for evaluating the potential for pesticides to affect the endocrine system. Most of these provisions reflect concerns that children may be more susceptible to chemicals than adults, thereby taking into account key recommendations of a National Academy of Sciences report, *Pesticides in the Diets of Infants and Children*.[13] Under FQPA, the EPA assumes an extra 10-fold uncertainty factor to account for increased susceptibility of children, including effects of in utero exposure, unless there are data to suggest otherwise.

STUDY REQUIREMENTS

Toxicology testing guidelines have been promulgated by the EPA[14]; the Japanese Ministry of Agriculture, Forestry, and Fisheries[15]; the European Community[16,17]; and the Organization for Economic and Cooperative Development.[18] These guidelines have been harmonized among the various regulatory authorities[15–20] and are revised or enhanced[19] as new testing procedures are developed (Table 16.1).

Acute toxicity studies are conducted by administering a chemical by oral, dermal, or inhalation routes to estimate the dose that is expected to cause mortality in 50% (LD_{50}) of the test animals. Studies are also conducted to evaluate the irritation potential of chemicals when applied to skin and eyes. The potential of chemicals to cause allergic reactions when applied to skin (e.g., skin sensitization) is also determined. Acute oral and inhalation studies are usually conducted in rats, dermal and eye irritation studies are typically conducted in rabbits, and the sensitization study is carried out in guinea pigs. The results from these studies are used to establish the precautionary language (Table 16.2) used on product labels for crop protection chemicals.[21]

Oral toxicity studies are conducted in rats, mice, or dogs fed diets containing the pesticide for various durations of time (28 days, 90 days, or 1 year) or for the lifetime of the animal (24 months for rats and 18 months for mice). Animals are randomly assigned to either a control group or one of several treatment groups, which are comprised of 10–50 rats or mice, or alternately 4–6 dogs per group. Typically, there are at least four groups in each study, with one control group and three groups of animals that receive either a low, medium, or high concentration of the pesticide in their diets. The high-dose group is typically administered a maximally tolerated dose,[22] or if the pesticide is nontoxic, a maximum limited dose of 1000 mg/kg/day. Lower doses are established to have minimal-to-moderate effects, and one dose ideally should have no effect. Typically, clinical signs, effects on survival, body weight, feed consumption, blood chemistry, and hematological and urinary parameters are evaluated on multiple occasions during the in-life phase of the study. At study termination, individual organs are weighed, and gross and microscopic examinations are conducted on approximately 50 tissues/animal. The effects of the tested pesticide are described (hazard identification), and the lowest observed effect level and the no observable effect (NOEL), or alternately the no observable adverse effect, are determined.

Dermal toxicity is evaluated by applying the chemical to the skin for 6 h a day for 21 days in rats, or for 28 days in rabbits. Developmental toxicity studies are conducted to evaluate the potential of the pesticide to affect the development of offspring, including an evaluation of birth defects in both rats and rabbits. In addition to developmental toxicity studies, a reproduction study is conducted in rats. This study involves feeding diets containing the chemical to young adult male and female rats for approximately 3 months prior to mating. The females are allowed to produce a litter of offspring that are then reared to adulthood. The animals are fed diets containing the test chemical during this entire period of time. After reaching sexual maturity, a second generation of animals is allowed to mate and produce a second litter of offspring (the F_2 generation) that are in turn administered the pesticide until they reach adulthood, at approximately 90 days of age. A variety of toxicological and reproductive parameters are assessed to determine the effect of the pesticide on neonatal development and reproductive function in young male and female animals.

The mutagenic potential of a pesticide is typically assessed by evaluating its possible interaction with (1) genes (gene mutation tests), (2) chromosomes (clastogenic tests), and (3) directly with the DNA (classified as other tests).

The carcinogenic potential of a pesticide is evaluated in mice and rats that are typically fed the chemical in their diets for 18 or 24 months, respectively. The dietary concentration of the chemical administered in chronic studies is generally selected based on the results from a 90-day feeding study.[22] Approximately 50 tissues from each animal are examined for the presence of tumors or for other evidence of tissue damage. Pesticides are considered to be potential human carcinogens if (1) they significantly increase the incidence of any tumor above the incidence observed in concurrent or historical control animals; (2) they increase the incidence of rare or malignant tumors; and/or (3) they shorten the latency to tumor development.

To determine whether a chemical is likely to be carcinogenic in humans, regulatory agencies around the world[20,23,24] conduct a weight-of-the-evidence assessment using methods similar to those described in the EPA cancer classification scheme.[20,24] In a weight-of-the-evidence assessment, the carcinogenic potential of a chemical is evaluated by considering the results from animal studies including (but not limited to) the details of the tumor responses seen in animal bioassays (dose–response functions, including evaluations of the evidence for nonlinearity, structure–activity considerations, and details on MOA, including descriptions of key events, temporal/dose congruity, biological plausibility, and alternative MOA, which include but are not limited to assessments of genotoxic potential). Results from epidemiological investigations are weighted heavily, if such data are available. The resulting assessment includes the classification of the pesticide into one of several categories shown in Table 16.3 for the EPA and International Agency for Research on Cancer (IARC).

In addition to assessments of mutagenicity, developmental toxicity, reproductive toxicity, and oncogenicity, it is possible to determine immunotoxicity, neurotoxicity, and other effects from associated EPA Series 870 Guideline studies.

However, the existing data related to these other studies is not consistently available or relevant, so these results will not be covered here.

FUNGICIDES

The Fungicide Resistance Action Committee (FRAC) has classified fungicides according to their mechanisms of action in fungi.[5] In Table 16.4, pesticides are grouped according to their assigned FRAC codes. Not all FRAC codes have been included in this chapter, and some commercially important members of

[a] The word *Poison* is used on the label if the *Danger* category is based on oral, dermal, or inhalation toxicity.

the selected FRAC codes may have been omitted. Table 16.4 provides a summary of the mechanisms of action of pesticides in fungi for the selected FRAC code. It also provides conclusions as to (1) whether the identified mechanism of action in fungi is likely conserved in humans and (2) whether there are any other bases for establishing a *common mechanism of toxicity group*, as set forth by FQPA and elaborated by EPA.[8]

Acylalanines and Oxazolidinones (FRAC Code A1)

The acylanine fungicides are represented here by metalaxyl and by mefenoxam, which is the active R-enantiomer of metalaxyl. These chemicals inhibit RNA synthesis in fungi by interfering with RNA polymerase I.[5] The spectrum of activity of mefenoxam is restricted to the control of downy mildew and late blight in a broad spectrum of crops.

There are data suggesting that structural features of ribosome gene promoters are conserved from plants to humans, but specific base sequences are not.[25] Therefore, it is unlikely that a pesticide selected to interfere with RNA polymerase I in fungi would have the same effect in mammalian cells. Furthermore, since RNA polymerase I is central to cell replication and growth,[26] it is unlikely that an effect on RNA polymerase I in animal bioassays would go unnoticed unless the chemicals were poorly absorbed, or rapidly metabolized and eliminated. The hazard profile for metalaxyl is unremarkable, and there is no indication of any effect on the cell cycle, although specific studies have not been conducted (Table 16.5).

Benzimidazoles and Thiophanates (FRAC Code B1)

The benzimidazole (thiabendazole) and thiophanate (thiophanate-methyl) fungicides have broad-spectrum activity, as indicated by a MOA involving the inhibition of mitosis by preventing polymerization of β-tubulin, one of the constituent building blocks of microtubules.[5] Microtubules play a critical role in both the plant and animal kingdoms during mitosis[27,28] and provide the basis for a cytoarchitecture that permits intracellular transport of molecules using the motor proteins dynein and kinesin.[27–29] Recently, it has

TABLE 16.3
Schemes for the Classification of Carcinogens

U.S. Environmental Protection Agency Original Classification Scheme[24]				International Agency for Research on Cancer 2012 Guidelines[264]	
		Risk Character			
Carcinogen Category	Criteria for Classification	RfD	Q_1*	Descriptive Characterization	
A—Human	Sufficient evidence in humans		X	Carcinogenic to humans	Group 1: The agent is carcinogenic to humans
B—Probable human					
B1	Limited evidence in humans Sufficient evidence in animals (two species with tumors)		X	Likely to be carcinogenic to humans	Group 2A: The agent is probably carcinogenic to humans
B2	Inadequate human evidence Sufficient animal evidence		X		
C—Possible human	No evidence in humans Limited evidence in animals	X	X	Suggestive evidence of carcinogenic potential	Group 2B: The agent is possibly carcinogenic to humans
D—Not classifiable	Inadequate animal or human evidence	X		Inadequate information to assess carcinogenic potential	Group 3: The agent is not classifiable as to its carcinogenicity to humans
E—Not a human carcinogen	Sufficient animal testing with no evidence of carcinogenicity and human experience	X		Not likely to be carcinogenic to humans	Group 4: The agent is probably not carcinogenic to humans

been suggested that microtubules may provide the network for laying down cellulose structural support in plants.[30] While the α- and β-tubulin subunits that make up microtubules are conserved between kingdoms, microtubules in plants are fundamentally different from those found in fungi and animals, because plant microtubules do not arise from discrete organizing centers, such as the centrosome or the spindle pole body, as they do in both fungi and animals.[31] During mitosis in fungal and animal cells, γ-tubulin serves as a microtubule nucleating factor, playing a role in assembling the α- and β-tubulin dimers that are embedded in, and grow out of, a pair of centrioles and their associated proteins. Recent data suggest that γ-tubulin may also play a role in microtubule nucleation in plant cells.[32]

Against this background of new and developing information, and considering that a number of isoforms of β-tubulin have been described in mammalian cells,[33] it is not known, but it is certainly possible, that the benzimidazole and thiophanate fungicides could interfere with microtubule formation in animal cells.

The structures, uses, and hazard profiles of the benzimidazole and thiophanate fungicides are presented in Table 16.6. The hazard characteristics of thiabendazole and thiophanate-methyl have been reviewed by the EPA and by members of the Joint Meeting of the FAO/WHO Panel of Experts on Pesticide Residues in Food (JMPR).[34–36]

Pyridinylmethyl-Benzamides (FRAC Code B5)

The pyridinylmethyl-benzamides, represented here by fluopicolide, act by delocalizing spectrin-like proteins that are believed to support membrane stability in *Ascomycetes* and *Oomycetes* fungus species.[5,37,38] Fluopicolide is applied to various crops in combination with other fungicides as a mesosystemic treatment, where it affects zoospore release, cyst germination, sporulation, and plant tissue mycelial growth.[37,39] 2,6-Dichlorobenzamide (BAM) is a common metabolite of both fluopicolide and dichlobenil that the EPA has classified as a possible human carcinogen (Group C), but the expected BAM residues are lower than those found after dichlobenil application.[40]

The structure, uses, and hazard profiles of fluopicolide are presented in Table 16.7. The hazard characteristics have been reviewed by both the EPA and the JMPR, and both claim to have sufficient data for safety assessment.[38–40]

Phenyl-Benzamides, Pyridinyl-Ethyl-Benzamides, and Pyrazole-Carboxamides (Carboxamides; FRAC Code C2)

There are three groups of carboxamide fungicides represented here: phenyl-benzamides, pyridinyl-ethyl-benzamides, and pyrazole-carboxamides. Carboxamides inhibit mitochondrial respiration by blocking electron transport at the succinate dehydrogenase stage (complex II) in the Krebs cycle (see Figures 16.1 and 16.2). A recent characterization of the crystalline structure of succinate dehydrogenase in *Escherichia coli*[41,42] has permitted structural modeling of the active site(s) of the enzyme.[43,44] Future work may permit a determination of where carboxamides bind to succinate dehydrogenase in fungi, and it may address the question of whether or not homologous binding sites are present in human mitochondria. If it is assumed that carboxamides bind to human mitochondrial targets, one would predict that they would be highly toxic. Flutolanil, for example, is remarkably nontoxic, which belies any effect as an inhibitor of mitochondrial respiration in mammals.

TABLE 16.4
Fungicides Listed according to FRAC Classification System

Chemical Group	Common Name	FRAC Code	FRAC MOA	MOA Conserved in Mammals?	Other Common MOA in Mammals
Acylalanines	Mefenoxam (Table 16.5)	A1	RNA polymerase I	Unlikely	None known
Benzimidazoles Thiophanates	Thiabendazole Thiophanate-methyl (Table 16.6)	B1	ß-Tubulin assembly in mitosis	Likely; in cancer chemotherapy, inhibition of mitosis at metaphase through interaction with tubulin	Induction of apoptosis in cancer cells
Pyridinylmethyl-benzamides	Fluopicolide (Table 16.7)	B5	Delocalization of spectrin-like proteins	Likely; spectrin-based skeleton, identified in erythrocytes and in many cellular processes	None known
Phenyl-benzamides Pyridinyl-ethyl-benzamides Pyrazole-carboxamides	Flutolanil Fluopyram Penflufen Penthiopyrad Sedaxane (Table 16.8)	C2	Complex II: succinate dehydrogenase	Likely: SDG has vital role in ATP production in the mitochondrial respiratory chain[265]	Glutathione activity in liver mitochondria
Methoxy-acrylates Oximinoacetates Dihydro-dioxazines Imidazolinones	Azoxystrobin Trifloxystrobin Fluoxastrobin Fenamidone (Table 16.9)	C3	Complex III: cytochrome bc1 (ubiquinol oxidase) at Q_o site (*cyt b gene*)	Potentially: superoxide generation site of complex III in cardiac myocytes may increase in TCA cycle activity[266]	None known
Cyano-imidazoles Sulfamoyl-triazoles	Cyazofamid Amisulbrom (Table 16.10)	C4	Complex III: cytochrome bc1 (ubiquinone reductase) at Q_i site	Likely[267]	None known
Organotins	Triphenyltin acetate/hydroxide (Table 16.11)	C6	Inhibitors of oxidative phosphorylation, ATP synthase	Likely but the active ingredient does not appear to reach target site	None known
Triazolopyrimidines	Ametoctradin (Table 16.12)	C8	Complex III: cytochrome bc1 (ubiquinone reductase) at Q x (unknown) site	Potentially[268]	None known
Anilinopyrimidines	Cyprodinil Pyrimethanil (Table 16.13)	D1	Methionine biosynthesis (proposed) (*cgs gene*)	Potentially: methionine sulfoxide reductase A and methionine metabolism are associated with oxidative stress[269]	None known
Quinolines	Quinoxyfen (Table 16.14)	E1	Signal transduction (mechanism unknown)	Possible[270]	None known
Phenylpyrroles	Fludioxonil (Table 16.15)	E2	MAP/histidine kinase in osmotic signal transduction (*os-2, HOG1*)	Possible as mammalian analogs of HOG1 exist	None known
Dicarboximides	Iprodione Vinclozolin (Table 16.16)	E3	MAP/histidine kinase in osmotic signal transduction (*os-1, Daf1*)	Likely as NAZDH cytochrome c reductase in lipid peroxidation (formerly F1)	Share a common metabolite 3,5-dichloro-aniline[85]; potential antiandrogen
Triazoles	Cyproconazole Difenoconazole Fenbuconazole Flutriafol Metconazole Myclobutanil Propiconazole	G1	C14-demethylase in sterol biosynthesis (*erg11/cyp51*)	Likely[271]	Aromatase (CYP19) inhibition[272]

TABLE 16.4 (continued)
Fungicides Listed according to FRAC Classification System

Chemical Group	Common Name	FRAC Code	FRAC MOA	MOA Conserved in Mammals?	Other Common MOA in Mammals
	Prothioconazole Tebuconazole Triadimefon Tetraconazole Triadimenol Imazalil				
Imidazoles	Prochloraz (Tables 16.17 and 16.18)				
Hydroxyanilides	Fenhexamid (Table 16.19)	G3	3-keto-reductase, C4-demethylation (*erg27*)	Unlikely, plants only[273]	None known
Peptidyl pyrimidine nucleoside	Polyoxin (Table 16.20)	H4	Chitin synthase	Unlikely, absent in plants and animals[274]	None known
Mandelic acid amides	Mandipropamid (Table 16.21)	H5	Cellulose synthase	Unlikely, plants only	None known
Phenylacetamides	Cyflufenamid (Table 16.22)	U6	Unknown	Unknown	Unknown
Benzophenones	Metrafenone (Table 16.23)	U8	Actin disruption (proposed)	Potentially[275]	None known
Guanidines	Dodine (Table 16.24)	U12	Cell membrane disruption (proposed)		
Dithiocarbamates	Ferbam, thiram, and ziram (Table 16.25)	M3	Interferes with oxygen uptake and inhibits sulfur-containing enzymes	Possible[276]	(Cholinesterase inhibition (ziram and metam sodium): neurotoxic (distal peripheral neuropathy); potential to chelate cations; mancozeb, maneb, and metiram share a common metabolite, ETU[98]
Ethylenebisdithiocarbamates	Mancozeb, maneb, and zineb (Table 16.26)		Breaks down cyanide that then reacts with sulfhydryl groups in cells		
Phthalimides	Captan (Table 16.27)	M4	Preferentially reacts with protein sulfhydryl groups; enzyme inhibitor	Likely	None known
Chloronitriles	Chlorothalonil (Table 16.28)	M5	Conjugates with cellular thiols	Likely	None known

Source: FRAC, FRAC code list 2012: Fungicides sorted by mode of action, 2012. Available from: http://www.frac.info/frac/index.htm.

Flutolanil represents the phenyl-benzamides. It is a systemic fungicide with protective and curative action. Flutolanil is used to control sheath blight, white mold, and snow blight in rice, cereals, sugar beet, and other crops.[37] The structure, uses, and hazard profile of flutolanil are given in Table 16.8.

The pyridinyl-ethyl-benzamides include fluopyram, which is used to combat gray mold, powdery mildew, and other fungal diseases in grapes, various fruits, and vegetables.[37] The structure, uses, and hazard profile of fluopyram are also provided in Table 16.8.

Penflufen, penthiopyrad, and sedaxane represent the pyrazole-carboxamide fungicide category. These are effective on many different types of fungal pathogens, including *Rhizoctonia*, rusts, gray mold, powdery mildew, and apple scab.[37] Structures, uses, and hazard profiles for these three fungicides appear in Table 16.8.

Methoxy-Acrylates, Dihydro-Dioxazines, and Imidazolinones (Strobilurins; FRAC Code C3)

The first member of the strobilurin family (Strobilurin A) was isolated independently from *Oudemansiella mucida* found growing on beech trees[45,46] and from the pine cone fungus, *Strobilurus tenacellus*.[47] Strobilurins are also known as quinone outside inhibitors, or QoI-fungicides.[5]

TABLE 16.5
Structure, Uses, and Hazard Profile for the Acylalanine (Metalaxyl, Mefenoxam) Fungicides (FRAC Code A1)

Structure	Principal Use/Crop	Application Rate (g a.i./ha)
	Used on alfalfa, apples, asparagus, avocadoes, berries, citrus, cole crops, cotton, cucurbits, hops, peanuts, stone fruit, soybeans, sugar beets, tobacco, and vegetables; also used as a seed treatment	100–1000 8.25–300 g/100 kg (seed)

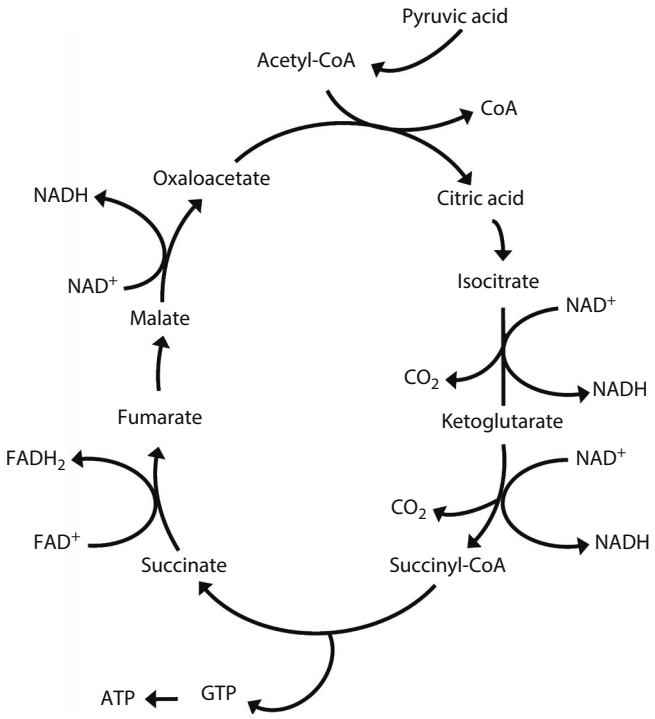

FIGURE 16.1 Krebs cycle.

The strobilurins are selective, yet they have broad fungicidal activity that includes protective, eradicant, and antisporant effects. The strobilurins inhibit mitochondrial respiration by binding to the Qo site on cytochrome b (Figure 16.2), thereby blocking electron transfer between cytochrome b and cytochrome c1 in the Krebs cycle (Figure 16.1), resulting in a disruption of ATP synthesis.[48] The crystalline structure of cytochrome bc1 complex has been elucidated alone[49] and bound to its substrate cytochrome c,[50] and details on the binding to the dimeric structure have been proposed.[51]

The Qo binding site for stigmatellin, an analogue of the strobilurins, has been identified by crystallization of cytochrome bc1 in the presence of an excess of the inhibitor.[49] The amino acid sequence of the Qo binding site appears to be highly conserved across species, including mammals, and tests carried out on 14 strobilurins on mitochondrial enzyme preparations from fungi, housefly, rats, and corn showed no selectivity.[48] The structures, uses, and hazard profiles for two economically important members of the methoxy-acrylates, as well as for the dihydro-dioxazine fluoxastrobin and the imidazolinone fenamidone, are presented in Table 16.9. The fact that the strobilurins are relatively nontoxic to animals suggests that they do not reach these mitochondrial targets.

Cyano-Imidazoles and Sulfamoyl-Triazoles (FRAC Code C4)

The quinone inside inhibitor fungicides (QiI-fungicides) include the cyano-imidazole fungicide cyazofamid and the sulfamoyl-triazole fungicide amisulbrom.[5] Like the strobilurins, cyazofamid and amisulbrom inhibit at complex III, or ubiquinol-cytochrome c reductase, in the mitochondrial respiratory chain.[37] But apparently because of differences in target enzyme susceptibility, both cyazofamid

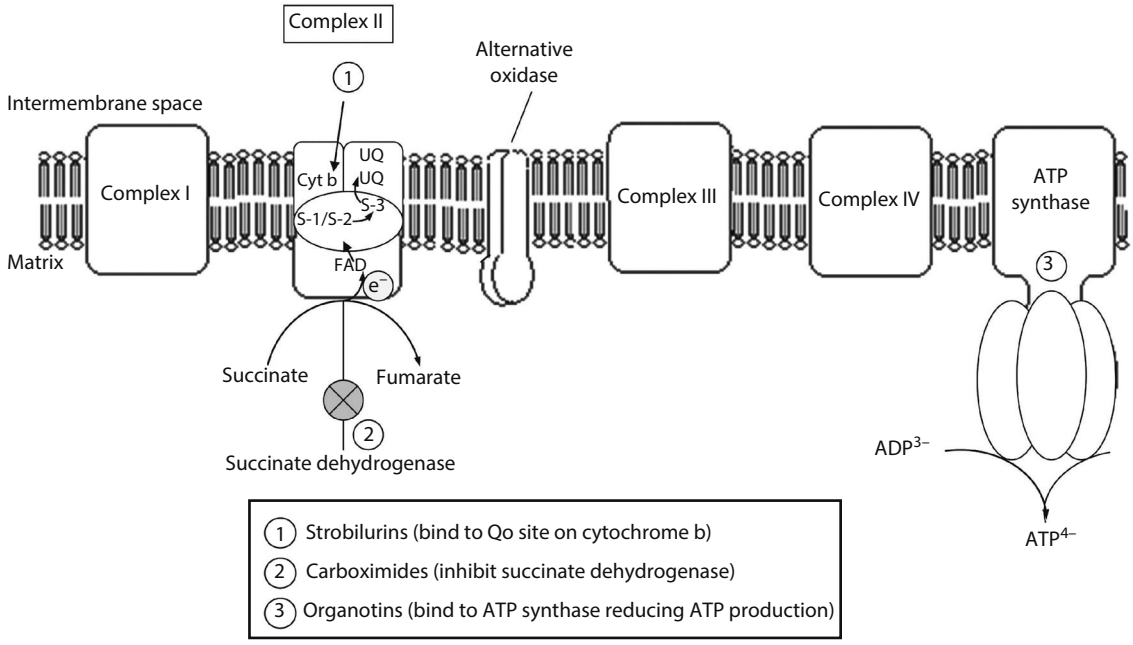

FIGURE 16.2 Mitochondrial respiration.

and amisulbrom inhibit Qi (ubiquinone reducing site) of cytochrome bc1 instead of the Qo (ubiquinol oxidizing site) affected by the strobilurins.[37] Cyazofamid and amisulbrom are both used in both foliar and soil applications to treat *Phytophthora infestans*, downy mildews, and other pathogens.[37,52,53] Amisulbrom shows some evidence suggestive of carcinogenic potential, but no additional studies are currently required by the EPA for its intended uses.[53] Structures, uses, and hazard profiles for these two fungicides appear in Table 16.10.

Organotins (FRAC Code C6)

The organometallic fungicides, which are represented here by triphenyltin, are limited in their spectrum for disease control, but are effective as protective, curative, and antisporulants in the treatment of early and late blight, scab, leaf blotch, and powdery mildew.[37] Trialkyltins affect mitochondrial respiration by (1) disrupting the membrane potential by exchanging halide ions for hydroxyl ions across the membrane; (2) binding to ATP synthase thereby reducing ATP production; and (3) causing mitochondrial swelling, especially for the more lipophilic compounds. They are also capable of causing cellular lysis in vitro[54] and in aquatic organisms.[55] Of these effects, the effect on ATP synthase is the most specific (see Figure 16.2).

ATP synthases are enzymes that make up two rotary motors. The membrane-embedded F_0 motor converts energy from a transmembrane electrochemical (Na^+) gradient into torque, which is transmitted through a common shaft to the water-exposed F_1 motor where it drives the synthesis of ATP from ADP and phosphate.[56,57] More is known about the operation of the F_1 motor than about the membrane-bound F_0 motor, the presumptive site of action of the organotin compounds.[58–60] However, interference with the production of ATP by organotin compounds would have significant toxicological consequences if those compounds reach and bind to ATP synthase.

The structure and mammalian toxicity profile of triphenyltin (Fentin) is presented in Table 16.11. Triphenyltin hydroxide is moderately acutely toxic (oral LD_{50} = 140 mg/kg/day), but is highly toxic following longer-term administration (ADI = 0.0005 mg/kg/day). It has been classified by the EPA as B2, a probable human carcinogen, based on mouse liver, tumors, as well as rat pituitary and testicular tumors. It has not been possible to predict toxicity across species based upon structure alone, because some substituted organotin compounds are more toxic to some species than to others (Table 16.11).[54,55]

Triazolopyrimidines (FRAC Code C8)

The triazolopyrimidines include the fungicide ametoctradin, which inhibits mitochondrial respiration via complex III inhibition.[5,37] Ametoctradin shows no signs of mammalian toxicity at tested doses and is unlikely to be carcinogenic or mutagenic.[61] The structure, uses, and hazard profile for ametoctradin appear in Table 16.12.

Anilinopyrimidines (FRAC Code D1)

The spectrum of activity for anilinopyrimidines, which are represented here by cyprodinil and pyrimethanil, is limited to ascomycetes and deuteromycetes.[37] The anilinopyrimidines are used to control gray mold on vines, fruit, vegetables, and

TABLE 16.8
Structures, Uses, and Hazard Profiles for the Carboxamide (Flutolanil) Fungicides (FRAC Code C1)

Fungicide	Structure	Principal Use/Crop	Application Rate (g a.i./ha)
Flutolanil (Folistar®, Moncut®)[37,280,284]		Used on peanuts, rice, cereals, sugar beets, fruits, and vegetables to control *Rhizoctonia* spp.	300–1000 (peanuts) 2500–10,000 (soil) 1500–3000 g/kg (seed)

	Mouse/18-month oral	157	Reproductive	Not a reproductive toxin
	cRfD	0.11	Oncogenicity	Likely (liver, thyroid, and uterine tumors)

ornamentals, as well as leaf scab on pome fruit. The anilinopyrimidine fungicides inhibit methionine biosynthesis,[62] but probably not through an action of cystathionine β-lyase as originally proposed.[63–65] Cystathionine γ-synthase and methionine synthase are other possible targets of the anilinopyrimidine fungicides, but the actual target in plants is not likely relevant to humans. Methionine is one of four *essential* sulfur-containing amino acids in the aspartate pathway, which also include lysine, threonine, and isoleucine, that humans and other monogastric animals cannot synthesize *de novo*.[66,67]

The structures, uses, and hazard profiles of the anilinopyrimidine fungicides cyprodinil and pyrimethanil are presented in Table 16.13. The hazard profiles for these chemicals suggest that there are minimal risks to humans.

Quinolines (FRAC Code E1)

Quinoline fungicides, which act as growth signal disruptors, include the economically important quinoxyfen.[5,37] These are used to control powdery mildew in grapes, hops, and vegetables.[37] There is some evidence of slight dermal sensitization in humans.[68] Quinoxyfen's structure, uses, and hazard profile are illustrated in Table 16.14.

Phenylpyrroles (FRAC Code E2)

It has been proposed that the phenylpyrrole fungicides, represented here by fludioxonil, interfere with the two-component MAP kinase–mediated osmotic signal transduction pathway shown in Figure 16.3.[69] *Neurospora crassa*, incubated with fludioxonil, responds by accumulating glycerol, which causes the fungus to rupture.[70,71] Os-2 mutants do not accumulate glycerol when treated with phenylpyrroles,[69,72] indicating that if the activation of the osmotic signal transduction pathway is blocked, then the fungicidal action of the phenylpyrroles is prevented.

Although the exact molecular target of the phenylpyrrole fungicides within the osmotic signal transduction pathway has not been convincingly demonstrated,[72,73] there is evidence that at least one of the two-component pathway (Figure 16.3) is conserved in vertebrate cells.[50,74,75] Therefore, it could be conservatively assumed that the phenylpyrroles may affect this signaling pathway in mammals.[76,77]

The structure, uses, and hazard profile of fludioxonil are presented in Table 16.15. Fludioxonil is not acutely toxic, and it does not exhibit a remarkable repeat-dose toxicity profile. Fludioxonil has been classified as a category D carcinogen (nonclassifiable in regard to carcinogenicity).

TABLE 16.9
Structures, Uses, and Hazard Profiles for the Methoxy-Acrylate, Oximinoacetate, Dihydro-Dioxanine, and Imidazoline Fungicides (FRAC Code C3)

Fungicide	Structure	Principal Use/Crop	Application Rate (g a.i./ha)
Azoxystrobin (Abound®, Heritage®, Quadris®)[37,280]		Used on vine crops, apples, cereals, cucurbits, tomatoes, pecans, coffee, potatoes, peanuts, peaches, citrus, rice, and turf	100–375
Trifloxystrobin (Flint®, Stratego™)[37,280]		Used on cucurbits, fruiting vegetables, pome fruits, stone fruits, grapes, hops, and pistachio	50–550
Fluoxastrobin (DISARM®, EVITO®)[37,280]		Used on cereals, vines, peanuts, bananas, and various vegetables; also used as a seed treatment in wheat	—
Fenamidone (Censor®, Consento®)[37,280]		Used as a foliar fungicide in grapes and in vegetables; also as a seed treatment or soil drench for *Pythium*	—

	cRfD	11.6	Oncogenicity	Suggestive (liver and for stomach tumors in rat)

Dicarboximides (FRAC Code E3)

It is proposed that the dicarboximides cause lipid peroxidation in membranes by inhibiting NADH cytochrome C reductase, which is part of the mitochondrial respiratory chain (Figures 16.1 and 16.2) present in all eukaryotic cells.[78] The dicarboximides may also inhibit spore germination, and because there are reports of resistance development for the phenylpyrroles and the dicarboximides, it has been suggested that the dicarboximides may also have effects on the osmotic signal transduction pathway discussed for the phenylpyrroles.[73,79–81]

The dicarboximides have a narrow spectrum of activity limited to *Botrytis*, *Sclerotinia*, *Monilinia*, and *Alternaria*. The dicarboximides are used to treat diseases in turf, strawberries, stone fruit, peanuts, and vines. The structures, uses, and hazard profiles of the dicarboximide fungicides iprodione and vinclozolin are presented in Table 16.16.

Iprodione interferes with androgen synthesis[82] and causes an elevated incidence of interstitial cell tumors in male rats at a concentration of 1600 ppm in the diet. Vinclozolin is metabolized in animals to the antiandrogenic metabolites, 2-1[(3,5-dichlorophenyl) carbamoyl] oxyl-2-methyl-3-butenoic acid and 3,5′-dichloro-2-hydroxy-2 methylbutyl-3-enanilide. These metabolites are presumed to cause infertility in male rats.[83] It has been proposed that this effect is due to a feminization of the outer genital organs of males exposed to the metabolites during development.[84]

The EPA has not established a common mechanism of toxicity group for the dicarboximide fungicides based upon their antiandrogenic potential. For cancer risk assessment, however, the EPA has applied a linear low-dose method for evaluating the cumulative risk resulting from exposure to the metabolite, 3,5-dichloroaniline, which is common to the dicarboximide fungicides, iprodione, procymidone,

and vinclozolin. The EPA has assumed that this terminal, plant, animal, and environmental metabolite is mutagenic and carcinogenic because of a predicted structure–activity relationship with p-chloroaniline,[85] which caused an increased incidence of sarcoma in the spleen of male Fisher 344 rats.[86]

Demethylase Inhibitors (FRAC Code G1)

The sterol biosynthesis inhibitors or, more precisely, the sterol demethylase inhibitor (DMI) group is comprised of imidazole, piperazine, pyridine, pyrimidine, and triazole fungicides. DMI inhibitors affect fungi by inhibiting the synthesis of ergosterol.[5] Ergosterol synthesis inhibition results in an accumulation of methylated ergosterol derivatives, which due to their bulkier structure cannot be packed correctly into the lipid bilayer of the fungal membrane. These membrane alterations hinder the uptake and storage of nutrients resulting in cell death. Effects of DMIs on fungal lipid, nucleic acid, and protein synthesis are likely secondary to their effect on cell membranes.

DMI fungicides also inhibit 14-α-demethylase (P450, CYP51) in mammalian cells, where 14-α-demethylase catalyzes the conversion of lanosterol to zymosterol, a precursor to cholesterol and all the mammalian sex steroids. In addition to inhibiting 14-α-demethylase, the DMI fungicides have the potential to inhibit the P450, CYP 19 enzyme, aromatase, which catalyzes the conversion of testosterone to 17β-estrodiol and the conversion of androstenedione to estrone (Figure 16.4). EPA has not determined if there is a common mechanism grouping of the DMI fungicides based on these potential common molecular targets although it has conducted an aggregate dietary risk assessment for three DMI fungicides based upon the toxicity of the common metabolite, 1,2,4-triazole.[87]

The use and structures of the most prominent DMI fungicides are provided in Table 16.17 and their hazard profiles appear in Table 16.18.

High doses of the DMI fungicides cause a treatment-related increased incidence of mouse liver tumors for the majority of these chemicals (myclobutanil is an exception). These effects are apparently not mediated through a direct

Regist.*, 69(188), 58084, 2004.

genotoxicity mechanism. It has been suggested that a phenobarbital-like induction of P-450 enzymes is responsible for the liver tumor response seen in mice and that a similar response is unlikely to occur in humans.[88] In addition to the carcinogenic effect, evidence of developmental and/or reproductive system effects has been noted for several of the DMI fungicides including cyproconazole[89] and triadimenol.[90] The mechanism of action has not been established, but it has been postulated that some of these effects may be secondary to the effects of the azole fungicides on steroid biosynthesis.[91]

Hydroxyanilides (FRAC Code G3)

The hydroxyanilide fungicide group includes fenhexamid. This product affects sterol biosynthesis via 3-keto-reductase during C4-demethylation to hinder germ tube elongation and growth in the mycelium.[37] Fenhexamid is not likely to be carcinogenic in humans, based on rat and mouse oncogenicity and genotoxicity studies.[92] The structure, uses, and hazard profile for fenhexamid are shown in Table 16.19.

Peptidyl Pyrimidine Nucleosides (FRAC Code H4)

The peptidyl pyrimidine nucleoside category counts polyoxin as its most important member. These fungicides interfere with cell wall growth by inhibiting chitin biosynthesis.[5,37] The structure, uses, and hazard profile for polyoxin are shown in Table 16.20.

Mandelic Acid Amides (FRAC Code H5)

Mandipropamid is representative of the mandelic acid amide category, which is believed to affect phospholipid biosynthesis and cell wall development.[5,37] Mandipropamid is a minimal ocular irritant, and it is classified as a skin sensitizer, but it is not a skin irritant, and it has very low acute toxicity.[93] The structure, uses, and hazard profile for mandipropamid appear in Table 16.21.

Phenylacetamides (FRAC Code U6)

Cyflufenamid is an important member of the phenylacetamides, which act as preventative or even curative fungicides, though specifics regarding the biochemistry of these products remain unknown.[5,37] Despite the potential for carcinogenicity at high doses, it has low acute toxicity, and it is not an irritant or skin sensitizer.[94] The structure, uses, and hazard profile for fenhexamid are shown in Table 16.22.

Benzophenones (FRAC Code U8)

The benzophenone herbicide category includes the important fungicide metrafenone, which is used to prevent and cure fungal pathogen attacks and also to hinder sporulation.[5,37] Metrafenone demonstrates a low risk of carcinogenicity or oral toxicity and is not neurotoxic.[95] The structure, uses, and hazard profile for metrafenone are shown in Table 16.23.

TABLE 16.16
Structures, Uses, and Hazard Profiles for the Dicarboximide Fungicides (FRAC Code F1)

Fungicide	Structure	Principal Use/Crop	Application Rate (g a.i./ha)
Iprodione (Rovral®)[37,280]		Sunflowers, cereals, fruit trees, berries, oilseed rape, rice, cotton, vegetables, vines, turf, and seed application	500–12,000
Vinclozolin (Ronilan®, Flotilla®)[37,280]		Pome and stone fruit, oilseed rape, vegetables, vines, turf, and ornamentals	300–430

	Irritation		LD_{50} (mg/kg)				
Fungicide	**Eye**	**Skin**	**Oral**	**Dermal**	**LC_{50} (mg/L) Inhalation**	**Sensitization Potential**	**Signal Word**
Iprodione	Mild irritant	Nonirritant	>2000	>2000	>5.2	Negative	Caution
Vinclozolin	Minimal irritant	Minimal irritant	>15,000	>5000	29.1	Positive	Caution

Fungicide	Species/Study	NOEL (mg/kg/day)	Toxicity Study	Hazard Indicator
Iprodione[82,299,300]	Rat/2 years	6.0	Mutagenicity	No evidence
	Dog/52 weeks	4.2	Developmental	Not teratogenic
	Mouse/18 months	1870	Reproductive	Not a reproductive toxin
	RfD (UF = 300)	0.04	Oncogenicity	B2 (liver, testes)
Vinclozolin[83–85,301,302]	Rat/2 years	1.2	Mutagenicity	Not mutagenic
	Dog/52 weeks	2.4	Developmental	Not teratogenic
	Mouse/18 months	21	Reproductive	Antiandrogenic metabolite
	RfD	0.012	Oncogenicity	B2 with RfD (multiple benign tumors in rats)

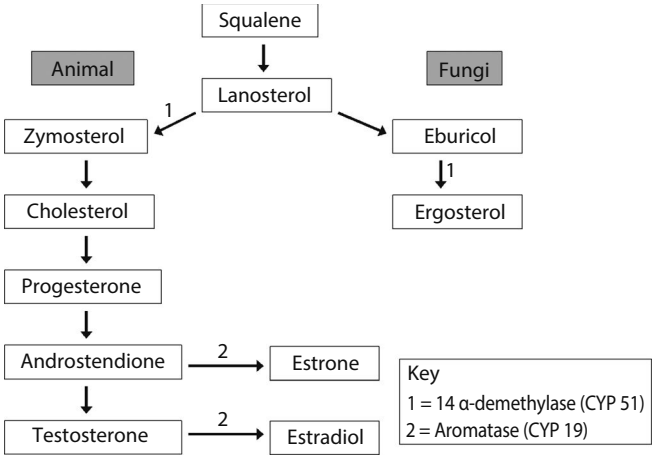

FIGURE 16.4 Steroid biosynthesis in fungi and animals.

Guanidines (FRAC Code U12)

Guanidine herbicides include dodine, a local systemic foliar fungicide that acts to both prevent and cure scab, leaf spot diseases, and other diseases.[5,37] Dodine has moderate acute oral, dermal, and inhalation toxicity, and it is known to be an irritant, but it is not a skin sensitizer.[96] The structure, uses, and hazard profile for dodine are shown in Table 16.24.

Inorganic Fungicides (FRAC Codes M1 and M2)

Inorganic chemicals such as sulfur were used before 1000 BC,[1] and elemental sulfur and copper (hydroxide, oxychloride, and sulfate) are still used as fungicides today. The MOA of the inorganic fungicides is protective or preventative, and they exert their effects by the inhibition of mitochondrial respiration.[37] The inorganic fungicides are

TABLE 16.17
Structures and Use Profiles for Demethylase Inhibitors (FRAC Code G1)

Fungicide	Structure	Principal Use/Crop
Cyproconazole (Alto®)[37]		Cereal, sugar beets, fruit trees, vines, coffee, turf, bananas, and vegetables for the application of rust, powdery mildew, *Septoria*, *Venturia*, and others; application rates are 60–100 g/ha
Difenoconazole (Dividend®)[37,280]		Seed application, grapes, fruit trees, potatoes, sugar beets, oilseed rape, banana, ornamentals, and vegetables for treating a variety of fungal diseases; application rates are 30–125 g/ha
Fenbuconazole (Indar®)[37,280]		Cereals, fruit trees, vines, beans, sugar beets, rice, bananas, ornamentals, tree nuts, and vegetables; application rates are 30–75 g/ha
Flutriafol (Armour®)[37,280]		Controls many ear and leaf diseases in cereals at 125 g/ha; also used as a seed treatment
Metconazole (Caramba®)[37,280]		*Fusarium*, *Septoria*, rusts, and other foliar diseases on a variety of crops, including cereals, at 90 g/ha
Myclobutanil (Rally®, Nova®)[37,280]		Seed application, grapes, fruit trees, rice, cotton, barley, wheat, maize, grass seed, ornamentals, and vegetables for treating a variety of fungal diseases; application rates are typically 30–60 g/ha

TABLE 16.17 (continued)
Structures and Use Profiles for Demethylase Inhibitors (FRAC Code G1)

Fungicide	Structure	Principal Use/Crop
Propiconazole (Tilt®)[37,280]		Wheat, rice, coffee, bananas, peanuts, stone fruit, maize, and turf for treating a variety of fungal diseases; application rates are roughly 24–110 g/ha
Prothioconazole (Input®)[37,280]		Used to control various blights, blotches, mildews, rusts, and eyespot in cereals and other crops; also used as a seed treatment
Tebuconazole (Folicur®)[37,280]		Seed application, cereals, coffee, fruit trees, grapes, grass seed, oilseed rape, soybeans, sugar beets, bananas, ornamentals, turf, and vegetables for treating a variety of fungal diseases; application rates range from 1 to 7.5 g/dt for seed and 200 to 375 g/ha (or 7.5–18.8 g/100 L) for spray
Triadimefon (Bayleton®)[37,280]		Cereals, corn, fruit trees, vines, berries, sugarcane, tobacco, and vegetables for treating a variety of fungal diseases; application rates range from 0.0025% to 0.0125% for fruits/vegetables and 125 to 500 g/ha for other crops
Tetraconazole (Domark®)[37,280]		Foliar treatment for mildews, rusts, leaf spots in sugar beets, cereals, various fruits, and vegetables at rates from 25 to 125 g/ha; also used as a seed treatment at rates from 3 to 12 g/100 kg
Triadimenol (Baytan®)[37,280]		Seed application, cereals, fruit trees, hops, vines, and vegetables for treating a variety of fungal diseases; rates range from 20 to 60 g/100 kg for seed, 0.0025% to 0.0125% for fruits/vegetables, and 100 to 500 g/ha for sprays
Imazalil (Fungaflor®)[37,280]		Seed, fruit trees, potatoes, bananas, vegetables, ornamentals, and cereals for treating a variety of fungal diseases; application rates range from 4 to 5 g/100 kg for seed, 5 to 30 g/ha for ornamentals/vegetables, and 2 to 4 g/t for fruit

(*continued*)

TABLE 16.17 (continued)
Structures and Use Profiles for Demethylase Inhibitors (FRAC Code G1)

Fungicide	Structure	Principal Use/Crop
Prochloraz (Sportak®)[37,280]		Citrus, tropical fruit (dip), beets, oilseed rape, mushrooms, ornamentals, and cereals (seed application); application rates range from 400 to 600 g/ha or 0.5/0.7 g/L for dip treatment

relatively ineffective since they must be applied at high use rates ranging from 1000 to 10,000 g/ha. Severe eye irritation is seen with copper hydroxide,[37] whereas copper oxychloride and copper sulfate are not eye irritants.[37] Elemental sulfur is considered practically nontoxic to humans and animals.[37]

DITHIOCARBAMATES AND ETHYLENEBISDITHIOCARBAMATES (FRAC CODE M3)

The dithiocarbamates are broad-spectrum protective fungicides having multiple sites of action.[37] They are used to control scab on pome fruit, blue mold on tobacco, rust on ornamentals, and numerous diseases on vegetables. These agents interfere with oxygen uptake and may bind to sulfur-containing enzymes. The dithiocarbamates are applied at rates of 500 to over 10,000 g/ha. Ferbam, thiram, and ziram are the commercially important chemicals in this group.

The ethylenebisdithiocarbamate fungicides (mancozeb, maneb, and zineb) have a broad spectrum of activity although their fungicidal MOA is primarily protective. Their mechanism of action is to form cyanide, which reacts with thiol compounds within cells.[37]

EPA has considered including the dithiocarbamates into a common mechanism group[97,98] based upon their potential (1) to generate carbon disulfide (potential to cause distal peripheral neuropathy)[98]; (2) to form the common metabolite ethylenethiourea (ETU), which has potential carcinogenic effects; (3) to chelate physiologically important polyvalent cations such as copper, zinc, lead, or cadmium (potential neurotoxicity resulting from nervous system sequestration of heavy metals); or (4) to inhibit acetylcholinesterase.[97] In their final decision, the EPA concluded that the available evidence suggests that neuropathology induced by the treatment of rats with the dithiocarbamates could not be linked with the formation of carbon disulfide. A common mechanism grouping for mancozeb, maneb, and metiram was supported based on their ability to form the common metabolite, ETU. It was also concluded that two dithiocarbamate pesticides, ziram and metam sodium, share a common mechanism for acetylcholinesterase inhibition.[98]

The structures, uses, and hazard profiles for the dithiocarbamates are given in Table 16.25. Ferbam, thiram, and ziram have significant acute toxicity, especially by inhalation. Both ferbam and ziram affect spermatozoa in mice, and thiram is teratogenic at high doses. There is no evidence that any of these fungicides is carcinogenic, although positive mutagenic studies were reported for thiram.

The structures, uses, and hazard profiles for mancozeb, maneb, and zineb and their common metabolite ETU are provided in Table 16.26. Both mancozeb and maneb are classified as B2, probable human carcinogens,[99] based on the formation of mouse liver tumors and/or thyroid follicular cell tumors in rats. Although zineb was not found to be oncogenic in the rat or mouse, it was observed to produce non-neoplastic hyperplasia of the follicular cells of the thyroid in rats.[100] All three fungicides are transformed in animals to the metabolite, ETU. ETU inhibits thyroid peroxidase and causes progressive lesions in the thyroid follicular cells, often leading to tumor formation.[101–103] The EPA has regulated the risk associated with exposure to ETU using a cancer slope factor (Q_1*) of 0.06 $(mg/kg/day)^{-1}$.[104]

Phthalimides (FRAC Code M4)

The phthalimide fungicides represent a relatively old group of synthetic chemicals, of which only captan remains in use. Captan has a broad spectrum of activity, which is attributed to the formation of thiophosgene.[105] Thiophosgene has the potential to react with thiol groups, most likely at the point of contact with the mucosa of the stomach, as shown in Figure 16.5. Folpet, another member of this class of fungicides, is also capable of producing thiophosgene.

The structure, uses, and hazard profile for captan are given in Table 16.27. Captan has been shown to bind to DNA in vitro but not in vivo. Captan has been classified by the EPA

TABLE 16.18

	Mouse/18 months	11.7	Reproductive	Decreased litter size
	ADI	0.009	Oncogenicity	C-Q* (mouse liver tumors in both sexes)

as a category B2 carcinogen (probable human carcinogen) based on gastrointestinal tract tumors in the mouse.[99]

Chloronitriles (FRAC Code M5)

The chloronitrile fungicides, represented here by chlorothalonil, have a broad spectrum of fungicidal activity and are considered protective. Chlorothalonil controls fungal infection by binding to sulfur-containing enzymes.[37] The structure, uses, and hazard profile of chlorothalonil are given in Table 16.28.

Chlorothalonil is a severe eye irritant, a moderate skin irritant, and a potential skin sensitizer. The EPA has classified chlorothalonil as a likely human carcinogen based on kidney and forestomach tumors in both rats and mice.[106] The occurrence of kidney tumors was preceded by a pronounced hyperplasia in the proximal tubules. It has been proposed that these preneoplastic changes are due to the formation of nephrotoxic thiol metabolites of chlorothalonil.[107] It has also been suggested that β-lyase catalyzes the conversion of the cysteine conjugate to the ultimate toxiphore (see Figure 16.6). Because the activity of glutathione-S-transferase and β-lyase in the human kidney is about 10% of the rat kidney, it is likely that humans are less susceptible to chlorothalonil than are rats.

INSECTICIDES

Table 16.29 provides the list of insecticides reviewed in this chapter, grouped into categories according to the MOA[7] as defined by the Insecticide Resistance Action Committee (IRAC). The majority of the insecticidal MOA described later are relevant to humans, although a few exceptions are noted in Table 16.29 and discussed in the appropriate section provided in the following text.

Carbamates: AChE Inhibitors (IRAC Code 1A)

Acetylcholine is an excitatory neurotransmitter substance that is released from synaptic vesicles that are found within boutons of the presynaptic neuron (Figure 16.7).

Regist.*, 69(188), 58084, 2004.

Neurotransmitter release is triggered by voltage-dependent calcium ion influx across the presynaptic membrane in response to an action potential-driven depolarization (sodium current) of the membrane. Once the neurotransmitter is released, it diffuses into the synaptic cleft where it binds to a postsynaptic receptor, triggering an excitatory postsynaptic potential (EPSP).

The carbamate insecticides inhibit the enzyme, acetylcholinesterase (AChE), which is found in the postsynaptic cleft and which catalyzes the cleavage of acetylcholine, into its constituent components acetyl and choline, thereby inactivating the neurotransmitter. Cholinesterase inhibition, which is defined as the percent reduction in AChE activity, results in a prolonged stimulation of the cholinergic receptors leading to a hyperexcitatory state downstream from the site of action. This translates into an intense activation of the autonomic nervous system, which depending on the severity of AChE inhibition results in piloerection, salivation, tremor, convulsion, respiratory arrest, and death.

Carbamates affect neurotransmission in an almost identical fashion to the organophosphorus insecticides (OPs) except that carbamate insecticides carbamylate AChE whereas the OPs phosphorylate AChE as shown in Figure 16.8.

Carbamate insecticides exist as esters of carbamic acid, typically having an aryl (ring) substituent as the leaving group. Carbamates react with the serine group on acetylcholinesterase to yield a carbamylation of the serine hydroxyl group. A hydroxylated leaving group is generated. The carbamylation of AChE is reversible, unlike the phosphorylation of the AChE by organophosphate insecticides. The carbamylated complex will typically hydrolyze in minutes.

The OP reacts with acetylcholinesterase at a serine hydroxyl group within the enzyme's active site. In this reaction, the hydroxyl group is phosphorylated, yielding a leaving group. Reactivation of the enzyme can take many hours or even days.

The pesticidal MOA of the carbamate and organophosphorus insecticides are preserved in mammals. EPA has determined that a separate common mechanism grouping exists for the N-methyl carbamate and the OPs[108] based upon the differences shown in Figure 16.8.

The structure and use of some representative carbamate insecticides are given in Table 16.30 and their hazard profiles appear in Table 16.31. Aldicarb is the most acutely toxic of the carbamates selected for inclusion in this chapter, with an oral LD_{50} below 1 mg/kg and a dermal LD_{50} of 20 mg/kg. Aldicarb, carbofuran, methomyl,

and propoxur have been classified as category C (possible human carcinogens) or D (aldicarb) by the EPA.[99]

Organophosphorus Insecticides: AChE Inhibitors (IRAC Code 1B)

OPs vary tremendously in chemical structure and properties. The OPs are classified into the following groups depending on the positioning of the central phosphorus atom: phosphates, phosphonates, phosphorothionates, phosphorodithioates, and phosphoroamidothioates. Examples of OPs within these different subgroups are presented in Table 16.32. The toxicological profiles for the OPs are presented in Table 16.33. Of the OPs reviewed here, azinphos-methyl is the most acutely toxic, and malathion is the least toxic. Acephate causes liver tumors in mice, and delayed neurotoxicity was seen in studies on dichlorvos. Monocrotophos has the lowest chronic reference dose.

Cyclodiene Organochlorines: GABA Antagonists (IRAC Codes 2A and 2B)

In both insects and mammals, chloride channel–blocking insecticides cause hyperexcitability, convulsions, and death.[109] Overstimulation of neuronal pathways in the central nervous system (CNS) results from blocking the action of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). Normally, when GABA is released from the presynaptic nerve terminal, it binds to a postsynaptic receptor protein containing an intrinsic chloride ion channel. When GABA binds to its receptor, the chloride channel is opened and chloride ions flow across the postsynaptic membrane. This increase in chloride permeability hyperpolarizes (makes more negative) the membrane, resulting in an inhibitory postsynaptic potential, which has a dampening effect on neuronal excitation, making it less likely that a postsynaptic action potential will occur. Attenuation of GABA-mediated neuronal inhibition leads to hyperexcitation of downstream neuronal pathway because GABA neuronal pathways are inhibitory.[110]

The structures, uses, and hazard profiles for the cyclodiene organochlorines, represented here by endosulfan and fipronil, are given in Table 16.34. They are moderately acutely toxic and have relatively low chronic reference doses. They are neither mutagens, developmental toxins, or reproductive toxins, nor carcinogens.

Pyrethroids: Sodium Channel Modulators (IRAC Code 3A)

The pyrethroid insecticides, typically esters of chrysanthemic acid, were isolated from the flowers of chrysanthemums, and three of these comprise the pyrethrum extract approved for organic farming methods.[37,111,112] Synthetic pyrethroid chemistry and insecticidal effects for type I pyrethroids are rather broadly defined, and these include pyrethroids containing descyano-3-phenoxybenzyl or other alcohols.[74] Many of the older nonphenoxybenzyl type I compounds (e.g., pyrethrins, allethrin, and tetramethrin) are unstable in the environment, and this characteristic prevented their use in row crops. Introduction of the phenoxybenzyl (e.g., permethrin) or halogenated alcohols (e.g., tefluthrin) improved chemical stability and allowed the use of pyrethroids on these crops. The characteristic clinical signs seen

in mammals following exposure to type I pyrethroids[113] include the occurrence of fine tremors, hyperexcitability, and myoclonus (T-syndrome).

The type II pyrethroids are more narrowly defined in terms of their chemical structure. They contain an α-cyano-3-phenoxybenzyl alcohol, which increases insecticidal activity about 10-fold.[114] Clinical signs seen in mammals following exposure to type II pyrethroids[113] include sinuous writhing (choreoathetosis), salivation, hyperactivity, and clonic/tonic convulsions (CS-syndrome).

The distinction between types I and II pyrethroids was confirmed in a recent comparative acute neurotoxicity study aimed at providing a detailed description of clinical signs at the time of peak effect, using a modern functional observatory battery (FOB) of tests in rats treated with minimally effective or maximally tolerated doses of type I (bifenthrin, S-bioallethrin, permethrin, pyrethrin, resmethrin, and tefluthrin) and type II (β-cyfluthrin, cypermethrin, deltamethrin, esfenvalerate, fenpropathrin, and λ-cyhalothrin) pyrethroids. The FOB data, which were subjected to a principal components/factor analysis, confirmed that two major factors (T and CS) accounted for more than 90% of the variability in the group means. Dose responsiveness was observed, with marginally effective doses clustering with the control groups near the origin, whereas groups receiving larger doses tended to be deployed along the T or CS axes (Figure 16.9).

Despite clear differences in the profile of mammalian clinical signs between type I and type II pyrethroids, it is generally believed that the pyrethroids exert their effects by modifying the kinetic characteristics of the sodium channel function, largely based upon results from studies conducted ex vivo[115] and by the observation that the development of knockdown resistance (kdr-associated gene mutations) confers decreased sensitivity of insects to both DDT and the pyrethroid insecticides.[116,117]

In a comparative study where the $NA_V1.8$ mammalian sodium channel was expressed in xenopus oocytes,[118] the kinetics of the sodium channel response to electrical stimulation differed among 11 pyrethroids. Multidimensional scaling was used to quantify and to display the magnitude of differences between chemicals with respect to the kinetics of activation, fast inactivation, and tail current decay parameters (see Figure 16.10). The results show that in general, the pyrethroids cluster (e.g., are similar) with respect to sodium channel kinetic parameters along the type I/type II classification. Exceptions were noted for bifenthrin (type I), as well as for fenvalerate and fenpropathrin (type II), which appear intermediated between the predominant type I/type II groupings. Similar results have been seen in comparative

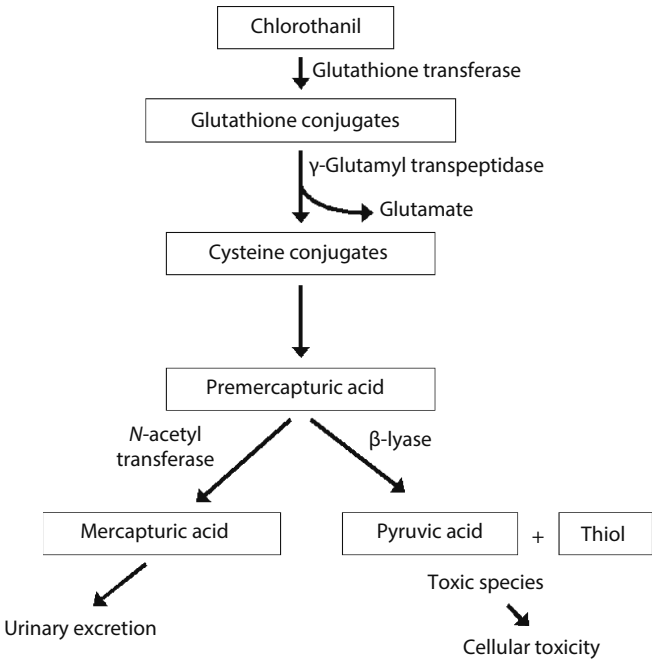

FIGURE 16.6 Proposed mechanism of action for chlorothalonil.

studies of the effects of pyrethroid insecticides on functional characteristics of the calcium[119] and chloride[120] channels (data not shown).

The voltage-gated sodium channel is formed by transmembrane proteins,[116] which in insects is comprised of an α-subunit that has four repeated-homologous domains (I–IV) each having six members (S1–S6) spanning the membrane, and these are connected to each other by intracellular and extracellular loops of amino acids (Figure 16.11). The S5 and S6 sections of each domain line the ion channel pore with S4 being the voltage sensor element.[121]

Nine sodium channel isoforms have been identified in mammals,[122] as compared to only one found in insects.[116] There is evidence of structural and functional homology between mammalian sodium channel isoforms and the insect sodium channel,[123] although there are exceptions. For example, Usherwood et al. showed that specific mutations that result in resistance to the pyrethroids do not confer resistance to DDT, contrary to expectation.[124] Gilles et al. reported that α-like toxin from the venom of scorpion, which inhibits sodium current inactivation in insects, is bound to receptor site three of the insect sodium channel, but did not bind to rat brain synaptosomes.[125] Gordon et al. reported that scorpion

Insecticides Listed according to IRAC Classification System

Chemical Group	Common Name	IRAC Code	IRAC MOA	Biochemical Target Conserved in Mammals?	Other Biochemical Target(s) in Mammals?
Pyrroles	Chlorfenapyr (propesticide requiring oxidative N-dealkylation to the NH derivative) (Tables 16.48 and 16.49)	13	Disrupt proton gradient by transporting protons across the mitochondrial membrane	Yes	None known
Benzylureas	Diflubenzuron (Table 16.45)		Blocks chitin biosynthesis; interferes with molt	Unlikely	None known
Aminotriazines	Cyromazine (Table 16.43)	17	Dipteran molting disruptor	Unlikely	None known
Diacylhydrazine	Tebufenozide (Table 16.46)	18	Ecdysone receptor agonist	Possible	None known
Formamidine	Amitraz (Table 16.47)	19	Octopaminergic receptor agonist	Yes—Homologous receptor is the α_2 adrenergic receptor	Inhibit synthesis of monoamine oxidase and prostaglandin E2[185]
Hydramethylnon	Hydramethylnon	20A	Block electron transport in mitochondrial complex III	Yes	Complex III, major site of superoxide radical formation; inhibition is detrimental to developing cardiac cells[328]
Amidinohydrazones	Pyridaben	21A	Block electron transport in mitochondrial complex I	Yes	Induces autophagic and cell death mediated by reactive oxygen species[329]
Pyridazinones	Rotenone	21B			
Semicarbazones	Metaflumizone (Tables 16.48 and 16.49)	22B	Blocks sodium channels by binding selectively to the slow-inactivated state	Yes	None known
Diamides	Chlorantraniliprole Cyantraniliprole Flubendiamide (Table 16.50)	28	Ryanodine receptor modulators	Yes	Ryanodine causes release of calcium from stores in the sarcoplasmic reticulum leading to massive muscular contractions; this is true for mammals and insects

Source: IRAC. Mode of action classification, Version 7.1, 2012.

toxin binds to homologous but not identical receptor sites in rat brain and insect sodium channels.[126]

In recent years, there has been evidence of a biological basis for a common mechanism of toxicity for type I and type II pyrethroids in terms of their effects on the sodium, calcium, and GABA-gated chloride channels.[127–129] In 2009, the EPA concluded that although there is support for the separation of type I and type II subgroups based on α-cyano group absence or presence, the in vivo evidence for the distinction is less apparent, based on functional observational batteries.[130]

The structures and use of some of economically important noncyano (type I) pyrethroids are given in Table 16.35 and their hazard profiles appear in Table 16.36. Comparable information for type II (cyano-substituted) pyrethroids is given in Tables 16.37 and 16.38.

The synthetic pyrethroids are generally effective as insecticides in the low grams per hectare range. In general, the mammalian acute toxicity of the type II pyrethroids is greater than type I pyrethroids. Because the pyrethroids are highly lipophilic, the acute oral LD_{50} can differ by up to 40-fold depending on the lipophilic characteristics and the volume of the vehicle used to administer the chemical. For example, deltamethrin's LD_{50} is reported to be in the range from 128 mg/kg to greater than 5000 mg/kg.[131] Since pyrethroids are 500–4500 times less toxic to mammals than to insects, they have been safely used with relatively few reports

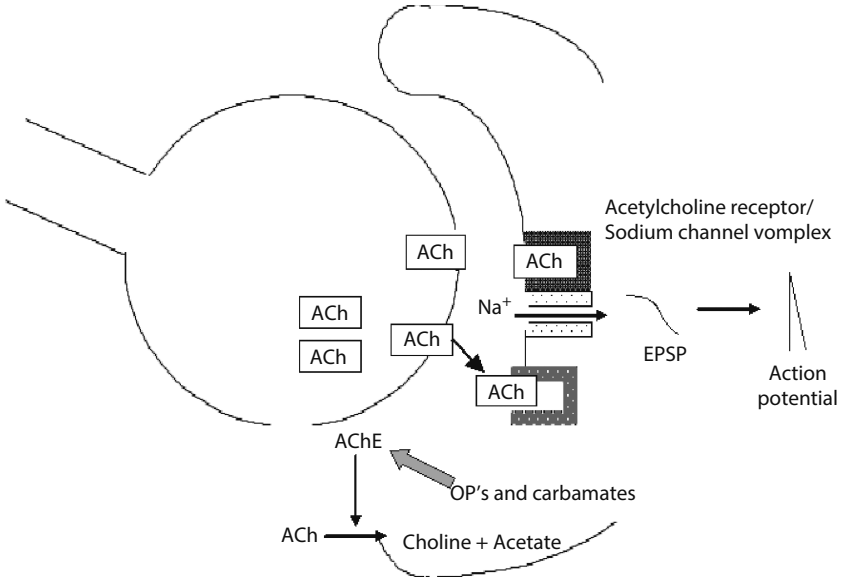

FIGURE 16.7 Pre-/postsynaptic events associated with acetylcholine-mediated neurotransmission.

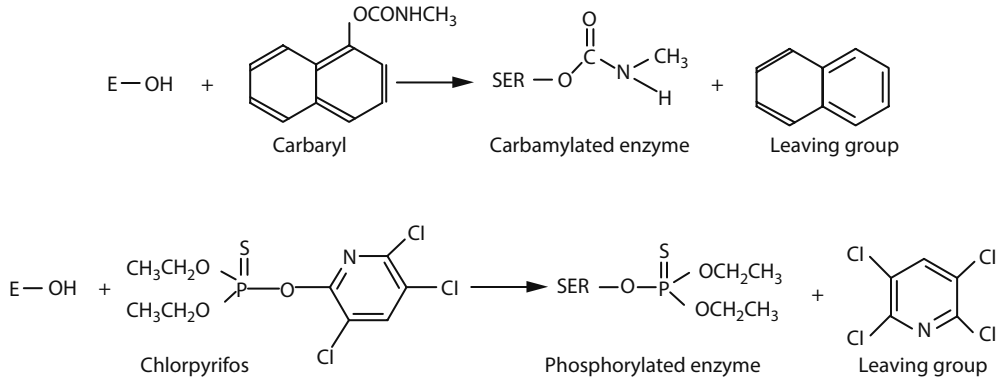

FIGURE 16.8 Interaction of organophosphate and carbamate insecticides with AChE.

of human poisoning.[132] Aside from acute neurotoxicity, the hazard profile for the pyrethroids is unremarkable, although a treatment-related increase in the incidence of lung and liver tumors has been reported for permethrin.[133]

Organochlorine: Sodium Channel Modulators (IRAC Code 3B)

The organochlorines are one of the oldest groups of synthetic insecticides, dating back to the early 1940s.[134] These lipophilic compounds are environmentally stable and persistent, and many like dieldrin, endrin, and DDT have been banned in the United States. However, more biodegradable materials like endosulfan still have limited use today in some countries. Fipronil, which is an arylheterocycle with a similar MOA, has improved selective toxicity toward insects.

The organochlorine insecticides induce repetitive action potentials by slowing the kinetics of sodium channel activation and inactivation (closing), resulting in prolonged tail currents that cause a state of hyperstimulation of the CNS.[135] Because organochlorines are highly lipophilic, and because of the relatively small size of insects and their lower body temperatures, they more readily reach their target (the sodium channel in the nervous system), and they have a greater effect (approximately 500–4500 times greater) in insects than in mammals.[135]

The structure, uses, and hazard profile for methoxychlor are provided in Table 16.39. Methoxychlor induces weak estrogenic activity.[136]

Neonicotinoids and Sulfoxaflor–Acetylcholine Receptor Agonists (IRAC Codes 4A and 4C)

Nicotine has been used as a contact insecticide since the middle of the eighteenth century.[37] Nicotine mimics the action of acetylcholine, which is a major excitatory neurotransmitter in the CNS. Nicotine, which acts as a ligand to the postsynaptic nicotinic acetylcholine receptor (nAchR), activates an intrinsic cation channel resulting in the depolarization of the postsynaptic cell due to an influx of sodium. The resulting EPSP triggers an action potential if there is sufficient degree

TABLE 16.30
Structures and Use Profiles for Carbamate AChE-Inhibiting Insecticides (IRAC Code 1A)

Insecticide	Structure	Principal Use/Crop	Application Rate (g a.i./ha)
Aldicarb (Temik®)[37,280]		Controls chewing and sucking insects in vegetables and crops	500–3400
Carbaryl (Sevin®)[37,280]		Controls chewing and sucking insects in vegetables and various crops	250–2000
Carbofuran (Furadan®)[37,280]		Controls soil dwelling and foliar feeding insects in food crops	260–2050
Methomyl (LanoxC®)[37,280]		Controls chewing and sucking insects in vegetables, food crops, and turf	120–2000
Propoxur (Aprocarb®)[37,280]		Controls cockroaches, flies, fleas, ants, and mosquitoes	1200

of membrane depolarization. Persistent activation of the nicotinic acetylcholine receptors result in an overstimulation of the cholinergic neurotransmission system, resulting in hyperexcitation, convulsions, paralysis, and death.

The neonicotinoids, represented here by imidacloprid and thiamethoxam, are nicotine-like agonists that are used as insecticides. These chemicals, which are absorbed by plants either following foliar application or applied as seed treatment, are effective in controlling piercing and sucking insects such as aphids, leafhoppers, and whiteflies.[137] While the neonicotinoids act as ligands on homologous receptors in insects and vertebrates, the affinity of the neonicotinoid for the insect nicotinic acetylcholine receptor is reported to be 5- to 3500-fold greater than that observed in vertebrates.[137,138] The molecular basis for differences in affinity has been proposed,[137,139] and molecular design aimed at achieving greater selectivity for insects has been discussed.[140] Differences in absorption, distribution, metabolism, and elimination are also expected to play a role in insect selectivity. A common mechanism grouping for neonicotinoid insecticides has not yet been proposed, but appears to be supported by what is known about their MOA.

The structures, uses, and hazard profiles for imidacloprid, thiamethoxam, and sulfoxaflor are presented in Table 16.40. Imidacloprid and thiamethoxam are moderately acutely toxic by the oral route and are much less toxic to mammals than nicotine. Imidacloprid is not a developmental toxin or a carcinogen. High doses of thiamethoxam caused testicular effects in the multigeneration reproduction study and caused liver tumors in the mouse. A MOA underlying the occurrence of the mouse liver tumors has been described,[141,142] and the EPA has classified thiamethoxam as not likely a human carcinogen.

Spinosyns: Acetylcholine Receptor Agonists (IRAC Code 5)

Two of the most important spinosyns are spinosad and spinetoram. Spinosad, a fermentation-produced macrolide, was initially derived from the soil actinomycete *Saccharopolyspora spinosa* and is comprised of spinosyns A and D (Figure 16.12). It is highly toxic to *Lepidopteran*, *Dipteran*, and some *Coleopteran* insects.[143] Symptoms seen in insects include CNS hyperexcitation, involuntary muscle

	Mouse/18 months	40	Reproductive	Not a reproductive toxin
	ADI	0.01	Oncogenicity	C with RfD

contraction, and tremors, which ultimately result in neuromuscular fatigue and paralysis.[143,144] Spinosyns are believed to be nicotinic acetylcholine receptor (nAchR) agonists, although the experimental evidence supporting this proposed MOA remains inconclusive.[145] In addition to the proposed effects mediated by binding to nAchR, the spinosyns caused a dose-responsive reduction in the response to GABA rundown in isolated small-diameter cockroach neurons,[146] an effect that is probably mediated through the chloride channel/current.

The hazard profile for spinosad, which is shown in Table 16.41, suggests that the MOA is highly selective for insects. Spinosad is not very acutely toxic to mammals (Oral LD_{50} = 3738 mg/kg), and it is not neurotoxic.[147] Spinosad is listed at the Organic Materials Research Institute (OMRI) as approved for certified organic production under the USDA's National Organic Program §[206.207](e).[111,112]

Spinetoram is more active than spinosad in terms of its effects on insects, and it is created synthetically via 3′-*O*-ethylation of the rhamnose sugar moiety found in naturally occurring spinosyns and then modified further by 5,6-hydrogenation of the tetracyclic ring system.[37] The hazard profile for spinetoram is also included in Table 16.41.

Avermectins and Milbemycin: Chloride Channel Activators (IRAC Code 6)

The avermectins, along with milbemycin, comprise a group of closely related 16-membered macrocyclic lactones, isolated from *Streptomyces avermitilis* and *Streptomyces hygroscopicus*.[148] The chemical structures for abamectin, emamectin benzoate, and milbemycin are shown in Figure 16.13. These potent acaracides cause signs of ataxia, paralysis, and death, but the hyperexcitation typically found with most other insecticides is absent.[149] While a number of pharmacologic effects of ivermectin have been described,[150] it is generally agreed that the principal MOA of this class is an activation of chloride ion current by a GABA-like opening of the chloride channel.[109,151] In addition, opening of a glutamate-gated chloride channel has also been implicated.[152,153]

The toxicity profiles for abamectin, emamectin benzoate, and milbemycin are given in Table 16.41. Abamectin and emamectin are neurotoxic in mammals, which exhibit hyperexcitability, tremors, incoordination, ataxia, and coma-like sedation.[154] Much of the early hazard evaluation for abamectin and emamectin was conducted in the wild-type CF-1 mouse,[154,155] which has been found to be heterozygous for p-glycoprotein.[156–159] The toxic effects of abamectin were reduced in studies using animals having a fully intact p-glycoprotein blood–brain barrier, supporting the idea that differential expression of p-glycoprotein, which is a substrate for the avermectins, might account for differences in selectivity among species.[160] The importance of an intact blood–brain barrier in humans has been considered.[161]

Milbemycin is less acutely toxic than the avermectins, and it is not a developmental toxin in animal bioassays. Its toxicity profile is also found in Table 16.41.

Juvenile Hormone Mimics and Selective Feeding Blockers (IRAC Codes 7A, 7B, 7C, and 9B)

Juvenile hormones modulate an extraordinarily broad range of morphological and physiological processes during larval development and metamorphosis,[162] in addition to having effects on various aspects of adult reproduction and behavior.[163] Juvenile hormones are terpenoid-based compounds (Figure 16.14) that from an evolutionary point of view could be precursors to steroids and retinoids, which are also terpenoid derivatives.[164] The failure to identify classical nuclear

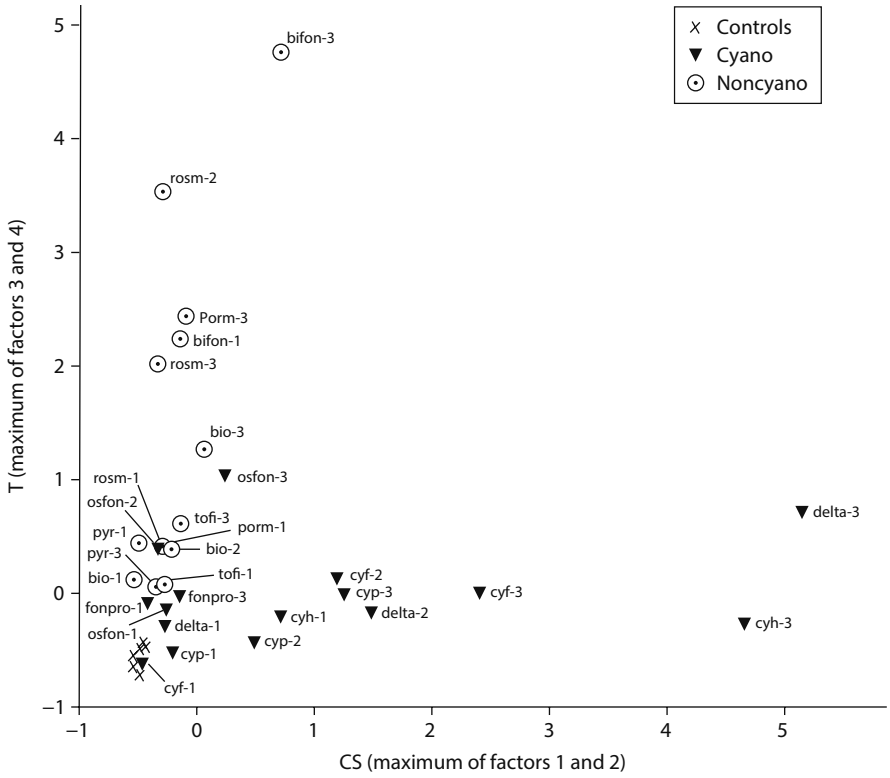

FIGURE 16.9 Results from a principal components/factor analysis of FOB data.

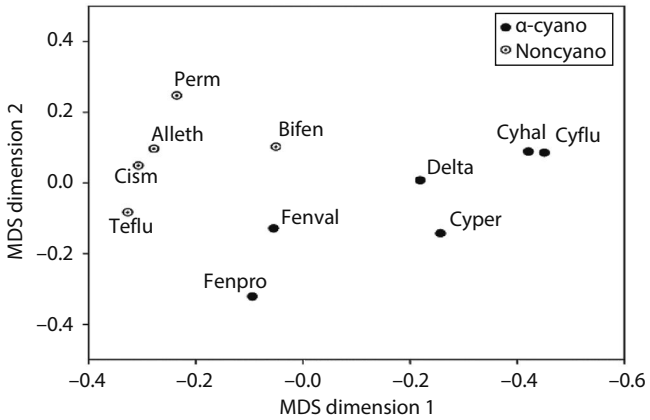

FIGURE 16.10 Multidimensional scaling of sodium channel kinetic parameters.

receptors for juvenile hormones, despite decades of effort,[165] may be attributed to the possibility that juvenile hormones signal through membrane receptors.[166] Because juvenile hormones are capable of binding to a large number of proteins, they may exert their effects by binding to G-coupled membrane receptors, which could in turn trigger a cascade of intracellular MAP kinase signaling molecules, such as those that have been described for gonadotropin-releasing hormone in mammals.[167]

The juvenile hormone mimics (JHMs) are compounds that bear a structural resemblance to the juvenile hormones

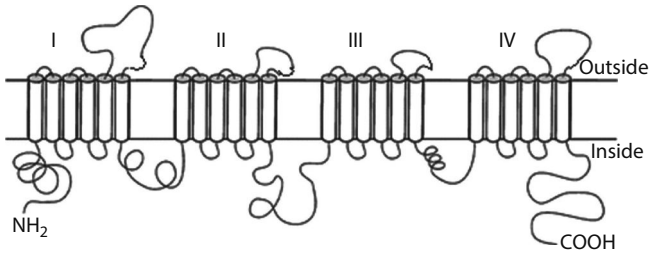

FIGURE 16.11 Schematic of the transmembrane voltage-gated sodium channel.

in insects, which are lipophilic sesquiterpenoids containing an epoxide and methyl ester groups (see Figure 16.14). These chemicals mimic the action of juvenile hormones affecting a number of physiological processes, such as molting and reproduction. Exposure to JHMs at molting cause death by producing mixed larval/pupal or larval/adult morphologies. The efficacy of these compounds is greatest when normal juvenile hormone titers are low, namely, in the last larval or early pupal stages.[162,165,168]

The structures, uses, and hazard profiles of three JHMs (methoprene, fenoxycarb, and pyriproxyfen) and the feeding inhibitor pymetrozine[169] are presented in Table 16.42. These chemicals are not acutely toxic, and no endocrinological effects have been reported for methoprene.[170]

High doses of pymetrozine caused liver tumors in male and female mice, as well as in female rats, and fenoxycarb induced

lung tumors in mice, presumably through its metabolite ethyl carbamate, which is known to cause murine lung tumors.[171] Difolatan, a structural analogue of fenoxycarb, which does not have the ethyl carbamate moiety, does not cause lung tumors in mice. There does not appear to be a basis for creating a common mechanism grouping for this diverse group of chemicals, because the juvenile hormone is unique to insects.

Phenyltetrazines and Aminotriazines: Larvicides/Molt Disruptors (IRAC Codes 10A and 17)

The structures, uses, and hazard profiles for a diverse group of insecticides that are larvicidal (cyromazine) and/or molting disruptors (clofentezine and hexythiazox) through unknown or nonspecific MOA are presented in Table 16.43. These insecticides are not acutely toxic and do not have effects on development. Clofentezine causes thyroid tumors in male rats, and hexythiazox causes liver tumors.

Delta-Endotoxins Derived from *Bacillus thuringiensis* (IRAC Code 11A)

Bacillus thuringiensis (Bt) forms a crystalline inclusion body during sporulation that contains a number of insecticidal proteins.[37] When consumed by an insect, the inclusion body is dissolved in the midgut, and it subsequently releases delta-endotoxins. Mixtures of different delta-endotoxins are usually present in the inclusion body, and individual toxin proteins are designated with the prefix cry. These proteins contain anywhere from a few hundred to over a thousand amino acids. After they are ingested, delta-endotoxins are cleaved to an active form by proteases within the midgut. The active toxins bind specifically to the membranes of the midgut epithelia and alter their ion permeability by forming a cation channel or pore. Ion movements through this pore disrupt potassium and the pH gradients and lead to lysis of the epithelium, gut paralysis, and eventual death.[3,172,173]

TABLE 16.37
Structure and Use Profiles for the α-Cyano Pyrethroid Insecticides (IRAC Code 3)

Insecticide	Structure	Principal Use/Crop	Application Rate (g a.i./ha)
Cyfluthrin (Baythroid®)[37,280]		Contact, nonsystemic insecticide used on cereals, cotton, fruit, and vegetables	15–40
Cypermethrin (Ammo™)[37,280]		Contact, nonsystemic insecticide used on fruits, vines, coffee, cereals, and ornamentals	10–100
Deltamethrin (Crackdown™)[37,280]		Contact, nonsystemic insecticide used on cereals, citrus, cotton, grapes, cotton, maize, oilseed rape, and soybeans	2.5–21
Lambda-cyhalothrin (Karate®)[37,280]		Controls a broad spectrum of chewing and piercing insects on cereals, hops, ornamentals, vegetables, and cotton	2–5

Delta-endotoxins derived from Bt have been used as insecticides for over 30 years, and more recently, plants have been genetically engineered to express delta-endotoxins. Considering that these bacterial strains of Bt are found in nature and that there is no evidence of adverse effects on human health resulting from the use of delta-endotoxin as an insecticide,[174–177] the EPA requires a limited toxicological assessment of new Bt products. Acute oral toxicity, in vitro digestibility, and infectivity/pathogenicity studies are required, along with evaluations of amino acid homologies.[177] Bt is also listed at OMRI for use in organic crop protection methods.[111,112] The structures, uses, and hazard profiles for delta-endotoxins derived from Bt subspecies are shown in Table 16.44.

Benzoylureas: Chitin Synthesis Inhibitors (IRAC Code 15)

The benzoylureas, represented here by diflubenzuron, block molting in insects by preventing the formation of a new cuticle exoskeleton, which is comprised of about 50% chitin. Chitin is a polysaccharide comprised of *N*-acetylglucosamine. It has been proposed that polymerization is blocked by the benzoylureas by (1) the inhibition of chitin synthase or its biosynthesis, (2) the inhibition of proteases or their biosynthesis, or (3) the inhibition of a membrane-transport step involving UDP-*N*-acetylglucosamine.[178] These biochemical pathways are not present in mammals.[179]

Diflubenzuron is not toxic to mammals. It is highly lipophilic, and it therefore tends to bioconcentrate in fat, which has led to the expression of delayed toxicity in animal studies for some members of this class (including lufenuron), apparently due to tissue bioaccumulation. The structure, uses, and hazard profile of diflubenzuron are presented in Table 16.45.

Diacylhydrazine Ecdysone Agonists (IRAC Code 18A)

The hormone 20-hydroxyecdysone (20E) is synthesized by insects either from cholesterol or from phytosteroids, which they obtain from their diets, as insects do not possess the biochemical pathways needed to synthesize the steroid nucleus.[180] Ecdysone levels, titered in hemolymph, rise progressively up until the time of molting, and then they fall precipitously. Ablation of the eyestalk, the source of this hormone in crustaceans, results in a failure of molting behavior, with no change in ecdysteroid concentration in hemolymph.[181] The ecdysteroid hormone, 20E, apparently mediates this effect on molting and reproductive function by binding to the nuclear ecdysteroid receptor, EcR.[182] The ecdysone agonists,

represented here by tebufenozide, are lethal to lepidopteran pests by inducing premature molting.[162] The toxicity of tebufenozide (RH-5992) to insect larvae is proportional to its binding affinity to EcR proteins (Figure 16.15).[183]

The EcR receptor is comprised of at least two proteins, which are gene products of the EcR and USP (ultraspiracle) genes. These genes are members of the steroid hormone receptor superfamily and are the insect homologues of the vertebrate retinoid X-receptor gene.[184] As such, it is possible that ecdysone agonists could have affinity for vertebrate receptor proteins.

The structure, uses, and hazard profile of tebufenozide are presented in Table 16.46. It is neither acutely toxic nor a developmental or reproductive toxin.

Octopaminergic Agonists and Monoamine Oxidase Inhibitors (IRAC Code 19)

Octopamine is an excitatory neurotransmitter in insects. The octopaminergic agonist amitraz, a member of the formamidine class of insecticides, is selective for parasitic mites and ticks, as well as some *Lepidoptera* and *Homoptera* species.[185] Recent studies in vertebrates have shown that amitraz causes sympathomimetic effects,[186] apparently by binding to α-2 adrenergic receptors.[187,188] It has been suggested that amines like the octopamines could signal through G-coupled protein receptors.[189] Human poisoning associated with amitraz exposure has been reported.[190]

Piperonyl butoxide inhibits methyl farnesoate epoxidase, which catalyzes the synthesis of juvenile hormone III, thereby affecting molting behavior and reproductive function in insects.[48] Piperonyl butoxide also inhibits P450 monooxygenases, thereby retarding the metabolism of the pyrethroid insecticides and serving to prolong their period of effective action.

The structures, uses, and hazard profiles for amitraz and piperonyl butoxide are provided in Table 16.47. Amitraz is moderately acutely neurotoxic and has effects on the development and reproductive function. It is also an animal carcinogen. Piperonyl butoxide neither is acutely toxic nor has reproductive or developmental effects.[191]

Respiratory Inhibitors and Uncouplers (IRAC Codes 13, 20A, 21A, 21B, and 22B)

Compounds that disrupt energy metabolism have been identified from both natural and synthetic sources. An important natural product is rotenone, which is derived from roots of

Derris and *Lonchocarpus*,[192] as well as the leaves of some species of *Tephrosia*.[193] The synthetic compounds in this structurally diverse group include the pyrrole known as chlorfenapyr, as well as the amidinohydrazones, including hydramethylnon and pyridaben.

Disruption of energy metabolism occurs in the mitochondria and usually takes the form of either an inhibition of the electron transport system or an uncoupling of the transport system from ATP production. Inhibition of the electron transport system blocks the production of ATP and causes a decrease in oxygen consumption by the mitochondria. These uncouplers act on either coenzyme Q oxidoreductase in the electron transport chain or the cytochrome b–Ci complex.[194] The electron transport system functions normally, but the production of ATP is uncoupled from the electron transport process due to a dissipation of the proton gradient across the inner mitochondrial membrane (see Figure 16.2). In the presence of uncouplers, oxygen consumption increases, but no ATP is produced.[37] The disruption of energy metabolism and the subsequent loss of ATP result in a slowly developing toxicity, and the effects of all these insecticides include inactivity, paralysis, and death. It is expected that this MOA would be preserved in mammalian systems if the chemical reached its enzyme target. Thus, chemicals that interfere with mitochondrial respiration are expected to have similar effects in mammalian species.

The structures, uses, and hazard profiles for these insecticides that inhibit mitochondrial respiration (chlorfenapyr, hydramethylnon, pyridaben, rotenone, and metaflumizone) are given in Tables 16.48 and 16.49.

Diamides (IRAC Code 28)

The diamide insecticide group includes chlorantraniliprole, cyantraniliprole, and flubendiamide, which represent the three most important products commercially. When *Lepidoptera* and other pests ingest diamides, their ryanodine receptors are activated, causing an uncontrollable loss of calcium stores.[37] The insects quickly become lethargic, show signs of muscle paralysis, stop feeding, and then die.[37] The structures, uses, and hazard profiles for the representative diamides are found in Table 16.50.

Pheromones

Pheromones are chemical attractants secreted by special glands of insects to assist them in identifying or locating members of the opposite gender.[195] EPA has defined pheromones as chemicals produced by arthropods (insects, arachnids, or crustaceans) that modify the behavior of other individuals of the same species.[196] The EPA has registered 17 arthropod pheromones as active ingredients, 11 of which are lepidopteran pheromones.[196] The information submitted covered

TABLE 16.40
Hazard Profiles for Neonicotinoid Insecticides (IRAC Codes 4A and 4C)

Insecticide	Structure	Principal Use	Application Rate (g a.i./ha)
Imidacloprid (Admire®, Provado®)[37,280]		Used to control sucking insects including aphids, thrips, and whiteflies; also used as a seed treatment	25–100 (foliar) 50–700 g/100 kg (seed)
Thiamethoxam (Actara®, Cruiser®, Platinum®)[37,280]		Used to control sucking insects including ricehoppers, aphids, thrips, and whiteflies	10–200
Sulfoxaflor (Transform™)[37,280,370]		Used to control sap-feeding insects	—

Insecticide	Irritation: Eye	Irritation: Skin	LD_{50} (mg/kg): Oral	LD_{50} (mg/kg): Dermal	LC_{50} (mg/L) Inhalation	Sensitization Potential	Signal Word
Imidacloprid	Nonirritant	Nonirritant	424	>5000	0.07	Negative	Warning
Thiamethoxam	Nonirritant	Nonirritant	1563	>2000	>3.72	Negative	Caution

compounds that were from 6- to 16-carbon unbranched alcohols, acetates, and aldehydes, which are volatile.

There are lower data requirements for the registration of pheromones. The available data on lepidopteran and other arthropod pheromones, including several aromatic pheromones, have shown no acute mammalian toxicity at the limit dose levels tested, and these chemicals are also approved for use in organic farming methods.[112] The acute toxicity profiles generally reveal oral and dermal LD_{50} values of greater than 5000 and 2000 mg/kg, respectively.[197] Acute inhalation LC_{50} values generally are greater than 5 mg/L. Eye and skin irritation potentials fall in the mild or nonirritating range, and there is no evidence of skin sensitization potential. Since small amounts of the pheromone are present inside bait stations, there is practically no human contact, and, therefore, the full data package requirement for conventional pesticides is waived by the EPA.[196]

HERBICIDES

The MOA of herbicides used in crop protection have been classified by the Herbicide Resistance Action Committee (HRAC) into groups,[6] as presented in Table 16.51. It has been suggested that the MOA for 60% of herbicides introduced during the period from 1960 to 2000 involve biochemical pathways specific to either chloroplasts or plant-signaling hormones.[198] Whether or not any of the molecular targets of these herbicides in plants have homologous targets in animals will be considered in the following section.

TABLE 16.45
Structure, Uses, and Hazard Profile for the Benzoylurea Chitin Synthesis Inhibitor Diflubenzuron (DIMILIN®) (IRAC Code 15)

Structure	Principal Use	Application Rate (g a.i./ha)
	Used to control major insect pests in cotton, soy, citrus, tea, vegetables, and mushrooms, including larvae of flies, mosquitoes, grasshoppers, and locusts	25–150

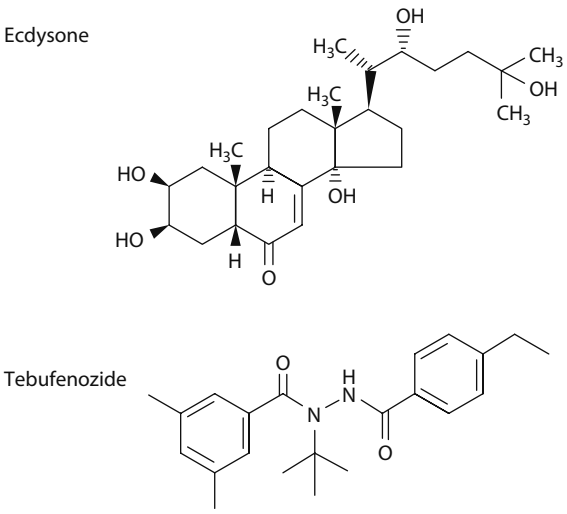

FIGURE 16.15 Comparison of the structure of ecdysone 20 to tebufenozide.

Acetyl-CoA Carboxylase Inhibitors (HRAC Code A)

The aryloxyphenoxypropionate, cyclohexanedione, and phenylpyrazoline herbicides inhibit acetyl coenzyme A (acetyl-CoA) carboxylase (ACCase), although the exact binding site of these herbicides on this enzyme has not yet been determined.[199] They block the synthesis of fatty acids essential for the production of plant lipids, which are vital to the integrity of cell membranes and to the formation of cuticle waxes during new plant growth (see Figure 16.16). Injury is slow to develop (7–10 days) and appears first on new leaves emerging from the whorl of the grass plant. The herbicide is taken up by the foliage and moves via the phloem to areas of new growth.[200]

ACCase exists in two forms in plants: the prokaryote form, which is found in broadleaf dicotyledonous plants that are 400–6000 times more tolerant to these herbicides, and the eukaryote form found in perennial and annual grasses, which are more susceptible. The prokaryotic form of ACCase is heterodimeric, comprised of four gene products, the biotin carboxyl carrier (BCC) and biotin carboxylase (BCase), as well as both the α- and β-subunits of carboxyltransferase (CTase). The eukaryotic, homodimeric form is a single 220–230 dDA polypeptide comprised of linked BCC, BCase, and CTase domains.[199,201] Differences in tolerance among the monocotyledonous plants are attributed to differences in the rate of detoxification among the subspecies.[202–204] Resistance development is attributed to the acquisition of mutations that (1) increase the expression of ACCase, (2) alter binding of the herbicide to ACCase, or (3) increase expression of enzymes involved in herbicide metabolism.[199]

Biochemical pathways for fatty acid synthesis are conserved in mammalian species (Figure 16.16). ACCase in mammals is like the eukaryotic form. There are no specific data to indicate that the AOPP or CHD herbicides alter fatty acid synthesis in animal studies, although drugs have been developed to block this pathway. For example, the rate-limiting enzyme for sterol synthesis, HMG-CoA

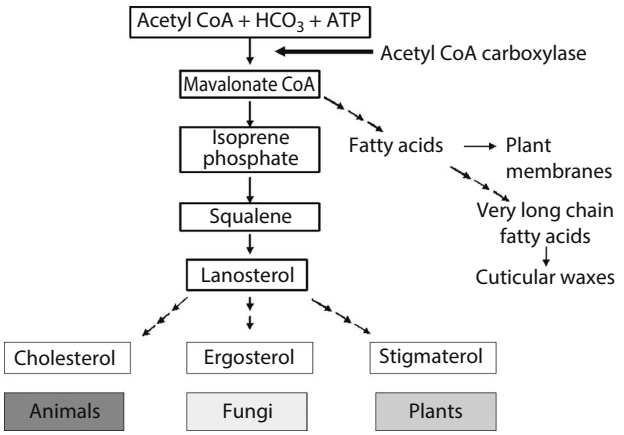

FIGURE 16.16 Fatty acid synthesis and by-products in plants, fungi, and animals.

reductase, is inhibited by simvastatin, a drug designed to reduce cholesterol biosynthesis.

Aryloxyphenoxypropionates (HRAC Code A)

The structures, uses, and hazard profiles for six aryloxyphenoxypropionate herbicides are presented in Table 16.52. These herbicides are generally not acutely toxic. Clodinafop-propargyl has been identified as a peroxisomal proliferator in rodents. The relevance of peroxisomal proliferation to humans is determined on a case-by-case basis, using a framework assessment of the weight of the evidence.[205]

Cyclohexanediones (HRAC Code A)

The structures, uses, and hazard profiles for the cyclohexanedione herbicides, clethodim and sethoxydim, are presented in Table 16.53. Both clethodim and sethoxydim have limited toxicity in acute and repeat-dose toxicity studies. They are not mutagenic, carcinogenic, developmental, or reproductive toxicants.

Phenylpyrazolines (HRAC Code A)

The structure, uses, and hazard profile for the phenylpyrazoline herbicide pinoxaden are presented in Table 16.53. Pinoxaden affects fatty acid synthesis when it is used as a postemergent, systemic herbicide, and it is the only phenylpyrazoline herbicide noted by the HRAC.[6,37]

Acetolactate Synthase Inhibitors (HRAC Code B)

The acetolactate synthase (ALS) inhibitors, which are comprised of the sulfonylureas (SUs), imidazolinones, triazolopyrimidines, and pyrimidinylthiobenzoates, interact with the ALS enzyme, thereby blocking the biosynthesis of

TABLE 16.52

branched-chain amino acids, valine, leucine, and isoleucine, as illustrated in Figure 16.17.[206] The binding site is considered to be a vestigial quinine-binding site on the enzyme.[207] Because the biochemical pathway for the synthesis of branched-chain amino acids does not exist in monogastric animals, this herbicidal MOA is not relevant to humans. In fact, some researchers have taken advantage of this selectivity to design antituberculosis drugs.[208]

Sulfonylureas (HRAC Code B)

SU herbicides belong to a class of compounds comprised of three distinct components, as each is formed by an aryl group linked to a nitrogen-containing heterocycle via an SU bridge. SU herbicides inhibit root and shoot growth in rapidly growing plants by suppressing cell division.[79] Initial research conducted on *E. coli* and *Salmonella typhimurium*, and later confirmed in plants and yeasts, indicates that the herbicidal activity is due to the inhibition of ALS, an enzyme necessary for the biosynthesis of branched-chain amino acids in bacteria, fungi, and higher plants.

A large number of SU herbicides have been developed for commercial use in North America and Europe. The structures, uses, and application rates for the most commonly used SUs are provided in Table 16.54.

SU herbicides generally are neither acutely toxic or irritating to the skin and eye, nor mutagenic, developmentally toxic, or oncogenic. Their hazard profiles are given in Table 16.55. Various target organs have been identified at high doses in chronic studies in rodents and dogs, including bone marrows, livers, kidneys, and testes, as well as the peripheral system and CNS. Tumor incidence was elevated above control levels in the liver (primisulfuron) at doses that exceed the maximum tolerated dose. An earlier appearance of mammary tumors has also been observed in female Sprague-Dawley rats (prosulfuron and tribenuron).

A unitary MOA underlying effects of this class of chemical on mammalian systems is not discernable. The diversity of the effects observed in various target organs is attributed to specific functional groups and not to the defining characteristic of the class, the SU bridge.

An alternate MOA for the SUs is derived from the fact that an SU receptor protein in pancreatic β-cell plays an important role in glucose regulation. An ATP-sensitive potassium ion channel known as K_{ATP} has been identified in β-cells of the pancreas. The ultrastructure of the K_{ATP} channel is unique among K^+ ion channels in that it is comprised of two proteins: a sulfonylurea receptor (SUR) protein, which belongs to the family of ABC (ATP cassette) transporter proteins, and a smaller protein, Kir6.2, which belongs to a family of inward-rectifying potassium current proteins. Four Kir6.2 subunits are constitutively expressed with four SUR subunits to make up the selective K^+ pore.[209] K_{ATP} channels containing the SUR1 isoform can be blocked by SUs[210] and can be opened with diazoxide. SUR1 is thus critically involved in the regulation of K_{ATP} channel activity. It is proposed that an elevation in blood glucose concentration leads to an increased rate of glucose metabolism in pancreatic β-cells and a consequent alteration in the intracellular ratio of ATP/ADP, resulting in the inhibition of K_{ATP} channels. The subsequent depolarization of the β-cell plasma membrane activates voltage-sensitive Ca^{2+} channels, and the ensuing influx of Ca^{2+} initiates insulin secretion.[211]

TABLE 16.53
Structures, Uses, and Hazard Profiles of Acetyl-CoA Carboxylase-Inhibiting Cyclohexanedione (CHD) Herbicides and the Phenylpyrazoline Herbicide Pinoxaden (HRAC Code A)

Herbicide	Structure	Principal Use/Crop	Application Rate (g a.i./ha)
Clethodim (Select®)[37,280]		Used to control grasses in soybeans and cotton	60–240
Sethoxydim (Nabu®)[37,280]		Used to control grasses in soybean, cotton, and peanut crops	200–500
Pinoxaden (AXIAL®)[37,280]		Control of postemergent annual grasses in wheat and barley crops	30–60

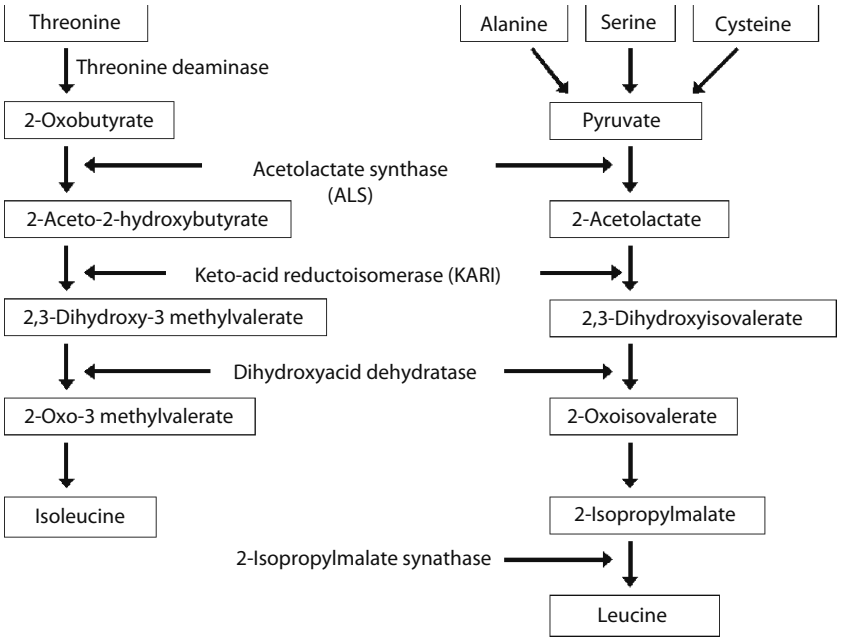

FIGURE 16.17 Branched-chain amino acid synthesis: acetolactate synthase (ALS).

It appears that the SU herbicides have rather low affinity to SUR, because there is no evidence of an effect on glucose regulation in the animal studies.

Imidazolinones (HRAC Code B)

The structures, uses, and hazard profiles for the imidazolinones imazameth and imazamethabenz-methyl are provided in Table 16.48. These ALS inhibitors are relatively nontoxic, even at high doses, with no evidence of mutagenic, developmental, or oncogenic effects.

The triazolopyrimidine ALS inhibitors include imazamox, imazapyr, imazaquin, and imazethapyr. As with the imidazolinones, these chemicals also have excellent hazard profiles (Table 16.56). No evidence of significant target organ toxicity, mutagenic, developmental, or oncogenic potential has been realized, even at doses that approximate the limit dose of 1000 mg/kg/day.

Triazolopyrimidines, Pyrimidinylthiobenzoates, and Sulfonylaminocarbons (HRAC Code B)

The members of this class of ALS-inhibiting herbicides, including flumetsulam (Table 16.57), are slightly less well tolerated in mammalian systems than for other ALS inhibitors, as evidenced by lower NOELs. However, the hazard profiles for these chemicals are still favorable, as no mutagenic, developmental, or oncogenic effects have been reported.

Inhibition of Photosynthetic Electron Transport (HRAC Codes C and D)

Photosynthesis is a process unique to plants whereby light energy captured by chlorophyll is converted to electrochemical energy through an electron transport chain to produce NADPH (photosystem I) or ATP (photosystem II). Herbicides that interfere with electron transport in the photosynthetic pathways have been grouped into two groups by HRAC.[6] The group D herbicides (bipyridyliums), represented here by paraquat and diquat, block photosynthesis at the photosystem I stage by capturing electrons that reduce the herbicide (Figure 16.18). The reduced form of the herbicide is then oxidized, leading to the formation of supraoxides and hydrogen peroxide and then ultimately hydroxyl radicals that damage cellular components affecting unsaturated membrane lipids, resulting in fatty acid peroxidation, losses in membrane semipermeability, desiccation, and cell death.[211] Group C1 (triazines, triazolinones, uracils, pyridazinones, and phenyl-carbamates), C2 (ureas and amides), and C3 herbicides (nitriles, benzothiadiazinone, and phenylpyridazines) all affect photosystem II (Figure 16.18). When electron transport is interrupted by Group C herbicides, and light continues to fall on the chloroplast, the energy level of chlorophyll is raised from a singlet to a triplet state, which itself damages cell membrane lipids or creates reactive oxygen species that interact with cellular lipids, proteins, and nucleic acids.[213,214]

Aside from creating reactive oxygen species, photosynthesis inhibitors also block food-producing processes in susceptible plants by limiting the availability of NADPH and ATP to enter into the so-called dark reaction (Calvin cycle), where CO_2 is fixed and carbohydrates are produced. The reduction in carbohydrate synthesis may result in a slow starvation of the plant.[215] Signs of injury include yellowing (chlorosis) of leaf tissue followed by death (necrosis) of the tissue. Preemergent- or early postemergent–applied herbicides like the triazines are taken up into the plant via the roots or foliage and are then transported via the xylem to the plant leaves. As a result, signs of injury first appear

Triasulfuron (Amber®, Logran®)[37,280]		Cereal (wheat) and IWC	5–10
Tribenuron-methyl (Express®)[37,280]		Cereals (wheat)	7.5–30

on older leaves or along leaf margins. Foliar-applied photosynthetic inhibitors generally remain in the foliar portion of the treated plant, with the movement from foliage to roots being negligible.[216]

Triazines and Triazinone (HRAC Code C1)

The S-triazines, phenylureas, and uracil herbicides all inhibit photosynthetic electron transport (Hill reaction) in photosystem II [662[217]] by binding to the D1 protein[218] and blocking the mobile electron carrier, plastoquinone.[213] The most common mechanism of resistance to s-triazines is a mutation of the psbA gene, which encodes the D1 protein, whereby glycine is substituted for serine at amino acid 264 in the stromal loop of the D1 protein.[218]

While the molecular targets relating to the inhibition of the Hill reaction do not exist in mammalian systems, a common MOA of toxicity for the chloro-s-triazines has been defined, based on effects on the hypothalamic–pituitary–gonadal axis.[219] The specific molecular target underlying this MOA has not been identified. However, it is likely related to the formation of a good leaving group by the chlorine atom, as indicated by reactivity with glutathione to form glutathione conjugates as part of the detoxification pathway or by reactions with sulfhydryl groups to form adducts to proteins.[220,221]

The structure and use of the symmetrical triazines, as well as the asymmetrical triazine or triazinone, metribuzin, are presented in Table 16.58. The hazard profiles are given in Table 16.59.

The triazines are generally not acutely toxic. The symmetrical chloro-s-triazines, including atrazine, propazine, and simazine, induce an earlier onset and/or an increase in the incidence of mammary tumors in lifetime feeding studies in Sprague-Dawley female rats.[222,223] The MOA underlying the occurrence of these tumors in female

Sprague-Dawley rats has been described, and it is not considered relevant to humans.[224] The IARC has classified atrazine and simazine as "not classifiable as to carcinogenicity to humans."[23] The EPA has also classified atrazine and simazine as "not likely to be carcinogenic to humans."[224,225]

Uracils and Pyridazinones (HRAC Code C1)

The structures, uses, and hazard profiles for two uracils (bromacil and terbacil) and the pyridazinone herbicide, norflurazon, are given in Table 16.60.

The acute toxicities of bromacil, terbacil, and norflurazon are unremarkable. These herbicides are not mutagenic, teratogenic, or reproductive toxins. However, bromacil and norflurazon have been classified as category C (possible human carcinogens), based on mouse liver tumors.

Ureas (HRAC Code C2)

The structures, uses, and toxicity for the urea class of photosynthesis-inhibiting herbicides diuron, fluometuron, and linuron are provided in Table 16.61.

Diuron, linuron, and fluometuron have limited acute toxicity. Fluometuron caused hemosiderosis in the spleen in repeat-dose studies. Diuron and linuron have been classified by the EPA as either known or likely human carcinogens as defined in the EPA 1996 classification scheme[37] or as category C (possible human carcinogens) based on an earlier scheme.[37] The cancer classification of fluometuron is

pending; a slight elevation in the incidence of lymphoma was noted in the rat study on fluometuron.

Nitriles (HRAC Code C3)

The nitrile herbicides act against cellulose biosynthesis and are used as systemic herbicides.[37] The structures and uses of the nitriles dichlobenil and bromoxynil are presented, along with their hazard profiles, in Table 16.62. Dichlobenil and bromoxynil are classified as category C carcinogens, based on mouse liver tumors.

Benzothiadiazinones (HRAC Code C3)

This class of herbicides is represented by bentazon, which is also known as bentazone. Benzothiadiazinones interfere with photosynthetic electron transport via photosystem II receptors, and they are used as selective contact herbicides.[37] Bentazon is not toxic in either acute or repeated-dose studies.

Bipyridyliums (HRAC Code D)

Diquat and paraquat, which are bipyridylium photosynthesis inhibitors, are unlike the HRAC Code C1–C3 herbicides in

TABLE 16.58
Structures and Use Profiles of the Photosynthesis-Inhibiting Triazine and Triazinone Herbicides (HRAC Code C1)

Herbicide	Structure	Principal Crops/Use	Application Rate (kg a.i./ha)
Atrazine (Aatrex®)[37,280]		Pre- and postemergence control of annual broadleaved and annual grasses in corn, sorghum, sugarcane, and pineapple	1.5–2.5
Propazine (Milo-Pro®)[37,280]		Pre- and postemergence control of annual broadleaved and annual grasses in sorghum, carrots, chervil, and parsley	0.5–3
Simazine (Princep®)[37,280]		Pre- and postemergence control of annual broadleaved and annual grasses in pome fruit, stone fruit, citrus, vines, corn, sorghum, sugarcane, and pineapple	1.5–3
Ametryn (Evik®)[37,280]		Pre- and postemergence control of annual broadleaved and annual grasses in bananas, citrus fruit, corn, coffee, sugarcane, and pineapple	2–4
Prometryn (Caparol®)[37,280]		Preemergence in vegetables, cotton, sunflower, and peanuts, plus postemergence in cotton and vegetables	0.8–2.5 (preemergence) 0.8–1.5 (postemergence)
Prometon (Pramitol®)[37,280]		Control of most annual and many perennial broadleaved weeds, grasses, and brush weeds in noncrop areas	10–20
Metribuzin (Sencor®)[37,280]		Pre- and postemergence control of annual broadleaved and annual grasses in soybeans, potatoes, corn, cereals, sugarcane, alfalfa, and asparagus	0.07–1.45

that the bipyridyliums inhibit electron flow in photosystem I. The structures, uses, and hazard profiles for diquat and paraquat are provided in Table 16.63.

Diquat is less acutely toxic than paraquat, but they both are moderately toxic in long-term studies. Neither bipyridyliums are mutagenic, teratogenic, or carcinogenic, nor are they reproductive toxicants. However, both diquat and paraquat are capable of undergoing redox recycling, as they are reduced by electron donors, and they then undergo oxidization as they react with oxygen to form reactive oxygen species.[213,226] This redox potential is believed to account for tissue damage seen in the lung of animals treated with paraquat,[227] as well as cataractogenic effects in diquat-treated animals at low-to-moderate doses.[228] EPA concluded that while both diquat and paraquat are capable of generating oxygen free radicals, their effects are unlikely to be additive, because of differences in tissue distribution and hence target organ selectivity.[227]

Protoporphyrinogen Oxidase Inhibitors (HRAC Code E)

Protoporphyrinogen oxidase (PPO) inhibitors block the biosynthesis of chlorophyll by inhibiting PPO found in chloroplasts and mitochondria in plants. A similar action in animals

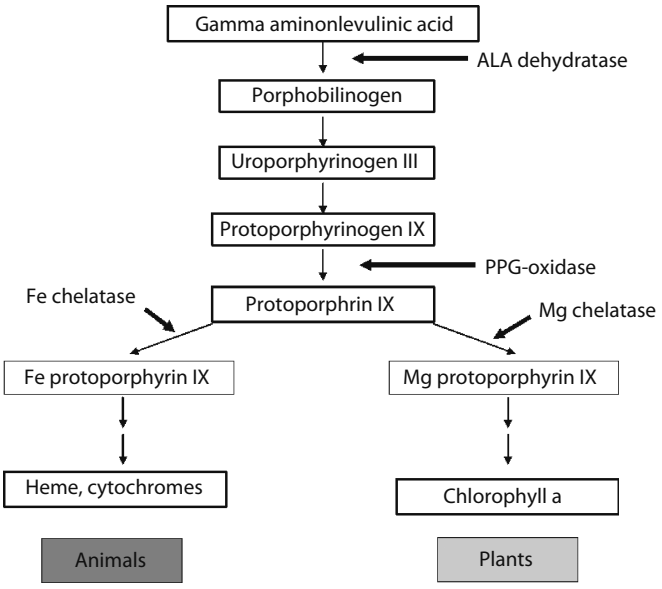

FIGURE 16.19 Protoporphyrin biosynthetic pathway.

interferes with the biosynthesis of heme and cytochrome P450 enzymes (Figure 16.19).

It is not uncommon to find evidence of anemia in rodents, especially rats, exposed to PPO-inhibiting herbicides. In addition to effects on heme synthesis, it is theorized that light-dependent (porphyria) and oxygen-dependent peroxidation of cell membrane lipids may lead to cell lysis and death, particularly in organs where protoporphyrin IX forms or bioconcentrates as a result of PPO inhibition.[229] Such a hypothesis is consistent with experimental observations that liver damage and liver tumor formation, particularly in mice, often result from high-dose exposures to PPO inhibitors.

It has also been postulated that liver damage and the subsequent tumor response seen in animals following high-dose exposures to PPO inhibitors may result from the peroxisome proliferative effects of these herbicides. Furthermore, it has been postulated that there may be a linkage between peroxisome proliferation and binding to PPARα receptors, as discussed in greater detail in the following text.[205,228]

TABLE 16.64
Structures, Uses, and Hazard Profiles for the Protoporphyrin-Inhibiting Diphenyl Ether Herbicides (HRAC Code E)

Herbicide	Structure	Principal Use/Crop	Application Rate (g a.i./ha)
Acifluorfen (Scepter®)[37,280]		Used to control annual broadleaf weeds in peanuts, beans, and rice	200–600
Fomesafen (Flosil®)[37,280]		Used to control annual broadleaf weeds in soybeans	200–400
Lactofen (Cobra®)[37,280]		Used to control annual broadleaf weeds in cereals, potatoes, soy, and rice	70–220
Oxyfluorfen (Goal®)[37,280]		Used to control annual broadleaf weeds in conifers, vegetables, nuts, and vine crops	250–2240

	Mouse/18 months	0.3	Reproductive	Not a reproductive toxin
	RfD	0.003	Oncogenicity	C (liver tumors in mice)

Diphenyl Ethers (HRAC Code E)

The diphenyl ether PPO inhibitors are represented here by acifluorfen, fomesafen, lactofen, and oxyfluorfen. Their structures, uses, and hazard profiles are presented in Table 16.64.

Lactofen is a severe eye irritant, but otherwise the acute toxicity of the PPO inhibitors is not remarkable. Acifluorfen and lactofen are classified as B2 (probable human carcinogens) based upon an increased incidence of liver and stomach tumors. Oxyfluorfen and fomesafen are classified as category C (possible human carcinogens) based on an increased incidence of liver tumors.

A MOA underlying liver tumors commonly seen in this class of herbicide has been proposed.[205,230] The key events leading to tumor expression are redrawn in Figure 16.20 from the paper by Klaunig et al.[205] It has been proposed that diphenyl ethers serve as ligands to the PPARα receptor, thereby activating genes involved in peroxisome proliferation (key event 2a), the regulation of the cell cycle, the suppression of apoptosis (key event 2b), and lipid metabolism (key event 2c). Suppression of apoptosis, coupled with a stimulation of cell proliferation, allows cells with mutation to be selected for clonal expansion (key event 7), leading to preneoplastic foci and tumors. Peroxisome proliferation may cause oxidative stress (key event 5) and cell death, thereby further stimulating cell turnover.[205]

N-Phenylphthalimides, Thiadiazoles, and Triazolinones (HRAC Code E)

The structures, uses, and hazard profiles for the *N*-phenylphthalimide (flumiclorac-pentyl and flumioxazin), thiadiazole (fluthiacet-methyl), and triazolinone (carfentrazone-ethyl and sulfentrazone) PPO inhibitors are presented in Table 16.65. Flumiclorac-pentyl, which is applied at a rate of 30–90 g/ha, is not toxic in acute or repeat-dose studies. The thiadiazole, fluthiacet-methyl, which is also applied at a low rate of 4–15 g/ha, has a low reference dose, based upon results from the chronic mouse study. Fluthiacet-methyl caused liver tumors in mice and pancreatic tumors in rats. The reference dose for carfentrazone-ethyl (RfD = 0.03 mg/kg/day) is based upon the chronic rat study, where evidence of porphyrin deposits was seen in the liver at high doses.[231]

Oxadiazole and Pyrimidinedione Herbicides (HRAC Code E)

The structure, uses, and hazard profile for the oxadiazole PPO-inhibiting herbicide oxadiazon are presented in Table 16.65. Oxadiazon has an extremely low reference dose based on the hepatotoxicity and hemolytic anemia seen at high doses. Oxadiazon has been classified by EPA as a likely human carcinogen.

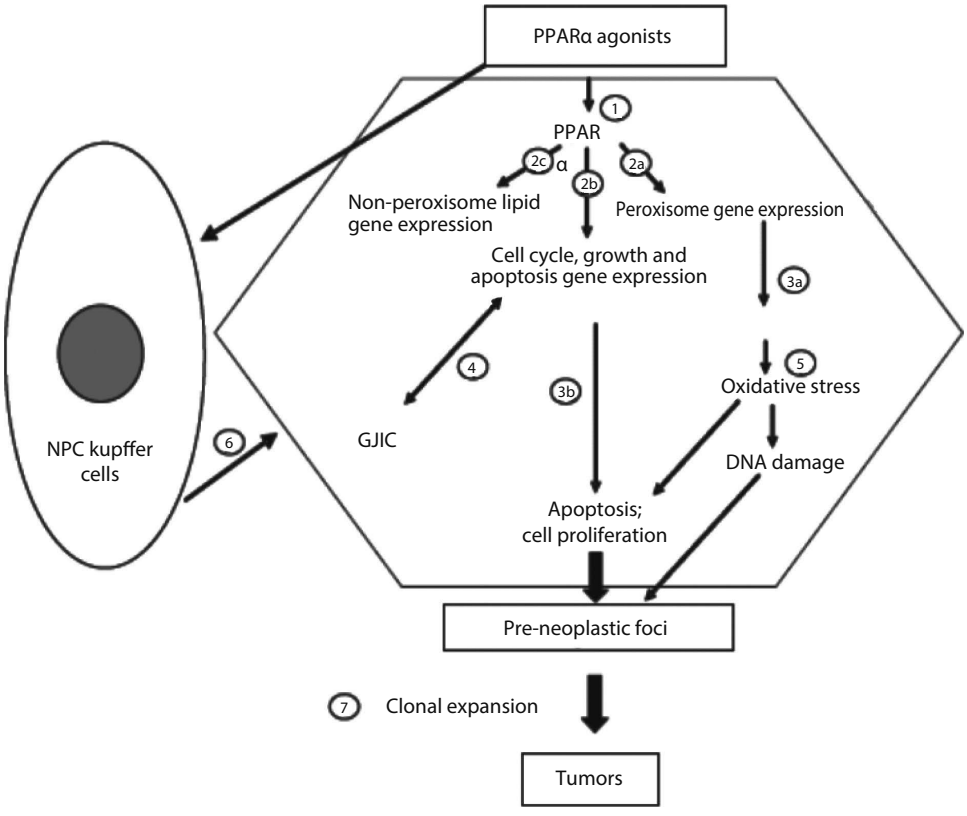

FIGURE 16.20 Proposed MOA for PPARα agonists.

Bleaching Herbicides (HRAC Code F1)

The bleaching herbicides disrupt the synthesis of carotenoid pigments, which protect chlorophyll pigments from photo-oxidation in strong light (see Figure 16.21). In the absence of carotenoids, chlorophyll is destroyed and turns white, thus the leaves of the plant have a bleached appearance. The pyridazinone, triketone, and isoxazole bleaching herbicides are considered here. The pyridazinones inhibit carotenoid biosynthesis at the phytoene desaturase step,[232] whereas the triketones, which were initially identified in the bottlebrush plant,[233,234] and the isoxazoles inhibit 4-hydroxyphenylpyruvate dioxygenase (HPDD).[233] The site of action for the triazoles and isoxazolidinones is unknown.[6] Of these MOA, only the HPDD inhibition is relevant to humans because blocking HPDD results in an increased incidence of tryrosinemia in animals.[235]

Pyridazinones (HRAC Code F1)

The structures, uses, and hazard profiles for norflurazon and fluridone are given in Table 16.66. Neither norflurazon nor fluridone is acutely toxic; the repeated-dose profile for fluridone is unremarkable. Norflurazon is classified as category C (possible human carcinogen) based on mouse liver tumors.

Triketones and Isoxazoles (HRAC Code F2)

The structures, uses, and hazard profiles for mesotrione and tembotrione (triketone), as well as for isoxaflutole (isoxazole), are presented in Table 16.67. Mesotrione is not mutagenic, carcinogenic, or neurotoxic. It has a low reference dose based on effects on tyrosine and its sequelae in rats. Mice and dogs are less sensitive and more similar to humans than are rats with respect to the inhibition of HPDD in vitro. Isoxaflutole is not acutely toxic, but it causes developmental and neurotoxic effects and liver tumors in mice and rats.

Triazoles and Isoxazolidinones (HRAC Code F3)

The chemical structures, uses, and hazard profiles for amitrole (triazole), clomazone (isoxazolidinone), and topramezone (isoxazolidinone) are presented in Table 16.68. These compounds are not acutely toxic. Clomazone has

an unremarkable repeated-dose toxicity profile. Amitrole has been classified as category B2 (probable human carcinogen) based on thyroid tumors in rats and liver tumors in mice.[99] These tumor responses could be related to a *triazole-related action on the liver* (see the triazole fungicide section for a detailed discussion of this MOA and its relevance to man).

EPSP Synthase, Glutamine Synthase, and Dihydropteroate Synthase Inhibitors (HRAC Codes G, H, and I)

Glyphosate is a nonselective herbicide that inhibits 5-enolpyruvlshikimate-3-phosphate synthase (EPSPS) in the shikimate pathway (Figure 16.22) of plant plastids.[236] Inhibition of EPSPS blocks the biosynthesis of the aromatic amino acids phenylalanine (Phe), tyrosine (Tyr), and tryptophan (Trp), as well as secondary products important for plant growth and development including lignans, alkaloids, flavonoids, and benzoic acids.[237] This pathway does not exist in mammals, and therefore this MOA is not relevant to man.

Glutamine synthetase is the initial enzyme in the pathway that assimilates inorganic nitrogen into organic compounds in plants. It is the pivotal enzyme in nitrogen metabolism in plants that, in addition to assimilating ammonia, recycles ammonia produced by other processes, including photorespiration and deamination reactions (Figure 16.23). Glutamine synthetase is found in analogous pathways in mammals, and it plays a similar role in recycling nitrogen. Glufosinate (DL-phosphinothricin) is a close structural analogue of glutamic

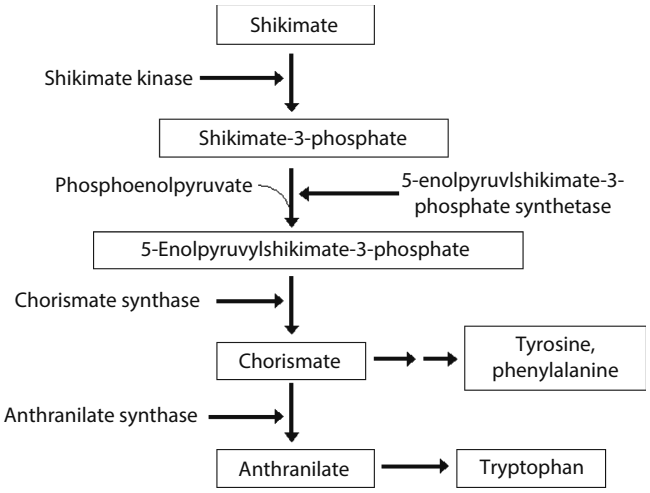

FIGURE 16.22 Aromatic amino acid biosynthetic pathway.

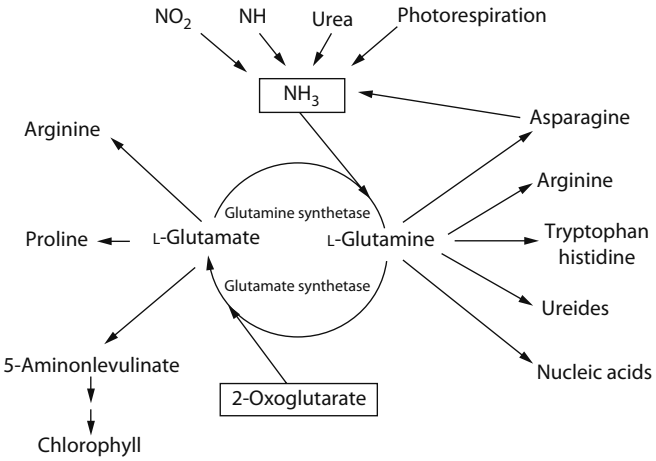

FIGURE 16.23 Nitrogen fixation and recycling in plants.

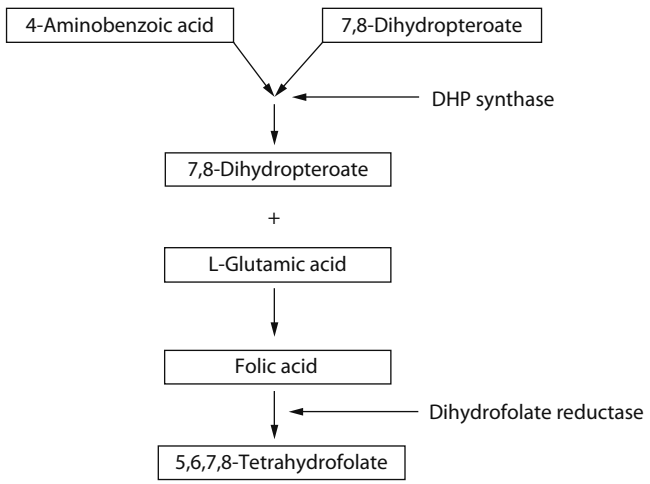

FIGURE 16.24 Folic acid synthesis.

acid and is considered to be the active pesticidal component in the natural tripeptide, phosphinothricin-alanyl-alanine (bialaphos), first discovered in *Streptomyces viridochromogenes*.[238] Glufosinate inhibits glutamine synthase, resulting in an accumulation of ammonium and the inhibition of photosynthesis.[237]

Folic acid, or its coenzyme form, serves as an intermediate carrier of hydroxymethyl, formyl, or methyl groups in enzyme-mediated reactions leading to the synthesis of amino acids, purines, and pyrimidines (Figure 16.24). Dihydropteroate (DHP) synthase catalyzes the first step of the folic acid biosynthetic pathway.[239]

Asulam inhibits DHP synthase, thereby blocking folic acid synthesis, which is needed for the formation of purine nucleotides required for cell division.[239] Asulam and other members of this class are structural analogues of 4-aminobenzoic acid and likely serve as substrates for DDP synthase, because the administration of 4-aminobenzoic acid reverses the phytotoxicity seen in plants and microbes treated with DHP synthase inhibitors.[239] The structures, uses, and hazard profiles for the representative EPSPS synthase, glutamine synthetase, and dihydropteroate synthase inhibitors are given in Table 16.69.

Glyphosate, glufosinate-ammonium, and asulam are not acutely toxic. Glyphosate and glufosinate-ammonium are not toxic in repeat-dose studies, and neither chemical is a developmental toxin, mutagen, or carcinogen. Asulam is not mutagenic, teratogenic, or a reproductive toxin, but a statistically significant increase in thyroid and adrenal gland tumors was observed in the male rat. A margin-of-exposure (MOE) approach was used to assess carcinogenic risk, likely because of asulam's structural similarity to products that occur naturally in plants.[240]

Dinitroaniline Microtubule Assembly Inhibitors (HRAC Code K1)

Several groups of herbicides, including the dinitroanilines (e.g., benfluralin, pendimethalin, and trifluralin), the phosphoroamidates (amiprophos-methyl and butamiphos), the pyridines (aminopyralid, dithiopyr, and thiazopyr), the benzamides (propyzamide and tebutam), and benzoic acid (DCPA), bind to tubulin monomers and prevent microtubule polymerization. This MOA is considered relevant to man (see the discussion on microtubule formation in the section on the benzimidazole and thiophanate fungicides).

The structures, uses, and hazard profiles of the three commercially important dinitroaniline microtubule assembly inhibitors are given in Table 16.70. Benfluralin, pendimethalin, and trifluralin are not acutely toxic. Benfluralin caused liver and thyroid tumors in rats at doses that exceeded the maximum tolerated dose and therefore was considered a suggestive human carcinogen; an MOE approach was used for cancer risk assessment.[241] Pendimethalin, which caused an increased incidence of thyroid tumors, was classified as a category C substance (possible human carcinogens) using an MOE approach

TABLE 16.69
Structures, Uses, and Hazard Profiles of EPSP Glutamine and DHP Synthase–Inhibiting Glycine and Phosphinic Acid Herbicides (HRAC Codes G, H, and I)

for cancer risk assessment.[242] Trifluralin caused thyroid, bladder, and kidney tumors, and its carcinogenic risk was regulated using Q_1*.[243,244] These tumorigenic effects are unlikely related to the herbicidal MOA of this class.

Chloroacetamide Inhibitors of Very-Long-Chain Fatty Acid Synthesis (HRAC Code K3)

Böger and Matthes reviewed the evidence suggesting that the chloroacetamides block the formation of very-long-chain saturated fatty acids (VLCFA) by inhibiting fatty acid elongase,[245] as shown in Figure 16.25. Vertebrates, including humans, have the biochemical mechanisms needed to synthesize long-chain fatty acids, including the enzyme, long-chain fatty acid acyl elongase.[246] Humans, however, lack the desaturase enzymes (not shown in Figure 16.25) that produce the health-promoting very-long-chain polyunsaturated fatty acids synthesized by plants and fish.[247] It is plausible that the chloroacetamides could perturb fatty acid synthesis in mammals, but there is no direct evidence of this in animal studies.

Aside from the herbicidal MOA of the chloroacetamides, alachlor, acetochlor, and butachlor have been identified as sharing a common mechanism of toxicity.[248] Alachlor, acetochlor, and butachlor all undergo dealkylation to form aniline and a reactive quinine imine (see Figure 16.26), the latter of which is thought to be the carcinogenic moiety ultimately responsible for nasal epithelial adenomas and carcinomas found in rats.[249] A sulfoxide metabolite of acetochlor was found in the plasma of rats treated with acetochlor, and this was bioconcentrated in the nasal epithelial tissue. Nasal epithelial tissue from humans apparently does not support the metabolic

Aminopyralid	Nonirritant	Nonirritant	>5000	>5000	>5.79	Negative	Caution

Herbicide	Species/Study	NOEL (mg/kg/day)	Toxicity Study	Hazard Indicator
Benfluralin[241]	Rat/2 years	0.5	Mutagenicity	No evidence
	Dog/52 weeks	25	Developmental	Not teratogenic
	Mouse/18 months	6.5	Reproductive	No evidence
	RfD	0.005	Oncogenicity	Suggestive (liver and thyroid tumors at doses greater than the MTD)
Pendimethalin[242,403,468]	Rat/2 years	10.0	Mutagenicity	No evidence
	Dog/104 weeks	12.5	Developmental	Not teratogenic
	Mouse/18 months	75	Reproductive	No evidence
	RfD	0.13	Oncogenicity	C with RfD (thyroid follicular cell adenomas)
Trifluralin[243,244,403]	Rat/2 years	2.5	Mutagenicity	No evidence
	Dog/52 weeks	2.4	Developmental	Not teratogenic
	Mouse/18 months	7.5	Reproductive	No evidence
	RfD	0.024	Oncogenicity	C-Q* (bladder, kidney, thyroid tumors)
Aminopyralid[469]	Rat/2 years	50	Mutagenicity	Not mutagenic
	Dog/52 weeks	93	Developmental	Not teratogenic
	Mouse/18 months	1000	Reproductive	Not a reproductive toxin
	RfD	0.5	Oncogenicity	Not likely to be carcinogenic

conversion of the sulfoxide to the sulfoxide of the quinine imine, whereas the rat made this conversion.[250]

The structures, uses, and hazard profiles for alachlor, acetochlor, metolachlor, and dimethenamid are provided in Table 16.71. All four chloracetamide herbicides are potential skin sensitizers. Alachlor and acetochlor both exhibit mutagenic potential and significant oncogenic potential in both rats and mice. Dimethenamid also has exhibited weak genotoxicity and a tumor response in the female rat. Metolachlor showed a weak oncogenic response in the liver of the female rat. A common mechanism of action has been proposed by EPA for alachlor and acetochlor based upon the carcinogenic potential of the quinine imine reactive intermediate.[248]

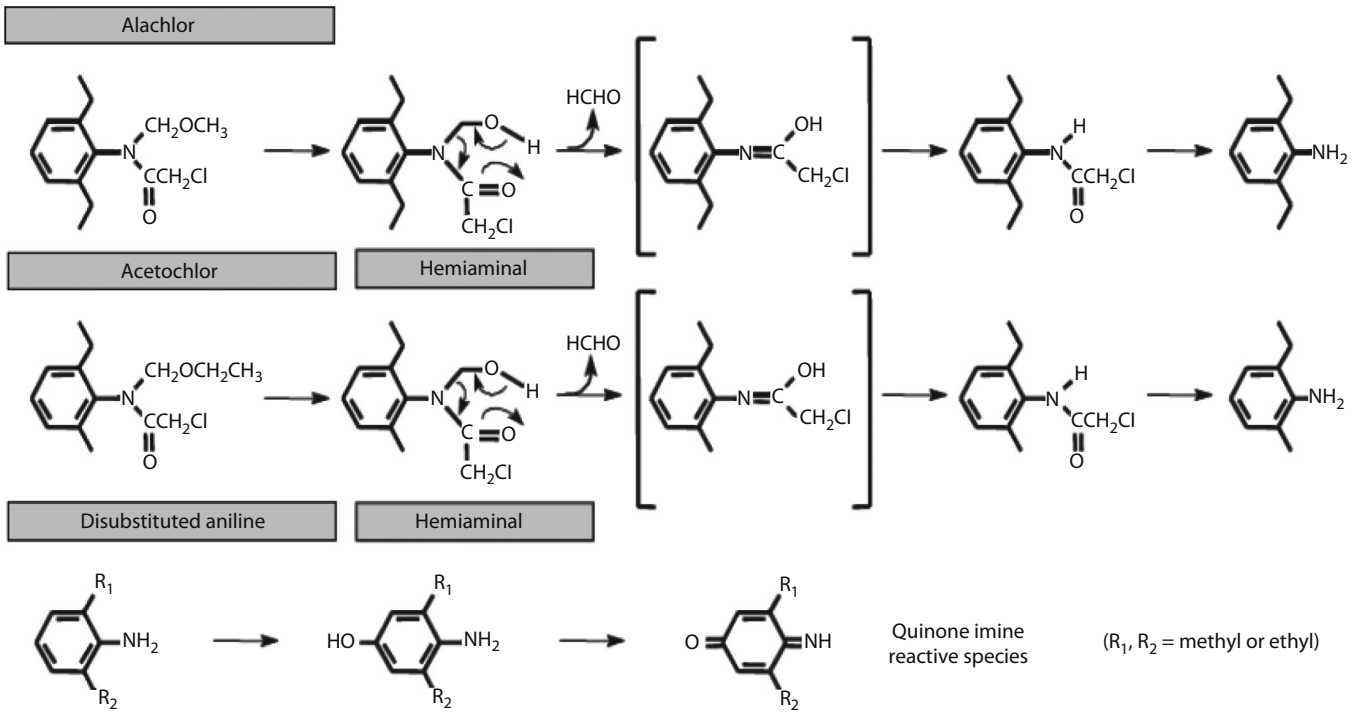

FIGURE 16.26 Chloroacetamide common mechanism grouping.

TABLE 16.71
Structures, Uses, and Hazard Profiles for the Chloroacetamide Inhibitors of Very-Long-Chain Fatty Acid Synthesis (HRAC Code K3)

Herbicide	Structure	Principal Use/Crop	Application Rate (g a.i./ha)
Alachlor (Lasso®)[37,280]		Corn, beans, peanuts, sorghum, soybeans, sunflowers, and ornamentals	1500–4500
Acetochlor (Surpass®)[37,280]		Corn, soybeans, sorghum, and wheat	900–3360
Metolachlor (Dual®)[37,280]		Corn, soybeans, sorghum, cucurbits, onions, peas, pecans, peppers, potatoes, and sugar beets	1250–6200
Dimethenamid (Frontier®)[37,280]		Corn and soybeans	850–1440

	Irritation		LD_{50} (mg/kg)				
Herbicide	Eye	Skin	Oral	Dermal	LC_{50} (mg/L) Inhalation	Sensitization Potential	Signal Word
Alachlor	Nonirritant	Nonirritant	930	13,300	>1.04	Positive	Caution
Acetochlor	Slight irritant	Nonirritant	2148	4166	>3.0	Positive	Caution
Metolachlor	Nonirritant	Minimal irritant	>2780	>10,000	>1.75	Positive	Caution
Dimethenamid	Slight irritant	Nonirritant	1570	>2000	>5.0	Positive	Caution

Herbicide	Species/Study	NOEL (mg/kg/day)	Toxicity Study	Hazard Indicator
Alachlor[230,248,470]	Rat/2 years	2.5	Mutagenicity	Positive (UDS)
	Dog/52 weeks	1.0	Developmental	Not teratogenic
	Mouse/18 months	16.6	Reproductive	Not a reproductive toxin
	RfD	0.01	Oncogenicity	C/RfD (nasal in rats; lungs in mice)
Acetochlor[248,250,471,472]	Rat/2 years	8.0	Mutagenicity	Positive (CHO, UDS, mouse lymphoma)
	Dog/52 weeks	2.0	Developmental	Not teratogenic
	Mouse/18 months	13	Reproductive	Not a reproductive toxin
	RfD	0.02	Oncogenicity	B2 (liver, thyroid, and nasal tumors in rats; lung tumors in mice)
Metolachlor[248,472]	Rat/2 years	15	Mutagenicity	Not mutagenic
	Dog/52 weeks	10	Developmental	Not teratogenic
	Mouse/18 months	120	Reproductive	Not a reproductive toxin
	RfD	0.1	Oncogenicity	C/RfD (liver tumors in female rats)
Dimethenamid[473]	Rat/2 years	5.0	Mutagenicity	Weakly positive (CHO: UDS)
	Dog/52 weeks	9.6	Developmental	Not teratogenic
	Mouse/18 months	40	Reproductive	Not a reproductive toxin
	RfD	0.05	Oncogenicity	C/RfD (livers, ovaries in female rats)

Cellulose and Lipid Synthesis Inhibitors (HRAC Code L and N)

Isoxaben is a member of the benzamide class of herbicides that block the incorporation of glucose into cellulose.[251] This mechanism whereby isoxaben has this effect is not well understood, but it is unlikely relevant to man. Quinclorac also blocks the radiolabeled uptake of glucose into cellulose in certain monocot species.[252] However, it has also been suggested that quinclorac activates the auxin receptor, which has been tentatively identified,[253] leading to increased ACC (1-aminocyclopropane-1-carboxylic acid) synthase activity that results in not only the production of ethylene but also the increased amount of cyanide (Figure 16.27). Ethylene triggers biochemical changes leading to senescence in plants but cyanide, which is formed in grasses treated with quinclorac, is directly phytotoxic.[254] This pathway is not present in mammals, although TIR1 has homology with the human SKP2 (S-phase kinase–associated protein) and its corresponding gene.[255]

The herbicidal MOA for the thiocarbamate herbicide butylate is through the inhibition of fatty acid synthesis. Inhibition is achieved, not by blocking ACCase (Figure 16.16), but rather by inhibiting long-chain fatty acid synthesis (Figure 16.25). Some of the thiocarbamate herbicides (EPTC, pebulate, and cycloate) have been determined to belong to a common mechanism grouping with the carbamate insecticides, based upon their ability to inhibit acetylcholinesterase.[98] However, the most sensitive toxicological endpoint of this class of herbicide is sciatic nerve degeneration, and it is the NOELs for these endpoints that are used to assess acute and chronic risks.[256] The EPA did not establish a common mechanism grouping for the thiocarbamate herbicides based upon neuropathology because they concluded that the proposed mechanism underlying this response[257] was not adequately understood.[258]

The structures, uses, and hazard profiles of the cellulose synthesis inhibitors isoxaben and quinclorac, as well as the lipid synthesis inhibitors represented by butylate, are given in Table 16.72.

Isoxaben exhibits low acute toxicity and is only moderately toxic in repeat-dose studies (chronic RfD = 0.05 mg/kg/day), but it is a developmental toxin at maternally toxic doses. There was a positive micronucleus test, and there were adrenal gland and liver tumors.

The toxicity profile for butylate is unremarkable. It was not neurotoxic, although it was positive in the skin sensitization study.

Synthetic Auxin Mimics (Phenoxy, Benzoic, and Pyridine Acids) (HRAC Code O)

Indole 3-acetic acid, which is the plant hormone auxin, plays a critical role in regulating plant cell growth and differentiation by binding to its receptor(s).[259–261] The mechanism of auxin signaling has been the subject of intense research efforts,[262,263] and progress has been made in identifying the critical receptor proteins, the TIR1, F-box proteins (AFB1, AFB2, and AFB3 in *Arabidopsis*),[253,260,261] which are involved in the activation of these signaling pathways. Auxin binding mediates the association of a set of transcriptional repressor proteins (AUX/IAA proteins; 29 members in *Arabidopsis*) with another protein, the SCF complex. The SCF complex mediates polyubiquitination of the repressor proteins, which are then targeted for degradation by proteasome. With the repressor proteins removed, various sets of genes are induced, including those involved with cell elongation and cell division.[259] Grossman has suggested that the herbicidal action of the auxin mimics is through auxin-induced ACC synthase upregulation that results in ethylene-mediated senescence as well as cyanide-mediated phytotoxicity.[217,254] These pathways are not present in mammalian systems, although homologues of the F-box proteins have been identified in mammals.[255]

Table 16.73 provides the structures, uses, and hazard profiles for the auxin mimics, 2,4-D (phenoxy) and dicamba (benzoic), as well as for clopyralid and picloram (pyridine acids). The hazard profile for 2,4-D is unremarkable. Dicamba,

TABLE 16.72
Structures, Uses, and Hazard Profiles for Benzamide, Quinoline Carboxylic Acid, and Thiocarbamate Inhibitors of Cellulose or Lipid Synthesis (HRAC Codes L and N)

Herbicide	Structure	Principal Use/Crop	Application Rate (g a.i./ha)
Isoxaben (Gallery®)[37,280]		Turf, ornamentals, nonbearing fruit trees, nut trees, and conifers	50–1000
Quinclorac (Facet®)[37,280]		Soybeans and rice	250–750
Butylate (Sutan®)[37,280]		Corn	3000–4000

	Irritation		LD_{50} (mg/kg)				
Herbicide	**Eye**	**Skin**	**Oral**	**Dermal**	**LC_{50} (mg/L) Inhalation**	**Sensitization Potential**	**Signal Word**
Isoxaben	Moderate irritant	Sight irritant	>10,000	>2000	>2.68	Negative	Caution
Quinclorac	Nonirritant	Nonirritant	2680	>2000	>5.2	—	Caution
Butylate	Nonirritant	Mild irritant	4659	1659	4.64	Positive	Caution

Herbicide	Species/Study	NOEL (mg/kg/day)	Toxicity Study	Hazard Indicator
Isoxaben[403]	Rat/2 years	5.0	Mutagenicity	Positive micronucleus test
	Dog/52 weeks	10.0	Developmental	Positive at maternal toxic doses
	Mouse/18 months	14.3	Reproductive	Not a reproductive toxin
	RfD or ADI	0.05	Oncogenicity	C (Adrenal and liver tumors)
Quinclorac[254]	Rat/2 years	675	Mutagenicity	Not mutagenic
	Dog/52 weeks	33	Developmental	Not teratogenic
	Mouse/18 months	42	Reproductive	Not a reproductive toxin
	RfD or ADI	0.38	Oncogenicity	Not carcinogenic
Butylate[403,475]	Rat/2 years	50	Mutagenicity	No evidence
	Dog/52 weeks	5.0	Developmental	Not teratogenic
	Mouse/18 months	20	Reproductive	Not a reproductive toxin
	RfD or ADI	0.05	Oncogenicity	E (No evidence)

clopyralid, and picloram are all eye irritants, and dicamba and picloram are potential skin sensitizers. Otherwise, the hazard profiles for the other chemicals are also unremarkable.

Semicarbazones (HRAC Code P)

The semicarbazones, represented here by diflufenzopyr-sodium, are often used in mixtures with dicamba to block auxin transport via carrier protein binding.[37] The structure, uses, and hazard profile of diflufenzopyr-sodium are listed in Table 16.74.

Herbicides with Unknown Mechanism of Action (HRAC Code Z)

The structure, uses, and hazard profile of monosodium methanearsonic acid (MSMA) are presented in Table 16.75.

MSMA, an organic arsenical, is a mild skin and eye irritant. MSMA caused decreased fertility in the rat reproduction study, and it is classified as a category B2 carcinogen (probable human carcinogen) based on bladder tumor incidence rates in rats.

TABLE 16.73
Structures, Uses, and Hazard Profiles for the Phenoxy, Benzoic, and Pyridine Acid Herbicides That Mimic Indole Acetic Acid (Auxin) (HRAC Code O)

Herbicide	Structure	Principal Use/Crop	Application Rate (g a.i./ha)
2,4-D (Wedare®)[37,280]		Turf, cereals, sorghum, corn, soybeans, asparagus, and fruit trees	280–2240
MCPA (CHIPTOX®)[37,280]		Cereals, flax, rice, vegetables, grasslands, and under fruit trees	280–2250
Dicamba (Banvel®)[37,280]		Corn, turf, sorghum, cereals, pastures, and asparagus	100–400
