Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

We would also like to thank Julie Shelby, Leslie Ardebili, and Ralph Chambers for their help in preparing this manuscript.

FOREWORD

Disturbances in cardiac rhythm occur in a large proportion of the population. Arrhythmias can have sequelae that range from inconsequential to life-shortening. Sudden cardiac deaths and chronic disability are among the most frequent serious complications resulting from arrhythmias.

Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine includes an excellent section on rhythm disturbances edited and largely written by Douglas Zipes, the most accomplished and respected investigator and clinician in this field. However, there are many subjects that simply cannot be discussed in sufficient detail, even in a 2000-page, densely packed book. For this reason, the current editors and I decided to commission a series of companions to the parent title. We were extremely fortunate to enlist Dr. Zipes' help in editing and writing *Clinical Arrhythmology and Electrophysiology*. Dr. Zipes, in turn, enlisted two talented collaborators, Drs. Ziad F. Issa and John M. Miller, to work with him to produce this excellent volume.

This second edition is superbly illustrated, with the number of figures and tables increasing by almost half from its predecessor. What has not changed, however, is the very high quality of the content, which is accurate, authoritative, and clear; second, it is as up-to-date as last month's journals; and third, the writing style and illustrations are consistent throughout with little, if any, duplication. As this important branch of cardiology has grown, so has this book.

The first seven chapters, on Molecular Mechanisms of Cardiac Electrical Activity, Cardiac Ion Channels, Electrophysiological Mechanisms of Cardiac Arrhythmias, Electrophysiological Testing, Conventional Intracardiac Mapping Techniques, Advanced Mapping and Navigation Modalities, and Ablation Energy Sources, provide a superb introduction to the field. This is followed by 24 chapters on individual arrhythmias, each following a similar outline. Here, the authors lead us from a basic understanding of the arrhythmia to its clinical recognition, natural history, and management. The latter is moving rapidly from being largely drug-based to device-based, although many patients receive combination device-drug therapy. These options, as well as ablation therapy, are clearly spelled out as they apply to each arrhythmia. The final chapter discusses the complications of catheter ablation of cardiac arrhythmias.

We are proud to include *Clinical Arrhythmology and Electrophysiology* as a Companion to *Braunwald's Heart Disease*, and we are fully confident that it will prove to be valuable to cardiologists, internists, investigators, and trainees.

PREFACE

Readers' responses to the first edition of this textbook have been extremely gratifying, so much so that we were encouraged to update and revise the text relatively early after its initial publication in 2009. As all who work in this field know, however, the knowledge base is changing very rapidly at virtually all levels, from basic understanding of mechanisms to new ablation techniques, mapping, imaging advances, and development of new ablation energy sources. In addition, we are learning about new clinical states that have been "right under our noses" for a long time, such as the short QT and J wave syndromes. We have therefore added new chapters on those topics as well as on molecular mechanisms and ion channels, advanced mapping and navigation, and arrhythmias in congenital heart disease. For clarity, we have divided the idiopathic ventricular tachycardias (VTs) into adenosine- and verapamil-sensitive types and have written new chapters on both epicardial VTs and VTs in the different cardiomyopathies. The "old" chapters are no longer old; all have been totally revised and expanded with updated information. Additionally, we have included 27 new videos that vividly exemplify a variety of techniques and mapping observations.

As with the first edition, this book has been written by just the three of us, so that once again we can "explain, integrate, coordinate

and educate in a comprehensive, cohesive fashion while avoiding redundancies and contradictions." Having lived through the changes of the past several years, we have been able to extract and write about those advances that we think are important and useful to the readers. This is similar to a travel guidebook written by someone who has actually stayed in that unique hotel or eaten in that special restaurant. We have experienced the progress firsthand and are able to pass on our experiences to you. In addition, as before—but expanded even further—readers have the option to delve deeper into basic mechanisms or invasive procedures... or not, depending on the level of interest. We have tried to keep the appeal for all levels of learners, from the beginner to the experienced electrophysiologist, so that you can stop reading with the fascinating array of ECGs or dig deeper into the mechanism of calcium handling—your call. We hope you enjoy learning from this second edition.

Ionic Equilibrium

The lipid bilayer of the cell membrane is hydrophobic and impermeable to water-soluble substances such as ions. Hence, for the hydrophilic ions to be able to cross the membrane, they need hydrophilic paths that span the membrane (i.e., pores), which are provided by transmembrane proteins called ion channels. Once a hydrophilic pore is available, ions move passively across the membrane driven by two forces: the electrical gradient (voltage difference) and the chemical gradient (concentration difference). The chemical gradient forces the ions to move from a compartment of a higher concentration to one of lower concentration. The electrical gradient forces ions to move in the direction of their inverse sign (i.e., cations [positively charged ions] move toward a negatively charged compartment, whereas anions [negatively charged ions] move toward a positively charged compartment). Because the chemical and electrical gradients can oppose each other, the direction of net ion movement will depend on the relative contributions of chemical gradient and electrical potential (i.e., the net electrochemical gradient), so that ions tend to move spontaneously from a higher to a lower electrochemical potential.^{1,3}

The movement of an ion down its chemical gradient in one direction across the cell membrane results in build-up of excess charge carried by the ion on one side of the membrane, which generates an electrical gradient that impedes continuing ionic movement in the same direction. When the driving force of the electrical gradient across the membrane becomes equal and opposite to the force generated by the chemical gradient, the ion is said to be in electrochemical equilibrium, and the net transmembrane flux (or current) of that particular ion is zero. In this setting, the electrical potential is called the equilibrium potential (E_{ion}) (reversal potential or Nernst potential) of that individual ion. The E_{ion} for a given ion depends on its concentration on either side of the membrane and the temperature, and it measures the voltage that the ion concentration gradient generates when it acts as a battery. At membrane voltages more positive to the reversal potential of the ion, passive ion movement is outward, whereas it is inward at a membrane potential (also known as transmembrane potential; E_m) more negative to the Nernst potential of that channel.^{1,3}

When multiple ions across a membrane are removed from their electrochemical equilibrium, each ion will tend to force the E_m toward its own E_{ion} . The contribution of each ion type to the overall E_m at any given moment is determined by the instantaneous permeability of the plasma membrane to that ion. The larger the membrane conductance to a particular ion, the greater is the ability of that ion to bring the E_m toward its own E_{ion} . Hence, the E_m is the average of the E_{ion} of all the ions to which the membrane is permeable, weighed according to the membrane conductance of each individual ion relative to the total ionic conductance of the membrane.^{1,2}

Transmembrane Potentials

All living cells, including cardiomyocytes, maintain a difference in the concentration of ions across their membranes. There is a slight excess of positive ions on the outside of the membrane and a slight

excess of negative ions on the inside of the membrane, resulting in a difference in the electrical charge (i.e., voltage difference) across the cell membrane, called the membrane potential (E_m). A membrane that exhibits an E_m is said to be polarized.²

In nonexcitable cells, and in excitable cells in their baseline states (i.e., not conducting electrical signals), the E_m is held at a relatively stable value, called the resting potential. All cells have a negative resting E_m (i.e., the cytoplasm is electrically negative relative to the extracellular fluid), which arises from the interaction of ion channels and ion pumps embedded in the membrane that maintain different ion concentrations on the intracellular and extracellular sides of the membrane.²

When an ion channel opens, it allows ion flux across the membrane that generates an electrical current (I). This current affects the E_m , depending on the membrane resistance (R), which refers to the ratio between the E_m and electrical current, as shown in Ohm's law: $E = I \times R$ or $R = E/I$. Resistance arises from the fact that the membrane impedes the movement of charges across it; hence, the cell membrane functions as a *resistor*. Conductance describes the ability of a membrane to allow the flux of charged ions in one direction across the membrane. The more permeable the membrane is to a particular ion, the greater is the conductance of the membrane to that ion. Membrane conductance (g) is the reciprocal of R : $g = 1/R$.¹

Because the lipid bilayer of the cell membrane is very thin, accumulation of charged ions on one side gives rise to an electrical force (potential) that pulls oppositely charged particles toward the other side. Hence, the cell membrane functions as a *capacitor*. Although the absolute potential differences across the cell membrane are small, they give rise to enormous electrical potential gradients because they occur across a very thin surface. As a consequence, apparently small changes in E_m can produce large changes in potential gradient and powerful forces that are able to induce molecular rearrangement in membrane proteins, such as those required for opening and closing ion channels embedded in the cell membrane. The capacitance of the membrane is generally fixed and unaffected by the molecules that are embedded in it. In contrast, membrane resistance is highly variable and depends on the conductance of ion channels embedded in the membrane.^{2,3}

The sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and chloride (Cl^-) ions are the major charge carriers, and their movement across the cell membrane creates a flow of current that generates excitation and signals in cardiac myocytes. The electrical current generated by the flux of an ion across the membrane is determined by the membrane conductance to that ion (g_{ion}) and the potential (voltage) difference across the membrane. The potential difference represents the potential at which there is no net ion flux (i.e., the E_{ion}) and the actual E_m : $current = g_{ion} \times (E_m - E_{ion})$.^{1,4}

By convention, an inward current increases the electropositivity within the cell (i.e., causes depolarization of the E_m [to be less negative]) and can result from either the movement of positively charged ions (most commonly Na^+ or Ca^{2+}) into the cell or the efflux of negatively charged ions (e.g., Cl^-) out of the cell. An outward current increases the electronegativity within the cell

(i.e., causes hyperpolarization of the E_m [to become more negative]) and can result from either the movement of anions into the cell or the efflux of cations (most commonly K^+) out of the cell.³

Opening and closing of ion channels can induce a departure from the relatively static resting E_m , called a depolarization if the interior voltage rises (becomes less negative) or a hyperpolarization if the interior voltage becomes more negative. The most important ion fluxes that depolarize or repolarize the membrane are passive (i.e., the ions move down their electrochemical gradient without requiring the expenditure of energy), occurring through transmembrane ion channels. In excitable cells, a sufficiently large depolarization can evoke a short-lasting all-or-none event called an action potential, in which the E_m very rapidly undergoes specific and large dynamic voltage changes.¹

Both resting E_m and dynamic voltage changes such as the action potential are caused by specific changes in membrane permeabilities for Na^+ , K^+ , Ca^{2+} , and Cl^- , which, in turn, result from concerted changes in functional activity of various ion channels, ion transporters, and exchangers.³

The Cardiac Action Potential

During physiological electrical activity, the E_m is a continuous function of time. The current flowing through the cell membrane is, at each instant, provided by multiple channels and transporters carrying charge in opposite directions because of their different ion selectivity. The algebraic summation of these contributions is referred to as net transmembrane current.¹

The cardiac action potential reflects a balance between inward and outward currents. When a depolarizing stimulus (typically from an electric current from an adjacent cell) abruptly changes the E_m of a resting cardiomyocyte to a critical value (the threshold level), the properties of the cell membrane and ion conductances change dramatically, precipitating a sequence of events involving the influx and efflux of multiple ions that together produce the action potential of the cell. In this fashion, an electrical stimulus is conducted from one cell to all the cells that are adjacent to it.²

Unlike skeletal muscle, cardiac muscle is electrically coupled so that the wave of depolarization propagates from one cell to the next, independent of neuronal input. The heart is activated by capacitive currents generated when a wave of depolarization approaches a region of the heart that is at its resting potential. Unlike ionic currents, which are generated by the flux of charged ions across the cell membrane, capacitive currents are generated by the movement of electrons toward and away from the surfaces of the membrane.^{2,3} The resulting decrease in positive charge at the outer side of the cell membrane reduces the negative charge on the intracellular surface of the membrane. These charge movements, which are carried by electrons, generate a capacitive current. When an excitatory stimulus causes the E_m to become less negative and beyond a threshold level (approximately -65 mV for working atrial and ventricular cardiomyocytes), Na^+ channels activate (open) and permit an inward Na^+ current (I_{Na}), resulting in a rapid shift of the E_m to a positive voltage range. This event triggers a series of successive opening and closure of selectively permeable ion channels. The direction and magnitude of passive ion movement (and the resulting current) at any given transmembrane voltage are determined by the ratio of the intracellular and extracellular concentrations and the reversal potential of that ion, with the net flux being larger when ions move from the more concentrated side.³

The threshold is the lowest E_m at which opening of enough Na^+ channels (or Ca^{2+} channels in the setting of nodal cells) is able to initiate the sequence of channel openings needed to generate a propagated action potential. Small (subthreshold) depolarizing stimuli depolarize the membrane in proportion to the strength of the stimulus and cause only local responses because they do not open enough Na^+ channels to generate depolarizing currents large enough to activate nearby resting cells (i.e., insufficient to initiate a regenerative action potential). On the other hand, when the stimulus is sufficiently intense to reduce the E_m to a threshold

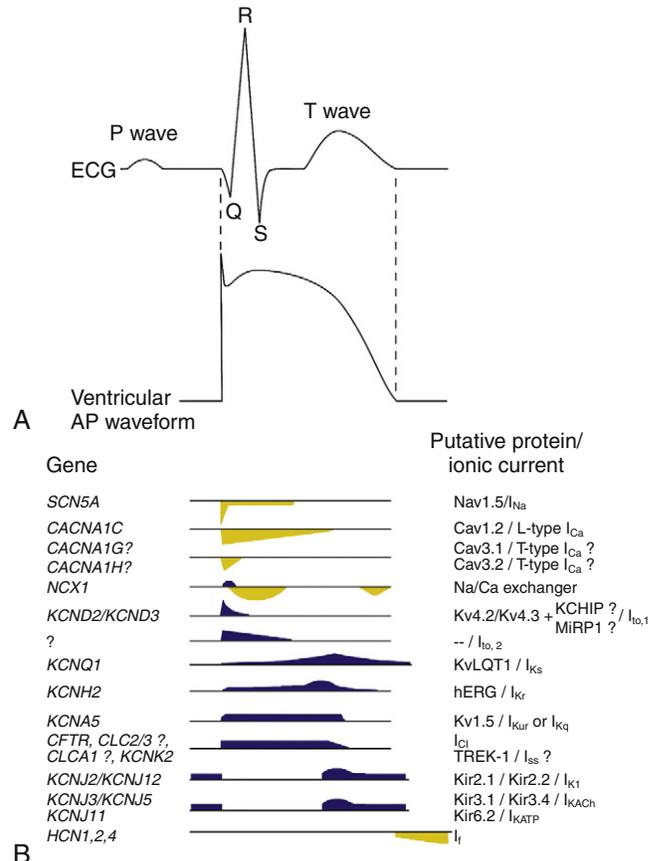

FIGURE 1-1 A, Depiction of a standard ECG tracing with respect to its underlying ventricular action potential (AP). B, The different ionic currents (see text) that contribute to action potential generation and the putative encoding genes are shown. Depolarizing currents are shown in yellow, repolarizing currents in blue. (Modified with permission from Saenena JB, Vrints CJ: Molecular aspects of the congenital and acquired long QT syndrome: clinical implications. *J Mol Cell Cardiol* 44:633-646, 2007.)

value, regenerative action potential results, whereby intracellular movement of Na^+ depolarizes the membrane more, a process that increases conductance to Na^+ more, which allows more Na^+ to enter, and so on. In this fashion, the extent of subsequent depolarization becomes independent of the initial depolarizing stimulus, and more intense stimuli do not produce larger action potential responses; rather, an all-or-none response results.²

Electrical changes in the action potential follow a relatively fixed time and voltage relationship that differs according to specific cell types. Whereas the entire action potential takes several milliseconds in nerve cells, the cardiac action potential lasts several hundred milliseconds. The course of the action potential can be divided into five phases (numbered 0 to 4). Phase 4 is the resting E_m , and it describes the E_m when the cell is not being stimulated.

During the action potential, membrane voltages fluctuate in the range of -94 to $+30$ mV (Fig. 1-1). With physiological external K^+ , the reversal potential of K^+ (E_K) is approximately -94 mV, and passive K^+ movement during an action potential is out of the cell. On the other hand, because the calculated reversal potential of a cardiac Ca^{2+} channel (E_{Ca}) is $+64$ mV, passive Ca^{2+} flux is into the cell.⁵

In normal atrial and ventricular myocytes and in His-Purkinje fibers, action potentials have very rapid upstrokes, mediated by the fast inward I_{Na} . These potentials are called fast response potentials. In contrast, action potentials in the normal sinus and atrioventricular (AV) nodal cells and many types of diseased tissues have very slow upstrokes, mediated by a slow inward, predominantly L-type voltage-gated Ca^{2+} current (I_{CaL}), rather than by the fast inward I_{Na} (Fig. 1-2). These potentials have been termed slow response potentials.^{2,5}

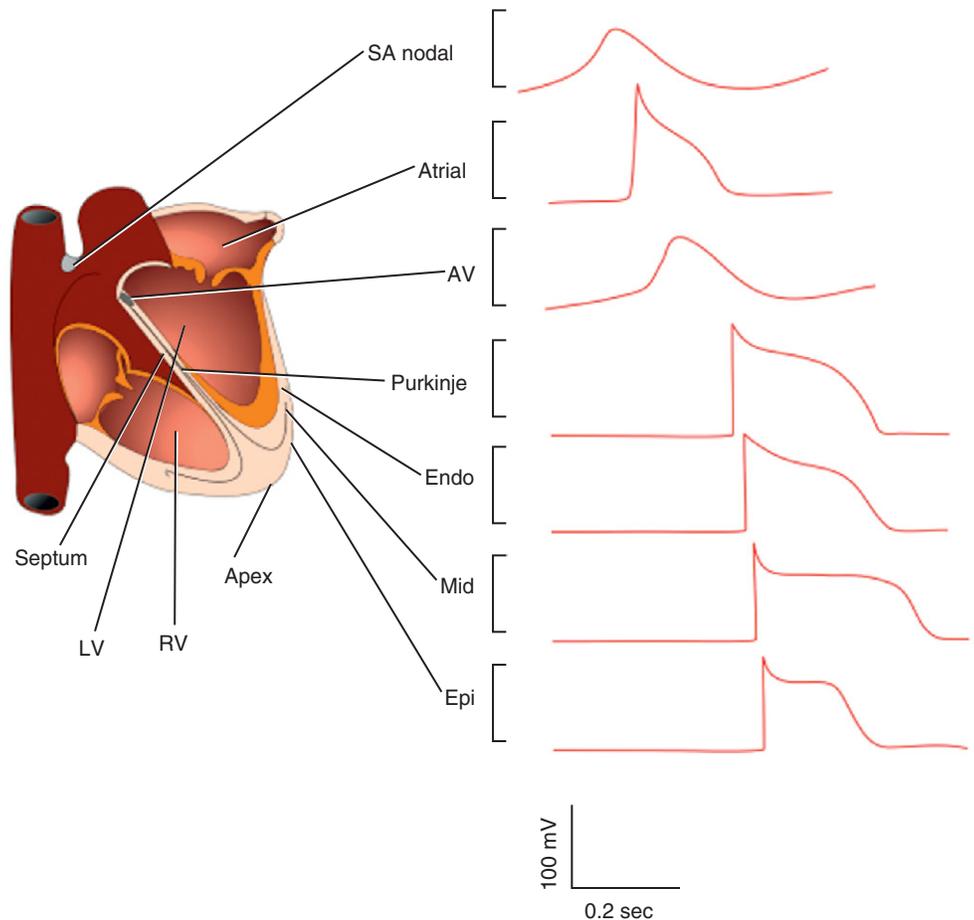

FIGURE 1-2 Action potential waveforms, displaced in time to reflect the temporal sequence of propagation, vary in different regions of the heart. AV = atrioventricular (node); endo = endocardial; epi = epicardial; mid = midmyocardial; LV = left ventricle; RV = right ventricle; SA = sinoatrial. (Modified with permission from Nerbonne JM: *Heterogeneous expression of repolarizing potassium currents in the mammalian myocardium*. In Zipes DP, Jalife J, editors: *Cardiac electrophysiology: from cell to bedside*, ed 5, Philadelphia, 2009, Saunders, pp 293-305.)

The Fast Response Action Potential

PHASE 4: THE RESTING MEMBRANE POTENTIAL

The E_m of resting atrial and ventricular cardiomyocytes remains steady throughout diastole. The resting E_m is caused by the differences in ionic concentrations across the membrane and the selective membrane permeability (conductance) to various ions. Large concentration gradients of Na^+ , K^+ , Ca^{2+} , and Cl^- across the cell membrane are maintained by the ion pumps and exchangers (Table 1-1).

Under normal conditions, the resting membrane is most permeable to K^+ and relatively impermeable to other ions. K^+ has the largest resting membrane conductance (g_{K} is 100 times greater than g_{Na}) because of the abundance of open K^+ channels at rest, whereas Na^+ and Ca^{2+} channels are generally closed. Thus, K^+ exerts the largest influence on the resting E_m . As a consequence, the resulting E_m is almost always close to the K^+ reversal potential (E_m approximates E_{K}). The actual resting E_m is slightly less negative than E_{K} because the cell membrane is slightly permeable to other ions.²

The inwardly rectifying K^+ (Kir) channels underlie an outward K^+ current (I_{K1}) responsible for maintaining the resting potential near the E_{K} in atrial, His-Purkinje, and ventricular cells, under normal conditions.^{6,7} Kir channels preferentially allow currents of K^+ ions to flow into the cell with a strongly voltage-dependent decline of K^+ efflux (i.e., reduction of outward current) on membrane depolarization. As such, I_{K1} is a strong rectifier that passes K^+ currents over a limited range of E_m (see Chap. 2 for detailed discussion on the concept of rectification); at a negative E_m , I_{K1} conductance is much larger than that of any other current, thus, it clamps the resting E_m close to the reversal potential for K^+ (E_{K}). I_{K1} density is

much higher in ventricular than in atrial myocytes, a feature that protects the ventricular cell from pacemaker activity. By contrast, I_{K1} is almost absent in sinus and AV nodal cells, thus allowing for relatively more depolarized resting diastolic potentials compared with atrial and ventricular myocytes (Table 1-2).²

A unique property of Kir currents is the unusual dependence of rectification on extracellular K^+ concentration. Specifically, on increase in extracellular K^+ , the I_{K1} current-voltage relationship shifts nearly in parallel with the E_{K} and leads to a crossover phenomenon. One important consequence of such behavior is that at potentials positive to the crossover, K^+ conductance increases rather than decreases, against an expectation based on a reduced driving force for K^+ ions as a result of elevated extracellular K^+ concentration.^{6,8}

The resting E_m also is powered by the $\text{Na}^+\text{-K}^+$ adenosine triphosphatase (ATPase) (the $\text{Na}^+\text{-K}^+$ pump), which helps establish concentration gradients of Na^+ and K^+ across the cell membrane. Under physiological conditions, the $\text{Na}^+\text{-K}^+$ pump transports two K^+ ions into the cell against its chemical gradient and three Na^+ ions outside against its electrochemical gradient at the cost of one adenosine triphosphate (ATP) molecule. Because the stoichiometry of ion movement is not 1:1, the $\text{Na}^+\text{-K}^+$ pump is electrogenic and generates a net outward movement of positive charges (i.e., an outward current). At faster heart rates, the rate of $\text{Na}^+\text{-K}^+$ pumping increases to maintain the same ionic gradients, thus counteracting the intracellular gain of Na^+ and loss of K^+ with each depolarization.

Although Ca^{2+} does not contribute directly to the resting E_m (since the voltage-activated Ca^{2+} channels are closed at the hyperpolarized resting E_m), changes in intracellular free Ca^{2+} concentration can affect other membrane conductance values. Increases in intracellular Ca^{2+} levels can stimulate the $\text{Na}^+\text{-Ca}^{2+}$ exchanger

TABLE 1-1 Intracellular and Extracellular Ion Concentrations and Equilibrium Potentials in Cardiomyocytes

ION	EXTRACELLULAR CONCENTRATION (mM)	INTRACELLULAR CONCENTRATION (mM)	EQUILIBRIUM POTENTIAL (mV)

AV = atrioventricular.

(I_{Na-Ca}), which exchanges three Na⁺ ions for one Ca²⁺ ion; the direction depends on the Na⁺ and Ca²⁺ concentrations on the two sides of the membrane and the E_m difference. At resting E_m and during a spontaneous sarcoplasmic reticulum Ca²⁺ release event, this exchanger would generate a net Na⁺ influx, possibly causing transient membrane depolarizations.³

PHASE 0: THE UPSTROKE—RAPID DEPOLARIZATION

On excitation of the cardiomyocyte by electrical stimuli from adjacent cells, its resting E_m (approximately –85 mV) depolarizes, leading to opening (activation) of Na⁺ channels from its resting (closed) state and enabling a large and rapid influx of Na⁺ ions (inward I_{Na}) into the cell down their electrochemical gradient. As a consequence of increased Na⁺ conductance, the excited membrane no longer behaves like a K⁺ electrode (i.e., exclusively permeable to K⁺), but more closely approximates an Na⁺ electrode, and the membrane potential moves toward the Na⁺ E_{ion} (E_{Na} ; see Table 1-1). Once an excitatory stimulus depolarizes the E_m beyond the threshold for activation of Na⁺ channels (approximately –65 mV), the activated I_{Na} is regenerative and no longer depends on the initial depolarizing stimulus; the influx of Na⁺ ions further depolarizes the membrane and thereby increases conductance to Na⁺ more, which allows more Na⁺ to enter.^{2,9}

Normally, activation of Na⁺ channels is transient; fast inactivation (closing of the pore) starts simultaneously with activation, but because inactivation is slightly delayed relative to activation, the channels remain transiently (less than 1 millisecond) open to conduct I_{Na} during phase 0 of the action potential before it closes. Additionally, the influx of Na⁺ into the cell increases the positive intracellular charges and reduces the driving force for Na⁺. When the E_{Na} is reached, no further Na⁺ ions enter the cell.⁹

The rate at which depolarization occurs during phase 0, that is, the maximum rate of change of voltage over time, is indicated by the expression dV/dt_{max} , which is a reasonable approximation of the rate and magnitude of Na⁺ entry into the cell and a determinant of conduction velocity for the propagated action potential.²

The threshold for activation of I_{CaL} is approximately –30 to –40 mV. Although I_{CaL} is normally activated during phase 0 by the regenerative depolarization caused by the fast I_{Na} , I_{CaL} is much smaller than the peak I_{Na} . The amplitude of I_{CaL} is not maximal near the action potential peak because of the time-dependent nature of I_{CaL} activation, as well as the low driving force ($E_m - E_{Ca}$) for I_{CaL} . Therefore, I_{CaL} contributes little to the action potential until the fast I_{Na} is inactivated, after completion of phase 0. As a result, I_{CaL} affects mainly the plateau of action potentials recorded in atrial and ventricular muscle and His-Purkinje fibers. On the other hand, I_{CaL} can play a

prominent role in the upstroke of slow response action potentials in partially depolarized cells in which the fast Na⁺ channels have been inactivated.²

PHASE 1: EARLY REPOLARIZATION

Phase 0 is followed by phase 1 (early repolarization) during which the membrane repolarizes rapidly and transiently to almost 0 mV (early notch), partly because of the inactivation of I_{Na} and concomitant activation of several outward currents. The transient outward K⁺ current (I_{to}) is mainly responsible for phase 1 of the action potential. I_{to} rapidly activates (with time constants less than 10 milliseconds) by depolarization and then rapidly inactivates (25 to 80 milliseconds for the fast component of I_{to} [$I_{to,f}$], and 80 to 200 milliseconds for the slow component of I_{to} [$I_{to,s}$]). The influx of K⁺ ions via I_{to} channels partially repolarizes the membrane, thus shaping the rapid (phase 1) repolarization of the action potential and setting the height of the initial plateau (phase 2; see Fig. 1-1). Additionally, an Na⁺ outward current through the Na⁺-Ca²⁺ exchanger operating in reverse mode likely contributes to early repolarization.^{3,6,10}

PHASE 2: THE PLATEAU

Phase 2 (plateau) represents a delicate balance between the depolarizing inward currents (I_{CaL} and a small residual component of inward I_{NaL}) and the repolarizing outward currents (ultrarapidly [I_{Kur}], rapidly [I_{Kr}], and slowly [I_{Ks}] activating delayed outward rectifying currents; see Fig. 1-1). Phase 2 is the longest phase of the action potential, lasting tens (atrium) to hundreds of milliseconds (His-Purkinje system and ventricle). The plateau phase is unique among excitable cells and marks the phase of Ca²⁺ entry into the cell. It is the phase that most clearly distinguishes the cardiac action potential from the brief action potentials of skeletal muscle and nerve.²

I_{CaL} is activated by membrane depolarization, is largely responsible for the action potential plateau, and is a major determinant of the duration of the plateau phase. I_{CaL} also links membrane depolarization to myocardial contraction. L-type Ca²⁺ channels activate on membrane depolarization to potentials positive to –40 mV. I_{CaL} peaks at an E_m of 0 to +10 mV and tends to reverse at +60 to +70 mV, following a bell-shaped current-voltage relationship.³

Na⁺ channels also make a contribution, although minor, to the plateau phase. After phase 0 of the action potential, some Na⁺ channels occasionally fail to inactivate or exhibit prolonged opening or reopening repetitively for hundreds of milliseconds after variable and prolonged latencies, resulting in a small inward I_{Na} (less than

1% of the peak I_{Na}). This persistent or “late” I_{Na} (I_{NaL}), along with I_{CaL} , helps maintain the action potential plateau.^{3,11,12}

I_{Kr} and I_{Ks} are activated at depolarized potentials. I_{Kr} activates relatively fast (in the order of tens of milliseconds) on membrane depolarization, thus allowing outward diffusion of K^+ ions in accordance with its electrochemical gradient, but voltage-dependent inactivation thereafter is very fast. Hence, only limited numbers of channels remain in the open state, whereas a considerable fraction resides in the nonconducting inactivated state. The fast voltage-dependent inactivation limits outward current through the channel at positive voltages and thus helps maintain the action potential plateau phase that controls contraction and prevents premature excitation. However, as the voltage becomes less positive at the end of the plateau phase of repolarization, the channels recover rapidly from inactivation; this process leads to a progressive increase in I_{Kr} amplitudes during action potential phases 2 and 3, with maximal outward current occurring before the final rapid declining phase of the action potential.^{6,12,13}

I_{Ks} , which is approximately 10 times larger than I_{Kr} , also contributes to the plateau phase. I_{Ks} activates in response to membrane depolarization to potentials greater than -30 mV and gradually increases during the plateau phase because its time course of activation is extremely slow, slower than any other known K^+ current, and steady-state amplitude is achieved only with extremely long membrane depolarization. Hence, the contribution of I_{Ks} to the net repolarizing current is greatest late in the plateau phase, particularly during action potentials of long duration. Importantly, although I_{Ks} activates slowly compared with action potential duration, it is also slowly inactivated. As heart rate increases, I_{Ks} increases because channel deactivation is slow and incomplete during the shortened diastole. This allows I_{Ks} channels to accumulate in the open state during rapid successive depolarizations and mediate the faster rate of repolarization. Hence, I_{Ks} plays an important role in determining the rate-dependent shortening of the cardiac action potential.^{6,12-14}

I_{Kur} is detected only in human atria but not in the ventricles, so that it is the predominant delayed rectifier current responsible for human atrial repolarization.^{3,12} The Na^+ - Ca^{2+} exchanger operating in forward mode and the Na^+ - K^+ pump provide minor current components during phase 2.

Importantly, during the plateau phase, membrane conductance to all ions falls to rather low values. Thus, less change in current is required near plateau levels than near resting potential levels to produce the same changes in E_m . In particular, K^+ conductance falls during the plateau phase as a result of inward rectification of I_{Kr} and I_{K1} (that is, voltage-dependent decline of K^+ efflux and hence reduction of outward current) on membrane depolarization, in spite of the large electrochemical driving force on K^+ ions during the positive phase of the action potential (phases 0, 1, and 2). This property allows membrane depolarization following Na^+ channel activation, slows membrane repolarization, and helps maintain a more prolonged cardiac action potential. This also confers energetic efficiency in the generation of the action potential.^{6,7,14}

PHASE 3: FINAL RAPID REPOLARIZATION

Phase 3 is the phase of rapid repolarization that restores the E_m to its resting value. Phase 3 is mediated by the increasing conductance of the delayed outward rectifying currents (I_{Kr} and I_{Ks}), the inwardly rectifying K^+ currents (I_{K1} and acetylcholine-activated K^+ current [I_{KACH}]), and time-dependent inactivation of I_{CaL} (see Fig. 1-1). Final repolarization during phase 3 results from K^+ efflux through the I_{K1} channels, which open at potentials negative to -20 mV.^{6,12-14}

PHASE 4: RESTORATION OF RESTING MEMBRANE POTENTIAL

During the action potential, Na^+ and Ca^{2+} ions enter the cell and depolarize the E_m . Although the E_m is quickly repolarized by the efflux of K^+ ions, restoration of transmembrane ionic concentration

gradients to the baseline resting state is necessary. This is achieved by the Na^+ - K^+ ATPase (Na^+ - K^+ pump, which exchanges two K^+ ions inside and three Na^+ ions outside) and by the Na^+ - Ca^{2+} exchanger (I_{Na-Ca} , which exchanges three Na^+ ions for one Ca^{2+} ion).

Reduction of cytosolic Ca^{2+} concentration during diastole is achieved by the reuptake Ca^{2+} by the sarcoplasmic reticulum via activation of the sarco/endoplasmic reticulum Ca^{2+} -ATPase Ca^{2+} pump (SERCA), in addition to extrusion across the sarcolemma via the Na^+ - Ca^{2+} exchanger. In the human heart under resting conditions, the time required for cardiac myocyte depolarization, contraction, relaxation, and recovery is approximately 600 milliseconds.^{5,15,16}

REGIONAL HETEROGENEITY OF THE ACTION POTENTIAL

Substantial differences in the expression levels of ion channels underlie the substantial heterogeneity in action potential duration and configuration between cardiomyocytes located in different cardiac regions. The characteristics of the action potential differ in atrial versus ventricular myocardium, as well as across the ventricular myocardial wall from endocardium, midmyocardium (putative M cells), to epicardium (see Fig. 1-2).^{3,12}

The density of I_{to} varies across the myocardial wall and in different regions of the heart. The markedly higher densities of I_{to} , together with the expression of I_{Kur} , accelerate the early phase of repolarization and lead to lower plateau potentials and shorter action potentials in atrial cells. In human ventricles, I_{to} densities are much higher in the epicardium and midmyocardium than in the endocardium. These regional differences are responsible for the shorter duration and the prominent phase 1 notch and the spike and dome morphology of epicardial and midmyocardial action potentials compared with endocardium. A prominent I_{to} -mediated action potential notch in ventricular epicardium but not endocardium produces a transmural voltage gradient during early ventricular repolarization that registers as a J wave or J point elevation on the ECG.¹⁷ I_{to} densities are also reportedly higher in right than in left (midmyocardial and epicardial) ventricular myocytes, consistent with the more pronounced spike and dome morphology of right, compared with left, ventricular action potentials.^{3,8,10,12}

Experimental studies in wedge preparations strongly suggest the presence of a subpopulation of cells in the midmyocardium (referred to as the M cells) that exhibits distinct electrophysiological (EP) properties, although the presence of M cells has not been consistently confirmed by intact heart experiments.^{18,21} The putative midmyocardial cells appear to have the longest action potential duration across the myocardial wall, largely attributed to their weaker I_{Ks} current but stronger late I_{Na} and Na^+ - Ca^{2+} exchanger currents. Hence, the M cells have been proposed to underlie the EP basis for transmural ventricular dispersion of repolarization and the T wave on the surface ECG, with the peak of the T wave (in wedge preparations) coinciding with the end of epicardial repolarization and the end of the T wave coinciding with the end of repolarization of the M cells. Although the role of M cells under physiological conditions remains controversial, these cells appear to have a significant role in arrhythmogenesis under a variety of pathological conditions, such as the long QT and Brugada syndromes, secondary to exaggeration of transmural repolarization gradients.^{18,19}

As noted, I_{Kur} is detected only in human atria and not in the ventricles, so that it is the predominant delayed rectifier current responsible for human atrial repolarization and is a basis for the much shorter duration of the action potential in the atrium (see Table 1-2).^{3,12}

I_{K1} density is much higher in ventricular than in atrial myocytes, and this explains the steep repolarization phase in the ventricles (where the more abundant I_{K1} plays a larger role in accelerating the terminal portion of repolarization) and the more shallow phase in the atria. The higher I_{K1} channel expression in the ventricle protects the ventricular cell from pacemaker activity.^{6,7}

Changes in expression levels or gating properties of ion channels in pathological conditions can aggravate the regional heterogeneities in action potential duration and configuration that can be arrhythmic.^{3,12}

The Slow Response Action Potential

In normal atrial and ventricular myocytes and in the His-Purkinje fibers, action potentials have very rapid upstrokes mediated by the fast inward I_{Na} . These potentials are called fast response potentials. In contrast, action potentials in the normal sinus and AV nodal cells and many types of diseased tissue have very slow upstrokes, mediated predominantly by the slow inward I_{CaL} , rather than by the fast inward I_{Na} (see Fig. 1-2). These potentials have been termed slow response potentials.⁵

As noted, the action potentials of pacemaker cells in the sinus and AV nodes are significantly different from those in working atrial and ventricular myocardium. The slow response action potentials are characterized by a more depolarized E_m at the onset of phase 4 (–50 to –65 mV), slow diastolic depolarization during phase 4, reduced action potential amplitude, and a much slower rate of depolarization in phase 0 than that in the working myocardial cells, thus resulting in slow conduction velocity of the cardiac impulse in the nodal regions (see Table 1-2). Cells in the His-Purkinje system can also exhibit phase 4 depolarization under special circumstances.^{6,7}

PHASE 4: DIASTOLIC DEPOLARIZATION

In contrast to working atrial and ventricular myocytes and fibers in the His-Purkinje system, which maintain a steady diastolic E_m level of approximately –85 mV, sinus and AV nodal excitable cells exhibit a spontaneous, slow, progressive decline in the E_m during diastole (spontaneous diastolic depolarization or phase 4 depolarization) that underlies normal automaticity and pacemaking function. Once this spontaneous depolarization reaches threshold (approximately –40 mV), a new action potential is generated.^{2,22,23}

The ionic mechanisms responsible for diastolic depolarization and normal pacemaker activity in the sinus node are still controversial. Originally, a major role was attributed to the decay of the delayed K^+ conductance (an outward current) activated during the preceding action potential (the I_K -decay theory). This model of pacemaker depolarization lost favor on the discovery of the “funny” current (I_f), sometimes referred to as the pacemaker current. Other ionic currents gated by membrane depolarization (i.e., I_{CaL} and T-type Ca^{2+} currents), nongated and nonspecific background leak currents, and a current generated by the Na^+ - Ca^{2+} exchanger were also proposed to be involved in pacemaking.

I_f is a hyperpolarization-activated inward current (often referred to as the funny current because, unlike the majority of voltage-sensitive currents, it is activated by hyperpolarization rather than depolarization) that is carried largely by Na^+ and, to a lesser extent, K^+ ions. The I_f channels are deactivated during the action potential upstroke and the initial plateau phase of repolarization. However, they begin to activate at the end of the action potential as repolarization brings the E_m to levels more negative than approximately –40 to –50 mV, and they are fully activated at approximately –100 mV. Once activated, I_f depolarizes the membrane to a level where the Ca^{2+} current activates to initiate an action potential.³ At the end of the repolarization phase of the action potential, because I_f activation occurs in the background of a decaying outward time-dependent K^+ current, the current flow quickly shifts from outward to inward, thus giving rise to a sudden reversal of voltage change (from repolarizing to depolarizing) at the maximum diastolic potential.²²⁻²⁶

On the other hand, several studies have shown that I_f is not the only current that can initiate the diastolic depolarization process in the sinus node. In addition to voltage and time, the electrogenic and regulatory molecules on the surface membrane of sinus node cells are strongly modulated by Ca^{2+} and phosphorylation,

a finding suggesting that intracellular Ca^{2+} is an important player in controlling pacemaker cell automaticity. Newer evidence suggests that the sarcoplasmic reticulum, a major Ca^{2+} store in sinus node cells, can function as a physiological clock within the cardiac pacemaker cells and have a substantial impact on late diastolic depolarization.

The sarcoplasmic reticulum generates spontaneous, rhythmic, local Ca^{2+} releases (via ryanodine receptors, RyR2) beneath the surface of the membrane, in the absence of Ca^{2+} overload. Activation of the local oscillatory Ca^{2+} releases is independent of membrane depolarization and is driven by a high level of basal state phosphorylation of Ca^{2+} cycling proteins. Critically timed Ca^{2+} releases occur during the later phase of diastolic depolarization in the form of multiple locally propagating wavelets beneath the cell membrane, and they activate the forward mode of the Na^+ - Ca^{2+} exchanger, thus resulting in an inward membrane current (I_{Na-Ca}). The I_{Na-Ca} causes the late diastolic depolarization to increase exponentially, driving the E_m to the threshold to activate a sufficient number of L-type Ca^{2+} channels and leading to generation of the upstroke of the next action potential. Although regulated by the E_m and submembrane Ca^{2+} , the Na^+ - Ca^{2+} exchanger does not have time-dependent gating, as do ion channels, but generates an inward current almost instantaneously when submembrane Ca^{2+} concentration increases.^{24,25,27,28}

Ca^{2+} influx via I_{CaL} during the action potential triggers Ca^{2+} -induced Ca^{2+} release from the sarcoplasmic reticulum. The resulting global sarcoplasmic reticular Ca^{2+} depletion synchronizes the sarcoplasmic reticulum throughout the cell in a Ca^{2+} -depleted state. Refilling of the sarcoplasmic reticulum ensures that the threshold of Ca^{2+} load required for spontaneous release is achieved at about the time when RyR2 inactivation is removed following prior activation; then the spontaneous local Ca^{2+} releases occur, thus activating I_{Na-Ca} to ignite the next action potential.^{5,24,28}

Such rhythmic, spontaneous intracellular Ca^{2+} cycling has been referred to as the intracellular Ca^{2+} clock. Phosphorylation-dependent gradation of speed at which Ca^{2+} clock cycles is the essential regulatory mechanism of normal pacemaker rate and rhythm. The robust regulation of pacemaker function is ensured by tight integration of the Ca^{2+} clock and the classic sarcolemmal ion channel clock (formed by voltage-dependent membrane ion channels) to form the overall pacemaker clock. The action potential shape and ion fluxes are tuned by membrane clocks to sustain operation of the Ca^{2+} clock, which produces timely and powerful ignition of the membrane clocks to effect action potentials.^{24,25,28}

There is some degree of uncertainty about the relative role of I_f versus that of intracellular Ca^{2+} cycling in controlling the normal pacemaker cell automaticity. Furthermore, the interactions between the membrane ion channel clock and the intracellular Ca^{2+} clock and cellular mechanisms underlying this internal Ca^{2+} clock are not completely elucidated. A further debate has arisen around their individual (or mutual) relevance in mediating the positive and negative chronotropic effects of neurotransmitters. Nevertheless, these interactions are of fundamental importance for understanding the integration of pacemaker mechanisms at the cellular level.^{24,25,27}

PHASE 0: THE UPSTROKE—SLOW DEPOLARIZATION

I_{K1} is almost absent in sinus and AV nodal cells, thus allowing for relatively more depolarized resting diastolic potentials (–50 to –65 mV) compared with atrial and ventricular myocytes and facilitating diastolic depolarization mediated by the inward currents (e.g., I_f). At the depolarized level of the maximum diastolic potential of pacemaker cells, most Na^+ channels are inactivated and unavailable for phase 0 depolarization. Consequently, action potential upstroke is mainly achieved by I_{CaL} .^{6,7}

L-type Ca^{2+} channels activate on depolarization to potentials positive to –40 mV, and I_{CaL} peaks at 0 to +10 mV. The peak amplitude I_{CaL} is less than 10% that of I_{Na} , and the time required for activation and inactivation of I_{CaL} is approximately an order of

magnitude slower than that for I_{Na} . As a consequence, the rate of depolarization in phase 0 (dV/dt) is much slower and the peak amplitude of the action potential is less than that in the working myocardial cells.^{5,15,29}

Excitability

Excitability of a cardiac cell describes the ease with which the cell responds to a stimulus with a regenerative action potential. A certain minimum charge has to be applied to the cell membrane to elicit a regenerative action potential (i.e., the stimulus should be sufficiently intense to reduce the E_m to the threshold value); excitability is inversely related to the charge required for excitation.³

Excitability of a cardiac cell depends on the passive and active properties of the cell membrane. The passive properties include the membrane resistance and capacitance and the intercellular resistance. The more negative the E_m , the more Na^+ channels are available for activation, the greater the influx of Na^+ into the cell during phase 0, and the greater the conduction velocity. In contrast, membrane depolarization to approximately -60 to -70 mV can inactivate half the Na^+ channels, and depolarization to -50 mV or less can inactivate all the Na^+ channels, thereby rendering Na^+ channels unavailable for mediating an action potential upstroke and reducing tissue excitability.⁵

On the other hand, supernormal excitability can be observed during a brief period at the end of phase 3 of the action potential. During the supernormal period, excitation is possible in response to an otherwise subthreshold stimulus; that same stimulus fails to elicit a response earlier or later than the supernormal period. Two factors are responsible for supernormality: the availability of fast Na^+ channels and the proximity of the E_m to threshold potential. During the supernormal phase of excitability, the cell has recovered enough to respond to a stimulus (i.e., an adequate number of Na^+ channels is available for activation). At the same time, because the E_m is still reduced, it requires only a little additional depolarization to bring the fiber to threshold; thus, a smaller stimulus than is normally required elicits an action potential.^{30,31}

Reduced membrane excitability occurs in certain physiological and pathophysiological conditions. Genetic mutations that result in loss of Na^+ channel function, Na^+ channel blockade with class I antiarrhythmic drugs, and acute myocardial ischemia can cause reduced membrane excitability.³²

Refractoriness

During a cardiac cycle, once an action potential is initiated, the cardiomyocyte becomes unexcitable to stimulation (i.e., unable to initiate another action potential in response to a stimulus of threshold intensity) for some duration of time (which is slightly shorter than the “true” action potential duration) until its membrane has repolarized to a certain level. This period of refractoriness to stimulation is physiologically necessary for the mechanical function of the heart; it allows only gradual recovery of excitability, thus permitting relaxation of cardiac muscle before subsequent activation. Additionally, the refractory period acts as a protective mechanism by preventing multiple, compounded action potentials from occurring (i.e., it limits the frequency of depolarization and heart rate). Therefore, this property is a determinant of susceptibility to arrhythmias.³³

There are different levels of refractoriness during the action potential. During the *absolute refractory period* (which extends over phases 0, 1, 2, and part of phase 3 of the action potential), no stimulus, regardless of its strength, can reexcite the cell. After the absolute refractory period, a stimulus may cause some cellular depolarization, but it does not lead to a propagated action potential. The sum of this period (which includes a short interval of phase 3 of the action potential) and the absolute refractory period is termed the *effective refractory period* (ERP). The ERP is followed by the *relative refractory period*, which extends over the middle and late parts of phase 3. During the relative refractory period, initiation

of a second action potential is *inhibited* but not impossible; a larger-than-normal stimulus can result in activation of the cell and lead to a propagating action potential. However, the upstroke of the new action potential is less steep and of lower amplitude, and its conduction velocity is slower than normal. As noted, there is a brief period in phase 3, the supernormal period, during which excitation is possible in response to an otherwise subthreshold stimulus (supernormal excitability).

The refractory period is determined, in part, by the action potential duration and the E_m , and the degree of refractoriness primarily reflects the number of Na^+ channels that have recovered from their inactive state. With repolarization, the Na^+ channel normally recovers rapidly from inactivation (within 10 milliseconds) and is ready to open again. The ERP extends from phase 0 to approximately -60 mV during phase 3 of the action potential, a time during which it is impossible for the myocardium to respond with a propagated action potential, or even to a strong stimulus. The relative refractory period extends from approximately -60 mV during phase 3 to the end of phase 3 of the action potential. During this period, a depressed response is possible to a strong stimulus. Therefore, when premature stimulation occurs during the relative refractory period (i.e., before full recovery and at less negative potentials of the cell membrane), a portion of Na^+ channels will still be refractory and unavailable for activation. Consequently, the I_{Na} and phase 0 of the next action potential will be reduced, and conduction of the premature stimulus will be slowed.^{3,32}

In pacemaking tissues, I_{Na} is predominantly absent, and excitability is mediated by the activation of I_{CaL} . After inactivation, the transition of Ca^{2+} channels from the inactivated to the closed resting state (i.e., recovery from inactivation) is relatively slow. The time constant for recovery from inactivation depends on both the E_m and the intracellular Ca^{2+} concentration (typically 100 to 200 milliseconds at -80 mV and low intracellular Ca^{2+} concentration). This means that I_{CaL} must recover from inactivation between action potentials. As a result, excitability in pacemaking cells may not be recovered by the end of phase 3 of the action potential and full restoration of maximum diastolic potential, because L-type Ca^{2+} channels require longer time to recovery from inactivation to be able to mediate the upstroke of a new action potential. In other words, sinus and AV nodal cells remain refractory for a time interval that is longer than the time it takes for full voltage repolarization to occur, a phenomenon termed postrepolarization refractoriness.^{5,29} This can also occur during some disease states such as myocardial infarction.

Conduction

Cardiac excitation involves generation of the action potential by individual cells, followed by propagation of the electrical impulse along each cardiac cell and rapidly from cell to cell throughout the cardiac tissue. The propagating electrical wavefront interacts with structural boundaries that exist at the cellular level (cell membranes, intercellular gap junctions), as well as at the more macroscopic level (microvasculature, connective tissue barriers, trabeculation).

Conduction velocity refers to the speed of propagation of the action potential through cardiac tissue and is determined by source-sink relationships, which reflect the interplay between the active membrane properties of cardiac cells (i.e., electrical excitability or refractoriness of the source generating the action potential, or both) and the passive properties determined by cell-to-cell coupling and tissue geometry (sink).^{3,34}

During action potential propagation, an excited cell serves as a source of electrical charge for depolarizing neighboring unexcited cells. The requirements of adjacent resting cells to reach the threshold E_m constitute an electrical sink (load) for the excited cell. For propagation to succeed, the excited cell must provide sufficient charge to bring the E_m at a site in the sink from its diastolic value to the threshold. Once threshold is reached and action potential is generated, the load on the excited cell is removed, and the newly

excited cell switches from being a sink to being a source for the downstream tissue, thus perpetuating the process of action potential propagation. Action potentials are “regenerative” because they can be conducted over large distances without attenuation.

The current provided by the source must reach the sink. The pathway between the source and the sink includes intracellular resistance (provided by the cytoplasm) and intercellular resistance (provided by the gap junctions). Extracellular resistance plays a role, but it can often be neglected. The coupling resistance is mainly determined by resistance of the gap junctions. Therefore, the number and distribution of gap junctions, as well as the conductance of the gap junction proteins (connexins) and the geometry of the source-sink relationship, are important factors for conduction of the action potential.

The safety factor for conduction predicts the success of action potential propagation and is based on the source-sink relationship. The *safety factor* is defined as the ratio of the current generated by the depolarizing ion channels of a cell (source) to the current consumed during the excitation cycle of a single cell in the tissue (sink). Thus, the safety factor for propagation is proportional to the excess of source current over the sink needs. By this definition, conduction fails when the safety factor drops to less than 1 and becomes increasingly stable as it rises to more than 1. This concept of propagation safety provides information about the dependence of propagation velocity on the state of the ion channels, cell-to-cell coupling, and tissue geometry.

An action potential traveling down a cardiac muscle fiber is propagated by local circuit currents, much as it does in nerve and skeletal muscle. Conduction velocity along the cardiac fiber is directly related to the action potential amplitude (i.e., the voltage difference between the fully depolarized and the fully polarized regions) and the rate of change of potential (i.e., the rate of rise of phase 0 of the action potential [dV/dt]). These factors depend on the amplitude of I_{Na} , which, in turn, is directly related to the E_m at the time of stimulation, the availability of Na^+ channels for stimulation, and the size of the Na^+ electrochemical potential gradient across the cell membrane. A reduction in I_{Na} , leading to a reduction in the rate or amplitude of depolarization during phase 0 of the action potential, can decrease axial current flow (and therefore capacitive current) and slow conduction or produce conduction block. Tissues with high concentration of Na^+ channels, such as Purkinje fibers, which contain up to 1 million Na^+ channels per cell, have a large, fast inward current. The large I_{Na} spreads quickly within and

between cells to support rapid conduction (approximately 4 m/sec). In contrast, at a less negative resting E_m , Na^+ channel availability is limited because of the inactivation of a portion of the channels; hence, I_{Na} amplitude is attenuated, and the upstroke velocity is slowed. With progressive reduction of excitability, less Na^+ source current is generated, and conduction velocity and the safety factor decrease monotonically. When the safety factor falls to less than 1, conduction can no longer be sustained, and failure (conduction block) occurs. Action potentials with reduced upstroke velocity resulting from partial inactivation of Na^+ channels are called depressed fast responses.³⁵

In tissues with slow response action potentials (sinus and AV nodes), the upstroke of the action potential is formed by I_{CaL} rather than I_{Na} . Because I_{CaL} has lower amplitude and slower activation kinetics than I_{Na} , slow response action potentials exhibit lower amplitudes and upstroke velocities. Hence, slow conduction (approximately 0.1 to 0.2 m/sec) and prolonged refractoriness are characteristic features of nodal regions. These cells also have a reduced safety factor for conduction, which means that the stimulating efficacy of the propagating impulse is low, and conduction block occurs easily.

Excitation-Contraction Coupling

Excitation-contraction coupling describes the physiological process by which electrical stimulation of the cardiomyocytes (the action potential) results in a mechanical response (muscle contraction). The contraction of a cardiac myocyte is governed primarily by intracellular Ca^{2+} concentration (Fig. 1-3). Ca^{2+} enters the cell during the plateau phase of the action potential through the L-type Ca^{2+} channels that line areas of specialized invaginations known as transverse (T) tubules. Although the rise in intracellular Ca^{2+} is small and not sufficient to induce contraction, the small amount of Ca^{2+} entering the cell via I_{CaL} triggers a massive release of Ca^{2+} from the sarcoplasmic reticulum (the major store for Ca^{2+}) into the cytosol by opening the RyR2 channels (present in the membrane of the sarcoplasmic reticulum) in a process known as Ca^{2+} -induced Ca^{2+} release (CICR). Approximately 75% of Ca^{2+} present in the cytoplasm during contraction is released from the sarcoplasmic reticulum.

Each junction between the sarcolemma (T tubule) and sarcoplasmic reticulum, where 10 to 25 L-type Ca^{2+} channels and 100 to 200 RyRs are clustered, constitutes a local Ca^{2+} signaling complex,

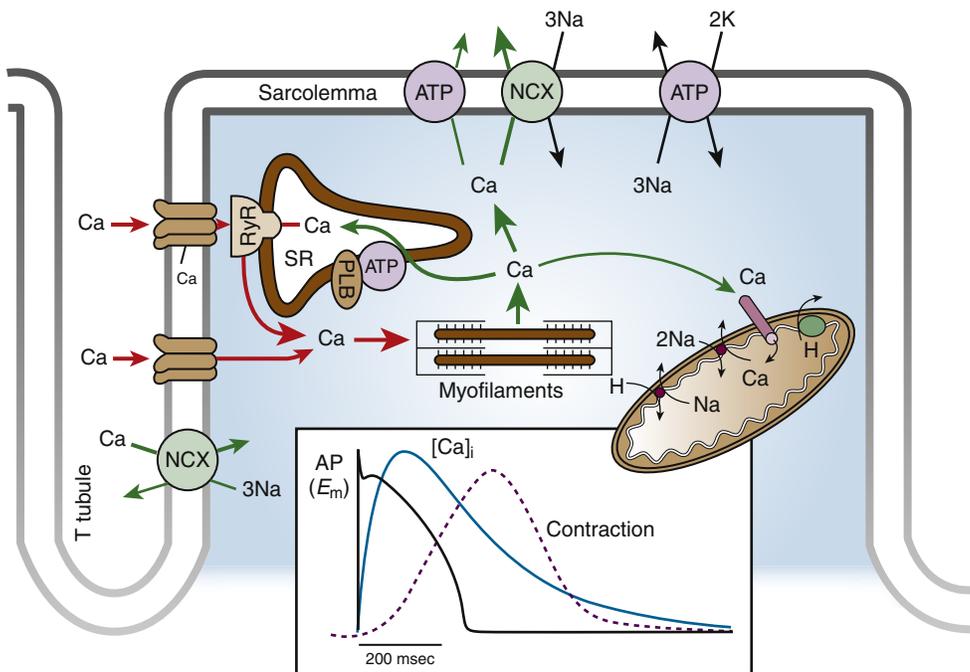

FIGURE 1-3 Ca^{2+} transport in ventricular myocytes. **Inset**, The time course of action potential (AP), Ca^{2+} transient and contraction at 37°C in a rabbit ventricular myocyte. ATP = Ca^{2+} adenosine triphosphatase; NCX = Na^+/Ca^{2+} exchanger; PLB = phospholamban; RyR = ryanodine receptor channel; SR = sarcoplasmic reticulum. (Modified with permission from Bers DM: Cardiac excitation-contraction coupling. *Nature* 415:198-205, 2002.)

or a couplon. When a Ca^{2+} channel opens, local cytosolic Ca^{2+} concentration rises in less than 1 millisecond in the junctional cleft to 10 to 20 μM , and this activates RyR2 to release Ca^{2+} from the sarcoplasmic reticulum. The close proximity of the RyR2 to the T tubule enables each L-type Ca^{2+} channel to activate 4 to 6 RyR2s and generate a Ca^{2+} spark. Ca^{2+} influx via I_{CaL} simultaneously activates approximately 10,000 to 20,000 couplons in each ventricular cardiomyocyte with every action potential.³⁶⁻³⁸

CICR raises cytosolic Ca^{2+} levels from approximately 10^{-7} M to approximately 10^{-5} M. The free Ca^{2+} binds to troponin C, a component of the thin filament regulatory complex, and thus causes a conformational change in the troponin-tropomyosin complex, such that troponin I exposes a site on the actin molecule that is able to bind to the myosin ATPase located on the myosin head. This binding results in ATP hydrolysis that supplies energy for a conformational change to occur in the actin-myosin complex. The result of these changes is a movement (ratcheting) between the myosin heads and the actin, such that the actin and myosin filaments slide past each other and thereby shorten the sarcomere length. Ratcheting cycles occur as long as cytosolic Ca^{2+} levels remain elevated.

CICR typically induces release of only approximately 50% to 60% of sarcoplasmic reticulum Ca^{2+} content. RyR2 channels are inactivated by a feedback mechanism from the rising Ca^{2+} concentration in the cleft and, more importantly, by the decline of sarcoplasmic reticulum Ca^{2+} content (a process referred to as luminal Ca^{2+} -dependent deactivation). This process ensures that the sarcoplasmic reticulum never is fully depleted of Ca^{2+} physiologically.^{38,39}

Relaxation requires the removal of Ca^{2+} from the cytosol, a process vital for enabling ventricular chamber relaxation and filling, as well as for prevention of arrhythmias. At the end of phase 2 of the action potential, Ca^{2+} entry into the cell slows, and most of the surplus Ca^{2+} in the cytosol is resequestered into the sarcoplasmic reticulum by the SERCA, the activity of which is controlled by the phosphoprotein phospholamban. Additionally, some of the Ca^{2+} is extruded from the cell by the sarcolemmal $\text{Na}^+\text{-Ca}^{2+}$ exchanger and, to a minor degree, the cell membrane Ca^{2+} ATPase, to balance the Ca^{2+} that enters with I_{CaL} . As the cytosolic Ca^{2+} concentration drops, Ca^{2+} dissociates rapidly from the myofilaments, thus inducing a conformational change in the troponin complex leading to troponin I inhibition of the actin binding site. At the end of the cycle, a new ATP binds to the myosin head and displaces the adenosine diphosphate, and the initial sarcomere length is restored, thus ending contraction. Recurring Ca^{2+} release-uptake cycles provide the basis for periodic elevations of cytosolic Ca^{2+} concentration and contractions of myocytes, hence for the orderly beating of the heart.^{38,39}

Ion channels are pore-forming membrane proteins that regulate the flow of ions passively down their electrochemical gradient across the membrane. Ion channels are present on all membranes of cells (plasma membrane) and intracellular organelles (nucleus, mitochondria, endoplasmic reticulum). There are more than 300 types of ion channels in a living cell. The channels are not randomly distributed in the membrane, but tend to cluster at the intercalated disc in association with modulatory subunits.¹

Ion channels are distinguished by two important characteristics: ion permeation selectivity and gating kinetics. Ion channels can be classified by the strongest permeant ion (sodium [Na^+], potassium [K^+], calcium [Ca^{2+}], and chloride [Cl^-]), but some channels are less selective or are not selective, as in gap junctional channels. Size, valency, and hydration energy are important determinants of selectivity. Na^+ channels have a selectivity ratio for Na^+ to K^+ of 12:1. Voltage-gated K^+ and Na^+ channels exhibit more than 10-fold discrimination against other monovalent and divalent cations, and voltage-gated Ca^{2+} channels exhibit a more than 1000-fold discrimination against Na^+ and K^+ ions and are impermeable to anions. Ions move through the channel pore at a very high rate (more than 10^6 ions/sec).

Gating is the mechanism of opening and closing of ion channels and represents time-dependent transitions among distinct conformational states of the channel protein resulting from molecular movements, most commonly in response to variations in voltage gradient across the plasma membrane (termed voltage-dependent gating) and, less commonly, in response to specific ligand molecules binding to the extracellular or intracellular side of the channel (ligand-dependent gating) or in response to mechanical stress such as stretch, pressure, shear, or displacement (mechanosensitive gating).

Importantly, channel opening and closing are not instantaneous but usually take time. The transition from the resting (closed) state to the open state is called activation. Once opened, channels do not remain in the open state, but instead they undergo conformational transition in a time-dependent manner to a stable nonconducting (inactivated) state. Inactivated channels are incapable of reopening and must undergo a recovery or reactivation process back to the resting state to regain their ability to open. Inactivation curves of the various voltage-gated ion channel types differ in their slopes and midpoints of inactivation and can overlap, in which case a steady-state or noninactivating current flows.¹

Ion channels differ with respect to the number of subunits of which they are composed and other aspects of structure. Many ion channels function as part of macromolecular complexes in which many components are assembled at specific sites within the membrane. For most ion channels, the pore-forming subunit is called the α subunit, whereas the auxiliary subunits are denoted β , γ , and so on. Most ion channels have a single pore; however, some have two.¹

Sodium Channels

Structure and Physiology

The cardiac Na^+ channel complex is composed of a primary α and multiple ancillary β subunits. The approximately 2000-amino-acid α subunit contains the channel's ion-conducting pore and controls the channel selectivity for Na^+ ions and voltage-dependent gating machinery. This subunit contains all the drug and toxin interaction sites identified to date. The α subunit ($\text{Na}_v1.5$), encoded by the *SCN5A* gene, consists of four internally homologous domains (I to IV) that are connected to each other by cytoplasmic linkers (Fig. 2-1). Each domain consists of six membrane-spanning segments (S1 to S6), connected to each other by alternating intracellular and extracellular peptide loops. The four domains are arranged in a fourfold circular symmetry to form the channel. The extracellular loops between S5 and S6 (termed the P segments) have a unique primary structure in each domain (Fig. 2-2). The P segments curve back into the membrane to form an ion-conducting central pore whose structural constituents determine the selectivity and conductance properties of the Na^+ channel.²

Four auxiliary β subunits ($\text{Na}_v\beta1$ to $\text{Na}_v\beta4$, encoded by the genes *SCN1B* to *SCN4B*, respectively) have been identified; each is a glycoprotein with a single membrane-spanning segment. The $\beta1$ subunit likely plays a role in modulation of the gating properties and level of expression of the Na^+ channel.²

Na^+ channels are the typical example of voltage-gated ion channels. Na^+ channels switch among three functional states: deactivated (closed), activated (open), and inactivated (closed), depending on the membrane potential (E_m). These channel states control Na^+ ion permeability through the channel into the

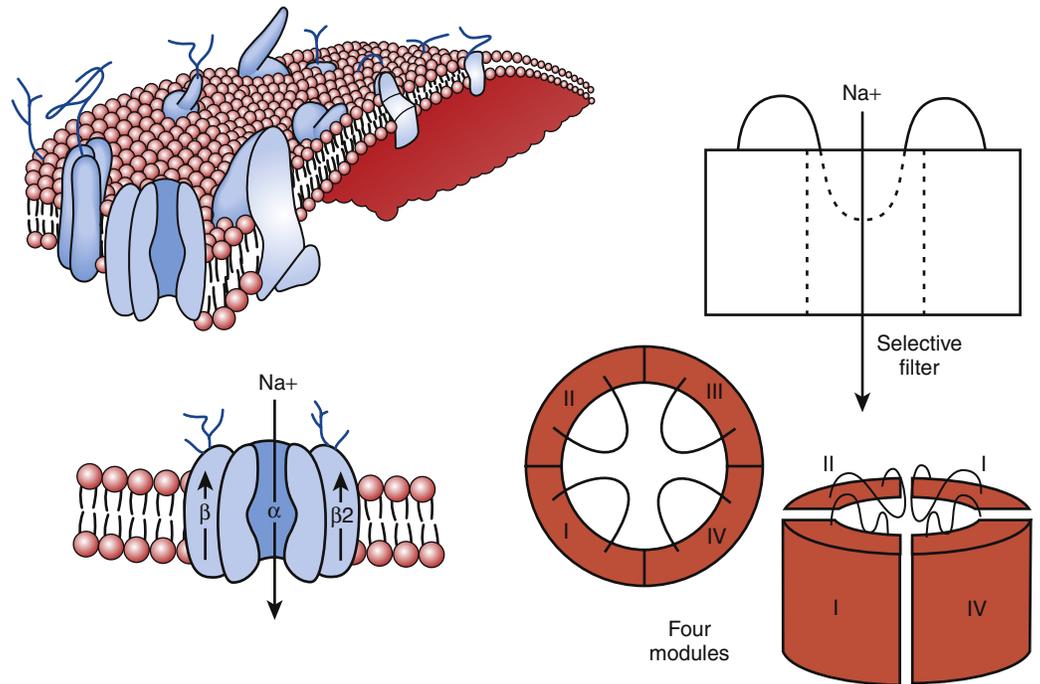

FIGURE 2-1 The sodium channel macromolecular complex. See text for discussion. (From Boussy T, Paparella G, de Asmundis C, et al: Genetic basis of ventricular arrhythmias. *Heart Fail Clin* 6:249-266, 2010.)

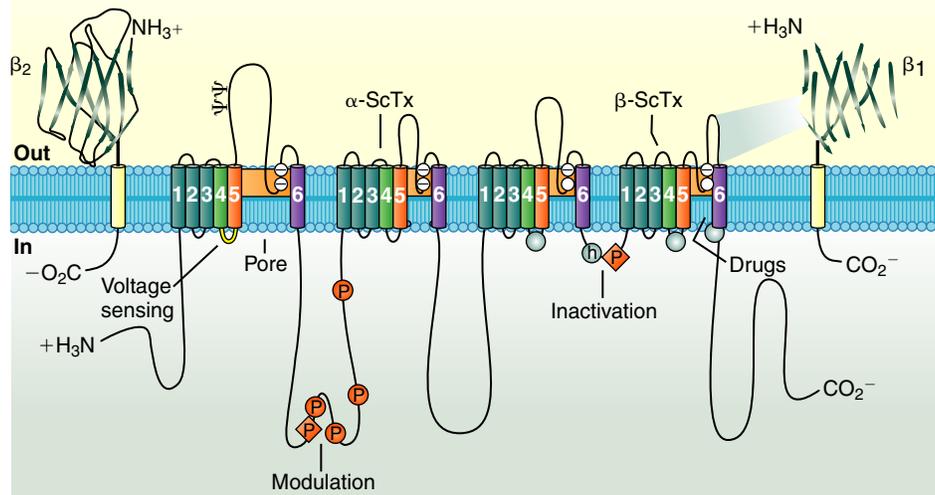

FIGURE 2-2 Transmembrane organization of sodium channel subunits. The primary structures of the subunits of the voltage-gated ion channels are illustrated as transmembrane folding diagrams. Cylinders represent probable α -helical segments: S1 to S3, blue; S4, green; S5, orange; S6, purple; outer pore loop, shaded orange area. Bold lines represent the polypeptide chains of each subunit, with length approximately proportional to the number of amino acid residues in the brain sodium channel subtypes. The extracellular domains of the β_1 and β_2 subunits are shown as immunoglobulin-like folds. Ψ shows sites of probable N-linked glycosylation. P represents sites of demonstrated protein phosphorylation by protein kinase A (red circles) and protein kinase C (red diamonds); h in the blue circle signifies an inactivation particle in the inactivation gate loop; the empty blue circles represent sites implicated in forming the inactivation gate receptor. The structure of the extracellular domain of the β subunits is illustrated as an immunoglobulin-like fold based on amino acid sequence homology to the myelin P0 protein. Sites of binding of α and β scorpion toxins (α -ScTx, β -ScTx) and a site of interaction between an α and β_1 subunits also are shown. H_3N and NH_3^+ = ammonia. (From Caterall WA, Maier SK: Voltage-gated sodium channels and electrical excitability of the heart. In Zipes DP, Jalife J, editors: *Cardiac electrophysiology: from cell to bedside*, ed 5, Philadelphia, 2009, Saunders, pp 9-17.)

cardiomyocyte. Na^+ channel activation allows Na^+ ion influx into the cell, and inactivation blocks entry of Na^+ ions.²

On excitation of the cardiomyocyte by electrical stimuli from adjacent cells, its resting E_m (approximately -85 mV) depolarizes. The positively charged S4 segment of each domain of the α subunit functions as the sensor of the transmembrane voltage; these segments are believed to undergo rapid structural conformational changes in response to membrane depolarization, thus leading to channel opening (activation) from its resting (closed) state and

enabling a large and rapid influx of Na^+ (inward Na^+ current [I_{Na}]) during the rapid upstroke (phase 0) of the action potential in atrial, ventricular, and Purkinje cardiomyocytes.³

Normally, activation of Na^+ channels is transient; fast inactivation (closing of the pore) starts simultaneously with activation, but because inactivation is slightly delayed relative to activation, the channels remain transiently open to conduct I_{Na} during phase 0 of the action potential before it closes. Each Na^+ channel opens very briefly (less than 1 millisecond) during phase 0 of the action

potential; collectively, activation of the channel lasts a few milliseconds and is followed by fast inactivation.

Na⁺ channel inactivation comprises different conformational states, including fast, intermediate, and slow inactivation. Fast inactivation is at least partly mediated by rapid occlusion of the inner mouth of the pore by the cytoplasmic interdomain linker between domains III and IV of the α subunit, which has a triplet of hydrophobic residues that likely functions as a hinged “latch” that limits or restricts Na⁺ ion pass through the pore. The carboxyl terminus (C-terminus) also plays an important role in the control of Na⁺ channel inactivation and stabilizing the channels in the inactivated state by interacting with the loop linking domains III and IV. Importantly, although most Na⁺ channels open before inactivating, some actually inactivate without ever opening (a process known as closed-state inactivation).^{1,4}

Once inactivated, Na⁺ channels do not conduct any more current and cannot be reactivated (reopened) until after recovery from inactivation. The recovery of the Na⁺ channel to reopen is voltage dependent. Channel inactivation is removed when the E_m of the cell repolarizes during phase 4 of the action potential. Membrane repolarization is facilitated by the fast inactivation of the Na⁺ channels (limiting the inward current) and is augmented by activation of voltage-gated K⁺ channels (allowing the outward current). The recovery of channels from inactivation is also time dependent; Na⁺ channels typically activate within 0.2 to 0.3 milliseconds and inactivate completely within 2 to 5 milliseconds.

Following recovery, Na⁺ channels enter a closed state that represents a nonconducting conformation, which allows the channels to be activated again during the next action potential. The fraction of channels available for opening varies from almost 100% at -90 mV and 50% at -75 mV to almost 0% at $+40$ mV. Consequently, highly polarized (-80 to -90 mV) cell membranes can be depolarized rapidly by stimuli because more Na⁺ channels reopen, whereas partially depolarized cells with potentials close to threshold -70 mV generate a much slower upstroke because of the inactivation of a proportion of Na⁺ channels. Given that Na⁺ channels are major determinants of conduction velocity, this velocity generally slows at a reduced E_m .

Na⁺ channel activation, inactivation, and recovery from inactivation occur within a few milliseconds. At the end of phase 1 of the action potential, more than 99% of Na⁺ channels transit from an open (activated) state to an inactivated state. However, a very few Na⁺ channels are not inactivated and may reactivate (reopen) during action potential phase 3. The small current produced by these channels (less than 1% of the peak I_{Na}) is called the “window” current because it arises when the sarcolemma reaches a potential that is depolarized sufficiently to reactivate some channels, but not enough to cause complete inactivation. The voltage range for the window current is very restricted and narrow in healthy hearts, thus granting it a small role during the cardiac action potential.

In addition to these rapid gating transitions, Na⁺ channels are also susceptible to slower inactivating processes (slow inactivation) if the membrane remains depolarized for a longer time. These slower events can contribute to the availability of active channels under various physiological conditions. Whereas fast-inactivated Na⁺ channels recover rapidly (within 10 milliseconds) during the hyperpolarized interval between stimuli, slow inactivation requires much longer recovery times (ranging from hundreds of milliseconds to many seconds). The molecular movements leading to slow inactivation are less well understood. The P segments seem to play a key role in slow inactivation.⁴

Some Na⁺ channels occasionally show alternative gating modes consisting of isolated brief openings occurring after variable and prolonged latencies and bursts of openings during which the channel opens repetitively for hundreds of milliseconds. The isolated brief openings are the result of the occasional return from the inactivated state. The bursts of openings are the result of occasional failure of inactivation.¹ Prolonged opening or reopening of some Na⁺ channels during phases 2 and 3 can result in a small late

I_{Na} (I_{NaL}). Despite its minor contribution in healthy hearts, I_{NaL} can potentially play an important role in diseased hearts.³

Function

Na⁺ channels play a pivotal role in the initiation, propagation, and maintenance of the normal cardiac rhythm. The I_{Na} determines excitability and conduction in atrial, His-Purkinje system (HPS), and ventricular myocardium. On membrane depolarization, the voltage-gated Na⁺ channels respond within a millisecond by opening, thus leading to the very rapid depolarization of the cardiac cell membrane (phase 0 of the action potential), reflected by the fast (within tenths of a microsecond) subsequent opening of Na⁺ channels triggering the excitation-contraction coupling. Na⁺ entry during phase 0 of the action potential also modulates intracellular Na⁺ levels and, through Na⁺-Ca²⁺ exchange, intracellular Ca²⁺ concentration and cell contraction.

The cardiac Na⁺ channel also plays a crucial role in the propagation of action potentials throughout the atrium, HPS, and ventricles. The opening of Na⁺ channels in the atria underlies the P wave on the ECG, and in the ventricles I_{Na} underlies the QRS complex and enables a synchronous ventricular contraction. Because the upstroke of the electrical potential primarily determines the speed of conduction between adjacent cells, Na⁺ channels are present in abundance in tissues where speed is of importance. Cardiac Purkinje cells contain up to 1 million Na⁺ channels, a finding that illustrates the importance of rapid conductance in the heart.²

Na⁺ channels also make a contribution in the plateau phase (phase 2) and help determine the duration of the action potential. After phase 0 of the action potential, I_{Na} decreases to less than 1% of its peak value over the next several milliseconds because of voltage-dependent inactivation. This persistent or “late” inward I_{Na} (I_{NaL}), along with the L-type Ca²⁺ current (I_{CaL}), helps maintain the action potential plateau.⁵

Furthermore, Na⁺ channel inactivation is very important as it prevents cells from being prematurely reexcited because of the unavailability of the voltage-gated Na⁺ channels. With repolarization, the Na⁺ channel normally recovers rapidly from inactivation (within 10 milliseconds) and is ready to open again. Hence, Na⁺ channels help to determine the frequency of action potential firing. To a lesser extent, cardiac Na⁺ channels are also present in the sinus node and the atrioventricular node (AVN), where they contribute to pacemaker activity.

Regulation

The regulatory proteins interacting with Na_v1.5 may be classified as follows: (1) anchoring-adaptor proteins (e.g., ankyrin-G, syntrophin proteins, multicopy suppressor of gsp1 [MOG1]), which play roles only in trafficking and targeting the channel protein in specific membrane compartments; (2) enzymes interacting with and modifying the channel structure (post-translational modifications), such as protein kinases or ubiquitin ligases; and (3) proteins modulating the biophysical properties of Na_v1.5 on binding (e.g., caveolin-3, calmodulin, glycerol 3-phosphate dehydrogenase 1-like [G3PD1L], telethonin, Plakophilin-2).⁵ Coexpression of Na_v1.5 with its β subunits induces acceleration in the recovery from inactivation and enhancement of I_{Na} amplitude.

The cardiac Na⁺ channels are subject to phosphorylation and dephosphorylation by kinases or phosphatases. The intracellular linker between domains I and II contains eight consensus sites for cyclic adenosine monophosphate (cAMP)-dependent protein kinase A (PKA) phosphorylation. cAMP-dependent PKA and G protein stimulatory α subunit ($G_s\alpha$) modulate the function of expressed cardiac Na⁺ channels on β -adrenergic stimulation and enhance I_{Na} .¹

In contrast, activation of α -adrenergic stimulating protein kinase C (PKC) results in the reduction of I_{Na} . The effect of PKC is largely attributable to phosphorylation of a highly conserved serine in the linker between domains III and IV. PKC reduces the maximal

conductance of the channels and alters gating. Na⁺ channels exhibit a hyperpolarizing shift in the steady-state availability curve, suggesting an enhancement of inactivation from closed states.

All subunits of the Na⁺ channel are modified by glycosylation. The β₁ and β₂ subunits are heavily glycosylated, with up to 40% of the mass being carbohydrate. In contrast, the cardiac α subunit is only 5% sugar by weight. Sialic acid is a prominent component of the N-linked carbohydrate of the Na⁺ channel. The addition of such a highly charged carbohydrate has predictable effects on the voltage dependence of gating through alteration of the surface charge of the channel protein.¹

Pharmacology

Na⁺ channels are the targets for the action of class I antiarrhythmic drugs. Na⁺ channel blockers bind to a specific receptor within the channel's pore. The binding blocks ion movement through the pore and stabilizes the inactivated state of Na⁺ channels. Blockade of Na⁺ channels tends to decrease tissue excitability and conduction velocity (by attenuating peak I_{Na}) and can shorten action potential duration (by attenuating late I_{Na}).^{1,6}

One important component in the action of antiarrhythmic drugs is a voltage-dependent change in the affinity of the drug-binding site (i.e., the channel is a modulated receptor). Additionally, restricted access to binding sites can contribute to drug action, a phenomenon that has been called the guarded receptor model. Open and inactivated channels are more susceptible to block than resting channels, likely because of a difference in binding affinity or state-dependent access to the binding site. Consequently, binding of antiarrhythmic drug occurs primarily during the action potential (known as use-dependent block), and the block dissipates after repolarization (i.e., in the interval between action potentials). When the time interval between depolarizations is insufficient for block to recover before the next depolarization occurs (secondary to either abbreviation of the interval between action potentials during fast heart rates or slow kinetics of the unbinding of the Na⁺ channel blocker), block of Na⁺ channels accumulates (resulting in an increased number of blocked channels and enhanced blockade).⁶ A drug with rapid kinetics produces less channel block with the subsequent depolarization than does a drug with slower recovery. Use-dependent block is important for the action of antiarrhythmic drugs because it allows strong drug effects during fast heart rates associated with tachyarrhythmias but limits Na⁺ channel block during normal heart rates. Importantly, drug recovery kinetics can potentially be slowed by pathophysiological conditions such as membrane depolarization, ischemia, and acidosis.¹ This property is known as use-dependence and is seen most frequently with the class IC agents, less frequently with the class IA drugs, and rarely with the class IB agents.

Class I antiarrhythmic drugs can be classified into three groups according to rates of drug binding to and dissociation from the channel receptor. Class IC drugs (flecainide and propafenone) block both the open and inactivated state (which is induced by depolarization) Na⁺ channels and have the slowest kinetics of unbinding during diastole. The results are prolongation of conduction at normal heart rates and a further increase in the effect at more rapid rate (use-dependence).

The class IB agents (lidocaine, mexiletine, and tocainide) block both open and inactivated Na⁺ channels and dissociate from the channel more rapidly than do other class I drugs. As a consequence, class IB drugs exhibit minimal or no effects on the Na⁺ channels in normal tissue but cause significant conduction slowing in depolarized tissue, especially at faster depolarization rates. Furthermore, class IB drugs are less effective in the atrium, where the action potential duration is so short that the Na⁺ channel is in the inactivated state only briefly compared with the relatively long diastolic recovery times; thus, accumulation of block is less likely to result from the rapid recovery of block.

Class IA drugs (quinidine, procainamide, and disopyramide) exhibit open state block, have intermediate effects on Na⁺ channels,

and generally only cause significant prolongation of conduction in cardiac tissue at rapid heart rates. Because the open state block is dominant and recovery from block is slow, these drugs are effective in both the atrium (where action potential duration is short) and the ventricle (where the action potential duration is long).

The late I_{Na} (I_{NaL}) also can be a target for blockade. Several drugs exhibit relative selectivity for block of late I_{NaL} over peak I_{Na}, including mexiletine, flecainide, lidocaine, amiodarone, and ranolazine.

Importantly, class IA drugs also have moderate K⁺ channel blocking activity (which tends to slow the rate of repolarization and prolong the action potential duration) and anticholinergic activity, and they tend to depress myocardial contractility. At slower heart rates, when use-dependent blockade of I_{Na} is not significant, K⁺ channel blockade becomes predominant (reverse use-dependence), leading to prolongation of the action potential duration and QT interval and increased automaticity. Flecainide and propafenone also have K⁺ channel blocking activity and can increase the action potential duration in ventricular myocytes. Propafenone has significant β-adrenergic blocking activity.

Inherited Channelopathies

Mutations in genes that encode various subunits of the cardiac Na⁺ channel or proteins involved in regulation of the inward I_{Na} have been linked to several types of electrical disorders (Table 2-1). Depending on the mutation, the consequence is either a gain of channel function (with consequent prolongation of action potential duration because more positive ions accumulate in the cell) or an overall loss of channel function that influences the initial depolarizing phase of the action potential (with consequent decrease in cardiac excitability and electrical conduction velocity). It is noteworthy that a single mutation can cause different phenotypes or combinations thereof.²

LONG QT SYNDROME

In contrast to most long QT syndrome (LQTS) phenotypes, which are based on mutations that modify the cardiac K⁺ currents, type 3 congenital LQTS (LQT3), which accounts for approximately 8% of congenital LQTS cases, is caused by gain-of-function mutations on the Na⁺ channel gene, *SCN5A*. More than 80 mutations have been identified in the *SCN5A* gene, with most being missense mutations mainly clustered in Na_v1.5 regions that are involved in fast inactivation (i.e., S4 segment of domain IV, the domain III–domain IV linker, and the cytoplasmic loops between the S4 and S5 segments of domain III and domain IV), or in regions that stabilize fast inactivation (e.g., the C-terminus).^{2,4,7}

Several mechanisms have been identified to underlie ionic effects of *SCN5A* mutations in LQT3. Most *SCN5A* mutations cause a gain of function through disruption of fast inactivation, thus allowing repeated reopening during sustained depolarization and resulting in an abnormal, small, but functionally important sustained (or persistent) noninactivating Na⁺ current (I_{sus}) during action potential plateau. Because the general membrane conductance is small during the action potential plateau, the presence of a persistent inward I_{Na}, even of small amplitude, can potentially have a major impact on the plateau duration and can be sufficient to prolong repolarization and QT interval. QT prolongation and the risk of developing arrhythmia are more pronounced at slow heart rates, when the action potential duration is longer, thereby allowing more I_{Na} to enter the cell.^{2,4,7}

Other less common mechanisms of *SCN5A* mutations to cause LQT3 include increased window current, which results from delayed inactivation of mutant Na⁺ channels, occurring at more positive potentials and widening the voltage range during which the Na⁺ channel may reactivate without inactivation. Additionally, some mutations cause slower inactivation, which allows longer channel openings and causes a slowly inactivating I_{Na}. This current is I_{NaL} and is to be distinguished from I_{sus} (which does not inactivate). Comparable to I_{sus}, both the window current and I_{NaL} exert

TABLE 2-1 Inherited Cardiac Sodium Channelopathies

CLINICAL PHENOTYPE	GENE	PROTEIN	SODIUM CHANNEL ALTERATION
Long QT syndrome			
LQT3	SCN5A	Na _v 1.5	Increase in late or sustained I _{Na}
LQT9	CAV3	Caveolin-3	Increase in sustained I _{Na}

I_{Na} = sodium current; LQTS = long QT syndrome.

their effects during phases 2 and 3 of the action potential, in which normally no or very small I_{Na} is present. Other mutations induce prolonged action potential duration by enhancing recovery from inactivation, an effect that leads to larger peak I_{Na} by increasing the fraction of channels available for activation (because of faster recovery) during subsequent depolarizations. Finally, some mutations can cause increased expression of mutant Na_v1.5 through enhanced mRNA translation or protein trafficking to the sarcolemma, decreased protein degradation, or altered modulation by β subunits and regulatory proteins. These effects lead to larger I_{Na} density during phase 0 of the action potential. Importantly, one single *SCN5A* mutation can potentially cause several changes in the expression and/or gating properties of the resulting Na⁺ channels.²

Regardless of the mechanism, increased Na⁺ current (I_{sus}, window current, I_{NaL}, or peak I_{Na}) upsets the balance between depolarizing and repolarizing currents in favor of depolarization. The resulting delay in the repolarization process triggers early afterdepolarizations (EADs; i.e., reactivation of the L-type Ca²⁺ channel during phase 2 or 3 of the action potential), especially in Purkinje fiber myocytes, in which action potential durations are intrinsically longer.²

LQT9 is caused by gain-of-function mutations on the *CAV3* gene, which encodes caveolin-3, a plasma membrane scaffolding protein that interacts with Na_v1.5 and plays a role in compartmentalization and regulation of channel function. Mutations in caveolin-3 induce kinetic alterations of the Na_v1.5 current that result in persistent Na⁺ current (I_{sus}) and have been reported in cases of sudden infant death syndrome (SIDS).^{2,8}

LQT10 is caused by loss-of-function mutations on the *SCN4B* gene, which encodes the β subunit (Na_vβ4) of the Na_v1.5 channel. To date, only a single mutation in one patient has been described. This mutation caused a shift in the inactivation of the I_{Na} toward more positive potentials, but it did not change the activation. This resulted in increased window currents at an E_m corresponding to the phase 3 of the action potential.^{2,8}

LQT12 is caused by mutations on the *SNTA1* gene, which encodes α₁ syntrophin, a cytoplasmic adaptor protein that enables

the interaction among Na_v1.5, nitric oxide synthase, and the sarcolemmal Ca²⁺ adenosine triphosphatase (ATPase) complex that appears to regulate ion channel function. By disrupting the interaction between Na_v1.5 and the sarcolemmal Ca²⁺ ATPase complex, *SNTA1* mutations cause increased Na_v1.5 nitrosylation with consequent reduction of channel inactivation and enhanced I_{sus} densities.^{2,9}

BRUGADA SYNDROME

The Brugada syndrome is an autosomal dominant inherited channelopathy characterized by an elevated ST segment or J wave appearing in the right precordial leads. This syndrome is associated with a high incidence of sudden cardiac death (SCD) secondary to a rapid polymorphic ventricular tachycardia (VT) or ventricular fibrillation (VF). Approximately 65% of mutations identified in the *SCN5A* gene are associated with the Brugada syndrome phenotype (Brugada syndrome type 1), and they account for approximately 18% to 30% of cases of Brugada syndrome. So far, more than 200 Brugada syndrome-associated loss-of-function (i.e., reduced peak I_{Na}) mutations have been described in *SCN5A*. Some of these mutations result in loss of function secondary to impaired channel trafficking to the cell membrane (i.e., reduced expression of functional Na⁺ channels), disrupted ion conductance (i.e., expression of nonfunctional Na⁺ channels), or altered gating function. Altered gating properties comprise delayed activation (i.e., activation at more positive potentials), earlier inactivation (i.e., inactivation at more negative potentials), faster inactivation, and enhanced slow inactivation.^{1-3,10}

Most of the mutations are missense mutations, whereby a single amino acid is replaced by a different amino acid. Missense mutations commonly alter the gating properties of mutant channels. Because virtually all reported *SCN5A* mutation carriers are heterozygous, mutant channels with altered gating may cause up to 50% reduction of I_{Na}. Different *SCN5A* mutations can cause different degrees of I_{Na} reduction and therefore different degrees of severity of the clinical phenotype of Brugada syndrome.¹⁰⁻¹²

In addition to *SCN5A* alterations, mutations in the *GPD1L* gene, which encodes the glycerol 3-phosphate dehydrogenase 1-like protein (G3PD1L), affect the trafficking of the cardiac Na^+ channel to the cell surface and result in reduction of I_{Na} and Brugada syndrome type 2.¹⁰ Brugada syndrome associated with *GPD1L* gene mutations is characterized by progressive conduction disease, a low sensitivity to procainamide, and a relatively good prognosis.^{2,13}

Furthermore, reduction in I_{Na} can be caused by mutations in the *SCN1B* gene (encoding the β_1 and β_{1b} subunits of the Na^+ channel) and the *SCN3B* gene (encoding the β_3 subunit of the Na^+ channel), resulting in Brugada syndrome type 5 and type 7, respectively.^{10,13}

FAMILIAL PROGRESSIVE CARDIAC CONDUCTION DISEASE

Loss-of-function *SCN5A* mutations have been linked to familial forms of progressive cardiac conduction disease (referred to as hereditary Lenègre disease, primary cardiac conduction system disease, and familial atrioventricular [AV] block). This disease is characterized by slowing of electrical conduction through the atria, AVN, His bundle, Purkinje fibers, and ventricles, accompanied by an age-related degenerative process and fibrosis of the cardiac conduction system, in the absence of structural or systemic disease. It is often reflected by varying degrees of AV block and bundle branch block. Whether the age-dependent fibrosis of the conduction system is a primary degenerative process in progressive cardiac conduction disease or a physiological process that is accelerated by I_{Na} reduction remains to be investigated. A single loss-of-function *SCN5A* mutation can cause isolated progressive cardiac conduction disease or can be combined with the Brugada syndrome (overlap syndrome). Loss-of-function mutations in *SCN1B* also have been identified in patients with progressive cardiac conduction disease who carried no mutation in *SCN5A*.²

CONGENITAL SICK SINUS SYNDROME

Although I_{Na} does not play a prominent role in sinus node activity, mutations in *SCN5A* have been linked to sick sinus syndrome, manifesting as sinus bradycardia, sinus arrest, sinoatrial block, or a combination of these conditions, which can progress to atrial inexcitability (atrial standstill). Loss-of-function *SCN5A* mutations result in reduced peak I_{Na} density, hyperpolarizing shifts in the voltage dependence of steady-state channel availability, and slow recovery from inactivation. These effects likely cause reduced automaticity, decreased excitability, and conduction slowing or block of impulses generated in the sinus node to the surrounding atrial tissue. Sinus node dysfunction can also manifest concomitantly with other phenotypes that are linked to *SCN5A* loss-of-function mutations such as Brugada syndrome and progressive cardiac conduction disorders.^{2,14}

FAMILIAL ATRIAL FIBRILLATION

Loss-of-function mutations, gain-of-function mutations, and common polymorphisms on the *SCN5A* gene have been identified in some cases of atrial fibrillation (AF) occurring in young patients with structurally normal hearts. It is speculated that I_{Na} reduction may predispose to AF by slowing the electrical conduction velocity and thereby facilitating reentry. On the other hand, gain-of-function mutations can potentially predispose to AF by increasing atrial excitability. AF can occur in patients with other phenotypes of Na^+ channelopathies, including LQT3, Brugada syndrome, dilated cardiomyopathy, and sinus node dysfunction. Furthermore, mutations in the *SCN1B* gene (encoding the β_1 subunit of the Na^+ channel) and the *SCN2B* gene (encoding the β_2 subunit of the Na^+ channel) have been identified in patients with AF, many of whom displayed ECG patterns suggestive of the Brugada syndrome.^{1,2}

DILATED CARDIOMYOPATHY

Some cases of familial dilated cardiomyopathy have been linked to *SCN5A* mutations. Dilated cardiomyopathy-linked *SCN5A* mutations cause diverse loss-of-function and gain-of-function changes in the gating properties, but how such changes evoke contractile dysfunction is not understood. It is speculated that *SCN5A* mutations disrupt the interactions between the mutant Na^+ channels and intracellular (or extracellular) proteins that are essential for normal cardiomyocyte structure and architecture. Notably, dilated cardiomyopathy with *SCN5A* mutations display atrial or ventricular arrhythmias (including AF, VT, and VF), or both, as well as sinus node dysfunction, AV block, and intraventricular conduction delay.²

SUDDEN INFANT DEATH SYNDROME

Gain-of-function mutations in *SCN5A* may be the most prevalent genetic cause of SIDS. *SCN5A* mutations in SIDS commonly increase I_{Na} . Less frequently, loss-of-function mutations in *SCN5A* or *CAV3* and gain-of-function mutations in *GPD1-L* have also been found in infants with SIDS. However, it is possible that in these patients SIDS represents a severe form of the Brugada syndrome or LQTS that manifests during infancy.

Acquired Diseases

In heart failure, peak I_{Na} is reduced (likely secondary to reduced *SCN5A* expression), whereas I_{NaL} is increased (likely because of increased phosphorylation of Na^+ channels). $\text{Na}_v1.5$ expression is reduced in the surviving myocytes in the border zone of the myocardial infarct (MI). Importantly, Na^+ channel blockers can increase the risk for SCD in patients with ischemic heart disease, possibly by facilitating the initiation of reentrant excitation waves. Additionally, I_{NaL} increases during myocardial ischemia, explaining why I_{NaL} inhibition may be an effective therapy for chronic stable angina. $\text{Na}_v1.5$ expression is reduced in response to persistent atrial tachyarrhythmias as part of the “electrical remodeling” process, leading to attenuation of I_{Na} .³

Furthermore, mutations in *SCN5A* can predispose affected individuals to acquired LQTS induced by a variety of drugs such as antihistamines or antibiotics. These mutations result in changes in channel activity that exert a significant impact on action potential duration only when combined with drug-induced alteration of other channels.

Potassium Channels

Structure and Physiology

Cardiac K^+ channels are membrane-spanning proteins that allow the passive movement of K^+ ions across the cell membrane along its electrochemical gradient. The ion-conducting or pore-forming subunit is generally referred to as the α subunit. The tripeptide sequence glycine-tyrosine-glycine GYG is common to the pore of all K^+ channels and constitutes the signature motif for determining K^+ ion selectivity. A gating mechanism controls switching between open-conducting and closed-nonconducting states.^{1,15}

K^+ channels represent the most diverse class of cardiac ion channels (Fig. 2-3). Cardiac K^+ currents can be categorized as voltage-gated (K_v) and ligand-gated channels. In K_v channels, pore opening is coupled to the movement of a voltage sensor within the membrane electric field, and they include the rapidly activating and inactivating transient outward current (I_{to}); the ultrarapid (I_{Kur}), rapid (I_{Kr}), and slow (I_{Ks}) components of the delayed rectifier current; and the inward rectifier current (I_{K1}). In contrast, pore opening in ligand-gated channels is coupled to the binding of an organic molecule, including channels activated by a decrease in the intracellular concentration of adenosine triphosphate (K_{ATP}) or activated by acetylcholine (K_{ACh}). Other classes of K^+ channels

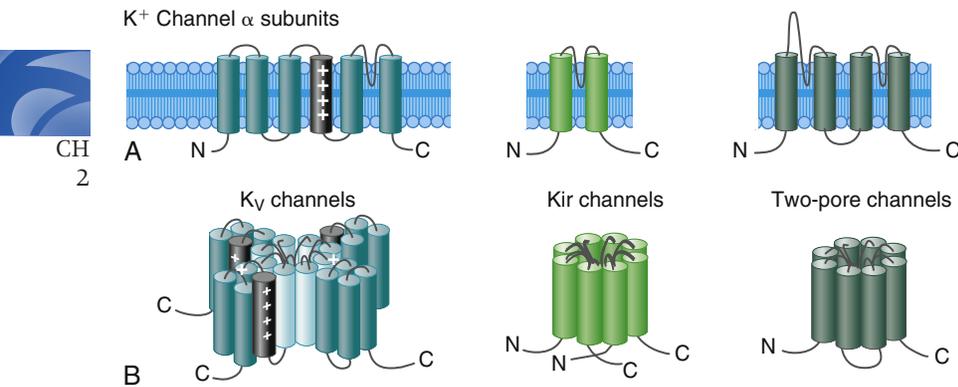

FIGURE 2-3 Molecular compositions of cardiac potassium (K^+) channels. Amino termini (N) and carboxyl termini (C) are indicated. **A**, Voltage-gated (K_v), inward rectifier (Kir), and two-pore α subunits are integral membrane proteins with six, two, and four membrane-spanning domains, respectively. **B**, These α subunits assemble as tetramers or dimers to form K^+ -selective pores. (Modified from Oudit GY, Backx PH: Voltage-regulated potassium channels. In Zipes DP, Jalife J, editors: Cardiac electrophysiology: from cell to bedside, ed 5, Philadelphia, 2009, Saunders, pp 29-42.)

TABLE 2-2 Genetic and Molecular Basis of Cardiac Ion Currents

CURRENT	α SUBUNIT	α -SUBUNIT GENE	β -SUBUNIT/ ACCESSORY PROTEINS	β -SUBUNIT GENE
$I_{to,f}$	$K_v4.2$ $K_v4.3$	KCND2 KCND3	MiRP1 MiRP2 KChIP1 KChIP2 DPP6	KCNE2 KCNE3 KCNE1 KCNE2 DPP6

I_f = cardiac pacemaker current; I_{K1} = inward rectifying current; I_{KACh} = acetylcholine-activated potassium current; I_{KATP} = adenosine triphosphate-dependent potassium current; I_{Kr} = rapidly activating delayed outward rectifying current; I_{Ks} = slowly activating delayed outward rectifying current; $I_{to,s}$ = slow transient outward current; K_{2p} = two-pore potassium channel.

respond to different stimuli, including changes in intracellular Ca^{2+} concentration and G proteins.¹⁵

On the basis of the primary amino acid sequence of the α subunit, K^+ channels have been classified into three major families (Table 2-2):

1. Channels containing six transmembrane segments and a single pore. This architecture is typical of K_v channels.
2. Channels containing two transmembrane segments (M1 and M2) and a pore. This architecture is typical of inward rectifier K^+ (Kir) channels, including $K1$, K_{ATP} , and K_{ACh} channels. They conduct K^+ currents more in the inward direction than the outward and play an important role in setting the resting potential close to the equilibrium potential for K^+ and in repolarization. Kir channels form either homotetramers or heterotetramers.

3. Channels containing four transmembrane segments and two pores (K_{2p}). These channels exist as homodimers or heterodimers. K_{2p} currents display little time or voltage dependence. There are four classes of cardiac K_{2p} : TASK, TWIK, TREK, and THIK.^{15,16}

Each voltage-gated K^+ channel (K_v family) is formed by the coassembly of 4 identical (homotetramers) or a combination of 4 different (from the same subfamily, heterotetramers) α subunits. A total of 38 genes has been cloned and assigned to 12 subfamilies of voltage-gated K channels (K_v1 to K_v12) on the basis of sequence similarities. Each α subunit contains one domain consisting of 6 membrane-spanning segments (S1 to S6), connected to each other by alternating intracellular and extracellular peptide loops (similar to 1 of the 4 domains of voltage-gated Na^+

and Ca^{2+} channels), with both the amino terminus (N-terminus) and the C-terminus located on the intracellular side of the membrane. The central ion-conducting pore region is formed by the S5 and S6 segments and the S5-S6 linker (P segment); the S5-S6 linker is responsible for K^+ ion selectivity. The S4 segment serves as the voltage sensor.^{1,15}

The α subunits of K_v channels can generate voltage dependent K^+ current when expressed in heterologous systems. However, the assembly of a functional tetramer can occur only in the presence of multiple auxiliary units (see Table 2-2). In many cases, auxiliary subunits coassociate with the α subunits and likely modulate cell surface expression, gating kinetics, and drug sensitivity of the α subunit complex. Most K^+ channel β subunits assemble with α subunits and give rise to an $\alpha_4\beta_4$ complex. K^+ channel β subunits represent a diverse molecular group, which includes cytoplasmic proteins ($\text{K}_v\beta 1$ to $\text{K}_v\beta 3$, KChIP, and KChAP) that interact with the intracellular domains of K_v channels; single transmembrane spanning proteins (e.g., minK and minK-related proteins [MiRPs]) encoded by the *KCNE* gene family; and large ATP-binding cassette (ABC) transport-related proteins (e.g., the sulfonylurea receptors [SURs]).^{1,16}

The diversity of K^+ currents in native tissues exceeds the number of K^+ channel genes identified. The explanations for this diversity include alternative splicing of gene products, post-translational modification, and heterologous assembly of β subunits within the same family and assembly with accessory β subunits that modulate channel properties.

As with voltage-dependent Na^+ and Ca^{2+} channels, K_v channels typically fluctuate among distinct conformational states because of molecular movements in response to voltage changes across the cell membrane (voltage-dependent gating). The K_v channel activates (opens) on membrane depolarization, thus allowing the rapid passage of K^+ ions across the sarcolemma. After opening, the channel undergoes conformational transition in a time-dependent manner to a stable nonconducting (inactivated) state. Inactivated channels are incapable of reopening, even if the transmembrane voltage is favorable, unless they “recover” from inactivation (i.e., enter the closed state) on membrane repolarization. Closed channels are nonconducting but can be activated on membrane depolarization.¹⁷

Three mechanistically distinct types of K_v channel inactivation that are associated with distinct molecular domains have been identified: N-type, C-type, and U-type. N-type (“ball and chain”) inactivation involves physical occlusion of the intracellular mouth of the channel pore through binding of a small group of amino acids (“inactivation ball tethered to a chain”) at the extreme N-terminus. In contrast, C-type inactivation involves conformational changes in the external mouth of the pore. C-type inactivation exists in almost all K^+ channels and may reflect a slow constriction of the pore. This inactivation process is thought to be voltage independent, coupled to channel opening, and is usually slower than N-type inactivation. Recovery from C-type inactivation is relatively slow and weakly voltage dependent. Importantly, the rate of C-type inactivation and recovery can be strongly influenced by other factors, such as N-type inactivation, drug binding, and changes in extracellular K^+ concentration. These interactions render C-type inactivation an important biophysical process in regulating repetitive electrical activity and determining certain physiological properties such as refractoriness, drug binding, and sensitivity to extracellular K^+ .¹⁷

In addition to N-type and C-type inactivation, some K_v channels also show another type of inactivation (U-type), which exhibits a U-shaped voltage dependence with prolonged stimulation rates. Those channels appear to exhibit preferential inactivation from partially activated closed states, rapid and strongly voltage-dependent recovery from inactivation and, in some channel types, accelerated inactivation with elevation of extracellular K^+ . The exact conformational changes underlying U-type inactivation remain unclear. Importantly, there is extreme diversity in the kinetic and potentially molecular properties of K_v channel inactivation, particularly of C-type inactivation.¹⁷

Function

K^+ channels are a diverse and ubiquitous group of membrane proteins that regulate K^+ ion flow across the cell membrane on the electrochemical gradient and regulate the resting E_m , the frequency of pacemaker cells, and the shape and duration of the cardiac action potential. Because the concentration of K^+ ions outside the cell membrane is approximately 25-fold lower than that in the intracellular fluid, on activation, the opening of K^+ channels generates an outward current resulting from the efflux of positively charged ions that offers a mechanism to counteract, dampen, or restrict the depolarization front (phases 1 through 4 of the action potential) triggered by an influx of cations (Na^+ and Ca^{2+}).^{1,3,15,16}

The variation in the level of expression of K^+ channels that participate in the genesis of the cardiac action potential explains the regional differences of the configuration and duration of cardiac action potentials from sinus node and atrial to ventricular myocytes and across the myocardial wall (endocardium, midmyocardium, and epicardium). Moreover, the expression and properties of K^+ channels are not static; heart rate, neurohumoral state, pharmacological agents, cardiovascular diseases (cardiac hypertrophy and failure, MI) and arrhythmias (e.g., AF) can influence those properties, and they underlie the change in action potential configuration in response to variation in heart rate and various physiological and pathological conditions.^{1,15,16}

Transient Outward Potassium Current (I_{to})

STRUCTURE AND PHYSIOLOGY

Cardiac I_{to} channels are macromolecular protein complexes, comprising four pore-forming K_v α subunits and a variety of K_v channel accessory (β) subunits (see Fig. 2-3). I_{to} is the sum of a voltage-dependent, Ca^{2+} -independent K^+ current (I_{to1}) and a Ca^{2+} -activated Cl^- or K^+ current (I_{to2}). In human atrial and ventricular myocytes, the presence of I_{to2} has not been clearly demonstrated.

I_{to1} (which is referred to as I_{to}) displays two phenotypes with distinct recovery kinetics: a rapid or fast I_{to} ($I_{to,fast}$ or $I_{to,f}$) phenotype and a slower phenotype ($I_{to,slow}$ or $I_{to,s}$). The transient nature of I_{to} is secondary to its rapid activation (with time constants of less than 10 milliseconds for both $I_{to,f}$ and $I_{to,s}$) and rapid inactivation (25 to 80 milliseconds for $I_{to,f}$ and 80 to 200 milliseconds for $I_{to,s}$). However, whereas $I_{to,f}$ recovers rapidly from inactivation (60 to 100 milliseconds), $I_{to,s}$ recovers slowly (with time constants on the order of seconds).

K_v channels mediating $I_{to,s}$ are formed by the coassembly of four α subunits from the $\text{K}_v 1.x$ subfamily (primarily $\text{K}_v 1.4$, and possibly $\text{K}_v 1.7$ and $\text{K}_v 3.4$), whereas those mediating $I_{to,f}$ are formed by the coassembly of four α subunits from the $\text{K}_v 4.x$ subfamily (primarily $\text{K}_v 4.3$, and possibly $\text{K}_v 4.2$) (see Table 2-2). Among the various accessory subunits identified, a crucial role has been definitively demonstrated only for KChIP2, and potentially for MiRP2.^{1,16,18}

FUNCTION

I_{to} is a prominent repolarizing current; it partially repolarizes the membrane, shapes the rapid (phase 1) repolarization of the action potential, and sets the height of the initial plateau (phase 2). Thus, the activity of I_{to} channels influences the activation of voltage-gated Ca^{2+} channels and the balance of inward and outward currents during the plateau (mainly I_{CaL} and the delayed rectifier K^+ currents), thereby mediating the duration and the amplitude of phase 2.

The density of I_{to} varies across the myocardial wall and in different regions of the heart. In human ventricles, I_{to} densities are much higher in the epicardium and midmyocardium than in the endocardium. Furthermore, $I_{to,f}$ and $I_{to,s}$ are differentially expressed in the myocardium, thus contributing to regional heterogeneities in action potential waveforms. $I_{to,f}$ is the principal subtype expressed

in human atrium. The markedly higher densities of $I_{to,f}$, together with the expression of the ultrarapid delayed rectifier current, accelerate the early phase of repolarization and lead to lower plateau potentials and shorter action potentials in atrial as compared with ventricular cells.^{17,18}

CH
2

Although both $I_{to,f}$ and $I_{to,s}$ are expressed in the ventricle, $I_{to,f}$ is more prominent in the epicardium and midmyocardium (putative M cells) than in the endocardium. These regional differences are responsible for the shorter duration and the prominent phase 1 notch and the “spike-and-dome” morphology of epicardial and midmyocardial compared with endocardial action potentials. A prominent I_{to} -mediated action potential notch in ventricular epicardium but not endocardium produces a transmural voltage gradient during early ventricular repolarization that registers as a J wave or J point elevation on the ECG.¹⁹ I_{to} densities are also reportedly higher in right than in left (midmyocardial and epicardial) ventricular myocytes, consistent with the more pronounced spike-and-dome morphology of right, compared with left, ventricular action potentials.^{1,3,17,18}

Furthermore, variations in cardiac repolarization associated with I_{to} regional differences strongly influence intracellular Ca^{2+} transient by modulating Ca^{2+} entry via I_{CaL} and Na^+Ca^{2+} exchange, thereby regulating excitation-contraction coupling and regional modulation of myocardial contractility and hence synchronizing the timing of force generation between different ventricular regions and enhancing mechanical efficiency.¹⁷

REGULATION

Transient outward channels are subject to α - and β -adrenergic regulation. α -Adrenergic stimulation reduces I_{to} ; concomitant β -adrenergic stimulation appears to counteract the α -adrenergic effect, at least in part. The effects of α - and β -adrenergic stimulation are exerted by phosphorylation of the $K_v1.4$, $K_v4.2$, and $K_v4.3$ α -subunits by PKA as well as PKC. Calmodulin-dependent kinase II, on the other hand, has been shown to be involved in enhancement of I_{to} . Adrenergic stimulation is also an important determinant of transient outward channel downregulation in cardiac disease. Chronic α -adrenergic stimulation and angiotensin II reduce I_{to} channel expression.²⁰

KChIP2, when coexpressed with $K_v4.3$, increases surface channel density and current amplitude, slows channel inactivation, and markedly accelerates the recovery from inactivation. In the ventricle, KChIP2 mRNA is 25-fold more abundant in the epicardium than in the endocardium. This gradient parallels the gradient in I_{to} expression, whereas $K_v4.3$ mRNA is expressed at equal levels across the ventricular wall. Thus, transcriptional regulation of the *KChIP2* gene (KChIP2) is the primary determinant of I_{to} expression in the ventricular wall.^{1,16}

Observations suggest that MiRP2 is required for the physiological functioning of human $I_{to,f}$ channels and that gain-of-function mutations in MiRP2 predispose to Brugada syndrome through augmentation of $I_{to,f}$.¹⁸

I_{to} is strongly rate dependent. I_{to} fails to recover from previous inactivation at very fast heart rates, which can be manifest as a decrease in the magnitude of the J wave on the surface ECG. Hence, abrupt changes in rate and pauses have important consequences for the early repolarization of the membrane.¹⁹

I_{to} can be enhanced by aging, low sympathetic activity, high parasympathetic activity, bradycardia, hypothermia, estrogen reduction, and drugs. Estrogen suppresses the expression of the $K_v4.3$ channel and results in reduced I_{to} and a shallow phase 1 notch.¹³

Phase 1 notch of the action potential modulates the kinetics of slower activating ion currents and consequently the later phases of the action potential. Initial enhancement of phase 1 notch promotes phase 2 dome and delays repolarization, presumably by delaying the peak of I_{CaL} . However, further enhancement of phase 1 notch prevents the rising of phase 2 dome and abbreviates action potential duration, presumably by deactivation or voltage modulation that reduces I_{CaL} . Thus, progressive deepening of phase 1

notch can cause initial enhancement followed by sudden disappearance of phase 2 dome and corresponding prolongation followed by abbreviation of action potential duration. On the other hand, modulators that decrease I_{to} lead to a shift of the plateau phase into the positive range of potentials, thus increasing the activation of the delayed rectifier currents, promoting faster repolarization, and reducing the electrochemical driving force for Ca^{2+} and hence I_{CaL} . Phase 1 notch also affects the function of the Na^+Ca^{2+} exchanger and subsequently intracellular Ca^{2+} handling and Na^+ channel function.^{1,16}

PHARMACOLOGY

Quinidine, 4-aminopyridine, flecainide, and propafenone produce an open channel blockade and accelerate I_{to} inactivation. Quinidine, but not flecainide or propafenone, produces a frequency-dependent block of I_{to} that results from a slow rate of drug dissociation from the channel. Quinidine has relatively strong I_{to} blocking effect, whereas flecainide mildly blocks I_{to} .^{18,20}

I_{to} blockers can potentially prolong the action potential duration in the atrial and in ischemic ventricular myocardium. However, because the net effects of I_{to} blockade on repolarization depend on secondary changes in other currents, the reduction of I_{to} density can result in a shortening of the ventricular action potential. Moreover, heterogeneous ventricular distribution of I_{to} can cause marked dispersion of repolarization across the ventricular wall that, when accompanied by prominent conduction delays related to Na^+ channel blockade, results in extrasystolic activity through a phase 2 reentrant mechanisms.^{18,20}

Currently, a cardioselective and channel-specific I_{to} opener or blocker is not available for clinical use. Development of an I_{to} -selective drug is expected to be beneficial in patients with primary abnormality in the I_{to} or in other channels, such as the Brugada syndrome, in which heterogeneity in the expression of I_{to} between epicardium and endocardium in the right ventricle (RV) results in the substrate responsible for reentry and ventricular arrhythmias.^{18,20}

INHERITED CHANNELOPATHIES

To date, only mutations in *KCNE3* (MiRP2) are linked to inherited arrhythmia. *KCNE3* mutations were identified in five related patients with Brugada syndrome. When expressed with $K_v4.3$, the mutation increased $I_{to,f}$ density.³

Another *KCNE3* mutation was identified in one patient with familial AF. The mutation was found to increase $I_{to,f}$ and was postulated to cause AF by shortening action potential duration and facilitating atrial reentrant excitation waves.³

A genome wide haplotype-sharing study associated a haplotype on chromosome 7, harboring DPP6, with idiopathic VF in three distantly related families. Overexpression of DPP6, which encodes dipeptidyl-peptidase 6, a putative component of the I_{to} channel complex, was proposed as the likely pathogenetic mechanism. DPP6 significantly alters the inactivation kinetics of both $K_v4.2$ and $K_v4.3$ and promotes expression of these α subunits in the cell membrane.^{3,21}

Importantly, the normally functioning I_{to} channels play an important role in the electrophysiological consequences of the ionic current abnormalities in the Brugada and J wave syndromes. Heterogeneity in the distribution of I_{to} channels across the myocardial wall, being more prominent in ventricular epicardium than endocardium, and particularly in the RV, results in the shorter duration and the prominent phase 1 notch and the spike-and-dome morphology of the epicardial action potential as compared with the endocardium. The resultant transmural voltage gradient during the early phases (phases 1 and 2) of the action potential is thought to be responsible for the inscription of the J wave on the surface ECG.^{18,19} An increase in net repolarizing current, secondary to either a decrease in the inward currents (I_{Na} and I_{CaL}) or an increase in the outward K^+ currents (I_{to} , I_{Kr} , I_{Ks} , I_{KACh} , I_{KATP}), or both, can accentuate the action potential notch and lead to augmentation of the J wave

or the appearance of ST segment elevation on the surface ECG. An outward shift of currents that extends beyond the action potential notch not only can accentuate the J wave but also can lead to partial or complete loss of the dome of the action potential, thus leading to a protracted transmural voltage gradient that manifests as greater ST segment elevation and gives rise to J wave syndromes. The type of the ion current affected and its regional distribution in the ventricles determine the particular phenotype (including the Brugada syndrome, early repolarization syndrome, hypothermia-induced ST segment elevation, and MI-induced ST segment elevation).^{18,19,22} The degree of accentuation of the action potential notch leading to loss of the dome depends on the magnitude of I_{to} . These changes are more prominent in regions of the myocardium exhibiting a relatively large I_{to} , such as the RV epicardium; this explains the appearance of coved ST segment elevation, characteristic of Brugada syndrome, in the right precordial ECG leads.^{19,20}

In this context, factors that influence the kinetics of I_{to} or the other repolarization currents can modify the manifestation of the J wave on the ECG. Na^+ channel blockers (procainamide, pilsicainide, propafenone, flecainide, and disopyramide), which reduce the inward I_{Na} , can accentuate the J wave and ST segment elevation in patients with concealed J wave syndromes. Quinidine, which inhibits both I_{to} and I_{Na} , reduces the magnitude of the J wave and normalizes ST segment elevation. Additionally, acceleration of the heart rate, which is associated with reduction of I_{to} (because of slow recovery of I_{to} from inactivation), results in a decrease in the magnitude of the J wave. Male predominance can potentially result from larger epicardial I_{to} density versus I_{to} in women.^{19,22}

The increased transmural heterogeneity of ventricular repolarization (i.e., dispersion of repolarization between epicardium and endocardium), which is responsible for J point elevation and early repolarization pattern on the surface ECG, is also responsible for the increased vulnerability to ventricular tachyarrhythmias. A significant outward shift in current can cause partial or complete loss of the dome of the action potential in regions where I_{to} is prominent (epicardium), with the consequent loss of activation of I_{CaL} . The dome of the action potential then can propagate from regions where it is preserved (midmyocardium endocardium) to regions where it is lost (epicardium), thus giving rise to phase 2 reentry, which can generate premature ventricular complexes that in turn can initiate polymorphic VT or VF.^{19,20,22,23}

ACQUIRED DISEASES

An alteration in the expression and distribution of I_{to} is observed in various pathophysiological conditions. Adrenergic effects seem to be involved in at least some of these I_{to} -regulating processes during heart disease.²⁰

In general, myocardial ischemia, MI, dilated cardiomyopathy, and end-stage heart failure cause downregulation of I_{to} . In fact, I_{to} downregulation is the most consistent ionic current change in the failing heart. The reduction in I_{to} results in attenuation of early repolarization (phase 1) and affects the level of plateau (phase 2) of the action potential and other currents involved in delayed repolarization (phase 3), with resulting prolongation and increased heterogeneity of action potential duration. The prominent epicardial I_{to} contributes to the selective electrical depression of the epicardium. This process leads to the development of a marked dispersion of repolarization between normal and abnormal epicardium and between epicardium and endocardium, which provides the substrate for reentrant arrhythmias and may underlie the increased predisposition to ventricular arrhythmias and SCD in patients with heart failure and ischemic heart disease.^{18,20,24} Additionally, downregulation of I_{to} in advanced heart failure likely slows the time course of force generation, thereby contributing to reduced myocardial performance.

On the other hand, compensatory ventricular hypertrophy preceding heart failure is associated with an upregulation of I_{to} . The prolongation of the action potential, concomitant with an increase in I_{to} , presumably results from the more negative level of the plateau

with less I_{CaL} inactivation and probably less delayed rectifier activation. In contrast, progression of hypertrophy to heart failure is associated with a clear reduction in I_{to} .²⁰

Chronic AF reduces I_{to} density and $K_v4.3$ mRNA levels. Hypothyroidism reduces the expression of *KCNQ2* ($K_v4.2$) genes. Additionally, I_{to} may also be reduced and contribute to QT interval prolongation in diabetes. Importantly, with some delay, insulin therapy partially restores I_{to} , maybe by enhancing $K_v4.3$ expression.³

Ultrarapidly Activating Delayed Outward Rectifying Current (I_{Kur})

STRUCTURE AND PHYSIOLOGY

The ion-conducting pore of I_{Kur} channels is formed by four $K_v1.5$ α subunits, whereas the ancillary β subunits $K_v\beta1.2$, $K_v\beta1.3$, and $K_v\beta2.1$ control channel trafficking and plasma membrane integration as well as activation and inactivation kinetics.^{3,25}

I_{Kur} activates rapidly on depolarization in the plateau range and displays outward rectification, but it inactivates very slowly during the time course of the action potential. Inactivation accelerates when $K_v1.5$ is coexpressed with its β subunits.³

FUNCTION

I_{Kur} is detected only in human atria and not in the ventricles, so that it is the predominant delayed rectifier current responsible for human atrial repolarization and is a basis for the much shorter duration of the action potential in the atrium.^{1,3}

REGULATION

β -Adrenergic stimulation enhances I_{Kur} , whereas α -adrenergic stimulation inhibits it, effects likely mediated by PKA and PKC, respectively. Membrane depolarization and elevated extracellular K^+ concentrations reduce $K_v1.5$ expression. Additionally, AMP, mechanical stretch, hyperthyroidism, and dexamethasone increase $K_v1.5$ expression, whereas extracellular acidosis, phenylephrine, and hypothyroidism decrease it.^{1,3}

Coexpression of $K_v\beta1.3$ with $K_v1.5$ induces a fast inactivation and a hyperpolarizing shift in the activation curve (i.e., $K_v\beta1.3$ subunit converts $K_v1.5$ from a delayed rectifier with a modest degree of slow inactivation to a channel with both fast and slow components of inactivation). Data suggest that $K_v\beta1.2$ and $K_v\beta1.3$ subunit modification of $K_v1.5$ currents requires phosphorylation by PKC or a related kinase.

PHARMACOLOGY

I_{Kur} is relatively insensitive to class III antiarrhythmics of the methanesulfonanilide group, but it is highly sensitive to 4-aminopyridine. Selective inhibition of I_{Kur} by 4-aminopyridine prolongs the human atrial action potential duration.¹⁶

I_{Kur} is a promising target for the development of new, safer antiarrhythmic drugs to prevent AF or atrial flutter, or both, without a risk of ventricular proarrhythmia. Because I_{Kur} is atrium specific, a drug specifically targeting $K_v1.5$ channels would be expected to terminate AF by preventing reentry through atrial action potential prolongation. The drug vernakalant is an I_{Kur}/I_{Na} channel blocker and is undergoing review by the U.S. Food and Drug Administration for the acute termination of AF. However, because $K_v1.5$ is downregulated in AF, the beneficial effect of I_{Kur} block becomes less certain. Furthermore, because $K_v1.5$ is also expressed in other organs (e.g., brain), discovery of drugs that selectively inhibit atrial $K_v1.5$ channels remains necessary.^{1,3,16}

Physiologically, rapid activation of I_{Kur} in the positive potential range following the action potential upstroke can offset depolarizing I_{CaL} and hence lead to the less positive plateau phase in atrial compared with ventricular cardiomyocytes. Conversely, block of I_{Kur} produces a more pronounced spike-and-dome configuration and therefore shifts the potential into a more positive range in

which I_{CaL} activation enhances systolic Ca^{2+} influx during a free-running action potential. Such an indirect effect on I_{CaL} should be shared by all I_{Kur} blockers and is expected to result in a positive atrial inotropic effect.²⁵

INHERITED CHANNELOPATHIES

KCNA5 nonsense mutations have been reported in individuals with familial AF. Heterologous expression of these mutations revealed complete I_{Kur} loss of function. Absence of I_{Kur} can excessively prolong atrial action potential duration with an enhanced risk of EADs that can trigger or maintain AF.^{3,25}

ACQUIRED DISEASES

A prolonged period of rapid activation of the atria as occurs during AF leads to a decrease in I_{Kur} . Additionally, I_{Kur} may be affected in myocardial ischemia. Decreased $K_v1.5$ mRNA levels were reported for the epicardial border zone of infarcted hearts. Moreover, ischemic damage disrupted the normal location of $K_v1.5$ in the intercalated discs.^{1,3,26}

Rapidly Activating Delayed Outward Rectifying Current (I_{Kr})

STRUCTURE AND PHYSIOLOGY

I_{Kr} is formed by coassembly of four pore-forming α subunits ($K_v11.1$, encoded by the *KCNH2* gene, also called the human-ether-a-go-go-related gene, *HERG*, so-named because the mutation in the *Drosophila* fruit fly caused it to shake like a go-go dancer) and β subunits (MiRP1, encoded by the *KCNE2* gene). The current generated by *HERG* channels shows unusual voltage dependence. In contrast to I_{Ks} , I_{Kr} activates relatively rapidly (on the order of 10s of milliseconds) on membrane depolarization. Activation of I_{Kr} occurs with steep voltage dependence and reaches half-maximum activation at membrane voltage of approximately -20 mV. The magnitude of I_{Kr} increases as a function of E_m up to approximately 0 mV, but it declines with stronger depolarization (higher than 0 mV), resulting in a negative slope conductance of the current-voltage relationship. During repolarization of the action potential, I_{Kr} rapidly recovers from inactivation, thus causing the current to peak at -40 mV. The amplitude of the tail current on repolarization exceeds that of the current during the depolarizing pulse.^{3,16,27,28}

The unusual voltage dependence of I_{Kr} results from a fast, voltage-dependent C-type inactivation process, which limits outward K^+ flow at positive voltages. The large tail current on repolarization from positive voltages results from the rapid recovery of inactivated channels into a conducting state.²⁷ On repolarization, *HERG* channels deactivate (close) via a slow, voltage-independent process (in contrast to the voltage-dependent inactivation process).³

Unlike most K_v channels, *HERG* channels exhibit inward rectification. Rectification describes the property of an ion channel to allow currents preferentially to flow in one direction or limit currents from flowing in the other direction. In other words, conductivity of channels carrying such currents is not constant but is altered at a different E_m . A channel that is inwardly rectifying is one that passes current (positive charge) more easily into the cell. This property is critical for limiting outward K^+ conductance during the plateau phase of the cardiac action potential. Unlike typical Kir channels, in which rectification derives from blockade of the channel pore by intracellular polyamines (see later discussion), the mechanism of *HERG* inward rectification is a very rapid inactivation that develops at far more negative potentials (-85 mV) than channel activation (-20 mV).²⁸

The inactivation of *HERG* channels resembles the C-type inactivation of other K_v channels in its sensitivity to extracellular cations (including K^+ and Na^+) and tetraethyl ammonium (TEA), and to mutations in the P segment. However, the gating behavior is distinctive. First, channel inactivation is much faster than

voltage-dependent activation, thus resulting in its characteristic rectification. Second, *HERG* inactivation displays intrinsic voltage dependence. Similar to the classic C-type inactivation, raising the concentration of extracellular K^+ slows *HERG* channel C-type inactivation, an effect that appears to result from occupancy of the pore selectivity filter by K^+ .

FUNCTION

I_{Kr} presents the principal repolarizing current at the end of the plateau phase in most cardiac cells and plays an important role in governing the cardiac action potential duration and refractoriness. I_{Kr} is differentially expressed, with high levels in left atrial and in ventricular endocardium.

I_{Kr} activates relatively fast on membrane depolarization and allows outward diffusion of K^+ ions in accordance with its electrochemical gradient, but voltage-dependent inactivation thereafter is very fast; hence, only limited numbers of channels remain in the open state, whereas a considerable fraction resides in the nonconducting inactivated state. The fast voltage-dependent inactivation limits outward current through the channel at positive voltages and thus helps maintain the action potential plateau phase that controls contraction and prevents premature excitation. However, as the voltage becomes less positive at the end of the plateau phase of repolarization, the channels recover rapidly from inactivation, thus leading to a progressive increase in I_{Kr} amplitudes during action potential phases 2 and 3, with maximal outward current occurring before the final rapid declining phase of the action potential. Next, the channel deactivates (closes) slowly. The resulting large and transient outward current adds considerably to the ongoing repolarization and makes *HERG* especially suitable for robust control of the repolarization phase.^{3,16,27}

REGULATION

β -Adrenergic stimulation and elevation of intracellular cAMP levels enhance I_{Kr} amplitude both through PKA-mediated effects and by direct interaction with the protein. α -Adrenergic stimulation is inhibitory. Coexpression of *HERG* with its β subunit (*KCNE1* or *KCNE2*) accentuates the cAMP-induced voltage shift. The net result of these effects is a reduction in I_{Kr} .^{3,16,27}

Extracellular Na^+ potentially inhibits I_{Kr} by binding to an outer pore site, and it also speeds recovery from inactivation. The inhibitory effect of Na^+ is potentially relieved by physiological levels of extracellular K^+ . Competition with external K^+ for a binding site near the external pore explains the finding that elevation of extracellular K^+ concentration paradoxically enhances I_{Kr} despite the decrease in the electrochemical driving force. Hypokalemia causes prolongation of the action potential duration as a result of reduced K^+ conductance. Low extracellular K^+ levels accelerate fast inactivation of the *HERG* channel and further decrease I_{Kr} .¹⁷

PHARMACOLOGY

I_{Kr} is the target of class III antiarrhythmic drugs of the methanesulfonanilide group (almokalant, dofetilide, D-sotalolol, E-4031, ibutilide, and MK-499). These drugs produce a voltage- and use-dependent block, shorten open times in a manner consistent with open channel block, and exhibit low affinity for closed and inactivated states. I_{Kr} blockers prolong atrial and ventricular action potential duration (and the QT interval) and refractoriness in the absence of significant changes in conduction velocity (A-H, H-V, and PR intervals do not prolong). Although selective I_{Kr} blockers exhibit antiarrhythmic properties against reentrant arrhythmias, they are probably not effective against triggered activity or increased automaticity.¹⁶

Selective I_{Kr} blockers have several disadvantages. These drugs tend to prolong the action potential duration in the Purkinje and midmyocardial cells more than in the subepicardial or subendocardial cells, thus resulting in increased dispersion of repolarization across the ventricular wall and, as a consequence, increased

arrhythmogenesis. Moreover, the effects of these drugs increase with decreasing heart rate. This reverse frequency-dependent nature of I_{Kr} blockers can potentially result in excessive prolongation of the QT interval during bradycardia, potentially precipitating torsades de pointes, whereas this prolongation is much less marked or even absent following β -adrenergic stimulation or during sustained tachycardia. This phenomenon limits the efficacy of these drugs in terminating tachyarrhythmias, while maximizing the risk of torsades de pointes during slow heart rates, such as during sinus rhythm after termination of AF. Reverse use-dependence has been attributed, at least in part, to the incomplete deactivation (accumulation) of I_{Ks} during fast heart rates that leads to a progressive increase in current amplitude, which counteracts the action potential prolongation effects of I_{Kr} blockers.^{3,16,27}

Azimidilide blocks I_{Kr} , I_{Ks} , and I_{Ca} , whereas amiodarone exhibits a complex mechanism of action because it blocks I_{Na} , I_{Ca} , I_{Kr} , I_{Ks} , I_{to} , and I_{KATP} . Quinidine, a class IA agent, also blocks I_{Kr} at concentrations lower than those required to block I_{Ks} , I_{to} , and I_{K1} .

Furthermore, *HERG* channels display an unusual susceptibility to blockade by a variety of drugs compared with other voltage-gated K^+ channels. Increasing numbers of drugs with diverse chemical structures (including some antihistaminics, antipsychotics, and antibiotics) decrease I_{Kr} by depressing *HERG* channel gating, delay ventricular repolarization, prolong the QT interval (acquired LQTS), and induce torsades de pointes. In fact, almost all drugs that cause acquired LQTS target *HERG* channels, likely because of unique structural properties rendering this channel unusually susceptible to a wide range of different drugs. Compared with other cardiac K^+ channels, the *HERG* channel has a large, funnel-like vestibule that allows many small molecules to enter and block the channel. The more spacious inner cavity results from a lack of the S6 helix bending Pro-X-Pro sequence, which presumably facilitates access of drugs to the pore region from the intracellular side of the channel to block the channel current. Additionally, the *HERG* channel contains two aromatic residues located in the S6 domain facing the channel vestibule (not present in most other K^+ channels) that provide high-affinity binding sites for a wide range of structurally diverse compounds. The accessory β subunit (MiRP1, *KCNE2*) also determines the drug sensitivity. Interaction of these compounds with the channel's pore causes functional alteration of its biophysical properties or occlusion of the permeation pathway, or both.^{8,16,29}

One novel mechanism for acquired LQTS involves compounds interfering with *HERG* trafficking (i.e., moving the *HERG* protein from the endoplasmic reticulum to the cell membrane), rather than direct pore blocking. These compounds include arsenic trioxide, pentamidine, probucol (a cholesterol-lowering therapeutic compound), and cardiac glycosides.^{16,29,30}

Some drugs (almokalant, norpropoxyphene, azimidilide, candesartan, and E3174, the active metabolite of losartan) can enhance I_{Kr} . Flufenamic acid and niflumic acid also increase I_{Kr} by accelerating channel opening. These observations open the possibility of developing new I_{Kr} openers for the treatment of patients with congenital (LQT2) or drug-induced LQTS.¹⁶

INHERITED CHANNELOPATHIES

Long QT Syndrome

The LQTS variants in which I_{Kr} is dysfunctional include LQT2 (caused by *KCNH2* [*HERG*] loss-of-function mutations) and LQT6 (caused by *KCNE2* [MiRP1] mutations); most are LQT2, which is the second most prevalent type of LQTS. More than 200 putative disease-causing mutations have been identified for *KCNH2*; most appear to disrupt the maturation and trafficking of I_{Kr} α subunit ($K_v11.1$) to the sarcolemma, thereby reducing the number of functional ion channels at the cell surface membrane. Mutations involving the pore region of the *HERG* channel are associated with a significantly more severe clinical course than nonpore mutations; most pore mutations are missense mutations with a dominant

negative effect. Attenuation of I_{Kr} results in prolongation of the action potential and the QT interval and can potentially generate EADs and torsades de pointes.^{3,7,27,30}

The trafficking of some mutant channels into the sarcolemma can be restored by *HERG* channel blockers (e.g., cisapride, terfenadine, astemizole, E-4031), even when fexofenadine rescues mutant *HERG* channels at concentrations that do not cause channel block. However, because I_{Kr} blockers failed to rescue other trafficking-defective mutants, it is evident that multiple mechanisms may exist for pharmacological rescue of LQT2 mutations.^{7,16}

Proarrhythmia induced by conditions associated with reduction of I_{Kr} (acquired or congenital LQTS) is related to excessive prolongation of action potential duration near plateau voltages, especially those that favor the development of EADs. It is also related to a more marked prolongation of the action potential duration in mid-myocardial than in subepicardial or subendocardial ventricular cells possibly because of the relative scarcity of I_{Ks} and hence less "repolarization reserve" in the midmyocardial cells. Thus, triggered focal activity and ventricular reentry associated with an increased heterogeneity of repolarization across the ventricular wall would lead to the development of torsades de pointes.¹⁶

Short QT Syndrome

Short QT syndrome (SQTS) is a rare disease associated with short QT intervals and increased risk for AF and VF. A gain-of-function mutation in *KCNH2* (*HERG*) is linked to SQTS type 1 (SQT1). A gain-of-function mutation on *KCNH2* causes a shift of voltage dependence of inactivation of I_{Kr} by +90 mV out of the range of the action potential leading to a significant increase of I_{Kr} during the action potential plateau. The resulting I_{Kr} increase achieved by altered gating hastens repolarization, thereby shortening action potential duration and facilitating reentrant excitation waves to induce atrial or ventricular arrhythmia, or both. Additionally, gain-of-function mutations in *KCNE2* (MiRP1) have been found in two families with AF.^{3,27,30}

ACQUIRED DISEASES

MI can result in reduction in $K_v11.1$ mRNA levels and I_{Kr} with consequent prolongation of the action potential duration. Conversely, I_{Kr} density increases in subendocardial Purkinje cells in the infarcted heart at 48 hours, which can potentially increase the proarrhythmic effects of I_{Kr} blockers in patients with MI. Additionally, during acute ischemia, I_{Kr} is increased and action potential duration is shortened. Such changes can be arrhythmogenic. I_{Kr} is unchanged in patients with chronic AF and is homogeneously distributed in failing canine hearts.^{3,16}

ATP, derived from either glycolysis or oxidative phosphorylation, is critical for *HERG* channel function. Both hyperglycemia and hypoglycemia depress I_{Kr} and can cause QT prolongation and ventricular arrhythmias. In diabetes, $K_v11.1$ levels are downregulated, leading to reduction in I_{Kr} and contributing to QT interval prolongation. Importantly, insulin therapy restores I_{Kr} function and shortens QT intervals.^{3,16}

Unlike with most other K^+ currents, I_{Kr} amplitude increases on elevation of extracellular K^+ concentrations and decreases after removal of extracellular K^+ . Elevation of extracellular K^+ concentration reduces C-type inactivation and increases the single channel conductance of *HERG* channels. This explains why the action potential durations are shorter at higher extracellular K^+ concentrations and longer at low concentrations, and it clarifies the associations among hypokalemia, action potential duration prolongation, and induction of torsades de pointes in patients treated with I_{Kr} blockers. In contrast, modest elevations of extracellular K^+ concentrations using K^+ supplements and spironolactone in patients given I_{Kr} blockers or with LQT2 significantly shorten the QT interval and may prevent torsades de pointes. Moreover, the antiarrhythmic actions of I_{Kr} blockers can be reversed during ischemia, which is frequently accompanied by elevations of the extracellular K^+ concentrations in the narrow intercellular spaces

and by catecholamine surges that occur with exercise or other activities associated with fast heart rates.¹⁶

Slowly Activating Delayed Outward Rectifying Current (I_{Ks})

STRUCTURE AND PHYSIOLOGY

I_{Ks} is formed by coassembly of four pore-forming α subunits ($K_v7.1$, encoded by the *KCNQ1* gene, also known as K_vLQT1) and β subunits (minK, encoded by the *KCNE1* gene). I_{Ks} is a K^+ -selective current that activates very slowly in response to membrane depolarization to potentials greater than -30 mV and reaches half-maximum activation close to $+20$ mV. I_{Ks} has a linear current-voltage relationship, its time course of activation is extremely slow, slower than any other known K^+ current, and steady-state amplitude is achieved only with extremely long membrane depolarization.^{3,16,27,28}

Inactivation of *KCNQ1* channels is half maximal at -18 mV and, at its maximum, inactivation reduces fully activated current by approximately 35%. In addition, unlike inactivation of other K_v channels, the onset of I_{Ks} inactivation occurs after a delay (a delay of approximately 75 milliseconds at $+40$ mV). In contrast, when inactivation is induced after transient recovery of channels to open states, the onset of inactivation is 10 times faster. The molecular mechanism of *KCNQ1* channel inactivation is unknown, but in contrast to a classical C-type inactivation, *KCNQ1* inactivation is independent of extracellular K^+ concentration.²⁸

FUNCTION

I_{Ks} contributes to human atrial and ventricular repolarization, particularly during action potentials of long duration. I_{Ks} gradually increases during the plateau phase of the action potential because its activation is delayed and very slow. As a consequence, the contribution of I_{Ks} to the net repolarizing current is greatest late in the cardiac action potential plateau phase. I_{Ks} is expressed in all cell types, but it is reduced in midmyocardial cells. The midmyocardial cells have the longest action potential duration across the myocardial wall.²⁸

I_{Ks} plays an important role in determining the rate-dependent shortening of the cardiac action potential. As heart rate increases, I_{Ks} increases because channel deactivation is slow and incomplete during the shortened diastole. This allows I_{Ks} channels to accumulate in the open state during rapid heart rates and contribute to the faster rate of repolarization.^{16,28}

Importantly, I_{Ks} is functionally upregulated when other repolarizing currents (e.g., I_{Kr}) are reduced, potentially serving as a safeguard against loss of repolarizing power. As such, several redundant mechanisms contribute to repolarization constituting the repolarization reserve, in which I_{Ks} plays an important role.^{8,28}

REGULATION

I_{Ks} is markedly enhanced by β -adrenergic stimulation through channel phosphorylation by PKA (requiring A-kinase anchoring protein 9 [AKAP9, also known as Yotiao]) and PKC (requiring minK). This produces a rate-dependent shortening of the action potential duration such as seen during exercise-induced sinus tachycardia. I_{Ks} is also modulated by α -adrenergic receptors through the PKC pathway. Lowering extracellular K^+ and Ca^{2+} concentrations increases I_{Ks} .^{16,27}

Coexpression of *KCNQ1* α subunits with minK regulates the α -subunit trafficking and behavior and results in a seven-fold increase in I_{Ks} magnitude, marked slowing of the time course of activation, and removal (or significant slowing) of inactivation of *KCNQ1* channels.¹⁶

As noted, I_{Kr} and I_{Ks} are functionally linked; when I_{Kr} is reduced, the action potential is prolonged, causing I_{Ks} activation to increase to prevent excess repolarization delay. Hence, the duration of the action potential is very tightly tuned via I_{Ks} and I_{Kr} regulation.²⁷

PHARMACOLOGY

I_{Ks} is resistant to methanesulfonanilides (almokalant, dofetilide, D-sotalol, E-4031, ibutilide, and MK-499), but it is selectively blocked by chromanols, indapamide, thiopentone, propofol, and benzodiazepines. I_{Ks} is also blocked, although nonselectively, by amiodarone, dronedarone, and azimilide. *KCNQ1* modulates the effects of I_{Ks} blockers and agonists. In fact, *KCNQ1/KCNE1* channels have 6- to 100-fold higher affinity for some I_{Ks} blockers than *KCNQ1* channels.¹⁶

Selective I_{Ks} blockers prolong the cardiac action potential duration and QT interval and suppress electrically induced ventricular tachyarrhythmias in animals with acute coronary ischemia and exercise superimposed on a healed MI.¹⁶

I_{Ks} blockade seems to have less proarrhythmic potency as compared with I_{Kr} blockade, likely the result of less drug-induced dispersion in repolarization. Additionally, because I_{Ks} accumulates at fast driving rates because of its slow deactivation, I_{Ks} blockers can be expected to be more effective in prolonging action potential duration and refractoriness at fast rates. Furthermore, because I_{Ks} activation occurs at approximately 0 mV and this voltage is more positive than the Purkinje fiber action potential plateau voltage, I_{Ks} blockade should not be expected to prolong the action potential duration at this level. Conversely, in ventricular muscle, the plateau voltage is more positive (approximately $+20$ mV), thus allowing I_{Ks} to be substantially more activated, so that I_{Ks} blockade would be expected to markedly increase action potential duration.¹⁶

β -Adrenergic agonists increase I_{Ks} density and produce a rate-dependent shortening of the action potential duration and can also decrease the antiarrhythmic effects of I_{Ks} blockers. Additionally, in the presence of I_{Ks} blockade, isoproterenol seems to abbreviate the action potential duration of epicardial and endocardial, but not midmyocardial, cells, an effect that can accentuate transmural dispersion of repolarization and precipitate torsades de pointes. These observations may explain the therapeutic actions of β -blockers in patients with LQTS syndromes linked to attenuation of I_{Ks} and the increased risk of fatal cardiac arrhythmias under physical activity or stressful situations that increase sympathetic activity in these patients.¹⁶

INHERITED CHANNELOPATHIES

KCNQ1 and *KCNE1* mutations can lead to a defective protein and several forms of inherited arrhythmias, including LQTS (comprising the autosomal dominant Romano-Ward syndrome and the autosomal recessive Jervell and Lange-Nielsen syndrome), SQTs, and familial AF.^{3,31}

Long QT Syndrome

The most common type of LQTS, LQT1, is caused by autosomal dominant loss-of-function mutations on the *KCNQ1* gene (K_vLQT1). More than 170 mutations of this gene have been reported. They comprise many Romano-Ward (autosomal dominant) syndromes and account for approximately 45% of all genotyped LQTS families.⁷ Individuals with the less prevalent LQTS type 5 (LQT5) carry loss-of-function autosomal dominant mutations in *KCNE1* and display a phenotype similar to that seen in patients with LQT1.⁸

Loss-of-function mutations in both alleles of *KCNQ1* or *KCNE1* (i.e., inherited from both parents, autosomal recessive) cause the very rare Jervell and Lange-Nielsen syndrome type 1 or 2, respectively. Jervell and Lange-Nielsen syndrome encompasses 1% to 7% of all genotyped patients with LQTS and is characterized by severe QT interval prolongation, high risk of sudden death, and congenital deafness; the deafness results from deficient endolymph secretion (*KCNQ1* and *KCNE1* are also expressed in the inner ear, where they enable endolymph secretion).^{3,8,9,31,32}

LQT11 is caused by loss-of-function mutations on the *AKAP9* gene, which encodes an A-kinase anchoring protein (Yotiao), shown to be an integral part of the I_{Ks} macromolecular complex.

The presence of Yotiao is necessary for the physiological response of the I_{Ks} channel to β -adrenergic stimulation.⁹ A mutation in *AKAP9* (Yotiao) in the I_{Ks} channel ($K_v7.1$) binding domain reduces the interaction between the I_{Ks} channel and Yotiao. This, in turn, reduces the cAMP-induced phosphorylation of the channel and prevents the functional response of the I_{Ks} channel to cAMP and adrenergic stimulation (i.e., prevents the increase in magnitude of I_{Ks} and the shortening of action potential duration in response to sympathetic stimulation). The final result is an attenuation of I_{Ks} , resulting in a delay in ventricular repolarization and QT interval prolongation.^{3,8}

Mutations in *LQT1*, *LQT5*, and *LQT11* result in attenuation of I_{Ks} , which causes prolongation of repolarization, action potential duration, and QT interval, which may be especially notable during periods of increased sympathetic activity, such as exercise, when I_{Ks} becomes the predominant repolarization current rather than I_{Kr} . In *LQT1*, ventricular arrhythmias are usually triggered by emotional or physical stress, probably because mutant I_{Ks} does not increase sufficiently (i.e., has less repolarization reserve) during β -adrenergic stimulation. Accordingly, β -adrenergic blocking drugs suppress arrhythmic events in *LQT1*.^{3,8,33}

Short QT Syndrome

SQT2 is caused by mutations on the *KCNQ1* gene (K_vLQT1). A gain-of-function mutation on *KCNQ1* causes a shift of voltage dependence of activation of I_{Ks} by -20 mV and acceleration of activation kinetics, leading to enhancement of I_{Ks} and shortening of the action potential duration and QT interval. *KCNQ1* gain-of-function mutations likely predispose to AF and VF by shortening refractoriness and facilitating reentry.^{3,8}

Familial Atrial Fibrillation

KCNQ1 gain-of-function mutations have been linked to familial AF with or without the *SQTS* phenotype.

ACQUIRED DISEASES

Heart failure reduces I_{Ks} in atrial, ventricular, and sinus node myocytes. Given that I_{Kr} is unchanged, I_{Ks} reduction may largely account for the prolonged action potential duration in heart failure.³

I_{Ks} density and *KCNQ1/KCNE1* mRNA levels are reduced in myocytes from infarcted border zones 2 days after MI. However, *KCNQ1* expression is restored 5 days after MI, whereas *KCNE1* expression remains decreased.³

Inward Rectifying Current (I_{K1})

STRUCTURE AND PHYSIOLOGY

The Kir channels are formed by the coassembly of four α subunits (see Fig. 2-3). The α subunit (Kir2.1) of I_{K1} is encoded by *KCNJ2* and consists of two transmembrane domains (M1 and M2) connected by a pore-forming P loop (H5) along with the cytoplasmic N- and C-termini. The tetrameric Kir channel complex can be formed by identical (homotetramers) or different (heterotetramers) α subunits. Several I_{K1} channels with different conductances are recorded in human atrial myocytes. Similarly, different gene families (Kir2.1 to Kir2.3) have been found in human heart encoding I_{K1} .^{16,34}

Kir channels exhibit a strong inward rectification property because conductance to K^+ ions alters at a different E_m . As noted, rectification describes the property of an ion channel to allow currents preferentially to flow in one direction or limit currents from flowing in the other direction. A channel that is inwardly rectifying is one that passes current (positive charge) more easily into the cell. In the case of Kir channels, inward rectification is a strongly voltage-dependent decline of K^+ efflux (i.e., reduction of outward current) on membrane depolarization that produces a characteristic region of so-called negative slope conductance. As such, I_{K1} is a strong rectifier that passes K^+ currents over a limited range of E_m ; at a negative E_m , I_{K1} conductance is much larger than that of any other current,

and so it clamps the resting E_m close to the reversal potential for K^+ (E_K). On depolarization, I_{K1} channels close almost immediately and thus limit K^+ efflux at potentials more positive than the E_K , remain closed throughout the plateau, and open again at potentials negative to -20 mV. Nevertheless, I_{K1} channels also conduct a substantial outward current at an E_m between -40 and -90 mV. Within this voltage range, outward I_{K1} is larger at more negative potentials. Thus, I_{K1} also contributes to terminal phase 3 of repolarization. Because an E_m negative to E_K is not reached in cardiomyocytes, only the outward I_{K1} plays a role in action potential formation.^{16,34}

The phenomenon of inward rectification of I_{K1} channels results from high-affinity and strongly voltage-dependent blockade of the inner channel pore by cytosolic magnesium (Mg^{2+}), Ca^{2+} , and polyamines (spermine, spermidine, putrescine), which plug the channel pore at depolarized potentials, resulting in a decline in outward currents, but are displaced by incoming K^+ ions at hyperpolarized potentials. This voltage-dependent block by polyamines causes currents to be conducted well only in the inward direction. As such, I_{K1} channels are voltage regulated despite the lack of the classic voltage-sensing mechanism of K_v channels.^{16,17,34}

FUNCTION

I_{K1} sets and stabilizes the resting E_m and regulates cellular excitability of atrial and ventricular myocytes during phase 4. It also contributes to the terminal portion of phase 3 repolarization. In addition to the contribution of I_{K1} to the T wave on surface ECG, data suggest that the U wave is strongly modulated by I_{K1} .

I_{K1} channels close on depolarization. The strong inward rectification of the I_{K1} limits the outward current during the positive phase of the action potential (phases 0, 1, and 2), thus allowing membrane depolarization following Na^+ channel activation, slowing membrane repolarization, and helping maintain a more prolonged cardiac action potential. This also confers energetic efficiency in the generation of the action potential.^{16,34}

I_{K1} density is much higher in ventricular than in atrial myocytes, a finding that explains the steep repolarization phase in the ventricles (where more abundant I_{K1} plays a larger role in accelerating the terminal portion of repolarization) and the more shallow phase in the atria. The higher I_{K1} channel expression in the ventricle protects the ventricular cell from pacemaker activity. By contrast, I_{K1} is almost absent in sinus node and AVN cells, thus allowing for relatively more depolarized resting diastolic potentials compared with atrial and ventricular myocytes.^{16,34}

A unique property of Kir currents is the unusual dependence of rectification on extracellular K^+ concentration. Specifically, on increase in extracellular K^+ , the I_{K1} current-voltage relationship shifts nearly in parallel with the E_K and leads to a crossover phenomenon. One important consequence of such behavior is that at potentials positive to the crossover, K^+ conductance increases rather than decreases, against an expectation based on a reduced driving force for K^+ ions in response to elevated extracellular K^+ concentration.³⁴

Fast heart rates increase the K^+ concentration in the narrow intercellular space to several millimolars and the I_{K1} density, which results in a shortening of the action potential duration that may offset the ability of I_{Kr} blockers to prolong the action potential duration under these conditions.^{16,34}

REGULATION

β -Adrenergic stimulation inhibits I_{K1} in ventricular myocytes via PKA-mediated phosphorylation of the channel. In atrial myocytes, α_1 -adrenergic stimulation reduces I_{K1} via PKC-dependent pathways.^{16,34}

Kir2.1 overexpression increases I_{K1} density, shortens the action potential duration, and hyperpolarizes the resting E_m . In contrast, suppression of I_{K1} prolongs the action potential duration and disrupts effective clamping of the resting E_m , thus precipitating spontaneous pacemaker activity in otherwise nonpacemaking atrial and ventricular cardiomyocytes.¹⁶

PHARMACOLOGY

Barium (Ba^{2+}) is a potent I_{K1} blocker. Blocking I_{K1} by extracellular Ba^{2+} results in depolarization of the resting potential and mild action potential prolongation.^{3,34}

CH I_{K1} blockers prolong atrial and ventricular action potential duration and are effective against various types of experimental reentrant VTs. Moreover, I_{K1} blockers produce membrane depolarization, an effect that slows conduction velocity as a result of voltage-dependent inactivation of Na^+ channels, and prolongs the QT interval; both actions are proarrhythmic.^{16,34}

INHERITED CHANNELOPATHIES

Long QT Syndrome

More than 33 loss-of-function mutations of *KCNJ2* gene encoding Kir2 result in dominant negative effects on the current and have been linked to Andersen-Tawil syndrome (LQT7), a rare autosomal dominant disorder characterized by the triad of skeletal developmental abnormalities, periodic paralysis, and usually ventricular arrhythmias, often associated with prominent U waves and mild QT interval prolongation ($Kir2.1$ channels are expressed primarily in skeletal muscle, heart, and brain).^{3,16,34} The arrhythmias displayed by affected patients are more benign compared with other LQTS and rarely degenerate into hemodynamically compromising rhythms such as torsades de pointes, as ultimately evidenced by the lack of SCD cases so far.^{8,35,36}

Disruption of the I_{K1} function can potentially lead to prolongation of the terminal repolarization phase and QT interval, which can predispose to the generation of EADs and delayed afterdepolarizations (DADs) that cause ventricular arrhythmias. However, unlike other types of LQTS in which the afterdepolarizations arise from reactivation of L-type Ca^{2+} channels, the EADs and DADs generated in LQT7 are likely secondary to Na^+Ca^{2+} exchanger-driven depolarization. It is believed that the differential origin of the triggering beat is responsible for the observed discrepancy in arrhythmogenesis and the clinical features compared with other types of LQTS. Additionally, it is likely that prolongation of the action potential duration in LQT7 is somewhat homogeneous across the ventricular wall (i.e., transmural dispersion of repolarization is less prominent than in other types of LQTS), and this can potentially explain the low frequency of torsades de pointes.^{8,35,36}

Catecholaminergic Polymorphic Ventricular Tachycardia

Three novel loss-of-function mutations of *KCNJ2* have been found in patients with catecholaminergic polymorphic VT (CPVT). These patients had prominent U waves, ventricular ectopy, and polymorphic VT, but no dysmorphic features or skeletal muscle abnormalities.³⁴

I_{K1} reduction can trigger arrhythmia by allowing inward currents, which are no longer counterbalanced by the strong outward I_{K1} , to depolarize the E_m gradually during phase 4. Membrane depolarization during phase 4 induces arrhythmia by facilitating spontaneous excitability.³

Short QT Syndrome

A gain-of-function mutation of *KCNJ2* has been identified and linked to SQTs type 3 (SQT3). The mutation causes a significant increase in the outward I_{K1} at potentials between -75 mV and -45 mV, thus leading to acceleration of the terminal phase of repolarization and, as a consequence, shortening the action potential duration and QT interval and asymmetrical T waves with a rapid terminal phase.³⁷

Familial Atrial Fibrillation

A gain-of-function *KCNJ2* mutation has been linked to familial AF. The affected members had normal QT intervals. The mutation was speculated to cause AF by shortening atrial action potential duration and facilitating reentrant excitation waves.^{3,34}

ACQUIRED DISEASES

I_{K1} is downregulated in patients with severe heart failure and cardiomyopathy. The downregulation of I_{K1} produces membrane depolarization and prolongation of the action potential duration, and it can facilitate spontaneous excitability and trigger arrhythmia (both EADs and DADs). The ventricular myocytes from patients with idiopathic dilated cardiomyopathy exhibit decreased channel activity, longer action potential duration, and a lower resting E_m than those from patients with ischemic cardiomyopathy. Upregulation of I_{K1} can be observed in ventricular hypertrophy.^{3,34}

Atrial I_{K1} is upregulated in patients with chronic AF, resulting in more negative resting potentials and, together with reduced I_{CaL} , accounting for action potential shortening in AF.³

Acetylcholine-Activated Potassium Current (I_{KACH})

STRUCTURE AND PHYSIOLOGY

I_{KACH} results from a heterotetrameric complex of two Kir3.1 (encoded by *KCNJ3*) and two Kir3.4 (encoded by *KCNJ5*) α subunits. I_{KACH} is a receptor-activated Kir channel; it has large cytoplasmic domains that harbor specific binding sites for cytosolic effectors (G proteins). The channel conducts I_{KACH} in response to the stimulation of G protein-coupled muscarinic (M_2) and adenosine (A_1) receptors.¹⁶

Cardiac I_{K1} and I_{KACH} are the major K^+ currents displaying classical strong inward rectification with membrane depolarization, a unique property that is critical for their roles in cardiac excitability.³⁴

FUNCTION

I_{KACH} has generally an opposite distribution to that of I_{K1} . I_{KACH} is more prominent in atrial tissue, as well as in the sinus node and AVN, and is largely absent in the ventricles. The regional distribution of I_{KACH} is also heterogeneous within and between the atria.^{16,34}

I_{KACH} mediates vagal influences on sinus rate and atrial repolarization, as well as AVN conduction. Activation I_{KACH} by acetylcholine hyperpolarizes the E_m and shortens action potential duration. These effects result in slowing of phase 4 depolarization, reduction in the spontaneous firing rate of the pacemaker cells of the sinus node and AVN, and slowing of AVN conduction. These effects explain why vagal maneuvers or intravenous adenosine can terminate reentrant supraventricular tachycardias using the AVN.^{16,34}

REGULATION

Vagal stimulation produces a nonuniform shortening of the atrial action potential duration and refractoriness mediated by activation of I_{KACH} , an effect that can contribute to the perpetuation of AF.¹⁶

I_{KACH} is also increased by purinergic stimulation. Adrenergic stimulation via β_1 -receptor-mediated signaling increases the amplitude of constitutively active current, whereas α_{1a} -stimulation decreases I_{KACH} .

Atrial I_{KACH} is inhibited by membrane stretch, possibly serving as a mechanoelectrical feedback pathway, a property conferred by the Kir3.4 subunit.¹⁶

PHARMACOLOGY

I_{KACH} activity can be stimulated by intracellular ATP, the phospholipid phosphatidylinositol 4,5-bisphosphate (PIP_2) and ETA endothelin, A opioid, and α_2 -adrenergic agonists. α_1 -Adenosine receptor agonists stimulate I_{KACH} , whereas methylxanthines, such as theophylline and aminophylline, antagonize the effects of adenosine. Dipyridamole prolongs the action of adenosine by disturbing the action of the cell membrane transporter of adenosine.^{1,38}

$I_{K_{ACH}}$ is inhibited by several antiarrhythmic drugs, including amiodarone, dronedarone, disopyramide, procainamide, flecainide, and propafenone. Disopyramide and procainamide mainly block the muscarinic receptors, whereas flecainide and propafenone act as open channel blockers. Blockade of $I_{K_{ACH}}$ by dronedarone is approximately 100 times more potent than that of amiodarone.¹⁶

A potent $I_{K_{ACH}}$ blocking property is of additional therapeutic value especially for treatment of AF, because $I_{K_{ACH}}$ plays a prominent role in vagally induced AF and has been shown to be constitutively active in chronic AF. In fact, $I_{K_{ACH}}$ is a promising target for AF therapy, and series of chemical compounds have been tested as antiarrhythmic agents. Inhibition of $I_{K_{ACH}}$ in the setting of AF can potentially produce proportionally greater action potential duration prolongation than under control conditions and can even terminate experimental atrial tachyarrhythmias and AF without ventricular side effects.²⁶

INHERITED CHANNELOPATHIES

LQT13 is caused by loss-of-function mutations on the *KCNJ5* gene. The *KCNJ5* mutation is the most recently identified LQTS-associated gene, and it exerts dominant-negative effects on Kir3.1-Kir3.4 channel complexes by disrupting membrane targeting and stability of Kir3.4.³⁹

ACQUIRED DISEASES

$I_{K_{ACH}}$ is downregulated during chronic AF possibly to counteract the AF-induced nonuniform shortening of the atrial refractoriness.¹⁶ However, $I_{K_{ACH}}$ channels can develop constitutive activity during human AF (i.e., these channels become activated despite the absence of stimulating acetylcholine). This increase in functionally uncoupled $I_{K_{ACH}}$ in human AF is possibly the result of increased phosphorylation of Kir3 channels by PKC or a reduction in inhibitory $G_{\alpha i-3}$ subunits. Constitutively active $I_{K_{ACH}}$ can hyperpolarize the membrane and, hence, contribute to AF-related electrical remodeling and to the persistence of AF by stabilization of rotors. Therefore, selectively targeting constitutively active $I_{K_{ACH}}$ channels only may preserve physiological stimulation by vagal nerves and could serve as a promising remodeling-related drug target.^{26,40}

ATP-Dependent Potassium Current ($I_{K_{ATP}}$)

STRUCTURE AND PHYSIOLOGY

Cardiac ATP-sensitive K^+ (K_{ATP}) channels (also termed the adenosine diphosphate [ADP]-activated K^+ channel) are formed by the unique combination of two dissimilar proteins: four pore-forming α subunits (Kir6.2, encoded by *KCNJ4*) and four regulatory ATP-binding cassette proteins (sulfonylurea receptor subunits [SUR2A] encoded by *ABCC9*). The Kir6.2 subunits have two transmembrane spans and form the channel's pore and large cytoplasmic domains that provide the binding sites for ATP. The SUR2A subunits have three transmembrane domains and contain two nucleotide-binding domains on the cytoplasmic side. These allow for nucleotide-mediated regulation of K_{ATP} and are critical in its role as a sensor of metabolic status. The SUR2A subunits are also sensitive to sulfonylureas, Mg-ATP, Mg-ADP, and some other pharmacological channel openers. The SUR2A subunit also harbors an ATPase for ATP hydrolysis, which gates the K^+ permeation through the Kir6.2 α subunit.^{16,41-43}

K_{ATP} is a receptor-activated weak inward rectifier channel, regulated by intracellular ATP and ADP concentrations. An increase in the ratio of ATP to ADP closes the channel, and a decrease opens it, linking the metabolic state to the cellular E_m .^{16,41-43}

FUNCTION

$I_{K_{ATP}}$ is inhibited by intracellular ATP and activated by Mg-ADP, so that the channel activity is regulated by the ATP/ADP ratio,

coupling cell metabolism to the E_m . In responding to cytoplasmic nucleotide levels, K_{ATP} channel activity provides a unique link between cellular energetics and electrical excitability and hence contractility. Under normal metabolic conditions, sarcolemmal K_{ATP} channels are predominantly closed (inhibited by intracellular ATP), and they do not significantly contribute to the cardiac action potential, resting E_m , or cell excitability. However, when exposed to a severe metabolic stress such as anoxia, metabolic inhibition, or ischemia, K_{ATP} channels become activated (secondary to reduced intracellular ATP levels) and conduct an outward repolarizing K^+ current ($I_{K_{ATP}}$), which results in abbreviation of the action potential duration and reduction of Ca^{2+} influx through L-type Ca^{2+} channels. By reducing Ca^{2+} entry, K_{ATP} channels depress muscle contractility, thereby conserving scarce energy resources, and prevent the damaging effects of intracellular Ca^{2+} overload.^{42,43}

Accordingly, cardiac K_{ATP} channels act as membrane-based metabolic sensors that receive energetic signals of cellular distress and provide adaptive response to acute stress capable of controlling cardiac action potential duration and associated cellular functions and adjusting cellular excitability to match demand.⁴³

Additionally, activation of $I_{K_{ATP}}$ plays an important role in ischemic preconditioning; brief periods of myocardial ischemia confer protection against subsequent prolonged ischemia, reducing MI size, severity of stunning, and incidence of cardiac arrhythmias. However, the role of sarcolemmal K_{ATP} channels in ischemic preconditioning versus that of mitochondrial K_{ATP} channels (which appear to be pharmacologically distinct from sarcolemmal K_{ATP}) has been debated.^{42,43}

On the other hand, activation of $I_{K_{ATP}}$ also results in shortening of the action potential duration, accumulation of extracellular K^+ , membrane depolarization, and slowed conduction velocity, effects that render the ischemic heart vulnerable to reentrant arrhythmias.⁴²

K_{ATP} channels have been further implicated in the adaptive cardiac response to chronic pathophysiological hemodynamic load. K_{ATP} channel deficiency affects structural remodeling, renders the heart vulnerable to Ca^{2+} -dependent maladaptation, and predisposes to heart failure.⁴³

REGULATION

ATP (with or without Mg^{2+}) inhibits $I_{K_{ATP}}$ by stabilizing the closed state of the channel by interacting directly with Kir6.2. In addition, in the presence of Mg^{2+} , ATP and ADP can activate the channel through interaction with the SUR2A subunit. Inhibition by ATP binding to Kir6.2 and activation by Mg nucleotides is the primary physiological regulatory mechanism.^{16,41-43}

K_{ATP} channel's sensitivity to ATP is not fixed, and it can be modulated by other cellular factors. Nucleotide diphosphates, lactate, oxygen-derived free radicals, and adenosine α_1 receptor stimulation desensitize K_{ATP} to inhibition by intracellular ATP. Additionally, the phospholipid PIP_2 directly interacts with Kir6.2 subunit stabilizing the open state of the channel and antagonizes ATP inhibition of $I_{K_{ATP}}$.⁴²

PHARMACOLOGY

K^+ channel openers (pinacidil, cromakalim, rimakalim, and nicorandil) bind at two distinct regions of SUR2A subunits and can exert cardioprotective effects in patients with acute MI. However, K^+ channel openers also activate vascular K_{ATP} (Kir6.1/SUR2B) and produce hypotensive effects that limit their use in the treatment of myocardial ischemia. Moreover, because $I_{K_{ATP}}$ density is larger in the epicardium, K^+ channel openers produce a more marked shortening of action potential duration in epicardial cells, thus leading to a marked dispersion of repolarization and to the development of extrasystolic activity via a mechanism of phase 2 reentry. On the other hand, K^+ channel openers shorten the action potential duration (and QT interval), reduce transmural dispersion of repolarization, and suppress EADs and DADs induced in patients with LQT1.

Thus, K⁺ channel openers may prevent spontaneous torsades de pointes when congenital or acquired LQTS is secondary to reduced I_{Kr} or I_{Ks}.^{16,42}

I_{KATP} blockers (e.g., sulfonylureas and various antiarrhythmic drugs) prevent the shortening of the action potential duration and can potentially prevent VF during myocardial ischemia. Nonetheless, they can also be arrhythmogenic. Moreover, because K_{ATP} channels are present in pancreatic β cells and vascular smooth muscle, I_{KATP} blockers can produce hypoglycemia and coronary vasoconstriction, effects that may preclude their interest as antiarrhythmic agents.

On the other hand, cardioselective I_{KATP} blockers (clamikalant, HMR 1098) inhibited hypoxia-induced shortening of the action potential duration and prevented VF induced by coronary artery occlusion in postinfarcted conscious dogs at doses that had no effect on insulin release, blood pressure, or coronary blood flow. Thus, these drugs may represent a new therapeutic approach to the treatment of ventricular arrhythmias in patients with coronary heart disease.^{16,42}

It is still unclear whether opening of K_{ATP} channels has completely proarrhythmic or antiarrhythmic effects. Increased K⁺ conductance should stabilize the E_m during ischemic insults and reduce the extent of infarct and ectopic pacemaker activity. On the other hand, K⁺ channel opening accelerates repolarization of the action potential, possibly inducing arrhythmic reentry.^{16,42}

INHERITED CHANNELOPATHIES

Mutations in *ABCC9* resulting in reduced intrinsic channel ATPase activity, metabolic sensing deficit, and dysfunctional K_{ATP} channels have been found in patients with idiopathic dilated cardiomyopathy and rhythm disturbances. These mutations confer susceptibility to Ca²⁺-dependent maladaptive remodeling, progressing to cardiomyopathy and congestive heart failure. Additionally, a loss-of-function *ABCC9* mutation has been linked to predisposition to adrenergic AF. K_{ATP} channel-pore polymorphisms have also been linked to SCD.⁴³

Many mutations in the Kir6.2 subunit have now been identified as causal in human neonatal diabetes mellitus, a very severe form of diabetes that typically occurs within the first days or weeks of life. All the identified Kir6.2 mutations result in a reduced channel sensitivity to ATP inhibition, leading to channel activation at elevated glucose, maintained hyperpolarization of pancreatic islet α cells, and electrical inexcitability, with consequent inhibition of insulin secretion. Although cardiac K_{ATP} channels (Kir6.2/SUR2A) have the same Kir6.2 subunit as that in pancreatic K_{ATP} channels (Kir6.2/SUR1), there are no reports of any cardiac abnormalities in patients with neonatal diabetes mellitus; this finding suggests that factors other than nucleotide sensitivity play an important role.⁴²

ACQUIRED DISEASES

Metabolic dysregulation of I_{KATP} created by disease-induced structural remodeling appears to contribute to the dysfunction of heart failure.^{26,43}

The effects of Kir6.2 modulation in AF have not extensively been studied. However, evidence indicates a reduction of I_{KATP} in patients with chronic AF, a finding suggesting that regulation of this current may not contribute importantly to AF-related ionic remodeling.^{26,43}

Two-Pore Potassium Channels (K_{2P})

STRUCTURE AND PHYSIOLOGY

K_{2P} channels are composed of four transmembrane domains and two pore-forming P loops arranged in tandem, one between the first and second transmembrane domains and the other between the third and fourth domains (see Fig. 2-3). The proteins mainly form functional homodimers, although heterodimers combining different K_{2P} subunits have been reported. Several subfamilies of

K_{2P} channels have been identified, including the TWIK-related acid-sensitive K⁺ (TASK) channels and TWIK-related K⁺ (TREK) channels.⁴⁴

TASK channels exhibit sensitivity to variations in extracellular pH over a narrow physiological range. TASK-1 (*KCNK3*) and TASK-3 (*KCNK9*) subunits are functional when associated as homodimers or heterodimers. TASK channels display strong basal currents with very fast activation and inactivation kinetics.

TREK channels, which comprise TREK-1 (*KCNK2*), TREK-2 (*KCNK10*), and TRAAK (*KCNK4*), display low basal activity, but are stimulated by stretch of the cell membrane, lysophospholipids, and arachidonic acid and are inactivated by hypo osmolarity and phosphorylation by PKA and PKC.⁴⁴

Several members of the K_{2P} channel family are expressed in the heart and in the systemic or pulmonary circulations, and some contribute to background K⁺ currents and the control of E_m in vascular smooth muscle cells. The K⁺ selectivity, voltage-independent gating, and rectification of K_{2P} currents are characteristics that make them strong candidates for mediating background K⁺ currents. Importantly, the sensitivity of K_{2P} channels to numerous chemical and physical physiological stimuli (e.g., pH, oxygen, phospholipids, neurotransmitters, G protein-coupled receptors, and stretch) allow these channels to play a role in regulating the E_m and excitability in various cell types under a range of physiological and pathological situations.^{44,45}

FUNCTION

There is clear evidence for TREK-1 and TASK-1 in the heart and these channels are likely to regulate cardiac action potential duration through their regulation by stretch, polyunsaturated fatty acids, pH, and neurotransmitters. TREK-1 may also have a critical role in mediating the vasodilator response of resistance arteries to polyunsaturated fatty acids, thus contributing to their protective effect on the cardiovascular system. TASK-1, on the other hand, is a strong candidate for a role in hypoxic vasoconstriction of pulmonary arteries.⁴⁴

In working atrial and ventricular myocytes, background K⁺ currents are crucial for stabilizing the E_m at a hyperpolarized value toward the K⁺ equilibrium potential and regulating action potential duration in various physiological and pathological conditions. The background current is mainly carried by inward rectifier channels (including I_{K1}, I_{KACH}, and I_{KATP}). Several K_{2P} channels have been proposed to contribute to the cardiac background or “leak” K⁺ channels (i.e., channels with properties similar to the steady-state noninactivating K⁺ current [I_{ss}] that is well characterized in rodent myocytes). Among them, TREK-1 and TASK-1 have been the most extensively studied.⁴⁴

TREK-1, as an outwardly rectifying current, can potentially participate in balancing the E_m and action potential duration. Indeed, on a beat-to-beat basis, it could be involved in a negative feedback loop, hyperpolarizing the E_m in response to a stretch stimulus following the stretch activation of nonselective cation channels. The expression of TREK-1 appears to be nonuniform in the heart, with stronger TREK-1 mRNA expression in endocardial cells compared with epicardial cells. This finding possibly reflects different amounts of stretch experienced by muscle cells in different parts of the ventricular wall, leading to differential mechano-electrical feedback and thereby reducing action potential repolarization in areas of the myocardium where conduction velocity is slower. Mechano-electric feedback following an increase in atrial volume may be arrhythmogenic, changing the shape of the action potential. Physiological evidence of the direct involvement of TREK-1 current in mechano-electric feedback in the heart has still to be provided.⁴⁴

ACQUIRED DISEASES

TREK-1 activity may have some importance in pathological conditions such as ischemia, when released purinergic agonists such

as ADP and ATP lead to arachidonic acid production. Activation of TREK-1 by ATP during ischemia may contribute to electrophysiological disturbances in the ventricular wall. As a stretch-activated K⁺ channel in atrial cells, TREK-1 could additionally be involved in regulating the release of atrial natriuretic peptide, which is released by a stretch-induced increase in intracellular Ca²⁺ concentration. Further work will be necessary to clarify the possible role of TREK or other stretch-dependent channels in the pathological heart.⁴⁴

L-Type Calcium Current (I_{CaL})

Structure and Physiology

In cardiac muscle, two types of voltage-dependent Ca²⁺ channels, the L-type and the T-type, transport Ca²⁺ into the cells. The L-type channel (L for long-lasting, because of its slow kinetics of current decay as compared with Na⁺ channels) is found in all cardiac cell types. The T-type channel (T for tiny and transient) is found principally in pacemaker, atrial, and Purkinje cells. The term Ca²⁺ channels is used to refer to the L-type channel.⁴⁶⁻⁴⁸

Cardiac L-type Ca²⁺ channels are composed of four polypeptide subunits (α_{1C} , β , α_2 , δ) and form a heterotetrameric complex. The α_{1C} subunit (Ca_v1.2, encoded by the *CACNA1C* gene) has a structure similar to that of the Na⁺ channel: four homologous domains (I to IV), each consisting of six transmembrane segments (S1 to S6). The S5 and S6 segments and the membrane-associated pore loop (P loop) between them form the central pore through which ions flow down their electrochemical gradient. The P loop contains four negatively charged glutamate residues (EEEE) that are required for the Ca²⁺ selectivity of the channel. S4 in each homologous domain contains a highly conserved positively charged residue (arginine or lysine) at every third or fourth position. This segment serves as the voltage sensor for gating.^{46,47,49}

The α_{1C} subunit is the main and largest subunit, and it determines most of the channel characteristics because it harbors the ion-selective pore, voltage sensor, gating apparatus, and binding sites for channel-modulating drugs and is autoregulatory. To form a functional L-type Ca²⁺ channel, the α_{1C} subunit coassembles with auxiliary subunits in a 1:1:1 ratio: the β subunit, the α_2 subunit, and the δ subunit.^{46,47,49}

The β subunit (Ca_v β , encoded by the *CACNB* gene) is entirely intracellular and is tightly bound to a highly conserved motif in the cytoplasmic linker between domains I and II of the α_{1C} subunit. Coexpression of β subunits modulates the biophysical properties of the α_{1C} subunit. The β subunit has a prominent role in channel expression, trafficking, regulation, and facilitation. Sites possible for phosphorylation by various protein kinases (PKA, PKC, protein kinase G [PKG]) have been identified in these subunits. The β subunits are also involved in channel regulation by β -adrenergic stimulation and in response to the changes of the pH of the cell. In addition, the β subunit increases Ca²⁺ current amplitude, accelerates the kinetics of Ca²⁺ channel activation, and alters pharmacological properties of the channel.^{46,47}

The α_2 and δ subunits are encoded by the same gene (*CACNA2D*); the mature forms of these subunits are derived by post-translational proteolytic cleavage, but they remain associated through a disulfide bond. The α_2 subunit is completely extracellular, whereas the δ subunit has a single membrane-spanning segment with a very short intracellular part that anchors the α_2 - δ subunit complex to the α_{1C} subunit. The α_2 - δ subunit complex has less influence on channel function than the β subunit. The α_2 - δ subunit slightly increases Ca²⁺ current amplitude and accelerates channel inactivation and can change the properties of Ca²⁺ channel activation. It can also affect channel density trafficking.^{46,47}

L-type Ca²⁺ channels are characterized by a large single channel conductance. The channels are closed at the resting potential, but they activate on depolarization to potentials positive to -40 mV. I_{CaL} peaks at 0 to +10 mV, and tends to reverse at +60 to +70 mV, following a bell-shaped current-voltage relationship.

Although I_{CaL} is normally activated during phase 0 by the regenerative depolarization caused by the fast I_{Na}, I_{CaL} is much smaller than the peak I_{Na}. In addition, the amplitude of I_{CaL} is not maximal near the action potential peak because of the time-dependent nature of I_{CaL} activation, as well as the low driving force ($E_m - E_{Ca}$) for I_{CaL}.⁵⁰

The decay of I_{CaL} during depolarization (i.e., time-dependent inactivation) is very slow and depends on two mechanisms: voltage-dependent inactivation and Ca²⁺-dependent inactivation. These two mechanisms control Ca²⁺ influx into cardiomyocytes and hence regulate signal transduction to sarcoplasmic reticulum Ca²⁺ channels (ryanodine receptor 2 [RyR2]) and ensure normal contraction and relaxation of the heart.⁴⁶⁻⁴⁸

Fast Ca²⁺-dependent inactivation serves as a negative feedback for Ca²⁺ to limit further Ca²⁺ entry via L-type Ca²⁺ channels. The slow voltage-dependent inactivation (induced by membrane depolarization) prevents a premature rise in I_{CaL} when intracellular Ca²⁺ concentration decreases and Ca²⁺-dependent inactivation terminates during maintained depolarization. Although still under dispute, the relative contribution of Ca²⁺-dependent inactivation to total inactivation of I_{CaL} appears to be greater at negative potentials when voltage-dependent inactivation, which typically exhibits a U-shaped availability curve, is weak. After β -adrenergic stimulation, Ca²⁺-dependent inactivation becomes the main inactivation mechanism as a result of a slowing down of voltage-dependent inactivation.⁴⁶⁻⁴⁸

The Ca²⁺-dependent inactivation mechanism depends primarily on Ca²⁺ released from the sarcoplasmic reticulum. The Ca²⁺-binding protein calmodulin functions as a critical sensor mediating Ca²⁺-induced inactivation of L-type Ca²⁺ channels. Calmodulin binds to two α_{1C} subunit amino acid sequences (called domains L and K). When local intracellular Ca²⁺ concentration increases (secondary to influx Ca²⁺ via the L-type Ca²⁺ channel, as well as Ca²⁺-induced Ca²⁺ release from the sarcoplasmic reticulum), more Ca²⁺ ions bind to calmodulin, which harbors four Ca²⁺-binding sites. When saturated with Ca²⁺, conformational change of both calmodulin and α_{1C} subunit leads to blockage of the channel pore.

Voltage steady-state activation and inactivation are sigmoidal, with an activation range over -40 to +10 mV (with a half-activation potential near -15 mV) and a half-inactivation potential near -35 mV. However, a relief of inactivation for voltages positive to 0 mV leads to a U-shaped voltage curve for steady-state inactivation. Overlap of the steady-state voltage-dependent inactivation and activation relations defines a window current near the action potential plateau, within which transitions from closed and open states can occur that may participate in action potential repolarization and may play a major role in the initiation of EADs.^{47,48}

After inactivation, the transition of Ca²⁺ channels from the inactivated to the closed resting state (i.e., recovery from inactivation [reactivation, restoration, or repriming]) is also Ca²⁺ and voltage dependent. Reduction of intracellular Ca²⁺ concentration in the immediate vicinity of the channel allows recovery from Ca²⁺-dependent inactivation. Acceleration of Ca²⁺ channel reactivation, as may occur secondary to reuptake of Ca²⁺ by the sarcoplasmic reticulum during prolonged depolarization, can result in the recovery from Ca²⁺-dependent inactivation and enable secondary depolarization. This leads to instability of the cell E_m during repolarization and may be the basis for the EADs that are capable of initiating torsades de pointes.^{46,48}

Voltage-dependent recovery of I_{CaL} from inactivation between action potentials is slow at a low (depolarized) E_m , and it becomes very fast as the action potential repolarization is nearly complete. As a consequence, I_{CaL} declines in response to repetitive stimulation at a partially depolarized E_m between pulses (resulting from Ca²⁺ channel incomplete recovery from inactivation), and a negative staircase of contractility is observed.

In contrast, at normal resting potentials, recovery of I_{CaL} from inactivation is fast, and I_{CaL} may increase progressively during repetitive stimulation. This positive staircase or rate-dependent potentiation of contractility is Ca²⁺ dependent and likely is the

result of diminished Ca^{2+} -dependent inactivation at frequencies with less sarcoplasmic reticulum Ca^{2+} release. Additionally, similar to Ca^{2+} -dependent inactivation, Ca^{2+} -dependent facilitation requires high-affinity binding of calmodulin to the C-terminal tail of the $\text{Ca}_v1.2$ channel and may be facilitated by calmodulin kinase II-dependent phosphorylation. Calmodulin kinase II is a Ca^{2+} /calmodulin-dependent serine/threonine kinase that is activated by low intracellular Ca^{2+} concentration. The facilitatory effect of Ca^{2+} entry on subsequent I_{CaL} is distinct from, but coexistent with, Ca^{2+} -dependent inactivation.⁴⁶⁻⁴⁸

Function

I_{CaL} is activated by membrane depolarization. It is largely responsible for the action potential plateau and is a major determinant of the duration of the plateau phase and hence of action potential duration and refractoriness. I_{CaL} also links membrane depolarization to myocardial contraction and constitutes the dominant factor in mediating positive inotropy in all types of cardiac tissue. Additionally, I_{CaL} is responsible for the upstroke (phase 0) of slow response action potentials (in pacemaking cardiomyocytes and regions of depressed resting E_m) and contributes to physiological frequency regulation in the sinus node.⁴⁶⁻⁴⁸

L-type Ca^{2+} channels are the principal portal of entry of Ca^{2+} into the cells during depolarization. Ca^{2+} influx during the action potential plateau triggers more massive Ca^{2+} release (Ca^{2+} transients) from the sarcoplasmic reticulum into the cytosol via activation of Ca^{2+} -release channels (e.g., RyR2). This amplifying process, termed Ca^{2+} -induced Ca^{2+} release (CICR), causes a rapid increase in intracellular Ca^{2+} concentration (from approximately 100 nM to approximately 1 μM) to a level required for optimal binding of Ca^{2+} to troponin C and induction of contraction. Most of the L-type Ca^{2+} channels in the adult myocyte are localized in the transverse tubules (T tubules) facing the sarcoplasmic reticulum junction and the RyR2, organized as a “complex” that ensures coordinated Ca^{2+} release during excitation-contraction coupling.^{46,49}

Cytosolic Ca^{2+} concentration decreases during diastole: contraction is followed by Ca^{2+} release from troponin C and its reuptake by the sarcoplasmic reticulum via activation of the sarcoplasmic reticulum Ca^{2+} -ATPase Ca^{2+} pump, in addition to extrusion across the sarcolemma via the Na^+ - Ca^{2+} exchanger. Intracellular Ca^{2+} -dependent inactivation limits Ca^{2+} influx during action potential.^{46,47,49}

For maintenance of intracellular Ca^{2+} homeostasis and balanced cardiac activity, Ca^{2+} influx into cytoplasm via L-type Ca^{2+} channels has to be terminated. This is achieved by Ca^{2+} -dependent inactivation of L-type Ca^{2+} channels. This inactivation serves as a negative feedback mechanism for regulating Ca^{2+} entry into the cell and as a physiological safety mechanism against a harmful Ca^{2+} overload in the cell, which can cause both arrhythmias and cell death. Ca^{2+} -dependent inactivation is also a major determinant of action potential duration, and it ensures that contraction and relaxation cycles of the heart muscle fiber are coordinated. A failure to deactivate I_{CaL} completely may possibly be an essential mechanism underlying EADs caused by suppression of the K^+ delayed rectifier currents.⁵⁰

Inhibition of α_{1C} subunit binding to calmodulin eliminates Ca^{2+} -dependent inactivation, thus promoting Ca^{2+} -dependent facilitation, which contributes to a force-frequency relationship in the heart.^{46,47,49}

Regulation

Phosphorylation of the pore-forming α_{1C} subunits by different kinases is one of the most important pathways to change the activity of the L-type Ca^{2+} channel. Phosphorylation by PKA is the main mechanism of Ca^{2+} channel activation, because it increases the probability and duration of the open state of the channels and consequently increases I_{CaL} .^{46,47,49}

Several different agonists (e.g., catecholamines, glucagon, histamine, serotonin) can activate PKA-mediated phosphorylation and

activation of the L-type Ca^{2+} channel via an intracellular signaling cascade. Once one of these agonists binds to its receptor, receptor stimulation activates guanosine triphosphate (GTP)-binding protein (G_s), which activates adenylyl cyclase, which, in turn, mediates the conversion of ATP into cAMP. The increased cAMP levels stimulate cAMP-dependent PKA phosphorylation of the α_{1C} subunit of L-type Ca^{2+} channels and result in an increase in I_{CaL} amplitude and a shift in activation to a more negative E_m . cAMP is degraded by cAMP phosphodiesterases, and the signaling cascade is then suppressed limiting cAMP-dependent phosphorylation; in addition, the signaling cascade is terminated by serine/threonine phosphatases that remove a phosphate group from kinase-phosphorylated proteins.^{46,47}

The suppression of adenylyl cyclase activity is one of the most common pathways to interrupt PKA-dependent Ca^{2+} channel stimulation. Adenylyl cyclase is usually suppressed (and cAMP synthesis is blocked) by activation of G_i proteins. Stimulation of various G_i protein-coupled receptors (e.g., M_2 muscarinic receptors, adenosine A_1 receptors, opiates, and atrial natriuretic peptides) does not change basal I_{CaL} in most cases, but reduces I_{CaL} increased via stimulation of β -adrenergic receptors. Activation of phosphodiesterases is another way to reduce PKA-dependent channel phosphorylation. Phosphodiesterases hydrolyze cAMP and cyclic guanosine monophosphate (cGMP) and decrease their intracellular concentrations.^{46,47,49}

The physiological functions of cardiac L-type Ca^{2+} channels are under control of catecholamines of circulating and neurohumoral origin. The effects of adrenergic stimulation are exerted by phosphorylation of the L-type Ca^{2+} channel subunits by PKA, PKC, and PKG. β_1 -Adrenergic receptors couple exclusively to the G_s protein, thus producing a widespread increase in cAMP levels in the cell, whereas β_2 -adrenergic receptors couple to both G_s and G_i , thus producing a more localized activation of L-type Ca^{2+} channels.^{46,49}

The effect of PKC-mediated phosphorylation on I_{CaL} can be highly diverse. PKC can either increase or decrease I_{CaL} . Activation of G_q subunits by G_q protein-coupled receptors (e.g., α -adrenergic receptors, endothelin, angiotensin II, and muscarinic receptors) stimulates phospholipase C, which hydrolyzes PIP_2 to inositol 1,4,5-triphosphate (InsP_3) and diacylglycerol (DAG). DAG activates PKC, which, in turn, phosphorylates L-type Ca^{2+} channels. The mechanism of the effect of PKC on the activity of cardiac L-type Ca^{2+} channels is not exactly known. PKC phosphorylates the N-terminus of the α_{1C} subunit, and the effect on the channel can be either stimulating or suppressive.^{46,47}

Activation of soluble guanylate cyclase (primarily by nitric oxide) results in the conversion of GTP into cGMP. cGMP activates PKG, which phosphorylates the α_{1C} subunit of the L-type Ca^{2+} channel, with a resulting inhibition of I_{CaL} . Besides direct phosphorylation of the L-type Ca^{2+} channel, it is also possible that PKG activates a protein phosphatase, which dephosphorylates the channel, or that cGMP activates phosphodiesterase 2, which reduces cAMP levels. Thus, stimulation of I_{CaL} by PKA is inhibited. However, besides an inhibition of I_{CaL} , stimulatory effects of the PKG pathway have been shown.^{46,47,49}

I_{CaL} is blocked by several cations (e.g., Mg^{2+} , nickel [Ni^{2+}], zinc [Zn^{2+}]) and drugs (dihydropyridines, phenylalkylamines, benzothiazepines). In addition, coexpression of the β -subunit increases I_{CaL} amplitude, accelerates the kinetics of Ca^{2+} channel activation, and alters pharmacological properties of the channel.^{47,49}

Pharmacology

Cardiac L-type Ca^{2+} channels are the targets for the interaction with class IV antiarrhythmic drugs. The three classes of organic Ca^{2+} channel blockers include dihydropyridines (e.g., nifedipine, nicardipine, amlodipine, felodipine), phenylalkylamines (verapamil), and benzothiazepines (diltiazem). Each drug type binds specifically to separate binding sites on the channel's

α_{1C} subunit. The combined use of Ca^{2+} channel blockers can enhance or weaken the block effect because, at least in part, of the different binding sites for those drugs. It is noteworthy that increased extracellular Ca^{2+} concentrations inhibit the binding of phenylalkylamines and dihydropyridines to their receptors on the Ca^{2+} channel.

Verapamil and diltiazem preferentially block open and inactivated states of the channel. The more frequently the Ca^{2+} channel opens, the better is the penetration of the drug to the binding site; hence, these drugs cause use-dependent block of conduction in cells with Ca^{2+} -dependent action potentials such as those in the sinus node and AVN. This explains their preferential effect on nodal tissue in paroxysmal supraventricular tachycardia.^{46,47,49}

The dihydropyridines block open Ca^{2+} channels. However, the lack of use-dependence and the presence of voltage sensitivity of the dihydropyridines with regard to their binding explain their vascular selectivity. The kinetics of recovery from block is sufficiently fast that these drugs produce no significant cardiac effect but effectively block the smooth muscle Ca^{2+} channel because of its low resting potential.^{46,47,49}

Inherited Channelopathies

LONG QT SYNDROME

Gain-of-function mutations of the *CACNA1C* gene encoding the α_{1C} subunit ($\text{Ca}_v1.2$) result in nearly complete elimination of voltage-dependent inactivation of $\text{Ca}_v1.2$ channels, thus leading to inappropriate continuation of the depolarizing I_{CaL} and lengthening the plateau phase. The resultant sustained Ca^{2+} influx, action potential (and QT interval) prolongation, and Ca^{2+} overload promote EADs and DADs. These mutations have been linked to Timothy syndrome, a rare disease with QT interval prolongation (LQT8). Because the Ca^{2+} channel $\text{Ca}_v1.2$ is abundant in many tissues, patients with Timothy syndrome have many clinical manifestations including congenital heart disease, autism, syndactyly, and immune deficiency.^{3,47,49}

BRUGADA SYNDROME

Approximately 12% of cases of the Brugada syndrome are attributable to loss-of-function mutations in the cardiac Ca^{2+} channel resulting in a reduction of the depolarizing I_{CaL} . Brugada syndrome type 3 is caused by mutations in the *CACNA1C* gene, which encodes the pore-forming α_1 subunit ($\text{Ca}_v1.2$). Brugada syndrome type 4 is caused by mutations in the *CACNB2* gene, which encodes for the regulatory β_2 subunit ($\text{Ca}_v\beta_2$), which modifies gating of I_{CaL} . The mechanism of Brugada syndrome type 3 and type 4 involves a reduction of the depolarizing I_{CaL} . Mutations in the α and β subunits of the Ca^{2+} channel can also lead to a shorter than normal QT interval, creating a new clinical entity consisting of a combined Brugada/short QT syndrome.¹⁰

SHORT QT SYNDROME

SQT4 is caused by mutations on the *CACNA1C* gene (encoding the α_{1C} subunit, $\text{Ca}_v1.2$) and SQT5 is caused by mutations on the *CACNB2* gene (encoding the β_{2b} subunit). Loss-of-function mutations on those genes result in major attenuation in I_{CaL} amplitude, leading to shortening of the action potential duration, and are associated with asymmetrical T waves, an attenuated QT–heart rate relationship, and AF. The three patients reported to harbor these mutations had a Brugada type 1 phenotype.^{1,49}

Acquired Diseases

Abnormalities in Ca^{2+} currents or intracellular Ca^{2+} transients, or both, in acquired diseases may induce both arrhythmia and contractile dysfunction. In AF, $\text{Ca}_v1.2$ mRNA and protein levels are

downregulated, resulting in I_{CaL} reduction, which contributes to action potential shortening.³

In heart failure, the membrane density of I_{CaL} channels is reduced. However, channel phosphorylation is increased, leading to reduced response to phosphorylating interventions and causing increased single channel open probability that compensates for the reductions in channel density. Despite unchanged I_{CaL} , sarcoplasmic reticulum Ca^{2+} transients are smaller and slower in heart failure, and they cause contractile dysfunction.^{3,24,49}

T-Type Calcium Current (I_{CaT})

Structure and Physiology

The cardiac T-type Ca^{2+} channel (originally called low-voltage-activated channels) is composed of a single α subunit. $\text{Ca}_v3.1$ (α_{1G} subunit encoded by *CACNA1G*) and $\text{Ca}_v3.2$ (α_{1H} subunit encoded by *CACNA1H*) isoforms are major candidates for the cardiac T-type Ca^{2+} channel. It is not yet clear whether auxiliary subunits exist for native T-type Ca^{2+} channels. The structure of the α_{1H} and α_{1G} subunits is similar to that involved in the L-type Ca^{2+} channels.^{46,48}

T-type Ca^{2+} channels can be distinguished from L-type Ca^{2+} channels on the basis of their distinctive gating and conductance properties. Compared with L-type Ca^{2+} channels, T-type Ca^{2+} channels have a smaller conductance and transient openings, and they open at the significantly more negative E_m that overlaps the pacemaker potentials of sinus node cells. The threshold for activation of I_{CaT} is -70 to -60 mV, and I_{CaT} is fully activated at -30 to -10 mV at physiological Ca^{2+} concentration. Membrane depolarization also causes inactivation of I_{CaT} . The inactivation threshold is near -90 mV, with half-maximal inactivation of -60 mV. In contrast to L-type Ca^{2+} channels, T-type Ca^{2+} channels do not inactivate in a Ca^{2+} -dependent manner. The activation and steady-state inactivation overlap near the activation threshold (-60 to -30 mV), thus providing a constant inward current (a window current). This window component may help in facilitating the slow diastolic depolarization in sinus node cells and contribute to automaticity. Unlike L-type channels, T-type Ca^{2+} channels are relatively insensitive to dihydropyridines.^{46,48}

Function

Ca_v3 channels conduct the T-type Ca^{2+} current (I_{CaT}), which is important in a wide variety of physiological functions, including neuronal firing, hormone secretion, smooth muscle contraction, cell proliferation of some cardiac tissues, and myoblast fusion. In the heart, T-type channels are abundant in sinus node pacemaker cells and Purkinje fibers of many species and are important for maintenance of pacemaker activity by setting the frequency of action potential firing.^{46,48}

T-type Ca^{2+} channels are functionally expressed in embryonic hearts, but they are almost undetectable or markedly reduced in postnatal ventricular myocytes, although some reports described substantial amplitude of I_{CaT} . In the adult heart, the largest I_{CaT} densities are seen in pacemaker cells located in the conduction system.

Because T-type Ca^{2+} channels are most prevalent in the conduction system in the adult heart and the activation range of I_{CaT} overlaps the pacemaker potential, it has been suggested that T-type Ca^{2+} channels play a role in generating pacemaker depolarization and contribute to automaticity. However, experimental evidence indicates that I_{CaT} is not a primary pacemaker current, but it can modify depolarization frequency only slightly. Although organic T-type Ca^{2+} channel blockers (mibefradil) result in marked decrease in firing frequency of sinus node cells in clinical studies, the possibility that these blockers affect other ionic currents, including I_{CaL} , cannot be entirely excluded. In fact, it is has not yet been determined whether I_{CaT} exists functionally in atrial, ventricular, and sinoatrial node cells in the human heart. Further studies are necessary to clarify

whether T-type Ca^{2+} channels contribute to the automaticity of the human heart.^{48,51}

Acquired Diseases

CH
2

Interestingly, the T-type Ca^{2+} channels are re-expressed in atrial and ventricular myocytes in animal models under various pathological conditions such as cardiac hypertrophy, MI, and heart failure. These findings reflect a reversion to a fetal or neonatal pattern of gene expression, and I_{CaT} contributes to abnormal electrical activity and excitation-contraction coupling. It is possible that similar remodeling occurs in the hypertrophied human heart; however, to date, T-type Ca^{2+} channels have not been detected in normal or diseased human myocardial cells.^{46,48,51}

Furthermore, experimental evidence suggests that T-type Ca^{2+} channels may be of functional importance in arrhythmogenesis in cardiomyocytes in pulmonary veins, which can initiate paroxysmal AF. I_{CaT} may directly and indirectly participate in pacemaker depolarization in sinoatrial and other regions of the heart, and this mechanism may become more important in failing hearts.^{46,48}

Cardiac Pacemaker Current (I_f)

Structure and Physiology

Channels responsible for the pacemaker current (I_f ; also called the funny current because it displays unusual gating properties) are named hyperpolarization-activated cyclic nucleotide-gated (HCN) channels. HCN channels are members of the voltage-gated cation channel superfamily and, based on sequence homology, are most closely related to the cyclic nucleotide-gated (CNG) channel and ether-a-go-go (EAG) K^+ channel families. Four α -subunit isoforms are described (HCN1 to HCN4, encoded by *HCN1* to *HCN4* genes), which are preferentially expressed in sinus and AVN myocytes and Purkinje fibers. HCN isoforms differ in the extent of voltage-dependent gating and sensitivity to cAMP, and they have different relative rates of activation and deactivation, with HCN1 the fastest, HCN4 the slowest, and HCN2 and HCN3 intermediate. HCN4 is the isoform primarily expressed in the sinus node, AVN, and ventricular conducting system, but low levels of HCN1 and HCN2 have also been reported.

It is likely that the HCN channel is formed by the coassembly of four either identical (homotetramers) or nonidentical (heterotetramers) α subunits that create an ion-conducting pore. Each α subunit comprises six transmembrane segments (S1 to S6), with a voltage sensor domain in the S4 segment and a pore-forming region between S5 and S6 carrying the GYG triplet signature of K^+ -permeable channels. Their intracellular C-terminus contains cyclic nucleotide-binding domains, which enable direct cAMP binding. A potential auxiliary subunit of HCN channels is MiRP1 (encoded by *KCNE2*).

I_f is a mixed Na^+ - K^+ current, with a threefold higher selectivity for Na^+ than for K^+ . Despite the GYG amino acid motif, HCN channels are more permeable Na^+ than K^+ ions. Unlike most voltage-gated channels, which are activated on membrane depolarization, HCN channels are activated on hyperpolarization. The HCN channel activates slowly on hyperpolarization (at voltages lower than approximately -40 to -45 mV) and inactivate slowly in a voltage-independent manner on depolarization. The speed of channel opening is strongly dependent on E_m and is faster at more negative potentials. I_f conducts an inward current during phases 3 and 4 of the action potential and may underlie slow membrane depolarization in cells with pacemaker activity (i.e., cells with I_f and little or no I_{K1}).⁵²

Function

I_f is a major player in both generation of spontaneous activity and rate control of cardiac pacemaker cells, and it is sometimes referred to as the pacemaker current.

The I_f channels are deactivated during the action potential upstroke and the initial plateau phase of repolarization, but they begin to activate at the end of the action potential as repolarization brings the E_m to levels more negative than approximately -40 to -50 mV, and they are fully activated at approximately -100 mV. Once activated, I_f depolarizes the membrane back toward a level at which the Ca^{2+} current activates to initiate the action potential.¹ In its range of activation, which quite properly comprises the voltage range of diastolic depolarization in sinus node cells (approximately -40 to -65 mV), the current is inward, and its reversal occurs at approximately -10 to -20 mV. At the end of the repolarization phase of an action potential, because I_f activation occurs in the background of a decaying outward (K^+ time-dependent) current, current flow quickly shifts from outward to inward, giving rise to a sudden reversal of voltage change (from repolarizing to depolarizing) at the maximum diastolic potential. Hence, I_f first opposes and then stops the repolarization process (at the maximum diastolic potential) and finally initiates the diastolic depolarization.⁵²⁻⁵⁵

The I_f contribution terminates when, in the late part of diastolic depolarization, Ca^{2+} -dependent processes take over, and the threshold for L-type Ca^{2+} current activation and action potential firing is reached. Although deactivation of I_f at depolarized voltages is rapid, complete switch off of the current occurs only during the very early fraction of the action potential, which provides a brief time interval during which I_f carries an outward current at positive voltages.⁵²

I_f is not only involved in principal rhythm generation but also plays a key role in heart rate regulation. The degree of activation of I_f determines, at the end of an action potential, the steepness of phase 4 depolarization and hence the frequency of action potential firing. Additionally, I_f represents a basic physiological mechanism mediating autonomic regulation of heart rate. I_f is regulated by intracellular cAMP and is thus activated and inhibited by β -adrenergic and muscarinic M_2 receptor stimulation, respectively.^{52,56}

However, given the complexity of the cellular processes involved in rhythmic activity, exact quantification of the extent to which I_f and other mechanisms contribute to pacemaking is still a debated issue.⁵²

Regulation

The voltage dependence of I_f activation is regulated by cAMP direct binding to the cyclic nucleotide-binding domain in the HCN channel and not via phosphorylation-dependent activation mechanisms. Direct interaction of cAMP to the channel shifts the activation curve to more depolarized voltages and strongly accelerates channel activation kinetics. Sympathetic stimulation activates I_f and hence accelerates heart rate via β -adrenoceptor-triggered cAMP production, whereas low-level vagal stimulation lowers heart rate via inhibition of cAMP synthesis and an ensuing inhibition of I_f activity. High vagal tone most likely lowers the heart rate mainly via the activation of I_{KACH} .⁵⁶

HCN channels are inhibited by increased intracellular acidity (e.g., during myocardial ischemia). Protons shift the activation of I_f to more hyperpolarized potentials and slow pacemaker activity.

Pharmacology

Given the key role of HCN channels in cardiac pacemaking, I_f has become a pharmacological target for the development of novel and more specific heart rate-reducing agents in patients with ischemic heart disease. Whereas current heart rate-lowering drugs adversely affect cardiac contractility, selective I_f inhibition is believed to lower heart rate without impairing contractility. In the past, several agents inhibiting cardiac I_f were developed. Early drugs identified as pure bradycardic agents include zatebradine and cilobradine, which are derived from the L-type Ca^{2+} channel blocker verapamil. More recently, ivabradine was introduced

into clinical use as the first therapeutic I_f blocker for the treatment of chronic stable angina. The principal action of all these substances is to reduce the frequency of pacemaker potentials in the sinus node by inducing a reduction of the diastolic depolarization slope. Ivabradine blocks HCN4 and HCN1 channels by accessing the channels from their intracellular side and by exerting a use- and current-dependent block. Interestingly, ivabradine acts as open channel blocker in HCN4 (as in sinus nodal I_f), whereas block of HCN1 requires channels either to be closed or in a transitional state between an open and closed configuration.^{52,56} With the exception of ivabradine, other HCN channel blockers are not specific enough for sinus nodal (mainly HCN4-mediated) I_f ; they also block neuronal HCN channels (I_h current) in several regions of the nervous system, and this has prevented their clinical utility.⁵⁶

Clonidine, an α_2 -adrenergic agonist, was shown to block sinus nodal I_f . Clonidine produces a shift in the voltage dependence of the channel by 10 to 20 mV to more hyperpolarizing potentials.⁵⁶

Inherited Channelopathies

Heterozygous *HCN4* mutations have been identified in individuals with sinus bradycardia and chronotropic incompetence. Severe bradycardia, QT prolongation, and torsades de pointes have been described in another family. HCN mutations slow channel activation kinetics or, when located in cyclic nucleotide-binding domains, abolish sensitivity of HCN channels to cAMP, thus reducing I_f and the speed of diastolic depolarization.

Acquired Diseases

HCN2/HCN4 expression is upregulated in the atria of patients with AF and in ventricular tissues in cardiac hypertrophy and congestive heart failure. This response may contribute to the arrhythmias observed in these disease states. Enhancement of I_f in these pathological conditions can potentially initiate arrhythmia by triggering spontaneous excitation of nonpacemaker cardiomyocytes.

Sarcoplasmic Reticulum Calcium Release Channels (Ryanodine Receptor 2)

Structure and Physiology

The Ca^{2+} release channel is a macromolecular complex, formed by the cardiac ryanodine receptor isoform (RyR2, encoded by the *RYR2* gene) homotetramer and certain proteins localized on both the cytosolic and the luminal side of the sarcoplasmic reticulum membrane. The cardiac RyR2, by far the largest protein of the complex, operates as a Ca^{2+} -conducting channel. RyR2 channels are approximately 10 times larger than voltage-gated Ca^{2+} and Na^+ channels.^{57,58}

Each RyR2 monomer contains a transmembrane domain, the pore-forming region that is composed of an even, but still undetermined number (likely six to eight) of transmembrane segments. This domain encompasses only approximately 10% of the protein clustered at the C-terminus, but it has a critical functional role because it contains sequences that control RyR2 localization and oligomerization and is sufficient to form a functional Ca^{2+} release channel. The remaining 90% of the protein at the N-terminus comprises an enormous cytoplasmic domain that serves as a cytosolic scaffold that interacts with regulatory molecules (including Ca^{2+} , ATP) and proteins (including FKBP12.6, calmodulin). On the luminal (sarcoplasmic reticulum) side, RyR2 forms a part of a large quaternary complex with calsequestrin (CASQ2), triadin, and junctin. Together these four proteins form the core of the Ca^{2+} release channel complex.⁵⁷⁻⁶⁰

Cardiac RyR2 functions as a ligand-activated ion channel that activates (opens) on Ca^{2+} binding. However, the exact structural determinants of RyR gating are as yet unknown. RyR2 is normally

closed at low cytosolic diastolic Ca^{2+} concentrations (approximately 100 to 200 nM). At submicromolar cytosolic Ca^{2+} concentrations, Ca^{2+} binds to high-affinity binding sites on RyR2 and thus increases the open probability of the channel (two Ca^{2+} ions are required to open the RyR2 channel) and allows Ca^{2+} release from the sarcoplasmic reticulum into the cytosol.^{50,59,60}

The precise juxtaposition of the sarcolemmal specialized invaginations (known as T tubules) and sarcoplasmic reticulum forms specific junctional microdomains, creating a 10- to 12-nM gap, known as the dyadic cleft. RyR2s are assembled in a paracrystalline lattice in each dyad, containing 80 to 260 channels, where the RyR2 cytoplasmic region resides, and its transmembrane region spans the sarcoplasmic reticulum membrane to immerse the luminal portion into the sarcoplasmic reticulum Ca^{2+} store. Each array of RyR2s is faced by 10 to 25 L-type Ca^{2+} channels in the sarcolemmal T tubule. Hence, each dyad constitutes a local Ca^{2+} signaling complex, or couplon, whereby these proteins are coordinately regulated via the changing concentrations of Ca^{2+} , Na^+ , and K^+ within the dyadic cleft.^{50,59,60}

After approximately 10 milliseconds of RyR2 channel opening, Ca^{2+} release from the sarcoplasmic reticulum terminates, and the Ca^{2+} spark signal starts to decay, mostly owing to diffusion of Ca^{2+} away from its source. RyR2 channel activity is maximal at cytosolic Ca^{2+} concentrations of approximately 10 μ M. Elevating cytosolic Ca^{2+} concentrations beyond this point leads to a reduction in the open probability of the channel, possibly because of Ca^{2+} binding to low-affinity inhibitory binding sites on the RyR2 channel.⁶⁰

Inactivation of Ca^{2+} release is not well understood. It is likely mediated by Ca^{2+} -induced inactivation of RyR2, thus extinguishing of CICR by stochastic attrition, or by Ca^{2+} depletion of the sarcoplasmic reticulum, or both.

RyR2 open probability increases by elevation of sarcoplasmic reticulum Ca^{2+} concentration. When levels of Ca^{2+} in the sarcoplasmic reticulum reach a critical threshold, spontaneous Ca^{2+} release (spillover) can occur even in the presence of normal channels (store overload-induced Ca^{2+} release [SOICR]). Ca^{2+} concentration in the sarcoplasmic reticulum is physiologically increased as an effect of adrenergic (sympathetic) stimulation.

Function

The RyR2 channels are an essential component of the excitation-contraction coupling and act as sentinels to the large sarcoplasmic reticulum Ca^{2+} store. Excitation-contraction coupling describes the physiological process of converting an electrical stimulus (action potential) to a mechanical response (muscle contraction). The contraction of a cardiac myocyte is governed primarily by intracellular Ca^{2+} concentration (see Fig. 1-3). Ca^{2+} enters the cell during the plateau phase of the action potential through L-type Ca^{2+} channels that line the sarcolemmal T tubules. However, the rise in intracellular Ca^{2+} is small and not sufficient to induce contraction. Nonetheless, the small amount of Ca^{2+} entering the cell via I_{CaL} triggers a rapid mobilization of Ca^{2+} from the sarcoplasmic reticulum into the cytosol by opening the RyR2 channels in the CICR process. Approximately 75% of Ca^{2+} present in the cytoplasm during contraction is released from the sarcoplasmic reticulum. The close proximity of the RyR2 to the T tubule enables each L-type Ca^{2+} channel to activate 4 to 6 RyR2s and generate a Ca^{2+} spark. Ca^{2+} influx via I_{CaL} simultaneously activates approximately 10,000 to 20,000 couplons in each ventricular myocyte with every action potential. Such sophisticated coordination in opening and closing is required to ensure that Ca^{2+} release occurs during the systolic phase of the cardiac cycle and functional silence during diastole.^{50,59,60}

Luminal Ca^{2+} -dependent deactivation of RyR2 is a process by which the decline in sarcoplasmic reticulum Ca^{2+} that follows sarcoplasmic reticulum Ca^{2+} release renders RyR2s functionally inactive. This results in termination of CICR and induction of a refractory state that suppresses Ca^{2+} release during the diastolic phase, which

is an important determinant of the mechanical refractoriness required for efficient relaxation and refilling of the heart.^{50,58}

Regulation

CH
2

Many proteins interact directly and indirectly with the N-terminal cytoplasmic domain of RyR2 including FK506-binding protein (calstabin2 or FKBP12.6), PKA, Ca²⁺-calmodulin-dependent kinase II (CaMKII), phosphodiesterase 4D3, calmodulin, protein phosphatases 1 and 2A, and sorcin. CASQ2, junctin, and triadin bind with the luminal (sarcoplasmic reticulum) C-terminus of RyR2.⁵⁸⁻⁶⁰

CALSEQUESTRIN

CASQ2 is a low-affinity, high-capacity Ca²⁺-binding protein, which serves as a Ca²⁺ storage reservoir that is able to bind luminal Ca²⁺ (40 to 50 Ca²⁺ ions per molecule) during diastole, thus buffering Ca²⁺ within the sarcoplasmic reticulum (i.e., preventing Ca²⁺ precipitation and lowering luminal free Ca²⁺ concentration) and preventing diastolic Ca²⁺ release via RyR2 to cytosol. CASQ2 presumably serves as a luminal Ca²⁺ sensor that modulates the responsiveness of the RyR2 to luminal Ca²⁺. At low luminal Ca²⁺ concentrations, CASQ2 interacts with RyR2 via binding to triadin and junctin and inhibits the activity of the RyR2. When sarcoplasmic reticulum Ca²⁺ levels increase, Ca²⁺ binds to CASQ2, resulting in weakened interactions or complete dissociation of CASQ2 from triadin. This process relieves the inhibitory action of CASQ2 on the RyR2 complex, allows Ca²⁺ release to the cytosol, and hence normalizes sarcoplasmic reticulum Ca²⁺ load. Triadin and junctin not only mediate functional interactions of CASQ2 and RyR2 but also modulate RyR2 function by themselves by increasing the activity of the RyR2 channel. This Ca²⁺-dependent modulation of RyR2s by triadin, junctin, and CASQ2 may contribute to deactivation and refractoriness of RyR2 channels after sarcoplasmic reticulum Ca²⁺ release.^{58,60,61}

FK506-BINDING PROTEIN

FKBP12.6 (the 12.6-kDa cytosolic FK506-binding protein), also known as calstabin2 (Ca²⁺ channel-stabilizing binding protein), stabilizes the closed conformational state of the RyR2 channel, thus enabling the channel to close completely during diastole (at low intracellular Ca²⁺ concentrations), preventing aberrant Ca²⁺ leakage from the sarcoplasmic reticulum, and ensuring muscle relaxation. PKA phosphorylation of RyR2 decreases the binding affinity of FKBP12.6 to RyR2 and thereby increases the probability of an open state and amplifies the response to Ca²⁺-dependent activation.^{50,59,60,62}

CALMODULIN

Calmodulin is a Ca²⁺-binding protein containing four Ca²⁺-binding sites and four sites that bind to RyR2 monomers. Calmodulin preferentially inhibits RyR2 at Ca²⁺ concentrations lower than 10 μM by binding to a region on RyR2. Calmodulin may function to assist closing RyR2 following sarcoplasmic reticulum Ca²⁺ release in excitation-contraction coupling.⁶⁰

PROTEIN KINASE A

Stimulation of β-adrenergic receptors results in an increase in cAMP and consequent PKA activation. PKA interacts with the RyR2 channel via binding to the muscle A kinase anchoring protein (mA-KAP). PKA phosphorylation of RyR2 activates the channel, at least in part by increasing the sensitivity of RyR2 to cytosolic Ca²⁺ and a transient decrease in the binding affinity of calstabin2. This allows for increased sarcoplasmic reticulum Ca²⁺ release on Ca²⁺ influx via I_{CaL} as a part of the fight-or-flight mechanism. By contrast, chronic PKA hyperphosphorylation of RyR2 can result in incomplete channel closure and a Ca²⁺ leak during diastole, which

causes depletion of the sarcoplasmic reticulum Ca²⁺ store and reduced Ca²⁺ release on receptor activation.^{50,60,62}

Ca²⁺-CALMODULIN-DEPENDENT PROTEIN KINASE II

CaMKII is a dodecameric holoenzyme activated by Ca²⁺-bound calmodulin, possibly at high cellular Ca²⁺ loads. CaMKII phosphorylation increases RyR2 channel open probability, but to a smaller extent than PKA phosphorylation. CaMKII activity increases at faster heart rates (typically mediated by β-adrenergic stimulation) and PKA activation and associated with increased cytosolic Ca²⁺ and phosphorylates RyR2 to enhance sarcoplasmic reticulum Ca²⁺ release, which helps maintain the positive force-frequency relationship (i.e., cardiac contractility increases as a function of heart rate). Increased CaMKII activity also phosphorylates phospholamban to help accelerate diastolic filling of the ventricles at higher heart rates. Physiologically, sympathetic activation stimulates both PKA and CaMKII, which thus function synergistically. CaMKII is typically considered to be downstream of PKA and elevated Ca²⁺ transients.^{50,60,62}

Pharmacology

RyR2s are targets of multiple experimental drugs. However, thus far, no compounds in clinical use are known to target RyR2 directly.

The plant alkaloid ryanodine binds the RyR2 channel with high affinity in a Ca²⁺-dependent and use-dependent fashion, thus making it an important tool for biochemical characterization of the channel. Two ryanodine-binding sites, a high-affinity site and a low-affinity one, have been described at the C-terminus of RyR2. At the high-affinity site, ryanodine induces long-lasting channel openings at a subconductance state, whereas high concentrations block the channel.

Caffeine, in high concentrations (5 to 20 mM), increases the RyR2 sensitivity to Ca²⁺ and ATP and results in increased RyR2 mean open time and open probability. Caffeine is used experimentally to measure sarcoplasmic reticulum Ca²⁺ content indirectly because its application causes emptying of the sarcoplasmic reticulum Ca²⁺ store.

JTV-519, also known as K201, is a benzothiazepine derivative (an analogue of diltiazem) and an L-type Ca²⁺ channel blocker and stabilizer. JTV-519 can increase the binding affinity of calstabin2 for RyR2, thus stabilizing the closed conformational state of the RyR2 channel and hence preventing diastolic sarcoplasmic reticulum Ca²⁺ leak. JTV-519 can potentially offer an antiarrhythmic benefit in a variety of pathological conditions that lead to destabilization of the RyR2 channel's closed state, such as RyR2 mutations, hyperphosphorylation of the RyR2 during heart failure, and sarcoplasmic reticulum Ca²⁺ overload.

Among class I antiarrhythmic drugs, only flecainide and propafenone were found to inhibit RyR2 channels (by inducing brief closures of open RyR2 to subconductance states), suppress arrhythmogenic Ca²⁺ sparks, and prevent CPVT in experimental studies. The potency of RyR2 channel inhibition rather than Na⁺ channel blockade appears to determine the efficacy of class I agents for the prevention of CPVT. Flecainide has been demonstrated to prevent lethal ventricular arrhythmias in patients with familial CPVT.^{63,64}

Several toxins (e.g., the scorpion toxins imperatoxin A and imperatoxin I), some anticancer drugs (e.g., doxorubicin), and some immunosuppressants (e.g., rapamycin) can potentially cause cardiac adverse events likely related to effects on the gating kinetics of RyR2 channels.

Inherited Channelopathies

CPVT is caused by mutations in genes that encode for key Ca²⁺ regulatory proteins. Two genetic variants of CPVT have been described: an autosomal-dominant trait (CPVT1; most common) caused by mutations in the cardiac RyR2 gene, and a recessive form (CPVT2; rare) associated with homozygous mutations in the CASQ2 gene (CASQ2).

Approximately 50% to 70% of patients with CPVT harbor RyR2 mutations. More than 70 RyR2 mutations linked to CPVT have been identified. CPVT mutant RyR2 typically shows gain-of-function defects following channel activation by PKA phosphorylation (in response to β -adrenergic stimulation or caffeine), resulting in uncontrolled Ca^{2+} release from the sarcoplasmic reticulum during electrical diastole. The exaggerated spontaneous Ca^{2+} release from the sarcoplasmic reticulum facilitates the development of DADs and triggered arrhythmias.^{58,59}

The molecular mechanisms by which RyR2 mutations alter the physiological properties and function of RyR2 are not completely defined. It has been suggested that CPVT mutations in RyR2 reduce the binding affinity of RyR2 for the regulatory protein FKBP12.6 (calstabin2) that stabilizes the closed conformational state of the RyR2 channel, thus enabling the channel to close completely during diastole (at low intracellular Ca^{2+} concentrations), preventing aberrant Ca^{2+} leakage from the sarcoplasmic reticulum, and ensuring muscle relaxation. PKA phosphorylation (induced by β -adrenergic stimulation) of the mutant channels results in further worsening of the binding affinity of FKBP12.6 to the mutant RyR2 and increases the probability of an open state at diastolic Ca^{2+} concentrations. As a consequence, the mutant RyR2 channel fails to close completely during diastole, with a resulting diastolic Ca^{2+} leak from the sarcoplasmic reticulum during stress or exercise.⁵⁸⁻⁶⁰

An alternative hypothesis is that CPVT mutations in RyR2 sensitize the channel to luminal (sarcoplasmic reticulum) Ca^{2+} such that under baseline conditions, when sarcoplasmic reticulum load is normal, there is no Ca^{2+} leak. Under β -adrenergic (sympathetic) stimulation, sarcoplasmic reticulum Ca^{2+} concentration becomes elevated above the reduced threshold, causing Ca^{2+} to leak out of the sarcoplasmic reticulum. A third hypothesis for RyR2-related CPVT is that mutations in RyR2 impair the intermolecular interactions between discrete RyR2 domains necessary for proper folding of the channel and self-regulation of channel gating.^{58,60}

So far, seven *CASQ2* mutations linked to CPVT have been reported. Although some of these mutations are thought to compromise *CASQ2* synthesis and result in reduced expression or complete absence of *CASQ2* in the heart, other mutations seem to cause expression of defective *CASQ2* proteins with abnormal regulation of cellular Ca^{2+} homeostasis. *CASQ2* mutations result in disruption of the control of RyR2s by luminal Ca^{2+} required for effective termination of sarcoplasmic reticulum Ca^{2+} release and prevention of spontaneous Ca^{2+} release during diastole, thus leading to diminished Ca^{2+} signaling refractoriness and generation of arrhythmogenic spontaneous Ca^{2+} releases.^{58,59,65}

Importantly, in the setting of digitalis poisoning, the abnormal RyR2 behavior leading to spontaneous Ca^{2+} release and DADs is secondary to the elevation of the sarcoplasmic reticulum Ca^{2+} content (SOICR). In CPVT, on the other hand, spontaneous Ca^{2+} release and DADs can occur without Ca^{2+} overload. Mutations in RyR2 or *CASQ2* lead to defective Ca^{2+} signaling lowering of the sarcoplasmic reticulum Ca^{2+} threshold for spontaneous Ca^{2+} release to less than the normal baseline level (perceived Ca^{2+} overload).⁵⁸

Missense mutations in RyR2 also been linked to a form of arrhythmogenic cardiomyopathy (ARVD-2) characterized by exercise-induced polymorphic VT that does not appear to have a reentrant mechanism and occurs in the absence of significant structural abnormalities. Patients do not develop characteristic features of ARVD on the 12-lead ECG or signal-averaged ECG, and global RV function remains unaffected. ARVD-2 shows a closer resemblance to familial CPVT in both etiology and phenotype; its inclusion under the umbrella term of ARVD remains controversial.⁶⁶⁻⁶⁸

Acquired Diseases

RyR2 dysfunction is a key factor leading to arrhythmias in heart failure. Chronic β -adrenergic stimulation results in PKA

hyperphosphorylation of RyR2. This process causes the dissociation of the channel-stabilizing protein calstabin and leads to diastolic Ca^{2+} leak from the sarcoplasmic reticulum and the generation of spontaneous Ca^{2+} waves, which can be maintained despite a reduced Ca^{2+} gradient, thus underlying DAD-induced triggered arrhythmias in heart failure.^{24,69,70}

Cardiac Gap Junctions

Structure and Physiology

Cardiomyocytes make contact with each other via multiple intercalated discs, which mediate the transmission of force, electrical continuity, and chemical communication between adjacent cells. Three types of specialized junctions exist in the intercalated disc: (1) the fascia adherens, (2) the macula adherens (desmosome), and (3) the gap junction (nexus). The fascia adherens is an anchoring site for myofibrils, facilitating the transmission of mechanical energy between neighboring cells. The desmosomes link to the cytoskeleton of adjacent cells to provide strong localized adhesion sites that resist shearing forces generated during contraction. Gap junctions are assemblies of intercellular channels that provide electrical continuity and chemical communication between adjacent cells.⁷¹

In addition to the end-to-end and side-to-side gap junctions localized at the intercalated discs, lateral (side-to-side) gap junctions can exist in nondisc lateral membranes of cardiomyocytes, but they are much less common, occurring more in atrial than ventricular myocardium.⁷¹

Each gap junction channel is constructed of two hemichannels (connexons) aligned head-to-head in mirror symmetry across a narrow extracellular gap, one provided by each of the adjoining cells. Each connexon is composed of six integral membrane proteins called connexins (Cx) hexagonally arranged around the pore. Each connexin consists of four membrane-spanning domains (M1 to M4), two extracellular loops (E1, E2), one intracellular loop, and cytoplasmic N- and C-termini. The extracellular loops mediate the docking of the two hemichannels.^{71,72}

Up to 24 different connexin types have been identified. They are named after their theoretical molecular weight in daltons. In the heart, Cx40, Cx43, and Cx45 are most important for action potential propagation. Although each connexin exhibits a distinct tissue distribution, most cardiomyocytes express more than one connexin isoform. Cx43 is by far the most abundant and is expressed between atrial and ventricular myocytes and distal parts of the Purkinje system. Cx40 is mainly expressed in the atrial myocytes, AVN, and HPS. Cx45 appears to be primarily expressed in nodal tissue (the sinus and compact AVNs), and more weakly in the atrium, His bundle, bundle branches, and Purkinje fibers.⁷¹

Connexons can be composed by the oligomerization of a single connexin type (homomeric) or of different types (heteromeric). In addition, the gap junction channel as a whole may be formed of two matching hemichannels (homotypic) or nonmatching hemichannels (heterotypic).⁷¹

Cardiac connexins exhibit distinctive biophysical properties; hence, the connexin composition of a gap junction channel determines its unitary conductance, voltage sensitivity, and ion selectivity. Cx40 gap junctions express the largest conductance, and Cx45 expresses the smallest. Both Cx40 and Cx45 are highly cation selective, and their conductance is voltage dependent. Cx43 has an intermediate conductance and is nonselective.

The individual gap junction channels allow exchange of nutrients, metabolites, ions (e.g., Na^+ , Cl^- , K^+ , Ca^{2+}) and small molecules (e.g., cAMP, cGMP, inositol triphosphate [IP_3]) with molecular weights up to approximately 1000 Da.⁷¹

Function

Gap junctions maintain direct cell-to-cell communication in the heart by providing biochemical and low-resistance electrical

coupling between adjacent cardiomyocytes. Thus, gap junctions are responsible for myocardial electrical current flow propagation from one cardiac cell to another and are crucial in myocardial synchronization and heart function. Gap junctions also provide biochemical coupling, which allows intercellular movement of second-messenger substances (e.g., ATP, cyclic nucleotides, and IP₃) and hence enables coordinated responses of the myocardial syncytium to physiological stimuli.

The role of gap junction channels in action potential propagation and conduction velocity in cardiac tissue depends primarily on static factors of the channels (e.g., the number of channels, channel conductance, and voltage sensitivity) and dynamic factors (e.g., channel gating kinetics), as well as on properties of the propagated action potential, structural aspects of the cell geometry, and tissue architecture. Tissue-specific connexin expression and gap junction spatial distribution, as well as the variation in the structural composition of gap junction channels, allow for a greater versatility of gap junction physiological features and for disparate conduction properties in cardiac tissue. The myocytes of the sinus and AVNs are equipped with small, sparse, dispersed gap junctions containing Cx45, a connexin that forms low conductance channels; this feature underlies the relatively poor intercellular coupling in nodal tissues, a property that is linked to slowing of conduction. In contrast, ventricular muscle expresses predominantly Cx43 and Cx45, which have larger conductance. Atrial muscle and Purkinje fibers express all three cardiac connexins.

Under physiological conditions, a given cardiomyocyte in the adult working myocardium is electrically coupled to an average of approximately 11 adjacent cells, with gap junctions predominantly localized at the intercalated discs at the ends of the rod-shaped cells. Lateral (side-to-side) gap junctions in nondisc lateral membranes of cardiomyocytes are much less abundant and occur more often in atrial than ventricular tissues.⁷¹ Thus, intercellular current flow occurs primarily at the cell termini, although propagation can occur both longitudinally and transversely. This particular subcellular distribution of gap junctions underlies uniform anisotropic impulse propagation throughout the myocardium, whereby conduction in the direction parallel to the long axis of the myocardial fiber bundles is approximately 3 to 5 times more rapid than that in the transverse direction. This property is attributable principally to the lower resistivity of myocardium provided by the gap junctions in the longitudinal versus the transverse direction.⁷³⁻⁷⁵

Regulation

Gap junction channels have a voltage-dependent gating mechanism, depending primarily on transjunctional voltage (i.e., the potential difference between the cytoplasm of the two adjacent cells). At rest, when the junctional voltage is zero, the channels usually are open. During the course of a propagated action potential, the channels tend to close in a voltage- and time-dependent manner. Gap junction channel gating can also be altered by specific changes in intracellular ions and by post-translational modifications ("loop" gating). Cytosolic Na⁺ and Ca²⁺ overload, acidosis, and reduced ATP levels decrease gap junction channel function. Unlike the voltage gate, which closes rapidly and incompletely, the chemical gate closes slowly and completely.⁷⁶

The regulation of gap junction trafficking, assembly and disassembly, and degradation is likely to be critical in the control of intercellular communication. Phosphorylation also appears to play a key role in channel gating that determines channel conductance and has been implicated in the regulation of the connexin "life cycle" at several stages. Gap junction coupling also is regulated by certain endogenous mediators (e.g., acetylcholine, norepinephrine, and angiotensin), likely via phosphorylation-mediated mechanisms. Importantly, channels composed of different connexins possess different properties and are susceptible to different regulation.^{71,76}

Pharmacology

Several agents have been found to decrease gap junction channel coupling, including long-chain alcohols (e.g., heptanol, octanol), fatty acids (myristoleic acid, decanoic acid, palmitoleic acid), general anesthetics (e.g., halothane, isoflurane), carbachol (an acetylcholine analogue), α -adrenergic agonists (phenylephrine), angiotensin, insulin, insulin-like growth factor, and the nonsteroidal agents fenamates (e.g., flufenamic acid, meclofenamic acid). The mechanism of action of those agents remain largely unknown.

Antimalarial drugs, particularly quinine and quinine derivatives such as mefloquine, can reduce gap junction channel conductance, and their effects seem to be connexin subtype specific. In addition, it has been suggested that the cardiac glycosides strophanthidin, ouabain, and digitoxin decrease intercellular coupling.⁷⁶

Experimental evidence suggests that increasing gap junction conductance can potentially confer an antiarrhythmic effect. Some compounds, including antiarrhythmic peptides and their derivatives (e.g., AAP10, ZP123, rotigaptide) can upregulate Cx43 via modulation either synthesis or degradation and enhance gap junctional communication and were found to reduce conduction slowing and prevent AF and ischemic reentrant VT in various cell and animal models. These peptides presumably act by modulating Cx43 phosphorylation.^{77,78}

Acquired Diseases

Modification of cell-to-cell coupling occurs in numerous pathophysiological settings (e.g., myocardial ischemia, ventricular hypertrophy, cardiomyopathy) as a consequence of acute changes in the average conductance of gap junctions secondary to ischemia, hypoxia, acidification, or an increase in intracellular Ca²⁺, or it can be produced by changes in expression or cellular distribution patterns of gap junctions.^{74,79-81}

Remodeling includes a decrease in the number of gap junction channels resulting from the interruption of communication between cells by fibrosis and downregulation of Cx43 formation or of trafficking to the intercalated disc. Additionally, gap junctions can become more prominent along lateral membranes of myocytes (so-called structural remodeling). Influences of Cx43 lateralization on impulse propagation have not yet been well defined.⁸²

Alterations in distribution and function of cardiac gap junctions are associated with conduction delay or block. Inactivation of gap junctions decreases transverse conduction velocity to a greater degree than longitudinal conduction, thus resulting in exaggeration of anisotropy and providing a substrate for reentrant activity and increased susceptibility to arrhythmias.⁷⁴

AF is associated with abnormal expression and distribution of atrial Cx40, which can potentially lead to inhomogeneous electrical coupling and abnormal impulse formation and conduction and thereby provide the substrate for atrial arrhythmias. Furthermore, a rare single nucleotide polymorphism in the atrial-specific Cx40 gene has been found to increase the risk of idiopathic AF.⁸³

Importantly, there is a high redundancy in connexin expression in the heart with regard to conduction of electrical impulse. It has been shown that a 50% reduction in Cx43 does not alter ventricular impulse conduction. Cx43 expression must decrease by 90% to affect conduction, but even then conduction velocity is reduced only by 20%.

REFERENCES, 60

The mechanisms responsible for cardiac arrhythmias are generally divided into categories of disorders of impulse formation (automaticity or triggered activity), disorders of impulse conduction (reentry), or combinations of both. Automaticity is the property of cardiac cells to initiate an impulse spontaneously, without need for prior stimulation. Triggered activity is impulse initiation in cardiac fibers caused by depolarizing oscillations in membrane voltage (known as afterdepolarizations) that occur consequent to one or more preceding action potentials.¹ Reentry occurs when a propagating action potential wave fails to extinguish after initial tissue activation; instead, it blocks in circumscribed areas, circulates around the zones of block, and reenters and reactivates the site of original excitation after it recovers excitability. Reentry is the likely mechanism of most recurrent clinical arrhythmias.

Diagnosis of the underlying mechanism of an arrhythmia can be of great importance in guiding appropriate treatment strategies. Spontaneous behavior of the arrhythmia, mode of initiation and termination, and response to premature stimulation and overdrive pacing are the most commonly used tools to distinguish among the different mechanisms responsible for cardiac arrhythmias. Our present diagnostic tools, however, do not always permit unequivocal determination of the electrophysiological (EP) mechanisms responsible for many clinical arrhythmias or their ionic bases. In particular, it can be difficult to distinguish among several mechanisms that appear to have a focal origin with centrifugal spread of activation (automaticity, triggered activity, microreentry). This is further complicated by the fact that some arrhythmias can be started by one mechanism and perpetuated by another.

Automaticity

Automaticity, or spontaneous impulse initiation, is the ability of cardiac cells to depolarize spontaneously, reach threshold potential, and initiate a propagated action potential in the absence of external electrical stimulation. Altered automaticity can be caused by enhanced normal automaticity or abnormal automaticity.¹

Enhanced normal automaticity refers to the accelerated generation of an action potential by normal pacemaker tissue and is found in the primary pacemaker of the heart, the sinus node, as well as in certain subsidiary or latent pacemakers that can become the functional pacemaker under certain conditions. Impulse initiation is a normal property of these latent pacemakers.

Abnormal automaticity occurs in cardiac cells only when there are major abnormalities in their transmembrane potentials, in particular in steady-state depolarization of the membrane potential. This property of abnormal automaticity is not confined to any specific latent pacemaker cell type but can occur almost anywhere in the heart.

The discharge rate of normal or abnormal pacemakers can be accelerated by drugs, various forms of cardiac disease, reduction in extracellular potassium (K^+), or alterations of autonomic nervous system tone.

Enhanced Normal Automaticity

PACEMAKER MECHANISMS

Normal automaticity involves a spontaneous, slow, progressive decline (less negative) in the transmembrane potential during diastole (spontaneous diastolic depolarization or phase 4 depolarization) (see Chap. 1). Once this spontaneous depolarization reaches threshold (approximately -40 mV), a new action potential is generated.²

The ionic mechanisms responsible for normal pacemaker activity in the sinus node are still controversial. The fall in membrane potential during phase 4 seems to arise from a changing balance between positive inward currents, which favor depolarization, and positive outward currents, with a net gain in intracellular positive charges during diastole (i.e., inward depolarizing current; Fig. 3-1).^{1,6}

Originally, a major role was attributed to the decay of the delayed K^+ conductance (an outward current) activated during the preceding action potential, (the I_K -decay theory). This model of pacemaker depolarization lost interest on the discovery of the pacemaker current (I_f). Other ionic currents gated by membrane depolarization (i.e., L-type and T-type calcium [Ca^{2+}] currents), nongated and non-specific background leak currents, and a current generated by the sodium (Na^+)– Ca^{2+} exchanger, were also proposed to be involved in pacemaking.

Evidence suggests that I_f (named the “funny” current because, unlike most voltage-sensitive currents, it is activated by hyperpolarization rather than depolarization) is one of the most important ionic currents involved in the rate regulation of cardiac pacemaker cells, hence its designation as the pacemaker current. I_f is an inward current carried largely by Na^+ and, to a lesser extent, K^+ ions. The I_f channels are deactivated during the action potential upstroke and the initial plateau phase of repolarization. However, they begin to activate at the end of the action potential as repolarization brings the membrane potential to levels more negative than approximately -40 to -50 mV, and I_f is fully activated at approximately -100 mV. Once activated, I_f depolarizes the membrane to a level where the Ca^{2+} current activates to initiate the action potential.⁷ In its range of activation, which quite properly comprises the voltage range of diastolic depolarization, the current is inward, and its reversal occurs at approximately -10 to -20 mV because of the mixed Na^+ – K^+ permeability of I_f channels. At the end of the repolarization phase of an action potential, because I_f activation occurs in the background of a decaying outward (K^+ time-dependent) current, current flow quickly shifts from outward to inward, thus giving rise to a sudden reversal of voltage change (from repolarizing to depolarizing) at the maximum diastolic potential. The major role of I_f has been reinforced by the findings that drugs such as ivabradine targeted to block I_f slow heart rate and mutations in the I_f channel are associated with slowed heart rate.^{2,5,8-10}

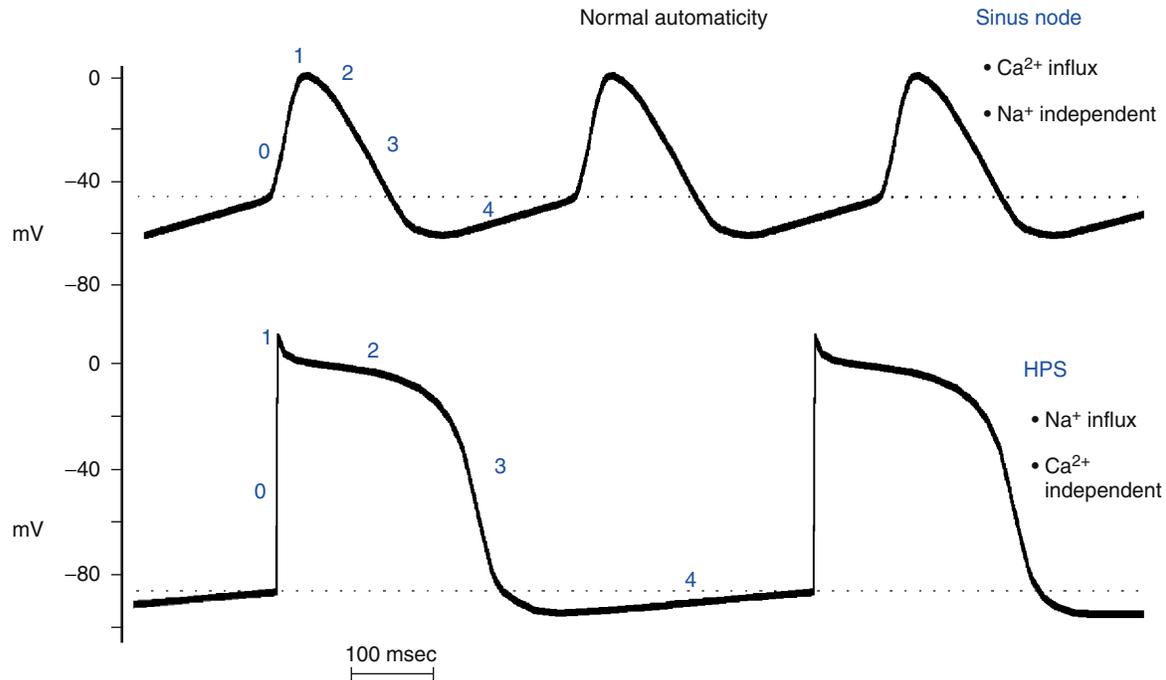

FIGURE 3-1 Normal cardiac automaticity. Action potentials from typical sinus nodal and His-Purkinje cells are shown with the voltage scale on the vertical axes; dashed lines are threshold potential, and numbers on the figure refer to phases of the action potential. Note the qualitative differences between the two types of cells, as well as different rates of spontaneous depolarization. Ca^{2+} = calcium; Na^{+} = sodium.

On the other hand, several studies have shown that I_f is not the only current that can initiate the diastolic depolarization process in the sinus node. In addition to voltage and time, the electrogenic and regulatory molecules on the surface membrane of sinus node cells are strongly modulated by Ca^{2+} and phosphorylation, a finding suggesting that intracellular Ca^{2+} is an important player in controlling pacemaker cell automaticity. Newer evidence points to a substantial impact of another current on the late diastolic depolarization; that is, the $\text{Na}^{+}\text{-Ca}^{2+}$ exchanger current activated by submembrane spontaneous rhythmic local Ca^{2+} releases from the sarcoplasmic reticulum, a major Ca^{2+} store within sinus node cells, via ryanodine receptors (RyR2). Activation of the local oscillatory Ca^{2+} releases is independent of membrane depolarization and is driven by a high level of basal state phosphorylation of Ca^{2+} cycling proteins. Critically timed Ca^{2+} releases occur during the later phase of diastolic depolarization and activate the forward mode of the $\text{Na}^{+}\text{-Ca}^{2+}$ exchanger (one Ca^{2+} for three Na^{+}). The result is in an inward membrane current that causes the late diastolic depolarization to increase exponentially, thus driving the membrane potential to the threshold to activate a sufficient number of voltage-gated L-type Ca^{2+} channels and leading to generation of the rapid upstroke of the next action potential (see Fig. 1-3). Although regulated by membrane potential and submembrane Ca^{2+} , the $\text{Na}^{+}\text{-Ca}^{2+}$ exchanger does not have time-dependent gating, as do ion channels, but generates an inward current almost instantaneously when submembrane Ca^{2+} concentration increases.^{8,9,11}

Such rhythmic, spontaneous intracellular Ca^{2+} cycling has been referred to as an “intracellular Ca^{2+} clock.” Phosphorylation-dependent gradation of the speed at which Ca^{2+} clock cycles is the essential regulatory mechanism of normal pacemaker rate and rhythm. The robust regulation of pacemaker function is ensured by tight integration of the Ca^{2+} clock and the classic sarcolemmal “ion channel clock” (formed by voltage-dependent membrane ion channels) to form the overall pacemaker clock. The action potential shape and ion fluxes are tuned by membrane clocks to sustain operation of the Ca^{2+} clock, which produces timely and powerful ignition of the membrane clocks to effect action potentials.

There is some degree of uncertainty about the relative role of I_f versus that of intracellular Ca^{2+} cycling in controlling the normal

pacemaker cell automaticity and their individual (or mutual) relevance in mediating the positive-negative chronotropic effect of neurotransmitters. Furthermore, the interactions between the membrane ion channel clock and the intracellular Ca^{2+} clock and the cellular mechanisms underlying this internal Ca^{2+} clock are not completely elucidated.^{8,9,11}

Automaticity in subsidiary pacemakers appears to arise via a mechanism similar to that occurring in the sinus node.

HIERARCHY OF PACEMAKER FUNCTION

Automaticity is not limited to the cells within the sinus node. Under physiological conditions, cells in parts of the atria and within the atrioventricular node (AVN) and the His-Purkinje system (HPS) also possess pacemaking capability. However, the occurrence of spontaneous activity in these cells is prevented by the natural hierarchy of pacemaker function that causes these sites to be latent or subsidiary pacemakers.¹ The spontaneous discharge rate of the sinus node normally exceeds that of all other subsidiary pacemakers (see Fig. 3-1). Therefore, the impulse initiated by the sinus node depolarizes subsidiary pacemaker sites and keeps their activity depressed before they can spontaneously reach threshold. However, slowly depolarizing and previously suppressed pacemakers in the atrium, AVN, or ventricle can become active and assume pacemaker control of the cardiac rhythm if the sinus node pacemaker becomes slow or unable to generate an impulse (e.g., secondary to depressed sinus node automaticity) or if impulses generated by the sinus node are unable to activate the subsidiary pacemaker sites (e.g., sinoatrial exit block, or atrioventricular [AV] block). The emergence of subsidiary or latent pacemakers under such circumstances is an appropriate fail-safe mechanism, which ensures that ventricular activation is maintained. Because spontaneous diastolic depolarization is a normal property, the automaticity generated by these cells is classified as normal.

There is also a natural hierarchy of intrinsic rates of subsidiary pacemakers that have normal automaticity, with atrial pacemakers having faster intrinsic rates than AV junctional pacemakers, and AV junctional pacemakers having faster rates than ventricular pacemakers.

SUBSIDIARY PACEMAKERS

Subsidiary Atrial Pacemakers

Subsidiary atrial pacemakers have been identified in the atrial myocardium, especially in the crista terminalis, at the junction of the inferior right atrium and inferior vena cava, near or on the eustachian ridge, near the coronary sinus ostium, in the atrial muscle that extends into the tricuspid and mitral valves, and in the muscle sleeves that extend into the cardiac veins (venae cavae and pulmonary veins).¹²

Latent atrial pacemakers can contribute to impulse initiation in the atrium if the discharge rate of the sinus node is reduced temporarily or permanently. In contrast to the normal sinus node, these latent or ectopic pacemakers usually generate a fast action potential (referring to the rate of upstroke of the action potential [dV/dt]) mediated by Na⁺ fluxes. However, when severely damaged, the atrial tissue may not be able to generate a fast action potential (which is energy dependent), but rather generates a slow, Ca²⁺-mediated action potential (which is energy independent). Automaticity of subsidiary atrial pacemakers can also be enhanced by coronary disease and ischemia, chronic pulmonary disease, or drugs such as digitalis and alcohol, possibly overriding normal sinus activity.

Subsidiary Atrioventricular Junctional Pacemakers

Some data suggest that the AVN itself has pacemaker cells, but that concept is controversial. However, it is clear that the AV junction, which is an area that includes atrial tissue, the AVN, and His-Purkinje tissue, does have pacemaker cells and is capable of exhibiting automaticity.

Subsidiary Ventricular Pacemakers

In the ventricles, latent pacemakers are found in the HPS, where Purkinje fibers have the property of spontaneous diastolic depolarization. Isolated cells of the HPS discharge spontaneously at rates of 15 to 60 beats/min, whereas ventricular myocardial cells do not normally exhibit spontaneous diastolic depolarization or automaticity. The relatively slow spontaneous discharge rate of the HPS pacemakers, which further decreases from the His bundle to the distal Purkinje branches, ensures that pacemaker activity in the HPS will be suppressed on a beat-to-beat basis by the more rapid discharge rate of the sinus node and atrial and AV junctional pacemakers. However, enhanced Purkinje fiber automaticity can be induced by certain situations, such as myocardial infarction (MI). In this setting, some Purkinje fibers that survive the infarction develop moderately reduced maximum diastolic membrane potentials and therefore accelerated spontaneous discharge rates.¹³

REGULATION OF PACEMAKER FUNCTION

The intrinsic rate at which the sinus node pacemaker cells generate impulses is determined by the interplay of three factors: the maximum diastolic potential, the threshold potential at which the action potential is initiated, and the rate or slope of phase 4 depolarization (Fig. 3-2). A change in any one of these factors will alter the time required for phase 4 depolarization to carry the membrane potential from its maximum diastolic level to threshold and thus alter the rate of impulse initiation.¹

The sinus node is innervated by the parasympathetic and sympathetic nervous systems, and the balance between these systems importantly controls the pacemaker rate. The classic concept has been that of a reciprocal relationship between sympathetic and parasympathetic inputs. More recent investigations, however, stress dynamic, demand-oriented interactions, and the anatomical distribution of fibers that allows both autonomic systems to act quite selectively. Muscarinic cholinergic and beta₁-adrenergic receptors are nonuniformly distributed in the sinus node, and they modulate both the rate of depolarization and impulse propagation.¹

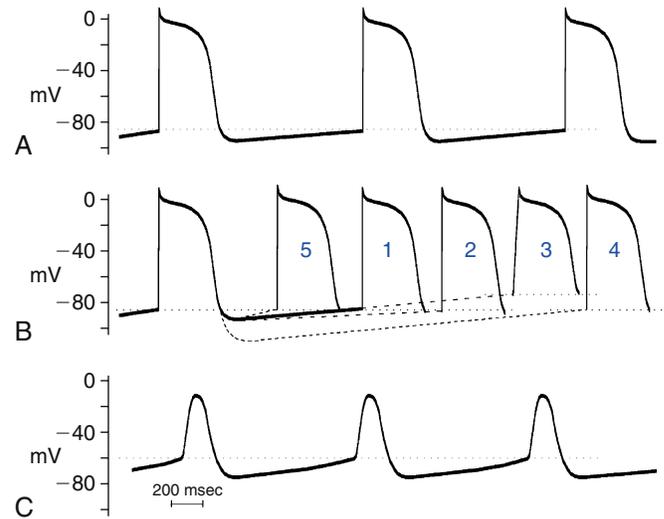

FIGURE 3-2 Abnormalities of automaticity. **A**, Normal His-Purkinje action potential. **B**, Modulation of rate of depolarization from baseline (1) by slowing rate of phase 4 depolarization (2), increasing threshold potential (3), starting from a more negative resting membrane potential (4), all of which slow discharge rate, or by increasing rate of phase 4 depolarization (5), thus yielding a faster discharge rate. **C**, Abnormal automaticity with change in action potential contour (resembling sinus nodal cell) when resting membrane potential is less negative, inactivating most sodium channels.

Parasympathetic Activity

Parasympathetic tone reduces the spontaneous discharge rate of the sinus node, whereas its withdrawal accelerates sinus node automaticity. Acetylcholine, the principal neurotransmitter of the parasympathetic nervous system, inhibits spontaneous impulse generation in the sinus node by increasing K⁺ conductance. Acetylcholine acts through M₂ muscarinic receptors to activate the G_i protein, which subsequently results in activation of I_{K_{ACh}} (an acetylcholine-activated subtype of inward rectifying current) in tissues of the sinus node and AVN as well as of the atria, Purkinje fibers, and ventricles. The increased outward repolarizing K⁺ current (I_K) leads to membrane hyperpolarization (i.e., the resting potential and the maximum diastolic potential become more negative). The resulting hyperpolarization of the membrane potential lengthens the time required for the membrane potential to depolarize to threshold and thereby decreases the automaticity of the sinus node (see Fig. 3-2). In addition, activation of the G_i protein results in inhibition of beta-receptor-stimulated adenylate cyclase activity, thus reducing cyclic adenosine monophosphate (cAMP) and inhibiting protein kinase A, with subsequent inhibition of the inward Ca²⁺ current. This results in reduction of the rate of diastolic depolarization because of less Ca²⁺ entry and subsequent slowing of the pacemaker activity. Inhibition of beta-receptor-stimulated adenylate cyclase activity can also inhibit the inward I_f current.

Sympathetic Activity

Increased sympathetic nerve traffic and the adrenomedullary release of catecholamines increase sinus node discharge rate. Stimulation of beta₁-receptors by catecholamines enhances the L-type of inward Ca²⁺ current (I_{CaL}) by increasing cAMP and activating the protein kinase A system; the increment in inward Ca²⁺ current increases the slope of diastolic depolarization and enhances pacemaker activity (see Fig. 3-2). The redistribution of Ca²⁺ can also increase the completeness and the rate of deactivation of the rapid (I_{Kr}) and slow (I_{Ks}) components of the delayed rectifier I_K; the ensuing decline in the opposing outward current results in a further net increase in inward current. Catecholamines can also enhance the inward I_f current by shifting the voltage dependence

of I_f to more positive potentials, thus augmenting the slope of phase 4 and increasing the rate of sinus node firing.¹⁰

In addition to altering ionic conductance, changes in autonomic tone can produce changes in the rate of the sinus node by shifting the primary pacemaker region within the pacemaker complex. Mapping of activation indicates that, at faster rates, the sinus node impulse usually originates in the superior portion of the sinus node, whereas at slower rates, it usually arises from a more inferior portion of the sinus node. The sinus node can be insulated from the surrounding atrial myocytes, except at a limited number of preferential exit sites. Shifting pacemaker sites can select different exit pathways to the atria. As a result, autonomically mediated shifts of pacemaker regions can be accompanied by changes in the sinus rate. Vagal fibers are denser in the cranial portion of the sinus node, and stimulation of the parasympathetic nervous system shifts the pacemaker center to a more caudal region of the sinus node complex, thus resulting in slowing of the heart rate. In contrast, stimulation of the sympathetic nervous system or withdrawal of vagal stimulation shifts the pacemaker center cranially, resulting in an increase in heart rate.

Atrial, AV junctional, and HPS subsidiary pacemakers are also under similar autonomic control, with the sympathetic nervous system enhancing pacemaker activity through β_1 -adrenergic stimulation and the parasympathetic nervous system inhibiting pacemaker activity through muscarinic receptor stimulation.¹

Other Influences

Adenosine binds to A_1 -receptors, thus activating $I_{K_{ACH}}$ and increasing outward I_K in a manner similar to that of marked parasympathetic stimulation. It also has similar effects on I_f channels.

Digitalis exerts two effects on the sinus rate. It has a direct positive chronotropic effect on the sinus node, resulting from depolarization of the membrane potential caused by inhibition of the Na^+ - K^+ exchange pump. The reduction in the maximum diastolic membrane potential decreases the time required for the membrane to depolarize to threshold and thereby accelerates the spontaneous discharge rate. However, digitalis also enhances vagal tone, which decreases spontaneous sinus discharge.

Enhanced subsidiary pacemaker activity may not require sympathetic stimulation. Normal automaticity can be affected by certain other factors associated with heart disease. Inhibition of the electrogenic Na^+ - K^+ exchange pump results in a net increase in inward current during diastole because of the decrease in outward current normally generated by the pump, and therefore it can increase automaticity in subsidiary pacemakers sufficiently to cause arrhythmias. This can occur when adenosine triphosphate (ATP) is depleted during prolonged hypoxia or ischemia or in the presence of toxic amounts of digitalis. Hypokalemia can reduce the activity of the Na^+ - K^+ exchange pump, thereby reducing the background repolarizing current and enhancing phase 4 diastolic depolarization. The end result would be an increase in the discharge rate of pacemaking cells. Additionally, the flow of current between partially depolarized myocardium and normally polarized latent pacemaker cells can enhance automaticity. This mechanism has been proposed to be a cause of some of the ectopic complexes that arise at the borders of ischemic areas in the ventricle. Slightly increased extracellular K^+ can render the maximum diastolic potential more positive (i.e., reduced or less negative), thereby also increasing the discharge rate of pacemaking cells. A greater increase in extracellular K^+ , however, renders the heart inexcitable by depolarizing the membrane potential and inactivating the Na^+ current (I_{Na}).

Evidence indicates that active and passive changes in the mechanical environment of the heart provide feedback to modify cardiac rate and rhythm and are capable of influencing both the initiation and spread of cardiac excitation. This direction of the crosstalk between cardiac electrical and mechanical activity is referred to as mechanoelectric feedback and is thought to be involved in the adjustment of heart rate to changes in mechanical load, which would help explain the precise beat-to-beat regulation

of cardiac performance. Acute mechanical stretch enhances automaticity, reversibly depolarizes the cell membrane, and shortens the action potential duration. Feedback from cardiac mechanics to electrical activity involves mechanosensitive ion channels and ATP-sensitive K^+ channels. In addition, Na^+ and Ca^{2+} entering the cells via nonselective ion channels are thought to contribute to the genesis of stretch-induced arrhythmia.¹⁴

Abnormal Automaticity

In the normal heart, automaticity is confined to the sinus node and other specialized conducting tissues. Working atrial and ventricular myocardial cells do not normally have spontaneous diastolic depolarization and do not initiate spontaneous impulses, even when they are not excited for long periods of time by propagating impulses. Although these cells do have an I_f , the range of activation of this current in these cells is much more negative (-120 to -170 mV) than in Purkinje fibers or in the sinus node. As a result, during physiological resting membrane potentials (-85 to -95 mV), the I_f is not activated, and ventricular cells do not depolarize spontaneously.¹ When the resting potentials of these cells are depolarized sufficiently, to approximately -70 to -30 mV, however, spontaneous diastolic depolarization can occur and cause repetitive impulse initiation, a phenomenon called depolarization-induced automaticity or abnormal automaticity (see Fig. 3-2). Similarly, cells in the Purkinje system, which are normally automatic at high levels of membrane potential, show abnormal automaticity when the membrane potential is reduced to approximately -60 mV or less, as can occur in ischemic regions of the heart. When the steady-state membrane potential of Purkinje fibers is reduced to approximately -60 mV or less, the I_f channels that participate in normal pacemaker activity in Purkinje fibers are closed and nonfunctional, and automaticity is therefore not caused by the normal pacemaker mechanism. It can, however, be caused by an "abnormal" mechanism. In contrast, enhanced automaticity of the sinus node, subsidiary atrial pacemakers, or the AVN caused by a mechanism other than acceleration of normal automaticity has not been demonstrated clinically.¹⁵

A low level of membrane potential is not the only criterion for defining abnormal automaticity. If this were so, the automaticity of the sinus node would have to be considered abnormal. Therefore, an important distinction between abnormal and normal automaticity is that the membrane potentials of fibers showing the abnormal type of activity are reduced from their own normal level. For this reason, automaticity in the AVN (e.g., where the membrane potential is normally low) is not classified as abnormal automaticity.

Several different mechanisms probably cause abnormal pacemaker activity at low membrane potentials, including activation and deactivation of the delayed rectifier I_K , intracellular Ca^{2+} release from the sarcoplasmic reticulum that causes activation of inward Ca^{2+} currents and the inward I_{Na} (through the Na^+ - Ca^{2+} exchanger), and a potential contribution by I_f .¹⁶ It has not been determined which of these mechanisms are operative in the different pathological conditions in which abnormal automaticity can occur.¹

The upstroke of the spontaneously occurring action potentials generated by abnormal automaticity can be caused by Na^+ or Ca^{2+} inward currents or possibly a combination of the two.¹ In the range of diastolic potentials between approximately -70 and -50 mV, repetitive activity is dependent on extracellular Na^+ concentration and can be decreased or abolished by Na^+ channel blockers. In a diastolic potential range of approximately -50 to -30 mV, Na^+ channels are predominantly inactivated; repetitive activity depends on extracellular Ca^{2+} concentration and is reduced by L-type Ca^{2+} channel blockers.

The intrinsic rate of a focus with abnormal automaticity is a function of the membrane potential. The more positive the membrane potential is, the faster the automatic rate will be (see Fig. 3-2). Abnormal automaticity is less vulnerable to suppression by overdrive pacing (see later). Therefore, even occasional slowing of the sinus node rate can allow an ectopic focus with abnormal

automaticity to fire without a preceding long period of quiescence. Catecholamines can increase the rate of discharge caused by abnormal automaticity and therefore can contribute to a shift in the pacemaker site from the sinus node to a region with abnormal automaticity.

CH
3

The decrease in the membrane potential of cardiac cells required for abnormal automaticity to occur can be induced by a variety of factors related to cardiac disease, such as ischemia and infarction. The circumstance under which membrane depolarization occurs, however, can influence the development of abnormal automaticity. For example, an increase in extracellular K^+ concentration, as occurs in acutely ischemic myocardium, can reduce membrane potential; however, normal or abnormal automaticity in working atrial, ventricular, and Purkinje fibers usually does not occur because of an increase in K^+ conductance (and hence net outward current) that results from the increase in extracellular K^+ concentration.

Overdrive Suppression of Automatic Rhythms

SUPPRESSION OF NORMAL AND ABNORMAL AUTOMATIC SUBSIDIARY PACEMAKERS

The sinus node likely maintains its dominance over subsidiary pacemakers in the AVN and the Purkinje fibers by several mechanisms. During sinus rhythm in a normal heart, the intrinsic automatic rate of the sinus node is faster than that of the other potentially automatic cells. Consequently, the latent pacemakers are excited by propagated impulses from the sinus node before they have a chance to depolarize spontaneously to threshold potential. The higher frequency of sinus node discharge also suppresses the automaticity of other pacemaker sites by a mechanism called overdrive suppression. The diastolic (phase 4) depolarization of the latent pacemaker cells with the property of normal automaticity is actually inhibited because the cells are repeatedly depolarized by the impulses from the sinus node.¹ Electrotonic interaction between the pacemaker cells and the nonpacemaker cells in the surrounding myocardium via intercalated discs and gap junctions can also hyperpolarize the latent pacemakers and contribute to their suppression (Fig. 3-3).

MECHANISM OF OVERDRIVE SUPPRESSION

The mechanism of overdrive suppression is mediated mostly by enhanced activity of the Na^+K^+ exchange pump that results from driving a pacemaker cell faster than its intrinsic spontaneous rate. During normal sinus rhythm (NSR), latent pacemakers are depolarized at a higher frequency than their intrinsic rate of automaticity. The increased frequency of depolarizations leads to an increase in intracellular Na^+ , which enters the cell with every action potential, because more Na^+ enters the cell per unit time.¹ The increased intracellular Na^+ stimulates the Na^+K^+ exchange pump. Because the Na^+K^+ exchange pump is electrogenic (i.e., moves more Na^+ outward than K^+ inward), it generates a net outward (hyperpolarizing) current across the cell membrane. This drives the membrane potential more negative, thereby offsetting the depolarizing I_f being carried into the cell and slowing the rate of phase 4 diastolic depolarization. This effectively prevents the I_f from depolarizing the cell to its threshold potential and thereby suppresses spontaneous impulse initiation in these cells.

When the dominant (overdrive) pacemaker is stopped, suppression of subsidiary pacemakers continues because the Na^+K^+ exchange pump continues to generate the outward current as it reduces the intracellular Na^+ levels toward normal. This continued Na^+K^+ exchange pump-generated outward current is responsible for the period of quiescence, which lasts until the intracellular Na^+ concentration, and hence the pump current, becomes low enough to allow subsidiary pacemaker cells to depolarize spontaneously to threshold. Intracellular Na^+ concentration decreases during the quiescent period because Na^+ is constantly being

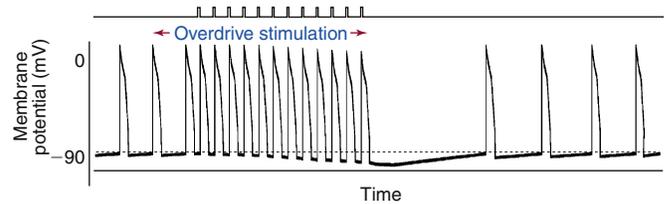

FIGURE 3-3 Overdrive suppression of automaticity. A spontaneously firing cell is paced more rapidly, resulting in depression of resting membrane potential; after pacing is stopped, spontaneous depolarization takes longer than usual and gradually resumes baseline rate. Dashed line = threshold potential.

pumped out of the cell and little is entering. Additionally, the spontaneous rate of the suppressed cell remains lower than it would be otherwise until the intracellular Na^+ concentration has a chance to decrease. Intracellular Na^+ concentration and pump current continue to decline even after spontaneous discharge begins because of the slow firing rate, thus causing a gradual increase in the discharge rate of the subsidiary pacemaker. At slower rates and shorter overdrive periods, the Na^+ load is of lesser magnitude, as is the activity of the Na^+K^+ pump, resulting in a progressively rapid diastolic depolarization and warm-up. The higher the overdrive rate or the longer the duration of overdrive, the greater the enhancement of pump activity will be, so that the period of quiescence after the cessation of overdrive is directly related to the rate and duration of overdrive.

The sinus node itself also is vulnerable to overdrive suppression. When overdrive suppression of the normal sinus node occurs, however, it is generally of lesser magnitude than that of subsidiary pacemakers overdriven at comparable rates. The sinus node action potential upstroke is largely dependent on the slow inward current carried by I_{CaL} , and far less Na^+ enters the fiber during the upstroke than occurs in latent pacemaker cells such as the Purkinje fibers. As a result, the accumulation of intracellular Na^+ and enhancement of Na^+K^+ exchange pump activity occur to a lesser degree in sinus node cells after a period of overdrive; therefore, there is less overdrive suppression caused by enhanced Na^+K^+ exchange pump current. The relative resistance of the normal sinus node to overdrive suppression can be important in enabling it to remain the dominant pacemaker, even when its rhythm is perturbed transiently by external influences such as transient shifts of the pacemaker to an ectopic site. The diseased sinus node, however, can be much more easily overdrive suppressed, such as in the so-called tachycardia-bradycardia syndrome.

Abnormally automatic cells and tissues at reduced levels of membrane potential are less sensitive to overdrive suppression than cells and tissues that are fully polarized, with enhanced normal automaticity. The amount of overdrive suppression of spontaneous diastolic depolarization that causes abnormal automaticity is directly related to the level of membrane potential at which the automatic rhythm occurs. At low levels of membrane potential, Na^+ channels are inactivated, decreasing the fast inward I_{Na} ; therefore, there are reductions in the amount of Na^+ entering the cell during overdrive and the degree of stimulation of the Na^+K^+ exchange pump. The more polarized the membrane is during phase 4, the larger the amount will be of Na^+ entering the cell with each action potential, and the more overdrive suppression will occur. As a result of the lack of overdrive suppression of abnormally automatic cells, even transient sinus pauses can permit an ectopic focus with a slower rate than the sinus node to capture the heart for one or more beats. However, even in situations in which the cells can be sufficiently depolarized to inactivate the I_{Na} and limit intracellular Na^+ load, overdrive suppression can still be observed because of increased intracellular Ca^{2+} loading. Such Ca^{2+} loading can activate Ca^{2+} -dependent K^+ conductance (favoring repolarization) and promote Ca^{2+} extrusion through the Na^+Ca^{2+} exchanger and Ca^{2+} channel phosphorylation, thus increasing Na^+ load and thus Na^+K^+ exchange pump activity. The increase in intracellular Ca^{2+} load can

also reduce the depolarizing I_{CaL} by promoting Ca^{2+} -induced inactivation of the Ca^{2+} current.

In addition to overdrive suppression being of paramount importance for maintenance of NSR, the characteristic response of automatic pacemakers to overdrive is often useful to distinguish automaticity from triggered activity and reentry.

Arrhythmias Caused by Automaticity

INAPPROPRIATE SINUS NODE DISCHARGE

Such arrhythmias result simply from an alteration in the rate of impulse initiation by the normal sinus node pacemaker, without a shift of impulse origin to a subsidiary pacemaker at an ectopic site, although there can be shifts of the pacemaker site within the sinus node itself during alterations in sinus rate. These arrhythmias are often a result of the actions of the autonomic nervous system on the sinus node. Examples of these arrhythmias include sinus bradycardia, sinus arrest, inappropriate sinus tachycardia, and respiratory sinus arrhythmia. Respiratory sinus arrhythmia is primarily caused by withdrawal of vagal tone during inhalation and reinstatement of vagal tone during exhalation.

ESCAPE ECTOPIC AUTOMATIC RHYTHMS

Impairment of the sinus node can allow a latent pacemaker to initiate impulse formation. This would be expected to happen when the rate at which the sinus node overdrives subsidiary pacemakers falls considerably below the intrinsic rate of the latent pacemakers or when the inhibitory electrotonic influences between nonpacemaker cells and pacemaker cells are interrupted.

The rate at which the sinus node activates subsidiary pacemakers can be decreased in certain situations, including sinus node dysfunction, with depressed sinus automaticity (secondary to increased vagal tone, drugs, or intrinsic sinus node disease), sinoatrial exit block, AV block, and parasystolic focus. The sinus node and AVN are most sensitive to vagal influence, followed by atrial tissue, with the ventricular conducting system being least sensitive. Moderate vagal stimulation allows the pacemaker to shift to another atrial site, but severe vagal stimulation suppresses the sinus node and blocks conduction at the AVN and therefore can allow a ventricular escape pacemaker to become manifest.

Interruption of the inhibitory electrotonic influences between nonpacemaker cells and pacemaker cells allows those latent pacemakers to fire at their intrinsic rate. Uncoupling can be caused by fibrosis or damage (e.g., infarction) of the tissues surrounding the subsidiary pacemaker cells or by reduction in gap junction conductance secondary to increased intracellular Ca^{2+} , which can be caused by digitalis. Some inhibition of the sinus node is still necessary for the site of impulse initiation to shift to an ectopic site that is no longer inhibited by uncoupling from surrounding cells because the intrinsic firing rate of subsidiary pacemakers is still slower than that of the sinus node.

ACCELERATED ECTOPIC AUTOMATIC RHYTHMS

Accelerated ectopic automatic rhythms are caused by enhanced normal automaticity of subsidiary pacemakers. The rate of discharge of these latent pacemakers is then faster than the expected intrinsic automatic rate. Once the enhanced rate exceeds that of the sinus node, the enhanced ectopic pacemaker prevails and overdrives the sinus node and other subsidiary pacemakers. A premature impulse caused by enhanced automaticity of latent pacemakers comes early in the normal rhythm. In contrast, an escape beat secondary to relief of overdrive suppression occurs late in normal rhythm.

Enhanced automaticity is usually caused by increased sympathetic tone, which steepens the slope of diastolic depolarization of latent pacemaker cells and diminishes the inhibitory effects of overdrive. Such sympathetic effects can be localized to subsidiary

pacemakers in the absence of sinus node stimulation. Other causes of enhanced normal automaticity include periods of hypoxemia, ischemia, electrolyte disturbances, and certain drug toxicities. There is evidence that in the subacute phase of myocardial ischemia, increased activity of the sympathetic nervous system can enhance automaticity of Purkinje fibers, thus enabling them to escape from sinus node domination.

PARASYSTOLE

Parasystole is a result of interaction between two fixed rate pacemakers having different discharge rates. Parasystolic pacemakers can exist in either the atrium or the ventricle. The latent pacemaker is protected from being overdriven by the dominant rhythm (usually NSR) by intermittent or constant entrance block (i.e., impulses of sinus origin fail to depolarize the latent pacemaker secondary to block in the tissue surrounding the latent pacemaker focus). Various mechanisms have been postulated to explain the protected zone surrounding the ectopic focus. It is possible that the depolarized level of membrane potential at which abnormal automaticity occurs can cause entrance block, leading to parasystole. This would be an example of an arrhythmia caused by a combination of an abnormality of impulse conduction and impulse initiation. Such block, however, must be unidirectional, so that activity from the ectopic pacemaker can exit and produce depolarization whenever the surrounding myocardium is excitable. The protected pacemaker is said to be a parasystolic focus. In general, under these conditions, a protected focus of automaticity of this type fires at its own intrinsic frequency, and the intervals between the discharges of each pacemaker are multiples of its intrinsic discharge rate (sometimes described as *fixed parasystole*). Therefore, on the surface ECG, the coupling intervals of the manifest ectopic beats wander through the basic cycle of the sinus rhythm. Accordingly, the traditional ECG criteria used to recognize the fixed form of parasystole are (1) the presence of variable coupling intervals of the manifest ectopic beats, (2) interectopic intervals that are simple multiples of a common denominator, and (3) the presence of fusion beats. Occasionally, the parasystolic focus can exhibit exit block, during which it may fail to depolarize excitable myocardium.¹⁷

Although the parasystolic focus is protected, it may not be totally immune to the surrounding electrical activity. The effective electrical communication that permits the emergence of the ectopic discharges can also allow the rhythmic activity of the surrounding tissues to electrotonically influence the periodicity of the pacemaker discharge rate (described as *modulated parasystole*). Electrotonic influences arriving during the early stage of diastolic depolarization result in a delay in the firing of the parasystolic focus, whereas those arriving late accelerate the discharge of the parasystolic focus. As a consequence, the dominant pacemaker can entrain the partially protected parasystolic focus and force it to discharge at periods that may be faster or slower than its own intrinsic cycle and give rise to premature discharges whose patterns depend on the degree of modulation and the basic heart rate, occasionally mimic reentry, and occur at fixed coupling intervals. Therefore, appropriate diagnosis of modulated parasystole relies on the construction of a phase response curve as theoretical evidence of modulation of the ectopic pacemaker cycle length (CL) by the electrotonic activity generated by the sinus discharges across the area of protection.¹⁷

All these features of abnormal automaticity can be found in the Purkinje fibers that survive in regions of transmural MI and cause ventricular arrhythmias during the subacute phase.

ARRHYTHMIAS CAUSED BY ABNORMAL AUTOMATICITY

There appears to be an association between abnormal Purkinje fiber automaticity and the arrhythmias that occur during the acute phase of MI (e.g., an accelerated idioventricular rhythm). However, the role of abnormal automaticity in the development

of ventricular arrhythmias associated with chronic ischemic heart disease is less certain. Additionally, isolated myocytes obtained from hypertrophied and failing hearts have been shown to manifest spontaneous diastolic depolarization and enhanced I_f findings suggesting that abnormal automaticity can contribute to the occurrence of some arrhythmias in heart failure and left ventricular hypertrophy.

Abnormal automaticity can underlie atrial tachycardia, accelerated idioventricular rhythms, and ventricular tachycardia (VT), particularly that associated with ischemia and reperfusion. It has also been suggested that injury currents at the borders of ischemic zones can depolarize adjacent nonischemic tissue, thus predisposing to automatic VT.

Although automaticity is not responsible for most clinical tachyarrhythmias, which are usually caused by reentry, normal or abnormal automaticity can lead to arrhythmias caused by nonautomatic mechanisms. Premature beats, caused by automaticity, can initiate reentry. Rapid automatic activity in sites such as the cardiac veins can cause fibrillatory conduction, reentry, and atrial fibrillation (AF).

Triggered Activity

Triggered activity is impulse initiation in cardiac fibers caused by afterdepolarizations that occur consequent to a preceding impulse or series of impulses.¹ Afterdepolarizations are depolarizing oscillations in membrane potential that follow the upstroke of a preceding action potential. Afterdepolarizations can occur early during the repolarization phase of the action potential (early afterdepolarization [EAD]) or late, after completion of the repolarization phase (delayed afterdepolarization [DAD]; Fig. 3-4). When either type of afterdepolarization is large enough to reach the threshold potential for activation of a regenerative inward current, a new action potential is generated, which is referred to as *triggered*.

Unlike automaticity, triggered activity is not a self-generating rhythm. Instead, triggered activity occurs as a response to a preceding impulse (the trigger). Automatic rhythms, on the other hand, can arise *de novo* in the absence of any prior electrical activity.

Delayed Afterdepolarizations and Triggered Activity

DADs are oscillations in membrane voltage that occur after completion of repolarization of the action potential (i.e., during phase 4). The transient nature of the DAD distinguishes it from normal spontaneous diastolic (pacemaker) depolarization, during which the membrane potential declines almost monotonically until the next action potential occurs. DADs may or may not reach threshold. Subthreshold DADs do not initiate action potentials or trigger arrhythmias. When a DAD does reach threshold, only one triggered action potential occurs (Fig. 3-5). The triggered action potential can also be followed by a DAD that, again, may or may not reach threshold and may or may not trigger another action potential. The first triggered action potential is often followed by a short or long train of additional triggered action potentials, each arising from the DAD caused by the previous action potential.

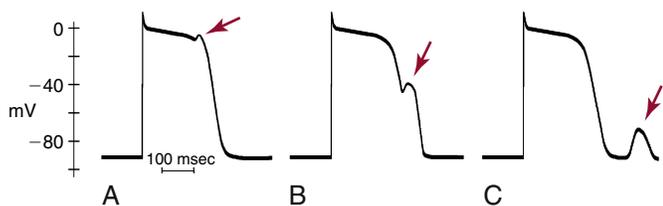

FIGURE 3-4 Types of afterdepolarizations. Afterdepolarizations are indicated by arrows. Purkinje cell action potentials are shown with phase 2 early afterdepolarizations (EADs) (A) and phase 3 EADs (B), as well as delayed afterdepolarizations (DADs) (C), which occur after full repolarization.

IONIC BASIS OF DELAYED AFTERDEPOLARIZATIONS

DADs usually occur under a variety of conditions in which Ca^{2+} overload develops in the cytoplasm and sarcoplasmic reticulum. During the plateau phase of the normal action potential, Ca^{2+} flows through voltage-dependent L-type Ca^{2+} channels (I_{CaL}). Although the rise in intracellular Ca^{2+} is small and not sufficient to induce contraction, the small amount of Ca^{2+} entering the cell via I_{CaL} triggers a massive release of Ca^{2+} from the sarcoplasmic reticulum (the major store for Ca^{2+}) into the cytosol by opening the RyR2 channels (present in the membrane of the sarcoplasmic reticulum) in a process known as Ca^{2+} -induced Ca^{2+} release (CICR).^{1,6} During repolarization (i.e., diastole), most of the surplus Ca^{2+} in the cytosol is resealed into the sarcoplasmic reticulum by the sarcoplasmic reticulum Ca^{2+} adenosine triphosphatase (SERCA), the activity of which is controlled by the phosphoprotein phospholamban. Additionally, some of the Ca^{2+} is extruded from the cell by the Na^+ - Ca^{2+} exchanger to balance the Ca^{2+} that enters with Ca^{2+} current. Recurring Ca^{2+} release-uptake cycles provide the basis for periodic elevations of the cytosolic Ca^{2+} concentration and contractions of myocytes, hence for the orderly beating of the heart (Fig. 3-6).¹⁸⁻²⁰

Under various pathological conditions, Ca^{2+} concentration in the sarcoplasmic reticulum can rise to a critical level during repolarization (i.e., Ca^{2+} overload), at which time a secondary spontaneous release of Ca^{2+} from the sarcoplasmic reticulum occurs after the action potential, rather than as a part of excitation-contraction coupling. This secondary release of Ca^{2+} results in inappropriately timed Ca^{2+} transients and contractions. Spontaneous Ca^{2+} waves are arrhythmogenic; they induce Ca^{2+} -dependent depolarizing membrane currents (transient inward current), mainly by activation of the Na^+ - Ca^{2+} exchanger, thereby causing oscillations of the membrane potential known as DADs. After one or several DADs, myoplasmic Ca^{2+} can decrease because the Na^+ - Ca^{2+} exchanger extrudes Ca^{2+} from the cell, and the membrane potential stops oscillating.¹⁸⁻²⁰

When the DADs are of low amplitude, they usually are not apparent or clinically significant. However, during pathological conditions (e.g., myocardial ischemia, acidosis, hypomagnesemia, digitalis toxicity, and increased catecholamines), the amplitude of the Ca^{2+} -mediated oscillations is increased and can reach the stimulation threshold, and an action potential is triggered. If this process continues, sustained tachycardia will develop. Probably the most important influence that causes subthreshold DADs to reach threshold is a decrease in the initiating CL, because that increases

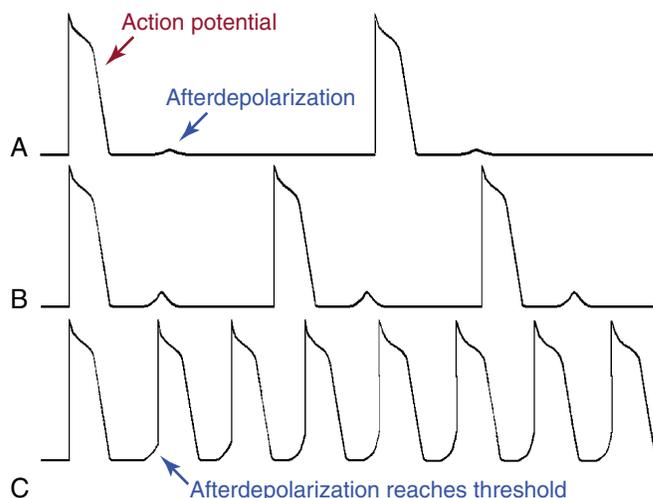

FIGURE 3-5 Behavior of delayed afterdepolarizations (DADs). A, The DAD is seen following the action potential at slow rates. B, At faster rates, the DAD occurs slightly earlier and increases in amplitude. C, At still more rapid rates, the DAD occurs even earlier and eventually reaches threshold, resulting in sustained firing.

both the amplitude and rate of the DADs. Therefore, initiation of arrhythmias triggered by DADs can be facilitated by a spontaneous or pacing-induced increase in the heart rate.

Digitalis causes DAD-dependent triggered arrhythmias by inhibiting the $\text{Na}^+\text{-K}^+$ exchange pump. In toxic amounts, this effect results in the accumulation of intracellular Na^+ and, consequentially, an enhancement of the $\text{Na}^+\text{-Ca}^{2+}$ exchanger in the reverse mode (Na^+ removal, Ca^{2+} entry) and an accumulation of intracellular Ca^{2+} .¹⁶ Spontaneously occurring accelerated ventricular arrhythmias that occur during digitalis toxicity are likely to be caused by DADs. Triggered ventricular arrhythmias caused by digitalis also can be initiated by pacing at rapid rates. As toxicity progresses, the duration of the trains of repetitive responses induced by pacing increases.

Catecholamines can cause DADs by increasing intracellular Ca^{2+} overload secondary to different mechanisms. Catecholamines increase the slow, inward I_{CaL} through stimulation of beta-adrenergic receptors and increasing cAMP, which result in an increase in transsarcolemmal Ca^{2+} influx and intracellular Ca^{2+} overload (see Fig. 3-6). Catecholamines can also enhance the activity of the $\text{Na}^+\text{-Ca}^{2+}$ exchanger, thus increasing the likelihood of DAD-mediated triggered activity. Additionally, catecholamines enhance the uptake of Ca^{2+} by the sarcoplasmic reticulum and lead to increased Ca^{2+} stored in the sarcoplasmic reticulum and the subsequent release of an increased amount of Ca^{2+} from the sarcoplasmic reticulum during contraction.¹⁶ Sympathetic stimulation can potentially cause triggered atrial and ventricular arrhythmias, possibly some of the ventricular arrhythmias that accompany exercise and those occurring during ischemia and infarction.

Elevations in intracellular Ca^{2+} in the ischemic myocardium are also associated with DADs and triggered arrhythmias. Accumulation of lysophosphoglycerides in the ischemic myocardium, with consequent Na^+ and Ca^{2+} overload, has been suggested as a mechanism for DADs and triggered activity. Cells from damaged areas or surviving the infarction can display spontaneous release of Ca^{2+} from sarcoplasmic reticulum, which can generate waves of intracellular Ca^{2+} elevation and arrhythmias.^{19,20}

Abnormal sarcoplasmic reticulum function caused by genetic defects that impair the ability of the sarcoplasmic reticulum to sequester Ca^{2+} during diastole can lead to DADs and be the cause of certain inherited ventricular tachyarrhythmias. Mutations in the cardiac RyR2, the sarcoplasmic reticulum Ca^{2+} release channel

in the heart, have been identified in kindreds with the syndrome of catecholaminergic polymorphic VT and ventricular fibrillation (VF) with short QT intervals. It seems likely that perturbed intracellular Ca^{2+} , and perhaps also DADs, underlie arrhythmias in this syndrome (see Fig. 3-6).^{18,21}

Several drugs can inhibit DAD-related triggered activity via different mechanisms, including reduction of the inward Ca^{2+} current and intracellular Ca^{2+} overload (Ca^{2+} channel blockers, beta-adrenergic blockers; see Fig. 3-6), reduction of Ca^{2+} release from the sarcoplasmic reticulum (caffeine, ryanodine, thapsigargin, cyclopiazonic acid), and reduction of the inward I_{Na} (tetrodotoxin, lidocaine, phenytoin).

DAD-related triggered activity is thought to be a mechanism for tachyarrhythmia associated with MI, reperfusion injury, some right ventricular outflow tract tachycardia, and some atrial tachyarrhythmias. DADs are more likely to occur with fast spontaneous or paced rates or with increased premature beats.^{15,18,20,22}

PROPERTIES OF DELAYED AFTERDEPOLARIZATIONS

The amplitude of DADs and the possibility of triggered activity are influenced by the level of membrane potential at which the action potential occurs. The reduction of the membrane potential during DADs may also result in Na^+ channel inactivation and a slowing of conduction.

The duration of the action potential is a critical determinant of the presence of DADs. Longer action potentials, which are associated with more transsarcolemmal Ca^{2+} influx, are more likely to be associated with DADs. Drugs that prolong action potential duration (e.g., class IA antiarrhythmic agents) can increase DAD amplitude, whereas drugs that shorten action potential duration (e.g., class IB antiarrhythmic agents) can decrease DAD amplitude.

The number of the action potentials preceding the DAD affects the amplitude of the DAD; that is, after a period of quiescence, the initiation of a single action potential can be followed by either no DAD or only a small one. With continued stimulation, the DADs increase in amplitude, and triggered activity can eventually occur.

The amplitude of DADs and the coupling interval between the first triggered impulse and the last stimulated impulse that induced them are directly related to the drive CL at which triggered impulses are initiated. A decrease in the basic drive CL (even a single drive

cycle; i.e., premature impulse), in addition to increasing the DAD amplitude, results in a decrease in the coupling interval between the last drive cycle and the first DAD-triggered impulse, with respect to the last driven action potential, and an increase of the rate of DADs. Triggered activity tends to be induced by a critical decrease in the drive CL, either spontaneous, such as in sinus tachycardia, or pacing induced. The increased time during which the membrane is in the depolarized state at shorter stimulation CLs or after premature impulses increases Ca^{2+} in the myoplasm and the sarcoplasmic reticulum, thus increasing the transient inward current responsible for the increased afterdepolarization amplitude, causing the current to reach its maximum amplitude more rapidly, and decreasing the coupling interval of triggered impulses. The repetitive depolarizations can increase intracellular Ca^{2+} because of repeated activation of I_{CaL} . This characteristic property can help distinguish triggered activity from reentrant activity because the relationship for reentry impulses initiated by rapid stimulation is often the opposite; that is, as the drive CL is reduced, the first reentrant impulse occurs later with respect to the last driven action potential because of rate-dependent conduction slowing in the reentrant pathway.

In general, triggered activity is influenced markedly by overdrive pacing. These effects are dependent on both the rate and the duration of overdrive pacing. When overdrive pacing is performed for a critical duration of time and at a critical rate during a catecholamine-dependent triggered rhythm, the rate of triggered activity slows until the triggered rhythm stops, because of enhanced activity of the electrogenic $\text{Na}^+\text{-K}^+$ exchange pump induced by the increase in intracellular Na^+ caused by the increased number of action potentials. When overdrive pacing is not rapid enough to terminate the triggered rhythm, it can cause overdrive *acceleration* (in contrast to overdrive suppression observed with automatic rhythms). Single premature stimuli also can terminate triggered rhythms, although termination is much less common than it is by overdrive pacing.

Early Afterdepolarizations and Triggered Activity

EADs are oscillations in membrane potential that occur during the action potential and interrupt the orderly repolarization of the myocyte. EADs manifest as a sudden change in the time course of repolarization of an action potential such that the membrane voltage suddenly shifts in a depolarizing direction.

IONIC BASIS OF EARLY AFTERDEPOLARIZATIONS

The plateau of the action potential is a time of high membrane resistance (i.e., membrane conductance to all ions falls to rather low values), when there is little current flow. Consequently, small changes in repolarizing or depolarizing currents can have profound effects on the action potential duration and profile. Normally, during phases 2 and 3, the net membrane current is outward. Any factor that transiently shifts the net current in the inward direction can potentially overcome and reverse repolarization and lead to EADs. Such a shift can arise from blockage of the outward current, carried by Na^+ or Ca^{2+} at that time, or enhancement of the inward current, mostly carried by K^+ at that time.¹

EADs have been classified as phase 2 (occurring at the plateau level of membrane potential) and phase 3 (occurring during phase 3 of repolarization; see Fig. 3-4). The ionic mechanisms of phase 2 and phase 3 EADs and the upstrokes of the action potentials they elicit can differ.¹ At the depolarized membrane voltages of phase 2, Na^+ channels are inactivated; hence, the I_{CaL} and $\text{Na}^+\text{-Ca}^{2+}$ exchanger current are the major currents potentially responsible for EADs. Voltage steady-state activation and inactivation of the L-type Ca^{2+} channels are sigmoidal, with an activation range over -40 to $+10$ mV (with a half-activation potential near -15 mV) and a half-inactivation potential near -35 mV. However, a relief of inactivation for voltages positive to 0 mV leads to a U-shaped voltage curve for steady-state inactivation. Overlap of the steady-state voltage-dependent inactivation and activation relations defines a

“window” current near the action potential plateau, within which transitions from closed and open states can occur. As the action potential repolarizes into the window region, I_{CaL} increases and can potentially be sufficient to reverse repolarization, thus generating the EAD upstroke (Fig. 3-7).²³

The cardiac $\text{Na}^+\text{-Ca}^{2+}$ exchanger exchanges three Na^+ ions for one Ca^{2+} ion; the direction is dependent on the Na^+ and Ca^{2+} concentrations on the two sides of the membrane and the transmembrane potential difference. When operating in forward mode, this exchanger generates a net Na^+ influx, thereby resisting repolarization. The increase in the window I_{CaL} further increases the $\text{Na}^+\text{-Ca}^{2+}$ exchanger, thus possibly facilitating EAD formation and increasing the probability of an EAD-triggered action potential.²³

EADs occurring late in repolarization develop at membrane potentials more negative than -60 mV in atrial, ventricular, or Purkinje cells that have normal resting potentials. Normally, a net outward membrane current shifts the membrane potential progressively in a negative direction during phase 3 repolarization of the action potential. Despite fewer data, it has been suggested that current through the $\text{Na}^+\text{-Ca}^{2+}$ exchanger and possibly the I_{Na} can participate in the activation of phase 3 EADs. Nevertheless, this concept was questioned by a study suggesting that phase 2 EADs appear to be responsible for inducing phase 3 EADs through electrotonic interactions and that a large voltage gradient related to heterogeneous repolarization is essential for phase 3 EADs.^{23,24}

The upstrokes of the action potentials elicited by phase 2 and phase 3 EADs also differ.¹ Phase 2 EAD-triggered action potential upstrokes are exclusively mediated by Ca^{2+} currents. Even when these triggered action potentials do not propagate, they can substantially exaggerate heterogeneity of the time course of repolarization of the action potential (a key substrate for reentry), because EADs occur more readily in some regions (e.g., Purkinje fibers, mid left ventricular myocardium, right ventricular outflow tract epicardium) than others (e.g., left ventricular epicardium, endocardium). Action potentials triggered by phase 3 EADs arise from more negative membrane voltages. Therefore, the upstrokes can be caused by Na^+ and Ca^{2+} currents and are more likely to propagate.

Under certain conditions, when an EAD is large enough, the decrease in membrane potential leads to an increase in net inward (depolarizing) current, and a second upstroke or an action potential is *triggered* before complete repolarization of the first. The triggered action potential also can be followed by other action potentials, all occurring at the low level of membrane potential characteristic of the plateau or at the higher level of membrane potential of later phase 3 (Fig. 3-8). The sustained rhythmic activity can continue for a variable number of impulses and terminates when repolarization of the initiating action potential returns membrane potential to a high level. As repolarization occurs, the rate of the triggered rhythm slows because the rate is dependent on the level of membrane potential. Sometimes repolarization to the high level of membrane potential may not occur, and membrane potential can remain at the plateau level or at a level intermediate between the plateau level and the resting potential. The sustained rhythmic activity then can continue at the reduced level of membrane potential and assumes the characteristics of abnormal automaticity. However, in contrast to automatic rhythms, without the initiating action potential, there can be no triggered action potentials.

The ability of the triggered action potentials to propagate is related to the level of membrane potential at which the triggered action potential occurs. The more negative the membrane potential is, the more Na^+ channels are available for activation, the greater the influx of Na^+ into the cell during phase 0, and the higher the conduction velocity. At more positive membrane potentials of the plateau (phase 2) and early during phase 3, most Na^+ channels are still inactivated, and the triggered action potentials most likely have upstrokes caused by the inward I_{CaL} . Therefore, those triggered action potentials have slow upstrokes and are less able to propagate. Increased dispersion of repolarization facilitates the ability of phase 2 EADs to trigger propagating ventricular responses.²⁴

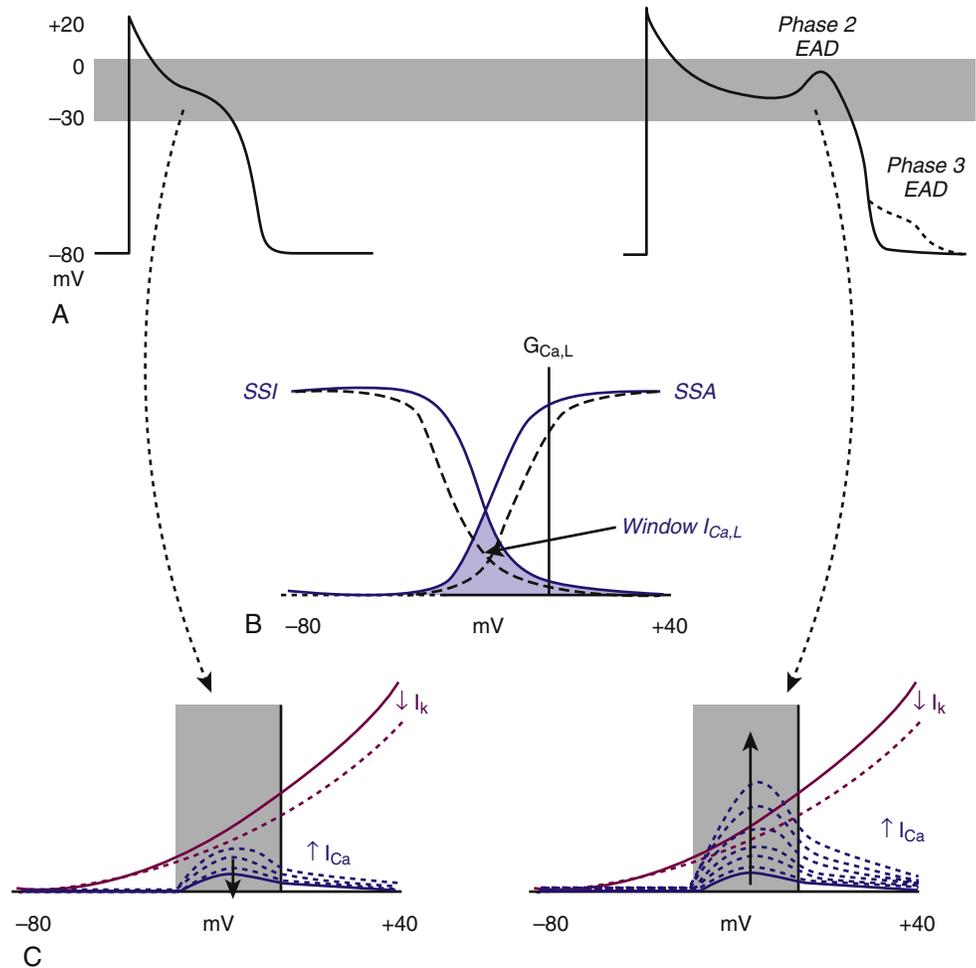

FIGURE 3-7 A, Normal action potential (left) and an action potential with phase 2 early afterdepolarization (EAD) (solid line) or phase 3 EAD (dashed line) (right). B, Schematic plot of L-type calcium (Ca^{2+}) channel conductance ($G_{\text{Ca,L}}$) versus membrane voltage (mV) showing the window L-type inward Ca^{2+} current ($I_{\text{Ca,L}}$) region (purple area) where the steady-state activation (SSA) and steady-state inactivation (SSI) curves overlap and a fraction of Ca channels remain continuously open. Dashed lines show a potential therapeutic intervention that shifts the SSA and SSI curves to reduce the overlapping window current region. C, Schematic diagram illustrating the interaction between time-dependent $I_{\text{Ca,L}}$ reactivation (blue dashed lines) and time-dependent deactivation of repolarizing currents (I_{K}) (dashed red lines) in the window voltage range during action potential repolarization. For the normal action potential (left), the repolarization rate is too fast for $I_{\text{Ca,L}}$ to grow larger than I_{K} . If the repolarization rate is too slow, however, $I_{\text{Ca,L}}$ can grow larger than I_{K} , thereby reversing repolarization to cause an EAD (right). (From Weiss JN, Garfinkel A, Karagueuzian HS, et al: Early afterdepolarizations and cardiac arrhythmias. *Heart Rhythm* 7:1891-1899, 2010.)

A fundamental condition that underlies the development of EADs is action potential prolongation, which is manifest on the surface ECG by QT prolongation. Hypokalemia, hypomagnesemia, bradycardia, and drugs can predispose to the formation of EADs, invariably in the context of prolonging the action potential duration; drugs are the most common cause. Class IA and III antiarrhythmic agents prolong the action potential duration and the QT interval, effects intended to be therapeutic but frequently causing proarrhythmia. Noncardiac drugs such as some phenothiazines, some non-sedating antihistamines, and some antibiotics can also prolong the action potential duration and predispose to EAD-mediated triggered arrhythmias, particularly when there is associated hypokalemia, bradycardia, or both. Decreased extracellular K^+ concentration paradoxically decreases some membrane I_{K} (particularly the I_{Kr}) in the ventricular myocyte. This finding explains why hypokalemia causes action potential prolongation and EADs. EAD-mediated triggered activity likely underlies initiation of the characteristic polymorphic VT, torsades de pointes, seen in patients with congenital and acquired forms of long QT syndrome (see Chapter 31). Although the genesis of ventricular arrhythmias in these patients is still unclear, marked transmural dispersion of repolarization can create a vulnerable window for development of reentry. EADs arising from these regions can underlie the premature complexes that initiate or perpetuate the tachycardia.¹ Structural heart disease such as cardiac hypertrophy and failure can also delay ventricular repolarization—so-called electrical remodeling—and predispose to arrhythmias related to abnormalities of repolarization. The abnormalities of repolarization in hypertrophy and failure are often magnified by concomitant drug therapy or electrolyte disturbances.

EADs are opposed by ATP-dependent K^+ channel (I_{KATP}) openers (pinacidil, cromakalim, rimakalim, and nicorandil), magnesium,

alpha-adrenergic blockade, tetrodotoxin, nitrendipine, and antiarrhythmic drugs that shorten action potential (e.g., lidocaine and mexiletine). Alpha-adrenergic stimulation can exacerbate EADs.

It was traditionally thought that unlike DADs, EADs do not depend on a rise in intracellular Ca^{2+} ; instead, action potential prolongation and reactivation of depolarizing currents are fundamental to their production. More recent experimental evidence suggested a previously unappreciated interrelationship between intracellular Ca^{2+} loading and EADs. Cytosolic Ca^{2+} levels can increase when action potentials are prolonged. This situation, in turn, appears to enhance $I_{\text{Ca,L}}$ (possibly via Ca^{2+} -calmodulin kinase activation), thus further prolonging the action potential duration as well as providing the inward current driving EADs. Intracellular Ca^{2+} loading by action potential prolongation can also enhance the likelihood of DADs. The interrelationship among intracellular Ca^{2+} , DADs, and EADs can be one explanation for the susceptibility of hearts that are Ca^{2+} loaded (e.g., in ischemia or congestive heart failure) to develop arrhythmias, particularly on exposure to action potential-prolonging drugs.

PROPERTIES OF EARLY AFTERDEPOLARIZATIONS

EAD-triggered arrhythmias exhibit rate dependence. In general, the amplitude of an EAD is augmented at slow rates when action potentials are longer in duration.⁶ Pacing-induced increases in rate shorten the action potential duration and reduce EAD amplitude. Action potential shortening and suppression of EADs with increased stimulation rate are likely the result of augmentation of delayed rectifier I_{K} and perhaps hastening of Ca^{2+} -induced inactivation of $I_{\text{Ca,L}}$. Once EADs have achieved a steady-state magnitude at a constant drive CL, any event that shortens the drive CL tends to reduce their amplitude. Hence, the initiation of

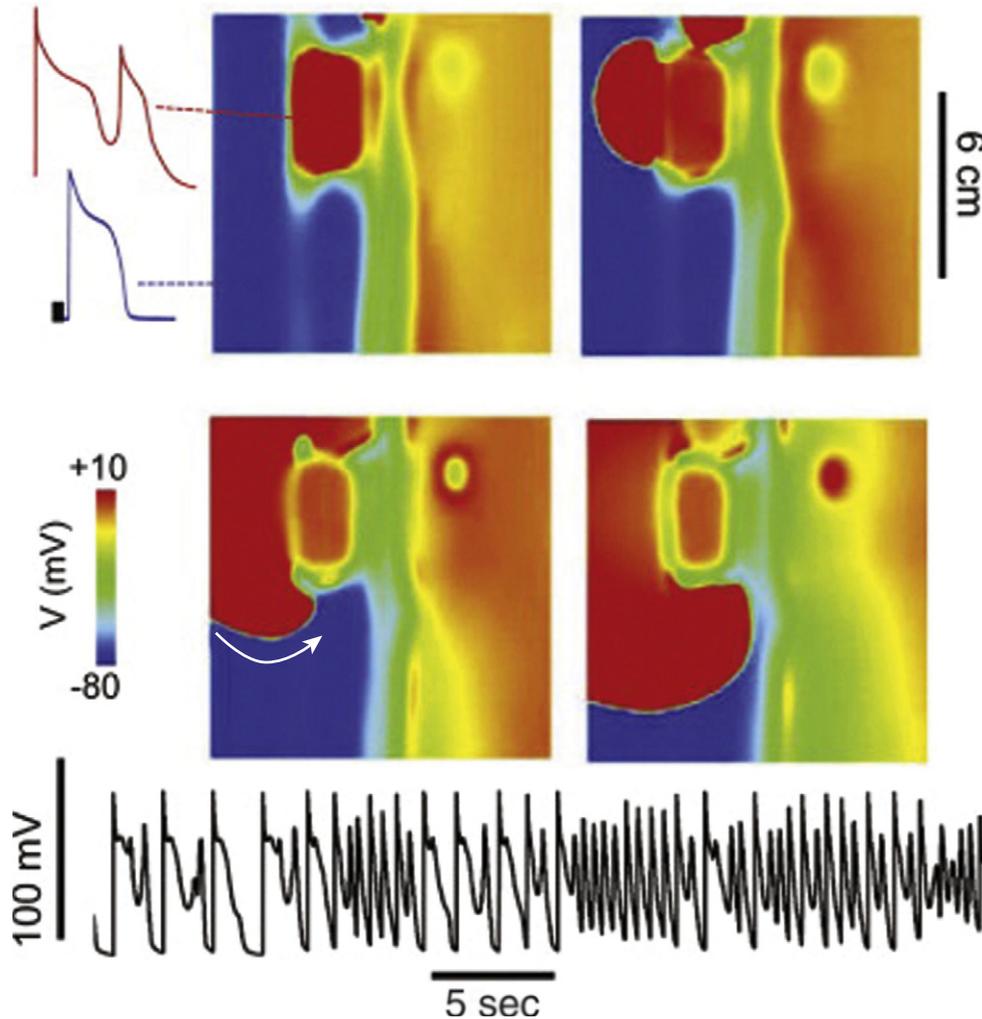

FIGURE 3-8 Mixed focal reentrant polymorphic ventricular tachycardia as a result of early afterdepolarization (EAD)-mediated premature ventricular complexes (PVCs) arising from EAD islands in simulated two-dimensional homogeneous tissue. The tissue was paced from the left edge at a slow rate. Four successive voltage snapshots show an EAD (red in upper left quadrant) that generates a PVC (red blob). The PVC then initiates reentry by reentering (white arrow) the receding waveback of the region without EADs (blue blob). The voltage trace below from a representative cell shows multiple EADs followed by rapid tachycardia resulting from a mixture of triggered activity and reentry. (From Weiss JN, Garfinkel A, Karagueuzian HS, et al: Early afterdepolarizations and cardiac arrhythmias. *Heart Rhythm* 7:1891-1899, 2010.)

a single premature depolarization, which is associated with an acceleration of repolarization, will reduce the magnitude of the EADs that accompany the premature action potential; as a result, triggered activity is not expected to follow premature stimulation. The exception is when a long compensatory pause follows a premature ventricular complex. This situation can predispose to the development of an EAD and can be the mechanism of torsades de pointes in some patients with the long QT syndrome. Thus, EADs are more likely to trigger rhythmic activity when the spontaneous heart rate is slow because bradycardia is associated with prolongation of the QT interval and action potential duration (e.g., bradycardia- or pause-induced torsades de pointes). Similarly, catecholamines increase heart rate and decrease action potential duration and EAD amplitude, despite the effect of beta-adrenergic stimulation to increase I_{CaL} .

Reentry

Basic Principles of Reentry

During each normal cardiac cycle, at the completion of normal cardiac excitation, the electrical impulse originating from the sinus node becomes extinct, and the subsequent excitation cycles originate from new pacemaker impulses.⁶ Physiological excitation waves vanish spontaneously after the entire heart has been activated because of the long duration of refractoriness in the cardiac tissue compared with the duration of the excitation period; therefore, after its first pass, the impulse, having no place to go, expires. Reentry occurs when a propagating

impulse fails to die out after normal activation of the heart and persists to reexcite the heart after expiration of the refractory period. In pathological settings, excitation waves can be blocked in circumscribed areas, rotate around these zones of block, and reenter the site of original excitation in repetitive cycles. The wavefront does not extinguish but rather propagates continuously and thus continues to excite the heart because it always encounters excitable tissue.

Reentrant tachycardia, also called reentrant excitation, reciprocating tachycardia, circus movement, or reciprocal or echo beats, is a continuous repetitive propagation of the activation wave in a circular path, returning to its site of origin to reactivate that site.^{1,25,26} Traditionally, reentry has been divided into two types: (1) anatomical reentry, when there is a distinct relationship of the reentry pathway with the underlying tissue structure; and (2) functional reentry, when reentrant circuits occur at random locations without clearly defined anatomical boundaries (Fig. 3-9). Although this distinction has a historical background and is useful for didactic purposes, both the anatomical and functional forms can coexist in a given pathological setting and share many common basic biophysical mechanisms.

The original 3 criteria for reentry proposed by Mines still hold true: (1) unidirectional block is necessary for initiation; (2) the wave of excitation should travel in a single direction around the pathway, returning to its point of origin and then restarting along the same path; and (3) the tachycardia should terminate when one limb of the pathway is cut or temporarily blocked. The 12 conditions that were proposed to prove or identify the existence of reentrant tachycardia in the EP laboratory are listed in Table 3-1.^{25,26}

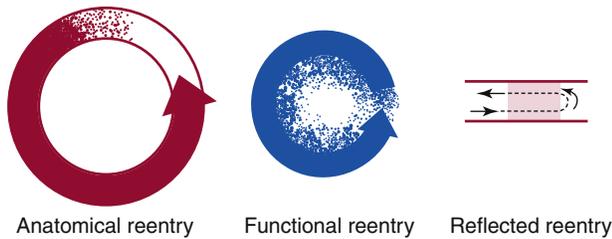

FIGURE 3-9 Models of reentry; the solid area is completely refractory tissue, and mottled area is partially refractory. In anatomical reentry, the circuit is determined by structures or scar in the heart, and a portion of the circuit that has fully recovered excitability can be stimulated while it awaits the next cycle. In functional reentry, however, the rate is as rapid as it can be and still allow all portions of the circuit to recover.

TABLE 3-1 Criteria for Diagnosis of Reentrant Tachycardia

1. Mapping activation in one direction around the continuous loop
2. Correlation of continuous electrical activity with occurrence of tachycardia
3. Correlation of unidirectional block with initiation of reentry
4. Initiation and termination by premature stimulation
5. Dependence of initiation of the arrhythmia on the site of pacing
6. Inverse relationship between the coupling interval of the initiating premature stimulus and the interval to the first tachycardia beat
7. Resetting of the tachycardia by a premature beat, with an inverse relationship between the coupling interval of the premature beat and the cycle length of the first or return beat of the tachycardia
8. Fusion between a premature beat and the tachycardia beat followed by resetting
9. Transient entrainment (with external overdrive pacing, the ability to enter the reentrant circuit and capture the circuit, resulting in tachycardia at the pacing rate with fused complexes)
10. Abrupt termination by premature stimulation
11. Dependence of initiation on critical slowing of conduction in the circuit
12. Similarity with experimental models in which reentry is proven and is the only mechanism of tachycardia

Requisites of Reentry

SUBSTRATE

The initiation and maintenance of a reentrant arrhythmia require the presence of myocardial tissue with adjacent tissue or pathways having different EP properties, conduction, and refractoriness, and that they be joined proximally and distally, forming a circuit. These circuits can be stationary or can move within the myocardial substrate.

The reentrant circuit can be an anatomical structure, such as a loop of fiber bundles in the Purkinje system or accessory pathways, or a functionally defined pathway, with its existence, size, and shape determined by the EP properties of cardiac tissues in which the reentrant wavefront circulates. The circuit can also be an anatomical-functional combination. The cardiac tissue that constitutes the substrate for reentrant excitation can be located almost anywhere in the heart.¹ The reentrant circuit can be a variety of sizes and shapes and can include different types of myocardial cells (e.g., atrial, ventricular, nodal, Purkinje; Fig. 3-10).

CENTRAL AREA OF BLOCK

A core of inexcitable tissue around which the wavefront circulates is required to sustain reentry. Without this central area of block, the excitation wavefront will not necessarily be conducted around the core of excitable tissue; rather, it could take a shortcut, permitting the circulating excitation wavefront to arrive early at the site where it originated. If it arrives sufficiently early, the tissue at the site of origination will still be refractory, and reentrant excitation will not be possible.

As mentioned earlier, the area of block can be anatomical, functional, or a combination of the two.^{6,27} Anatomical block is the result of a nonconductive medium in the center of the circuit, such as the tricuspid annulus in typical atrial flutter (AFL). Functional block at the center of a circuit occurs when there is block of impulses in otherwise excitable cardiac muscle. The central area of functional block develops during the initiation of the reentrant circuit by the formation of a line of block that most likely is caused by refractoriness. When the reentrant circuit forms, the line of block then is sustained by centripetal activation from the circulating wavefront that, by repeatedly bombarding the central area of block, maintains the state of refractoriness of this region. A combination of an anatomical and a functional central area of block in the reentrant circuit has been described in some models of AFL such as the orifice of one or both venae cavae and an area of functional block continuous with or adjacent to either or both caval orifice(s). Additionally, it has now been shown that a functional extension of an anatomical line of block can occur such that it plays a role in creating the necessary or critical substrate for reentry. Thus, a surgical incision in the right atrium made to repair a congenital heart lesion can, under certain circumstances, develop a functional extension to one or both of the venae cavae, such that the substrate to create and sustain AFL develops.

UNIDIRECTIONAL CONDUCTION BLOCK

Transient or permanent unidirectional block is usually a result of heterogeneity of EP properties of the myocardium and is essential for the initiation of reentry. The excitation wavefront propagating in the substrate must encounter unidirectional block; otherwise, the excitation wavefronts traveling down both limbs of the reentrant circuit will collide and extinguish each other.²⁷

AREA OF SLOW CONDUCTION

In a successful reentrant circuit, the wavefront of excitation must encounter excitable cells or the tachycardia will terminate. Therefore, a condition necessary for reentry is the maintenance of excitable tissue ahead of the propagating wavefront. In other words, the tissue initially activated by the excitation wavefront should have sufficient time to recover its excitability by the time the reentrant wavefront returns. Thus, conduction of the circulating wavefront must be sufficiently delayed in an alternate pathway to allow for expiration of the refractory period in the tissue proximal to the site of unidirectional block, and there must always be a gap of excitable tissue (fully or partially excitable) ahead of the circulating wavefront (i.e., the length of the reentrant pathway must equal or exceed the reentrant wavelength; see later). This is facilitated by a sufficiently long reentrant pathway (which is especially important when conduction is normal along the reentrant path), sufficiently slow conduction in all or part of the alternative pathway (because sufficiently long pathways are usually not present in the heart), sufficient shortening of the refractory period, or a combination of these factors.¹

CRITICAL TISSUE MASS

An additional requisite for random reentry is the necessity of a critical mass of tissue to sustain the one or usually more simultaneously circulating reentrant wavefronts. Thus, it is essentially impossible to achieve sustained fibrillation of ventricles of very small, normal, mammalian hearts and equally difficult to achieve sustained fibrillation of the completely normal atria of humans or smaller mammals.

INITIATING TRIGGER

Another prerequisite for reentrant excitation to occur is often, but not always, the presence of an initiating trigger, which invokes the necessary EP milieu for initiation of reentry.¹ Susceptible patients

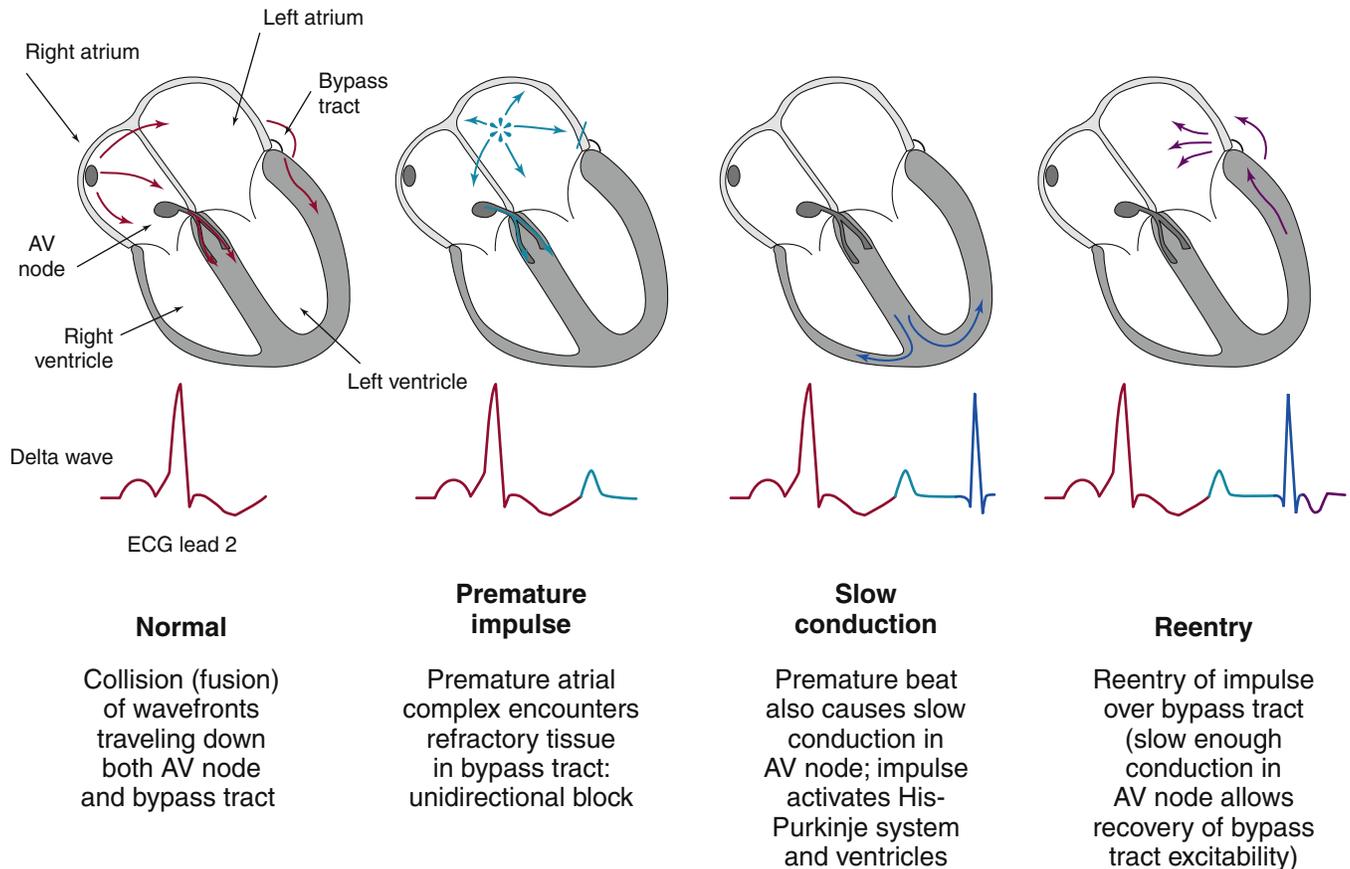

FIGURE 3-10 Reentry in the Wolff-Parkinson-White syndrome. AV = atrioventricular.

with appropriate underlying substrates usually do not suffer from incessant tachycardia because the different EP mechanisms required for the initiation and maintenance of a reentrant tachycardia are infrequently present at exactly the same time. However, changes in heart rate or autonomic tone, ischemia, electrolyte or pH abnormalities, or the occurrence of a premature depolarization can be sufficient to initiate reentrant tachycardia.

The trigger frequently is required because it elicits or brings to a critical state one or more of the conditions necessary to achieve reentrant excitation. In fact, premature depolarizations frequently initiate these tachyarrhythmias because they can cause slow conduction and unidirectional block. Thus, a premature impulse initiating reentry can arrive at one site in the potential reentrant circuit sufficiently early that it encounters unidirectional block, because that tissue has had insufficient time to recover excitability after excitation by the prior impulse. Furthermore, in the other limb of the potential reentrant circuit, the premature arrival of the excitation wavefront causes slow conduction or results in further slowing of conduction of the excitation wavefront through an area of already slow conduction. The resulting increase in conduction time around this limb of the potential reentrant circuit allows the region of unidirectional block in the tissue in the other limb activated initially by the premature beat to recover excitability. It should be noted that the mechanism causing the premature impulse can be different from the reentrant mechanism causing the tachycardia. Thus, the premature impulse can be caused by automaticity or triggered activity.

Types of Reentrant Circuits

ANATOMICAL REENTRY

In anatomically determined circuits, a discrete inexcitable anatomical obstacle creates a surrounding circular pathway, resulting

in a fixed length and location of the reentrant circuit. Because the length and location of the reentrant pathway are relatively fixed, the characteristics of the reentrant circuit are determined by the characteristics of the anatomical components of that circuit.

A reentrant tachycardia is initiated when an excitation wavefront splits into two limbs after going around the anatomical obstacle and travels down one pathway and not the other, thus creating a circus movement. Tachycardia rates are determined by the wavelength and by the length of the reentrant pathway (the path length). The initiation and maintenance of anatomical reentry depend on conduction velocity and refractory period. Thus, as long as the extension of the refractory zone behind the excitation wave, the so-called wavelength of excitation, is smaller than the entire length of the anatomically defined reentrant pathway, a zone of excitable tissue, the so-called excitable gap, exists between the tail of the preceding wave and the head of the following wave.²⁷ In essence, circus movements containing an excitable gap are stable with respect to their frequency of rotation and can persist at a constant rate for hours. In the setting where the wavelength of excitation exceeds the path length, the excitation wavefront becomes extinct when it encounters the not yet recovered inexcitable tissue. A special case is present in the intermediate situation, when the head of the following wavefront meets the partially refractory tail of the preceding wavefront (i.e., the wavelength approximates the path length). This situation is characterized by unstable reentrant CLs and complex dynamics of the reentrant wavefront. There is often a long excitable gap associated with anatomical reentry.

Anatomical circuits therefore are associated with ordered reentry. Examples of this type of reentry are AV reentrant tachycardia associated with an AV bypass tract, AVN reentrant tachycardia, AFL, VT originating within the HPS (bundle branch reentrant VT), and post-MIVT.

FUNCTIONAL REENTRY

In functionally determined circuits, the reentrant pathway depends on the intrinsic heterogeneity of the EP properties of the myocardium, not by a predetermined anatomical circuit (i.e., without involvement of an anatomical obstacle or anatomically defined conducting pathway). Such heterogeneity involves dispersion of excitability or refractoriness and conduction velocity, as well as anisotropic conduction properties of the myocardium.²⁸

Functional circuits typically tend to be small and unstable; the reentrant excitation wavefront can fragment, generating other areas of reentry. The location and size of these tachycardias can vary. The circumference of the leading circle around a functional obstacle can be as small as 6 to 8 mm and represents a pathway in which the efficacy of stimulation of the circulating wavefront is just sufficient to excite the tissue ahead, which is still in its relative refractory phase. Therefore, conduction through the functional reentrant circuit is slowed because impulses are propagating in partially refractory tissue. Consequently, this form of functional reentry has a partially excitable gap. The reentry CLs are therefore significantly dependent on the refractory period of the involved tissue.²⁸

The mechanisms for functionally determined reentrant circuits include the leading circle type of reentry, anisotropic reentry, and spiral wave reentry. Functional circuits can be associated with ordered reentry (the reentrant circuit remains in the same place) or random reentry (the reentrant circuit changes size and location). Random reentry can occur when leading circle reentry causes fibrillation.

Leading Circle Concept

To explain the properties of a single functional reentrant circuit, Allesie and colleagues formulated the leading circle concept (see Fig. 3-9).²⁸ It was postulated that during wavefront rotation in tissue without anatomical inexcitable obstacles, the wavefront impinges on its refractory tail and travels through partially refractory tissue. The interaction between the wavefront and the refractory tail determines the properties of functional reentry. In this model, functional reentry involves the propagation of an impulse around a functionally determined region of inexcitable tissue or a refractory core and among neighboring fibers with different EP properties. The tissue within this core is maintained in a state of refractoriness by constant centripetal bombardment from the circulating wavefront. The premature impulse that initiates reentry blocks in fibers with long refractory periods and conducts in fibers with shorter refractory periods and eventually returns to the initial region of block after excitability has recovered there. The impulse then continues to circulate around a central area that is kept refractory because it is bombarded constantly by wavelets propagating toward it from the circulating wavefront. This central area provides a functional obstacle that prevents excitation from propagating across the fulcrum of the circuit.

The leading circle was defined as “the smallest possible pathway in which the impulse can continue to circulate” and “in which the stimulating efficacy of the wavefront is just enough to excite the tissue ahead which is still in its relative refractory phase.”²⁸ Thus, the “head of the circulating wavefront is continuously biting its tail of refractoriness” and the length of the reentrant pathway equals the wavelength of the impulse; as a result, there is usually no fully excitable gap.²⁸ Because the wavefront propagates through partially refractory tissue, the conduction velocity is reduced.

The velocity value and the length of the circuit depend on the excitability of the partially refractory tissue and on the stimulating efficacy of the wavefront, which is determined by the amplitude and the upstroke velocity of the action potential and by the passive electrical properties of the tissue (e.g., gap junctional conductance). The partially refractory tissue determines the revolution time period. Because of the absence of a fully excitable gap, this form of reentry is less susceptible to resetting, entrainment, and

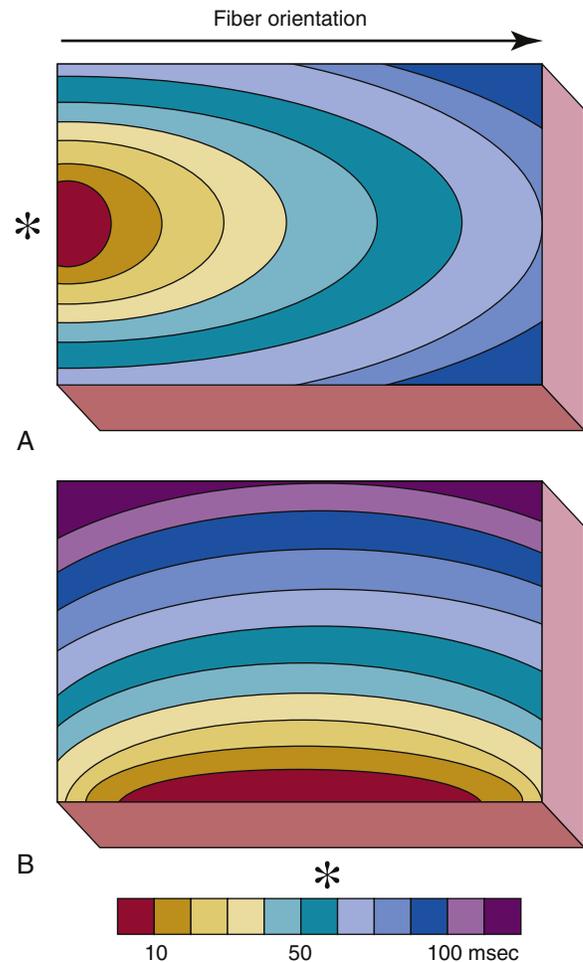

FIGURE 3-11 Anisotropic conduction. Progression of activation wavefronts in blocks of ventricular myocardium with longitudinal fiber orientation are shown. A wavefront stimulated (asterisk) at the left edge progresses more rapidly (wider isochrone spacing, A) than one starting perpendicularly (B) because of more favorable conduction parameters in the former direction.

termination by premature stimuli and pacing maneuvers. Leading circle reentry is thought to be the underlying mechanism of AF and VF and of at least some of the ventricular arrhythmias associated with acute ischemia.

Anisotropic Reentry

Isotropic conduction is uniform in all directions; anisotropic conduction is not. Anisotropy is a normal feature of heart muscle and is related to the differences in longitudinal and transverse conduction velocities, which are attributable to the lower resistivity of myocardium in the longitudinal (parallel to the long axis of the myocardial fiber bundles) versus the transverse direction (Fig. 3-11). Anisotropy in myocardium composed of tissue with structural features different from those of adjacent tissue results in heterogeneity in conduction velocities and repolarization properties (see later discussion), which can lead to blocked impulses and slowed conduction, thereby setting the stage for reentry (referred to as anisotropic reentry).

Unlike the functional characteristic that leads to the leading circle type of reentry (differences in refractoriness in adjacent areas caused by local differences in membrane properties), the functional characteristic that is important in functional reentry caused by anisotropy is the difference in effective axial resistance to impulse propagation dependent on fiber direction. In its pure form, the unidirectional conduction block and slow conduction in the reentrant circuit result from anisotropic, discontinuous propagation,

and there is no need for variations in membrane properties, such as regional differences in refractoriness or depression of the resting and action potentials.²⁹

Anisotropic circuits are elliptical or rectangular because of the directional differences in conduction velocities, with the long axis of the ellipse in the fast longitudinal direction and a central line of functional block parallel to the long axis of fibers. Circuits with this shape can have a smaller dimension than circular circuits, such as the leading circle. Reentrant circuits caused by anisotropy also can occur without well-defined anatomical pathways and may be classified as functional.

Anisotropic reentrant circuits usually remain in a fixed position and cause ordered reentry. The degree of anisotropy (i.e., the ratio of longitudinal to transverse conduction velocity) varies in different regions of the heart, and the circuit can reside only in a region in which the conduction transverse to the longitudinal axis is sufficiently slow to allow reentry. Stability of anisotropic reentrant circuits is also assisted by the presence of an excitable gap, which does not occur in the leading circle functional circuit. The excitable gap is caused by the sudden slowing of conduction velocity and a decrease in the wavelength of excitation as the reentrant impulse turns the corner from the fast longitudinal direction to the slow transverse direction and from the slow transverse direction to the fast longitudinal direction. Anisotropic reentry is typically initiated by a premature stimulus that blocks in the direction of propagation parallel to the long axis of the cells and then propagates slowly in the transverse direction of fiber orientation because of high axial resistance (see later).²⁹

Anisotropic reentry can potentially provide the substrate for sustained VT that occurs in the epicardial border zone region of healed infarcts, where viable normal myocytes are intermingled with islands of fibrous connective tissue that separate muscle-fiber bundles preferentially in the longitudinal direction and decrease the density of side-to-side junctional connections, therefore creating nonuniform anisotropy.

Figure-of-8 Reentry

The model of figure-of-8 or double-loop reentry involves two concomitant excitation wavefronts circulating in opposite directions, clockwise and counterclockwise, around a long line of functional conduction block rejoining on the distal side of the block. The wavefront then breaks through the arc of block to reexcite the tissue proximal to the block. The single arc of block is thus divided into two, and reentrant activation continues as two circulating wavefronts that travel clockwise and counterclockwise around the two arcs in a pretzel-like configuration.³⁰

This form of reentry has been shown in atrial and ventricular myocardia (Fig. 3-12, Video 1).

Reflection

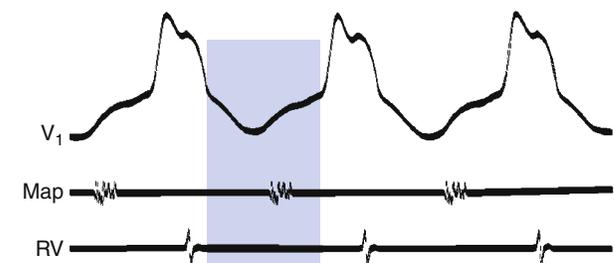

Reflection is a special subclass of reentry in which the excitation wavefront does not require a circuit but appears to travel back and forth in a linear segment of tissue (e.g., trabecula or Purkinje fiber) containing an area of conduction block (see Fig. 3-9). In such a situation, an action potential propagates toward, but not through, the inexcitable zone. Subsequently, an electrotonic current conducts passively (i.e., without eliciting an action potential) through the inexcitable zone toward the distal portion of the pathway. If the inexcitable zone is sufficiently small and the magnitude of the electrotonic current is sufficiently large, the segment of tissue distal to the blocked area will be excited (i.e., an action potential is elicited) but with a significant delay. The action potential generated in the distal portion of the pathway will then cause electrotonic current to flow back through the inexcitable zone toward the proximal region. Provided the proximal portion of the conduction pathway recovers quickly enough, this current may be sufficient to elicit a second action potential on the proximal side of the inexcitable zone, which propagates in the opposite direction to the first action potential, thus giving the appearance that the inexcitable zone has reflected the initial action potential.

Because reflection can occur within areas of tissue as small as 1 to 2 mm², it is likely to appear of focal origin. Its identification as a mechanism of arrhythmia may be difficult even with very high spatial resolution mapping of the electrical activity of discrete sites.

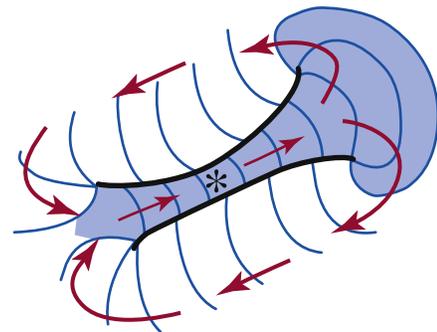

Phase 2 Reentry

As discussed in Chapter 1, substantial differences in the expression levels of ion channels underlie the substantial heterogeneity in action potential duration and configuration between cardiomyocytes across the ventricular wall. Heterogeneity in the distribution of the transient outward I_K (I_{to}) channels across the myocardial wall, being more prominent in ventricular epicardium than endocardium, results in the shorter duration and the prominent phase 1 notch and the “spike and dome” morphology of the epicardial action potential as compared with the endocardium. The resultant transmural voltage gradient during the early phases (phases 1 and 2) of the action potential is thought to be responsible for the inscription of the J wave on the surface ECG (see Fig. 31-6). A significant outward shift of currents, secondary to either a decrease in the inward currents (I_{Na} and I_{CaL}) or an increase in the outward I_K (I_{to} , I_{Kr} , I_{Ks} , I_{KACH} , I_{KATP}), or both, can cause partial or complete loss of the dome of the action potential in the epicardium that leads to exaggeration of transmural voltage gradient and dispersion of repolarization between the epicardium and endocardium. The type of the ion current affected and its regional distribution in the ventricles determine the particular phenotype (including the Brugada syndrome, early repolarization syndrome, hypothermia-induced ST segment elevation, and infarction-induced ST segment elevation).³¹

In this setting, the phase 2 dome (plateau) of the action potential can potentially propagate from regions where it is preserved (mid-myocardium and endocardium) to regions where it is abolished (epicardium), thus causing local reexcitation (phase 2 reentry) and the generation of a closely coupled extrasystole that, in turn, can initiate VT or VF (see Fig. 31-7).³²

A

B

FIGURE 3-12 Figure-of-8 reentry. **A**, ECG and intracardiac recordings from a left ventricular mapping catheter (Map) and the right ventricle (RV) are shown during scar-based ventricular tachycardia. **B**, A stylized tachycardia circuit is shown in which propagation proceeds through a central common pathway (small arrows and asterisk) constrained by scar or other barriers and then around the outside of these same barriers. Activation in the circuit during electrical diastole is shaded (also in **A**).

Spiral Wave (Rotor) Activity

The leading circle concept was based on properties of impulse propagation in a one-dimensional tissue that forms a closed pathway (e.g., a ring). The concept was a major breakthrough in the understanding of the mechanisms of reentrant excitation. However, it became evident that these considerations alone do not fully describe wave rotation in two- and three-dimensional cardiac tissue.³³

Spiral waves typically describe reentry in two dimensions. The term *rotor* initially described the rotating source, and the spiral wave defined the shape (i.e., curvature) of the wave emerging from the rotating source. In many publications, this difference has been blurred, and terms used in the literature include *rotors*, *vortices*, and *reverberators*.²⁷ The center of the spiral wave is called the core, and the distribution of the core in three dimensions is referred to as the filament. The three-dimensional form of the spiral wave is called a scroll wave.^{30,33}

Under appropriate circumstances, a pulse in two-dimensional, homogeneous, excitable media can be made to circulate as a rotor. When heterogeneities in recovery exist, the application of a second stimulus over a large geometric area to initiate a second excitation wave only excites a region in which there has been sufficient time for recovery from the previous excitation, not regions that have not yet recovered. An excitation wave is elicited at the excitable site in the form of a rotor because the wave cannot move in the direction of the wake of the previous wave but only in the opposite direction, thus moving into adjacent regions as they in turn recover. The inner tip of the wavefront circulates around an organizing center or core, which includes cells with transmembrane potentials that have a reduced amplitude, duration, and rate of depolarization (i.e., slow upstroke velocity of phase 0); these cells are potentially excitable, but they remain unexcited, instead of a region of conduction block. In the center of the rotating wave, the tip of the wave moves along a complex trajectory and radiates waves into the surrounding medium. In addition, the spiral waves can give rise to daughter spirals that can result in disorganized electrical activity.³⁴

The curvature of the spiral wave is the key to the formation of the core and the functional region of block.^{27,30} Propagation of two- and three-dimensional waves also depends on wavefront curvature, a property that is not present in one-dimensional preparations.²⁷ Because the maximal velocity of a convex rotating wavefront can never exceed the velocity of a flat front and the period of rotation remains constant in a stable rotating wave, the velocity has to decrease from the periphery (where the highest value corresponds to linear velocity) to the center of a rotating wave. As a consequence, any freely rotating wave in an excitation-diffusion system has to assume a spiral shape. A prominent curvature of the spiral wave is generally encountered following a wave break, a situation in which a planar wave encounters an obstacle and breaks up into two or more daughter waves. Because it has the greatest curvature, the broken end of the wave moves most slowly. As curvature decreases along the more distal parts of the spiral, propagation speed increases.³⁰ The rotor, by definition, has a marked curvature, and this curvature slows down its propagation. Slow conduction results from an increased electrical load; that is, not only must a curved wavefront depolarize cells ahead of it in the direction of propagation, but also current flows to cells on its sides.

Because the slow activation by a rotor is not dependent on conduction in relatively refractory myocardium, an excitable gap exists, despite the functional nature of reentry. This type of functional reentrant excitation does not require any inhomogeneities of refractory periods as in leading circle reentry, inhomogeneities in conduction properties as in anisotropic reentry, or a central obstacle, whether functional or anatomical. The heterogeneity that allows initiation can result from a previous excitation wave and the pattern of recovery from that wave. Even though non-uniform dispersions of refractoriness or anisotropy are not necessary for the initiation of reentrant excitation caused by rotors in excitable media, the myocardium, even when normal, is never

homogeneous, and anisotropy and anatomical obstacles can modify the characteristics and spatiotemporal behavior of the spiral.

The location of the rotor can occur wherever the second stimulated excitation encounters the wake of the first excitation with the appropriate characteristics. Spirals can be *stationary*, continuously drift or migrate away from their origin, or *anchored*, initially drifting and then becoming stationary by anchoring to a small obstacle.^{34,35}

In the heart, spiral waves have been implicated in the generation of cardiac arrhythmias for a long time. Both two-dimensional spiral waves and three-dimensional scroll waves have been implicated in the mechanisms of reentry in atrial and ventricular tachycardia and fibrillation.²⁷ Monomorphic VT results when the spiral wave is anchored and cannot drift within the ventricular myocardium away from its origin. In contrast, a polymorphic VT, such as the *torsades de pointes* encountered with long QT syndromes, is thought to be caused by a meandering or drifting spiral wave. VF seems to be the most complex representation of rotating spiral waves in the heart. VF develops when the single spiral wave responsible for VT breaks up, leading to the development of multiple spirals that are continuously extinguished and recreated.^{30,34,35}

Excitable Gaps in Reentrant Circuits

WAVELENGTH CONCEPT

The *wavelength* is defined as the product of the conduction velocity of the circulating excitation wavefront and the effective refractory period of the tissue in which the excitation wavefront is propagating.⁶ The wavelength quantifies how far the impulse travels relative to the duration of the refractory period. The wavelength of the reentrant excitation wavefront must be shorter than the length of the pathway of the potential reentrant circuit for reentrant excitation to occur; that is, the impulse must travel a distance during the refractory period that is less than the complete reentrant path length to give myocardium ahead of it sufficient time to recover excitability. Slowing of impulse conduction or shortening of refractoriness shortens the wavelength and increases the excitable gap.

For almost all clinically important reentrant arrhythmias resulting from ordered reentry and in the presence of uniform, normal conduction velocity along the potential reentrant pathway, the wavelength would be too long to permit reentrant excitation. Thus, almost all these arrhythmias must have, and do have, one or more areas of slow conduction as a part of the reentrant circuit. The associated changes in conduction velocity, as well as associated changes in refractory periods, actually cause the wavelength to change in different parts of the circuit. However, the presence of one or more areas of slow conduction permits the average wavelength of reentrant activation to be shorter than the path length.

The wavelength concept is a good predictive parameter of arrhythmia inducibility. A decrease in conduction velocity or shortening of refractoriness results in a decrease in the wavelength or lessening of the amount of tissue needed to sustain reentry. This situation favors initiation and maintenance of reentry. In contrast, an increase in conduction velocity or prolongation of refractoriness prolongs the wavelength of excitation and, in this situation, a larger anatomical circuit is necessary to sustain reentry. If a larger circuit is not possible, initiation or maintenance of tachycardia cannot occur.

EXCITABLE GAPS

The excitable gap in a reentrant circuit is the region of excitable myocardium that exists between the head of the reentrant wavefront and the tail of the preceding wavefront and, at any given time, is no longer refractory (i.e., is capable of being excited) if the excitation wavelength is shorter than the length of the reentrant circuit (Fig. 3-13).

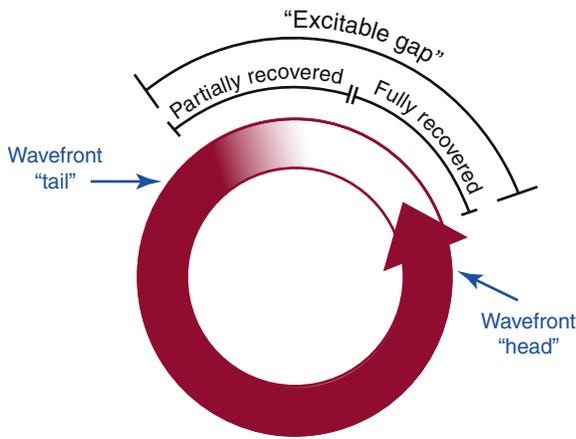

FIGURE 3-13 Excitable gap of recovered tissue in anatomically determined reentry.

The occurrence of an excitable gap is dependent on the recovery of excitability of the myocardium from its previous excitation by the reentrant wavefront. A fully excitable gap is defined as the segment of the reentrant circuit in which the tail of the preceding wavefront does not affect the head and velocity of the following wavefront (absence of head-tail interaction). A partially excitable gap is defined as the zone where the rotating wave can be captured by local stimulation in the presence of head-tail interaction. Whereas the excitable gap denotes a length of a segment within the reentrant circuit, the fully or partially excitable period denotes the time period during which a segment within the reentrant circuit is fully or partially excitable, respectively (see Fig. 3-13).

There are two different measurements of the excitable gap. The spatial excitable gap is the distance (in millimeters) of excitability occupied at any moment of time in the circuit ahead of the reentrant wavefront. On the other hand, the temporal excitable gap is the time interval (in milliseconds) of excitability between the head of activation of one impulse and the tail of refractoriness of the prior impulse. Both the spatial and temporal gaps can be composed of partially excitable or fully excitable myocardium, depending on the time interval between successive excitations of the circuit. The size of the spatial gap and the duration of the temporal gap vary in different parts of the circuit as the wavelength of the reentrant impulse changes because of changes in conduction velocity, refractory periods, or both.

The characteristics of the excitable gap can be different in different types of reentrant circuits. Many anatomically determined reentrant circuits have large excitable gaps with a fully excitable component, although, even in anatomically determined circuits, the gap can sometimes be only partially excitable. On the other hand, functional reentrant circuits caused by the leading circle mechanism have very small gaps that are only partially excitable, although parts of some functionally determined reentrant circuits (anisotropic reentrant circuits) can have fully excitable gaps. An excitable gap has been shown to occur during AF, VF, and AFL; these are examples of arrhythmias caused by functional reentrant mechanisms, possibly including spiral waves. The relationship between the excitable gap and the excitable period can be complex if the velocity of propagation changes within the reentry circuit.²⁷

The existence and the extent of an excitable gap in a reentrant circuit have important implications.²⁷ The presence of an excitable gap enables modulation of the frequency of a reentrant tachycardia by a locally applied stimulus or by field stimulation; the longer the excitable gap is, the more likely it will be for an extrastimulus to be able to enter the reentrant circuit and initiate or terminate a reentrant arrhythmia. In addition, resetting and entrainment are more likely to occur when the excitable gap is longer. The excitable gap can be exploited to terminate a reentrant tachycardia. The presence of a significant temporal and spatial excitable gap in some reentrant circuits enables reentry to be terminated by a

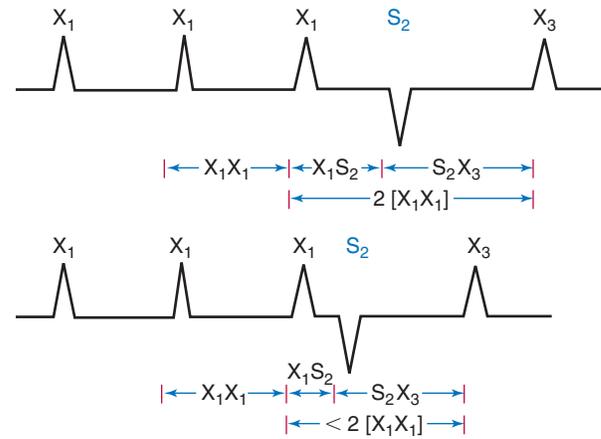

FIGURE 3-14 Response of tachycardia to a single extrastimulus (S_2). The tachycardia cycle length (CL) is $[X_1X_1]$. The coupling interval of the extrastimulus is $[X_1S_2]$. The return CL of the first complex of tachycardia after the extrastimulus is $[S_2X_3]$. In the **top portion** of the figure, the extrastimulus does not affect the tachycardia circuit, and a compensatory pause occurs. Resetting (i.e., advancement) of the tachycardia is shown at the **bottom of the figure**. (From Frazier DW, Stanton MS: *Resetting and transient entrainment of ventricular tachycardia*. *Pacing Clin Electrophysiol* 18:1919, 1995.)

single premature stimulus or by overdrive stimulation. Termination of arrhythmias by stimulation would be expected to be much more difficult when the reentrant circuit has only a small partially excitable gap. Additionally, the excitable gap can influence the effects of drugs on the reentrant circuit, so that reentry with a partially excitable gap and mainly functional components may respond more readily to drugs that prolong repolarization, without slowing conduction, whereas fixed anatomical reentry with a large excitable gap responds to drugs that decrease conduction velocity, preferentially at pivot points.

The properties of the excitable gap influence the characteristics of arrhythmias caused by reentry. Arrhythmias caused by leading circle reentry, in which the wavefront propagates in the just-recovered myocardium of the refractory tail and in which there is only a small partially excitable gap, are inherently unstable and often terminate after a short period or go on to fibrillation. On the other hand, the reentrant wavefront in anatomical and nonuniform anisotropic reentrant circuits, in general, is not propagating in myocardium that has just recovered excitability, and the excitable gap can be large. This property can contribute to the stability of these reentrant circuits.²⁷

The shape of the anatomical obstacle determines the path of a reentrant wave in fixed anatomical reentry. Therefore, instability of anatomical reentry is confined to variations of the rotating interval and wavelength of excitation. This instability is characterized by the wavefront's invading the repolarizing phase of the preceding wave, with resulting oscillations of the rotation period.²⁷

Resetting Reentrant Tachycardias

DEFINITION

Resetting is the advancement (acceleration) of a tachycardia impulse by timed premature electrical stimuli. The extrastimulus is followed by a pause that is less than fully compensatory before resumption of the original rhythm. The tachycardia complexes that return first should have the same morphology and CL as the tachycardia before the extrastimulus, regardless of whether single or multiple extrastimuli are used.³⁶⁻³⁸

The introduction of a single extrastimulus (S_2) during a tachycardia yields a return cycle (S_2X_3) if the tachycardia is not terminated (Fig. 3-14). If S_2 does not affect the arrhythmogenic focus, the coupling interval (X_1S_2) plus the return cycle (S_2X_3) will be equal to twice the tachycardia cycle ($2 \times [X_1X_1]$); that is, a fully

compensatory pause will occur. Resetting of the tachycardia occurs when a less than fully compensatory pause occurs. In this situation, $X_1S_2 + S_2X_3$ will be less than $2 \times (X_1X_1)$, as measured from the surface ECG. Tachycardia CL stability should be taken into account when the return cycle is measured. To account for any tachycardia CL instability, at least a 20-millisecond shortening of the return cycle is required to demonstrate resetting.³⁹

When more than a single extrastimulus is used, the relative prematurity should be corrected by subtracting the coupling interval or intervals from the spontaneous tachycardia cycles when the extrastimuli are delivered.⁴⁰

REENTRANT TACHYCARDIA RESETTING

To reset reentrant tachycardia, the stimulated wavefront must reach the reentrant circuit, encounter excitable tissue within the circuit (i.e., enter the excitable gap of the reentrant circuit), collide in the antidromic (retrograde) direction with the previous tachycardia impulse, and continue in the orthodromic (anterograde) direction to exit at an earlier than expected time and perpetuate the tachycardia (Fig. 3-15).³⁶⁻³⁸ If the extrastimulus encounters fully excitable tissue, which commonly occurs in reentrant tachycardias with large excitable gaps, the tachycardia will be advanced by the extent that the stimulated wavefront arrives at the entrance site prematurely. If the tissue is partially excitable, which can occur in reentrant tachycardias with small or partially excitable gaps or even in circuits with large excitable gaps when the extrastimulus is very premature, the stimulated wavefront will encounter some conduction delay in the orthodromic direction within the circuit (see Fig. 3-15). Therefore, the degree of advancement of the next tachycardia beat depends on both the degree of prematurity of the extrastimulus and the degree of slowing of its conduction within the circuit. The reset tachycardia beat consequently can be early, on time, or delayed.

Termination of the tachycardia occurs when the extrastimulus collides with the preceding tachycardia impulse antidromically and blocks in the reentrant circuit orthodromically (see Fig. 3-15). This occurs when the premature impulse enters the reentrant circuit early in the relative refractory period; it fails to propagate in the anterograde direction because it encounters absolutely refractory tissue. In the retrograde direction, it encounters increasingly recovered tissue and can propagate until it encroaches on the circulating wavefront and terminates the arrhythmia.^{39,40}

Resetting does not require that the pacing site be located in the reentrant circuit. The closer the pacing site is to the circuit, however, the less premature a single stimulus can be and reach the circuit without being extinguished by collision with a wave emerging from the circuit. The longest coupling interval for an extrastimulus to be able to reset a reentrant tachycardia depends on the tachycardia CL, the duration of the excitable gap of the tachycardia, refractoriness at the pacing site, and the conduction time from the pacing site to the reentrant circuit.³⁹

Resetting Zone and Excitable Gap

For an extrastimulus to be able to reset the reentrant circuit, it has to penetrate the circuit during its excitable gap. The difference between the longest and shortest coupling intervals resulting in resetting is defined as the *resetting interval* or *resetting zone*.^{37,39} Thus, the coupling intervals over which resetting occurs, the resetting zone, can be considered a measure of the duration of the temporal excitable gap existing in the reentrant circuit. Therefore, the entire extent of the fully excitable gap would be the zone of coupling intervals from the onset of tachycardia resetting until tachycardia termination. The excitable gap, however, can be underestimated by using only a single extrastimulus or by using single or double extrastimuli in the absence of tachycardia termination by the extrastimuli.

All tachycardias reset by a single extrastimulus can be reset by double extrastimuli, unless tachycardia termination occurs. Double extrastimuli produce resetting over a longer range of coupling intervals and should therefore be used to characterize the

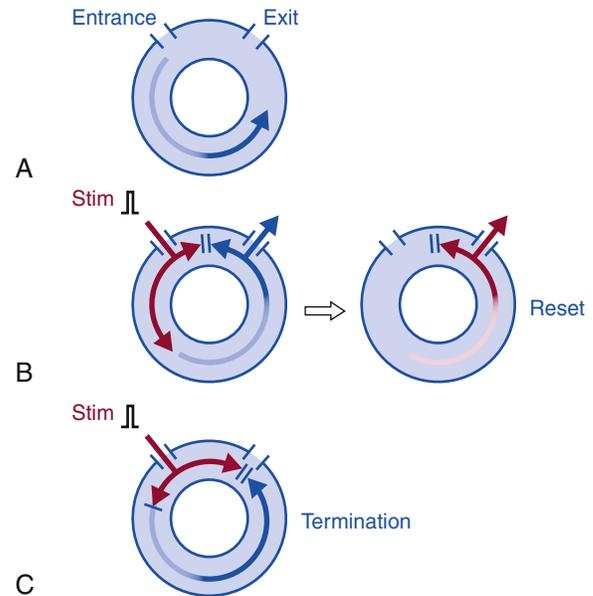

FIGURE 3-15 A, Schematic representation of the reentrant circuit is illustrated with separate entrance and exit sites. During tachycardia, a wavefront is shown propagating through the tissue of the reentrant circuit (arrow). The dark portion of the arrow represents fully refractory tissue, and the fading portion represents partially refractory tissue. B, A premature stimulus (Stim) introduced during the tachycardia results in a wavefront of depolarization (red arrow), which enters the reentrant circuit and conducts anterogradely over fully excitable tissue while it collides retrogradely with the already propagating wavefront (blue arrow). The premature wavefront (red arrow) then propagates around the circuit to the exit site, thus leading to the less than compensatory pause and resetting of the tachycardia. C, A more premature extrastimulus (Stim) results in a wavefront of depolarization (red arrow), which enters the circuit at a time when it collides retrogradely with the previously propagating wavefront (blue arrow) and encounters antegrade tissue incapable of sustaining further propagation. As a result, circus movement in the circuit is extinguished, and tachycardia terminates. (From Rosenthal ME, Stamato NJ, Almendral JM, et al: Coupling intervals of ventricular extrastimuli causing resetting of sustained ventricular tachycardia secondary to coronary artery disease: relation to subsequent termination. *Am J Cardiol* 61:770, 1988.)

excitable gap of the reentrant circuit more fully. During EP testing, only the temporal excitable gap of the entire circuit can be evaluated. It is impossible to assess the conduction velocity and refractoriness at any point in the circuit, which certainly must vary, with available technology.

Return Cycle

The return cycle is the time interval from the resetting stimulus to the next excitation of the pacing site by the new orthodromic wavefront. This corresponds to the time required for the stimulated impulse to reach the reentrant circuit, conduct through the circuit, exit the circuit, and travel back to the pacing site.^{37,39} The noncompensatory pause following the extrastimulus and the return cycle are typically measured at the pacing site; however, they may also be measured to the onset of the tachycardia complex on the surface ECG.

When the return cycle is measured from the extrastimulus producing resetting to the onset of the first return tachycardia complex on the surface ECG, conduction time into the tachycardia circuit is incorporated into that measurement. Conduction time between the pacing site and the tachycardia circuit may or may not be equal to that from the circuit to the pacing site. Differences in location of the site of stimulation, as well as the tachycardia circuit entrance and exit, can result in differences in conduction time to and from the pacing site.

Orthodromic and Antidromic Resetting

Antidromic resetting occurs when intracardiac sites are directly captured by the premature stimulus without traversing the reentrant circuit and the zone of slow conduction.³⁷ Therefore, antidromic

resetting of intracardiac sites occurs with a conduction interval from the pacing stimulus to the captured electrogram that is less than the tachycardia CL and with differing morphology of the captured as compared with the spontaneous electrogram. Although demonstration of an antidromic resetting response can indicate a tachycardia mechanism other than reentry, an antidromic resetting pattern can also be observed during reentry with an excitable gap if the pacing site is located distal to a region of slow conduction in the reentry circuit. Conversely, if the recording sites are located in regions activated proximal to a region of slow conduction, an antidromic resetting response will be observed.

Orthodromic resetting occurs when the premature stimulus traverses the reentrant circuit, including the zone of slow conduction, in the same direction as the spontaneous tachycardia impulse and with an identical exit site.³⁷ Intracardiac areas that are orthodromically reset are advanced by the premature extrastimulus but retain the same morphology because they are activated from the impulse emerging from the same reentrant circuit exit site. The conduction interval from the pacing stimulus to the orthodromically captured electrogram exceeds the tachycardia CL by the time required for the extrastimulus to travel from the pacing site to the reentrant circuit. Thus, an orthodromic resetting response implies that the pacing site is located proximal to a region of slow conduction in the reentry circuit and that the recording site is located distal to this region. The ability to demonstrate orthodromic resetting is critically dependent on the location of pacing and recording electrodes relative to the region of slow conduction in the circuit. Therefore, failure to demonstrate an orthodromic resetting response does not exclude reentry with an excitable gap as a possible tachycardia mechanism.

RESETTING RESPONSE CURVES

Response patterns during resetting are characterized by plotting the coupling interval of the extrastimulus producing resetting versus the return cycle measured at the pacing site. Alternatively, the return cycle is measured to the onset of the first tachycardia complex following stimulation on the surface ECG; then, qualitatively similar but quantitatively different response curves are obtained.³⁹ Demonstration of a noncompensatory pause following the extrastimulus is required, and the interval encompassing the extrastimulus should be 20 or more milliseconds earlier than the expected compensatory pause following a single extrastimulus and 20 or more milliseconds less than three tachycardia CLs when double extrastimuli are used.³⁹ As always, it is important to establish the stability of tachycardia CL before assessing any perturbation in tachycardia presumed to be caused by resetting.

Four resetting response patterns are possible (Fig. 3-16)³⁹:

1. During the *flat response pattern*, the return cycle is constant (less than a 10-millisecond difference) over a 30-millisecond range of coupling intervals.
2. With the *increasing response pattern*, the return cycle increases as the coupling interval increases.
3. With a *decreasing response pattern*, the return cycle decreases as the coupling interval increases.
4. A *mixed response pattern* meets the criteria for a flat response at long coupling intervals and for an increasing response at shorter coupling intervals.

Occasionally, a response pattern to a single extrastimulus cannot be characterized because resetting occurs over too narrow a range of coupling intervals as a result of significant variability of the baseline tachycardia CL or of variability in the return cycle. Triggered rhythms secondary to DADs usually have a flat or decreasing response. A flat response can be observed in automatic, triggered, or reentrant rhythms.

In all cases in which a single extrastimulus resets the tachycardia, double extrastimuli from the same pacing site produce an identical or expected resetting curve. Thus, if a single extrastimulus produces a flat curve, double extrastimuli will produce a flat or mixed curve. If a single extrastimulus produces an increasing or mixed curve, double extrastimuli will produce the same curve.

The types of resetting curves can vary depending on the site of stimulation. Extrastimuli from different pacing sites likely engage different sites in the reentrant circuit that are in different states of excitability or refractoriness and therefore result in different conduction velocities and resetting patterns.³⁹

Flat Response Curves in Reentrant Rhythms

A flat resetting curve implies the presence of a fully excitable gap within the reentrant circuit over a range of coupling intervals. The total duration of the excitable gap should exceed the range of coupling intervals that produce resetting with a flat response. Large excitable gaps are more likely to result in flat response curves, because the increasingly premature extrastimuli are less likely to encroach on the trailing edge of refractoriness and encounter decremental conduction (see Fig. 3-16). The flat return cycle also suggests the presence of fixed sites of entrance and exit from the circuit and fixed conduction time from the stimulation site through the reentrant circuit over a wide range of coupling intervals.

If a single extrastimulus produced resetting with a flat response, the response to double extrastimuli would also be flat. However, because the use of double extrastimuli allows engagement of the reentrant circuit at relatively long coupling intervals with greater prematurity, resetting will begin at longer coupling intervals and will continue over a greater range of coupling intervals than observed with a single extrastimulus. Therefore, double extrastimuli can produce a flat and then increasing response curve.

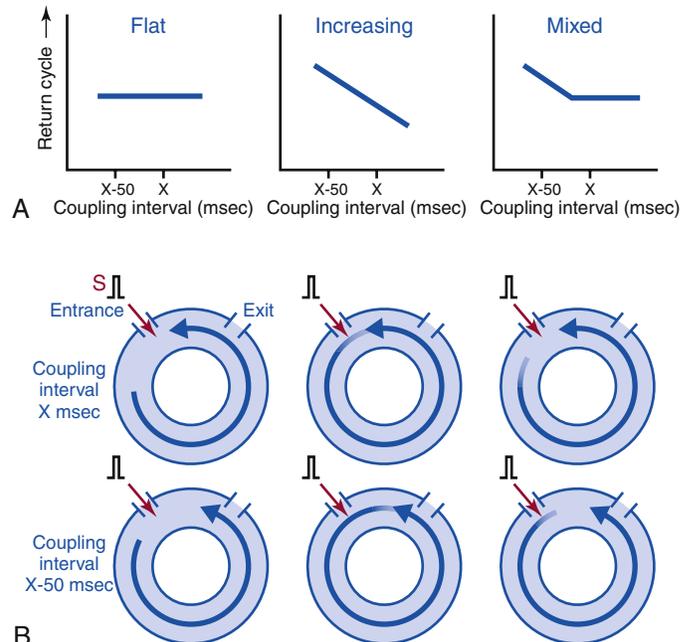

FIGURE 3-16 Mechanisms of various resetting response patterns. **A**, Schemas of three types of resetting response curves. **B**, A theoretical mechanism of resetting patterns in response to extrastimuli at coupling intervals of X and X-50 milliseconds. The reentrant circuit is depicted as having a separate entrance and exit in each pattern. Each tachycardia wavefront is followed by a period of absolute refractoriness (blue arrow), which is then followed by a period of relative refractoriness (fading tail of the arrow) of variable duration. On the **left side**, a flat curve results when the stimulated wavefront reaches the tachycardia circuit and finds a fully excitable gap between the head and tail of the tachycardia wavefront. The gap is still fully excitable at a coupling interval of X-50. Therefore, the conduction time from the entrance to exit is the same. An increasing curve is shown in the **middle**; this results when the initial stimulated wavefront enters the reentrant circuit when the excitable gap is partially refractory. The curve continues to increase at a coupling interval of X-50 because the tissue is still in a relative refractory state. A mixed curve (**right side**) results when the less premature extrastimuli find the reentrant circuit fully excitable, whereas the more premature one (at coupling intervals of X-50) finds it in the relative refractory period. (From Josephson ME: *Recurrent ventricular tachycardia*. In Josephson ME, editor: *Clinical cardiac electrophysiology*, ed 3, Philadelphia, 2004, Lippincott Williams & Wilkins, pp 425-610.)

Increasing Response Curves in Reentrant Rhythms

Increasing resetting curves result from progressively longer return cycles in response to increasingly premature extrastimuli and indicate a zone of decremental slow conduction, usually located within the reentrant circuit. The most probable mechanism underlying the decremental conduction is encroachment of the advancing wavefront from the premature extrastimuli on an increasingly more refractory tissue within the reentrant circuit, most likely within the zone of slow conduction (see Fig. 3-16).³⁹ This response pattern is possible only for reentrant arrhythmias and is not observed in triggered or automatic rhythms.

Mixed Response Curves in Reentrant Rhythms

In a mixed response curve, the initial coupling intervals demonstrate a flat portion of the curve of variable duration (but less than 30 milliseconds), followed by a zone during which the return cycle increases (see Fig. 3-16). Occasionally, a flat curve is seen with a single extrastimulus; it is only by using double extrastimuli that an increasing response can be observed.

Decreasing Response Curves in Reentrant Rhythms

Decreasing reset curves are not observed in reentry but can be seen in triggered rhythms, although flat responses are the most common response for triggered activity. The return cycle in triggered activity is typically 100% to 110% of the tachycardia CL.

RESETTING WITH FUSION

Fusion of the stimulated impulse can be observed on surface ECG or intracardiac recordings if the stimulated impulse is intermediate in morphology between a fully paced complex and the tachycardia complex. The ability to recognize ECG fusion requires a significant mass of myocardium to be depolarized by both the extrastimulus and the tachycardia.^{37,39,41} With early extrastimuli, the paced antidromic wavefront captures all or most of the myocardium prior to the orthodromic wavefront of the tachycardia impulse exiting from the reentrant circuit. Thus, no ECG fusion is present, although resetting can occur. With later coupled extrastimuli, the orthodromic wavefront exits from the reentrant circuit, thus capturing a certain portion of myocardium before colliding with the paced antidromic wavefront. In this situation, ECG fusion occurs. Resetting with ECG fusion requires wide separation of the entrance and exit of the reentrant circuit, with the stimulus wavefront preferentially engaging the entrance.

If presystolic activity in the reentrant circuit is recorded before delivery of the extrastimulus that resets the tachycardia, one must consider this to represent local fusion (Fig. 3-17).³⁹ Thus, an extrastimulus that is delivered after the onset of the tachycardia complex

and enters and resets the circuit always demonstrates local fusion. Resetting with local fusion and a totally paced complex morphology provides evidence that the reentrant circuit is electrocardiographically small.

The farther the pacing site is from the reentrant circuit, the less likely resetting with ECG fusion will occur because the extrastimulus should be delivered at a shorter coupling interval to reach the circuit with adequate prematurity. Consequently, the stimulated impulse is more likely to capture both the exit and entrance sites and therefore have a purely paced ECG complex morphology without fusion.

Reentrant circuits reset with fusion have a higher incidence of flat resetting curves, longer resetting zones, and significantly shorter return cycles measured from the stimulus to the onset of the tachycardia complex. Resetting with fusion is a potential indication that the pacing site is located proximal to the zone of slow conduction (i.e., prior to the entrance site) within the reentrant circuit, whereas resetting without fusion potentially suggests pacing distal to the zone of slow conduction, because pacing closer to the exit is more likely to capture both the exit and entrance sites and produce resetting without fusion.

RESETTING OF TACHYCARDIAS WITH DIVERSE MECHANISMS

Resetting can be demonstrated for tachycardias based on different mechanisms, including reentry, normal or abnormal automaticity, and triggered activity. Although the ability to reset an arrhythmia is not helpful in distinguishing the underlying mechanism, certain features of the resetting response can be useful for the differential diagnosis.³⁹

Site Specificity of Resetting

Triggered activity and automaticity do not demonstrate site specificity for resetting, whereas reentry can. Site specificity for resetting is decreased with the use of multiple extrastimuli.

Resetting Response Curves

Triggered rhythms secondary to DADs usually have a flat or decreasing resetting curve. A flat resetting curve can be seen in automatic, triggered, or reentrant rhythms. Reentrant rhythms never demonstrate a decreasing resetting curve to single or double extrastimuli.

Resetting with Fusion

The ability to reset tachycardia after it has begun activating the myocardium (i.e., resetting with fusion) is diagnostic of reentry and excludes automatic and triggered mechanisms.^{37,39,41}

In automaticity or triggered activity, resetting of the arrhythmia by an extrastimulus requires depolarization of the site of origin by

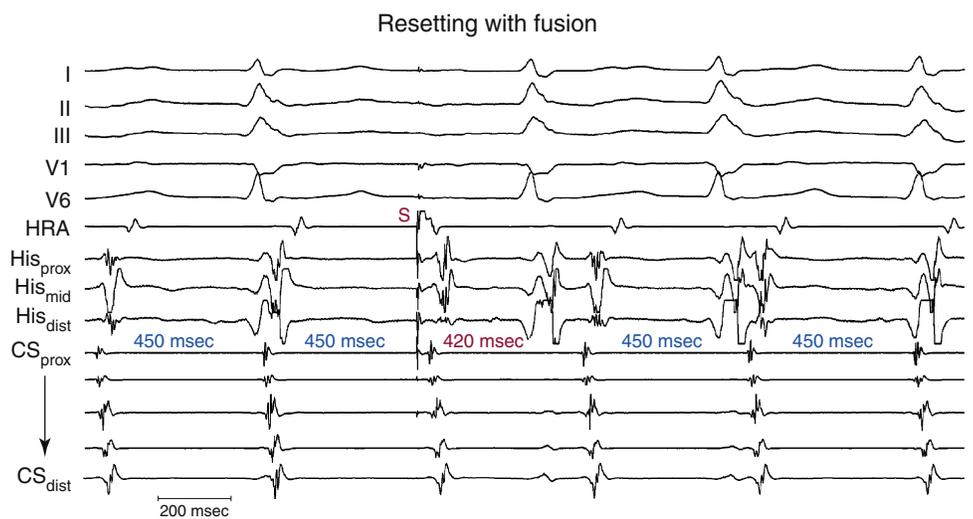

FIGURE 3-17 Resetting with fusion. An atrial tachycardia is shown with a stable cycle length (450 msec). A single extrastimulus (S) is delivered from the high right atrium (HRA) that resets or advances the timing of the next cycle (420 msec); however, the coronary sinus (CS) electrogram occurs on time when the extrastimulus is given. Thus, intracardiac fusion is evident when resetting occurs, signifying macroreentry. dist = distal; mid = middle; prox = proximal.

the paced wavefront. Because the entrance and exit sites of focal rhythms (automatic or triggered) are not separate, a tachycardia wavefront cannot exit the focus once the exit or entrance site has already been depolarized and rendered refractory by the paced wavefront.

CH
3

During automatic or triggered tachycardias, when an extrastimulus is delivered late in the tachycardia cycle, it can collide with the tachycardia impulse exiting the tachycardia focus and produce fusion of a single beat on the surface ECG or intracardiac recordings. In this case, however, resetting cannot occur because the surrounding myocardium is refractory to the advancing extrastimulus; that is, entrance block occurs. This produces a fully compensatory pause.

Entrainment of Reentrant Tachycardias

BASIC PRINCIPLES OF ENTRAINMENT

Entrainment of reentrant tachycardias by external stimuli was originally defined in the clinical setting as “an increase in the rate of a tachycardia to a faster pacing rate, with resumption of the intrinsic rate of the tachycardia upon either abrupt cessation of pacing or slowing of pacing beyond the intrinsic rate of the tachycardia” and taken to indicate an underlying reentrant mechanism. The ability to entrain a tachycardia also establishes that the reentrant circuit contains an excitable gap.^{27,39,42,43}

Orthodromic resetting and transient entrainment are manifestations of the same phenomenon (i.e., premature penetration of a tachycardia circuit by a paced wavefront), and the ability to demonstrate resetting is a strong indication that entrainment can occur from that specific pacing site. Entrainment is the continuous resetting of a reentrant circuit by a train of capturing stimuli. However, following the first stimulus of the pacing train that penetrates and resets the reentrant circuit, the subsequent stimuli interact with the reset circuit, which has an abbreviated excitable gap.²⁷

During entrainment, each pacing stimulus creates two activation wavefronts, one in the orthodromic direction and the other in the antidromic direction. The wavefront in the antidromic direction collides with the existing tachycardia wavefront. The wavefront that enters the reentrant circuit in the orthodromic direction (i.e., the same direction as the spontaneous tachycardia wavefront) conducts through the reentrant pathway, resets the tachycardia, and emerges through the exit site to activate the myocardium and collide with the antidromically paced wavefront from the next paced stimulus. This sequence continues until cessation of pacing or block somewhere within the reentrant circuit develops.³⁷ The first entrained stimulus results in retrograde collision between the stimulated and tachycardia wavefronts, whereas for all subsequent stimuli, the collision occurs between the currently stimulated wavefront and the one stimulated previously. Depending on the degree to which the excitable gap is preexcited (and abbreviated) by the first resetting stimulus, subsequent stimuli fall on fully or partially excitable tissue. Entrainment is said to be present when two consecutive extrastimuli conduct orthodromically through the circuit with the same conduction time while colliding antidromically with the preceding paced wavefront. Because all pacing impulses enter the tachycardia circuit during the excitable gap, each paced wavefront advances and resets the tachycardia. Thus, when pacing is terminated, the last paced impulse will continue to activate the entire tachycardia reentrant circuit orthodromically at the pacing CL and also will activate the entire myocardium orthodromically on exiting the reentrant circuit.^{42,43}

Overdrive pacing at long CLs (approximately 10 to 20 milliseconds shorter than the tachycardia CL) can almost always entrain reentrant circuits with large flat resetting curves and a post-pacing interval (PPI) equal to the return cycle observed during the flat part of the resetting curve.³⁹ During overdrive pacing, once the n^{th} pacing stimulus resets the circuit, the following pacing stimulus ($n + 1$)th will reach the circuit more prematurely. Depending on how premature it is, this ($n + 1$)th extrastimulus may produce no

change in the return cycle (compared with that in response to the n^{th} extrastimulus), encounter progressive conduction delay (until a fixed, longer return cycle is reached), or terminate the tachycardia. The larger the flat curve observed during resetting or the longer the pacing CL, or both, the more likely the return cycle of the n^{th} and ($n + 1$)th extrastimuli will be the same. In this case, no matter how many subsequent extrastimuli are delivered, the return cycle will be the same and equal to that observed during the flat portion of the resetting curve. However, if the flat portion of the resetting curve is small, the pacing CL is short, or both, the ($n + 1$)th extrastimulus will fall on partially refractory tissue and the return cycle will increase. Continued pacing at the same CL will result in a stable but longer return cycle than the n^{th} extrastimulus or termination of the tachycardia. Consequently, circuits with large fully excitable gaps (i.e., large flat resetting curves) can demonstrate prolonged return cycles or even termination at pacing CLs equal to coupling intervals of a single extrastimulus demonstrating a fully excitable gap.

ENTRAINMENT RESPONSE CURVES

During entrainment, the orthodromic wavefront of the last extrastimulus propagates around the circuit to become the first complex of the resumed tachycardia. The conduction time of this impulse to the exit site of the circuit is termed the *last entrained interval*, and it characterizes the properties of the reset circuit during entrainment.^{37,39} Measurement of the interval between the last paced extrastimulus to the first nonpaced tachycardia complex (on the surface ECG or presystolic electrogram) during entrainment at progressively shorter pacing CLs characterizes an entrainment response curve, analogous but not identical to resetting response curves with single extrastimuli. In this case, the return cycle depends critically on the number of extrastimuli delivered that reset the circuit before the return cycle is measured, because following the first extrastimulus producing resetting (the n^{th} extrastimulus), subsequent extrastimuli are relatively more premature and can lead to a different return cycle.^{42,43}

During entrainment, the return cycle measured at an orthodromically captured presystolic electrogram should equal the pacing CL regardless of the site of pacing, as long as the presystolic electrogram is orthodromically activated at a fixed stimulus-to-electrogram interval (i.e., fixed orthodromic conduction time). This would not be observed if the electrogram were captured antidromically. If the time from the orthodromically activated electrogram to the onset of the return cycle on the surface ECG remains constant, which is a requirement to prove that the electrogram is within or attached to the reentrant circuit proximal to the exit site, then the interval from the stimulus to the surface ECG complex will remain constant. The same is true for the electrogram measured at the stimulation site. In the absence of recording of a presystolic electrogram, other measurements may be used to characterize the last entrained interval at any pacing CL. Therefore, during entrainment, curves relating the pacing CL to the last entrained interval can be measured from the stimulus to the orthodromic presystolic electrogram, to the onset of the surface ECG of the first tachycardia (nonpaced) complex, or to the local activation time at the pacing site of the first tachycardia (nonpaced) complex. These measurements will be qualitatively identical but have different absolute values. As always, it is important to establish the stability of tachycardia CL and document the presence of entrainment before assessing the return cycle and PPI.^{42,43}

Termination is the usual response to overdrive pacing of circuits that demonstrate an increasing curve in response to resetting by a single extrastimulus. However, if the number of extrastimuli following the n^{th} extrastimulus is limited to one or two (especially at long pacing CLs), termination may not occur, although the return cycle will be progressively longer following each extrastimulus. Entrainment is not present until two consecutive PPIs are identical. In such cases, when termination does not occur, the return cycle will be longer than that observed if pacing were discontinued following the n^{th} extrastimulus at that pacing CL.^{37,39} Thus, if only the

return cycle following entrainment is used to analyze the excitable gap, an increasing curve suggesting decremental conduction can result, even though a flat curve is observed with single or double extrastimuli, or both. Therefore, only resetting phenomena describe the characteristics of the reentrant circuit. Entrainment analyzes a reset circuit that has a shorter excitable gap. Flat, mixed (flat and increasing), and increasing curves can be seen during entrainment of macroreentrant circuits. Increasing curves are almost always observed during entrainment of small or microreentrant circuits.

RELATIONSHIP OF PACING SITE AND CYCLE LENGTH TO ENTRAINMENT

As with resetting, entrainment does not require the pacing site be located in the reentrant circuit. The closer the pacing site is to the circuit, however, the less premature a single stimulus can be and reach the circuit and, with pacing trains, the fewer the number of stimuli required before a stimulated wavefront reaches the reentrant circuit without being extinguished by collision with a wave emerging from the circuit.

Overdrive pacing at long CLs (approximately 10 to 20 milliseconds shorter than the tachycardia CL) can almost always entrain reentrant tachycardias. However, the number of pacing stimuli required to entrain the reentrant circuit depends on the tachycardia CL, the duration of the excitable gap of the tachycardia, refractoriness at the pacing site, and the conduction time from the stimulation site to the reentrant circuit.^{39,42-45}

DIAGNOSTIC CRITERIA OF ENTRAINMENT

Entrainment is the continuous resetting of a tachycardia circuit. Therefore, during constant rate pacing, entrainment of tachycardia results in the activation of all myocardial tissue responsible for maintaining the tachycardia at the pacing CL, with the resumption of the intrinsic tachycardia morphology and rate after cessation of pacing. Unfortunately, it is almost impossible to document the acceleration of all tissues responsible for maintaining the reentrant circuit to the pacing CL. Therefore, certain surface ECG criteria have been proposed for establishing the presence of entrainment: (1) fixed fusion of the paced complexes at a constant pacing rate; (2) progressive fusion or different degrees of fusion at different pacing rates (i.e., the surface ECG and intracardiac morphology progressively look more like the purely paced configuration and less like the pure tachycardia complex in the course of pacing at progressively shorter pacing CLs); and (3) resumption of the same tachycardia morphology following cessation of pacing, with the first PPI displaying no fusion but occurring at a return cycle equal to the pacing CL.⁴⁶ These criteria are discussed in more detail in Chapter 5.^{42,43,47}

Mechanism of Slow Conduction in the Reentrant Circuit

As mentioned earlier, a condition necessary for reentry is that the impulse be delayed sufficiently in the alternative pathway or pathways to allow tissues proximal to the site of unidirectional block to recover excitability.²⁷ All types of reentrant arrhythmias have a basic feature in common—the wavefront must encounter a zone of tissue where local electrical inhomogeneity is present. This inhomogeneity can be related to (1) electrical properties of the individual cardiac myocyte that generates the action potential (inhomogeneity in electrical excitability or refractoriness, or both), (2) passive properties governing the flow of current among cardiac cells (cell-to-cell coupling and tissue geometry), or (3) combinations of those conditions.⁴⁸ Such changes can be permanent (e.g., in remodeling after ventricular hypertrophy or infarction), or they can be purely functional (e.g., inhomogeneity of refractoriness in acutely ischemic tissue). Additionally, some of those changes are needed only to set the initial condition for the deviation of the impulse, the so-called unidirectional conduction block. Once the

disturbance is initiated, an arrhythmia can develop in a perfectly homogeneous electrical medium.⁴⁸

Slow conduction within the reentrant circuit is also an important determinant of the size of the reentrant circuit. A decrease in conduction velocity results in a reduction in the wavelength and a lessening of the amount of tissue needed to sustain reentry. In contrast, an increase in conduction velocity prolongs the wavelength of excitation, and, hence, a larger anatomical circuit is necessary to sustain reentry. If a larger circuit is not possible, initiation or maintenance of tachycardia cannot occur.²⁷

In some cardiac tissues (e.g., the AVN), slow conduction is normal physiology. Slow conduction also can be secondary to pathophysiological settings (e.g., MI) or caused by functional properties that can develop as a result of premature stimulation or evolve during a rapid transitional rhythm.²⁷

As discussed in Chapter 1, action potential propagation and conduction velocity in cardiac tissue are determined by source-sink relationships, which reflect the interplay between the active membrane properties of cardiac cells (the source generating the action potential) and the passive properties determined by architectural features of the myocardium (sink), as well as the coupling resistance between source and sink. The current provided by the source must reach the sink. The pathway between the source and sink includes intracellular resistance (provided by the cytoplasm) and intercellular resistance (provided by the gap junctions). Extracellular resistance plays a role, but it can often be neglected. The coupling resistance is mainly determined by resistance of the gap junctions. Therefore, the number and distribution of gap junctions, as well as the conductance of the gap junction proteins (connexins), are important factors for conduction of the action potential.

The safety factor for conduction predicts the success of action potential propagation and is defined as the ratio of the current generated by the depolarizing ion channels of a cell (source) to the current consumed during the excitation cycle of a single cell in the tissue (sink).³⁹ Thus, the safety factor for propagation is proportional to the excess of source current over the sink needs. By this definition, conduction fails when the safety factor drops to less than 1 and becomes increasingly stable as it rises to more than 1.⁴⁹ This concept of propagation safety provides information about the dependence of propagation velocity on the state of the ion channels, cell-to-cell coupling, and tissue geometry. In essence, local source-sink relationships determine the formation of conduction heterogeneities and provide conditions for the development of slow conduction, unidirectional block, and reentry.^{27,50,51}

REDUCED MEMBRANE EXCITABILITY

Excitability of a cardiac cell describes the ease with which the cell responds to a stimulus with a regenerative action potential, and it depends on the passive and active properties of the cell membrane.⁷ The passive properties include the membrane resistance and capacitance and the intercellular resistance. The more negative the membrane potential is, the more Na⁺ channels are available for activation, the greater the influx of Na⁺ into the cell during phase 0, and the greater the conduction velocity.

In contrast, membrane depolarization to levels of -60 to -70 mV can inactivate half the Na⁺ channels, and depolarization to -50 mV or less can inactivate all the Na⁺ channels. Therefore, when stimulation occurs during phase 3 (e.g., during premature stimulation during the relative refractory period), before full recovery and at less negative potentials of the cell membrane, a portion of Na⁺ channels will still be refractory and unavailable for activation. As a result, I_{Na} and phase 0 of the next action potential are reduced, and conduction of the premature stimulus is slowed, facilitating reentry.^{6,27}

Reduced membrane excitability occurs in numerous physiological and pathophysiological conditions. Genetic mutations that result in loss of Na⁺ channel function, as occurs in the Brugada syndrome, can cause reduced membrane excitability.

Reduced membrane excitability is also present in cardiac cells with persistently low levels of resting potential caused by disease (e.g., during acute ischemia, tachycardia, certain electrical remodeling processes, and treatment with class I antiarrhythmic agents).^{27,50} At low resting potentials, the availability of excitable Na^+ channels is reduced because of inactivation of a significant proportion of the Na^+ channels and prolonged recovery of Na^+ channels from inactivation. With progressive reduction of excitability, less Na^+ source current is generated, and conduction velocity and the safety factor decrease monotonically. When the safety factor falls to less than 1, conduction can no longer be sustained, and failure (conduction block) occurs. Action potentials with reduced upstroke velocity resulting from partial inactivation of Na^+ channels are called depressed fast responses. These action potential changes are likely to be heterogeneous, with unequal degrees of Na^+ inactivation that create areas with minimally reduced velocity, more severely depressed zones, and areas of complete block. In addition, refractoriness in cells with reduced membrane potentials can outlast voltage recovery of the action potential; that is, the cell can still be refractory or partially refractory after the resting membrane potential returns to its most negative value.⁵⁰

Thus, in a diseased region with partially depolarized fibers, there can be some areas of slow conduction and some areas of conduction block, depending on the level of resting potential and the number of Na^+ channels that are inactivated. This combination can be the substrate for reentry. The chance for reentry in such fibers is even greater during premature activation or during rhythms at a rapid rate, because slow conduction or the possibility of block is increased even further.

REDUCED CELLULAR COUPLING

Intercellular communication is maintained by gap junctional channels that connect neighboring cells and allow biochemical and low-resistance electrical coupling.⁵² Although the resistivity of the gap junctional membrane for the passage of ions and small molecules and for electrical propagation is several orders of magnitude higher than the cytoplasmic intracellular resistivity, gap junction coupling provides a resistance pathway that is several orders of magnitude lower compared with uncoupled cell membranes.⁵³

In normal adult working myocardium, a given cardiomyocyte is electrically coupled to an average of approximately 11 adjacent cells, with gap junctions being predominantly localized at the intercalated discs at the ends of the rod-shaped cells. Lateral (side-to-side) gap junctions in nondisc lateral membranes of cardiomyocytes are much less abundant and occur more often in atrial than ventricular tissues.^{27,53-55} This particular subcellular distribution of gap junctions is a main determinant of anisotropic conduction in the heart; a wavefront must traverse more cells in the transverse direction than over an equivalent distance in the longitudinal direction, because cell diameter is much smaller than cell length. Additionally, less intercellular gap junctional coupling occurs and, hence, greater resistance and slower conduction transversely than longitudinally.^{27,52,55}

Modification of intercellular coupling occurs in numerous physiological and pathophysiological conditions.²⁷ Physiologically, cell-to-cell coupling is reduced in atrial and ventricular myocardium in the transverse direction to the main fiber axis relative to the longitudinal direction. Reduced intercellular coupling also likely contributes to slow impulse conduction in the AVN. In pathophysiological settings (e.g., myocardial ischemia, ventricular hypertrophy, cardiomyopathy),⁵⁶ modification of intercellular coupling can occur as a consequence of acute changes in the average conductance of gap junctions secondary to ischemia, hypoxia, acidification, or increase in intracellular Ca^{2+} , or it can be produced by changes in expression or cellular distribution patterns of gap junctions.^{57,58} Changes in the distribution and number of gap junctions (gap junction remodeling) have been reported in

almost all cardiac diseases predisposing to arrhythmias. Remodeling includes a decrease in some gap junction channels resulting from the interruption of communication between cells by fibrosis and downregulation of connexin-43 (Cx43) formation or trafficking to the intercalated disc. Additionally, gap junctions can become more prominent along lateral membranes of myocytes (so-called structural remodeling).^{54,59}

A reduction in the gap junctional conductance increases the intercellular resistance, thus leading to conduction delay or block. Similar to its behavior during reduced membrane excitability, conduction velocity decreases monotonically with reduction in intercellular coupling.⁵² However, the resulting reduction of conduction velocities is more than an order of magnitude larger than that observed during a reduction of excitability.²⁷ Importantly, the changes in the safety factor with uncoupling are opposite to those observed with a reduction in membrane excitability. As cells become less coupled, there is greater confinement of depolarizing current to the depolarizing cell, with less electrotonic load and axial flow of charge to the downstream cells. As a result, individual cells depolarize with a high margin of safety, but conduction proceeds with long intercellular delays. At such low levels of coupling, conduction is very slow but, paradoxically, very robust.^{27,57,58}

Importantly, there is a high redundancy in connexin expression in the heart with regard to conduction of electrical impulse, and a large reduction of intercellular coupling is required to cause major slowing of conduction velocity. It has been shown that a 50% reduction in Cx43 does not alter ventricular impulse conduction. Cx43 expression must decrease by 90% to affect conduction, but even then conduction velocity is reduced only by 20%.

TISSUE STRUCTURE AND GEOMETRY

Tissue geometry can influence action potential propagation and conduction velocity. In contrast to an uncoupled cell strand, in which the high resistance junctions alternate with the low cytoplasmic resistance of the cells, a high degree of discontinuity can be produced by large tissue segments (consisting of a segment with side branches) alternating with small tissue segments having a small tissue mass (connecting segments without branches).²⁷

When a small mass of cells has to excite the large mass (e.g., an impulse passing abruptly from a fiber of small diameter to one of large diameter or propagating into a region where there is an abrupt increase in branching of the myocardium), transient slowing of the conduction velocity can be observed at the junction. This occurs because of sink-source mismatch, during which the current provided by the excitation wavefront (source) is insufficient to charge the capacity and thus excite the much larger volume of tissue ahead (sink).^{27,49,60,61}

In a normal heart, abrupt changes in geometric properties are not of sufficient magnitude to provide sufficient sink-source mismatch and cause conduction block of the normal action potential because the safety factor for conduction is large; that is, there is a large excess of activating current over the amount required for propagation. However, when the action potential is abnormal, the unexcited area has decreased excitability (e.g., in the setting of acute ischemia), or both, anatomical impediments can result in conduction block.

Anisotropy and Reentry

The anisotropic cellular structure of the myocardium is important for the understanding of normal propagation and arrhythmogenesis. Structural anisotropy can relate to cell shape and to the cellular distribution pattern of proteins involved in impulse conduction, such as gap junction connexins and membrane ion channels. The anisotropic architecture of most myocardial regions, consisting of elongated cells forming strands and layers of tissue, leads to a dependence of propagation velocity on the direction of impulse spread.^{27,54} In normal ventricular myocardium, conduction in the direction parallel to the long axis of the myocardial fiber bundles

is approximately three to five times more rapid than that in the transverse direction. This is attributable principally to the lower resistivity of myocardium in the longitudinal versus the transverse direction; hence, intercellular current flow occurs primarily at the cell termini (although propagation also occurs transversely). As discussed previously, the gap junctions of the intercalated discs form a major source of intercellular resistance to current flow between fiber bundles. Therefore, the structure of the myocardium that governs the extent and distribution of these gap junctions has a profound influence on axial resistance and conduction.⁵⁵

CELLULAR COUPLING: GAP JUNCTIONAL ORGANIZATION

The anisotropic conductive properties of ventricular myocardium are dependent on the geometry of the interconnected cells and the number, size, and location of the gap junction channels between them. Additionally, gap junctions vary in their molecular composition, degree of expression, and distribution pattern, whereby each of these variations can contribute to the specific propagation properties of a given tissue in a given species. Tissue-specific connexin expression and gap junction spatial distribution, as well as the variation in the structural composition of gap junction channels, allow for a greater versatility of gap junction physiological features and enable disparate conduction properties in cardiac tissue. The myocytes of the sinus node and AVN are equipped with small, sparse, dispersed gap junctions containing Cx45, a connexin that forms low conductance channels, thus underlying the relatively poor intercellular coupling in nodal tissues, a property that is linked to slowing of conduction. In contrast, ventricular muscle expresses predominantly Cx43 and Cx45, which have larger conductance. Atrial muscle and Purkinje fibers express all three cardiac connexins.

Alterations in distribution and function of cardiac gap junctions are associated with conduction delay or block. Inactivation of gap junctions decreases transverse conduction velocity to a greater degree than longitudinal conduction, thereby resulting in exaggeration of anisotropy and providing a substrate for reentrant activity and increased susceptibility to arrhythmias.^{54,59}

MYOCYTE PACKING AND TISSUE GEOMETRY

Discontinuities in myocardial architecture exist at several levels. In addition to discontinuities imposed by cell borders, microvessels and connective tissue sheets separating bundles of excitable myocytes can act as resistive barriers. A propagating impulse is expected to collide with such barriers and travels around them wherever it encounters excitable tissue.⁴⁸

In some regions of the myocardium (e.g., the papillary muscles), connective tissue septa subdivide the myocardium into unit bundles composed of 2 to 30 cells surrounded by a connective tissue sheath.⁶ Within a unit bundle, cells are tightly connected or coupled to each other longitudinally and transversely through intercalated discs that contain the gap junctions and are activated uniformly and synchronously as an impulse propagates along the bundle. Adjacent unit bundles also are connected to each other. Unit bundles are coupled better in the direction of the long axis of its cells and bundles, because of the high frequency of the gap junctions within a unit bundle, than in the direction transverse to the long axis, because of the low frequency of interconnections between the unit bundles. This is reflected as a lower axial resistivity in the longitudinal direction than in the transverse direction in cardiac tissues composed of many unit bundles. Additionally, anisotropy on a macroscopic scale can influence conduction at sites at which a bundle of cardiac fibers branches or separate bundles will coalesce. Marked slowing can occur when there is a sudden change in the fiber direction, causing an abrupt increase in the effective axial resistivity. Conduction block, which sometimes can be unidirectional, can occur at such junction sites, particularly when membrane excitability is reduced.

UNIFORM VERSUS NONUNIFORM ANISOTROPY

Uniform anisotropy is characterized by smooth wavefront propagation in all directions and measured conduction velocity changes monotonically on moving from fast (longitudinal) to slow (transverse) axes, thus indicating relatively tight coupling between groups of fibers in all directions. However, this definition is based on the characteristics of activation at a macroscopic level, where the spatial resolution encompasses numerous myocardial cells and bundles, and therefore it describes the behavior of the myocardial syncytium. In contrast, when the three-dimensional network of cells is broken down into linear single-cell chains, gap junctions can be shown to limit axial current flow and induce saltatory conduction because of the recurrent increases in axial resistance at the sites of gap junctional coupling; that is, conduction is composed of rapid excitation of individual cells followed by a transjunctional conduction delay. In two- and three-dimensional tissue, these discontinuities disappear because of lateral gap junctional coupling, which serves to average local small differences in activation times of individual cardiomyocytes at the excitation wavefront.^{49,55}

In multicellular tissue, saltatory conduction reappears only under conditions of critical gap junctional uncoupling, in which it leads to a functional unmasking of the cellular structure and induces ultraslow and meandering conduction, well known to be a key ingredient in arrhythmogenesis.⁴⁹ Change in the characteristics of anisotropic propagation at the macroscopic scale from uniform to nonuniform strongly predisposes to reentrant arrhythmias. Nonuniform anisotropy has been defined as tight electrical coupling between cells in the longitudinal direction but uncoupling to the lateral gap junctional connections. Therefore, there is disruption of the smooth transverse pattern of conduction characteristic of uniform anisotropy that results in a markedly irregular sequence or zigzag conduction, producing the fractionated extracellular electrograms characteristic of nonuniform anisotropic conduction (Fig. 3-18). In nonuniformly anisotropic muscle, there also can be an abrupt transition in conduction velocity from the fast longitudinal direction to the slow transverse direction, unlike the case with uniform anisotropic muscle, in which intermediate velocities occur between the two directions.

Nonuniform anisotropic properties can exist in normal cardiac tissues secondary to separation of the fascicles of muscle bundles in the transverse direction by fibrous tissue that proliferates with aging to form longitudinally oriented insulating boundaries (e.g., crista terminalis, interatrial band in adult atria, or ventricular papillary muscle). Similar connective tissue septa cause nonuniform anisotropy in pathological situations such as chronic ischemia or a healing MI, in which fibrosis in the myocardium occurs (see Fig. 3-18).^{6,55}

Mechanism of Unidirectional Block in the Reentrant Circuit

Unidirectional block occurs when an impulse cannot conduct in one direction along a bundle of cardiac fibers but can conduct in the opposite direction. As mentioned earlier, this condition is necessary for the occurrence of classic reentrant rhythms. Several mechanisms, involving active and passive electrical properties of cardiac cells, can cause unidirectional block.²⁹

INHOMOGENEITY OF MEMBRANE EXCITABILITY AND REFRACTORINESS

Unidirectional block develops when the activation wavefront interacts with the repolarization phase (tail) of a preceding excitation wave. There is a critical or vulnerable window during the relative refractory period of a propagating action potential within which unidirectional block occurs. When a premature stimulus is delivered outside this window, the induced action potential propagates or blocks in both directions; specifically, a stimulus delivered too early fails to induce a propagating action potential in either

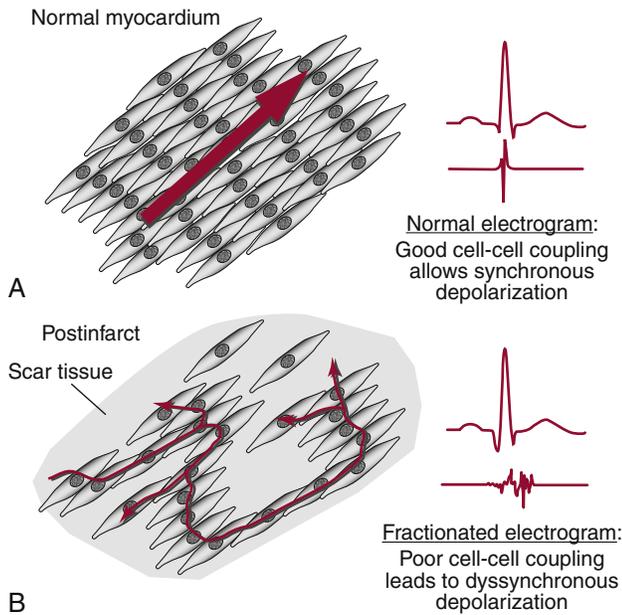

FIGURE 3-18 Effect of scar on electrical propagation. **A**, A homogeneous sheet of myocardium conducts an electrical wavefront rapidly, with synchronous activation of a large number of cells that leads to a sharp electrogram. **B**, Myocardial scarring produces disordered propagation, resulting in a low-amplitude electrogram, with multiple fragmented peaks.

direction (bidirectional block), whereas a late stimulus results in bidirectional conduction (no block). In contrast, when a stimulus is applied within the vulnerable window, the induced action potential propagates incrementally in the retrograde direction because the tissue is progressively more recovered as the distance from the window increases in this direction, but it blocks in the anterograde direction following a short distance of decremental conduction because the tissue is progressively less excitable as the distance from the window increases in this direction.²⁷

The size of the vulnerable window provides an index of the vulnerability to the development of reentrant arrhythmias. Therefore, the probability that a premature stimulus will fall inside the window and induce reentry is high when the vulnerable window is large. In contrast, precise timing of a premature stimulus is required to induce reentry in a small window, and the probability of such an event is low. In normal tissue, the vulnerable window is very small, and inducibility of unidirectional block and reentry is negligible. The width of the vulnerable window can be affected by changes in the availability of Na^+ channels for depolarization, cell-to-cell coupling, and repolarizing I_K . Additionally, the size of the vulnerable window can be widened (and reentry facilitated) by factors that increase the spatial inhomogeneity of refractoriness or decrease cellular coupling via gap junctions.

Unidirectional conduction block in a reentrant circuit also can be persistent and independent of premature activation, in which case it often occurs in a region of depressed and heterogeneous excitability (as occurs in acute ischemia); this leads to a widening of the vulnerable window. Asymmetry in excitability, which can occur because of asymmetrical distribution of a pathological event, can lead to an abrupt rise in the threshold for excitation in one direction and to a more gradual rise in the other. Conduction fails when the wavefront encounters the least depressed site first and is successful in the direction in which it encounters the most depressed site first. Additionally, impulses are conducted more easily from a rapidly conducting tissue to a slowly conducting tissue than in the opposite direction.²⁹

Local dispersion of refractory periods is a normal feature of ventricular myocardium. Critical increases in the dispersion of refractoriness, the difference between the shortest and longest refractory periods, can result in the local widening of the vulnerability

window and an increased probability for the generation of unidirectional block and reentry.^{6,27} Increased heterogeneity of repolarization and dispersion of refractoriness can be caused by acute or prolonged ischemia, the long QT syndrome, or electrical remodeling in the setting of ventricular hypertrophy and failure and in the setting of MI. When differences in the duration of the refractory periods occur in adjacent areas, conduction of an appropriately timed premature impulse can be blocked in the region with the longest refractory period, which then becomes a site of unidirectional block, whereas conduction continues through regions with a shorter refractory period.⁶

ANISOTROPY AND UNIDIRECTIONAL BLOCK

The anisotropic properties of cardiac muscle can contribute to the occurrence of unidirectional block.⁶ As mentioned earlier, in the anisotropic muscle, the safety factor for conduction is lower in the longitudinal direction of rapid than in the transverse direction of slow conduction. The low safety factor longitudinally is a result of a large current load on the membrane associated with the low axial resistivity and a large membrane capacitance in the longitudinal direction. This low safety factor can result in a preferential conduction block of premature impulses in the longitudinal direction while conduction in the transverse direction continues. The site of block in the longitudinal direction can become a site of unidirectional block that leads to reentry.⁶ In contrast to the propensity of premature impulses to block in the longitudinal direction in nonuniformly anisotropic myocardium because of the decreased depolarizing current and low safety factor, when coupling resistance between cells is increased, conduction of all impulses will block first in the transverse direction. Preferential block in this direction occurs because an increase in coupling resistance will reduce the safety factor below the critical level needed to maintain transverse conduction before the safety factor for longitudinal conduction is reduced to this critical level.^{6,55}

DISCONTINUITIES IN TISSUE STRUCTURE AND GEOMETRY

Geometric factors related to tissue architecture also can influence impulse conduction and, under certain conditions, lead to unidirectional block.²⁷ Structural discontinuities exist in the normal heart in the form of trabeculations of the atrial and ventricular walls, sheets interconnected by small trabeculae, or myocardial fibers with different diameters packed in a connective tissue matrix. Structural discontinuities can also be secondary to pathological settings, such as the connective tissue septa characteristic of aging, infarcted, hypertrophic, and failing myocardium. The propagating excitation wave is expected to interact with these normal and abnormal structural discontinuities. These structural features influence conduction by affecting the axial currents that flow ahead of the propagating wavefront.²⁷ Therefore, an impulse conducting in one direction can encounter a different sequence of changes in fiber diameter, branching, and frequency and distribution of gap junctions than it does when traveling in the opposite direction. The configuration of pathways in each direction is not the same.

Indications

Invasive electrophysiological (EP) testing involves recording a portion of cardiac electrical activity and programmed cardiac electrical stimulation via multipolar catheter electrodes positioned percutaneously strategically at various locations within the cardiac chambers. EP testing is used predominantly in patients with suspected or documented cardiac arrhythmias when the precise EP diagnosis is required for management decisions or when catheter ablation is planned. Additionally, EP testing is of value in selected groups of patients for stratification of risk of life-threatening arrhythmias. The role of EP testing in specific cardiac electrical and structural cardiac diseases is discussed in subsequent chapters.

Periprocedural Management

Preprocedure Evaluation

Heart failure, myocardial ischemia, and electrolyte abnormalities should be treated and adequately controlled before any invasive EP testing is undertaken. Patients with critical aortic stenosis, severe hypertrophic cardiomyopathy, left main or severe three-vessel coronary artery disease, or decompensated heart failure are at higher than average risk of complications. Induction of sustained tachyarrhythmias in these patients can cause severe deterioration. Anticoagulation to achieve an international normalized ratio (INR) in the therapeutic range (2.0 to 3.0) for 4 weeks before the procedure, transesophageal echocardiography (to exclude the presence of intracardiac thrombus), or both, is required before studying patients who have persistent atrial fibrillation (AF) and atrial flutter (AFL) who may have sinus rhythm restored intentionally or inadvertently (i.e., cardioversion of ventricular tachycardia [VT]).

Antiarrhythmic Drugs

Antiarrhythmic drugs are usually, but not always, stopped for at least five half-lives prior to EP testing. In selected cases, antiarrhythmic drugs can be continued if an arrhythmic event occurred while the patient was taking a specific agent.

Consent

Patients generally are not as familiar with EP procedures as they are with other invasive cardiac procedures, such as coronary angiography. Therefore, patient education is an essential part of the

procedure. The patient should be informed about the value of the EP study, its risks, and the expected outcome. Patients should also have a realistic idea of the benefit that they can derive from undergoing EP studies, including the possibility that the study result can be negative or equivocal.

Defibrillator Pads

A functioning cardioverter-defibrillator should be available at the patient's side throughout the EP study. Using preapplied adhesive defibrillator pads avoids the need to disrupt the sterile field in the event that electrical defibrillation or cardioversion is needed during the procedure. Biphasic devices are more effective than devices with monophasic waveforms.

Arterial Line

Although accurate monitoring of blood pressure is vital during any invasive procedure, indwelling arterial pressure monitoring lines are not used routinely in most EP laboratories. Automated cuff blood pressure devices are usually adequate. However, invasive blood pressure monitoring is generally used in unstable patients and when transseptal left atrial (LA) access is planned.

Sedation

Many patients benefit from mild sedation. Longer procedures and ablations are now routinely performed using intravenous conscious sedation. The combination of a benzodiazepine (most commonly midazolam) and a narcotic (e.g., fentanyl) is typically used. Propofol is used in some EP laboratories. Bispectral analysis of brain electrical activity is occasionally used for monitoring the depth and safety of sedation. In certain situations, especially when mapping and ablation of an automatic or triggered-activity tachycardia are expected, sedation can suppress the arrhythmic activity and delay or preclude the mapping-ablation procedure. In such cases, avoiding sedation is advisable until inducibility of the tachycardia is ensured.

Urinary Problems

Urinary retention can occur during lengthy EP procedures, particularly in combination with sedation, fluid administration, and tachycardia-related diuresis. When such situations are anticipated, it is useful to insert a urinary drainage catheter before the procedure.

Oxygen and Carbon Dioxide Monitoring

Monitoring of oxygen saturation is used routinely. Exhaled carbon dioxide monitors also can be useful in preventing hypercapnia in patients receiving supplemental oxygen, because oxygen saturation can be misleadingly high.

Anticoagulation

Periprocedural anticoagulation for catheter ablation of persistent AFL or AF is necessary to minimize thromboembolic stroke risk; LA stunning and increased spontaneous echo contrast within the LA can occur following cardioversion or ablation of these arrhythmias. Similarly, patients with mechanical valvular prosthesis require uninterrupted anticoagulation. A perception of increased bleeding risks of invasive procedures in patients taking therapeutic warfarin doses led many operators to adopt a “bridging” strategy of conversion to enoxaparin to allow ablation and subsequent hemostasis to be performed during a pause in anticoagulation.¹ This strategy involves discontinuation of warfarin at least 3 to 5 days prior to ablation, and starting heparin or enoxaparin after cessation of warfarin until the evening prior to the ablation procedure. Both enoxaparin and warfarin are then reinitiated within 4 to 6 hours after ablation and sheath removal, and enoxaparin is maintained until an optimal INR level is achieved.

An alternative strategy of uninterrupted oral anticoagulation during these procedures was found to be safe and feasible and more cost-effective for ablation of typical AFL or AF without increasing hemorrhagic complications. However, INR testing is required on the day of the procedure to confirm therapeutic anticoagulation. Transesophageal echocardiography is performed in patients with a subtherapeutic INR in the 3 weeks prior to the procedure. Another potential advantage of this strategy is the ability to reverse warfarin effects rapidly in the setting of a bleeding complication (e.g., pericardial bleeding) by using synthetic clotting factor concentrates or fresh frozen plasma infusion, whereas enoxaparin effects remain difficult to reverse; protamine has only a partial effect on its action. This anticoagulation strategy can potentially be used routinely for EP studies and ablation of right-sided arrhythmias for which anticoagulation is required.²⁻⁴

Catheterization Techniques

Electrode Catheters

Electrode catheters are used during EP testing for recording and pacing. These catheters consist of insulated wires; at the distal tip of the catheter, each wire is attached to an electrode, which is exposed to the intracardiac surface. At the proximal end of the catheter, each wire is attached to a plug, which can be connected to an external recording device. Electrode catheters are generally made of woven Dacron or newer synthetic materials, such as polyurethane. The Dacron catheters have the advantage of stiffness, which helps maintain catheter shape with enough softness at body temperature to allow formation of loops. Catheters made of synthetic materials cannot be easily manipulated and change shape within the body, but they are less expensive and can be made smaller. Some manufacturers use braided metal strands to enhance torque control.

Electrode catheters come in different sizes (3 to 8 Fr). In adults, sizes 5, 6, and 7 Fr catheters are the most commonly used. Recordings derived from electrodes can be unipolar (one pole) or bipolar (two poles). The electrodes are typically 1 to 2 mm in length. The interelectrode distance can range from 1 to 10 mm or more. The greater the interelectrode spacing is on a conventional bipolar electrode, the more the recorded electrogram resembles a unipolar recording. Catheters with a 2- or 5-mm interelectrode distance are most commonly used.⁵

Many multipolar electrode catheters have been developed to facilitate placement of the catheter in the desired place and to

fulfill various recording requirements. Bipolar or quadripolar electrode catheters are used to record and pace from specific sites of interest within the atria or ventricles. These catheters come with a variety of preformed distal curve shapes and sizes (Fig. 4-1). Multipolar recording electrode catheters are placed within the coronary sinus (CS) or along the crista terminalis in the right atrium (RA). The Halo catheter is a multipolar catheter used to map atrial electrical activity around the tricuspid annulus during atrial tachycardias, as well as for locating right-sided bypass tracts (BTs) (Fig. 4-2). A decapolar catheter with a distal ring configuration (Lasso catheter) is used to record electrical activity from the pulmonary vein (PV; Fig. 4-3). Basket catheters capable of conforming to the chamber size and shape have also been used for mapping atrial and ventricular arrhythmias (Fig. 4-4). Special catheters are also used to record LA and left ventricular (LV) epicardial activity from the CS branches.⁵

Catheters can have a fixed or deflectable tip. Steerable catheters allow deflection of the tip of the catheter in one or two directions in a single plane; some of these catheters have asymmetrical bidirectional deflectable curves (Fig. 4-5).

FIGURE 4-4 Basket catheter (Constellation). (Courtesy of Boston Scientific, Boston.)

Ablation catheters have tip electrodes that are conventionally 4 mm long and are available in sizes up to 10 mm in length (Fig. 4-6). The larger tip electrodes on ablation catheters reduce the resolution of a map obtained using recordings from the distal pair of electrodes.

Catheter Positioning

The percutaneous technique is used almost exclusively. RA, His bundle (HB), and right ventricular (RV) electrograms are most commonly recorded using catheters inserted via a femoral vein. Some other areas (e.g., the CS) are more easily reached through the superior vena cava (SVC), although the femoral approach can be adequate in most cases. Insertion sites can also include the ante-cubital, jugular, and subclavian veins. Femoral arterial access can be required for mapping of the LV or mitral annulus or for invasive blood pressure monitoring. Occasionally, an epicardial approach is required to map and ablate certain VTs and BTs as well as the sinus node. For this purpose, the epicardial surface is accessed via the CS and its branches or percutaneously (subxiphoid puncture).⁶

Fluoroscopy is conventionally used to guide intracardiac positioning of the catheters. It is important to remember that catheters

FIGURE 4-6 Ablation catheters with different tip electrode sizes and shapes. Left to right, Peanut 8-mm, 2-mm, 4-mm, and 8-mm tip electrodes. (Courtesy of Boston Scientific, Boston.)

can be withdrawn without fluoroscopy, but they should always be advanced under fluoroscopy guidance. More recently, newer navigation systems have been tested to guide catheter positioning in an effort to limit radiation exposure (see Chap. 6).

Transcaval Approach

The modified Seldinger technique is used to obtain multiple venous accesses. The femoral approach is most common, but the subclavian, internal jugular, or brachial approaches may be used, most often for the placement of a catheter in the CS.⁶

The femoral access should be avoided in patients with any of the following: known or suspected femoral vein or inferior vena cava (IVC) thrombosis, active lower extremity thrombophlebitis or postphlebotic syndrome, groin infection, bilateral leg amputation, extreme obesity, or severe peripheral vascular disease resulting in nonpalpable femoral arterial pulse. IVC umbrella filters are not necessarily a contraindication to the femoral approach.

Typically, the RA, HB, and RV catheters are introduced via the femoral veins. It is advisable to use the left femoral vein for diagnostic EP catheters and to save the right femoral vein for potential ablation or mapping catheter placement, which then would be easier to manipulate because it would be on the side closer to the operator. Multiple venous punctures and single vascular sheaths may be used for the different catheters. Alternatively, a single triport 12 Fr sheath can be used to introduce up to three EP catheters (usually the RA, HB, and RV catheters). The CS catheter is frequently introduced via the right internal jugular or subclavian vein, but also via the femoral approach.

RIGHT ATRIAL CATHETER

A fixed-tip, 5 or 6 Fr quadripolar electrode catheter is typically used. The RA may be entered from the IVC or SVC. The femoral veins are the usual entry sites. Most commonly, stimulation and recording

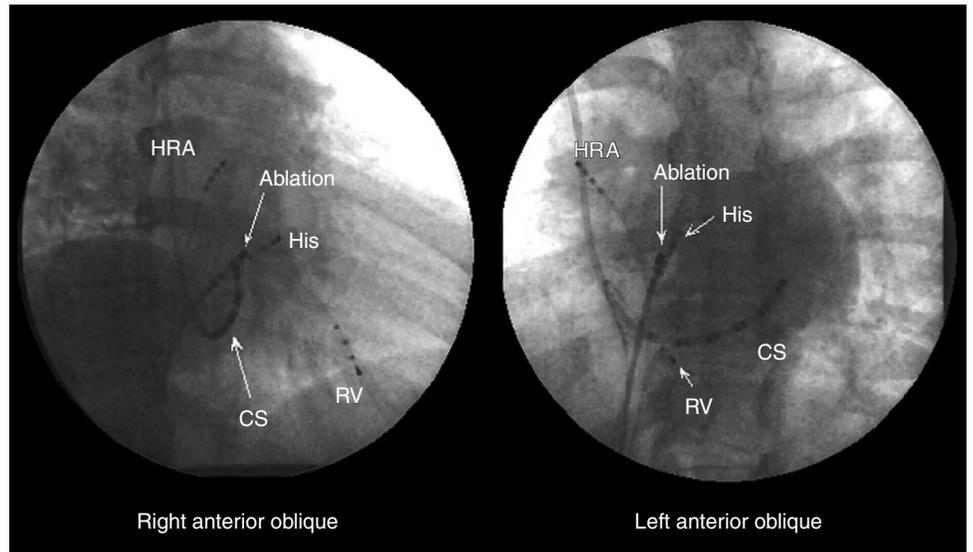

FIGURE 4-7 Fluoroscopic views of catheters in study for supraventricular tachycardia (superoparaseptal bypass tract ablation). Catheters are labeled HRA (high right atrium), right ventricle (RV), and coronary sinus (CS); the CS catheter was inserted from a jugular venous approach.

from the RA is performed by placing the RA catheter tip at the high posterolateral wall at the SVC-RA junction in the region of the sinus node or in the RA appendage (Fig. 4-7).

RIGHT VENTRICULAR CATHETER

A fixed-tip, 5 or 6 Fr quadripolar electrode catheter is typically used. All sites in the RV are accessible from any venous approach. The RV apex is most commonly chosen for stimulation and recording because of stability and reproducibility (see Fig. 4-7).

HIS BUNDLE CATHETER

A fixed- or deflectable-tip, 6 Fr quadripolar electrode catheter is typically used. The catheter is passed via the femoral vein into the RA and across the tricuspid annulus until it is clearly in the RV (under fluoroscopic monitoring, using the right anterior oblique [RAO] view; see Fig. 4-7). It is then withdrawn across the tricuspid orifice while maintaining a slight clockwise torque for good contact with the septum until a His potential is recorded. Initially, a large ventricular electrogram can be observed, then, as the catheter is withdrawn, the right bundle branch (RB) potential can appear (manifesting as a narrow spike less than 30 milliseconds before the ventricular electrogram). When the catheter is further withdrawn, the atrial electrogram appears and grows larger. The His potential usually appears once the atrial and ventricular electrograms are approximately equal in size and is manifest as a biphasic or triphasic deflection interposed between the local atrial and ventricular electrograms. If the first pass was unsuccessful, the catheter should be passed again into the RV and withdrawn with a slightly different rotation. If, after several attempts, a His potential cannot be recorded using a fixed-tip catheter, the catheter should be withdrawn and reshaped, or it may be exchanged with a deflectable-tip catheter. Once the catheter is in place, a stable recording can usually be obtained. Occasionally, continued clockwise torque on the catheter shaft is required to obtain a stable HB recording, which can be accomplished by looping the catheter shaft remaining outside the body and fixing the loop by placing a couple of towels on it, or by twisting the connection cable in the opposite direction so that it maintains a gentle torque on the catheter.

When the access is from the SVC, it is more difficult to record the His potential because the catheter does not lie across the superior margin of the tricuspid annulus. In this case, a deflectable-tip catheter is typically used, advanced into the RV, positioned near the HB region by deflecting the tip superiorly to form a J shape, and then withdrawing the catheter so that it lies across the superior margin of the tricuspid annulus. Alternatively, the catheter can be

looped in the RA (“figure-of-6” position); then the body of the loop is advanced into the RV so that the tip of the catheter is pointing toward the RA and lying on the septal aspect of the RA. Gently withdrawing the catheter can increase the size of the loop and allow the catheter tip to rest on the HB location.

Recording of the HB electrogram can also be obtained via the retrograde arterial approach. Using this approach, the catheter tip is positioned in the noncoronary sinus of Valsalva (just above the aortic valve) or in the LV outflow tract (LVOT), along the interventricular septum (just below the aortic valve).

CORONARY SINUS CATHETER

A femoral, internal jugular, or subclavian vein may be used. It is easier to cannulate the CS using the right internal jugular or left subclavian vein versus the femoral vein because the CS valve is oriented anterosuperiorly and, when prominent, can prevent easy access to the CS from the femoral venous approach. A fixed-tip, 6 Fr decapolar electrode catheter is typically used for access from the SVC, whereas a deflectable-tip catheter is preferred for CS access from the femoral veins.

The standardized RAO and left anterior oblique (LAO) fluoroscopic views are used to guide placement of catheters in the CS. Although the CS cannot be directly visualized with standard fluoroscopy, the epicardial fat found in the posteroseptal space just posterior to the CS os can be visualized as a characteristic radiolucency on cine fluoroscopy in the RAO projection, where the cardiac and diaphragmatic silhouettes meet.⁷

When cannulating the CS from the SVC approach, the LAO view is used, the catheter tip is directed to the left of the patient, and the catheter is advanced with some clockwise torque to engage the CS os; electrodes should resemble rectangles rather than ovals when the catheter tip is properly oriented to advance into the CS. Once the CS os is engaged, the catheter is further advanced gently into the CS, so that the most proximal electrodes lie at the CS os (see Fig. 4-7).

During cannulation of the CS from the IVC approach, the tip of the catheter is first placed into the RV, in the RAO fluoroscopy view, and flexed downward toward the RV inferior wall (Video 2). Subsequently, the catheter is withdrawn until it lies at the inferoseptal aspect of the tricuspid annulus. In the LAO or RAO view, the catheter is then withdrawn gently with clockwise rotation until the tip of the catheter drops into the CS os. Afterward, the catheter is advanced into the CS concomitantly with gradual release of the catheter curve (Fig. 4-8). Alternatively, the tip of the catheter is directed toward the posterolateral RA wall and advanced with a tight curve to form a loop in the RA, in the LAO view, with the tip directed toward the

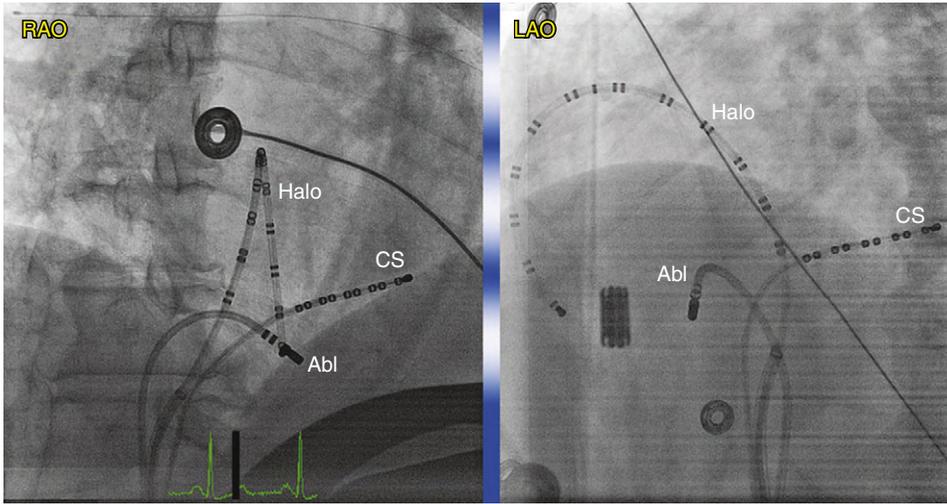

FIGURE 4-8 Right anterior oblique (RAO) and left anterior oblique (LAO) fluoroscopic views of catheters in a study of typical atrial flutter. A 20-pole Halo catheter is positioned along the tricuspid annulus. The coronary sinus (CS) catheter was introduced from a femoral venous approach. The ablation catheter (Abl) is at the cavotricuspid isthmus.

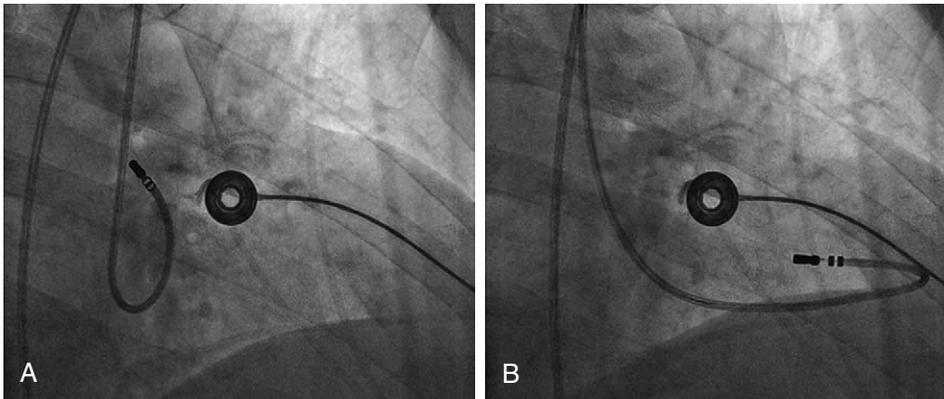

FIGURE 4-9 Right anterior oblique (RAO) fluoroscopic views of a mapping-ablation catheter introduced into the left ventricle (LV) via the retrograde transaortic approach. In a 30-degree RAO view, the curved catheter (A) is prolapsed across the aortic valve into the LV (B).

inferomedial RA. The tip is then advanced with gentle up-down, right-left manipulation using the LAO and RAO views to cannulate the CS. In the RAO view, the atrioventricular (AV) fat pad (containing the CS) appears as more radiolucent than surrounding heart tissue.

When attempting CS cannulation, the catheter can enter the RV, and premature ventricular complexes (PVCs) or VT can be observed. Catheter position in the RV outflow tract (RVOT) can be misleading and simulate a CS position. Confirming appropriate catheter positioning in the CS can be achieved by fluoroscopy and recorded electrograms. In the LAO view, further advancement in the CS directs the catheter toward the left heart border, where it curves toward the left shoulder. Conversely, advancement of a catheter lying in the RVOT leads to an upward direction of the catheter toward the pulmonary artery. In the RAO view, the CS catheter is directed posteriorly, posterior to the AV sulcus, whereas the RVOT position is directed anteriorly. Recording from the CS catheter shows simultaneous atrial and ventricular electrograms, with the atrial electrogram falling in the later part of the P wave, whereas a catheter lying in the RVOT records only a ventricular electrogram. The catheter can also pass into the LA via a patent foramen ovale, in which case it takes a straight course toward the left shoulder, and all recordings are atrial.

If used, the CS catheter should be placed first, because its positioning can be impeded by the presence of other catheters. It is also recommended that the CS catheter sheath be sutured to the skin to prevent displacement of the catheter during the course of the EP study.

Transaortic Approach

This approach is generally used for mapping the LV and mitral annulus (for VT and left-sided BTs). The right femoral artery is most commonly used. The mapping-ablation catheter is passed to the

descending aorta, and, in this position, a tight J curve is formed with the catheter tip before passage to the aortic root to minimize catheter manipulation in the arch. In a 30-degree RAO view, the curved catheter is advanced through the aortic valve with the J curve opening to the right, so the catheter passes into the LV oriented anterolaterally (Fig. 4-9; Video 3). The straight catheter tip must never be used to cross the aortic valve because of the risk of leaflet damage or perforation and also because the catheter tip can slip into the left or right coronary artery or a coronary bypass graft, thus mimicking entry to the LV and causing damage to these structures.

A long vascular sheath can provide added catheter stability. Anticoagulation should be started once the LV is accessed or before (intravenous heparin, a 5000-unit bolus followed by a 1000-unit infusion is usually used), to maintain the activated clotting time (ACT) between 250 and 300 seconds.

Transseptal Approach

Mapping and ablation in the LA are performed through a transseptal approach. Knowledge of septal anatomy and its relationship with adjacent structures is essential to ensure safe and effective access to the LA. Many apparent septal structures are not truly septal. The true interatrial septum is limited to the floor of the fossa ovalis, the flap valve, and the anteroinferior rim of the fossa. Therefore, the floor of the fossa (with an average diameter of 18.5 ± 6.9 mm [vertically] and 10.0 ± 2.4 mm [horizontally] and 2 mm thickness) is the target for atrial septal crossing. The area between the superior border of the fossa and the mouth of the SVC is an infolding of the atrial wall filled with adipose tissue. Although this area is often referred to as the septum secundum, it is not really a true septum, and puncture in this region would lead to exiting of the heart. The infolded groove ends at the superior margin (superior rim) of the

fossa ovalis. Anterior and superior to the fossa ovalis, the RA wall overlies the aortic root. Advancing the transseptal needle in this area can puncture the aorta.

A search for a patent foramen ovale, which is present in 15% to 20% of normal subjects, is initially performed. If one is absent, atrial septal puncture is performed. The challenge for a successful atrial septal puncture is positioning the Brockenbrough needle at the thinnest aspect of the atrial septum, the membranous fossa ovalis, guided by fluoroscopy or intracardiac echocardiography (ICE; Videos 4, 5, and 6).

Although fluoroscopy provides sufficient information to allow safe transseptal puncture in most cases, variations in septal anatomy, atrial or aortic root dilation, the need for multiple punctures, and the desired ability to direct the catheter to specific locations within the LA can make fluoroscopy an inadequate tool for complex LA ablation procedures. Intraoperative transesophageal echocardiography allows identification of the fossa ovalis and its relation to surrounding structures and provides real-time evaluation of the atrial septal puncture procedure, with demonstration of tenting of the fossa prior to entry into the LA and visualization of the sheath advancing across the septum (Video 7). However, the usefulness of transesophageal echocardiography is limited by the fact that the probe obstructs the fluoroscopic field, and it is impractical in the nonanesthetized patient. ICE, which provides similar information on septal anatomy, can be used for the conscious patient and does not impede fluoroscopy.

FLUOROSCOPY-GUIDED TRANSEPTAL CATHETERIZATION

Equipment required for atrial septal puncture includes the following: a 62-cm, 8 Fr transseptal sheath for LA cannulation (e.g., SR0, SL1, Mullins, or Agilis NxT Steerable sheath, St. Jude Medical, Minnetonka, Minn.), a 0.035-inch J guidewire, a 71-cm Brockenbrough needle (e.g., BRK, St. Jude Medical, Minnetonka, Minn.), and a 190-cm, 0.014-inch guidewire.

Venous access is obtained via the femoral vein, preferably the right femoral vein because it is closer to the operator. The sheath, dilator, and guidewires are flushed with heparinized saline. The transseptal sheath and dilator are advanced over a 0.035-inch J guidewire under fluoroscopy guidance into the SVC. The guidewire is then withdrawn, thus leaving the sheath and its dilator locked in place. The dilator within the sheath is flushed and attached to a syringe to avoid introduction of air into the RA.

Attention is then directed to preparing the transseptal needle. The Brockenbrough needle comes prepackaged with an inner stylet, which may be left in place to protect it as it is advanced within the sheath. Alternatively, the inner stylet may be removed and the needle connected to a pressure transducer line (pressure monitoring through the Brockenbrough needle will be required during the transseptal puncture); continuous flushing through the Brockenbrough needle is used while advancing the needle into the dilator. A third approach, when the use of contrast injection is planned, is to attach the Brockenbrough needle to a standard three-way stopcock via a freely rotating adapter. A 10-mL syringe filled with radiopaque contrast is attached to the other end of the stopcock while a pressure transducer line is attached to the third stopcock valve for continuous pressure monitoring. The entire apparatus should be vigorously flushed to ensure that no air bubbles are present within the circuit.

The Brockenbrough needle is advanced into the dilator until the needle tip is within 1 to 2 cm of the dilator tip. The needle tip must be kept within the dilator at all times, except during actual septal puncture. The curves of the dilator, sheath, and needle should be aligned so that they are all in agreement and not contradicting each other. The sheath, dilator, and needle assembly is then rotated leftward and posteriorly (usually with the Brockenbrough needle arrow pointing at the 3 to 6 o'clock position relative to its shaft) and retracted caudally as a single unit (while maintaining the relative positions of its components) to engage the tip of the dilator into the fossa ovalis. Under fluoroscopy monitoring (30-degree LAO

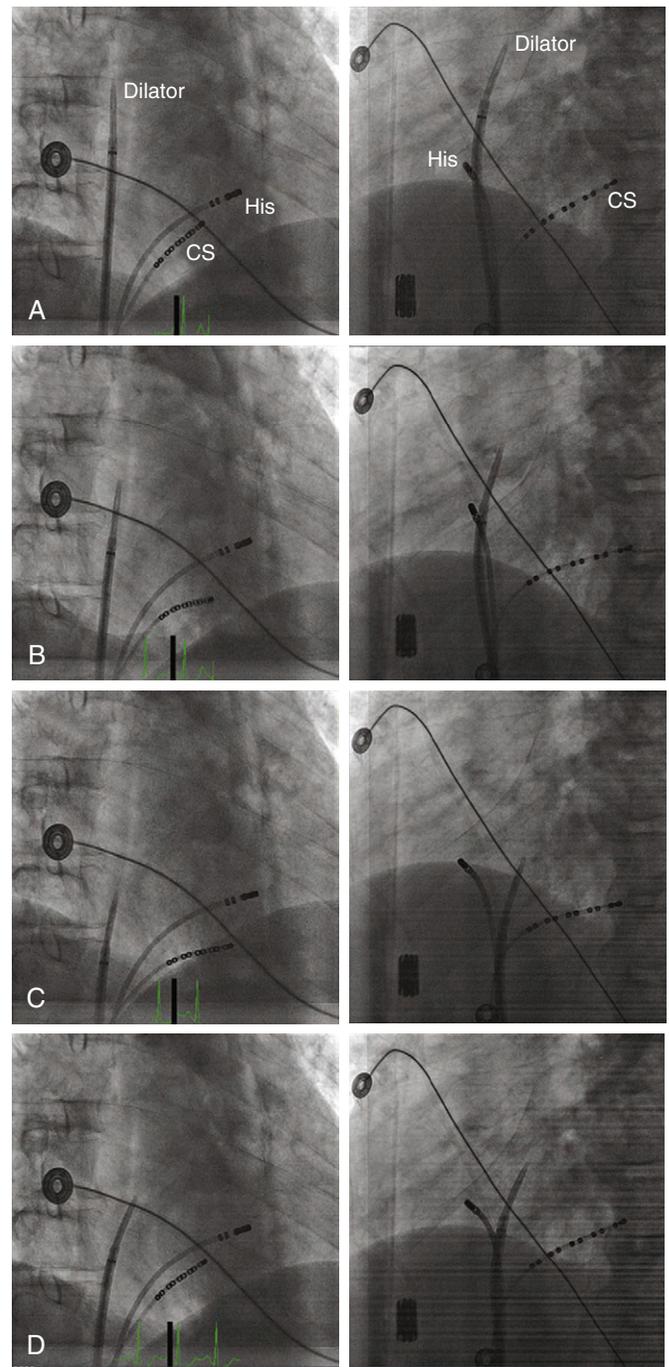

FIGURE 4-10 Right anterior oblique (RAO; left) and left anterior oblique (LAO; right) fluoroscopic views during transseptal catheterization. **A**, Initially, the transseptal sheath-dilator assembly is advanced into the superior vena cava. **B**, The transseptal assembly is withdrawn into the high right atrium. **C**, With further withdrawal, the dilator tip abruptly moves leftward, indicating passage over the limbus into the fossa ovalis at the level of the His bundle catheter. At the fossa ovalis, the dilator tip has an anteroposterior orientation in the RAO view and a leftward orientation in the LAO view. **D**, The transseptal assembly is advanced across the atrial septum. CS = coronary sinus.

view), the dilator tip moves slightly leftward on entering the RA and then leftward again while descending below the aortic root. A third abrupt leftward movement ("jump") below the aortic root indicates passage over the limbus into the fossa ovalis (Fig. 4-10). This jump generally occurs at the level of the HB region (marked by an EP catheter recording the HB potential). If the sheath and dilator assembly is pulled back farther than intended (i.e., below the level of the fossa and HB region), the needle should be withdrawn and

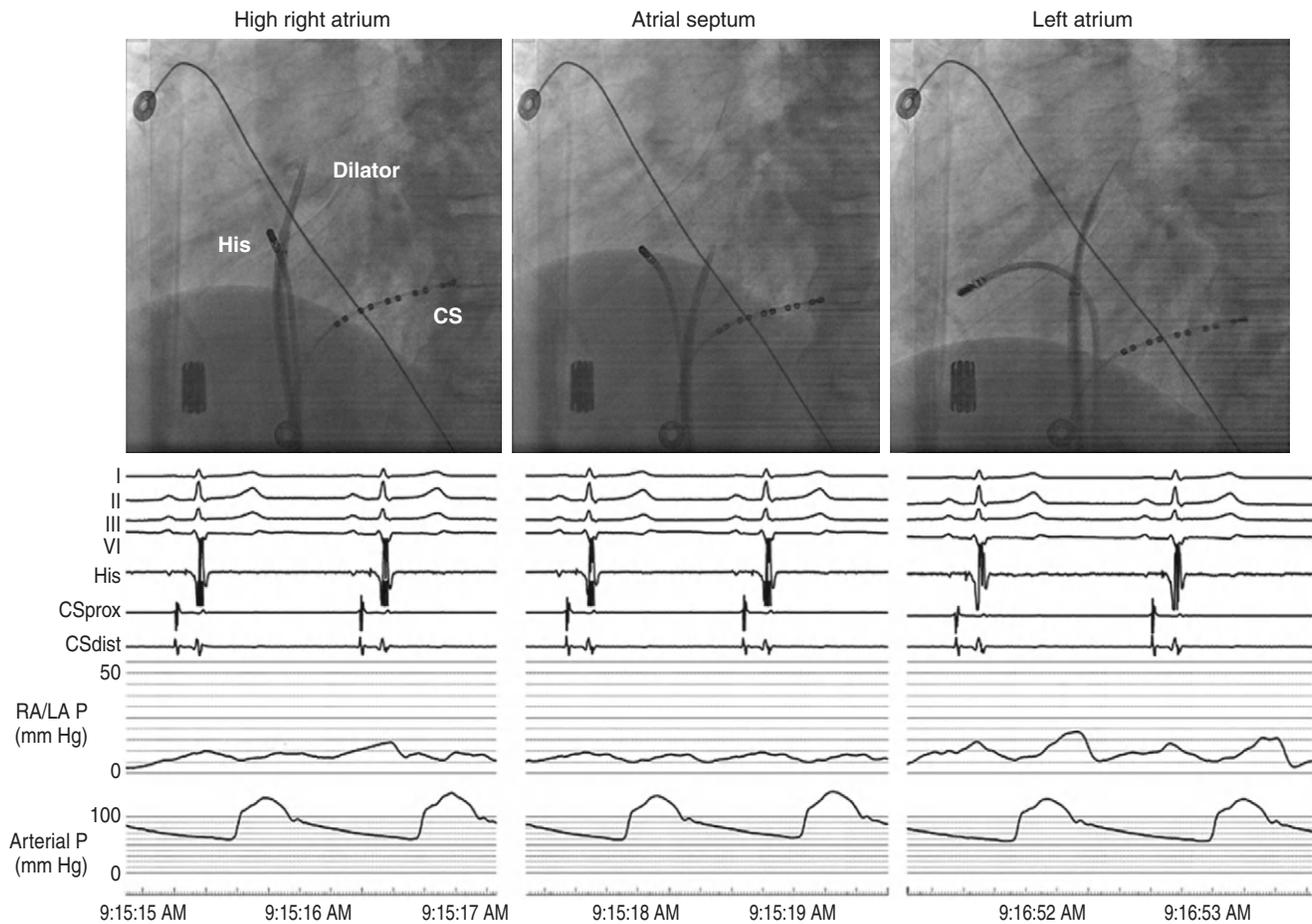

FIGURE 4-11 Left anterior oblique (LAO) fluoroscopic views and simultaneous electrical and pressure (P) recordings during transseptal catheterization. **Left**, The transseptal assembly is in the right atrium (RA), indicated by typical A and V waves of right-heart pressure tracing. **Middle**, The pressure waveform is dampened somewhat as the catheter tip abuts the septum. **Right**, The needle is across the atrial septum, and characteristic waves (V larger than A) are seen. CSdist = distal coronary sinus; CSprox = proximal coronary sinus; LA = left atrium.

the guidewire placed through the dilator into the SVC. The sheath and dilator assembly is then advanced over the guidewire into the SVC and repositioning attempted, as described earlier. The sheath and dilator assembly should never be advanced without the guidewire at any point during the procedure.

Several fluoroscopic markers are used to confirm the position of the dilator tip at the fossa ovalis. As noted, an abrupt leftward movement (jump) of the dilator tip below the aortic knob is observed as the tip passes under the muscular atrial septum onto the fossa ovalis (see Video 4). In addition, the posterior extent of the aortic root can be marked by a pigtail catheter positioned through the femoral artery in the noncoronary cusp or by the HB catheter (recording a stable proximal HB potential), which lies at the level of the fibrous trigone opposite and caudal to the noncoronary aortic cusp. When the dilator tip lies against the fossa ovalis, it is directed posteroinferiorly to the proximal HB electrode (or pigtail catheter) in the RAO view and to the left of the proximal HB electrode (or pigtail catheter) in the LAO view (see Fig. 4-10). Another method that can be used to ensure that the tip is against the fossa ovalis is injection of 3 to 5 mL of radiopaque contrast through the Brockenbrough needle to visualize the interatrial septum. The needle tip then can be seen tenting the fossa ovalis membrane with small movements of the entire transseptal apparatus. Typically, septal staining remains visible after contrast injection, which allows for real-time septal visualization while monitoring the pressure during transseptal puncture.

Once the position of the dilator tip is confirmed at the fossa ovalis, the needle, dilator, and sheath assembly is pushed slightly against the interatrial septum, and the needle is then briskly advanced to protrude outside the dilator in the LAO view during continuous pressure monitoring. If excessive force is applied without a

palpable “pop” to the fossa, then the Brockenbrough needle likely is not in proper position. After passage through the fossa ovalis and before advancing the dilator and sheath, an intraatrial position of the needle tip within the LA, rather than the ascending aorta or posteriorly into the pericardial space, needs to be confirmed. Recording an LA pressure waveform from the needle tip confirms an intraatrial location (Fig. 4-11). An arterial pressure waveform indicates intraaortic position of the needle. Absence of a pressure wave recording can indicate needle passage into the pericardial space or sliding up and not puncturing through the atrial septum. A second method is injection of contrast through the needle to assess the position of the needle tip. Opacification of the LA (rather than the pericardium or the aorta) verifies the successful transseptal access. Alternatively, passing a 0.014-inch floppy guidewire through the Brockenbrough needle into a left-sided PV (beyond the cardiac silhouette in the LAO fluoroscopy view) helps verify that needle tip position is within the LA (see Video 4). If the guidewire cannot be advanced beyond the fluoroscopic border of the heart, pericardial puncture should be suspected. In addition, aortic puncture should be suspected if the guidewire seems to follow the course of the aorta. In these situations, contrast should be injected to assess the position of the Brockenbrough needle before advancing the transseptal dilator. Sometimes, the guidewire enters the LA appendage rather than a PV; in this setting, a clockwise torque of the sheath and dilator assembly can help direct the guidewire posteriorly toward the ostium of the left superior or left inferior PV.

Once the position of the needle tip is confirmed to be in the LA, both the sheath and dilator are advanced as a single unit over the needle by using one hand while fixing the Brockenbrough needle in position with the other hand (to prevent any further

advancement of the needle). Preferably, the sheath and dilator assembly is advanced into the LA over a guidewire placed distally into a left-sided PV, which helps direct the path of the assembly as it enters the LA and minimize the risk of inadvertent puncture of the lateral LA wall. Once the dilator tip is advanced into the LA over the needle tip, the needle and dilator are firmly stabilized as a unit—to prevent any further advancement of the needle and dilator—and the sheath is advanced over the dilator into the LA. Once the transseptal sheath tip is within the LA, the dilator and needle are withdrawn slowly during continuous flushing through the needle or while suction is maintained through a syringe placed on the sheath side port to minimize the risk of air embolism and while fixing the sheath with the other hand to prevent dislodgment outside the LA. The sheath should be aspirated until blood appears without further bubbles; this usually requires aspiration of approximately 5 mL. The sheath is then flushed with heparinized saline at a flow rate of 3 mL/min during the entire procedure.

The mapping-ablation catheter is advanced through the sheath into the LA. Flexing the catheter tip and applying clockwise and counterclockwise torque to the sheath help confirm free movement of the catheter tip within the LA, rather than possibly in the pericardium. It is important to recognize that merely recording atrial electrograms does not confirm an LA catheter location because an LA recording can be obtained from the epicardial surface of the LA, from the RA, or even the aortic root.

When two transseptal accesses are required, the second access can be obtained through a separate transseptal puncture performed in a fashion similar to that described for the first puncture. Alternatively, the first transseptal puncture can be used for the second sheath. This technique entails passing a guidewire or thin catheter through the first transseptal sheath into the LA, preferably into the left inferior or superior PV, and then the sheath is pulled back into the RA. Subsequently, a deflectable tip catheter is used through the second long sheath to interrogate the fossa ovalis and to try to access the LA through the initial puncture site. Once this is accomplished, the first sheath is advanced back into the LA, and the guidewire is replaced with the mapping catheter. Alternatively, instead of using a deflectable catheter, the needle, dilator, and sheath assembly is advanced into the SVC and pulled back and positioned at the fossa ovalis (as described earlier for the first transseptal puncture). Once the tip of the dilator falls into the fossa ovalis, gentle manipulation of the assembly under biplane fluoroscopy guidance is performed until the dilator tip passes along the guidewire through the existing transseptal puncture, without advancing the needle through the dilator. The assembly is then advanced as a single unit into the LA.

An intravenous heparin bolus is administered just before or immediately after puncturing the atrial septum, followed by intermittent boluses or continuous heparin infusion to maintain an elevated ACT (more than 250 to 300 seconds).

INTRACARDIAC ECHOCARDIOGRAPHY–GUIDED TRANSEPTAL CATHETERIZATION

The intent of ICE-guided transseptal catheterization is to image intracardiac anatomy and identify the exact position of the distal aspect of the transseptal dilator along the atrial septum—in particular, to assess for tenting of the fossa ovalis with the dilator tip.

Two types of ICE imaging systems are currently available, the electronic phased-array ultrasound catheter and the mechanical ultrasound catheter.⁸ The electronic phased-array ultrasound catheter sector imaging system (AcuNav, Siemens Medical Solutions, Malvern, Pa.) uses an 8 or 10 Fr catheter that has a forward-facing 64-element vector phased-array transducer scanning in the longitudinal plane. The catheter has a four-way steerable tip (160-degree anteroposterior or left-right deflections). The catheter images a sector field oriented in the plane of the catheter. The mechanical ultrasound catheter radial imaging system (Ultra ICE, EP Technologies, Boston Scientific, San Jose, Calif.) uses a 9-MHz catheter-based ultrasound transducer contained within a 9 Fr (110-cm length)

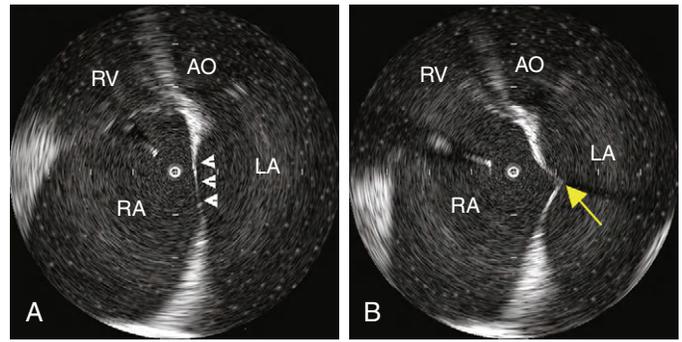

FIGURE 4-12 Intracardiac echocardiography (ICE)-guided transseptal puncture using the Ultra-ICE catheter. These ICE images, with the transducer placed in the right atrium (RA), show (A) the RA, fossa ovalis (arrowheads), left atrium (LA), and aorta (AO). B, The transseptal needle is properly positioned, with tenting (yellow arrow) against the midinteratrial septum at the fossa ovalis. RV= right ventricle.

catheter shaft. It has a single rotating crystal ultrasound transducer that images circumferentially for 360 degrees in the horizontal plane. The catheter is not freely deflectable.

When using the mechanical radial ICE imaging system, a 9 Fr sheath, preferably a long, preshaped sheath, for the ICE catheter is advanced via a femoral venous access. To enhance image quality, all air must be eliminated from the distal tip of the ICE catheter by flushing vigorously with 5 to 10 mL of sterile water. The catheter then is connected to the ultrasound console and advanced until the tip of the rotary ICE catheter images the fossa ovalis. Satisfactory imaging of the fossa ovalis for guiding transseptal puncture is viewed from the mid-RA (Fig. 4-12).⁸

The AcuNav ICE catheter is introduced under fluoroscopy guidance through a 23-cm femoral venous sheath. Once the catheter is advanced into the mid-RA with the catheter tension controls in neutral position (the ultrasound transducer oriented anteriorly and to the left), the RA, tricuspid valve, and RV are viewed. This is called the home view (Fig. 4-13A; see Video 5). Gradual clockwise rotation of a straight catheter from the home view allows sequential visualization of the aortic root and the pulmonary artery (see Fig. 4-13B), followed by the CS, the mitral valve, the LA appendage orifice, and a cross-sectional view of the fossa ovalis (see Fig. 4-13C and D). The mitral valve and interatrial septum are usually seen in the same plane as the LA appendage. Posterior deflection or right-left steering of the imaging tip in the RA, or both, is occasionally required to optimize visualization of the fossa ovalis; the tension knob (lock function) can then be used to hold the catheter tip in position. Further clockwise rotation beyond this location demonstrates images of the left PV ostia (see Fig. 4-13E). The optimal ICE image to guide transseptal puncture demonstrates adequate space behind the interatrial septum on the LA side and clearly identify adjacent structures, but it does not include the aortic root because it would be too anterior for the interatrial septum to be punctured safely. In patients with an enlarged LA, a cross-sectional view that includes the LA appendage is also optimal if adequate space exists behind the atrial septum on the LA side.⁸

The sheath, dilator, and needle assembly is introduced into the RA, and the dilator tip is positioned against the fossa ovalis, as described earlier. Before advancing the Brockenbrough needle, continuous ICE imaging should direct further adjustments in the dilator tip position until ICE confirms that the tip is in intimate contact with the middle of the fossa, confirms proper lateral movement of the dilator toward the fossa, and excludes inadvertent superior displacement toward the muscular septum and aortic valve. With further advancement of the dilator, ICE demonstrates tenting of the fossa (Fig. 4-14 and see Fig. 4-12). If the distance from the tented fossa to the LA free wall is small, minor adjustments in the dilator tip position can be made to maximize the space. The Brockenbrough needle is then advanced. With successful transseptal puncture, a palpable pop is felt, and sudden collapse of the tented

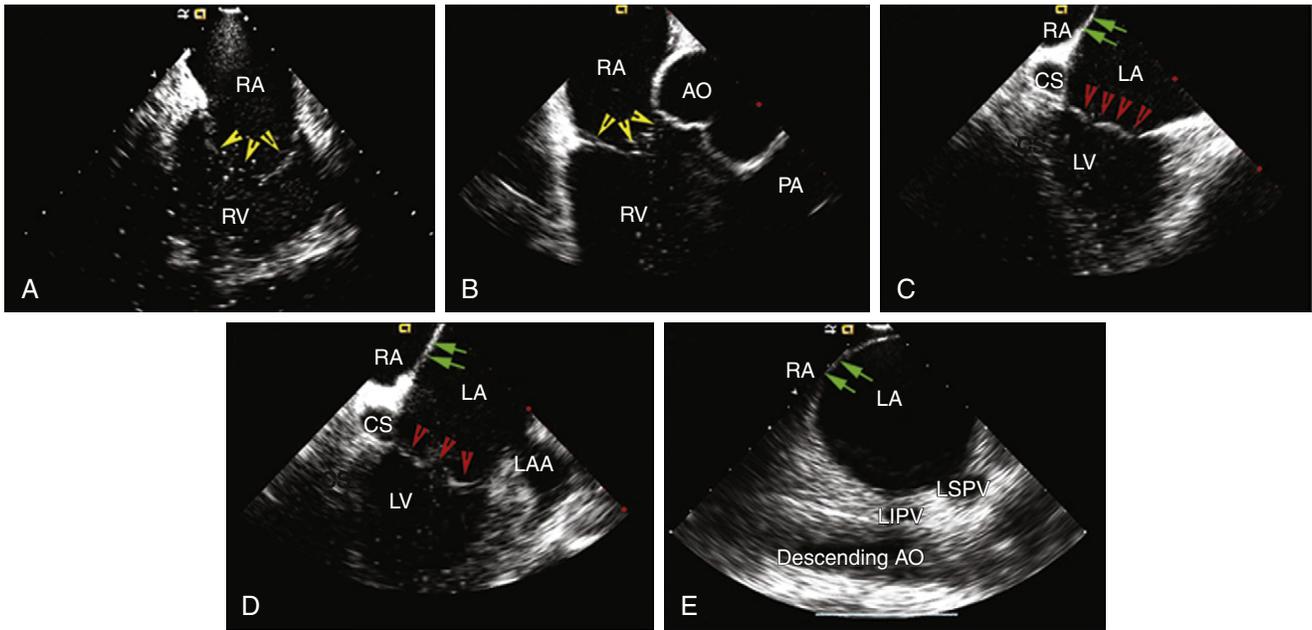

FIGURE 4-13 Phased-array intracardiac echocardiography (ICE) AcuNav serial images with the transducer placed in the middle right atrium (RA) demonstrate serial changes in tomographic imaging views following clockwise rotation of the transducer. Each view displays a left-right (L-R) orientation marker to the operator's left side (i.e., craniocaudal axis projects from image right to left). **A**, Starting from the home view, the RA, tricuspid valve (yellow arrowheads), and right ventricle (RV) are visualized. **B**, Clockwise rotation brings the aorta (AO) into view. PA = pulmonary artery. **C**, Further rotation allows visualization of the interatrial septum (green arrows), left atrium (LA), coronary sinus (CS), left ventricle (LV), and mitral valve (red arrowheads). **D**, Subsequently, the left atrium appendage (LAA) becomes visible. **E**, The ostia of the left superior pulmonary vein (LSPV) and left inferior PV (LIPV) can be visualized with further clockwise rotation. (Courtesy of AcuNav, Siemens Medical Solutions, Malvern, Pa.)

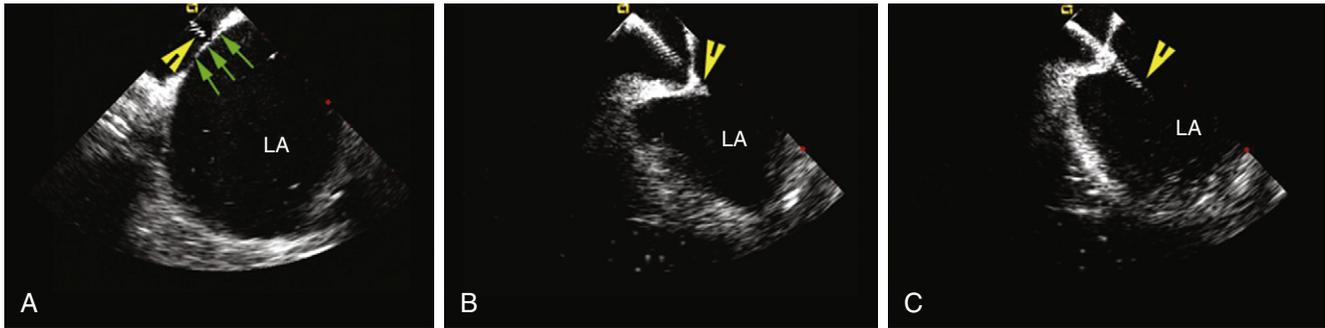

FIGURE 4-14 Phased-array intracardiac echocardiography (ICE)-guided transseptal puncture. **A**, These ICE images, with the transducer placed in the right atrium (RA), show a transseptal dilator tip (yellow arrowhead) lying against the interatrial septum (green arrows). **B**, With further advancement of the dilator, ICE demonstrates tenting of the interatrial septum at the fossa ovalis. **C**, Advancement of the transseptal needle is then performed, with the needle tip visualized in the left atrium (LA), and tenting of the interatrial septum is lost.

fossa is observed (see Fig 4-14). Advancement of the needle is then immediately stopped. Saline infusion through the needle is visualized on ICE as bubbles in the LA, thus confirming successful septal puncture (see Video 6). With no change in position of the Brockenbrough needle, the transseptal dilator and sheath are advanced over the guidewire into the LA, as described earlier.

ALTERNATIVE METHODS FOR DIFFICULT TRANSEPTAL CATHETERIZATION

In some cases, the conventional approach using a Brockenbrough needle sheath fails to pierce the septum because of the presence of a small fossa area, a thick interatrial septum, fibrosis and scarring of the septum from previous interventions, or an aneurysmal septum with excessive laxity. Applying excessive force to the needle, dilator, and sheath assembly against a resistant septum (which can be seen as bending and buckling of the assembly in the RA) can lead to building pressure of the needle tip on the septum, which can potentially lead to an uncontrolled sudden jump of the assembly once across the stiff or fibrotic fossa ovalis, thus perforating the

opposing lateral LA wall. Similarly, excessive tenting of the interatrial septum (beyond halfway into the LA) can bring it in close proximity to the lateral LA wall, so that the needle can potentially puncture the lateral LA wall once across the septum. Some of these difficulties can sometimes be overcome by manual reshaping of the curvature of the Brockenbrough needle tip, applying slight rotation on the needle and sheath assembly to puncture a different point on the fossa ovalis, using a sharper transseptal needle type (BRK-1 extra sharp), or utilizing a 0.014-inch, sharp-tipped, J-shaped transseptal guidewire (Safe Sept, Pressure Products, Inc., San Pedro, Calif.).⁹⁻¹³

Other techniques to facilitate transseptal puncture include radiofrequency (RF) perforation of the fossa ovalis and the application of pulses of electrocautery or RF energy to the proximal end of the Brockenbrough needle. Once the position of the dilator tip is confirmed at the fossa ovalis (under ICE guidance), the needle is advanced beyond the tip of the dilator in contact with the septum until resistance is met. RF energy (5 to 30 W for 1 to 11 seconds) can be applied through a conventional ablation catheter electrode brought manually in contact with the proximal hub

of the transseptal needle. Typically, the fossa is punctured almost instantaneously (within 1 to 2 seconds) following RF application. Alternatively, electrosurgical cautery (set to 15 to 20 W for a 1- to 2-second pulse of cut-mode cautery) is applied to the proximal hub of the needle as its tip is advanced out of the dilator. Importantly, the cautery should be initiated on the needle handle prior to pushing the needle tip beyond the dilator tip to help minimize the power needed to puncture the septum, and it should be stopped as soon as the needle is pushed out fully.¹⁴⁻¹⁶

Additionally, a specialized, electrically insulated RF-powered needle (Baylis Medical Company, Inc., Montreal) has been developed to facilitate transseptal puncture. The needle is connected to a proprietary RF generator (RFP-100 RF Puncture Generator, Baylis Medical), which delivers RF energy to the rounded, closed tip of the needle positioned at the interatrial septum. Once septal tenting is visualized on the ICE, RF energy is applied at 10 W for 2 seconds. The RF perforation generators apply a higher voltage for short durations, resulting in a high-energy electric field and an almost instantaneous temperature rise to 100°C, leading to steam popping and septal perforation with minimal collateral tissue damage. In contrast, conventional RF generators deliver a higher power with a lower voltage and impedance range for longer periods of time, with resulting thermal destruction of the local tissue around the needle tip, rather than perforation.^{17,18}

These methods help minimize pressure application to the needle as it crosses the septum and tenting of the septum, which can potentially reduce the chances of sudden advancement through the lateral LA as the needle crosses the septum. Nonetheless, the powered needle can potentially be more traumatic at the puncture site than a standard needle, and it is possible that the transseptal puncture site created with a powered needle is less likely to close spontaneously. Similarly, inadvertent cardiac perforation occurring in the setting of powered needles can potentially be associated with greater consequences. Whether RF is more likely to cause a thrombus at the puncture site compared with a standard needle is unknown.¹⁷⁻¹⁹

COMPLICATIONS OF ATRIAL TRANSEPTAL PUNCTURE

Injury to cardiac and extracardiac structures is the most feared complication. Because of its stiffness and large caliber, the transseptal dilator should never be advanced until the position of the Brockenbrough needle is confirmed with confidence. Advancing the dilator into an improper position can be fatal. Therefore, many operators recommend the use of ICE-guided transseptal puncture, especially for patients with normal atrial size.¹⁹

When the aorta is inadvertently punctured by the Brockenbrough needle—an arterial waveform is recorded from the needle tip and dye injected through the needle is carried away from the heart—the needle should be withdrawn back into the dilator. If the patient remains stable for 15 minutes and echocardiography shows no pericardial effusion, another attempt at LA access can be made. Advancing the dilator and sheath assembly into the aorta can lead to catastrophic consequences.

It is important to recognize that successful atrial septal puncture is a painless procedure for the patient. If the patient experiences significant discomfort, careful assessment should be made of the catheter and sheath locations (pericardial space, aorta).

Another potential complication is embolism of thrombus or air. To avoid air embolism, catheters must be advanced and withdrawn slowly so as not to introduce air into the assembly. Sheaths must be aspirated with a syringe on a stopcock to the amount of their volume (e.g., an 8 Fr sheath contains 5 mL when filled) to remove any retained air. Thromboembolic complications can be avoided by flushing all sheaths and guidewire with heparinized saline and maintaining the ACT at longer than 300 seconds. In addition, a guidewire should not be left in the LA for more than 1 minute, especially if no systemic heparin has been administered. Administration of heparin before, rather than after, the atrial septal puncture can also help reduce thromboembolism.¹⁹

Occasionally, ST segment elevation in the inferior ECG leads (with or without transient bradycardia or AV block) can occur following transseptal catheterization, potentially secondary to air embolism in coronary arteries, although a Bezold-Jarisch–like reflex mechanism can also be implicated.

Importantly, the presence of an LA thrombus is an absolute contraindication for transseptal catheterization. Additionally, caution should be used in the setting of the presence cardiac or thoracic malformation (e.g., congenital heart disease, kyphoscoliosis).

Transseptal catheterization is feasible and safe in most patients with atrial septal defect or patent foramen ovale repair. Nonetheless, because of the altered anatomical landmarks after repair, fluoroscopic guidance for transseptal puncture can be unreliable, and the procedure can be challenging. In these patients, an understanding of the method of repair and utilization of ICE guidance are essential.

In patients with atrial septal defect closure devices, puncture is preferably performed at the portion of the septum located inferior and posterior to the closure device and not through the device itself. In patients with a septal stitch or pericardial or Dacron patch, puncture can be achieved through the thickened septum or the patch. However, transseptal access is typically not achievable through a Gore-Tex patch (W.L. Gore & Associates, Flagstaff, Ariz.) because of its resistant texture; instead, puncture can be performed directly through neighboring native interatrial tissue. When the patch is wide, sufficient free septal tissue for transseptal puncture may not be available, in which setting transseptal access to the LA may not be feasible.^{19,20}

Epicardial Approach

Coronary veins can be used to perform epicardial mapping, but manipulation of the mapping catheter is limited by the anatomical distribution of these vessels. Therefore, the subxiphoid percutaneous approach to the epicardial space is the only technique currently available that allows extensive and unrestricted mapping of the epicardial surface of both ventricles, and it has been used most commonly for VT mapping and ablation. The epicardial approach for mapping and ablation is discussed in [Chapter 27](#).⁶

Baseline Measurements

Intracardiac Electrograms

Whereas the surface ECG records a summation of the electrical activity of the entire heart, intracardiac electrograms recorded by the electrode catheter represent only the electrical activity (phase 0 of the action potential) of the local cardiac tissue in the immediate vicinity of the catheter's electrodes. Cardiac electrograms are generated by the potential (voltage) differences recorded at two recording electrodes during the cardiac cycle. All clinical electrogram recordings are differential recordings from one source that is connected to the anodal (positive) input of the recording amplifier and a second source that is connected to the cathodal (negative) input.²¹

Recorded electrograms can provide three important pieces of information: (1) the local activation time (i.e., the time of activation of myocardium immediately adjacent to the recording electrode relative to a reference), (2) the direction of propagation of electrical activation within the field of view of the recording electrode, and (3) the complexity of myocardial activation within the field of view of the recording electrode.

ANALOG VERSUS DIGITAL RECORDINGS

Intracardiac electrograms are recorded with amplifiers that have high-input impedances (more than 1010 Ω), to decrease unwanted electrical interference and ensure high-quality recordings.²¹ Analog recording systems directly amplify the potential from the recording electrodes, plot the potential on a display oscilloscope,

and write it to recording paper or store it on magnetic tape, or both. Analog systems have largely been replaced by digital recording systems that use an analog to digital (A/D) converter that converts the amplitude of the potential recorded at each point in time to a number that is stored.

CH 4 The quality of digital data is influenced by the sampling frequency and precision of the amplitude measurement.²¹ The most common digital recording systems sample the signal approximately every 1 millisecond (i.e., 1000 Hz), which is generally adequate for practical purposes of activation mapping. However, higher sampling frequencies can be required for high-quality recording of high-frequency, rapid potentials that can originate from the Purkinje system or areas of infarction. The faster sampling places greater demands on the computer processor and increases the size of the stored data files.

UNIPOLAR RECORDINGS

A unipolar electrogram is the voltage difference recorded between an intracardiac electrode in close association with cardiac tissue and a distant *indifferent* (reference) electrode patch applied to the body surface (so that the indifferent electrode has little or no cardiac signal). The precordial ECG leads, for example, are unipolar

recordings that use an indifferent electrode created by connecting the arms and left leg electrodes through high-impedance resistors.²²

By convention, the exploring electrode in contact with the cardiac tissue is connected to the positive input of the recording amplifier. In this configuration, an approaching wavefront creates a positive deflection that quickly reverses itself as the wavefront passes directly under the electrode, thus generating an RS complex. In normal homogeneous tissue, the maximum negative slope (dV/dt) of the signal coincides with the arrival of the depolarization wavefront directly beneath the electrode, because the maximal negative dV/dt corresponds to the maximum sodium (Na^+) channel conductance; Fig. 4-15). This is true for filtered and unfiltered unipolar electrograms.^{21,23}

The unfiltered unipolar recordings provide information about the direction of impulse propagation; positive deflections (R waves) are generated by propagation toward the recording electrode, and negative deflections (QS complexes) are generated by propagation away from the electrode. Therefore, a wavefront of depolarization traveling past a unipolar electrode results in a biphasic electrogram (positive then negative) representing the approach and recession of the activation wavefront.²²

Unipolar recordings also allow pacing and recording at the same location while eliminating a possible anodal contribution to

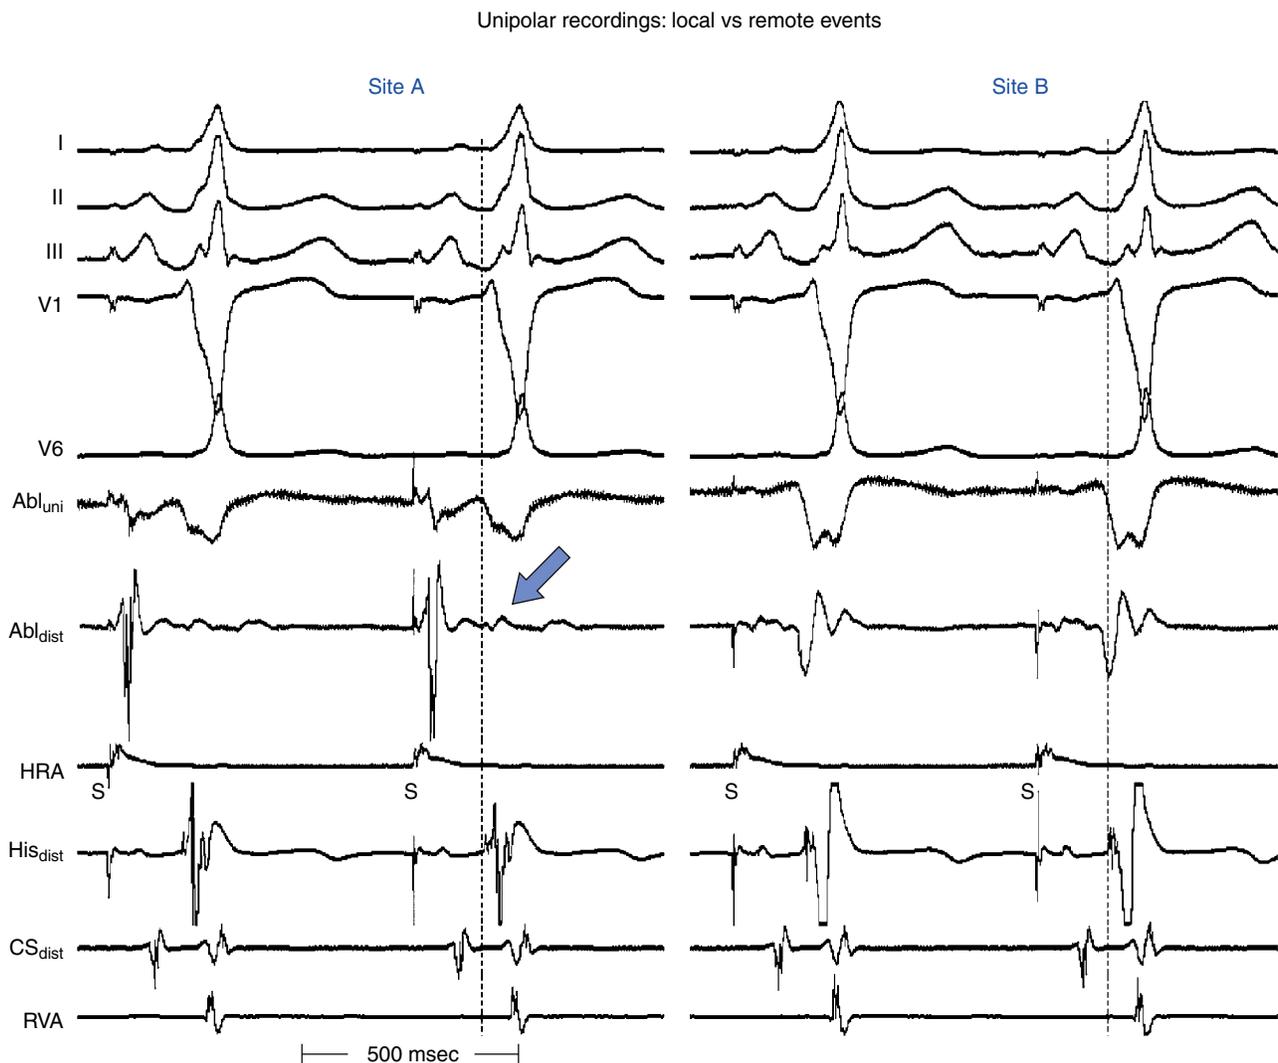

FIGURE 4-15 Unipolar and bipolar recordings. Two complexes from different sites are shown in a patient with Wolff-Parkinson-White syndrome. The dashed line denotes onset of the delta wave. In site A, the unfiltered unipolar recording shows a somewhat blunted “QS” complex and small atrial component, but the filtered (30- to 300-Hz) bipolar signal shows a very large atrial signal and very small ventricular signal (arrow), suggesting a poor choice for ablation site. Site B shows a sharper “QS” in the unipolar signal, with a larger ventricular than atrial electrogram, and the initial nadir of bipolar recording coincides with the maximal negative dV/dt of the unipolar recording. Ablation at this site was successful. Abl_{dist} = distal ablation; Abl_{uni} = unipolar ablation; CS_{dist} = distal coronary sinus; His_{dist} = distal His bundle; HRA = high right atrium; RVA = right ventricular apex.

depolarization that is sometimes seen with bipolar pacing at high output.²¹ However, one of the disadvantages of unipolar recording is the inability to record an undisturbed electrogram during or immediately after pacing.

The major disadvantage of unipolar recordings is that they contain substantial far-field signals generated by depolarization of tissue remote from the recording electrode, because the unipolar electrode records a potential difference between widely spaced electrodes.²³ Noise can be reduced by using an indifferent electrode in the IVC. The unipolar electrograms are generally unfiltered (0.05 to 300 Hz or more), but are usually filtered at settings comparable to those of bipolar electrograms (10 to 40 to 300 Hz or more) when an abnormal tissue (scars or infarct areas) is studied, where local electrograms can have very low amplitude and can be masked by larger far-field signals. Filtering the unipolar electrograms can help eliminate far-field signals; however, the filtered unipolar recordings lose the ability to provide directional information.

BIPOLAR RECORDINGS

Bipolar recordings are obtained by connecting two electrodes that are exploring the area of interest to the recording amplifier. At each point in time, the potential generated is the sum of the potential from the positive input and the potential at the negative input. The potential at the negative input is inverted; this is subtracted from the potential at the positive input so that the final recording is the difference between the two.²¹

Unlike unipolar recordings, bipolar electrodes with short inter-polar distances are relatively unaffected by far-field events. The bipolar electrogram is simply the difference between the two unipolar electrograms recorded at the two poles. Because the far-field signal is similar at each instant in time, it is largely subtracted out, thus leaving the local signal. Therefore, compared with unipolar recordings, bipolar recordings provide an improved signal-to-noise ratio, and high-frequency components are more accurately seen.^{6,23}

Although local activation is less precisely defined, in a homogeneous sheet of tissue the initial peak (or nadir) of a filtered (10 to 40 to 300 Hz or more) bipolar recording coincides with depolarization beneath the recording electrode and corresponds to the maximal negative dV/dt of the unipolar recording (see Fig. 4-15).

Several factors can affect bipolar electrogram amplitude and width, including conduction velocity (the greater the velocity, the higher the peak amplitude of the filtered bipolar electrogram), the mass of the activated tissue, the distance between the electrode and the propagating wavefront, the direction of propagation relative to the bipoles, the interelectrode distance, the amplifier gain, and other signal-processing techniques that can introduce artifacts. To acquire true local electrical activity, a bipolar electrogram with an interelectrode distance of less than 1 cm is desirable.²³

The direction of wavefront propagation cannot be reliably inferred from the morphology of the bipolar signal. Moreover, bipolar recordings do not allow simultaneous pacing and recording from the same location. To pace and record simultaneously in bipolar fashion at endocardial sites as close together as possible, electrodes 1 and 3 of the quadripolar mapping catheter are used for bipolar pacing, and electrodes 2 and 4 are used for recording.²³

The differences in unipolar and bipolar recordings can be used to assist in mapping by simultaneously recording bipolar and unipolar signals from the mapping catheter.²¹ Although bipolar recordings provide sufficient information for most mapping purposes in clinical EP laboratories, simultaneous unipolar recordings can provide an indication of the direction of wavefront propagation and a more precise measure of the timing of local activation.²³

SIGNAL FILTERING

The surface ECG is usually filtered at 0.1 to 100.0 Hz. The bulk of the energy is in the 0.1- to 20.0-Hz range. Because of interference from alternating current (AC), muscle twitches, and similar relatively high-frequency interference, it is sometimes necessary to

record the surface ECG over a lower frequency range or to use notch filters.⁶

Amplifiers are also used to filter the low- and high-frequency content of the intracardiac electrograms. Intracardiac electrograms are usually filtered to eliminate far-field noise, typically at 30 to 500 Hz. The range of frequencies not filtered out is frequently called the bandpass. The high-pass filter allows frequencies higher than a certain limit to remain in the signal (i.e., it filters out lower frequencies), and the low-pass filter filters out frequencies higher than a certain limit.

High-Pass Filtering

High-pass filtering attenuates frequencies slower than the specified cutoff (corner frequency) of the filter. If intracardiac recordings were not filtered, the signal would wander up and down as this potential fluctuated with respiration, catheter movement, and variable catheter contact.

For bipolar electrograms, high-pass filters with corner frequencies between 10 and 50 Hz are commonly used. Filtering can distort the electrogram morphology and reduce its amplitude. The bipolar signal becomes more complex, and additional peaks are introduced. In general, high-pass filtering can be viewed as differentiating the signal, so that the height of the signal is proportional to the rate of change of the signal, rather than only the amplitude.²²

Unipolar signals are commonly filtered at 0.05 to 0.5 Hz to remove baseline drift. Filtering at higher corner frequencies (e.g., 30 Hz) alters the morphology of the signal so that the morphology of the unipolar signal is no longer an indication of the direction of wavefront propagation and the presence or absence of a QS complex cannot be used to infer proximity to the site of earliest activation. However, filtering the unipolar signal does not affect its usefulness as a measure of the local activation time.⁵ As mentioned earlier, during mapping of areas with infarcts or scars, where local electrograms can have very low amplitude and can be masked by larger far-field signals, high-pass filtering of a unipolar signal (at 30 Hz) can help reduce the far-field signal and improve detection of the lower amplitude local signals.²²

Low-Pass Filtering

Low-pass filters attenuate frequencies that are faster than the specified corner frequency (usually 250 to 500 Hz). This approach is useful for reducing high-frequency noise without substantially affecting electrograms recorded with clinical systems because most of the signal content is lower than 300 Hz.²²

Band-Pass Filtering

Defining a band of frequencies to record, such as setting the high-pass filter to 30 Hz and the low-pass filter to 300 Hz, defines a band of frequencies from 30 to 300 Hz that are not attenuated (i.e., bandpass filtering). A notch filter is a special case of bandpass filtering, with specific attenuation of frequencies at 50 or 60 Hz to reduce electrical noise introduced by the frequency of common AC current.

TIMING OF LOCAL EVENTS

As noted, with an unfiltered unipolar electrogram, a wavefront of depolarization that is propagating toward the exploring electrode generates a positive deflection (an R wave). As the wavefront reaches the electrode and propagates away, the deflection sweeps steeply negative. This rapid reversal constitutes the intrinsic deflection of the electrogram and represents the timing of the most local event (i.e., at the site of the electrode). The maximum negative slope (dV/dt) of the signal coincides with the arrival of the depolarization wavefront directly beneath the electrode (see Fig. 4-15).²²

Filtering the unipolar signal does not affect its usefulness as a measure of the local activation time. The slew rate or dV/dt of the filtered electrogram is so rapid in normal heart tissue that the difference between the peak and the nadir of the deflection is 5 milliseconds or less. Identification of the local event is therefore easy with

filtered or unfiltered electrograms in normal tissue. On the other hand, diseased myocardium can conduct very slowly with fractionated electrograms, and this makes local events harder to identify.

To acquire true local electrical activity, a bipolar electrogram with an interelectrode distance of less than 1 cm is preferable. Smaller interelectrode distances record increasingly local events. In normal homogeneous tissue, the initial peak of a filtered (30 to 300 Hz or more) bipolar recording coincides with depolarization beneath the recording electrode and corresponds to the maximal negative dV/dt of the unipolar recording (see Fig. 4-15). However, in the setting of complex multicomponent bipolar electrograms, such as those with marked fractionation and prolonged duration seen in regions with complex conduction patterns, determination of local activation time becomes problematic.⁶

When the intracardiac electrogram of interest is small relative to the size of surrounding electrograms (e.g., His deflection), and the gain must be markedly increased to produce a measurable deflection, clipping the signals can help eliminate the highly amplified surrounding signals to allow concentration on the deflection of interest (Fig. 4-16). It is important to recognize, however, that clippers eliminate the ability to determine the amplitude and timing of the intrinsic deflection (local timing) of the signals being clipped.⁵

CHOICES OF SURFACE AND INTRACARDIAC SIGNALS

Baseline recordings obtained during a typical EP study include several surface ECG leads and several intracardiac electrograms, all of which are recorded simultaneously. Timing of events with respect to onset of the QRS complex or P wave on the surface ECG is often important during the EP study, but it is cumbersome to display all 12 leads of the regular surface ECG. It is more common to use leads I, II, III, V₁, and V₆, which provide most of the information required to determine the frontal plane axis, presence and type of intraventricular conduction abnormalities, and P wave morphology.

Intracardiac leads can be placed strategically at various locations within the cardiac chambers to record local events in the region of the lead. A classic display would include three to five

surface ECG leads, high RA recording, HB recording, CS recording, and RV apex recording (Fig. 4-17). Depending on the type of study and information sought, stimulation and recording from other sites can be appropriate and can include RB recording, LV recording, transeptal LA recording, and atrial and ventricular mapping catheter tracings for EP mapping and ablation.²¹

The intracardiac electrograms are generally displayed in the order of normal cardiac activation. The first intracardiac tracing is a recording from the high RA close to the sinus node. The next intracardiac tracing is the HB recording, obtained from a catheter positioned at the HB, which shows low septal RA, HB, and high septal RV depolarizations. One to five recordings may be obtained from the CS, which reflects LA activation, followed by a recording from the RV catheter (see Fig. 4-17).⁶

Right Atrial Electrogram

Depending on the exact location of the RA catheter, the high RA electrogram typically shows a local sharp, large atrial electrogram and a smaller, far-field ventricular electrogram. The catheter is usually positioned in the RA appendage because of stability and reproducibility. The recorded atrial electrogram is earlier in the P wave when the catheter is positioned close to the sinus node. Recordings from this site also help determine the direction of atrial activation (e.g., high-low versus low-high, and right-left versus left-right). Pacing at this position allows evaluation of sinus node function and AV conduction, as well as the induction of supraventricular, and occasionally ventricular, arrhythmias.

Coronary Sinus Electrogram

Because the CS lies in the AV groove, in close contact to both the LA and the LV, the CS catheter records both atrial and ventricular electrograms. However, the CS has a variable relationship with the mitral annulus. The CS lies 2 cm superior to the annulus as it crosses from the RA to the LA. More distally, the CS frequently overrides the LV. Consequently, the most proximal CS electrodes (located at the CS os) are closer to the atrium and typically show a local sharp, large atrial electrogram and a smaller, far-field ventricular

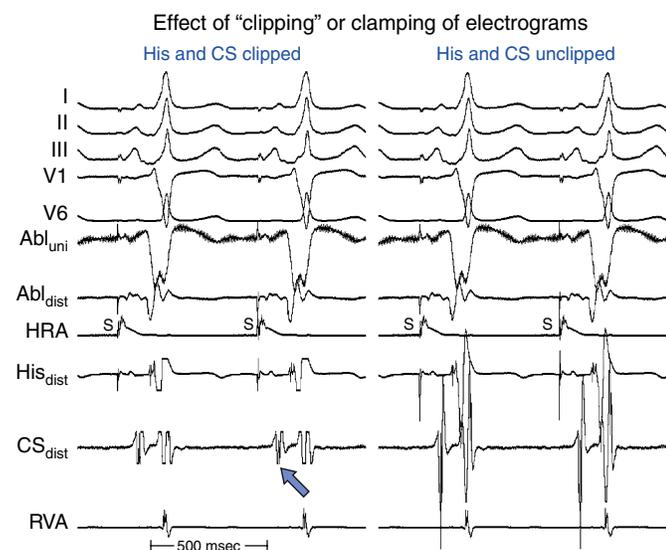

FIGURE 4-16 Effect of electronic clipping on recordings. The same two complexes are shown in both panels. **Left**, Both His and coronary sinus (CS) recordings are electronically attenuated (clipped) to reduce excursions on the display. The CS atrial and ventricular signals appear to have equal amplitude, and the ventricular electrogram in the His recording is small. **Right**, Without clipping, the true signal amplitudes are seen, showing a very large ventricular signal in the His recording and a larger atrial than ventricular signal in the CS recording. Abl_{dist} = distal ablation; Abl_{uni} = unipolar ablation; CS_{dist} = distal coronary sinus; His_{dist} = distal His bundle; HRA = high right atrium; RVA = right ventricular apex.

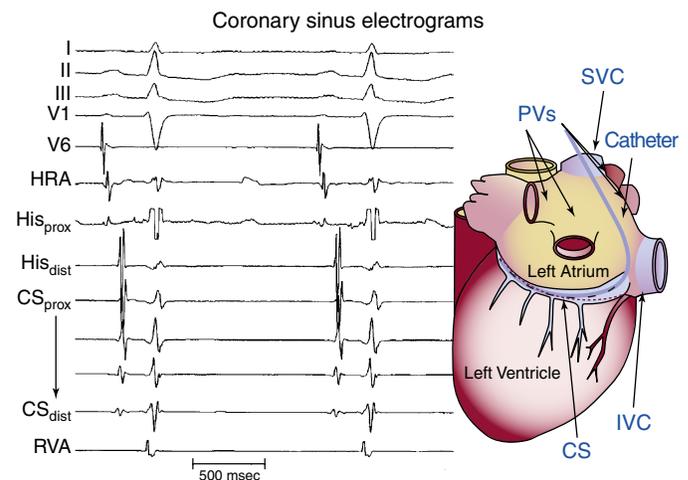

FIGURE 4-17 A classic display of surface ECG and intracardiac recordings during an electrophysiology study of supraventricular tachycardia. Included are four surface ECG leads, high right atrium (HRA) recording, two His bundle recordings (proximal and distal His [His_{prox} and His_{dist}]), five coronary sinus (CS) recordings (in a proximal-to-distal sequence), and a right ventricular apex (RVA) recording. The relative amplitudes of atrial and ventricular electrograms in CS recordings are also shown. **Right**, The back of the heart is shown with a CS catheter in position. The distal portion of the CS (CS_{dist}) is closer to the ventricle (originating as the great cardiac vein on the anterior wall); the CS crosses the atrioventricular groove at the lateral margin and becomes an entirely atrial structure as it empties into the right atrium. **Left**, Thus, proximal CS (CS_{prox}) recordings show large atrial and small ventricular signals, whereas more distal recordings show small atrial, large ventricular signals. IVC = inferior vena cava; PVs = pulmonary veins; SVC = superior vena cava.

electrogram. The more distal CS electrodes, lying closer to the LV than the LA, record progressively smaller, less sharp, far-field atrial electrograms and larger, sharper, near-field ventricular electrograms (see Fig. 4-17).

During normal sinus rhythm (NSR), the atrial activation sequence proceeds from the CS os distally. However, if the CS catheter is deeply seated in the CS, so that the most proximal electrodes are distal to the CS os and the most distal electrodes are anterolateral on the mitral annulus, then both proximal and distal electrodes can be activated at the same time (Fig. 4-18).

His Bundle Electrogram

The HB catheter is positioned at the junction of the RA and RV. Therefore, it records electrograms from local activation of the adjacent atrial, HB, and ventricular tissues (Fig. 4-19). Using a 5- to 10-mm bipolar recording, the His potential appears as a rapid biphasic spike, 15 to 25 milliseconds in duration, interposed between local atrial and ventricular electrograms. The use of a quadripolar catheter allows simultaneous recording of three bipolar pairs.²⁴

Before measuring conduction intervals within the HB electrogram, it is important to verify that the spike recorded between the atrial and ventricular electrograms on the HB catheter actually represents activation of the most proximal HB and not the distal HB or RB. The most proximal electrodes displaying the His potential should be chosen, and a large atrial electrogram should accompany the proximal His potential. Anatomically, the proximal portion of the HB originates in the atrial side of the tricuspid annulus; thus, the most proximal HB deflection is the one associated with the largest atrial electrogram. Recording of a His potential associated with a small atrial electrogram can reflect recording of the distal HB or RB and therefore would miss important intra-His conduction abnormalities and falsely shorten the measured HB-ventricular (HV)

interval (see Fig. 4-19). Even if a large His potential is recorded in association with a small atrial electrogram, the catheter should be withdrawn to obtain a His potential associated with a larger atrial electrogram. Using a multipolar (three or more) electrode catheter to record simultaneously proximal and distal HB electrograms (e.g., a quadripolar catheter records three bipolar electrograms over a 1.5-cm distance) can help evaluate intra-His conduction.⁵

Validation of the HB recording can be accomplished by assessment of the HV interval and establishing the relationship between the His potential and other electrograms.²⁴ The HV interval should be 35 milliseconds or longer (in the absence of preexcitation). In contrast, the RB potential invariably occurs within 30 milliseconds before ventricular activation. Atrial pacing can be necessary to distinguish a true His potential from a multicomponent atrial electrogram. With a true His potential, the atrial-HB (AH) interval should increase with incremental pacing rates. HB pacing can also be a valuable means for validating HB recording. The ability to pace the HB through the recording electrode and obtain HB capture (i.e., QRS identical to that during NSR and stimulus-to-QRS interval identical to the HV interval during NSR) provides the strongest evidence validating the His potential. However, this technique is inconsistent in accomplishing HB capture, especially at low current output. Higher output can result in nonselective HB capture. The use of closely spaced electrodes and the reversal of current polarity (i.e., anodal stimulation) can facilitate HB capture. Failure to capture the HB selectively does not necessarily imply that the recorded potential is from the RB.

Other measures that can be used, although rarely required, to validate the HB recording include recording of pressure simultaneously with a luminal electrode catheter (which should reveal atrial pressure wave when the catheter is at the proximal His electrogram position) and simultaneous left and right recording of the His potential. The His potential can be recorded in the noncoronary sinus of Valsalva (just above the aortic valve) or in the LVOT along the interventricular septum (just below the aortic valve). Because these sites are at the level of the central fibrous body, the proximal penetrating portion of the HB is recorded and can be used to time the His potential recorded via the standard venous route. Recording the HB from the noncoronary cusp (versus the LVOT) is preferred because only a true His potential can be recorded from that site.²⁵

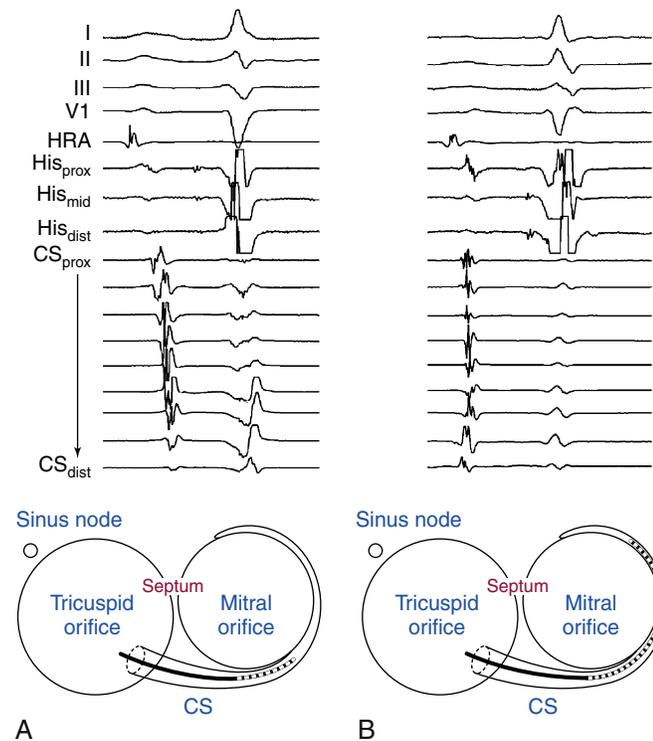

FIGURE 4-18 Influence of catheter position on coronary sinus (CS) atrial electrograms. Two different CS atrial activation sequences are shown from different patients. **A**, A proximal-to-distal sequence is shown. **B**, The latest activation is in the mid-CS electrodes. The diagrams at the bottom show relative positions of the CS catheter in each instance (atrioventricular grooves viewed from above). With more proximal CS position (CS_{prox}), propagation is proximal-distal, indicating relative distance from the sinus node. With a more distal CS position (CS_{dist}), the mid-CS electrodes are farthest from the sinus node. His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle; HRA = high right atrium.

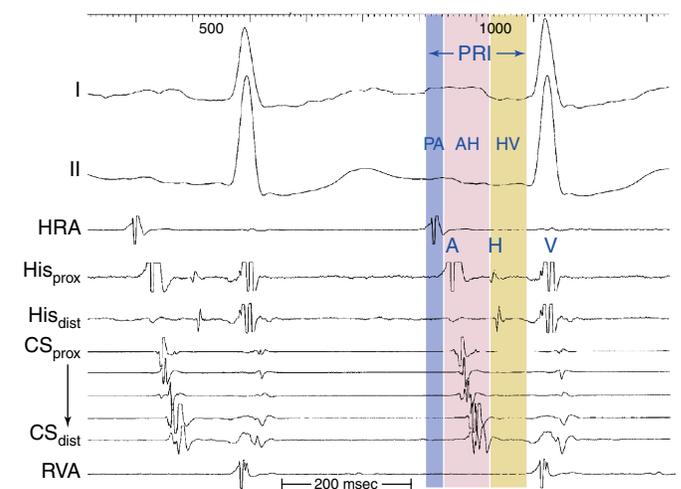

FIGURE 4-19 Intracardiac intervals. Shaded areas represent the P wave-atrial (PA) (blue), atrial-His bundle (AH) (pink), and His bundle-ventricular (HV) (yellow) intervals. It is important that the HV interval be measured from the onset of the His potential in the recording showing the most proximal (rather than the most prominent) His potential (His_{prox}) to the onset of the QRS on the surface ECG (rather than the ventricular electrogram on the His bundle [HB] recording). CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; HRA = high right atrium; PRI = PR interval; RVA = right ventricular apex. See text for details.

Right Ventricular Electrogram

The RV electrogram typically shows a local sharp and large ventricular electrogram and generally no atrial electrogram. The closer the RV catheter tip position is to the apex, the closer it is to the RB myocardial insertion site and the earlier the ventricular electrogram timing to the onset of the QRS. The catheter is usually positioned in the RV apex because of stability and reproducibility.

Baseline Intervals

The accuracy of measurements made at a screen speed of 100 mm/sec is ± 5 milliseconds, and at a speed of 400 mm/sec is ± 1 millisecond. In dealing with large intervals (e.g., sinus node function), a speed of 100 mm/sec is adequate. For refractory periods, a speed of 150 to 200 mm/sec is adequate, but for detailed mapping, a speed of 200 to 400 mm/sec is required.

P WAVE—ATRIAL INTERVAL

The P wave–atrial (PA) interval is measured from the first evidence of sinus node depolarization, whether on the intracardiac or surface ECG, to the atrial deflection as recorded in the HB lead. It represents conduction through the RA to the inferoposterior interatrial septum (in the region of the AV node [AVN] and HB; see Fig. 4-19).

The PA interval is a reflection of internodal (sinus node to AVN) conduction; prolonged PA intervals suggest abnormal atrial conduction and can be a clue to the presence of biatrial disease or disease confined to the RA. The normal range of the PA interval is 20 to 60 milliseconds. Rarely, diseased atrial conduction can underlie first-degree AV block, indicated by a prolonged PA interval. A short PA interval suggests an ectopic source of atrial activation.

INTERATRIAL CONDUCTION

Normal atrial activation begins in the high or mid-lateral RA (depending on the sinus rate), spreads from there to the low RA and AV junction, and then spreads to the LA.

Activation of the LA is mediated by three possible routes. Superiorly, activation proceeds through the Bachman bundle; this can be seen in 50% to 70% of patients and can be demonstrated by CS os activation followed by distal CS and then mid-CS activation. Activation also propagates through the mid-atrial septum at the fossa ovalis and at the region of the central fibrous trigone at the apex of the triangle of Koch. The latter provides the most consistent amount of LA activation.

Interatrial conduction is measured by the interval between the atrial electrogram in the high RA lead and that in the CS lead. LA-to-RA activation during LA pacing appears primarily to cross the fossa and low septum and not the Bachman bundle, as reflected by relatively late high RA activation.

Normal retrograde atrial activation proceeds over the AVN. The earliest atrial activation is recorded in the AV junction (HB recording), then in the adjacent RA and CS os, and finally in the high RA and LA. More detailed mapping reveals atrial activation to start at the HB recording, with secondary breakthrough sites in the CS (reflecting activation over the LA extension of the AVN) or the posterior triangle of Koch, or both. At faster ventricular pacing rates, the earliest atrial activation typically shifts to the posterior portion of the triangle of Koch, the CS os, or within the CS itself.

ATRIAL—HIS BUNDLE INTERVAL

The AH interval is measured from the first rapid deflection of the atrial deflection in the HB recording to the first evidence of HB depolarization in the HB recording (see Fig. 4-19). The AH interval is an approximation of the AVN conduction time, because it represents conduction time from the low RA at the interatrial septum through the AVN to the HB.

The AH interval can vary according to the site of atrial pacing. During LA or CS os pacing, the impulse can enter the AVN at a different site that bypasses part of the AVN, or it can just enter the AVN earlier in respect to the atrial deflection in the HB electrogram. Both mechanisms can give rise to a shorter AH interval.

The response of the AH interval to atrial pacing or drugs often provides more meaningful information about AVN function than an isolated measurement of the AH interval. Autonomic blockade with atropine (0.04 mg/kg) and propranolol (0.02 mg/kg) can be used to evaluate AVN function in the absence of autonomic influences. Not enough data, however, are available to define normal responses under these circumstances.²⁴

The AH interval has a wide range in normal subjects (50 to 120 milliseconds) and is markedly influenced by the autonomic nervous system. Short AH intervals can be observed in cases of increased sympathetic tone, reduced vagal tone, enhanced AVN conduction, and preferential LA input into the AVN, as well as unusual forms of preexcitation (atrio-His BTs).

Long AH intervals are usually caused by negative dromotropic drugs (such as digoxin, beta blockers, calcium channel blockers, and antiarrhythmic drugs), enhanced vagal tone, and intrinsic disease of the AVN. Artificially prolonged AH intervals can result from an improperly positioned catheter or the incorrect identification of an RB potential as a His potential. This situation needs to be distinguished from true AH interval prolongation.

HIS POTENTIAL

His potential duration reflects conduction through the short length of the HB that penetrates the fibrous septum. Disturbances of HB conduction can manifest as fractionation, prolongation (longer than 30 milliseconds), or splitting of the His potential.

HIS BUNDLE—VENTRICULAR INTERVAL

The HV interval is measured from the onset of the His potential to the onset of the earliest registered surface or intracardiac ventricular activation. It represents conduction time from the proximal HB through the distal His-Purkinje system (HPS) to the ventricular myocardium (see Fig. 4-19).²⁴

The HV interval is not significantly affected by the autonomic tone, and it usually remains stable. The range of HV intervals in normal subjects is narrow, 35 to 55 milliseconds. A prolonged HV interval is consistent with diseased distal conduction in all fascicles or in the HB itself. A validated short HV interval suggests ventricular preexcitation via a BT. A falsely shortened HV interval can occur during sinus rhythm with PVCs or an accelerated idioventricular rhythm that is isorhythmic with the sinus rhythm, or when an RB potential rather than a His potential is inadvertently recorded.

Programmed Electrical Stimulation Stimulators

Cardiac stimulation is carried out by delivering a pulse of electrical current through the electrode catheter from an external pacemaker (stimulator) to the cardiac surface. Such an electrical impulse depolarizes cardiac tissue near the pacing electrode, which then propagates through the heart. The paced impulses (stimuli) are introduced in predetermined patterns and at precise timed intervals using a programmable stimulator.

A typical stimulator has a constant current source and is capable of pacing at a wide range of CLs and variable current strengths (0.1 to 10 mA) and pulse widths (0.1 to 10 milliseconds). Additionally, current stimulators have at least two different channels of stimulation (preferably four) and allow delivery of multiple extra-stimuli (three or more) and synchronization of the pacing stimuli to selected electrograms during intrinsic or paced rhythms.

Pacing Techniques

PACING OUTPUT

Stimulation is usually carried out using an isolated constant current source that delivers a rectangular impulse. Pacing output at twice ($2\times$) diastolic threshold is generally used. *Pacing threshold* is defined as the lowest current required for consistent capture determined in late diastole. The pacing threshold can be influenced by the pacing cycle length (CL); therefore, the threshold should be determined at each pacing CL used. In general, refractory periods are somewhat longer when determined using $2\times$ threshold (as opposed to higher outputs), and this can reduce the incidence of induction of nonclinical tachyarrhythmias.²⁴ Additionally, diastolic excitability can be influenced by drug administration; re-evaluation of the pacing threshold and adjustment of the pacing output ($2\times$ threshold) are therefore required in such situations. A pulse duration of 1 or 2 milliseconds is generally used.

High current strength is generally used for determination of strength-interval curves to overcome drug-induced prolongation of refractoriness, assess the presence and mechanism of antiarrhythmic therapy, and overcome the effect of decreased tissue excitability (e.g., pace mapping in scar-related arrhythmias).

CYCLE LENGTH

During EP testing, CLs often change from beat to beat, so that these measures are more relevant than an overall rate expressed in beats per minute. The use of rates in beats per minute is retained mostly to facilitate communication with physicians who are more comfortable with this terminology. Pacing rate is determined by dividing 60,000 by the CL (in milliseconds).

INCREMENTAL VERSUS DECREMENTAL

The terms *incremental* and *decremental* can have opposite meaning, depending on whether one is considering the pacing rate in beats per minute or the pacing CL in milliseconds. The term *incremental pacing rate* is derived from stimulators controlled by an analog dial. Digitally controlled devices often increase the rate by choosing a sequence of CL decrements, but the term *incremental pacing* may still be used.

OVERDRIVE PACING (STRAIGHT PACING)

Pacing stimuli are delivered at a constant pacing rate (or pacing CL) throughout the duration of the stimulation. The pacing rate is faster than the rate of the baseline rhythm to ensure capture of the spontaneous rhythm.

BURST PACING

Pacing stimuli are delivered at a constant rate for a relatively short duration, but at successively faster rates with each burst until a predetermined maximum rate (or minimum CL) has been reached. This technique is generally used for induction or termination of tachycardias.

STEPWISE RATE-INCREMENTAL PACING

After pacing at a given rate for a predetermined number of stimuli or seconds, the rate is increased (with intervening pauses) in a series of steps until predetermined endpoints are reached. It is important to maintain the pacing at any given rate for at least 15 seconds (period of accommodation) before increasing the pacing rate. Otherwise, the initial stimuli at any given rate can produce effects different from those observed several seconds later, because the ability of a tissue to conduct is affected by the baseline rate or CL of the preceding beats. A disadvantage for this technique is the prolonged pacing required at each rate, which is time-consuming.

RAMP PACING

Ramp pacing implies a smooth change in the interval between successive stimuli, with gradual decrease of the pacing CL every several paced complexes (without intervening pauses). Ramps are often used as an alternative to the stepwise method for assessment of conduction. The pacing rate is slowly increased at 2 to 4 beats/min every several paced beats until block occurs. This method avoids prolonged rapid pacing at each pacing CL and is particularly useful when multiple assessments of conduction are planned (e.g., after therapeutic interventions) and in the assessment of retrograde conduction. Because each successive paced interval differs from its predecessor by only a few milliseconds, the interval at which block occurs can be determined more precisely using the ramp method. However, prolonged episodes of continuous high-rate pacing can provoke significant hypotension, and close monitoring of blood pressure is important while performing these maneuvers.

For tachycardia induction or termination, the ramp is decreased in duration, but the inter-stimulus intervals are decreased more rapidly. Ramp pacing is generally used in antitachycardia pacing algorithms in implantable cardioverter-defibrillators. Programmed rate-incremental ramps are also known as *autodecremental pacing*.

EXTRASTIMULUS TECHNIQUE

S₁-S₁ DRIVE STIMULI. The heart is paced, or driven, at a specified rate and duration (typically eight beats) after which a premature extrastimulus is delivered. The eight drive beats are each termed *S₁ stimulus*. The S₁-S₁ drive stimuli are sometimes called trains. These S₁ drive stimuli can be followed by first, second, third, and nth premature extrastimuli, which are designated as S₂, S₃, S₄, and S_N. When the extrastimuli follow a series of sinus beats, the sinus beats can also be designated as S₁.

S₁, S₂, S₃, . . . S_N. S₂ is the first extrastimulus, with the S₁-S₂ interval almost always shorter than the S₁-S₁ interval. S₃, S₄, . . . S_N are the second, third, . . . nth extrastimuli. When stimulation is performed in the atrium, capture of S₁, S₂, S₃, . . . S_N results in atrial depolarizations, termed A₁, A₂, A₃, . . . A_N, respectively, and when stimulation is performed in the ventricle, they are termed V₁, V₂, V₃, . . . V_N, corresponding to the resultant ventricular depolarizations, respectively.

One or more extrastimuli (designated S₂, S₃, and S_N) are introduced at specific coupling intervals based on previous S₁ drive stimuli or spontaneous beats. Thereafter, the S₁-S₂ interval is altered, usually in 10- to 20-millisecond steps, until an endpoint is reached, such as tissue refractoriness or termination or induction of a tachycardia. It is usual to begin late in diastole and successively decrement the S₁-S₂ interval. A second extrastimulus (S₃) can then be introduced, with the S₂-S₃ interval altered similarly to that used for S₁-S₂.

Two methods are in common clinical use for decreasing the coupling intervals during delivery of multiple extrastimuli. In the simple sequential method, the S₁-S₂ coupling interval is decreased until it fails to capture, at which time the coupling interval is increased until it captures (usually within 10 to 20 milliseconds). The S₁-S₂ coupling interval is then held constant while the S₂-S₃ interval is decreased similarly to that used for S₁-S₂, and then the same is done for S₃-S₄. In the tandem method, the S₁-S₂ coupling interval is decreased until S₂ fails to capture, and then the S₁-S₂ coupling interval is increased by 40 to 50 milliseconds and held there. S₃ is then introduced and the S₂-S₃ interval decreased until S₃ fails to capture. At that point, the S₁-S₂ interval is decreased, and S₃ is retested to see whether it captures. From that point on, the S₁-S₂ and S₂-S₃ intervals are decreased in tandem until refractory. As compared with the simple sequential method, the tandem method allows relatively longer intervals and provides a larger number of stimulation runs before moving on to the next extrastimulus. Prospective studies comparing the two methods have shown no differences between the two methods in any of the outcomes assessed.

ULTRARAPID TRAIN STIMULATION

Pacing at very short CLs (10 to 50 milliseconds) is rarely performed, mainly for induction of ventricular fibrillation (VF), to test defibrillation threshold during implantation of a cardioverter-defibrillator.

Conduction and Refractoriness

CONDUCTION

During depolarization, the electrical impulse spreads along each cardiac cell, and rapidly from cell to cell, because each myocyte is connected to its neighbors through low resistance gap junctions. As discussed in [Chapter 1](#), conduction velocity refers to the speed of propagation of an electrical impulse through cardiac tissue, which is dependent on both the active membrane properties of the individual cardiac myocyte that generates the action potential (i.e., electrical excitability or refractoriness, or both) and passive properties governing the flow of current between cardiac cells (cell-to-cell coupling and tissue geometry).^{26,27}

Conduction can be assessed by observing the propagation of wavefronts during pacing at progressively incremental rates. Rate-incremental pacing is delivered to a selected site in the heart while propagation to a selected distal point is assessed. Conduction velocity is assessed by measuring the time it takes for an impulse to travel from one intracardiac location to another. During tests of conduction, it is usual for capture to be maintained at the site of stimulation and block to occur at a distal point.⁶

REFRACTORINESS

As discussed in [Chapter 1](#), during a cardiac cycle, once an action potential is initiated, the cardiac cell is unexcitable to stimulation (i.e., unable to initiate another action potential in response to a stimulus of threshold intensity) for some duration of time (which is slightly shorter than the “true” action potential duration) until its membrane has repolarized to a certain level.²⁸⁻³⁰

There are different levels of refractoriness during the action potential. During the *absolute refractory period* (which extends over phases 0, 1, 2, and part of phase 3 of the action potential), the tissue is completely unexcitable and a second action potential absolutely cannot be initiated, no matter how large a stimulus is applied, because of inactivation of most Na⁺ channels. After the absolute refractory period, a stimulus may cause some cellular depolarization but does not lead to a propagated action potential. The sum of this period (which includes a short interval of phase 3 of the action potential) and the absolute refractory period is termed the *effective refractory period* (ERP). The ERP is followed by the *relative refractory period* (RRP), which extends over the middle and late parts of phase 3 of the action potential. During the RRP, initiation of a second action potential is *inhibited* but not impossible; a larger-than-normal stimulus can result in activation of the cell and lead to a propagating action potential. However, the upstroke of the new action potential is less steep and of lower amplitude and its conduction velocity slower than normal. Of note, there is a brief period in phase 3 of the action potential, the *supernormal period*, during which excitation is possible in response to an otherwise subthreshold stimulus; that same stimulus fails to elicit a response earlier or later than the supernormal period (see later).

MEASUREMENTS OF REFRACTORY PERIODS

Refractoriness (or, more appropriately, excitability) is defined by the response of a tissue to premature stimulation.^{31,32} Refractory periods are analyzed by the extrastimulus technique, with progressively premature extrastimuli delivered after a train of 8 to 10 paced beats at a fixed pacing CL to allow for reasonable (more than 95%) stabilization of refractoriness, which is usually accomplished after 3 or 4 paced beats.

Several variables are considered in the assessment of refractory periods, including the stimulus amplitude and the drive rate or CL. Longer CLs are generally associated with longer refractory periods, but refractory periods of different parts of the conducting system do not respond comparably with changes in the drive CLs.³⁰

Additionally, the measured ERP is invariably related to the current used. Thus, standardization of the pacing output is required. In most laboratories, it is arbitrarily standardized at twice the diastolic threshold. A more detailed method of assessing refractoriness is to define the strength-interval curves at these sites. The steep portion of that curve defines the ERP of that tissue. The use of increasing current strengths to 10 mA usually shortens the measured ERP by approximately 30 milliseconds. However, such a method does not offer a useful clinical advantage, except when the effects of antiarrhythmic drugs on ventricular excitability and refractoriness are to be characterized. Moreover, the safety of using high current strengths, especially when multiple extrastimuli are delivered, is questionable, because fibrillation is more likely to occur in such situations.

It is important that measurements of refractory periods be taken at specific sites. Measurements of atrial and ventricular ERP are taken at the site of stimulation. Measurements of AVN ERP and HPS ERP are taken from responses in the HB electrogram.²⁴

EFFECTIVE REFRACTORY PERIOD. The ERP is the longest premature coupling interval (S_1 - S_2) at a designated stimulus amplitude (usually 2× diastolic threshold) that results in failure of propagation of the premature impulse through a tissue (i.e., fails to capture). ERP therefore must be measured proximal to the refractory tissue.

RELATIVE REFRACTORY PERIOD. The RRP is defined as the longest premature coupling interval (S_1 - S_2) that results in prolonged conduction of the premature impulse (an increase in stimulus to distal response time) compared with the conduction of the stimulus delivered during the basic drive train. Conduction is slowed when a wavefront encounters tissue that is not completely repolarized. Thus, the RRP marks the end of the full recovery period, the zone during which conduction of the premature and basic drive impulses is identical. The RRP is generally slightly longer than the ERP by an amount called the *latency period*. During the latency period, the tissue is excitable, but the excitation wavefront conducts with slower or even decremental conduction.

FUNCTIONAL REFRACTORY PERIOD. The functional refractory period (FRP) is the shortest interval between two consecutively conducted impulses out of a cardiac tissue resulting from any two consecutive input impulses into that tissue (i.e., the shortest output interval that can occur in response to *any* input interval in a particular tissue). Because the FRP is a measure of output from a tissue, it is described by measuring points distal to that tissue. It is helpful to think of the FRP as a response-to-response measurement (in contrast, the ERP is a stimulus-to-stimulus measurement). Therefore, the FRP is a measure of refractoriness *and* conduction velocity of a tissue.

The definitions of anterograde ERP and FRP of the AV conduction system are given in [Table 4-1](#).²⁴

CYCLE LENGTHS RESPONSIVENESS OF REFRACTORY PERIODS

Normally, refractoriness of the atrial, HPS, and ventricular tissue is directly related to the basic drive CL (i.e., the ERP shortens with decreasing basic drive CL). This phenomenon (termed *peeling of refractoriness*) results from rate-related shortening of the action potential duration and is most marked in the HPS.³² Abrupt changes in the CL also affect refractoriness of these tissues. A change from a long- to short-drive CL (e.g., with introduction of an extrastimulus [S_2] following a pacing drive [S_1] with a long CL) shortens the ERP of the HPS and atrium, whereas a change from a short to a long drive CL markedly prolongs the HPS ERP but alters the ventricular ERP little, if at all. Refractoriness of the atrial, HPS, and ventricular tissue appears relatively independent of autonomic tone; however,

**TABLE 4-1 Definition of Refractory Periods**

	ERP	RRP	FRP
Atrium	Longest S ₁ -S ₂ interval that fails to achieve atrial capture	Longest S ₁ -S ₂ interval at which S ₂ -A ₂ is > S ₁ -A ₁	Shortest A ₁ -A ₂ interval (recorded at a designated site, often the HB region) in response to any S ₁ -S ₂
AVN	Longest A ₁ -A ₂ interval (measured at the HB region) that fails to propagate to the HB	Longest A ₁ -A ₂ interval at which A ₂ -H ₂ is > A ₁ -H ₁	Shortest H ₁ -H ₂ interval in response to any A ₁ -A ₂
HPS	Longest H ₁ -H ₂ interval that fails to propagate to the ventricles	Longest H ₁ -H ₂ interval at which H ₂ -V ₂ is > H ₁ -V ₁ or generates an aberrant QRS complex	Shortest V ₁ -V ₂ interval in response to any H ₁ -H ₂
Ventricle	Longest S ₁ -S ₂ interval that fails to achieve ventricular capture	Longest S ₁ -S ₂ interval at which S ₂ -V ₂ is > S ₁ -V ₁	Shortest V ₁ -V ₂ interval (recorded at a designated site or) in response to any S ₁ -S ₂

AVN = atrioventricular node; ERP = effective refractory period; FRP = functional refractory period; HB = His bundle; HPS = His-Purkinje system; RRP = relative refractory period.

TABLE 4-2 Normal Refractory Periods in Adults

Data from Denes P, Wu D, Dhingra R, et al: The effects of cycle length on cardiac refractory periods in man. *Circulation* 49:32, 1974; Akhtar M, Damato AN, Batsford WP, et al: A comparative analysis of anterograde and retrograde conduction patterns in man. *Circulation* 52:766, 1975; and Josephson ME: Electrophysiologic investigation: general aspects. In Josephson ME, editor: *Clinical cardiac electrophysiology*, ed 3, Philadelphia, 2002, Lippincott Williams & Wilkins, pp 19-67.

data have shown that increased vagal tone reduces atrial ERP and increases ventricular ERP.³⁰

In contrast, the AVN ERP increases with increasing basic drive CL in response to the fatigue phenomenon, which most likely results because AVN refractoriness is time-dependent and exceeds its action potential duration (unlike HPS refractoriness). Additionally, AVN refractory periods are labile and can be markedly affected by the autonomic tone. On the other hand, the response of AVN FRP to changes in pacing CL is variable, but it tends to decrease with decreasing pacing CL.³² This paradox occurs because the FRP is not a true measure of refractoriness encountered by an atrial extrastimulus (AES; A₂); it is significantly determined by the AVN conduction time of the basic drive beat (A₁-H₁); the longer the A₁-H₁ is, the shorter the calculated FRP will be at any A₂-H₂.³³

LIMITATIONS OF TESTS OF CONDUCTION AND REFRACTORINESS

It is unusual to be able to collect a complete set of measurements. With refractory period testing, the atrial ERP is often longer than the AVN ERP, so that atrial refractoriness is encountered before AVN refractoriness, thus limiting the ability to assess the latter. Moreover, an AES cannot be used to test the HPS if conduction is blocked at the AVN level. This is a limitation that applies to most patients undergoing conduction or refractory period testing.³¹ On the other hand, it is possible to assess anterograde conduction and refractoriness distal to the AVN by direct pacing of the HB. This is not part of the routine EP evaluation, however, and is reserved for cases in which the information is particularly desired.⁶

It is important to recognize that atrial conduction can materially affect the determination of refractory periods. Therefore, refractory periods should not be timed from the site of stimulation, but from the point in the conduction cascade that is being assessed. For example, if the high RA is stimulated in a patient with a left lateral BT, an early AES can encounter the RRP of the atrium, so that intraatrial conduction time is prolonged. Thus, the timing of the S₁-S₂ stimuli in the high RA would be shorter than the timing of the propagated impulse when it arrives at the region of the BT as the local A₁-A₂ interval.

A wide range of normal values has been reported for refractory periods (Table 4-2). However, it is difficult to interpret these so-called normal values because they come from pooled data using different standards (different pacing CLs, stimulus strengths, and pulse widths).^{24,31,32}

Atrial Stimulation

Technical Aspects

Atrial stimulation provides a method for evaluation of the functional properties of the sinus node and AV conduction system and of the means of induction of different arrhythmias (supraventricular and, occasionally, ventricular arrhythmias). Atrial stimulation from different atrial sites can result in different patterns of AV conduction. Thus, stimulation should be performed from the same site if the effects of drugs and physiological maneuvers are to be studied. Atrial stimulation is usually performed from the high RA and CS.

Rate-incremental atrial pacing is usually started at a pacing CL just shorter than the sinus CL, with progressive shortening of the pacing CL (by 10- to 20-millisecond decrements) until 1:1 atrial capture is lost, Wenckebach AVN block develops, or a pacing CL of 200 to 250 milliseconds is reached. Ramp atrial pacing is equivalent to rate-incremental pacing if AVN Wenckebach CL is all that is required. Stepwise rate-incremental pacing, however, also allows evaluation of sinus node recovery time at each drive CL. Atrial pacing should always be synchronized because alteration of the coupling interval of the first paced beat of the pacing drive can affect subsequent AV conduction.

During stepwise rate-incremental pacing, pacing should be continued long enough (usually 15 to 60 seconds) at each pacing CL to ensure stability of conduction intervals and to overcome two factors that significantly influence the development of a steady state: the phenomenon of accommodation and the effects of autonomic tone. During rate-incremental pacing, if the coupling interval of the first beat of the drive is not synchronized, it can be shorter, longer, or equal to the subsequent pacing CL. Therefore, one can observe an increasing, decreasing, or stable AH interval pattern for several cycles, and the initial AH interval can be different from

the steady-state AH interval. Oscillations of the AH interval, which dampen to a steady level, or AVN Wenckebach can occur under these circumstances. With regard to influence of the autonomic tone on AVN conduction, rapid pacing can produce variations in AVN conduction, depending on the patient's immediate autonomic state. Rapid pacing can also provoke symptoms or hypotension in patients who then produce neurohumoral responses that can alter results. Therefore, for assessment of AV conduction, ramp pacing is often an attractive alternative to the stepwise method. The pacing rate is slowly increased at 2 to 4 beats/min/sec (or the pacing CL is decreased by 10 milliseconds every several paced beats) until block occurs.²⁴

AES is used for assessment of atrial and AVN refractory periods and for induction of arrhythmias. During programmed stimulation, a sequence of eight paced stimuli is delivered at a constant rate (the S_1 drive), which allows stable AVN conduction. Following these eight beats, an AES (S_2) is delivered. This stimulation sequence is repeated at progressively shorter S_1 - S_2 coupling intervals, thus allowing the response of the sinus node and AVN to be recorded across a range of premature test stimuli.

Normal Response to Rate-Incremental Atrial Pacing

SINUS NODE RESPONSE TO ATRIAL PACING

The sinus node is the prototype of an automatic focus. Automatic rhythms are characterized by spontaneous depolarization, overdrive suppression, and post-overdrive warm-up to baseline CL. Rapid atrial pacing results in overdrive suppression of the sinus rate, with prolongation of the return sinus CL following termination of the pacing train. Longer pacing trains and faster pacing rates further prolong the return cycle. After cessation of pacing, the sinus rate resumes discharge at a slower rate and gradually speeds up (warms up) to return to the prepacing sinus rate.

Sinus node recovery time is the interval between the end of a period of pacing-induced overdrive suppression of sinus node

activity and the return of sinus node function, manifested on the surface ECG by a post-pacing sinus P wave.

ATRIOVENTRICULAR NODE RESPONSE TO ATRIAL PACING

The normal AVN response to rate-incremental atrial pacing is for the PR and AH intervals to increase gradually as the pacing CL decreases until AVN Wenckebach block appears (Fig. 4-20). With further decrease in the pacing CL, higher degrees of AV block (2:1 or 3:1) can appear. Infranodal conduction (HV interval) generally remains unaffected.

Wenckebach block is frequently atypical; that is, the AH interval does not increase gradually in decreasing increments but stabilizes for several beats before the block, or it can show its greatest increment in the last conducted beat. The incidence of atypical Wenckebach block is highest during long Wenckebach cycles (longer than 6.5). It is important to distinguish atypical Wenckebach periodicity from Mobitz II AV block. Additionally, it is important to ensure that the ventricular pauses observed during atrial pacing are not secondary to loss of atrial capture or the occurrence of AVN echo beats (pseudoblock; see Fig. 4-20).

AVN Wenckebach CL is the longest pacing CL at which Wenckebach block in the AVN is observed. Normally, Wenckebach CL is 500 to 350 milliseconds, and it is sensitive to the autonomic tone. There is a correlation between the AH interval during NSR and the Wenckebach CL; patients with a long AH interval during NSR tend to develop Wenckebach block at a longer pacing CL, and vice versa.

At short pacing CLs (less than 350 milliseconds), infranodal block can occasionally occur in patients with a normal baseline HV interval and QRS. This occurs especially when atrial pacing is started during NSR with the first or second paced impulses acting as a long-short sequence. The HPS can also show accommodation following the initiation of pacing. Prolongation of the HV interval or infranodal block at a pacing CL longer than 400 milliseconds is abnormal and indicates infranodal conduction abnormalities.

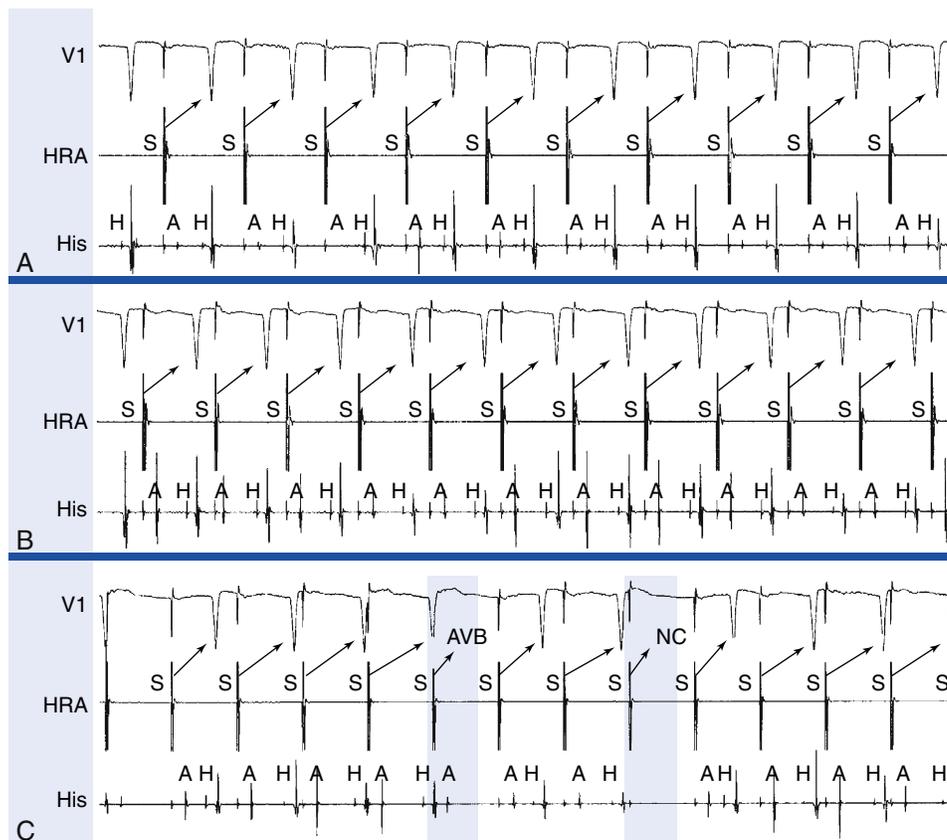

FIGURE 4-20 Normal atrioventricular node (AVN) response to rate-incremental atrial pacing. **A**, Fixed-rate high right atrial (HRA) pacing (S) at a cycle length (CL) of 600 milliseconds. **B**, Decreasing the pacing CL to 500 milliseconds results in prolongation of the atrial-His bundle (AH) interval, as illustrated in the His bundle recording (His). Infranodal conduction (His bundle-ventricular [HV] interval) remains unaffected. **C**, Further decrement of the pacing CL results in progressive prolongation of the AH interval until block occurs in the AVN (AVB), followed by resumption of conduction, indicating Wenckebach CL. The site of block is in the AVN because no His bundle deflection is present after the nonconducted atrial stimulus. Of note, apparent block of another atrial stimulus is observed (pseudoblock) because of failure of the atrial stimulus to capture (NC), which is confirmed by the absence of an atrial electrogram on the His bundle recording after the stimulus artifact.

ATRIAL RESPONSE TO ATRIAL PACING

It is usually possible to maintain 1:1 atrial capture with rate-incremental pacing techniques to a pacing CL of 200 to 300 milliseconds. Pacing threshold normally tends to increase at faster rates. Rate-incremental pacing can result in prolongation of the intraatrial (PA interval) and interatrial conduction. At rapid pacing rates, induction of AF is not rare and is not necessarily an abnormal response. Vagal tone and medications such as adenosine and edrophonium can slow the sinus rate, but they tend to shorten the atrial ERP, which makes the atrium more vulnerable to induction of AF.

Normal Response to Atrial Premature Stimulation

SINUS NODE RESPONSE TO ATRIAL EXTRASTIMULATION

Four zones of response of the sinus node to AES have been identified: the zone of collision, the zone of reset, the zone of interpolation, and the zone of reentry (Fig. 4-21).

ZONE I. A late-coupled AES with very long A_1 - A_2 intervals (with A_2 falling in the last 20% to 30% of the sinus CL) collides with the impulse already emerging from the sinus node, resulting in fusion of atrial activation (fusion between the AES [A_2] with the spontaneous sinus impulse [A_1]) or paced-only atrial activation sequence; it fails to affect the timing of the next sinus beat, thus producing a fully compensatory pause. This zone, also known as the zone of collision, zone of interference, and nonreset zone, is defined by the range of A_1 - A_2 at which A_2 - A_3 is fully compensatory (see Fig. 4-21).²⁴

ZONE II. An earlier coupled AES results in penetration of the sinus node with resetting so that the resulting pause is less than compensatory (i.e., A_1 - A_3 is $< 2 \times [A_1$ - $A_1]$), but without changing sinus node automaticity. The range of A_1 - A_2 at which resetting of the sinus pacemaker occurs, resulting in a less than compensatory pause, defines zone II, also known as the zone of reset (see Fig. 4-21). This zone is typically of long duration (40% to 50% of the sinus CL). In most patients, A_2 - A_3 remains constant throughout zone II, thus producing a plateau in the curve because, although A_2 penetrates and resets the sinus node, it does so without changing the sinus pacemaker automaticity. Hence, A_2 - A_3 should equal the spontaneous sinus CL (A_1 - A_1) plus the time it takes the AES (A_2) to enter and exit the sinus node. The difference between A_2 - A_3 and A_1 - A_1 therefore has been taken as an estimate of total sinoatrial conduction time.²⁴

ZONE III. A very early coupled AES encounters a refractory sinus node (following the last sinus discharge) and fails to enter or reset the sinus node. The next sinus discharge is on time because the atrium is already fully recovered following that early AES. The range of A_1 - A_2 coupling intervals at which A_2 - A_3 is less than A_1 - A_1 , and A_1 - A_3 is less than $2 \times (A_1$ - $A_1)$, defines zone III, also known as the zone of interpolation (see Fig. 4-21). The A_1 - A_2 coupling intervals at which incomplete interpolation is first observed define the RRP of the perinodal tissue. Some refer to this as the sinus node refractory period. In this case, A_3 represents delay of A_1 exiting the sinus node, which has not been affected.³⁴ The A_1 - A_2 coupling interval at which complete interpolation is observed probably defines the ERP of the most peripheral of the perinodal tissue because the sinus impulse does not encounter refractory tissue on its exit from the sinus node. In this case, $(A_1$ - A_2) + $(A_2$ - A_3) = A_1 - A_1 and sinus node entrance block is said to exist.³⁴

ZONE IV. This zone, also known as the zone of reentry, is defined as the range of A_1 - A_2 at which A_2 - A_3 is less than A_1 - A_1 , $(A_1$ - A_2) + $(A_2$ - A_3) is less than A_1 - A_1 , and the atrial activation sequence and P wave morphology are identical to those of the sinus. The incidence of single beats of sinus node reentry is approximately 11% in the normal population.

ATRIOVENTRICULAR NODAL RESPONSE TO ATRIAL EXTRASTIMULATION

Progressively premature AES results in prolongation of PR and AH intervals, with inverse relationship between the AES coupling interval (A_1 - A_2) and the AH interval (A_2 - H_2). The shorter the coupling interval

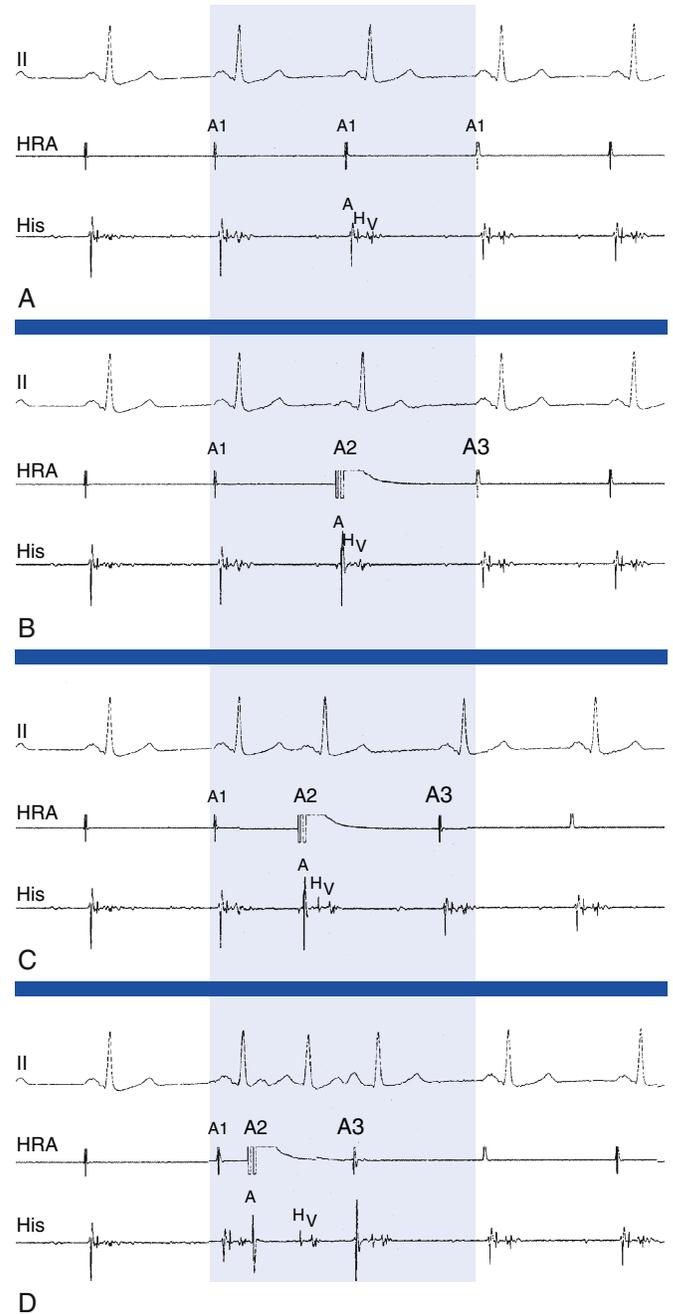

FIGURE 4-21 Normal sinus node and atrioventricular node response to atrial extrastimulation. **A**, Baseline sinus rhythm shown in surface ECG lead II, high right atrium (HRA) recording, and His bundle (His) recording. The shaded area represents two sinus cycle lengths ($2 \times [A_1$ - $A_1]$). **B**, A late coupled atrial extrastimulus (AES) (A_2) collides with the exiting sinus impulse and therefore does not affect (or reset) the sinus pacemaker (zone of collision). The next sinus impulse (A_3) occurs at exactly twice the baseline sinus cycle length. **C**, An early coupled AES is able to penetrate and reset the sinus node (zone of resetting). **D**, An even earlier coupled AES reaches refractory tissue around the sinus node and is thus unable to penetrate the sinus node (entrance block); therefore, it does not affect sinus node discharge. The next spontaneous sinus beat (A_3) arrives exactly at the sinus interval (zone of interpolation). The atrial-His bundle (AH) interval progressively prolongs with progressively premature coupling intervals (**B** to **D**). In contrast, the His bundle-ventricular (HV) interval remains constant.

of the AES is, the longer the A_2 - H_2 interval will be (see Fig. 4-21). More premature AES can block in the AVN with no conduction to the ventricle (defining AVN ERP). Occasionally, conduction delay and block occur in the HPS, especially when the AES is delivered following long basic drive CLs, because HPS refractoriness frequently exceeds the AVN FRP at long pacing CLs.

The patterns of AV conduction can be expressed by plotting refractory period relating the A_1 - A_2 interval to the responses of the AVN and HPS. Plotting the A_1 - A_2 interval versus the H_1 - H_2 and V_1 - V_2 intervals illustrates the functional input-output relationship between the basic drive beat and the AES and provides an assessment of the FRP of the AV conduction system. In contrast, plotting the A_2 - H_2 interval (AVN conduction time of the AES) and the H_2 - V_2 interval (HPS conduction time of the AES) versus the A_1 - A_2 interval (the AES coupling interval) allows determination of the conduction times through the various components of the AV conduction system.³²

TYPE I RESPONSE. In this type, the progressively premature AES encounters progressive delay in the AVN without any changes in the HPS. Therefore, refractoriness of the AVN determines the FRP of the entire AV conduction, and the ERP of the AV conduction system is determined at the atrial or AVN level. This response is characterized by initial shortening of the H_1 - H_2 and V_1 - V_2 intervals as the AES coupling interval (A_1 - A_2) shortens, whereas AVN conduction (A_2 - H_2) and HPS conduction (H_2 - V_2) remain stable (Fig. 4-22). With further shortening of the A_1 - A_2 interval, the RRP of the AVN is encountered, resulting in progressive delay in AVN conduction (manifesting as progressive prolongation of the A_2 - H_2 interval) accompanied by stable HPS conduction (H_2 - V_2) and a progressive but identical prolongation of both the H_1 - H_2 and V_1 - V_2 intervals, until the AES is blocked within the AVN (AVN ERP) or until the atrial ERP is reached. The minimum H_1 - H_2 and V_1 - V_2 intervals attained define the FRP of the AVN and entire AV conduction system. AVN conduction (A_2 - H_2) usually increases by 2 to 3x baseline values before block.²⁴

TYPE II RESPONSE. In type II response, conduction delay occurs initially in the AVN; however, with further shortening of the AES coupling interval, progressive delay develops in the HPS. Therefore, refractoriness of the HPS determines the FRP of the entire AV conduction system, and the ERP of the AV conduction system is determined at any level. At longer A_1 - A_2 intervals, type II response is similar to type I response; however, as the A_1 - A_2 interval shortens, conduction delay develops initially in the AVN (manifesting as progressive prolongation of the A_2 - H_2 interval) but then in the HPS (manifesting as aberrant QRS conduction and progressive prolongation of the H_2 - V_2 interval) as the RRP of the HPS is encountered. Therefore, in contrast to type I response, both A_2 - H_2 and H_2 - V_2 intervals prolong in response to progressively shorter A_1 - A_2 , resulting in divergence in the H_1 - H_2 and V_1 - V_2 curves until the AES is blocked within the AVN (AVN ERP), in the HPS (HPS ERP), or until the atrial ERP is reached (see Fig. 4-22). Block usually occurs in the AVN, but it can occur in the atrium and occasionally in the HPS (modified type II response). AVN conduction (A_2 - H_2) usually increases only modestly (by less than 2x baseline values before block).²⁴

TYPE III RESPONSE. In type III response, conduction delay occurs initially in the AVN; however, at a critical AES coupling interval, sudden and marked delay develops in the HPS. Therefore, refractoriness of the HPS determines the FRP of the entire AV conduction system, and the ERP of the AV conduction system is determined at any level. However, in contrast to type II response, the HPS is invariably the first site of block. At longer A_1 - A_2 intervals, type II response is similar to type I response; however, as the A_1 - A_2 interval shortens, progressive delay is noted initially in the AVN (manifest as progressive prolongation in the A_2 - H_2 interval), but then a sudden delay of conduction in the HPS occurs (manifesting as aberrant QRS conduction and a sudden jump in the H_2 - V_2 interval). This results in a break in the V_1 - V_2 curve, which subsequently descends until, at a critical A_1 - A_2 interval, the impulse blocks in the AVN or HPS (see Fig. 4-22). The FRP of the HPS occurs just

before the marked jump in H_2 - V_2 . AVN conduction (A_2 - H_2) usually increases by less than 2x baseline values before block.²⁴

Type I response is the most common pattern, whereas type III response is the least common. The pattern of AV conduction (type I, II, or III), however, is not fixed in any patient. Drugs (e.g., atropine, isoproterenol) or changes in CL can alter the refractory period relationship among different tissues so that one type of response can be switched to another. For example, atropine can decrease the FRP of the AVN and allow the impulse to reach the HPS during its RRP, changing type I response to type II or III.

The ERP of the atrium is not infrequently reached earlier than that of the AVN, especially when the basic drive is slow (which increases atrial ERP and decreases AVN ERP) or when the patient is agitated, which increases sympathetic tone and decreases AVN ERP. The first site of block is in the AVN in most patients (45%), in the atrium in 40%, and in the HPS in 15%.³¹

ATRIAL RESPONSE TO ATRIAL EXTRASTIMULATION

Early AESs can impinge on the atrial RRP, with resulting local latency (i.e., long interval between the pacing artifact and the atrial electrogram on the pacing electrode).³¹ A very early AES delivered during the atrial ERP fails to capture the atrium. The atrial ERP can be longer or shorter than the AVN ERP, especially at long basic drive CLs or in cases of enhanced AVN conduction secondary to autonomic influences.

As with rate-incremental pacing, AES can result in prolongation of intraatrial and interatrial conduction, which is more pronounced in patients with a history of atrial arrhythmias. Development of a fractionated atrial electrogram is more often observed in patients who have a history of AF. Intraatrial block in response to AES is unusual. Occasionally, double or triple AESs induce AF in patients with no history of such arrhythmia. Such episodes usually terminate spontaneously and are not clinically relevant in the absence of a history of known or suspected atrial arrhythmias.

Repetitive Atrial Responses

Atrial stimulation can trigger extra atrial complexes or echo beats. Those complexes can be caused by different mechanisms; the most common are intraatrial reentrant beats and AVN echo beats.

Intraatrial reentrant beats usually occur at short coupling intervals. They can originate anywhere in the atrium, and atrial activation sequence depends on the site of origin of the beat. The incidence of these responses increases with increasing both the number of AESs and the number of drive-pacing CLs and stimulation sites used.

Repetitive atrial responses can also be caused by reentry in the AVN. These patients have anterograde dual AVN physiology, and the last paced beat conducts slowly down the slow AVN pathway and then retrogradely up the fast pathway to produce the echo beat (Fig. 4-23). Atrial activation sequence is consistent with retrograde conduction over the fast AVN pathway, earliest in the HB catheter recording. Atrial and ventricular activations occur simultaneously.

Ventricular Stimulation

Technical Aspects

Ventricular stimulation is used to assess retrograde (ventricular-atrial [VA]) conduction and refractory periods, retrograde atrial activation patterns, including sequences that can indicate the presence of a BT, and vulnerability to inducible ventricular arrhythmias.³¹

Stepwise rate-incremental ventricular pacing or ramp pacing is used in the assessment of VA conduction. It is unusual to provoke ventricular arrhythmias with these tests, even in patients with

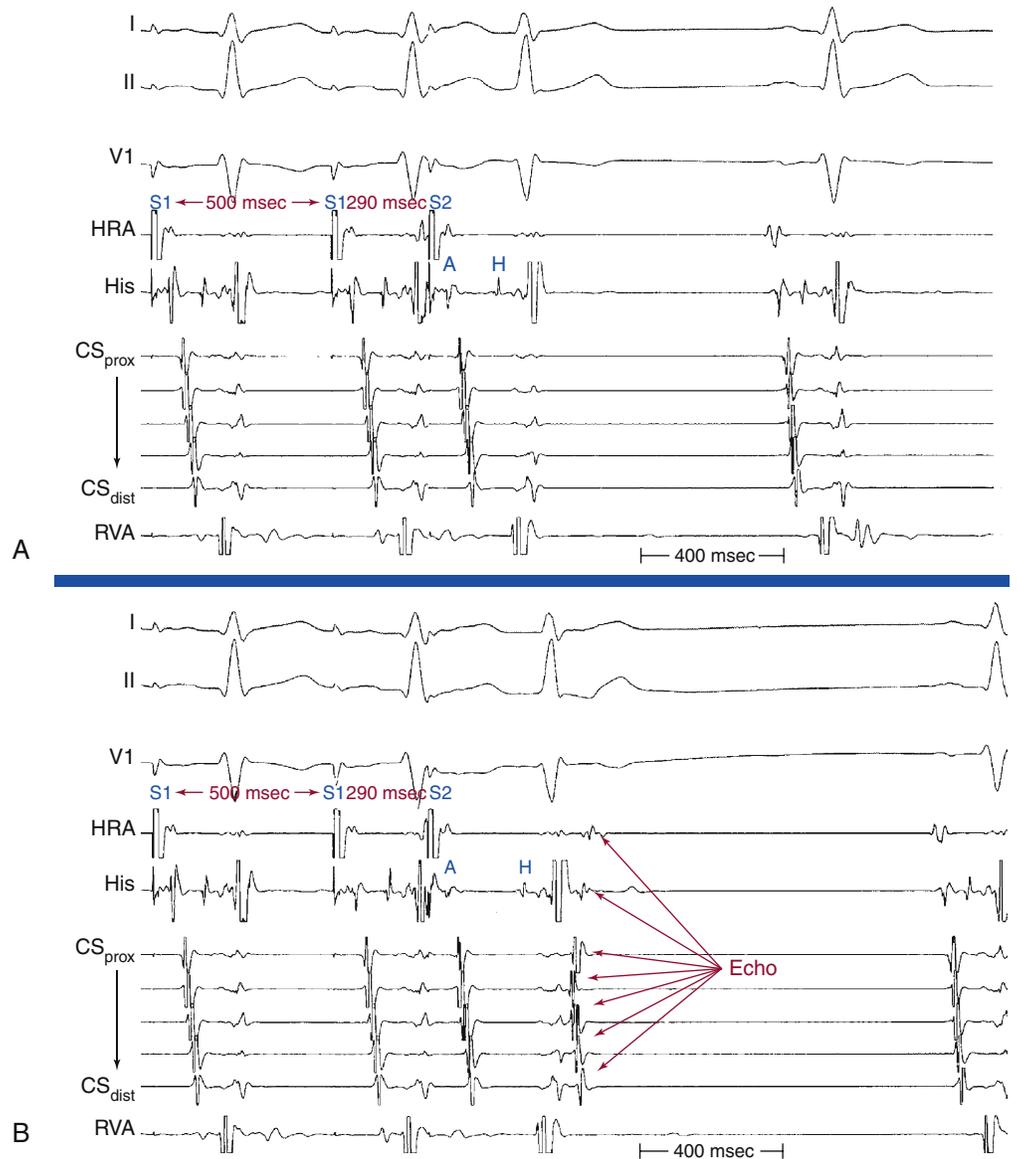

FIGURE 4-23 Anterograde dual atrio-ventricular nodal pathways. **Top**, A single extrastimulus is introduced from the high right atrium (HRA; S_2) at 290 milliseconds after the last afterdrive stimulus (S_1). This results in an atrial-His bundle (AH) interval of 140 milliseconds. **Bottom**, An extrastimulus is delivered 10 milliseconds earlier than above (280 milliseconds), resulting in marked prolongation of the AH interval to 202 milliseconds and an atrial echo. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

known ventricular arrhythmia. Rate-incremental ventricular pacing is usually started at a pacing CL just shorter than the sinus CL, and the pacing CL is then gradually decreased (in 10- to 20-millisecond decrements) down to 300 milliseconds. Shorter pacing CL may be used to assess rapid conduction in patients with supraventricular tachycardia (SVT) or to induce VT. With ramp pacing, the pacing rate is slowly increased at 2 to 4 beats/min/sec (or the pacing CL is decreased by 10 milliseconds every several paced beats) until VA block occurs.

Ventricular extrastimulus (VES) testing is used to assess ventricular, HPS, and AVN refractory periods and to induce arrhythmias.³¹ During programmed stimulation, a sequence of eight paced stimuli is delivered at a constant rate (the S_1 drive), which allows stable VA conduction. Following these eight beats, a VES (S_2) is delivered. This stimulation sequence is repeated at progressively shorter S_1 - S_2 intervals, thus allowing the response of the HPS and AVN to be recorded across a range of premature test stimuli.

During ventricular stimulation, the HB electrogram shows a retrograde His potential in 85% of patients with a normal QRS during NSR.²⁴ Ventricular pacing at the base of the heart close to the AV junction facilitates recording a retrograde His potential because it allows the ventricles to be activated much earlier relative to the HB (Fig. 4-24). The ventricular-HB (VH) or stimulus-HB (S-H) interval always exceeds the anterograde HV interval by the time it takes for the impulse to travel from the stimulation site to the ipsilateral bundle branch. In patients with normal HV intervals, a retrograde His potential can usually be seen before the ventricular electrogram in the HB recording during RV apical pacing. In contrast, when ipsilateral bundle branch block (BBB) is present, especially with long HV intervals, a retrograde His potential is less frequently seen; when it is seen, it is usually inscribed after the QRS when pacing from the ipsilateral ventricle (Fig. 4-25).

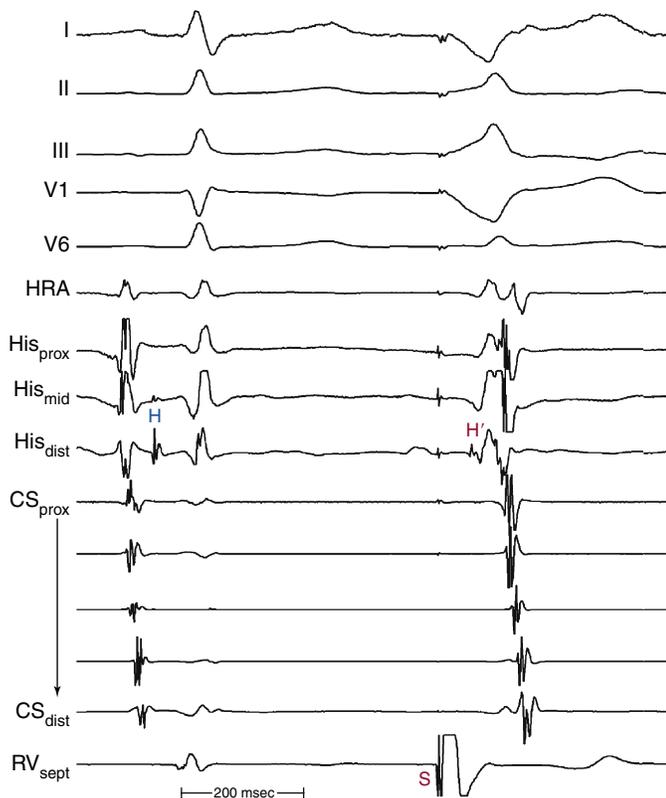

FIGURE 4-24 Retrograde activation with right ventricular (RV) septal (RV_{sept}) stimulation. Sinus and RV septal stimulated complexes (S) are shown. Retrograde atrial activation is concentric, following a retrograde His potential (H). CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; HRA = high right atrium.

Ventricular stimulation is relatively safe; however, induction of clinically irrelevant serious arrhythmias, including VF, can occur in patients with normal hearts and those who have not had spontaneous ventricular arrhythmias. The induction of these arrhythmias is directly related to the aggressiveness of the ventricular stimulation protocol. Thus, the stimulation protocol is usually limited to single or double VES in patients without a clinical history consistent with malignant ventricular arrhythmias.²⁴ The use of high pacing output can also increase the risk of such arrhythmias. Therefore, ventricular stimulation at $2\times$ diastolic threshold and 1-millisecond pulse width is preferable.

Normal Response to Rate-Incremental Ventricular Pacing

Ventricular pacing provides information about VA conduction, which is present in 40% to 90% of patients, depending on the population studied. Absence of VA conduction at any paced rate is common and normal. There is no difference in the capability of VA conduction regarding the site of ventricular stimulation in patients with a normal HPS. When present, normal VA conduction uses the normal AV conduction system, with the earliest atrial activation site usually in the septal region in proximity to the AVN. In some cases, the slow posterior AVN pathway is preferentially engaged so that the earliest atrial activation site is somewhat posterior to the AVN, closer to the CS os.²⁴

The normal AVN response to rate-incremental ventricular pacing is a gradual delay of VA conduction (manifest as gradual prolongation of the HA interval) as the pacing CL decreases. Retrograde VA Wenckebach block and a higher degree of block appear at shorter pacing CLs. Occasionally, VA Wenckebach cycles are terminated with ventricular echo beats secondary to retrograde dual AVN physiology. When a retrograde His potential is visible, a relatively constant VH interval at a rapid pacing rate, despite the development of retrograde VA block, localizes the site of block to the AVN (Fig. 4-26). When a retrograde His potential is not visible during ventricular pacing, the site of VA block, when it occurs, must be inferred from the effect of paced impulses on conduction of spontaneous or stimulated atrial beats (i.e., by analyzing the level of retrograde concealment; see Fig. 4-26). If the AH interval of the atrial beat is independent of the time relationship of the paced impulse, the site of block is in the HPS (infranodal). On the other hand, if the AH interval varies according to the coupling interval of the atrial beat to the paced QRS, or if the atrial beat fails to depolarize the HB, the site of block is in the AVN. Moreover, drugs that enhance AVN (but not HPS) conduction (e.g., atropine) improve VA conduction if the site of block is in the AVN, but they do not affect VA conduction if the site of block is in the HPS.

At comparable pacing CLs, anterograde AV conduction is better than retrograde VA conduction in most patients. AVN conduction is the major determinant of retrograde VA conduction. Patients with prolonged PR intervals are much less likely to demonstrate retrograde VA conduction.³¹ Furthermore, patients with prolonged AVN conduction are less capable of VA conduction than patients with infranodal conduction delay. Anterograde AV block in the AVN is almost universally associated with retrograde VA block. On the other hand, anterograde AV block in the HPS is associated with some degree of VA conduction in up to 40% of cases. However, the exact comparison between anterograde and retrograde AVN conduction can be limited by the absence of a visible retrograde His potential during ventricular stimulation. Consequently, localization of the exact site of conduction delay or block (AVN versus HPS) may not be feasible. The response to rate-incremental pacing at two different pacing CLs may differ because of the opposite effects of the pacing CL on AVN and HPS refractoriness.²⁴

Rapid ventricular pacing can result in ipsilateral retrograde BBB, with subsequent impulse propagation across the septum, retrogradely up the contralateral bundle branch, and then to the HB. Such an event can manifest as sudden prolongation of the HV interval during pacing. This can be followed by resumption

of VA conduction after a period of VA block in the AVN when the VH interval is short, because the delay in the HPS allows recovery of the AVN (the gap phenomenon). This occurrence can permit better visualization of the His potential, and, by comparing the ventricular electrogram in the HB recording when the His potential is clearly delayed with that with normal retrograde

ipsilateral bundle branch conduction, a previously unappreciated His potential within that electrogram can then be visualized (see Fig. 4-26).

To exclude the presence of a nondecremental retrogradely conducting BT, the VES technique is usually more effective than rate-incremental ventricular pacing for demonstrating normal

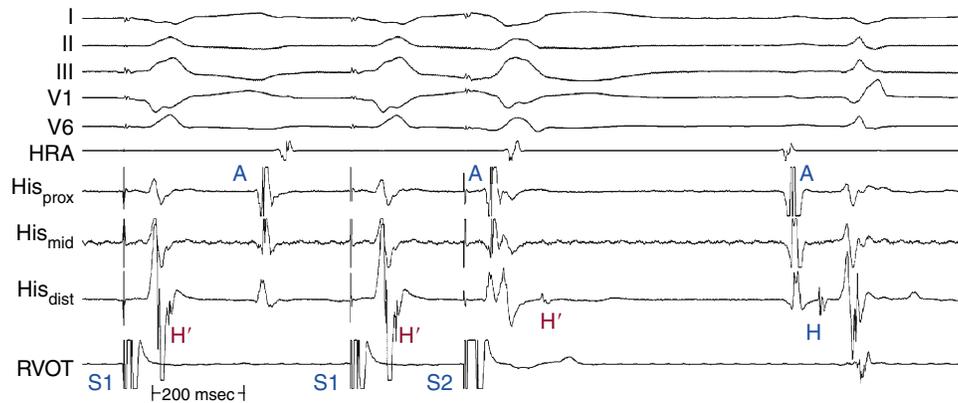

FIGURE 4-25 His recordings in the presence of right bundle branch block (RBBB). Two right ventricular drive complexes (S_1) and an extrastimulus (S_2) are shown, with a subsequent sinus complex with typical RBBB. Retrograde His activation (H') cannot traverse the blocked right bundle branch and must occur over the left bundle branch following transeptal ventricular activation, resulting in a long S- H' interval. The S- H' interval prolongs further following the extrastimulus (S_2). Of note, S_2 is associated with retrograde ventricular-atrial block in the atrioventricular node. His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; RVOT = right ventricular outflow tract.

FIGURE 4-26 Complete retrograde ventricular-atrial (VA) block in the atrioventricular node (AVN). Three ventricular paced complexes are shown, the first two of which have a clear retrograde His potential (H') and no retrograde atrial activation (sinus rhythm in atria), suggesting the AVN as the site of VA block. However, the site of VA block (AVN versus His-Purkinje system) following the third ventricular complex is not obvious because there is no His potential visible following that ventricular stimulus. The site of VA block, however, can be inferred from the effect of paced impulses on conduction of the sinus complex after cessation of pacing. The atrial-His (AH) interval of the conducted sinus complex after the last paced ventricular complex is longer than the baseline AH interval (at right), consistent with retrograde penetration of the AVN by the ventricular stimulus (resulting in concealed conduction) and therefore suggesting the AVN as the site of VA block. His_{dist} = distal His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; RVA = right ventricular apex.

prolongation of the VA interval. If uncertainty continues to exist, adenosine can be extremely helpful, which is much more likely to block AVN conduction than BT.

Normal Response to Ventricular Premature Stimulation

Because a retrograde His potential may not be visible in 15% to 20% of patients during ventricular pacing, evaluation of the HPS, and consequently VA conduction, is often incomplete. Additionally, in the absence of a visible His potential during ventricular pacing, the FRP of the HPS (theoretically, the shortest H_1-H_2 interval at any coupling interval) must be approximated by the S_1-H_2 interval (S_1 being the stimulus artifact of the basic drive CL), so that the S_1-H_2 interval approximates the H_1-H_2 interval, but exceeds it by a fixed amount, the S_1-H_1 interval. Retrograde AVN conduction time (H_2-A_2) is best measured from the end of the His potential to the onset of the atrial electrogram on the HB tracing.

Typically, VA conduction proceeds over the RB or left bundle branch (LB), and then to the HB, AVN, and atrium. With a progressively premature VES, the initial delay occurs in the HPS, and the most common site of retrograde VA block is in the HPS. Delay or block in the AVN can occur but is less common.³¹

The typical response can be graphically displayed by plotting the S_1-S_2 interval versus S_2-H_2 , S_2-A_2 , and H_2-A_2 intervals, as well as the S_1-S_2 interval versus S_1-H_2 and A_1-A_2 intervals.³¹ At long S_1-S_2 intervals, no delay occurs in the retrograde conduction (S_2-A_2). Further shortening of the S_1-S_2 intervals results in prolongation in the S_2-A_2 intervals, and localization of the exact site of S_2-A_2 delay may not be feasible unless a retrograde His potential is visible (Fig. 4-27A and B). During RV pacing, the initial delay usually occurs in retrograde RB conduction. At a critical coupling interval (S_1-S_2), block in the RB occurs, and retrograde conduction proceeds over the LB. A retrograde His potential (H_2) eventually becomes visible after the ventricular electrogram in the HB recording (see Fig. 4-27D). Once a retrograde His potential is seen, progressive prolongation in the S_2-H_2 interval (HPS conduction delay) occurs as the S_1-S_2 interval shortens, and the VA conduction time (S_2-A_2) is determined by the HPS conduction delay (S_2-H_2), as demonstrated by parallel S_2-A_2 and S_2-H_2 curves. The degree of prolongation of the S_2-H_2 interval varies, but it can exceed 300 milliseconds.²⁴

In patients with preexistent BBB, retrograde block in the same bundle is common. This is suggested by a prolonged VH interval during a constant paced drive CL or late VES from the ventricle ipsilateral to the BBB, so that a retrograde His potential is usually seen after the ventricular electrogram in the HB tracing (see Fig. 4-25).

In most cases, once a retrograde His potential is visible, the S_1-H_2 curve becomes almost horizontal because the increase in the S_2-H_2 interval is similar to the decrease in the S_1-S_2 interval. This response results in a relatively constant input to the AVN (as determined by measuring the S_1-H_2 interval) and consequently a fixed H_2-A_2 interval. Occasionally, the increase in the S_2-H_2 interval greatly exceeds the decrease in the S_1-S_2 interval, thus giving rise to an ascending limb on the curve, with a subsequent decrease in the AVN conduction time (H_2-A_2) because of decreased input to the AVN. As the S_1-S_2 interval is further shortened, block within the HPS appears, or ventricular ERP is reached.²⁴

HPS refractoriness depends markedly on the CL, and shortening of the basic drive CL shortens the FRP and ERP of the HPS and ventricle. The general pattern, however, remains the same, with an almost linear increase in the S_2-H_2 interval as the S_1-S_2 interval is shortened. The curves for S_2-H_2 versus S_1-S_2 are shifted to the left, and the curves for S_1-S_2 versus S_1-H_2 are shifted down.

Repetitive Ventricular Responses

Ventricular stimulation can trigger extra ventricular beats. Those beats can be caused by different mechanisms; the most common are bundle branch reentry (BBR) beats, ventricular echo beats,

and intraventricular reentrant beats. Multiple mechanisms may be responsible for repetitive responses in the same patient. Almost always, one of these responses is BBR.

BUNDLE BRANCH REENTRY BEATS

This is the most common response and can occur in up to 50% of normal individuals. In patients with normal hearts, BBR is rarely sustained and is usually self-limiting in one or two complexes. The occurrence of nonsustained BBR in patients with or without structural heart disease is not related to the presence of spontaneous ventricular arrhythmias.

The longest refractory periods in the HPS are found most distally, at or near the Purkinje-myocardial junction. This creates a distal gate that inhibits retrograde conduction of early VES. Thus, when an early VES is delivered to the RV apex, the nearby distal gate of the RB can still be refractory. The results are progressive retrograde conduction delay and block occurring in the distal RB, with subsequent transeptal conduction of the impulse to the LV, leading to retrograde conduction up the LB to the HB (see Fig. 4-27D). At this point, the His potential usually follows the local ventricular electrogram in the HB recording, and retrograde atrial stimulation, if present, follows the His potential. Further decrease in the VES coupling interval produces progressive delay in retrograde HPS conduction. When a critical degree of HPS delay (S_2-H_2) is attained, the impulse can return down the initially blocked RB, thus producing a QRS with a typical LBBB pattern and left-axis deviation, because ventricular activation originates solely from conduction over the RB (see Fig. 4-27E). This beat is called a BBR beat or V_3 phenomenon.²⁴

The HV interval of the BBR beat usually approximates that during anterograde conduction. However, it can be shorter or longer, depending on the site of HB recording relative to the turnaround point and on anterograde conduction delay down the RB.

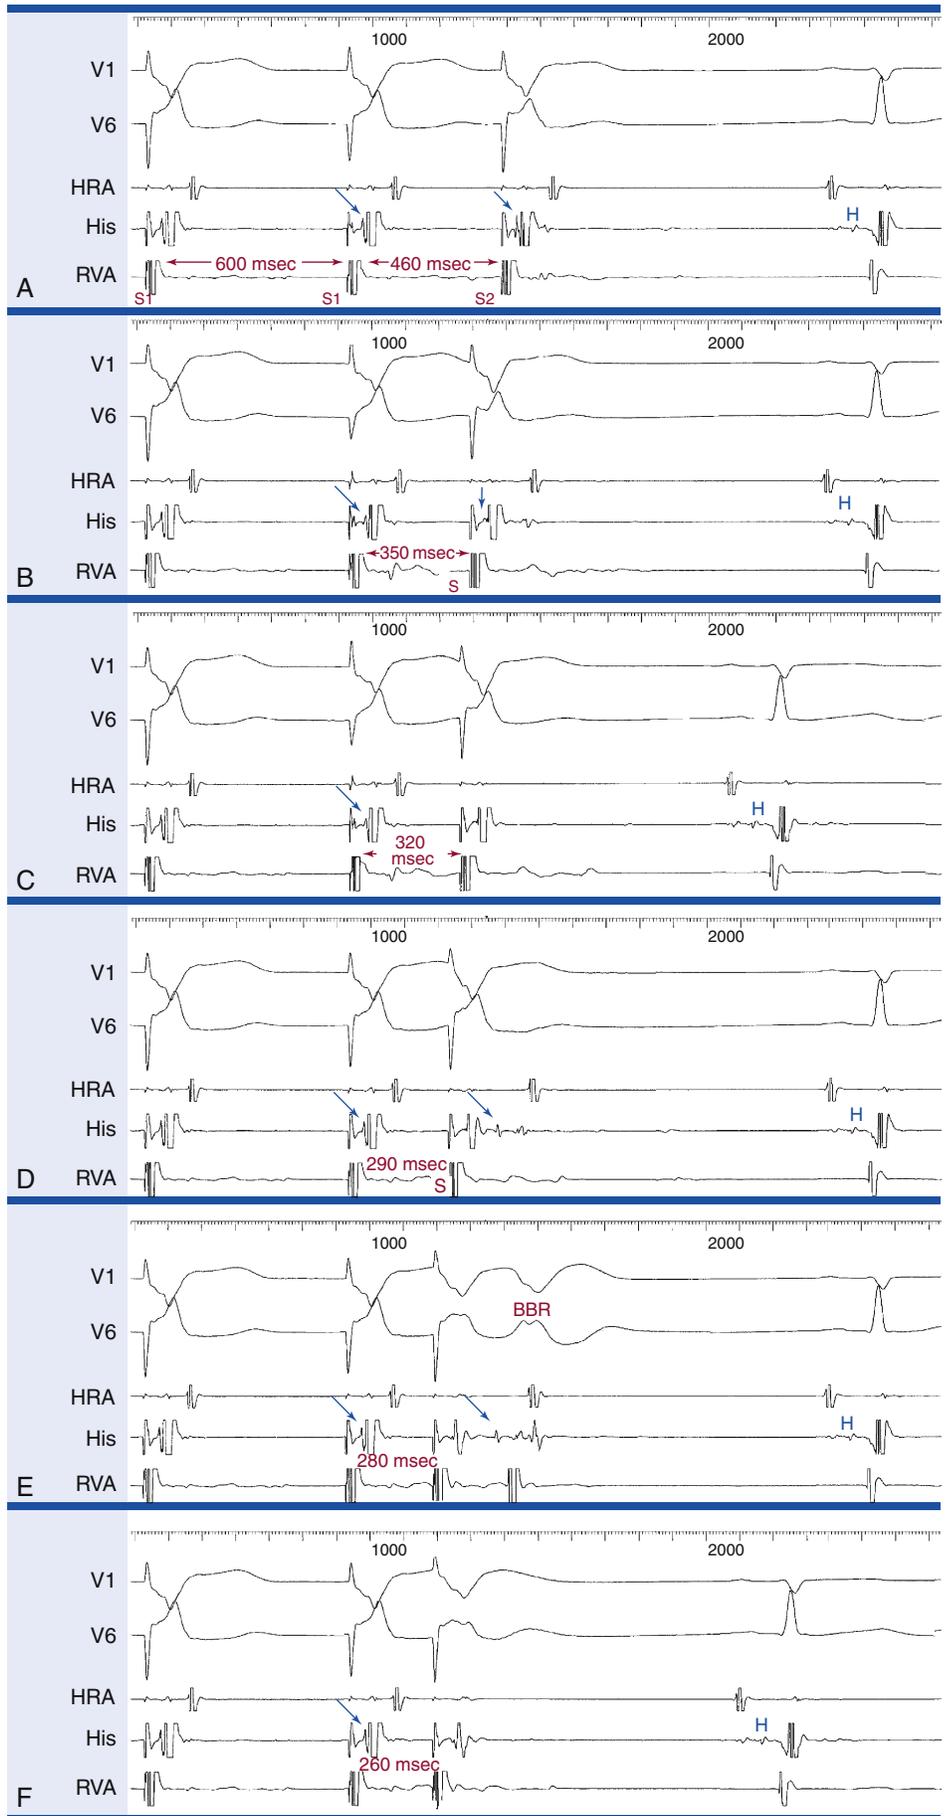

VENTRICULAR ECHO BEATS

This is the second most common response and can occur in 15% to 30% of normal individuals. It is caused by reentry in the AVN, and it appears when a critical degree of retrograde AVN delay is achieved. These patients have retrograde dual AVN physiology, and the last paced beat conducts slowly retrogradely up the slow AVN pathway and then anterogradely down the fast pathway to produce the echo beat (Fig. 4-28). In most cases, this delay is achieved before the appearance of a retrograde His potential beyond the local ventricular electrogram. At a critical H_2-A_2 interval (or V_2-A_2 interval, when the His potential cannot be seen), an extra beat with a normal anterograde QRS morphology results. Atrial activity also precedes the His potential before the echo beat.

This phenomenon can occur at long or short coupling intervals and depends only on the degree of retrograde AVN conduction delay. The presence of block within the HPS prevents its occurrence, as does block within the AVN. If a retrograde His potential can be seen throughout the zone of coupling intervals, a reciprocal relationship between the H_2-A_2 and A_2-H_3 intervals can often be noted.

INTRAVENTRICULAR REENTRANT BEATS

This response usually occurs in the setting of a cardiac pathological condition, especially coronary artery disease with a prior myocardial infarction (MI). It usually occurs at short coupling intervals and can have any morphology, but more often RBBB than LBBB in patients with a prior MI. Such beats occur in fewer than 15% of normal patients with a single VES at 2x diastolic threshold and in 24% with double VESs. In contrast, intraventricular reentrant beats occur following single or double VESs in 70% to 75% of patients with prior VT or VF and cardiac disease. The incidence of this response increases with increasing the number of VESs, basic drive CLs, and stimulation sites used. These responses are usually nonsustained (1 to 30 complexes) and typically polymorphic. In

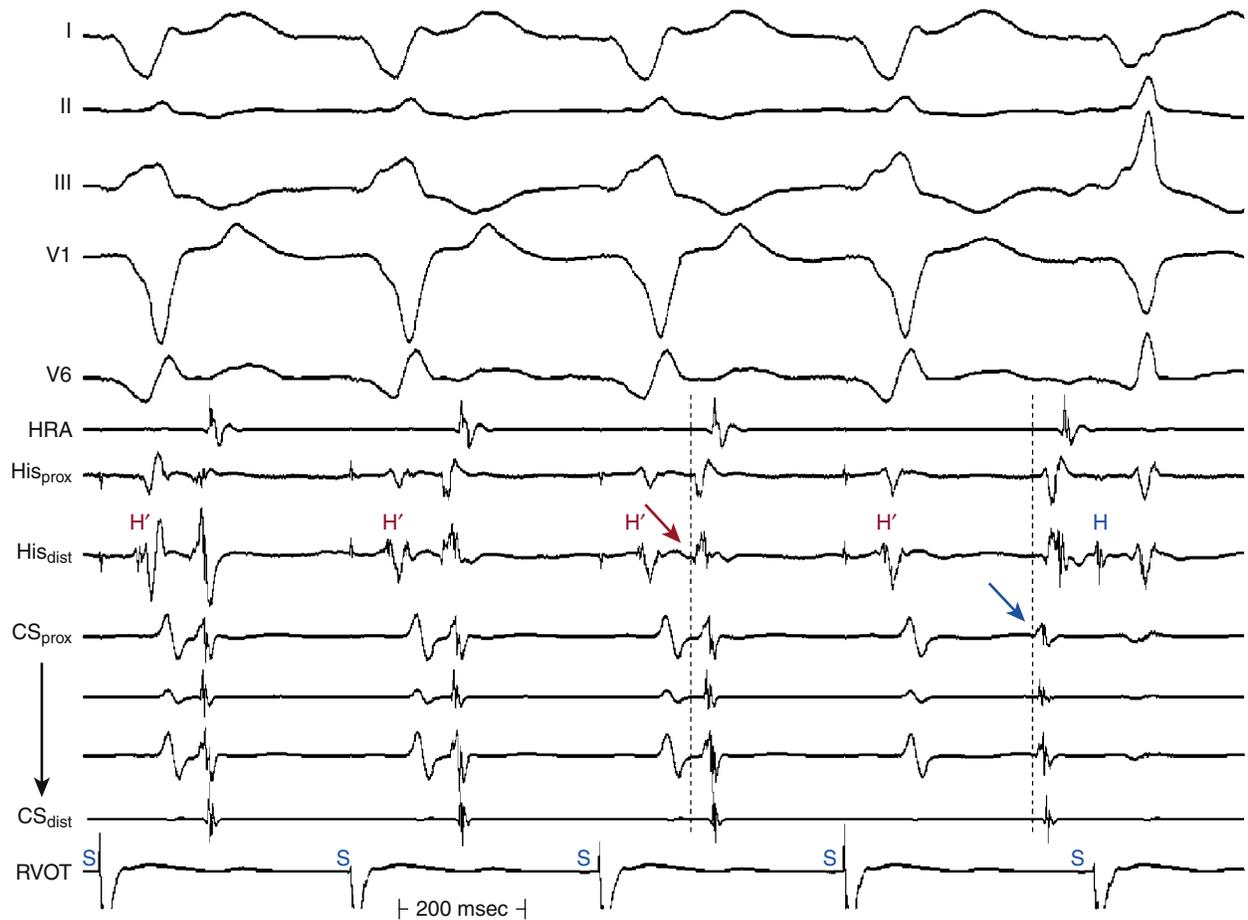

FIGURE 4-28 Retrograde dual atrioventricular pathways. Fixed-rate ventricular pacing results in retrograde conduction; retrograde His potential is labeled H'. The first three complexes are conducted over a fast atrioventricular nodal (AVN) pathway; with the fourth complex, the fast AVN pathway conduction is blocked and retrograde conduction proceeds up the slow pathway (longer VA interval), followed by a fused QRS complex, partially paced and partially conducted to the His bundle anterogradely over the fast pathway. The two AVN pathways have different earliest atrial activation sites, indicated by colored arrows and dashed lines. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; RVOT = right ventricular outflow tract.

patients without prior clinical arrhythmias, such responses are of no clinical significance.

Miscellaneous Electrophysiological Phenomena

Concealed Conduction

Concealed conduction can be defined as the propagation of an impulse within the specialized conduction system of the heart that can be recognized only from its effect on the subsequent impulse, interval, or cycle.³⁵ This phenomenon can occur in any portion of the AV conduction system. As long as the cardiac impulse is traveling in the specialized conduction system, the amount of electrical current generated is too small to be recorded on the surface ECG. However, if this impulse travels only a limited distance—incomplete anterograde or retrograde penetration—within the system, it can interfere with the formation or propagation of another impulse. When this interference can be recognized in the tracing because of an unexpected behavior of the subsequent impulse, unexpected in the sense that the event cannot be explained on the basis of readily apparent physiological or pathophysiological processes, it is known as concealed conduction.^{25,35,36}

The effect on subsequent events is an important part of the definition of concealed conduction because it differentiates the concept of concealed conduction from other forms of incomplete conduction, such as block of conduction at the level of the AVN or HPS. Ideally, a diagnosis of concealed conduction is supported

by evidence in other areas of the same tracing where, given the opportunity and proper physiological setting, an impulse that is occasionally concealed can be conducted. However, this condition cannot always be satisfied, nor is it absolutely necessary for the diagnosis of concealed conduction. Following are descriptions of the most frequent clinical circumstances in which concealed conduction can be observed.

VENTRICULAR RESPONSE DURING ATRIAL FIBRILLATION

Repetitive concealed conduction is the mechanism of a slow ventricular rate during AF and AFL, with varying degrees of penetration into the AVN.^{25,35,36} During AF, the irregular ventricular response is caused by the varying depth of penetration of the numerous wavefronts approaching the AVN. Although the AVN would be expected to conduct whenever it recovers excitability after the last conducted atrial impulse, which would then be at regular intervals, the ventricular response is irregularly irregular because some fibrillatory impulses penetrate the AVN incompletely and block, thus leaving it refractory in the presence of subsequent atrial impulses.

UNEXPECTED PROLONGATION OR FAILURE OF CONDUCTION

Prolongation of the PR (and AH) interval or AVN block can occur secondary to a nonconducted premature depolarization of any origin (atrium, ventricle, or HB). The premature impulse

incompletely penetrates the AVN (anterogradely or retrogradely), resets its refractoriness, and can make it fully or partially refractory in the presence of the next sinus beat, which may then be blocked or may conduct with longer PR interval (see Fig. 4-26). For example, concealed junctional (HB) impulses can manifest as isolated PR interval prolongation, pseudo-type I AV block, or pseudo-type II AV block. ECG clues to concealed junctional extrasystoles causing such unexpected events include abrupt unexplained prolongation of the PR interval, the presence of apparent type II AV block in the presence of a normal QRS, the presence of types I and II AV block in the same tracing, and the presence of manifest junctional extrasystoles elsewhere in the tracing.

UNEXPECTED FACILITATION OF CONDUCTION

When a premature impulse penetrates the AV conduction system, it can result in facilitation of AV conduction and normalization of a previously present AV block or BBB by one of two mechanisms: (1) preexciting parts of the conduction system so that its refractory period ends earlier than expected (i.e., peeling back the refractory period of that tissue, thus allowing more time to recover excitability), or (2) causing CL-dependent shortening of refractoriness of tissues (i.e., atria, HPS, and ventricles) by decreasing the CL preceding the subsequent spontaneous impulse.^{25,35,36} Abrupt normalization of the aberration by a PVC, the finding of which proves retrograde concealment as the mechanism for perpetuation of aberration, is based on these principles.

PERPETUATION OF ABERRANT CONDUCTION DURING SUPRAVENTRICULAR TACHYCARDIAS

The most common mechanism (70%) of perpetuation of aberrant conduction during tachyarrhythmias is retrograde penetration of the blocked bundle branch subsequent to transeptal conduction. For example, a PVC from the LV during an SVT can activate the LB early and then conduct transeptally and later penetrate the RB retrogradely. Subsequently, the LB recovers in time for the next SVT impulse, whereas the RB remains refractory. Therefore, the next SVT impulse travels to the LV over the LB (with an RBBB pattern, phase 3 aberration). Conduction subsequently propagates from the LV across the septum to the RV. By this time, the distal RB has recovered, thereby allowing retrograde penetration of the RB by the transeptal wavefront and rendering the RB refractory to each subsequent SVT impulse. This scenario is repeated and RBBB continues until another, well-timed PVC preexcites the RB (and either peels back or shortens its refractoriness), so that the next impulse from above finds the RB fully recovered and conducts without aberration.

Gap Phenomenon

The term *gap* in AVN conduction was originally used to define a zone in the cardiac cycle during which PACs failed to evoke ventricular responses, whereas PACs of greater or lesser prematurity conducted to the ventricles. The physiological basis of the gap phenomenon depends on a distal area with a long refractory period and a proximal site with a shorter refractory period. During the gap phenomenon, initial block occurs distally. With earlier impulses, proximal conduction delay is encountered, which allows the distal site of early block to recover excitability and resume conduction.³⁵⁻³⁷

The gap phenomenon is not an abnormality, but reflects the interplay between conduction velocity and refractory periods at two different levels in the AV conduction system. Demonstration of the gap phenomenon can be enhanced or eliminated by any intervention that alters the relationship between the EP properties of those structures (e.g., changes in the neurohumoral tone created by drugs or changes in the heart rate by pacing).

An example of the most common type of gap phenomenon is an AES (A_2) conducting with modest delay through the AVN that finds

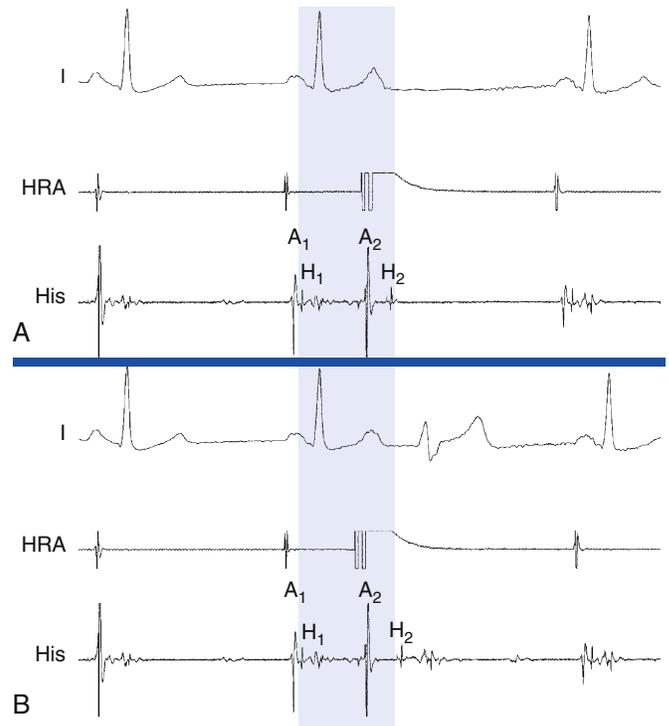

FIGURE 4-29 Anterograde atrioventricular (AV) gap phenomenon. **A**, An atrial extrastimulus (AES; A_2) conducting with modest delay through the AV node (AVN) finds the His bundle (HB) still refractory, causing AV block. **B**, An earlier AES results in further prolongation of the A_2 - H_2 interval and the subsequent H_1 - H_2 interval (shaded area). The longer H_1 - H_2 interval now exceeds the refractory period of the HB, and, by the time the impulse traverses the AVN, the HB has completed its effective refractory period and conduction resumes; however, the conducted QRS has a left bundle branch block morphology and a longer HV interval because the left bundle is still refractory. HRA = high right atrium.

the HB still refractory, thus causing block. With increasing prematurity of the AES, the AES travels more slowly through the AVN (i.e., the A_2 - H_2 interval prolongs further), so that the H_1 - H_2 interval now exceeds the refractory period of the HB. By the time the impulse traverses the AVN, the HB has completed its ERP and conduction resumes (Fig. 4-29).

Other types of the gap phenomenon are described in which the required conduction delay is in the HB, proximal AVN, or atria. The gap phenomenon depends on the relationship between the EP properties of two sites; any pair of structures in the AV conduction system that has the appropriate physiological relationship can exhibit the gap phenomenon (e.g., AVN-HB, HB-HPS, atrium-AVN, atrium-HPS, proximal AVN-distal AVN, proximal HPS-distal HPS), and gap can occur during anterograde or retrograde stimulation. Therefore, there are almost endless possibilities for gaps, all based on the fundamental precept of “proximal delay allows distal recovery” (see Fig. 4-27C and D).^{35,36}

Supernormality

Supernormal conduction implies conduction that is better than anticipated or conduction that occurs when block is expected. Electrocardiographically, however, supernormal conduction is not better than normal conduction, only better than expected. Conduction is better earlier in the cycle than later and occurs when block is expected. When an alteration in conduction can be explained in terms of known physiological events, true supernormal conduction need not be invoked.³⁵

Supernormal conduction is dependent on supernormal excitability, a condition that exists during a brief period of repolarization, at the end of phase 3. During the supernormal period, excitation is possible in response to an otherwise subthreshold

stimulus; that same stimulus fails to elicit a response earlier or later than the supernormal period.^{35,36,38} Two factors are responsible for supernormality: the availability of fast Na⁺ channels and the proximity of the membrane potential to threshold potential. During the supernormal phase of excitability, the cell has recovered enough to respond to a stimulus. However, because the membrane potential is still reduced, it requires only a little additional depolarization to bring the fiber to threshold; thus, a smaller stimulus than is normally required elicits an action potential. Supernormality has been demonstrated in the HPS, Bachmann bundle in the dog, and working myocardium of the atrium and ventricle, but not in the AVN.

Supernormal excitability is diagnosed when the myocardium responds to a stimulus that is ineffective when applied earlier or later in the cycle. Some ECG manifestations of supernormality include the following:

1. Paradoxical normalization of bundle branch conduction at an R-R interval shorter than that with BBB. This can occur with a premature atrial complex conducting with a normal QRS during baseline NSR with BBB or with acceleration-dependent BBB that normalizes at even faster rates.
2. Intermittent AV conduction during periods of high-degree AV block. Only the P waves falling on or just after the terminal part of the T wave are conducted, whereas other timed P waves fail to conduct.
3. A failing pacemaker captures just at the end of the T wave, but not elsewhere in the cardiac cycle.

Although supernormal conduction is a proven property of the HPS and has been demonstrated *in vitro*, it is uncertain whether true supernormal conduction is a clinically important phenomenon. Other physiological mechanisms can be invoked to explain almost all reported examples of supernormal conduction in humans. Causes of apparent or pseudosupernormal conduction include the gap phenomenon (the most common mechanism of pseudosupernormal conduction), peeling back of refractoriness, shortening of refractoriness by changing the preceding CL, Wenckebach phenomena in the bundle branches, bradycardia-dependent (phase 4) block, summation, dual AVN physiology, reentry with ventricular echo beats, and concealed junctional extrasystoles.^{35,36,38}

Complications

Risks and Complications

The complication rate of EP testing is relatively low (less than that of coronary arteriography) when only right-heart catheterization is performed, with almost negligible mortality. The risk of complications increases significantly in patients with severe or decompensated cardiac disease. Complications of EP testing include vascular injury (hematoma, pseudoaneurysm, and arteriovenous fistula), bleeding requiring transfusion, deep venous thrombosis and pulmonary embolism, systemic thromboembolism, infection at catheter sites, systemic infection, pneumothorax, hemothorax, pericarditis, cardiac perforation and tamponade, MI, worsening heart failure, stroke, complete AV block, and BBB. Although potentially lethal arrhythmias such as rapid VT or VF can occur in the EP laboratory, they are not necessarily regarded as complications, but are often expected and anticipated.

The addition of left-heart access or therapeutic maneuvers (e.g., ablation) to the procedure increases the incidence of complications, especially with the increasing use of extensive ablation to treat AF and ischemic VT. In the 1998 North American Society for Pacing and Electrophysiology (NASPE) Prospective Catheter Ablation Registry, 3357 patients were treated with RF ablation for a variety of cardiac arrhythmias. Major complications were reported in 1% to 4%, with procedure-related deaths in approximately 0.2%. There was no significant difference in the incidence of complications comparing patients older than 60 with those younger than 60 years of age or comparing large-volume centers (more than 100 ablation procedures/year) with lower-volume centers or between teaching and nonteaching hospitals.² Complications

following specific ablation procedures are discussed in subsequent chapters.

Iatrogenic Problems Encountered during Electrophysiological Testing

Mechanical irritation from catheters during placement inside the heart, even when they are not being manipulated, can cause arrhythmias and conduction disturbances, including induction of atrial, junctional, and ventricular ectopic beats or tachyarrhythmias, BBB, and AV block. AV block can occur especially during RV catheterization in patients with preexisting LBBB, and occasionally secondary to mechanical trauma of the compact AVN. Ventricular stimulation can also occur from physical movement of the ventricular catheter coincident with atrial contraction, thus producing patterns of ventricular preexcitation on the surface ECG. Recognition of all these iatrogenic patterns is important for avoiding misinterpretation of EP phenomena and determining the significance of findings in the laboratory.

AF and VF are to be avoided unless they are the subject of the study. AF obviously does not permit study of any other form of SVT, and VF requires prompt defibrillation. If AF must be initiated for diagnostic purposes (e.g., to assess ventricular response over an AV BT), it is preferably induced at the end of the diagnostic portion of the study. Patients with a prior history of AF are more prone to the occurrence of sustained AF in the EP laboratory. Frequently, this occurs during initial placement of catheters; excessive manipulation of catheters in the atria should therefore be avoided.

Another iatrogenic problem is catheter trauma resulting in abolition of BT conduction or injury to the focus of a tachycardia or to the reentrant pathway, which can make the mapping and curative ablation difficult or impossible.

Cardiac mapping refers to the process of identifying the temporal and spatial distributions of myocardial electrical potentials during a particular heart rhythm. Cardiac mapping is a broad term that covers several modes of mapping such as body surface, endocardial, and epicardial mapping. Mapping during tachycardia aims at elucidation of the mechanism or mechanisms of the tachycardia, description of the propagation of activation from its initiation to its completion within a region of interest, and identification of the site of origin or a critical site of conduction to serve as a target for catheter ablation.

Activation Mapping

Fundamental Concepts

Essential to the effective management of any cardiac arrhythmia is a thorough understanding of the mechanisms of its initiation and maintenance. Conventionally, this has been achieved by careful study of the surface ECG and correlation of the changes therein with data from intracardiac electrograms recorded by catheters at various key locations within the cardiac chambers (i.e., activation mapping). A record of these electrograms documenting multiple sites simultaneously is studied to determine the mechanisms of an arrhythmic event.

The main value of intracardiac and surface ECG tracings consists of the comparative timing of electrical events and the determination of the location and direction of impulse propagation. Additionally, electrogram morphology can be of significant importance during mapping. Interpretation of recorded electrograms is fundamental to the clinical investigation of arrhythmias during electrophysiological (EP) studies. Establishing electrogram criteria, which permit accurate determination of the moment of myocardial activation at the recording electrode, is critical for construction of an area map of the activation sequence. Bipolar recordings are generally used for activation mapping. Unipolar recordings are used to supplement the information obtained from bipolar recordings. The differences in unipolar and bipolar recordings can be used to assist in mapping by simultaneously recording bipolar and unipolar signals from the mapping catheter.¹

UNIPOLAR RECORDINGS

TIMING OF LOCAL ACTIVATION. The major component of the unipolar electrogram allows determination of the local activation time, although there are exceptions. The point of maximum amplitude, the zero crossing, the point of maximum slope (maximum first derivative), and the minimum second derivative of the electrogram have been proposed as indicators of underlying myocardial activation (Fig. 5-1). The maximum negative slope (i.e., maximum change in potential, dV/dt) of the signal coincides best with the arrival of the depolarization wavefront directly beneath the electrode because the maximal negative dV/dt corresponds to the maximum sodium channel conductance. Using this fiducial point, errors in determining the local activation time as compared with intracellular recordings have typically been less

than 1 millisecond. This is true for filtered and unfiltered unipolar electrograms.^{1,2}

DIRECTION OF LOCAL ACTIVATION. The morphology of the unfiltered unipolar recording indicates the direction of wavefront propagation. By convention, the mapping electrode that is in contact with the myocardium is connected to the positive input of the recording amplifier. In this configuration, positive deflections (R waves) are generated by propagation *toward* the recording electrode, and negative deflections (QS complexes) are generated by propagation *away* from the electrode (Figs. 5-2 and 5-3). If a recording electrode is at the source from which all wavefronts propagate (at the site of initial activation), depolarization will produce a wavefront that spreads away from the electrode, thus generating a monophasic QS complex. It is also important to recognize that a QS complex can be recorded when the mapping electrode is not in contact with the myocardium, but is floating in the cavity. In that situation, the initial negative slope of the recording is typically slow, suggesting that the electrogram is a far-field signal, generated by tissue some distance from the recording electrode.¹ Filtering at higher corner frequencies (e.g., 30 Hz) alters the morphology of the signal, so that the morphology of the unipolar electrogram is no longer an indication of the direction of wavefront propagation, and the presence or absence of a QS complex cannot be used to infer proximity to the site of earliest activation (Fig. 5-4).²

ADVANTAGES OF UNIPOLAR RECORDINGS. One important value of unipolar recordings is that they provide a more precise measure of local activation. This is true for filtered and unfiltered unipolar electrograms. In addition, unfiltered unipolar recordings provide information about the direction of impulse propagation. Using the unipolar configuration also eliminates a possible anodal contribution to depolarization and allows pacing and recording at the same location. This generally facilitates the use of other mapping modalities, namely pace mapping.

DISADVANTAGES OF UNIPOLAR RECORDINGS. The major disadvantage of unipolar recordings is that they have poor signal-to-noise ratio and contain substantial far-field signal generated by depolarization of tissue remote from the recording electrode. Therefore, distant activity can be difficult to separate from local activity. This is especially true when recording from areas of prior myocardial infarction (MI), where the fractionated ventricular potentials are ubiquitous and it is often impossible to select a rapid negative dV/dt when the entire QS potential is slowly inscribed—that is, cavity potential.² Another disadvantage is the inability to record an undisturbed electrogram during or immediately after pacing. This is a significant disadvantage when entrainment mapping is to be performed during activation mapping, because recording of the return tachycardia complex on the pacing electrode immediately after cessation of pacing is required to interpret entrainment mapping results.¹

BIPOLAR RECORDINGS

TIMING OF LOCAL ACTIVATION. Algorithms for detecting local activation time from bipolar electrograms have been more problematic, partly because of generation of the bipolar electrogram

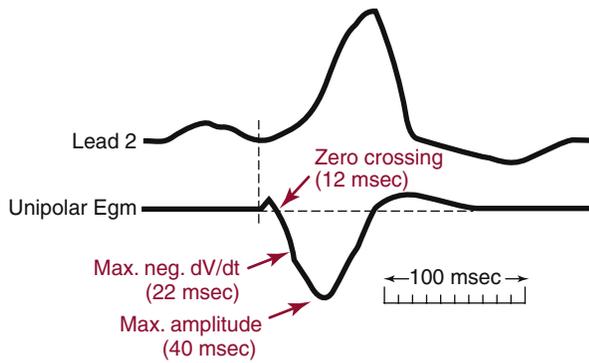

FIGURE 5-1 Unipolar electrogram activation times. A lead II electrocardiogram and a unipolar electrogram (Egm) from the ventricle of a patient with Wolff-Parkinson-White syndrome are shown. The vertical dashed line denotes the onset of the delta wave; the horizontal dotted line is the baseline of the unipolar recording. Several candidates for the timing of unipolar activation are labeled with corresponding activation times relative to delta wave onset.

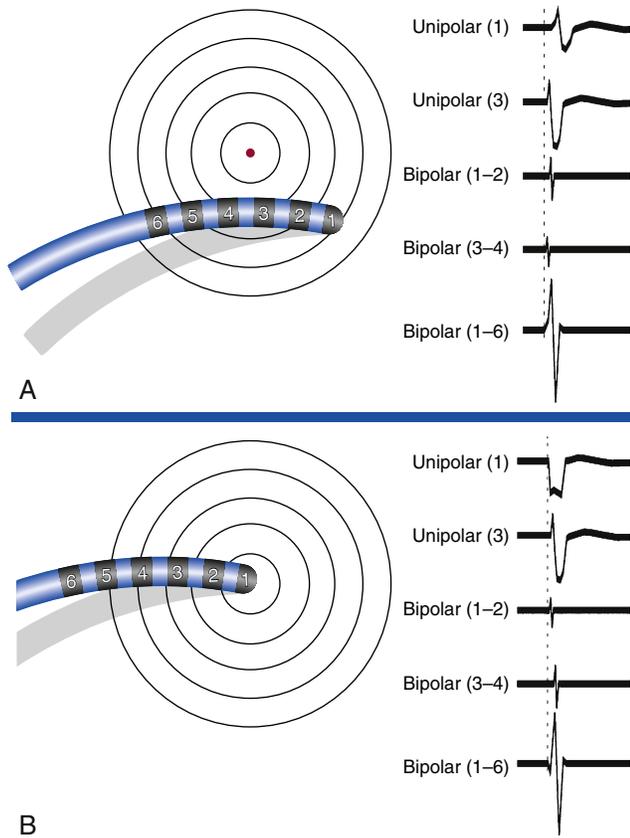

FIGURE 5-2 Hypothetical recordings from a multipolar electrode catheter. **A**, The electrodes are near a point source of activation (red dot in center of concentric rings). Note the timing and shape of the resultant electrogram patterns based on distance from point source, unipolar or bipolar recording, and width of bipole. **B**, The tip electrode (1) is at the point source of activation. Note the differences in timing and shape of the electrograms compared with **A**.

by two spatially separated recording poles. In a homogeneous sheet of tissue, the initial peak of a filtered (30 to 300 Hz) bipolar signal, the absolute maximum electrogram amplitude, coincides with depolarization beneath the recording electrode, appears to correlate most consistently with local activation time, and corresponds to the maximal negative dV/dt of the unipolar recording (see Fig. 5-3).² However, in the case of complex multicomponent bipolar electrograms, such as those with marked fractionation and prolonged duration seen in regions with complex conduction patterns (e.g., in regions of slow conduction in macroreentrant

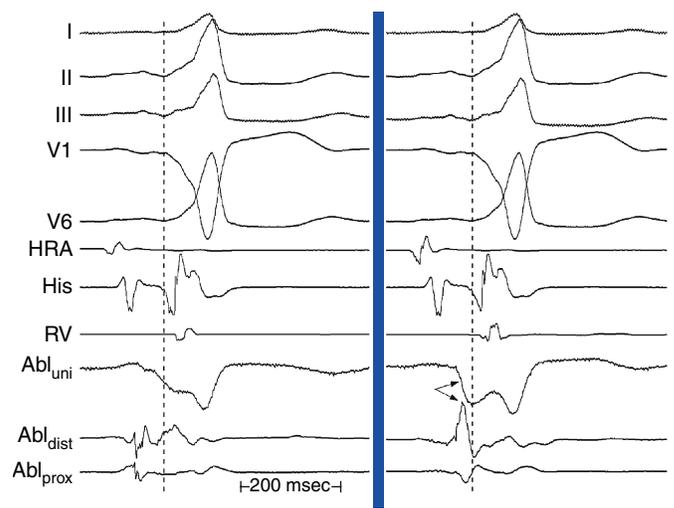

FIGURE 5-3 Unipolar and bipolar recordings from a patient with Wolff-Parkinson-White syndrome. The dashed line denotes the onset of the QRS complex (delta wave). **Right panel**, Recordings at the successful ablation site, characterized by QS in the unipolar recording. The most rapid component precedes the delta wave onset by 22 milliseconds, has the same timing as the peak of the ablation distal electrode recording, and precedes the ablation proximal electrode recording (arrows). **Left panel**, Recordings from a poorer site, with an rS in the unipolar recording; most of the bipolar recordings are atrial. Abl_{dist} = distal ablation; Abl_{prox} = proximal ablation; Abl_{uni} = unipolar ablation; HRA = high right atrium; RV = right ventricle.

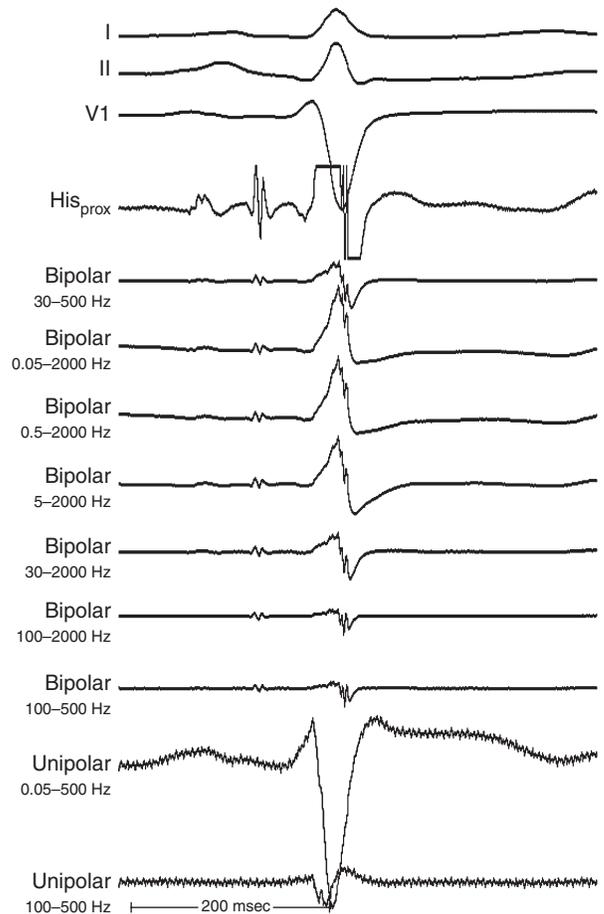

FIGURE 5-4 Effect of filtering on intracardiac recordings. The signal labeled "Bipolar 30-500 Hz" is the same signal as the proximal His bundle signal (His_{prox}) above it, displayed at lower gain. All signals beneath this are of the same gain but different filter bandwidths, and they illustrate progressive loss of signal amplitude as the bandwidth is narrowed. Unipolar signals below are of the same gain.

atrial tachycardia [AT] or ventricular tachycardia [VT]), determination of local activation time becomes problematic, and the decision about which activation time is most appropriate needs to be made in the context of the particular rhythm being mapped. To acquire true local electrical activity, a bipolar electrogram with an interelectrode distance of less than 1 cm is desirable. Smaller interelectrode distances record increasingly local events (as opposed to far-field). Elimination of far-field noise is usually accomplished by filtering the intracardiac electrograms, typically at 30 to 500 Hz.^{1,2}

DIRECTION OF LOCAL ACTIVATION. The morphology and amplitude of bipolar electrograms are influenced by the orientation of the bipolar recording axis to the direction of propagation of the activation wavefront. A wavefront that is propagating in the direction exactly perpendicular to the axis of the recording dipole produces no difference in potential between the electrodes and hence no signal.^{1,2} However, the direction of wavefront propagation cannot be reliably inferred from the morphology of the bipolar signal, although a change in morphology can be a useful finding. For example, when recording from the lateral aspect of the cavotricuspid isthmus during pacing from the coronary sinus (CS), a reversal in the bipolar electrogram polarity from positive to negative at the ablation line indicates complete isthmus block. Similarly, if bipolar recordings are obtained with the same catheter orientation parallel to the atrioventricular (AV) annulus during retrograde bypass tract (BT) conduction, an RS configuration electrogram will be present on one side of the BT, where the wavefront is propagating from the distal electrode toward the proximal electrode, and a QR morphology electrogram will be present on the other side, where the wavefront is propagating from the proximal electrode toward the distal electrode (Fig. 5-5).

ADVANTAGES OF BIPOLAR RECORDINGS. Bipolar recordings provide an improved signal-to-noise ratio. In addition, high-frequency components are more accurately seen, which facilitates identification of local depolarization, especially in abnormal areas of infarction or scar.

DISADVANTAGES OF BIPOLAR RECORDINGS. In contrast to unipolar signals, the direction of wavefront propagation cannot be reliably inferred from the morphology of the bipolar signal. Furthermore, bipolar recordings do not allow simultaneous pacing and recording from the same location. To pace and record simultaneously in bipolar fashion at endocardial sites as close together as possible, electrodes 1 and 3 of the mapping catheter are used for bipolar pacing, and electrodes 2 and 4 are used for recording. The precision of locating the source of a particular electrical signal depends on the distance between the recording electrodes, because the signal of interest can be beneath the distal or proximal electrode (or both) of the recording pair.¹

Mapping Procedure

PREREQUISITES FOR ACTIVATION MAPPING. Several factors are important for the success of activation mapping, including inducibility of tachycardia at the time of EP testing, hemodynamic stability of the tachycardia, and stable tachycardia morphology. In addition, determinations of an electrical reference point, of the mechanism of the tachycardia (focal versus macroreentrant), and, subsequently, of the goal of mapping are essential prerequisites.

SELECTION OF THE ELECTRICAL REFERENCE POINT. Local activation times must be relative to some external and consistent fiducial marker, such as the onset of the P wave or QRS complex on the surface ECG or a reference intracardiac electrode. For VT, the QRS complex onset should be assessed using all surface ECG leads to search for the lead with the earliest QRS onset. This lead should then be used for subsequent activation mapping. Similarly, the P wave during AT should be assessed using multiple ECG leads and choosing the one with the earliest P onset. However, determining the onset of the P wave can be impossible if the preceding T wave or QRS is superimposed. To facilitate visualization

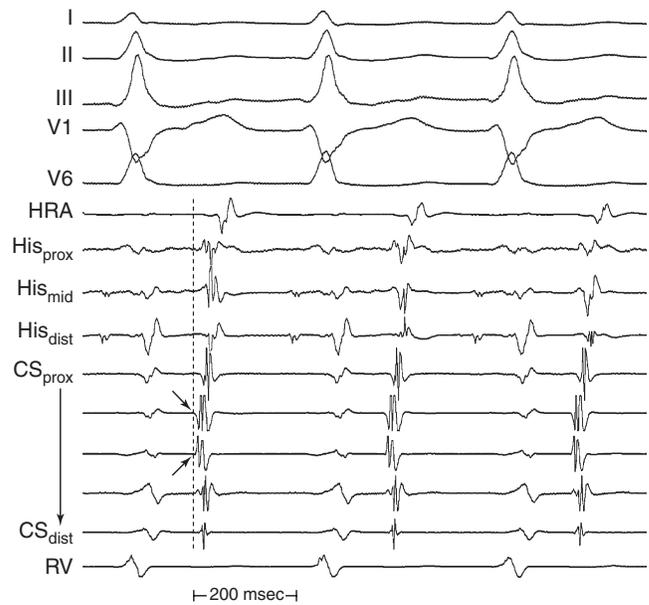

FIGURE 5-5 Recordings from a patient with a left lateral bypass tract during orthodromic atrioventricular reentrant tachycardia showing electrogram inversion at the middle of the coronary sinus (CS) (arrows), where the earliest retrograde atrial activation (over the bypass tract) occurs (dashed line). CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; RV = right ventricle.

of the P wave, a ventricular extrastimulus (VES) or a train of ventricular pacing can be delivered to anticipate ventricular activation and repolarization and permit careful distinction of the P wave onset (Fig. 5-6). After determining P wave onset, a surrogate marker, such as a right atrial (RA) or CS electrogram indexed to the P wave onset, where it is clearly seen, can be used rather than the P wave onset.

DEFINING THE GOAL OF MAPPING. Determination of the mechanism of the tachycardia (focal versus macroreentrant) is essential to define the goal of activation mapping. For focal tachycardias, activation mapping entails localizing the site of origin of the tachycardia focus. This is reflected by the earliest presystolic activity that precedes the onset of the P wave (during focal AT) or QRS (during focal VT) by an average of 10 to 40 milliseconds, because only this short amount of time is required after the focus discharges to activate enough myocardium and begin generating a P wave or QRS complex (Fig. 5-7). For mapping macroreentrant tachycardias, the goal of mapping is identification of the critical isthmus of the reentrant circuit, as indicated by finding the site with a continuous activity spanning diastole or with an isolated mid-diastolic potential (see Fig. 5-7).

EPICARDIAL VERSUS ENDOCARDIAL MAPPING. Activation mapping is predominantly performed endocardially. Occasionally, epicardial mapping is required because of an inability to ablate some VTs, ATs, or AV BTs by using the endocardial approach. Limited epicardial mapping can be performed with special recording catheters that can be steered in the branches of the CS. This technique has been used for mapping VTs and AV BTs, but its scope is limited by the anatomy of the coronary venous system.

Another epicardial mapping technique utilizes a subxiphoid percutaneous approach for accessing the epicardial surface. This technique has become an important adjunctive strategy to ablate a diverse range of cardiac arrhythmias including cardiomyopathic VT, BTs, atrial fibrillation, and idiopathic VTs. Transthoracic epicardial mapping and ablation are seeing increasingly wider application, especially in patients with scar-related VT, in whom more reentrant circuits with vulnerable isthmuses are on the epicardial

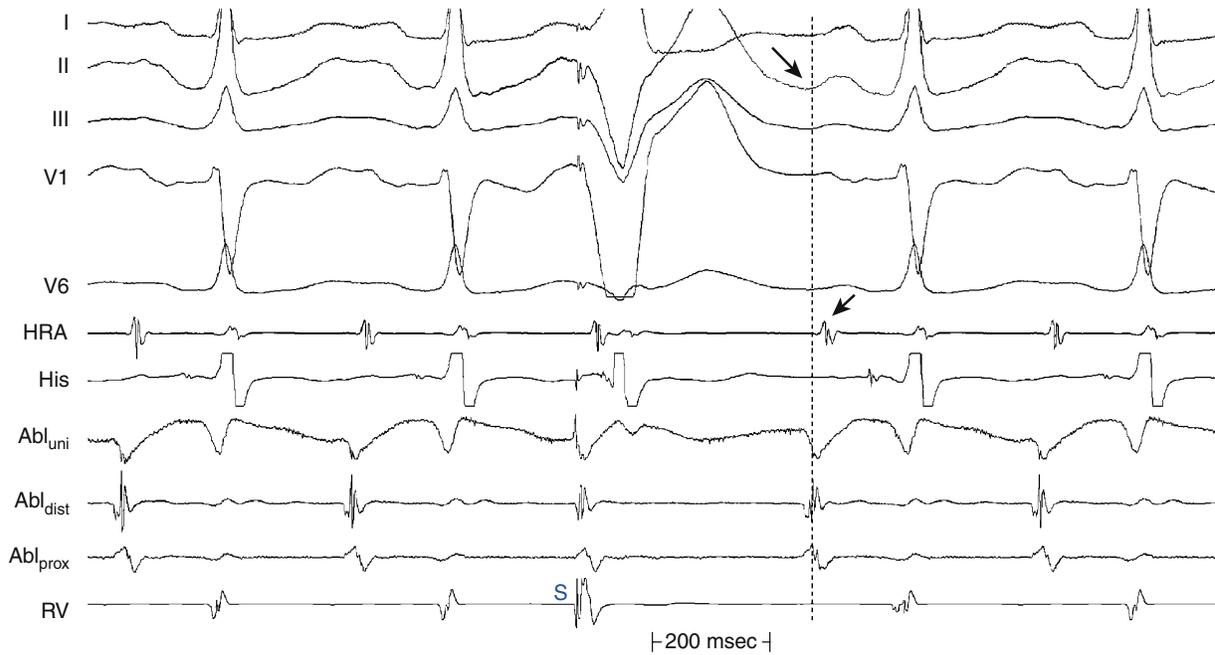

FIGURE 5-6 Use of ventricular extrastimulus (VES) to clarify onset of the P wave during atrial tachycardia (AT). A single VES (S) delivered during AT advances the timing of ventricular activation to show the P wave (long arrow) by itself without the overlying ST segment and T wave, which made it difficult to determine P wave onset during ongoing tachycardia. The dashed line denotes onset of the P wave; timing of the reference electrogram (high right atrium [HRA]; short arrow) can thereafter be used as a surrogate for P wave onset. Abl_{dist} = distal ablation; Abl_{prox} = proximal ablation; Abl_{uni} = unipolar ablation; RV = right ventricle.

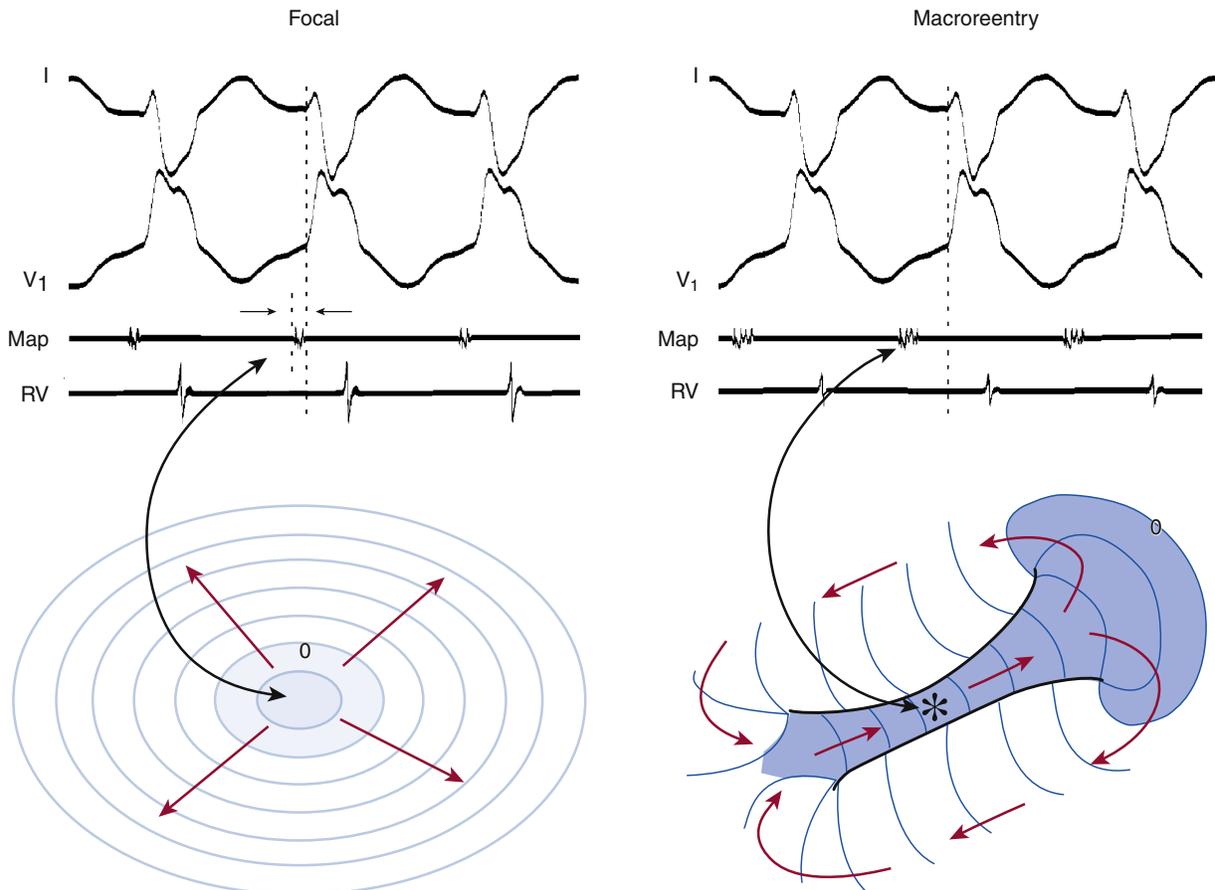

FIGURE 5-7 Focal versus macroreentrant ventricular tachycardia (VT). **Top**, ECG and intracardiac electrograms from the mapping (Map) and right ventricle (RV) catheters. **Bottom**, Depictions of events at sites where mapped electrograms are obtained. **Left**, VT focus fires and activation spreads to normal myocardium within 30 to 40 milliseconds, generating a QRS complex. Thus, the electrogram at the site of the focus is generally 40 milliseconds or less prior to the QRS onset. **Right**, In contrast, in a macroreentrant VT, some myocardium is being activated at each instant in the cardiac cycle. During surface ECG diastole, only a few cells are activating (too few to cause surface ECG deflections). The area of a protected diastolic corridor, often cordoned off by scar, contains mid-diastolic recordings and is an attractive ablation site. The 0 isochrone indicates the time at which the QRS complex begins.

surface. The same fundamental principles of activation mapping are used for both endocardial mapping and epicardial mapping.³⁻⁷

MAPPING CATHETERS. The simplest form of mapping is achieved by moving the mapping catheter sequentially to sample various points of interest on the endocardium to measure local activation. The precision of locating the source of a particular electrical signal depends on the distance between the recording electrodes on the mapping catheter. For ablation procedures, recordings between adjacent electrode pairs are commonly used (e.g., between electrodes 1 and 2, 2 and 3, and 3 and 4), with 1- to 5-mm interelectrode spacing. In some studies, wider bipolar recordings (e.g., between electrodes 1 and 3 and 2 and 4) have been used to provide an overlapping field of view. For bipolar recordings, the signal of interest can be beneath the distal or proximal electrode (or both) of the recording pair. As noted, this is germane in that ablation energy can be delivered only from the distal (tip) electrode.

MAPPING FOCAL TACHYCARDIAS

The goal of activation mapping of focal tachycardias (automatic, triggered activity, or microreentrant) is identifying the site of origin, defined as the site with the earliest presystolic bipolar recording in which the distal electrode shows the earliest intrinsic deflection and QS unipolar electrogram configuration (Figs. 5-8 and 5-9). Local activation at the site of origin precedes the onset of the tachycardia complex on the surface ECG by an average of 10 to 40 milliseconds. Earlier electrograms occurring in mid-diastole, as in the setting of macroreentrant tachycardias, are not expected and do not constitute a target for mapping.¹

Endocardial activation mapping of focal tachycardias can trace the origin of activation to a specific area, from which it

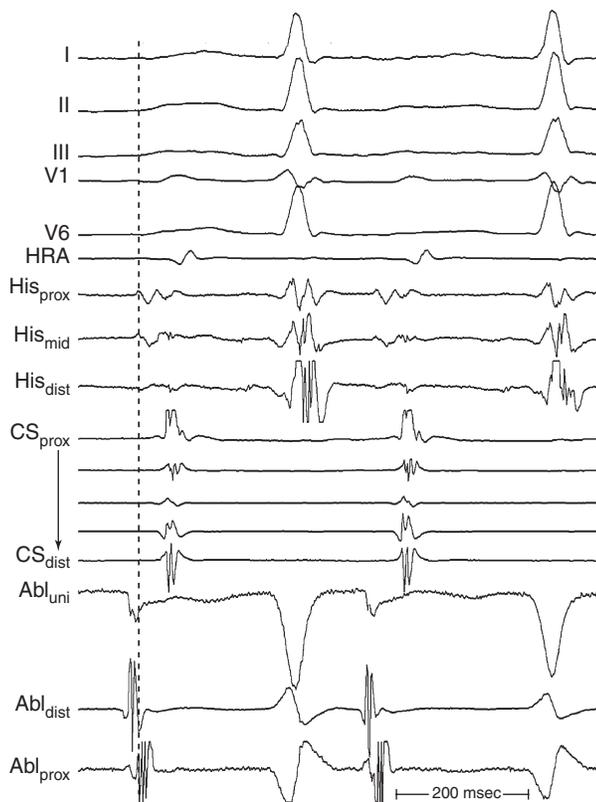

FIGURE 5-8 Focal atrial tachycardia. The unipolar electrogram recorded by the distal ablation electrode (Abl_{uni}) shows a QS configuration, and its timing coincides with the distal ablation (Abl_{dist}) recording at the site of successful ablation. The dashed line marks the onset of the P wave on the surface ECG. Abl_{prox} = proximal ablation; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle; HRA = high right atrium.

spreads centrifugally. There is generally an electrically silent period in the tachycardia cycle length (CL) that is reflected on the surface ECG by an isoelectric line between tachycardia complexes. Intracardiac mapping shows significant portions of the tachycardia CL without recorded electrical activity, even when recording from the entire cardiac chamber of tachycardia origin. However, in the presence of complex intramyocardial conduction disturbances, activation during focal tachycardias can extend over a large proportion of the tachycardia CL, and conduction spread can follow circular patterns suggestive of macroreentrant activation.^{2,4}

Technique of Activation Mapping of Focal Tachycardias

Initially, one should seek the general region of the origin of the tachycardia as indicated by the surface ECG. In the EP laboratory, additional data can be obtained by placing a limited number of catheters within the heart in addition to the mapping catheter or catheters; these catheters are frequently placed at the right ventricular apex, His bundle region, high RA, and CS. During initial arrhythmia evaluation, recording from this limited number of sites allows a rough estimation of the site of interest. Mapping simultaneously from as many sites as possible greatly enhances the precision, detail, and speed of identifying regions of interest.¹

Subsequently, a single mapping catheter is moved under the guidance of fluoroscopy over the endocardium of the chamber of interest to sample bipolar signals. Using standard equipment, mapping a tachycardia requires recording and mapping performed at several sites, based on the ability of the investigator to recognize the mapping sites of interest from the morphology of the tachycardia on the surface ECG and baseline intracardiac recordings.

Local activation time is then determined from the filtered (30 to 300 Hz) bipolar signal recorded from the distal electrode pair on the mapping catheter; this time is determined and compared with the timing reference (fiducial point). The distal pole of the mapping catheter should be used for mapping the earliest activation site because it is the pole through which RF energy is delivered. Activation times are generally measured from the onset of the first rapid deflection of the bipolar electrogram to the onset of the tachycardia complex on the surface ECG or surrogate marker (see Fig. 5-6). Using the onset (rather than the peak or nadir) of a local bipolar electrogram is preferable because it is easier to determine reproducibly, especially when measuring heavily fractionated, low-amplitude local electrograms.⁴

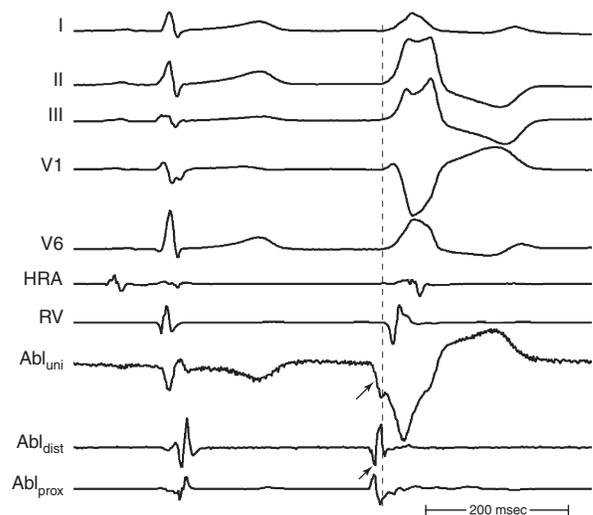

FIGURE 5-9 Sinus rhythm and a single premature ventricular complex from a patient with focal ventricular tachycardia. The unipolar ablation site (Abl_{uni}) shows a QS configuration, the most rapid slope of which times with the initial peak in the distal ablation (Abl_{dist}) recording (arrows) at the site of successful ablation. The dashed line marks the onset of the QRS complex on the surface ECG. Abl_{prox} = proximal ablation; HRA = high right atrium; RV = right ventricle.

Once an area of relatively early local activation is found, small movements of the catheter tip in the general target region are undertaken until the site is identified with the earliest possible local activation relative to the tachycardia complex. Recording from multiple bipolar pairs from a multipolar electrode catheter is helpful in that if the proximal pair has a more attractive electrogram than the distal, the catheter may be withdrawn slightly to achieve the same position with the distal electrode.

Once the site with the earliest bipolar signal is identified, the unipolar signal from the distal ablation electrode should be used to supplement bipolar mapping.² The unfiltered (0.05 to 300 Hz) unipolar signal morphology should show a monophasic QS complex with a rapid negative deflection if the site was at the origin of impulse formation (see Figs. 5-8 and 5-9). However, the size of the area with a QS complex can be larger than the tachycardia focus, exceeding 1 cm in diameter. Thus, a QS complex should not be the only mapping finding used to guide ablation. Successful ablation is unusual, however, at sites with an RS complex on the unipolar recording, because these are generally distant from the focus (see Fig. 5-2). Concordance of the timing of the onset of the bipolar electrogram with that of the filtered or unfiltered unipolar electrogram (with the rapid downslope of the S wave of the unipolar QS complex coinciding with the initial peak of the bipolar signal) helps ensure that the tip electrode, which is the ablation electrode, is responsible for the early component of the bipolar electrogram. The presence of ST elevation on the unipolar recording and the ability to capture the site with unipolar pacing are used to indicate good electrode-tissue contact.⁴

MAPPING MACROREENTRANT TACHYCARDIAS

The main goal of activation mapping of macroreentrant tachycardias (e.g., post-MI VT, macroreentrant AT) is identification of the isthmus critical for the macroreentrant circuit.⁸ The site of origin of a tachycardia is the source of electrical activity producing the tachycardia complex. Although this is a discrete site of impulse formation in focal rhythms, during macroreentry it represents the exit site from the diastolic pathway (i.e., from the critical isthmus of the reentrant circuit) to the myocardium that gives rise to the ECG deflection. During macroreentry, an isthmus is defined as a corridor of conductive myocardial tissue bounded by nonconductive tissue (barriers) through which the depolarization wavefront must propagate to perpetuate the tachycardia. These barriers can be scar areas or naturally occurring anatomical or functional (present only during tachycardia, but not in sinus rhythm) obstacles. The earliest presystolic electrogram closest to mid-diastole is the most commonly used definition for the site of origin of the reentrant circuit. However, recording continuous diastolic activity or bridging of diastole at adjacent sites, or both, or mapping a discrete diastolic pathway is more specific. Therefore, the goal of activation mapping during macroreentry is finding the site or sites with continuous activity spanning diastole or with an isolated mid-diastolic potential. Unlike focal tachycardias, a presystolic electrogram preceding the tachycardia complex by 10 to 40 milliseconds is not adequate in defining the site of origin of a macroreentrant tachycardia (Figs. 5-10 and 5-11; see also Fig. 5-7).^{2,4}

However, identification of critical isthmuses is often challenging. The abnormal area of scarring, where the isthmus is located, is frequently large and contains false isthmuses (bystanders) that confound mapping. Additionally, multiple potential reentry circuits can be present, giving rise to multiple different tachycardias in a single patient. Furthermore, in abnormal regions such as infarct scars, the tissue beneath the recording electrode can be small relative to the surrounding myocardium outside the scar; thus, a large far-field signal can obscure the small local potential. For this reason, despite the limitations of bipolar recordings, these recordings are preferred in scar-related VTs because the noise is removed and high-frequency components are more accurately seen. Unipolar recordings are usually of little help when mapping arrhythmias

associated with regions of scar, unless the recordings are filtered to remove far-field signal. Much of the far-field signal in a unipolar recording consists of lower frequencies than the signal generated by local depolarization because the high-frequency content of a signal diminishes more rapidly with distance from the source than the low-frequency content. Therefore, high-pass filtering of unipolar signals (at 30 or 100 Hz) is generally used when mapping scar-related arrhythmias to reduce the far-field signal and improve detection of lower amplitude local signals from abnormal regions.¹

Although activation mapping alone is usually inadequate for defining the critical isthmus of a macroreentrant tachycardia, it can help guide other mapping modalities (e.g., entrainment or pace mapping, or both) to the approximate region of the isthmus.^{4,8}

Continuous Activity

Theoretically, if reentry were the mechanism of the tachycardia, electrical activity should occur throughout the tachycardia cycle. For example, in macroreentrant AT, the recorded electrical activity

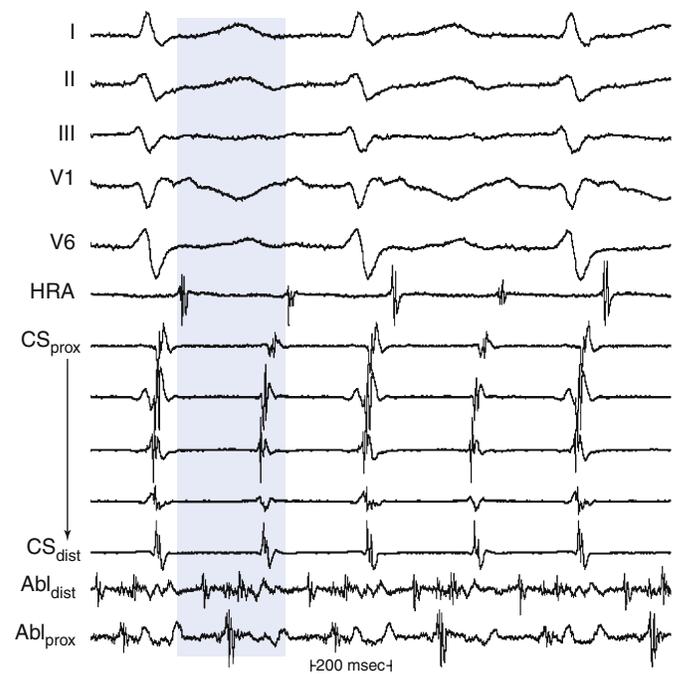

FIGURE 5-10 Macroreentrant atrial tachycardia. Electrical activity spans the tachycardia cycle length (shaded); thus, a merely presystolic electrogram is a poor indicator of optimal ablation site. Abl_{dist} = distal ablation; Abl_{prox} = proximal ablation; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium.

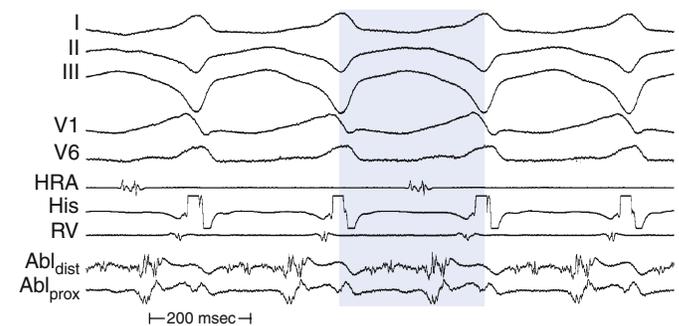

FIGURE 5-11 Macroreentrant post-myocardial infarction ventricular tachycardia. Electrical activity spans diastole and nearly the tachycardia cycle length (shaded); thus, a simply presystolic electrogram is a poor indicator of the optimal ablation site. Abl_{dist} = distal ablation; Abl_{prox} = proximal ablation; HRA = high right atrium; RV = right ventricle.

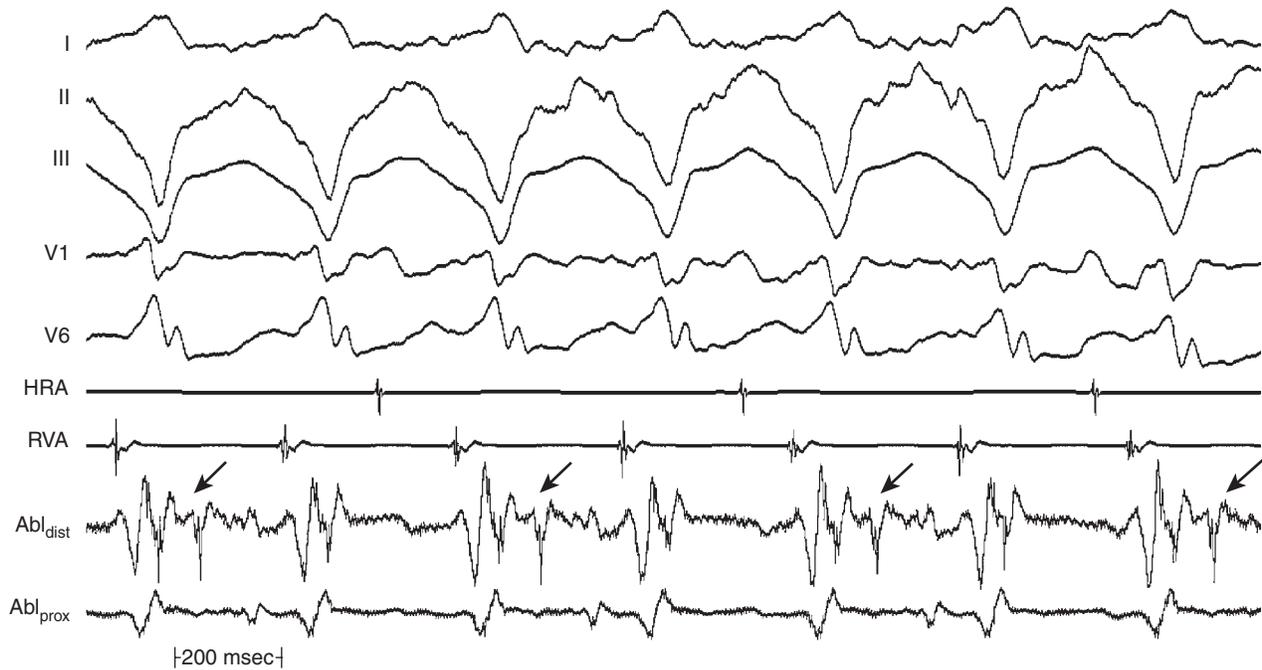

FIGURE 5-12 Diastolic recordings during ventricular tachycardia that have a 2:1 conduction ratio (arrows). Cells causing these recordings are clearly not integrally involved in the ongoing arrhythmia. They are not atrial, because atrial-ventricular dissociation is evident in the high right atrium (HRA) recording. Abl_{dist} = distal ablation; Abl_{prox} = proximal ablation; RVA = right ventricular apex.

at different locations in the atrium should span the tachycardia CL (see Fig. 5-10).

For macroreentrant VT, conduction during diastole is extremely slow and is in a small area so that it is not recorded on the surface ECG. The QRS complex is caused by propagation of the wavefront from the exit of the circuit from that isthmus to the surrounding myocardium. After leaving the exit of the isthmus, the circulating wavefront propagates through a broad path (loop) along the border of the scar, back to the entrance of the isthmus (see Fig. 5-7).⁸ Continuous diastolic activity is likely to be recorded only if the bipolar pair records a small circuit; if a large circuit is recorded (i.e., the reentrant circuit is larger than the recording area of the catheter, the catheter is not covering the entire circuit, or both), nonholodiastolic activity will be recorded. In such circuits, repositioning of the catheter to other sites may allow visualization of what is termed *bridging of diastole*; electrical activity in these adjacent sites spans diastole.^{2,4}

All areas from which diastolic activity is recorded are not necessarily part of the reentrant circuit. Such sites can reflect late activation and may not be related to the tachycardia site of origin. Analysis of the response of these electrograms to spontaneous or induced changes in tachycardia CL is critical in deciding their relationship to the tachycardia mechanism. Additionally, electrical signals that come and go throughout diastole should not be considered continuous (Fig. 5-12). For continuous activity to be consistent with reentry, it must be demonstrated that such electrical activity is required for initiation and maintenance of the tachycardia, so that termination of the continuous activity, either spontaneously or following stimulation, without affecting the tachycardia, would exclude such continuous activity as requisite for sustaining the tachycardia. It is also important to verify that an electrogram that extends throughout diastole is not just a broad electrogram whose duration equals the tachycardia CL. This can be achieved by analyzing the local electrogram during pacing at a CL comparable to tachycardia CL; if pacing produces continuous diastolic activity in the absence of tachycardia, the continuous electrogram has no mechanistic significance. Furthermore, the continuous activity should be recorded from a circumscribed area, and motion artifact should be excluded.^{4,8}

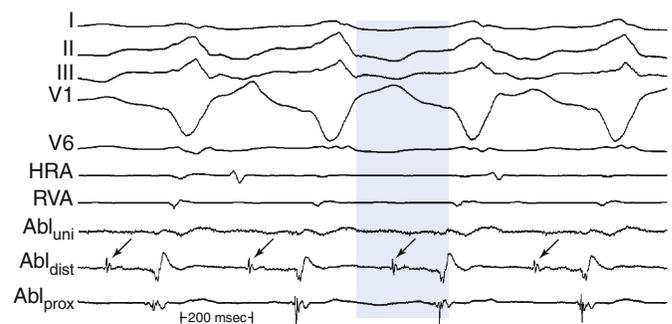

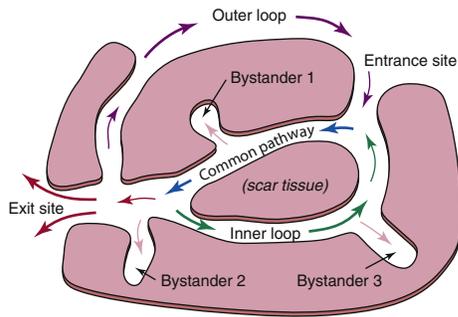

FIGURE 5-13 Mid-diastolic potential during ventricular tachycardia (VT)—duration of diastole (shaded area), with isolated mid-diastolic potential from the site at which ablation eliminated VT (arrows). Abl_{dist} = distal ablation; Abl_{prox} = proximal ablation; Abl_{uni} = unipolar ablation; HRA = high right atrium; RVA = right ventricular apex.

Mid-Diastolic Activity

An isolated mid-diastolic potential is defined as a low-amplitude, high-frequency diastolic potential separated from the preceding and subsequent electrograms by an isoelectric segment (Fig. 5-13). Sometimes, these discrete potentials provide information that defines a diastolic pathway, which is believed to be generated from a narrow isthmus of conduction critical to the reentrant circuit. Localization of this pathway is critical for guiding catheter-based ablation.⁸

Detailed mapping usually reveals more than one site of presystolic activity, and mid-diastolic potentials can be recorded from a bystander site attached to the isthmus. Therefore, regardless of where in diastole the presystolic electrogram occurs (early, middle, or late), its position and appearance on initiation of the tachycardia, although necessary, does not confirm its relevance to the tachycardia mechanism. One must always confirm that the electrogram is required to maintain, and cannot be dissociated from, the tachycardia.⁸ Thus, during spontaneous changes in the tachycardia CL or those produced by programmed stimulation, the electrogram, regardless of its position in diastole, should show a fixed relationship with the subsequent tachycardia complex (and

FIGURE 5-14 Representation of a ventricular tachycardia (VT) circuit, showing a common diastolic pathway, entrance and exit sites, inner and outer loops, and bystander dead-end paths in three locations. The accompanying table describes the behavior of each of these locations during VT, as well as pacing during VT and sinus rhythm. Egm = electrogram; S = stimulus; TCL = tachycardia cycle length.

not the preceding one). Very early diastolic potentials, in the first half of diastole, can represent an area of slow conduction at the entrance of a protected isthmus. These potentials remain fixed to the prior tachycardia complex (exit site from the isthmus), and a delay between this complex and the subsequent tachycardia complex would reflect delay in entering or propagating through the protected diastolic pathway.⁴

If, after very detailed mapping, the earliest recorded site is not at least 50 milliseconds presystolic, this suggests that the map is inadequate (most common), the mechanism of tachycardia is not macroreentry, or the diastolic corridor is deeper than the subendocardium (in the midmyocardium or subepicardium).

Limitations

Standard transcatheter endocardial mapping, as performed in the EP laboratory, is limited by the number, size, and type of electrodes that can be placed within the heart. Therefore, these methods do not cover a vast area of the endocardial surface. Time-consuming, point-by-point maneuvering of the catheter is required to trace the origin of an arrhythmic event and its activation sequence in the neighboring areas.

The success of roving point mapping depends on the sequential beat-by-beat stability of the activation sequence being mapped and the ability of the patient to tolerate sustained arrhythmia. Therefore, it can be difficult to perform activation mapping in poorly inducible tachycardias, in hemodynamically unstable tachycardias, and in tachycardias with unstable morphology. Sometimes, poorly tolerated rapid tachycardias can be slowed by antiarrhythmic agents to allow for mapping. Alternatively, mapping can be facilitated by starting and stopping the tachycardia after data acquisition at each site. Additionally, newer techniques (e.g., basket catheter and non-contact mapping) can facilitate activation mapping in these cases by simultaneous multipoint mapping.

Although activation mapping is adequate for defining the site of origin of focal tachycardias, it is deficient by itself in defining the critical isthmus of macroreentrant tachycardias, and adjunctive mapping modalities (e.g., entrainment mapping, pace mapping) are required. Moreover, the laborious process of precise mapping with conventional techniques can expose the electrophysiologist, staff, and patient to undesirable levels of radiation from the extended fluoroscopy time.

Using conventional activation mapping techniques, it is difficult to conceive the three-dimensional orientation of cardiac structures because a limited number of recording electrodes guided by fluoroscopy is used. Although catheters using multiple electrodes to acquire data points are available, the exact location of an acquired unit of EP data is difficult to ascertain because of inaccurate delineation of the location of anatomical structures. The inability to associate the intracardiac electrogram with a specific endocardial site accurately also limits the reliability with which the roving catheter tip can be placed at a site that was previously mapped. This results in limitations when the creation of long linear ablation lesions is required to modify the substrate, as well as when multiple isthmuses or channels are present. The inability to identify, for example, the site of a previous ablation increases the risk of repeated ablation of areas already dealt with and the likelihood that new sites can be missed.

Entrainment Mapping

Fundamental Concepts

To help understand the concept of entrainment, a hypothetical reentrant circuit is shown in Figure 5-14. This reentrant circuit has several components—a common pathway, an exit site, an outer loop, an inner loop, an entry site, and bystander sites. The reentrant wavefront propagates through the common pathway (protected critical isthmus) during electrical diastole. Because this zone is usually composed of a small amount of myocardium and is bordered by anatomical or functional barriers preventing spread of the electrical signal except in the orthodromic direction, propagation of the wavefront in the protected isthmus is electrocardiographically silent. The exit site is the site at which the reentrant wavefront exits the protected isthmus to start activation of the rest of the myocardium, including the outer loop. Activation of the exit site corresponds to the onset of the tachycardia complex on the surface ECG. The outer loop is the path through which the reentrant wavefront propagates while at the same time activating the rest of the myocardium. Activation of the outer loop corresponds to electrical systole (P wave during AT and QRS during VT) on the surface ECG. An inner loop can serve as an integral part of the reentrant circuit or function as a bystander pathway. If conduction through the inner loop is slower than conduction from the exit to

entrance sites (through the outer loop), the inner loop will serve as a bystander, and the outer loop will be the dominant. If conduction through the inner loop is faster than conduction through the outer loop, it will form an integral component of the reentrant circuit. The entry site is where the reentrant wavefront enters the critical isthmus. Bystander sites are sites that are activated by the reentrant wavefront but are not an essential part of the reentrant circuit. These sites can be remote, adjacent, or attached to the circuit. Elimination of these sites does not terminate reentry.^{4,8}

Understanding the concepts associated with resetting is critical to understanding entrainment. When a premature stimulus is delivered to sites remote from the reentrant circuit, it can interact with the circuit in different ways. When the stimulus is late-coupled, it can reach the circuit after it has just been activated by the reentrant wavefront. Consequently, although the extrastimulus may have resulted in activation of part of the myocardium, it fails to affect the reentrant circuit, and the reentrant wavefront continues to propagate in the critical isthmus and through the exit site to produce the next tachycardia complex on time. To reset reentrant tachycardia, the paced wavefront must reach the reentrant circuit (entry site, critical isthmus, or both), encounter excitable tissue within the circuit

(i.e., enter the excitable gap of the reentrant circuit), collide in the antidromic (retrograde) direction with the previous tachycardia complex, and propagate in the orthodromic (anterograde) direction through the same tachycardia reentrant path (critical isthmus) to exit at an earlier than expected time and perpetuate the tachycardia (Fig. 5-15). If the extrastimulus encounters fully excitable tissue, as commonly occurs in reentrant tachycardias with large excitable gaps, the tachycardia is advanced by the extent that the paced wavefront arrives at the entrance site prematurely. If the tissue is partially excitable, as can occur in reentrant tachycardias with small or partially excitable gaps, or even in circuits with large excitable gaps when the extrastimulus is very premature, the paced wavefront will encounter some conduction delay in the orthodromic direction within the circuit. Consequently, the degree of advancement of the next tachycardia complex depends on both the degree of prematurity of the extrastimulus and the degree of slowing of its conduction within the circuit. Therefore, the reset tachycardia complex may be early, on time, or later than expected.^{4,8}

Termination of the tachycardia occurs when the extrastimulus collides with the preceding tachycardia impulse antidromically and blocks in the reentrant circuit orthodromically. This occurs when

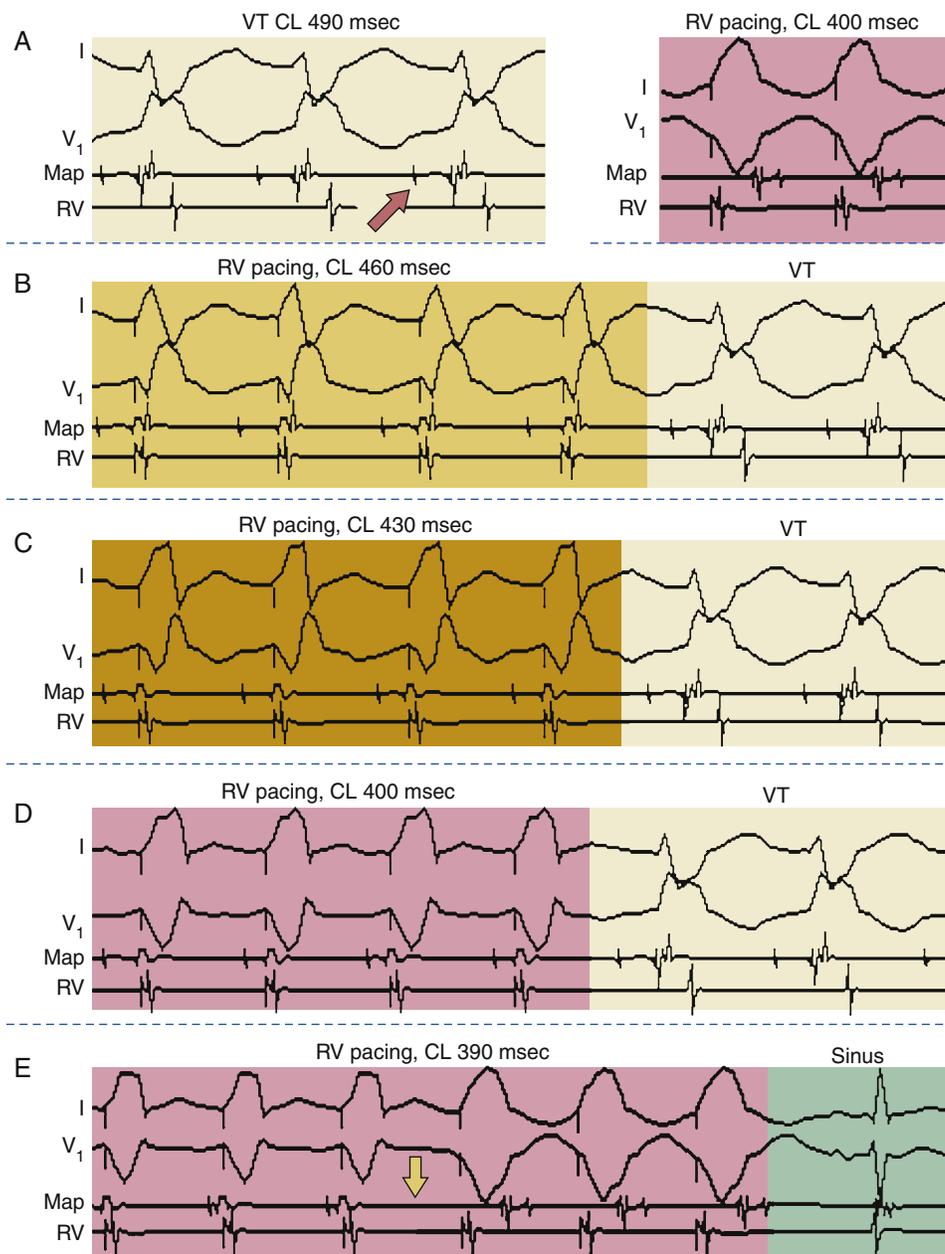

FIGURE 5-15 Entrainment of ventricular tachycardia (VT). **A**, Pure VT is shown in yellow (right bundle branch block, right axis), pure right ventricle (RV) pacing in red (left bundle branch block, left axis). A mid-diastolic potential during VT (arrow) is recorded by the mapping catheter. **B**, Pacing the RV at 460 milliseconds (30 milliseconds faster than VT), each paced complex is a stable blend of pacing and VT (gold). This illustrates fixed fusion. After cessation of pacing, VT resumes. **C**, Pacing the RV faster (430 milliseconds), all complexes are again identical to each other but different than with pacing at 460 milliseconds; they look slightly more like pure RV pacing (deeper gold shading). **D**, Pacing the RV faster still (400 milliseconds), QRS complexes again are identical to each other (fixed fusion) but look progressively more like fully paced (progressive fusion). **E**, Finally, with pacing rapidly enough, an antidromic wavefront captures the diastolic potential, QRS complexes become fully paced, and when pacing ceases, sinus rhythm resumes. This figure demonstrates all established entrainment criteria (fixed fusion at a given paced cycle length [CL], progressive fusion over a range of paced CLs, and antidromic capture of critical circuit elements leading to termination of the tachycardia).

the premature impulse enters the reentrant circuit early enough in the relative refractory period, because it fails to propagate in the anterograde direction, given that it encounters absolutely refractory tissue (see Fig. 5-15). In the retrograde direction, it encounters increasingly recovered tissue and is able to propagate until it meets the circulating wavefront and terminates the arrhythmia.⁸

Entrainment is the continuous resetting of a reentrant circuit by a train of capturing stimuli. However, following the first stimulus of the pacing train that penetrates and resets the reentrant circuit, the subsequent stimuli interact with the reset circuit, which has an abbreviated excitable gap. The first entrained complex results in retrograde collision between the stimulated and tachycardia wavefronts, whereas in all subsequent beats, the collision occurs between the currently stimulated wavefront and that stimulated previously. Depending on the degree that the excitable gap is pre-excited by that first resetting stimulus, subsequent stimuli fall on fully or partially excitable tissue. Entrainment is said to be present when two consecutive extrastimuli conduct orthodromically through the circuit with the same conduction time while colliding antidromically with the preceding paced wavefront.⁴

During entrainment, each pacing impulse creates two activation wavefronts, one in the orthodromic direction and the other in the antidromic direction. The wavefront in the antidromic direction collides with the existing tachycardia wavefront. The wavefront that enters the reentrant circuit in the orthodromic direction (i.e., the same direction as the spontaneous tachycardia wavefront) conducts through the critical isthmus, resets the tachycardia, and emerges through the exit site to activate the myocardium and collide with the antidromically paced wavefront from the next paced stimulus. This sequence continues until cessation of pacing or development of block somewhere within the reentrant circuit. Because all pacing impulses enter the tachycardia circuit during the excitable gap, each paced wavefront advances and resets the tachycardia. Thus, when pacing is terminated, the last paced impulse continues to activate the entire tachycardia reentrant circuit orthodromically at the pacing CL and also activates the entire myocardium orthodromically on exiting the reentrant circuit.

Entrainment of reentrant tachycardias by external stimuli was originally defined in the clinical setting as an increase in the rate of a tachycardia to a faster pacing rate, with resumption of the intrinsic rate of the tachycardia on either abrupt cessation of pacing or slowing of pacing beyond the intrinsic rate of the tachycardia, and it was taken to indicate an underlying reentrant mechanism. The ability to entrain a tachycardia also establishes that the reentrant circuit contains an excitable gap.^{4,8}

Entrainment does not require that the pacing site be located in the reentrant circuit. The closer the pacing site is to the circuit, however, the less premature a single stimulus needs to be to reach the circuit and, with pacing trains, the fewer stimuli will be required before a stimulated wavefront reaches the reentrant circuit without being extinguished by collision with a wave emerging from the circuit. Overdrive pacing at relatively long CLs (i.e., 10 to 30 milliseconds shorter than the tachycardia CL) can almost always entrain reentrant tachycardias. However, the number of pacing stimuli required to entrain the reentrant circuit depends on the tachycardia CL, the duration of the excitable gap of the tachycardia, refractoriness at the pacing site, and the conduction time from the stimulation site to the reentrant circuit.⁸

During constant-rate pacing, entrainment of a reentrant tachycardia results in the activation of all myocardial tissue responsible for maintaining the tachycardia at the pacing CL, with the resumption of the intrinsic tachycardia morphology and rate after cessation of pacing. Unfortunately, it is almost impossible to document the acceleration of all tissue responsible for maintaining the reentrant circuit to the pacing CL. Therefore, several surface ECG and intracardiac electrogram criteria have been proposed for establishing the presence of entrainment (see Fig. 5-15): (1) fixed fusion of the paced complexes at a constant pacing rate; (2) progressive fusion or different degrees of fusion at different pacing rates (i.e., the surface ECG and intracardiac morphology progressively look more like the purely paced configuration and less like the pure tachycardia beat in the course of pacing at progressively shorter pacing CLs; Fig. 5-16); and (3) resumption of the same tachycardia morphology following cessation of pacing, with the first post-pacing complex

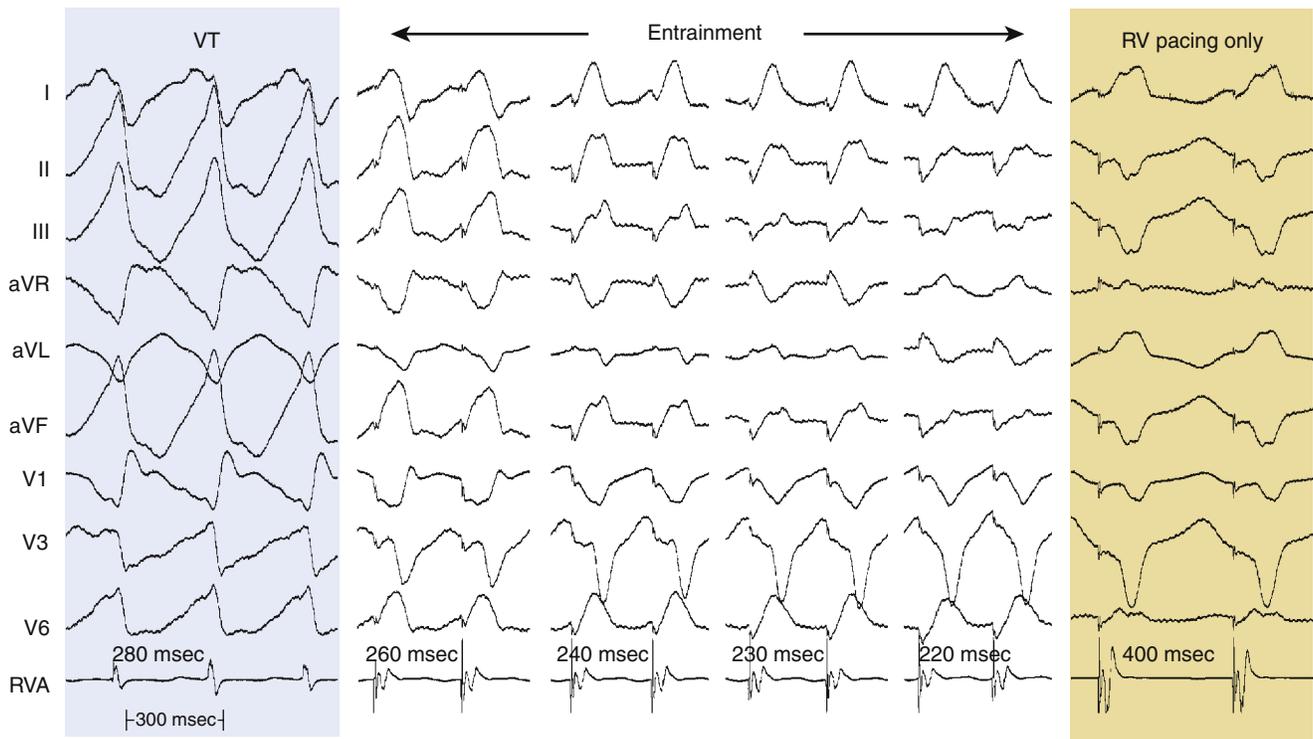

FIGURE 5-16 QRS fusion during entrainment of ventricular tachycardia (VT). Progressive ECG fusion is shown over a range of paced cycle lengths (CLs). Pure tachycardia complexes are shown on the left; fully paced complexes are shown on the right. As the paced CL shortens, complexes gradually appear more like those that are fully paced. RV = right ventricle.

displaying no fusion but occurring at a return cycle equal to the pacing CL.⁸

FUSION DURING ENTRAINMENT

CH
5

A stimulated impulse is said to be fused when its morphology is a hybrid between that of a fully paced complex and a tachycardia complex. Fusion can be observed on the surface ECG, intracardiac recordings, or both. For fusion to be observed on the surface ECG, the tachycardia and stimulated wavefronts must collide within the reentrant circuit after the tachycardia wavefront has exited from the isthmus. This requires the paced wavefront to have access to an entrance site of the reentrant circuit that is anatomically distinct from the exit site. If the antidromically stimulated wavefront penetrates the reentrant circuit and collides with the tachycardia wavefront (or the previously stimulated orthodromic wavefront) before the point at which the tachycardia wavefront would be exiting to the mass of the myocardium, then no fusion will be evident on the surface ECG, and the surface ECG will appear entirely paced.⁴

The ability to demonstrate surface ECG fusion requires that a significant mass of myocardium be depolarized by the extrastimulus and the tachycardia. The degree of fusion represents the relative amounts of myocardium depolarized by the two separate wavefronts. The relative degree of myocardium antidromically activated by the paced wavefront depends on the site of pacing relative to the reentrant circuit, the pacing CL, and the degree of conduction delay within the reentrant circuit. With a single extrastimulus, the farther the stimulation site is from the reentrant circuit, the less likely ECG fusion will be to occur, because the extrastimulus must be delivered at a shorter coupling interval, well before the tachycardia wavefront exits the circuit, to reach the circuit with adequate prematurity. Therefore, by the time the tachycardia wavefront exits the circuit, most of the myocardium has already been activated by the paced wavefront. Consequently, the stimulated impulse will have a purely paced morphology with no ECG fusion. Nevertheless, continuous pacing at a slow CL at a site remote from the exit site affords the best opportunity to demonstrate fusion, whereas pacing closer to the presumed exit site shows less fusion. Presystolic electrograms in the reentrant circuit that are activated orthodromically can be used to demonstrate the presence of intracardiac (local) fusion when the ECG is insufficiently sensitive. This is particularly helpful with ATs because the P waves are small and often obscured by the QRS complex, ST segments, and T waves.

Once stability in collision sites of the antidromic and orthodromic wavefronts occurs, constant surface ECG fusion is achieved. Fixed fusion in the surface ECG is said to be present during entrainment if one of the following criteria is met: (1) the surface ECG complex is of constant morphology, representing a hybrid of the complex morphology of the tachycardia and that observed during pacing during normal sinus rhythm (NSR; see Figs. 5-15 and 5-16), or (2) the onset of the surface ECG complex precedes the pacing stimulus artifact of each paced beat by a fixed interval (see Figs. 12-9 and 13-5). It is worth noting that to be certain a hybrid or blended ECG complex is present, one must know the configurations of both pure tachycardia and pure pacing (Fig. 5-17; see also Figs. 5-15 and 5-16).

Focal tachycardias (automatic, triggered activity, or microreentrant) cannot manifest fixed fusion during overdrive pacing. However, overdrive pacing of tachycardia of any mechanism can result in a certain degree of fusion, especially when the pacing CL is only slightly shorter than the tachycardia CL. Such fusion, however, is unstable during the same pacing drive at a constant CL, because pacing stimuli fall on a progressively earlier portion of the tachycardia cycle and produce progressively less fusion and more fully paced morphology. Such phenomena should be distinguished from entrainment, and sometimes this distinction requires pacing for long intervals to demonstrate variable degrees of fusion. Moreover, overdrive pacing frequently results in suppression (automatic) or acceleration (triggered activity) of focal tachycardias, rather than resumption of the original tachycardia with an unchanged tachycardia CL.⁴

Varying degrees of fusion at different pacing rates are caused by a progressive increase in the amount of myocardium activated by the antidromic wavefront at progressively shorter pacing CLs (see Figs. 5-15 and 5-16). At slower pacing CLs, a larger amount of the myocardium is activated by the orthodromic wavefront exiting from the reentrant circuit prior to its intracardiac collision, with the subsequent antidromic wavefront incoming from the pacing site. With a faster pacing rate, more myocardium is antidromically activated because the orthodromic wavefront must continue to traverse the zone of slow conduction within the reentrant circuit, thus creating progressive fusion with changing pacing CLs. In the extreme situation, the antidromic wavefront can capture the exit site of the reentrant circuit and produce a fully paced complex. Once this occurs, pacing at shorter pacing CLs does not cause further progressive fusion, although entrainment is still present. As noted, progressive fusion at decreasing pacing CLs during entrainment of tachycardia excludes the possibility of automaticity or triggered activity as the mechanism of the tachycardia. In those cases, overdrive pacing would yield solely the morphology of the pacing stimulus for a nonprotected focus or would yield varying (not progressive) degrees of fusion for a protected focus with entrance block. Of note, a microreentrant circuit with entrance block could also yield variable fusion during overdrive pacing; thus, this finding would not exclude reentry as the underlying mechanism.^{4,8}

On cessation of pacing, the last paced wavefront traverses the protected isthmus and exits the circuit to produce a normal (non-fused) tachycardia complex at the pacing CL, because there is no paced antidromic wavefront with which to fuse. The wavefront continues around the reentrant circuit to maintain the tachycardia. Constant fusion of the surface ECG can occur, however, without the first nonpaced beat occurring at the pacing CL. When surface ECG fusion occurs, the initial portion of the ECG complex usually reflects activation of the myocardium by the paced wavefront, whereas the terminal portion represents the orthodromically activated wavefront exiting from the tachycardia circuit. The point at which this wavefront exits the circuit can be late in the surface ECG complex. The degree to which the first ECG post-pacing interval (PPI) exceeds the pacing CL is primarily a reflection of the time from the onset of the paced surface ECG complex to the exit of the orthodromic wavefront from the reentrant circuit. This represents the period of time during which the myocardium is depolarized by the stimulated wavefront before the activation of any portion of the myocardium by the tachycardia wavefront. Thus, constant fusion occurring in the absence of the first ECG PPI being equal to the pacing CL can be a valid manifestation of entrainment. In this situation, appropriate placement of intracardiac electrodes demonstrates orthodromic entrainment of some intracardiac recording sites occurring at the pacing CL, even though the last entrained ECG complex occurred at an interval longer than the pacing CL. Alternatively, decremental conduction within the reentrant circuit can explain a first PPI that exceeds the pacing CL.⁴

ENTRAINMENT WITH MANIFEST FUSION. Entrainment with manifest fusion demonstrates surface ECG evidence of constant fusion at a constant pacing rate and progressive fusion with incremental-rate pacing (see Fig. 5-16).⁸ When entrainment is manifest, the last captured wave is entrained at the pacing CL but does not demonstrate fusion.⁹

ENTRAINMENT WITH INAPPARENT, LOCAL, OR INTRACARDIAC FUSION. Entrainment with inapparent fusion (also referred to as local or intracardiac fusion) is said to be present when a fully paced morphology with no ECG fusion results, even when the tachycardia impulse exits the reentrant circuit (orthodromic activation of the presystolic electrogram present). Fusion is limited to a small area and does not produce surface ECG fusion, and only intracardiac (local) fusion is recognized (Fig. 5-18; see also Fig. 13-5).⁸ Local fusion can occur only when the presystolic electrogram is activated orthodromically. Collision with the last paced impulse must occur distal to the presystolic electrogram, either at the exit from the circuit or outside the circuit. In such cases, the return cycle measured at this local electrogram equals

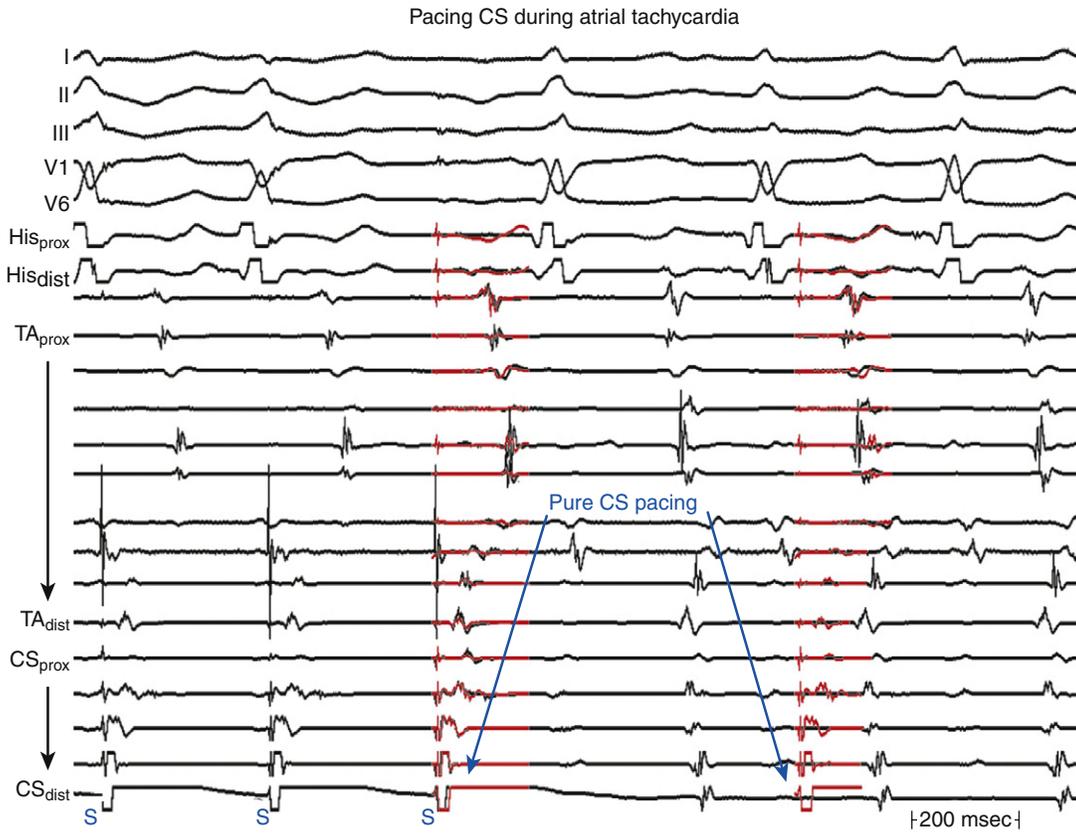

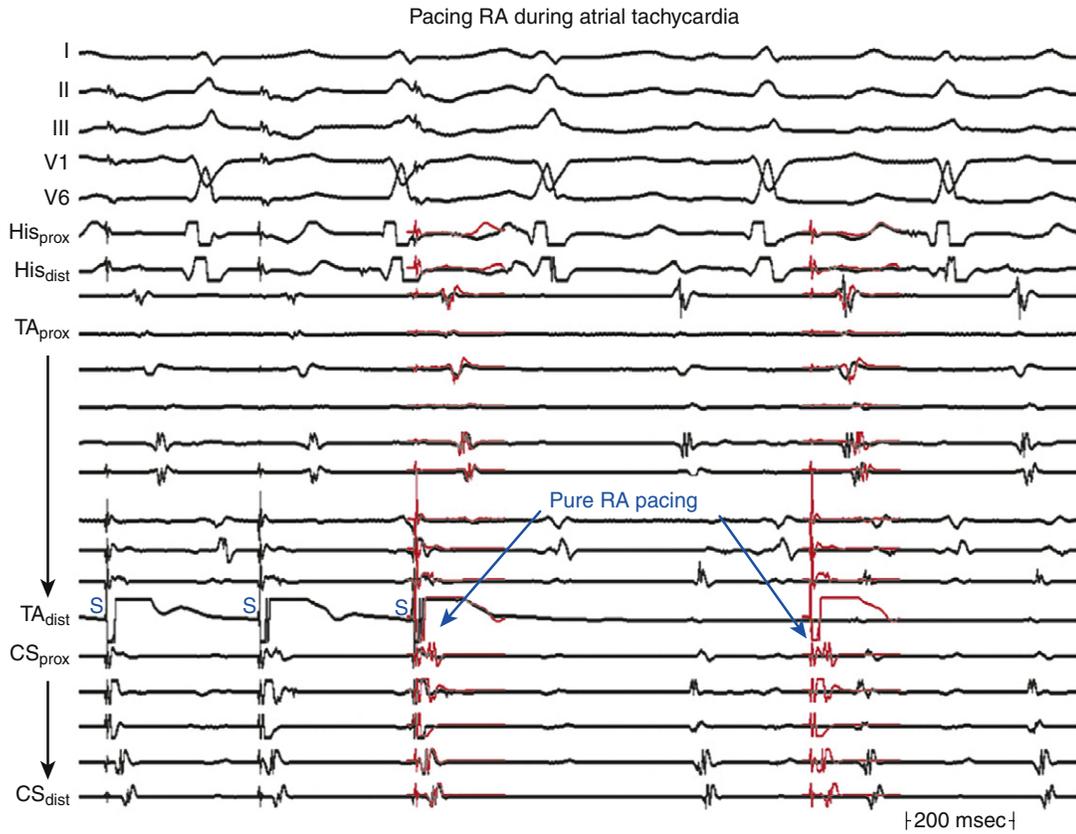

FIGURE 5-17 Overdrive pacing during focal atrial tachycardia (AT). **Top**, The last three complexes of pacing (S) from the high right atrium (RA) are shown, following which AT resumes. The red overlay represents recordings of pure high RA pacing that perfectly match the electrogram sequence of high RA pacing during AT; thus, fusion is absent. **Bottom**, Similar findings with pacing from distal coronary sinus (CS_{dist}). The red overlay of pure CS pacing perfectly matches the electrogram sequence of CS pacing during AT; thus, there is no fusion. CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{prox} = proximal His bundle; TA_{dist} = distal tricuspid annulus; TA_{prox} = proximal tricuspid annulus.

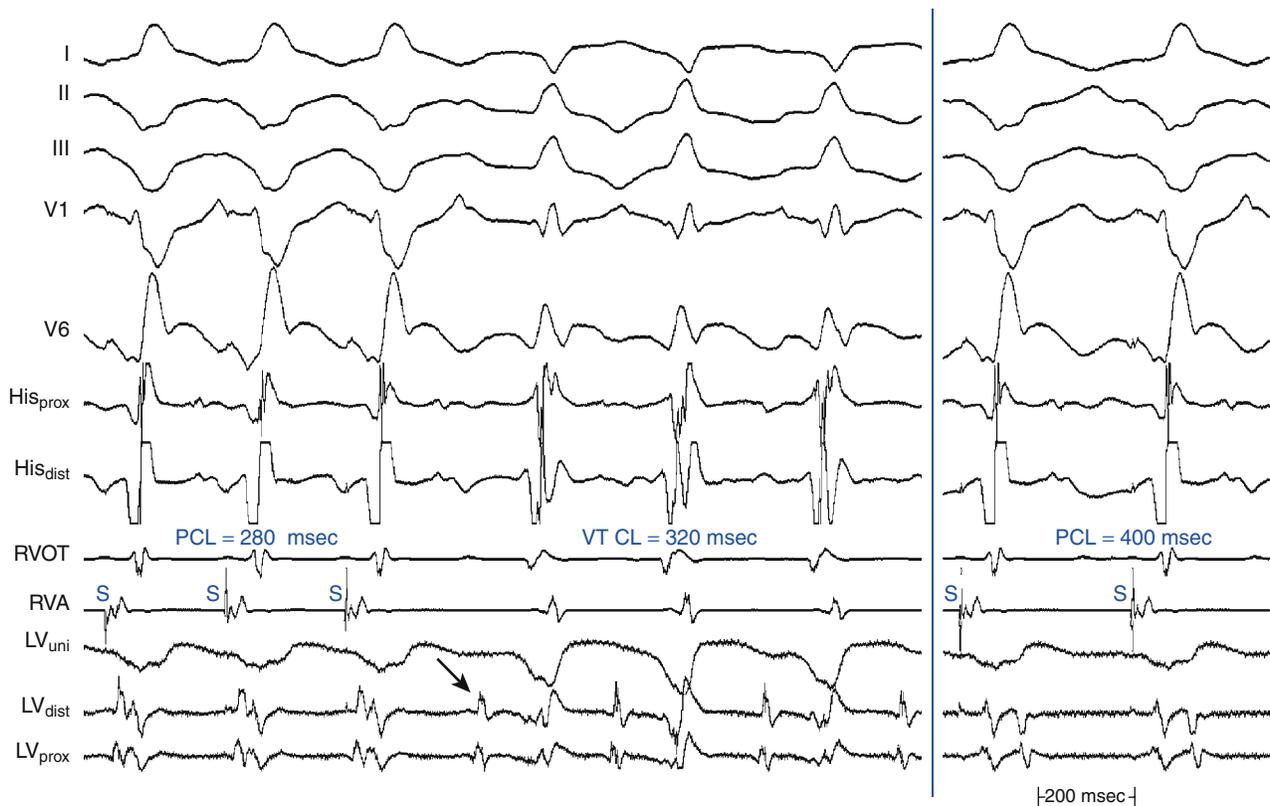

FIGURE 5-18 Inapparent fusion. The last three complexes paced from the right ventricular apex during ventricular tachycardia (VT) are shown; VT resumes on cessation of pacing. Fusion is not evident on the surface ECG because these complexes are identical to fully paced QRS complexes at the far right, yet fusion is present on the distal ablation (Abl_{dist}) recording (mid-diastolic potential at arrow seen during pacing as well). CL = cycle length; PCL = pacing cycle length; His_{dist} = distal His bundle; His_{prox} = proximal His bundle; LV_{dist} = distal left ventricle; LV_{prox} = proximal left ventricle; LV_{uni} = unipolar left ventricle; RVA = right ventricular apex; RVOT = right ventricular outflow tract.

the pacing CL. Therefore, a stimulus delivered after the onset of the tachycardia complex on the surface ECG during entrainment always demonstrates local fusion. This is to be distinguished from entrainment with antidromic capture. As noted, when antidromic (retrograde) capture of the local presystolic electrogram occurs, the return cycle, even when measured at the site of the presystolic electrogram, exceeds the pacing CL.^{8,9}

ENTRAINMENT WITH ANTIDROMIC CAPTURE. Entrainment with antidromic capture should be distinguished from entrainment with local fusion. When pacing is performed at a CL significantly shorter than the tachycardia CL, the paced impulse can penetrate the circuit antidromically and retrogradely capture the presystolic electrogram so that no exit from the tachycardia circuit is possible. When pacing is stopped, the impulse that conducts antidromically also conducts orthodromically to reset the reentrant circuit with orthodromic activation of the presystolic electrogram. When antidromic (retrograde) capture of the local presystolic electrogram occurs, the return cycle, even when measured at the site of the presystolic electrogram, exceeds the pacing CL by the difference in time from when the electrogram is activated retrogradely (i.e., preexcited antidromically) and when it would have been activated orthodromically.^{4,8,9}

ENTRAINMENT WITH CONCEALED FUSION. Entrainment with concealed fusion (sometimes also referred to as concealed entrainment or exact entrainment) is defined as entrainment with orthodromic capture and a surface ECG complex (or intracardiac activation sequence, or both) identical to that of the tachycardia (see Figs. 12-9 and 13-5). Entrainment with concealed fusion suggests that the pacing site is within a protected isthmus inside or outside, but attached to, the reentrant circuit (see Fig. 5-14). In this situation, transient entrainment is achieved when the orthodromically directed stimulated wavefront resets the tachycardia, but the antidromically directed stimulated wavefront collides with the

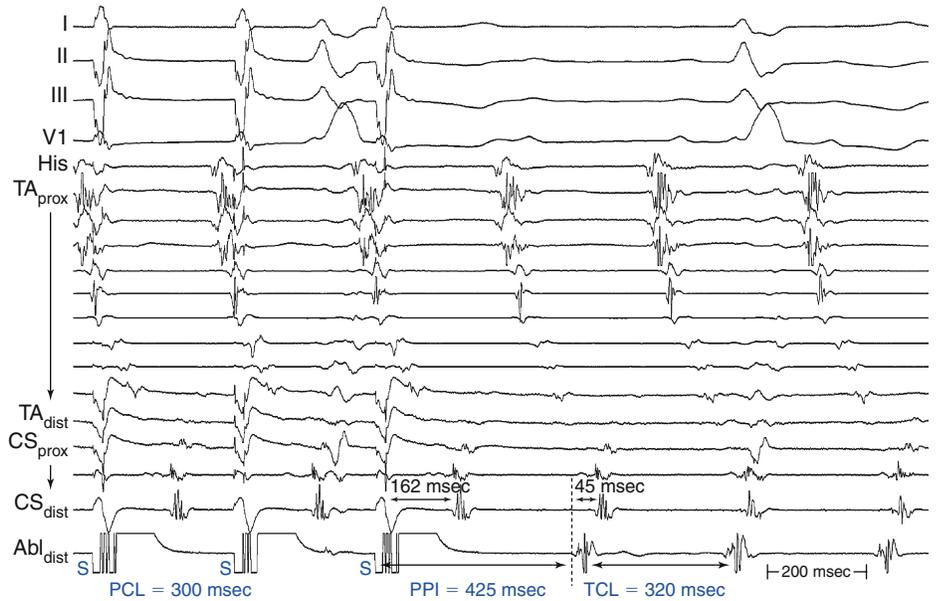

tachycardia wavefront in or near the reentry circuit and fails to exit the slow conduction zone. Only tissue near the pacing site within the critical isthmus is antidromically activated; hence, there is no evidence of fusion. Compared with the intrinsic tachycardia, this antidromic capture may result in earlier intracardiac recordings from sites located adjacent to the pacing region. The morphological appearance of the ECG, however, is the same during entrainment as during the tachycardia. Entrainment with concealed fusion can occur by pacing from bystander pathways, such as a blind alley, alternate pathway, or inner loop, that are not critical to the maintenance of reentry. In this case, activation propagates from the main circuit loop but is constrained by block lines having the shape of a cul-de-sac; ablation there does not terminate reentry (unless it is fortuitously close to a critical portion of the circuit).^{4,8,9}

POST-PACING INTERVAL

The PPI is the time interval from the last pacing stimulus that entrained the tachycardia to the next nonpaced recorded electrogram at the pacing site (Fig. 5-19). During entrainment from sites within the reentrant circuit, the orthodromic wavefront from the last stimulus propagates through the reentry circuit and returns to the pacing site, following the same path as the circulating reentry wavefronts. The conduction time required is the revolution time through the circuit. Thus, the PPI (measured from the pacing site recording) should be equal (within 30 milliseconds) to the tachycardia CL (given that conduction velocities and the reentrant path did not change during pacing; see Fig. 5-14). At sites remote from the circuit, stimulated wavefronts propagate to the circuit, then through the circuit, and finally back to the pacing site. Thus, the PPI should equal the tachycardia CL plus the time required for the stimulus to propagate from the pacing site to the tachycardia circuit and back. The greater the difference is between the PPI and

FIGURE 5-19 Bystander site during atypical left atrial (LA) flutter. The last three complexes of pacing from the posterior LA are shown in a patient with LA macroreentry. Although the timing of the electrogram at the pacing site is in early mid-diastole and the paced activation sequence is similar to tachycardia, thereby giving the appearance of an attractive ablation site, the results of entrainment indicate otherwise, with a large difference between the stimulus–coronary sinus (CS) electrogram interval (162 milliseconds) and the ablation recording–CS electrogram interval (45 milliseconds), as well as a large difference between the post-pacing interval (PPI) (425 milliseconds) and tachycardia cycle length (TCL, 320 milliseconds). Abl_{dist} = distal ablation; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; PCL = pacing cycle length; TA_{dist} = distal tricuspid annulus; TA_{prox} = proximal tricuspid annulus.

the tachycardia CL (PPI – tachycardia CL), the longer the conduction time will be between the pacing site and reentry circuit, and the greater the physical distance will be between the pacing site and the circuit (see Figs. 12-9 and 13-5).⁹

Several factors have to be considered when evaluating the PPI. The PPI should be measured to the near-field potential that indicates depolarization of tissue at the pacing site. In regions of scar, electrode catheters often record multiple potentials separated in time, some of which are far-field potentials that result from depolarization of adjacent myocardium. The near-field potential is obscured by capture during pacing, whereas far-field potentials can be undisturbed during pacing. Furthermore, when pacing artifacts obscure recordings from the pacing site and prevent assessment of the PPI, the electrograms from the proximal electrodes of the mapping catheter may be utilized, provided such electrograms are also present in the distal electrode recordings. When the electrograms from the pacing site are not discernible because of stimulus artifact, relating the timing of the near-field potential to a consistent intracardiac electrogram or surface ECG wave can be used to determine the PPI.

CONDUCTION TIME FROM THE PACING SITE TO THE CIRCUIT EXIT SITE

During entrainment of reentrant tachycardia, the interval between the pacing stimulus and the onset of the tachycardia complex on the surface ECG (QRS or P wave) reflects the conduction time from the pacing site to the exit of the reentrant circuit (stimulus-exit interval), regardless of whether the pacing site is inside or outside the reentrant circuit, because activation starts at the pacing site and propagates in sequence to the circuit exit site. On the other hand, during tachycardia, the interval between the local electrogram at a given site and circuit exit (electrogram-exit interval) can reflect the true conduction time between those two sites if they are activated in sequence (as occurs when that particular site is located within the reentrant pathway), or it may be shorter than the true conduction time if those two sites are activated in parallel (which occurs when that particular site is located outside the reentrant circuit) (see Figs. 5-14 and 5-19).⁸

Therefore, at any given pacing site, an electrogram-exit interval that is equal (± 20 milliseconds) to the stimulus-exit interval indicates that the pacing site lies within the reentry circuit and excludes the possibility that the site is a dead-end pathway attached to the circuit (i.e., not a bystander). On the other hand, pacing sites outside the reentrant circuit have an electrogram-exit

interval significantly (more than 20 milliseconds) shorter than the stimulus-exit interval.

However, the electrogram-exit interval may not be exactly equal to the stimulus-exit interval at sites within the reentrant circuit. Several factors can explain this. One potential factor is decremental conduction properties of the zone of slow conduction that produce lengthening of the stimulus-exit interval during pacing; however, this appears to occur rarely. Therefore, the stimulus-exit interval should be measured during pacing at the slower CL that reliably entrains the tachycardia. Moreover, stimulus latency in an area of diseased tissue can account for a delay in the stimulus-exit interval compared with the electrogram-QRS interval. Additionally, failure of the recording electrodes to detect low-amplitude depolarizations at the pacing site can account for a mismatch of the stimulus-exit and electrogram-exit intervals.⁸

Mapping Procedure

Before attempting to use entrainment methods for mapping, it is necessary to demonstrate that the tachycardia can be entrained, by providing strong evidence that it is caused by reentry rather than by triggered activity or automaticity. Potential ablation sites are sought by pacing at sites thought to be related to the reentrant circuit, based on other mapping modalities, such as activation mapping and pace mapping. The areas of slow conduction can be identified by endocardial mapping revealing fractionated electrograms, mid-diastolic electrograms, or long delays between the pacing stimulus and the captured surface ECG complex (see Fig. 5-14). These sites are then targeted by entrainment mapping. However, proof of entrainment is best obtained by pacing from sites remote from the circuit, which most readily demonstrate fusion.⁹

Entrainment mapping can be reliably carried out only if one can record and stimulate from the same area (e.g., for 2-5-2-mm spacing catheters, record from the second and fourth poles and stimulate from the first and third poles). Pacing is usually started at a CL just shorter (10 to 20 milliseconds) than the tachycardia CL. Pacing should be continued for a long enough duration to allow for entrainment; short pacing trains are usually not helpful. Pacing is then repeated at progressively shorter pacing CLs.⁸

After cessation of each pacing drive, the presence of entrainment should be verified by demonstrating the presence of fixed fusion of the paced complexes at a given pacing CL, progressive fusion at faster pacing CLs, and resumption of the same tachycardia morphology following cessation of pacing with a nonfused complex at a return cycle equal to the pacing CL. The mere acceleration of the

tachycardia to the pacing rate and then resumption of the original tachycardia after cessation of pacing do not establish the presence of entrainment. Evaluation of the PPI or other criteria is meaningless when the presence of true entrainment has not been established. Moreover, it is important to verify the absence of termination and reinitiation of the tachycardia during the same pacing drive.⁴

Once the presence of entrainment is verified, several criteria can be used to indicate the relation of the pacing site to the reentrant circuit. The first entrainment criterion to be sought is concealed fusion. Entrainment with concealed fusion indicates that the pacing site is in a protected isthmus located within or attached to the reentrant circuit. Whether this protected isthmus is crucial to the reentrant circuit or is just a bystander site needs to be verified by other criteria, mainly comparing the PPI with the tachycardia CL and comparing the stimulus-exit interval with the electrogram-exit interval. Features of entrainment when pacing from different sites are listed in Table 5-1 (see also Figs. 5-14, 5-18, and 5-19).^{9,10}

A graphical representation of entrainment mapping can be constructed by plotting the values of the difference between the PPI and the tachycardia CL [PPI–tachycardia CL] on an electroanatomical mapping system (CARTO, Biosense Webster, Inc., Diamond Bar, Calif.; or NavX, St. Jude Medical, Inc., St. Paul, Minn.) to generate color-coded three-dimensional entrainment maps (see Chap. 6 for discussion).^{11,12}

Clinical Implications

Entrainment mapping is the gold standard for ablation of reentrant circuits generating hemodynamically well-tolerated tachycardias. Achievement of entrainment of tachycardia establishes a reentrant mechanism of that tachycardia and excludes triggered activity and abnormal automaticity as potential mechanisms. Entrainment may also be used to estimate how far the reentrant circuit is from the pacing site qualitatively. For example, entrainment of an AT from multiple sites in the RA with a PPI significantly longer than the tachycardia CL can help identify a left atrial origin of the AT before attempting LA access (see Fig. 13-5). In addition, pacing at multiple sites and measuring the difference between the PPI and tachycardia CL provide an indication of how far or near the pacing site is from the circuit (Fig. 5-20).^{4,8,9}

Entrainment mapping has been useful to identify the critical isthmus in patients with macroreentrant VT or AT. Focal ablation of all sites defined as within the reentrant circuit may not result in a cure of reentrant tachycardia. Cure requires ablation of an isthmus bordered by barriers on either side, which is critical to the reentrant circuit. Entrainment mapping helps identify this critical part of the reentrant circuit. Sites demonstrating entrainment with concealed fusion are initially sought. Once these sites are identified, their relationship to the reentrant circuit is verified using the PPI or stimulus-exit interval (see earlier). Sites demonstrating concealed fusion, a PPI equal to the tachycardia CL (± 30 milliseconds), and a stimulus-exit interval equal to the electrogram-exit interval

TABLE 5-1 Entrainment Mapping of Reentrant Tachycardias

Pacing from Sites Outside the Reentrant Circuit

- Manifest fusion on surface ECG or intracardiac recordings, or both
- PPI-tachycardia CL > 30 msec
- Stimulus-exit interval $>$ electrogram-exit interval

Pacing from Sites Inside the Reentrant Circuit

- Manifest fusion on surface ECG or intracardiac recordings, or both
- PPI-tachycardia CL < 30 msec
- Stimulus-exit interval = electrogram-exit interval (± 20 msec)

Pacing from a Protected Isthmus Inside the Reentrant Circuit

- Concealed fusion
- PPI-tachycardia CL < 30 msec
- Stimulus-exit interval = electrogram-exit interval (± 20 msec)

CL = cycle length; PPI = post-pacing interval.

(± 20 milliseconds) have a very high positive predictive value for successful ablation.^{4,9,10}

Limitations

One of the limitations of entrainment mapping is the requirement of the presence of sustained, hemodynamically well-tolerated tachycardia of stable morphology and CL. Furthermore, attempts at entrainment can result in termination, acceleration, or transformation of the index tachycardia into a different one, thus making further mapping challenging. Bipolar pacing at relatively high stimulus strengths used during entrainment can result in capture of an area larger than the local area. Additionally, errors can be introduced by the decremental conduction properties of the zone of slow conduction that may cause a rate-dependent lengthening of the PPI. This is more likely to occur at rapid pacing rates.^{4,8}

Pacing and recording from the same area are required for entrainment mapping. This requirement is usually satisfied by pacing from electrodes 1 and 3 and recording from electrodes 2 and 4 of the mapping catheter. However, this technique has several limitations:

- There are differences, albeit slight, of the area from which the second and fourth electrodes record as compared with the first and third. When the local electrogram is not recorded from the same pair of electrodes used for pacing, errors can be introduced when comparing the PPI with the tachycardia CL.
- The bipolar pacing technique has the potential for anodal contribution to local capture.
- The total area captured by the pacing stimulus can exceed the local area, especially when high currents (more than 10 mA) are required for stimulation.
- The pacing artifact can obscure the early part of the captured local electrogram. In such a case, a comparable component of the electrogram can be used to measure the PPI.
- Far-field electrical signals generated by depolarization of adjacent tissue can cause false-positive entrainment criteria at some sites.^{4,8}

Pace Mapping

Fundamental Concepts

Pace mapping is a technique designed to help locate tachycardia sources by pacing at different endocardial sites to reproduce the ECG morphology of the tachycardia. Pace mapping is based on the

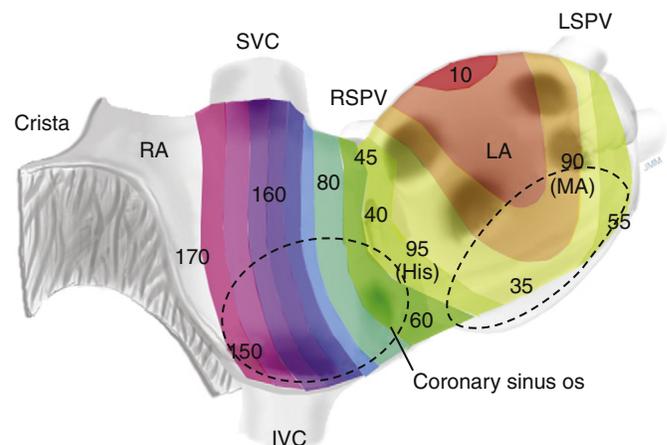

FIGURE 5-20 The post-pacing interval (PPI)–tachycardia cycle length (TCL) interval as an indicator of distance from the pacing site to the reentrant circuit (located in the dome of the left atrium [LA], near 10). In this representation of both atria viewed from the front, colors indicate isochrones of the difference between PPI and TCL in milliseconds at various pacing sites (indicated by numbers). IVC = inferior vena cava; LSPV = left superior pulmonary vein; MA = mitral annulus; os = ostium; RA = right atrium; RSPV = right superior pulmonary vein; SVC = superior vena cava.

principle that pacing from the site of origin of a focal tachycardia at a pacing CL similar to the tachycardia CL results in the same activation sequence as that during the tachycardia.⁴

When myocardial activation originates from a point-like source, such as during focal tachycardia or during pacing from an electrode catheter, ECG configuration of the resultant tachycardia or paced complex (QRS or P wave) is determined by the sequence

of myocardial activation, which is largely determined by the initial site of myocardial depolarization, assuming no conduction abnormalities from that site. Analysis of specific surface ECG configurations in multiple leads allows estimation of the pacing site location to within several square centimeters, and comparing the paced complex configuration with that of tachycardia can be used to locate the arrhythmia focus (Fig. 5-21).^{13,14}

On the other hand, reentry circuits in healed infarct scars (e.g., post-MI VT) often extend over several square centimeters and can have various configurations. In many circuits, the excitation wave propagates through surviving myocytes in the scarred region, depolarization of which is not detectable in the standard surface ECG. The QRS complex is then inscribed after the reentry wavefront activates a sufficient amount of muscle outside the dense scar area. At sites at which the reentrant wavefront exits the scar, pace mapping is expected to produce a QRS configuration similar to that of VT. Pace mapping at sites more proximally located in the isthmus of the reentrant circuit should also produce a similar QRS complex, but with a longer stimulus-to-QRS (S-QRS) interval.

INTERPRETATION OF PACE MAPPING

Pace maps with identical or nearly identical matches of tachycardia morphology in all 12 surface ECG leads can be indicative of the site of origin of the tachycardia (Fig. 5-22). Differences in the morphology between pacing and spontaneous tachycardia in a single lead can be critical. For VT, pacing at a site 5 mm from the index pacing site results in minor differences in QRS configuration (e.g., notching, new small component, change in amplitude of individual component, or overall change in QRS shape) in at least one lead in most patients. In contrast, if only major changes in QRS morphology are considered, pacing sites separated by as much as 15 mm can produce similar QRS morphologies.

Although qualitative comparison of the 12-lead ECG morphology between a pace map and clinical tachycardia is frequently performed, there are few objective criteria for quantifying the similarity between 2 12-lead ECG waveform morphologies. Such comparisons are frequently completely subjective or semiquantitative,

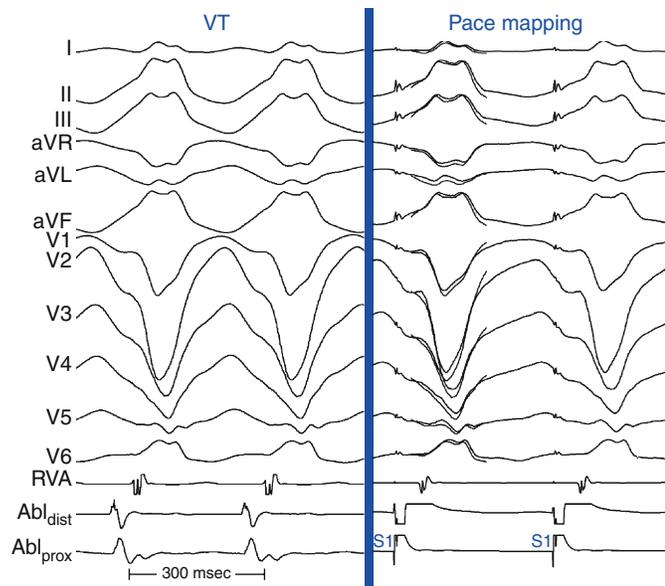

FIGURE 5-21 Pace mapping of ventricular tachycardia (VT). At left, 12 ECG leads and intracardiac recordings during idiopathic right ventricular outflow tract VT are shown (cycle length [CL], 280 milliseconds). At right, pace mapping from the site of earliest ventricular activation at CL 350 milliseconds produces an identical 12-lead ECG configuration (the VT complex superimposed on the first paced complex). Abl_{dist} = distal ablation; Abl_{prox} = proximal ablation; RVA = right ventricular apex.

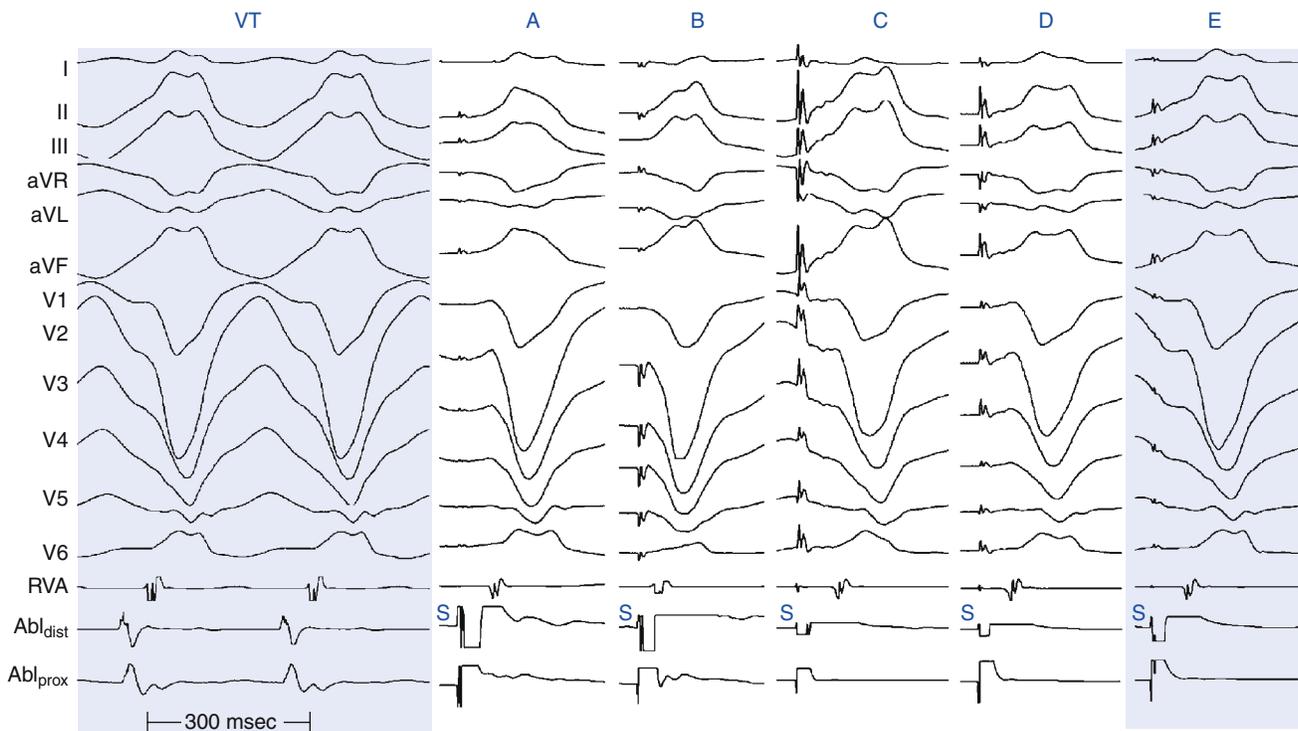

FIGURE 5-22 Pace mapping of ventricular tachycardia (VT). Pace mapping at various sites in the right ventricular outflow tract produces QRS configurations (A to D) with less or more similarity to the VT QRS (left panel); E shows an exact match. Abl_{dist} = distal ablation; Abl_{prox} = proximal ablation; RVA = right ventricular apex.

such as a 10/12 lead match. Unsuccessful ablation can result, in part, from subjective differences in the opinion of a pace map match to the clinical tachycardia. Furthermore, criteria for comparing the similarity in 12-lead ECG waveforms from one laboratory with those of another or for describing such comparisons in the literature are lacking. Two waveform comparison metrics, the correlation coefficient (CORR) and the mean absolute deviation (MAD), have been evaluated to quantify the similarity of 12-lead ECG waveforms during VT and pace mapping objectively. It has been suggested that an automated objective interpretation can have some advantage to qualitative interpretation. Although CORR is more commonly used, MAD is more sensitive to differences in waveform amplitude. The most common human error is not appreciating subtle amplitude or precordial lead transition differences between the ECG patterns. It is important to note that such subtle differences in multiple leads can be reflected in a single quantitative number.

The MAD score grades 12-lead ECG waveform similarity as a single number ranging from 0% (identical) to 100% (completely different). A MAD score of up to 12% was 93% sensitive and 75% specific for a successful ablation site (see Fig. 23-11). It is not surprising that the MAD score is more sensitive than specific; characteristics other than a 12-lead ECG match are necessary for successful ablation, including catheter-tissue contact, catheter orientation, and tissue heating. MAD scores higher than 12%, and certainly higher than 15% (100% negative predictive value), suggest sufficient dissimilarity between the pace map and clinical tachycardia to dissuade ablation at that site. MAD scores of up to 12% should be considered an excellent match, and ablation at these sites is warranted if catheter contact and stability are adequate.

S-QRS INTERVAL DURING PACE MAPPING

Ventricular pacing in normal myocardium is associated with an S-QRS interval shorter than 20 milliseconds. On the other hand, an S-QRS interval longer than 40 milliseconds is consistent with slow conduction from the pacing site and is typically associated with abnormal fractionated electrograms recorded from that site. Thus, pace mapping can provide a measure of slow conduction, as indicated by the S-QRS interval. For post-MIVTs, at sites at which the reentrant wavefront exits the scar, pace mapping is expected to produce a QRS configuration similar to that of the VT. Pace mapping at sites more proximally located in the isthmus should also produce a similar QRS complex, but with a longer S-QRS interval. The S-QRS interval lengthens progressively as the pacing site is moved along the isthmus, a finding consistent with pacing progressively farther from the exit. Therefore, parts of VT reentry circuit isthmuses can be traced during NSR by combining both the QRS morphology and the S-QRS delay from pace mapping in anatomical maps. This works well when pacing is performed during tachycardia, at which time wavefront propagation is constrained in one direction through a corridor bounded by barriers that can be anatomically or functionally determined. However, pace mapping at the same sites during sinus rhythm can yield different results because the barriers may not exist then, the preferential direction of propagation may not be the same as during tachycardia, or both. This is especially true for pacing at circuit entrance sites (Fig. 5-23). It is likely that pacing sites with long S-QRS delays are in an isthmus adjacent to regions of conduction block. However, this isthmus can be part of the reentrant circuit or a bystander.⁴

Mapping Procedure

Initially, the exact morphology of the tachycardia complex should be determined and used as a template for pace mapping. For VT, QRS morphology during the tachycardia should be inspected in all 12 surface ECG leads. For AT, determining the morphology of the P wave during the tachycardia can be challenging, and proper interpretation of discrete changes in P wave shape is limited by its low voltage and distortion or masking by the preceding ST segment and T wave. Therefore, the P wave during AT should be assessed using multiple ECG leads, in addition to the intracardiac

electrogram activation sequence. Delivery of a vesicular extrastimulus (or a train of ventricular pacing) to advance ventricular activation and repolarization can allow careful distinction of the P wave onset and morphology. Using multiple intraatrial catheters (e.g., Halo and CS catheters) can provide more intracardiac atrial electrograms that are useful for comparing the paced and tachycardia atrial activation sequence.⁴

Pace mapping during tachycardia (at a pacing CL 20 to 40 milliseconds shorter than the tachycardia CL) is preferable whenever possible, because it facilitates rapid comparison of tachycardia and paced complexes at the end of the pacing train in a simultaneously displayed 12-lead ECG. If sustained tachycardia cannot be induced, mapping is performed during spontaneous nonsustained runs or ectopic beats. In this setting, the pacing CL and coupling intervals of the extrastimuli should match those of spontaneous ectopy. For atrial pace mapping, it is unclear whether the conduction pattern of an atrial stimulus depends on the pacing CL; in fact, some have suggested that it is not mandatory to pace exactly at the same tachycardia CL to reproduce a similar atrial sequence.

Pace mapping is preferably performed with unipolar stimuli (10 mA, 2 milliseconds) from the distal electrode of the mapping catheter (cathode) and an electrode in the inferior vena cava (anode), or with closely spaced bipolar pacing at twice diastolic threshold to eliminate far-field stimulation effects.

The resulting 12-lead ECG morphology is compared with that of the tachycardia. ECG recordings should be reviewed at the same gain and filter settings and at a paper-sweep speed of 100 mm/sec. It is often helpful to display all 12 ECG leads side by side in review windows on screen, as well as a printout of regular 12-lead ECGs for side-by-side comparison on paper. The greater is the degree of concordance between the morphology during pacing and tachycardia, the closer the catheter will be to the site of origin of the tachycardia. Concordance occurring in 12 of 12 leads on the surface ECG is indicative of the site of origin of the tachycardia.

For mapping macroreentrant VT circuits, evaluation of the S-QRS interval, the interval from the pacing stimulus to the onset of the earliest QRS on the 12-lead ECG, is of value. The reentry circuit exit, which is more likely to be at the border of the infarct and close to the normal myocardium, often has a short S-QRS interval during pace mapping during NSR even though it is a desirable target for ablation. A delay between the pacing stimulus and QRS onset is consistent with slow conduction away from the pacing site; this can indicate a greater likelihood that the pacing site is in a reentry circuit. This method can be useful for initially screening sites during NSR.

Clinical Implications

Pace mapping is typically used to confirm the results of activation mapping. It can be of great help, especially when the tachycardia is difficult to induce. The highest benefit of pace mapping has been found in focal tachycardias, especially in idiopathic VT.¹³

For macroreentrant VT, pace mapping remains at best a corroborative method of localizing the isthmus critical to the reentrant circuit. It can be used to focus initial mapping efforts to regions likely to contain the reentrant circuit exit or abnormal conduction, but it may not be sufficiently specific or sensitive to be the sole guide for ablation. Pace mapping can also be used in conjunction with substrate mapping when other mapping techniques are not feasible, so that it can provide information on where ablation can be directed. Pace mapping has advantages over activation mapping in that induction of VT is not required; thus, it allows identification of the site of origin when the induced VT is poorly tolerated or when VT is not inducible by EP techniques but the QRS morphology from a prior 12-lead ECG during VT is available.⁴

Limitations

An optimal spatial pace mapping resolution requires a short maximum distance between two points generating a similar ECG configuration. Usually, the spatial resolution of unipolar stimulation is

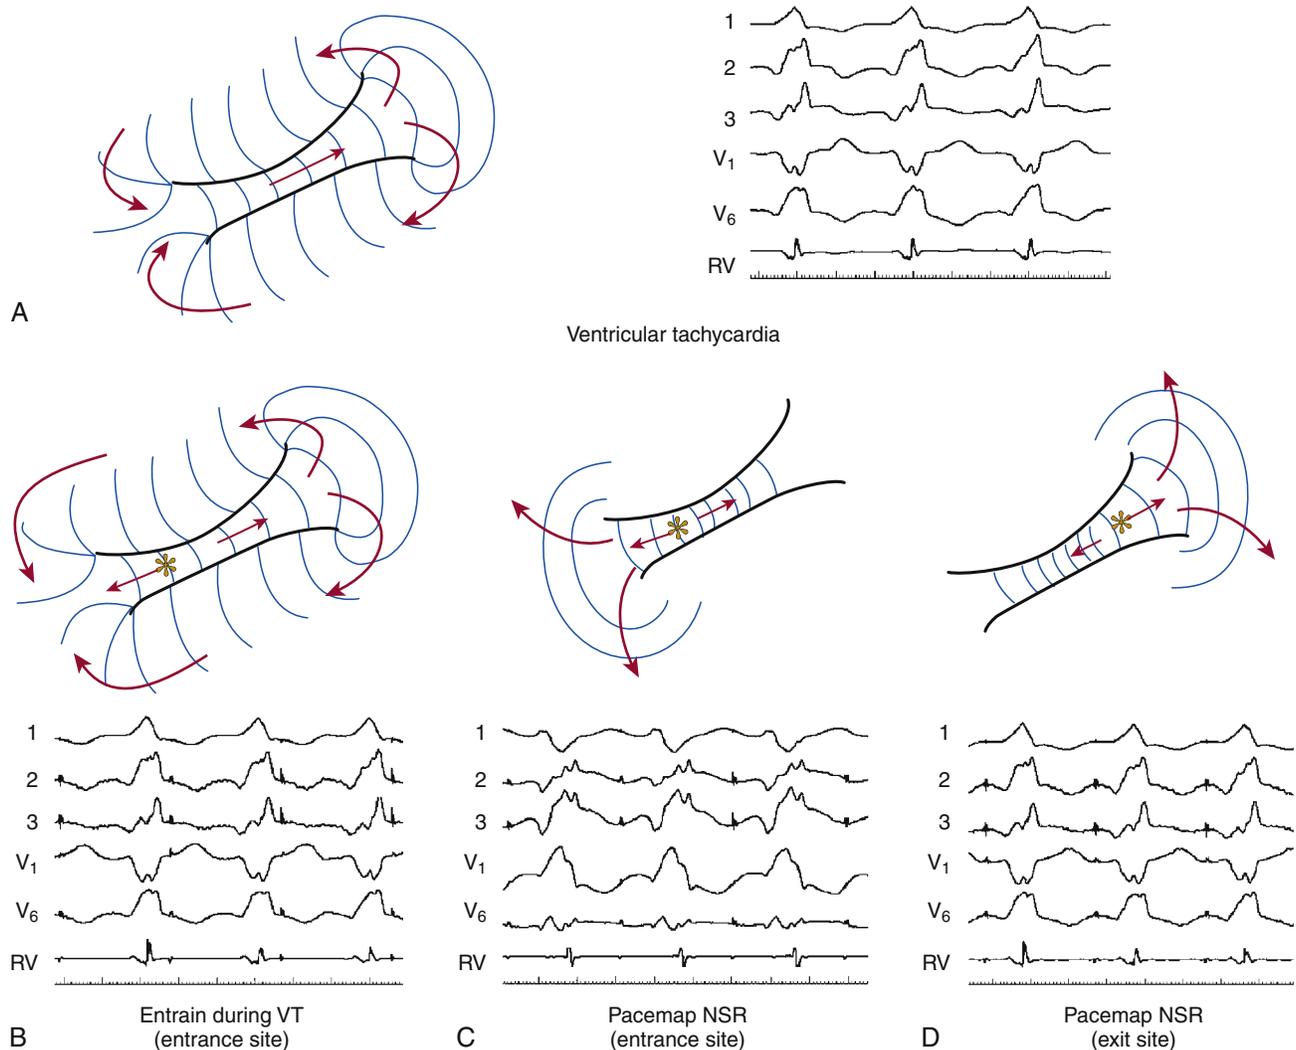

FIGURE 5-23 Pacing to verify ablation sites in reentrant ventricular tachycardia (VT). **A**, Five ECG leads of VT are shown with a figure-of-8 circuit with propagation of the reentrant wavefront (arrows); the protected diastolic corridor is also shown (short straight arrow). **B**, Pacing is performed during VT from a site near the entrance to the diastolic corridor (asterisk); the impulse must traverse a significant slow conduction zone before exiting to generate a QRS complex, resulting in a long S-QRS as shown. **C**, Pacing is performed at the same site as in **B**, but during sinus rhythm; the impulse exits in the opposite direction from **B** because it takes less time to propagate in this direction (short S-QRS). The resulting QRS complex is completely different, despite pacing at the same site. **D**, Pacing is performed during sinus rhythm from a site closer to the exit of the diastolic corridor. The QRS is the same as VT because the path taken is the same as in VT, and the S-QRS is short. NSR = normal sinus rhythm; RV = right ventricle.

5 mm or less. Spatial resolution deteriorates with wide electrodes, bipolar stimulation, and pacing at pathological areas. Spatial resolution worsens with bipolar stimulation by inducing electrical capture at both electrodes with variable contribution of the proximal electrode (generally anode) to depolarization. Such changes in paced ECG morphology that are potentially induced by bipolar pacing can be minimized by low pacing outputs and a small inter-electrode distance (5 mm or less).

It is important to understand that morphology of single paced complexes can vary, depending on the coupling interval, and the paced complex morphology during overdrive pacing is affected by the pacing CL. Therefore, the coupling interval or CL of the template arrhythmia should be matched during pace mapping, especially during mapping of VTs. Similarly, spontaneous couplets from the same focus can have slight variations in QRS morphology that must be considered when seeking a pace match.

Pace mapping during post-MI VT has several other limitations. Some areas of conduction block are not anatomically determined but can be functional. Therefore, pacing within the diastolic corridor of the VT circuit during NSR can generate a completely different QRS complex from that of the VT (see Fig. 5-23). Consequently, during pace mapping, a QRS configuration different from VT does

not reliably indicate that the pacing site is distant from the reentry circuit. On the other hand, pacing during NSR from sites attached to the reentrant circuit but not part of the circuit can occasionally produce a QRS morphology identical to that of the VT. The reason is that the stimulated wavefront can be physiologically forced to follow the same route of activation as the VT as long as pacing is carried out between the entrance and exit of the protected isthmus. At best, a pace map that matches the VT would identify only the exit site to the normal myocardium, and this site can be distant from the critical sites of the circuit required for ablation.

Conventional radiofrequency (RF) ablation has revolutionized the treatment of many supraventricular tachycardias (SVTs) as well as ventricular tachycardias (VTs). Success in stable arrhythmias with predictable anatomical locations or characteristics identifying endocardial electrograms, such as idiopathic VT, atrioventricular nodal reentrant tachycardia (AVNRT), atrioventricular reentrant tachycardia (AVRT), or typical atrial flutter (AFL), has approached 90% to 99%. However, as interest has turned to a broad array of more complex arrhythmias, including some atrial tachycardias (ATs), many forms of intraatrial reentry, most VTs, and atrial fibrillation (AF), ablation of such arrhythmias continues to pose a major challenge. This stems in part from the limitations of fluoroscopy and conventional catheter-based mapping techniques to localize arrhythmogenic substrates that are removed from fluoroscopic landmarks and the lack of characteristic electrographic patterns.

Newer mapping systems have transformed the clinical electrophysiology (EP) laboratory, have enabled physicians to overcome some of the limitations of conventional mapping, and have offered new insights into arrhythmia mechanisms. These newer systems are aimed at improving the resolution, three-dimensional (3-D) spatial localization, and rapidity of acquisition of cardiac activation maps. These systems use novel approaches to determine the 3-D location of the mapping catheter accurately, and local electrograms are acquired using conventional, well-established methods. Recorded data of the catheter location and associated intracardiac electrogram at that location are used to reconstruct in real time a representation of the 3-D geometry of the chamber, color-coded with relevant EP information.

The application of these various techniques for mapping of specific arrhythmias is described elsewhere in this text, as are the details of the diagnosis, mapping, and treatment of specific arrhythmias.

Basket Catheter Mapping

Fundamental Concepts

The basket catheter mapping system consists of a basket catheter (Constellation, EPT, Inkster, Mich.), a conventional ablation catheter, the Astronomer (Boston Scientific, Natick, Mass.), and a mapping system.

The basket catheter consists of an open-lumen catheter shaft with a collapsible, basket-shaped, distal end. Currently, baskets are composed of 64 platinum-iridium ring electrodes mounted on eight equidistant, flexible, self-expanding nitinol splines (metallic arms; see Fig. 4-4). Each spline contains eight 1.5-mm electrodes equally spaced at 4 or 5 mm apart, depending on the size of the basket catheter used. Each spline is identified by a letter (from A to H) and each electrode by a number (distal 1 to proximal 8). The basket catheter is constructed of a superelastic material to allow passive deployment of the array catheter and optimize endocardial contact. The size of the basket catheter used depends on the dimensions of the chamber to be mapped, and it requires antecedent evaluation (usually by echocardiogram) to ensure proper size selection.

The Astronomer is used for navigation with the ablation-mapping catheter inside the basket catheter. This system consists of a switching-locating device and a laptop computer with proprietary software. The device and the laptop communicate on a standard RS-232 interface. The device delivers AC current (32 kHz, 320 mA) between the ablation catheter tip electrode and a reference electrode (skin patch), and the resulting electrical potentials are sensed at each basket catheter electrode. On the basis of the sensed voltages at each of the basket catheter electrodes, the Astronomer device determines whether the roving electrode is in close proximity to a basket catheter electrode and lights the corresponding electrodes on a representation of the basket catheter displayed on the laptop.

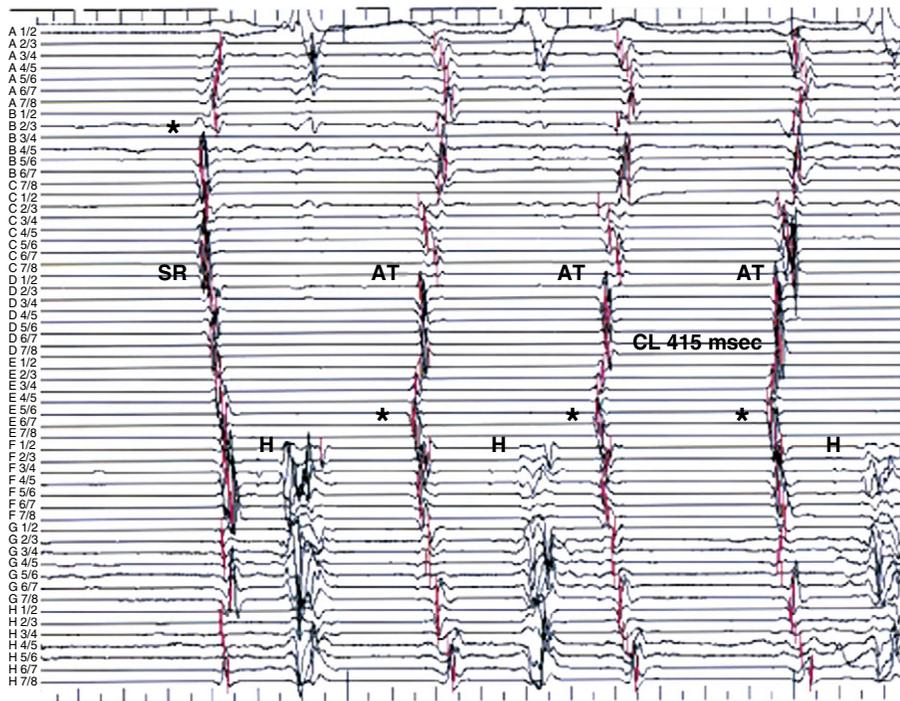

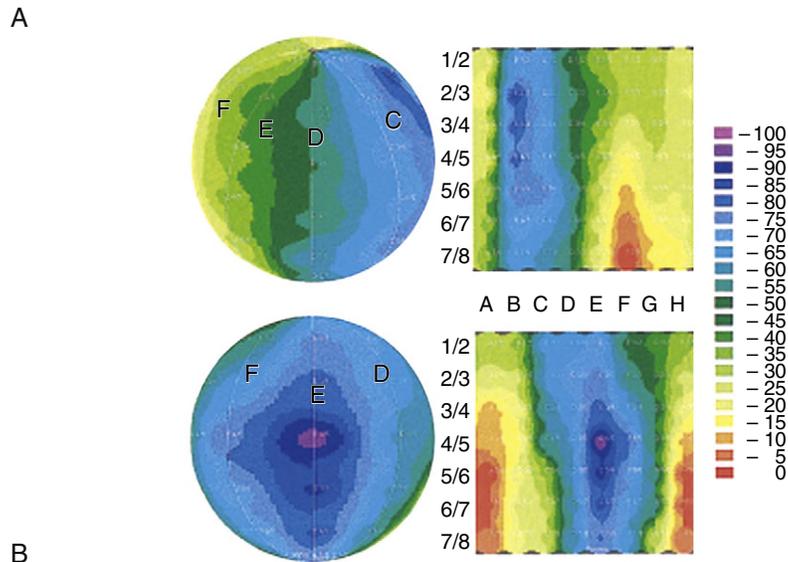

FIGURE 6-1 Basket catheter mapping during focal atrial tachycardia (AT). **A**, Simultaneous recordings of the surface ECG leads I and aVF and 56 bipolar electrograms from the basket catheter in a patient with focal AT. The first beat is a sinus beat. The next three beats are tachycardia beats. His bundle (H) potential is recorded in electrode pairs F2/3 and F3/4. The earliest spot of activation during sinus rhythm (SR) and AT is shown (asterisks). Spline A was located in the anterolateral right atrium (RA), splines B and C in the lateral region, splines D and E in the posterior region, and splines G and H across the tricuspid valve. The activation times are marked with red bars. **B**, **Upper panel**, Animated map of the SR beats. **Lower panel**, Animated map of the AT beats. Planar and three-dimensional options are shown. During SR, the impulse emerged in the high lateral area (spline B1-2) and propagated rapidly down the lateral wall. The complete activation of the RA took 85 milliseconds. During focal AT, the earliest activity emerged in the midposterior wall (spline E4-5). The activation sequence of the RA was entirely different from that of SR. The complete activation of the RA took 95 milliseconds. CL = cycle length. (From Zrenner B, Ndrepepa G, Schneider M, et al: Computer-assisted animation of atrial tachyarrhythmias recorded with a 64-electrode basket catheter. *J Am Coll Cardiol* 34:2051, 1999.)

The mapping system consists of an acquisition module connected to a computer, which is capable of simultaneously processing bipolar electrograms from the basket catheter, 16 bipolar-unipolar electrogram signals, a 12-lead ECG, and a pressure signal. Color-coded activation maps are reconstructed on-line. The color-coded animation images simplify the analysis of multielectrode recordings and help establish the relation between activation patterns and anatomical structures (Fig. 6-1). The electrograms and activation maps are displayed on a computer monitor, and the acquired signals can be stored on optical disk for off-line analysis. Activation marks are generated automatically with a peak or slope (dV/dt) algorithm, and activation times are then edited manually as needed.

Mapping Procedure

The size of the cardiac chamber of interest is initially evaluated, usually with echocardiography, to help select the appropriate size of the basket catheter. The collapsed basket catheter is advanced

under fluoroscopic guidance through a long sheath into the chamber of interest; the catheter is then expanded (Fig. 6-2). Electrical-anatomical relations are determined by fluoroscopically identifiable markers (spline A has one marker and spline B has two markers located near the shaft of the basket catheter) and by the electrical signals recorded from certain electrodes (e.g., ventricular, atrial, or His bundle electrograms), which can help identify the location of those particular splines.

From the 64 electrodes, 64 unipolar signals and 32 to 56 bipolar signals can be recorded (by combining electrodes 1-2, 3-4, 5-6, 7-8, or 1-2, 2-3 until 7-8 electrodes are on each spline). Color-coded activation maps can be reconstructed (see Fig. 6-1). The concepts of activation mapping discussed earlier are then used to determine the site of origin of the tachycardia.

The Astronomer navigation system permits precise and reproducible guidance of the ablation catheter tip electrode to targets identified by the basket catheter. Without the use of this navigation system, it is often difficult to identify the alphabetical order of the splines by fluoroscopic guidance.

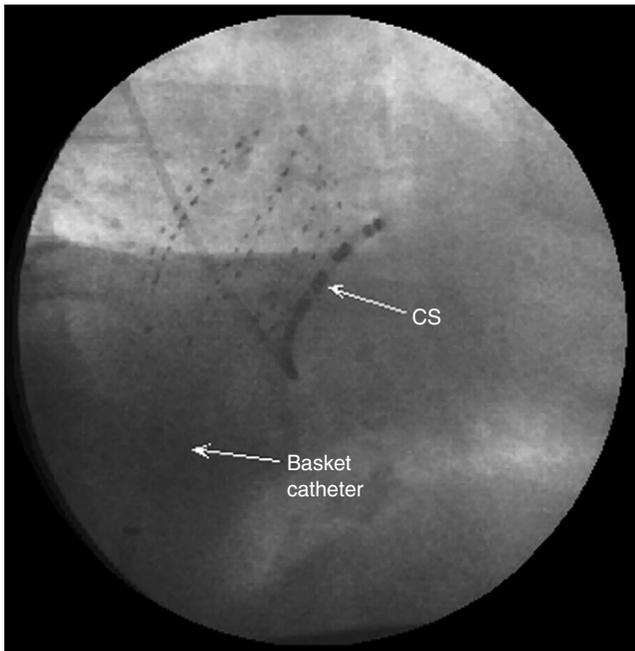

FIGURE 6-2 Fluoroscopic appearance of the basket catheter in the right atrium (right anterior oblique view). Note the radiopaque electrodes on the splines of the basket catheter. CS = coronary sinus.

The electrograms recorded from the basket catheter can be used to monitor changes in the activation sequence in real time and thereby indicate the effects of ablation as lesions are created. The capacity of pacing from most basket electrodes allows the evaluation of activation patterns, pace mapping, and entrainment mapping.

Clinical Implications

The multielectrode endocardial mapping system allows simultaneous recording of electrical activation from multiple sites and fast reconstruction of endocardial activation maps. This can limit the time endured in tachycardia compared with single point mapping techniques without the insertion of multiple electrodes. It also facilitates endocardial mapping of hemodynamically unstable or nonsustained tachycardias. Importantly, the recording of only a single beat can be sufficient to enable analysis of the arrhythmogenic substrate.

Endocardial mapping with a multielectrode basket catheter has been shown to be feasible and safe for various arrhythmias, including AT, AFL, VT, and pulmonary vein (PV) isolation. However, in view of more advanced mapping systems, and because of significant limitations of the current basket catheters, its use has been limited.

Limitations

Because of its poor spatial resolution, the basket catheter in its current iteration has demonstrated only limited clinical usefulness for guiding ablation of reentrant atrial or ventricular arrhythmias. The relatively large interelectrode spacing in available catheters prevents high-resolution reconstruction of the tachycardia and is generally not sufficient for a catheter-based ablation procedure, given the small size and precise localization associated with RF lesions. In addition, the quality of recordings is critically dependent on proper selection of the basket size. Resolution is limited to the proportion of electrodes in contact with the endocardium and by unequal deployment and spacing of the splines. Unfortunately, the electrode array does not expand to provide adequate contact with the entire cardiac chamber; therefore, good electrode contact at all sites on the endocardium is difficult to ensure because of

irregularities in the cardiac chamber surface, so that areas crucial to arrhythmia circuit or focus may not be recorded. Moreover, regions such as the right atrial (RA) and left atrial (LA) appendages and cavotricuspid isthmus are incompletely covered by the basket catheter. As a result, arrhythmia substrates involving these structures are not recorded by the basket catheter.

Voltage, duration, and late potential maps are not provided by this mapping approach. Additionally, basket catheter mapping does not permit immediate correlation of activation times to precise anatomical sites, and a second mapping-ablation catheter is still required to be manipulated to the site identified for more precise mapping and localization of the target for ablation, as well as for RF energy delivery. Basket catheters also have limited torque capabilities and limited maneuverability, which hamper correct placement, and they can abrade the endocardium.

Carbonizations occasionally observed after ablation on the splines of the basket catheter can potentially cause embolism. Carbonizations, which appear as dark material attached to the basket catheter electrodes or splines, are thought to be caused by the concentration of RF energy on the thin splines that results in very high local temperatures that induce denaturation of proteins. Carbonization can be greatly diminished with the use of an irrigated tip catheter, as opposed to conventional ablation catheters.

HIGH-DENSITY MAPPING CATHETER

One study evaluated a mapping approach for AT that uses a novel high-density multielectrode mapping catheter (PentaRay; Biosense Webster, Inc., Diamond Bar, Calif.).¹ This 7 Fr steerable catheter (180 degrees of unidirectional flexion) has 20 electrodes distributed over 5 soft, radiating spines (1-mm electrodes separated by 4-4-4 or 2-6-2 mm interelectrode spacing), thus allowing splaying of the catheter to cover a surface diameter of 3.5 cm. The spines have been given alphabetical nomenclature (A to E), and spines A and B are recognized by radiopaque markers (Fig. 6-3).¹

Localization of the atrial focus can be performed during tachycardia or atrial ectopy.¹ Guided by the ECG appearance, the catheter is sequentially applied to the endocardial surface in various atrial regions to allow rapid activation mapping. By identifying the earliest site of activation around the circumference of the high-density catheter, vector mapping is performed, moving the catheter and applying it to the endocardium in the direction of earliest activation (outer bipoles) to identify the tachycardia origin and bracket activation (i.e., demonstrating later activation in all surrounding regions).

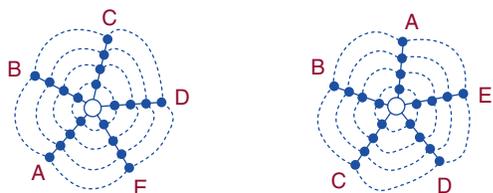

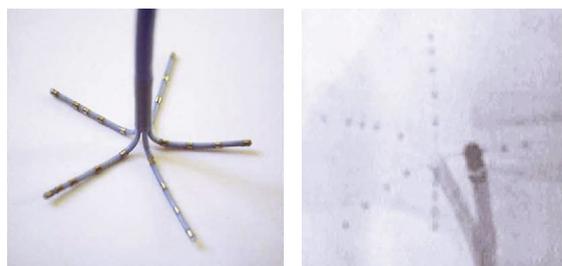

The high-density mapping catheter can offer several potential advantages.¹ In contrast to the basket catheter, which provides a global density of mapping but limited localized resolution, the high-density mapping catheter allows splaying of the spines against the endocardial surface to achieve high-density contact mapping and better localized resolution.¹

EnSite Noncontact Mapping System

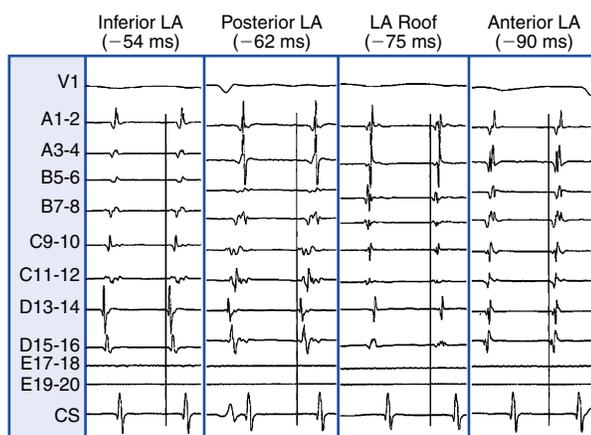

Fundamental Concepts

The noncontact mapping system (EnSite 3000, St. Jude Medical, Inc., St. Paul, Minn.) consists of a catheter-mounted multielectrode array (MEA), which serves as the probe, a custom-designed amplifier system, a computer workstation used to display 3-D maps of cardiac electrical activity, and a conventional ablation catheter.^{2,3}

The MEA catheter consists of a 7.5-mL ellipsoid balloon mounted on a 9 Fr catheter around which is woven a braid of 64 insulated 0.003-mm-diameter wires (Fig. 6-4). Each wire has a 0.025-mm break in insulation that serves as a noncontact unipolar electrode.³ The system acquires more than 3000 noncontact unipolar electrograms from all points in the chamber simultaneously. The unipolar signals are recorded using a ring electrode located on the shaft of the array catheter as a reference. The raw far-field EP data acquired by the array catheter are fed into a multichannel

A

B

FIGURE 6-3 The high-density mapping catheter. **A**, Picture and a fluoroscopic image of the high-density mapping catheter. Below each figure is a schematic representation indicating the orientation of the catheter spines. Note that the marker band on spine A is between electrodes 1 and 2, and on spine B it is between electrodes 2 and 3. **B**, Vector mapping using the high-density mapping catheter to identify the earliest site of activation of focal atrial tachycardia. Shown is the catheter in four distinct locations within the left atrium (LA). Mapping is commenced along the inferior LA, where the earliest activation is 54 milliseconds ahead of the coronary sinus (CS). The catheter is moved in the direction of the spine demonstrating the earliest activation (spine D). In the midposterior LA, activation precedes the coronary sinus (CS) by 62 milliseconds. Again, the catheter is moved in the earliest direction (spine D) to a more cranial location on the LA roof. At this site, activation precedes the CS by 75 milliseconds. At this site, spine B, which is slightly anterior, is the earliest. Moving the catheter in the direction of spine B to the anterosuperior LA demonstrates the site with the earliest endocardial activation (90 milliseconds ahead of the CS, which was 40 milliseconds ahead of the P wave). (From Sanders P, Hocini M, Jais P, et al: Characterization of focal atrial tachycardia using high-density mapping, *J Am Coll Cardiol*. 46:2088, 2005.)

recorder and amplifier system that also has 16 channels for conventional contact catheters, 12 channels for the surface ECG, and pressure channels. Using data from the 64-electrode array catheter suspended in the heart chamber, the computer uses sophisticated algorithms to compute an inverse solution to determine the activation sequence on the endocardial surface.

The EnSite 3000 mapping system is based on the premise that endocardial activation creates a chamber voltage field that obeys the Laplace's equation. Therefore, when one 3-D surface of known geometry is placed within another of known geometry, if the electrical potential on one surface is known, the potential on the other can be calculated.³ Because the geometry of the balloon catheter is known, and the geometry of the cardiac chamber can be

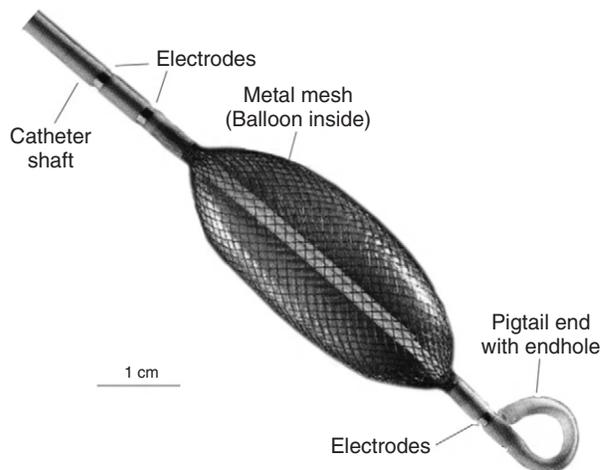

FIGURE 6-4 The multielectrode array for noncontact endocardial mapping.

reconstructed during the procedure (see later), endocardial surface potential can then be determined once the potentials over the balloon catheter are recorded. Using this concept, the raw far-field EP data acquired by the array catheter, which are generally lower in amplitude and frequency than the source potential of the endocardium itself and therefore have limited usefulness, are mathematically enhanced and resolved. The solution to the inverse Laplace's equation using the boundary element method predicts how a remotely detected signal by the MEA would have appeared at its source, the endocardial surface, so that electrograms are reconstructed at endocardial sites in the absence of physical electrode contact at those locations (virtual electrograms). Once the potential field has been established, more than 3000 activation points can be displayed as computed electrograms or as isopotential maps. The activation time at each endocardial site is determined by taking the time instant with maximum negative time derivative ($-dV/dt$) on the electrogram.

The system can locate any conventional mapping-ablation catheter in space with respect to the array catheter (and thus with respect to the cardiac chamber being mapped).³ A low-current (5.68 kHz) locator signal is passed between the contact catheter electrode being located and reference electrodes on the non-contact MEA. This creates a potential gradient across the array electrodes, which is then used to position the source. This locator system is also used to construct the 3-D computer model of the endocardium (virtual endocardium) that is required for the reconstruction of endocardial electrograms and isopotential maps. This model is acquired by moving a conventional contact catheter around the endocardial surface of the cardiac chamber; the system collects the location information, thus building up a series of coordinates for the endocardium and generating a patient-specific, anatomically contoured model of its geometry. During geometry creation, only the most distant points visited by the roving catheter are recorded to ignore those detected when the catheter is not in contact with the endocardial wall.

Using mathematical techniques to process potentials recorded from the array, the system is able to reconstruct more than 3000 unipolar electrograms simultaneously and superimpose them onto the virtual endocardium, thus producing isopotential maps with a color range representing voltage amplitudes. Additionally, the locator signal can be used to display and track the position of any catheter on the endocardial model (virtual endocardium) and allows marking of anatomical locations identified using fluoroscopy and electrographic characteristics. During catheter ablation procedures, the locator system is used in real time to navigate the ablation catheter to sites of interest identified from the isopotential color maps, catalog the position of RF energy applications on the virtual endocardium, and facilitate revisitation of sites of interest by the ablation catheter.²

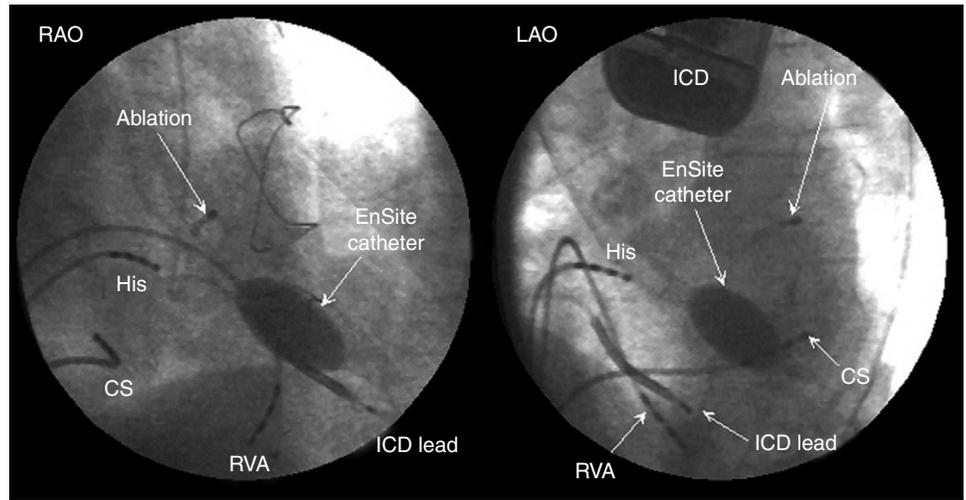

FIGURE 6-5 Fluoroscopic views of noncontact mapping catheter (EnSite, St. Jude Medical, Inc., St. Paul, Minn.) situated in the left ventricle (LV). CS = coronary sinus; ICD = implantable cardioverter-defibrillator; LAO = left anterior oblique; RAO = right anterior oblique; RVA = right ventricular apex.

In addition, the most recent version of the EnSite software provides the capability of point-to-point contact mapping, to allow the creation of activation and voltage maps by acquiring serial contact electrograms and displaying them on the virtual endocardium (see later). This is useful for adding detail, familiarity, and validation of the information obtained by the noncontact method.⁴

Mapping Procedure

The EnSite 3000 system requires placing a 9 Fr MEA and a mapping-ablation catheter.³ To create a map, the balloon catheter is advanced over a 0.035-inch guidewire under fluoroscopic guidance into the cardiac chamber of interest. For RA arrhythmias, the guidewire is advanced into the SVC and the balloon is deployed in the upper third of the RA for tachycardia originating in the SVC, in the middle third for ectopic AT, and in the lower third for typical AFL. For LA arrhythmias, the guidewire is advanced into the left superior PV, and the balloon is deployed in the middle of the LA. For right ventricular (RV) arrhythmias, the guidewire is advanced into the pulmonary artery, and the balloon is deployed close to the RV outflow tract (RVOT) or in the middle of the RV. The balloon can be filled with contrast dye, thus permitting it to be visualized fluoroscopically (Fig. 6-5). The balloon is positioned in the center of the cardiac chamber of interest and does not come in contact with the walls of the chamber being mapped. In addition, the position of the array in the chamber must be secured to avoid significant movement that would invalidate the electrical and anatomical information. The array must be positioned as closely as possible (and in direct line of sight through the blood pool) to the endocardial surface being mapped, because the accuracy of the map is sensitive to the distance between the center of the balloon and the endocardium being mapped.^{2,4,5}

During the use of this mapping modality, systemic anticoagulation is critical to avoid thromboembolic complications. Intravenous heparin is usually given to maintain the activated clotting time longer than 250 seconds for right-sided and longer than 300 seconds for left-sided mapping.

A conventional (roving) deflectable mapping catheter is also positioned in the chamber being mapped and used to collect geometry information. The mapping catheter is initially moved to known anatomical locations, which are tagged. A detailed geometry of the chamber is then reconstructed by moving the mapping catheter and tracing the contour of the endocardium (using the locator technology). To create detailed geometry, attempts must be made to make contact with as much endocardium as possible. This requires maneuvering on all sides of the array, which can be challenging and can require decreasing the profile of the balloon by withdrawing a few milliliters of fluid. This results in the rapid formation of a relatively accurate 3-D geometric model of the cardiac

chamber. Creation of chamber geometry can be performed during sinus rhythm or tachycardia.^{2,4}

Once the chamber geometry has been delineated, tachycardia is induced and mapping is started. The data acquisition process is performed automatically by the system, and all data for the entire chamber are acquired simultaneously. Following this, the segment must be analyzed by the operator to find the early activation during the tachycardia (Fig. 6-6).

The noncontact mapping system is capable of simultaneously reconstructing more than 3360 unipolar electrograms over the virtual endocardium. From these electrograms, isopotential or isochronal maps can be reconstructed (see Fig. 6-6). Because of the high density of data, color-coded isopotential maps are used to depict graphically regions that are depolarized, and wavefront propagation is displayed as a user-controlled 3-D “movie” (Videos 8 and 9). The color range represents voltage or timing of onset. The highest chamber voltage is at the site of origin of the electrical impulse. Although the electrode closest to the origin of the impulse is influenced the most, all the electrodes on the array catheter are influenced, the degree of influence diminishing with the distance between the electrode and each endocardial point.

In addition, the system can simultaneously display as many as 32 electrograms as waveforms (see Fig. 6-6). Unipolar or bipolar electrograms (virtual electrograms) can be selected at any given interval of the tachycardia cycle by using the mouse from any part of the created geometry and displayed as waveforms as if from point, array, or plaque electrodes. The reconstructed electrograms are subject to the same electrical principles as contact catheter electrograms, because they contain far-field electrical information from the surrounding endocardium, as well as the underlying myocardium signal vector, and distance from measurement may affect the contribution to the electrogram. These selected unipolar waveforms are used to augment information obtained from the 3-D map by demonstrating the slope of depolarization, the presence of double potentials or fractionation, and differentiation of far-field signals from more relevant endocardial activation.⁴

In the unipolar electrogram, signals associated with high conduction velocity (e.g., the His-Purkinje system) possess a greater slope ($-dV/dt$), and thus are characterized by high-frequency spectral components (more than 32 Hz). Electrograms recorded in normally conducting atrial or ventricular myocardium possess spectral components in the midrange from 4 Hz to 16 Hz, whereas electrograms in regions of slow conduction are composed of lower frequency spectral components from 1 Hz to 4 Hz. Thus, the high-pass filter must be adjusted between 1 Hz and 32 Hz, helping to modulate the extent to which low-frequency signals are visible on the 3-D display. Identification of true local activation and its differentiation from the far-field signals are essential to successful utilization of noncontact mapping. The true local activation always shows

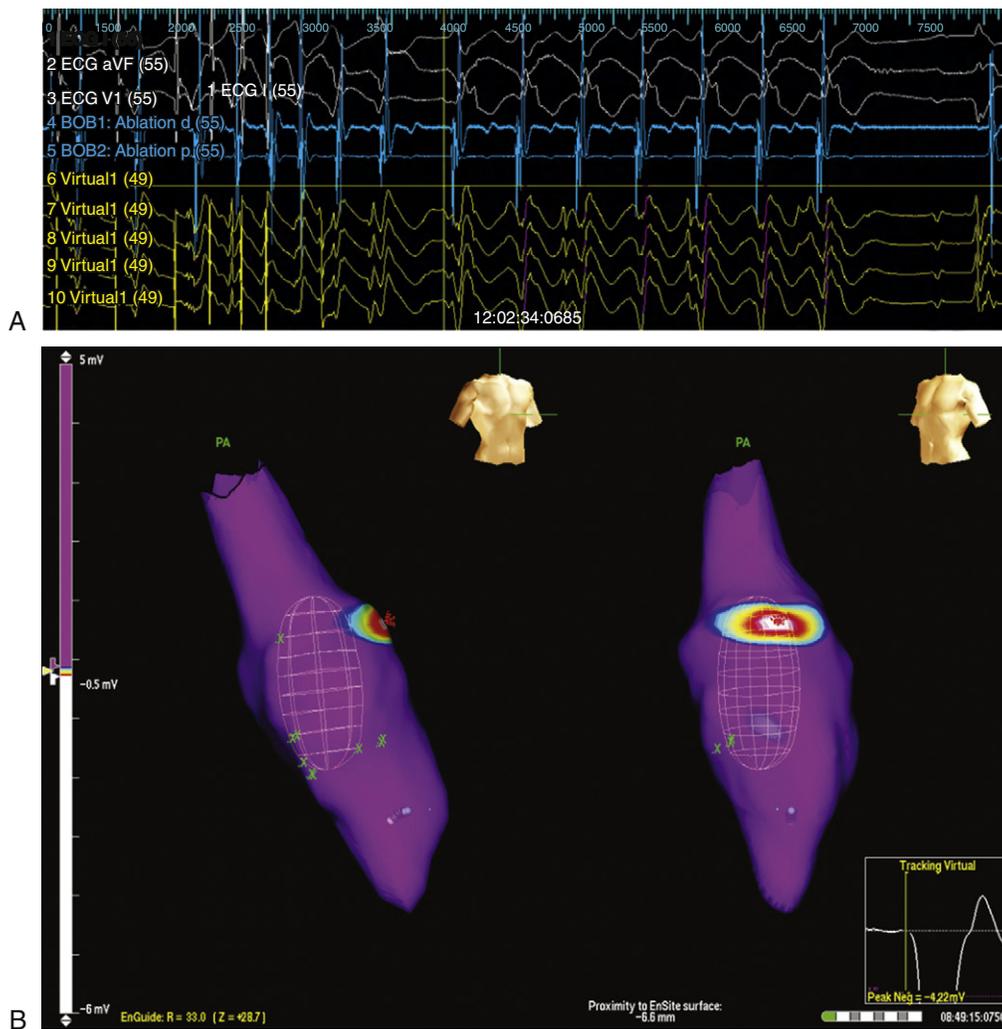

FIGURE 6-6 Noncontact mapping of idiopathic right ventricular outflow tract (RVOT) tachycardia. **A**, Right anterior oblique and right lateral views of color-coded isopotential map of RVOT activation during a single premature ventricular complex (PVC). **B**, Surface electrocardiographic (white) and intracardiac contact (blue) and virtual noncontact (yellow, V_{1-1} through V_{1-4}) electrograms are shown during the PVC. **Inset**, Virtual electrograms at the site of earliest activation (note the QS pattern).

advancement of isopotential lines, but far-field signals would show retraction of isopotential lines on the 3-D display when the whole electrograms are traced.⁵

Substrate mapping based on scar or diseased tissue has been introduced to the noncontact mapping technology. High-density voltage mapping of the atrial substrate is performed using the peak negative voltage of the reconstructed unipolar electrograms. Areas with slow conduction are identified along the reentrant circuit of the atypical AFL. An atrial substrate characterized by an abnormally low peak negative voltage can potentially predict areas with slow conduction during macroreentrant tachycardias, which would provide a substrate for reentry.⁶

Clinical Implications

The MEA has been successfully deployed in all four cardiac chambers by using a transvenous, transseptal, or retrograde transaortic approach to map atrial and ventricular tachyarrhythmias.

The biggest advantage of noncontact endocardial mapping is its ability to recreate the endocardial activation sequence from simultaneously acquired multiple data points over a few (theoretically one) tachycardia beats, without requiring sequential point-to-point acquisitions, thus obviating the need for prolonged tachycardia episodes that the patient might tolerate poorly. This technique can be used to map nonsustained arrhythmias, premature atrial complexes (PACs), premature ventricular complexes (PVCs), and irregular rhythms such as AF or polymorphic VT, and rhythms that are not hemodynamically stable, such as very rapid VT (see Fig. 6-6). The system generates isopotential maps of the endocardial surface at

successive cross sections of time, and when these are animated, the spread of the depolarization wave can be visualized. These maps are particularly useful for identifying rapid breakthrough points and slowly conducting macroreentrant pathways, such as the critical slow pathways in ischemic VT or reentrant AT in patients with surgically corrected congenital heart disease. In macroreentrant tachycardias such as typical AFL or VT, the reentry circuit can be fully identifiable, along with other aspects, such as the slowing, narrowing, and splitting of activation wavefronts in the isthmus. The system can also map multiple cardiac cycles in real time, a method that discloses changes in the activation sequence from one beat to the next. Because mapping data are acquired without direct contact of conventional electrode catheters with the endocardium, the use of noncontact mapping can help avoid the mechanical induction of ectopic activity that is frequently seen during conventional mapping. An additional advantage of this system is that any catheter from any manufacturer can be used in conjunction with this mapping platform. Other useful features include radiation-free catheter navigation, revisitation of points of interest, and cataloging ablation points on the 3-D model.²

In complex substrate-related arrhythmias, the use of activation mapping alone may not be sufficient for rhythm analysis or identifying ablation targets. Substrate mapping based on scar or diseased tissue is of value in these cases. Although substrate mapping used to be relatively limited with the noncontact mapping technology (very low-amplitude signals may not be detected, particularly if the distance between the center of the balloon catheter and endocardial surface exceeds 40 mm), dynamic substrate mapping, which has been introduced, allows the creation of voltage maps from a

single cardiac cycle (in contrast to the contact mapping system, in which the mapping catheter is moved point to point over the endocardial surface). Dynamic substrate mapping also provides the capability of identifying low-voltage areas, as well as fixed and functional block, on the virtual endocardium through non-contact methods, provided that points more than 40 mm from the electrode array are excluded from analysis. Combining substrate mapping with the ability of the noncontact system to assess activation over a broad area from a single beat may facilitate ablation of hemodynamically unstable or nonsustained macroreentrant tachycardias.^{4,6,7}

Limitations

Because the geometry of the cardiac chamber is contoured at the beginning of the study during sinus rhythm, changes of the chamber size and contraction pattern during tachycardia or administration of medications (e.g., isoproterenol) can adversely affect the accuracy of the location of the endocardial electrograms. Moreover, because isopotential maps are predominantly used, ventricular repolarization must be distinguished from atrial depolarization and diastolic activity. Early diastole can be challenging to map during VT.⁸

The overall accuracy of the reconstructed electrograms decreases with the distance of the area mapped from the array catheter, thus creating problems in mapping large cardiac chambers. Virtual electrogram quality deteriorates at a distance of more than 4 cm from the array catheter and at polar regions. Therefore, the array must be positioned as closely as possible to the endocardial area of interest, and at times it can be necessary to reposition the array catheter to acquire adequate isopotential maps.

Only data segments up to a maximum of 10 seconds in length can be stored retroactively by the EnSite system once the record button has been pushed. Thus, continuous recording and storage of all segments of an arrhythmia are not possible at the time of evaluation of the arrhythmia maps. Therefore, some isolated PACs or PVCs that can be of interest during evaluation and mapping could be missed. In addition, the acquired geometry with the current version of software is somewhat distorted, requiring multiple set points to establish the origin and shape of complicated structures such as the LA appendage or PVs clearly. Otherwise, these structures can be lost in the interpolation among several neighboring points. In addition, synchronized mapping of multiple chambers requires multiple systems. Importantly, maps are highly sensitive to changes in filtering frequencies used in postprocessing analysis.

Sometimes it is difficult to manipulate the ablation catheter around the outside of the balloon, especially during mapping in the LA. Special attention and care also are necessary during placement of the large balloon electrode in a relatively small cardiac chamber. Another disadvantage is that the balloon catheter cannot be moved after completion of geometry creation because it will change the activation localization and result in distortion of isopotential maps.⁵

Although the risk of complications is low, aggressive anticoagulation measures because of balloon deployment in the cardiac chamber expose patients to potential bleeding complications.

CARTO Electroanatomical Mapping System

Fundamental Concepts

The CARTO mapping system (Biosense Webster, Inc.) consists of an ultralow magnetic field emitter, a magnetic field generator locator pad (placed beneath the operating table), an external reference patch (fixed on the patient's back), a deflectable 7 Fr quadri-polar mapping-ablation catheter with a 4- or 8-mm tip and proximal 2-mm ring electrodes, location sensors inside the mapping-ablation catheter tip (the three location sensors are located orthogonally to

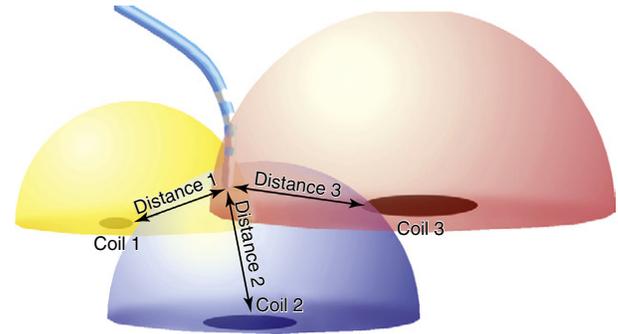

FIGURE 6-7 CARTO (Biosense Webster, Inc., Diamond Bar, Calif.) electroanatomical map setup. The three hemispheres represent fields from three different electromagnets situated beneath the patient. The catheter tip contains an element that is sensed by these fields, and this triangulating information is used to monitor the location and orientation of the catheter tip in the heart.

each other and lie just proximal to the tip electrode, totally embedded within the catheter), a reference catheter (placed intracardially), a data processing unit, and a graphic display unit to generate the electroanatomical model of the chamber being mapped.

CARTO is a nonfluoroscopic mapping system that uses a special catheter to generate 3-D electroanatomical maps of the heart chambers. This system uses magnetic technology to determine the location and orientation of the mapping-ablation catheter accurately while simultaneously recording local electrograms from the catheter tip. By sampling electrical and spatial information from different endocardial sites, the 3-D geometry of the mapped chamber is reconstructed in real time and analyzed to assess the mechanism of arrhythmia and the appropriate site for ablation.²

Electroanatomical mapping is based on the premise that a metal coil generates an electrical current when it is placed in a magnetic field. The magnitude of the current depends on the strength of the magnetic field and the orientation of the coil in it. The CARTO mapping system uses a triangulation algorithm similar to that used by a global positioning system (GPS). The magnetic field emitter, mounted under the operating table, consists of three coils that generate a low-intensity magnetic field, approximately 0.05 to 0.2 gauss, which is a very small fraction of the magnetic field intensity inside a magnetic resonance imaging (MRI) machine (Fig. 6-7).

The sensor embedded proximal to the tip of a specialized mapping catheter detects the intensity of the magnetic field generated by each coil and allows for determination of its distance from each coil. These distances determine the area of theoretical spheres around each coil, and the intersection of these three spheres determines the location of the tip of the catheter. The accuracy of determination of the location is highest in the center of the magnetic field; therefore, it is important to position the location pad under the patient's chest. In addition to the x, y, and z coordinates of the catheter tip, the CARTO system can determine three orientation determinants—roll, yaw, and pitch—for the electrode at the catheter tip. The position and orientation of the catheter tip can be seen on the screen and monitored in real time as the catheter moves within the electroanatomical model of the chamber mapped. The catheter icon has four color bars (green, red, yellow, and blue), enabling the operator to view the catheter as it turns clockwise or counterclockwise. In addition, because the catheter always deflects in the same direction, each catheter will always deflect toward a single color. Hence, to deflect the catheter to a specific wall, the operator should first turn the catheter so that this color faces the desired wall.²

The unipolar and bipolar electrograms recorded by the mapping catheter at each endocardial site are archived within that positional context. Using this approach, local tissue activation at each successive recording site produces activation maps within the framework of the acquired surrogate geometry.

When mapping the heart, the system can deal with four types of motion artifacts: cardiac motion (the heart is in constant motion; thus the location of the mapping catheter changes throughout the cardiac cycle), respiratory motion (intrathoracic change in the position of the heart during the respiratory cycle), patient motion, and system motion. Several steps are taken by the CARTO mapping system to compensate for these possible motion artifacts and to ensure that the initial map coordinates are appropriate, including using a reference electrogram and an anatomical reference.

ELECTRICAL REFERENCE

The electrical reference is the fiducial marker on which the entire mapping procedure is based. The timing of the fiducial point is used to determine the activation timing in the mapping catheter in relation to the acquired points and to ensure collection of data during the same part of the cardiac cycle. It is therefore vital to the performance of the system. All the local activation timing information recorded by the mapping catheter at different anatomical locations during mapping (displayed on the completed 3-D map) is relative to this fiducial point, with the acquisition gated so that each point is acquired during the same part of the cardiac electrical signal (Video 10). It is important that the rhythm being mapped is monomorphic and the fiducial point is reproducible at each sampled site. The fiducial point is defined by the user by assigning a reference channel and an annotation criterion. The system has a great deal of flexibility in terms of choosing the reference electrogram and gating locations. Any surface ECG lead or intracardiac electrogram in bipolar or unipolar mode can serve as a reference electrogram. For the purpose of stability when intracardiac electrograms are selected, coronary sinus (CS) electrograms are usually chosen for mapping supraventricular rhythms, and an RV electrode or a surface ECG lead is commonly chosen as the electrical reference during mapping ventricular rhythms. Care must be taken to ensure that automatic sensing of the reference is reproducible and is not subject to oversensing in the case of annular electrograms (e.g., oversensing of a ventricular electrogram on the CS reference electrode during mapping an atrial rhythm). Any component of the reference electrogram may be chosen for a timing reference, including maximum (peak positive) deflection, minimum (peak negative) deflection, maximum upslope (dV/dt), or maximum downslope.^{9,10}

ANATOMICAL REFERENCE

Once the mapping catheter is placed inside the heart, its location in relation to the fixed magnetic field sensors placed under the patient can be determined. However, several of the factors mentioned earlier, including a change in the patient's position during the procedure, can result in loss of orientation of the structures. To overcome the effect of motion artifacts, a reference catheter with a sensor similar to that of the mapping catheter is used. This reference catheter is fixed in its location inside the heart or on the body surface. The anatomical reference (location sensor) is typically placed in an adhesive reference patch secured on the patient's back. The fluoroscopic (anteroposterior view) location of the anatomical reference should be close to the cardiac chamber being mapped. Movement of the anatomical reference indicates movement of the patient's chest, which must be corrected to prevent distortion of the electroanatomical map.

The CARTO mapping system continuously calculates the position of the mapping catheter in relation to the anatomical reference, thus solving the problem of any possible motion artifacts. An intracardiac reference catheter has the advantage of moving with the patient's body and with the heart during the phases of respiration. However, the intracardiac reference catheter can change its position during the course of the procedure, especially during manipulation of the other catheters. It is therefore better to use an externally positioned reference patch strapped to the back of the patient's chest in the interscapular area. The movement of the

ablation catheter is then tracked relative to the position of this reference. Should the location reference magnet or patch become displaced during the procedure, the original location is recorded by CARTO to allow proper repositioning.

WINDOW OF INTEREST

Defining an electrical window of interest is a crucial aspect in ensuring the accuracy of the initial map coordinates. The window of interest is defined as the time interval relative to the fiducial point during which the local activation time is determined (Fig. 6-8). Within this window, activation is considered early or late relative to the reference. The total length of the window of interest should not exceed the tachycardia cycle length (CL; usually 90% of the tachycardia CL; Videos 11 and 12). The boundaries are set relative to the reference electrogram. Thus, the window is defined by two intervals, one extending before the reference electrogram and the other after it. For macroreentrant circuits, the sensing window should approximate the tachycardia CL, and designating activation times in a circuit as early or late is arbitrary. In theory, a change in the window or reference would not change a macroreentrant circuit but only result in a phase shift of the map. If the activation window spans two adjacent beats of an arrhythmia, the resulting map can be ambiguous, lack coherency, and give rise to a spurious pattern of adjacent regions of early and late activation (see Fig. 6-8).^{9,10}

LOCAL ACTIVATION TIME

Another important concept in CARTO mapping is determination of the local activation time. Once the reference electrogram, anatomical reference, and window of interest have been chosen, the mapping catheter is moved from point to point along the endocardial surface of the cardiac chamber being mapped (Fig. 6-9; see Video 10). These points can be acquired in a unipolar or bipolar configuration. These electrograms are analyzed using the principles of activation mapping discussed in Chapter 5. The local activation time at each sampled site is calculated as the time interval between the fiducial point on the reference electrogram and the corresponding local activation determined from the unipolar or bipolar local electrogram recorded from that site.²

CARTOMERGE

The CARTOMerge Module (Biosense Webster, Inc.) allows for images from a preacquired computed tomography (CT) angiogram or MRI scan to be integrated on the electroanatomical image of the cardiac chamber created with the CARTO system (Fig. 6-10).¹¹ CARTOMerge helps to guide real-time catheter ablation by using the detailed cardiac chamber anatomy acquired from the CT/MRI (see later discussion). These images have also been used in AF catheter ablation procedures to identify correctly the anatomy and location of the PVs, as well as other structures such as the esophagus (Video 13).

CARTOSOUND

The CARTOSound Image Integration Module (Biosense Webster, Inc.) incorporates the electroanatomical map to a map derived from intracardiac echocardiography (ICE) and allows for 3-D reconstruction of the cardiac chambers using real-time ICE. Echocardiographic imaging is performed using a 10 Fr phased-array transducer catheter incorporating a navigation sensor (SoundStar, Biosense Webster, Inc.) that records individual 90-degree sector image planes of the cardiac chamber of interest, including their location and orientation, to the CARTO workspace. A 3-D volume-rendered image is created by obtaining ECG-gated ICE images of the endocardial surface of the cardiac chamber of interest (Fig. 6-11). Following optimizing each image by adjusting frequency (5 to 10 MHz) and contrast, the chamber endocardial surfaces are identified (based on differences in the echo intensity of blood and tissue), and their contours are traced automatically, and

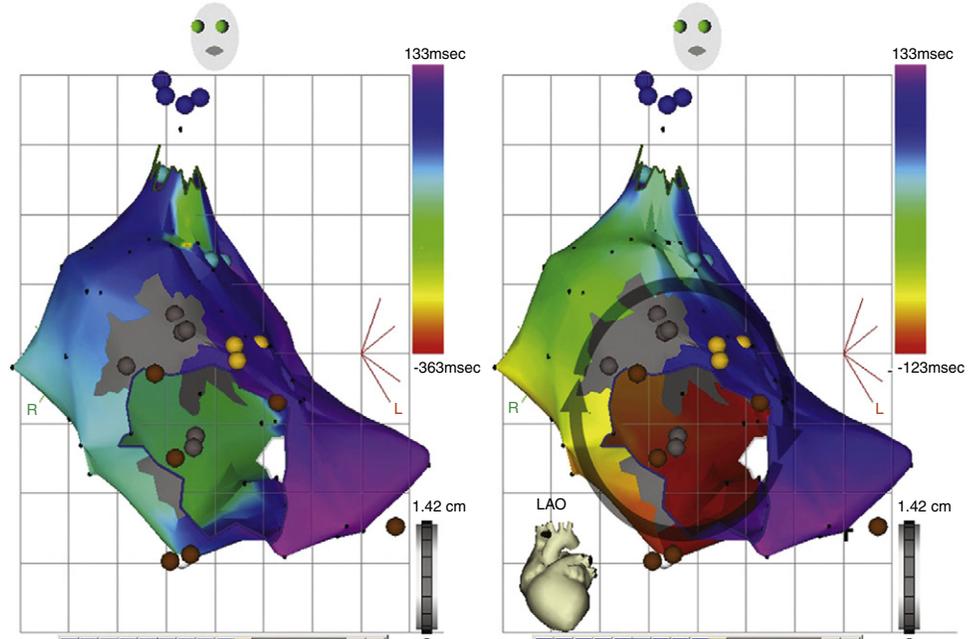

FIGURE 6-8 CARTO (Biosense Webster, Inc., Diamond Bar, Calif.) window of interest and influence on activation map. **Top**, Activation maps of macroreentrant typical atrial flutter (cycle length [CL], 268 milliseconds, with “clockwise” rotation around the tricuspid annulus). **Bottom**, So-called window of interest for the atrial flutter. Figures on **left half** show results of having the window too wide (spanning more than one tachycardia cycle); the computer picks an inappropriately “early” activation time (–365 milliseconds, more than the flutter CL), thus yielding a map (above) that makes little sense. When the same site has correct activation time (–122 milliseconds) assigned by narrowing the window (**lower right**), the color activation map clearly reveals peritricuspid reentry.

Incorrect window

Correct window

overwritten by hand as necessary, using the CARTOSound software. The software then resolves each contour into a series of discrete spatial points, with an interpoint spacing of up to 3 millimeters (closer spacing on curved contours or at angulations). The CARTO software interpolates these points to create models of the chamber endocardial surface in the CARTO workspace. CARTOSound allows for detailed real-time visualization of the cardiac chamber and of its adjacent structures and elimination of chamber deformity, which often happens with contact mapping (Video 14). The CARTOSound volume map of the cardiac chamber may be used as a stand-alone tool to guide navigation and ablation or as a facilitator of CT/MRI image integration (see later).^{12,13}

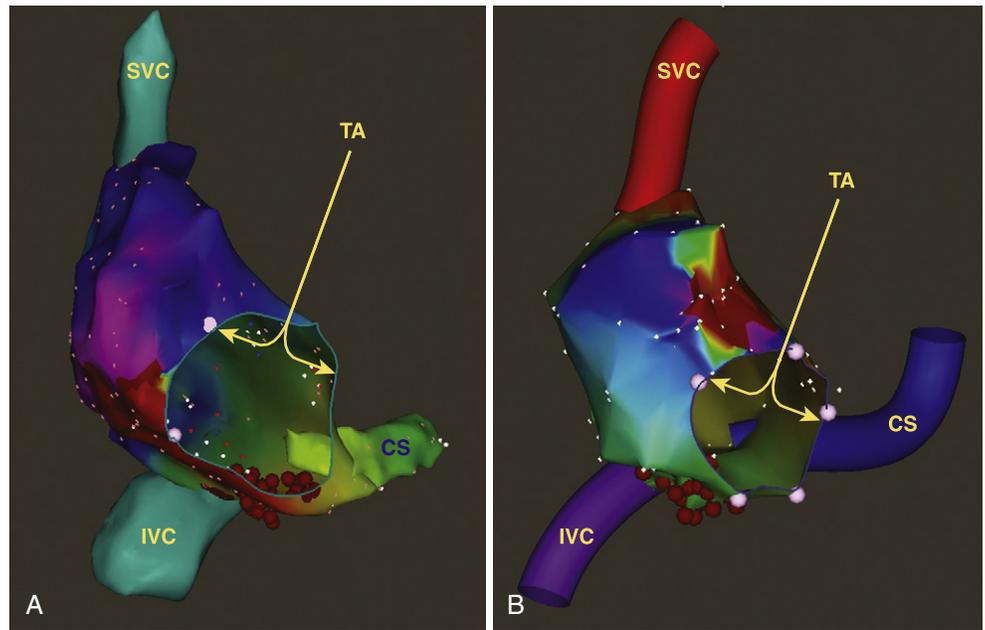

CARTO 3

The CARTO 3 system is the third-generation platform from Biosense Webster that offers three unique features: Advanced Catheter Location Technology, Fast Anatomical Mapping (FAM), and a streamlined workflow feature set referred to as Connection of Choice. Advanced Catheter Location technology is a hybrid technology

that combines magnetic location technology and current-based visualization data to provide accurate visualization of multiple catheter tips and curves on the electroanatomical map. It can visualize up to five catheters (with and without the magnetic sensors) simultaneously with clear distinction of all electrodes. Three coils generate a magnetic field, and a location sensor in the catheter measures the strength of the field and the distance from each coil. The location of the sensor in the catheter is determined by the intersection of the three fields. In addition to this magnetic field, CARTO 3 uses an electrical field created by two sets of patches. The magnetic technology calibrates the current-based technology and thereby minimizes distortions at the periphery of the electrical field. The system generates a small current that is sent from the electrodes of the catheters to six patches on the patient's thorax. Each electrode emits current at a unique frequency. The strength of the current emitted by each electrode is measured at each patch and creates a current ratio that is unique to each electrode's location.

Mapping is performed in two steps. Initially, the magnetic mapping permits precise localization of the catheter with the sensor. This is associated with the current ratio of the electrode closest to

FIGURE 6-12 Electroanatomical CARTO 3 and CARTO XP (Biosense Webster, Inc., Diamond Bar, Calif.) activation maps of the right atrium in the left anterior oblique view constructed during typical atrial flutter. **A**, CARTO 3 activation map during tachycardia. The depolarization wavefront travels counterclockwise around the tricuspid annulus (TA), as indicated by a continuous progression of colors (from red to purple) with close proximity of earliest and latest local activation (red meeting purple). Purple dots denote ablation lesions delivered across the cavotricuspid isthmus. **B**, CARTO XP during clockwise typical tachycardia is shown. Note the difference between the two systems in geometry reconstruction of the cardiac chamber and vascular structures. CS = coronary sinus; IVC = inferior vena cava; SVC = superior vena cava.

the sensor. As the catheter with the sensor moves around a chamber, multiple locations are created and stored by the system. The system integrates the current-based points with their respective magnetic locations, resulting in a calibrated current-based field that permits accurate visualization of catheters and their locations. Each electrode emits a unique frequency that provides clear distinction of the electrodes, especially when they are close to each other. Fast Anatomical Mapping is a feature that permits rapid creation of anatomical maps by movement of a sensor-based catheter throughout the cardiac chamber. Unlike point-by-point electroanatomical mapping, volume data can be collected with Fast Anatomical Mapping (Fig. 6-12; Video 15). Catheters other than the ablation catheter, such as the multipolar Lasso, can further enhance the collection of points and increase the mapping speed. The CARTO 3 system provides highly accurate geometry of a cardiac chamber, which can be visualized in multiple views. Connection of Choice is enabled by a CARTO hardware configuration featuring a central connection point for all catheters and equipment while preserving the signal quality of intracardiac electrograms. Catheter connections have been redesigned for “plug-and-play” functionality and automatic catheter recognition.

Mapping Procedure

Following selection of the reference electrogram, positioning of the anatomical reference, and determination of the window of interest, the mapping catheter is positioned in the cardiac chamber of interest under fluoroscopic guidance. The CARTO system requires the use of a special Biosense Webster catheter with a location sensor embedded in its distal end. The 7 Fr quadripolar catheters come with a deflectable tip in one or two directions in a single plane and various deflectable curve sizes; some of these catheters have asymmetrical bidirectional deflectable curves. The distal tip is capable of RF energy delivery. Catheters with 4- or 8-mm-tip conventional RF ablation electrodes are available, as well as 3.5-mm irrigated tip ablation catheters.

The mapping catheter is initially positioned (using fluoroscopy) at known anatomical points that serve as landmarks for the electroanatomical map. For example, to map the RA, points such as the superior vena cava (SVC), inferior vena cava (IVC), His bundle, tricuspid annulus, and CS ostium (CS os) are marked. The catheter is then advanced slowly around the chamber walls to sample multiple points along the endocardium, thus sequentially acquiring the location of its tip together with the local electrogram.²

Points are selected only when the catheter is in stable contact with the wall. The system continuously monitors the quality of catheter-tissue contact and local activation time stability to ensure validity and reproducibility of each local measurement. The stability of the catheter and contact is evaluated at every site by examining the following: (1) local activation time stability, defined as a difference between the local activation calculated from two consecutive beats of less than 2 milliseconds; (2) location stability, defined as a distance between two consecutive gated locations of less than 2 mm; (3) morphological superpositioning of the intracardiac electrogram recorded on two consecutive beats; and (4) CL stability, defined as the difference between the CL of the last beat and the median CL during the procedure. Respiratory excursions that can cause significant shifts in apparent catheter location can be addressed by visually selecting points during the same phase of the respiratory cycle.

Each selected point is tagged on the 3-D map. The local activation time at each site is determined from the intracardiac bipolar electrogram and is measured in relation to the fixed reference electrogram (see Video 10). Lines of block (manifest as double potentials) are tagged for easy identification because they can serve as boundaries for subsequent design of ablation strategies. Electrically silent areas (defined as having an endocardial potential amplitude less than 0.05 mV, which is the baseline noise in the CARTO system and the absence of capture at 20 mA) and surgically related scars are tagged as “scar” and therefore appear in gray on the 3-D maps and are not assigned an activation time (see Figs. 14-1 and 14-2). The map can also be used to catalog sites at which pacing maneuvers are performed during assessment of the tachycardia.

Sampling the location of the catheter together with the local electrogram is performed from a plurality of endocardial sites. The points sampled are connected by lines to form several adjoining triangles in a global model of the chamber. Next, gated electrograms are used to create an activation map, which is superimposed on the anatomical model. The acquired local activation times are then color-coded and superimposed on the anatomical map with red indicating early-activated sites, blue and purple late-activated areas, and yellow and green intermediate activation times (see Figs. 11-17, 11-19, and 12-10). Between these points, colors are interpolated, and the adjoining triangles are colored with these interpolated values. However, if the points are spaced widely apart, no interpolation is done. The degree to which the system interpolates activation times is programmable (as the triangle fill threshold) and can be modified if necessary. As each new site is acquired,

the reconstruction is updated in real time to create a 3-D chamber geometry color progressively encoded with activation time.²

Sampling an adequate number of homogeneously distributed points is necessary. If a map is incomplete, bystander sites can be mistakenly identified as part of a reentrant circuit. Regions that are poorly sampled have activation interpolated between widely separated points. This can give the appearance of conduction, but critical features such as lines of block can be missed. In addition, low-resolution mapping can obscure other interesting phenomena, such as the second loop of a dual-loop tachycardia. Some arrhythmias, such as complex reentrant circuits, require more than 80 to 100 points to obtain adequate resolution. Other tachycardias can be mapped with fewer points, including focal tachycardias and some less complex reentrant arrhythmias, such as isthmus-dependent AFL.^{9,10}

It is also important to identify areas of scar or central obstacles to conduction; failure to do so can confuse an electroanatomical map because interpolation of activation through areas of conduction block can give the appearance of wavefront propagation through, rather than around, those obstacles. This occurrence precludes identification of a critical isthmus in reentrant arrhythmias to target for ablation. A line of conduction block can be inferred if there are adjacent regions with wavefront propagation in opposite directions separated by a line of double potentials or dense isochrones.⁹

The electroanatomical model, which can be seen in a single view or in multiple views simultaneously and freely rotated in any direction, forms a reliable road map for navigation of the ablation catheter. Any portion of the chamber can be seen in relation to the catheter tip in real time, and points of interest can easily be revisited even without fluoroscopy. The electroanatomical maps can be presented in two or three dimensions as activation, isochronal, propagation, or voltage maps.

ACTIVATION MAP

The activation maps display the local activation time color-coded overlaid on the reconstructed 3-D geometry (see Fig. 6-8; also see Figs. 11-17, 11-19, and 12-10). Activation mapping is performed to define the activation sequence. A reasonable number of points homogeneously distributed in the chamber of interest must be recorded. The selected points of local activation time are color-coded—red for the earliest electrical activation areas and orange, yellow, green, blue, and purple for progressively delayed activation

areas (see Videos 10 and 11). The electroanatomical maps of focal tachycardias demonstrate radial spreading of activation, from the earliest local activation site (red) in all directions, and, in these cases, activation time is markedly shorter than tachycardia CL (see Figs. 11-17 and 11-19). On the other hand, a continuous progression of colors (from red to purple) around the mapped chamber, with close proximity of earliest and latest local activation, suggests the presence of a macroreentrant tachycardia (see Figs. 12-10, 14-1, and 14-2). It is important to recognize that if an insufficient number of points is obtained in this early meets late zone, it may be falsely concluded through the interpolation of activation times that the wavefront propagates in the wrong direction (Fig. 6-13).^{2,9,10}

ISOCHRONAL MAP

The system can generate isochrones of electrical activity as color-coded static maps. The isochronal map depicts all the points with an activation time within a specific range (e.g., 10 milliseconds) with the same color. Depending on conduction velocity, each color layer is of variable width; isochrones are narrow in areas of slow conduction and broad in areas of fast conduction. Displaying information as an isochronal map helps demonstrate the direction of wavefront propagation, which is perpendicular to the isochronal lines. Furthermore, isochronal crowding indicating a conduction velocity of 0.033 cm/msec (slower than 0.05 cm/msec) is considered a zone of slow conduction, whereas a collision of two wavefronts traveling in different directions separated temporally by 50 milliseconds is defined as a region of local block. Spontaneous zones of block or slow conduction (less than 0.033 cm/msec) may have a major role in the stabilization of certain arrhythmias.²

PROPAGATION MAP

The CARTO system also can generate color-coded animated dynamic maps of activation wavefront (propagation maps). This is a two-colored map, in which the whole chamber is blue and electrical activation waves are seen in red, spreading throughout the chamber as a continuous animated loop (see Figs. 11-19 and 12-10). Propagation of electrical activation is visualized superimposed on the 3-D anatomical reconstruction of the cardiac chamber in relation to the anatomical landmarks and barriers (see Videos 11 and 12). Analysis of the propagation map can allow estimation of the

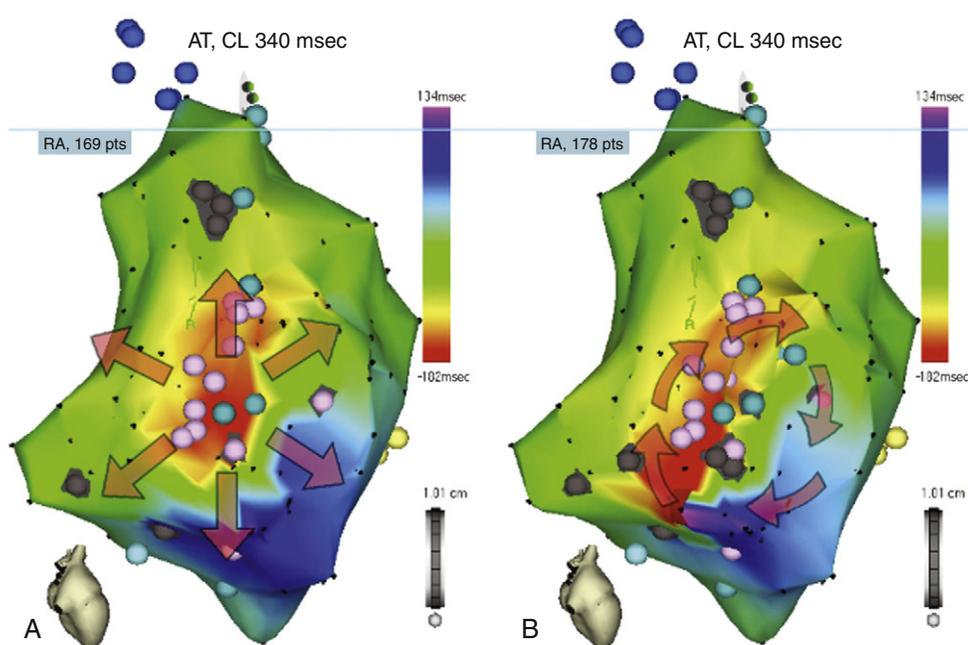

FIGURE 6-13 Right atrial electroanatomical (CARTO, Biosense Webster, Inc., Diamond Bar, Calif.) activation map in a patient with prior atrial tachycardia following atrial septal defect repair years before. The view is from the aspect of the right rib margin (upward toward the lateral right atrium). **A**, The activation pattern suggests a focal process with centrifugal spread of activation from the central red area (169 data points taken). **B**, With additional detailed mapping below the red area, a return path for a reentrant circuit is evident (178 data points). Entrainment data had already diagnosed macroreentry, but the relatively detailed activation map had missed the small area that became clear on more detailed mapping. CL = cycle length.

conduction velocity along the reentrant circuit and identification of areas of slow conduction.

VOLTAGE MAP

The voltage map displays the peak-to-peak amplitude of the electrogram sampled at each site. This value is color-coded and superimposed on the anatomical model, with red as the lowest amplitude and orange, yellow, green, blue, and purple indicating progressively higher amplitudes (Fig. 6-14). The gain on the 3-D color display allows the user to concentrate on a narrow or wide range of potentials. By diminishing the color scale, as may be required to see a fascicular potential or diastolic depolarization during reentry, larger amplitude signals are eliminated. To visualize the broad spectrum

of potentials present during a tachycardia cycle, the scale would be opened up to include an array of colors representing a spectrum of voltages. Local electrogram voltage mapping during sinus, paced, or any other rhythm can help define anatomically correct regions of no voltage (presumed scars or electrical scars), low voltage, and normal voltage. The true range of normal is often difficult to define, however, especially with bipolar recordings, and different criteria have been used. Myocardial scars are seen as low voltage, and their delineation can help in understanding the location of the arrhythmia.

ENTRAINMENT MAP

A graphical representation of entrainment mapping can be constructed by plotting values of the differences between the post-pacing intervals (PPIs) and the tachycardia CLs (PPI–tachycardia CL) on the electroanatomical mapping system to generate color-coded 3-D entrainment maps (Fig. 6-15). This approach can potentially help accurately determine and visualize the 3-D location of the entire reentrant circuit, even though the area of slow conduction of the tachycardia is not specified. Because neither of the electroanatomical mapping systems (CARTO, NavX) contains an algorithm for color-coding of entrainment information, the modus for activation mapping is altered manually. At each 3-D location of the catheter tip stored on the electroanatomical mapping system, entrainment stimulation is performed, and the difference between PPI and tachycardia CL (PPI–tachycardia CL) is calculated and plugged into the electroanatomical mapping system (as if it would be an “activation time”). For that, the local electrogram stored at the 3-D location is completely disregarded. The annotation marker is manually moved into a position where the numeric timing information equals the entrainment information (PPI–tachycardia CL). That timing information then is displayed in a color-coded fashion as if it were activation time, but instead it represents information on the length of the entrainment return cycle. With the color range, red represents points closest to the reentrant circuit (i.e., sites with smaller PPI–tachycardia CL differences, approaching 0, signifying their inclusion in the reentrant circuit) and purple represents points far away from the circuit (i.e., sites with the largest PPI–tachycardia CL differences).^{14,15}

Color-coded 3-D entrainment mapping allows determination of the full active reentrant circuit (versus passively activated regions of the chamber) and the obstacle around which the tachycardia is circulating, and it provides very useful information on the location of potential ablation sites (see Fig. 6-15). However, not all these sites will terminate reentry (just as, although the circuit in orthodromic SVT includes the ventricle, ablation at one or two sites in that ventricle will not eliminate reentry); the final choice is determined by location of anatomical barriers and width of putative isthmuses, so that strategic ablation lines, mainly connecting to anatomical barriers, can be applied to transect the circuit and treat the arrhythmia.^{14,15}

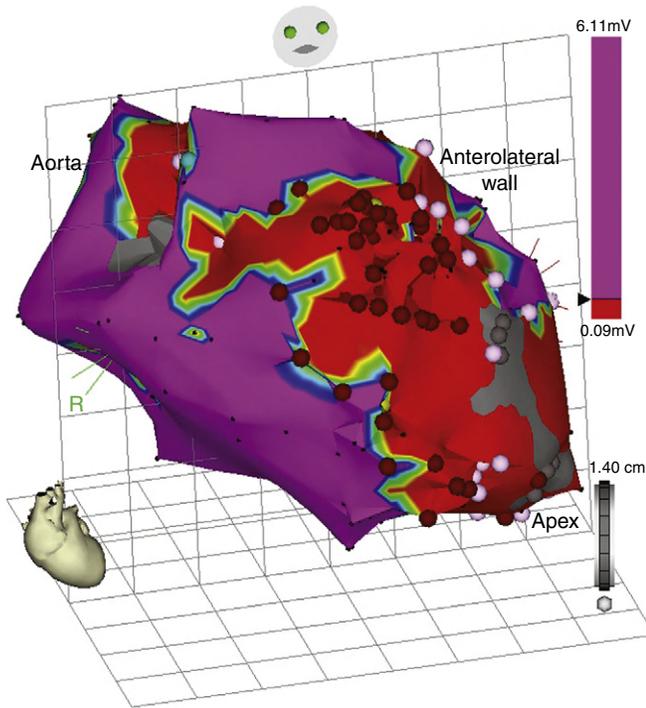

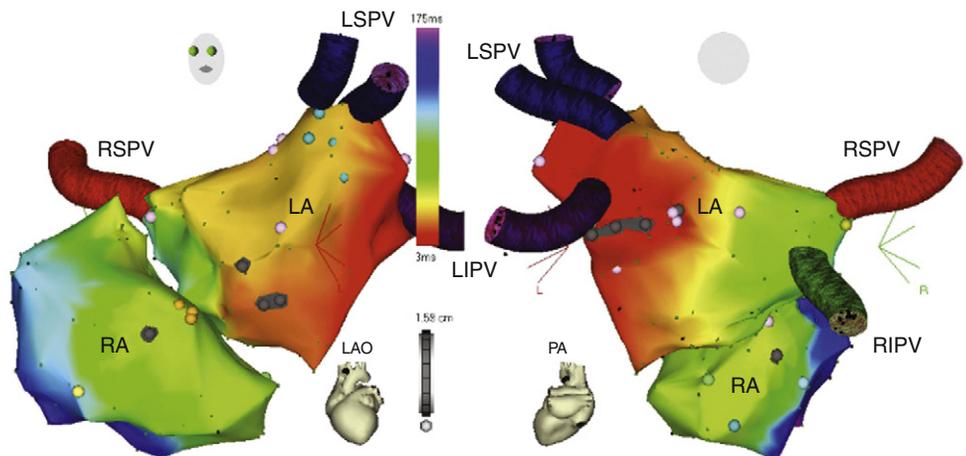

FIGURE 6-14 Electroanatomical (CARTO, Biosense Webster, Inc., Diamond Bar, Calif.) voltage map of the left ventricle in a patient with ventricular tachycardia after anteroapical myocardial infarction. An adjusted voltage scale is shown at right; all sites with voltage lower than 0.5 mV are red on the map, and those with voltage higher than 0.6 mV are purple, with interpolation of color for intermediate amplitudes. The gray area denotes no detectable signal (scar). A large anteroapical infarction is clearly evident. Red circles denote ablation sites.

FIGURE 6-15 Right atrial (RA) and left atrial (LA) electroanatomical color-coded entrainment map in a patient with atrial tachycardia following pulmonary vein (PV) isolation for treatment of atrial fibrillation. The colors represent the difference between the post-pacing interval at each site following entrainment pacing and the tachycardia cycle length: the less the difference, the closer to the circuit. In this case, the zone of reentry goes around the left inferior PV (LIPV). LAO = left anterior oblique; LSPV = left superior pulmonary vein; PA = posteroanterior; RIPV = right inferior pulmonary vein; RSPV = right superior pulmonary vein.

Clinical Implications

The capability of the CARTO system to associate relevant EP information with the appropriate spatial location in the heart and the ability to study activation patterns with high spatial resolution (less than 1 mm) during tachycardia in relation to normal anatomical structures and areas of scar significantly facilitate the mapping and ablation procedure. This mapping system facilitates defining the mechanisms underlying the arrhythmia, making a rapid distinction between a focal origin and macroreentrant tachycardia, precisely describing macroreentrant circuits and the sequence of activation during the tachycardia, understanding the reentrant circuit in relation to native barriers and surgical scars, identifying all slow-conducting pathways, rapidly visualizing the activation wavefront (propagation maps), and identifying appropriate sites for entrainment and pace mapping.

The CARTO system provides a highly accurate geometric rendering of a cardiac chamber with a straightforward geometric display having the capability to determine the 3-D location and orientation of the ablation catheter accurately. The position of the mapping tip at any point in time is readily apparent from a tip icon, provided that the tip is at or beyond the rendered chamber geometry. The catheter can anatomically and accurately revisit a critically important recording site (e.g., sites with double potentials or those with good pace maps) identified previously during the study, even if the tachycardia is no longer present or inducible and map-guided catheter navigation is no longer possible. This accurate repositioning provides significant advantages over conventional techniques and is of great value in ablation procedures. Ablation lesions can be tagged, thus facilitating creation of lines of block with considerable accuracy by serial RF lesion placement and allowing verification of the continuity of the ablation line (see Fig. 6-10). This is of particular value after incomplete ablations caused by catheter dislocation or early coagulum formation, especially if these ablations had caused interruption of the target tachycardia. Extra RF applications can be delivered closely around an apparently successful ablation site to ensure elimination of the arrhythmogenic area.²

Voltage maps can help define the arrhythmogenic substrate when the arrhythmia arises in the setting of cardiac structural abnormalities; this is of particular value during mapping of hemodynamically unstable or nonsustained arrhythmias. Additionally, fluoroscopy time can be reduced via electromagnetic catheter navigation, and the catheter can be accurately guided to positions removed from fluoroscopic markers. Although fluoroscopy is always needed for initial orientation, an experienced operator can usually generate an extensive endocardial activation map with substantially reduced radiation exposure for himself or herself and for the patient and laboratory staff.²

The CARTOMerge Module has proved very valuable in guiding real-time catheter ablation using the detailed cardiac chamber anatomy acquired from the CT/MRI (see later discussion).¹⁶

The CARTOSound Image Integration Module has been successfully utilized to facilitate AF catheter ablation by incorporating a real-time ICE volume map of the LA and PVs with the electroanatomical map, either as a stand-alone tool to guide navigation and ablation or as a facilitator of CT/MRI image integration. Additionally, studies have shown the feasibility of using CARTOSound to define scar boundaries in the left ventricle (LV, identified on ICE imaging by both by wall thickness and motion) to facilitate substrate mapping and ablation of ischemic VT.^{12,13}

Limitations

The sequential data acquisition required for map creation remains very time-consuming because the process of creation of an electroanatomical map requires tagging many points, depending on the spatial details needed to analyze a given arrhythmia. Because the acquired data are not coherent in time, multiple beats are required, and stable, sustained, or frequently repetitive arrhythmia is usually needed for creation of the activation map. Given that these points

do not provide real-time, constantly updated information, more time can be needed for making new maps to see a current endocardial activation sequence, detect a change in arrhythmia, or fully visualize multiple tachycardias. In addition, rapidly changing or transient arrhythmias are not easily recorded and may be mapped only if significant substrate abnormalities are present. For macroreentrant tachycardias, variation of the tachycardia CL by more than 10% can prevent complete understanding of a circuit, and it decreases the confidence in the CARTO map. Single PVCs or PACs or nonsustained events may be mapped, although at the expense of an appreciable amount of time.

One difficulty with current methods is that incorrect assignment of activation for a few electrograms can invalidate the entire activation map, and manual adjustment is often required to achieve the optimal representation. Additionally, data interpolation between mapped points is used to improve the quality of the display; however, areas of unmapped myocardium are then assigned simple estimates of timing and voltage information that may not be accurate.

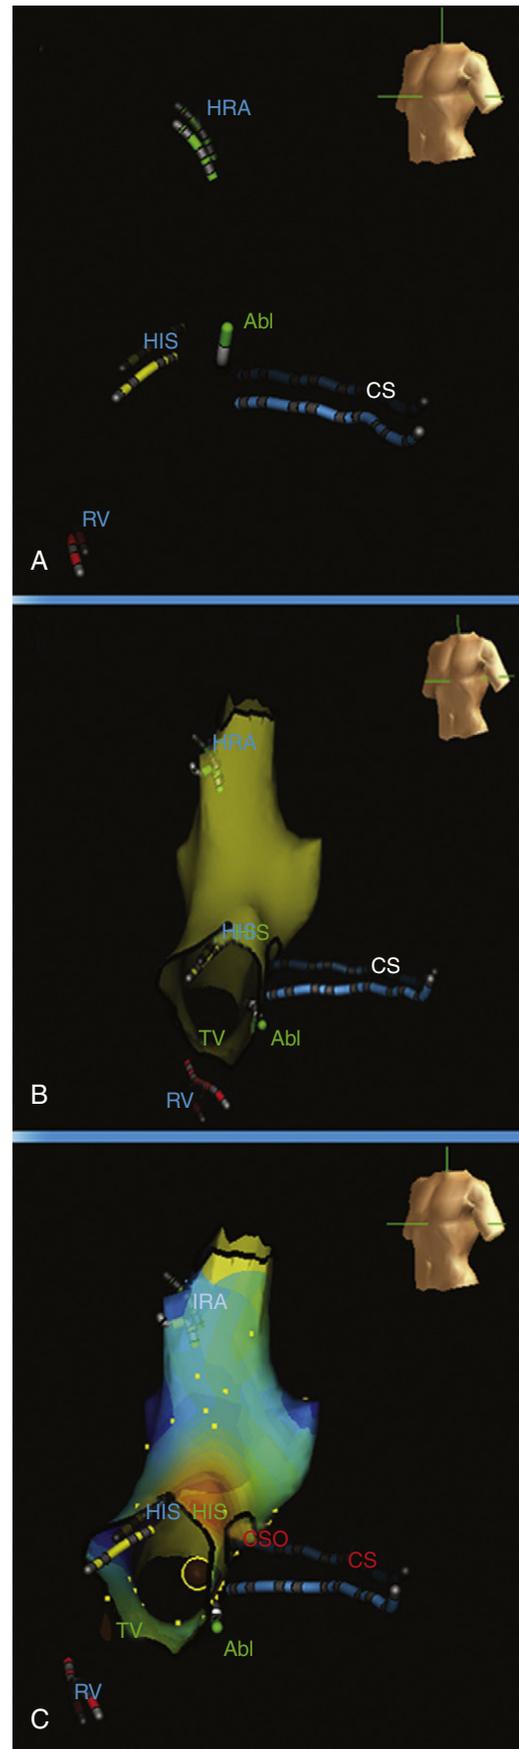

If highly fractionated and wide potentials are present, it can be difficult to assign an activation time. In some macroreentrant circuits, much of the tachycardia CL is occupied by fractionated low-amplitude potentials. The subjective selection of an individual local potential within a multicomponent electrogram can drastically alter a propagation map. If these potentials are dismissed or assigned relatively late activation times, a macroreentrant tachycardia may mimic a focal arrhythmia, and it will appear as if substantially less than 90% of the tachycardia CL is mapped. Additionally, with current methods, only a single value of timing or voltage can be assigned to those low-amplitude fractionated electrograms, and this is suboptimal in representing their potential importance to the reentrant circuit. To address this issue, one study described a novel form of electroanatomical mapping called "ripple mapping," whereby voltage, timing, and location are simultaneously displayed with continuous display of electrograms that were previously sampled and postprocessed. This novel technique for representation of endocardial activation can potentially help to simplify activation mapping by minimizing operator dependence, to eliminate interpolation of data between mapped points, and to eliminate assignment bias by developing software to register continuous or fractionated electrograms, thereby removing a single, isolated local value as representing an entire coordinate. The extent to which this technology will be incorporated into "real-time" application requires prospective evaluation.¹⁷

A change in rhythm during the mapping procedure can alter cardiac geometry to the extent that anatomical points acquired during one rhythm cannot be relied on after a change in rhythm. This is relevant during mapping of isolated ectopic beats or nonsustained arrhythmias, because locations assigned to early activation sites during the arrhythmia can potentially be removed from the same locations when they are assigned during normal rhythm (e.g., at the time of RF delivery after tachycardia termination). Therefore, after termination of the arrhythmia, revisiting the site of early activation tagged during PVCs or tachycardia may be unfeasible or even misleading as a target for ablation.

Additionally, significant movement of the patient or the intracardiac reference catheter would necessitate remapping. Older versions of CARTO did not record or display the location of diagnostic/reference catheters; consequently, it was not easy to relocate a displaced intracardiac reference catheter. This issue has been addressed in the third generation of CARTO (CARTO 3), which allows visualization of up to five EP catheters simultaneously.

Another limitation of the CARTO system is the requirement of a special Biosense Webster catheter with a location sensor embedded proximal to its tip. No other catheter types may be used with this system. Furthermore, the magnetic signal necessary for the CARTO system can potentially create interference with other EP laboratory recording systems. Implantable cardioverter-defibrillators and pacemakers are safe with the system, but the magnetic field can prevent device communication with its programmer, and the magnetic field may need to be disabled temporarily to allow device programming.

FIGURE 6-16 The NavX system (St. Jude Medical, Austin, Tex.). **A**, Left anterior oblique view of four standard diagnostic catheters (positioned in the high right atrium [HRA], His bundle [HIS], right ventricular [RV] apex, and coronary sinus [CS]) and a standard ablation catheter (Abl) as visualized by the NavX system during mapping of a focal atrial tachycardia. Note the shadows placed over the four diagnostic catheters to record their original position and recognize displacement during the procedure. **B**, Virtual anatomical geometry of the RA is acquired by moving the catheter in all directions throughout the chamber of interest. Any electrode catheter (not just the mapping catheter) can be used to create the three-dimensional (3-D) geometry. **C**, Color-coded activation map superimposed on the RA 3-D geometry localizing the origin of the atrial tachycardia to the triangle of Koch between the His bundle, coronary sinus ostium (CSO), and tricuspid valve (TV).

EnSite NavX Navigation System

Fundamental Concepts

The EnSite NavX system (St. Jude Medical, Austin, Tex.) consists of a set of 3 pairs of skin patches, a system reference patch, 10 ECG electrodes, a display workstation, and a patient interface unit. The reference patch is placed on the patient's abdomen and serves as the electrical reference for the system. The EnSite NavX combines catheter location and tracking features of the LocaLisa system (Medtronic, Minneapolis, Minn.) with the ability to create an anatomical model of the cardiac chamber using only a single conventional EP catheter and skin patches.⁸

This mapping modality is based on currents across the thorax, developed as originally applied in the LocaLisa system. In contrast to the NavX system, LocaLisa does not allow generation of 3-D geometry of the heart cavity because catheters and desired anatomical landmarks are displayed in a cartesian frame of reference.² This technology has undergone substantial additional development in the NavX iteration.

For 3-D navigation, 6 electrodes (skin patches) are placed on the skin of the patient to create electrical fields along 3 orthogonal axes (x, y, and z). The patches are placed on both sides of the patient (x-axis), the chest and back of the patient (y-axis), and the back of the neck and inner left thigh (z-axis). Analogous to the Frank lead system, the 3 orthogonal electrode pairs are used to send 3 independent, alternating, low-power currents of 350 mA at a frequency of 5.7 kHz through the patient's chest in 3 orthogonal (x, y, and z) directions, with slightly different frequencies of approximately 30 kHz used for each direction, to form a 3-D transthoracic electrical field with the heart at the center. The absolute range of voltage along each axis varies from each other, depending on the volume and type of tissue subtended between each surface-electrode pair. The voltage gradient is divided by the known applied current to determine the impedance field that has equal unit magnitudes in all 3 axes. Each level of impedance along each axis corresponds to a specific anatomical location within the thorax. As standard catheter electrodes are maneuvered within the chambers, each catheter electrode senses the corresponding levels of impedance, derived from the measured voltage. The mixture of the 30-kHz signals, recorded from each catheter electrode, is digitally separated to measure the amplitude of each of the 3 frequency components. The 3 electrical field strengths are calculated automatically by use of the difference in amplitudes measured from neighboring electrode pairs with a known interelectrode distance for 3 or more different spatial orientations of that dipole. Timed with the current delivery, NavX calculates the x-y-z impedance coordinates at each catheter electrode by dividing each of the 3 amplitudes (V) by the corresponding electrical field strength (V/cm) and expresses them in millimeters to locate the catheters graphically in real time to enable nonfluoroscopic navigation. The NavX system allows real-time visualization of the position and motion of up to 64 electrodes on both ablation and standard catheters positioned elsewhere in the heart (Fig. 6-16).

The NavX system also allows for rapid creation of detailed models of cardiac anatomy (see Fig. 6-16). Sequential positioning of a catheter at multiple sites along the endocardial surface of a specific chamber establishes that chamber's geometry. The system automatically acquires points from a nominated electrode at a rate of 96 points/sec. Chamber geometry is created by several thousand points. The algorithm defines the surface by using the most distant points in any given angle from the geometry center, which can be chosen by the operator or defined by the system. In addition, the operator is able to specify fixed points that represent contact points during geometry acquisition; the algorithm that calculates the surface cannot eliminate these points. In addition to mapping at specific points, there is additional interpolation, providing a smooth surface onto which activation voltages and times can be registered. To control for variations related to the cardiac cycle, acquisition can be gated to any electrogram.

Similar to the CARTO system, the voltage or the activation map can be superimposed on the 3-D geometry (see Fig. 6-16). Principles of activation and voltage mapping using the NavX system are similar to those discussed previously for the CARTO system.

Additionally, the NavX Fusion has the capability to integrate images from a preacquired CT/MRI scan on the electroanatomical image the cardiac chamber created with the NavX system to facilitate anatomically based ablation procedures (see later discussion).

Mapping Procedure

NavX-guided procedures are performed using the same catheter setup as conventional approaches. Any electrode can be used to gather data, create static isochronal and voltage maps, and perform ablation procedures. Standard EP catheters of choice are introduced into the heart; up to 12 catheters and 64 electrodes can be viewed simultaneously. The system can locate the position of the catheters from the moment that they are inserted in the vein. Therefore, all catheters can be navigated to the heart under guidance of the EnSite NavX system, and the use of fluoroscopy can be minimized for preliminary catheter positioning. However, interrupted fluoroscopy has to be used repeatedly when an obstacle to catheter advancement is encountered. Once in the heart, one intracardiac catheter is used as reference for geometry reconstruction. A shadow (to record original position) is placed over this catheter to recognize displacement during the procedure, in which case the catheter can be returned easily to its original location under the guidance of NavX. A shadow can also be displayed on each of the other catheters to record the catheter's spatial position (see Fig. 6-16).

Subsequently, 3-D intracardiac geometry is obtained. Respiratory compensation is collected just before mapping to filter low-frequency cardiac shift associated with the breathing cycle. Characteristic anatomical landmarks in the chamber of interest are initially acquired and marked. The system is then allowed to create the geometry automatically. A virtual anatomical geometry is acquired by moving the catheter in all directions throughout the chamber of interest, keeping contact with the endocardial wall.¹⁸ If a CT reconstruction of the mapped cardiac chamber is available, the image can be visualized on a split screen and used to guide finer anatomical definition with the ablation catheter. On completion, maps can be edited to eliminate "false space" (i.e., geometry with sparse geometry points) and erroneous structure definition. Subsequently, a scaling algorithm (Field Scaling) is applied to the completed detailed geometry to compensate for variations in impedance between the heart chambers and venous structures (which can otherwise result in a distortion of the x-y-z coordinates when a "roving" catheter is maneuvered among the differing regions of impedance). Field scaling is based on the measured interelectrode spacing for all locations within the geometry. Adjustments to the local strength of the navigation fields are made so that the computed catheter electrode positions match the known interelectrode spacing of the catheters used to create the geometry.¹⁹

Additional tagging of sites of interest and ablation points can be done during the procedure. Point-to-point activation mapping is carried out to create static isochronal, voltage, and activation maps (Videos 16 and 17; see Fig. 6-16). Standard catheters are used to sample voltage and activation timing at various locations during a sustained rhythm. The system collects and visually organizes activation timing and voltage data and permanently saves 10 beats with every collected point for later review. An unlimited number of maps can be created per procedure. The system works with most manufacturers' ablation catheters, RF generators, or cryogenerators. Ablation lesions can be tagged, thus facilitating creation of lines of block with considerable accuracy by serial RF lesion placement and allowing verification of the continuity of the ablation line.¹⁸

Clinical Implications

NavX is a novel mapping and navigation system with the ability to visualize and navigate a complete set of intracardiac catheters in any cardiac chamber for diagnostic and therapeutic applications.⁸ It enables the electrophysiologist to display in real time up to 64 electrodes simultaneously on 12 catheters with almost every commercially available catheter, including pacemaker leads. Earlier versions of NavX permitted the creation of 3-D cardiac geometry by using all these catheters, without visualization of electrical activity. Thus, they are particularly suitable for ablation of arrhythmias with well-known substrates that can be treated by an anatomical approach, such as AFL and linear LA ablation for AF.¹⁸ A software upgrade allowing point-to-point activation mapping for the NavX system has also been introduced. This is a substantial improvement, permitting the same type of activation mapping and display as are possible with other systems, with the similar advantage of specified voltage mapping as well. This point-to-point mapping, however, is suited only for sustained arrhythmias or frequently recurrent PACs, PVCs, or nonsustained arrhythmias. Unlike with the CARTO system, however, activation times can be acquired simultaneously by the EnSite NavX system from multiple poles on all catheters utilized during the study (and not just the mapping-ablation catheter). This acquisition can be augmented by the addition of noncontact mapping to the procedure.⁸

NavX technology has an important advantage in reducing operator and patient radiation exposure. The ability to position catheters for ablation without the use of fluoroscopy is important because NavX allows the display of catheters from the puncture site to the final destination in the heart. Indeed, this nonfluoroscopic navigation system allows real-time assessment of wall contact and catheter stability, as well as assessment of the anatomical position and the relation between the ablation catheter and other intracardiac catheters. Because of these capabilities, catheter displacement and insufficient wall contact are readily recognized without the use of fluoroscopy, thus resulting in reduction of radiation exposure, procedure duration, and the trend to reduced RF energy delivery.

The ablation procedure is also facilitated by NavX.^{8,18} As noted, the system works with most manufacturers' ablation catheters, RF generators, or cryogenerators. The ablation lesions can be tagged, thus facilitating creation of lines of block with considerable accuracy by serial RF lesion placement and allowing verification of the continuity of the ablation line and anatomical visualization of the remaining gaps, where additional RF applications can be delivered. It also helps avoid repeated ablations at the same location. The catheter can anatomically and accurately revisit a critically important recording site identified previously during the study.

As in the CARTO system, the voltage or the activation map can be superimposed on the 3-D geometry. Complex fractionated electrograms can be targeted in persistent AF by using the software to depict the mean electrogram CL map. The NavX system also has the capability to import and integrate 3-D CT or MRI images to facilitate anatomically based ablation procedures. NavX Fusion provides a significant advancement in image integration with the EnSite NavX

system and has the ability to mold the created geometry dynamically into the CT/MRI image (see later discussion).

Limitations

The point-to-point activation mapping required while using the NavX system is suited only for sustained arrhythmias or frequently recurrent ectopy or nonsustained arrhythmias. Additionally, in the NavX system, the algorithm defines the surface by using the most distant points in any given angle from the geometric center, and the catheter can protrude out against the wall of the cardiac chamber when acquiring points; thus, chamber geometry of the NavX system is oversized.

Furthermore, with individual interpolation schemes, significant anatomical distortions in complex structures can occur, because there may be interpolations in the region of curvature that do not depict the accurate geometry, especially at areas of exvaginations (e.g., the PVs, LA or RA appendages). One strategy to minimize this is to incorporate a family of fixed points into the geometry to preserve critical junctions between those structures. A second strategy is to create volumes of these structures in separate maps and then combine them to the main chamber.

The position of the intracardiac catheter used as reference for geometry reconstruction needs to be stable throughout the procedure to maintain the accurate position of the electroanatomical map. Any significant shift in its position can frequently lead to remapping. Although a shadow (to record original position) can be placed over the reference catheter to recognize displacement during the procedure, in which case the catheter can be returned to its original location, this may not always be feasible or accurate.

Stereotaxis Magnetic Navigation System

Fundamental Concepts

Catheter navigation by magnetic force was initially introduced in the early 1990s for diagnostic studies in neonates. However, the development of conventional steerable electrodes with integrated pull wires to deflect the catheter tip was pursued, and this constitutes the current technique for catheter ablation. The conventional technique is limited by the fixed maximal catheter deflection and relies mostly on the skill of the operator to ensure stable catheter positioning. A novel magnetic navigation system (MNS; 0.15 T, Telstar, Stereotaxis, St. Louis, Mo.) was introduced to clinical practice. It was proven to be a safe and feasible tool for catheter ablation, although it did not allow remote catheter ablation. The second-generation MNS (Niobe, Stereotaxis) now allows, for the first time, complete, remote RF catheter ablation.²⁰

The Niobe MNS consists of two permanent neodymium-iron-boron magnets; their positions, relative to each other, are computer controlled inside a fixed housing and positioned on either side of the single-plane fluoroscopy table.²⁰ While positioned in the “navigate” position, the magnets create a 360-degree omnidirectional rotation of the device by a uniform magnetic field (0.08 tesla) within an approximately spherical navigation volume 20 cm in diameter (NaviSphere), sufficient to encompass the heart when the patient is properly positioned. The combination of rotation, translation, and tilt movements of the magnets adjusts the magnetic field to any desired orientation within the NaviSphere.^{20,21}

The mapping and ablation catheters are extremely flexible distally, especially the distal shaft of the catheter, and have tiny magnets (single or multiple, in various configurations) inserted in their distal portion. The latest catheters have three tiny magnets distributed along the distal shaft and tip of the catheter to increase responsiveness of the catheter to the magnetic field generated (Fig. 6-17). The catheter magnets align themselves with the direction of the externally controlled magnetic field to enable the catheter tip to be steered effectively. By changing the orientation of the outer magnets relative to each other, the orientation of the magnetic field changes, thereby leading to deflection of the catheter.²⁰

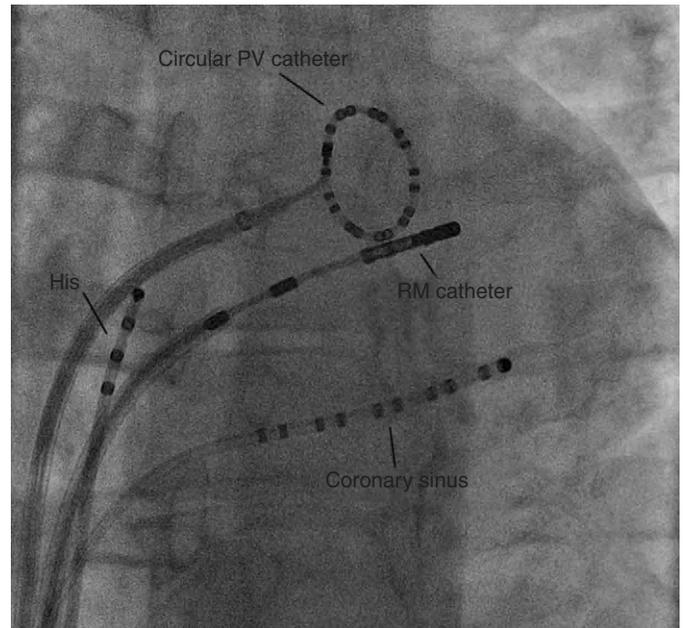

FIGURE 6-17 Stereotaxis catheters (Stereotaxis, St. Louis, Mo.). Anteroposterior fluoroscopic view of the Stereotaxis remote magnetic (RM) catheter in the left atrium. Multipolar circular mapping, coronary sinus, and His bundle catheters are also shown. The RM catheter has a large distal mapping and ablation electrode; this and three other opaque regions more proximally on the catheter shaft contain magnetic elements that conform to changes in direction of an externally applied magnetic field. PV = pulmonary vein.

The system is integrated with a modified C-arm digital x-ray system, mainly a single-plane unit because of the limitations imposed by the magnets, although a biplane system can be installed for use when the magnets are stowed and not in use. Because of the magnets, the rotation of the imaging system is limited to approximately 30 degrees right anterior oblique (RAO) and left anterior oblique (LAO) in Niobe I and almost 45 degrees with Niobe II. In the Niobe I iteration, the magnets can be swung only in (active navigation) or stowed, whereas in the Niobe II the magnets have a different housing and can also be tilted to allow for more angulation of the single-plane C-arm imaging system.²⁰

It is important to emphasize that the external magnetic field does not pull or push the tiny magnets and the catheters or guide-wires in which they are contained. The position of the magnetic catheter within the heart is controlled by manual advancement or retraction of the catheter through the vascular sheath. A computer-controlled catheter advancer system (Cardiodrive unit, Stereotaxis) is used to allow truly remote catheter navigation without the need for manual manipulation. The operator is positioned in a separate control room, at a distance from the x-ray beam and the patient's body. The graphic workstation (Navigant II, Stereotaxis), in conjunction with the Cardiodrive unit, allows precise orientation of the catheter by 1-degree increments and by 1-mm steps in advancement or retraction. The system is controlled by a joystick or mouse and allows remote control of the ablation catheter from inside the control room. Additionally, the x-ray image data can be transferred from the x-ray system to the user interface of the MNS system to provide an anatomical reference.

Directional catheter navigation is accomplished by drawing a desired magnetic field vector on orthogonal fluoroscopic views with a digitization tablet (Fig. 6-18). A control computer then calculates the appropriate currents to each of the superconducting electromagnets. The resultant composite magnetic field interacts with a permanent magnet in the tip of the magnetic ablation catheter and deflects the catheter to align parallel to the magnetic field. Magnetic field orientations corresponding to specific map points can be stored on the MNS and reapplied to return repeatedly and accurately to previously visited locations on the map. Navigation

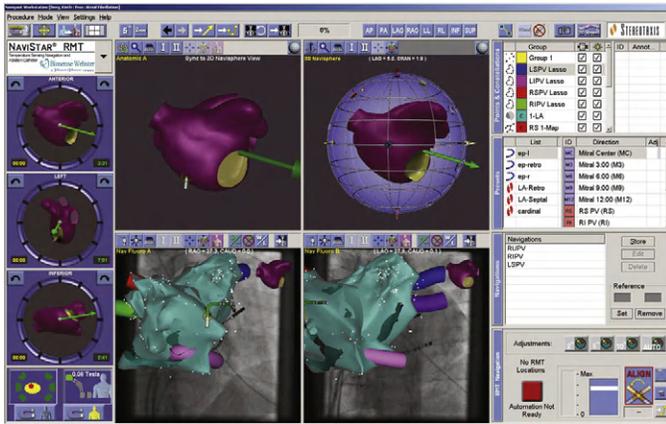

FIGURE 6-18 Stereotaxis monitor—screen shot of the remote magnetic guidance system (Stereotaxis, St. Louis, Mo.). **Top two central panels,** Representation of idealized left atrium shells with a green arrow (“vector”) that can be pointed in any direction with a computer mouse, commanding the magnetic steering mechanism to deflect the catheter tip in that direction. **Bottom two central panels,** Shell generated by electroanatomical mapping, integrated with the images on the Stereotaxis unit. These overlie the patient’s initial right anterior oblique and left anterior oblique fluoroscopic images. Tubular structures are the pulmonary veins and coronary sinus (pink). Other panels on the screen are various controls and indicators for the Stereotaxis manipulation.

to a particular target often requires two or three manipulations of the magnetic field to refine the catheter position. Each magnetic field manipulation requires less than 20 seconds to activate. By changing the orientation of the outer magnets, the orientation of the magnetic field changes, thereby leading to the deflection of the catheter in parallel.²⁰

The MNS has become integrated with CARTO RMT (Biosense Webster, Inc.) electroanatomical mapping system. The CARTO RMT system is similar to the standard CARTO system but is able to localize the ablation catheter without interference from the magnetic field. CARTO RMT is able to send real-time catheter tip location and orientation data to the MNS. It also sends target locations, groups of points, and anatomical surface information from the electroanatomical map to the MNS.

Mapping Procedure

All the components of the MNS, as well as the x-ray, ablator, and stimulator, can be operated from the control room. Therefore, after initial placement of sheaths and catheters, the entire ablation procedure can be performed remotely from the control room. The Navigant system is the computerized graphical user interface system. It includes the software used for image integration and for control of the magnetic fields that orient the catheter within the heart and allow the operator to direct the movement of the tip of the catheter to access the region of interest (see Fig. 6-18).²⁰

After synchronizing with respiratory and cardiac cycles, such as inspiration and the end-diastolic period, a pair of best-matched RAO-LAO images is transferred and kept in the Navigant screen as background references for orientation and navigation (see Fig. 6-18). Thus, the real-time catheter location information can be displayed on the Navigant reference x-ray images, thus enabling continuous real-time monitoring of the catheter tip position, even without acquiring a fresh x-ray image.²⁰

The operator can access an area of interest by using vector-based or target-based navigation. In vector-based navigation, the operator tells the system, by drawing a vector in virtual 3-D space on the computer, what orientation of the magnetic field is required. In target-based navigation, a target is placed on a specified point using the stored orthogonal fluoroscopic views; the user marks the support or base of the catheter (the distal portion of the sheath) on the pair of x-ray images. This provides Navigant with the data

needed to compute field orientations corresponding to particular targets. Each time a vector is selected or a target is marked, the computer sends information to the magnets, which changes their relative orientation, and with it the orientation of the uniform magnetic field in the chest, so that catheter orientation is then changed within a few seconds (see Fig. 6-18). A target can also be defined by selecting a preset magnetic field vector based on a selected study protocol from the list on the Navigant. The software contains several preset vectors selected by the manufacturer, after careful appraisal of multiple CT images and reconstructions, for positioning the catheter at various anatomical landmarks. When a preset vector is applied, it can steer the catheter near the approximate region indicated. In addition, the software can be used to map various chambers of the heart automatically.²⁰

The magnetic catheter is advanced to target positions in the cardiac chamber of interest and guided by using the x-ray system, user interface monitors, and catheter advancer (Cardiodrive) system, which allows precise orientation of the catheter in extremely small increments (1-degree increments, by 1-mm steps) within the heart and vessels in advancement or retraction, thus making mapping more accurate. All vectors and targets selected can be saved, as can relative positions of the catheter advancer system, to allow specific areas in the heart or side branches of vessels to be revisited reproducibly.

CARTO RMT has also been integrated with the MNS and has been specifically redesigned to work in the magnetic environment of Stereotaxis. CARTO RMT includes all the latest updates such as CARTOMerge, in which a 3-D reconstruction of a CT or MRI image can be integrated into the electroanatomical map. With the CARTO integration, communication between the two systems allows for real-time catheter orientation and positioning data to be sent from CARTO to the Stereotaxis system and for the catheter tip to be displayed on the saved images stored on the Navigant system. This permits tracking of the ablation catheter without having to update the radiographic image as often. Magnetic vectors can also be applied from the CARTO screen. A feature called “design line” can be used to send a line of points, either for mapping a specific area or potentially as a line of ablation points. “Click and go” is a tool allowing for an area of the map to be clicked on to set a target and have the system guide the catheter to this point. Because Stereotaxis and CARTO have feedback integration, the CARTO system can feed back to the Stereotaxis system if the exact point is not reached, thus allowing for further automatic compensation by the software until the desired point is reached. The combined system has the capability of automatically mapping chambers (anatomy and activation times) by using predetermined scripts. The accuracy of such automaps is highly dependent on the anatomy, as well as where in the heart the operator designates the starting point for mapping. At present, standard 4- and 8-mm-tip and irrigated 3.5-mm-tip RF catheters are available.

Clinical Implications

Precise target localization and catheter stability are prerequisites for successful RF applications and to minimize risks of potential complications. Stiff, manually deflectable catheters, with a unidirectional or bidirectional deflection radius, which deflect in a single plane, have several inherent limitations because stable electrode-tissue contact can be difficult to achieve, particularly in regions of complex cardiac anatomy. In contrast, the promise of the current MNS lies in the precision of catheter movement and the ability to steer the flexible distal portion of the catheter in any direction in 3-D space.²⁰

The MNS is increasingly used for ablation of AVNRT, atrioventricular bypass tracts (BTs), AFL, idiopathic outflow tract VT, scar-related VT, and especially AF. Intracardiac electrograms and stimulation thresholds are not significantly different from those recorded with a standard, manually deflected ablation catheter, and the safety of standard EP procedures has not been compromised by use of the MNS.²¹⁻²⁶

Although the current MNS does not offer a distinct advantage over conventional catheters for navigation to targets that are easily reached, it has potential advantages for complex catheter maneuvers and navigation to sites that are exceptionally difficult to reach with a standard catheter. In addition, catheter mobility and endocardial stability can be superior by virtue of the compliance of the distal catheter and lack of constraints on the magnetic vector used to steer the catheter. Cardiac and respiratory motion can be buffered by the catheter compliance, thereby contributing to endocardial contact stability.

After the diagnostic catheters are positioned, the EP study and ablation process can be performed completely from inside the control room. This offers several potential advantages, including reducing fluoroscopic exposure time for the operator, reducing the strain from standing next to the bed for long periods while wearing a lead apron, and facilitating simultaneous catheter navigation and electrogram analysis.

A unique feature of the current MNS is that the magnetic vector coordinates used to navigate the magnetic catheter to a particular site can be stored and reused later in the study to return to a site of interest. The integration of a stable magnetic catheter with the CARTO electroanatomical mapping system is useful to reconstruct an accurate electroanatomical map by acquiring many more points than are possible manually for successful ablation, even of challenging areas.²⁰

The maximum tissue force that can be applied by the flexible catheter used in the MNS is less than the average and significantly less than the maximum that can be applied using a standard catheter. Because of the flexibility of the catheters, cardiac perforation is extremely unlikely.

For certain procedures, notably AF ablation, MNS can decrease fluoroscopy time significantly. Although the use of MNS may increase total procedure duration, procedure times decrease with increasing operator experience.²³⁻²⁶

Limitations

A potential limitation of the MNS is the interference induced by the magnetic field in the surface ECG. The origin of the induced potentials is thought to be attributable to blood flow within the magnetic field. Blood is an electrolyte solution that can induce the potential because of motion within the magnetic field. The magnetic field strength used for catheter manipulation is approximately one order of magnitude less than that associated with MRI. The interaction of the magnetic field with the surface ECG is therefore less in magnitude compared with MRI and is restricted to the ST segment, and the temporal distribution of the interfering signal component probably would not compromise cardiac rhythm analysis or analysis of the P wave or QRS morphology. However, interpretation of changes in the ST segment would be predictably compromised by this interference. Whether this distortion will affect arrhythmia analysis is currently being investigated.

Claustrophobia and morbid obesity are contraindications for using the MNS because of the restricted space within the system. The next generation of the MNS features an open design that is more comfortable for obese patients and those with claustrophobia. Patients with pacemakers or defibrillators are also excluded because of electromagnetic interference. Further study is required to determine whether the magnetic field strength is compatible with these devices. Additionally, the MNS requires monitoring instruments that are compatible with magnetic fields.

The angulation of the fluoroscopic system is limited to 30 to 45 degrees for both LAO and RAO projections when the magnets are in the “navigate” position. Although this may not be important in simple ablations, addressing more complex substrates can be more challenging.²⁰

The MNS is an evolving technology. Further technical development through the availability of additional catheter designs (e.g., number of recording electrodes) is necessary to address more complex arrhythmias in the future.

The use of the MNS for ablation of AF, atypical AFL, and typical AFL was associated with long procedure times as compared with conventional catheter navigation. The preparation of the devices (registration and positioning of the magnets for MNS; flushing sheaths and gain transeptal access for MNS) is still time-consuming. Furthermore, the use of the MNS for catheter ablation of typical AFL resulted in a lower overall success rate (achievement of cavotricuspid isthmus block and freedom from AFL recurrence during follow-up). A lower success rate of PV electrical isolation was also observed when a standard 4-mm-tip ablation catheter was used. Some reports also expressed concern about a higher incidence of char formation during MNS-guided ablation of AF and AFL.^{21,24,25} Irrigated magnetic catheters have become available and may reduce the risk of char formation, and they may also increase lesion efficacy during MNS-guided ablation.²²

Sensei Robotic Navigation System

Fundamental Concepts

The Sensei robotic navigation system (Hansen Medical, Mountain View, Calif.) is an electromechanical system that realizes catheter navigation by two concentric steerable sheaths (Artisan, Hansen Medical) incorporating an ablation catheter. The outer sheath (14 Fr) and the inner sheath (10.5 Fr) are both manipulated via a pull-wire mechanism by a sheath-carrying robotic arm that is fixed at the foot of the patient's table. The robot arm obeys the commands of the central workstation (master console) positioned in the control room. Catheter navigation is realized using a 3-D joystick (Instinctive Motion Control, Hansen Medical) and allows a broad range of motion in virtually any direction. At the master console, fluoroscopic images, ICE images, and other 3-D representations (electroanatomical maps) are displayed, providing immediate feedback to the operator. Seamless instinctive integration and interpreted motion logic allow the physician to direct catheter movement in 3-D regardless of image orientation or perspective. To provide a representation of tactile feedback, the system continuously monitors the contact force that is exerted by the catheter tip by using a specially designed algorithm (IntelliSense, Hansen Medical). If the contact force exceeds a preset limit, an optical alarm is displayed, and catheter advancement is rendered virtually impossible. In general, all catheters and all electroanatomical mapping systems may be used. Apart from the different navigational approach, the technical aspects of the ablation are identical to the manual ones.^{21,27-29}

Mapping Procedure

Both the inner and the outer sheaths should be flushed with heparinized normal saline before insertion and continuously throughout the procedure to prevent clot formation and air embolism. The steerable guide sheath is manually inserted via a 14 Fr sheath in the right femoral vein and advanced manually into the inferior RA under fluoroscopy guidance. To minimize the risk of vascular complications, it is advisable to obtain venous access under ultrasound guidance, initially insert an 8 Fr sheath and upsize to 11 Fr and then 14 Fr, and then insert a long, 30-cm 14 Fr sheath that usually ends at the level of the liver. Through this, the steerable sheath is inserted with the ablation catheter leading by at least 10 cm into the RA. At this level, the ablation catheter is withdrawn into the steerable sheath with only the distal electrodes protruding. Failure to leave the ablation catheter out beyond the end of the Artisan sheath and to observe the catheter system advance up to the RA increases the risk of vascular injury.²⁹

Then, the position of the sheath is registered into the robotic catheter remote control system. The registration process involves the use of two orthogonal fluoroscopic views of the heart (anteroposterior and lateral) to allow saving the position of the guide sheath in 3-D space. Following registration, the remote control system is used to steer the tip of the ablation catheter to various targets in all four cardiac chambers.

For ablation of AF, the first transseptal puncture is usually performed manually with a standard transseptal sheath and needle system. The guidewire or a circular catheter placed in the LA through the first transseptal puncture is used as a marker of the second puncture site. Fluoroscopy and ICE images are used for confirmation of robotic navigation system placement in the LA. The second transseptal puncture is performed with the Sensei system by using a transseptal sheath and dilator (Hansen Medical, Inc.); a custom-made transseptal needle (Hansen Medical, Inc.) is advanced through a dilator lumen under fluoroscopy and ICE guidance. After the septum is punctured, the steerable guide sheath and dilator are advanced robotically in the LA, and the dilator is replaced with the ablation catheter, which is then inserted into the guide sheath with approximately 1 cm of the ablation catheter exposed from the tip of the guide sheath. Integration of this robotic system with available mapping systems (CARTO and EnSite NavX) is feasible.

The steerable sheath housing the ablation catheter is remotely controlled by a physician at the master console. Manipulation of other catheters, including the circular mapping catheter, however, is performed manually by a second operator at the procedure tableside.

The amount of energy applied during remote navigation cases is generally lower than that of manual cases, likely because of enhanced catheter contact and stability throughout the cardiac cycle afforded by the robotic sheath. As a result, the rate of steam pop and potential thermal complications may be higher if compensatory energy-lowering strategies are not implemented.²⁹

Clinical Implications

Endocardial navigation using conventional manual steerable diagnostic and ablation catheters and transseptal puncture using standard equipment can be challenging and time-consuming, and they require certain skills and experience. The robotic catheter remote control system was designed to facilitate control and allow precise and stable positioning of catheters within the cardiovascular system. It can help overcome the limitations of manual control by combining the ease of navigation with a readily available wide navigational field.

The main advantages of remote navigation are the opportunity to reduce the operator's radiation exposure because of the remote location of the workstation from the fluoroscopy unit. Furthermore, because of better catheter stability and easier navigation with the robotic system, total fluoroscopy time and patient and staff radiation exposure can potentially be reduced; however, this remains to be determined.^{21,29,30}

Several studies have shown that robotic navigation and ablation of AF are as safe and effective as manual ablation. Furthermore, the use of the robotic catheter remote control system for transseptal puncture and endocardial navigation is safe and feasible. However, its usefulness in decreasing procedure time and improving procedural efficacy and safety compared with current approaches requires further evaluation in randomized clinical trials. In addition, a comparison between this technology and remote magnetic navigation may be warranted. It is conceivable that, in the future, a completely automated remotely performed procedure could set new and more homogeneous treatment standards for this complex procedure.^{21,28}

In contrast to the magnetic guidance system (Niobe, Stereotaxis), which requires specific compatible magnetic-guided catheters, the Sensei robotic navigation system is an open platform system whereby almost any mapping or ablation catheter of appropriate size can be introduced into the remotely steerable catheter or sheath. Additionally, the MNS requires continuous alteration and adjustment of the magnetic field and then advancement of the catheter in that direction. With the use of the Sensei robotic navigation system, a continuous uninterrupted motion of the ablation catheter can be achieved with the use of the instinctive motion controller.^{21,29,30} Finally, the Sensei robotic system is, at least in

principle, portable and could be transported from one laboratory to another in the facility, whereas the remote MNS requires large magnets permanently installed in one location.

Limitations

Although the remote location of the workstation from the fluoroscopy can significantly reduce radiation exposure to the physician, there is a need for a second physician or operator to manipulate the circular mapping catheter at the bedside during a PV isolation procedure. Radiation exposure is not reduced to this operator or to the patient. With the use of other AF ablation strategies, such as anatomically based ablation, however, there would be no need for a separate mapping catheter. In the future, it is possible that both the ablation and mapping catheters will be controlled in tandem with two coordinated robotic steerable guides.

The steerable robotic sheath is inherently stiff to make it pushable and mechanically steerable, and it has to be advanced through a 14 Fr vascular sheath. The size of the introducer sheath itself increases the likelihood of complications, and advancing the steerable sheath into the vein may cause dissection. The amount of force required to advance the Artisan through the hemostatic valve of the sheath at the groin is significant. Therefore, insertion of the 14 Fr sheath and the Artisan catheter does require special care to avoid retroperitoneal vascular complications.^{27,29}

Infrequent cases of cardiac perforations and PV stenosis were reported in several studies using the Sensei robotic navigation system for catheter ablation of AF. Some of those events were thought to be consequent to the use of high power output during RF ablation. Therefore, it is important to recognize that with better catheter contact and stability offered by the robotic sheath, the effectiveness of ablation is increased, and less power is probably needed to achieve adequate attenuation of electrograms. Further studies will be required to evaluate adequate and optimal tissue contact during navigation mapping and ablation, as well as the optimal ablation energy parameters while using a robotic system at different pressure levels, and compare those with the parameters used with conventional manually operated catheters.²⁷

During catheter ablation of AF the major advantage of robotic navigation with respect to stability as compared with manual navigation is along the LA roof. However, at the anterior inferior portion along the lateral circumferential ablation line, catheter stability is suboptimal in almost 50% of the cases despite robotic navigation. This may be explained by the fact that this is the most distant location from the transseptal puncture site. This limitation can be partially compensated for by a "deeper" LA position of the outer sheath and application of a distal bend. Additionally, electrical isolation of the right inferior PV is challenging using this system. Because of the large outer diameter of the sheath, robotic navigation to the distal CS is discouraged. This may limit its use in ablation procedures for long-lasting persistent AF or perimitral LA macroreentrant tachycardias, which frequently require epicardial ablation via the CS.

Certain ablation catheters with flat wire deflection mechanisms, such as the current version of the Cool Path ablation catheter manufactured by St. Jude Medical, are not compatible with the Sensei robotic navigation system, thereby rendering the system truly a semi-open rather than a fully open platform. The flat wire mechanism allows the catheter to only bend along a two-dimensional (2-D) plane described by the flat surface of the wire without causing tension. When the robotic sheath moves in a direction that is not along the 2-D plane of the flat wire, tension is created, resulting in an uncontrolled rebound rapid correction of the system, which can potentially cause cardiac perforation. This rarely happens with manual manipulation of the catheter alone because the operator rotates the catheter appropriately to achieve the desired position.^{27,31}

Although the robotic system affords greater stability at ablation targets, complications that occur with the manual approach can also occur with the robotic system. Given the stability of the system and also the stiffness and rigidity of the sheath, it is crucial that the

operator understands the anatomy of the LA and adjacent structures. Even more so with the robotic navigation system, it is very important that the operator is cognizant of possible complications and is able to manage such complications effectively.²⁷

Body Surface Potential Mapping

Fundamental Concepts

Although the conventional 12-lead ECG is extensively used, its limitations for optimal detection of cardiac abnormalities are widely appreciated. The main deficiency in the 12-lead approach is that only 6 chest electrodes are incorporated, and they cover a relatively constrained area of the precordium. The main reason for the choice of the location of the conventional precordial electrodes, suggested by Wilson in the 1940s, was the need to adopt some standard, which to this day has remained relatively unchallenged. In the years since then, the growing appreciation for the limitations of the conventional precordial electrode positions and the increase in understanding of the localization of various cardiac abnormalities on the body surface have led to the suggestion of various alternatives.^{32,33}

One of the most widely studied alternatives to the 12-lead ECG in clinical and experimental electrocardiology has been body surface potential mapping (BSPM). In this approach, 32 to 219 electrodes are used in an attempt to sample all ECG information as projected onto the body's surface. The merits of this enhanced spatial sampling are obvious, in that localized abnormalities that may be difficult to detect using the 12-lead approach can readily be picked up with the additional electrodes.³²

BSPM is defined as the temporal sequence of potential distributions observed on the thorax throughout one or more electrical cardiac cycles. BSPM is an extension of conventional ECG aimed at refining the noninvasive characterization and use of cardiac-generated potentials. The improved characterization is accomplished by increased spatial sampling of the body surface ECG, recorded as tens or even hundreds of unipolar ECGs, simultaneously or individually, with subsequent time alignment.³³

BSPMs provide much more electrical and diagnostic information than the 12-lead ECG. They contain all the electrical information that can be obtained from the surface of the body, and they reveal diagnostically significant electrical features in areas that are not sampled by the 12-lead ECG systems. In addition, BSPMs often show distinct electrical manifestations of two or more events simultaneously evolving in the heart; they make it possible to compute any ECG that would be obtained from any pair or combination of body surface electrodes (i.e., from any current or future lead system). In addition, the recorded data can be displayed as a sequence of contour maps, thus allowing isolation of significant ECG events in both space and time.³²

BSPMs can be used to reconstruct epicardial and, in some cases, endocardial potential distributions, excitation times, and electrograms noninvasively, by means of inverse procedures, which help transform the ECG into an imaging method of electrical activity. This yields 3-D images that depict anatomical features with superimposed activation isochrones or excitation and recovery potentials, isochrones, and electrograms.³³

In BSPM measurements, unipolar potentials of single heartbeats are acquired simultaneously at more than 60 locations covering the whole thorax. A Wilson central terminal is used as a reference for the unipolar leads. Lead sites in the array are arranged in columns and rows, and the electrodes are attached to flexible plastic strips, attached to dozens of thoracic sites vertically, with the highest electrode density at the left anterior thorax. Recordings are bandpass-filtered at 0.16 to 300 Hz, digitized with a sampling frequency of 1 kHz, and stored on a CD.³³

BSPMs depict the spatial distribution of heart potentials on the surface of the torso. Initially, all lead tracings are visually screened to reject poor-quality signals. The amplitude of every electrogram is measured at a given time instant during the cardiac cycle and

plotted on a chart representing the torso surface. Several analytical procedures are used to convert the grid of data points into map contours. The time interval between successive instantaneous maps (frames) is generally 1 to 2 milliseconds. A sequence of 400 to 800 frames shows the evolution of the potential pattern during the cardiac cycle. Often, 20 to 50 properly selected maps are sufficient to show the essential features of the time-varying surface field.³³

Localization of the site of origin of focal tachycardia, pacing site, or myocardial insertion site of a BT relates to the thoracic site of greatest negativity in the isointegral map. An activation wavefront moving away from such sites yields a negative body surface identifier because of the dominant effect of activating the remainder of the myocardial mass away from the stimulus site.

Clinical Implications

BSPM has been used for patients with conditions such as pulmonary embolism, aortic dissection, and acute coronary syndromes. It has also been used for diagnosing an old myocardial infarction, localizing the BT in Wolff-Parkinson-White syndrome, recognizing ventricular hypertrophy, and ascertaining the location, size, and severity of myocardial infarction and the effects of different interventions designed to reduce the size of the infarct.³³ From an EP standpoint, BSPM has been studied for the discrimination of clockwise and counterclockwise AFL, localization of the earliest retrograde atrial activation site in dogs with simulated Wolff-Parkinson-White syndrome and orthodromic AVRT, localization of the ventricular insertion site of BTs during preexcitation, localization of sites of origin of ATs and VTs, and localization of endocardial or epicardial pacing sites.

Although ongoing research continues to address the role of BSPM, and how BSPM addresses many of the inadequacies associated with the conventional 12-lead approach, the clinical effectiveness of this procedure has not been established. BSPM is mostly used as a research tool, rather than a routine diagnostic method because of significant limitations.³²

Limitations

The main limitation of BSPM is the complexity of the recording, which requires many leads from each patient, sophisticated instrumentation, and dedicated personnel.³² Complexity of the interpretation is another limitation, because it is mostly based on pattern recognition and knowledge of variability in normal subjects and patients, features that are difficult to memorize. Therefore, visual inspection and measurement of BSPMs cannot result, per se, in direct localization of single or multiple electrical events as they occur in the heart. Furthermore, BSPMs do not offer a picture of the heart, but they show an attenuated and distorted projection of epicardial and intracardiac events on the body surface. Additionally, the method of interpolating maps from acquired data is vulnerable to the precision of localization of the electrode sites and to the assurance that each electrode is receiving a true signal.³²

Electrocardiographic Imaging

Fundamental Concepts

ECGI has three main components: a multielectrode ECG vest, a multichannel mapping system for ECG signal acquisition, and an anatomical imaging modality to determine the heart-torso geometry. ECGI is a cardiac functional imaging modality that noninvasively reconstructs epicardial potentials, electrograms, and isochrones (activation maps) from multichannel body surface potential recordings by using geometrical information from CT and a mathematical algorithm.^{34,35}

ECGI has two requirements: ECG unipolar potentials measured over the entire body surface and the heart-torso geometrical relationship relating the epicardial surface to the location of the recording ECG electrodes. The body surface ECG unipolar potentials are

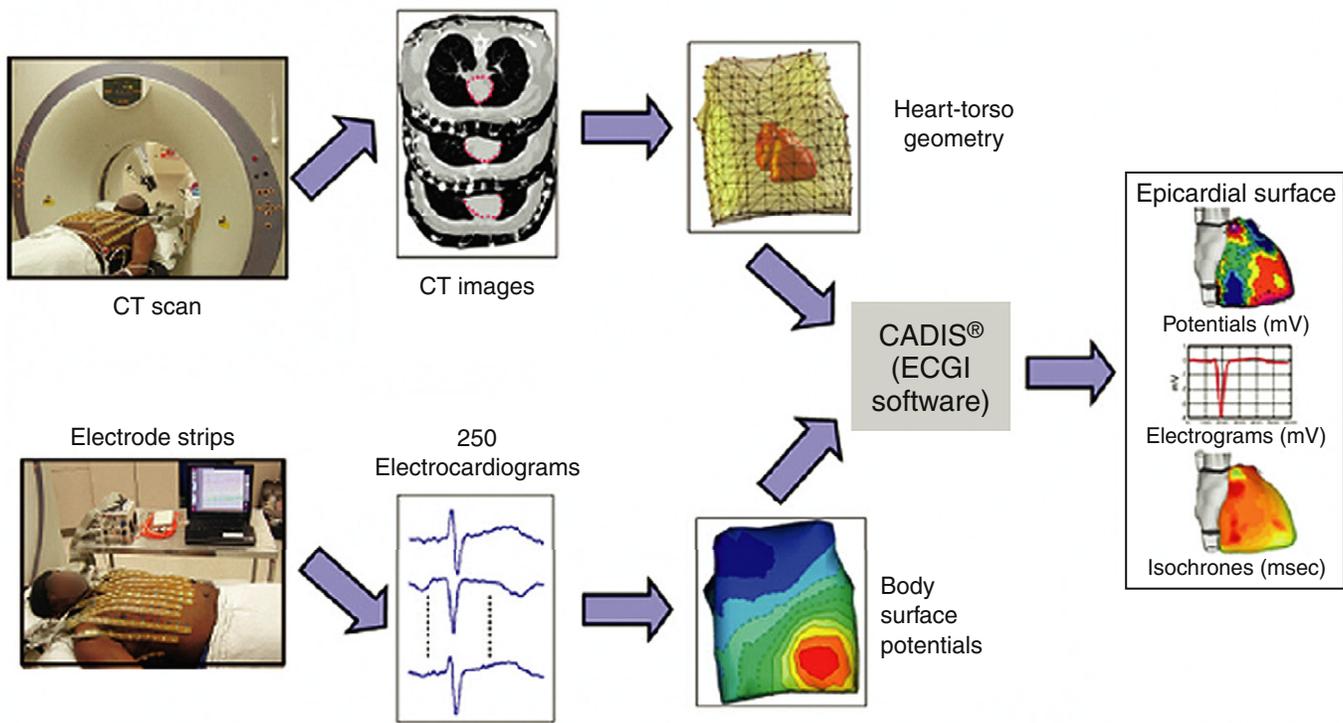

FIGURE 6-19 Electrocardiographic imaging (ECGI) procedure. Body surface potential mapping (BSPM) is recorded using a multichannel (256-electrode) mapping system. Noncontrast CT images with the body surface ECGI electrodes applied simultaneously record the locations of the electrodes (shining dots in CT images) and the geometry of the heart surface. By combining the BSPM and heart-torso geometry information, ECGI reconstructs potential maps, electrograms, and isochrones (activation patterns) on the epicardial surface of the heart. (From Wang Y, Cuculich PS, Woodard PK, et al: Focal atrial tachycardia after pulmonary vein isolation: noninvasive mapping with electrocardiographic imaging [ECGI]. *Heart Rhythm* 4:1081, 2007.)

measured using a multielectrode ECG vest. The prototype ECG vest has 250 electrodes arranged in rows and columns on strips, with Velcro attachments at the sides to secure the vest to the torso (Fig. 6-19). The vest is connected to a multichannel mapping system, which measures ECG unipolar potentials over the entire body surface and facilitates simultaneous signal acquisition and amplification from all channels. Body surface potentials are monitored to ensure proper contact and gain adjustment, and then signals are recorded over several heartbeats.³⁴⁻³⁷

After signal acquisition, the exact geometry of the epicardial and torso surfaces and vest electrode positions is obtained by anatomical imaging modalities, such as thoracic CT or MRI. Scans are usually set to an axial resolution between 0.6 and 1 mm and are typically gated at the R wave of the ECG to obtain diastolic volume (geometry for reconstruction of activation). Systolic volume, gated during the T wave of the ECG, is also measured to obtain suitable geometry for reconstruction during the repolarization phase. The transverse slices are segmented slice by slice to obtain heart geometry (as epicardial contours on each slice) and torso geometry (described by body surface electrode positions, seen as bright dots on the images; see Fig. 6-19). The geometry of the heart and torso surfaces is then assembled in a common x-y-z coordinate system to provide the geometrical heart-torso relationship.³⁴⁻³⁷

ECGI noninvasively computes potentials on the heart surface by solving the Laplace equation within the torso volume, with torso surface potentials and the geometric relationship between the epicardial and torso surfaces as inputs. The potential and geometry data are processed through CADIS, the ECGI software package (see Fig. 6-19). The software has four modules. The pre-processing module pre-processes the acquired ECG signals by noise filtration, baseline correction, elimination of bad signals (poor contact), and interpolation of missing signals. The geometry module includes image segmentation algorithms for heart and body surface segmentation and meshing of heart and torso surfaces. The numerical module includes boundary element algorithms to derive the transfer matrix

relating body surface potentials to epicardial potentials and epicardial potential reconstruction algorithms that use regularized inverse solutions such as Tikhonov zero-order or the generalized minimal residual methods to compute unipolar epicardial potentials from the transfer matrix and body surface potentials. Regularization is necessary because of the ill-posed nature of the inverse problem (i.e., large noise fluctuations in the input data [noise on the ECGs or inaccurate electrode locations] may precipitate large errors in the solution). The fourth module is the postprocessing module, which includes tools to analyze reconstructed epicardial data and formats for efficient visualization and analysis.^{36,37}

Four modes of display are typically used. Epicardial potential maps depict the spatial distributions of potentials on the epicardium (see Fig. 6-19). Each map depicts one instant of time; maps are computed at 1-millisecond intervals during the entire cardiac cycle. The electrograms depict the variation of potential with respect to time at a single point on the epicardium. The electrograms are computed at many points (typically 400 to 900 sites) around the epicardium. Isochrone maps depict the sequence of epicardial activation based on local activation time, taken as the point of maximum negative derivative ($-dV/dt_{max}$) of the QRS segment in each electrogram (intrinsic deflection). Recovery times are assigned as the point of maximum derivative (dV/dt_{max}) of the T wave segment. Activation times are determined as the time of maximum negative derivative in the epicardial electrograms. Information from neighboring electrograms is used to edit activation times in electrograms with multiple large negative derivatives. Lines of block are drawn to separate sites with activation time differences more than 30 milliseconds.^{34,35}

Clinical Implications

A noninvasive imaging modality for cardiac EP is much needed for risk stratification of patients with genetic predisposition or altered myocardial substrate (e.g., after infarction), for specific

diagnosis of the arrhythmia mechanism to determine the most suitable intervention, for determination of cardiac location for optimal localized intervention, for evaluation of efficacy and guidance of therapy over time, and for studying the mechanisms and properties of cardiac arrhythmias in humans. Noninvasive diagnosis of arrhythmias is currently based on the standard 12-lead ECG, BSPMs, or paced body surface QRS integral mapping. Standard diagnostic techniques such as the ECG provide only low-resolution projections of cardiac electrical activity on the body surface and cannot provide detailed information on regional electrical activity in the heart, such as the origin of arrhythmogenic activity, sequence of arrhythmic activation, or existence and location of an abnormal EP substrate.

ECGI reconstructs an epicardial electroanatomical map non-invasively by combining a 250-electrode body surface ECG with a CT scan of the heart-torso geometry. The ECGI images can be presented as epicardial potential maps, electrograms, isochrones, or repolarization maps during activation and repolarization. The major strengths of ECGI include the following: characteristics of activation can be analyzed at any point in the cardiac cycle with fine temporal resolution, atrial and ventricular patterns can be displayed, and information about the intramural nature of activation is available.

ECGI has been successfully applied and validated in human subjects, including comparison with intraoperative multielectrode mapping, determination of ECGI accuracy in locating focal sites of initial activation in humans by comparison with known locations of pacing electrodes in various RV and LV positions, comparison with catheter-based localization of focal VT, determination of the origin of human AT, and characterization of reentrant circuits.^{34,35,38} ECGI has been applied in humans to reconstruct epicardial activation and repolarization during normal sinus rhythm, right bundle branch block, ventricular pacing, ventricular preexcitation, focal tachycardias, and AFL, in open heart surgery patients, and in patients receiving devices for cardiac resynchronization therapy. Additionally, ECGI can image the reentry pathway and its key components in atrial and ventricular macroreentrant tachycardias, including the critical isthmus, its entry and exit sites, lines of block, and regions of slow and fast conduction. Although clinical reentry usually occurs in the endocardium, the subepicardium plays an important role in the maintenance of reentry in a small proportion of patients undergoing ablation therapy. Interpretation of intramural arrhythmogenic activity can be further enhanced by direct catheter mapping or noncontact catheter reconstruction of EP information on the endocardial surface simultaneously with noninvasive epicardial ECGI. The combination of epicardial and endocardial EP information, with knowledge of the intramural anatomical organization of the myocardium, can provide an unprecedented ability to localize arrhythmogenic activity within the myocardial depth by using only noninvasive or minimally invasive procedures.³⁶⁻³⁹

ECGI's ability to image noninvasively regions of dispersion of repolarization in the form of QRST integral maps (or other metrics of repolarization dispersion) during a single beat provides a feasible and computationally efficient method for evaluating the severity of the substrate in patients at risk of developing arrhythmias. Noninvasive reconstruction of epicardial measures of repolarization dispersion can therefore provide a tool for rapid screening of patients at a high risk of life-threatening arrhythmias. After screening, prophylactic measures (e.g., implantable defibrillators, ablation, drug therapy, or genetic or molecular modification) can be instituted before sudden cardiac death occurs. The significance of applying ECGI for risk stratification is amplified by the lack of sensitivity of body surface measures (e.g., QT dispersion) at reflecting underlying dispersion of repolarization.^{36,37,39}

Limitations

ECGI provides EP information about the heart's epicardial surface; it does not directly reconstruct endocardial information in the 3-D myocardium. Computation of endocardial activation is not

yet possible because the electrical signal amplitude from the mid-wall and endocardium is much smaller. Nevertheless, in contrast to BSPMs, epicardial potentials provide high-resolution reflection of underlying intramural activity.³⁵ In addition, ECGI can have limited success in defining components of arrhythmia pathways that involve small volumes of tissue, such as microreentry. Furthermore, the need to use CT limits the clinical application of ECGI during intervention in the EP laboratory, where CT is not available. To render the ECGI procedure more practical for mainstream adoption, newer methods for obtaining patient-specific geometry using biplane fluoroscopy or pseudo-3-D ultrasound have been developed and successfully tested in the context of ECGI in the EP laboratory.³⁹

Intracardiac Echocardiography

Catheter Design

Two types of ICE imaging systems are currently available: the mechanical ultrasound catheter radial imaging system and the electronic phased-array catheter sector imaging system.

MECHANICAL ULTRASOUND CATHETER RADIAL IMAGING SYSTEM

In the mechanical ultrasound catheter (Ultra ICE) radial imaging system (EP Technologies, Boston Scientific), the ultrasound transducer is mounted at the end of a nonsteerable 9 Fr (110-cm length) catheter and has a single, rotating, crystal ultrasound transducer. An external motor drive unit rotates the crystal at 1800 rpm within the catheter to provide an imaging plane that is 360 degrees circumferential and perpendicular to the long axis of the catheter, with the catheter located centrally. Mechanical ICE uses imaging frequencies of 9 to 12 MHz, which provide near-field clarity (within 5 to 7 cm of the transducer) but poor tissue penetration and far-field resolution. As a result, these systems have not allowed clear imaging of the LA and PV, except when they are introduced directly into the LA (transseptally). This technology lacks Doppler capability, and the catheter is not freely deflectable.⁴⁰

ELECTRONIC PHASED-ARRAY CATHETER SECTOR IMAGING SYSTEM

In the electronic phased-array ultrasound catheter (AcuNav) sector imaging system (Acuson Corporation, Siemens Medical Solutions, Malvern, Pa.), the ultrasound transducer is mounted on the distal end of an 8 or 10 Fr (90-cm length) catheter and has a forward-facing 64-element vector phased-array transducer scanning in the longitudinal plane. The catheter has a four-way steerable tip (160 degrees anteroposterior and left-right deflections). The catheter images a sector (wedge-shaped) field in a plane in line with the catheter shaft and oriented in the plane of the catheter. Imaging capabilities include 90-degree sector 2-D, M-mode, and Doppler imaging (pulsed-wave, continuous-wave, color, and tissue Doppler), with tissue penetration up to 16 cm, and variable ultrasound frequency (5.5, 7.5, 8.5, and 10 MHz).⁴⁰

Imaging Technique

USING THE MECHANICAL RADIAL INTRACARDIAC ECHOCARDIOGRAPHIC CATHETER

Initially, all air must be eliminated from the distal tip of the ICE catheter by flushing vigorously with 5 to 10 mL of sterile water to optimize the ultrasound image. The ICE catheter is introduced through a long femoral venous sheath. Because the catheter is not deflectable, preshaped angled long sheaths are preferred to allow some steerability.⁴⁰ The mechanical radial ICE catheter generates a panoramic 360-degree image perpendicular to the catheter, with the tip as a central reference point. The catheter is connected to

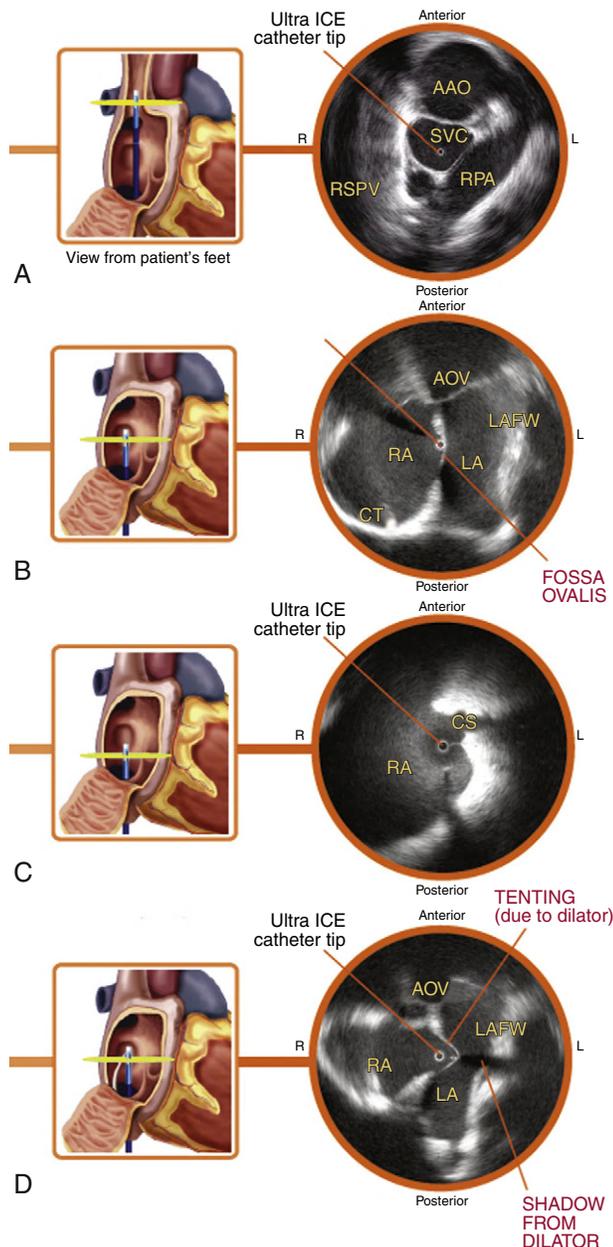

FIGURE 6-20 Mechanical radial intracardiac echocardiographic (ICE) images from different levels in the right atrium (RA) and superior vena cava (SVC). **A**, With the transducer tip in the SVC, typical structures visible in this plane are the ascending aorta (AAO), right pulmonary artery (RPA), and right superior pulmonary vein (RSPV). **B**, Withdrawing the ICE catheter into the mid-RA brings the fossa ovalis into view. Typical structures visible in this plane are the left atrium (LA), LA free wall (LAFW), aortic valve (AOV), and crista terminalis (CT). **C**, Withdrawing the ICE catheter down to the RA floor visualizes the coronary sinus (CS) and inferior vena cava (IVC). **D**, During transseptal puncture, tenting of the fossa is observed on the ICE. (Courtesy of Boston Scientific, Natick, Mass.)

the ultrasound console and advanced until the tip of the rotary ICE catheter image is in the RA.

When the transducer is advanced into the SVC, the ascending aorta, the right pulmonary artery, and, occasionally, the right superior PV are viewed.⁴¹ Withdrawing the catheter into the mid-RA brings the fossa ovalis and LA in view; the crista terminalis and aortic valve are usually visible in this view (Fig 6-20). The LA, left PV orifices, and aortic root are imaged by positioning the transducer at the fossa ovalis. However, visualization of the LA and PV ostia is limited because of limited penetration depth. Withdrawing the catheter to the low RA allows visualization of the eustachian valve, lateral crista terminalis, and CS ostium (see Fig 6-20).⁴¹ When the

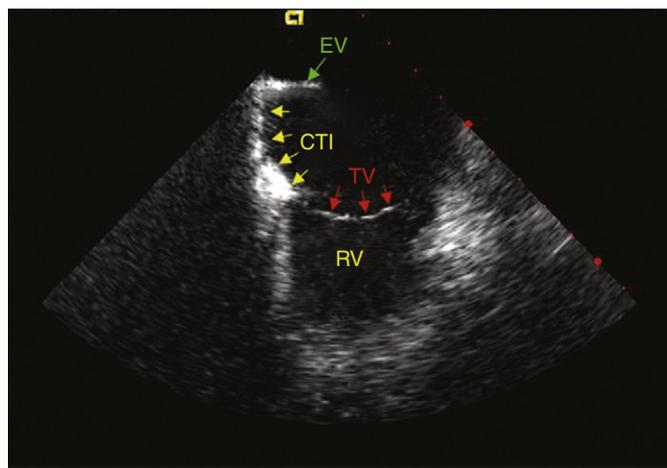

FIGURE 6-21 Intracardiac echocardiographic (ICE) image of the cavotricuspid isthmus (CTI, yellow arrows) between the eustachian valve (EV, green arrow) and the tricuspid valve (TV, red arrows). RV = right ventricle.

transducer is placed in the RV through the tricuspid valve and further advanced into the RVOT, both ventricles and the pulmonary artery can be visualized.

USING THE ACUNAV CATHETER

A femoral venous approach is used for the insertion of the ICE catheter. The catheter is advanced to the RA under fluoroscopy guidance. ICE 2-D 90-degree sector scanning demonstrates a cross-sectional anatomical view oriented from the tip to the shaft of the imaging catheter's active face.⁴⁰ The left-right (L-R) orientation marker indicates the catheter's shaft side. When the L-R orientation marker is set to the operator's right, the craniocaudal axis projects from the image top to bottom and the posterior to anterior axis projects from the image left to right from the image and the posterior to anterior axis projects from the image top to bottom. Changing the L-R marker to the left side inverts the image but does not change the top-to-bottom image orientation. Image orientation can be adjusted to visualize targeted structures by simple catheter advancement or withdrawal, by tip deflection in four directions (anteroposterior and left-right), or by catheter rotation.

The AcuNav ICE catheter includes variable ultrasound frequency (5.5, 7.5, 8.5, and 10 MHz). Increasing ultrasound frequency improves axial image resolution; however, tissue penetration decreases and reduces imaging depth. An ultrasound frequency of 7.5 MHz is useful for imaging most cardiac structures. Frequency can then be increased (to 8.5 or 10 MHz) for imaging near-field structures, or decreased (to 5.5 MHz) for imaging far-field structures.⁴⁰

RIGHT ATRIAL TARGETS. All RA targets are visualized by advancing or withdrawing the ICE catheter to an appropriate level within the RA and rotating the catheter to bring the target into view. The best resolution of near-field and mid-field structures is obtained at an 8.5-MHz frequency. Once the catheter is advanced into the mid-RA with the catheter tension controls in neutral position (the ultrasound transducer oriented anteriorly and to the left), the RA, tricuspid valve, and RV are viewed. This is called the home view (see Fig 4-13 and Video 5), and it can serve as a starting point; whenever the operator gets lost, he or she can go back to the home view and start over. From the home view, counterclockwise rotation of the catheter brings the RA appendage into view, whereas anterior deflection of the catheter tip toward the RV allows visualization of the tricuspid valve and cavotricuspid isthmus (Fig 6-21). The superior crista terminalis is visualized when the catheter is advanced to the RA-SVC junction in an anterior direction.⁴¹

INTERATRIAL SEPTUM. Gradual clockwise rotation of a straight catheter from the home view allows sequential visualization of the aortic root and the pulmonary artery, followed by the CS, mitral valve, the LA appendage orifice, and a cross-sectional

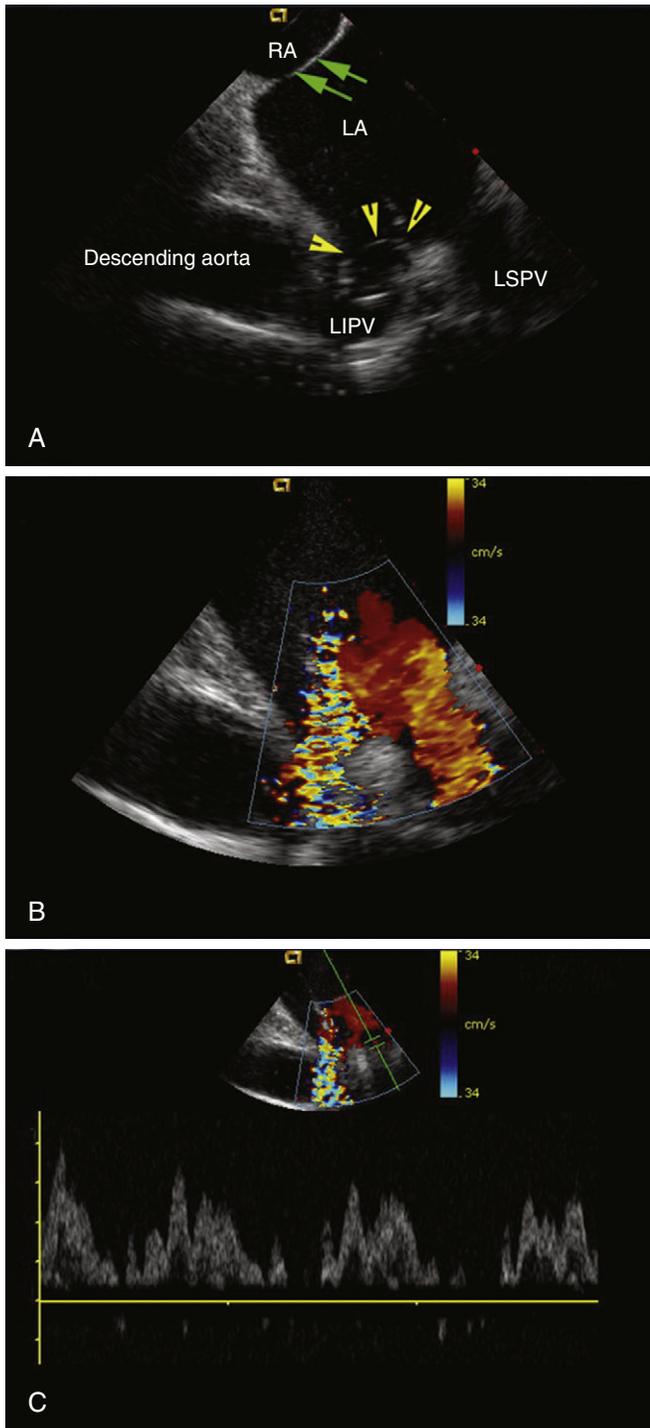

FIGURE 6-22 Intracardiac echocardiographic (ICE) images of the left pulmonary veins with transducer placed in the right atrium (RA). **A**, The RA, interatrial septum (green arrows), left inferior pulmonary vein (LIPV), left superior pulmonary vein (LSPV), and descending aorta are visualized. The Lasso catheter (yellow arrowheads) is visualized at the ostium of the LIPV. Color Doppler images of both LIPV and LSPV (**B**) and a pulsed-wave Doppler tracing (**C**) obtained from the LSPV are shown. LA = left atrium.

view of the fossa ovalis (see Fig. 4-13 and Video 5). The mitral valve and interatrial septum are usually seen in the same plane as the LA appendage. Posterior deflection, right-left steering, or both, of the imaging tip in the RA is occasionally required to optimize visualization of the fossa ovalis; the tension knob (lock function) can then be used to hold the catheter tip in position. Further clockwise rotation beyond this location demonstrates images of the left PV ostia (see Fig. 4-13). The optimum ICE image to guide

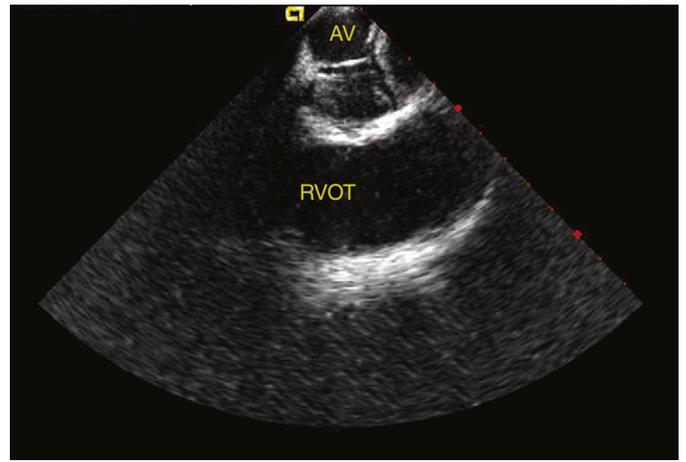

FIGURE 6-23 Short-axis view of the aortic valve (AV) cusps with the intracardiac echocardiographic (ICE) transducer placed in the midright atrium deflected near the posterior wall of the aortic root. RVOT = right ventricular outflow tract.

transeptal puncture demonstrates adequate space behind the interatrial septum on the LA side and clearly identifies adjacent structures (see Fig. 4-14 and Video 6).

LEFT ATRIAL STRUCTURES. A 7.5- or 8.5-MHz imaging frequency optimizes visualization of LA structures and PVs beyond the interatrial septum. PV imaging is possible by first visualizing the membranous fossa from a mid-RA to low-RA catheter tip position. With clockwise catheter rotation, the LA appendage can be visualized, followed by long-axis views of the left superior and inferior PVs (Fig. 6-22; see also Fig. 4-13). Further clockwise rotation of the catheter brings the orifices of the right superior and inferior PVs into view. The ostia of these veins are typically viewed en face, yielding an owl's eyes appearance at the vein's orifice. The LA appendage can also be visualized with the transducer positioned in the CS.

LEFT AND RIGHT VENTRICULAR TARGETS. Imaging of each targeted LV structure at depths of 6 to 15 cm is accomplished with the catheter tip in a low-RA position. When the catheter transducer is placed near the fossa and oriented anteriorly and to the left, the LV outflow tract (LVOT) and truncated LV are imaged. With clockwise rotation and slight adjustment of the transducer level, the mitral valve and LV apex can be viewed. To image the mitral valve in a long-axis, two-chamber view (LA, mitral valve, and LV), a mild degree of apically directed catheter tip deflection can be required. The RVOT, LVOT, and aortic root with coronary artery ostia can be imaged by advancing the catheter in the RA to the level of the outflow tracts (mid-RA), with an appropriate deflection to the right. The aortic valve can also be imaged in its cross section from this region (Fig. 6-23). A long-axis view of the LV can also be visualized by advancing the catheter with its anteriorly deflected tip into the RV with clockwise rotation against the interventricular septum (Fig. 6-24). Further clockwise rotation or right-left steering of the catheter tip allows a short-axis view of the LV, as well as the mitral valve (see Fig. 6-24). Pericardial effusions usually can be readily identified from these views. Withdrawing the catheter back to the base of the RVOT and rotating the shaft allow the RVOT to be visualized in its long axis, with a cross-sectional view of the pulmonic valve.⁴⁰

Clinical Implications

Transesophageal imaging has been used to guide ablation of VT and BTs, as well as transeptal catheterization, and for the closure of atrial septal defects or cardiac biopsy. This approach, however, has been limited in the interventional arena by aspiration risk and patient discomfort accompanying prolonged esophageal intubation, and it requires a second ultrasound operator to complete the study.

Previous human applications of ICE have been limited to those generated by the mechanical rotation of a single piezoelectric

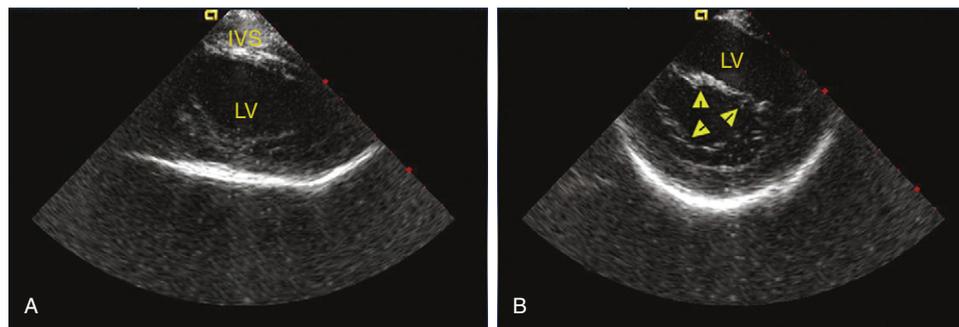

FIGURE 6-24 Intracardiac echocardiographic (ICE) images of the left ventricle (LV), with transducer placed in the right ventricle (RV) against the interventricular septum (IVS). **A**, Long-axis view of the LV. **B**, Short-axis view of the LV at the level of the mitral valve (arrowheads).

element in 6 to 10 Fr catheters. Miniaturization of these elements required the use of higher 10- to 20-MHz transducer frequencies, thus limiting ultrasound penetration to surrounding cardiac tissues. This technology has been applied to the imaging of RA structures in humans and animals, membranous fossa ovalis, crista terminalis, eustachian ridge, tricuspid annulus, and the SVC-RA junction in the region of the sinus node. However, visualization of the LA and PV ostia is limited using this system because of limited penetration depth, except when it is introduced directly into the LA (transseptally).

The electronic phased-array ultrasound system offers deeper field, standard intracardiac visualization of specific right- and left-sided cardiac structures, as well as color flow and pulsed-wave and continuous-wave Doppler imaging by a single operator. These features have been of significant value for PV isolation procedures and LA linear ablation for AF.

Several practical uses for ICE have emerged in the setting of EP procedures, including the following: (1) assessment of catheter contact with cardiac tissues; (2) determination of catheter location relative to cardiac structures (specifically useful in otherwise difficult to localize areas; e.g., the PVs); (3) guidance of transseptal puncture, particularly in the setting of complex or unusual anatomy; (4) facilitation of deployment of mapping or ablation systems (e.g., PV encircling devices, noncontact mapping systems, and basket technologies); (5) visualization of evolving lesions during RF energy delivery; both changing tissue echogenicity and microbubbles reflect tissue heating, with the latter providing a signal for energy termination; (6) evaluation of cardiac structures before and after intervention (e.g., cardiac valves and PVs); (7) assessment of PV anatomy, dimensions, and function via 2-D anatomical imaging and Doppler physiological measurements; (8) assessment of complications (e.g., tamponade, electromechanical dissociation, or thrombus formation; see Fig. 32-1)⁴²; (9) identification of the anatomical origin of certain arrhythmias (e.g., ICE can facilitate ablation of inappropriate sinus tachycardia or sinus nodal reentrant tachycardia); and (10) definition of the proximity of the catheter tip and coronary arteries (during mapping and ablation of arrhythmias originating from the aortic cusp).

As mentioned previously, the CARTOSound Image Integration Module (Biosense Webster, Inc.) incorporates the electroanatomical map to an ICE volume map of the cardiac chamber derived from a phased-array transducer catheter incorporating a position sensor (SoundStar, Biosense Webster, Inc.), which may be used as a stand-alone tool to guide navigation and ablation or as a facilitator of CT/MRI image integration. This navigation approach has been successfully utilized for catheter ablation of AF. Additionally, 3-D ultrasound images can potentially yield anatomically accurate chamber geometries and identify scar in the LV (both by wall thickness and motion) to facilitate substrate mapping and ablation of ischemic VT.^{12,13}

Computed Tomography and Magnetic Resonance Imaging

Fundamental Concepts

During catheter ablation procedures, the catheters are usually manipulated under the guidance of fluoroscopy. However,

fluoroscopy does not provide adequate depiction of cardiac anatomy because of its poor soft tissue contrast and the 2-D projective nature of the formed image, which hinders its application for complex procedures such as AF ablation. On the other hand, CT and MRI images offer anatomical detail in 3-D. However, these images are presented out of the context of the ablation catheter, thus greatly diminishing their potential value. An optimal strategy would therefore be to integrate the 3-D images generated by CT or MRI with the electrical and navigational information obtained by an interventional system. This can be achieved through the process of integration. Image integration refers to the process of aligning the pre-procedural cardiac CT and MRI images with the real-time 3-D electroanatomical maps reconstructed from multiple endocardial locations. The process of image integration consists of three steps: pre-procedural CT and MRI image acquisition, image segmentation and extraction, and image registration.

IMAGE ACQUISITION

Cross-sectional or axial CT or MRI images are acquired at sufficient resolution to delineate cardiac structures less than 1 to 2 mm in thickness. Images at 0.625-mm thickness can be reconstructed from images obtained at 1.25-mm intervals with currently available multirow helical scanners. A simultaneous ECG is recorded to assign the source images retrospectively to the respective phases of the cardiac cycle. MRI images are similarly obtainable, although at a slightly lower spatial resolution. Reconstructing any cardiac chamber in 3-D from the axial images is performed using any one of various software packages.⁴³

IMAGE SEGMENTATION

Image segmentation refers to the process of extracting the 3-D anatomy of individual cardiac structures from its surrounding structures. Methods of image segmentation include thresholding, boundary detection, and region identification. Thresholding involves assigning pixels with intensities lower than a threshold to one class and the remaining pixels to a different class. Connecting adjacent pixels of the same class then forms regions. Boundary differentiation methods use information about intensity differences between adjacent regions to separate the regions from each other. Region identification techniques then form regions by combining pixels of similar properties.⁴³⁻⁴⁵ For cardiac ablation procedures, the volume of cardiac structures is extracted from the whole-volume data set using a computerized algorithm that differentiates the boundary between the blood pool (which is high in contrast) and the endocardium (which is not contrast enhanced). This allows for clear differentiation between the chamber lumen and endocardial wall (Fig. 6-25). Subsequently, the volumes of individual cardiac structures are separated from each other with the use of another algorithm capable of detecting their boundaries. Using a third algorithm, the segmented volumes for individual cardiac structures are extracted as 3-D surface reconstructions. The segmented volumes can be viewed from an external perspective or from within the chamber using virtual endoscopic or cardioscopic displays. These images, in addition to providing a road map for ablation, can also be used for registration (see Fig. 6-25).

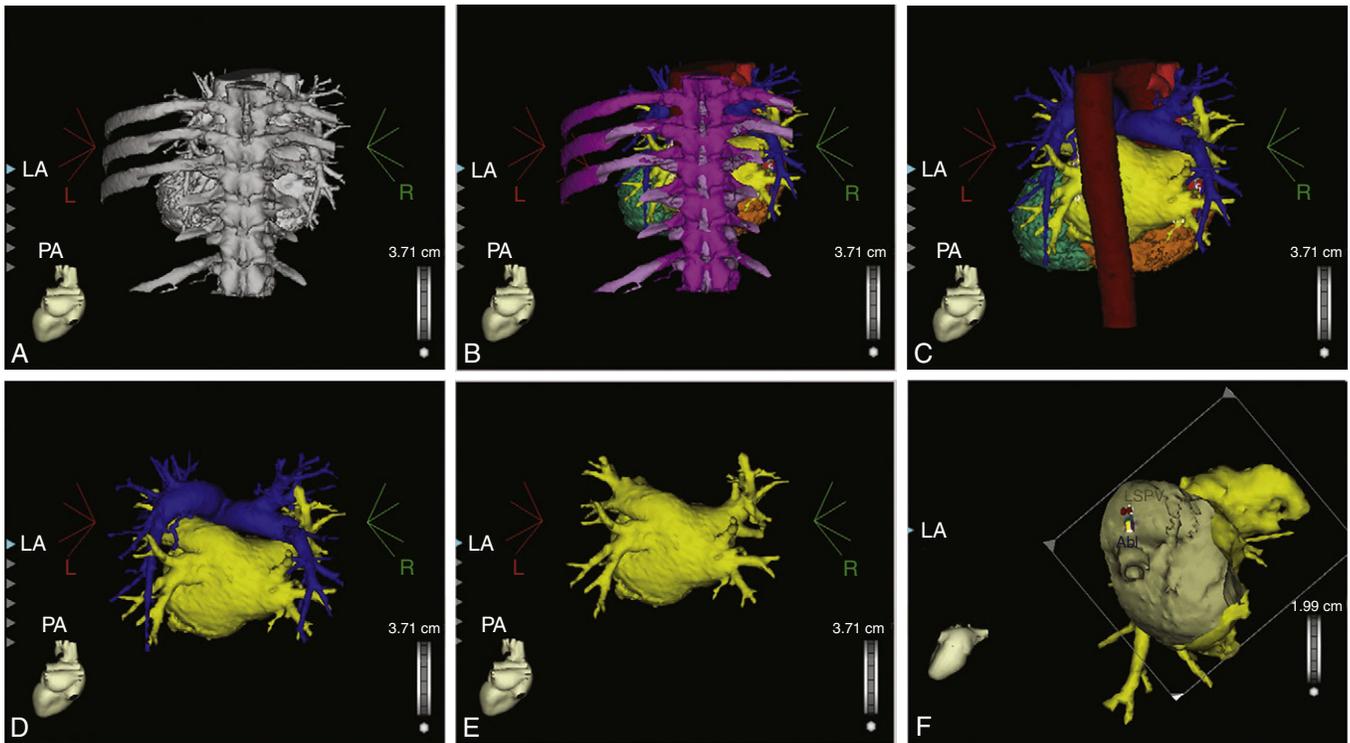

FIGURE 6-25 CT image segmentation and integration with electroanatomical mapping (CARTO) data. **A**, Three-dimensional reconstruction of the heart and part of the spine from the two-dimensional CT image (posteroanterior [PA] view). **B** and **C**, Individual cardiac chambers are segmented from each other using computerized algorithms capable of detecting their boundaries (aorta, red; left atrium [LA], yellow; left ventricle, green; pulmonary artery, blue; right atrium, orange). **D** and **E**, The cardiac chamber is selected (LA in this case), and others are deleted. **F**, Integration of CT and electroanatomical mapping (CARTO) data. Shown is a left lateral cardio-scope view of the ostia of the left pulmonary veins (PVs) during PV electrical isolation. Radiofrequency applications (small red circles) were deployed at the posterior aspect of the ostium of the left superior PV (LSPV). The ablation (Abl) catheter tip is positioned at the inferior aspect of the LSPV.

IMAGE REGISTRATION

Although the segmented structures are highly useful for visualizing the cardiac structures and characteristics of the tissue forming that structure, they do not convey the physiology of an arrhythmia. Integrating that physiology, as captured by electroanatomical or noncontact mapping with the spatial information contained in the CT or MRI images, requires registration of activation or voltage data to an appropriate location on a 3-D representation of a chamber. This is of critical importance in that it establishes the relationship between anatomy and physiology as required for the structure- and activity-based understanding of arrhythmias and for enabling image-guided intervention. Image registration refers to superimposing the 3-D CT/MRI surface reconstruction onto the real-time electroanatomical maps yielded by the 3-D mapping system (see Fig. 6-10).

During registration, the assumption is made that the anatomy of the organ being registered has not changed. Two computerized algorithms are used to accomplish the image registration process: landmark registration and surface registration. Landmark registration aligns the 3-D CT/MRI image reconstruction with corresponding electroanatomical maps through linking two sets of corresponding fiducial points in each set of the images to be registered. Under the guidance of fluoroscopy or ICE, or both, at least three landmark pairs are created by real-time catheter tip locations on the interventional system being used for registration and then placed on their estimated locations on the 3-D CT/MRI image reconstructions. Using more landmark points increases the accuracy of the registration process. Surface registration is an algorithm that attaches the acquired endocardial points to the closest CT/MRI surface to compose the best fit of the two sets of images by minimizing the average distance between the landmarks, and the distance from multiple endocardial locations, to the surface of 3-D CT/MRI image reconstructions. Surface registration complements landmark registration to improve the registration accuracy.

However, because of surface indentation and potentially missed areas during mapping, the acquired electroanatomical map does not represent the perfect anatomy of the cardiac chamber.⁴³⁻⁴⁵

COMPUTED TOMOGRAPHY OVERLAY

A novel application (EP Navigator prototype, Philips Healthcare, Best, The Netherlands) has been developed to superimpose a preacquired segmented 3-D CT image of the LA over real-time fluoroscopy system (“CT overlay”) to help in guiding ablation of atrial arrhythmias, particularly AF. This application can be used on monoplane or biplane fluoroscopy. It permits fluoroscopy-directed guiding of an ablation catheter and diagnostic catheters in a virtual 3-D model of the LA, and subsequent tagging of ablation sites on the registered 3-D image without the simultaneous use of an electroanatomical mapping system, thus facilitating the creation of continuous lines and returning to critical ablation sites. Furthermore, it is feasible to identify and segment the esophagus on the CT scan, which can subsequently be overlaid on the fluoroscopic images along with the cardiac structures.⁴⁶⁻⁴⁸

Image Integration Procedure

IMAGE REGISTRATION USING CARTOMERGE

The preacquired CT/MRI digital imaging data are imported by a CD into the CARTO XP system equipped with commercially available software (CARTOMerge Image Integration Software Module) that allows structures of interest to be easily and quickly segmented and reconstructed in 3-D. The segmented images are then imported into the real-time mapping system. Once created using the CARTO system (as described previously), the electroanatomical map of the cardiac chamber is “fused” to the CT/MRI. The most frequently used registration technique is a combination of *landmark*

registration and *surface registration*. Landmark registration involves the 3-D orientation of the imported CT/MRI image on the x, y, and z axes and requires the acquisition of at least three noncollinear endocardial landmark points using the mapping-ablation catheter. The precise location of these on the 3-D image is a critical factor in this technique and remains challenging. Biplane fluoroscopy, angiography, and ICE can be used to facilitate identification of the landmark point. Catheter contact is ensured by fluoroscopy visualization of the catheter mobility in relation to the cardiac motion and by a discrete electrogram. The estimated corresponding locations of these endocardial landmark points are then marked on the imported 3-D CT/MRI image, thus creating a landmark pair, with one landmark point on the real-time electroanatomical map and the other on the 3-D CT/MRI image.

Landmark registration approximates the electroanatomical map to the 3-D CT/MRI surface reconstruction by matching the landmark pair. Surface registration fits the 3-D CT/MRI surface reconstruction with the electroanatomical map points by rendering the smallest average distance of the two datasets. Although the registration of surface points should improve alignment of the two images, registering points from the entire surface of the cardiac chamber involves the risk of incorporating errors related to potential indentation of the chamber wall and distortion of chamber geometry resulting from the pressure of the mapping catheter on the most mobile regions. The mapping system then provides an average tip-to-surface distance, which ideally should be less than 2 mm. While manipulating the catheter during ablation, the projected catheter distance to the surface is used as an additional guide to assess catheter contact. This can be complemented by information from electrograms recorded by the catheter, fluoroscopy, and ICE.¹⁶

IMAGE REGISTRATION USING CARTOSOUND

The CARTOSound utilizes a 10 Fr phased-array ICE catheter with an embedded navigation sensor (SoundStar, Biosense Webster, Inc.), which records individual 90-degree sector image planes of the cardiac chamber of interest, including their location and orientation, to the CARTO workspace. To correct for respiratory phase, all ICE images should be acquired during expiratory breath-hold. Once the CARTOSound volume map of the cardiac chamber is created, registration is performed using CARTOMerge software. First, the CT/MRI image is visually aligned with the ICE-created cardiac chamber anatomical shell. Second, landmark registration is performed whereby three echocardiographically discrete anatomical sites identified with ICE (landmark points) are tagged on the ICE contour and matched to a corresponding location on the CT/MRI image. Finally, the CARTOMerge surface registration algorithm is performed. This algorithm attempts optimally to juxtapose, or integrate, the CT/MRI image spatially with the CARTOSound model to minimize the average distance between each point on the ICE-created anatomical

rendering of the cardiac chamber and the corresponding CT/MRI image, thus permitting the CT model to guide navigation.

Registration is based on the best fit between the cardiac chamber surface reconstruction obtained with each ICE contour and the corresponding CT/MRI image, and it is not based on the LA volume obtained with ICE and the corresponding CT/MRI image.¹² ICE-guided focused endocardial surface registration seems to be superior to landmark registration in achieving a better alignment between the CT/MRI image and the electroanatomical map. The 3-D ultrasound images can help create anatomically accurate, real-time chamber geometries and eliminate chamber deformity (as often happens with contact mapping), potentially to yield more accurate CT/MRI registration.^{12,13}

IMAGE REGISTRATION USING NAVX FUSION

The cardiac chamber of interest is segmented and reconstructed in 3-D from CT/MRI slices using EnSite Verismo software. The 3-D virtual anatomical geometry of the cardiac chamber is created using NavX Fusion (as described previously). The CT/MRI reconstruction of the mapped cardiac chamber is displayed on a split screen and used to guide finer anatomical definition with the ablation catheter and help edit the virtual 3-D geometry to eliminate “false space.” Subsequently, “field scaling” is applied to the geometry to compensate for variations in impedance between the heart chambers and venous structures and render the geometry and navigational space more physiologically relevant and to more closely resemble the CT/MRI image. The field scaled geometry is fused to the CT/MRI in two stages, termed *primary (rigid) fusion* and *secondary (dynamic) fusion*. Primary fusion uses three fiducial (i.e., landmark) corresponding points on the created geometry and the CT/MRI image to superimpose, or lock together, both images (Fig. 6-26). These points are chosen to ensure reasonable 3-D anatomical separation and allow orientation of the CT/MRI, but the registration error is high. Therefore, secondary fusion points or fiducials are applied to the primary fused geometry at sites of local mismatch between the two superimposed geometries.

In this unique component of image fusion, the created geometry surface is molded to the CT/MRI surface while also “bending” the 3-D navigation space within the geometry. This process is continued, adding supplemental (usually more than 15) fiducial point pairs until good correspondence between the NavX geometry and CT/MRI models is achieved. For example, if the anterior wall of the geometry is fused anteriorly to the CT/MRI, the catheter location also will be moved so that, when the catheter is repositioned on the anterior wall after fusion, it should be visualized on the CT/MRI surface and not within the bounds of the original prefusion geometry. Although the principle of CT/MRI image integration is common to both the EnSite NavX Fusion and CARTOMerge systems, there is a significant difference in how registration is achieved.

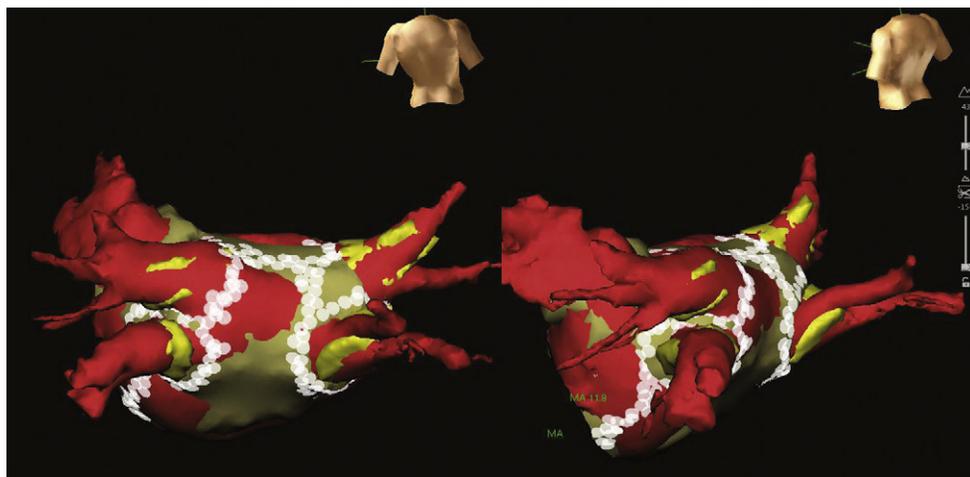

FIGURE 6-26 Integration of CT and ESI-NavX electroanatomical mapping data. Shown are posterior anterior and left lateral views of the electroanatomical contour acquired with catheter manipulation in the left atrium during atrial fibrillation ablation overlaid on a CT image of the left atrium acquired several days earlier. Small white circles are tagged sites at which radiofrequency energy was applied to isolate the pulmonary veins. MA = mitral annulus.

As described previously, the EnSite system uses a dynamic registration process (with four or more fiducials) to optimize both rotation and stretching of the surface of the NavX geometry to match the CT/MRI. With the CARTOMerge system, the whole registration process is rigid with rotation of the CT/MRI to minimize the distance between the surface of the anatomical model generated and that of the CT, but no stretching of the model itself. Despite this difference, the registration error is similar with both techniques (CARTOMerge, 2.3 ± 1.8 mm, versus EnSite NavX Fusion, 3.2 ± 0.9 mm).^{19,49}

IMAGE REGISTRATION USING FLUOROSCOPY (CT OVERLAY)

The preacquired CT data set is imported into the software, the cardiac chamber of interest is automatically segmented, and a 3-D volume of the LA and PVs is constructed. Before CT registration is performed, the patient must be properly positioned, and the structure of interest must be isocentered in two orthogonal fluoroscopic projections. Initial registration is based on the heart contour to allow for quick alignment of the CT-rendered volume with the fluoroscopic image. On an anteroposterior fluoroscopic projection (without contrast injection), the CT volume overlay is aligned by first using the right lateral atrial contour. The rest of the cardiac contour then is superimposed on the fluoroscopic image, based on the best visual estimate. Subsequently, fluoroscopic identification of intracardiac landmarks by catheter manipulation within the LA and PVs improves the overlay accuracy (e.g., caudal drop of the catheter when withdrawing from a PV into the LA helps identify the PV ostium; insertion of the ablation catheter into readily identifiable anatomical landmarks such as PV branches immediately connected to PV ostium, accessory PVs; and looping of the ablation catheter in the LA resulting in circumferential catheter-endocardium contact). Finally, angiography of the right and left superior PVs (sequentially or simultaneously) in two orthogonal views is performed to adjust the CT image further and improve registration by matching the superior border of the LA and the superior PV ostia, as well as certain landmarks, such as PV bifurcations, between 3-D image and fluoroscopy.

After registration and locking, the 3-D CT image is always depicted at the same angle as the fluoroscopy (i.e., the CT-generated volume rotates on the screen following the rotation of the C-arm), thus allowing for constant visualization of the CT and fluoroscopic images under the same viewing angle. The transparency of the overlaid CT 3-D volume is adjustable, to allow visualization of the catheters in the fluoroscopic image. In addition, the 3-D image can be clipped with a customizable cutting plane, to permit internal (endoscopic) views. Moreover, tags can be placed on the surface of the registered 3-D image to mark ablation sites and other sites of interest.⁴⁶⁻⁴⁸

Clinical Implications

CT and MRI imaging approaches have already been of significant benefit in AF catheter ablation procedures. These approaches provide critical information regarding the number, location, and size of PVs, as needed for planning the ablation and selecting appropriately sized ablation devices.⁵⁰ Resulting images also identify branching patterns of potentially arrhythmogenic PVs, disclose the presence of fused superior and inferior veins into antral structures, and clarify the potentially confounding origins of far-field electrograms that masquerade as PV potentials. CT has also been used for postablation evaluation for PV stenosis.

The 21st century has also seen the rapid development of integrated, anatomy-based mapping and ablation. This progress has been driven by a realization of both the critical coupling and dependence of arrhythmias on their underlying anatomy and the limitations of surrogate geometries of contemporary mapping systems for reflecting that anatomy. Over this same time frame, rapid CT and MRI imaging systems have emerged as the mainstays of

imaging in the EP laboratory and have been used to plan or guide ablation. Each company is actively working on image incorporation into its system.^{11,47,51} Helical 16- to 64-row CT and MRI studies provide a broad anatomy library of an individual patient at one point in time. Segmented CT volumes can be downloaded on the CARTO and NavX platforms. These systems are able to register the surrogate map fully onto actual CT and MRI anatomy; they also enable integration of electroanatomical mapping with preacquired CT and MRI images and allow real-time visualization of the location and orientation of the catheter tip within the registered CT anatomical framework (see Figs. 6-10 and 6-25).^{4,16,43-45}

The use of registered CT and MRI images to guide catheter ablation presents a significant advantage over the less detailed surrogate geometry created by previously available 3-D mapping systems. Because it provides detailed anatomical information on the catheter tip location in relation to the true cardiac anatomy, the image integration technique has the potential to facilitate many ablation procedures, especially anatomically based ablation strategies, such as AF ablation (see Video 13), nonidiopathic VT ablation, and ablation of intraatrial reentrant tachycardias following corrective surgery for congenital heart diseases. Initial experience has shown that the registered CT and MRI of LA reconstructions can provide accurate information on the catheter tip location in relation to the important LA structures, such as the PV ostium and LA appendage. The real-time update of the catheter tip location and the marking of ablation lesions on the detailed 3-D image can potentially improve the quality of lesion sets, reduce complications, and shorten procedure and fluoroscopy times.

Registration of a preacquired 3-D CT image on fluoroscopy potentially combines the accuracy of CT with the real-time fluoroscopy to guide catheter ablation of AF. Compared with an established and widely used electroanatomical mapping technique for PV antrum isolation, procedural duration can be shortened significantly without a concomitant increase in radiation burden. An additional advantage to CT overlay is the ability to perform a quick repeat registration in case of major changes in a patient's position. However, unlike the CARTO system, which provides notification for significant patient movements, the operator needs to be alert on discrepancies between catheters and anatomy and must check registration in case of suspected movement. Additionally, with the CARTO system, one can return to the catheter-based LA reconstruction without Merge, which may be more accurate than the CT image.⁴⁶⁻⁴⁸

Limitations

Although CT and MRI provide exquisite images of the underlying structures relevant in arrhythmogenesis, they are limited by the requirement of off-line generation of the CT and MRI libraries and the inability to reflect all phases of the cardiac cycle during an arrhythmia. Because CT and MRI is performed prior to the ablation procedure, registration error can arise from interval changes in the heart size because of differences in rhythm, rate, contractility, or fluid status. Performing image registration and ablation procedures within 24 hours after CT and MRI scans and CT and MRI image acquisition and image registration during the same rhythm may help limit interval changes. This situation is confounded by the inevitable imperfection of the created virtual geometry of the cardiac chamber. These factors can impede the clinical utility of image integration in approximately 25% of patients.⁵²

Furthermore, the static images of the registered CT and MRI reconstructions provide little information on true catheter-tissue contact. In addition, because the initial landmark points are picked up by the operator using fluoroscopy, the exact location of these points in the 3-D space can be deceptive, and registration errors in the identification of these points are very common, even when angiography and ICE are used for guidance. In addition, because multiple points are needed for surface registration, the accuracy of chamber reconstruction is directly dependent on the number of points taken and the position of the catheter, thus adding

a significant amount of time and a manual component to the process.^{4,43,47,53}

To overcome some of these limitations, fusion of real-time ICE images with those generated by CT and MRI scans is becoming available and can provide a more real-time interactive display, as well as real-time information on catheter-tissue contact and RF lesion formation. In addition, it is highly likely that subsequent generations of CT or MRI scanners will be sufficiently fast to permit real-time or almost real-time imaging for interventional guidance. Studies have demonstrated the ability to merge the 3-D CT and MRI images with real-time 2-D fluoroscopy images for navigation on virtual anatomy, because the images can be corrected against the background of real-time fluoroscopy as needed.^{4,47,54}

The accuracy of registration remains the subject of investigation. 3-D image integration aims at improving the operator's perception of the catheter spatial location in relation to the patient's cardiac structures. However, the success of this approach is primarily dependent on the accuracy of the image integration process. Even if the 3-D cardiac chamber image provides an accurate model of a matched phase of the chamber volume at the time of the procedure, it needs to be accurately registered to the procedural chamber orientation to provide reliable navigation. Current registration algorithms depend on accurate catheter geometry; this requires an accurate update of 3-D coordinates of the catheter tip, as recorded and displayed on the computer image. The exact location of the initial fiducial points picked by the operator using fluoroscopy in the 3-D space may be deceptive. Movement of the catheter tip is complex and is affected by wall motion and respiration. Point collection should therefore be gated to the same phase of the cardiac and respiratory cycle as the CT or MRI scan. Additionally, catheter tip pressure can cause tenting of the chamber wall, thereby distorting the chamber geometry. Stability of catheter contact with the endocardial wall should also be optimized. Catheter contact can vary with the type of ablation catheter and introducer sheath, as well as the degree of regional wall motion; for example, the mitral annulus and appendage are more dynamic than the posterior atrial wall. Ideally, geometry points should be collected from stable catheter positions. The operator can then accept good points or delete bad points. This process can be aided by fluoroscopy, electrogram morphology, and confirmation of the catheter tip location on ICE. However, the process still remains a subjective art.^{43,53}

Several studies of AF catheter ablation have reported success using different integration modalities with CT or MRI, by using either noncontact mapping or fluoroscopy as a second integrated image. The registration technique has also varied, including three- or four-point registration or surface registration. Alternatively, a single point and the surface have been used as well (visual alignment). Different techniques for point localization have been reported, including fluoroscopy alone, angiography, or ICE for direct visualization of the catheter at the designated site. The mean error for surface registration in most studies varied between 1.8 and 2.7 mm; one study that compared the landmark registration with and without surface registration found that surface registration increases the accuracy of image integration. On the other hand, a more recent study found that the most accurate landmark registration is achieved when posterior points are acquired at the PV-LA junction, whereas points acquired on the anterior wall, LA appendage, or other structures outside the LA, such as the CS or SVC, afford less accuracy. In addition, surface registration usually results in shifting the landmark points away from the initially acquired position on the corresponding PVs using ICE.⁵⁵ Furthermore, accurate surface registration does not guarantee accurate alignment with the important anatomical structures. Another report found that serious inaccuracies of the CARTOMerge image integration algorithms still exist, despite using the precautions discussed earlier.⁵⁶ Importantly, registration quality has not yet been shown necessarily to correlate with ablation accuracy.^{12,56}

It is important to recognize that the registered CT model still is prone to subjective inaccuracies and should remain only a guide, and a combination of fluoroscopy and the electrogram

appearance must also be used in assessing contact with the endocardial surface and the true position of the catheter. Although 3-D mapping systems with image integration have been widely adopted for ablation procedures, many of their theoretical benefits remain unproven; therefore, these systems should remain just one type among the tools facilitating complex catheter ablation procedures and should not distract the electrophysiologist from established EP principles and endpoints.⁵⁷

Three-Dimensional Rotational Angiography

Fundamental Concepts

3-D rotational angiography combines the accuracy of direct angiography with the benefits of computer animation and supplements conventional 2-D fluoroscopy to provide real-time representation of cardiac structures. Its feasibility and clinical utility in the setting of LA imaging and AF ablation have been described. This method provides rapid intraprocedural visualization of LA anatomy and of important nearby structures such as the esophagus. Prior studies have demonstrated that the diagnostic value of 3-D rotational angiography is comparable to that of CT imaging.^{58,59}

The principle of 3-D rotational angiography is similar to the CT scan, in which images acquired from different angles are reconstructed to a 3-D image. The C-arc x-ray system is rotated around the patient over 240 degrees to create a circumferential run of many exposure images of the region of interest distributed over the 360-degree (or similar) trajectory. To improve differentiation of the cardiac structures, the cardiac chamber of interest can be opacified with a contrast medium injected either directly into the LA or indirectly into the right side of the heart, in which case rotation of the fluoroscopic system is started after passage of the contrast medium through the lungs. The esophagus can be opacified using a barium paste prior to the image acquisition. The rotational angiographic images of the LA, PVs, esophagus, and other surrounding structures can be segmented and registered with the fluoroscopy on a specialized computer system (EP Navigator, Philips Healthcare or similar system, such as DynaCT Cardiac, Siemens, Forchheim, Germany). The latest version of the software allows registration of the segmented 3-D volume on a live fluoroscopy screen.^{60,61}

Imaging Technique

First, the patient must be properly positioned, and the structure of interest must be isocentered. The patient's arms may be extended above the head to reduce mass artifact. Oral contrast (5 mL barium sulfate esophageal cream) is administered immediately prior to initiation of the rotational run, and once it is visualized in the esophagus, intravenous contrast may be injected into the main pulmonary artery, RV, RA, or IVC via a 6 Fr pigtail catheter to obtain adequate levophase opacification of the LA. In general, contrast injection at the IVC-RA junction results in adequate LA and PV opacification in most patients. In addition, this method is technically simpler and potentially safer than more downstream injections. Higher amounts of contrast and longer injection time are generally used with RA and IVC injections than with main pulmonary artery injection. Direct contrast injection into the LA was described and seemed to provide great detail of LA and PV anatomy, but it required a high-dose (30 to 50 mg) adenosine injection immediately prior to the rotational run. Transient cessation of contractions prevents antero-grade washout of contrast from the PVs, thus keeping them opacified during the rotational run. Deep sedation, intubation, and RV pacing are usually needed to counteract apnea and asystole produced by adenosine. Additionally, high doses of adenosine are not tolerated by the conscious patient because of the induced flush and dyspnea. Given such complexities, this method may be more difficult to implement in clinical practice.⁵⁸⁻⁶¹

For injection at the RA-IVC junction, 80 to 100 mL of contrast is injected over 4 seconds via a pigtail catheter using a power injector. The C-arm is rotated over a 240-degree arc (120-degree RAO to 120-degree LAO view) in a 4.1-second period. The x-ray acquisition speed is 30 frames per second, which results in a total of 120 frames in the rotational run. Continuous fluoroscopic monitoring for contrast appearance in the LA is used to trigger the rotational run, based on visual guidance rather than on an empirically determined delay. The patient is instructed to stop breathing immediately prior to initiation of the rotational run to prevent respiratory movement of the structure of interest and inadequate reconstruction. Normal breathing can be resumed immediately on the completion of rotation.

The rotational angiogram is judged to be adequate when the LA is filled with contrast during most of the run and antral portions of all PVs are opacified without truncation. A resultant movie file is then transferred to an EP Navigator workstation to be segmented and overlaid on a live fluoroscopy screen. After the catheters are advanced into the LA, the 3-D image is used for navigation. With registration of the 3-D volume, all movements of the C-arm are translated into the appropriate rotation or shift, thus keeping the relationship between the fluoroscopic heart shadow and reconstructed image unchanged.

Image integration of intraprocedural rotational angiography-based 3-D reconstructions of LA and PVs into the electroanatomical mapping system (CARTOMerge) has become feasible. The images of the segmented LA are saved on a compact disc and transferred to the electroanatomical mapping system by using custom-designed software and integrated without further segmentation.

Theoretically, no registration for 3-D rotational angiography image overlay is necessary if the original x-ray table position and the patient's position during the rotational run are maintained. However, moving the x-ray table is often required after 3-D rotational angiography, especially given the fact that intracardiac catheters should be placed only after the rotational run to prevent artifacts. Therefore, registration is often necessary because, in its current iteration, overlay movement is linked only to C-arm rotation and not to x-ray table repositioning. Several registration methods using different primary landmarks, such as catheter placement, heart contour, and PV angiography, have been evaluated. These methods are particularly useful when registering previously obtained CT images on live fluoroscopy (i.e., CT overlay), which is another imaging input available in the EP Navigator (as discussed previously).

The current software version allows for the inner surface of the LA and PVs to be visualized (endoscopic view), further aiding the physician when navigating around the LA. Ablation points can be marked on the overlaid 3-D rotational angiography model to track the completeness of lesions. LA proximity to the esophagus can be evaluated and catheter ablation modified as necessary to avoid ablation near the esophagus.⁶²⁻⁶⁴

Clinical Implications

One of the advantages of 3-D rotational angiography over conventional 2-D fluoroscopy is the capability of depth perception and volume appreciation. 3-D rotational angiography provides direct visualization of cardiac structures, whereas electroanatomical methods require either operator imagination or confirmation via other imaging modalities, such as CT. Although pre-procedure CT/MRI images provide visualization of the LA and the PVs and facilitate integration with the electroanatomical mapping systems, a significant drawback is the time lag to the actual procedure. Interval changes in volume status, respiratory phase, and cardiac rhythm can result in temporal changes in the size and location of the anatomical structures between the time of image acquisition and the registration process. These limitations may be overcome by intraprocedural acquisition of the LA volume and PV anatomy; 3-D rotational angiography can be performed immediately before ablation using the same fluoroscopic imaging system, thus providing realistic anatomical detail at the time of the intervention.⁵⁸⁻⁶⁰

Other advantages of 3-D rotational angiography technology include quick and accurate repeat registration of the 3-D volume in case of patient movement not requiring a new map, as is frequently the case with electroanatomical methods.^{61,62}

Despite exclusively fluoroscopic guidance of the ablation catheter using the 3-D rotational angiography technology, total fluoroscopy time and fluoroscopy time for PV isolation have been comparable to reported times for AF ablation procedures performed with different nonfluoroscopic mapping systems. Additionally, 3-D rotational angiography has the potential to eliminate the need for pre-procedural CT/MRI imaging, and the radiation exposure is less than that of CT scanning (estimated at 2.2 ± 0.2 mSv exposure with one rotational angiography run).^{63,64}

Imaging by 3-D rotational angiography should not be confined to the LA and PVs. Other cardiac structures (current possibilities include RA and RVOT) can be easily visualized by timing the rotational run with the passage of contrast through the structures. The possibility of "whole heart" imaging has been reported.

Limitations

The use of contrast makes 3-D rotational angiography a less appealing option for patients with heart failure or insufficiency. In addition, the technique is sensitive to patient movements during the study period.

One shortfall of 3-D rotational angiography is the absence of streaming electrogram data. Additionally, because of the lack of respiratory compensation in the 3-D rotational angiography-fluoroscopy fusion, the end-expiratory phase is used as reference for monitoring the position of the ablation catheter tip during RF application.^{58,59}

Proper isocentering is important to obtain adequate 3-D rotational angiography. Concerns have been raised about the frequent difficulty in fitting the LA and PVs into one rotational run with the commonly used detector. However, with proper isocentering, even a dilated LA and the PV anatomy can be adequately imaged; truncation may occur more easily if the structures of interest are not at the center of rotation.⁵⁸

3-D rotational angiography is quickly evolving into a true online imaging tool; however, further refinements are needed before it can be widely adopted. These include incorporation of respiratory and cardiac motion compensation and the ability to display electrogram data on the 3-D shell (activation timing, scar and voltage maps, and dominant frequency). Further development is likely to involve several aspects of the method: automation of the workflow, injection protocols, and software; imaging of cardiac structures other than the LA and development of methods to visualize highly mobile structures such as the ventricles; and integration of anatomical 3-D rotational angiography information with electrogram data.⁵⁸⁻⁶⁰

Conclusions

Recording and analyzing extracellular electrograms form the basis for cardiac mapping. More commonly, cardiac mapping is performed with catheters introduced percutaneously into the heart chambers that sequentially record the endocardial electrograms with the purpose of correlating local electrogram to cardiac anatomy. These EP catheters are navigated and localized with the use of fluoroscopy.

However, the use of fluoroscopy for these purposes can be problematic for several reasons, including the following: (1) intracardiac electrograms cannot be associated accurately with their precise location within the heart; (2) the endocardial surface is invisible using fluoroscopy, and target sites may be approximated only by their relationship with nearby structures, such as ribs, blood vessels, and the position of other catheters; (3) because of the limitations of 2-D fluoroscopy, navigation is not exact, it is time-consuming, and it requires multiple views to estimate the 3-D location of the catheter; (4) the catheter cannot accurately and precisely be returned

to a previously mapped site; and (5) the patient and medical team are exposed to radiation.

The limitations of conventional mapping are being overcome with the introduction of sophisticated mapping systems that integrate 3-D catheter localization with sophisticated complex arrhythmia maps. The choice of a specific mapping system for a particular interventional case is shaped by the importance of a specific characteristic in the mapping process. Advanced mapping systems have a limited role in the ablation of typical AFL, AVNRT, or BTs, given the high success rate of the conventional approach. However, for more complex arrhythmias, such as macroreentrant AT, AF, and unstable VT, advanced mapping modalities offer a clear advantage. Additionally, advanced mapping systems can potentially shorten procedural time, reduce radiation exposure, and enhance the success rate for the ablation of typical AFL, idiopathic outflow tract VT, and sustained, stable macroreentrant VT.

In cases for which an undistorted anatomical rendering with high spatial accuracy is required, the CARTO system is of advantage; it has fewer problems with interstructure delineation and requires fewer fixed or snap points to preserve the anatomy. The CARTO and NavX systems work well for mapping sustained, stable arrhythmias. Mapping nonsustained arrhythmias, PACs, or PVCs can be tedious with each of these three approaches. With these arrhythmias, the noncontact mapping array works well, although the maps can be filter frequency dependent. The noncontact approach provides a quick snapshot of activation during unstable VTs and obviates the need for long periods of tachycardia. Substrate mapping, such as scar or voltage mapping, is a useful alternative to noncontact mapping. CARTO performs very well in this regard. NavX also works reasonably well with its dynamic substrate mapping capabilities.

In some cases, the choice of mapping system depends on the skill and experience of the operator. The user interfaces of the CARTO and NavX systems are acceptably straightforward. The noncontact system requires more steps in the creation of user-friendly working geometry. Each of these systems is currently in the development stage, and their various capabilities can change substantially over the next several years. However, to date, the integration of anatomical, EP and software information by an experienced physician is an indispensable prerequisite to accomplish a safe and successful procedure. At most, such systems must be used as an adjunctive tool to facilitate mapping and ablation. The operator should understand the advantages and shortcomings of each system and should recognize that these systems can be misleading and confusing and provide inaccurate information as a result of either incorrect data acquisition or inherent limitations of the technology.

Radiofrequency Ablation

Biophysics of Radiofrequency Energy

Radiofrequency (RF) refers to the portion of the electromagnetic spectrum in which electromagnetic waves can be generated by alternating current fed to an antenna.¹ Electrosurgery ablation currently uses hectometric wavelengths found in band 6 (300 to 3000 kHz), which are similar to those used for broadcast radio. However, the RF energy is electrically conducted, not radiated, during catheter ablation. The RF current is similar to low-frequency alternating current or direct current with regard to its ability to heat tissue and create a lesion, but it oscillates so rapidly that cardiac and skeletal muscles are not stimulated, thereby avoiding induction of arrhythmias and decreasing the pain perceived by the patient. RF current rarely induces rapid polymorphic arrhythmias; such arrhythmias can be observed in response to low-frequency (60-Hz) stimulation. Frequencies higher than 1000 kHz are also effective in generating tissue heating; however, such high frequencies are associated with considerable energy loss along the transmission line. Therefore, frequencies of the RF current commonly used are in the range of 300 to 1000 kHz, a range that combines efficacy and safety.^{2,3}

RADIOFREQUENCY ENERGY DELIVERY

Delivery of RF energy depends on the establishment of an electrical circuit involving the human body as one of its in-series elements. The RF current is applied to the tissue via a metal electrode at the tip of the ablation catheter and is generally delivered in a unipolar fashion between the tip electrode and a large dispersive electrode (indifferent electrode, or ground pad) applied to the patient's skin. The polarity of connections from the electrodes to the generator is not important because the RF current is an alternating current. Bipolar RF systems also exist, in which the current flows between two closely apposed small electrodes, thus limiting the current flow to small tissue volumes interposed between the metal conductors. Bipolar systems, partly because of their relative safety, are now the preferred tools in electrosurgery (oncology, plastic surgery, and ophthalmology). Their clinical application for catheter-based ablation has not yet been evaluated.^{2,3}

The system impedance comprises the impedance of the generator, transmission lines, catheter, electrode-tissue interface, dispersive electrode-skin interface, and interposed tissues. As electricity flows through a circuit, every point of that circuit represents a drop in voltage, and some energy is dissipated as heat. The point of greatest drop in line voltage represents the area of highest impedance

and is where most of that electrical energy becomes dissipated as heat. Therefore, with excessive electrical resistance in the transmission line, the line actually warms up and power is lost. Current electrical conductors from the generator all the way through to the patient and from the dispersive electrode back to the generator have low impedance, to minimize power loss.^{2,3}

With normal electrode-tissue contact, only a fraction of all power is effectively applied to the tissue. The rest is dissipated in the blood pool and elsewhere in the patient. With an ablation electrode in contact with the endocardial wall, part of the electrode contacts tissue and the rest contacts blood, and the RF current flows through both the myocardium and the blood pool in contact with the electrode. The distribution between both depends on the impedance of both routes and also on how much electrode surface contacts blood versus endocardial wall. Whereas tissue heating is the target of power delivery, the blood pool is the most attractive route for RF current because blood is a better conductor and has significantly lower impedance than tissue and because the contact between electrode and blood is often better than with tissue. Therefore, with normal electrode-tissue contact, much more power is generally delivered to blood than to cardiac tissue.^{2,4}

After leaving the electrode-blood-tissue interface, the current flows through the thorax to the indifferent electrode. Part of the RF power is lost in the patient's body, including the area near the patch. Dissipation of energy can occur at the dispersive electrode site (at the contact point between that ground pad and the skin) to a degree that can limit lesion formation. In fact, if ablation is performed with a high-amplitude current (more than 50 W) and skin contact by the dispersive electrode is poor, it is possible to cause skin burns (Fig. 7-1).¹ Nevertheless, because the surface area of the ablation electrode (approximately 12 mm²) is much smaller than that of the dispersive electrode (approximately 100 to 250 cm²), the current density is higher at the ablation site, and heating occurs preferentially at that site, with no significant heating occurring at the dispersive electrode.⁵

The dispersive electrode may be placed on any convenient skin surface. The geometry of the RF current field is defined by the geometry of the ablation electrode and is relatively uniform in the region of volume heating. Thus, the position of the dispersive electrode (on the patient's back or thigh) has little effect on impedance, voltage, current delivery, catheter tip temperature, or geometry of the resulting lesion.^{2,3,5}

The size of the dispersive electrode, however, is important. Sometimes it is advantageous to increase the surface area of the dispersive electrode. This increase leads to lower impedance, higher current delivery, increased catheter tip temperatures, and more

FIGURE 7-1 Second-degree skin burns at the site of ablation ground pad contact to the patient's thigh. Skin burns occurred secondary to poor contact between the skin and the pad during radiofrequency ablation of atrial fibrillation.

effective tissue heating. This is especially true in patients with baseline system impedance greater than 100 Ω . Moreover, when the system is power limited, as with a 50-W generator, heat production at the catheter tip varies with the proportion of the local electrode-tissue interface impedance to the overall system impedance. If the impedance at the skin-dispersive electrode interface is high, then a smaller amount of energy is available for tissue heating at the electrode tip. Therefore, when ablating certain sites, adding a second dispersive electrode or optimizing the contact between the dispersive electrode and skin should result in relatively more power delivery to the target tissue.^{5,6}

TISSUE HEATING

During alternating current flow, charged carriers in tissue (ions) attempt to follow the changes in the direction of the alternating current, thus converting electromagnetic (current) energy into molecular mechanical energy or heat. This type of electric current-mediated heating is known as ohmic (resistive) heating. Using Ohm's law, with resistive heating, the amount of power (= heat) per unit volume equals the square of current density times the specific impedance of the tissue. With a spherical electrode, the current flows outward radially, and current density therefore decreases with the square of distance from the center of the electrode. Consequently, power dissipation per unit volume decreases with the fourth power of distance. The thickness of the electrode eliminates the first steepest part of this curve, however, and the decrease in dissipated power with distance is therefore somewhat less dramatic.^{2,3}

Approximately 90% of all power that is delivered to the tissue is absorbed within the first 1 to 1.5 mm from the electrode surface. Therefore, only a thin rim of tissue in immediate contact with the RF electrode is directly heated (within the first 2 mm of depth from the electrode). The remainder of tissue heating occurs as a result of heat conduction from this rim to the surrounding tissues. On initiation of fixed-level energy application, the temperature at the electrode-tissue interface rises monoexponentially to reach steady state within 7 to 10 seconds, and the steady state is usually maintained between 80° and 90°C. However, whereas resistive heating starts immediately with the delivery of RF current, conduction of heat to deeper tissue sites is relatively slow and requires 1 to 2 minutes to equilibrate (thermal equilibrium). Therefore, the rate of tissue temperature rise beyond the immediate vicinity of the RF electrode is much slower, resulting in a steep radial temperature gradient as tissue temperature decreases radially in proportion to the distance from the ablation electrode; however, deep tissue temperatures continue to rise for several seconds after interruption of RF delivery (the so-called thermal latency phenomenon).⁴

Therefore, RF ablation requires at least 30 to 60 seconds to create full-grown lesions. In addition, when temperature differences between adjacent areas develop because of differences in local current density or local heat capacity, heat conducts from hotter to colder areas, thus causing the temperature of the former to decrease and that of the latter to increase. Furthermore, heat loss to the blood pool at the surface and to intramyocardial vessels determines the temperature profile within the tissue.^{2,3}

At steady state, the lesion size is proportional to the temperature measured at the interface between the tissue and the electrode, as well as to the RF power amplitude. By using higher powers and achieving higher tissue temperatures, the lesion size can be increased. However, once the peak tissue temperature exceeds the threshold of 100°C, boiling of the plasma at the electrode-tissue interface can ensue. When boiling occurs, denatured serum proteins and charred tissue form a thin film that adheres to the electrode, thus producing an electrically insulating coagulum, which is accompanied by a sudden increase in electrical impedance that prevents further current flow into the tissue and further heating.^{2,3}

The range of tissue temperatures used for RF ablation is 50° to 90°C. Within this range, smooth desiccation of tissue can be expected. If the temperature is lower than 50°C, no or only minimal tissue necrosis results. Because the rate of temperature rise at deeper sites within the myocardium is slow, a continuous energy delivery of at least 60 seconds is often warranted to maximize depth of lesion formation.

CONVECTIVE COOLING

The dominant factor opposing effective heating of myocardium is the convective heat loss into the circulating blood pool. Because the tissue surface is cooled by the blood flow, the highest temperature during RF delivery occurs slightly below the endocardial surface. Consequently, the width of the endocardial lesion matures earlier than the intramural lesion width (20 seconds versus 90 to 120 seconds). Therefore, the maximum lesion width is usually located intramurally, and the resultant lesion is usually teardrop shaped, with less necrosis of the superficial tissue.³

As the magnitude of convective cooling increases (e.g., unstable catheter position, poor catheter-tissue contact, or high blood flow in the region of catheter position), there is decreased efficiency of heating as more energy is carried away in the blood and less energy is delivered to the tissue. When RF power is limited, lesion size is reduced by such convective heat loss. On the other hand, when RF power delivery is not limited, convective cooling allows for more power to be delivered into the tissue, and higher tissue temperatures can be achieved (despite low temperatures measured by the catheter tip sensors), resulting in larger lesion size, without the risk of overheating and coagulum formation.^{2,3}

The concept of convective cooling can explain why there are few coronary complications with conventional RF ablation. Coronary arteries act as a heat sink; substantive heating of vascular endothelium is prevented by heat dissipation in the high-velocity coronary blood flow, even when the catheter is positioned close to the vessel. Although this is advantageous, because coronary arteries are being protected, it can limit success of the ablation lesion if a large perforating artery is close to the ablation target.⁵

The effects of convective cooling have been exploited to increase the size of catheter ablative lesions. Active electrode cooling by irrigation is currently used to eliminate the risk of overheating at the electrode-tissue contact point and increase the magnitude of power delivery and the depth of volume heating.

CATHETER TIP TEMPERATURE

Ablation catheter tip temperature depends on tissue temperature, convective cooling by the surrounding blood, tissue contact of the ablation electrode, electrode material and its heat capacity, and type and location of the temperature sensor.^{2,7}

Catheter tip temperature is measured by a sensor located in the ablation electrode. There are two different types of temperature sensors: thermistors and thermocouples. Thermistors require a driving current, and the electrical resistance changes as the temperature of the electrical conductor changes. More frequently used are thermocouples, which consist of copper and constantan wires and are incorporated in the center of the ablation electrode. Thermocouples are based on the so-called Seebeck effect; when two different metals are connected (sensing junction), a voltage can be measured at the reference junction that is proportional to the temperature difference between the two metals.^{2,7}

The electrode temperature rise is an indirect process—the ablation electrode is not heated by RF energy, but it heats up because it happens to touch heated tissue. Consequently, the catheter tip temperature is always lower than, or ideally equal to, the superficial tissue temperature. Conventional electrode catheters with temperature monitoring report the temperature only from the center of the electrode mass with one design or from the apex of the tip of the catheter with another design. It is likely that the measured temperature underestimates the peak tissue temperature; it can be significantly lower than tissue temperature.

Several other factors can increase the disparity between catheter tip temperature and tissue temperature, including catheter tip irrigation, large ablation electrode size, and poor electrode-tissue contact. Catheter tip irrigation increases the disparity between tissue temperature and electrode temperature because it results in cooling of the ablation electrode, but not the tissue. With a large electrode tip, a larger area of the electrode tip is exposed to the cooling effects of the blood flow than with standard tip lengths, thus resulting in lower electrode temperatures. Similarly, with poor electrode-tissue contact, less electrode material is in contact with the tissue, and heating of the tip by the tissue occurs at a lower rate, resulting in relatively low tip temperatures.^{3,6-8}

Pathophysiology of Lesion Formation by Radiofrequency Ablation

CELLULAR EFFECTS OF RADIOFREQUENCY ABLATION

The primary mechanism of tissue injury by RF ablation is likely to be thermally mediated. Hyperthermic injury to the myocyte is both time- and temperature-dependent, and it can be caused by changes in the cell membrane, protein inactivation, cytoskeletal disruption, nuclear degeneration, or other potential mechanisms.^{2,3}

Experimentally, the resting membrane depolarization is related to temperature. In the low hyperthermic range (37° to 45°C), little tissue injury occurs, and a minor change may be observed in the resting membrane potential and action potential amplitude. However, action potential duration shortens significantly, and conduction velocity becomes greater than at baseline. In the intermediate hyperthermic range (45° to 50°C), progressive depolarization of the resting membrane potential occurs, and action potential amplitude decreases. Additionally, abnormal automaticity is observed, reversible loss of excitability occurs, and conduction velocity progressively decreases. In the high temperature ranges (higher than 50°C), marked depolarization of the resting membrane potential occurs, and permanent loss of excitability is observed. Temporary (at temperatures of 49.5° to 51.5°C) and then permanent (at 51.7° to 54.4°C) conduction block develops, and fairly reliable irreversible myocardial injury occurs with a short hyperthermic exposure.³

In the clinical setting, the success of ablation is related to the mean temperature measured at the electrode-tissue interface. Block of conduction in an atrioventricular (AV) bypass tract (BT) usually occurs at 62° ± 15°C. During ablation of the AV junction, an accelerated junctional rhythm, which is probably caused by thermally or electrically induced cellular automaticity or triggered activity, is observed at temperatures of 51° ± 4°C, whereas reversible complete AV block occurs at 58° ± 6°C, and irreversible complete AV block occurs at 60° ± 7°C.

FIGURE 7-2 Standard radiofrequency ablation catheter with char formed on the tip.

RF ablation typically results in high temperatures (70° to 90°C) for a short time (up to 60 seconds) at the electrode-tissue interface, but significantly lower temperatures at deeper tissue sites. This leads to rapid tissue injury within the immediate vicinity of the RF electrode but relatively delayed myocardial injury with increasing distance from the RF electrode. Therefore, although irreversible loss of EP function can usually be demonstrated immediately after successful RF ablation, this finding can be delayed because tissue temperatures continue to rise somewhat after termination of RF energy delivery (thermal latency phenomenon). This effect can account for the observation that patients undergoing AV node (AVN) modification procedures who demonstrate transient heart block during RF energy delivery can progress to persisting complete heart block, even if RF energy delivery is terminated immediately. Reversible loss of conduction can be demonstrated within seconds of initiating the RF application, which can be caused by an acute electrotonic effect. On the other hand, there can be late recovery of electrophysiological (EP) function after an initial successful ablation.⁵

In addition to the dominant thermal effects of RF ablation, some of the cellular injury has been hypothesized to be caused by a direct electrical effect, which can result in dielectric breakdown of the sarcolemmal membrane with creation of transmembrane pores (electroporation), resulting in nonspecific ion transit, cellular depolarization, calcium overload, and cell death. Such an effect has been demonstrated with the use of high-voltage electrical current. However, it is difficult to examine the purely electrical effects in isolation of the dominant thermal injury.

TISSUE EFFECTS OF RADIOFREQUENCY ABLATION

Changes in myocardial tissue are apparent immediately on completion of the RF lesion. Pallor of the central zone of the lesion is attributable to denaturation of myocyte proteins (principally myoglobin) and subsequent loss of the red pigmentation. Slight deformation, indicating volume loss, occurs at the point of catheter contact in the central region of lesion formation. The endocardial surface is usually covered with a thin fibrin layer and, occasionally, if a temperature of 100°C has been exceeded, with char and thrombus (Fig. 7-2). In addition, a coagulum (an accumulation of fibrin, platelets, and other blood and tissue components) can form at the ablation electrode because of the boiling of blood and tissue serum.²

On sectioning, the central portion of the RF ablation lesion shows desiccation, with a surrounding region of hemorrhagic tissue and then normal-appearing tissue. Histologic examination of an acute lesion shows typical coagulation necrosis with basophilic stippling consistent with intracellular calcium overload. Immediately

surrounding the central lesion is a region of hemorrhage and acute monocellular and neutrophilic inflammation. The progressive changes seen in the evolution of an RF lesion are typical of healing after any acute injury. Within 2 months of the ablation, the lesion shows fibrosis, granulation tissue, chronic inflammatory infiltrates, and significant volume contraction. The lesion border is well demarcated from the surrounding viable myocardium without evidence of a transitional zone. This likely accounts for the absence of proarrhythmic side effects of RF catheter ablation. As noted, because of the high-velocity blood flow within the epicardial coronary arteries, these vessels are continuously cooled and are typically spared from injury, despite nearby delivery of RF energy. However, high RF power delivery in small hearts, such as in pediatric patients, or in direct contact with the vessel can potentially cause coronary arterial injury.³

The border zone around the acute pathological RF lesion accounts for several phenomena observed clinically. The border zone is characterized by marked ultrastructural abnormalities of the microvasculature and myocytes acutely, as well as a typical inflammatory response later. The most thermally sensitive structures appear to be the plasma membrane and gap junctions, which show morphological changes as far as 6 mm from the edge of the pathological lesion. The border zone accounts for documented effects of RF lesion formation well beyond the acute pathological lesion. The progression of the EP effects after completion of the ablation procedure can be caused by further inflammatory injury and necrosis in the border zone region that result in late progression of physiological block and a delayed cure in some cases. On the other hand, initial stunning and then early or late recovery of function can be demonstrated in the border zone, thus accounting for the recovery of EP function after successful catheter ablation in the clinical setting, which can be caused by healing of the damaged, but surviving, myocardium.²

Determinants of Lesion Size

Lesion size is defined as the total volume or dimensions (width and depth) of the lesion. The size of the lesion created by RF power is determined by the amount of tissue heated to more than the critical temperature for producing irreversible myocardial damage (50°C). As noted, only a thin rim (1 to 2 mm) of tissue immediately under the ablating electrode is directly heated. This heat then radiates to adjacent tissue; however, conduction of heat to deeper tissue sites is relatively slow and very inefficient. The distance at which temperature drops to less than 50°C delimits the depth of lesion formation. The use of higher-power output to achieve higher tissue temperatures results in larger lesions by raising the temperature of the rim of resistively heated tissue to substantially more than 50°C for deeper tissue to reach the 50°C threshold required for tissue necrosis. However, the rim of heated tissue in direct contact with the ablating electrode conducts not only to deeper tissue but also to the electrode tip itself. Higher electrode temperatures either limit further energy delivery (in temperature-controlled power delivery mode) or increase electrode impedance as a result of coagulum formation, or both; these effects potentially limit lesion size. Furthermore, tissue temperatures higher than 100°C are unsafe because they are associated with higher risk of steam “pops.” Cooling of the ablating electrode (passively by using a larger electrode length or actively by using catheter irrigation) can help diminish electrode heating, allowing for greater power delivery and creation of larger lesions.⁹

ELECTRODE TIP TEMPERATURE

It is important to understand that it is the amount of RF power delivered effectively into the tissue that determines tissue heating and thus lesion size, and the recorded catheter tip temperature is poorly correlated with lesion size. As noted, catheter tip temperature is always lower than the superficial tissue temperature. With good contact between catheter tip and tissue and low cooling of

the catheter tip, the target temperature can be reached with little power, thus resulting in fairly small lesions although a high catheter tip temperature is being measured. In contrast, a low catheter tip temperature can be caused by a high level of convective cooling, which allows a higher amount of RF power to be delivered to the tissue (because it is no longer limited by temperature rise of the ablation electrode) and yields relatively large lesions. This is best illustrated with active cooling of the ablation electrode using irrigation during RF energy delivery; the tip temperature is usually less than 40°C, which allows the application of high-power output for longer durations.

RADIOFREQUENCY DURATION

The RF lesion is predominantly generated within the first 10 seconds of target energy delivery and tissue temperatures, and it reaches a maximum after 30 seconds. Further extension of RF delivery during power-controlled RF delivery does not seem to increase lesion size further.

ELECTRODE-TISSUE CONTACT

The efficiency of energy transfer to the myocardium largely depends on electrode-tissue contact. An improvement in tissue contact leads to a higher amount of RF power that can be effectively delivered to the tissue. Consequently, the same tissue temperatures and lesion size can be reached at a much lower power level. However, at a certain moderate contact force, further increase in contact firmness results in progressively smaller lesions because a lesser amount of RF power is required to reach target temperature.⁴

Additionally, the surface area at the electrode-tissue interface influences the lesion size. When the catheter is wedged (i.e., between ventricular trabeculae or under a valvular leaflet), the electrode surface area exposed to tissue can be much higher. With half the electrode in contact with blood and the other half in contact with (twice) more resistive tissue, the amount of power delivered to blood is two times higher than the amount of power delivered to tissue (as compared with six times with 25% contact). The result is a more than twofold increase in tissue heating. In practice, however, power output rarely reaches 50 W in these situations; a temperature rise of the ablation electrode signals excessive tissue heating and limits power delivery.⁴

Close monitoring of changes in temperature and impedance provides information regarding the degree of electrode-tissue contact. Increased contact results in elevated initial impedance levels (by a mean of 22%) and an increase in the rate and level of impedance reduction, and the plateau is reached later. Additionally, increased electrode-tissue contact results in higher tissue temperatures, and the plateau is achieved later. Beat-to-beat stability of electrograms and pacing threshold also provide some information about tissue contact.

ELECTRODE ORIENTATION

When the catheter tip is perpendicular to the tissue surface, a much smaller surface area is in contact with the tissue (versus that exposed to the cooling effect of blood flow) than when the catheter electrode tip is lying on its side. Clinically, perpendicular electrode orientation yields larger lesion volumes and uses less power than parallel electrode orientation. However, if the RF power level is adjusted to maintain a constant current density, lesion size will increase proportionally to the electrode-tissue contact area, which is larger with parallel tip orientation. Lesion depth is only slightly affected by catheter tip orientation using 4-mm-long tip catheters, but lesions are slightly longer in the parallel orientation as compared with the perpendicular orientation. Moreover, the character of the lesion created with temperature control depends on the placement of the temperature sensors relative to the portion of the electrode in contact with tissue. Thus, the orientation of the electrode and of its temperature sensors determines the appropriate

target temperature required to create maximal lesions while avoiding coagulum formation caused by overheating at any location within the electrode-tissue interface.^{2,3,10}

ELECTRODE LENGTH

Ablation catheters have tip electrodes that are conventionally 4 mm long and are available in sizes up to 10 mm long (see Fig. 4-6). An increased electrode size reduces the interface impedance with blood and tissue, but the impedance through the rest of the patient remains the same. The ratio between interface impedance and the impedance through the rest of the patient is thus lower with an 8-mm electrode than with a 4-mm electrode, which reduces the efficiency of power transfer to the tissue. Therefore, with the same total power, lesions created with a larger electrode are always smaller than lesions created with a smaller electrode (Fig. 7-3). A larger electrode size also creates a greater variability in power transfer to the tissue because of greater variability of tissue contact, and tissue contact becomes much more dependent on catheter orientation with longer electrodes. Consequently, an 8-mm electrode may require a 1.5 to 4 times higher power level than a 4-mm electrode to create the same lesion size.⁴

When the power is not limited, however, catheters with large distal electrodes create larger lesions, both by increasing the ablation electrode surface area in contact with the bloodstream, thus resulting in an augmented convective cooling effect, and by increasing the volume of tissue directly heated because of an increased surface area at the electrode-tissue interface (see Fig. 7-3). However, this assumes that the electrode-tissue contact, tissue heat dissipation, and blood flow are uniform throughout the electrode-tissue interface. As the electrode size increases, the likelihood that these assumptions are true diminishes because of variability in cardiac chamber trabeculations and curvature, tissue perfusion, and intracardiac blood flow, which affect the heat dissipation and tissue contact. These factors result in unpredictable lesion size and uniformity for electrodes more than 8 mm long.^{2,3}

There is a potential safety concern with the use of long ablation electrodes because of nonuniform heating, with maximal heating occurring at the electrode edges. Thus, large electrode-tipped catheters with only a single thermistor can underestimate maximal temperature and allow char formation and potential thromboembolic

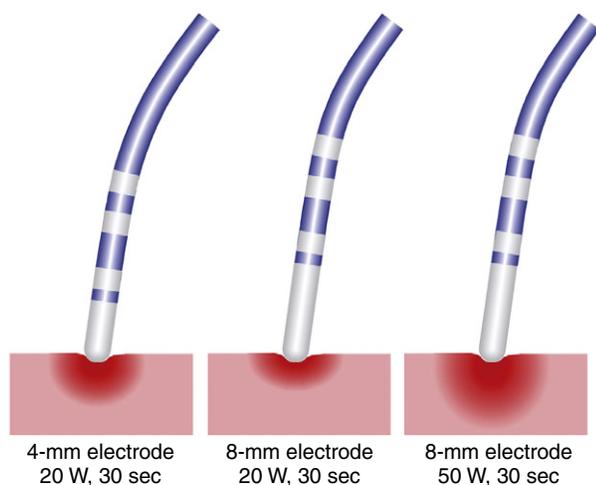

FIGURE 7-3 Effect of electrode size and power delivery on lesion size. Representative blocks of myocardium are shown with lesions (dark shading) resulting from optimal radiofrequency energy delivery for each electrode type. The effect of 20 W delivered for 30 seconds is shown for a 4-mm electrode (left) and an 8-mm electrode (center). The larger electrode dissipates more of the energy into the blood pool and thus paradoxically creates a smaller lesion. Because of electrode cooling from its larger surface area, the same 8-mm electrode can deliver more power than the 4-mm electrode and could create a larger lesion (right).

complications. Catheter tips with multiple temperature sensors at the electrode edges may be preferable for temperature feedback. In addition, the greater variation in power delivered to the tissue and the greater discrepancy between electrode and tissue temperature make it difficult to avoid intramural gas explosions and blood clot formation. Another point of concern is that the formation of blood clots may only minimally affect electrode impedance by covering a much smaller part of the electrode surface. Therefore, the lower electrode temperature and the absence of any impedance rise may erroneously suggest a safer ablation process.⁴

The principal limitations of a large ablation electrode (8 to 10 mm in length) are the reduction in mobility and the flexibility of the catheter, which can impair positioning of the ablation electrode, and a reduction in the resolution of recordings from the ablation electrode, thus making it more difficult to identify the optimal ablation site. A larger electrode dampens the local electrogram, especially that of the distal electrode. With an 8- or 10-mm long distal and a 1-mm short proximal ring electrode, the latter can be the main source for the bipolar electrogram; this then confuses localization of the optimal ablation site. In contrast, a smaller electrode improves mapping accuracy and feedback of tissue heating. Its only drawback is the limited power level that can be applied to the tissue.⁴

ABLATION ELECTRODE MATERIAL

Although platinum-iridium electrodes have been the standard for most RF ablation catheters, gold exhibits excellent electrical conductive properties, as well as a more than four times greater thermal conductivity than platinum (300 versus 70 W/m °K), although both materials have similar heat capacities (130 and 135 J/kg °K). The higher thermal conductivity of gold can potentially lead to a higher mean rate of power because of better heat conduction at the tissue-electrode interface and to enhanced cooling as a result of heat loss to the surrounding blood with this electrode material.¹¹ Therefore, gold electrodes allow for greater power delivery to create deeper lesions at a given electrode temperature without impedance increases.¹² Enhanced electrode cooling allows for more RF power to be applied at constant temperature, before the temperature limit is reached or before the impedance of the electrode rises.⁴ However, the higher thermal conductivity of gold electrodes is no longer an advantage in areas of low blood flow (e.g., among myocardial trabeculae), where convective cooling at the electrode tip is minimal. Under these circumstances, electrode materials with a low thermal conductivity can produce larger lesions.^{3,11}

Conflicting results were observed in clinical studies comparing 8-mm gold-tip with platinum-iridium-tip catheters for ablation of the cavotricuspid isthmus.¹³ During catheter ablation of the slow AVN pathway in patients with AVN reentrant tachycardia (AVNRT), no significant differences were observed between 4-mm gold-tip and platinum-iridium-tip catheters in the primary endpoint or in the increases of power or temperature at any of the measured time points. However, ablation with gold electrodes seemed to be safe and well tolerated and specifically did not increase the risk of AV block. Interestingly, a significant reduction of charring on gold tips was observed, compared with platinum-iridium material, a finding suggesting a possible advantage of this material beyond its better conduction properties.¹¹

REFERENCE PATCH ELECTRODE LOCATION AND SIZE

The RF current path and skin reference electrode interface present significant impedance for the ablation current flow, thereby dissipating part of the power. Increasing patch size (or using two patches) provides for increased heating at the electrode-endocardium interface and thus increases ablation efficiency and increases lesion size. On the other hand, the position of the dispersive electrode (on the patient's back or thigh) has little effect on the size of the resulting lesion.⁵

BLOOD FLOW

The ablation electrode temperature is dependent on the opposing effects of heating from the tissue and cooling by the blood flowing around the electrode. Because lesion size is primarily dependent on the RF power delivered to the tissue, lesion size varies with the magnitude of local blood flow. At any given electrode temperature, the RF power delivered to the tissue is significantly reduced in areas of low local blood flow (e.g., deep pouch in the cavotricuspid isthmus, dilated and poorly contracting atria, and dilated and poorly contracting ventricles). The reduced cooling associated with low blood flow causes the electrode to reach the target temperature at lower power levels, and if the ablation lesion is temperature-controlled, power delivery will be limited. In these locations, increasing electrode temperature to 65° or 70°C only minimally increases RF power and increases the risk of thrombus formation and impedance rise. In contrast, increasing local blood flow is associated with increased convective cooling of the ablation electrode. Consequently, more power is delivered to the tissue to reach and maintain target temperature, thus resulting in larger lesion volumes.^{2,3,7}

RADIOFREQUENCY SYSTEM POLARITY

Most RF lesions are created by applying energy in a unipolar fashion between an ablating electrode touching the myocardium and

a grounded reference patch electrode placed externally on the skin. The unipolar configuration creates a highly localized lesion, with the least amount of surface injury. Energy can also be applied in a bipolar mode between two endocardial electrodes. Bipolar energy delivery produces larger lesions than unipolar delivery. A novel ablation system (GENius, Ablation Frontiers, Carlsbad, Calif.) has been developed for ablation of atrial fibrillation (AF), in which duty-cycled and alternating unipolar and bipolar (between adjacent electrodes) energy RF ablation is used to create contiguous lesions in the pulmonary vein (PV) antrum using a ring catheter with 10 electrodes (Pulmonary Vein Ablation Catheter [PVAC], Ablation Frontiers, Medtronic Inc., Minneapolis, Minn.) (Figs. 7-4 and 7-5).¹⁴ Other catheter designs, which use the same multichannel duty-cycled RF generator, also have been developed for left atrial ablation of fractionated electrograms (Multi-Array Ablation Catheter [MAAC], Ablation Frontiers), septal ablation (Multi-Array Septal Catheter [MASC], Ablation Frontiers), and linear ablation (Tip-Versatile Ablation Catheter [TVAC], Ablation Frontiers) (see Fig. 7-4).¹⁵ One advantage of this approach is the simultaneous application of RF energy across an electrode array, intended to create contiguous lesions near an anatomical structure. Additionally, the multielectrode catheters allow selective mapping and ablation through any or all electrodes as required. This system is still undergoing investigation. Another novel ablation catheter system delivers RF energy through a flexible mesh electrode (C.R. Bard, Inc.,

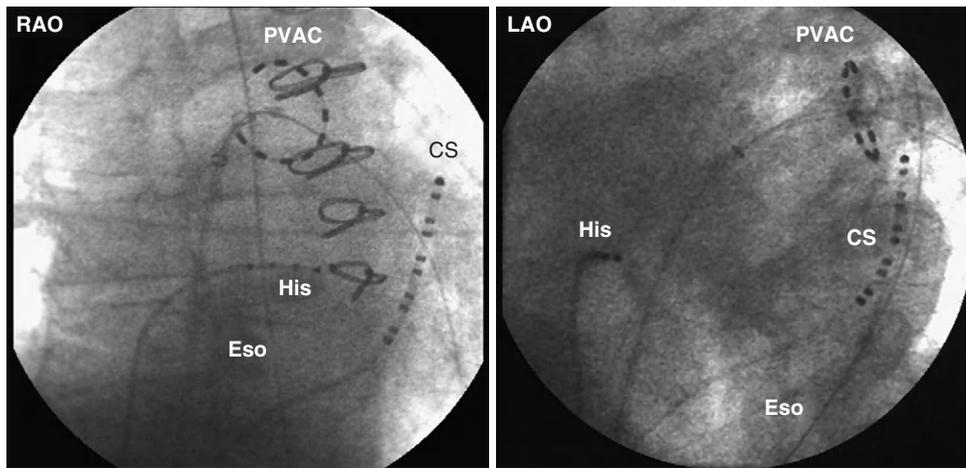

FIGURE 7-5 Ablation Frontiers (Medtronic Inc., Minneapolis, Minn.) Pulmonary Vein Ablation Catheter (PVAC) in the left inferior pulmonary vein. The electrodes of the PVAC catheter, which is deployed over a guidewire into the antrum of a pulmonary vein, can be used for both recording and ablating around the perimeter of the vein. Billerica, Mass.) that is deployed in the PV ostium. This system is undergoing investigation for PV isolation.¹⁶

Monitoring Radiofrequency Energy Delivery

The goal of optimizing RF ablation is to create an adequate-sized lesion while minimizing the chance of an impedance increase because of coagulum formation at the electrode itself, or steam formation within the tissue. As discussed previously, for ablation to be effective, power must be increased sufficiently to achieve temperatures at the tissue directly in contact with the ablating electrode that are substantially higher than 50°C to achieve tissue necrosis. At the same time, for ablation to be safe, the highest tissue temperature must be maintained at less than 100°C to prevent steam pops. Monitoring of RF energy delivery is therefore very important to help achieve successful as well as safe ablation.⁹

Lesion creation is influenced by many factors, some of which can be controlled, whereas others are variable and can be unpredictable. With standard RF power delivery is titrated to electrode temperature, typically at 55° to 65°C. Higher temperatures can increase the chance of reaching 100°C at edges of the ablation electrode, thus resulting in coagulum formation. An increase in tissue temperature is accompanied by a decrease in impedance, also a reliable marker of tissue heating. Impedance reduction and temperature rise correlate with both lesion width and depth; maximum temperature rise is best correlated with lesion width, and maximum impedance reduction is best correlated with lesion depth.^{3,7}

The efficiency of tissue heating (i.e., the temperature per watt of applied power) is dependent on several variables, including catheter stability, electrode-tissue contact pressure, electrode orientation relative to the endocardium, effective electrode contact area, convective heat loss into the blood pool, and target location. Thus, applied energy, power, and current are poor indicators of the extent of lesion formation, and the actual electrode-tissue interface temperature remains the only predictor of the actual lesion size. Currently, although less than ideal, monitoring temperature and impedance are used to help ensure adequate but not excessive heating at the electrode-tissue interface. Newer technologies may be implemented in the future to monitor tissue temperatures during RF delivery, including infrared sensors and ultrasound transducers.

In addition to impedance and catheter tip temperature monitoring, reductions in amplitude and steepness of the local electrogram are important indicators for monitoring lesion growth. These indicators, however, apply only to the unipolar distal electrogram. With a bipolar recording, the signal from the ring electrode may dominate the electrogram, and the bipolar amplitude may theoretically even rise during ablation because of a greater difference between the signals from both electrodes.⁴

Some operators have used visualization of microbubbles on intracardiac ultrasound (ICE) as an indication of excessive tissue

heating that is predictive of char and steam pops during ablation and that warrants reduction or termination of RF energy.⁶

IMPEDANCE MONITORING

The magnitude of the current delivered by the RF generator used in ablation is largely determined by the impedance between the ablation catheter and the dispersive electrode. This impedance is influenced by several factors, including intrinsic tissue properties, catheter contact pressure, catheter electrode size, dispersive electrode size, presence of coagulum, and body surface area. Impedance measurement does not require any specific catheter-based sensor circuitry and can be performed with any catheter designed for RF ablation. Larger dispersive electrodes and larger ablation electrodes result in lower impedance.^{3,7}

Typically, the impedance associated with firm catheter contact (before tissue heating has occurred) is 90 to 120 Ω. When catheter contact is poor, the initial impedance is 20% to 50% less, because of the lower resistivity of blood. Moreover, larger electrodes have larger contact area and consequently lower impedance.

The impedance drop during RF ablation occurs mainly because of a reversible phenomenon, such as tissue temperature rise, rather than from an irreversible change in tissues secondary to ablation of myocardial tissue. Therefore, impedance provides a useful qualitative assessment of tissue heating; however, it does not correlate well with lesion size.⁴ A 5- to 10-Ω reduction in impedance is usually observed in clinically successful RF applications, it correlates with a tissue temperature of 55° to 60°C, and it is rarely associated with coagulum formation. Larger decrements in impedance are noted when coagulum formation is imminent. Once a coagulum is formed, an abrupt rise in impedance to more than 250 Ω is usually observed.^{3,7}

To titrate RF energy using impedance monitoring alone, the initial power output is set at 20 to 30 W and is then gradually increased to target a 5- to 10-Ω decrement in impedance. When target impedance is reached, power output should be manually adjusted throughout the RF application, as needed, to maintain the impedance in the target range. A larger decrement of impedance should prompt reduction in power output.

The drop in impedance as a monitoring tool has several limitations. When blood flow rates are low, blood can also be heated, and electrode impedance drops accordingly. Moreover, a large rise in tissue temperature at a small contact area and a smaller rise with better tissue contact can result in a similar drop in impedance. Inversely, similar tissue heating with different tissue contact can result in a different change in impedance. In addition, resistive heating nearby is fast, whereas conductive heating to deeper layers is relatively slow. The former, at close distance, has a much greater effect on impedance than the latter, which occurs at greater distance. Like electrode temperature rise, the drop in impedance during RF application is not a reliable parameter for estimating tissue heating and lesion growth.^{3,4,7}

Although coagulum formation is usually accompanied by an abrupt rise in impedance, the absence of impedance rise during ablation does not guarantee the absence of blood clot formation on the tissue contact site, which can unnoticeably be created on the lesion surface. In addition, as noted, with large ablation electrodes, formation of blood clots may only minimally affect electrode impedance by covering a much smaller part of the electrode surface. Any increase in impedance during RF application can, however, indicate the beginning of thrombus formation or unintended catheter movement; in either case, RF application is discontinued.

TEMPERATURE MONITORING

Monitoring of catheter tip temperature and closed-loop control of power output are useful to avoid excessive heating at the tissue surface, which can result in coagulum formation, and to accomplish effective heating at the target area. However, catheter tip temperature is affected by cooling effects and electrode-tissue contact and thus poorly correlates with lesion size. Tissue temperature can be markedly higher than catheter tip temperature; a higher target temperature can increase the incidence of tissue overheating associated with crater formation and coagulum formation. In high-flow areas, the tip is cooled and more RF power is delivered to the tissue to reach target temperature, thus resulting in relatively large lesions and vice versa.⁷

As mentioned earlier, temperature monitoring requires a dedicated sensor within the catheter. Two types of sensors are available: thermistor and thermocouple. No catheter or thermometry technology has been demonstrated to be superior in clinical use; however, closed-loop control of power output is easier to use than manual power titration. Conventional electrode catheters with temperature monitoring report the temperature only from the center of the electrode mass with one design or from the apex of the tip of the catheter with another design, and it is likely that the measured temperature underestimates the peak tissue temperature. Therefore, it is best if target temperatures no higher than 70° to 80°C are selected in the clinical setting.^{3,7}

Titration of RF energy using temperature monitoring is usually done automatically by a closed-loop temperature monitoring system. When manual power titration is directed by temperature monitoring, the power initially is set to 20 to 30 W and then is gradually increased until the target temperature is achieved. With both manual and automatic power titration, change in power output is frequently required throughout the RF application to maintain the target temperature. Application of RF energy is continued if the desired clinical effect is observed within 5 to 10 seconds after the target temperature or impedance is achieved. If the desired endpoint does not occur within this time, the failed application is probably because of inadequate mapping. If the target temperature or impedance is not achieved with maximum generator output within 20 seconds, the time it takes to achieve subendocardial steady-state temperature, the RF application can be terminated, and catheter adjustment should be considered to obtain better tissue contact.⁷

The target ablation electrode temperature varies according to the arrhythmia substrate. For AVNRT, target temperature is usually 50° to 55°C. For BT, AV junction, atrial tachycardia (AT), and ventricular tachycardia (VT), a higher temperature (55° to 60°C) is usually targeted.

When using 4-mm-tip catheters, the target temperature should be lower than 80°C. In high-flow areas in the heart, the disparity between tip temperature and tissue temperature is large and a lower target temperature should be considered (e.g., 60°C), whereas in low flow areas tissue temperature is much better reflected by tip temperature and a higher target temperature can be considered (e.g., 70° to 80°C). The duration of RF application can be limited to 30 seconds for nonirrigated 4-mm-tip electrodes. The lesion is predominantly formed within the first 30 seconds. A longer duration does not create larger lesions.

When using 8-mm-tip catheters, a larger portion of the ablation electrode is exposed to the blood and thus cooled by blood flow, and a relatively large difference between catheter tip temperature and tissue temperature can be expected. Consequently, a moderate target temperature (e.g., 60°C) should be chosen; the RF power may be limited to 50 to 60 W to avoid tissue overheating and coagulum formation.³

It is important to recognize that prevention of coagulum formation is difficult, even with temperature and impedance monitoring. The clot first adheres to the tissue because that is the site with the highest temperature and may only loosely attach to the cooler electrode. The denatured proteins probably have higher electrical impedance than blood, but the contact area with the electrode can be small, and RF impedance may not rise noticeably. The absence of flow inside the clot and its presumed higher impedance accelerate local heating and, because of some contact with the electrode, also accelerate heating of the electrode. Desiccation and adherence to the electrode then lead to coagulum formation on the metal electrode and impedance rise. Automatic power reduction by temperature-controlled RF ablation compensates for the reduction of electrode cooling and may prevent desiccation and impedance rise. The clot, however, can still be formed as demonstrated by experimental *in vivo* studies, and this can remain unnoticeable until it detaches from the tissue. Therefore, the absence of thermal and electrical phenomena does not imply that the ablation has been performed safely.⁷

ULTRASOUND IMAGING

Ultrasound imaging can allow assessment of tissue heating and pops. The presence of microbubbles on intracardiac or transesophageal echocardiography is typically associated with a tissue temperature higher than 60°C and increased lesion size, and continued RF application after the appearance of the bubbles is usually followed by an increase in impedance. Moreover, pops are not always audible but can be seen well on ultrasound, often with a sudden explosion of echocardiographic contrast.⁶ Microbubble formation, however, is not a straightforward surrogate for tissue heating. The absence of microbubble formation clearly does not indicate that tissue heating is inadequate or that the power level should be increased, nor does the presence of scattered microbubbles indicate safe tissue heating. This marker is fairly specific for tissue heating as judged by tissue temperatures but is not routinely sensitive. Specifically, scattered microbubbles can occur over the entire spectrum of tissue temperatures, whereas dense showers of microbubbles appear only at tissue temperatures higher than 60°C. Scattered microbubbles can represent an electrolytic phenomenon, whereas dense showers of microbubbles suggest steam formation, with associated tissue disruption and impedance rises.⁶

Clinical Applications of Radiofrequency Ablation

RF is the most frequently used mode of ablation energy and has become a widely accepted treatment for most atrial and ventricular arrhythmias. Studies have demonstrated the effectiveness of RF current in producing precise and effective lesions.

Although RF energy for catheter- and surgical-based treatment of cardiac arrhythmias has been proven to be effective and relatively safe, several limitations exist. Many of these limitations center on how RF creates the tissue lesion. Current flow and energy delivery are critically dependent on a low-impedance electrode-tissue junction, but tissue desiccation, coagulation, and charring around the electrode can result in marked falls in conductivity.

Temporal evolution of ablation lesions can potentially alter the immediate postablation substrate, by producing either lesion expansion (mediated in part by secondary myocyte loss from disrupted microcirculation) or lesion regression (resolution of edema and healing).

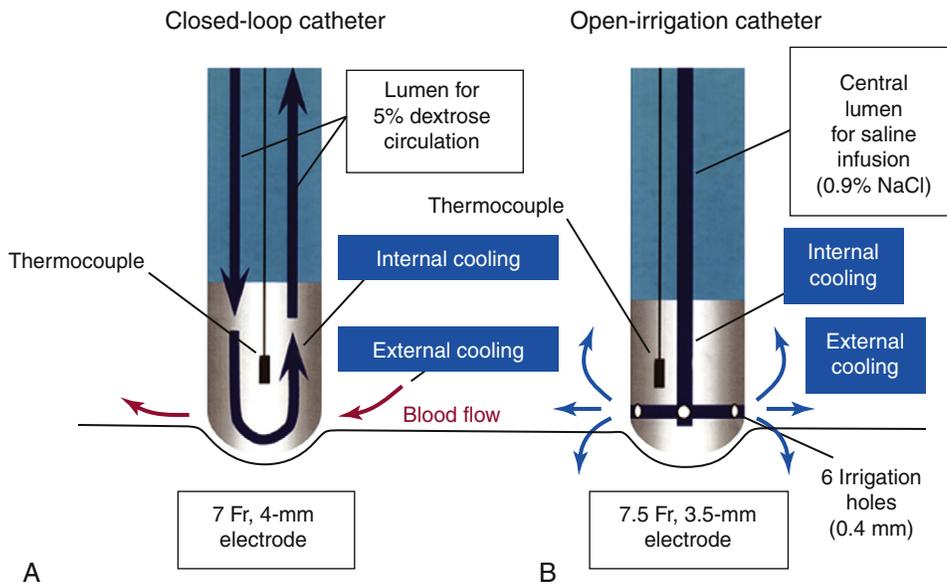

FIGURE 7-6 Schematic representation of irrigated electrode catheters. **A**, The closed-loop irrigation catheter has a 7 Fr, 4-mm-tip electrode with an internal thermocouple. **B**, The open-irrigated catheter has a 7.5 Fr, 3.5-mm-tip electrode with an internal thermocouple and six irrigation holes (0.4-mm diameter) located around the electrode, 1.0 mm from the tip. NaCl = sodium chloride. (From Yokoyama K, Nakagawa H, Wittkamp FH, et al: Comparison of electrode cooling between internal and open irrigation in radiofrequency ablation lesion depth and incidence of thrombus and steam pop. *Circulation* 113:11, 2006.)

A major limitation of RF ablation is the relatively small depth of tissue injury produced by this technique. This can be attributed to the precipitous fall-off of direct tissue heating (volume heating) by the RF energy as the distance from the electrode-tissue interface increases. Deeper tissue layers can be ablated by heat conduction from the volume-heated source, but the maximum lesion depth is limited.

Because the success of RF catheter ablation in the clinical setting is sometimes limited by the relatively small size of the lesion, attempts have been made to increase the size of those lesions reliably and safely. One approach is to increase the size and surface area of the electrode. The RF power needs to be increased comparably to achieve a similar current density and temperature at the electrode-tissue interface, and the results are greater depth of volume heating and a larger lesion. Modifications to the RF energy delivery mechanism, including cooled catheters and pulsed energy, have also helped address some of these limitations. Moreover, investigation into alternative energy sources appears to be more promising, including microwave, ultrasound, laser, and cryoablation.²

Delivery of RF energy on the epicardial surface generally requires an irrigated-tip catheter because there is otherwise no passive cooling of the electrode (outside the blood pool) and relatively little power can be delivered without being limited by temperature increases.

Cooled Radiofrequency Ablation

Biophysics

MECHANISM

Excessive surface heating invites coagulum formation, carbonization, and steam popping. These adverse effects may limit the depth of RF lesions, thus making it difficult to produce lesions of sufficient depth in scar tissue or thickened ventricular walls. Such limitations of conventional RF systems have stimulated the evaluation of modified electrode systems. One important modification involves cooling of the ablation electrode, which was designed to prevent overheating of the endocardium while allowing sufficient energy delivery to achieve a larger lesion size and depth.¹⁷

There are two methods of active electrode cooling by irrigation: internal and external (Fig. 7-6). With the internal (closed-loop) system (Chilli, Boston Scientific, Natick, Mass.), cooling of the ablation electrode is performed by circulating fluid within the electrode.¹⁸ In contrast, with the external (open-loop) system (Celsius

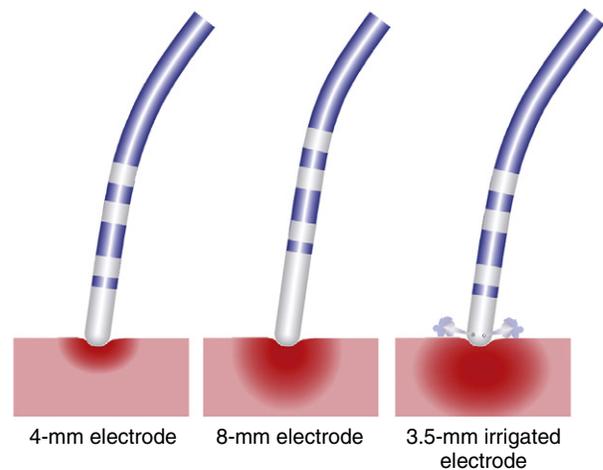

FIGURE 7-7 Effect of electrode type on lesion size. Representative blocks of myocardium are shown with lesions (dark shading) resulting from optimal radiofrequency energy delivery for each electrode type. A 4-mm electrode makes a small shallow lesion (left). An 8-mm electrode makes a larger, deeper lesion (center). The open-irrigated electrode makes a larger, deeper lesion, with a maximum width at some tissue depth (right).

or Navistar ThermoCool, Biosense Webster, Inc., Diamond Bar, Calif.; and Therapy Cool Path, St. Jude Medical, Inc., St. Paul, Minn.), electrode cooling is performed by flushing saline through openings in the porous-tipped electrode (showerhead-type system).¹⁸ Another cooling system is sheath-based open irrigation, which uses a long sheath around the ablation catheter for open irrigation. The latter system was found to provide the best results, but this type of catheter tip cooling is not clinically available.

Active electrode cooling by irrigation can produce higher tissue temperatures and create larger lesions, compared with standard RF ablation catheters, because of a reduction in overheating at the tissue-electrode interface, even at sites with low blood flow. This allows the delivery of higher amounts of RF power for a longer duration to create relatively large lesions with greater depth but without the risk of coagulum and char formation. Unlike with standard RF ablation, the area of maximum temperature with cooled ablation is within the myocardium, rather than at the electrode-myocardial interface. Higher power results in greater depth of volume heating, but if the ablation is power limited, power dissipation into the circulating blood pool can actually result in decreased lesion depth (Fig. 7-7).¹⁸ Compared with large-tip catheters, active cooling has

been shown to produce equivalent lesions with energy delivery via smaller electrodes, with less dependence on catheter tip orientation and extrinsic cooling, whereas larger electrodes have significant variability in their electrode-tissue interface, depending on catheter orientation (see Fig. 7-7). For the nonirrigated catheter, greater lesion volumes are observed with a horizontal orientation of the RF electrode compared with a vertical orientation. In contrast, for irrigated catheters, lesion volume increased with a perpendicular electrode orientation compared with the horizontal orientation.¹⁰

Lesion depth seems to be similar between closed-loop and open-irrigation electrodes. However, open irrigation appears to be more effective in cooling the electrode-tissue interface, as reflected by lower interface temperature, lower incidence of thrombus, and smaller lesion diameter at the surface (with the maximum diameter produced deeper in the tissue). These differences between the two electrodes are greater in low blood flow, presumably because the flow of saline irrigation out of the electrode provides additional cooling of the electrode-tissue interface (external cooling). Ablation with the closed-loop electrode, with irrigation providing only internal cooling, in low blood flow frequently results in high electrode-tissue interface temperature (despite low electrode temperature) and thrombus formation.¹⁸

When maximum power and temperature parameters that did not result in increased rates of complications and any evidence of excessive heating (including popping, boiling, or impedance rise) for each catheter type were selected, closed-irrigation catheters resulted in slightly larger lesion volumes and greater lesion depths than the open-irrigation catheters. Both cooled catheters fared better than the standard 4-mm-tip and large 10-mm-tip catheters with larger lesions achieved within the range of safe energy delivery.¹⁹

Monitoring Radiofrequency Energy Delivery

There is a significant discrepancy between monitored electrode temperature and tissue temperature during cooled RF ablation.^{6,8} The thermal effects on the electrode temperature are dependent on electrode heating from the tissue, internal cooling by the irrigation fluid, and external cooling from blood flow or open irrigation. With high irrigation flow rates, catheter tip temperature is not representative of tissue temperature, and therefore feedback cannot be used to guide power output. The difference between the electrode temperature and interface temperature is greater with the closed-loop electrode than with the open-irrigation electrode. The discrepancy is likely to be increased in areas of high blood flow, by increasing the irrigation flow rate, or by cooling the irrigant. Saline-irrigated catheters cause peak tissue heating several millimeters from the electrode-tissue interface. Because maximum tissue heating does not occur at the electrode-tissue interface, the value of temperature and impedance monitoring is limited with this type of catheter.

Therefore, it has been challenging to monitor lesion formation and optimize power delivery during cooled RF ablation.⁶ Appropriate energy titration is important to allow greater power application and to produce large lesions while avoiding overheating of tissue with steam formation leading to pops. Moreover, the inability to assess tissue heating, and hence to titrate power to an objective endpoint, prevents the operator from determining whether unsuccessful applications are caused by inadequate mapping or inadequate heating.

Electrode-tissue contact and orientation and the cooling effect of blood flow around the electrode and within the tissue are not as easily adjusted, and they also influence tissue heating. However, several other factors can be potentially manipulated to adjust ablation with saline-irrigated catheters, including flow rate, irrigant temperature, and RF power and duration. The most easily controllable factors are the power and duration of RF application. Instead of increasing the power to achieve the desired effect, which increases the likelihood of crater formation, the duration may be increased. A moderate power of 20 to 35 W with a relatively long RF duration of

60 to 300 seconds should be considered to achieve relatively large lesions, with a limited risk of crater formation.⁶

The flow rate of the irrigant determines the degree of cooling. Faster flow rates likely allow greater power application without impedance rises, increase the difference between tissue and electrode temperature, and thereby potentially increase the risk of steam pops if temperature is used to guide ablation. With the internally irrigated ablation system, the approved flow rate is fixed at 36 mL/min and is not currently manipulated.⁶ With the externally irrigated ablation system, an irrigation flow rate of 10 to 17 mL/min during RF application (and 2 mL/min during all other times to maintain patency of the pores in the electrode) may be selected in a power-controlled mode with a delivered power of up to 30 W. The irrigation flow rate should be increased to 20 to 30 mL/min with delivery of more than 30 W, to avoid excessive heat development at the superficial tissue layers. Additionally, the temperature of the irrigant can potentially be manipulated. Cooling the irrigant can allow power delivery to be increased without coagulum formation. The cooled irrigant is warmed as it passes through the tubing to reach the catheter and through the length of the catheter. The impact of cooling the irrigant has not been well studied. In most studies, the irrigant that enters the catheter is at room temperature.

Several indicators of tissue heating may be monitored, including catheter tip temperature, EP effects of RF, and the use of ICE. As noted, with cooled RF, the discrepancy between measured electrode temperature and tissue temperature is greater than during standard RF ablation.⁸ Identification of microbubbles on ICE has been used as an indication of excessive tissue heating during ablation with nonirrigated and internally irrigated catheters. External irrigation, on the other hand, produces visible bubbles, precluding the use of this method.^{17,19}

Evidence of tissue heating from an effect on recorded electrograms or the arrhythmia can be used to guide ablation energy.⁶ Interruption of tachycardia (VT, atrial flutter [AFL], supraventricular tachycardia) or block in conduction over a pathway (AVN or BT) during the process of ablation provides immediate feedback about the disruption of tissue integrity. Additionally, an increase in pacing threshold and a decrease in electrogram amplitude can indicate tissue damage. These factors, however, are not easily monitored during the RF application, particularly the change in pacing threshold. Moreover, the decrease in electrogram amplitude is often not visible during RF application because of superimposed electrical artifact.

With the internally irrigated system, the room temperature irrigant flowing at 36 mL/min typically cools the measured electrode temperature to 28° to 30°C. During RF application, the temperature increases; temperatures of 50°C can indicate that cooling is inadequate or has stopped, which warrants termination of RF application. The measured impedance typically decreases during cooled RF ablation by 5 to 10 Ω, in a manner similar to that observed during standard RF ablation.⁶

During open-irrigation RF ablation, initiation of irrigation results in a drop of electrode temperature by several degrees. Failure of electrode temperature to decrease indicates a lack of irrigant flow. When power delivery begins, catheter tip temperature should rise to 36° to 42°C (the presence of rising temperature, not the magnitude, reflects tissue heating). Temperatures higher than 40°C achieved with low power (less than 20 W) can indicate that the electrode is in a location with little or no cooling from the surrounding circulating blood, or that there is a failure of the catheter cooling system that requires attention. In contrast, the absence of any increase in tip temperature should raise the possibility of poor catheter contact.⁹

The optimal method for adjusting power during saline-irrigated RF ablation is not yet clearly defined, but some useful guidelines have emerged. The most commonly recommended approach is to perform ablation in a power-controlled mode, typically starting at 20 to 30 W and gradually increasing power to achieve evidence of tissue heating or damage. An impedance fall likely indicates tissue heating, similar to that observed with conventional RF

When catheter temperature is between 28° and 31°C, power can be ramped up, watching for a 5- to 10- Ω impedance fall. Measured electrode temperature will generally increase. A measured electrode temperature of 37° to 40°C is commonly achieved.

Temperatures exceeding 40° to 42°C with power greater than 30 W during open-irrigation RF ablation can be associated with a greater risk of steam pops and impedance rises, particularly during long RF applications, exceeding 60 seconds. Steam pops are often, but not always, audible. A sudden decrease in temperature, sudden catheter movement (as a consequence of the pop blowing the catheter out of position), and a sudden change in impedance are all potential indications that a pop has occurred. Whether the catheter is maintained in a stable position, as opposed to dragging it across the tissue, also likely influences tissue heating. High power can be applied continuously during dragging with little risk of excessive heating, although the duration of time to spend at each site to create an effective lesion may be difficult to ascertain.¹⁷ As a rule, the lowest effective power setting, shortest duration, and fewest applications should be employed whenever possible.⁹

Clinical Applications of Cooled Radiofrequency Ablation

Cooled tip catheters have several advantages. First, they allow the desired power to be delivered independent of local blood flow, and that results in increased lesion size. Second, they reduce the temperature of the ablation electrode as well as the temperature at the tissue interface, especially with the open-irrigation system, and that helps spare the endocardium and reduce the risk of clots and charring. Third, when compared with standard 8-mm-tip ablation catheters, a 3.5- to 4-mm irrigated electrode offers higher mapping accuracy while providing comparable ablation lesion size.

Cooled tip catheters are preferred (1) for long linear ablations (in the right or left atrium) and complex atrial arrhythmias (AFL or AF), (2) when there is a high probability of encountering thick or trabeculated tissue, (3) for specific areas with low local blood flow (including the coronary sinus [CS], particularly CS aneurysms, and pericardial space), (4) when ablating in the arterial circulation (to minimize the likelihood of arterial thromboembolism), and (5) for targets resistant to previous conventional ablation (focal tachycardias or BTs). Clinical trials have found irrigated tip catheters to be more effective than and as safe as conventional catheters for AFL ablation, thus facilitating the rapid achievement of bidirectional isthmus block. Irrigated tip catheters also were found to be safe and effective in eliminating BT conduction resistant to conventional catheters, irrespective of the location, and they have been successfully used for PV isolation for treatment of AF. Irrigated tip catheters also offer an advantage over conventional RF catheters in the case of scar-related VTs, by facilitating creation of larger and deeper lesions that can help eliminate intramyocardial or subepicardial reentrant pathways necessary for the VT circuit.^{9,17,20}

Internally cooled RF ablation is an attractive choice for use in pericardial ablation because no fluid is infused, and one need not worry about monitoring pericardial fluid throughout the ablation procedure, although drainage of irrigant during open-irrigation RF ablation can be managed in this setting.⁹

Power levels typically used during open-irrigation ablation depend on the site of ablation: 25 to 30 W in the left and right atrial free wall, 35 to 40 W for cavotricuspid isthmus and mitral isthmus ablation, 50 W in the left ventricle, and 20 W in the CS. At low power levels, the irrigation flow rate may be set lower than at higher levels; 17 mL/min is used for power output lower than 30 W, whereas 30 mL/min is used for power output of 30 to 50 W. Using a lower irrigation flow rate (10 mL/min) in the left atrium can help maintain some temperature feedback, with a cutoff temperature of 43°C. Lesion formation is monitored via attenuation of the local unipolar electrogram. Because of the very limited or absent temperature feedback, tissue overheating (pops) is a potential risk, especially in thin-walled chambers. The temperature is usually set at 40° to 45°C. If the temperature at the tip is lower than 40°C, the flow rate may be reduced. If the desired power is not met because the target temperature is reached at a lower power, the irrigation flow rate may be increased to a maximum of 60 mL/min.⁴ Parameters for epicardial ablation are similar to those used for endocardial ablation.¹⁷

Potential Risks of Cooled Radiofrequency Ablation

Although creation of larger ablation lesions can improve the efficacy of ablation for some patients, particularly when the targeted arrhythmia originates deep to the endocardium and when large areas require ablation, it is associated with increased risk of damage to tissue outside the target region (Table 7-1).

Higher power can be used with convective cooling, but higher power can cause superheating within the tissue (with subendocardial tissue temperatures exceeding 100°C) that can result in boiling of any liquids under the electrode. Consequently, evaporation and rapid steam expansion can occur intramurally, and a gas bubble can develop in the tissue under the electrode. Continuous application of RF energy causes the bubble to expand and its pressure to increase, which can lead to eruption of the gas bubble (causing a popping sound) through the path with the least mechanical resistance that leaves behind a gaping hole (the so-called pop lesion). This often occurs toward the heat-damaged endocardial surface (crater formation) or, more rarely, across the myocardial wall (myocardial rupture).¹⁸

Steam pops are often associated with a sudden (although small, less than 10 Ω) impedance rise and a sudden drop in electrode temperature. The consequence of a steam pop depends on the area of the heart being ablated. The risk of cardiac perforation is low in areas of dense ventricular scar. The risk of perforation and cardiac tamponade is likely to be higher for ablation in the thin-walled right ventricular outflow tract and in the atria. Therefore,

TABLE 7-1 Comparison of Features of Ablation Electrodes

FEATURE	4-MM RF	8-MM RF	4-MM COOLED RF (CLOSED)	4-MM COOLED RF (OPEN)	6-MM CRYOABLATION

0 = none; + = least, worst; ++ = minimal; +++ = moderate; ++++ = most, best; RF = radiofrequency.

it may be reasonable to take a more conservative approach to power application in these areas. Electrode orientation also seems to affect the significance of pops; pops that occur when the electrode tip is perpendicular to the tissue can be more likely to cause cardiac perforation than those that occur when the electrode is lying horizontally on the tissue. Therefore, one should try to avoid perpendicular (high-pressure) tissue contact, especially at higher power levels.¹⁷ RF applications with steam pops have a greater decrease in impedance and occur at a higher maximum RF power than applications without pops. Because of the considerable overlap of impedance changes in lesions with and without steam pops, it is not possible to advocate a general limit for impedance decrease for all RF lesions. However, when ablation is performed in areas at risk for perforation (i.e., especially in thin-walled structures), reducing power to achieve an impedance decrease of less than $18\ \Omega$ is a reasonable strategy to reduce the chance of a pop.²⁰

Although increasing power delivery and convective cooling can create large lesions, lesion production is somewhat difficult to control. Surface cooling does reduce the risk of boiling and coagulum formation. However, it does not allow the temperature at the tip to be monitored, and thus some feedback about lesion formation is lost.¹⁸

These concerns can be more pronounced with internal cooling as compared with open irrigation. Open irrigation cools the electrode and its direct environment, blood, and tissue surface. In contrast, with internal cooling, the main parameter affected by cooling is the temperature of the electrode. There can be minimal cooling of the direct electrode-tissue interface, but only at the true contact site between metal and tissue. Blood flow around the electrode makes it highly unlikely that there will be any noticeable cooling of the tissue surface at a distance of a few millimeters from the contact site. Consequently, one would not expect much effect of internal electrode cooling on the surface area or depth of the lesion. Electrode cooling does, however, enable larger lesions (at higher power levels) because the ablation process is no longer limited by electrode temperature rise. This can also be dangerous; in cases with good tissue contact, power delivery to the tissue can be much higher than average. With standard electrodes, this situation is signaled by an excessive electrode temperature rise, but without this warning, tissue overheating can occur. Blood clots can also be formed, but they do not adhere to a cool electrode and do not cause an impedance rise.⁴

With open-irrigation catheters, extensive ablation often performed for AF and scar-related VT can result in substantial saline administration. Therefore, management of the patient's volume status before, during, and after the procedure is crucial. This is also important during epicardial ablation, in which an obligatory fluid volume enters the pericardial sac and, if not intermittently or continuously evacuated, gradually results in cardiac tamponade. This complication can be prevented by having the side port of the introducer sheath attached to a suction bottle or gravity drain or by intermittent aspiration of accumulated fluid. Internal irrigation, on the other hand, has the advantages that no fluid is infused into the vasculature or pericardial space, and there is no possibility of embolization from the irrigation system.¹⁷

Cryoablation

Biophysics of Cryothermal Energy

Cryoablation uses a steerable catheter and a dedicated console, which are connected by a coaxial cable used to deliver fluid nitrous oxide to the catheter and to remove the gas from the catheter separately.²¹ A tank of fluid nitrous oxide is located inside the console; the gas removed from the catheter to the console is evacuated through a scavenging hose into the vacuum line of the EP laboratory. The system has several sensors to avoid inadvertent leaks of nitrous oxide into the patient body and to check connections of the different cables to the console.

Cryoablation catheters have a terminal segment whose temperature can be lowered to -75°C or less by delivery of precooled compressed liquid refrigerant (nitrous oxide argon) across a sudden luminal widening at the end of the catheters' refrigerant circulation system (Fig. 7-8). Decompression and expansion of the refrigerant (liquid to gas phase change) achieve cooling based on the Joule-Thompson effect.²²

The effect produced by cryothermal ablation is secondary to tissue freezing, the result of a temperature gradient occurring at the electrode-tissue interface (i.e., local heat absorption by the cooled catheter tip). It greatly depends on the minimum temperature reached, the duration of energy application, and the temperature time constant. The temperature time constant indicates the course of the descent of temperature to the target temperature, and a shorter value (expressed in seconds) identifies a more effective application. Important modulatory variables that can affect tissue damage produced by cryoablation include firmness of the catheter-tissue contact, tip temperature, freeze duration, and blood flow.²²

At the electrode-tissue interface, the coldest area is the one adjacent to the catheter tip, where functional effects of energy delivery are observed earlier (Fig. 7-9). Conversely, the less cooled area is the one at the periphery of the cryolesion, whose dimensions can also vary according to the duration of freezing. Because of limited cooling of the outer limit of the lesion (both in time and

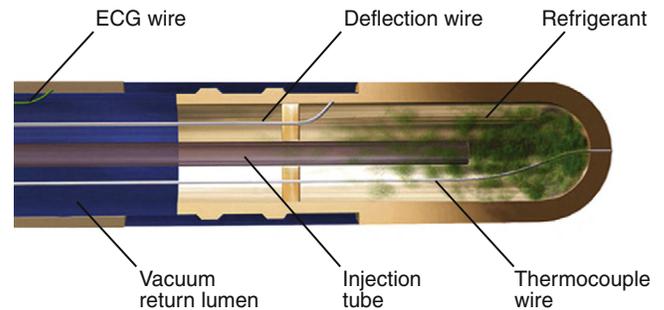

FIGURE 7-8 Schematic diagram demonstrating the CryoCath Freezor cryo-catheter internal design. (Courtesy of CryoCath Technologies, Montreal, Canada.)

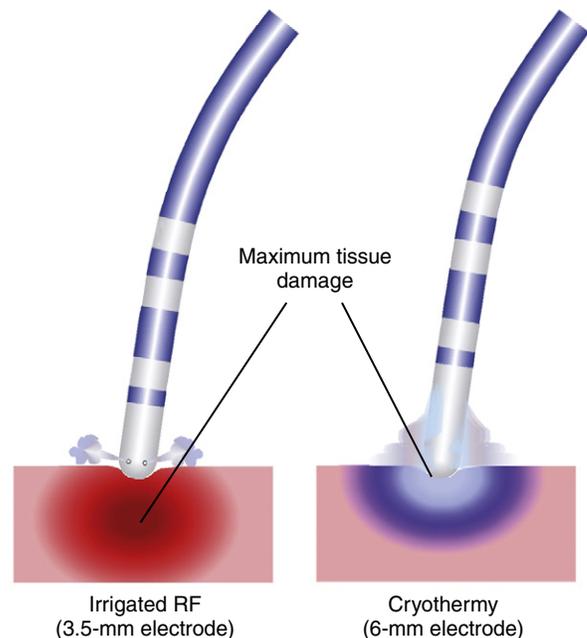

FIGURE 7-9 Depth of maximum tissue injury with irrigated-tip radiofrequency (RF) versus cryotherapy. With irrigated RF (left), the maximum tissue heating occurs at some tissue depth because of cooling at the surface. With cryotherapy (right), the maximum effect is at the endocardial surface.

temperature), this region is less likely to suffer irreversible damage. As a consequence, the effects obtained late during cryothermal energy application are likely to be reversible early on rewarming, and, therefore, any expected functional modification induced by cryoenergy should occur early (usually within the first 30 seconds of the application) to obtain a successful and permanent ablation of a given arrhythmogenic substrate.²²

Currently, two different systems of catheter cryoablation are available for clinical and experimental use: the CryoCath system (CryoCath Technologies, a division of Medtronic, Inc., Minneapolis, Minn.) and the CryoCor system (CryoCor, San Diego, Calif.). CryoCath uses 7 or 9 Fr steerable catheters with 4-, 6-, or 8-mm-long-tip electrodes. The ablation catheter is connected to a dedicated console, which has two algorithms available. The first is for cryomapping with a slow decrease of temperature to -30°C for up to 80 seconds, and the second is for cryoablation with a faster decrease of temperature to -75°C for up to 480 seconds. Additionally, the target temperature can be manually preset on the console at any value between -30° and -75°C . The CryoCor system has 10 Fr steerable catheters with 6.5- or 10-mm-long-tip electrodes. The console has a built-in closed-loop precooler for the fluid nitrous oxide, whose flow at the catheter tip is adjusted during the application to maintain a temperature of -80°C .²²

An expandable cryoablation balloon catheter (Arctic Front, CryoCath Technologies, Inc.), 18 to 30 mm in diameter, has been specifically designed for PV isolation. The cryoballoon is deployed at the ostium of targeted PVs, and cryoenergy is delivered over the occluding balloon system to create circumferential lesions around the PV ostium. This design helps limit the convective warming effects of the high blood flow at the PV ostium, which can limit lesion size and ablation efficacy, as well as shorten the lengthy procedure times required for circumferential point-by-point cryoablation around the PV ostia with the standard steerable cryocatheters.²³⁻²⁵

Pathophysiology of Lesion Formation by Cryoablation

MECHANISM OF TISSUE INJURY

The mechanisms underlying lesion formation by cryoenergy are twofold: direct cell injury and vascular-mediated tissue injury. The mechanisms of cellular death associated with tissue freezing involve immediate cellular effects, as well as late effects that determine the lesion produced.²²

Direct Cell Injury

EXTRACELLULAR ICE (SOLUTION EFFECT INJURY). Direct cellular injury results from ice formation. Ice forms only extracellularly when the tissue is cooled to mild temperatures (0° to -20°C) and results in hypertonic stress (the extracellular environment becomes hyperosmotic). The consequent shift of water from the intracellular to the extracellular space ultimately causes cell shrinkage and damage to the plasma membrane cellular constituents. These effects are reversible when rewarming is achieved within a short period (30 to 60 seconds). However, extended periods of extracellular freezing result in cellular death, and rewarming then results in cellular swelling sufficient to disrupt cellular membranes.²¹

INTRACELLULAR ICE. When the tissue is cooled to -40°C or lower, especially if it is cooled at rapid rates, ice forms extracellularly and intracellularly. Intracellular ice results in major and irreversible disruption of organelles, with cellular death.²¹ Although ice crystals do not characteristically destroy cell membranes, they compress and deform nuclei and cytoplasmic components. Mitochondria are particularly sensitive to ice crystals and are the first structures to suffer irreversible damage. Furthermore, intracellular ice can propagate from one cell to another via intercellular channels, thus potentially resulting in lesion growth. Cellular injury, disruption of membranous organelles in particular, is importantly enhanced on cellular thawing; rewarming causes

intracellular crystals to enlarge and fuse into larger masses that extend cellular destruction. Cellular injury can be extended by repeated freeze-thaw cycles. Final rewarming evokes an inflammation response to released cellular constituents and reperfusion hemorrhage, leading to tissue repair and eventual dense scarring.²² The size of ice crystals and their density depend on the proximity to the cryoenergy source, local tissue temperature achieved, rate of freezing, and surface area in contact with freezing temperatures.^{26,27}

Vascular-Mediated Tissue Injury

Tissue freezing results in vasoconstriction, hypoperfusion, and ischemic necrosis.²¹ Subsequent tissue rewarming produces a hyperemic response with increased vascular permeability and edema formation. Endothelial disruption within the frozen tissue is also observed and results in platelet aggregation, microthrombi, and microcirculatory stagnation within the lesion. Cryolesions, however, are associated with substantially less degree of endothelial damage and overlying thrombus formation than standard RF lesions. Extensive surgical experience has shown that cryolesions result in dense homogeneous fibrosis, with a well-demarcated border zone. They are nonarrhythmogenic and preserve the underlying extracellular matrix and tensile strength.²²

In the final phase of cryoinjury, replacement fibrosis and apoptosis of cells near the periphery of frozen tissue give rise to a mature lesion within weeks. Typically, these lesions are well circumscribed, with distinct borders, dense areas of fibrotic tissue, contraction band necrosis, and a conserved tissue matrix, including endothelial cell layers.²⁶

DETERMINANTS OF LESION SIZE

During cryoablation, lesion size and tissue temperature are related to convective warming, electrode orientation, electrode contact pressure, electrode size, refrigerant flow rate, and electrode temperature.²⁸ Lesion sizes during catheter cryoablation can be maximized by use of larger ablation electrodes with higher refrigerant delivery rates. A horizontal electrode orientation to the tissue and firm contact pressure also enhance lesion size. For a given electrode size, electrode temperature may be a poor predictor of tissue cooling and lesion size. In contrast to RF ablation, cryoablation in areas of high blood flow can result in limited tissue cooling and smaller lesion sizes because of convective warming. Conversely, cryoablation lesion size can be maximized in areas of low blood flow.^{22,28} The time to reach -80°C can predict cryoablation lesion size; cryoablation lesion volume increases as the time to reach -80°C decreases.²⁹ The 6- and 8-mm electrode-tip cryocatheters produce ablation lesions of similar depth that are more than two- and threefold larger than 4-mm catheters, respectively. Despite larger lesions, endothelial cell layers remain intact and devoid of thrombosis. Surface areas and volumes may be particularly sensitive to catheter tip-to-tissue contact angles with larger electrodes. As such, particular attention in catheter orientation is required with 8-mm electrode-tip cryocatheters to produce desired lesions.²⁷

Technical Aspects of Cryoablation

The intervention is often performed in two steps. First, "cryomaps" are obtained by moderate reversible cooling of tissue (electrode-tissue interface temperature approximately -28° to -32°C). Second, cryoablation cools the selected cryomapped pathways to much lower temperatures (electrode-tissue interface temperature lower than -68°C) and produces ice formation inside and outside of cells, a mechanism of irreversible cellular injury.²²

CRYOMAPPING

Cryomapping is designed to verify that ablation at the chosen site will have the desired effect and to ensure the absence of complications (i.e., to localize electric pathways to be destroyed or spared).

This procedure is generally performed using various pacing protocols that can be performed during cryomapping (or ice mapping) at -32°C . At this temperature, the lesion is reversible (for up to 60 seconds), and the catheter is stuck to the adjacent frozen tissue because of the presence of an ice ball that includes the tip of the catheter (cryoadherence). This permits programmed electrical stimulation to test the functionality of a potential ablation target during ongoing ablation and prior to permanent destruction. It also allows ablation to be performed during tachycardia without the risk of catheter dislodgment on termination of the tachycardia.

In the cryomapping mode, the temperature is not allowed to drop to less than -30°C , and the time of application is limited to 60 seconds. Formation of an ice ball at the catheter tip and adherence to the underlying myocardium are signaled by the appearance of electrical noise recorded from the ablation catheter's distal bipole. Once an ice ball is formed, programmed stimulation is repeated to verify achievement of the desired effect. If cryomapping does not yield the desired result within 20 to 30 seconds or results in unintended effect (e.g., AV conduction delay or block), cryomapping is interrupted, to allow the catheter to thaw and become dislodged from the tissue. After a few seconds, the catheter may be moved to a different site and cryomapping repeated.²²

CRYOABLATION

When sites of successful cryomapping are identified by demonstrating the desired effect with no adverse effects, the cryoablation mode is activated, in which a target temperature lower than -75°C is sought (a temperature of -75° to -80°C is generally achieved). The application is then continued for 4 to 8 minutes, thus creating an irreversible lesion. If the catheter tip is in close contact with the endocardium, a prompt drop in catheter tip temperature should be observed as soon as the cryoablation mode is activated. A slow decline in catheter tip temperature or a very high flow rate of refrigerant during ablation suggests poor electrode-tissue contact. In such cases, cryoablation is interrupted, and the catheter is repositioned.²²

Advantages of Cryoablation

The use of cryoablation in the EP laboratory provides some distinct advantages not seen with conventional RF ablation. The slow development of the cryolesion (approximately 240 seconds), although time-consuming, enables the creation of reversible lesions and modulation of lesion formation in critical areas. As noted, cryomapping allows functional assessment of a putative ablation site during ongoing ablation and prior to permanent destruction. This offers a safety advantage when ablation is performed close to critical structures such as the AVN or His bundle (HB).³⁰

Compared with standard RF lesions, cryolesions are associated with a substantially lower degree of endothelial disruption, less platelet activation, and lower thrombogenic tendency. Therefore, the risk of coagulum formation, charring, and steam popping is less than with RF ablation (see Table 7-1). Furthermore, cryoablation results in dense homogeneous fibrotic lesions with a well-demarcated border zone and does not cause collagen denaturation or contracture related to hyperthermic effects. Therefore, cryothermal energy application in close proximity to the coronary arteries (e.g., during epicardial ablation) or in venous vessels (CS, middle cardiac vein, and PVs) does not result in damage, perforation, or chronic stenosis of their lumen.^{22,30}

The cryoadherence effect results in the formation of a very focal lesion because of fixed and stable tip electrode contact to adjacent frozen tissue throughout the whole application. This has a particular safety advantage, especially for ablation in the proximity of critical areas, such as the AVN and HB. In addition, cryoadherence augments catheter stability throughout the energy application, even when sudden changes in heart rhythm that can potentially displace the ablation catheter (e.g., tachycardia termination) occur. At the same time, cryoadherence does not compromise

safety. On discontinuation of cryothermal application, the defrost phase is fast (within 3 seconds), and the catheter can be immediately disengaged from the ablation position.

Cryothermal energy application is characterized by the absence of pain perception in nonsedated patients. In fact, cryoablation can be performed without analgesia. Occasionally, a light sense of cold or headache is perceived as minor discomfort. This characteristic can be particularly useful in younger and pediatric patients.²²

Clinical Applications of Cryoablation

As noted, catheter-based cryoablation can have specific advantages over RF catheter ablation, including greater safety as a result of greater catheter stability, reduced risk of systemic embolization, low propensity for thrombus formation and endothelial disruption, and preservation of ultrastructural tissue integrity. As a result, cryoablation has quickly been adapted for specific arrhythmogenic substrates in which RF has specific limitations that can potentially be overcome by cryotherapy.³⁰

It is unlikely that cryoablation will replace standard RF ablation in unselected cases. Nevertheless, for the previously mentioned peculiarities, cryothermal ablation has proven effective and safe for the ablation of arrhythmogenic substrates close to the normal conduction pathways. It has become the first-choice method to ablate superoparaseptal and midseptal BTs and difficult cases of AVNRT because of its widely demonstrated safety profile. As the technology evolves and further iterations of the catheter proceed, the role for this technology is likely to grow.³¹

ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

So far, slow pathway ablation for AVNRT by cryothermal energy represents the larger experience in the clinical application of this technology.^{21,32} Previously published reports with cryoablation of AVNRT in pediatric patients demonstrated procedural success rates of 83% to 97% and recurrence rates ranging from 0% to 20%. Although the use of bonus cryoapplications to consolidate the acutely successful cryoablation and the availability of larger tip cryocatheters (6 to 8 mm and 6 mm versus 4 mm) to create larger lesions have been associated with fewer recurrences on long-term follow-up without compromising safety, the overall procedural success rates have remained consistently lower than those (95% to 99%) with RF ablation.^{31,33-36}

According to current data, cryothermal energy is a valuable and useful alternative to RF energy to treat patients with AVNRT. The absence of permanent inadvertent damage of AV conduction makes this new technology particularly useful for patients with difficult anatomy after an unsuccessful prior standard ablation procedure, in pediatric patients, and in patients in whom even the small risk of AV block associated with RF ablation is considered unacceptable. Cryoablation can be of particular advantage in several situations, including posterior displacement of the fast pathway or AVN, a small space in the triangle of Koch between the HB and the CS ostium, and the need for ablation to be performed in the midseptum. However, given the high success rate and low risk of RF slow pathway ablation, it can be difficult to demonstrate a clinical advantage of cryoablation over RF ablation in unselected AVNRT cases.²²

BYPASS TRACTS

Cryothermal ablation of BTs in the superoparaseptal and midseptal areas, both at high risk of complete permanent AV block when standard RF energy is applied, is highly safe and successful (Fig. 7-10).³² Cryoablation can also be successfully and safely used to ablate selected cases of epicardial left-sided BTs within the CS, well beyond the middle cardiac vein, once attempts using the transeptal and transaortic approaches have failed.²¹ However, the experience with cryoablation in unselected BTs is more limited

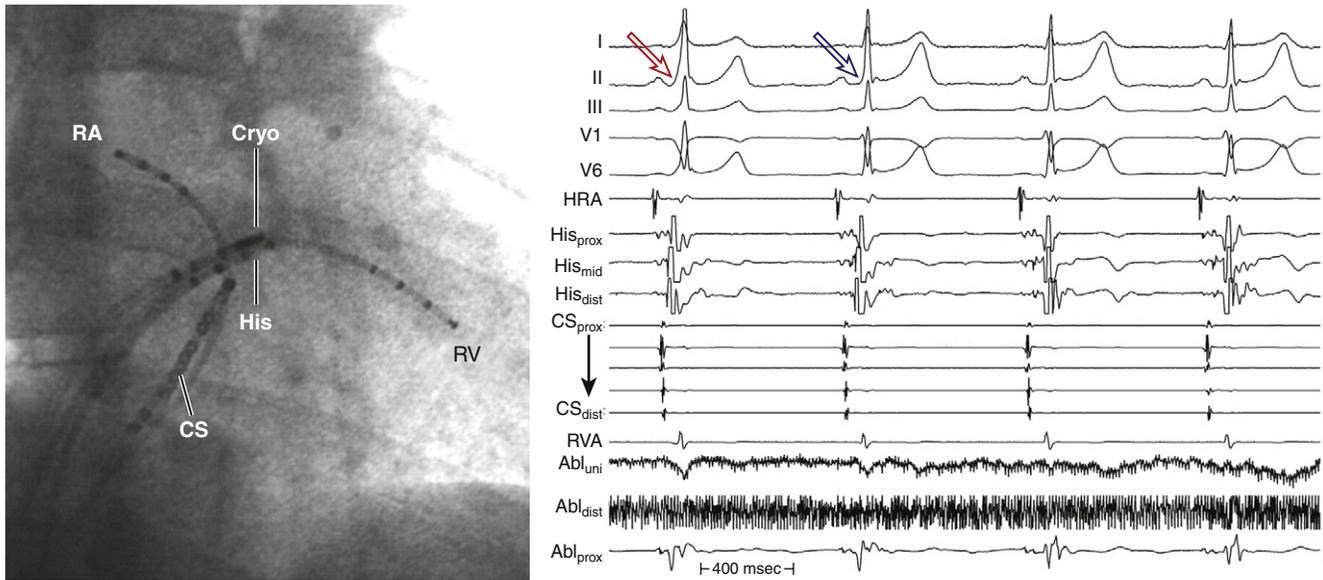

FIGURE 7-10 Cryoablation of a para-Hisian bypass tract (BT). Right anterior oblique fluoroscopic view of cryoablation catheter (Cryo) position and ECG and intracardiac recordings during cryoablation of para-Hisian BT. The first two QRS complexes at left are preexcited, with the second QRS complex (blue arrow) less so than the first (red arrow), as cryoablation begins to affect pathway conduction. Preexcitation disappears afterward. The ablation recordings at bottom are severely disrupted by the delivery of cryoenergy. Abl_{dist} = distal ablation site; Abl_{prox} = proximal ablation site; Abl_{uni} = unipolar ablation site; CS = coronary sinus; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; RA = right atrium; RV = right ventricle; RVA = right ventricular apex.

and less satisfactory; this can be related to multiple factors, including the learning curve and the smaller size of the lesion produced by cryoablation. In addition, all the peculiarities of cryothermal energy, which are optimal for septal ablation, are less important or even useless for ablation of BTs located elsewhere.²¹

In more recent series, the short-term success rate of cryoablation of BTs in the superoparaseptal and midseptal regions exceeded 90%; however, resumption of BT conduction with recurrence of symptoms can occur in up to 20% of patients, and overall success rates have been lower than those of AVNRT cryoablation. It is, however, important to note that alternatives for elimination of some of those BTs are limited by a prohibitive risk of AV block with RF ablation. Although transient modifications of the normal AVN conduction pathways can be observed during cooling and right bundle branch block has occurred on occasion, no permanent modifications have been observed, and inadvertent AV block has yet to be reported. In fact, immediate discontinuation of cryothermal energy application at any temperature on observation of modification of conduction over normal pathways results in return to baseline condition soon after discontinuation.³⁰

FOCAL ATRIAL TACHYCARDIA

Occasionally, successful cryoablation of focal AT has been reported. Its safety has also been confirmed for ablation of atrial foci located close to the AVN. Cryoenergy can also be particularly valuable in ablating focal sources within venous structures.³⁰

TYPICAL ATRIAL FLUTTER

Complete cavotricuspid isthmus block can be achieved by cryothermal ablation. In addition to the safety advantages of cryoenergy discussed earlier, cryolesions are limited by convective warming effects of blood flow, which reduces the risk of damage to nearby coronary arteries. Another advantage of using cryothermal energy for the ablation of typical AFL is the absence of pain perception related to energy application.^{30,37} Previous studies reported cryoablation of the cavotricuspid isthmus for typical AFL with short-term and long-term success comparable to results with RF ablation. However, a more recent prospective randomized study comparing

RF and cryothermal energy for ablation of typical AFL suggested that lesion durability from cryoablation was significantly inferior to that of RF ablation. Although acutely successful ablation rates in the cryoablation group were comparable to those for RF ablation (89% versus 91%), persistence of bidirectional isthmus block in patients treated with cryoablation reinvestigated 3 months following ablation was inferior to that in patients treated with RF ablation, as evidenced by the higher recurrence rate of symptomatic, ECG-documented AFL (10.9% versus 0%), and higher asymptomatic conduction recurrence rates (23.4% versus 15%). Additionally, compared with RF ablation, cryoablation is associated with significantly longer procedure times. This is driven mainly by differences in ablation duration, which can be attributed to the longer duration of each cryoablation (4 minutes) compared with RF ablation (up to 60 seconds).^{22,38}

PULMONARY VEIN ISOLATION

For the characteristics mentioned earlier, cryothermal energy ablation can be considered an ideal and safer energy source for PV isolation, and the incidence of PV stenosis and thromboembolic events is expected to be dramatically reduced compared with RF ablation. Additionally, cryoablation has never been associated with atrioesophageal fistula.^{39,40} On the other hand, cryothermal injury is sensitive to surrounding thermal conditions. The high flow of the PVs can present a considerable heat load to cryothermal technologies, which can limit the size and depth of the lesion produced by cryothermal energy at the ostium of the PV. Furthermore, cryoablation of PVs by standard steerable catheters is very time-consuming, considering that one single ablation point takes about 4 minutes.

A new catheter design for circumferential ostial ablation of the PVs has been developed, with the option of deploying an inflatable balloon in the PVs to reduce the heat load related to blood flow (Fig. 7-11).^{21,39} The cryoballoon is deployed at the ostium of targeted PVs, and cryoenergy is delivered over the occluding balloon system to create circumferential lesions around the PV ostium. The clinical short-term and long-term success rates of this approach are acceptable; however, the risk of phrenic nerve injury is relatively high because of ablation in the region of the right superior PV. To date, thromboembolism or PV stenosis has yet to be reported.^{23-25,41-45}

FIGURE 7-11 Cryothermal balloon catheter. (Courtesy of Medtronic, Inc., Minneapolis, Minn.)

VENTRICULAR TACHYCARDIA

Data regarding cryoablation for VT remain scant. Small reports described feasibility and success of cryoenergy for ablation of out-flow tract VT. Additionally, cryothermal energy can be of potential advantage in percutaneous subxiphoid epicardial ablation of VT because of less potential damage to the epicardial coronary arteries. The reduced heat load in the pericardial space related to the absence of blood flow limits RF energy delivery but can be to the advantage of cryoablation, with the possibility of producing larger transmural lesions.²²

Microwave Ablation

Biophysics of Microwave Energy

Microwaves are the portion of the electromagnetic spectrum between 0.3 and 300 GHz. For the ablation of cardiac arrhythmias, microwave energy has been used at frequencies of 0.915 and 2.450 GHz. Similar to RF, microwave energy produces thermal cell necrosis. However, in contrast to heating by electrical resistance as observed during RF ablation, the mechanism of heating from a high-frequency microwave energy source is dielectrics. Dielectric heating occurs when high-frequency electromagnetic radiation stimulates the oscillation of dipolar molecules (e.g., water molecules) in the surrounding medium at a very high speed, thereby converting electromagnetic energy into kinetic energy. This high-speed vibration favors friction between water molecules within the myocardial wall that results in an increase of myocardial tissue heat.¹ This mode of heating lends microwave ablation the potential for a greater depth of volume heating than RF ablation and should theoretically result in a larger lesion size.⁴⁶

Microwave energy is not absorbed by blood and can propagate through blood, desiccated tissue, or scar. It also can be deposited directly into the myocardial tissue at a distance, regardless

of the intervening medium. The microwave energy field generated around the ablation catheter antenna can create myocardial lesions up to 6 to 8 mm in depth without overheating the endocardial surface, a feature that can potentially limit the risk of charring, coagulum formation, and intramyocardial steam explosions. Penetration depth achieved with microwave energy depends on several factors—dielectric properties of the tissue, frequency of the microwave energy, antenna design, and composition and thickness of the cardiac layers.

The effectiveness of microwave ablation depends on the radiating ability of the microwave antenna that directs the electric field and determines the amount transmitted into the myocardium, which is critical for heating. An end-firing monopolar antenna has been used to produce lesions at depths of 1 cm without disruption of the endocardium in porcine ventricles. The depth of these lesions increased exponentially over time as compared with standard nonirrigated RF energy, which had minimal lesion expansion after 60 seconds of ablation.¹ To concentrate more of the energy distribution near the electrode tip, circularly polarized coil antennas have been developed. Other configurations of the microwave antenna include helical, dipole, and whip designs; these have a large effect on the magnetic field created. However, many of these catheters are still under clinical investigation.

Pathophysiology of Lesion Formation by Microwave Ablation

Microwave energy produces thermal cell necrosis and transmural damage, with foci of coagulation necrosis of myocytes in the central part of the lesion. Hyperthermia (more than 56°C) causes protein denaturation and changes in myocardial cellular EP properties resulting from movement of mobile ions within the aqueous biological medium and altering membrane permeability. The acute myocyte changes include architectural disarray, loss of contractile filaments, and focal interruption of the plasma membrane, which are signs of irreversible injury. Additionally, occlusion of the lumen of the small intramyocardial vessels and severe disruption of endothelial and adventitial layers are observed.⁴⁶ Carbonization does not occur on tissue surfaces because of the good penetration of microwave energy. Fibrotic tissue eventually replaces the necrotic muscle, which typically becomes sharply demarcated from normal myocardium.⁴⁶

In vitro and in vivo experiments have demonstrated good uniformity in the distribution of the electromagnetic energy throughout the tissue and excellent penetration depth, with no areas of discontinuity over the length of the ablating probe. Energy distribution is maximal near the center of the ablating element, a finding indicating that depth of ablation is relatively deeper at the midpoint of a lesion. There is no indication of edge effect along the ablating tip, which can potentially produce overheating of the tissue surface and induce charring. The temperature at the tissue surface typically remains at less than 100°C over the time required to produce a 6-mm-deep lesion. This is a critical finding because the ability to raise the tissue temperature to 50°C while maintaining it at less than 100°C is paramount to effective and safe hyperthermic ablation.

In addition to the frequency of the microwave energy and length of antenna used, penetration of microwave into the tissue and lesion dimensions is proportional to the power and duration of energy application.

Although microwave ablation in theory should be less likely than RF to induce surface overheating, in vivo studies found that a higher targeted temperature of 90°C resulted in a surface temperature of more than 70°C and was associated with some tissue surface charring when compared with lower temperatures. Therefore, the use of the temperature-controlled mode of microwave energy delivery to limit the targeted temperature to 80°C may prevent tissue overheating and reduce the risk of tissue charring. It should be noted that no coagulation formation and no popping were observed during any of the microwave ablations performed.^{47,48}

In contrast to RF energy, in which lesion expansion is maximal after 60 seconds, microwave lesion size continues to increase after 300 seconds of energy application. As compared with conventional 4-mm-tip RF ablation, microwave ablation creates a similar lesion depth and width. Lesion length created by a 10-mm antenna is comparable to that created by 8-mm-tip RF ablation. However, because of the lack of physical limitations on the length of the microwave antenna that can be made, microwave ablation may be more advantageous in creating long linear lesions by using longer antenna. Nevertheless, a parallel antenna orientation is needed for optimal energy delivery because the growth in lesion sizes is limited beyond the energy field as a result of the finite radial energy distribution of the microwave ablation antenna. Furthermore, the lesion depth created with an 8-mm-tip or saline-irrigated electrode catheter appears to be larger than the lesion depth created by microwave ablation. However, direct comparisons among these different ablation technologies are not available.^{47,48}

Clinical Applications of Microwave Ablation

Microwave ablation can be a promising technique that is potentially capable of treating a wide range of ventricular and supraventricular arrhythmias. The physics of the microwave energy source can be particularly useful for transmural ablation lesions of atrial tissue, as well as the treatment of tachyarrhythmias arising from deep foci of ventricular myocardium.⁴⁶

Microwave can potentially overcome several limitations of RF energy for linear ablation. In contrast to resistive heating produced by RF, microwave generates frictional heat by inducing oscillation of dipoles in a medium such as water. Tissue with higher water content, such as cardiac tissue, allows better energy transfer during the propagation of microwave energy deep into the tissue. Therefore, microwave energy is capable of creating deeper lesions, to penetrate scar tissue and to reduce surface heating with less endocardial disruption or coagulation formation. Furthermore, delivery of microwave energy is not limited by electrode size as in RF, and microwave ablation can be applied over a larger surface by modifying antenna size and shape. Another hypothetical advantage of microwave energy is that it provides sufficient lesions, independent of contact. However, experimental data have shown that penetration of electromagnetic fields into tissue declines exponentially, and the decline is steep when using frequencies in the microwave range; therefore, distance is still an important consideration. Nevertheless, this theoretical advantage can potentially improve the versatility of microwave ablation, especially in areas where muscular ridges and valleys may pose problems for conventional RF ablation.^{1,49}

Currently, microwave ablation has been increasingly used intraoperatively (epicardially or endocardially) during surgical maze procedures. The ability to make microwave antennas into flexible linear applicators and place them parallel to the endocardium by means of clamps has increased the effectiveness of microwave as a tool in open-chest surgery and in minimally invasive surgery.^{50,51}

The development and manufacture of antennae for delivery of microwave energy is technically more complex than for RF electrodes because the efficacy of microwave energy transmission depends mainly on its delivery apparatus. As a result, microwave antennae were previously bulky and were limited to surgical use. Developments in the catheter-based microwave system may allow the transvenous delivery of microwave energy for endocardial ablation. Only a few case reports have described the successful use of transvenous catheter microwave ablation of the AV junction and cavotricuspid isthmus.^{47,52,53}

Currently, only one transvenous microwave catheter system (MedWaves, San Diego, Calif.) is available for investigational use. This system includes a deflectable, 10 Fr catheter with 10-mm or 20-mm helical coil antenna with temperature monitoring, bipolar electrode recording, and a generator delivering microwave at 900 to 930 MHz. Microwave energy is delivered by using a

temperature-controlled mode in which the generator automatically adjusts the power output to maintain the targeted temperature of the temperature sensor inside the antenna. For ablation of typical AFL, linear lesions are created with a point-by-point technique with gradual pullback of the microwave catheter across the cavotricuspid isthmus. Interestingly, microwave causes no perception of pain during ablation of the cavotricuspid isthmus with energy delivery in the inferior vena cava region.^{49,53}

Clinical studies on the use of transvenous catheter microwave ablation for AF and AFL ablation are currently under way to investigate the safety and feasibility of this technique.^{52,53}

Ultrasound Energy

Biophysics of Ultrasound Energy

Sound is a propagation of cyclical (oscillatory) displacements of atoms and molecules around their average position in the direction of propagation. When the cyclical events occur at frequencies of more than 20,000 Hz (i.e., higher than the average threshold of the human hearing), the sound is defined as ultrasound.^{1,52}

Ultrasound beams can be treated in a manner analogous to light beams, including focusing (ultrasonic lens) and minimization of convergence and divergence (collimation). These optical geometric manipulations allow for ultrasound to be directed toward confined distant (deep) tissue volumes. This is a pivotal capability of therapeutic ultrasound.

Ultrasound energy transmission is subject to attenuation with distance and medium, especially with air. The amount of ultrasound energy transferred to tissue is proportional to the intensity of the wave and the absorption coefficient of the tissue. Because of this property, ultrasound ablation does not require direct contact with the myocardium, in contrast to RF ablation. Ultrasound energy decreases proportionally with the distance ($1/r$), whereas RF ablation electrical conduction decreases with the square of the distance ($1/r^2$). This feature allows ultrasound energy to create deeper and transmural lesions. The duration of application and acoustic power used have a direct relationship with the lesion depth.⁵²

Pathophysiology of Lesion Formation by Ultrasound Energy

Tissue injury caused by ultrasound is mediated by two mechanisms: thermal and mechanical energy. Ultrasound waves can propagate through living tissue and fluids without causing any harm to the cells. However, by focusing highly energetic ultrasound waves (high-intensity focused ultrasound [HIFU]) to a well-defined volume, local heating (achieving a tissue temperature of 65° to 100°C) occurs and causes rapid tissue necrosis by coagulative necrosis. Thermal energy results when the energy transported by an ultrasound beam becomes attenuated as it propagates through viscous (viscoelastic) media, such as human soft tissue. The attenuation partly represents conversion of ultrasound energy into heat. Another mechanism by which HIFU destroys tissue is mechanical energy, which results from pressure waves (sound waves) propagating in gas-containing tissues as they cyclically expand (explode) and shrink (implode) microbubbles in the tissue (i.e., oscillation and collapse of gas microbubbles), a process known as microcavitation. This process of vibration of cellular structures causes local hyperthermia and mechanical stress by bubble formation because of rapid changes in local pressure, thus leading to cell death.¹

Previous studies showed that rapid, focused absorption of HIFU energy in noncardiac tissue produced a steep tissue temperature gradient (2° to 5°C/sec) between the focus and the surrounding tissue, thus allowing for the production of sharply demarcated lesions and reducing collateral damage. However, a more recent study using HIFU for PV isolation in canine hearts found that HIFU produced a dual temperature profile, probably because of immediate direct acoustic heating and subsequent conductive

heating. Additionally, the region of direct acoustic heating with HIFU energy in vivo was largely predictable from the distance of the target tissue to the HIFU balloon surface; actual tissue temperatures exceeding 50°C (the temperature at which permanent tissue damage is supposed to occur) were focused within a 7-mm width and 7.5-mm depth around the HIFU exit site (significantly larger than the 2- to 3-mm area of resistive heating observed with RF energy). However, the actual distribution of tissue temperatures during lesion generation may be affected by other factors, such as the following: blood circulation; location of different tissue thicknesses within the atrium, venoatrial junction, or PV; or energy attenuation at various interfaces between the target tissue and the energy source.⁵⁴

HIFU lesion depth increases with longer duration of energy delivery from 15 to 60 seconds, and there is a linear relationship between increasing power and depth of lesions.¹ HIFU applications were found to achieve transmural lesions and PV isolation. However, although this can translate into increased effectiveness of ablation, it also can potentially lead to collateral damage, namely to the phrenic nerve and esophagus. HIFU ablation can produce damage to the phrenic nerve when it is located within 4 to 7 mm of HIFU exit.⁵⁴

Clinical Applications of Ultrasound Energy

HIFU is an attractive alternative energy source. Because it can be focused at specific depths, ultrasound can be advantageous when considering epicardial ablation. The presence of epicardial fat makes the use of standard RF current difficult, both with catheter-based epicardial ablation and minimally invasive surgical ablation.^{1,55} Furthermore, the ability of ultrasound to be collimated through echolucent fluid medium (e.g., water, blood) makes it ideal for a balloon delivery system, which can potentially facilitate circumferential ablation at the PV orifice with a single energy delivery.¹ Another potential advantage of ultrasound is that it does not rely on extensive heating on the vein surface. This can be of value in PV isolation procedures, to help prevent PV stenosis seen with RF ablation. Because HIFU is delivered at the beam convergence site rather than at the tissue surface, successful ablation is less dependent on absolute balloon-tissue contact than other balloon-based technologies. Furthermore, unlike other energy sources, HIFU can be deflected within the balloon to create a wide, focused zone of energy delivery outside the PV orifice, thereby mimicking current wide area circumferential ablative approaches. Currently, no HIFU catheters are available that can be used for linear (instead of circular) ablation.^{54,56-58}

An 8-MHz cylindrical transducer mounted within a saline-filled balloon has been designed for PV isolation. The ablation system (Atrionix, Palo Alto, Calif.) consists of a 0.035-inch-diameter luminal catheter with a distal balloon (maximum diameter, 2.2 cm) housing a centrally located ultrasound transducer. The system is advanced over a guidewire into the target PV. Tissue surface temperature monitoring is achieved by thermocouples on the balloon and the ultrasound transducer. Despite initial enthusiasm, the long-term report including 33 patients was disappointing, with a long-term cure rate of approximately 30%, although short-term electrical isolation was achieved in all but 1 of the PVs targeted. Surprisingly, several applications were required to achieve PV isolation. The variability of the PV anatomy was the main culprit for the system failure. In larger PV orifices, it was difficult to achieve adequate heating. The system delivered a narrow band of ultrasound energy radially from a centrally located transducer, and it was at times challenging to place the catheter in all PVs at the proximal portion. Therefore, foci at the most proximal lip of a PV may not be ablated successfully.

More recently, a forward-projecting HIFU balloon catheter (ProRhythm, Inc., Ronkonkoma, N.Y.) was developed for circumferential PV isolation outside the PV ostia (to limit the risk of PV stenosis). Radially emitted ultrasound is reflected from the back of the balloon, thus resulting in forward projection of ultrasound

energy, with a focal point at the balloon-endocardial interface (Fig. 7-12). This system has two noncompliant balloons. A 9-MHz ultrasound crystal is located in the distal balloon filled with contrast and water. The proximal balloon, filled with carbon dioxide, forms a parabolic interface with the distal balloon to reflect the ultrasound energy in the forward direction, by focusing a 360-degree ring (sonicating ring) of ultrasound energy 2 to 6 mm in front of the distal balloon surface. The distal balloon has three sizes—24, 28, or 32 mm in diameter—producing sonicating rings of 20, 25, or 30 mm in diameter. The acoustic power of the system is 45 W for all three balloons, with negligible loss of power in the balloon. The distal balloon is irrigated with contrast and water at 20 mL/min during ablation to keep the balloon cool (lower than 42°C). The catheter has a central lumen used for insertion of a hexapolar, spiral mapping catheter (ProMap, ProRhythm, Inc.) for real-time assessment of PV potentials.⁵⁹⁻⁶¹

Clinical application of this system for PV isolation was evaluated and was shown to be feasible, but fatal esophageal injury was also observed.⁵⁶⁻⁵⁸ A study of 28 patients using an esophageal

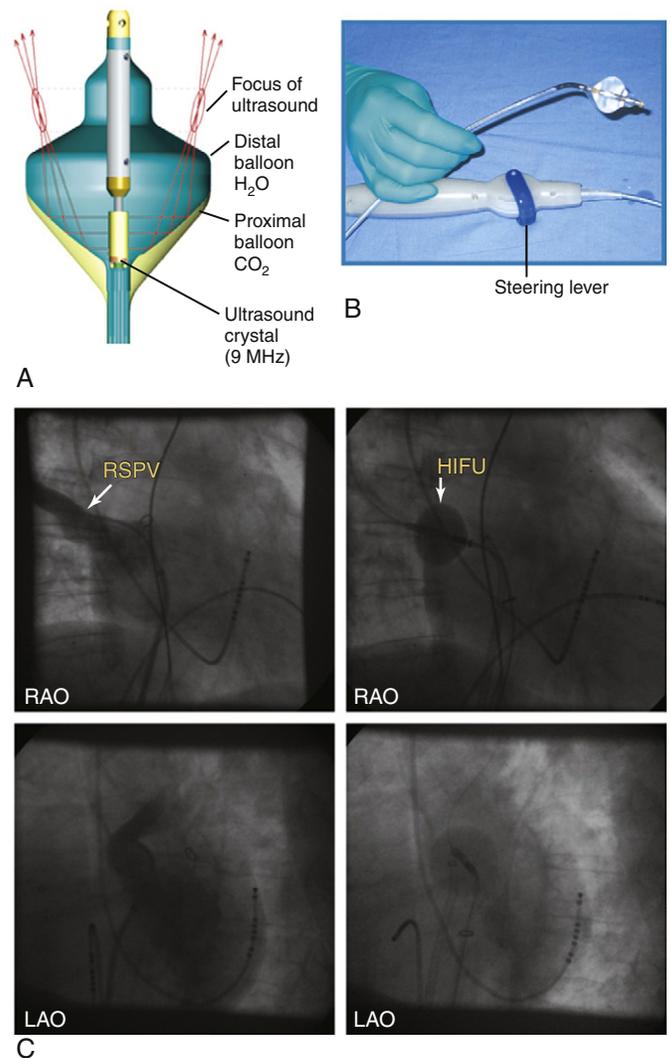

FIGURE 7-12 Circumferential antral pulmonary vein (PV) isolation using the high-intensity focused ultrasound (HIFU) balloon catheter. **A**, Schematic representation of the HIFU balloon catheter designed to focus ultrasound energy circumferentially outside the PV (PV antrum). **B**, HIFU balloon. **C**, Right anterior oblique (RAO) and left anterior oblique (LAO) fluoroscopic views of the angiograms (right) and HIFU balloon positioning (left) in the right superior PV (RSPV). (From Schmidt B, Antz M, Ernst S, et al: Pulmonary vein isolation by high-intensity focused ultrasound: first-in-man study with a steerable balloon catheter. *Heart Rhythm* 4:575, 2007.)

temperature-guided safety algorithm demonstrated that acute PV electrical isolation with HIFU ablation could be achieved in only 77% of PVs. Eight percent of PVs could not be isolated with HIFU as a result of excessive esophageal heating or balloon catheter dislodgment. In only 32% of patients, all PVs could be isolated using HIFU ablation only. Although power modulation did not negatively influence short-term success rates of PV electrical isolation, it also did not prevent esophageal temperature from exceeding levels higher than 40.0°C at the end of the ablation; elevated esophageal temperature prompting cessation of energy delivery occurred in 9% of PVs. Despite use of the safety algorithm and continuous phrenic nerve pacing, transient and persistent phrenic nerve palsy occurred in 14% and 7% of patients, respectively. Even worse, use of the safety algorithm could not prevent occurrence of esophageal thermal damage and lethal atrioesophageal fistula. PV isolation with HIFU has proven to be successful but is not yet safe for everyday clinical use. The problems of phrenic nerve palsy and atrioesophageal fistula occurrence remain unresolved. Still, the concept of the energy source and mode of energy delivery may be very interesting for future treatment of AF. With mean PV isolation times of less than 15 seconds and a high number of complications, it is evident that the present energy source is too powerful in some patients.⁵⁹

Laser Energy

Biophysics of Microwave Energy

Light amplification by stimulated emission of radiation (laser) produces a monochromatic (narrow-frequency range) phase-coherent beam at a specific wavelength (Fig. 7-13). This beam can be directed for a specific duration and intensity, and as it penetrates the tissue, it is absorbed and scattered. The photothermal effect occurs with the absorption of photon energy, thus producing a vibrational excited state in molecules (chromophores). By absorbing this energy, the tissue is heated and a lesion is created (i.e., tissue injury is thermally mediated).¹

Laser energy can be delivered in a continuous or a pulsed mode. Laser energy is selectively absorbed by the tissues over several millimeters, and it decays exponentially as it passes through the tissue secondary to absorption and scatter, the extent of which depends on laser beam diameter and the optical properties of the tissue. Lesion size is determined by the extent of light diffusion and heat transport.¹

Three major laser systems are used: argon laser, neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, and diode laser.

FIGURE 7-13 Laser balloon aiming beam. (Courtesy of CardioFocus, Inc., Marlborough, Mass.)

ARGON LASER. This system uses a gaseous lasing medium (argon), which emits light at a wavelength of 500 nm. With this system, the light energy is absorbed rapidly in the first few millimeters of tissue, with resulting surface vaporization with crater formation.

NEODYMIUM:YTTTRIUM-ALUMINUM-GARNET LASER. This system uses a solid lasing medium (Nd:YAG), which emits energy at a wavelength of 1060 to 2000 nm in the infrared spectrum. This system is associated with significant scatter in tissue. It causes more diffuse and deeper tissue injury and results in photocoagulation necrosis.

DIODE LASER. This system uses semiconductors and emits energy at a wavelength of 700 to 1500 nm (near-infrared).

Clinical Applications of Laser Energy

Early studies of laser ablation used a high-energy laser that carried a high risk of crater formation and endothelial damage. These studies focused on the intraoperative use of lasers in the ultraviolet and visible range (308- to 755-nm wavelength), and they appeared to show effectiveness of the lesions placed. Laser energy can also be delivered along the entire length of a linear diffuser, which provides uniform linear laser ablation and a superior transmural lesion when compared with previous end-firing optical delivery systems. The use of the linear diffuser in combination with lasers in the infrared or near-infrared wavelength (800 to 1100 nm) is currently under investigation.^{1,62}

Laser energy is absorbed by blood; as a consequence, its application directly into blood results in thrombus formation. This limitation is obviated by application of laser energy through a fluid-filled balloon positioned against the tissue to provide a bloodless interface for ablation. Laser energy has been used with balloon technology for PV isolation. The most recent generation of this balloon catheter is a nonsteerable, variable-diameter, compliant balloon (CardioFocus, Inc., Marlborough, Mass.). The laser balloon is inserted at the PV antrum through a 12 Fr deflectable sheath. Varying balloon inflation pressure allows for adjustment to the individual PV anatomy to optimize PV occlusion and maximize balloon-tissue contact. The balloon is filled with a mixture of contrast and deuterium dioxide and irrigated internally at 20 mL/min to minimize absorption of laser energy.

The efficacy of the laser balloon ablation depends on good contact around the balloon circumference. The laser ablation catheter system incorporates an endoscopic visualization capability using a 2 Fr fiberoptic endoscope positioned at the proximal end of the balloon. Once the balloon is deployed, the endoscope enables real-time visualization of the face of the balloon at the targeted PV antrum and monitoring for the intrusion of blood into the space between the balloon and the tissue.^{62,63}

The arc generator consists of an optical fiber located within the central shaft that projects a 30-degree arc of light onto regions of balloon-tissue contact guided by an endoscopic view of the PV antrum (areas of balloon-tissue contact are visualized as blanched white, whereas contact with blood is visualized as red). This arc serves as an aiming beam for laser delivery and can be steered along the balloon face with endoscopic visualization, to facilitate individual lesion application in an anatomically flexible lesion design that adapts to the highly variable PV anatomy. Once the proper location is identified, a diode laser is used to deliver laser energy at 980 nm. The laser fiber can be advanced or withdrawn to shift the site of lasing along the longitudinal axis of the catheter. Lesions are deployed in a point-by-point fashion; each individual ablation lesion covers 30 degrees of a circle. Laser energy is delivered at power output of 5.5 to 18 W for 20 to 30 seconds, depending on the thickness of tissue or the proximity of the esophagus, or both.

The laser ablation catheter technology is still in clinical trials. The initial clinical experience with this technology suggests the ability to achieve reliable and lasting PV electrical isolation in patients with highly variable PV shapes and sizes.⁶²⁻⁶⁵

General Considerations

Anatomy and Physiology of the Sinus Node

The sinus node is the dominant pacemaker of the heart. Its pacemaker function is determined by its low maximum diastolic membrane potential and steep phase 4 spontaneous depolarization. The molecular mechanisms of pacemaker function of the sinus node are discussed in detail in [Chapters 1 and 3](#).¹

The sinus node is a subepicardial specialized muscular structure located laterally within the epicardial groove of the sulcus terminalis of the right atrium (RA) at the junction of the anterior trabeculated appendage with the posterior smooth-walled venous component. The endocardial aspect of the sulcus terminalis is marked by the crista terminalis. Starting epicardially at the junction of the superior vena cava (SVC) and the RA appendage, it courses downward and to the left along the sulcus terminalis, to end subendocardially almost to the inferior vena cava (IVC). The sinus node is a spindle-shaped structure with a central body and tapering ends; the head extends toward the interatrial groove, and the tail extends toward the orifice of IVC. In adults, the sinus node measures 10 to 20 mm long and 2 to 3 mm wide and thick.^{1,5}

The sinus node consists of densely packed specialized myocytes of no definite orientation within a background of extracellular connective tissue matrix.⁴ The nodal margins can be discrete with fibrous separation from the surrounding atrial myocardium or interdigitate through a transitional zone. Commonly, prongs of nodal (P) cells and transitional (T) cells extend from the nodal body into the atrial myocardium, but actual cell-to-cell interaction is uncertain.⁶

The sinus node is in reality a region, which is functionally larger and less well defined than initially believed. It is composed of nests of principal pacemaker cells (referred to as P cells because of their relatively pale appearance on electron micrography), which spontaneously depolarize. In addition to this principal nest of cells, other nests contain cells with slower intrinsic depolarization rates and serve as backup pacemakers in response to changing physiological and pathological conditions. Normal conduction velocities within the sinus node are slow (2 to 5 cm/sec), thus increasing the likelihood of intranodal conduction block.

The pacemaker activity is not confined to a single cell in the sinus node; rather, sinus node cells function as electrically coupled oscillators that discharge synchronously because of mutual entrainment. In fact, it is likely that sinus rhythm results from impulse origin at widely separated sites, with two or three individual wavefronts created that merge to form a single, widely disseminated wavefront. The sinus node is insulated electrically from the surrounding atrial myocytes, except at a limited number of preferential exit sites. Neural and hormonal factors influence both the site of pacemaker activation, likely via shifting points of initial activity, and the point of exit from the sinus node complex. At faster rates, the sinus impulse originates in the superior portion

of the sinus node, whereas at slower rates, it arises from a more inferior portion.⁷ High-density simultaneous endocardial unipolar mapping studies demonstrated the frequent occurrence of spontaneous variations in the P wave and sinus activation sequence in normal individuals. These findings suggested that the sinus node complex in normal hearts displays a dynamic range of activation sites along the posterolateral RA. Furthermore, preferential pathways of conduction were also found to exist between the sinus node and the atrial exit sites, thus potentially contributing to the multicentricity of the sinus node complex.^{1,5,8}

The blood supply to the sinus node region is variable and is therefore vulnerable to damage during operative procedures. The blood supply predominantly comes from a large central artery, the sinus nodal artery, which is a branch of the right coronary artery in 55% to 60% of patients, and from the circumflex artery in 40% to 45%. The sinus nodal artery typically passes centrally through the length of the sinus body, and it is disproportionately large, which is considered physiologically important in that its perfusion pressure can affect the sinus rate. Distention of the artery slows the sinus rate, whereas collapse causes an increase in rate.^{1,3}

The sinus node is densely innervated with postganglionic adrenergic and cholinergic nerve terminals (threefold greater density of beta-adrenergic and muscarinic cholinergic receptors than adjacent atrial tissue), both of which influence the rate of spontaneous depolarization in pacemaker cells and can cause a shift in the principal pacemaker site within the sinus node region, which is often associated with subtle changes in P wave morphology. Enhanced vagal activity can produce sinus bradycardia, sinus arrest, and sinoatrial exit block, whereas increased sympathetic activity can increase the sinus rate and reverse sinus arrest and sinoatrial exit block. Sinus node responses to brief vagal bursts begin after a short latency and dissipate quickly; in contrast, responses to sympathetic stimulation begin and dissipate slowly. The rapid onset and offset of responses to vagal stimulation allow dynamic beat-to-beat vagal modulation of the heart rate, whereas the slow temporal response to sympathetic stimulation precludes any beat-to-beat regulation by sympathetic activity.¹

Periodic vagal bursting (as may occur each time a systolic pressure wave arrives at the baroreceptor regions in the aortic and carotid sinuses) induces phasic changes in the sinus cycle length (CL) and can entrain the sinus node to discharge faster or slower at periods identical to those of the vagal burst.³ Because the peak vagal effects on sinus rate and atrioventricular node (AVN) conduction occur at different times in the cardiac cycle, a brief vagal burst can slow the sinus rate without affecting AVN conduction or can prolong AVN conduction time and not slow the sinus rate.¹

Pathophysiology of Sinus Node Dysfunction

The cause of sinus node dysfunction (SND) can be classified as intrinsic (secondary to a pathological condition involving the sinus node proper) or extrinsic (caused by depression of sinus

node function by external factors such as drugs or autonomic influences).

INTRINSIC SINUS NODE DYSFUNCTION

Idiopathic degenerative disease is probably the most common cause of intrinsic SND.² Ischemic heart disease can be responsible for one third of cases of SND. Transient slowing of the sinus rate or sinus arrest can complicate acute myocardial infarction, which is usually seen with acute inferior wall infarction and is caused by autonomic influences. Possible mechanisms for sinus bradycardia after an acute myocardial infarction include neurological reflexes (Bezold-Jarisch reflex), coronary chemoreflexes (vagally mediated), humoral reflexes (enzymes, adenosine, potassium [K⁺]), oxygen-conserving reflex (“diving” reflex), and infarction or ischemia of the sinus node or the surrounding atrium (e.g., secondary to proximal occlusion of the right or the circumflex coronary artery).

Cardiomyopathy, long-standing hypertension, infiltrative disorders (e.g., amyloidosis and sarcoidosis), collagen vascular diseases, and surgical trauma can also result in SND.^{9,10} Orthotropic cardiac transplantation with atrial-atrial anastomosis is associated with a high incidence of SND in the donor heart (likely because of sinus nodal artery damage). Musculoskeletal disorders such as myotonic dystrophy or Friedreich ataxia are rare causes of SND. Congenital heart disease, such as sinus venosus and secundum atrial septal defects, can be associated with SND, even though no surgery has been performed.¹¹ Surgical trauma is responsible for most cases of SND in the pediatric population. Most commonly associated with this complication is the Mustard procedure for transposition of the great arteries and repair of atrial septal defects, especially of the sinus venosus type.¹¹

Furthermore, atrial tachyarrhythmias can precipitate SND, likely secondary to remodeling of sinus node function. Although early studies implicated anatomical structural abnormalities in the sinus node, which suggested a fixed SND substrate, more recent evidence implicated a functional, and potentially reversible, component involving remodeling of sinus node ion channel expression and function. This finding was supported clinically by the observation that successful catheter ablation of atrial fibrillation (AF) and atrial flutter can be followed by significant improvements in sinus node function. In particular, downregulation of the funny current (I_f) and malfunction of the calcium (Ca²⁺) clock (characterized by reduced sarcoplasmic reticulum Ca²⁺ release and downregulated ryanodine receptors in the sinus node) seem to account largely for atrial tachycardia-induced remodeling of sinus node. The remodeled atria are associated with more caudal activation of the sinus node complex, slower conduction time along preferential pathways, and only modest shifts within the functional pacemaker complex.^{5,12,13}

On the other hand, SND has been associated with an increased propensity of atrial tachyarrhythmias, AF in particular. The mechanism leading to AF in patients with SND is unlikely to be bradycardia-dependent because AF was found to develop despite pacing in these patients. Importantly, patients with SND appear to have more widespread atrial changes beyond the sinus node, a finding indicating atrial myopathy, as evidenced by increased atrial refractoriness, prolonged P wave duration, delayed conduction, slowing electrogram fractionation, regions of low voltage and scar, and caudal shift of the pacemaker complex with loss of normal multicentric pattern of activation. Furthermore, abnormal atrial electromechanical properties, chronic atrial stretch, and neurohormonal activation are likely contributors to SND and its related atrial myopathy. The diffuse atrial myopathy potentially underlies the increased propensity to AF. The cause of these diffuse atrial abnormalities remains unknown, but there appears to be a relationship between atrial remodeling that predisposes to AF and sinus node remodeling that results in SND.^{5,14}

Genetic defects in ion channels and structural proteins have been shown to contribute to SND, manifesting as sinus bradycardia, sinus arrest, sinoatrial block, or a combination. Mutations in

the *SCN5A* gene (which encodes the alpha subunit of the cardiac sodium [Na⁺] channel [I_{Na}]), the *HCN4* gene (which encodes the protein that contributes to formation of I_f channels), the *KCNQ1* gene (which encodes the alpha subunit of the voltage-gated slowly activating delayed rectifier K⁺ channel responsible for I_{Ks}), the *GJA5* gene (which encodes for connexin 40, a gap junction protein), the *ANK2* gene (which encodes for ankyrin, which links the integral membrane proteins to the underlying cytoskeleton), and the *EMD* gene (which encodes the nuclear membrane protein emerin) have been associated with familial forms of SND, many of which also exhibit an increased propensity to AF.¹⁵⁻¹⁸

EXTRINSIC SINUS NODE DYSFUNCTION

In the absence of structural abnormalities, the predominant causes of SND are drug effects and autonomic influences. Drugs can alter sinus node function by direct pharmacological effects on nodal tissue or indirectly by neurally mediated effects.¹⁹ Drugs known to depress sinus node function include beta blockers, calcium channel blockers (verapamil and diltiazem), digoxin, sympatholytic antihypertensive agents (e.g., clonidine), and antiarrhythmic agents (classes IA, IC, and III).

SND can sometimes result from excessive vagal tone in individuals without intrinsic sinus node disease. Hypervagotonia can be seen in hypersensitive carotid sinus syndrome and neurocardiogenic syncope. Well-trained athletes with increased vagal tone occasionally may require some deconditioning to help prevent symptomatic bradyarrhythmias.²⁰ Surges in vagal tone also can occur during Valsalva maneuvers, endotracheal intubation, vomiting, and suctioning. Sinus slowing in this setting is characteristically paroxysmal and may be associated with evidence of AV conduction delay, secondary to effects of the enhanced vagal tone on both the sinus node and AVN. Less common extrinsic causes of SND include electrolyte abnormalities such as hyperkalemia, hypothermia, increased intracranial pressure (the Cushing response), sleep apnea, hypoxia, hypercapnia, hypothyroidism, advanced liver disease, typhoid fever, brucellosis, and sepsis.

Clinical Presentation

More than 50% of the patients with SND are older than 50 years. Patients often are asymptomatic or have symptoms that are mild and nonspecific, and the intermittent nature of these symptoms makes documentation of the associated arrhythmia difficult at times. Symptoms, which may have been present for months or years, include paroxysmal dizziness, presyncope, or syncope, which are predominantly related to prolonged sinus pauses. Episodes of syncope are often unheralded and can manifest in older patients as repeated falls. The highest incidence of syncope associated with SND probably occurs in patients with tachycardia-bradycardia syndrome, in whom syncope typically occurs secondary to a long sinus pause following cessation of the supraventricular tachycardia (usually AF). Occasionally, a stroke can be the first manifestation of SND in patients presenting with paroxysmal AF and thromboembolism.^{3,19,21}

Patients with sinus bradycardia or chronotropic incompetence can present with decreased exercise capacity or fatigue (Fig. 8-1). Chronotropic incompetence is estimated to be present in 20% to 60% of patients with SND.^{22,23} Other symptoms include irritability, nocturnal wakefulness, memory loss, lightheadedness, and lethargy. More subtle symptoms include mild digestive disturbances, periodic oliguria or edema, and mild intermittent dyspnea. Additionally, symptoms caused by the worsening of conditions such as congestive heart failure and angina pectoris can be precipitated by SND.

Natural History

The natural history of SND can be variable, but slow progression (over 10 to 30 years) is expected. The prognosis largely depends on the type of dysfunction and the presence and severity of the

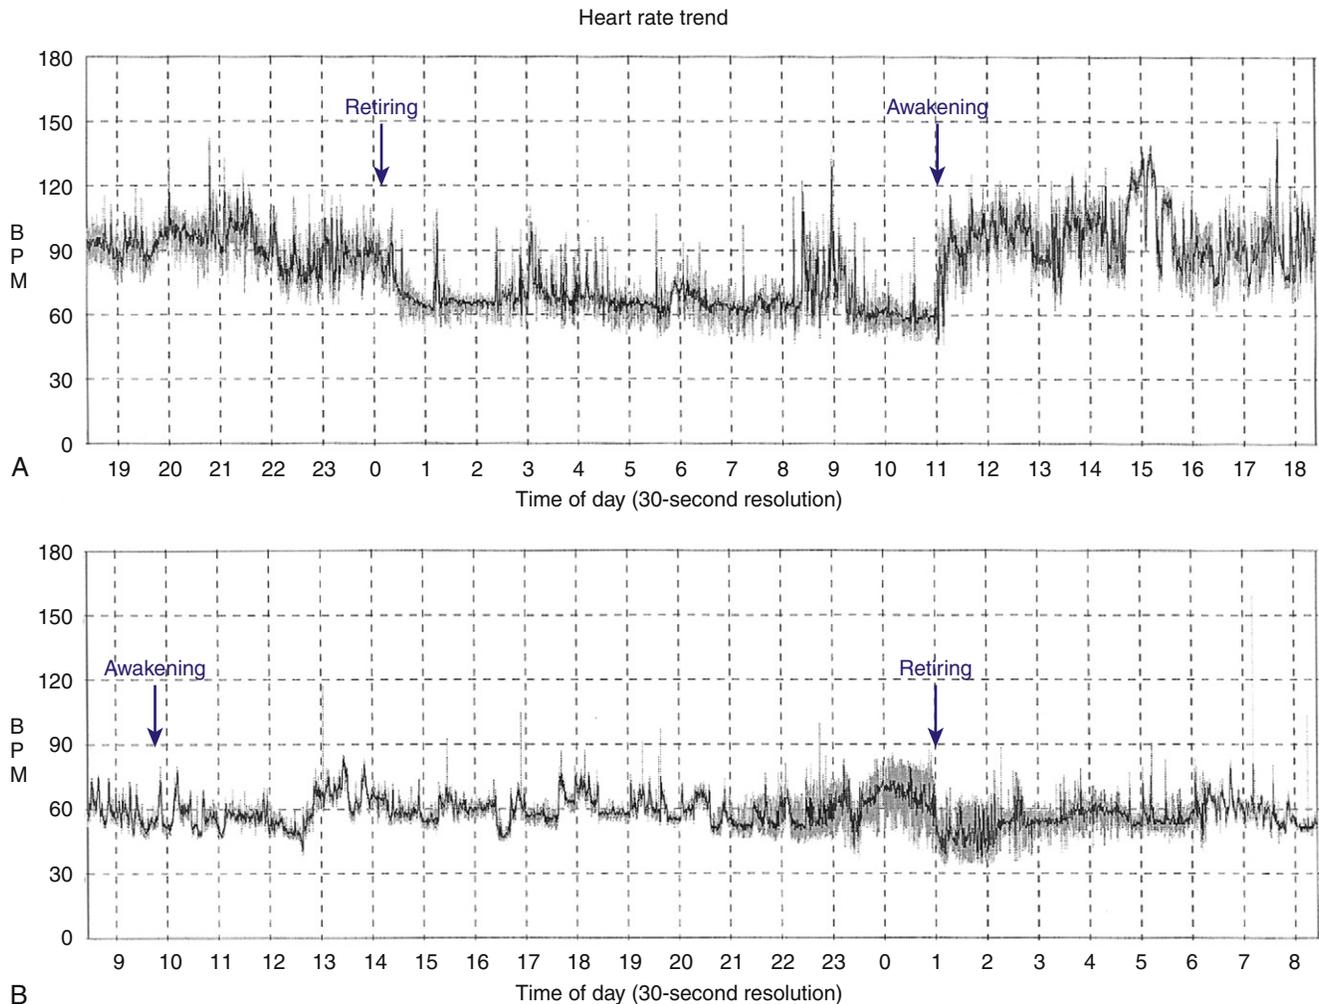

CH
8

FIGURE 8-1 Chronotropic incompetence. **A**, A 24-hour Holter recording in a normal subject showing normal sinus rate diurnal variation and response to activity. **B**, A 24-hour Holter recording in a different patient with chronotropic incompetence and activity intolerance. Note the blunted response of the sinus rate to activity during waking hours and the slow average heart rate.

underlying heart disease. The worst prognosis is associated with the tachycardia-bradycardia syndrome (mostly because of the risk for thromboembolic complications), whereas sinus bradycardia is much more benign. The incidence of new-onset AF in patients with SND is about 5.2% per year. New atrial tachyarrhythmias occur with less frequency in patients who are treated with atrial pacing (3.9%) compared with a greatly increased incidence of similar arrhythmias in patients with only ventricular pacing (22.3%).²⁴ Furthermore, thromboembolism occurs in 15.2% among unpaced patients with SND versus 13% among patients treated with only ventricular pacing versus 1.6% among those treated with atrial pacing.^{19,21,25}

The incidence of advanced AV conduction system disease in patients with SND is low (5% to 10%), and, when present, its progression is slow. At the time of diagnosis of SND, approximately 17% of the patients have some degree of AV conduction system disease (PR interval longer than 240 milliseconds, bundle branch block, His bundle-ventricular (HV) interval prolongation, AV Wenckebach rate less than 120 beats/min, or second- or third-degree AV block). New AV conduction abnormalities develop at a rate of approximately 2.7% per year. The incidence of advanced AV block during long-term follow-up is low (approximately 1% per year).²¹

Diagnostic Evaluation

Generally, the noninvasive methods of ECG monitoring, exercise testing, and autonomic testing are used first. However, if symptoms

are infrequent and noninvasive evaluation is unrevealing, invasive electrophysiological (EP) testing may be pursued.²⁶

ELECTROCARDIOGRAM AND AMBULATORY MONITORING.

A 12-lead electrocardiogram (ECG) needs to be obtained in symptomatic patients. However, the diagnosis of SND as the cause of the symptoms is rarely made from the ECG. In patients with frequent symptoms, 24- or 48-hour ambulatory Holter monitoring can be useful. Cardiac event monitoring or implantable loop recorders may be necessary in patients with less frequent symptoms.²⁷ Documentation of symptoms in a diary by the patient while wearing the cardiac monitor is essential for correlation of symptoms with the heart rhythm at the time. In some cases, ambulatory monitoring can exclude SND as the cause of symptoms if normal sinus rhythm (NSR) is documented at the time of symptom occurrence. In contrast, recorded sinus pauses may not be associated with symptoms.

AUTONOMIC MODULATION. An abnormal response to carotid sinus massage (pause longer than 3 seconds) can indicate SND, but this response can also occur in asymptomatic older individuals. Heart rate response to the Valsalva maneuver (normally decreased) or upright tilt (normally increased) can also be used to verify that the autonomic nervous system itself is intact. Complete pharmacological autonomic blockade is used to determine the intrinsic heart rate (see later).³

EXERCISE TESTING. Exercise testing to assess chronotropic incompetence is of value in patients with exertional symptoms (see later).

ELECTROPHYSIOLOGICAL TESTING. Noninvasive testing is usually adequate in establishing the diagnosis of SND and guiding subsequent therapy. However, invasive EP testing can be of value in symptomatic patients in whom SND is suspected but cannot be documented in association with symptoms. In addition to assessing SND, EP testing can be useful in evaluating other potential causes for symptoms of syncope and palpitations (e.g., AV block, supraventricular tachycardia, and ventricular tachycardia).^{19,21}

Electrocardiographic Features

SINUS BRADYCARDIA. Sinus bradycardia (less than 60 beats/min) is considered abnormal when it is persistent, unexplained, and inappropriate for physiological circumstances. Sinus bradycardia slower than 40 beats/min (not associated with sleep or physical conditioning) is generally considered abnormal.³

SINUS PAUSES. Sinus arrest and sinoatrial exit block can result in sinus pauses, and they are definite evidence of SND.

SINUS ARREST. The terms sinus arrest and sinus pause are often used interchangeably; sinus arrest is a result of total cessation of impulse formation within the sinus node. The pause is not an exact multiple of the preceding P-P interval but is random in duration (Fig. 8-2). Although asymptomatic pauses of 2 to 3 seconds can be seen in up to 11% of normal individuals and in one third of trained athletes, pauses longer than 3 seconds are rare in normal individuals and may or may not be associated with symptoms, but they are usually caused by SND.³

SINOATRIAL EXIT BLOCK. Sinoatrial exit block results when a normally generated sinus impulse fails to conduct to the atria because of delay in conduction or block within the sinus node itself or perinodal tissue. Sinoatrial exit block produces a pause that is eventually terminated by a delayed sinus beat or an atrial or junctional escape beat.²⁸ In theory, sinoatrial exit block can be distinguished from sinus arrest because the exit block pause is an exact multiple of the baseline P-P interval. However, sinus arrhythmia causing normal beat-to-beat variations in the sinus rate often makes the distinction impossible. Furthermore, establishing the diagnosis of sinoatrial exit block versus sinus arrest is often of academic interest only.³

Exit block is classified into three types, analogous to those of AV block: first-degree, second-degree, and third-degree exit block.²⁸ First-degree sinoatrial exit block is caused by abnormal prolongation of the sinoatrial conduction time (SACT). It occurs every time a sinus impulse reaches the atrium, but it is conducted with a delay

at a fixed interval. This type of sinoatrial exit block is concealed on the surface ECG and can be diagnosed only by direct sinus node recording or indirect measurement of SACT during an EP study. Second-degree sinoatrial exit block is marked by intermittent failure of the sinus impulse to exit the sinus node. Type I block is viewed as Wenckebach periodicity of the P wave on the surface ECG, and it manifests as progressive delay in conduction of the sinus-generated impulse through the sinus node to the atrium, finally resulting in a nonconducted sinus impulse and absence of a P wave on the surface ECG. Because the sinus discharge is a silent event on the surface ECG, this arrhythmia can be inferred only, because of a missing P wave and the signs of Wenckebach periodicity seen with this type of arrhythmia. The increment in delay in impulse conduction through the sinus node tissue is progressively less; thus, the P-P intervals become progressively shorter until a P wave fails to occur. The pauses associated with this type of sinoatrial exit block are less than twice the shortest sinus cycle. Type II block manifests as an abrupt absence of one or more P waves because of failure of the atrial impulse to exit the sinus node, without previous progressive prolongation of SACT (and without progressive shortening of the P-P intervals). Sometimes, two or more consecutive sinus impulses are blocked within the sinus node, thus creating considerably long pauses. The sinus pause should be an exact multiple of the immediately preceding P-P interval. However, normal variations in the sinus rate caused by sinus arrhythmia can obscure this measurement. Third-degree or complete sinoatrial exit block manifests as absence of P waves, with long pauses resulting in lower pacemaker escape rhythm. This type of block is impossible to distinguish from sinus arrest with certainty without invasive sinus node recordings.^{21,29,30}

TACHYCARDIA-BRADYCARDIA SYNDROME. Tachycardia-bradycardia syndrome, frequently referred to as sick sinus syndrome, is a common manifestation of SND, and it refers to the presence of intermittent sinus or junctional bradycardia alternating with atrial tachyarrhythmias (Fig. 8-3). The atrial tachyarrhythmia is most commonly paroxysmal AF, but atrial tachycardia, atrial flutter, and occasionally AVN reentrant tachycardia or AV reentrant tachycardia can also occur.³

Apart from underlying sinus bradycardia of varying severity, these patients often experience prolonged sinus arrest and asystole on termination of the atrial tachyarrhythmia, resulting from overdrive suppression of the sinus node and secondary pacemakers by the tachycardia. Long sinus pauses that occur following electrical cardioversion of AF constitute another manifestation of SND.

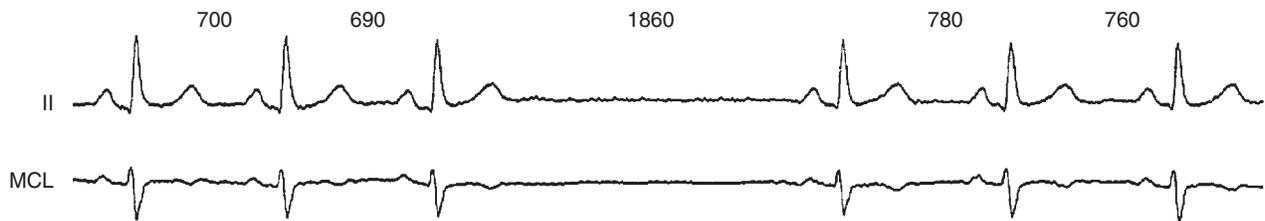

FIGURE 8-2 Sinus pause is shown in two monitor leads. Although the sinus rate is slightly irregular, the pause significantly exceeds any two P-P intervals (excluding sinus exit block). MCL = modified chest-lead.

FIGURE 8-3 Tachycardia-bradycardia syndrome. Two surface ECG leads showing atrial fibrillation that spontaneously terminates followed by a 5.9-second pause before sinus rhythm resumes. The patient became lightheaded during this period.

Therapeutic strategies to control the tachyarrhythmias often result in the need for pacemaker therapy (Fig. 8-4). On the other hand, atrial tachyarrhythmias can be precipitated by prolonged sinus pauses.^{2,3,31,32} SND is often caused by functional remodeling from the tachycardia and can be reversible in some patients, thus obviating the need for pacing.

CH
8

ATRIAL FIBRILLATION WITH SLOW VENTRICULAR RESPONSE. Persistent AF with a slow ventricular response in the absence of AVN blocking drugs is often present in patients with SND. These patients can demonstrate very slow ventricular rates at rest or during sleep and occasionally have long pauses. Occasionally, they can develop complete AV block with a junctional or ventricular escape rhythm. They can also conduct rapidly and develop symptoms caused by tachycardia during exercise. In some cases, cardioversion results in a long sinus pause or junctional escape rhythm before the appearance of sinus rhythm. Although a combination of sinus node and AV conduction disease can be present in many cases, examples of rapid ventricular responses during atrial tachyarrhythmias are frequently found.²

PERSISTENT ATRIAL STANDSTILL. Atrial standstill is a rare clinical syndrome in which there is no spontaneous atrial activity and the atria cannot be electrically stimulated. The surface ECG usually reveals junctional bradycardia without atrial activity. The atria are generally fibrotic and without any functional myocardium. Lack of mechanical atrial contraction poses a high risk for thromboembolism in these patients.^{33,34}

CHRONOTROPIC INCOMPETENCE. Treadmill exercise testing can be of substantial value in assessing the chronotropic response (“competence”) to increases in metabolic demands in patients with sinus bradycardia who are suspected of having SND. Although the resting heart rate can be normal, these patients may be unable to increase their heart rate during exercise or may have unpredictable fluctuations in the heart rate during

activity. Some patients can initially experience a normal increase in the heart rate with exercise, which then plateaus or decreases inappropriately.^{22,23,29,30}

The definition of chronotropic incompetence is not agreed on, but it is reasonable to designate it as an abnormally slow heart rate response to exercise manifesting as a less than normal increase in the sinus rate at each stage of exercise, with a plateau at less than 70% to 75% of the age-predicted maximum heart rate ($220 - \text{age}$) or an inability to achieve a sinus rate of 100 to 120 beats/min at maximum effort. Irregular (and nonreproducible) increases, and even decreases, in the sinus rate during exercise, can also occur but are rare. Other patients with SND can achieve an appropriate peak heart rate during exercise but may have slow sinus rate acceleration in the initial stage or rapid deceleration of heart rate in the recovery stage.^{22,23}

CAROTID SINUS HYPERSENSITIVITY. An abnormal response to carotid sinus massage (pause longer than 3 seconds) can indicate SND, but this response may also occur in asymptomatic older individuals (Fig. 8-5).^{1,28-30}

SINUS ARRHYTHMIA. Respiratory sinus arrhythmia, in which the sinus rate increases with inspiration and decreases with expiration, is not an abnormal rhythm and is most commonly seen in young healthy subjects. Sinus arrhythmia is present when the P wave morphology is normal and consistent and the P-P intervals vary by more than 120 milliseconds. Nonrespiratory sinus arrhythmia, in which phasic changes in sinus rate are not related to the respiratory cycle, can be accentuated by the use of vagal agents such as digitalis and morphine; its mechanism is unknown. Patients with nonrespiratory sinus arrhythmia are likely to be older and to have underlying cardiac disease, although the arrhythmia is not a marker for structural heart disease. None of the sinus arrhythmias (respiratory or nonrespiratory) indicate SND. Additionally, respiratory variation in the sinus P wave contour

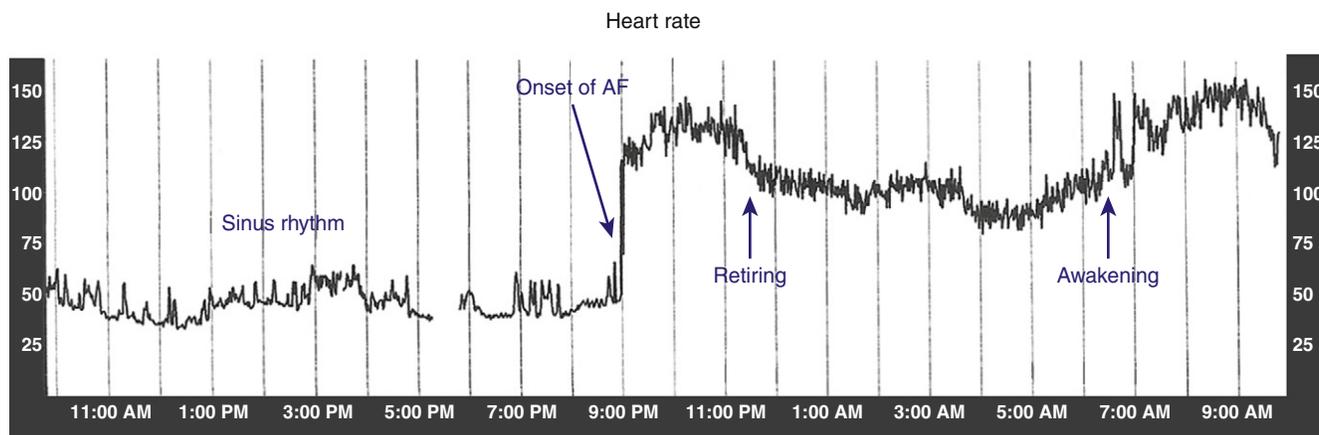

FIGURE 8-4 A 24-hour Holter heart rate trend showing slow sinus rhythm rates during waking hours. Onset of atrial fibrillation (AF) is associated with rapid ventricular response, even during sleep hours. Pacing was required in this patient to prevent symptomatic bradycardia and allow the use of drug therapy to control the tachycardia.

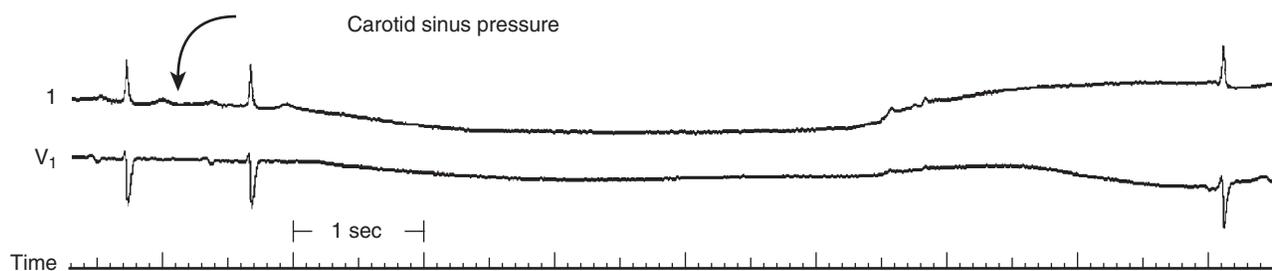

FIGURE 8-5 Carotid sinus hypersensitivity. Two surface ECG leads are shown during carotid sinus pressure, as indicated. The PR interval is prolonged, followed by a 7.5-second sinus pause ended by a P wave and probable junctional escape complex. The patient was nearly syncopal during this period.

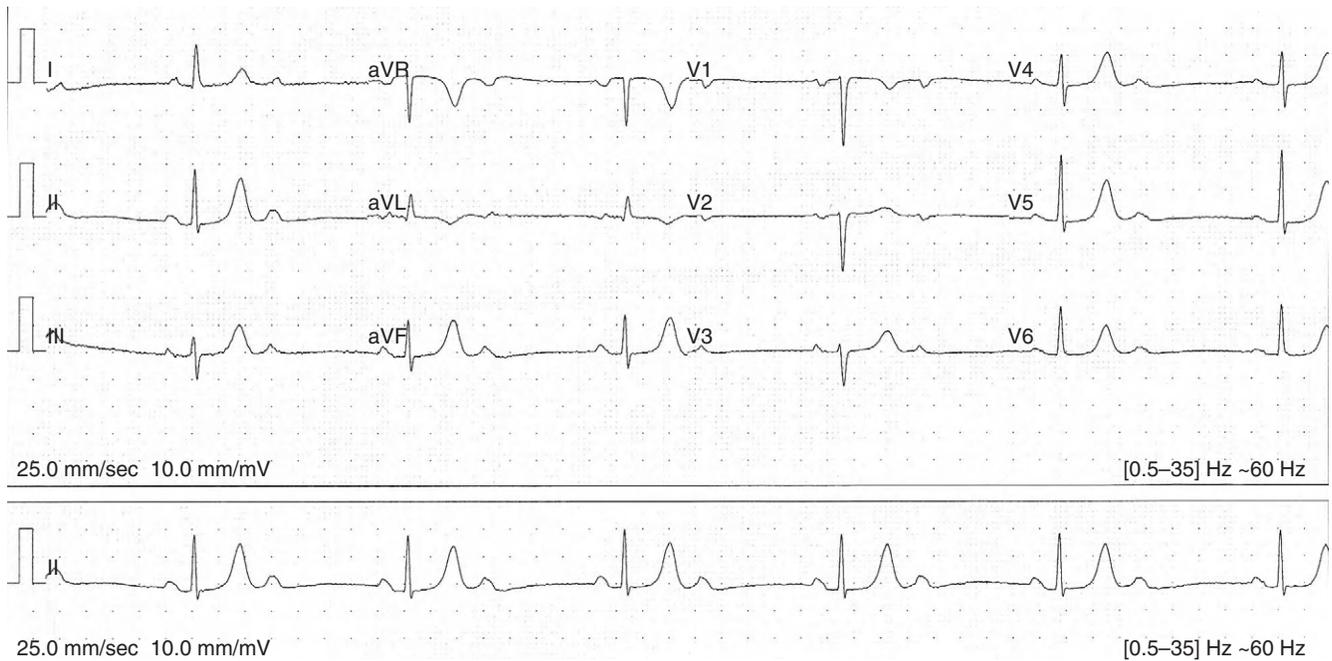

FIGURE 8-6 Ventriculophasic sinus arrhythmia. Surface ECG during sinus rhythm with second-degree 2:1 atrioventricular block. Consecutive sinus P waves enclosing a QRS occur at shorter intervals than that of consecutive P waves without a QRS in between (ventriculophasic arrhythmia).

can be seen in the inferior leads and should not be confused with wandering atrial pacemaker, which is unrelated to breathing and therefore is not phasic.^{29,30}

Ventriculophasic sinus arrhythmia is an unusual rhythm that occurs when sinus rhythm and high-grade or complete AV block coexist; it is characterized by shorter P-P intervals when they enclose QRS complexes and longer P-P intervals when no QRS complexes are enclosed (Fig. 8-6). The mechanism is uncertain but may be related to the effects of the mechanical ventricular systole itself: ventricular contraction increases the blood supply to the sinus node, thereby transiently increasing its firing rate. Ventriculophasic sinus arrhythmia is not a pathological arrhythmia and should not be confused with premature atrial complexes or sinoatrial block.

Electrophysiological Testing

Role of Electrophysiological Testing

The diagnosis of SND usually can be made based on clinical and ECG findings, which are typically adequate for deciding subsequent treatment. Once symptoms and SND are correlated with ECG findings, further documentation by invasive studies is not required. Similarly, asymptomatic patients with evidence of SND need not be tested because no therapy is indicated. However, EP testing can be important to assess sinus node function in patients who have had symptoms compatible with SND and in whom no documentation of the arrhythmia responsible for these symptoms has been obtained by prolonged monitoring. In these cases, EP testing can yield information that may be used to guide appropriate therapy. The most useful measures of the overall sinus node function are a combination of the responses to atropine and exercise and the sinus node recovery time (SNRT).²⁸

Sinus Node Recovery Time

The sinus node is the archetype of an automatic focus. Automatic rhythms are characterized by spontaneous depolarization, overdrive suppression, and post-overdrive warm-up or a gradual return to baseline CL. SNRT is the interval between the end of a period of pacing-induced overdrive suppression of sinus node activity and

the return of sinus node function, manifest on the surface ECG by a post-pacing sinus P wave. Clinically, SNRT is used to test sinus node automaticity.^{29,30,35}

TECHNIQUE

PACING SITE. Pacing is performed in the high RA at a site near the sinus node, to decrease the conduction time to and from the sinus node.²⁸

PACING CYCLE LENGTH. SNRT is preferably measured after pacing at multiple CLs. Pacing is started at a CL just shorter than the sinus CL. After a 1-minute rest, pacing is repeated at progressively shorter CLs (with 50- to 100-millisecond decrements) down to a pacing CL of 300 milliseconds.²⁸

PACING DURATION. Pacing is continued for 30 or 60 seconds at a time. Although pacing durations beyond 15 seconds usually have little effect on the SNRT in healthy subjects, patients with SND can have marked suppression after longer pacing durations. It is also preferable to perform pacing at each CL for different durations (30, 60, or 120 seconds), to ensure that sinus entrance block has not obscured the true SNRT.²⁸

MEASUREMENTS

Several intervals have been used as a measure of SNRT.

SINUS NODE RECOVERY TIME. SNRT is the longest pause from the last paced beat to the first sinus return beat at a particular pacing CL. Normally, the SNRT is less than 1500 milliseconds, with a scatter on multiple tests of less than 250 milliseconds (Fig. 8-7). SNRT tends to be shorter with shorter baseline sinus CLs, and therefore various corrections have been introduced.^{29,30,35}

CORRECTED SINUS NODE RECOVERY TIME. Corrected SNRT equals SNRT minus the baseline sinus CL. Normal values of corrected SNRT have been reported from 350 to 550 milliseconds, with 500 milliseconds most commonly used (see Fig. 8-7). However, the use of corrections at slow sinus rates can produce odd results. For example, in a patient with symptomatic bradycardia at a 1500-millisecond CL and an SNRT of 2000 milliseconds, the corrected SNRT is 500 milliseconds. For cases of severe bradycardia, an abnormal uncorrected SNRT of 2000 milliseconds is more accurate; in fact, one does not need SNRT to make the clinical diagnosis.

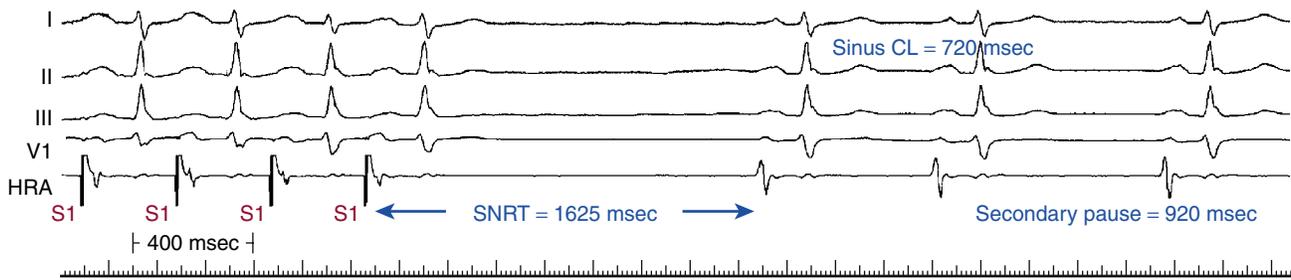

FIGURE 8-7 Sinus node recovery time (SNRT). Surface ECG leads and high right atrial (HRA) recordings are shown at the end of a burst of atrial pacing, suppressing sinus node automaticity. The interval at which the first sinus complex returns (SNRT) is abnormally long at 1625 milliseconds. With a baseline sinus cycle (CL) of 720 milliseconds, the corrected SNRT ($1625 - 720 = 905$ milliseconds) is also prolonged. In addition, there is a secondary pause after the first two sinus complexes.

MAXIMUM SINUS NODE RECOVERY TIME. Maximum SNRT is the longest pause from the last paced beat to the first sinus return beat at any pacing CL.

RATIO OF SINUS NODE RECOVERY TIME TO SINUS CYCLE LENGTH. The ratio of $[(\text{SNRT}/\text{sinus CL}) \times 100\%]$ is lower than 160% in normal subjects.

TOTAL RECOVERY TIME. On cessation of atrial pacing, the pattern of subsequent beats returning to the basic sinus CL should be analyzed. Various patterns exist.²⁸ Total recovery time equals the time to return to basic sinus CL (normal total recovery time is less than 5 seconds, usually by the fourth to sixth recovery beat).

SECONDARY PAUSES. Normally, following cessation of overdrive pacing, a gradual shortening of the sinus CL is observed until the baseline sinus CL is reached, typically within a few beats. Limited oscillations of recovery CLs before full recovery can be observed, especially at faster pacing rates.²⁸ Secondary pauses are identified when there is an initial shortening of the sinus CL after the SNRT, followed by an unexpected lengthening of the CL (see Fig. 8-7). Sudden and marked secondary pauses occurring during sinus recovery are abnormal. Sinoatrial exit block of variable duration is the primary mechanism of prolonged pauses, with a lesser component of depression of automaticity. Both may, and often do, coexist. However, secondary pauses can be a normal reflex following hypotension induced by pacing at rapid rates or in response to pressure overshoot in the first recovery beat resulting from the prolonged filling time. Because these secondary pauses represent SND and because they occur more frequently following rapid atrial pacing, pacing should be performed at rates up to 200 beats/min.^{28,29,35,36}

LIMITATIONS OF SINUS NODE RECOVERY TIME

Many factors in addition to automaticity are involved in the measurement of SNRT, including proximity of the pacing site to the sinus node and conduction time from the pacing site to the sinus node and vice versa, as well as conduction time in and out of the sinus node. Sinus node entrance block during rapid atrial pacing can lead to a shorter SNRT, whereas sinus node exit block after cessation of pacing can result in marked prolongation of the SNRT.²⁸ Moreover, sometimes SNRT cannot be measured because of atrial ectopic or junctional escape beats that preempt the sinus beat.^{29,30}

Despite these limitations, SNRT is probably the best and most widely used test for sinus node automaticity. Pacing at rates near the baseline sinus CL causes no overdrive suppression, so that the interval between the last paced beat and the next sinus beat is comparable with the baseline CL. If the SNRT after pacing at 500 milliseconds is shorter than after 600 milliseconds, or if there is marked variation (more than 250 milliseconds) in the SNRTs when multiple tests are performed after pacing at 500 milliseconds, this finding can imply that some impulses have not penetrated the sinus node (i.e., some degree of atrial-nodal block exists). At pacing CLs shorter than 500 milliseconds, there is usually little further prolongation of the SNRT; on the contrary, changes in neurohumoral tone may result in shorter SNRTs.^{29,35}

The durations of the maximum SNRT and corrected SNRT are independent of age. Evaluation of the corrected SNRT following pharmacological denervation (see later) can increase the sensitivity of the test.³⁶

SINUS NODE RECOVERY TIME IN PATIENTS WITH SINUS NODE DYSFUNCTION

The sensitivity of a single SNRT measurement is approximately 35% in patients with SND. This rises to more than 85% when multiple SNRTs at different rates are recorded, along with scatter and total recovery time, with a specificity of more than 90%. A prolonged SNRT or corrected SNRT is found in 35% to 93% of patients suspected of having SND (depending on the population studied). The incidence is lowest in patients with sinus bradycardia. Marked abnormalities in the corrected SNRT usually occur in symptomatic patients with clinical evidence of sinoatrial block or bradycardia-tachycardia syndrome.^{28,36}

The pacing CL at which maximum suppression occurs in patients with SND is unpredictable and, unlike in healthy subjects, tends to be affected by the rate and duration of pacing. However, if sinus entrance block is present, the greatest suppression is likely to occur at relatively long pacing CLs. If the longest SNRT occurs at pacing CLs longer than 600 milliseconds, a normal value can reflect the presence of entrance block. In such cases, a normal SNRT is an unreliable assessment of sinus node automaticity. The fact that the longest SNRT occurs at pacing CLs longer than 600 milliseconds is in itself a marker of SND.²⁸

Marked secondary pauses are another manifestation of SND and can occasionally occur in the absence of prolongation of SNRT, in which case sinoatrial block is the mechanism. Approximately 69% of patients with secondary pauses have clinical evidence of sinoatrial exit block, and 92% of patients with sinoatrial exit block demonstrate marked secondary pauses.²⁸

Sinoatrial Conduction Time

Although the sinus node is the dominant cardiac pacemaker, neither sinus node impulse initiation nor conduction is visible on the surface ECG or on the standard intracardiac recordings because depolarization within the sinus node is of very low amplitude. Sinus node function therefore has usually been assessed indirectly. Normal sinus node function is assumed when the atrial musculature is depolarized at a normal rate and in a normal temporal sequence—so-called *normal sinus rhythm*. In NSR, the atrial rate is assumed to correspond to the rate of impulse formation within the sinus node; however, the time of impulse conduction from the sinus node to the atrium cannot be ascertained. Several methods have been developed for the assessment of SACT, either indirectly (the Strauss and Narula methods) or by directly recording the sinus node electrogram. Signal-averaging techniques have also been used to measure SACT noninvasively.^{29,30,36}

DIRECT RECORDINGS

Sinus node depolarization can be recorded directly using high-gain unfiltered electrograms in approximately 50% of patients.²⁸ A catheter with a 0.5- to 1.5-mm interelectrode distance is used. The catheter is placed directly at the SVC-RA junction, or a loop is formed in the RA and the tip of the catheter is then placed at the SVC-RA junction. Optimizing the filter setting can help reduce baseline drift (0.1 to 0.6 Hz to 20 to 50 Hz), with signal gain at 50 to 100 mV/cm.³⁶

SACT is measured as the interval between the pacemaker prepotential on the local electrogram and the onset of the rapid atrial deflection (Fig. 8-8). When SACT is normal, a smooth upstroke

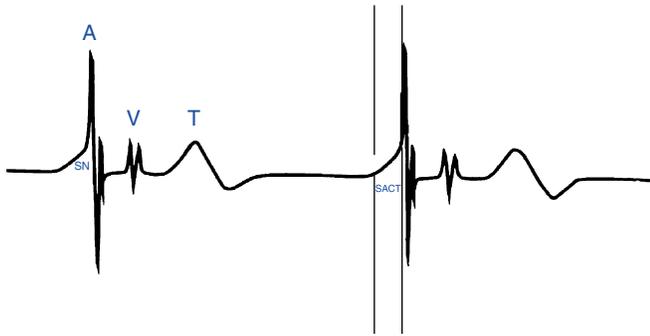

FIGURE 8-8 Schematic illustration showing the direct measurement of sinoatrial conduction time (SACT). A schematic copy of a sinus node electrogram is shown. On the sinus node electrogram, high right atrial depolarization (A), ventricular depolarization (V), T wave (T), and the sinus node potential (SN) are identified. In the second beat, reference lines are drawn through the point at which the SN potential first becomes evident and the point at which atrial activation begins. SACT is the interval between these two reference lines. (From Reiffel JA: *The human sinus node electrogram: a transvenous catheter technique and a comparison of directly measured and indirectly estimated sinoatrial conduction time in adults.* *Circulation* 62:1324, 1980.)

slope merges into the atrial electrogram. When SACT is prolonged, an increasing amount of sinus node potential becomes visible before the rapid atrial deflection. Sinoatrial block is said to occur when the entire sinus node electrogram is seen in the absence of a propagated response to the atrium.²⁸

The sinus node electrogram can be validated by the ability to record the electrogram in only a local area, with loss of the upstroke potential during overdrive atrial pacing. Additionally, persistence of the sinus node electrogram following carotid sinus massage, following induced pauses, or during pauses following overdrive suppression is an important method for validation.

STRAUSS TECHNIQUE

The Strauss technique uses atrial premature stimulation to assess SACT. Baseline sinus beats are designated A_1 . Progressively premature atrial extrastimuli (AESs; A_2) are delivered after every eighth to tenth A_1 , and the timing of the recovery beat (A_3) is measured.²⁸ The Strauss method is useful as part of an overall EP study when information is also sought on conduction system refractoriness or possible dual AVN physiology or bypass tracts during sinus rhythm. Four zones of response of the sinus node to AES have been identified. SACT can be measured only in the zone of reset (Fig. 8-9).^{29,30,35}

1. ZONE I: ZONE OF COLLISION, ZONE OF INTERFERENCE, NONRESET ZONE. This zone is defined by the range of A_1 - A_2 intervals at which the A_2 - A_3 interval is fully compensatory (see Fig. 8-9). Very long A_1 - A_2 intervals (with A_2 falling in the last 20% to 30% of the sinus CL) generally result in collision of the AES (A_2) with the spontaneous sinus impulse (A_1). The sinus pacemaker and the timing of the subsequent sinus beat (A_3) are therefore unaffected by A_2 , and a complete compensatory pause occurs—that is, A_1 - $A_3 = 2 \times (A_1 - A_1)$.

2. ZONE II: ZONE OF RESET. The range of A_1 - A_2 intervals at which reset of the sinus pacemaker occurs, resulting in a less than compensatory pause, defines the zone of reset (see Fig. 8-9). Shorter A_1 - A_2 intervals result in penetration of the sinus node with

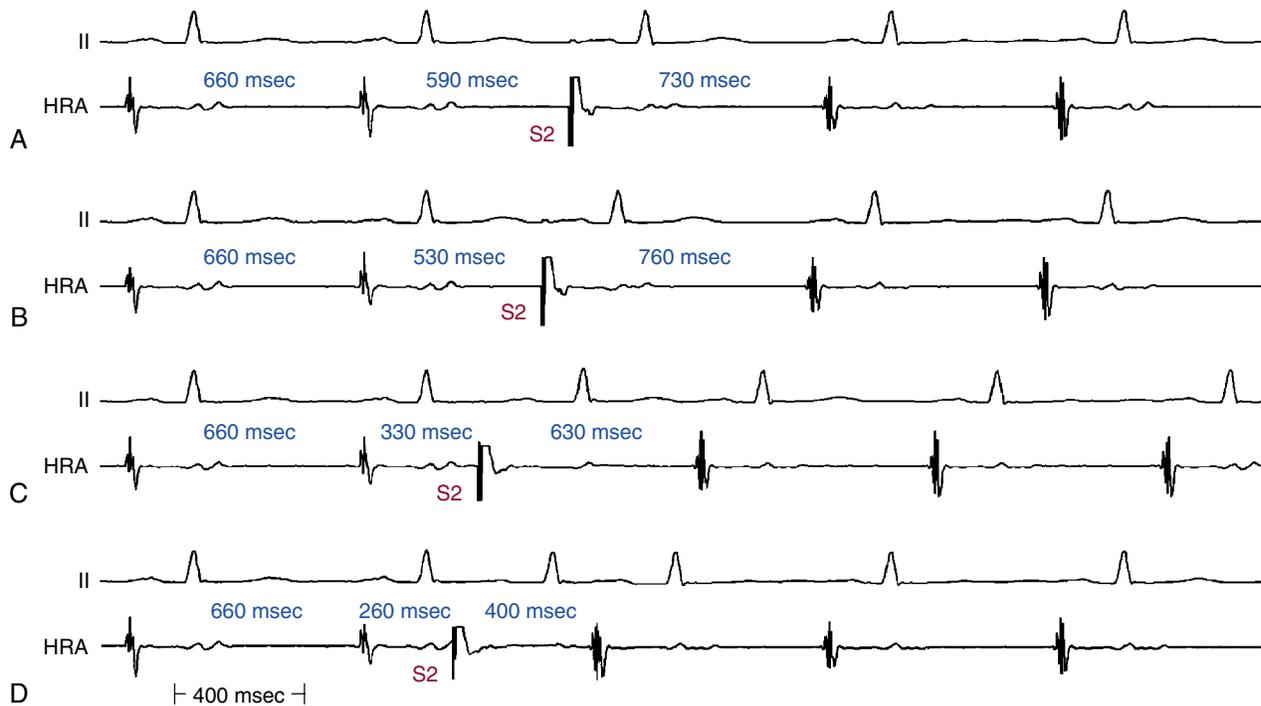

FIGURE 8-9 Strauss sinoatrial conduction time zones. Leads 2 and recording from the high right atrium (HRA) are shown, with a single extrastimulus (S) delivered during sinus rhythm (cycle length, 660 milliseconds) at progressively shorter coupling intervals as indicated relative to the preceding sinus complex. The timing of the subsequent sinus P wave relative to when it would be expected if there were no extrastimulus determines the zone of effect: A, collision; B, reset; C, interpolation; and D, reentry. See text for details.

resetting so that the resulting pause is less than compensatory— $A_1-A_3 < 2 \times (A_1-A_2)$ —but without changing sinus node automaticity. This zone typically occupies a long duration (40% to 50% of the sinus CL). In most patients, the A_2-A_3 interval remains constant throughout zone II, thus producing a plateau in the curve because A_2 penetrates and resets the sinus node, but it does so without changing the sinus pacemaker automaticity. Hence, the A_2-A_3 interval should equal the spontaneous sinus CL (A_1-A_2) plus the time it takes the AES (A_2) to enter and exit the sinus node. The difference between the A_2-A_3 and A_1-A_2 intervals therefore has been taken as an estimate of total SACT (Fig. 8-10).³⁶

Conventionally, it is assumed that conduction times into and out of the sinus node are equal (i.e., $SACT = [A_2-A_3 - A_1-A_2]/2$). Data, however, suggest that conduction time into the sinus node is shorter than that out of the sinus node (see Fig. 8-10). The Strauss method for assessment of SACT can be affected by the site of stimulation; the farther the site of stimulation is from the sinus node, the greater the overestimation of SACT will be (because conduction through more intervening atrial and perinodal tissue will be incorporated in the measurement). The value of SACT can also be affected by the prematurity of the AES (A_2); the more premature is an A_2 , the more likely it will be to encroach on perinodal or atrial refractoriness and slow conduction into the sinus node. In addition, an early AES commonly causes pacemaker shift to a peripheral latent pacemaker, which can exit the atrium earlier because of its proximity to the tissue, thus shortening conduction time out of the sinus node.^{28,29,36}

Despite those limitations, for practical purposes, the Strauss method is a reasonable estimate of functional SACT, provided that stimulation is performed as closely as possible to the sinus node and the measurement is taken when a true plateau is present in zone II.²⁸ SACT appears to be independent of the spontaneous sinus CL. However, marked sinus arrhythmia invalidates the calculation of SACT because it is impossible to know whether the return cycle is a result of spontaneous oscillation or is a result of the AES. To eliminate the effects of sinus arrhythmia, multiple tests need to be performed at each coupling interval. Alternatively, atrial pacing drive at a rate just faster than the sinus rate is used instead of delivery of AES during NSR (Narula method; see later). However, this latter method can result in depression of sinus node automaticity, pacemaker shifts, sinus entrance block, sinus acceleration (if the drive pacing CL is within 50 milliseconds of sinus CL), and shortening of sinus action potential and can lead to an earlier onset of phase IV; each of these actions can yield misleading results.^{35,36}

In an occasional patient, in response to progressively premature AESs, the A_2-A_3 interval prolongs either continuously or after a brief

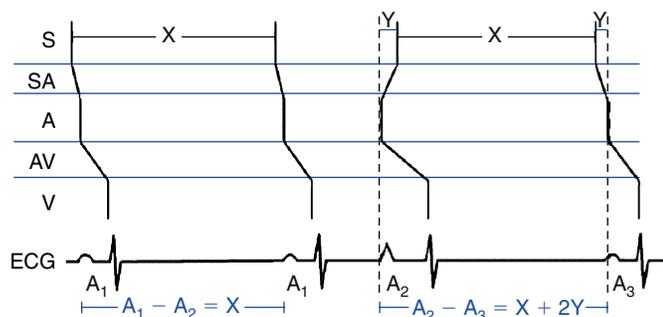

FIGURE 8-10 Calculation of sinoatrial conduction time (SACT) using the Strauss method. The baseline sinus cycle length (A_1-A_2) equals X . The third P wave represents an atrial extrasystole (A_2) that reaches and discharges the sinoatrial (SA) node, which causes the next sinus cycle to begin at that time. Therefore, the A_2-A_3 interval = $X + 2Y$ milliseconds, assuming no depression of sinus node automaticity. Consequently, $SACT = Y = [(A_2-A_3) - X]/2$. AV = atrioventricular. (From Olgin JE, Zipes DP. *Specific arrhythmias: diagnosis and treatment*. In Libby P, Bonow RO, Mann DL, Zipes DP, editors: *Braunwald's heart disease: a textbook of cardiovascular medicine*, ed 8, Philadelphia, 2008, Saunders, pp 869.)

plateau (in both cases, the pause remains less than compensatory). This progressive prolongation of the A_2-A_3 interval during zone II can be caused by suppression of sinus node automaticity, a shift to a slower latent pacemaker, or an increase in conduction time into the sinus node because of encroachment of A_2 on perinodal tissue refractoriness. Thus, it is recommended to use the first third of zone II to measure SACT because it is less likely to introduce such errors.²⁸ Analysis of the A_3-A_4 interval may provide insights into changes in sinus node automaticity or pacemaker shift. If the A_3-A_4 interval is longer than the A_1-A_2 interval, depression of sinus node automaticity is suggested. Therefore, the calculated SACT overestimates the true SACT, and correction of SACT is necessary (in which case the A_3-A_4 interval is used as the basic sinus CL to which the A_2-A_3 interval is compared).²⁸

3. ZONE III: ZONE OF INTERPOLATION. This zone is defined as the range of A_1-A_2 intervals at which the A_2-A_3 interval is less than the A_1-A_2 interval and the A_1-A_3 interval is less than twice the A_1-A_2 interval (see Fig. 8-9).²⁸ The A_1-A_2 coupling intervals at which incomplete interpolation is first observed define the relative refractory period of the perinodal tissue. Some investigators refer to this as the sinus node refractory period. In this case, A_3 represents delay of A_1 exiting the sinus node, which has not been affected.²⁸ The A_1-A_2 coupling interval at which complete interpolation is observed probably defines the effective refractory period of the most peripheral of the perinodal tissue because the sinus impulse does not encounter refractory tissue on its exit from the sinus node. In this case, $(A_1-A_2) + (A_2-A_3) = A_1-A_1$, and sinus node entrance block is said to exist.

4. ZONE IV: ZONE OF REENTRY. This zone is defined as the range of A_1-A_2 intervals at which the A_2-A_3 interval is less than the A_1-A_2 interval and $(A_1-A_2) + (A_2-A_3)$ is less than A_1-A_1 , and the atrial activation sequence and P wave morphology are identical to sinus beats. The incidence of single beats of sinus node reentry is approximately 11% in the normal population.^{29,30,35}

NARULA METHOD

The Narula method for measuring SACT is simpler than the Strauss technique. Instead of atrial premature stimulation, atrial pacing at a rate slightly faster (10 beats/min or more) than the sinus rate is used as A_2 . It is assumed that such atrial pacing will depolarize the sinus node without significant overdrive suppression. The SACT is then calculated using the same formula as for the Strauss method. The Narula method is the quickest and easiest to perform, but it gives only SACT and does not provide information about the AV conduction system.^{29,30,35}

KIRKORIAN-TOUBOUL METHOD

In contrast to the Strauss method, which uses progressively premature AESs delivered during NSR to evaluate SACT, the Kirkorian-Touboul method uses progressively premature AESs delivered following an eight-beat pacing train at a fixed rate. This method was designed to determine SACT independently of baseline sinus CL, which can normally be somewhat variable. It can have several advantages, especially for the study of drug effects at identical basic rates, but it is less widely used than the other methods.

SINOATRIAL CONDUCTION TIME IN PATIENTS WITH SINUS NODE DYSFUNCTION

The normal SACT is 45 to 125 milliseconds. There is a good correlation between direct and indirect measurements of SACT in a patient with or without SND. However, SACT is an insensitive indicator of SND, especially in patients with isolated sinus bradycardia. SACT is prolonged in only 40% of patients with SND, and more frequently (78%) in patients with sinoatrial exit block or bradycardia-tachycardia syndrome, or both.²⁸ In patients with sinus pauses, corrected SNRT is more commonly abnormal than SACT (80% versus 53%). SACT appears to be directly related to the baseline

sinus CL, and the sinus node refractory period is directly related to the drive CL.³⁶

Effects of Drugs

AUTONOMIC BLOCKADE (INTRINSIC HEART RATE). Autonomic blockade is the most commonly used pharmacological intervention for evaluation of SND, and it is used to determine the intrinsic heart rate (i.e., the rate independent of autonomic influences). Autonomic blockade is accomplished by administering atropine, 0.04 mg/kg, and propranolol, 0.2 mg/kg (or atenolol, 0.22 mg/kg). The resulting intrinsic heart rate represents sinus node rate without autonomic influences. The normal intrinsic heart rate is age-dependent and can be calculated using the following equation: intrinsic heart rate (beats/min) = $118.1 - (0.57 \times \text{age})$; normal values are $\pm 14\%$ for age younger than 45 years and $\pm 18\%$ for age older than 45 years. A low intrinsic heart rate is consistent with intrinsic SND. A normal intrinsic heart rate in a patient with known SND suggests extrinsic SND caused by abnormal autonomic regulation. Autonomic blockade with atropine and propranolol also results in shortening of corrected SNRT, as well as sinus CL and SACT.³⁶

ATROPINE. The normal sinus node responses to atropine are an acceleration of heart rate to more than 90 beats/min and an increase over the baseline rate by 20% to 50%. Atropine-induced sinus rate acceleration is usually blunted in patients with intrinsic SND. Failure to increase the sinus rate to more than the predicted intrinsic heart rate following 0.04 mg/kg of atropine is diagnostic of impaired sinus node automaticity. Atropine (1 to 3 mg) markedly shortens SNRT and, in most cases, corrected SNRT. Atropine also abolishes the marked oscillations frequently observed following cessation of rapid pacing. Atropine occasionally results in the appearance of a junctional escape rhythm on cessation of pacing before sinus escape beats in normal subjects (especially in young men with borderline slow sinus rate) and, more commonly, in patients with SND. When this occurs, the junctional escape rhythm is usually transient (lasting only a few beats). Persistence of junctional rhythm and failure of the sinus rate to increase are indicative of SND.²⁸ Atropine, with or without propranolol, shortens SACT (unrelated to its effects on the sinus rate).^{35,36}

PROPRANOLOL. Propranolol (0.1 mg/kg) produces a 12% to 22.5% increase in sinus CL in normal subjects. Patients with SND have a similar chronotropic response to propranolol, a finding suggesting that sympathetic tone or responsiveness, or both, is intact in most patients with SND. Propranolol increases SNRT by 160% in approximately 40% of patients with SND and increases SACT in most patients with SND. The mechanism of these effects is unclear. Effects are minimal in normal subjects.²⁸

ISOPROTERENOL. Isoproterenol (1 to 3 mg/min) produces sinus acceleration of at least 25% in normal subjects. An impaired response to isoproterenol correlates well with a blunted chronotropic response to exercise observed in some patients with SND.²⁸

DIGOXIN. Digoxin shortens SNRT or corrected SNRT, or both, in some patients with clinical SND, probably because of increased perinodal tissue refractoriness with consequent sinus node entrance block.²⁸

VERAPAMIL AND DILTIAZEM. Verapamil and diltiazem have minimal effects on SNRT and SACT in normal persons. Effects in patients with SND have not been studied, but worsening of the SND is expected.²⁸

ANTIARRHYTHMIC AGENTS. Procainamide, quinidine, mexiletine, dronedarone, and amiodarone can adversely affect sinus node function in patients with SND. Severe sinus bradycardia and sinus pauses are the most common problems encountered. Amiodarone is the worst offender and has even caused severe SND in patients without prior evidence of SND. In general, other drugs have minimal effects on sinus node function in normal persons.^{29,36}

Principles of Management

Although pacing is the mainstay of treatment for symptomatic SND, identifying transient or reversible causes for SND is the first step in management. Withdrawal of any offending drugs, correction of any electrolyte abnormalities, and treatment of any extrinsic causes for SND (e.g., obstructive sleep apnea, hypothyroidism, hypoxemia) should be considered prior to permanent pacing therapy. Additionally, the specific clinical circumstance in which SND occurred should be analyzed to document potential heightened vagal tone as a cause of sinus bradycardia or pauses. Hypervagotonia as a cause of SND is often suspected by its transient nature and by the symptoms associated with specific clinical circumstances associated with surges in vagal tone, such as vomiting, coughing, gagging, endotracheal intubation, nasogastric tube placement, airway suctioning, and neurocardiogenic syncope. Vagally induced SND may respond to atropine, but it needs to be treated only if the patient is symptomatic.

Pharmacological therapy (atropine, isoproterenol) is effective only as a short-term emergency measure until pacing can be accomplished. Temporary percutaneous or transvenous pacing is necessary in patients with hemodynamically significant SND and bradycardia, to provide immediate stabilization prior to permanent pacemaker placement or to provide pacemaker support when the bradycardia is precipitated by what is presumed to be a transient event, such as electrolyte abnormality or drug toxicity.

Once all reversible causes are excluded or treated, correlation of symptoms with ECG evidence of SND is an essential part of the management strategy. Because of the episodic nature of symptomatic arrhythmias, ambulatory monitoring is often required. For the patient with asymptomatic bradycardia or sinus pauses, the long-term prognosis is generally benign, and no treatment is necessary. For symptomatic patients with SND, pacing is the mainstay of treatment (Table 8-1). SND is currently the most common reported diagnosis for pacemaker implantation, and it accounts for 40% to 60% of new pacemaker implants. For symptomatic

TABLE 8-1 Guidelines for Permanent Pacing in Sinus Node Dysfunction

Class I

- Sinus node dysfunction with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms
- Symptomatic chronotropic incompetence
- Symptomatic sinus bradycardia that results from required drug therapy for medical conditions

Class IIa

- Sinus node dysfunction with heart rate <40 beats/min when a clear association between significant symptoms consistent with bradycardia and the actual presence of bradycardia has not been documented
- Syncope of unexplained origin when clinically significant abnormalities of sinus node function are discovered or provoked in electrophysiological studies

Class IIb

- Minimally symptomatic patients with chronic heart rate <40 beats/min while awake

Class III

- Sinus node dysfunction in asymptomatic patients
- Sinus node dysfunction in patients whose symptoms suggestive of bradycardia have been clearly documented to occur in the absence of bradycardia
- Sinus node dysfunction with symptomatic bradycardia caused by nonessential drug therapy

patients with tachycardia-bradycardia syndrome, pacing may be required to prevent symptomatic bradycardia and allow the use of drug therapy for control of the tachycardia (see Fig. 8-4). These patients are at increased risk for thromboembolism, and the issue of long-term anticoagulation for stroke prevention should be addressed.^{25,26,29,30,37-39}

Once the decision to pace is made, choosing the optimal pacemaker prescription is essential. For those patients with SND who have normal AV conduction, a single-chamber atrial pacemaker is a reasonable consideration, although in the United States, a dual-chamber pacemaker is usually implanted, largely because of the 1% to 3% annual risk of developing AV block.⁴⁰ The use of rate-adaptive pacing is important for patients with chronotropic incompetence. For patients with intermittent atrial tachyarrhythmias, atrial pacing has been shown to decrease the incidence of AF and thromboembolism greatly, whereas patients who have only ventricular pacing have not seen a similar benefit.²⁴ Current pacemakers used to treat the tachycardia-bradycardia syndrome follow a special algorithm to switch from a DDD or DDDR mode of operation to a VVI, VVIR, DDI, or DDIR mode on sensing an atrial tachyarrhythmia, and back again to DDD or DDDR mode when a normal atrial rate is sensed. For patients with permanent AF, implantation of a single-chamber ventricular pacemaker is appropriate.^{3,25,29,30}

General Considerations

Anatomy and Physiology of the Atrioventricular Junction

INTERNODAL AND INTRAATRIAL CONDUCTION

Evidence indicates the presence of preferential impulse propagation from the sinus node to the atrioventricular node (AVN)—that is, higher conduction velocity between the nodes in some parts of the atrium than in other parts. However, whether preferential internodal conduction is caused by fiber orientation, size, or geometry or by the presence of specialized preferentially conducting pathways located between the nodes has been controversial.¹⁻³

Anatomical evidence suggests the presence of three intraatrial pathways. The anterior internodal pathway begins at the anterior margin of the sinus node and curves anteriorly around the superior vena cava (SVC) to enter the anterior interatrial band, called the Bachmann bundle. This band continues to the left atrium (LA), with the anterior internodal pathway entering the superior margin of the AVN. The Bachmann bundle is a large muscle bundle that appears to conduct the cardiac impulse preferentially from the right atrium (RA) to the LA. The middle internodal tract begins at the superior and posterior margins of the sinus node, travels behind the SVC to the crest of the interatrial septum, and descends in the interatrial septum to the superior margin of the AVN. The posterior internodal tract starts at the posterior margin of the sinus node and travels posteriorly around the SVC and along the crista terminalis to the eustachian ridge, and then into the interatrial septum above the coronary sinus (CS), where it joins the posterior portion of the AVN. Some fibers from all three pathways bypass the crest of the AVN and enter its more distal segment. These groups of internodal tissue are best referred to as *internodal atrial myocardium*, not tracts, because they do not appear to be histologically recognizable specialized tracts, only plain atrial myocardium. Detailed electroanatomical activation maps do not reveal more rapidly conducting tracts.

ATRIOVENTRICULAR NODE

The AVN is an interatrial structure, measuring approximately 5 mm long, 5 mm wide, and 0.8 mm thick in adults. The AVN is located beneath the RA endocardium at the apex of the triangle of Koch. The triangle of Koch is septal and constitutes the RA endocardial surface of the muscular AV septum. It is bordered anteriorly by the annulus of the septal leaflet of the tricuspid valve, posteriorly by the tendon of Todaro, and inferiorly by the orifice of the CS ostium (CS os) (see Fig. 17-1). The central fibrous body is composed of a thickened area of fibrous continuity between the leaflets of the mitral and aortic valves, termed the right fibrous trigone, together with the membranous component of the cardiac septum. The tendon of Todaro runs within the eustachian ridge and inserts into

the central fibrous body; the annulus of the septal leaflet of the tricuspid valve crosses the membranous septum.^{4,6}

The compact AVN lies anterior to the CS os and directly above the insertion of the septal leaflet of the tricuspid valve, where the tendon of Todaro merges with the central fibrous body. Slightly more anteriorly and superiorly is where the His bundle (HB) penetrates the AV junction through the central fibrous body and the posterior aspect of the membranous AV septum.⁷ The compact node is adjacent to the central fibrous body on the right side but is uninsulated by fibrous tissue on its other sides, thus allowing contiguity with the atrial myocardium. Because the AV valves are not isoplanar (the attachment of the tricuspid valve into the most anterior part of the central body is a few millimeters apically relative to the mitral valve), the AVN lies just beneath the RA endocardium. When traced inferiorly, toward the base of the triangle of Koch, the compact AVN area separates into two extensions, usually with the artery supplying the AVN running between them. The prongs bifurcate toward the tricuspid and mitral annuli, respectively. The rightward posterior extensions have been implicated in the so-called slow pathway in AVN reentrant tachycardia (AVNRT) circuit.^{4,6}

The normal AV junctional area can be divided into distinct regions: the transitional cell zone (which represents the approaches from the working atrial myocardium to the AVN), the compact AVN, and the penetrating part of the HB.⁸ The AVN and perinodal area are composed of at least three electrophysiologically distinct cells: the atrionodal (AN), nodal (N), and nodal-His (NH) cells. The AN region corresponds to the cells in the transitional region that are activated shortly after the atrial cells. Transitional cells are histologically distinct from both the cells of the compact AVN and the working atrial myocytes, and they are not insulated from the surrounding myocardium, but tend to be separated from one another by thin fibrous strands. Transitional cells do not represent conducting tracts but a bridge funneling atrial depolarization into the compact AVN via discrete AVN inputs (approaches). Transitional cells approaches connect the working atrial myocardium from the left and right sides of the atrial septum to the left and right margins of the compact node, with wider extensions inferiorly and posteriorly between the compact node and the CS os and into the eustachian ridge. In humans and animals, two such inputs are commonly recognized in the right septal region: the anterior (superior) approaches, which travel from the anterior limbus of the fossa ovalis and merge with the AVN closer to the apex of the triangle of Koch; and the posterior (inferior) approaches, which are located in the inferoseptal RA and serve as a bridge with the atrial myocardium at the CS os. Although both inputs have traditionally been assumed to be RA structures, growing evidence supports the AV conduction apparatus as a transseptal structure that reaches both atria. A third, middle group of transitional cells has also been identified to account for the nodal connections with the septum and LA.^{4,6}

The N region corresponds to the region where the transitional cells merge with midnodal cells. The N cells represent the most typical of the nodal cells, which are smaller than atrial myocytes, are

closely grouped, and frequently are arranged in an interweaving fashion. The N cells in the compact AVN appear to be responsible for the major part of AV conduction delay and exhibit decremental properties in response to premature stimulation because of their slow rising and longer action potentials. Fast pathway conduction through the AVN apparently bypasses many of the N cells by transitional cells, whereas slow pathway conduction traverses the entire compact AVN. Importantly, the recovery of excitability after conduction of an impulse is faster for the slow pathway than for the fast pathway, for reasons that are unclear.⁴

The NH region corresponds to the lower nodal cells, connecting to the insulated penetrating portion of the HB. Sodium (Na^+) channel density is lower in the midnodal zone of the AVN than in the AN and NH cell zones, and the inward L-type calcium (Ca^{2+}) current is the basis of the upstroke of the N cell action potential. Therefore, conduction is slower through the compact AVN than the AN and NH cell zones.^{9,10}

The AVN is the only normal electrical connection between the atria and the ventricles; the fibrous skeleton acts as an insulator to prevent electrical impulses from entering the ventricles by any other route. The main function of the AVN is modulation of atrial impulse transmission to the ventricles, thereby coordinating atrial and ventricular contractions. The AVN receives, slows down, and conveys atrial impulses to the ventricles. A primary function of the AVN is to limit the number of impulses conducted from the atria to the ventricles. This function is particularly important during fast atrial rates (e.g., during atrial fibrillation [AF] or atrial flutter), in which only a few impulses are conducted to the ventricles, and the remaining impulses are blocked in the AVN. Additionally, fibers in the lower part of the AVN can exhibit automatic impulse formation, and the AVN may serve as a subsidiary pacemaker.^{5,6,9}

The AVN region is innervated by a rich supply of cholinergic and adrenergic fibers. Sympathetic stimulation shortens AVN conduction time and refractoriness, whereas vagal stimulation prolongs AVN conduction time and refractoriness. The negative dromotropic response of the AVN to vagal stimulation is mediated by activation of the inwardly rectifying potassium (K^+) current I_{KACH} , which results in hyperpolarization and action potential shortening of AVN cells, increased threshold of excitation, depression of action potential amplitude, and prolonged conduction time. The positive dromotropic effect of sympathetic stimulation arises as a consequence of activation of the L-type Ca^{2+} current.⁷

The blood supply to the AVN predominantly comes from a branch of the right coronary artery in 85% to 90% of patients and from the circumflex artery in 10% to 15%.

HIS BUNDLE

The HB connects with the distal part of the compact AVN and passes through the fibrous core of the central fibrous body in a leftward direction (away from the RA endocardium and toward the ventricular septum). The HB then continues through the annulus fibrosus (where it is called the nonbranching portion) as it penetrates the membranous septum, along the crest of the left side of the interventricular septum, for 1 to 2 cm and then divides into the right and left bundle branches.⁴

Proximal cells of the penetrating portion are heterogeneous and resemble those of the compact AVN; distal cells are larger, similar to cells in the proximal bundle branches and ventricular myocytes. The HB is insulated from the atrial myocardium by the membranous septum and from the ventricular myocardium by connective tissue of the central fibrous body, thus preventing atrial impulses from bypassing the AVN. The area of fibrous continuity between the aortic and mitral valves adjacent to the membranous septum marks the HB as viewed from the left ventricle (LV). Viewed from the aorta, the HB passes beneath the part of the membranous septum that adjoins the interleaflet fibrous triangle between the right and the noncoronary sinuses.⁴

The HB has a dual blood supply from branches of the anterior and posterior descending coronary arteries that makes the

conduction system at this site less vulnerable to ischemic damage unless the ischemia is extensive.

The AVN and the HB region are innervated by a rich supply of cholinergic and adrenergic fibers, with a density exceeding that found in the ventricular myocardium. Although neither sympathetic stimulation nor vagal stimulation affects normal conduction in the HB, either can affect abnormal AV conduction.

Pathophysiology of Atrioventricular Block

Block or delay of a cardiac impulse can take place anywhere in the heart, or even within a single cell. AV block can be defined as a delay or interruption in the transmission of an impulse from the atria to the ventricles caused by an anatomical or functional impairment in the conduction system. The conduction disturbance can be transient or permanent.

CONGENITAL ATRIOVENTRICULAR BLOCK

Congenital complete AV block is thought to result from embryonic maldevelopment of the AVN (and, much less frequently, the His-Purkinje system [HPS]), mainly secondary to a lack of connection between the atria and the peripheral conduction system, with fatty replacement of the AVN and nodal approaches.⁴ The incidence of congenital complete AV block varies from 1 in 15,000 to 1 in 22,000 live births. The defect usually occurs proximal to the HB, and QRS duration is shorter than 120 milliseconds.¹¹ Maternal lupus, caused by antibodies targeting intracellular ribonucleoproteins that cross the placenta to affect the fetal heart but not the maternal heart, is responsible for 60% to 90% of cases of congenital complete AV block.¹²

Approximately 50% of patients with congenital AV block have concurrent congenital heart disease (e.g., congenitally corrected transposition of the great vessels, AV discordance, ventricular septal defects, AV canal defect, tricuspid atresia, and Ebstein anomaly of the tricuspid valve).¹³ The AV conduction system may be displaced if atrial and ventricular septa are malaligned, AV arrangements are discordant, or the heart is univentricular. Generally, if the AV conduction system is displaced, it will also tend to be more fragile and susceptible to degeneration, thus placing patients at greater risk for AV block.¹⁴

HEREDITARY PROGRESSIVE CARDIAC CONDUCTION DISEASE

Cardiac ion channelopathies have been described as a rare cause of familial forms of AV block. Mutations in the *SCN5A* gene (encoding the alpha-subunit of the cardiac Na^+ channel) and the *KCNJ2* gene (encoding the inward rectifier $\text{Kir}2.1$, a critical component of the cardiac inward K^+ rectifier current, I_{K1}) have been associated with AV block. Additionally, mutations in the *PRKAG2* gene (encoding the γ_2 regulatory subunit of adenosine monophosphate-activated protein kinase) have been described in patients with Wolff-Parkinson-White syndrome and AV conduction block.^{15,16}

ACQUIRED ATRIOVENTRICULAR BLOCK

DRUGS. Various drugs can impair conduction and cause AV block. Digoxin and beta blockers act indirectly on the AVN through their effects on the autonomic nervous system. Calcium channel blockers and other antiarrhythmic drugs, such as amiodarone and dronedarone, act directly to slow conduction in the AVN. Class I and III antiarrhythmic drugs can also affect conduction in the HPS that results in infranodal block. These effects, however, typically occur in patients with preexisting conduction abnormalities. Patients with a normal conduction system function rarely develop complete heart block as a result of using antiarrhythmic agents.¹⁷

ACUTE MYOCARDIAL INFARCTION. AV block occurs in 12% to 25% of all patients with acute myocardial infarction (MI);

first-degree AV block occurs in 2% to 12% second-degree AV block occurs in 3% to 10%, and third-degree AV block occurs in 3% to 7%. First-degree AV block and type 1 second-degree (Wenckebach) AV block occur more commonly in inferior MI, usually caused by increased vagal tone and generally associated with other signs of vagotonia, such as sinus bradycardia and responsiveness to atropine and catecholamine stimulation. Wenckebach AV block in the setting of acute inferior MI is usually transient (resolving within 48 to 72 hours of MI) and asymptomatic, and it rarely progresses to high-grade or complete AV block. Wenckebach AV block occurring later in the course of acute inferior MI is less responsive to atropine and probably is associated with ischemia of the AVN or the release of adenosine during acute MI. In this setting, Wenckebach AV block rarely progresses to more advanced block and commonly resolves within 2 to 3 days of onset. The site of conduction block is usually in the AVN.

Type 2 second-degree (Mobitz type II) AV block occurs in only 1% of patients with acute MI (more commonly in anterior than inferior MI) and has a worse prognosis than type 1 second-degree block. Type 2 second-degree AV block occurring during acute anterior MI is typically associated with HB or bundle branch ischemia or infarction and frequently progresses to complete heart block.

Complete AV block occurs in 8% to 13% of patients with acute MI. It can occur with anterior or inferior acute MI. In the setting of acute inferior MI, the site of the block is usually at the level of the AVN, and it results in a junctional escape rhythm with a narrow QRS complex and a rate of 40 to 60 beats/min. The block tends to be reversed by vagolytic drugs or catecholamines and usually resolves within several days. Development of complete AV block in the setting of acute anterior MI, however, is associated with a higher risk of ventricular tachycardia (VT) and ventricular fibrillation, hypotension, pulmonary edema, and in-hospital mortality. In this setting, the block is usually associated with ischemia or infarction of the HB or bundle branches and is less likely to be reversible. Complete AV block during acute anterior MI is often preceded by bundle branch block (BBB), fascicular block, or type 2 second-degree AV block. The escape rhythm usually originates from the bundle branch and Purkinje system, with a rate less than 40 beats/min and a wide QRS complex. In general, patients who develop transient or irreversible AV block are older and have a larger area of damage associated with their acute MI.^{11,18}

CHRONIC ISCHEMIC HEART DISEASE. Chronic ischemic heart disease, with or without infarction, can result in persistent AV block secondary to fibrotic changes in the bifurcating HB and bundle branches. Transient AV block can occur during angina pectoris and Prinzmetal angina.

DEGENERATIVE DISEASES. Fibrosis and sclerosis of the conduction system are the most common causes of acquired conduction system disease. These disorders account for approximately half the cases of AV block and can be induced by several different conditions, which often cannot be distinguished clinically.

Progressive cardiac conduction disease (including Lev disease or Lenègre disease) manifests as progressive slowing of electrical conduction through the atria, AVN, HB, Purkinje fibers, and ventricles, accompanied by an age-related degenerative process, in which fibrosis affects only the cardiac conduction system. Complete AV block can develop and cause syncope or sudden death. Lev disease is a result of proximal bundle branch calcification or fibrosis and is often described as senile degeneration of the conduction system. It is postulated as a hastening of the aging process by hypertension and arteriosclerosis of the blood vessels supplying the conduction system. Lenègre disease is a sclerodegenerative process that occurs in a younger population and involves the more distal portions of the bundle branches. As noted, in heritable progressive cardiac conduction disease (referred to as hereditary Lenègre disease, progressive cardiac conduction disease, and familial AV block), conduction slowing may be attributed to loss-of-function mutations in *SCN5A*. Whether age-dependent fibrosis of the conduction system is a primary degenerative process in progressive cardiac conduction disease or a physiological

process that is accelerated by Na^+ current (I_{Na}) reduction is still unknown.¹⁶

Calcification of the aortic or (less commonly) mitral valve annulus can extend to the nearby conduction system and produce AV block. As noted, the HB penetrates the central fibrous body adjacent to the fibrous continuity between the aortic and mitral valves that is the usual site of dystrophic calcification, and extension of calcification can directly involve the HB or the origin of the left bundle branch, or both.^{4,11,18}

RHEUMATIC DISEASES. AV block can occur in association with collagen vascular diseases such as scleroderma, rheumatoid arthritis, Reiter syndrome, systemic lupus erythematosus, ankylosing spondylitis, and polymyositis. Polyarteritis nodosa and Wegener granulomatosis also can cause AV block.

INFILTRATIVE PROCESSES. Infiltrative cardiomyopathies such as amyloidosis, sarcoidosis, hemochromatosis, and tumors can be associated with AV block.

NEUROMYOPATHIES. AV conduction disturbance is usually the major cardiac manifestation of neuromuscular diseases, including Becker muscular dystrophy, peroneal muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy, and myotonic muscular dystrophy. AV block can be an important cause of mortality in such cases.¹⁹

INFECTIOUS DISEASES. Infective endocarditis (especially of the aortic valve) and myocarditis of various viral, bacterial, and parasitic causes (including Lyme disease, rheumatic fever, Chagas disease, tuberculosis, measles, and mumps) result in varying degrees of AV block. Complete AV block occurs in 3% of cases.¹⁷ Lyme carditis is of particular importance because in most cases, AV block resolves completely within weeks.

IATROGENIC. Cardiac surgery can be complicated by varying degrees of AV block caused by trauma and ischemic damage to the conduction system. AV block is most frequently associated with aortic valve replacement; less commonly, it occurs following coronary artery bypass grafting.²⁰ Repair of congenital heart defects in the region of the conduction system, such as endocardial cushion malformations, ventricular septal defects, and tricuspid valve abnormalities, can lead to transient or persistent AV block.^{13,21,22} The block is usually temporary and is thought to be secondary to postoperative local inflammation. However, AV block can appear years later, usually in patients who had transient block just after the operation.^{23,24} Intracardiac catheter manipulation can inadvertently produce varying degrees of heart block, which is usually temporary. Alcohol septal ablation in patients with obstructive hypertrophic cardiomyopathy also can be complicated by AV block. Complete heart block can occur during right-sided heart catheterization in a patient with preexisting left BBB (LBBB) or during LV catheterization (LV angiography or ablation procedures) in a patient with preexisting right BBB (RBBB).²⁵ AV block can also complicate catheter ablation of AVNRT, bypass tracts and atrial tachycardias in the AVN vicinity, as well as VTs originating in the interventricular septum adjacent to the HB.²⁶

VAGALLY MEDIATED ATRIOVENTRICULAR BLOCK. Vagally induced AV block can occur in otherwise normal patients, in those with cough or hiccups, and during swallowing or micturition when vagal discharge is enhanced.²⁷ Vagally mediated AV block occurs in the AVN, is associated with a narrow QRS complex, and is generally benign. The block is characteristically paroxysmal and is often associated with clearly visible sinus slowing on the ECG because the vagal surge can cause simultaneous sinus slowing and AVN block. Additionally, transient AV block can occur secondary to enhanced vagal tone caused by carotid sinus massage, hypersensitive carotid sinus syndrome, or neurocardiogenic syncope. AV block in athletes is typically type 1 second-degree block, probably an expression of hypervagotonia related to physical training, and it resolves after physical deconditioning. This form of AV block may or may not be associated with sinus bradycardia because the relative effects of sympathetic and parasympathetic systems on the AVN and sinus node can differ.

LONG QT SYNDROME. In long QT syndrome (LQTS) with a very long QT interval (e.g., in LQT2, LQT3, LQT8, and LQT9), functional block between the HB and ventricular muscle caused by prolonged ventricular refractoriness can lead to 2:1 AV block and severe bradycardia. Conduction abnormalities of the HPS, including PQ prolongation and RBBB or LBBB, occur in some patients with LQTS.

Clinical Presentation

Symptoms in patients with AV conduction abnormalities are generally caused by bradycardia and loss of AV synchrony. Individuals with first-degree AV block are usually asymptomatic; however, patients with marked prolongation of the PR interval (longer than 300 milliseconds) can experience symptoms similar to those with pacemaker syndrome caused by loss of AV synchrony and atrial contraction against closed AV valves. Additionally, in patients with LV dysfunction, severe first-degree AV block can cause worsening of heart failure symptoms.²⁸ Symptoms caused by more advanced AV block can range from exercise intolerance, easy fatigability, dyspnea on exertion, angina, mental status changes, dizziness, and near syncope to frank syncope.^{11,18} In patients with paroxysmal or intermittent complete heart block, symptoms are episodic, and routine ECGs may not be diagnostic.

Congenital AV block can be apparent in utero or at birth; however, many individuals have few or no symptoms and reach their teens or young adulthood before the diagnosis is made. Because of the presence of reliable subsidiary HB pacemakers with adequate rates (especially in the presence of catecholamines), syncope is rare with congenital complete AVN block. Some patients become symptomatic only when aging produces chronotropic incompetence of the HB rhythm.^{11,18}

Natural History of Atrioventricular Block

The natural history of patients with AV block depends on the underlying cardiac condition; however, the site of the block and the resulting rhythm disturbances themselves contribute to the prognosis. Patients with first-degree AV block have an excellent prognosis, even when the condition is associated with chronic bifascicular block, because the rate of progression to third-degree AV block is low.²⁸ Type 1 second-degree AV block is generally benign; however, when type 1 AV block occurs in association with bifascicular block, the risk of progression to complete heart block is significantly increased because of probable infranodal disease. Type 2 second-degree AV block, usually seen with BBB, carries a high risk of progression to advanced or complete AV block. The prognosis of 2:1 AV block depends on whether the site of block is within or below the AVN.¹¹

The prognosis for patients with symptomatic acquired complete heart block is very poor in the absence of pacing, regardless of the extent of underlying heart disease. Once appropriate pacing therapy has been established, however, the prognosis depends on the underlying disease process.¹⁷ Complete heart block secondary to anterior MI carries a poor prognosis because of the coexisting extensive infarction and pump failure. In contrast, complete heart block secondary to idiopathic fibrosis of the conduction system in the absence of additional cardiac disease carries a more benign prognosis.¹¹ AV block after valve surgery can recover; however, if conduction has not recovered by 48 hours after surgery, permanent pacing will likely be necessary.²⁹

Congenital complete heart block generally carries a more favorable prognosis than the acquired form when it is not associated with underlying heart disease. Patients with concomitant structural heart disease, a wide QRS complex, LQTS, or complete heart block discovered at an early age are more likely to develop symptoms early and are at an increased risk for sudden death.

Diagnostic Evaluation of Atrioventricular Block

Because the prognosis and, in some cases, the treatment of AV block differ depending on whether the block is within the AVN or

is infranodal, determining the site of block is important. In most cases, this can be achieved noninvasively.

ELECTROCARDIOGRAPHY

The QRS duration, PR interval, and ventricular rate on the surface ECG can provide important clues for localizing the level of AV block (see later).

AUTONOMIC MODULATION

Whereas the AVN is richly innervated and highly responsive to both sympathetic and vagal stimuli, the HPS is influenced minimally by the autonomic nervous system. Carotid sinus massage increases vagal tone and worsens second-degree AVN block, whereas exercise and atropine improve AVN conduction because of sympathetic stimulation or parasympatholysis, or both. In contrast, carotid sinus massage can improve second-degree infranodal block by slowing the sinus rate and allowing HPS refractoriness to recover. Also, exercise and atropine worsen infranodal block because of the enhanced function of the sinus node and AVN and, as a consequence, the increased rate of impulses conducted to the HPS without changing HPS refractoriness.^{11,18}

EXERCISE TESTING

Vagolysis and increased sympathetic drive that occur with exercise enhance AVN conduction. Thus, patients with first-degree AV block can have shorter PR intervals during exercise, and patients with type 1 second-degree AV block can develop higher AV conduction ratios (e.g., 3:2 at rest becoming 6:5 during exercise).

Exercise testing can be a useful tool to help confirm the level of block in second- or third-degree AV block associated with a narrow or wide QRS complex. Patients with presumed type 1 block or congenital complete heart block and a normal QRS complex usually have an increased ventricular rate with exercise. On the other hand, patients with acquired complete heart block and a wide QRS complex usually show minimal or no increase in ventricular rate. Additionally, patients with 2:1 AV block in whom the site of conduction block is uncertain can benefit from exercise testing by observing whether the AV conduction ratio increases in a Wenckebach-like manner (e.g., to 3:2 or 4:3) or decreases (e.g., to 3:1 or 4:1). In the latter case, the increase in the sinus rate finds the HPS refractory, thus causing the higher degrees of block. This response is always abnormal, and it indicates intra-Hisian or infra-Hisian block, which requires permanent cardiac pacing.

ELECTROPHYSIOLOGICAL TESTING

Electrophysiological (EP) testing is usually not required for the diagnosis or treatment of AV block, because the previously described noninvasive measures are usually adequate. Nevertheless, EP testing can be of value in symptomatic patients in whom AV conduction abnormalities are suspected but cannot be documented or in patients with equivocal ECG findings.

Electrocardiographic Features

First-Degree Atrioventricular Block (Delay)

First-degree AV block manifests on the surface ECG as a PR interval longer than 200 milliseconds following a normally timed (nonpre-mature) P wave. All P waves are conducted, but with delay; each P wave is followed by a QRS complex with a constant, prolonged PR interval.

SITE OF BLOCK

The degree of PR interval prolongation and QRS duration can help predict the site of conduction delay. Very long (more than

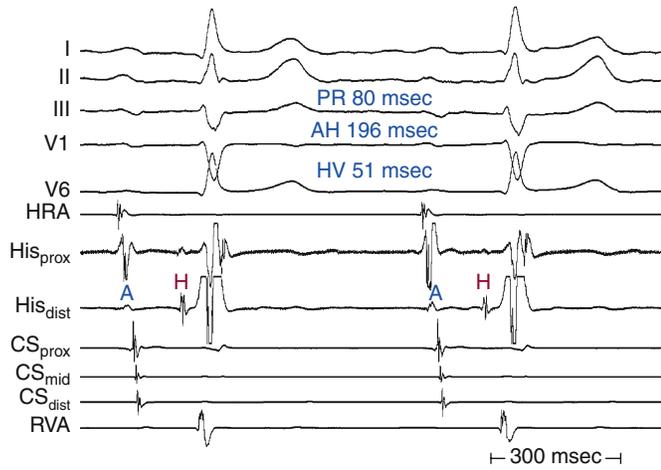

FIGURE 9-1 First-degree atrioventricular block caused by intranodal conduction delay, as indicated by the prolonged atrial–His bundle (AH) and normal PA and His bundle–ventricular (HV) intervals. CS_{dist} = distal coronary sinus; CS_{mid} = middle coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; RVA = right ventricular apex.

300 milliseconds) or highly variable PR intervals suggest involvement of the AVN. Normal QRS duration also suggests involvement of the AVN.^{17,30}

ATRIOVENTRICULAR NODE. Although conduction delay can be anywhere along the AVN-HPS, the AVN is the most common site of delay (87% when the QRS complex is narrow, and more than 90% when the PR interval is longer than 300 milliseconds; Fig. 9-1).

HIS-PURKINJE SYSTEM. Intra-Hisian conduction delay or HPS disease can cause first-degree AV block. First-degree AV block in the presence of BBB is caused by infranodal conduction delay in 45% of cases. A combination of delay within the AVN and in the HPS must also be considered (Fig. 9-2).

ATRIUM. First-degree AV block caused by intraatrial or interatrial conduction delay is not uncommon. An LA enlargement pattern on the ECG (i.e., prolonged P wave duration) reflects the presence of interatrial conduction delay. RA enlargement can prolong the PR interval (Fig. 9-3). In certain cases of congenital structural heart disease, such as Ebstein anomaly of the tricuspid valve or endocardial cushion defects, intraatrial conduction delay can cause first-degree AV block.³¹

Second-Degree Atrioventricular Block

The term *second-degree AV block* is applied when intermittent failure of AV conduction is present (i.e., one or more atrial impulses that should be conducted fail to reach the ventricles). This term encompasses several conduction patterns. Types 1 and 2 AV block are ECG patterns that describe the behavior of the PR intervals (in sinus rhythm) in sequences (with at least two consecutively conducted PR intervals) in which a *single* P wave fails to conduct to the ventricles. The anatomical site of block should not be characterized as either type 1 or type 2 because type 1 and type 2 designations refer only to ECG patterns.¹¹

TYPE 1 SECOND-DEGREE ATRIOVENTRICULAR BLOCK

Type 1 second-degree AV block (Wenckebach or Mobitz type I block) manifests on the surface ECG as progressive prolongation of the PR interval before failure of an atrial impulse to conduct to the ventricles. The PR interval immediately after the nonconducted P wave returns to its baseline value, and the sequence begins again.

The behavior of Wenckebach block can be simplified by relating it to an abnormally long relative refractory period of the AVN. In this setting, the rate of AVN conduction depends on the time that

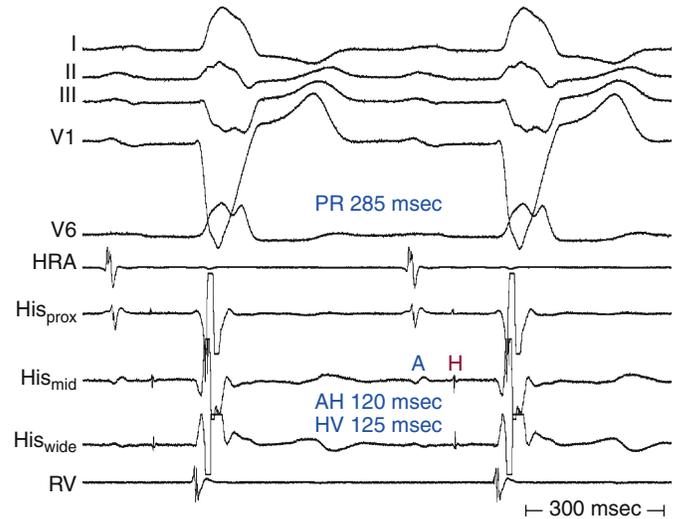

FIGURE 9-2 First-degree atrioventricular block secondary to His-Purkinje system disease. The atrial–His bundle (AH) interval is normal but the His bundle–ventricular (HV) interval is markedly prolonged and associated with complete left bundle branch block. His_{mid} = middle His bundle; His_{prox} = proximal His bundle; His_{wide} = wide His bundle; HRA = high right atrium; RV = right ventricle.

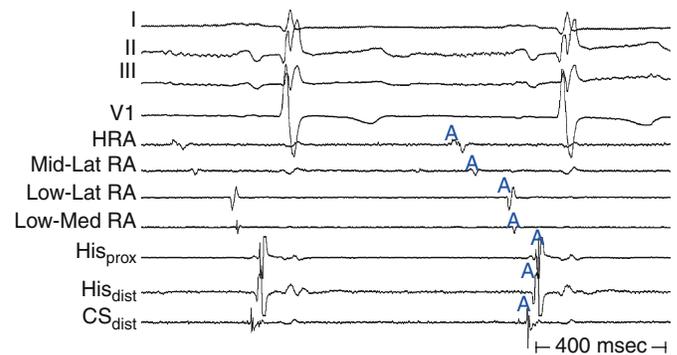

FIGURE 9-3 First-degree atrioventricular block caused by intraatrial conduction delay. The long PR interval (240 milliseconds) is caused by prolonged conduction in the right atrium (prolonged PA interval) in a patient who has undergone Fontan repair for complex congenital heart disease. CS_{dist} = distal coronary sinus; His_{dist} = distal His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; Low-Lat RA = low lateral right atrium; Low-Med RA = low medial right atrium; Mid-Lat RA = middle lateral right atrium.

the impulse arrives at the AVN. The earlier it arrives at the AVN, the longer it takes to propagate through the AVN, and the longer the PR interval will be; the later it arrives, the shorter the conduction time, and the shorter the PR interval. Thus, Wenckebach periodicity develops because each successive atrial impulse arrives earlier and earlier in the relative refractory period of the AVN, thus resulting in longer and longer conduction delay and PR interval, until one impulse arrives during the absolute refractory period and fails to conduct, with a consequent ventricular pause. In other words, the shorter the RP interval is, the longer the PR interval will be; and the longer the RP interval is, the shorter the PR interval will be. This is referred to as RP-PR reciprocity or RP-dependent PR interval. Using this concept, it is easy to explain the behavior of the PR interval during the Wenckebach periodicity. The first atrial impulse conducting after the pause has an unusually long RP interval, whereas with the following atrial impulse, the RP interval dramatically shortens, thus resulting in prolongation of the PR interval. Although the following atrial impulses have shorter RP intervals, such shortening is not as dramatic, and consequently the progressive prolongation of the PR interval is of lesser degree. In other words, although each successive PR interval prolongs, it does so at a decreasing increment. So, for example, if the PR interval following the first conducted P wave

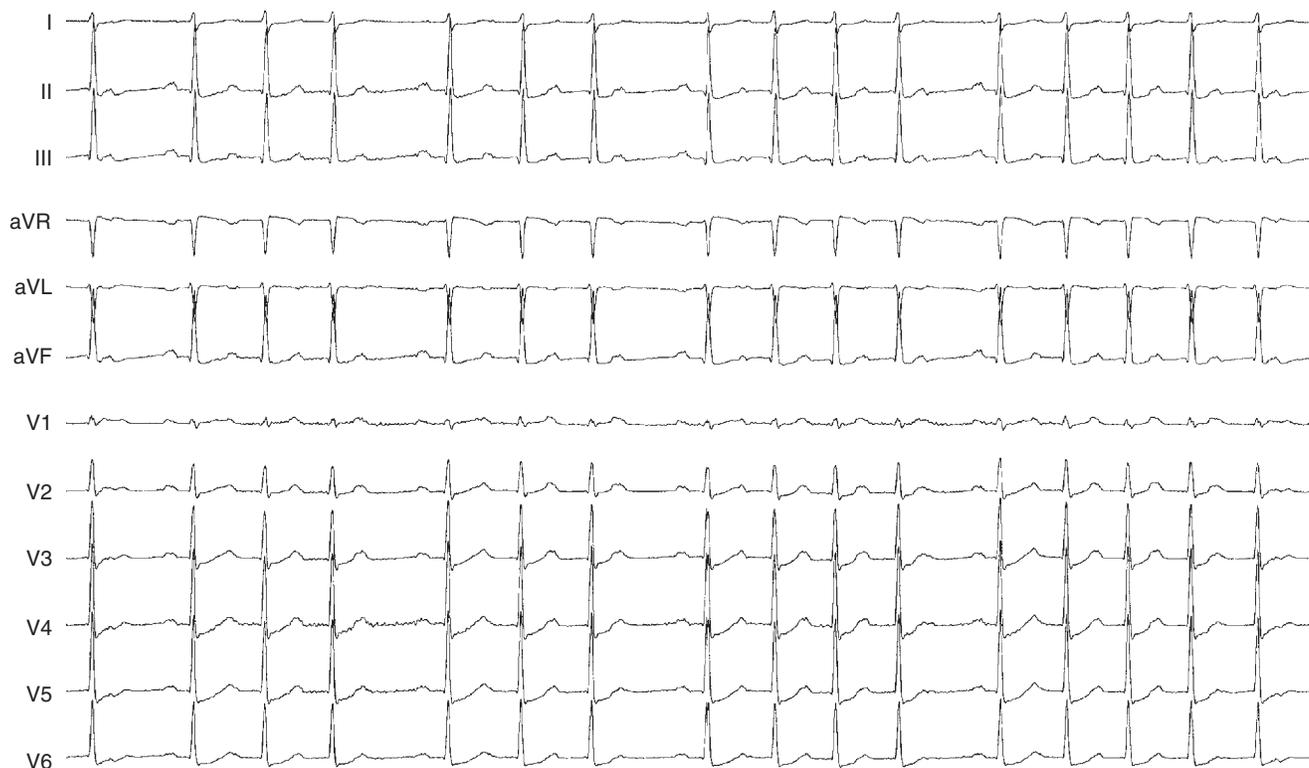

FIGURE 9-4 Typical Wenckebach periodicity. Normal sinus rhythm with type 1 second-degree atrioventricular block is characterized by progressive prolongation of the PR intervals preceding the nonconducted P wave and group beating.

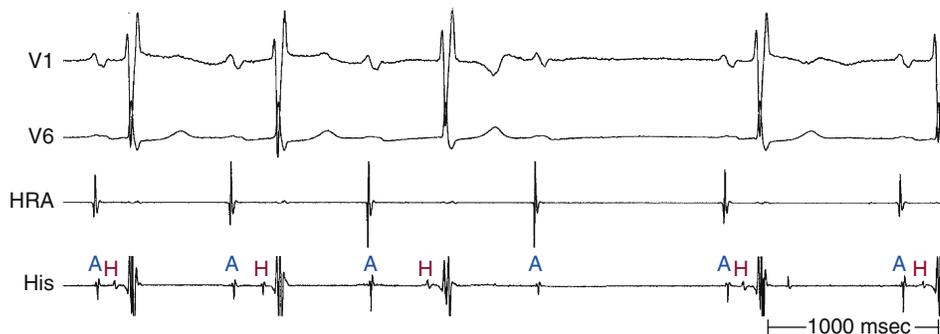

FIGURE 9-5 Atypical Wenckebach periodicity (type 1 second-degree atrioventricular [AV] block) caused by heightened vagal tone. Note the greatest increment occurs in the PR interval of the last conducted beat in the cycle and not in the second PR interval after the pause. Also note the slowing in the sinus rate coinciding with significant prolongation in the PR interval and then AV block, a finding suggesting that increased vagal tone is responsible for both slowing of the sinus rate and atrioventricular nodal block. HRA = high right atrium.

in the cycle increased by 100 milliseconds, the PR interval of the next beat would increase by 50 milliseconds, and so forth.

Features of typical Wenckebach periodicity include the following: (1) progressive lengthening of the PR interval throughout the Wenckebach cycle; (2) lengthening of the PR interval occurring at progressively decreasing increments and resulting in progressively shorter R-R intervals; (3) a pause between QRS complexes encompassing the nonconducted P wave that is less than the sum of R-R intervals of any two consecutively conducted beats; (4) shortening of the PR interval after block, compared with the PR interval just preceding the blocked cycle; and (5) group beating, which offers a footprint that identifies Wenckebach periodicity (Fig. 9-4). It is important to recognize that, during Wenckebach periodicity, the atrial impulse conducted to the ventricles is not always represented by the P wave that immediately precedes the QRS complex; the PR interval can be very long and exceed the P-P interval.^{11,18}

Less than 50% of type 1 AV block cases follow this typical pattern. Typical Wenckebach periodicity is more frequently observed during pacing-induced AV block. Atypical patterns are more likely found with longer Wenckebach periods (more than 6:5). In patients with dual AVN physiology, Wenckebach cycles are almost always atypical; the greatest increment in the AH interval occurs

when block occurs in the fast pathway, whichever beat this may be. Differentiating atypical from typical patterns is of little clinical significance. However, an atypical pattern can be misdiagnosed as type 2 second-degree AV block. Some possible atypical features of Wenckebach periodicity include the following: (1) the second (conducted) PR interval (after the pause) often fails to show the greatest increment, and the increment may actually increase for the PR interval of the last conducted beat in the cycle (Fig. 9-5); (2) very little incremental conduction delay and no discernible change in the duration of the PR intervals for a few beats just before termination of a sequence (this is seen most often during long Wenckebach cycles and in association with increased vagal tone, and is usually accompanied by slowing of the sinus rate; Fig. 9-6); (3) the PR interval can actually shorten and then lengthen in the middle of a Wenckebach sequence; and (4) a junctional escape beat can end the pause following a nonconducted P wave, resulting in an apparent shortening of the PR interval.^{30,32}

AVN block usually can be reversed completely or partially by altering the autonomic tone (e.g., with atropine). However, these measures fail occasionally, especially in the presence of structural damage (congenital heart disease or inferior wall MI) to the AVN. In such cases, progression to complete AV block can occur, although such an event is more likely to occur with block in the HPS.

FIGURE 9-6 Atypical Wenckebach periodicity (type 1 second-degree atrioventricular block). Note the very small increments in the duration of the PR intervals for a few beats just before termination of a sequence. The first conducted P wave after the pause, however, is associated with obvious shortening of the PR interval.

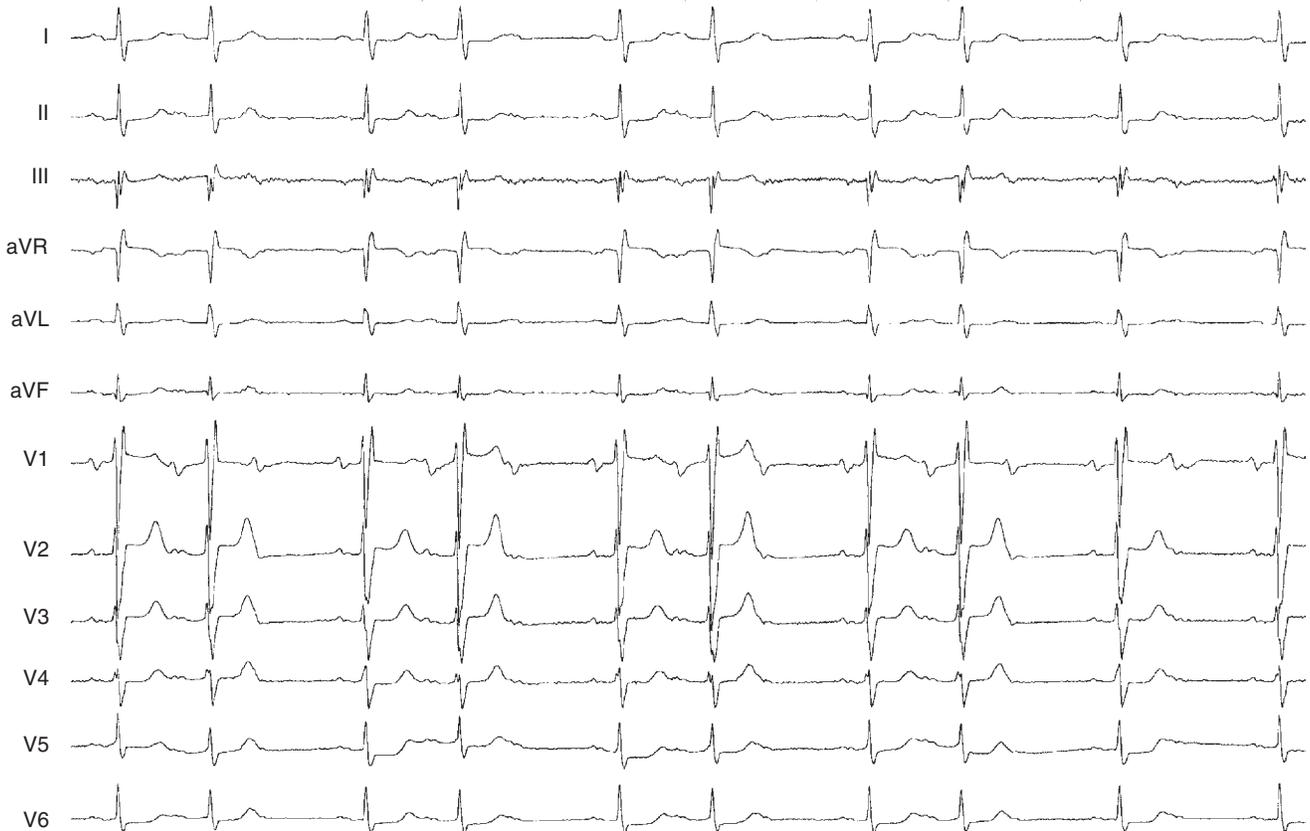

FIGURE 9-7 Typical Wenckebach periodicity. Normal sinus rhythm with type 1 second-degree atrioventricular (AV) block is characterized by progressive prolongation of the PR intervals preceding the nonconducted P wave and group beating. Despite the presence of His-Purkinje system disease (as indicated by incomplete right bundle branch block), Wenckebach AV block is more common in the atrioventricular node. At right, the last four P waves encountered 2:1 AV block.

Site of Block

The degree of PR interval prolongation and QRS duration can help predict the site of block. A normal QRS duration usually suggests AVN involvement, whereas the presence of BBB suggests (but does not prove) HPS involvement. Furthermore, short baseline PR interval and small PR interval increments preceding the block suggest HPS involvement.^{30,32}

ATRIOVENTRICULAR NODE. Wenckebach block is almost always within the AVN (and rarely intra-Hisian) when a narrow QRS complex is present.

HIS-PURKINJE SYSTEM. When type 1 block is seen with the presence of BBB, the block is still more likely to be in the AVN (Fig. 9-7), but it can also be localized within or below the HPS (Fig. 9-8). In this setting, a very long PR interval is more consistent with AVN block.^{30,32}

TYPE 2 SECOND-DEGREE ATRIOVENTRICULAR BLOCK

Type 2 second-degree (Mobitz type II) AV block is characterized on the surface ECG by a constant (normal or prolonged) PR interval of *all* conducted P waves, followed by sudden failure of a P wave to be conducted to the ventricles (Fig. 9-9). RP-PR reciprocity, the hallmark of type 1 block, is absent in type 2 block. Consequently,

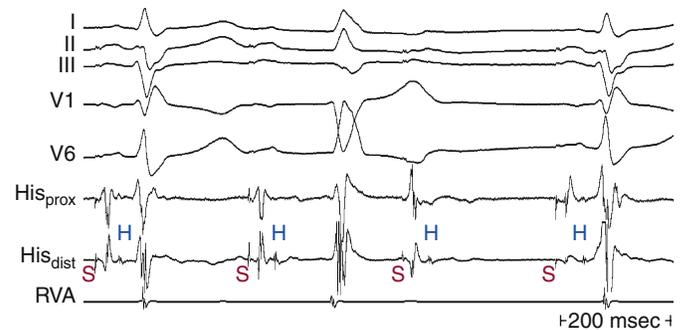

FIGURE 9-8 Infra-Hisian second-degree Wenckebach atrioventricular (AV) block. Atrial pacing in a patient with a normal prolonged atrial–His bundle (AH) interval but prolonged His bundle–ventricular (HV) interval and right bundle branch block (RBBB). On the second complex, the HV is dramatically prolonged and left bundle branch block is present, suggesting very slow conduction over the right bundle branch. With the third paced complex, AV block occurs below the His bundle recording, and on the fourth complex, conduction with RBBB resumes, suggesting a Wenckebach cycle in the His-Purkinje system. His_{dist} = distal His bundle; His_{prox} = proximal His bundle; RVA = right ventricular apex.

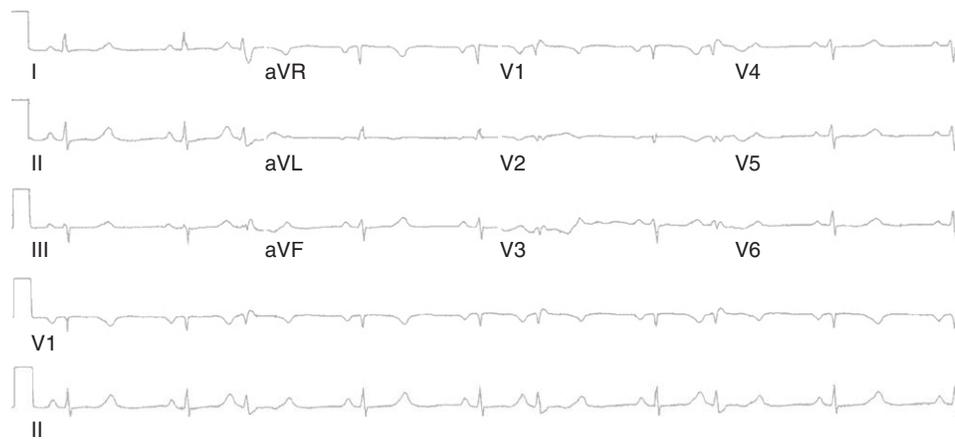

FIGURE 9-9 Second-degree atrioventricular block. Despite the presence of narrow QRS complexes, the site of block is likely intra-Hisian, as suggested by the short PR intervals on conducted beats and no increment in the PR intervals on 3:2 cycles. The P waves frequently are partially concealed within the preceding T waves (especially in view of the presence of long QT intervals) and are more obvious in lead V₃. Note slight QRS aberrancy resulting from the long-short RR intervals.

FIGURE 9-10 Manifest and concealed His bundle (junctional) extrasystoles. The lead II rhythm strip shows sinus rhythm with normal atrioventricular conduction, but the second complex (black arrow) is a normal QRS not preceded by a P wave (thus His extrasystole) with retrograde conduction (inverted P wave following QRS). The white arrow shows a nonconducted P wave that would ordinarily indicate Mobitz II block, but in this patient with known His extrasystoles, the P wave more likely fails to conduct because of concealed conduction into the atrioventricular node following a concealed His extrasystole (no resultant QRS or retrograde P wave). Note that the nonconducted P wave has a slightly different contour, perhaps as a result of fusion between the sinus P wave and retrograde atrial capture from the concealed His extrasystole.

the PR interval following a long RP interval (immediately following the pause) is identical to that following a short RP interval (immediately preceding the pause). Type 2 block cannot be diagnosed if the first P wave after a blocked beat is absent or if the PR interval following the pause is shorter than all the other PR intervals of the conducted P waves, regardless of the number of constant PR intervals before the block (see Fig. 9-6). The P-P intervals remain constant, and the pause encompassing the nonconducted P wave equals twice the P-P interval.

A true Mobitz type II AV block in conjunction with a narrow QRS complex is relatively rare and occurs without sinus slowing and without the characteristic Wenckebach sequences. Atypical forms of Wenckebach block with only minimal PR interval variation should be excluded (see Fig. 9-6). Apparent type 2 second-degree AV block can be observed under the influence of increased vagal tone during sleep, in which case Wenckebach block without discernible or measurable increments in the PR intervals is the actual diagnosis; sinus slowing with AV block essentially excludes Mobitz type II block.³⁰ When an apparent Mobitz type II-like pattern with a narrow QRS complex occurs with intermittent Wenckebach AV block sequences (as in Holter recordings), a true Mobitz type II block can be safely excluded because narrow QRS type 1 and type 2 second-degree AV blocks almost never coexist within the HB. Sustained advanced second-degree AV block is far more common in association with true Mobitz type II block than with Wenckebach block or its variant.

Apparent Mobitz type II AV block can also be caused by concealed junctional extrasystoles (confined to the specialized conduction system and not propagated to the myocardium) and junctional parasystole (Fig. 9-10). Exercise-induced second-degree AV block is most commonly infranodal and rarely is secondary to AVN disease or cardiac ischemia.

Site of Block

HIS-PURKINJE SYSTEM. Type 2 second-degree AV block is almost always below the AVN, occurring in the HB in approximately

30% of cases and in the bundle branches in the remainder. Infrequently, type 2 second-degree AV block is found with a narrow QRS complex and is caused by intra-Hisian block (Fig. 9-9; see Fig. 9-9).

ATRIOVENTRICULAR NODE. Type 2 second-degree AV block has not yet been convincingly demonstrated in the body of the AVN or the N zone. Although multiple reports have described the occurrence of type 2 second-degree AV block in the AVN, in each case either the block could have been localized to the HPS, rather than the AVN, or the block probably was atypical Wenckebach block.

2:1 ATRIOVENTRICULAR BLOCK

When only alternate beats are conducted, resulting in a 2:1 ratio, the PR interval is constant for the conducted beats, provided that the atrial rhythm is regular (Fig. 9-12). A 2:1 AV block cannot be classified as type 1 or type 2; using the term *type 1* to describe 2:1 AV block when the lesion is in the AVN or when there is evidence of decremental conduction and using the term *type 2* to describe 2:1 AV block when it is infranodal or when there is evidence of all-or-none conduction should be discouraged because this practice violates the well-accepted traditional definitions of types 1 and 2 block based on ECG patterns, not on the anatomical site of block. Both types 1 and 2 block can progress to a 2:1 AV block, and a 2:1 AV block can regress to type 1 or 2 block.

Site of Block

Fixed 2:1 AV block poses a diagnostic dilemma because it can be difficult to localize the site of block by the surface ECG alone. Several ECG features can help in the differential diagnosis:

1. 2:1 AV block associated with a narrow QRS complex is likely to be infranodal, whereas that associated with a wide QRS complex is likely to be infranodal, but it could still be at the level of the AVN (Fig. 9-13; see Fig. 9-12).

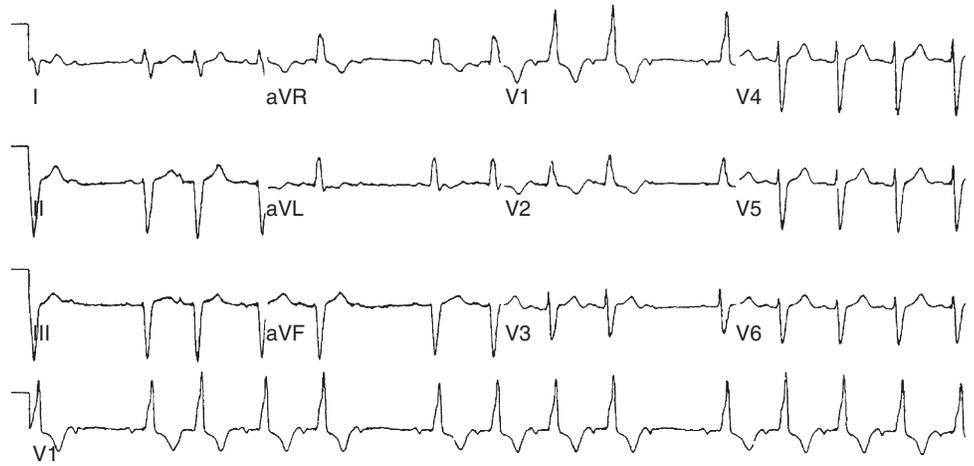

FIGURE 9-11 Second-degree infranodal atrioventricular block. Bifascicular block (right bundle branch block and left anterior fascicular block) and normal, constant PR intervals (196 milliseconds) are observed during conducted beats, consistent with infranodal block.

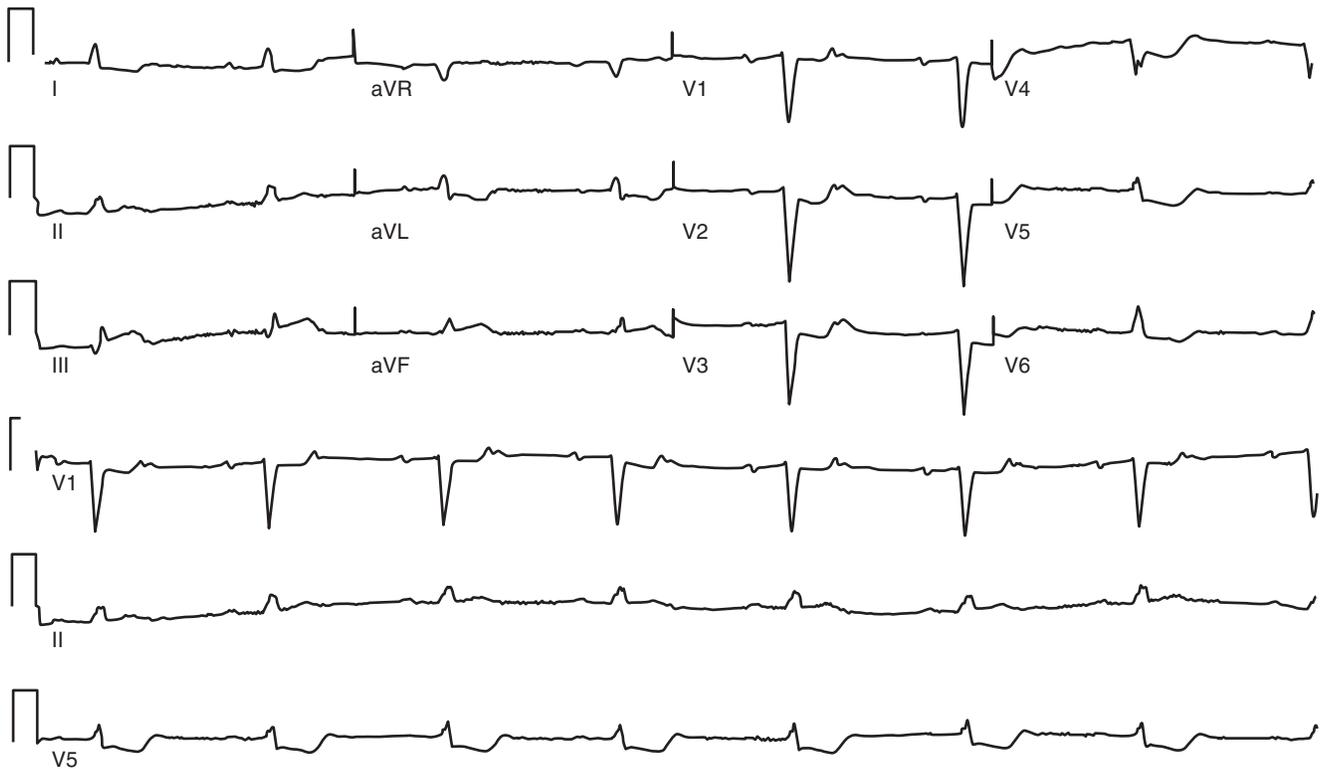

FIGURE 9-12 Second-degree 2:1 atrioventricular block. Note the long PR interval during conducted complexes and the narrow QRS complexes, suggesting intranodal block. The acute current of injury in the inferior leads is consistent with an acute inferior wall myocardial infarction and an intranodal site of AV conduction block.

- Fixed 2:1 AV block with PR intervals shorter than 160 milliseconds suggests intra-Hisian or infra-Hisian block, whereas very long PR intervals (more than 300 milliseconds) suggest AVN block.
- If the PR interval of all the conducted complexes is constant despite a varying RP interval, infranodal block is likely.
- The presence of Wenckebach block before or after episodes of 2:1 AV block is highly suggestive of block at the AVN level (see Fig. 9-7).
- Improvement of block with atropine or exercise suggests AVN block; however, the absence of such response does not exclude intranodal block.³⁰

HIGH-GRADE ATRIOVENTRICULAR BLOCK

Failure of conduction of two or more consecutive P waves when AV synchrony is otherwise maintained is sometimes termed *high-grade AV block* or *advanced second-degree AV block* (Fig. 9-14).¹⁷

This block must happen because of the existing block itself, and not because of retrograde concealment in the AVN or HPS resulting from junctional or ventricular escape complexes that prevent conduction.

Site of Block

The level of block can be at the AVN or the HPS. When high-degree AV block is caused by block in the AVN, QRS complexes of the conducted beats are usually narrow. Wenckebach periodicity can also be seen, and atropine administration produces lesser degrees of AV block. Features suggesting block in the HPS are conducted beats with BBB and no improvement in block with atropine.

Third-Degree (Complete) Atrioventricular Block

AV block is termed *complete* when all P waves fail to conduct, despite having ample opportunity for conduction. Therefore, if there is less than optimal opportunity for the AVN-HPS to conduct, it

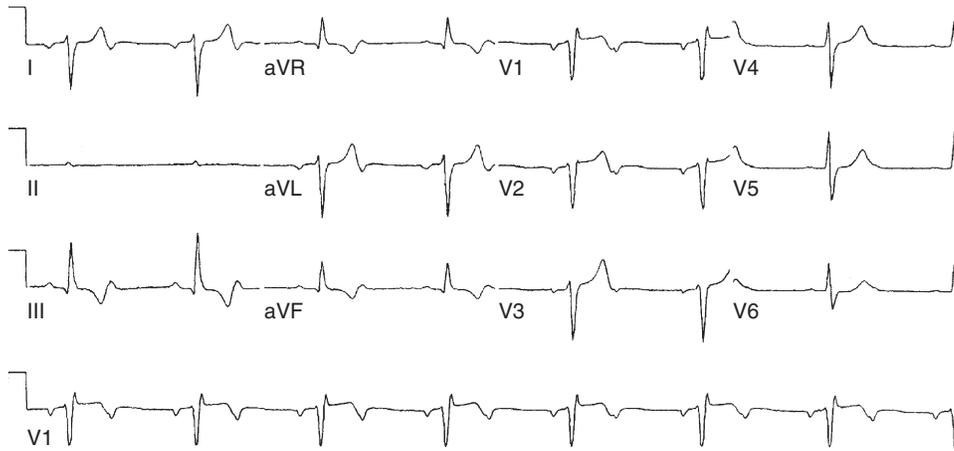

FIGURE 9-13 Second-degree 2:1 atrioventricular block. Note the short PR interval during conducted complexes and the wide QRS complexes, suggesting block in the His-Purkinje system.

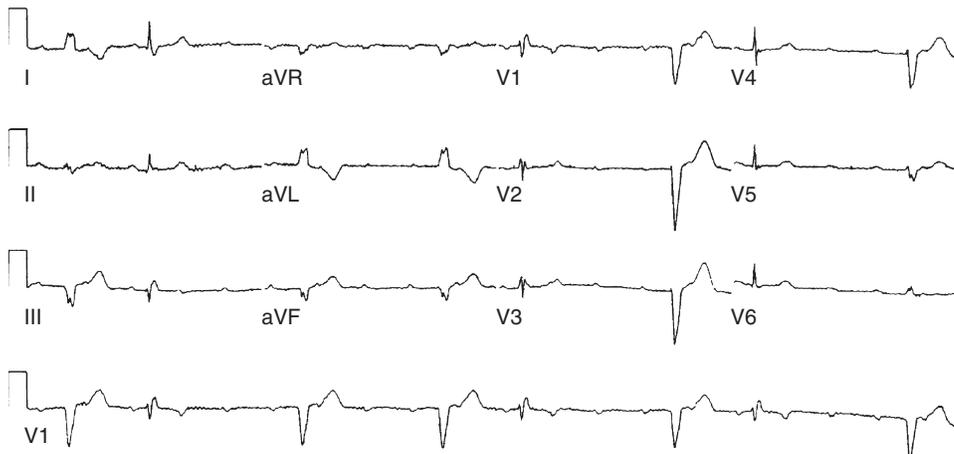

FIGURE 9-14 High-grade atrioventricular block. Note that only three P waves conducted to the ventricle in the whole tracing. Conducted P waves were associated with normal PR intervals and right bundle branch block, a finding suggesting infranodal block. All other P waves were blocked, and ventricular escape rhythm with a left bundle branch block pattern is observed. Note that the block is not caused by retrograde concealment in the atrioventricular node or His-Purkinje system from the ventricular escape complexes because the conducted P waves occurred at a short cycle following the escape complexes.

FIGURE 9-15 Congenital third-degree atrioventricular (AV) block. Sinus rhythm with complete AV block and junctional escape rhythm with a narrow QRS are seen, consistent with intranodal block.

cannot be regarded as a failure if it does not conduct. Third-degree AV block is seen on the surface ECG as completely dissociated P waves and QRS complexes, each firing at its own pacemaker rate, with a continuously changing P-R relationship as the P waves march through all phases of the ventricular cycle in the presence of a regular ventricular rhythm (Fig. 9-15). Every possible chance for conduction is afforded, with the P waves occurring at every conceivable RP interval, but the atrial impulse is never conducted to the ventricles. The atrial rate is always faster than the ventricular rate (Fig. 9-16).^{30,32}

SITE OF BLOCK

ATRIOVENTRICULAR NODE. Most cases of congenital third-degree AV block are localized to the AVN (see Fig. 9-15), as is

transient AV block associated with acute inferior wall MI, beta blockers, calcium channel blockers, and digitalis toxicity. Complete AVN block is characterized by a junctional escape rhythm with a narrow QRS complex and a rate of 40 to 60 beats/min, which tends to increase with exercise or atropine. However, in 20% to 50% of patients with chronic AV block, a wide QRS escape rhythm may occur. Rhythms originating in the distal HB may have a wide QRS. Those rhythms are usually slower and nonresponsive to atropine.³⁰

HIS-PURKINJE SYSTEM. Acquired complete heart block is usually associated with block in the HPS that results in an escape rhythm with a wide QRS complex with a rate of 20 to 40 beats/min (Fig. 9-17).

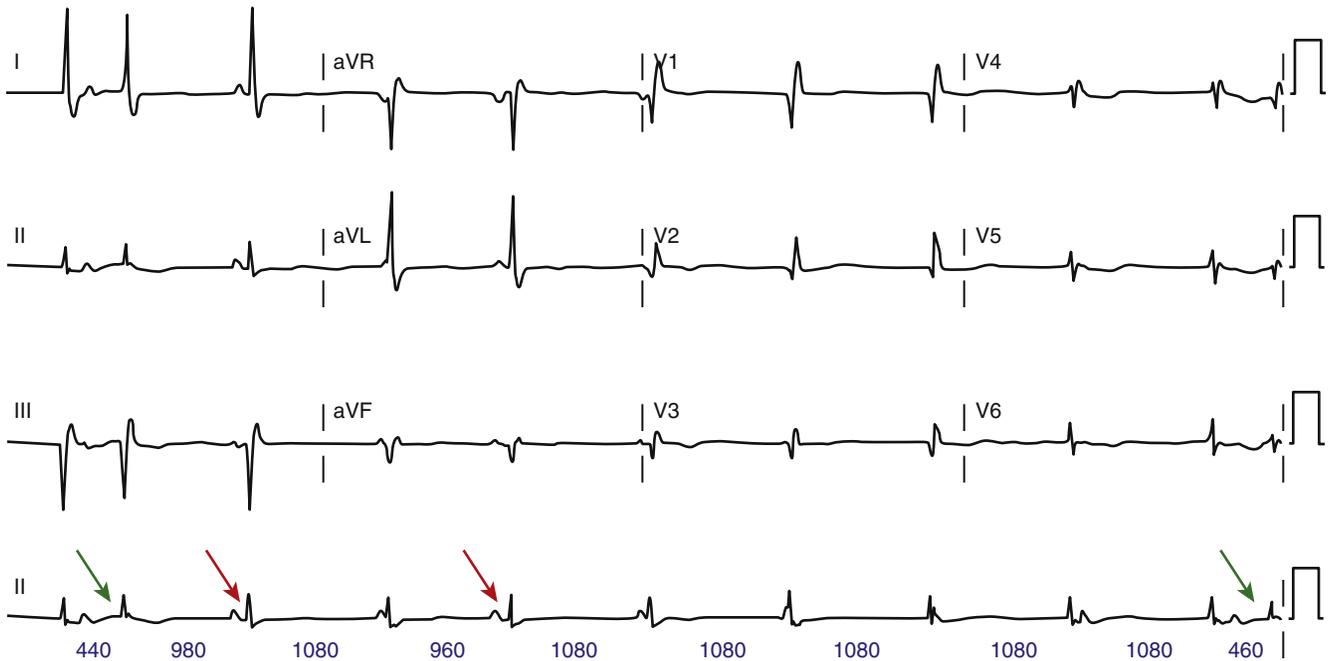

FIGURE 9-16 Surface ECG of sinus bradycardia at a cycle length (CL) of 1180 milliseconds and junctional escape rhythm at a shorter CL (1080 milliseconds). Junctional impulses fail to conduct retrogradely to the atrium, thus setting the stage for atrioventricular (AV) dissociation, which is observed during most of the recording. Note that no pathological AV block is present; failure of AV conduction of several sinus impulses occurred secondary to the physiological refractoriness of the atrioventricular node (AVN) and His bundle (HB) caused by retrograde concealment by the escape junctional impulses. However, whenever sinus P waves occurred at appropriate timings, they did conduct to the ventricle (red and green arrows) and elicited QRS complexes at CLs shorter than the expected junctional rhythm CL. Note that retrograde concealment of the junctional impulses occurred in the AVN and not just the HB, evident by the prolonged PR intervals of conducted sinus P waves when they closely follow the preceding QRS complex (green arrows). Numbers denote R-R intervals in milliseconds.

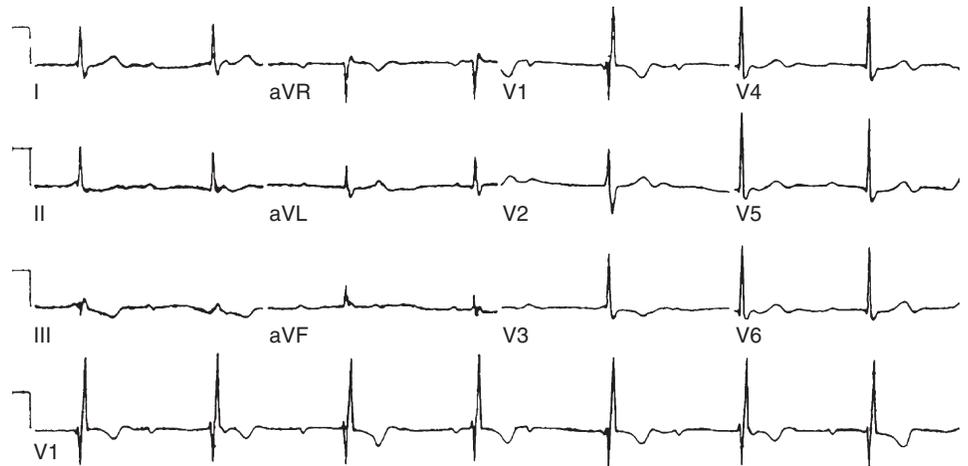

FIGURE 9-17 Complete infranodal atrioventricular (AV) block. Complete AV dissociation is observed, and all the P waves fail to conduct despite having ample opportunity for conduction. Note the slow ventricular escape rhythm with a wide QRS complex and a rate of 40 beats/min, consistent with block in the His-Purkinje system.

Paroxysmal Atrioventricular Block

CLINICAL PRESENTATION

Paroxysmal AV block is characterized by abrupt and sustained AV block in the absence of structural heart disease.³² The block usually starts following a conducted or nonconducted premature atrial complex (PAC) or premature ventricular complex (PVC), and it persists until another PAC or PVC terminates it (Fig. 9-18). Episodes of AV block are commonly associated with prolonged periods of ventricular asystole (of unpredictable duration) precipitating presyncope or syncope or even sudden death. The natural history of paroxysmal AV block is unknown, and it is unclear whether paroxysmal AV block is reversible.³³

MECHANISM

Paroxysmal AV block is a unique disorder of the HPS and is believed to be caused by local phase 4 block in the HB or in the bundle

branches after a critical change in the H-H interval (see Chap. 10). During a long pause (prolonged diastolic period), the fibers of the often-diseased HPS spontaneously depolarize (membrane potential becomes less negative) and become less responsive to subsequent impulses as a result of Na⁺ channel inactivation. Once such critical diastolic membrane potential is reached, conduction may no longer resume without an appropriately timed escape beat or premature beat (sinus or ectopic) that can reset the transmembrane potential to its maximal resting value. Nonetheless, this explanation is controversial because experimental data indicate that partial membrane depolarization can actually *improve* conduction, given that the voltage is closer to threshold. Prolongation of the H-H interval can result from spontaneous sinus rate slowing or post-extrasystolic pauses following atrial, ventricular, or His extrasystoles or tachycardia.³³

DIAGNOSTIC EVALUATION

No specific or optimal tests exist to diagnose paroxysmal AV block. Patients with paroxysmal AV block may not have structural heart

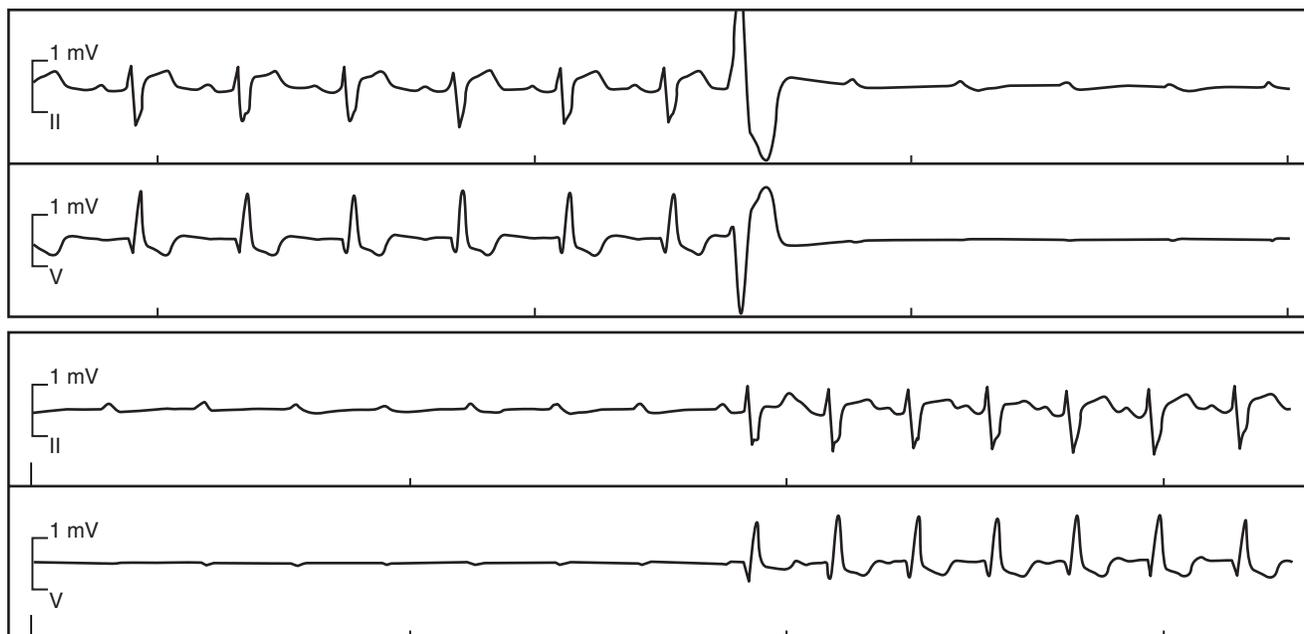

FIGURE 9-18 Paroxysmal atrioventricular block. Shown are two-channel rhythm strips during sinus rhythm with prolonged but stable PR interval and right bundle branch block. A premature ventricular complex (middle, top panel) occurs and is followed by a string of nonconducted P waves for almost 10 seconds until conduction resumes (at a faster sinus rate and with slightly shorter PR intervals, likely because of sympathetic discharge during the asystole).

disease at baseline, and conduction abnormalities may not be evident on resting ECGs. Although no established predictors for paroxysmal AV block exist, evidence of distal conduction disease at baseline is often present, with RBBB the most common finding. A positive response to carotid sinus massage for paroxysmal AV block includes P-P lengthening without changes in preceding PR intervals before heart block (in contrast to a vagally mediated AV block, for which the PR interval lengthens before the block). Additional workup for arrhythmogenic causes including long-term ambulatory monitoring or an implantable loop recorder can also be of value.^{33,34}

The role of EP testing remains uncertain because there is no predictable marker for identifying patients at risk for paroxysmal AV block. EP testing is recommended when suspicion for arrhythmic syncope remains high despite a negative noninvasive workup. Pharmacological provocation (using ajmaline or procainamide) of infranodal block or HV lengthening (via stressing the HPS) was reported to be a potentially useful tool in diagnosing infra-Hisian AV block. However, a positive ajmaline or procainamide response simply suggests infranodal conduction disorder and is not specific for identifying patients at risk of developing paroxysmal AV block over other types of acquired AV block. Paroxysmal AV block may also be reproduced in an EP laboratory via critically timed atrial or ventricular extrastimulus and during rapid ventricular pacing. However, a negative EP study result does not exclude the diagnosis of paroxysmal AV block; at least 10% of patients with baseline BBB and syncope developed paroxysmal AV block during a 3-year follow-up despite a negative EP study result. Furthermore, a normal HV interval cannot rule out a risk for paroxysmal AV block. EP testing is therefore a specific test with low sensitivity, and it should be used in conjunction with supplementary clinical data obtained from personal history and ambulatory and implantable loop recordings.³³

PAROXYSMAL VERSUS VAGAL ATRIOVENTRICULAR BLOCK

Distinction between paroxysmal AV block and the often benign and reversible vagal AV block (whereby an abrupt complete AV block can be precipitated by heightened vagal tone) has important prognostic and therapeutic implications. Unlike vagal AV block,

paroxysmal AV block is often initiated by a PAC or PVC or by tachycardia, with sinus acceleration occurring during ventricular asystole without affecting the block (see Fig. 9-18). In contrast, a classic vagal effect on the conduction system includes gradual slowing of the sinus rate and AV conduction (first-degree or Wenckebach block), occasionally followed by sinus arrest or complete AV block (although a more prominent AV response with sudden block can also occur with heightened vagal tone). Subsequently, the sinus rate continues to slow down during ventricular asystole, followed by gradual resumption of AV conduction and sinus acceleration. Additionally, the clinical history, such as during micturition and phlebotomy, among others, can be highly suggestive of heightened vagal tone.^{33,34}

Electrophysiological Testing

Role of Electrophysiological Testing

ECG diagnosis of AV block is usually adequate for deciding subsequent treatment. Once symptoms and AV block are correlated with ECG findings, further documentation by invasive studies is not required unless additional information is needed. Similarly, asymptomatic patients with transient Wenckebach block associated with increased vagal tone should not undergo EP testing.

Nevertheless, EP testing can help diagnose an equivocal ECG pattern or delineate the site of conduction abnormality, if that is required for decision making. EP testing is indicated in a patient with suspected high-grade AV block as the cause of syncope or presyncope when documentation cannot be obtained noninvasively. Similarly, in patients with coronary artery disease, it can be unclear whether symptoms are secondary to AV block or VT; therefore, EP testing can be useful in establishing the diagnosis. Some patients with known second- or third-degree block can benefit from an invasive study to localize the site of AV block to help determine therapy or assess prognosis.^{30,32}

Normal Atrioventricular Conduction

The normal PR interval is 120 to 200 milliseconds. This interval reflects the conduction time from the high RA to the point of ventricular activation (i.e., QRS onset), and it includes activation of the

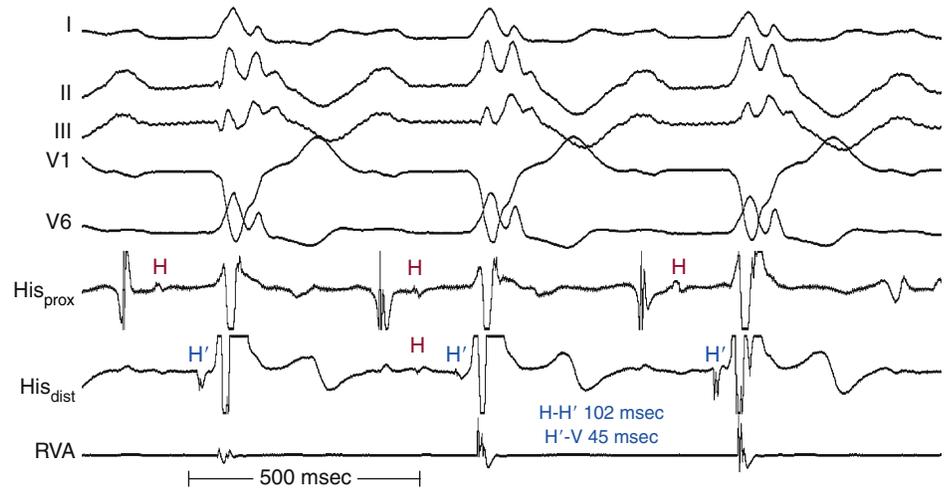

FIGURE 9-19 Split His potentials in a patient with cardiomyopathy and left bundle branch block. Recording only the distal His signal (H') would give the false impression of normal infranodal conduction ($HV = 42$ milliseconds). His_{dist} = distal His bundle; His_{prox} = proximal His bundle; RVA = right ventricular apex.

atrium, AVN, HB, bundle branches and fascicles, and terminal Purkinje fibers. To measure the different components of the conduction system contained in the PR interval, intracardiac tracings from the high RA and HB region are required (see Fig. 4-19).

The PA interval, measured from the high RA electrogram to the low RA deflection in the HB recording, gives an indirect approximation of the intraatrial conduction time. The normal PA interval is 20 to 60 milliseconds.

The atrial-HB (AH) interval is measured from the first rapid deflection of the atrial deflection in the HB recording to the first evidence of HB depolarization in the HB recording. The AH interval is an approximation of AVN conduction time because it represents conduction time from the low RA at the interatrial septum through the AVN to the HB. The AH interval has a wide range in normal subjects (50 to 120 milliseconds) and is markedly influenced by the autonomic tone.

His potential duration reflects conduction through the short length of the HB that penetrates the fibrous septum. Disturbances of the HB conduction can manifest as fractionation, prolongation (more than 30 milliseconds), or splitting of the His potential.

The HB-ventricular (HV) interval is measured from the onset of the His potential to the onset of the earliest registered surface or intracardiac ventricular activation, and it represents conduction time from the proximal HB through the distal HPS to the ventricular myocardium. The most proximal electrodes displaying the His potential should be chosen, and a large atrial electrogram should accompany the proximal His potential. The HV interval is not significantly affected by the autonomic tone, and it usually remains stable. The range of HV intervals in normal subjects is narrow, 35 to 55 milliseconds.

Localization of the Site of Atrioventricular Block

EP testing allows analysis of the HB electrogram, as well as providing atrial and ventricular pacing to uncover conduction abnormalities. A markedly prolonged HV interval (100 milliseconds or longer) is associated with a high incidence of progression to complete heart block. In addition, a His potential 30 milliseconds or longer in duration or that is frankly split into two deflections is indicative of intra-Hisian conduction delay.

When the His potential is recorded during atrial pacing at progressively shorter cycle lengths (CLs), the AH interval normally gradually lengthens until Wenckebach block develops. The HV interval normally remains constant despite different pacing rates. Abnormal AVN conduction produces Wenckebach block at slower atrial pacing rates than what is normally seen (i.e., at a pacing CL longer than 500 milliseconds). To determine whether AVN disease is truly present or whether AVN conduction is just under the influence of excessive vagal tone, atropine or isoproterenol

can be administered to evaluate for improvement in conduction. Infranodal block is present when the atrial deflection is followed by the His potential but no ventricular depolarization is seen. Block below the HB is abnormal unless it is associated with short pacing CLs (350 milliseconds or less). Block in the HB can be masked by prolonged AVN conduction time or refractoriness. When block in the AVN develops at slow pacing rate, atropine can be administered to improve AVN conduction and allow evaluation of the HPS at faster pacing rates.

SITE OF FIRST-DEGREE ATRIOVENTRICULAR BLOCK

ATRIOVENTRICULAR NODE. An AH interval longer than 130 milliseconds with a normal HV interval indicates intranodal conduction delay (see Fig. 9-1). Dual AVN physiology can produce transient, abrupt, or alternating first-degree block caused by block in the fast AVN pathway and conduction down the slow pathway. The change in the PR interval seen on the surface ECG corresponds to a jump in the AH interval viewed on the HB electrogram.³⁰

HIS-PURKINJE SYSTEM. As long as at least one fascicle conducts normally, the HV interval should not exceed 55 milliseconds (or 60 milliseconds in the presence of LBBB). A prolonged HV interval (more than 55 to 60 milliseconds) with or without prolonged His potential duration (more than 30 milliseconds) or a split His potential is diagnostic for HPS disease, even in the presence of a normal PR interval (Fig. 9-19; see Fig. 9-2). A prolonged HV interval is almost always associated with an abnormal QRS because the impairment of intra-Hisian conduction is not homogeneous. Most patients have an HV interval of 60 to 100 milliseconds, and occasionally more than 100 milliseconds. With pure intra-Hisian conduction delay, the atrial-to-proximal His (AH) interval and the distal His-to-ventricular ($H'-V$) interval are normal, whereas the duration of the His potential is longer than 30 milliseconds, with a notched, fragmented, or split His potential. In this case, verification of the origin of the "split H" from the HB (and not part of the atrial or ventricular electrograms) is critical. This can be achieved by dissociation of the His potential from atrial activation with atrial pacing, adenosine, or vagal stimulation and dissociation of the His potential from ventricular activation by documenting that the HV interval is longer than 30 milliseconds.³⁰

ATRIUM. A prolonged PA interval with normal AH and HV intervals indicates intraatrial conduction delay (see Fig. 9-3).

SITE OF TYPE 1 SECOND-DEGREE ATRIOVENTRICULAR BLOCK

ATRIOVENTRICULAR NODE. Wenckebach block in the AVN is characterized by progressive prolongation of the AH interval, until an atrial deflection is not followed by His and ventricular deflections (see Figs. 9-5 and 9-6).

HIS BUNDLE. A prolonged His potential duration or a split His potential is indicative of intra-Hisian disease. Intra-Hisian Wenckebach block can occur between the two His deflections, characterized by progressive conduction delay until the first His deflection is not followed by the second one.

BUNDLE BRANCHES. In Wenckebach AV block secondary to block below the HB, progressive prolongation of the HV interval is followed by a His deflection without an associated ventricular activation (see Fig. 9-8).

SITE OF TYPE 2 SECOND-DEGREE ATRIOVENTRICULAR BLOCK (MOBITZ TYPE II BLOCK)

HIS-PURKINJE SYSTEM. The blocked cycle features atrial and HB deflections without ventricular depolarization (Fig. 9-20). The conducted beats usually show evidence of infranodal conduction system disease, with a prolonged HV interval, or even a split His potential, and BBB. Multilevel AV block (intranodal and infranodal) can also occur, especially during rapid atrial tachycardias or atrial pacing. Typically, infranodal AV block occurs in the presence of prolonged HPS refractoriness caused by antiarrhythmic agents or during Wenckebach cycles in the AVN (Fig. 9-21).

SITE OF THIRD-DEGREE (COMPLETE) ATRIOVENTRICULAR BLOCK

ATRIOVENTRICULAR NODE. Complete heart block at the AVN level is usually seen on the intracardiac tracings as His potentials consistently preceding each ventricular electrogram. The atrial electrograms are dissociated from the HV complexes (Fig. 9-22). Most often, the escape rhythm originates in the HB (with normal QRS preceded by a His potential and normal HV interval); however, in 20% to 50% of patients with chronic AV block, a wide QRS escape rhythm can occur. Rhythms originating in the distal HB can have a QRS preceded by a retrograde His potential or no His potential at all. Those rhythms are usually slower and nonresponsive to atropine. The stability of the HB rhythm can be assessed by noting the effects of overdrive suppression produced by ventricular pacing (in a manner analogous to testing sinus node function); prolonged pauses (i.e., the lack of HB escapes) herald failure of the escape rhythm.³⁰

HIS-PURKINJE SYSTEM. The intracardiac electrogram shows HB deflections consistently following atrial electrograms, but ventricular depolarizations are completely dissociated from the AH complexes. Block below the HB is thus demonstrated.^{17,32}

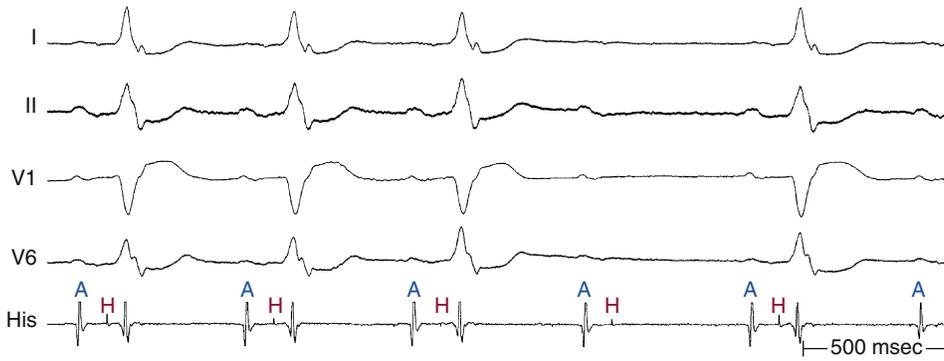

FIGURE 9-20 Type 2 second-degree (Mobitz type II) atrioventricular (AV) block. Sinus rhythm is observed with a wide QRS complex. The PR interval of all conducted P waves is constant and slightly prolonged (224 milliseconds). The fourth P wave fails to conduct to the ventricle but is followed by a His potential, suggesting that the level of AV block is infra-Hisian.

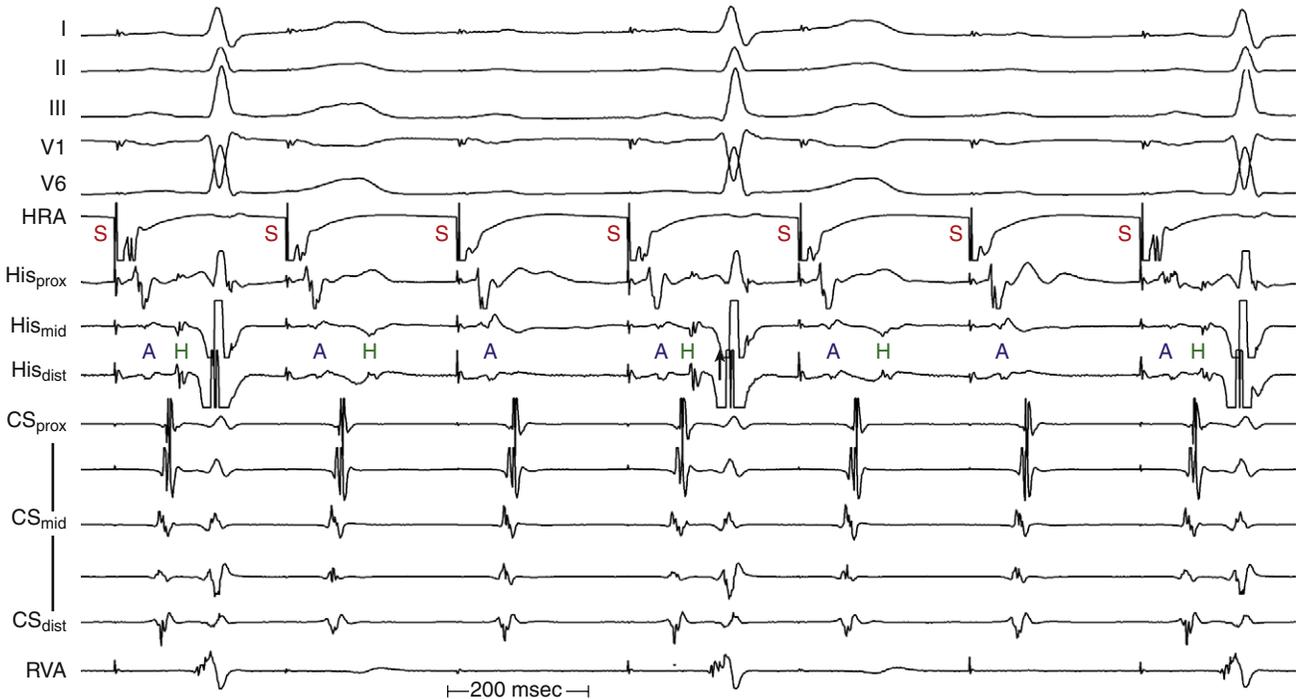

FIGURE 9-21 Multiple levels of atrioventricular block. Rapid atrial pacing (at a cycle length of 330 milliseconds) from the high right atrium (HRA) shows repeating pattern of atrial impulses with normal atrio-His (AH) intervals conducted to the ventricle, atrial impulses associated with AH interval prolongation with block below the His bundle, and atrial impulses associated with atrioventricular nodal block (no His potential). CS_{dist} = distal coronary sinus; CS_{mid} = middle coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle; RVA = right ventricular apex.

Exclusion of Other Phenomena

NONCONDUCTED PREMATURE ATRIAL COMPLEXES

Early PACs can arrive at the AVN during the absolute refractory period and fail to conduct to the ventricle. This condition can be misdiagnosed as type 1 or type 2 second-degree AV block. Similarly, atrial bigeminy, with failure of conduction of the PACs, can be misinterpreted as 2:1 AV block (Fig. 9-23). In type 2 second-degree AV block, the atrial rhythm is regular, the P-P interval is constant, the nonconducted P wave occurs on time as expected, and P wave morphology is constant. On the other hand, in the setting of nonconducted PACs, the P wave occurs prematurely and usually has a different morphology from that of the baseline atrial rhythm. Nonconducted PACs can often be hidden in the preceding T wave (Fig. 9-24). Additionally, the mere occurrence of PACs in a trigeminal or quadrigeminal pattern can produce a periodicity mimicking Wenckebach periodicity (Fig. 9-25).

CONCEALED JUNCTIONAL ECTOPY

Ectopic beats arising from the HB that fail to conduct to both the atria and ventricles, with retrograde concealment in the AVN, slowing or blocking conduction of the following sinus P wave, can manifest as type 2 second-degree AV block. Such a phenomenon can be difficult to differentiate from actual block without EP testing. ECG clues to concealed junctional extrasystoles causing such unexpected events include the following: (1) abrupt, unexplained prolongation of the PR interval; (2) the presence of apparent Mobitz type II block in the presence of a normal QRS; (3) the presence of types 1 and 2 AV block in the same tracing; and (4) the presence of manifest junctional extrasystoles elsewhere in the tracing (see Fig. 9-10).

ATRIOVENTRICULAR DISSOCIATION

The distinction between AV dissociation and complete AV block is important. AV dissociation is present when the atria and ventricles

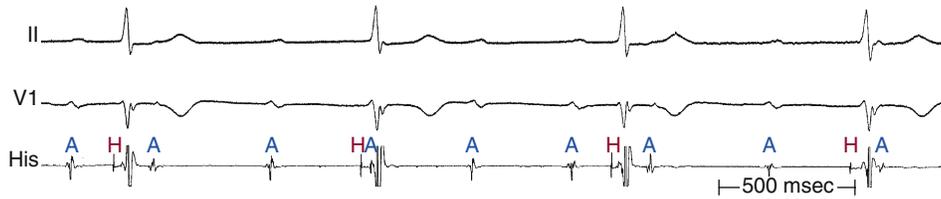

FIGURE 9-22 Complete atrioventricular (AV) block. Complete AV dissociation is observed, and all the P waves fail to conduct despite having ample opportunity for conduction. Note the junctional escape rhythm with a narrow QRS complex and a rate of 45 beats/min, consistent with block in the AVN. Note that the P waves surrounding a QRS complex occur at a faster rate when compared with the P waves that occur sequentially without an intervening QRS complex (ventriculophasic arrhythmia).

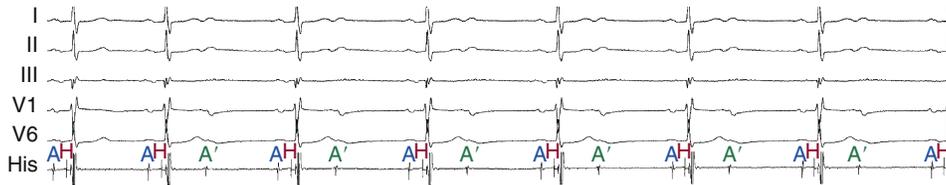

FIGURE 9-23 Sinus rhythm atrial bigeminy mimicking 2:1 atrioventricular block. Frequent premature atrial complexes (PACs; A') are observed in a bigeminal pattern. The PACs arrive at the atrioventricular node during the absolute refractory period and fail to conduct to the ventricle, thus mimicking 2:1 AV block. In contrast to 2:1 AV block, the nonconducted P waves are premature (compare with the first A-A interval, which is not interrupted by a PAC) and have different morphology than the conducted sinus P waves.

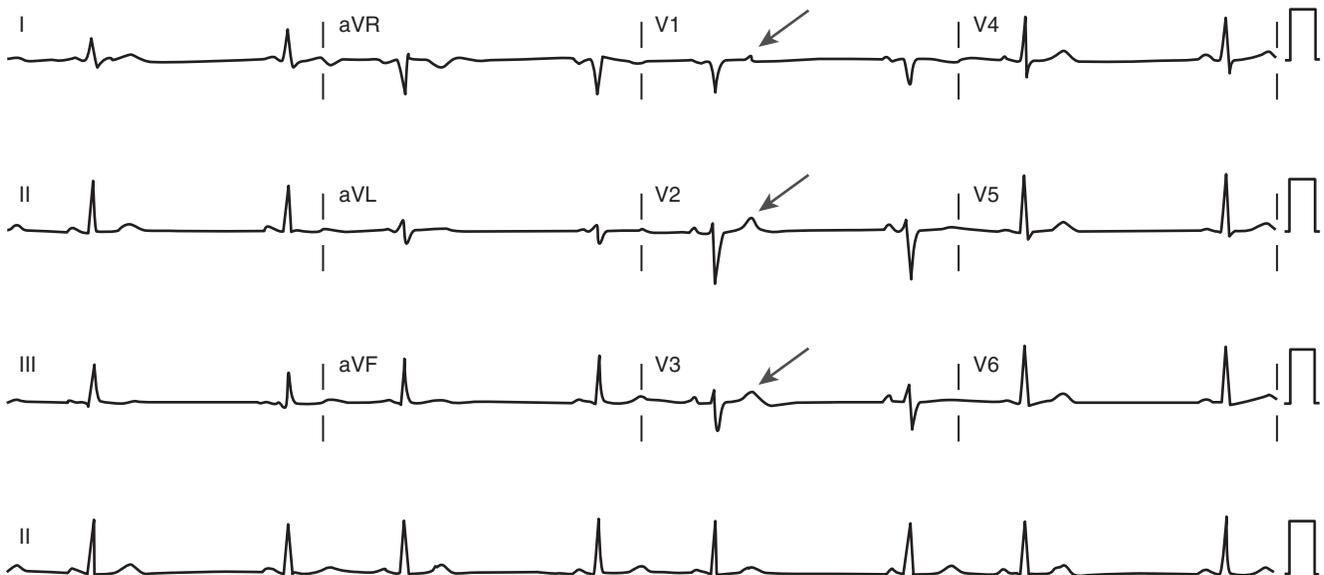

FIGURE 9-24 Sinus rhythm with atrial trigeminy resulting from blocked premature atrial complexes mimicking Mobitz type II atrioventricular block. Note the nonconducted P waves occur early (premature) and lie within the preceding T wave (arrows). All sinus P waves are conducted with a normal, constant PR interval.

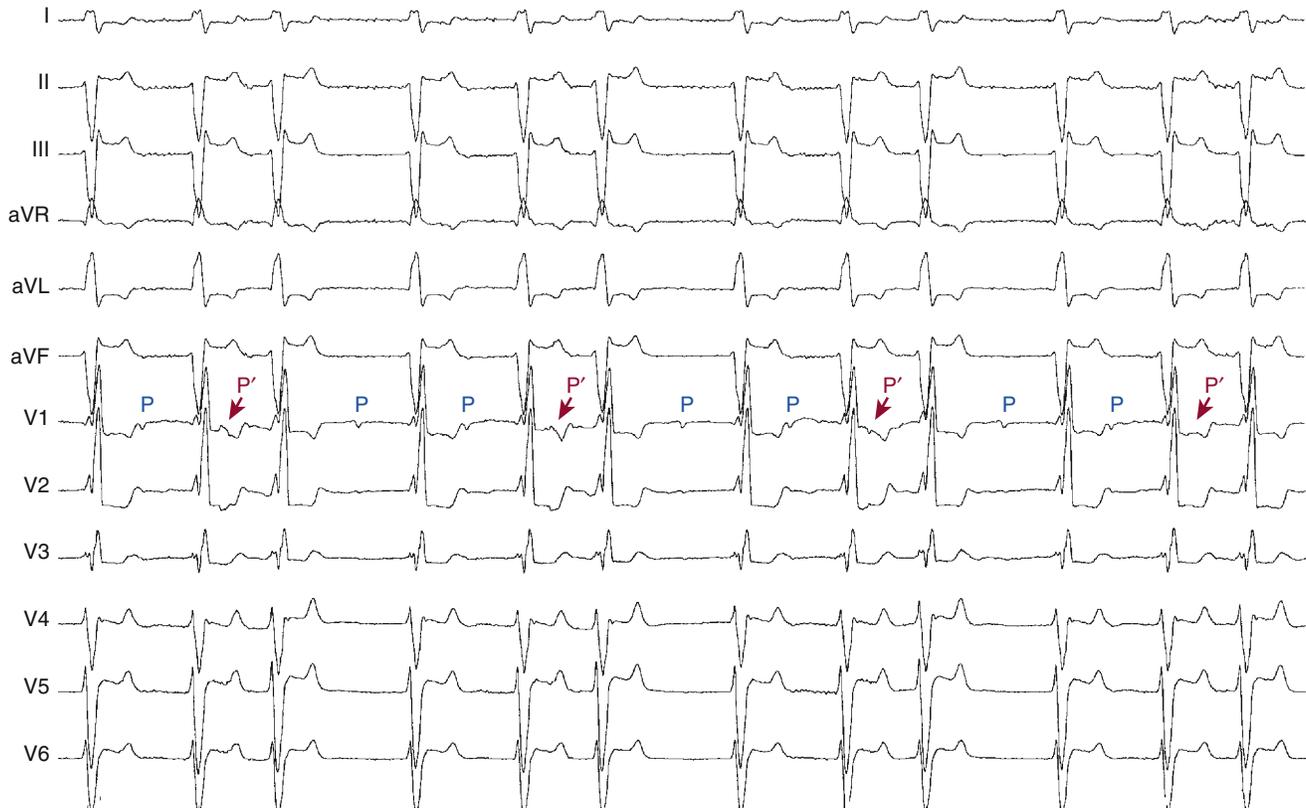

FIGURE 9-25 Sinus rhythm with marked first-degree atrioventricular (AV) block and bifascicular block (right bundle branch block and left anterior fascicular block). Frequent premature atrial complexes (PACs; P') are observed in a trigeminal pattern. The PACs are conducted to the ventricles; however, they produce a periodicity, thus mimicking Wenckebach AV block. Note that no P waves fail to conduct to the ventricle. Despite the presence of marked His-Purkinje system disease, the marked prolongation of the PR intervals (420 milliseconds) suggests the atrioventricular node as the site of AV conduction delay.

depolarize independently of each other. The ventricles are activated by a nonatrial source and are uninfluenced by atrial activity. By definition, there is no retrograde conduction from the ventricles to the atria.¹⁷ AV dissociation can occur secondary to complete AV block, atrial bradycardia with a faster independent junctional-ventricular escape rhythm, or increased discharge rate of a subsidiary pacemaker that takes control of the ventricular rhythm.^{11,35}

In complete AV block, the atrial rate is faster than the ventricular rate. For AV block to be diagnosed, the P waves must fail to conduct, given every opportunity for optimal conduction. Thus, failure of conduction of all the P waves, even those occurring at long RP intervals and throughout the phases of the ventricular cycle, has to be documented. Occasionally, the rate of the junctional or ventricular rhythm during AV dissociation is only slightly different from that of the atrial rhythm. In this case, the standard ECG may not provide a recording opportunity long enough to verify failure of conduction, because all the P waves recorded on a single ECG recording may not occur at an appropriate time to allow conduction. Thus, obtaining ECG recording for an adequate length of time is important (Fig. 9-26). Regularity of both atrial and ventricular rhythms with constantly changing P-R relationships, despite the fact that the P wave falls at every conceivable RP interval, and an independent ventricular rate of 40 beats/min or less (faster in congenital complete AV block) are diagnostic of complete AV block. On the other hand, some irregularity of the ventricular rhythm should immediately draw attention to the possibility of intermittent conduction of P waves, which may reflect lesser degrees of AV block or incomplete AV dissociation. Moreover, with complete AV block, the ventricular rate is almost always slower than the atrial rate, whereas in other forms of AV dissociation, the reverse is true.^{11,35} Therefore, complete AV block with a junctional or ventricular escape rhythm is one form of AV dissociation. However, AV dissociation (complete or incomplete) can occur in the absence of AV block.

In the setting of atrial bradycardia, the atrial rate can become slower than a subsidiary escape focus from the AV junction or ventricle. When the faster junctional or ventricular escape rhythm is associated with VA block, it results in failure of the atrial impulses to conduct anterogradely secondary to retrograde concealment by the escape rhythm impulses (see Fig. 9-16).

An increase in the discharge rate of a subsidiary pacemaker, such as accelerated junctional rhythm, accelerated idioventricular rhythm, or VT, which then exceeds the normal sinus rate, can result in a competing junctional or ventricular rhythm, in which case the atrial rate is always slower than the ventricular rate (see Fig. 9-26).

AV dissociation can be complete or incomplete. In the setting of complete AV dissociation, both the atrial and ventricular rates remain constant and, therefore, the PR interval varies, with none of the atrial complexes conducted to the ventricles. In incomplete AV dissociation, ventricular capture beats occur because some of the atrial impulses arrive at the AV junction when the AV junction is no longer refractory. This phenomenon is common in advanced AV block with periodic capture beats.

ECHO BEATS

AVN echo beats can manifest as “group beating” and be misdiagnosed as Wenckebach block. Verification of constant P-P intervals and P wave morphology during the Wenckebach cycle can avoid such misinterpretation. On the other hand, in the presence of dual AVN physiology, not infrequently Wenckebach AV block can result in AVN echo beats.

ATRIAL TACHYARRHYTHMIAS

Failure of the AVN to conduct during fast atrial tachyarrhythmias (atrial tachycardia or flutter) should not be considered

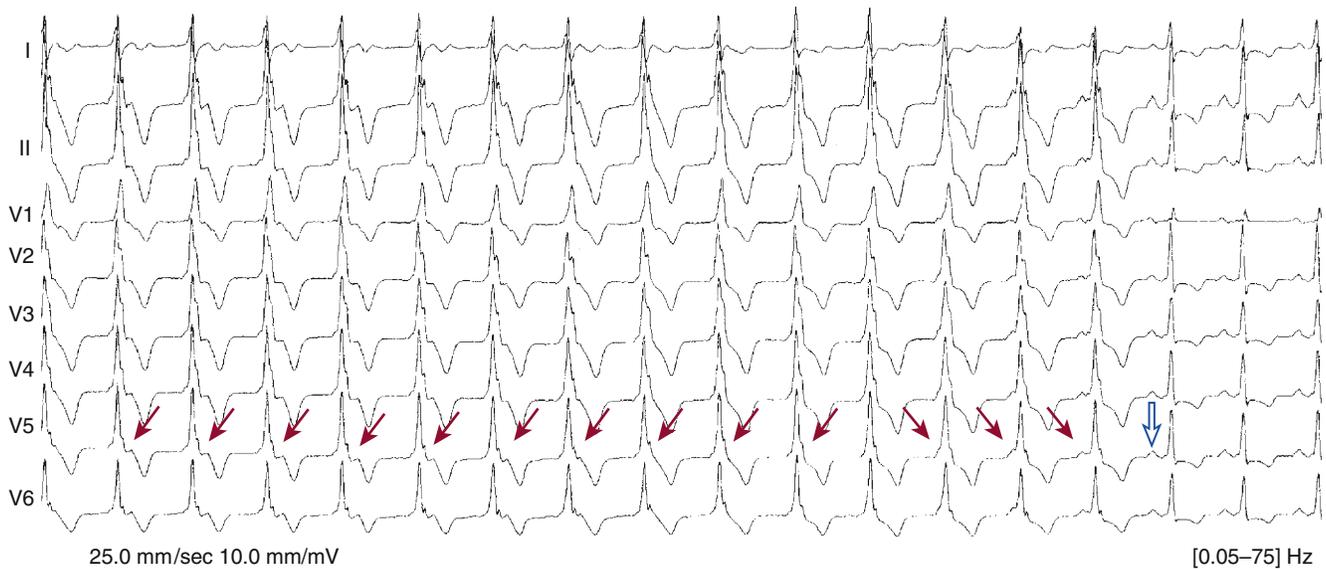

FIGURE 9-26 Atrioventricular (AV) dissociation. Slow ventricular tachycardia and normal sinus rhythm coexist with slightly different rates and ventricular-atrial dissociation. Sinus P waves are marked by red arrows. Note that no AV block is present, and that once the sinus P wave had the chance to conduct, it did (blue arrow).

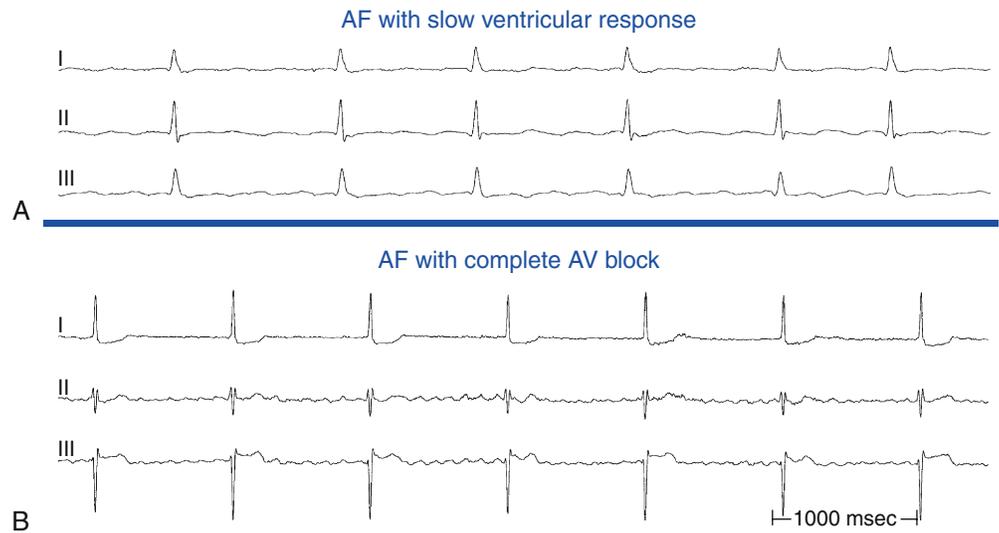

FIGURE 9-27 Atrial fibrillation (AF) with slow ventricular rate. **A**, The ventricular rhythm is irregular, indicating that it is the result of conducted atrial beats. **B**, The ventricular rhythm is regular, consistent with the presence of complete atrioventricular (AV) block and a regular junctional escape rhythm.

pathological AV block. One of the main physiological roles of the AVN is to safeguard the ventricles from rapid atrial rates. Therefore, failure of the AVN to conduct every atrial impulse occurring at a fast rate should be considered a normal physiological finding caused by normal refractoriness. In such situations, terms such as *3:2* and *2:1 AV conduction* are more appropriate than *3:2* or *2:1 AV block*.

ATRIAL FIBRILLATION WITH SLOW VENTRICULAR RATE

AF with slow ventricular response can be misinterpreted as complete AV block. Verification of the regularity of the slow ventricular rhythm is critical. When AV block is present, the escape rhythm is regular, whereas in AF associated with very slow ventricular response, the ventricular rhythm is a result of conducted atrial beats and is irregular (Fig. 9-27).

VENTRICULOPHASIC SINUS ARRHYTHMIA

Ventriculophasic sinus arrhythmia can be observed whenever there is second- or third-degree AV block, and it is manifest as intermittent differences in the P-P intervals based on their relationship with

the QRS complex. The two P waves surrounding a QRS complex have a shortened interval or occur at a faster rate when compared with two P waves that occur sequentially without an intervening QRS complex (see Fig. 9-22). The mechanism of this phenomenon is not certain. However, it has been suggested that ventricular contractions enhance sinus node automaticity by increasing the pulsatile blood flow through the sinus nodal artery and by mechanical stretch on the sinus node.

Principles of Management

Pacing is the mainstay of treatment for symptomatic AV block (Table 9-1). Identifying transient or reversible causes for AV conduction disturbances is the first step in management. Withdrawal of any offending drugs, correction of any electrolyte abnormalities, or treatment of any infectious processes or myocardial ischemia should be considered prior to permanent pacing therapy. Pharmacological therapy (atropine, isoproterenol) can be effective in intranodal AV block but only as a short-term emergency measure until pacing can be accomplished. Temporary percutaneous or transvenous pacing is necessary in patients with hemodynamically significant AV block and bradycardia to provide immediate stabilization

TABLE 9-1 Indications for Permanent Pacing in Acquired Atrioventricular Block in Adults**Class I**

Third-degree and advanced second-degree AV block at any level, associated with any one of the following:

- Symptomatic bradycardia (including heart failure)
- Ventricular arrhythmias presumed to result from AV block
- Arrhythmias and other conditions that require drugs that result in symptomatic bradycardia
- Asymptomatic awake patients with documented periods of asystole ≥ 3.0 seconds or any escape rate < 40 beats/min, or with an escape rhythm that is below the AVN
- After catheter ablation of the AV junction
- Postoperative AV block that is not expected to resolve
- Neuromuscular diseases, such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy, with or without symptoms
- Awake, symptom-free patients with atrial fibrillation and bradycardia with one or more pauses of at least 5 seconds
- Average awake ventricular rates of 40 beats/min or faster if cardiomegaly or left ventricular dysfunction is present or if the site of block is below the AVN

Second-degree AV block with associated symptomatic bradycardia regardless of type or site of block

Second- or third-degree AV block during exercise in the absence of myocardial ischemia

Class IIa

Persistent third-degree AV block with an escape rate > 40 beats/min in asymptomatic adult patients without cardiomegaly

Asymptomatic second-degree AV block at intra-Hisian or infra-Hisian levels found at electrophysiological study

First- or second-degree AV block with symptoms similar to those of pacemaker syndrome or hemodynamic compromise

Asymptomatic type II second-degree AV block with a narrow QRS; when type II second-degree AV block occurs with a wide QRS, including isolated right bundle branch block, pacing becomes a class I recommendation

Class IIb

Neuromuscular diseases such as myotonic muscular dystrophy, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy with any degree of AV block (including first-degree AV block), with or without symptoms, because there may be unpredictable progression of AV conduction disease

AV block in the setting of drug use and/or drug toxicity when the block is expected to recur even after the drug is withdrawn

Class III

Asymptomatic first-degree AV block

Asymptomatic type I second-degree AV block at the AVN level or that which is not known to be intra-Hisian or infra-Hisian

AV block that is expected to resolve and is unlikely to recur (e.g., drug toxicity, Lyme disease, or transient increases in vagal tone, or during hypoxia in sleep apnea syndrome in the absence of symptoms)

AV = atrioventricular; AVN = atrioventricular node.

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to revise the ACC/AHA/NASPE 2002 guideline update for implantation of cardiac pacemakers and antiarrhythmia devices). Developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *Circulation* 117:e350-408, 2008.

prior to permanent pacemaker placement or to provide pacemaker support when the block is precipitated by what is presumed to be a transient event, such as ischemia or drug toxicity.³⁶

Once all reversible causes are excluded or treated, correlation of symptoms with ECG evidence of AV block is an essential part of the diagnostic strategy. In the setting of intermittent AV block or Wenckebach AV block, ambulatory monitoring often is required to correlate symptoms with the presence and severity of AV conduction abnormalities. As discussed previously, exercise testing can be a useful tool to help confirm the level of block in second- or third-degree AV block associated with a narrow or wide QRS complex. Additionally, EP testing can be required in a patient with suspected high-grade AV block as the cause of syncope or presyncope when documentation cannot be obtained noninvasively. Similarly, in patients with coronary artery disease, in whom symptoms can be secondary to AV block or VT, EP testing can be useful in establishing the diagnosis. Some patients with known second- or third-degree block also can benefit from an invasive study to localize the site of AV block to help determine therapy or assess prognosis.

Permanent pacemaker implantation is indicated in most patients with symptomatic advanced heart block, regardless of the site of block. Permanent pacemakers are also indicated in asymptomatic patients with complete heart block or infra-Hisian second-degree AV block, especially those with documented ventricular pauses longer than 3 seconds or a ventricular escape rhythm of less than 40 beats/min.³⁶

In children with congenital heart block, permanent pacing is recommended in those with exercise intolerance, abrupt pauses in the intrinsic rate (longer than two to three times the basic CL), or inappropriately slow average ventricular rate (less than 50 beats/min). Furthermore, prophylactic pacing can considerably reduce

the incidence of syncope and sudden death in asymptomatic patients with congenital heart block with severe bradycardia (resting heart rate less than 40 beats/min), ventricular pauses longer than 3 seconds, wide QRS escape rhythm, complex congenital heart disease, ventricular dysfunction, complex ventricular ectopy, or a long QT interval.^{22,36}

Dual-chamber pacing can be beneficial in some patients with marked first-degree AV block (more than 300 milliseconds) and symptoms similar to pacemaker syndrome, as well as in patients with LV dysfunction and heart failure symptoms in whom a shorter AV interval results in hemodynamic improvement, presumably by decreasing LA filling pressure. The latter recommendation, however, is now questionable because a conventional DDD(R) pacemaker with an optimized AV delay would have to pace the ventricle almost 100% of the time. The benefit of pacing with optimized AV synchrony (with a shorter AV delay) should be weighed against the impairment of LV function produced by right ventricular pacing with resultant LV dyssynchrony. However, such a determination can be difficult or impossible.²⁸

Temporary pacing is sometimes required in patients with acute MI (more often in anterior than inferior wall MI). Patients with asymptomatic first-degree or type 1 second-degree AV block do not require pacing. However, patients with type 2 second-degree or complete AV block should be temporarily paced, even if they are asymptomatic. In the setting of MI, the criteria for permanent pacing depends less on the presence of symptoms (Table 9-2). If type 2 second-degree or complete AV block persists once past the peri-infarct period, permanent pacing is indicated. Even if the type 2 or third-degree AV block was transient but associated with BBB that persists following resolution of the AV block, permanent pacing of the post-MI patient improves long-term survival.³⁶

TABLE 9-2 Indications for Permanent Pacing in Atrioventricular Block with Acute Myocardial Infarction

Class I

Persistent second-degree AV block in the His-Purkinje system with bilateral bundle branch block or third-degree AV block within or below the His-Purkinje system after acute MI
 Transient advanced (second- or third-degree) infranodal AV block and associated bundle branch block; if the site of block is uncertain, an electrophysiology study may be necessary
 Persistent and symptomatic second- or third-degree AV block

Class IIb

Persistent second- or third-degree AV block at the AV node level, even in the absence of symptoms

Class III

Transient AV block in the absence of intraventricular conduction defects
 Transient AV block in the presence of isolated left anterior fascicular block
 Acquired left anterior fascicular block in the absence of AV block
 Persistent first-degree AV block in the presence of bundle branch block that is old or age indeterminate

AV = atrioventricular; MI = myocardial infarction.

Most patients with AV block require dual-chamber pacemakers to maintain AV synchrony, prevent development of pacemaker syndrome, and, possibly, prevent subsequent development of AF. In patients with normal sinus node function and AV block, VDD pacing using a single lead with a series of electrodes for atrial sensing and ventricular pacing and sensing is appropriate. In patients with permanent AF and bradycardia, rate-responsive single-chamber ventricular pacing (VVIR) is adequate.

General Considerations

A narrow QRS complex requires highly synchronous electrical activation of the ventricular myocardium, which can be achieved only through the rapidly conducting His-Purkinje system (HPS). The term *intraventricular conduction disturbances* (IVCDs) refers to abnormalities in the intraventricular propagation of supraventricular impulses resulting in changes in the morphology or duration, or both, of the QRS complex. These changes in intraventricular conduction can be fixed and present at all heart rates, or they can be intermittent (transient) and tachycardia- or bradycardia-dependent. They can be caused by structural abnormalities in the HPS or ventricular myocardium, functional refractoriness in a portion of the conduction system (i.e., aberrant ventricular conduction), or ventricular preexcitation over a bypass tract.¹

Transient Bundle Branch Block

The term aberration is used to describe transient bundle branch block (BBB) and does not include QRS abnormalities caused by pre-existing BBB, preexcitation, or the effect of drugs. Transient BBB can have several mechanisms, including phase 3 block, phase 4 block, and concealed conduction. These mechanisms of aberration can occur anywhere in the HPS, and, unlike in chronic BBB, the site of block during aberration can shift. Right BBB (RBBB) is the most common pattern of aberration, occurring in 80% of patients with aberration and in up to 100% of cases of aberration in normal hearts.²⁻⁷

PHASE 3 BLOCK

Conduction velocity depends, in part, on the rate of rise of phase 0 of the action potential (dV/dt) and the height to which it rises (V_{max}). These factors, in turn, depend on the membrane potential at the time of stimulation. The more negative the membrane potential is, the more sodium (Na^+) channels are available for activation, the greater the influx of Na^+ into the cell during phase 0, and the greater the conduction velocity. Therefore, when stimulation occurs during phase 3 of the action potential, before full recovery and at less negative potentials of the cell membrane, a portion of Na^+ channels remains refractory and unavailable for activation. Consequently, the Na^+ current and phase 0 of the next action potential are reduced, and conduction is then slower.^{6,8-10}

Phase 3 block, also called tachycardia-dependent block, occurs when an impulse arrives at tissues that are still refractory caused by incomplete repolarization. Manifestations of phase 3 block include BBB and fascicular block, as well as complete atrioventricular (AV) block.^{3,11}

Functional or physiological phase 3 aberration can occur in normal fibers if the impulse is sufficiently premature to encroach on the physiological refractory period of the preceding beat, when the membrane potential is still reduced. This is commonly seen with very early premature atrial complexes (PACs) that conduct aberrantly. Phase 3 aberration can also occur pathologically if electrical systole and the refractory period are abnormally prolonged (with refractoriness extending beyond the action potential duration or

the QT interval) and the involved fascicle is stimulated at a relatively rapid rate.^{3,11} Transient left BBB (LBBB) is less common than RBBB (only 25% of phase 3 aberration is of the LBBB type). The block usually occurs in the very proximal portion of the bundle branch.^{6,9,10}

Phase 3 block constitutes the physiological explanation of several phenomena, including aberration caused by premature excitation, Ashman phenomenon, and acceleration-dependent aberration.

Aberration Caused by Premature Excitation

Premature excitation can cause aberration (BBB) by encroaching on the refractory period of the bundle branch prior to full recovery of the action potential, namely during so-called voltage-dependent refractoriness (see Fig. 4-29).¹¹ In normal hearts, this type of aberration is almost always in the form of RBBB (Fig. 10-1), whereas such aberration in the abnormal heart can be that of RBBB or LBBB.

At normal heart rates, the effective refractory period (ERP) of the right bundle branch (RB) exceeds the ERP of the AV node (AVN), HB, and left bundle branch (LB). At faster heart rates, the ERP of both bundle branches shortens. However, RB ERP shortens to a greater degree than LB ERP, so that the duration of the refractory periods of the two bundles crosses over, and LB ERP becomes longer than that of the RB. This explains the tendency of aberration to be in the form of RBBB when premature excitation occurs during normal heart rates and in the form of LBBB when it occurs during fast heart rates.^{2,3,6,8-10,12}

Ashman Phenomenon

The Ashman phenomenon refers to aberration occurring when a short cycle follows a long one (long-short cycle sequence) (see Fig. 10-1).^{11,13} Aberrancy is caused by the physiological changes of the conduction system refractory periods associated with the R-R interval. Normally, the refractory period of the HPS lengthens as the heart rate slows and shortens as the heart rate increases, even when heart rate changes are abrupt. Thus, aberrant conduction can result when a short cycle follows a long R-R interval. In this scenario, the QRS complex that ends the long pause is conducted normally but creates a prolonged ERP of the bundle branches. If the next QRS complex occurs after a short coupling interval, it may be conducted aberrantly because one of the bundles is still refractory as a result of a lengthening of the refractory period (phase 3 block; Fig. 10-2).^{6,7}

RBBB aberration is more common than LBBB in this setting because the RB has a longer ERP than the LB. The Ashman phenomenon can occur during second-degree AV block (see Fig. 9-9), but it is most common during atrial fibrillation (AF), whereby the irregularity of the ventricular response results in frequently occurring long-short cycle sequences.

The aberrancy can be present for one beat and have a morphology resembling a premature ventricular complex (PVC), or it can involve several sequential complexes, a finding suggesting ventricular tachycardia (VT). In the setting of aberrancy during AF, the long-short cycle sequence characteristic of the Ashman phenomenon may not be helpful in differentiating aberration from ventricular ectopy. Although a long cycle (pause) sets the stage for the Ashman phenomenon, it also tends to precipitate ventricular ectopy. Furthermore, concealed conduction occurs frequently

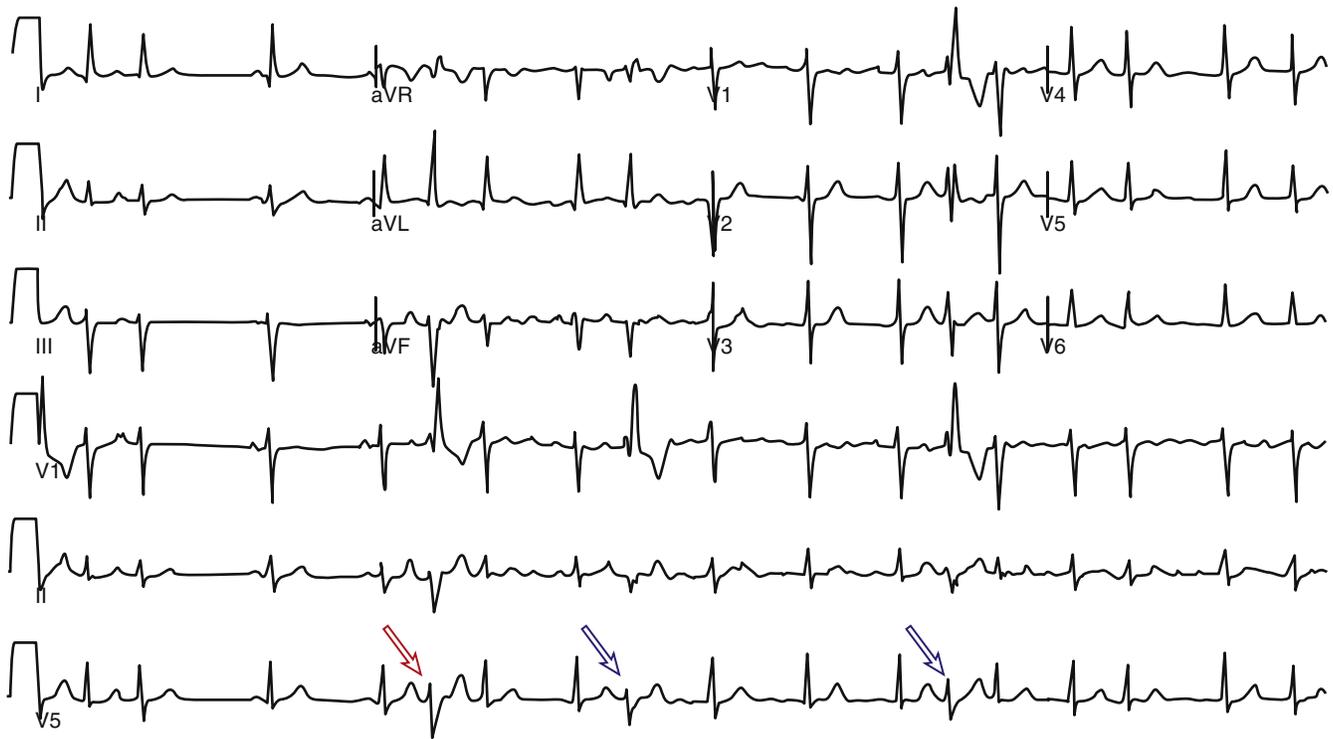

FIGURE 10-1 Ashman phenomenon. A premature atrial complex (PAC, red arrow) during sinus rhythm induces atrial fibrillation (AF). Note that the PAC is conducted with right bundle branch block (RBBB) aberrancy (phase 3 block). During AF, long-short cycle sequences occur repeatedly and are associated with RBBB aberrancy (Ashman phenomenon, phase 3 block). Note that the aberrantly conducted complex (blue arrows) during AF occur at variable coupling intervals to the preceding beats. See text for discussion.

FIGURE 10-2 Atrial tachycardia (AT) with variable atrioventricular (AV) conduction and intermittent aberrancy. **Left**, AT with 2:1 AV conduction and normal QRS morphology is observed. Once 1:1 AV conduction occurs (QRS 3), left bundle branch block (LBBB) aberration develops (caused by long-short cycle sequence, phase 3 block). LBBB aberration is also observed during QRS 4, likely secondary to concealed transseptal conduction causing perpetuation of aberration. After a pause, both bundle branches recover from refractoriness producing a normal QRS 5. Ashman phenomenon (long-short cycle sequence) explains phase 3 block during QRS 6, but this time it manifests as a right bundle branch block (RBBB) pattern. This is because activation during QRS 4 propagated down the right bundle branch (RB) and across the septum, thus activating the left bundle branch (LB) retrogradely after some delay (concealed transseptal conduction), so that the LB-LB interval (between QRS 4 and QRS 5) resulted in a shorter effective refractory period (ERP) of the LB following QRS 5. Conversely, the RB-RB interval (between QRS 4 and QRS 5) was longer and, consequently, the ERP of the RB was still prolonged following QRS 5, thereby setting the stage for a long-short cycle sequence of the RB but not the LB. Therefore, RBBB (rather than LBBB) aberration develops. RBBB aberration during QRS complexes 7 and 8 is secondary to either concealed transseptal conduction or rate-dependent aberration. However, because LBBB (rather than RBBB) was observed during QRS 4 (although QRS 4 occurred following a similar cycle length to that of QRS 8), concealed transseptal conduction is more likely to be the mechanism of aberration. After a pause, both bundle branches recover from refractoriness to produce a normal QRS 9. Long-short cycle sequence explains phase 3 block during QRS 10, but this time it manifests as LBBB. This is because activation during QRS 8 propagated down the LB and across the septum, thus activating the RB after some delay (concealed transseptal conduction). The result is that the RB-RB interval (following QRS 8) and ERP of the RB became shorter, whereas the LB-LB interval (following QRS 8) was longer. Consequently, the ERP of the LB was still prolonged following QRS 9, thereby setting the stage for a long-short cycle sequence and LBBB aberration. LBBB aberration during QRS 11 is caused by concealed transseptal conduction. The Ashman phenomenon (long-short cycle sequence) underlies RBBB aberration during QRS 14. HRA = high right atrium.

during AF and, therefore, it is never possible to know from the surface ECG exactly when a bundle branch is activated. Thus, if an aberrant beat does end a long-short cycle sequence during AF, it can be because of refractoriness of a bundle branch secondary to concealed conduction into it, rather than because of changes in the length of the ventricular cycle.^{8-10,12}

Nevertheless, there are several features of ventricular ectopy that can help distinguish a PVC from an aberrantly conducted or Ashman beat during AF. PVCs are usually followed by a longer R-R cycle, indicating the occurrence of a compensatory pause, the result of retrograde conduction into the AVN and anterograde block of the impulse originating in the atrium. A ventricular origin is also likely when there is a fixed coupling cycle between the normal and aberrant QRS complexes. The presence of long and identical R-R cycles after the aberrated beats and the absence of a long-short cycle sequence associated with the wide or aberrant QRS complex also suggest ventricular ectopy. Additionally, the absence of aberrancy, despite the presence of R-R cycle length (CL) combinations that are longer and shorter than those associated with the wide QRS

complex, suggests ventricular ectopy. QRS morphology inconsistent with LBBB or RBBB aberrancy argues against aberration (Fig. 10-3).^{6,8-10,12}

Aberration caused by the Ashman phenomenon can persist for several cycles. The persistence of aberration can reflect a time-dependent adjustment of refractoriness of the bundle branch to the abrupt change in CL, or it can be the result of concealed transseptal activation (see later).

Aberration Caused by Heart Rate Acceleration

As the heart rate accelerates, the HPS refractory period shortens; normal conduction tends to be preserved because of this response. However, refractoriness of the HPS eventually reaches a critical value beyond which an increase in heart rate no longer abbreviates it; at this point, AV block may occur. Conversely, the refractory period lengthens as the heart rate slows. Acceleration-dependent BBB is a result of failure of the action potential of the bundle branches to shorten, or, paradoxically, the action potential lengthens in response to acceleration of the heart rate (Fig. 10-4).^{3,11} As

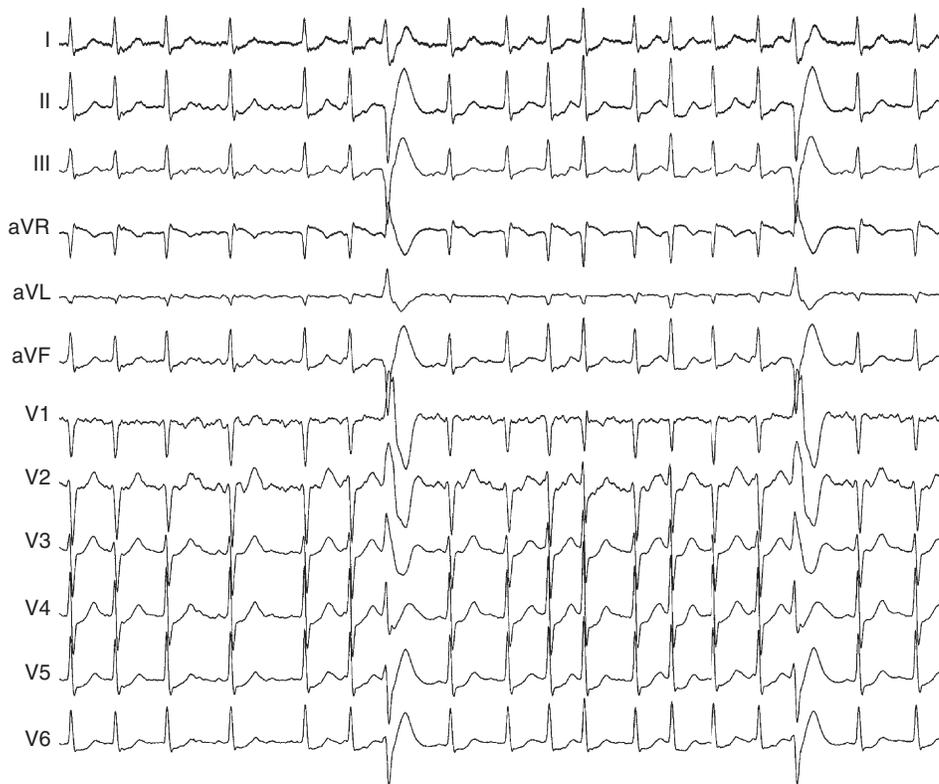

FIGURE 10-3 Premature ventricular complexes during atrial fibrillation. Several features suggest that the wide QRS complexes are caused by ventricular ectopy rather than aberration. QRS morphology is inconsistent with LBBB or RBBB aberrancy. Additionally, there is a fixed coupling cycle between the normal and aberrant QRS complex. The absence of a long-short cycle sequence associated with the wide QRS complex and the absence of aberrancy despite the presence of R-R cycle length combinations that are longer and shorter than those associated with the wide QRS complex also suggest ventricular ectopy.

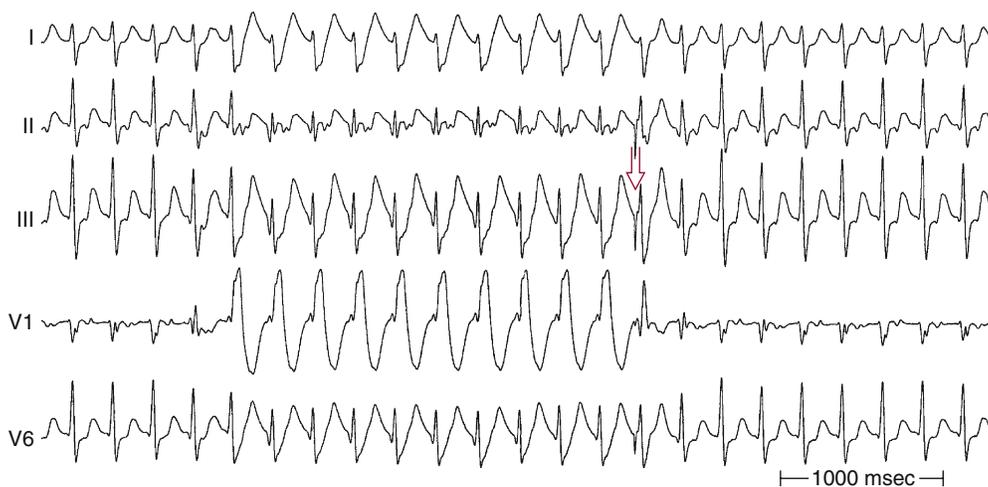

FIGURE 10-4 Supraventricular tachycardia (SVT) with tachycardia-dependent (phase 3) right bundle branch block. Delivery of a late ventricular extrastimulus (arrow) during the SVT preexcites the right bundle branch (and either peels back or shortens its refractoriness) and restores normal conduction.

noted, the ERP of the RB normally shortens at faster heart rates to a greater degree than that of the LB; this finding explains the more frequent RBBB aberration at longer CLs and LBBB aberration at shorter CLs.^{4,8,10}

This form of aberration is a marker of some type of cardiac abnormality when it appears at relatively slow heart rates (less than 70 beats/min), displays LBBB (Fig. 10-5), appears after several cycles of accelerated but regular rate, or appears with gradual rather than abrupt acceleration of the heart rate and at CL shortening by less than 5 milliseconds. Because of the small changes in the duration of the CL that may initiate aberration (critical cycle), recognition of acceleration-dependent aberration may require a long record to document the gradual, and at times minimal, shortening of the R-R interval.⁸⁻¹⁰

With increasing heart rate or persistence of fast heart rate, acceleration-dependent aberration can occasionally disappear. The normalization of a previously aberrant QRS complex can be explained by a greater shortening of the ERP of the bundle branches than that of the AVN or by a time-dependent gradual shortening of the refractory period of the affected bundle branch (a phenomenon occasionally referred to as *restitution*).⁶

During slowing of the heart rate, intraventricular conduction often fails to normalize at the critical CL, and aberration persists at cycles longer than the critical cycle that initiated the aberration. Once acceleration-dependent BBB is established, the actual cycle for the blocked bundle does not begin until approximately halfway through the QRS complex because of concealed transseptal conduction (see later); thus, it is necessary for the heart rate to slow down more than would be expected to reestablish normal conduction.⁸⁻¹⁰

PHASE 4 BLOCK

Phase 4 block occurs when conduction of an impulse is blocked in tissues well after their normal refractory periods have ended.^{3,11} Phase 4 block is governed by the same physiological principles as those for phase 3 block. Membrane responsiveness is determined by the relationship of the membrane potential at excitation with the maximum height of phase 0. The availability of the Na⁺ channels is reduced at less negative membrane potentials, and activation at a reduced membrane potential is likely to cause aberration or block.⁶

The cause of membrane depolarization (i.e., reduction of membrane potential) in the setting of phase 4 block, however, is different from that in phase 3 block. Enhanced phase 4 depolarization within the bundle branches can be caused by enhanced automaticity or partial depolarization of injured myocardial tissue, or both. In this setting, the maximum diastolic potential immediately follows repolarization, from which point the membrane potential is steadily reduced (by the pacemaker current). This reduction, in turn, results in inactivation of some Na⁺ channels. Thus, an action potential initiated early in the cycle (immediately after repolarization) would have a steeper and higher phase 0 and consequently better conduction than would an action potential initiated later in the cycle when the membrane potential at the time of the stimulus is reduced, with resulting reductions in the velocity and height of phase 0 and slower conduction.^{8,10,12}

Phase 4 aberration is one explanation for the development of aberration at the end of a long cycle. As a result of a gradual spontaneous depolarization made possible by a prolonged cycle, the cell is activated from a less negative potential, and the result is impaired

FIGURE 10-5 Acceleration-dependent aberration. The lead II continuous rhythm strip demonstrates sinus rhythm with rate-related left bundle branch block (LBBB). Note that small changes in rate can result in acceleration-dependent aberration. LBBB develops at a sinus rate faster than 70 beats/min, and normal QRS complexes are observed at slower sinus rates. The LBBB and the slow rate at which aberration develops strongly suggest an abnormality in the left bundle branch (LB), rather than physiological aberration, often associated with underlying structural heart disease such as cardiomyopathy. Interestingly, the onset and offset of the LBBB demonstrate hysteresis in that the cycle length (CL) required to initiate the LBBB is shorter than the CL required to maintain it, probably because of retrograde concealed penetration of the LB.

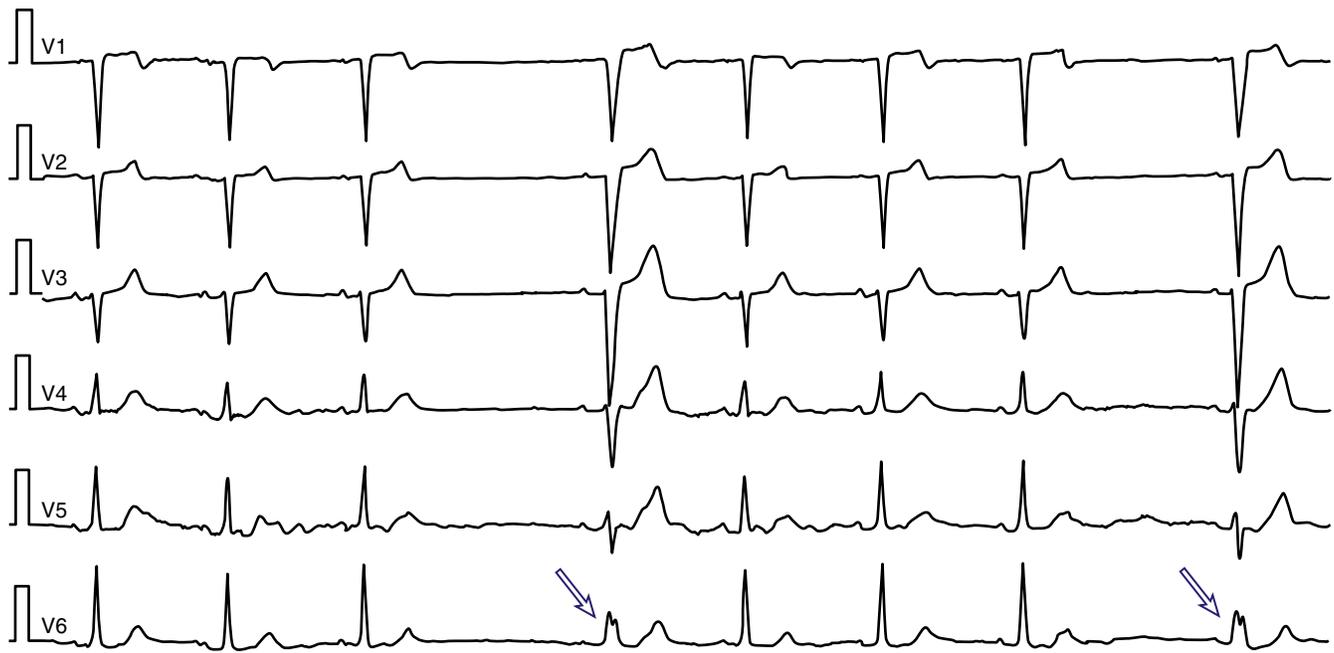

FIGURE 10-6 Bradycardia-dependent left bundle branch block (LBBB). Normal intraventricular conduction is observed during sinus rhythm. Premature atrial complexes (hidden within the T waves) are not conducted to the ventricles, resulting in pauses. The sinus complex following the pause is conducted with LBBB pattern (arrows) presumably secondary to phase 4 block. See text for discussion.

conduction. This type of aberration is sometimes referred to as bradycardia-dependent BBB (Fig. 10-6).⁶ Importantly, the membrane potential has to depolarize significantly before conduction becomes impaired. Mild depolarization can actually improve conduction because the voltage is closer to threshold.

Phase 4 aberration would be expected in the setting of bradycardia or enhanced normal automaticity. However, despite the fact that bradycardia is common and cells with phase 4 depolarization are abundant, phase 4 block is not commonly seen; most reported cases are associated with structural heart disease. One explanation for this phenomenon is that in normal fibers, conduction is well maintained at membrane potentials more negative than -70 to -75 mV. Significant conduction disturbances are first manifested when the membrane potential is less negative than -70 mV at the time of stimulation; local block appears at -65 to -60 mV. Because the threshold potential for normal His-Purkinje fibers is -70 mV, spontaneous firing occurs before the membrane can actually be reduced to the potential necessary for conduction impairment or block. Phase 4 block is therefore pathological when it does occur, and it requires one or more of the following: (1) the presence of slow diastolic depolarization, which needs to be enhanced; (2) a decrease in excitability (a shift in threshold potential toward zero) so that, in the presence of significant bradycardia, sufficient time elapses before the impulse arrives, thus enabling the bundle branch fibers to reach a potential at which conduction is impaired; and (3) a deterioration in membrane responsiveness so that significant conduction impairment develops at -75 mV instead of -65 mV; this occurrence would also negate the necessity for such a long cycle before conduction fails.^{8,10,12}

Bradycardia-dependent or phase 4 block almost always manifests an LBBB pattern, likely because the left ventricular (LV) conduction system is more susceptible to ischemic damage and has a higher rate of spontaneous phase 4 depolarization than the right ventricle (RV).¹²

Both tachycardia-dependent and bradycardia-dependent BBB can be seen in the same patient with an intermediate range of CLs associated with normal conduction. The prognosis of rate-dependent BBB largely depends on the presence and severity of the underlying heart disease. Its clinical implications are not clear, and it usually occurs in diseased tissue and in the setting of myocardial infarction (MI), especially inferior wall MI.⁶

ABERRATION CAUSED BY CONCEALED TRANSEPTAL CONDUCTION

Concealed transseptal conduction is the underlying mechanism of aberration occurring in several situations, including perpetuation of aberrant conduction during tachyarrhythmias, unexpected persistence of acceleration-dependent aberration, and alternation of aberration during atrial bigeminal rhythm.^{8-10,12,14,15}

Perpetuation of Aberrant Conduction during Tachyarrhythmias

During a supraventricular tachycardia (SVT) with normal ventricular activation, a PVC originating from the RV can retrogradely activate the RB early, whereas retrograde activation of the LB occurs later, following transseptal conduction of the PVC. Consequently, although the RB ERP expires in time for the next SVT impulse, the LB remains refractory because its actual cycle began later than the RB. Therefore, the next SVT impulse traveling down the His bundle (HB) encounters an excitable RB and a refractory LB; thus, it propagates to the RV over the RB (with an LBBB pattern, phase 3 aberration). Conduction subsequently propagates from the RV across the septum to the LV. By this time, the distal LB has recovered, allowing for retrograde penetration of the LB by the SVT impulse propagating transseptally, thereby rendering the LB refractory to each subsequent SVT impulse (Fig. 10-7). This process is repeated, and the LBBB pattern continues until another well-timed PVC preexcites the LB (and either peels back or shortens its refractoriness), so that the next impulse from above finds the LB fully recovered (see Fig. 10-4).^{4,14,15}

Unexpected Persistence of Acceleration-Dependent Aberration

Acceleration-dependent BBB develops at a critical rate faster than the rate at which it disappears (Fig. 10-8). This paradox is most commonly ascribed to concealed conduction from the contralateral conducting bundle branch across the septum with delayed activation of the blocked bundle. Such concealed transseptal activation results in a bundle branch-to-bundle branch (RB-RB or LB-LB) interval shorter than the manifest R-R cycle. The reason is that the actual cycle for the blocked bundle does not begin until approximately halfway through the QRS complex, because it takes 60 to 100 milliseconds for the impulse to propagate down the RB and transseptally reach the blocked LB. Consequently, for normal

FIGURE 10-7 Perpetuation of aberrant conduction during supraventricular tachycardia (SVT) secondary to concealed transseptal conduction. At left, SVT is associated with normal ventricular activation and narrow QRS complexes. Critically timed ventricular extrastimulus delivered from the right ventricle (arrow) precipitates left bundle branch block aberrancy during the SVT. See text for discussion.

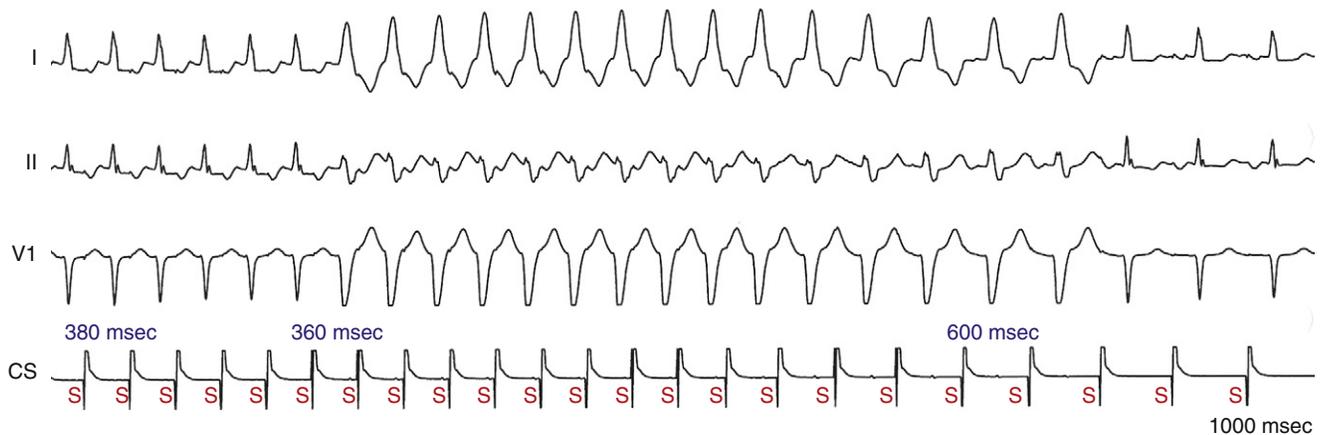

FIGURE 10-8 Unexpected persistence of acceleration-dependent aberration. During incremental-rate atrial pacing from the coronary sinus (CS), acceleration-dependent bundle branch block develops at a cycle length (CL) of up to 370 milliseconds. Aberrancy continues despite progressively increasing the pacing CL and disappears only when pacing at a CL of more than 600 milliseconds. See text for discussion.

conduction to resume, the cycle (R-R interval) during deceleration must be longer than the critical cycle during acceleration by at least 60 to 100 milliseconds.^{8-10,12,14,15}

However, unexpected delay of normalization of conduction cannot always be explained by concealed conduction. Conduction sometimes normalizes with slowing of the heart rate, only to recur at cycles that are still longer than the critical cycle. Such a sequence excludes transseptal concealment as the mechanism of recurrence of the aberration. Similarly, when the discrepancy between the critical cycle and the cycle at which normalization

finally occurs is longer than the expected transseptal activation time (approximately 60 milliseconds in the normal heart and 100 milliseconds in the diseased states), transseptal concealment alone cannot explain the delay (see Fig. 10-8). Fatigue and overdrive suppression have been suggested as possible mechanisms of the delayed normalization of conduction.⁸⁻¹⁰

Alternation of Aberration during Atrial Bigeminal Rhythm

A bigeminal rhythm can be caused by atrial bigeminy, 3:2 AV block, or atrial flutter with alternating 2:1 and 4:1 AV conduction. The

alternation can be between a normal QRS complex and BBB or between RBBB and LBBB.

When alternation occurs between a normal QRS complex and RBBB during atrial bigeminy, the ERP of both RB and LB starts simultaneously following the normally conducted PAC, and the ERP of both branches is relatively short because of the preceding short cycle. After the pause, the sinus beat conducts normally, and the ERP of both bundle branches starts simultaneously but is relatively long because of the preceding long cycle. However, because the RB ERP is relatively longer than that of the LB, the next PAC encroaches on the RB refractoriness and conducts with an RBBB pattern (phase 3 block). Subsequently, that PAC is conducted down the LB and across the septum. The PAC activates the RB retrogradely after some delay (concealed transseptal conduction), so that the RB-RB interval (during the following pause) and the RB ERP become shorter. As a result, by the time the next PAC reaches the RB, the RB is fully recovered because of its abbreviated ERP (reflecting the shorter preceding RB-RB interval, which is shorter than the manifest R-R interval during the preceding pause), and normal conduction occurs (see Fig. 10-2).^{14,15}

The same phenomenon (concealed transseptal conduction) explains alternating RBBB and LBBB during bigeminal rhythms. In the presence of RBBB, transseptal concealed conduction from the LB to the RB shortens the RB-RB interval relative to the now longer LB-LB interval. As a result, the ERP of the LB is longer and conduction in the LB fails. In the presence of a refractory LB, conduction propagates through the RB. The delayed transseptal activation of the LB shortens the LB-LB interval. The ERP of the RB is now relatively longer, because RB conduction is blocked.^{9,10,12}

Chronic Bundle Branch Block

ANATOMICAL CONSIDERATIONS

Normal ventricular activation requires the synchronized participation of the distal components of the specialized conduction system (i.e., the main bundle branches and their ramifications). An IVCD is the result of abnormal activation of the ventricles caused by conduction delay or block in one or more parts of the specialized conduction system. Abnormalities of local myocardial activation can further alter the specific pattern of ventricular activation.^{1,6}

Traditionally, three major fascicles are considered to be operative in normal persons: the RB, the left anterior fascicle (LAF), and the left posterior fascicle (LPF). An estimated 65% of individuals have a third fascicle of the LB, the left median fascicle (LMF). The HB divides at the junction of the fibrous and muscular boundaries of the intraventricular septum into the RB and LB. The RB is an anatomically compact unit that travels as the extension of the HB after the origin of the LB. The LB and its divisions are, unlike the RB, diffuse structures that fan out just beyond their origin. The LAF represents the superior (anterior) division of the LB, the LPF represents the inferior (posterior) division of the LB, and the LMF represents the septal (median) division of the LB.⁶

The bundle branches and fascicles consist of bundles of Purkinje cells covered by a dense sheath of connective tissue. The terminal Purkinje fibers connect the ends of the bundle branches to the ventricular myocardium. Purkinje fibers form interweaving networks on the endocardial surface of both ventricles and penetrate only the inner third of the endocardium, and they tend to be less concentrated at the base of the ventricle and at the papillary muscle tips. Purkinje cells are specialized to conduct rapidly, at 1 to 3 m/sec, because phase 0 of the action potential is dependent on the rapid inward Na^+ current (I_{Na}). This characteristic results in almost simultaneous depolarization of the terminal HPS and propagation of the cardiac impulse to the entire RV and LV endocardium.⁶

Characteristics of the Right Bundle

The RB courses down the right side of interventricular septum near the endocardium in its upper third, deeper in the muscular

portion of the septum in the middle third, and then again near the endocardium in its lower third. The RB is a long, thin, discrete structure. It does not divide throughout most of its course, and it begins to ramify as it approaches the base of the right anterior papillary muscle, with fascicles going to the septal and free walls of the RV.

The RB is vulnerable to stretch and trauma for two thirds of its course when it travels subendocardially. Chronic RBBB pattern can result from three levels of conduction delay in the RV: proximal, distal, or terminal.³ Proximal RBBB is the most common site of conduction delay. Distal RBBB occurs at the level of the moderator band, and it is an unusual site of conduction delay unless there has been transection of the moderator band during surgery. Terminal RBBB involves the distal conduction system of the RB or, more likely, the ventricular muscle itself, and it can be produced by ventriculotomy or transatrial resection of parietal bands in repair of tetralogy of Fallot. In addition, RBBB can be induced by events in the HB, because certain fibers of the HB are organized longitudinally and predestined to activate only one fascicle or bundle branch. Disease in these areas can result in activation that is asynchronous from that in the rest of the infranodal conducting system, possibly with resulting bundle branch or fascicular block.

The development of RBBB after a normal pattern can suggest the presence of structural heart disease, although less often than the development of LBBB; however, RBBB in younger individuals generally is not indicative of serious underlying heart disease. Causes of RBBB include increased RV pressure, RV hypertrophy or dilatation, ischemic heart disease, myocarditis, cor pulmonale, acute and chronic pulmonary embolism, hypertension, cardiomyopathies, congenital heart disease, and mechanical damage, as well as Lev and Lenègre diseases.

Characteristics of the Left Bundle and Its Fascicles

The predivisional portion of the LB penetrates the membranous portion of the interventricular septum under the aortic ring and then divides into three discrete branches: the LAF, the LPF, and the LMF.³ The LAF crosses the anterobasal LV region toward the anterior papillary muscle and terminates in the Purkinje system of the anterolateral wall of the LV. The LPF appears as an extension of the main LB and is large in its initial course. It then fans out extensively toward the posterior papillary muscle and terminates in the Purkinje system of the posteroinferior wall of the LV. The LMF runs to the interventricular septum; it arises in most cases from the LPF, less frequently from the LAF, or from both, and in a few cases it has an independent origin from the central part of the main LB at the site of its bifurcation.¹⁶

The clinical presentation of conduction disturbances, in order of decreasing incidence, is LAF block, RBBB, LBBB, and LPF block. This rank depends not only on the intrinsic, anatomical, and genetically determined differences among branches and fascicles but also on the manner in which the intraventricular conduction system is exposed to the various pathological processes of the surrounding cardiac structures. LBBB is usually caused by ischemic or mechanical factors, and the site of block is typically in the predivisional segment at the junction of the LB and HB. LBBB is encountered usually in patients with structural heart disease involving dilation, hypertrophy, or fibrosis of the LV such as ischemic heart disease, valvular heart disease, and various cardiomyopathies. LBBB can also be caused by Lev and Lenègre diseases. The location of conduction delay in LBBB can be proximal (particularly in diffuse myocardial disease), distal, or a combination of both.

The LAF can be injured by diseases that involve primarily the LV basal septum, the anterior half of the ventricular septum, and the anterolateral LV wall. In fact, isolated LAF block is the most common type of IVCD seen in acute anterior MI. Other disorders and situations that can also cause LAF block include hypertension, cardiomyopathies, aortic valve disease, Lev and Lenègre diseases, spontaneous and surgical closure of a ventricular septal defect, and other surgical procedures.¹⁶⁻¹⁸

In contrast, the LPF is the least vulnerable segment of the whole system because it is short and wide and is located in the inflow

tract of the LV, which is a less turbulent region than the outflow tract. Additionally, the LPF has a dual blood supply, from the anterior and posterior descending coronary arteries, and it is not related to structures that are so potentially dangerous.¹⁶ LPF block is a rare finding, and rather nonspecific for cardiac disease. LPF block is almost always associated with RBBB.

SITE OF BLOCK

Interest in the site of block stems from the fact that bifascicular block (especially RBBB and LAF block) is the most common ECG pattern preceding the development of AV block. Determining the site of block therefore can help predict the risk of AV block.

Despite ECG anatomical correlates, the site of block producing BBB patterns is not certain in all cases. Data suggest that fibers to the RV and LV are already predestined within the HB and that lesions in the HB can produce characteristic BBB patterns. Longitudinal dissociation with asynchronous conduction in the HB can give rise to abnormal patterns of ventricular activation; hence, the conduction problem may not necessarily lie in the individual bundle branch. Moreover, it is not uncommon for intra-Hisian disease to be accompanied by BBB (especially LBBB).³ Pacing distal to the site of block can normalize the QRS. Furthermore, the problem may not be actual block, because conduction *delay* within the bundle in the range of 10 milliseconds can give rise to an ECG pattern of BBB.

CLINICAL RELEVANCE

The prognosis of BBB is related largely to the type and severity of the underlying heart disease and to the possible presence of other conduction disturbances. Isolated BBB in the absence of apparent structural heart disease and not associated with block in the other fascicles is usually benign.

Bifascicular block (especially RBBB and LAF block) is the most common ECG pattern preceding complete heart block in adults. Other forms of IVCD precede the bulk of the remaining cases of complete intra-Hisian and infra-Hisian AV block. The incidence of progression to complete AV block is approximately 2% in asymptomatic patients with an IVCD and approximately 6% in patients with an IVCD and neurological symptoms (e.g., syncope).^{19,20}

Patients with BBB have an unusually high incidence of cardiac disease and sudden cardiac death. The highest incidence of sudden cardiac death is among patients with LBBB and cardiac disease.¹⁹⁻²² However, most sudden cardiac deaths are caused by VT or ventricular fibrillation, do not seem to be related to AV block, and are not prevented by pacemakers (although pacing can potentially relieve symptoms such as syncope). Complete electrophysiological (EP) testing and ventricular stimulation are therefore necessary in patients with syncope and BBB because VT can be found in up to 30% to 50%. Although the poor prognosis associated with BBB is related to myocardial dysfunction, heart failure, and ventricular fibrillation rather than heart block, symptoms such as syncope are often related to heart block.²³⁻²⁵

RBBB is a common finding in the general population. In patients without evidence of structural heart disease, RBBB has no prognostic significance. However, new-onset RBBB does predict a higher rate of coronary artery disease, heart failure, and cardiovascular mortality. When cardiac disease is present, the coexistence of RBBB suggests advanced disease. RBBB is an independent predictor of all-cause mortality in patients with known or suspected coronary heart disease, and in the setting of an acute MI, RBBB is associated with a significant increase in mortality.²⁶

The prevalence of LBBB in the general population has been reported to vary considerably according to population size and sampling criteria; it ranges from 0.1% to 0.8%. The presence of isolated LBBB has no adverse prognostic significance. In patients with LBBB associated with ischemic heart disease, hypertension, or cardiomyopathy, the prognosis depends on the severity of the underlying heart disease. Nevertheless, among patients with acute

MI, cardiomyopathy, and heart failure, the presence of LBBB is associated with a worse prognosis. Because the presence of LBBB can represent the clinical onset of LV structural disease such as dilated cardiomyopathy or an infective, hypertensive, or valvular heart disease, the finding of LBBB on resting ECG requires further evaluation with echocardiogram and Holter monitoring for assessment of LV function, as well as identifying both advanced degrees of AV block and heart disease-related tachyarrhythmias. Evaluation for ischemic heart disease can be necessary based on the presence of risk factors and typical symptoms.²⁶

The prevalence of LAF block in the general population ranges from 0.9% to 6.2%. Isolated LAF block does not itself imply a risk factor for cardiac mortality or morbidity, and in a healthy population it should be regarded as an incidental ECG finding.¹⁶ The prognosis of LAF block is primarily related to the underlying heart disease. LAF block in the setting of acute MI is probably associated with increased mortality.

As noted, LPF block is a rare finding and rather nonspecific for cardiac disease. LPF block is almost always associated with RBBB, in that LPF block and RBBB share cause, pathogenesis, and prognosis. The combination of LPF block and RBBB in acute MI is associated with a high mortality rate (80% to 87%) during the first weeks after the coronary event. Similarly, the risk of progression toward complete AV block (a form of trifascicular block) is also considerable (42%), and approximately 75% of these patients die of pump failure.¹⁶

Electrocardiographic Features

Bundle Branch Block

The ECG criteria for different types of fascicular blocks and BBB are listed in [Table 10-1](#). The ECG pattern of BBB can represent complete block or conduction delay (relative to the other fascicles) that produces asynchronous ventricular activation without necessarily implying complete failure of conduction in the diseased fascicle. Therefore, an ECG pattern of complete BBB can have varying degrees or alternate with contralateral complete BBB pattern, phenomena explained by delay, rather than complete block, as the underlying pathophysiologic feature of the ECG pattern.^{3,20,27}

BBB leads to prolongation of the QRS duration and sometimes to alterations in the QRS vector. The degree of prolongation of the QRS duration depends on the severity of the impairment. With complete BBB, the QRS is 120 milliseconds or longer in duration; with incomplete BBB, the QRS duration is 100 to 120 milliseconds. The QRS vector in BBB is generally oriented in the direction of the myocardial region in which depolarization is delayed.¹

BBB is characteristically associated with secondary repolarization (ST-T) abnormalities. The T wave is typically opposite in polarity to the last deflection of the QRS, a discordance that is caused by the altered sequence of repolarization that occurs secondary to altered depolarization.

RIGHT BUNDLE BRANCH BLOCK

Development of RBBB alters the activation sequence of the RV but not the LV. Because the LB is not affected, the initial septal activation (the initial 30 milliseconds of the QRS complex), which depends on the LB, remains normal, occurring from left to right, and results in septal q waves in leads I, aVL, and V₆ and r waves in leads V₁, V₂, and aVR.²⁶ Thus, the Q wave of a prior MI remains unchanged. Septal activation is followed by LV activation (within the subsequent 40 to 60 milliseconds), occurring over the LB in a leftward and posterior vector and resulting in R waves in the leftward leads (I, aVL, and V₆), as well as s (or S) waves in the anterior precordial leads (V₁ and V₂). This appearance is usually similar to that in normal subjects.

The asynchronous depolarization caused by RBBB is primarily manifested in the later portion of the QRS, at 80 milliseconds and

beyond. During this time, RV activation spreads slowly by conduction through working muscle fibers rather than the specialized Purkinje system, and it occurs predominantly after activation of the LV has completed. The forces generated by the late, unopposed RV free wall activation result in a terminal rightward and anterior positivity, manifesting as a second positive deflection that

can be small (r') or large (R') in the anterior precordial leads (V_1 and V_2) and S waves in the leftward leads (I, aVL, and V_6 ; Fig. 10-9).^{3,26} The QRS axis is unaffected by RBBB; left or right axis deviation can indicate concurrent LAF or LPF block, respectively (see Fig. 10-9).

RBBB also results in an abnormality of ventricular repolarization of the RV myocardium. Thus, there are often secondary ST segment and T wave changes present in the right precordial leads. The ST segment change is usually small and, when present, is discordant (i.e., has an axis in the opposite direction) to the terminal mean QRS spatial vector. The T wave also tends to be discordant to the terminal conduction disturbance, resulting in inverted T waves in the right precordial leads (where there is a terminal R' wave) and upright T waves in the left precordial leads (where there is a terminal S wave).

The time interval necessary for full depolarization of the ventricular free wall (from the endocardium to the epicardium) beneath any given ECG electrode corresponds to the interval from the beginning of the QRS complex to the time of initial downstroke of the R wave after it has peaked (or to the time of initial upstroke of the S wave after it has reached its nadir). This interval is termed *R wave peak time* (in preference to the term *intrinsicoid deflection*). In the right precordial leads, the upper limit of normal for R wave peak time is 35 milliseconds, whereas in the left precordial leads, it is 45 milliseconds. In RBBB, the R wave peak time is delayed in the right precordial leads (more than 50 milliseconds).¹

Atypical Right Bundle Branch Block

Atypical RBBB can be caused by attenuation or loss of posterior deflections in the anteroposterior leads, resulting in an rsR' , qR , or M-shaped QRS pattern in V_1 . This pattern can be a normal variant, a consequence of a gain of midtemporal anterior forces secondary to RV enlargement or concurrent LAF block, or the result of a loss of posterior forces caused by a posterior wall MI.

Incomplete Right Bundle Branch Block

An incomplete RBBB can result from lesser degrees of conduction delay in the RB. The ECG pattern of incomplete RBBB is similar to that of complete RBBB, except that the QRS duration is between 110 and 120 milliseconds (see Fig. 10-9). An RBBB pattern with a QRS duration shorter than 100 milliseconds can be a normal variant, presumably reflecting a slight delay in the terminal posterobasal forces in some individuals.¹

The ECG pattern of incomplete or complete RBBB in association with a distinct ST segment elevation in the right precordial leads can be observed in the Brugada syndrome. The Brugada ECG pattern, however, is characterized by the absence of a wide terminal S wave in the left lateral leads (I, aVL, V_5 , V_6) and no broad terminal R wave in aVR, findings indicating that true RBBB is not present

TABLE 10-1 ECG Criteria for Fascicular and Bundle Branch Block

Complete Right Bundle Branch Block

- QRS duration ≥ 120 msec in adults
- Broad, notched secondary R waves (rsr' , rsR' , or rSR' patterns) in right precordial leads (V_1 and V_2); R' or r' deflection usually wider than the initial R wave; in a minority of patients, a wide and often notched R wave pattern may be seen in lead V_1 and/or V_2
- Wide, deep S waves (qRS pattern) of greater duration than R wave or greater than 40 msec in leads I and V_6
- Normal R wave peak time in leads V_5 and V_6 but >50 msec in lead V_1
- Of the foregoing criteria, the first three should be present to make the diagnosis; when a pure dominant R wave with or without a notch is present in V_1 , criterion 4 should be satisfied

Complete Left Bundle Branch Block

- QRS duration ≥ 120 msec in adults
- Broad notched or slurred R wave in leads I, aVL, V_5 , and V_6 and an occasional RS pattern in V_5 and V_6 attributed to displaced transition of QRS complex
- Absent q waves in leads I, V_5 , and V_6 , but in the lead aVL, a narrow q wave may be present in the absence of myocardial disease
- R wave peak time >60 msec in leads V_5 and V_6 but normal in leads V_1 , V_2 , and V_3 , when small initial r waves can be discerned in the above leads
- ST and T waves usually opposite in direction to QRS
- Positive T wave in leads with upright QRS may be normal (positive concordance)
- Depressed ST segment and/or negative T wave in leads with negative QRS (negative concordance) are abnormal
- Appearance of LBBB may change the mean QRS axis in the frontal plane to the right, to the left, or superiorly, in some cases in a rate-dependent manner

Left Anterior Fascicular Block

- Frontal plane axis between -45 and -90 degrees
- qR pattern in lead aVL
- R wave peak time in lead aVL ≥ 45 msec
- QRS duration < 120 msec

Left Posterior Fascicular Block

- Frontal plane axis between 90 and 180 degrees in adults
- rS pattern in leads I and aVL
- qR pattern in leads III and aVF
- QRS duration < 120 msec

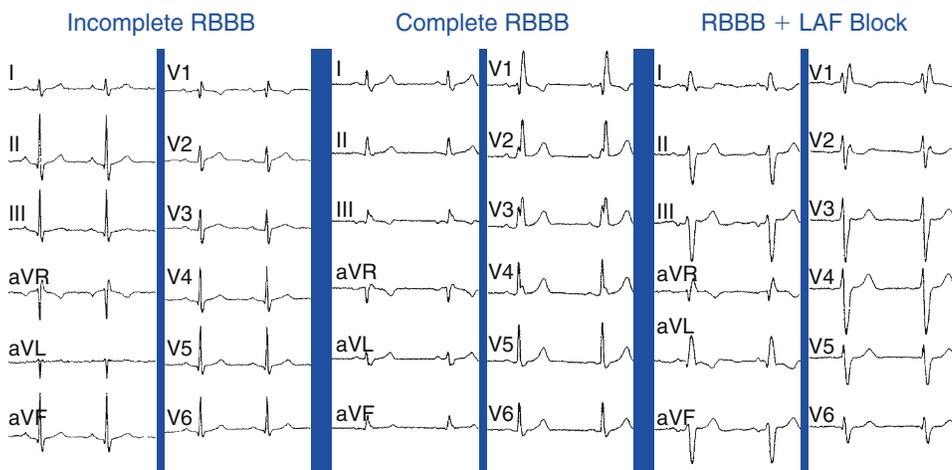

FIGURE 10-9 Surface ECG of incomplete and complete right bundle branch block (RBBB) and bifascicular block. LAF = left anterior fascicle.

(see Fig. 31-5). Additionally, the ECG manifestations of the Brugada syndrome are often dynamic or concealed and can be unmasked or modulated primarily by sodium channel blockers but also during a febrile state or with vagotonic agents.²⁸

LEFT BUNDLE BRANCH BLOCK

The normal sequence of ventricular activation is altered dramatically in LBBB. Complete LBBB results in delayed and abnormal activation and diffuse slowing of conduction throughout the LV. Activation of the LV originates from the RB in a right to left direction, in contrast to the normal situation in which the first part of the LV myocardium to be activated is the septum in a left to right direction via a small septal branch of the LB. Thus, LBBB results in reversal of the direction of the initial septal activation sequence (within the initial 30 milliseconds of the QRS complex), with the activation traveling from right to left and from apex to base and to the RV apex and free wall. RV activation is typically completed within the first 45 milliseconds of the onset of the QRS, before the onset of LV activation. However, because the septum is a larger structure than the RV free wall, septal activation predominates, eliciting a leftward and usually anterior vector and resulting in loss of the normal small q waves and initiation of a wide, slurred R wave in leads I, aVL, and V₆ and an rS or QS pattern in lead V₁ (Fig. 10-10). Thus, Q waves of a prior MI may disappear, and new Q waves can emerge.

Following septal activation, LV activation (starting as late as 44 to 58 milliseconds into the QRS) spreads slowly by conduction through working muscle fibers rather than the specialized conduction system, with spatial vectors oriented to the left and posteriorly because the LV is a leftward and posterior structure. As a consequence, the delayed LV activation (unopposed by the now completed RV activation) produces large, broad, and notched or slurred R waves (without q or s waves) in the leftward leads (I, aVL, and V₆), with delayed R wave peak time in the left precordial leads (more than 60 milliseconds). The slowing and notching of the mid-QRS portion are caused by slow transeptal conduction. The terminal activation vector results from depolarization of the anterolateral LV wall that produces a small vector that is also directed to the left and posteriorly.^{1,3,25}

The altered activation sequence also changes the sequence of repolarization. Both the ST segment and T wave vectors are discordant from the QRS complex.

Incomplete Left Bundle Branch Block

Incomplete LBBB can result from lesser degrees of conduction delay in the LB. Although LV activation begins abnormally on the right side of the septum (as in complete LBBB), much of the subsequent LV activation occurs via the normal conduction system. Incomplete LBBB is characterized by the following: (1) QRS duration of 110 to 119 milliseconds; (2) presence of an LV hypertrophy pattern; (3) R wave peak time longer than 60 milliseconds in leads V₄, V₅, and V₆; and (4) absence of q wave in leads I, V₅, and V₆ and frequent replacement by a slurred initial upstroke (pseudo-delta wave) (see Fig. 10-10). This entity can bear an ECG resemblance to a Wolff-Parkinson-White ECG pattern secondary to the delayed upstroke of the R wave, although the PR interval is usually short in Wolff-Parkinson-White syndrome, whereas it should be normal in cases of incomplete LBBB.¹

Fascicular Block

Hemiblocks in the LB system affect the LAF, LPF, or LMF. Fascicular block generally does not substantially prolong QRS duration, but alters only the sequence of LV activation. The primary ECG change is a shift in the frontal plane QRS axis because the conduction disturbance primarily involves the early phases of activation. The QRS duration is usually less than 100 milliseconds (unless complicated by BBB or hypertrophy), although some investigators allow a QRS duration of up to 120 milliseconds, or 20 milliseconds higher than the previous baseline.¹⁶⁻¹⁸

LEFT ANTERIOR FASCICULAR BLOCK

The LAF normally initiates activation in the upper part of the septum, the anterolateral LV free wall, and the left anterior papillary muscle. Delayed activation of these regions secondary to damage to the LAF causes unopposed activation wavefronts by the LPF and LMF early during the QRS complex and unopposed anterosuperior forces late during ventricular activation. All these changes occur with a QRS that widens no more than 20 milliseconds in pure and uncomplicated LAF block.¹⁶

As a consequence, the initial (first 20 milliseconds) QRS vector is normal in time, but it has an abnormal direction. Rather than proceeding superiorly and to the left, the QRS vector depicts an inferior and rightward shift in the frontal plane (frontal plane axis more than +120 degrees) that produces a small, sharp r wave in the

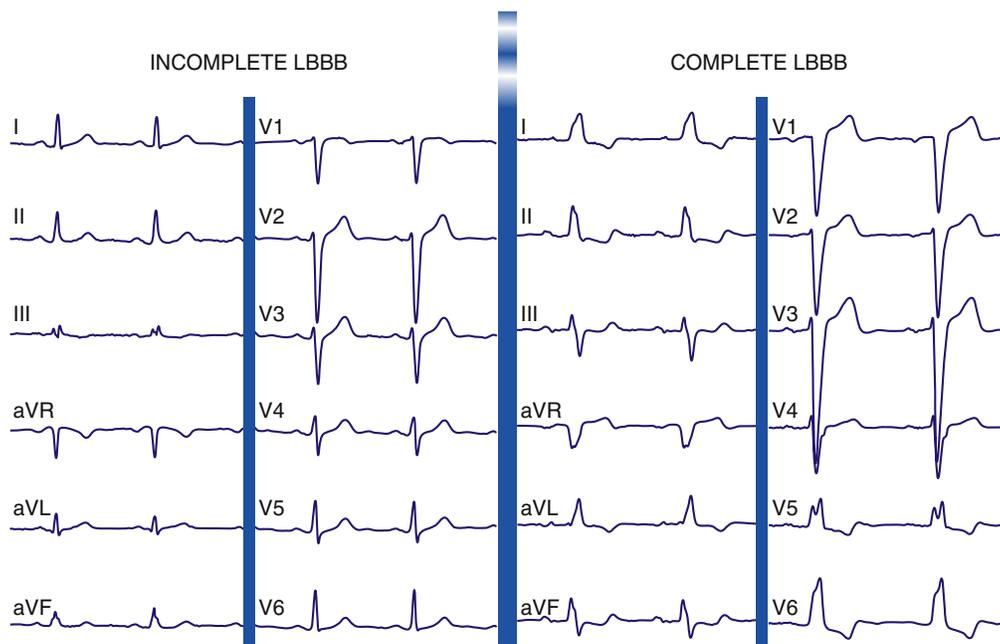

FIGURE 10-10 Surface ECG of incomplete and complete left bundle branch block (LBBB).

inferior leads (II, III, and aVF) and a small q wave in leads I, aVL, V₅, and V₆. Additionally, the inferior and rightward shift in the initial QRS forces can occasionally result in a small, sharp q wave in leads V₂ and V₃ (mimicking old anteroseptal infarction patterns) when the electrodes are placed at the normal level and, in almost all cases, when they are placed in a higher position.¹⁶

During the midportion of the QRS, the main forces of LV activation are oriented superiorly and to the left (frontal plane axis more than -45 or -60 degrees), with a wide-open counterclockwise-rotated loop in the frontal plane caused by the delayed activation of the high lateral wall, which is normally activated by the LAF. This results in deep S waves in leads II, III, and aVF (S wave deeper in lead III than in lead II), and R waves in aVR and aVL. The net effect is an rS pattern in leads II, III, and aVF and a qR or R pattern in leads I, aVL, V₅, and V₆. Additionally, as a result of the superiorly directed forces, deeper S waves are recorded in leads V₅ and V₆; these waves tend to disappear when the electrodes are placed above the normal level and are deeper when the electrodes are placed below the normal level.^{1,16-18}

The ECG pattern of LAF block can simulate LV hypertrophy in limb leads I and aVL. Conversely, it can conceal signs of LV hypertrophy in the left precordial leads, and it can also hide signs of inferior ischemia.

LEFT POSTERIOR FASCICULAR BLOCK

The early unopposed activation of the anterolateral wall of the LV by the normally conducting LAF and LMF causes the initial forces to be oriented superiorly and to the left, producing initial small r waves in leads I, aVL, V₁, and V₆ and small q waves in leads II, III, and aVF. However, the main and terminal forces of the QRS are directed posteriorly, inferiorly, and to the right with a wide-open clockwise-rotated loop, because of the late unopposed activation of the areas normally activated by the LPF (the inferoposterior LV free wall). This is responsible for the characteristic rightward frontal plane axis of $+120$ to $+180$ degrees. As a result, there is a qR morphology in leads II, III, and aVF and an rS morphology in leads I and aVL. In fact, the ECG pattern of LPF block is the exact mirror image of LAF block in the standard and unipolar leads. LPF block is almost always associated with RBBB. Isolated LPF block is extremely rare, and a firm diagnosis requires that other causes of right axis deviation have been excluded.^{1,16}

LEFT MEDIAN FASCICULAR BLOCK

The ECG pattern seen with LMF block is probably determined by the differences in the sites of insertion of the LMF, LAF, and LPF. Functional block in the LMF can lead to the apparent loss of anterior forces and can result in the transient development of q waves in leads V₁ and V₂, which normally have a positive initial deflection caused by septal depolarization. These changes are similar to those that occur in septal MI. On the other hand, prominent R waves are seen in the right precordial leads when LMF block leads to a gain of anterior forces. These changes are similar to those caused by true posterior MI. The prominence of the R waves may be increased when LMF block occurs in association with RBBB.

Other Types

NONSPECIFIC INTRAVENTRICULAR CONDUCTION DEFECTS

A nonspecific IVCD is the result of diffuse slowing of impulse conduction involving the entire HPS that causes a generalized and uniform delay in activation of the ventricular myocardium. A nonspecific IVCD is diagnosed in the presence of a QRS duration longer than 120 milliseconds and a QRS morphology that does not resemble either LBBB or RBBB and may even resemble the normal QRS complex. Nonspecific IVCDs can be classified as LV or RV IVCD, depending on the site of delayed R wave peak time and the direction of the terminal forces.

BIFASCICULAR BLOCKS

Bifascicular block refers to different combinations of fascicular block and BBB. Examples of bifascicular block include RBBB with LAF block (most common; see Fig. 10-9), RBBB with LPF block, and LAF block plus LPF block (which manifests as LBBB).

TRIFASCICULAR BLOCKS

Trifascicular block involves conduction delay in the RB and either the main LB or both the LAF and LPF. The resulting ECG pattern depends on the relative degree of conduction delay in the affected fascicles. Ventricular activation starts at the insertion site of the fastest conducting fascicle, with subsequent spread of activation from that site to the remainder of the ventricles. ECG documentation of trifascicular block during 1:1 AV conduction is rare. ECG manifestations of trifascicular block include the following: (1) complete AV block with a slow ventricular escape rhythm with a wide, bizarre QRS; (2) alternating RBBB and LBBB; and (3) fixed RBBB with alternating LAF and LPF block.

The combination of bifascicular block (RBBB plus LAF block, RBBB plus LPF block, or LBBB) with first-degree AV block on the surface ECG (Fig. 10-11) cannot be considered as trifascicular block because the site of AV block can be in the AVN or HPS, and such a pattern can reflect slow conduction in the AVN with concomitant bifascicular block. In such circumstances, the PR interval on the ECG does not appear to be helpful in selecting those individuals with a prolonged His bundle–ventricular (HV) interval because a normal PR interval can easily conceal a significantly prolonged HV interval and a prolonged PR interval can be caused by a prolonged atrial–His bundle (AH) interval. However, two criteria can be of value: (1) a short PR interval (less than 160 milliseconds) makes a markedly prolonged HV interval (i.e., more than 100 milliseconds) unlikely, and (2) a markedly prolonged PR interval (more than 300 milliseconds) almost always indicates that at least some of the abnormality, if not all, is caused by AVN conduction.

ALTERNATING BUNDLE BRANCH BLOCK

Alternating RBBB and LBBB is manifested by QRS complexes with LBBB morphology coexisting with complexes with RBBB morphology (Fig. 10-12). Often, every other complex is an RBBB or LBBB. Spontaneous alternating BBB, especially when associated with a change in the PR interval, represents the most common ominous sign for progression to AV block (Fig. 10-13). Beat-to-beat alternation is the most concerning, whereas a change in BBB noted on different days is less ominous.

This phenomenon implies instability of the HPS and a disease process involving the HB or bundle branches. In most patients with diffuse HPS disease, delay or block in one of the bundle branches consistently predominates, and alternating BBB is uncommon. The HV interval in alternating BBB is almost universally prolonged and typically varies with the change in BBB. This group has the highest incidence of HV interval exceeding 100 milliseconds.³

Alternating BBB is infrequent but is associated with the most predictable progression to complete AV block (70% of patients develop high-grade AV block within weeks of diagnosis). As a rule, AV conduction delay or block can be assumed to be caused by BBB only in the presence of an alternating or intermittent RBBB and LBBB with a changing PR interval. Not infrequently, the bilateral BBB is caused by acceleration-dependent aberration.

INTERMITTENT BUNDLE BRANCH BLOCK

Intermittent BBB, either right or left, is diagnosed on the surface ECG when there are occasional QRS complexes with RBBB or LBBB morphology, interspersed with QRS complexes that have a normal morphology. Most often, the intermittent BBB is rate-related; thus, the R-R intervals of the QRS complexes manifesting the BBB are shorter when compared with the intervals of the normal QRS complexes. In other cases, there is no rate-related change in the QRS intervals, but the occurrence of the BBB is a random or sporadic event.

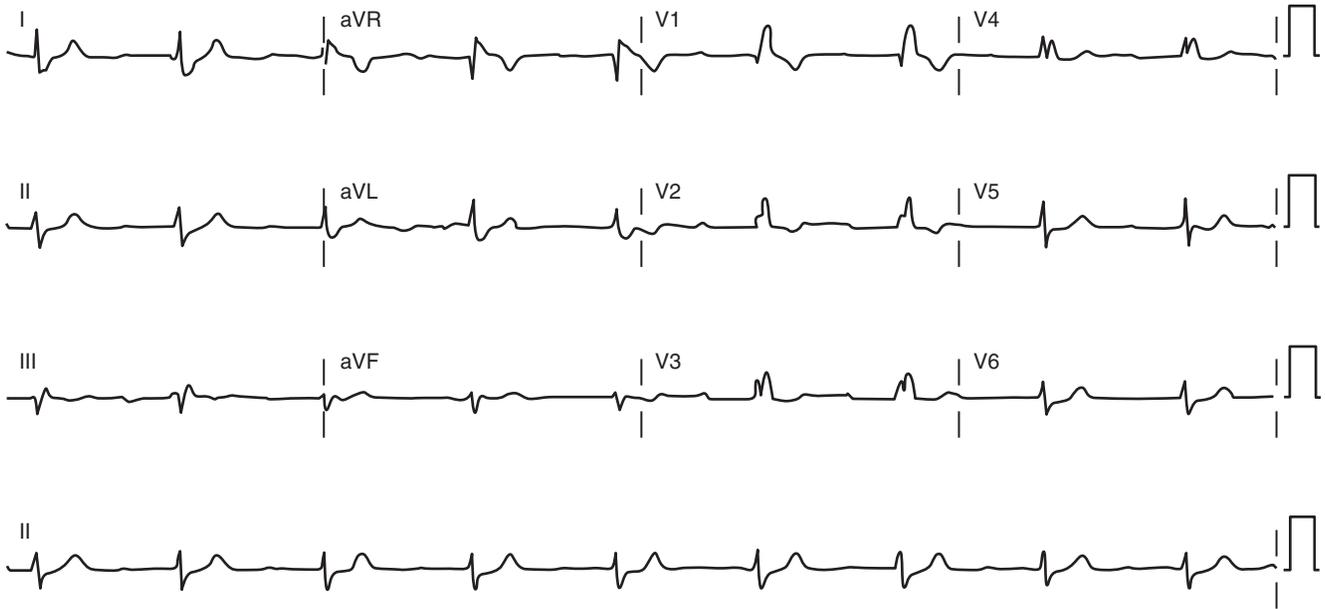

FIGURE 10-11 Surface ECG of sinus rhythm with first-degree atrioventricular (AV) block and bifascicular block (right bundle branch block and left anterior fascicular block). The PR interval is markedly prolonged (480 msec), which suggests that at least some of the AV conduction delay, if not all, occurs in the atrioventricular node and is not exclusively in the His-Purkinje system. A diagnosis of trifascicular block cannot be made solely based on this ECG.

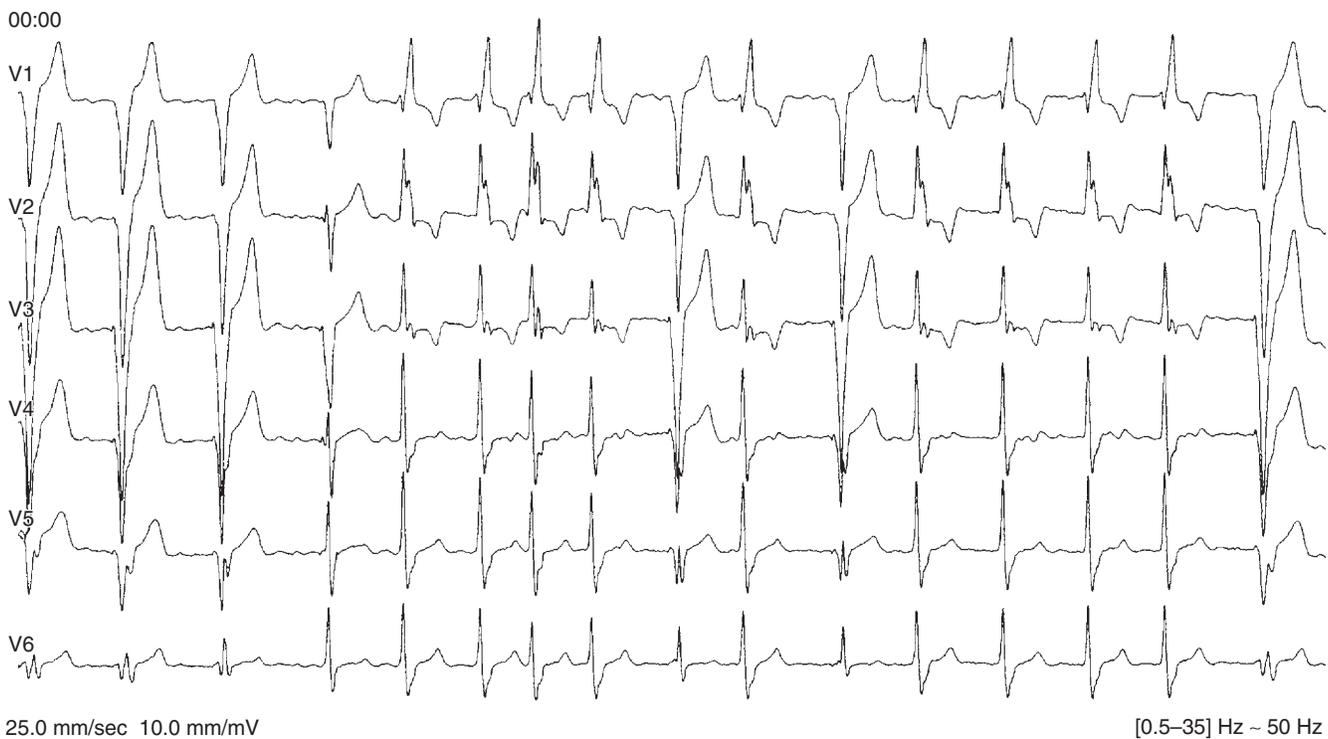

FIGURE 10-12 Alternating bundle branch block: surface ECG precordial leads during atrial fibrillation. QRS complexes with left bundle branch block configuration are observed mostly at long cycle lengths, and complexes with right bundle branch block configuration are observed mostly at shorter cycle lengths.

Electrophysiological Testing

Baseline Intervals

HIS BUNDLE–VENTRICULAR INTERVAL

The use of multipolar catheters to record distal, middle, and proximal HB potentials can help localize the site of conduction delay or block within the HB. The value of prolonged HV interval in predicting the risk of AV block is controversial. Studies have shown that an HV interval longer than 70 milliseconds predicts a higher

risk of AV block, especially in symptomatic patients. The risk of AV block, however, even in the high-risk group, approaches at most only 6% per year. An HV interval exceeding 100 milliseconds identifies a group of patients at a very high risk of AV block (25% over 22 months).³

In the presence of RBBB with or without additional fascicular block, the HV interval should be normal as long as conduction is unimpaired in the remaining fascicle (Fig. 10-14). However, 50% of patients with RBBB plus LAF block and 75% of those with LBBB have a prolonged HV interval; thus, a prolonged HV interval itself is nonspecific as a predictor of AV block.

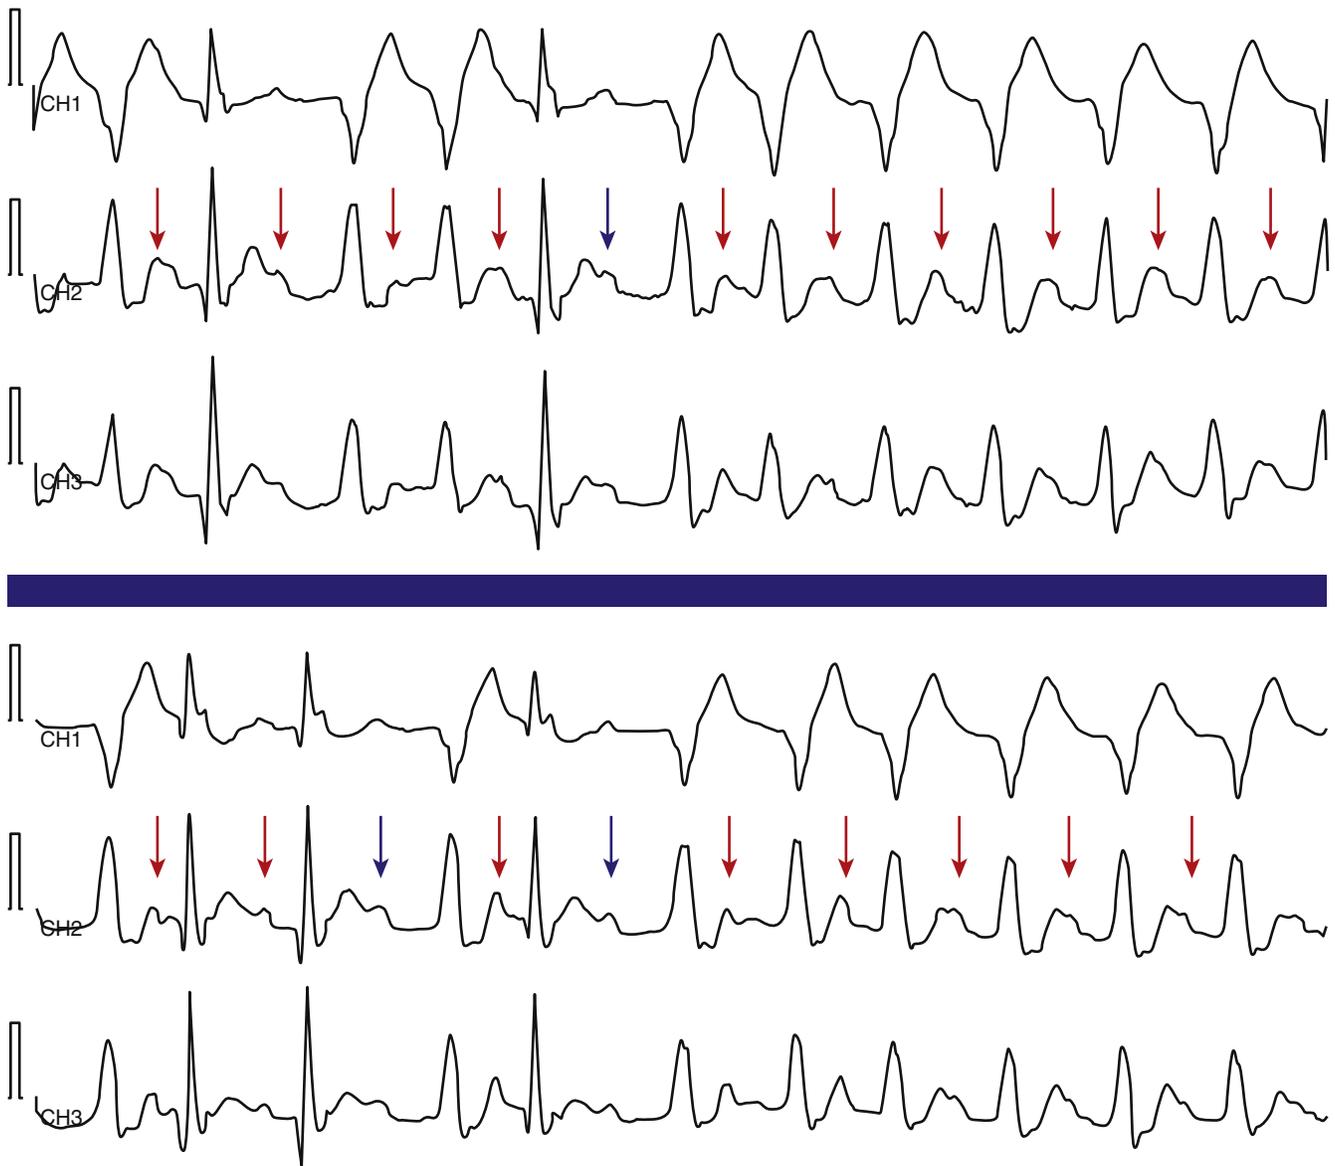

FIGURE 10-13 Alternating bundle branch block. Continuous Holter three-lead recordings demonstrating sinus rhythm with first-degree atrioventricular (AV) block and right bundle branch block (RBBB) alternating with left bundle branch block (LBBB). Arrows denote sinus P waves, which are commonly masked by the preceding T waves. Note that sinus beats conducted with RBBB are associated with shorter PR intervals compared with those conducted with LBBB. This suggests that conduction delay in the right bundle branch (RB) is more severe than that in the left bundle branch (LB); hence, the PR interval is longer when conduction occurs only over the RB (i.e., with LBBB pattern), but shorter when conduction occurs only over the LB (i.e., with RBBB pattern). The first sinus P waves to conduct with LBBB (blue arrows) are associated with the longest PR intervals, with subsequent P waves conducting with somewhat shorter PR intervals, resulting in gross irregularity of the QRS complexes despite relatively regular sinus P waves. These findings are suggestive of severe His-Purkinje system disease and high risk for complete AV block.

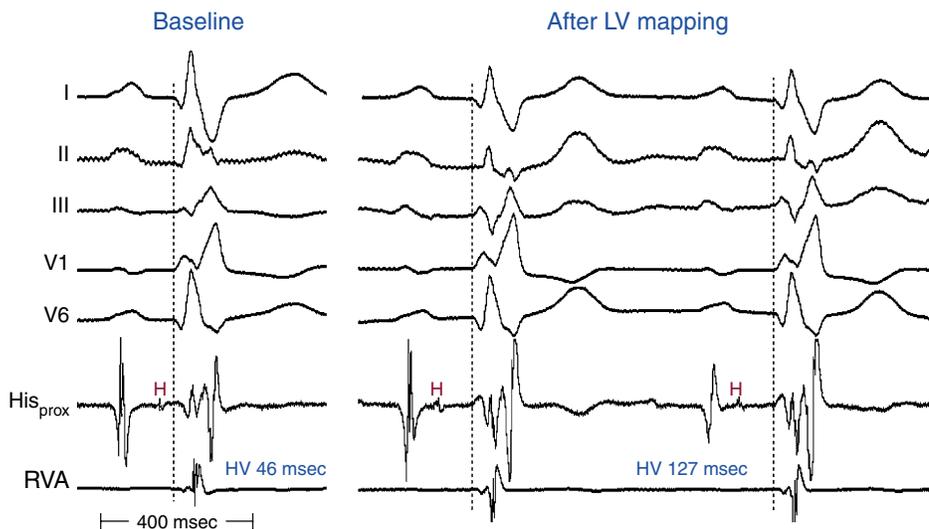

FIGURE 10-14 Catheter-induced His bundle-ventricular (HV) interval prolongation. Right bundle branch block with a normal HV is present at baseline (at left). Prolongation of the HV interval is observed after introducing a mapping catheter into the left ventricle that traumatized a portion of the His-Purkinje system. The QRS is also slightly different from baseline. His_{prox} = proximal His bundle; RVA = right ventricular apex.

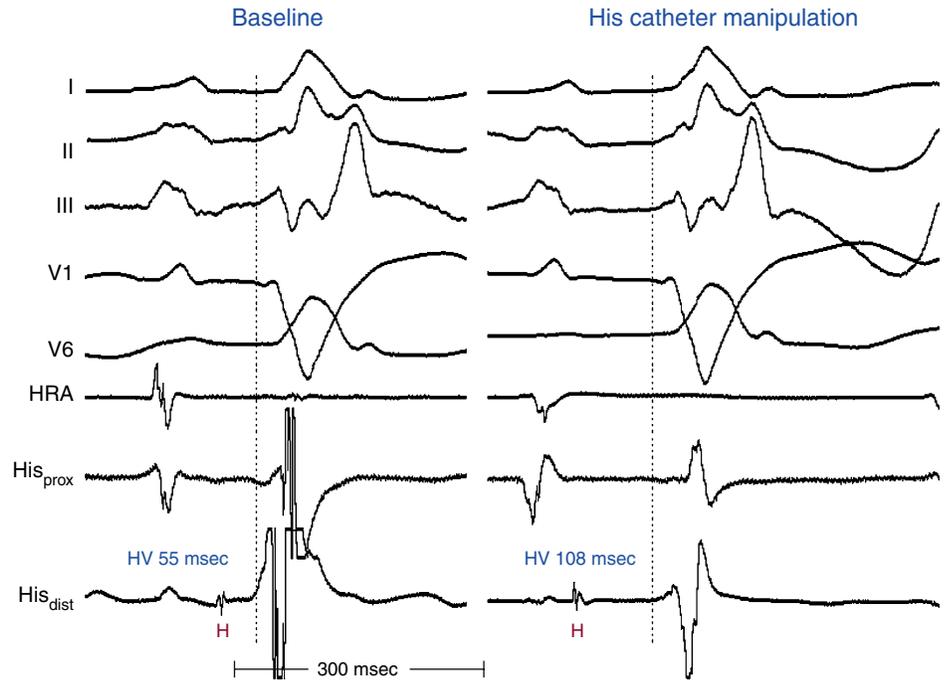

FIGURE 10-15 Catheter-induced His bundle-ventricular (HV) interval prolongation. Left bundle branch block (LBBB) and HV interval at the upper limit of normal are observed at baseline (at left). Manipulation of the His bundle recording catheter results in prolongation of the HV interval. This is not an artifact of the location of His recording, because the PR interval is also prolonged. There is no change in the QRS complex (LBBB pattern), suggesting trauma to the right bundle (RB) or His fibers destined to the RB. His_{dist} = distal His bundle; His_{prox} = proximal His bundle; HRA = high right atrium.

In the presence of LBBB, and in the absence of a change in the HB-RB and HB-RV intervals, the HV interval may be slightly prolonged because the earliest site of depolarization on the left side of the septum via the LB precedes activation of the RB by 5 to 15 milliseconds. Therefore, an HV interval of up to 60 milliseconds in the presence of LBBB should be considered normal and does not by itself indicate associated RB or HB disease (Fig. 10-15).³

Catheter manipulation in the LV or RV can inadvertently produce prolongation of the HV interval and varying degrees of AV block or BBB, or both, usually temporarily (see Figs. 10-14 and 10-15). Complete heart block can occur during right-sided heart catheterization in a patient with preexisting LBBB or during LV catheterization (LV angiography or ablation procedures) in a patient with preexisting RBBB. Among patients with chronic LBBB, the presence of an r wave of more than 1 mm in lead V₁ appears to identify a subgroup at lower risk for complete AV block in response to catheter trauma to the RB. This ECG sign likely suggests intact conduction over the septal fibers of the LBB.²⁹

LOCALIZATION OF THE SITE OF BLOCK IN RIGHT BUNDLE BRANCH BLOCK

As noted, a chronic RBBB pattern can result from three levels of conduction delay in the RV: proximal RBBB, distal RBBB at the level of the moderator band, and terminal RBBB involving the distal conduction system of the RB or, more likely, the muscle itself.

With proximal RBBB, loss of RB potential occurs where it is typically recorded. Activation at these RV septal sites is via transseptal spread following LV activation. The transseptal activation begins at the apex and then sequentially activates the midanterior wall and base of the RV. The midseptum and apical septum are activated at least 30 milliseconds after the onset of the QRS.

In the setting of distal RBBB, activation of the HB and proximal RB is normal. RB potentials persist at the base of the moderator band and are absent at the midanterior wall (where the moderator band normally inserts). The apical and midseptum are normally activated, but activation of the free wall at the level of the moderator band is delayed, as is the subsequent activation of the RV outflow tract (RVOT) and the remaining RV.

With terminal RBBB, activation along the HB and RB remains normal up the Purkinje-myocardium junction. Activation of the midanterior wall also remains normal, and only the RVOT shows delayed activation.

Measurement of activation times at different areas of the RV has been used to assess conduction properties of the RB indirectly. In the presence of RBBB, measuring the HV interval, HB-proximal RB interval, ventricular-RV (V-RV) apex interval (from onset of the surface QRS to RV apical local activation), and V-RVOT interval can help localize the site of block (Fig. 10-16). In the presence of RBBB, a normal HV interval and a V-RV apex interval of less than 30 milliseconds suggest terminal RBBB. On the other hand, a normal HV interval and a V-RV apex interval of less than 30 milliseconds, with delayed activation in the anterior wall (prolonged V-RVOT interval), suggest distal RBBB. With proximal RBBB, the V-RV apex interval is longer than 30 milliseconds.

LOCALIZATION OF THE SITE OF BLOCK IN LEFT BUNDLE BRANCH BLOCK

Measurement of activation times at different areas of the LV to assess conduction properties of the LB, LAF, and LPF indirectly has many limitations. It is not as feasible as that used for evaluation of the RB, mainly because the LB does not divide into two discrete fascicles, but it rapidly fans out over the entire LV. Therefore, for practical reasons, clinical evaluation has primarily focused on the surface ECG pattern and the HV interval.

In chronic LBBB, RV activation occurs relatively earlier in the QRS. A discrete LV breakthrough site is absent, in contrast to normal findings, in which two or three breakthrough sites may be seen. Moreover, transseptal conduction is slow. In LBBB with normal axis, the latest LV site activated is the AV sulcus, as it is with normal conduction.

A common observation in patients with LBBB is a delay in transseptal activation. The pattern in which the LV is activated initially (i.e., the site of breakthrough), as well as the remainder of the LV endocardium and transmural activation, depends critically on the nature of the underlying heart disease; the bizarreness of the QRS width and morphology is more a reflection of the underlying LV disease than of the primary conduction disturbance.³ Patients with normal hearts and those with cardiomyopathy appear to have an intact distal conducting system and, hence, early engagement and rapid spread throughout the rest of the intramural myocardium. In patients with large infarcts, the bulk of their distal specialized conducting system has been destroyed; consequently, endocardial activation occurs via muscle-to-muscle conduction and thus is much slower.

Diagnostic Maneuvers

ATRIAL EXTRA STIMULATION

Atrial premature stimulation helps determine the ERP of HPS. Normally, the HPS ERP is 450 milliseconds or less and it decreases with decreasing pacing drive CL. Because the AVN functional refractory period usually exceeds the HPS ERP it can be difficult to evaluate the HPS ERP. Administration of atropine can help decrease AVN refractoriness and allow impulses to reach the HPS earlier so that HPS ERP can be determined. A grossly prolonged HPS ERP or a paradoxical increase in the HPS ERP in response to shortening of the pacing drive CL indicates an abnormal HPS and predicts a higher risk for progression to AV block.

ATRIAL PACING

During incremental-rate atrial pacing, normal shortening of the HPS refractoriness at decreased pacing CLs facilitates 1:1 AV conduction. The development of second- or third-degree AV block within the HPS (in the absence of changing AH intervals) at pacing CLs longer than 400 milliseconds is abnormal and suggests a high risk (50%) for progression to high-grade AV block (Fig. 10-17).

HIS BUNDLE PACING

Normalization of the QRS during HB pacing is suggestive of HB disease proximal to the pacing site (Fig. 10-18).

VENTRICULAR PACING

Assessment of retrograde VH (or VA) conduction is not useful as an indicator of anterograde HPS reserve. Anterograde RBBB is usually

proximal, whereas during RV stimulation, block usually occurs at the gate, which is at the distal HPS–myocardial junction. Bidirectional RBBB is characterized by His activation following local ventricular activation in the HB recording, caused by propagation from the RV pacing site across the interventricular septum to the LB and then to the HB, rather than the more direct retrograde route up the RB (Fig. 10-19).

PROCAINAMIDE CHALLENGE

The administration of drugs known to impair the HPS (e.g., procainamide) can unmask extraordinary sensitivity to the usual therapeutic doses of the drug, which can itself indicate poor HPS reserve. In normal persons and in most patients with a moderately increased HV interval (55 to 80 milliseconds), procainamide typically produces a 10% to 20% increase in the HV interval. Abnormal HV interval responses to procainamide representing evidence of a higher risk for infra-Hisian AV block include any of the following: (1) doubling of the HV interval, (2) prolongation of the HV interval to more than 100 milliseconds, or (3) second- or third-degree infra-Hisian block.

Role of Electrophysiological Testing

The guidelines for pacing in chronic BBB are listed in Table 10-2. EP testing is used to obtain information that could predict which patients are at risk for syncope, AV block, or sudden cardiac death (Table 10-3).^{3,18} Complete EP testing with programmed atrial and ventricular stimulation is necessary in patients with syncope and BBB because VT can be induced in 30% to 50% of such patients. Pacemaker therapy clearly can help prevent syncope in those patients in whom that event most likely was caused by transient bradyarrhythmia, but it has not been shown to prevent sudden cardiac death or reduce cardiac mortality.^{3,18,30}

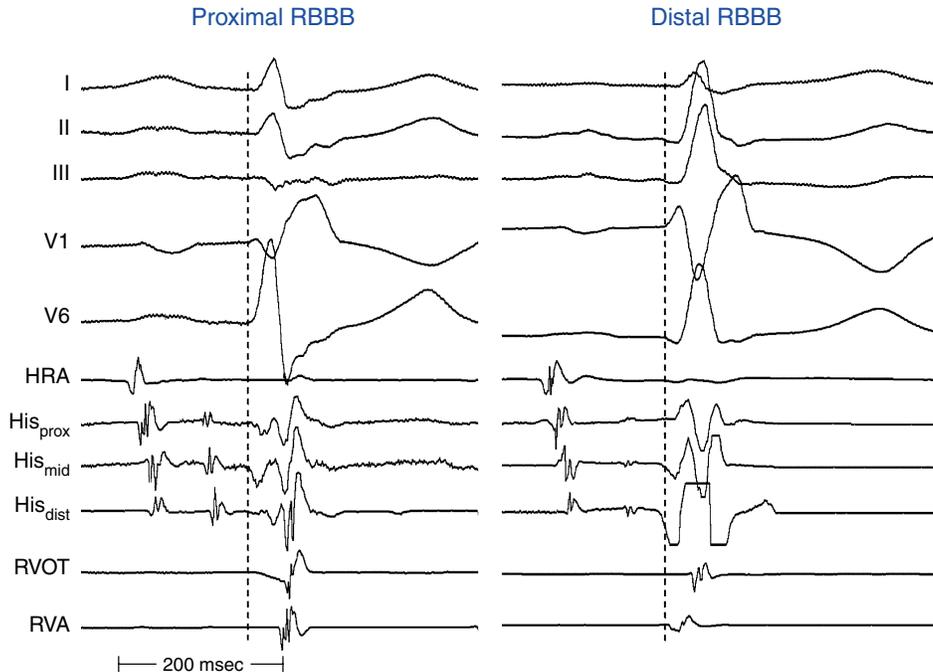

FIGURE 10-16 Localization of the site of block in right bundle branch block (RBBB). Two complexes from different patients are shown, with proximal (left panel) and distal (right panel) RBBB, distinguished by the interval from QRS onset to right ventricle apical (RVA) recording. His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle; RVA = right ventricular apex; RVOT = right ventricular outflow tract.

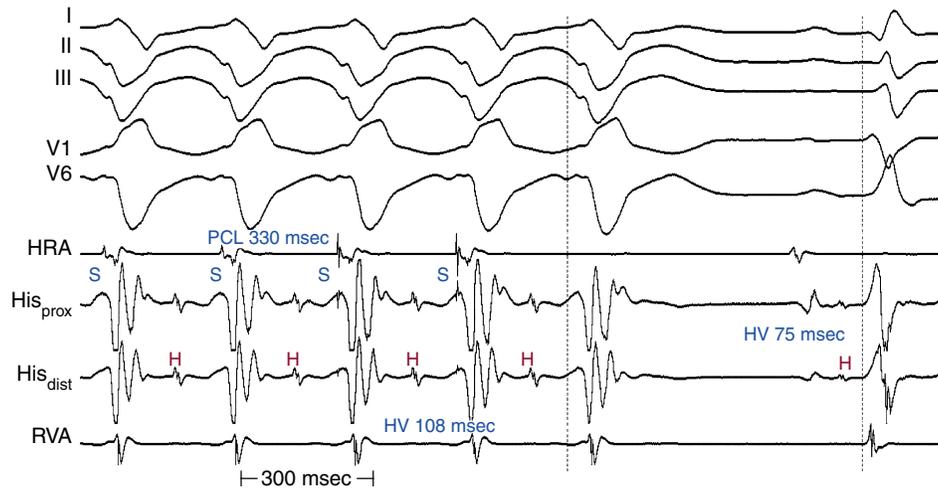

FIGURE 10-17 His-Purkinje system (HPS) disease. The PR interval is borderline (210 milliseconds), and the His bundle–ventricular (HV) interval is prolonged (75 milliseconds) during normal sinus rhythm (at right). Atrial pacing at a cycle length of 330 milliseconds results in stressing the HPS and further prolonging the HV interval (108 milliseconds). Right bundle branch block also develops during atrial pacing, a finding suggesting slower conduction over the right bundle than the left bundle. His_{dist} = distal His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; PCL = pacing cycle length.

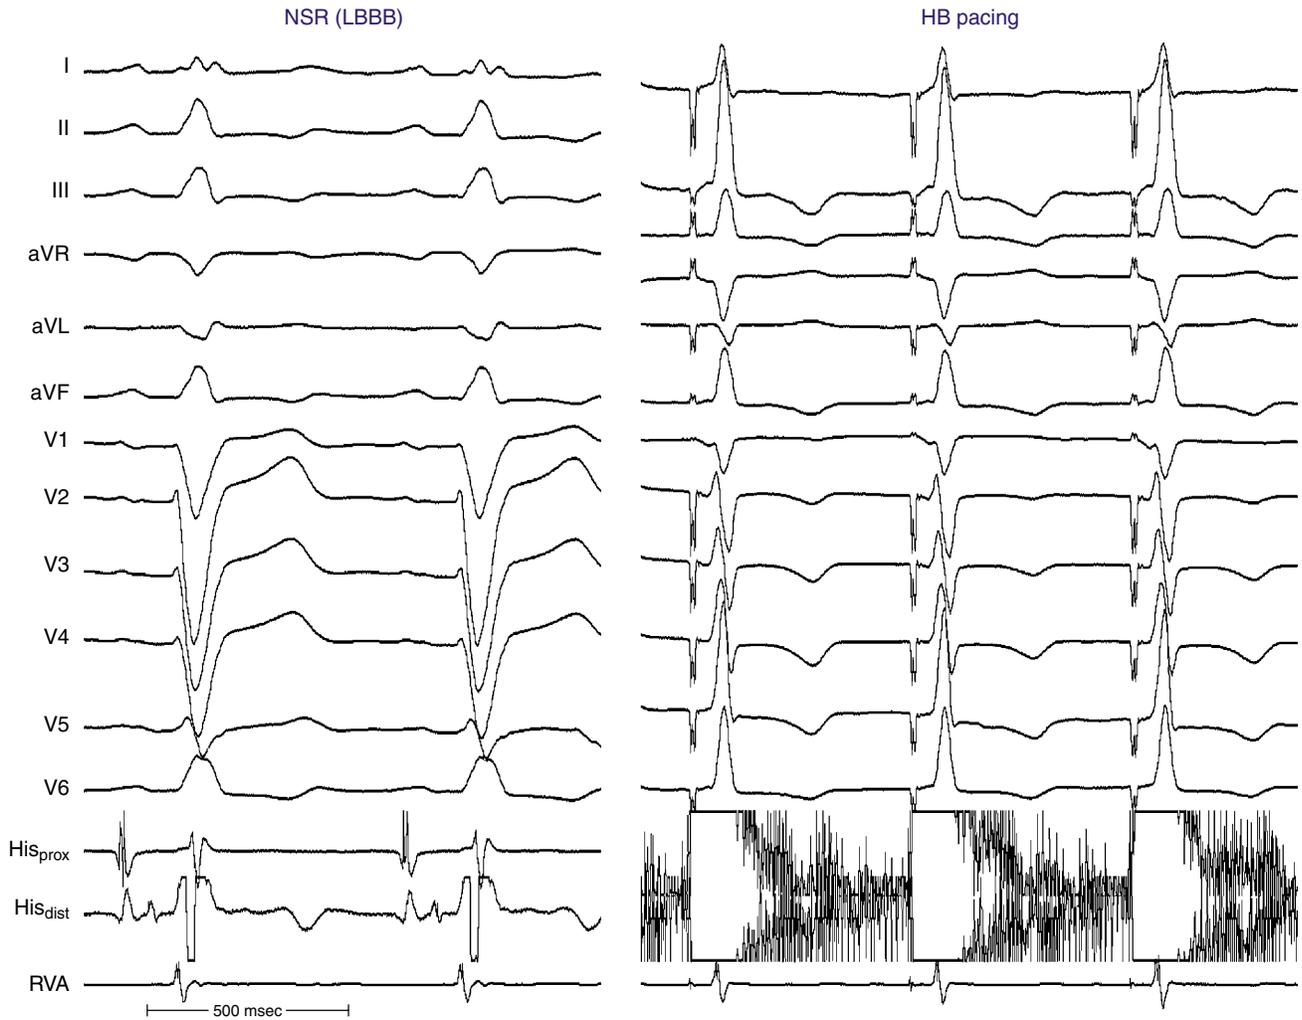

FIGURE 10-18 Left bundle branch block (LBBB) secondary to intra-Hisian disease. **Left**, ECG leads and intracardiac recordings in a patient with complete LBBB. **Right**, Pacing from the His bundle (HB) pacing normalizes the QRS complex, a finding suggesting that the LBBB is caused by HB disease proximal to the pacing site. His_{dist} = distal His bundle; His_{prox} = proximal His bundle; NSR = normal sinus rhythm; RVA = right ventricular apex.

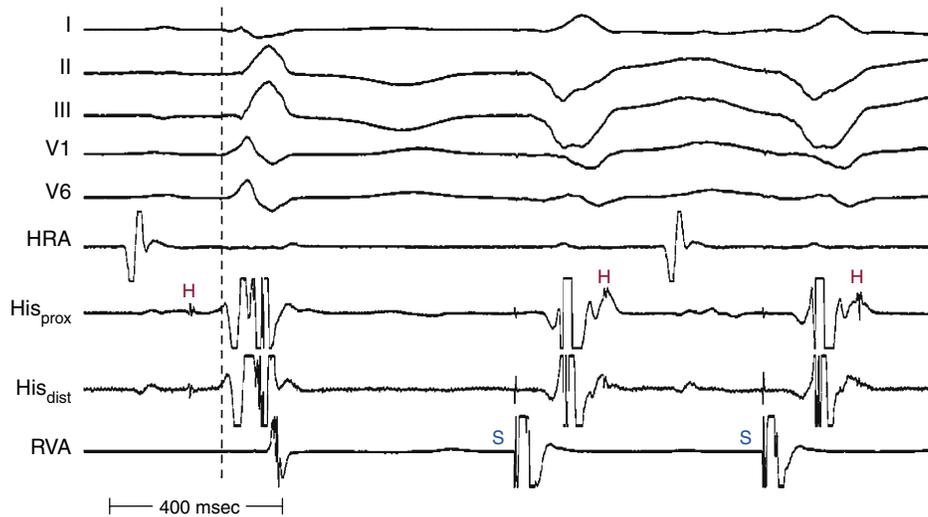

FIGURE 10-19 Bidirectional right bundle branch block (RBBB). The sinus complex at left has proximal RBBB, indicated by a very prolonged ventricular–right ventricular apical (V-RVA) time (more than 100 milliseconds). RV pacing with the next two complexes show His activation following local ventricular activation in the His bundle (HB) recording, caused by propagation from the RV pacing site across the interventricular septum to the left bundle and then to the HB, rather than the more direct route retrogradely up the right bundle. This is consistent with both anterograde and retrograde proximal RBBB. His_{dist} = distal His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; RVA = right ventricular apex.

TABLE 10-2 Guidelines for Permanent Pacing in Chronic Bifascicular and Trifascicular Block

Class I

- Advanced second-degree AV block or intermittent third-degree AV block
- Type 2 second-degree AV block
- Alternating bundle branch block

Class IIa

- Syncope not demonstrated to result from AV block, when other likely causes have been excluded, especially ventricular tachycardia
- Incidental finding at EP study of HV interval ≥ 100 msec
- Incidental finding at EP study of pacing-induced block below the bundle of His that is not physiological

Class IIb

- Neuromuscular diseases, with or without symptoms

Class III

- Fascicular block without AV block or symptoms
- Fascicular block with first-degree AV block without symptoms

AV = atrioventricular; EP = electrophysiological; HV = His bundle–ventricular.

TABLE 10-3 Role of Electrophysiological Testing in Patients with Bundle Branch Block

EP Indicators of HPS Disease

- HV interval > 55 msec
- Infra-Hisian block at atrial pacing CL ≥ 400 msec
- HPS ERP ≥ 450 msec
- HPS ERPs inversely related to pacing CLs
- Abnormal response to procainamide: prolongation of the HV interval by 100% or to > 100 msec, or second- or third-degree infra-Hisian AV block

EP Indicators of High Risk for AV Block in Patients with IVCD

- HV interval > 100 msec
- Infra-Hisian AV block or HV interval prolongation at atrial pacing CL > 400 msec
- HPS-ERPs inversely related to pacing CLs
- Infra-Hisian AV block or doubling of the HV interval following procainamide in patients with neurological symptoms compatible with bradyarrhythmia

Recommendations for Pacing in Patients with IVCD

- LBBB, RBBB, IVCD, RBBB + LAF block, or RBBB + LPF block associated with the following: HV interval > 100 msec or HV interval = 60–99 msec in the presence of unexplained syncope or presyncope
- Infra-Hisian block at atrial pacing CL ≥ 400 msec (regardless of HV interval or presence of symptoms)
- Alternating BBB (regardless of HV interval or presence of symptoms)

AV = atrioventricular; BBB = bundle branch block; CL = cycle length; EP = electrophysiological; ERP = effective refractory period; HPS = His-Purkinje system; HV = His bundle–ventricular; IVCD = intraventricular conduction defect; LAF = left anterior fascicle; LBBB = left bundle branch block; LPF = left posterior fascicle; RBBB = right bundle branch block.

Classification of Atrial Tachycardias

Previous classification of regular atrial tachycardias (ATs) had been based exclusively on the surface electrocardiogram (ECG). According to this classification, AT is defined as a regular atrial rhythm at a constant rate greater than 100 beats/min originating outside the sinus node region. The mechanism can be caused by focal pacemaker activity (automaticity or triggered activity) or reentry (microreentry or macroreentry). Atrial flutter (AFL) refers to a pattern of regular tachycardia with a rate of 240 beats/min or more (tachycardia cycle length [CL] 250 milliseconds or less) lacking an isoelectric baseline between deflections. Differentiation between AFL and AT depends on a rate cutoff of approximately 240 to 250 beats/min and the presence of an isoelectric baseline between atrial deflections in AT, but not in AFL. Atypical AFL is only a descriptive term for an AT with an ECG pattern of continuous undulation of the atrial complex, different from typical clockwise or counterclockwise isthmus-dependent AFL, at an atrial rate of 240 beats/min or more.

This ECG classification, however, has several major limitations. Neither rate nor lack of isoelectric baseline is specific for any tachycardia mechanism. Rapid ATs in a diseased atrium can mimic AFL. On the other hand, true AFL may show distinct isoelectric intervals between flutter waves. This dilemma is not solvable in terms of analyses of routine ECGs. Moreover, AT mechanisms, defined by electrophysiological (EP) studies and radiofrequency (RF) catheter ablation, do not correlate with ECG patterns as defined currently.

Therefore, ECG-based classifications are obsolete for this purpose, and a mechanistic classification of ATs has been proposed (Table 11-1).^{1,2} If the mechanism of AT or AFL can be elucidated, either through conventional mapping and entrainment or with special multipoint mapping techniques, description of the mechanism should be stated. However, even when using this classification, there are other tachycardias described in the literature that cannot be well classified because of inadequate understanding of their mechanisms, including “type II” AFL, inappropriate sinus tachycardia, and fibrillatory conduction from a focal source with rapid, regular discharge.

This chapter discusses focal AT. Typical AFL and macroreentrant AT are discussed in subsequent chapters.

Pathophysiology

Focal AT is characterized by atrial activation starting rhythmically at a small area (focus), from which it spreads out centrifugally.¹ “Focal” implies that the site of origin cannot be mapped spatially beyond a single point or a few adjacent points with the resolution

of a standard 4-mm-tip catheter. In contrast, macroreentrant AT is defined by activation that can be recorded over the entire tachycardia CL around a large central obstacle, which is generally several centimeters in diameter.¹ Relatively small reentry circuits may resemble focal AT, especially if limited numbers of endocardial recordings are collected. The term *localized reentry* has been used to refer to reentry in which the circuit is localized to a small area (covering a surface diameter of less than 3 cm) and does not have a central obstacle. Focal AT CL is usually longer than 250 milliseconds; however, it can be as short as 200 milliseconds. Over a prolonged period of observation (minutes to hours), the AT CL can exhibit significant variations.

Most focal ATs arise from the right atrium (RA), approximately two thirds of which are distributed along the long axis of the crista terminalis (cristal tachycardias) from the sinus node to the coronary sinus (CS) and atrioventricular (AV) junction (called the “ring of fire”), with an apparent gradation in frequency from superior to inferior.^{3,4} This particular anatomical distribution of ATs may be related to the marked anisotropy characterizing the region of the crista terminalis. Such anisotropy, which is related to the poor transverse cell-to-cell coupling, favors the development of microreentry by creating regions of slow conduction. Fractionated electrograms often seen at a successful AT ablation site may be markers of the requisite nonuniformly anisotropic substrate. In addition, the normal sinus pacemaker complex is distributed along the long axis of the crista terminalis. The presence of automatic tissue, together with relative cellular uncoupling, may be a requirement for abnormal automaticity such that a normal atrium is prevented from electrotonically inhibiting abnormal phase 4 depolarization. The presence of structural heart disease increases the probability of RA location of the AT, but from sites outside the crista terminalis.

The pulmonary vein (PV) ostia are the most common sites of origin of focal tachycardias within the left atrium (LA), and they account for between 3% and 29% of all focal ATs and approximately 67% of LA ATs.⁵⁻⁷ Other sites of AT clustering include the CS ostium (CS os),^{4,8-11} mitral and tricuspid annuli,^{3,5,12,13} bases of RA and LA appendages, para-Hisian region, and atrial septum. Experience gained during catheter ablation of atrial fibrillation (AF) has indicated that focal ATs also can arise within the vein of Marshall, superior vena cava (SVC),¹⁴ or inferior vena cava (IVC). ATs have been described originating from the noncoronary cusp of the aortic valve. The distribution of AT foci may differ, depending on the patient population.^{15,16}

Available information suggests that focal activity can be caused by automaticity, triggered activity, or microreentry. There is some overlap based on the pharmacological characterization of these different AT mechanisms. Delineating the mechanism of focal AT, however, can be difficult, and the means of distinguishing focal

AT mechanisms are fraught with exceptions.¹⁷ The major limiting factor in the analysis of mechanisms is the absence of a gold standard for determining the tachycardia mechanism, so these remain largely descriptive. In addition, there is a significant overlap in the EP characteristics of tachycardias with differing mechanisms.¹⁸ It is especially difficult to discriminate definitively between triggered activity and microreentry as a mechanism of focal AT; therefore, some investigators have classified focal ATs as automatic or nonautomatic.¹ Furthermore, it is not clear that making such mechanistic distinctions among various types of focal ATs carries any clinical significance, although it is possible that such information could be useful in guiding drug therapy. In contrast, determination of the likely focal versus macroreentrant mechanism is critical for planning mapping and ablation strategy.

The term “incessant” is applied to an AT that is present for at least 50% of the time that a patient is monitored.¹⁹ Incessant AT frequently is automatic, but it can also be secondary to reentry or triggered activity. Incessant tachycardias occur in approximately 25% of patients with focal AT. Foci arising from the atrial appendages and PVs are frequently incessant.²⁰

Arrhythmias originating from the PVs can have a critical role in the development of AF in susceptible individuals. Focal ATs arising from the PVs, however, appear to be a distinct clinical entity from the PV arrhythmias associated with AF. Patients with focal PV ATs do not seem to be at risk of AF in the long term; they resemble patients with focal ATs originating elsewhere with a localized isolated substrate that is successfully addressed with a focal ablative approach. Several potential explanations have been suggested for the different behavior. The underlying pathophysiological process in patients with AF is probably fundamentally different. It is a generalized process diffusely affecting the muscular sleeves in all four PVs, with frequently multiple PV foci originating distally (up to 2 to 4 cm) within the vein, compared with the focal nature of the process in patients with isolated PV tachycardia. Additionally, the CLs of the PV ATs are longer (mean CL 340 milliseconds) than the reported CLs of PV tachycardia in AF patients (130 milliseconds). The CL of AT also tends to be irregular in patients with AF but not in patients with PV AT. It is possible that foci with shorter CL and irregular activity may not conduct in a 1:1 fashion from the PV to the LA, with resulting fibrillatory conduction and AF. Furthermore, patients with AF tend to be older than those with PV AT and consequently more prone to more widespread atrial remodeling associated with age, hypertension, or other pathologic processes.^{6,7,21,22}

Up to 10% of patients with focal AT have ATs with more than one focus. In these patients, the AT appears to have different EP characteristics from focal AT with a single focus, because it tends to involve the LA and has greater cardiovascular comorbidity, shorter CL, longer total activation time, and lower acute and long-term success rates of catheter ablation.²³

Other forms of AT in which EP testing and catheter ablation are not indicated are beyond the scope of this chapter and are

discussed briefly. Multifocal AT is usually caused by enhanced automaticity and is characterized by varying morphology of the P waves and the PR interval (Fig. 11-1). This finding suggests that the pacemaker arises in different atrial locations, but a single focus with different exit pathways or abnormalities in intraatrial conduction can produce identical electrocardiographic manifestations. Nonparoxysmal AT typically occurs in patients with significant heart disease or digitalis toxicity, or both. The latter may be caused by triggered activity. Repetitive automatic AT, also called repetitive focal AT, is thought to be caused in most cases by enhanced automaticity. It frequently occurs in patients with structural heart disease and is often related to some acute event, such as a myocardial infarction, pulmonary decompensation, infection, alcohol excess, hypokalemia, hypoxia, or use of stimulants, cocaine, or theophylline.

Early studies of sinus node function described the response to a single atrial extrastimulus (AES). The curve produced by plotting return cycles against the coupling interval could be divided into several phases, including compensatory pause, reset, interpolation, and reentry. Sinus node reentrant tachycardia was described on the basis of these findings as a tachycardia that could be induced and terminated by programmed electrical stimulation with a P wave morphology identical or similar to sinus P waves and tachycardia CLs of 350 to 550 milliseconds (see Fig. 16-3).²⁴ There have been some reports of endocardial ablation of sinus node reentrant tachycardias identified by these criteria. However, the precise identification of sinus node reentrant tachycardia remains elusive. The mechanism of focal AT can be reentrant, and the CL of such ATs completely overlaps that described for sinus node reentrant tachycardia. The location of AT foci is often along the crista terminalis, very close to the supposed location of the sinus node. An added problem is that the origin of the sinus activation can be variable, according to epicardial mapping studies. Furthermore, endocardial origin of sinus activation during normal sinus rhythm (NSR) has not been systematically studied in humans, and specific criteria do not exist to pinpoint a specific sinus node area. Finally, reentry strictly limited to the sinus node area has never been demonstrated and has even been questioned.²⁴

Clinical Considerations

Epidemiology

Nonsustained AT is frequently found on Holter recordings and is seldom associated with symptoms. Sustained focal ATs are relatively infrequent; they are diagnosed in approximately 5% to 15% of patients referred for catheter ablation of supraventricular tachycardia (SVT).²⁵ However, ATs comprise a progressively greater proportion of paroxysmal SVTs with increasing age and account for 23% in patients older than 70 years. Age-related changes in the atrial EP substrate, including cellular coupling and autonomic influences, can contribute to the increased incidence of AT in older individuals.²⁵

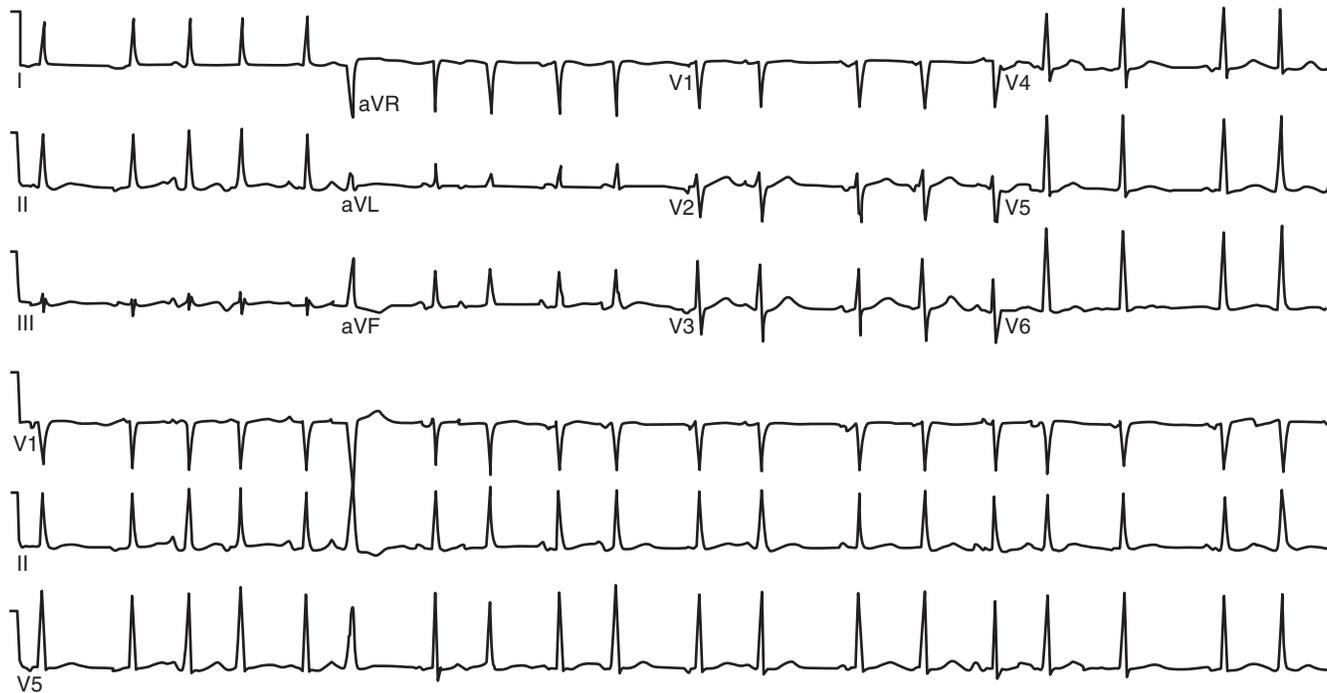

FIGURE 11-1 Surface ECG of multifocal atrial tachycardia. Note the varying morphology of the P waves and the PR intervals.

In adults, focal AT can occur in the absence of cardiac disease, but it is often associated with underlying cardiac abnormalities. Not infrequently, two or more foci of AT can be found in the same patient.²⁶

Clinical Presentation

Focal ATs can manifest as paroxysmal or incessant tachycardias. When paroxysmal, AT manifests with the clinical syndrome of paroxysmal SVT (discussed in Chap. 20). Symptoms, however, may be more severe or associated with cardiac decompensation caused by the higher prevalence of structural heart disease in this group of patients. Incessant tachycardia can result in tachycardia-induced cardiomyopathy and manifest with symptoms of congestive heart failure. AT can also manifest as a frequently repetitive tachycardia, with frequent episodes of AT interrupted by short periods of NSR. The repetitive type may be tolerated well for years. It may cause symptoms only in cases of fast heart rates during phases of tachycardia, and it infrequently induces dilated cardiomyopathy.

In one study, tachycardia-induced ventricular cardiomyopathy occurred in 10% of the total population of patients with focal AT. Incessant tachycardia was necessary for the development of cardiomyopathy, and cardiomyopathy was observed in approximately one third of patients with incessant AT. Incessant tachycardias precipitating cardiomyopathy characteristically tend to have slower atrial rates as compared with ATs not associated with cardiomyopathy. In contrast to patients with rapid paroxysmal AT, incessant tachycardia may produce negligible symptoms and may go unrecognized by the patient until symptoms related to cardiomyopathy develop.²⁰

Initial Evaluation

History, physical examination, 12-lead ECG, and echocardiography constitute an appropriate initial evaluation. Differentiation of paroxysmal AT from other mechanisms of SVT can be challenging and may require invasive EP testing. However, diagnosis of the incessant and frequently repetitive forms of AT usually can be readily made based on P wave morphology and the frequent presence of AV block during the tachycardia on ECG recordings. An ECG pattern of AT with discrete P waves and isoelectric intervals is suggestive of a focal mechanism of the AT, but it does not rule out macroreentrant AT, especially if complex structural heart disease is present or

there has been prior surgery for congenital heart disease, or both. The diagnosis of focal AT can be established with certainty only by an EP study. ATs often occur in older patients and in the context of structural heart disease; therefore, coronary artery disease and left ventricular (LV) dysfunction should be excluded.

Principles of Management

SHORT-TERM MANAGEMENT

On rare occasions, ATs can be terminated with vagal maneuvers. Conversely, a significant proportion of focal ATs will terminate with administration of adenosine. Persistence of the tachycardia with AV block is also a common response to adenosine. In addition, ATs responsive to intravenous verapamil or beta blockers have been reported. It is conceivable that the mechanism of AT in these patients relates to microentry, involving tissue with slow conduction, or to triggered activity. Class IA or IC drugs can suppress automaticity or prolong action potential duration and hence can be effective in some patients with AT.

For patients with automatic AT, atrial pacing (or adenosine) can result in transient slowing but no tachycardia termination. Similarly, DC cardioversion seldom terminates automatic ATs, but DC cardioversion can be successful for those in whom the tachycardia mechanism is microentry or triggered activity. An attempt at DC cardioversion should therefore be considered for symptomatic patients with drug-resistant arrhythmia.

The usual acute therapy for AT consists of intravenous beta blockers or calcium channel blockers either to terminate the arrhythmia, which is rare, or to achieve rate control through AV block, which is often difficult.¹⁹ Direct suppression of the tachycardia focus may be achieved by the use of intravenous class IA and IC or class III agents. Intravenous class IA or IC agents may be taken by patients without heart failure, whereas intravenous amiodarone is preferred for those with poor LV function.¹⁹

LONG-TERM MANAGEMENT

As with other forms of SVT, AT is usually benign and associated with only mild to moderate symptoms. Thus, most patients with AT are treated initially with medical therapy. Patient preference

and refractoriness to pharmacological therapy are reasonable indications for catheter ablation.¹⁹

The efficacy of antiarrhythmic drugs is poorly defined because the clinical definition of focal ATs is often not rigorous. No large studies have been conducted to assess the effect of pharmacological treatment in patients with focal ATs, but both paroxysmal and, especially, incessant ATs are reported to be difficult to treat medically. Available data support a recommendation for initial therapy with calcium channel blockers or beta blockers because these agents may prove to be effective and have minimal side effects. If these drugs are unsuccessful, then class IA agents, class IC (flecainide and propafenone) agents in combination with an AV node (AVN) blocking agent, or class III agents (sotalol and amiodarone) may be tried; however, the potential benefit should be balanced by the potential risks of proarrhythmia and toxicity. Because ATs often occur in older patients and in the context of structural heart disease, class IC agents should be used only after cardiomyopathy and coronary artery disease are excluded.¹⁹

For patients with drug-refractory AT or incessant AT, especially when tachycardia-induced cardiomyopathy has developed, the best therapy appears to be catheter ablation of the AT focus. In case reports and small series, patients with tachycardia-induced cardiomyopathy frequently have complete resolution of LV dysfunction with successful RF catheter ablation of the atrial focus.^{19,20} Regardless of whether the arrhythmia is caused by abnormal automaticity, triggered activity, or microreentry, focal AT is ablated by targeting the site of origin of the AT. Catheter ablation for focal AT carries a success rate of more than 90%, with a recurrence rate of 9%. The incidence of significant complications is relatively low (1% to 3%) in experienced centers.

Electrocardiographic Features

P Wave Morphology

During AT, typically there are discrete P waves at rates of 130 to 240 beats/min, but possibly as slow as 100 beats/min or as fast as 300 beats/min. Antiarrhythmic drugs can slow the tachycardia rate without abolishing the AT. Classically, there are clearly defined isoelectric intervals between the P waves in all leads (Fig. 11-2). However, in the presence of rapid rates, intraatrial conduction disturbances, or both, the P waves can be broad, and there may be no isoelectric baseline. In these cases, the ECG shows an AFL pattern (continuous undulation without isoelectric baseline; Fig. 11-3).¹ Nevertheless, one report demonstrated a high sensitivity (90%) and specificity (90%) of *quantitative* ECG indexes of shorter atrial activation and longer diastolic intervals in distinguishing focal from macroreentrant AT. This approach was effective in cases with and without 1:1 AV conduction and when the P or flutter waves overlay T waves.²⁷

P wave morphology depends on the location of the atrial focus, and it can be used to localize the site of origin of the AT approximately. However, the P wave can be partially masked by the preceding ST segment or T wave, or both. Vagal maneuvers and adenosine infusion to provide transient AV block can be used to obtain a clear view of the P wave, assuming that the tachycardia does not terminate with AV block. The compensatory pause following a premature ventricular complex during the AT can also be used to delineate P wave morphology (Fig. 11-4). It has been suggested that the multilead body surface potential recording can be used to help localize the site of origin of the tachycardia.

One report described a clinical application of ECG imaging (ECGI) as an adjunctive noninvasive technology to identify the site of origin of a focal AT accurately prior to catheter ablation (Fig. 11-5).²⁸

Focal automatic ATs start with a P wave identical to the P wave during the arrhythmia, and the rate generally increases gradually (warms up) over the first few seconds. In comparison, intraatrial reentry or triggered-activity AT is usually initiated by a P wave from a premature atrial complex (PAC) that generally differs in morphology from the P wave during the established arrhythmia (Fig. 11-6).

QRS Morphology

QRS morphology during AT is usually the same as during NSR. However, functional aberration can occur at rapid atrial rates.

P/QRS Relationship

The atrial to ventricular relationship is usually 1:1 during ATs, but Wenckebach (Fig. 11-7) or 2:1 AV block (see Figs. 11-3 and 11-4) can occur at rapid rates, in the presence of AVN disease, or in the presence of drugs that slow AVN conduction. The presence of AV block during an SVT strongly suggests AT, excludes AV reentrant tachycardia (AVRT), and renders AVN reentrant tachycardia (AVNRT) unlikely.

ATs usually have a long RP interval, but the RP interval can also be short, depending on the degree of AV conduction delay (i.e., PR interval prolongation) during the tachycardia.

Localization of the Atrial Tachycardia Site of Origin Using P Wave Morphology

GENERAL OBSERVATIONS RELATING P WAVE MORPHOLOGY TO SITE OF ORIGIN OF ATRIAL TACHYCARDIA

P wave morphology provides a useful guide to the localization of focal AT in patients without structural heart disease. In patients with prior surgery or extensive atrial ablation or in those with significant structural heart disease, activation patterns can be altered, significantly rendering P wave morphology less helpful.²⁹

ECG lead V₁ is the most useful in identifying the likely anatomical site of origin for focal AT. Lead V₁ is located to the right and anteriorly in relation to the atria, which should be considered anatomically as right anterior and left posterior structures. Thus, for example, tachycardias originating from the tricuspid annulus have negative P waves in lead V₁ because of the anterior and rightward location of this structure (i.e., activation travels *away* from lead V₁). The P wave in lead V₁ is universally positive for tachycardias originating from the PVs because of the posterior location of these structures (i.e., the impulse travels *toward* lead V₁).^{6,30,31}

Several features of P wave morphology can help predict whether an AT is arising from the RA or the LA. In one report, a negative or biphasic (positive-negative) P wave in lead V₁ was associated with 100% specificity, 100% positive predictive value, 69% sensitivity, and 66% negative predictive value for a tachycardia arising from the RA. Conversely, a positive or negative-positive biphasic P wave in lead V₁ had 100% sensitivity, 81% specificity, 76% positive predictive value, and 100% negative predictive value for an LA origin. A positive or biphasic P wave in lead aVL predicted an RA focus; however, some patients with right superior PV foci had positive P waves in lead aVL. An isoelectric or negative P wave in lead I was 100% specific (but only 50% sensitive) for LA foci.⁶

The predictive value of P wave morphology for localizing the atrium of origin is more limited when the tachycardia foci arise from the interatrial septum. Those ATs are associated with variable P wave morphology and considerable overlap for tachycardias located on the left and right sides of the septum. Of note, P waves during ATs arising near the septum are generally narrower than those arising in the RA or LA free wall.

P waves identical to the sinus P wave are suggestive of sinus node reentrant tachycardia or perinodal AT. Negative P waves in the anterior precordial leads suggest an anterior RA or LA free wall location. Negative P waves in the inferior leads suggest a low (inferior) atrial origin.

Several algorithms have been proposed for ECG localization of focal AT using P wave morphology. Figure 11-8 summarizes some of those algorithms.⁶

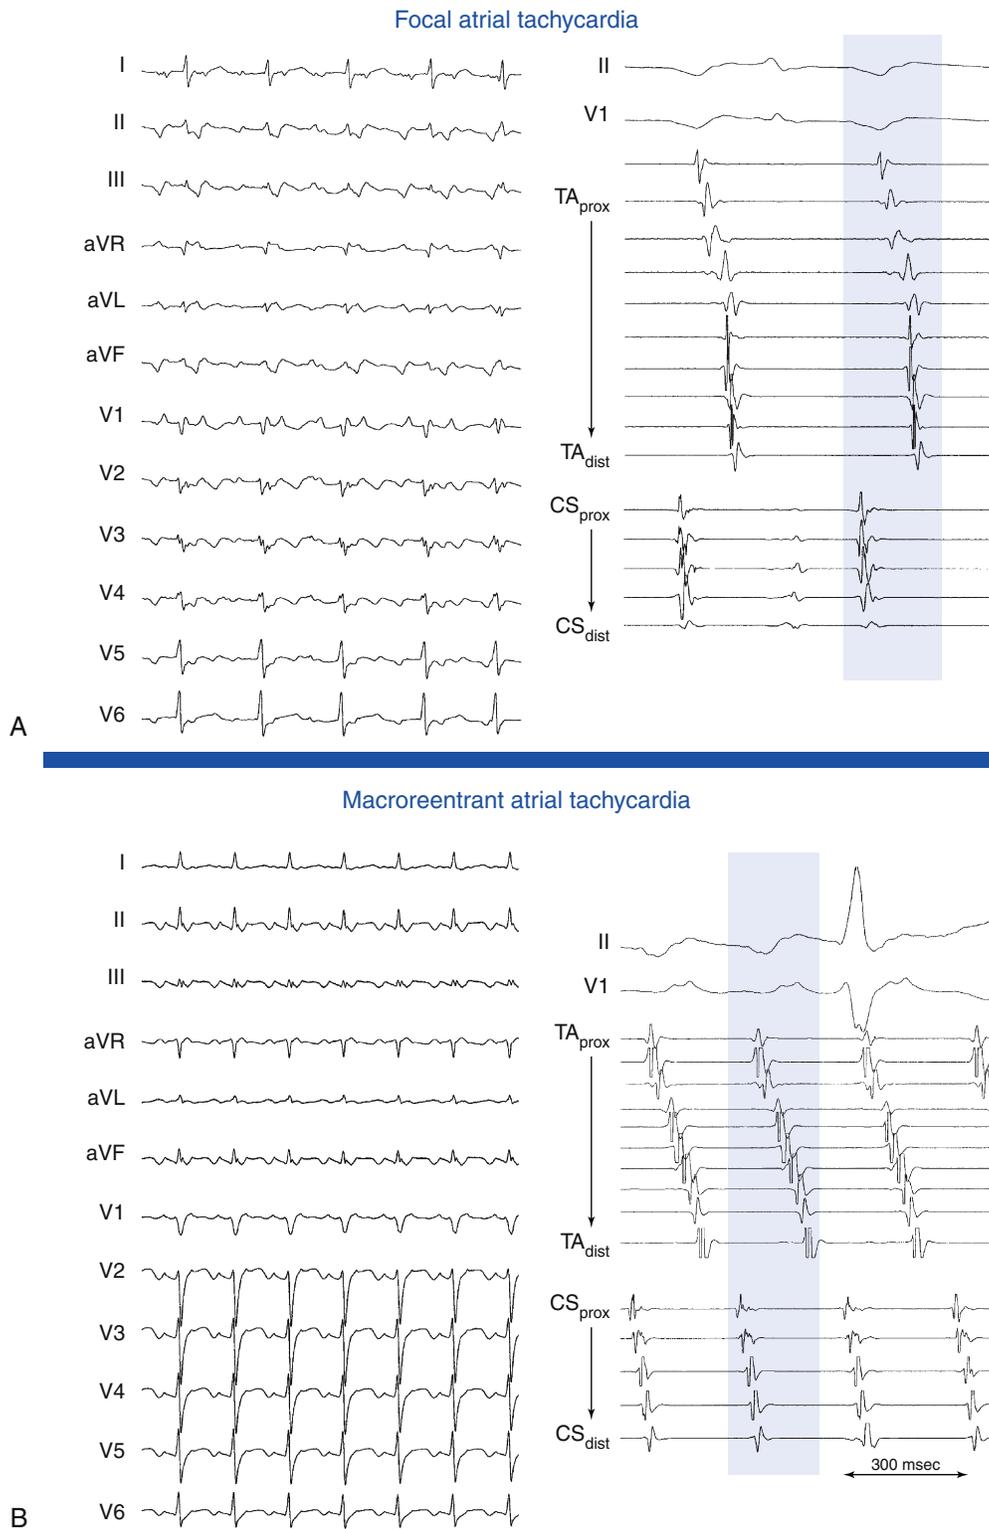

FIGURE 11-2 Comparison of focal and macroreentrant atrial tachycardia (AT). **A**, Surface ECG and endocardial activation sequence of focal AT originating from inferior aspect of the mitral annulus with 2:1 atrioventricular (AV) conduction. **B**, Endocardial activation macroreentrant AT around the tricuspid annulus (counterclockwise, typical atrial flutter) with 2:1 AV conduction. As illustrated in this case, discrimination between focal and macroreentry as the mechanism of AT based on the presence of distinct isoelectric intervals between the tachycardia P waves can be challenging caused by superimposition of the QRS and ST-T waves. Endocardial activation (shaded area), however, clearly demonstrates that batrial activation from all electrodes of the 20-pole (“Halo”) catheter (around the tricuspid annulus [TA]) and the coronary sinus (CS) catheter occupies only a small fraction (less than 50%) of the tachycardia cycle length (CL) during focal AT with over half of the tachycardia CL without recorded activity. In contrast, batrial activation occupies most (~90%) of the tachycardia CL during macroreentrant AT. dist = distal; prox = proximal.

RIGHT ATRIAL TACHYCARDIAS

Cristal ATs (i.e., ATs arising from the crista terminalis) are characterized by right-to-left activation sequence resulting in P waves that are positive and broad in leads I and II, positive in lead aVL, and biphasic in lead V₁ (Fig. 11-9). A negative P wave in lead aVR predicts a cristal origin compared with anterior RA foci with a sensitivity of 100% and specificity of 93%. Biphasic P waves (positive-negative) in lead V₁ (or positive V₁ during both tachycardia and sinus rhythm), positive P waves in leads I and II, and negative P waves in lead aVR predict a cristal origin with

93% sensitivity, 95% specificity, 84% positive predictive value, and 98% negative predictive value. Although there can be overlap in P wave morphology between the superior crista and the right superior PV as a result of the anatomical proximity of the two sites, these can be distinguishable on the basis of changes to the P wave morphology in lead V₁ during tachycardia as compared with sinus P waves. In right superior PV AT, P waves in lead V₁ are invariably upright during tachycardia and biphasic (positive-negative) in sinus rhythm. When cristal AT has an upright P wave in lead V₁ (approximately 10%), it is invariably also upright

FIGURE 11-3 Surface ECG of focal atrial tachycardia originating from the right superior pulmonary vein. Second-degree 2:1 atrioventricular block is observed during the tachycardia. Note that the tachycardia in the inferior leads mimics atrial flutter as a result of intraatrial conduction abnormalities as well as overlapping T waves.

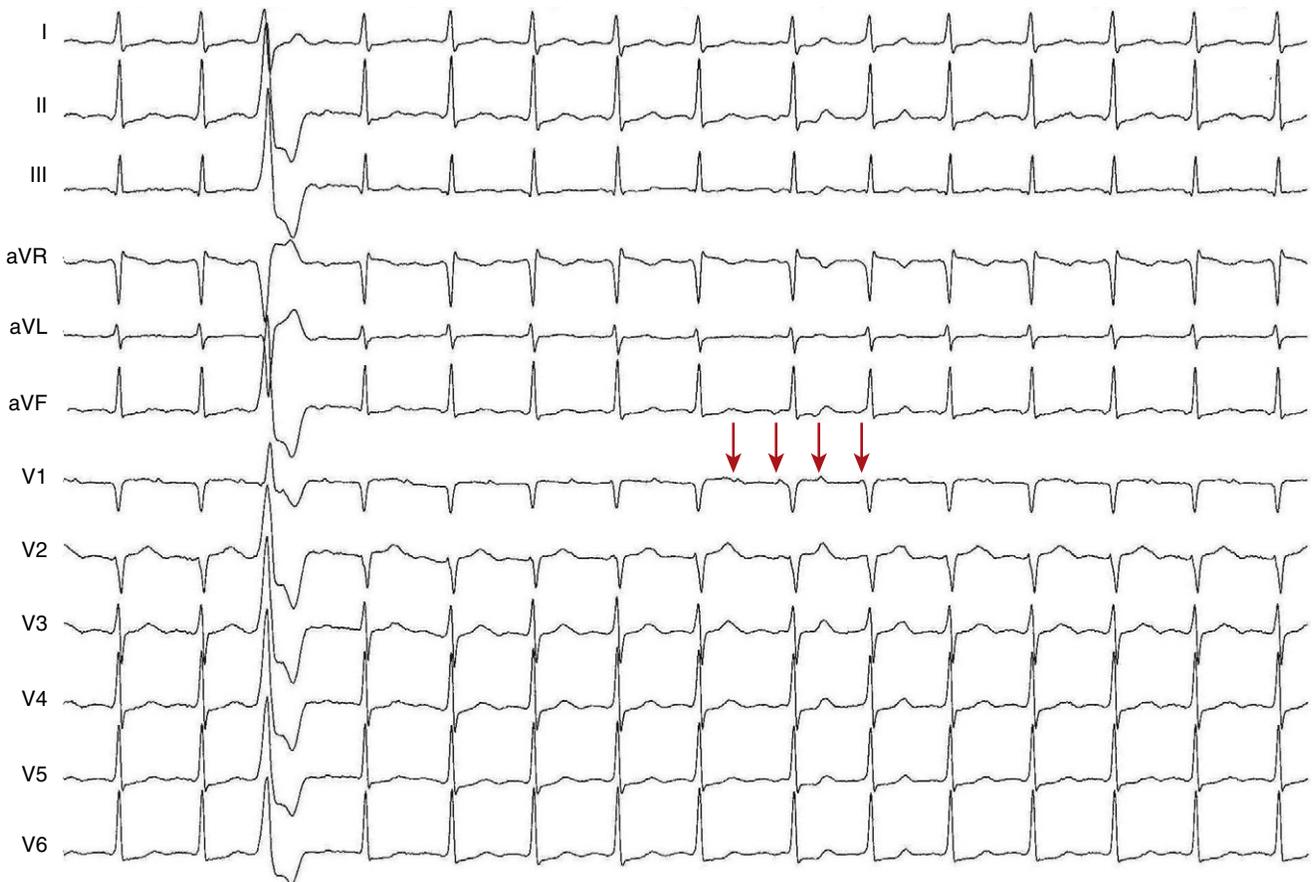

FIGURE 11-4 Surface ECG of focal atrial tachycardia with 2:1 atrioventricular (AV) block. Note that every other P wave lies within the QRS, a pattern mimicking supraventricular tachycardia with 1:1 AV conduction. Careful inspection of the whole recording reveals the hidden P waves sometimes occurring at varying timings within the QRS, as indicated by the arrows.

during sinus rhythm. High, middle, or low cristal locations can be identified by P wave polarity in the inferior leads.²⁹

In anteroseptal ATs (originating above the membranous septum), the P wave is biphasic or negative in lead V₁ and positive in the inferior leads. Because of relatively simultaneous biatrial activation, P wave duration is approximately 20 milliseconds narrower than the sinus P wave. Those ATs can mimic slow-fast AVNRT or orthodromic AVRT with superoparaseptal bypass tracts (BTs).

Midseptal ATs (originating below the membranous septum and above the CS os) are associated with P waves that are biphasic or negative in lead V₁ and negative in the inferior leads. Those ATs can mimic fast-intermediate AVNRT or orthodromic AVRT with midseptal BTs.

In the setting of posteroseptal ATs (originating below and around the CS os), the P wave is positive in lead V₁, negative in the inferior leads, and positive in leads aVL and aVR. Those ATs can mimic fast-slow AVNRT or orthodromic AVRT using a posteroseptal BT.

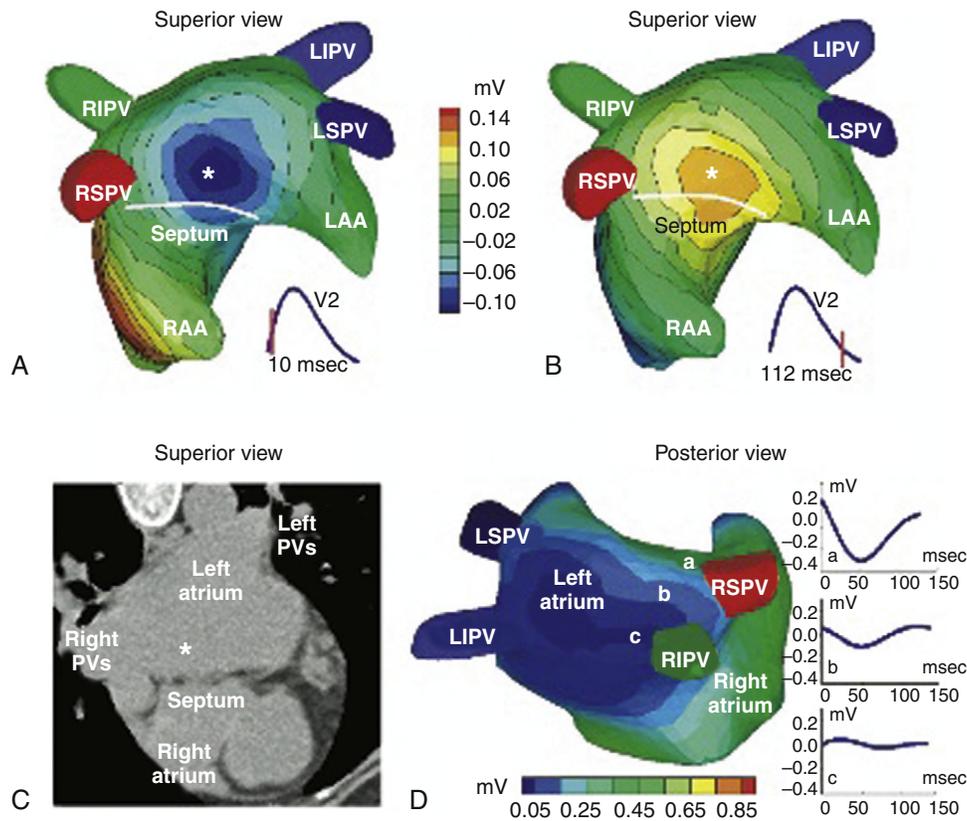

FIGURE 11-5 ECG imaging (ECGI) three-dimensional voltage and electrogram maps during focal atrial tachycardia in a patient with prior pulmonary vein (PV) electrical isolation. **A** and **B**, ECGI-reconstructed atrial epicardial surface voltage maps were produced for a single P wave extracted during the tachycardia at 10 and 112 milliseconds after the onset of the surface P wave. At the onset of the surface P wave, an epicardial breakthrough (local potential minimum, white asterisk) was imaged on the left atrium (LA), near the atrial septum (**A**). During the end of the surface P wave, a repolarization pattern with reverse polarity (local potential maximum) appeared at the same site (**B**, white asterisk). These observations strongly suggested the existence of an activation source at the breakthrough site. **C** superimposes the site of the breakthrough (white asterisk) on a computed tomography image of the atria. As shown, the earliest site of activation determined by ECGI was located on the roof of the LA, between the right superior PV and the atrial septum (**C**). **D** is an electrogram magnitude map (peak-to-peak) reconstructed by ECGI (posterior view). The dark blue represents a region of low-magnitude electrograms that indicates a scar region. Three electrograms selected from a nonscar region (**a**) and from the scar region (**b**, **c**) are shown. Location of low-magnitude electrograms is consistent with prior PV isolations and LA substrate modification. LAA = LA appendage; LIPV = left inferior PV; LSPV = left superior PV; RAA = right atrial appendage; RIPV = right inferior PV; RSPV = right superior PV. (From Wang Y, Cuculich PS, Woodard PK, et al: *Focal atrial tachycardia after pulmonary vein isolation: noninvasive mapping with electrocardiographic imaging (ECGI)*, *Heart Rhythm* 4:1081-1084, 2008; with permission.)

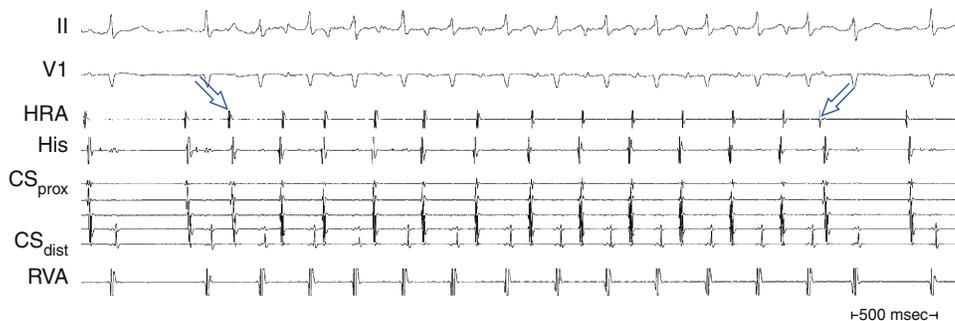

FIGURE 11-6 Spontaneous initiation and termination of a midseptal focal atrial tachycardia (AT; arrows). The tachycardia is initiated and terminated by a premature atrial complex of different morphology from that of the AT, a finding suggesting a nonautomatic mechanism. Note the narrow P wave during AT, consistent with a septal origin. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

The circumference of the tricuspid annulus is the second most common site of origin for RA tachycardias. A common feature of tricuspid annular ATs is the presence of an inverted P wave in leads V₁ and V₂ with late precordial transition to an upright appearance. The nonseptal sites demonstrate negative P waves in lead V₁, whereas anteroinferior sites tend to have inverted P waves across the precordial leads, and superior sites closer to the septum show transition from negative in lead V₁ through biphasic to upright in the lateral precordial leads.³ In general, the polarity of leads II and III is deeply negative for an inferoanterior location and low amplitude, positive, or biphasic for a superior location. Additionally, tricuspid annular ATs typically have positive P waves in lead aVL and positive or isoelectric P waves in lead I.²⁹

Focal ATs originating from the RA appendage typically originate from the lateral base of the appendage but are also well described from an apical location. Because of their close anatomical proximity, these tachycardias are generally indistinguishable from superior tricuspid annular foci; they exhibit negative P waves in leads V₁ and V₂ and variable precordial transition to positive in lead V₆. P waves in the inferior leads characteristically have low positive amplitudes.^{29,32}

LEFT ATRIAL TACHYCARDIAS

ATs arising from the PVs are characterized by entirely positive P waves in lead V₁ (in 100% of cases) and across the precordial leads, isoelectric or negative waves in lead aVL in 86%, and negative

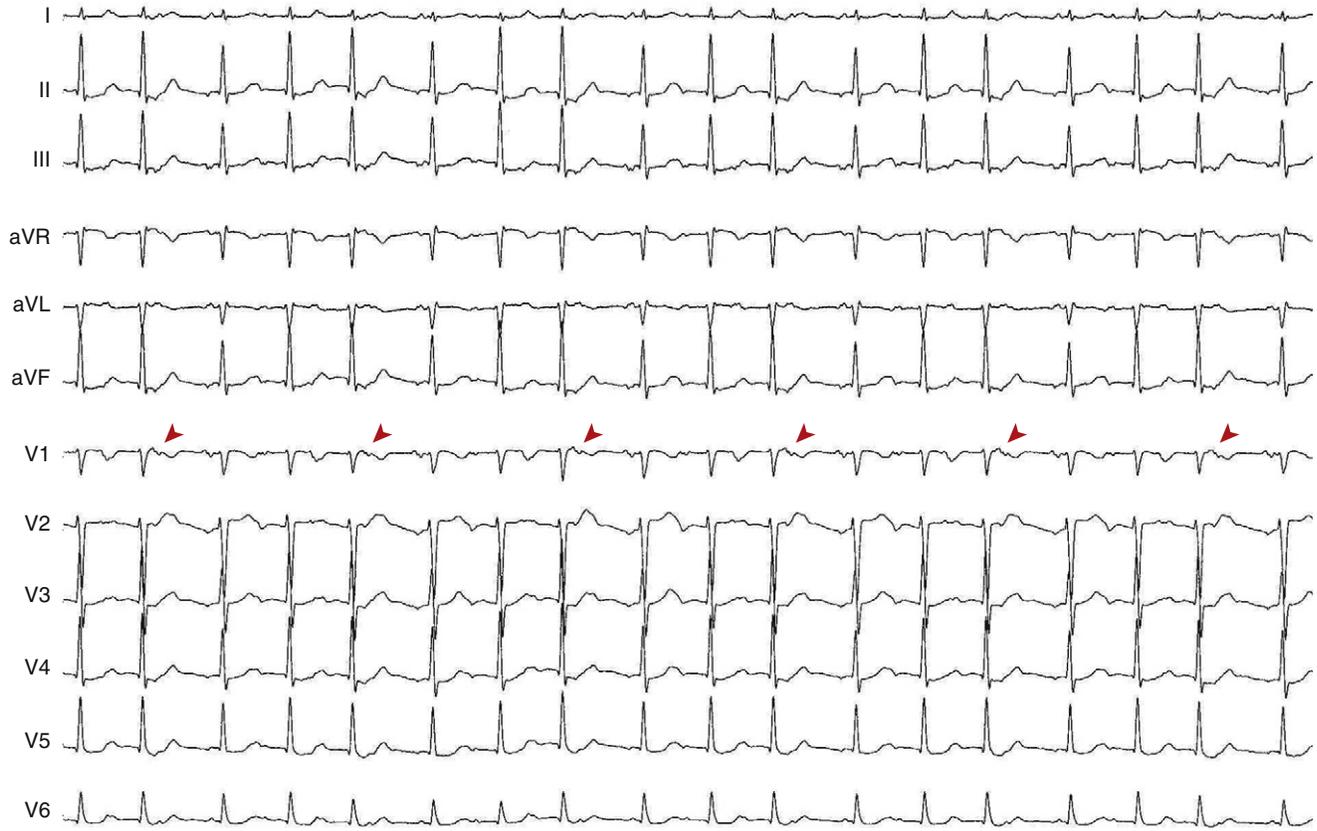

FIGURE 11-7 Surface ECG of focal atrial tachycardia originating from the inferior portion of the right atrial septum. Wenckebach atrioventricular block is observed. Arrowheads indicate blocked P waves.

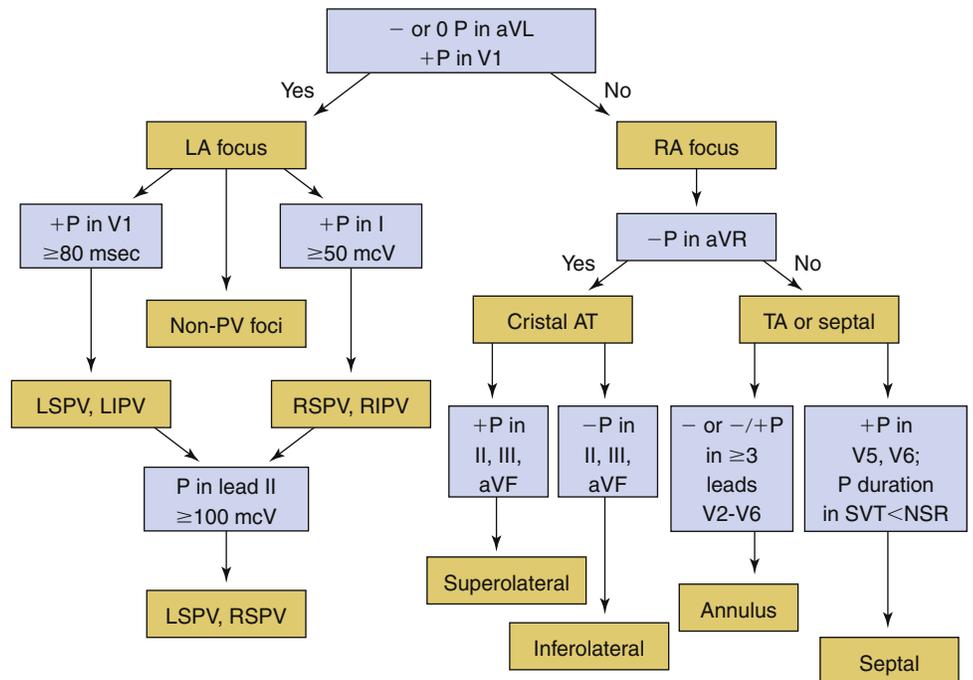

FIGURE 11-8 Algorithm for localization of atrial tachycardia (AT) origin based on P wave morphology on the surface ECG. -/+ = biphasic P wave; LA = left atrial; LIPV = left inferior pulmonary vein; LSPV = left superior pulmonary vein; mcV = microvolt; NSR = normal sinus rhythm; 0 = isoelectric P wave; +P = positive P wave; -P = negative P wave; RA = right atrial; RIPV = right inferior pulmonary vein; RSPV = right superior pulmonary vein; TA = tricuspid annulus. (From Ellenbogen KA, Wood MA: *Atrial tachycardia*. In Zipes DP, Jalife J, editors: *Cardiac electrophysiology: from cell to bedside*, ed 4, Philadelphia, 2002, Saunders, pp 500-511.)

waves in lead aVR in 96%. Lead aVL can be biphasic or positive in right-sided PV ATs.⁷ Compared with the right-sided PVs, the left-sided PV foci have several characteristics: positive notching in the P waves in two or more surface leads, an isoelectric or negative P wave in lead I, P wave amplitude in lead III/II ratio greater than 0.8, and broad P waves in lead V₁ (Fig. 11-10). Right-sided PV foci

usually have positive P waves in lead I. ATs arising from the superior PVs invariably have a positive P wave in the inferior leads. In contrast, ATs arising from the inferior PVs can have inverted, low-amplitude positive or isoelectric inferior P waves. However, because of the close proximity of the superior and inferior veins and marked anatomical variation, P wave morphology generally

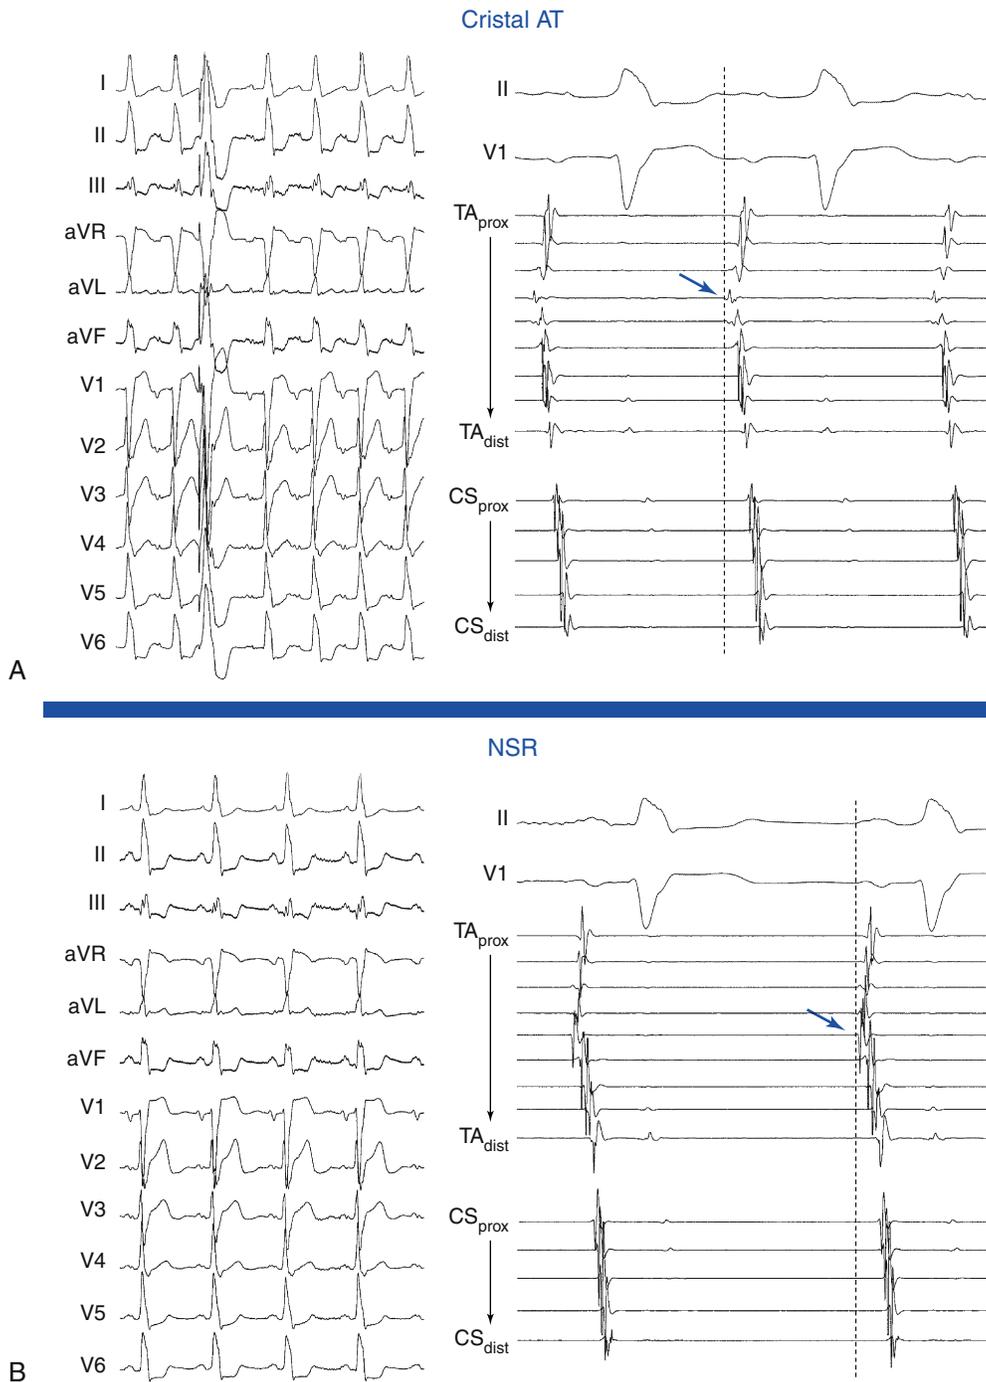

FIGURE 11-9 Comparison of P wave morphology and endocardial atrial activation sequence between focal atrial tachycardia (AT) originating from the crista terminalis (A) and normal sinus rhythm (NSR) (B) in the same patient. A Halo catheter is positioned around the tricuspid annulus (TA). CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

is of greater accuracy in distinguishing right-sided from left-sided PVs, in contrast to distinguishing superior from inferior PVs.

ATs arising from the right superior PV are associated with P waves that are narrow and positive in the inferior leads, of equal amplitude in leads II and III, positive in lead V₁, and isoelectric in lead I. The right superior PV is a common site of origin for LA ATs. It is only a few centimeters from the sinus node. Activation rapidly crosses the septum via Bachmann's bundle to activate the RA in a fashion similar to NSR, a feature explaining the similarities in P wave morphology. However, whereas the P wave is biphasic in lead V₁ during NSR, it is positive in that lead during right superior PV AT (Fig. 11-11).⁷

Despite prior posterior LA ablation, the surface ECG morphology of ATs originating from the PV ostia in patients with prior AF ablation procedures is similar to those in patients without prior

ablation. However, ATs originating from the bottom of the right or left PVs after prior PV isolation can have a significant negative component or can be completely negative in the inferior leads. This may be related to prior ablation in the superoposterior LA or to a more inferior origin of the tachycardia after prior ablation outside the PV ostium.³³

In the setting of LA appendage ATs, the P wave is positive in the inferior leads (more positive in lead III than in II), positive in lead V₁, and negative in leads I and aVL. The LA appendage is closely approximated to the left superior PV, and, as such, ATs arising from those locations tend to have similar P wave morphologies. When P wave morphology suggestive of a left superior PV focus (broad upright and notched in lead V₁ and in the inferior leads) exhibits a deeply inverted P wave in lead I, an origin from the LA appendage should be strongly suspected. P waves are typically more positive

FIGURE 11-10 Surface ECG of nonsustained focal atrial tachycardia originating from the ostium of the left superior pulmonary vein.

in lead III than in lead II. A negative P wave in leads I and aVL predicts an LA appendage focus with a sensitivity and specificity of 92% and 97%, respectively.²⁹

Mitral annular ATs typically cluster at the superior aspect of the mitral annulus in close proximity to the aortomitral continuity. ATs originating in this circumscribed area are characterized by P waves with an initial narrow negative deflection in lead V₁ followed by a positive deflection. The positivity of the P wave becomes progressively less from V₁ through V₆. The P wave is negative in leads I and aVL and isoelectric or slightly positive in the inferior leads.³⁴

ATs arising from the CS musculature typically demonstrate deeply inverted P waves in the inferior leads. Lead V₁ usually exhibits isoelectric-positive or biphasic (negative-positive) P waves, with variable precordial transition. P waves are invariably positive in leads aVL and aVR.⁴ Compared with AT originating from the CS os, AT originating from 3 to 4 cm into the body of the CS have broad and upright P waves in lead V₁.²⁹

ATs have been described originating from the noncoronary cusp of the aortic valve. Because of the close anatomical proximity, the P wave morphology is similar to that of ATs arising from the aortomitral continuity. The P waves in leads V₁ and V₂ are also characteristically negative. However, unlike aortomitral ATs, those arising from the noncoronary cusp demonstrate upright P waves in leads I and aVL. In the inferior leads, the P waves are biphasic negative-positive but of low amplitude.^{15,16,29}

Electrophysiological Testing

Baseline Observations during Normal Sinus Rhythm

Preexcitation, when present, suggests AVRT but does not exclude AT. In addition, the presence of dual AVN physiology suggests AVNRT but does not exclude AT. On the other hand, broad sinus P wave and intraatrial conduction delay suggest macroreentrant AT.

Induction of Tachycardia

Frequently, AT foci can become inactive in the EP laboratory environment because of sedative medications, changes in autonomic tone that can be caused by prolonged supine position, patient anxiety, deviation from normal diet, or other changes in daily activities that can have an impact on the circadian variation of AT activity. Thus, in preparation for an AT ablation procedure, several measures should be undertaken. Antiarrhythmic drugs should be

discontinued for at least five half-lives before the EP study. Sedation should be minimized throughout the procedure. It may be an appropriate policy to monitor the patient in the EP laboratory initially without sedation. If no spontaneous tachycardia is induced, isoproterenol is administered. If no AT can be induced, a single quadripolar catheter is placed in the RA, and programmed electrical stimulation is performed without and, if no AT is induced, with isoproterenol infusion. If AT remains quiescent, the procedure is aborted and retried at a future date. If AT is inducible at any step, the full EP catheter arrangement and EP study are undertaken (Table 11-2).^{17,24,31}

INITIATION BY ATRIAL EXTRASTIMULATION OR ATRIAL PACING

Microreentrant AT is usually easy to initiate with a wide range of AES coupling intervals (A₁-A₂ intervals). The initiating AES coupling interval and the interval between the initiating AES and first beat of AT are inversely related. Triggered ATs also can be initiated by AES or (more commonly) atrial pacing. However, initiation frequently requires catecholamines (isoproterenol), and, in contrast to microreentrant AT, there is usually a direct relationship between the coupling interval or pacing CL initiating the AT and the interval to the onset of the AT and the early CL of the AT. On the other hand, automatic ATs cannot be reproducibly initiated by AES or atrial pacing.

In the setting of microentry and triggered activity, the first tachycardia P wave is different from subsequent P waves; the first P wave is usually a PAC or an AES that is necessary to start the AT (see Fig. 11-6). In contrast, the first tachycardia P wave and subsequent P waves during automatic AT are identical; the AT does not require a PAC to start (Fig. 11-12). Furthermore, the automatic AT CL tends to shorten progressively (warm up) for several beats until its ultimate rate is achieved.

No delay in the atrial-His bundle (HB) interval (AH interval) or PR interval is required for initiation of AT, although it can occur. AV block can also occur at initiation.²⁴

INITIATION BY VENTRICULAR EXTRASTIMULATION OR VENTRICULAR PACING

It is uncommon to initiate AT with ventricular extrastimulation (VES) or ventricular pacing because decremental retrograde conduction over the AVN prevents adequate prematurity of atrial activation. However, in the presence of an AV BT, fast retrograde atrial activation mediates adequate prematurity of the conducted ventricular stimulus to the atrium, and AT may be induced.²⁴

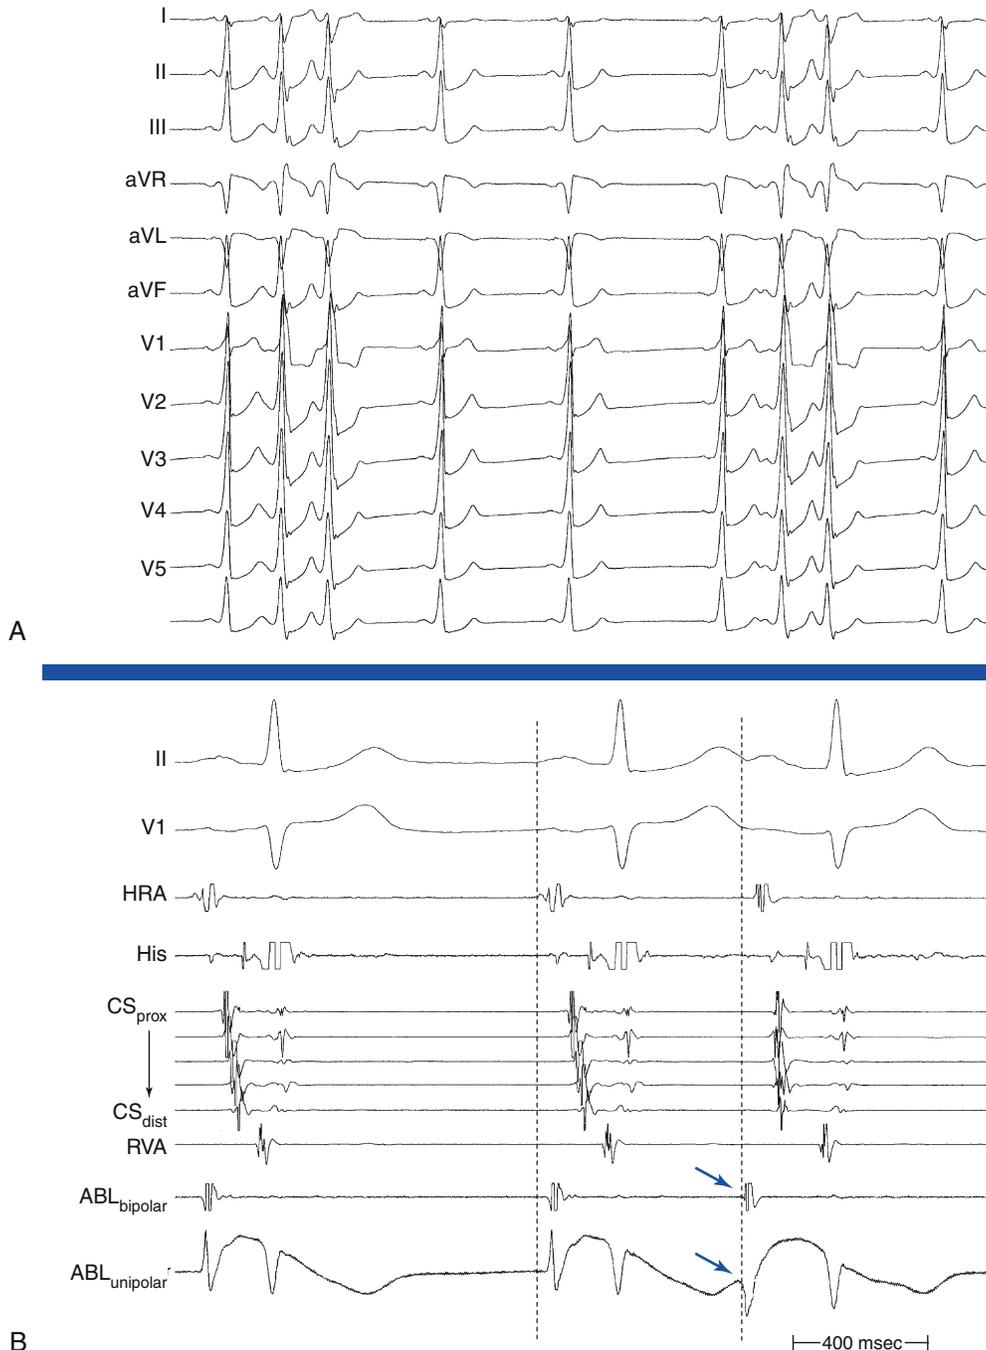

FIGURE 11-11 Premature atrial complexes (PACs) originating from the right superior pulmonary vein (PV). **A**, 12-lead surface ECG illustrating atrial couplets during normal sinus rhythm (NSR). Note the similarities in P wave morphology during PACs versus NSR. **B**, Intracardiac recordings from the same patient. Detailed mapping localized the origin of the PACs to the ostium of the right superior PV (as illustrated by bipolar and unipolar recordings from the ablation catheter [ABL]). Note the concordance of timing of the bipolar and unipolar recordings and the QS unipolar electrogram morphology (blue arrows), suggesting the site of origin and a good ablation site. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

TABLE 11-2 Programmed Electrical Stimulation Protocol for Electrophysiological Testing of Atrial Tachycardia

- Atrial burst pacing from the RA and CS (down to a pacing CL at which 2:1 atrial capture occurs)
- Single and double AES at multiple CLs (600–400 msec) from the RA and CS (down to atrial ERP)
- Ventricular burst pacing from the RV apex (down to VA Wenckebach CL)
- Single and double VES at multiple CLs (600–400 msec) from the RV apex (down to ventricular ERP)

AES = atrial extrastimulation; CL = cycle length; CS = coronary sinus; ERP = effective refractory period; RA = right atrium; RV = right ventricle; VA = ventricular-atrial; VES = ventricular extrastimulation.

Tachycardia Features

ATRIAL ACTIVATION SEQUENCE

P wave morphology and atrial activation sequence depend on the site of origin of the AT. Intracardiac mapping shows significant portions of the tachycardia CL without recorded atrial activity, and atrial activation time is markedly less than the tachycardia CL (see Fig. 11-2).²⁴ However, in the presence of extensive atrial scarring or prior ablation, depolarization from the AT focus can occasionally be followed by very disordered and prolonged conduction so that activation of the entire chamber can extend over (or even exceed) the entire tachycardia CL, thus mimicking macroreentrant AT.¹² Conversely, long isoelectric intervals can occur between the P waves during macroreentrant ATs and can incorrectly suggest a focal mechanism. This pattern is particularly observed for LA

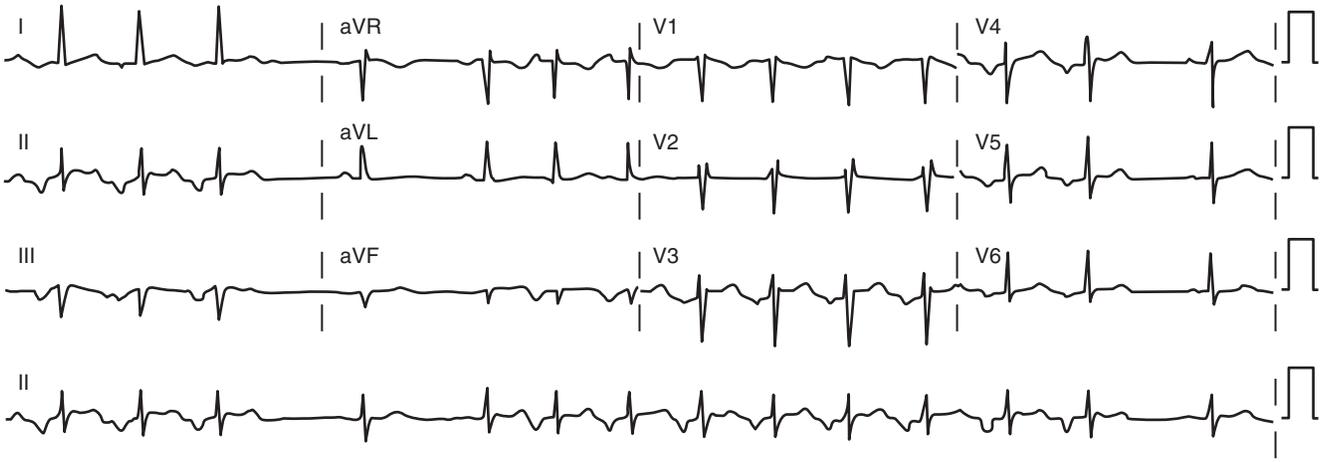

FIGURE 11-12 Surface ECG of repetitive nonsustained atrial tachycardia (AT). Note that the first P wave of the tachycardia is similar in morphology to the subsequent P waves, consistent with abnormal automaticity as the mechanism of the AT.

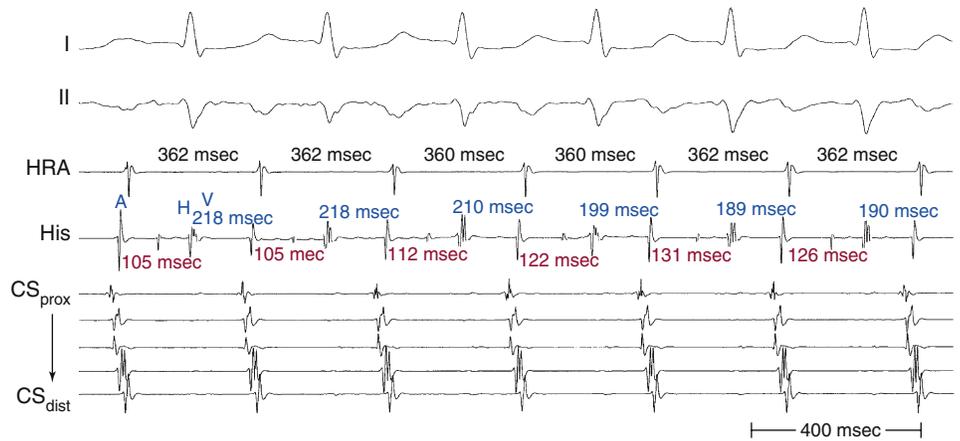

FIGURE 11-13 Supraventricular tachycardia (SVT) with concentric atrial activation sequence. Note the constant atrial cycle length (numbers in black) but variable atrial–His bundle (AH) interval (numbers in red) and ventricular–atrial (VA) interval (numbers in blue). This observation favors atrial tachycardia (originating from the posteroseptal region) as the mechanism of the tachycardia over other types of SVTs. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium.

flutters in the presence of large areas of electrical scar. However, a *thorough* intracardiac activation map reveals atrial activation spanning the tachycardia CL. When mapping is limited to only the atrium contralateral to the origin of the macroreentrant circuit or to only parts of the ipsilateral atrium, a focal mechanism can be falsely implied.

ATRIAL-VENTRICULAR RELATIONSHIP

The AH and PR intervals during AT are appropriate for the AT rate and are usually longer than those during NSR. The faster the AT rate is, the longer the AH and PR intervals will be. Thus, the PR interval may be shorter than, longer than, or equal to the RP interval. The PR interval may also be equal to the RR, and the P wave may fall inside the preceding QRS, thereby mimicking typical AVNRT.²⁴

AV block can be observed during AT because neither the AVN nor the ventricle is part of the AT circuit. Most incessant SVTs with AV block are probably automatic ATs.

OSCILLATION IN THE TACHYCARDIA CYCLE LENGTH

Oscillation of the ventricular CL occurs frequently during AT and is the result of changes either in the AT CL or in AVN conduction. When CL variability results from oscillation of the AT CL, changes in the atrial CL are expected to precede and predict similar changes in the ventricular CL. On the other hand, ventricular CL variability can be caused by changes in AV conduction instead of changes in the CL of the AT, in which setting ventricular CL variability is not predicted by a prior change in atrial CL. Because there is no VA conduction during AT, ventricular CL variability by itself is not

expected to result in atrial CL variability during AT.³⁵ Additionally, spontaneous changes in the PR and RP intervals with fixed A-A intervals favor AT over other types of SVT (Fig. 11-13).

In contrast to AT, typical AVNRT and orthodromic AVRT generally have CL variability caused by changes in anterograde AVN conduction. Because retrograde conduction through a fast AVN pathway or a BT generally is much less variable than the anterograde conduction through the AVN, the changes in ventricular CL that result from variability in anterograde AVN conduction are expected to precede the subsequent changes in atrial CL.³⁵

Variation in the AT CL of more than 15% has been suggested as a reliable marker of a focal AT. In contrast, it is rare for macroreentrant ATs to display considerable variation in the CL. However, a regular AT can be either focal or macroreentrant.³⁶

EFFECTS OF BUNDLE BRANCH BLOCK

Bundle branch block may occur during AT but does not affect the tachycardia CL because the ventricles are not participants in AT.²⁴

TERMINATION AND RESPONSE TO PHYSIOLOGICAL AND PHARMACOLOGICAL MANEUVERS

In the setting of spontaneous termination, ATs terminate with a QRS complex following the last P wave of the tachycardia. Most ATs (50% to 80%) are terminated by adenosine; therefore, termination of an SVT in response to adenosine is not helpful in differentiating AT from other SVTs.^{24,37} Usually (in 80% of cases), termination of AT in response to adenosine occurs prior to the onset of AV block (i.e., termination occurs with a tachycardia P wave followed by a

QRS). Reproducible termination with a P wave not followed by a QRS indicates other types of SVT because it occurs in AT only if adenosine terminates the AT at the same moment it causes AV block, an unlikely coincidence. In the atrium, adenosine produces antiadrenergic effects (presumably responsible for terminating triggered activity) and increases the acetylcholine- or adenosine-activated potassium (K^+) current (I_{KACH}). The results are shortening of the action potential duration and reduction of the resting membrane potential, which may be responsible for terminating atrial microreentry. Adenosine can also help identify automatic ATs, which are generally transiently slowed but not terminated, with gradual resumption of the AT rate.¹

Carotid sinus massage, vagal maneuvers, and adenosine reproducibly slow or terminate sinus node reentrant tachycardia and 25% of microreentrant ATs (especially those with long tachycardia CLs and those arising in the RA). Spontaneous termination of AT is usually accompanied by progressive prolongation of the A-A interval, with or without changes in AV conduction. Triggered activity AT also can terminate in response to carotid sinus massage, vagal maneuvers, adenosine, verapamil, beta blockers, and sodium channel blockers. In contrast, although carotid sinus massage can cause AV block and adenosine can slow automatic AT, these interventions generally do not terminate the AT. Only beta blockers have been useful in termination of paroxysmal (but not incessant) automatic AT. Termination of automatic AT is usually preceded by a cool-down phenomenon of the AT rate.¹

Diagnostic Maneuvers during Tachycardia

ATRIAL EXTRASTIMULATION AND ATRIAL PACING DURING FOCAL ATRIAL TACHYCARDIA

MICROREENTRANT ATRIAL TACHYCARDIA. AES can reset microreentrant AT with a resetting response classic for reentry (increasing or mixed response). Atrial pacing can entrain microreentrant AT. However, because the microreentrant circuit is very small, only orthodromic capture is usually observed. In addition, entrainment with constant fusion (at a fixed pacing CL) or progressive fusion (at progressively shorter pacing CLs), as demonstrated by intermediate P wave morphologies on the surface ECG, or partial activation change recorded by multiple endocardial electrodes, or both, cannot be demonstrated in microreentrant AT.

Fusion during resetting or entrainment (a hallmark of macroreentrant tachycardias) cannot be demonstrated in microreentrant AT. For atrial fusion (i.e., fusion of atrial activation from both the tachycardia wavefront and the atrial stimulus) to occur during resetting or entrainment, the atrial paced impulse should be able to enter the reentrant circuit while at the same time the tachycardia wavefront should be able to exit the circuit. This requires spatial separation between the entry and exit sites to the reentrant circuit, a condition that is lacking in the setting of focal AT. Once the tachycardia wavefront exits the reentry circuit to activate the atrium, any atrial stimulus delivered beyond that time and that results in atrial fusion would not be capable of reaching the reentry circuit because the entry-exit site is already refractory as a result of activation by the exiting tachycardia wavefront, and the atrial stimulus has no alternative way for reaching the circuit. Similarly, once an atrial stimulus is capable of reaching the reentry circuit, the shared entry-exit site is made refractory and incapable of allowing a simultaneous exit of the tachycardia wavefront. Therefore, during entrainment of microreentrant AT by atrial pacing, the atrial activation sequence and P wave morphology are always that of pure paced morphology.

However, it is important to understand that overdrive pacing of a tachycardia of any mechanism (automatic, triggered activity, or microreentrant) can result in a certain degree of fusion, especially when the pacing CL is only slightly shorter than the tachycardia CL. Such fusion, however, is unstable during the same pacing drive at a constant CL because pacing stimuli fall on a progressively earlier portion of the tachycardia cycle, thus producing progressively less

fusion and more fully paced morphology. Such phenomena should be distinguished from entrainment, and sometimes this requires pacing for many cycles to demonstrate variable degrees of fusion.

During entrainment of microreentrant AT, the return CL and post-pacing interval (PPI) are fixed regardless of the number of beats in the pacing train. AES and atrial pacing can almost always terminate microreentrant AT (especially sinus node reentrant tachycardia).²⁴ **TRIGGERED-ACTIVITY ATRIAL TACHYCARDIA.** AES can reset triggered-activity AT (with a decreasing resetting response). However, triggered-activity AT cannot be entrained by atrial pacing. Following the delivery of an AES or atrial overdrive pacing during triggered-activity AT, the return CL tends to shorten with shortening of the AES coupling interval or pacing CL. AES and, more effectively, atrial pacing can usually terminate triggered-activity AT.²⁴

AUTOMATIC ATRIAL TACHYCARDIA. The response of automatic AT to AES is similar to that of the sinus node. A late-coupled AES collides with the tachycardia impulse already exiting the AT focus (zone of collision), resulting in fusion of atrial activation (fusion between the paced and the tachycardia wavefronts) or paced-only atrial activation sequence, and it does not affect the timing of the next AT complex (producing a full compensatory pause). An earlier coupled AES enters the AT focus before the time of the next tachycardia wavefront and therefore resets the AT focus (zone of reset), with a return CL that is not fully compensatory. The return cycle usually remains constant over a range of coupling intervals during the zone of reset. A very early coupled AES encounters a refractory AT focus (following the last tachycardia complex) and would not be able to enter or reset the AT focus. Therefore, the next AT complex is on time because the atrium is already fully recovered following that early AES (zone of interpolation).

Automatic AT cannot be entrained by atrial pacing. Rapid atrial pacing results in overdrive suppression of the AT rate. The AT resumes after cessation of atrial pacing but at a slower rate and gradually speeds up (warms up) to return back to prepacing tachycardia CL. The tachycardia return CL following cessation progressively prolongs with increasing the duration of overdrive pacing. Occasionally, overdrive pacing produces no effect at all on automatic AT.²⁴

VENTRICULOATRIAL LINKING. Following cessation of overdrive atrial pacing (with 1:1 AV conduction) during focal AT, the VA interval (the interval between the last captured QRS complex and the first AT complex) can vary significantly from the VA interval during AT, because the timing of the AT return cycle is not related to the preceding QRS. In contrast, in the setting of typical AVNRT and orthodromic AVRT, the post-pacing VA interval remains fixed and similar to that during tachycardia (with a less than 10-millisecond variation) after different attempts at SVT entrainment. VA linking occurs in the setting of typical AVNRT and orthodromic AVRT because the timing of atrial activation is related to or dependent on ventricular activation and is the result of retrograde VA conduction over the AVN fast pathway (during typical AVNRT) or the BT (during orthodromic AVRT).^{38,39}

DIFFERENTIAL-SITE ATRIAL PACING. Differential-site atrial pacing can help distinguish AT from other mechanisms of SVT. Overdrive pacing is performed during tachycardia from different atrial sites (high RA [HRA] and proximal CS) at the same pacing CL. Once the presence of 1:1 AV conduction during atrial pacing is verified and the SVT resumes following cessation of pacing, the maximal difference in the post-pacing VA intervals (the interval from the last captured ventricular electrogram to the earliest atrial electrogram of the initial tachycardia beat after pacing) among the different pacing sites is calculated (Δ VA interval). In one report, a Δ VA interval of more than 14 milliseconds was diagnostic of AT, whereas a Δ VA interval of less than 14 milliseconds favored AVNRT or orthodromic AVRT (with the sensitivity, specificity, and positive and negative predictive values all equal to 100%). In orthodromic AVRT and AVNRT, the initial atrial complex following cessation of atrial pacing entraining the SVT is *linked* to, and

cannot be dissociated from, the last captured ventricular complex. In contrast, in the setting of AT, the first atrial return cycle following cessation of pacing is dependent on the distance between the AT origin and pacing site, atrial conduction properties, and mode of the resetting response of the AT, and it is not related to the preceding ventricular activation. Hence, the post-pacing VA intervals vary among the pacing sites, and the Δ VA interval is relatively large (more than 14 milliseconds).³⁹

VARIABILITY IN POST-PACING INTERVALS. The global pattern of activation of an atrial arrhythmia can be rapidly determined by comparing the differences in PPIs obtained with overdrive pacing from a single site (proximal CS) at CLs 10, 20, and 30 milliseconds shorter than the tachycardia CL. Relative stability of the PPI, regardless of its relation to the tachycardia CL, is highly suggestive of circuitous activation of the atrium. High variability of the PPI, on the other hand, is nearly diagnostic of a centrifugal activation pattern. In fact, in one report, PPI variability was significantly shorter for macroreentrant ATs (6.0 ± 2.5 milliseconds) than for focal ATs (56.5 ± 20.6 milliseconds). A clinical prediction rule was derived wherein low PPI variability (less than 10 milliseconds) identified macroreentrant ATs with a sensitivity of 94% and a specificity of 100%, whereas high PPI variability (more than 30 milliseconds) identified focal ATs with a sensitivity of 93% and a specificity of 100%.⁴⁰

In macroentry, the PPI reflects the time required for the stimulated wavefront to travel to a reentrant circuit, revolve once around the circuit, and travel back to the pacing site. Because this distance remains unchanged, pacing at faster rates should theoretically not change the distance traveled, and thus the PPI remains stable (PPI variability should approach zero). Faster pacing rates, however, can decrease conduction velocity because of decremental tissue conduction leading to prolongation of the PPI. Nevertheless, this is less likely to occur when overdrive pacing CLs are limited to within 30 milliseconds of the tachycardia CL. In contrast, variability in the PPI is expected in the setting of automatic ATs; by virtue of the phenomenon of overdrive suppression, automatic foci tend to require more time for recovery as pacing rate or duration increases. Unexpectedly, however, large PPI variability was exhibited by all centrifugal tachycardias regardless of mechanism (including microentry). By virtue of their small circuits, the microreentrant ATs have a short excitable gap; it is likely that the paced wavefront will penetrate the circuit during relative refractoriness, with decremental conduction resulting in progressive PPI prolongation.⁴⁰

VENTRICULAR EXTRASTIMULATION AND VENTRICULAR PACING DURING FOCAL ATRIAL TACHYCARDIA

It is uncommon for VES or ventricular pacing to affect an AT unless rapid 1:1 VA conduction is present (especially in the presence of an AV BT) and the tachycardia CL is relatively long. Cessation of overdrive ventricular pacing during AT (with 1:1 VA conduction without terminating the tachycardia) results in an A-A-V pattern, which is suggestive of AT as the mechanism of the SVT and practically excludes AVNRT and orthodromic AVRT, whereas an A-V pattern is consistent with AVNRT or orthodromic AVRT and makes AT less likely.²⁴

ATRIAL AND VENTRICULAR ELECTROGRAM SEQUENCE FOLLOWING CESSATION OF VENTRICULAR PACING

TECHNIQUE. During SVT, ventricular pacing is initiated at a pacing CL 10 to 60 milliseconds shorter than the tachycardia CL until 1:1 VA conduction occurs, at which point pacing is discontinued. If pacing results in termination of the tachycardia, SVT is reinduced, and the maneuver is repeated. If ventricular pacing does not terminate the tachycardia and the presence of stable 1:1 VA conduction is verified, the electrogram sequence immediately after the last paced ventricular complex is categorized as atrial-ventricular (A-V) or atrial-atrial-ventricular (A-A-V) (Fig. 11-14).

INTERPRETATION. During AVNRT or orthodromic AVRT, when the ventricle is paced at a CL shorter than the tachycardia CL and all electrograms are accelerated to the pacing rate without terminating the tachycardia (i.e., entrainment of the tachycardia is achieved), VA conduction occurs through the retrograde limb of the circuit. Therefore, after the last paced ventricular complex, the anterograde limb of the tachycardia circuit is not refractory, and the last entrained retrograde atrial complex can conduct to the ventricle. This results in an A-V response following cessation of pacing. However, when the ventricle is paced during AT and 1:1 VA conduction is produced, retrograde conduction occurs through the AVN. In this setting, the last retrograde atrial complex resulting from ventricular pacing is unable to conduct to the ventricle because the AVN is refractory to anterograde conduction, and the result is an A-A-V response.

PITFALLS. This pacing maneuver is not useful when 1:1 VA conduction during ventricular pacing is absent. Thus, when determining the response after ventricular pacing during SVT, the presence of 1:1 VA conduction must be confirmed. Isorhythmic VA dissociation can mimic 1:1 VA conduction, especially when the pacing train is not long enough or the pacing CL is too slow (see Fig. 11-14).

A pseudo-A-A-V response can occur during atypical AVNRT. Because retrograde conduction during ventricular pacing occurs through the slow pathway, the VA interval is long and can be longer than the pacing CL (V-V interval), so that the last paced QRS is followed first by the atrial complex resulting from slow VA conduction of the preceding paced QRS and then by the atrial complex resulting from the last paced QRS. Careful examination of the last atrial electrogram that resulted from VA conduction during ventricular pacing avoids this potential pitfall; the last retrograde atrial complex characteristically occurs at an A-A interval equal to the ventricular pacing CL, whereas the first tachycardia atrial complex usually occurs at a different return CL. A pseudo-A-A-V response may also occur when 1:1 VA conduction is absent during overdrive ventricular pacing, during typical AVNRT with long HB-ventricular (HV) intervals or short HA intervals whereby atrial activation may precede ventricular activation, and in patients with a bystander BT. Replacing ventricular activation with HB activation (i.e., characterizing the response as A-A-H or A-H instead of A-A-V or A-V, respectively) can be more accurate and can help eliminate the pseudo-A-A-V response in patients with AVNRT and long HV intervals, short HA intervals, or both.⁴¹

On the other hand, a pseudo-A-V response can occur with automatic AT when the maneuver is performed during isoproterenol infusion. Ventricular pacing with 1:1 VA conduction can result in overdrive suppression of the atrial focus, and isoproterenol may cause an increase in junctional automaticity, so that an apparent A-V response occurs. Therefore, when ventricular pacing is performed during an isoproterenol infusion, it is important to determine that the response after cessation of ventricular pacing is reproducible.³⁹

A pseudo-A-V response can theoretically occur when AT coexists with retrograde dual AVN pathways or bystander BT. In such cases, the last retrograde atrial complex would have an alternative route for anterograde conduction to the ventricle, other than the one used for retrograde VA conduction during ventricular pacing, thus resulting in an A-V response. However, clinical occurrence of these theoretical scenarios has not been observed, probably because of retrograde penetration of both AVN pathways or of the AVN and the BT during ventricular pacing, so that both pathways are refractory to anterograde conduction on cessation of pacing.³⁹

Exclusion of Other Arrhythmia Mechanisms

Focal AT should be differentiated from other SVTs, including AVNRT, orthodromic AVRT, and macroreentrant AT. Programmed electrical stimulation is usually adequate in excluding AVNRT and AVRT as the mechanism of SVT (Tables 11-3 and 11-4).²⁴ Macroreentry, however, can be more difficult to exclude, and electroanatomical mapping is of value in some cases (Table 11-5).

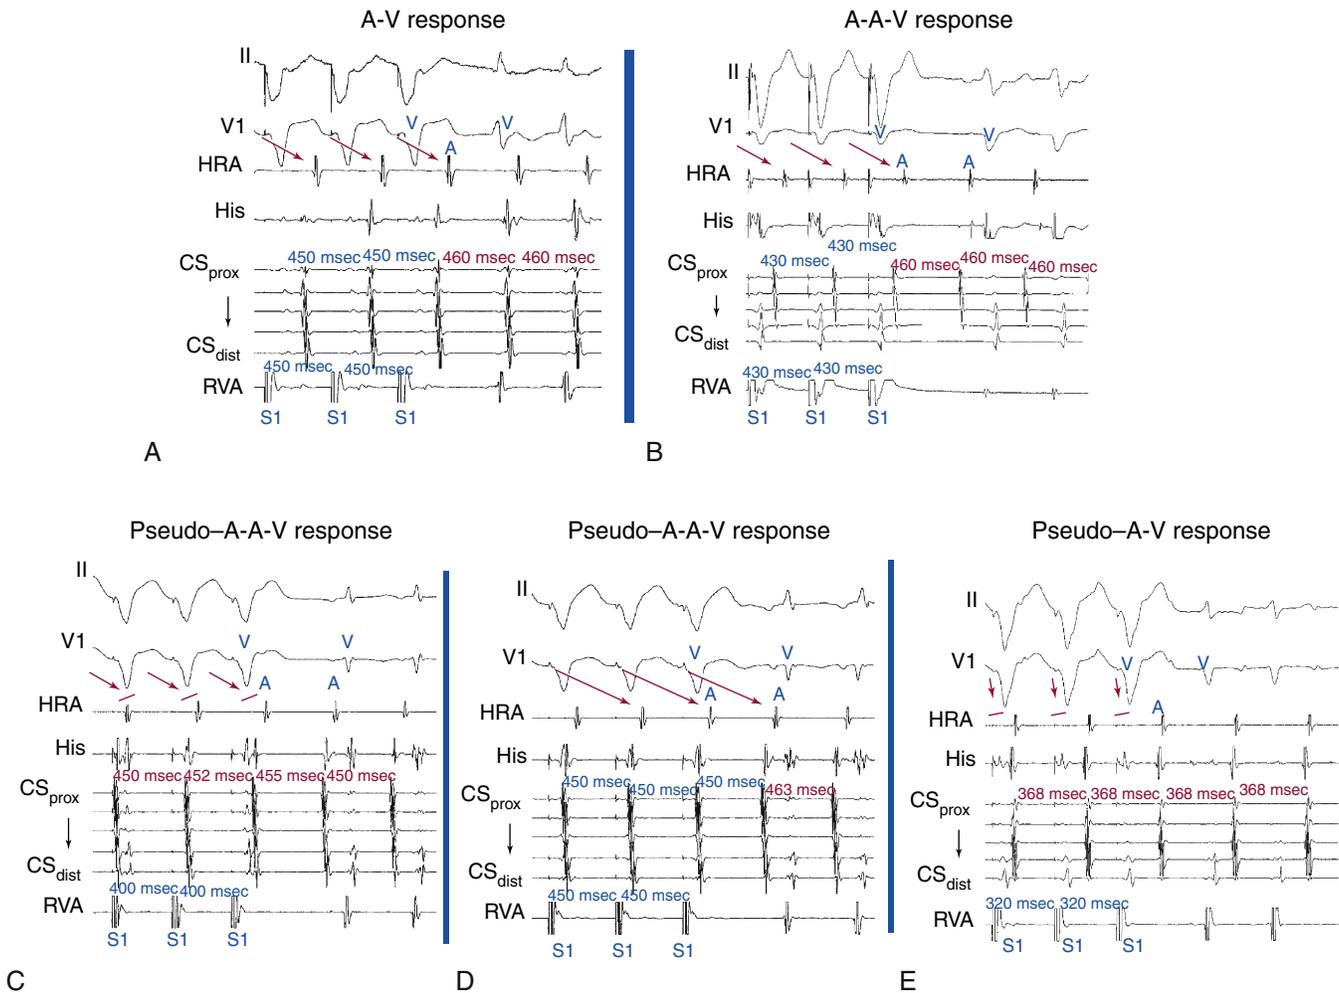

FIGURE 11-14 A-V versus A-A-V response after ventricular pacing during supraventricular tachycardia (SVT). Overdrive ventricular pacing is performed during five SVTs with concentric atrial activation sequence. Red arrows track ventricular-atrial (VA) conduction during ventricular pacing. Numbers indicate ventricular pacing cycle lengths (CLs) and atrial CLs during and after pacing. **A**, A-V response is observed following cessation of pacing during typical atrioventricular nodal reentrant tachycardia (AVNRT), which is inconsistent with atrial tachycardia (AT). **B**, A-A-V response is observed, consistent with AT originating in the posteroseptal region. **C**, Pseudo-A-A-V response is observed during atypical AVNRT secondary to VA dissociation (i.e., absence of VA conduction) during ventricular pacing. **D**, Pseudo-A-A-V response is observed during atypical AVNRT despite the presence of 1:1 VA conduction during ventricular pacing. Retrograde conduction during ventricular pacing, however, occurs through the slow atrioventricular node pathway with a long VA interval (red arrows) that is longer than the pacing CL; hence, the last ventricular paced impulse will be followed first by the P wave conducted slowly from the previous paced QRS, and then by the P wave resulting from the last paced QRS, thus mimicking an A-A-V response. This is verified by observing that the last retrograde atrial complex characteristically occurs at an A-A interval equal to the ventricular pacing CL, whereas the first tachycardia atrial complex usually occurs at a different return CL. **E**, Pseudo-A-V response is observed during focal AT secondary to VA dissociation (i.e., absence of VA conduction) during ventricular pacing. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

Mapping

Activation Mapping

Activation mapping entails localizing the site of earliest presystolic activity to the onset of the P wave during AT. Endocardial activation mapping can trace the origin of activation to a specific area, from which it spreads to both atria. However, spread of activation from the focus or origin may not be uniformly radial; anatomical or functional pathways and barriers can influence conduction and force the tachycardia wavefront to travel away from the focal source into noncentrifugal patterns.

There is generally an electrically silent period in the atrial CL reflected by an isoelectric line between atrial deflections on the surface ECG. Intracardiac mapping typically shows significant portions of the tachycardia CL without recorded activity, even when recording from the entire RA, LA, or CS (see Fig. 11-2). However, in the presence of complex intraatrial conduction disturbances, intraatrial activation may extend over a large proportion of the tachycardia CL, and conduction spread

may follow circular patterns suggestive of macroreentrant activation.^{17,24,31,42}

As noted, the term localized reentry has been used to refer to reentry in which the circuit is localized to a small area and does not have a central obstacle. Thus, if activity accounting for more than 85% of the tachycardia CL is present in an area with a diameter of up to 3 cm, localized reentry is considered (Fig. 11-15).

Determining the onset of the tachycardia P wave is important in activation mapping, but it may be impossible if the preceding T wave or QRS is superimposed. Thus, the P wave during AT should be assessed using multiple surface ECG leads and choosing the one with the earliest P onset. To facilitate visualization of the P wave, a VES (or a train of ventricular pacing) is delivered to accelerate ventricular activation and repolarization and permit careful distinction of the P wave onset. After determining P wave onset, a surrogate marker that is easier to track during mapping, such as an HRA or CS electrogram indexed to P wave onset where it is clearly seen, may be used, rather than the P wave onset on the surface ECG (Fig. 11-16).

TABLE 11-3 Exclusion of Atrioventricular Nodal Reentrant Tachycardia

PARAMETER	FEATURES
Atrial activation sequence	<ul style="list-style-type: none"> Eccentric atrial activation sequence generally excludes AVNRT (with the exception of left variant of AVNRT).
AV block	<ul style="list-style-type: none"> Spontaneous or induced AV block with continuation of the tachycardia is uncommon in AVNRT.
Oscillations in SVT CL	<ul style="list-style-type: none"> Spontaneous changes in PR and RP intervals with fixed A-A interval excludes AVNRT.
Overdrive ventricular pacing during SVT	<ul style="list-style-type: none"> If overdrive pacing entrains the SVT with an atrial activation sequence different from that during the SVT, AVNRT is unlikely. The presence of an A-A-V electrogram sequence following cessation of overdrive ventricular pacing practically excludes AVNRT.
Overdrive atrial pacing during SVT	<ul style="list-style-type: none"> $\Delta AH (AH_{\text{pacing}} - AH_{\text{SVT}}) < 20$ msec excludes AVNRT. If entrainment cannot be achieved or overdrive suppression is demonstrated, AVNRT is excluded.
Atrial pacing during NSR at the tachycardia CL	<ul style="list-style-type: none"> $\Delta AH (AH_{\text{pacing}} - AH_{\text{SVT}}) < 20$ msec excludes AVNRT.

AH = atrial-His bundle interval; AV = atrioventricular; AVNRT = atrioventricular nodal reentrant tachycardia; CL = cycle length; NSR = normal sinus rhythm; SVT = supraventricular tachycardia.

A single roving catheter is used to find the site, with the earliest atrial electrogram using unipolar and bipolar recordings. Small movements of the catheter tip in the general target region are undertaken under the guidance of fluoroscopy until the site with the earliest possible atrial activation relative to the P wave is identified.^{17,24,31,42} Activation times are generally measured from the onset or the first rapid deflection of the atrial bipolar electrogram to the onset of the P wave or (preferably) surrogate marker during AT. Using the onset of the local bipolar electrogram is preferable, because it is easier to determine reproducibly when measuring heavily fractionated, low-amplitude atrial electrograms. On the recording system display, placing the intracardiac channel with the earliest local activation timing adjacent to the mapping catheter channel allows the operator to recognize early activation times immediately at sites sequentially visited by the mapping catheter by visual inspection, rather than having to pause and manually measure local activation times. A triggered sweep mode (constant temporal alignment of the display to a reference electrogram) can also be useful for rapid visual assessment of relative timing of mapped sites. The distal pole of the mapping catheter should be the one used for mapping for the earliest atrial activation site because it is the pole through which RF energy is delivered.

Unipolar recordings from the distal ablation electrode are used to supplement conventional bipolar activation mapping. Unipolar signals can be filtered or unfiltered, but unfiltered signals offer more directional information. Unipolar recordings are helpful by showing negative (QS) patterns with sharp initial deflections at the location of the focus (see Fig. 11-11). Timing of the unipolar electrograms can help ensure that the tip electrode, which is the ablation electrode, is responsible for the early component of the bipolar electrograms. The site of origin of the AT is defined as the site with the earliest presystolic (i.e., preceding the onset of the P wave on the surface ECG) bipolar recording in which the distal tip shows the earliest intrinsic deflection and QS unipolar electrogram configuration (see Fig. 11-11).

Low-amplitude early signals followed by a sharper discrete signal may represent early components of a fragmented electrogram or far-field signal associated with a second discrete local signal.

TABLE 11-4 Exclusion of Orthodromic Atrioventricular Reentrant Tachycardia

PARAMETER	FEATURES
Atrial activation sequence	<ul style="list-style-type: none"> Initial atrial activation site away from the AV groove excludes orthodromic AVRT.
VA interval	<ul style="list-style-type: none"> VA interval < 70 msec or V-high RA interval < 95 msec during SVT excludes orthodromic AVRT.
AV block	<ul style="list-style-type: none"> Spontaneous or induced AV block with continuation of the SVT excludes orthodromic AVRT.
Oscillations in SVT CL	<ul style="list-style-type: none"> Spontaneous changes in PR and RP intervals with a fixed A-A interval excludes orthodromic AVRT.
VES delivered during the SVT	<ul style="list-style-type: none"> With failure to reset (advance or delay) atrial activation with early VES on multiple occasions and at different VES coupling intervals, despite advancement of the local ventricular activation at all sites (including the site of the suspected BT) by > 30 msec, orthodromic AVRT and presence of AV BT are excluded.
Overdrive ventricular pacing during SVT	<ul style="list-style-type: none"> Ventriculoatrial dissociation during overdrive pacing excludes AVRT. If overdrive pacing entrains the SVT with an atrial activation sequence different from that during the SVT, orthodromic AVRT is unlikely. The presence of an A-A-V electrogram sequence following cessation of overdrive ventricular pacing practically excludes orthodromic AVRT. Lack of VA linking (i.e., the VA interval following the last entrained QRS varies [> 14 msec] depending on site, CL, or duration of pacing) argues against orthodromic AVRT.
Overdrive ventricular pacing during SVT	<ul style="list-style-type: none"> If entrainment cannot be achieved or overdrive suppression is demonstrated, orthodromic AVRT is excluded. If the VA interval of the return cycle after cessation of atrial pacing is variable, orthodromic AVRT is excluded.
Ventricular pacing during NSR at the tachycardia CL	<ul style="list-style-type: none"> VA block during pacing excludes orthodromic AVRT.

AV = atrioventricular; AVRT = atrioventricular reentrant tachycardia; BT = bypass tract; CL = cycle length; NSR = normal sinus rhythm; RA = right atrium; SVT = supraventricular tachycardia; VA = ventriculoatrial; VES = ventricular extrastimulation.

This is most likely to happen in the superior posterior RA, where it can actually represent electrical activity generated from the right superior PV. In this situation, the unipolar electrogram demonstrates a sharp negative deflection timing with the later, high-frequency potential on the bipolar electrogram.

Transient catheter-induced interruption of AT by pressure of the catheter may suggest an appropriate site for ablation. This sign is more useful when it is a reproducible phenomenon. Often, however, the tachycardia terminates as the catheter is passing the area, and where the catheter comes to rest may not be the same site as where transient AT termination occurred.

Assessment of simultaneous RA and CS activation sequences by using a multipolar catheter (e.g., duodecapolar or Halo catheters) in the RA around the tricuspid annulus and a decapolar catheter in the CS can facilitate mapping of ATs. In addition to predicting the likely origin of AT, it may facilitate recognition of transformation of the index tachycardia to a different morphology induced by catheter manipulation or by pacing maneuvers. This can be especially important when mapping nonsustained AT or PACs.

TABLE 11-5 Exclusion of Macroreentrant Atrial Tachycardia

PARAMETER	FEATURES
ECG	<ul style="list-style-type: none"> Focal AT usually has a clearly defined isoelectric baseline between P waves in all leads. Macroreentrant AT usually lacks an isoelectric baseline between deflections.
Atrial activation sequence	<ul style="list-style-type: none"> Focal AT is characterized by atrial activation starting rhythmically at a small area (focus), and intracardiac mapping shows significant portions of the CL without recorded atrial activity. Macroreentrant AT endocardial recordings typically show activation spanning the whole tachycardia CL.
Programmed electrical stimulation	<ul style="list-style-type: none"> Focal AT is defined on the basis of dissociation of almost the entire atria from the tachycardia with AES. Macroreentrant AT circuit usually incorporates large portions of the RA or LA, which would be identified with resetting and entrainment mapping.
Tachycardia CL variability	<ul style="list-style-type: none"> Variation in the AT CL of >15% favors focal AT.
Entrainment mapping	<ul style="list-style-type: none"> Focal AT cannot be entrained, except for microreentrant AT; in this case, because the microreentrant circuit is very small, only orthodromic capture is usually observed. In addition, constant or progressive fusion, as demonstrated by intermediate P wave morphologies on the ECG, cannot be demonstrated. Macroreentrant AT is defined by demonstration of concealed or manifest entrainment of the tachycardia with atrial pacing.
PPI variability	<ul style="list-style-type: none"> PPI variability of >30 msec favors focal ATs. PPI variability of <10 msec favors macroreentrant ATs.
Electroanatomical three-dimensional mapping	<ul style="list-style-type: none"> Focal AT is suggested by electroanatomical maps demonstrating radial spreading of activation, from the earliest local activation site in all directions. Macroreentrant AT is suggested by electroanatomical maps demonstrating continuous progression of colors around the RA with close proximity of earliest and latest local activation.
Response to adenosine	<ul style="list-style-type: none"> Focal AT usually responds to adenosine by slowing or termination. Macroreentrant AT usually is not influenced by adenosine and may actually accelerate (when the tachycardia CL is refractoriness-dependent) secondary to shortening of atrial refractoriness by adenosine.

AES = atrial extrastimulation; AT = atrial tachycardia; CL = cycle length; LA = left atrium; RA = right atrium.

Occasionally, multiple unstable focal ATs or PACs can be encountered during mapping. In this setting, the goal should be to focus mapping on the most frequently encountered AT or PAC. Ablation of the most frequent AT often results in organization of the atria and allows for mapping and ablation of other successive ATs. Importantly, care has to be taken to ensure that the correct AT is being mapped and to avoid incorrect sampling of activation times during beats originating from the different foci, which can result in erroneous and confusing activation maps. This can be facilitated by careful attention to changes in P wave morphology or shifting of atrial activation sequences (in the RA or CS) or CLs, or both, during the mapping procedure.⁴³

Occasionally, several areas may show equivalently early activation, sometimes even with a central area of early local activation time surrounded with areas having later local activation times. This finding may indicate a deeper focus (e.g., in the crista terminalis) or multiple breakthrough sites from a single focus. This can obviously cause confusion during mapping and ablation attempts, with little apparent effect of ablation at a site with very good electrogram characteristics or successful ablation at a site with less optimal parameters.

Special attention should be given to ATs mapped to the midseptum and the right anteroseptal region. For ATs mapped to the midseptum, especially if presystolic activity is not particularly early (i.e., less than 30 milliseconds presystolic), the electrogram is not fractionated, and multiple sites have similar activation times, exclusion of LA ATs using transeptal access to the LA is important (Fig. 11-17). For ATs arising from the PVs, CS activation times may not clearly indicate an LA site of origin. For ATs mapped to the right anteroseptal region (HB region), great care must be given to the anteromedial LA septum, right superior PV, and LA free wall because sites in these regions break through early to the right anteroseptal region, where ablation not only is unsuccessful but also can result in AV block.

Endocardial atrial activation sequences from the RA, HB, and CS catheters can help predict the location of PAC or AT foci in the SVC versus the right superior PV before atrial transeptal puncture. In one report, the difference in *interatrial* conduction time (between the HRA and distal CS [CS_{dist}] recording electrodes) during NSR versus PAC ([HRA – CS_{dist}]_{NSR-PAC}) was significantly larger for right superior PV tachycardias compared with SVC tachycardias, and a cutoff value of 20 milliseconds or more of the interatrial conduction time [HRA – CS_{dist}]_{NSR-PAC} was able to differentiate 100% between both locations. During SVC tachycardia, after exiting the SVC and entering the RA, the tachycardia wavefront activates the RA in a high-low sequence and at the same time propagates through the interatrial connection to the LA similar to the activation pathway in NSR. As a consequence, there is little change in the interatrial conduction time compared with that during NSR. Conversely, during right superior PV tachycardias, after leaving the vein and entering the LA, the tachycardia wavefront travels to the rest of the LA and simultaneously crosses the interatrial septum to activate the RA. Thus, the interatrial conduction time would be much shorter than that during NSR. As a consequence, the difference of interatrial conduction time [HRA – CS_{dist}]_{NSR-PAC} between the two groups of tachycardias can be a useful prospective method to define the sources of tachycardia before atrial transeptal puncture.⁴⁴

Similarly, analyzing *intraatrial* conduction times can facilitate the distinction between PACs or ATs originating from the SVC and high crista terminalis from PV foci. The time interval between HRA and HB atrial activation during PACs originating from the SVC and crista terminalis is significantly longer than that of the sinus beats. A difference in intraatrial conduction time ([HRA – HB]_{NSR-PAC}) of less than 0 milliseconds favors SVC or crista terminalis origin. The increased intraatrial conduction delay between HRA and HB recording electrodes is a physiological response to the PACs from the SVC and crista terminalis in the human atrium. In contrast, intraatrial conduction time between the HRA and HB electrodes is shortened in the setting of PV tachycardias because both locations are activated in parallel during PV tachycardias, but in sequence during NSR.⁴⁵

Pace Mapping

When atrial activation originates from a point-like source, such as during focal AT or during pacing from an electrode catheter, the resultant P wave recorded on the surface ECG is determined by the sequence of atrial activation, which depends to a large extent on the initial site of myocardial depolarization. Additionally, analysis of specific P wave configurations in multiple leads allows estimation of the pacing site location to within several square centimeters. Therefore, comparing the paced P wave configuration with that of

FIGURE 11-15 Localized atrial reentry. Atrial tachycardia had a pattern of activation consistent with emanation from a focus yet could be entrained from multiple sites without evidence of ECG or intracardiac fusion. Electrogram at ablation site is very prolonged and fractionated, occupying more than 80 milliseconds of tachycardia CL (shaded), consistent with microreentry or localized reentry. Abl_{dist} = distal ablation site; Abl_{prox} = proximal ablation site; CS_{dist} = distal coronary sinus; CS_{mid} = middle coronary sinus; CS_{prox} = proximal coronary sinus; TA = tricuspid annulus.

FIGURE 11-16 P wave onset during atrial tachycardia (AT) revealed by premature ventricular stimulation. During AT, P wave onset is difficult to discern (buried in T wave). Double ventricular extrastimuli (S) during AT pull the QRS complexes earlier and allow the P wave to be seen clearly (dark arrow, dashed line). Thereafter, a stable atrial electrogram (e.g., high right atrium [HRA] or proximal coronary sinus [CS_{prox}]) can be used as a surrogate marker for the P wave onset during mapping. CS_{dist} = distal coronary sinus; His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; RVA = right ventricular apex.

AT is particularly useful for locating a small arrhythmia focus in a structurally normal heart.^{5,17,24}

Pace mapping involves pacing from the distal tip of the mapping catheter at sites of interest. Initially, the exact morphology of the tachycardia complex should be determined and used as a template for pace mapping. Pace mapping during the tachycardia (at a pacing CL 20 to 40 milliseconds shorter than the tachycardia CL) is preferable whenever possible because it facilitates rapid comparison of tachycardia and paced complexes at the end of the pacing train. If sustained tachycardia cannot be induced, mapping is performed during spontaneous nonsustained runs or ectopic beats. Although it is preferable to match the pacing CL and coupling intervals of AESs to those of spontaneous tachycardia or PACs, some reports have suggested that it is not mandatory to stimulate exactly at the same tachycardia CL to reproduce a similar atrial activation sequence and P wave morphology. Pace mapping is preferably performed with unipolar stimuli (up to 10 mA, 2 milliseconds) from the distal electrode of the mapping catheter (cathode) and an electrode in the IVC (anode), or with closely spaced bipolar pacing at twice the diastolic threshold, to eliminate far-field stimulation effects.¹⁷

The greater the degree of concordance between the morphology during pacing and that during tachycardia, the closer the catheter will be to the site of origin of the tachycardia. Pace maps with identical or nearly identical matches of the tachycardia morphology in all 12 surface ECG leads and intracardiac atrial electrograms can be indicative of the site of origin of the tachycardia (Fig. 11-18).

Pace mapping is used as an adjunct to other methods of mapping to corroborate putative ablation sites. It can be of great help, especially when the AT is difficult to induce. Although there are

some limitations to this technique, many studies have demonstrated efficacy using pace mapping to choose ablation target sites; concordance of P wave morphology during pace mapping and AT has a sensitivity of 86% and a specificity of 37%. However, difficulties in precisely comparing P wave morphologies and intracardiac activation sequences limit the applicability of pace mapping. Moreover, the spatial resolution of atrial pace mapping is up to 2 cm, which is too imprecise.

Mapping Post-Pacing Intervals

Following overdrive atrial pacing from a given site during a relatively regular and stable focal AT, the PPI represents the sum of the conduction time to reach the perifocal tissue, the time required to penetrate the perifocal tissue and reset the focus, the tachycardia CL, and the conduction back to the pacing site. Consequently, if the pacing site is directly at the AT focus, the PPI should be equivalent to the AT CL as a result of the minimal perifocal conduction time between the pacing site and the AT focus. Conversely, pacing at sites distant from the AT focus results in a PPI that is greater than the AT CL as a result of conduction delay between the pacing site and the focus. In fact, the difference between the PPI and tachycardia CL ($[PPI - AT CL]$ difference) after atrial overdrive pacing of a focal AT was found to have a direct relationship with proximity to the focus, regardless of whether or not the tachycardia was actually entrained. The $[PPI - AT CL]$ difference approaches zero (and is no more than 20 milliseconds) when pacing directly at the focus of the tachycardia. There appears to be no significant overdrive suppression or acceleration of the AT when pacing at a rate just faster than the AT rate, regardless of the underlying AT mechanism.

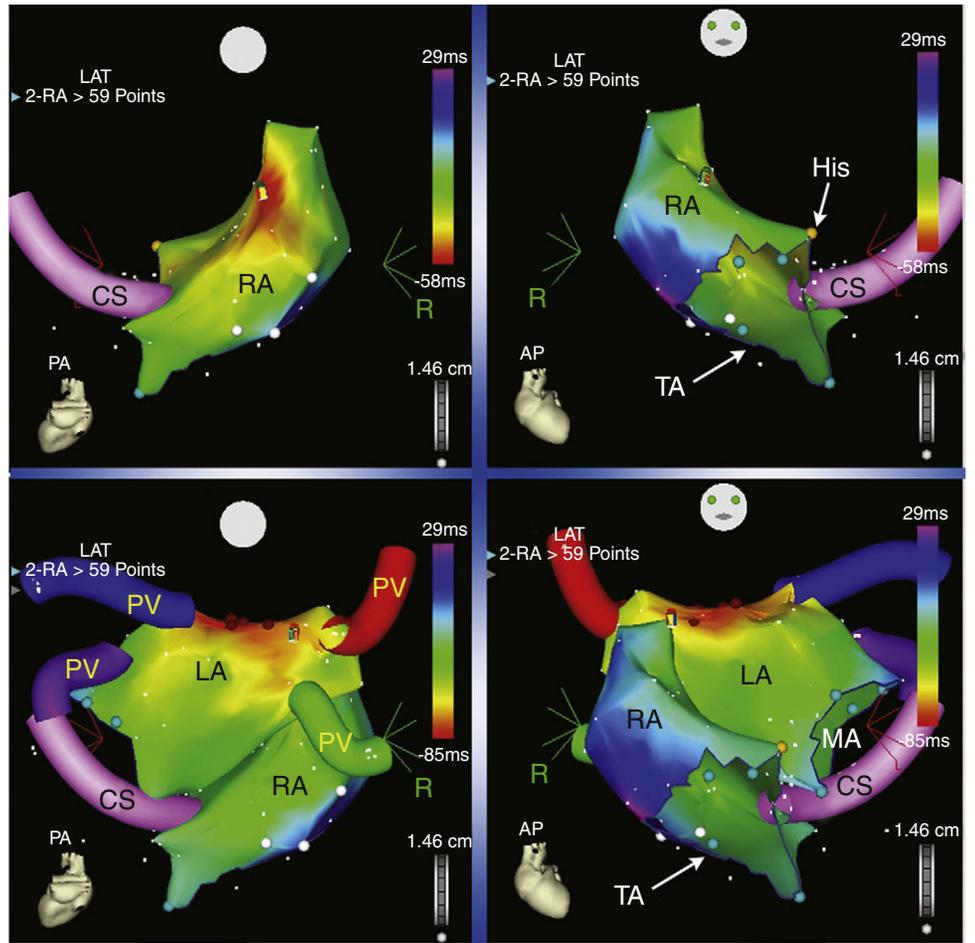

FIGURE 11-17 Three-dimensional electroanatomical (CARTO, Biosense Webster, Diamond Bar, Calif) activation map of focal atrial tachycardia (AT) originating from the left atrial (LA) roof. **Upper panels**, Posteroanterior (PA) and anteroposterior (AP) projections of the CARTO activation map of the right atrium (RA). **Lower panels**, PA and AP projections of the CARTO activation map of both the RA and left atrium (LA). When mapping is limited to the RA (**upper panels**), the site of earliest atrial activation was localized to the interatrial septum, with local activation preceding the reference electrogram by 58 milliseconds. When activation mapping is extended to the LA (**lower panels**), a site with earlier local activation (preceding the reference electrogram by 85 milliseconds) was localized to the LA roof. Radiofrequency ablation (red dots) at that site eliminated the tachycardia. LAT = local activation time; MA = mitral annulus; PV = pulmonary vein; TA = tricuspid annulus.

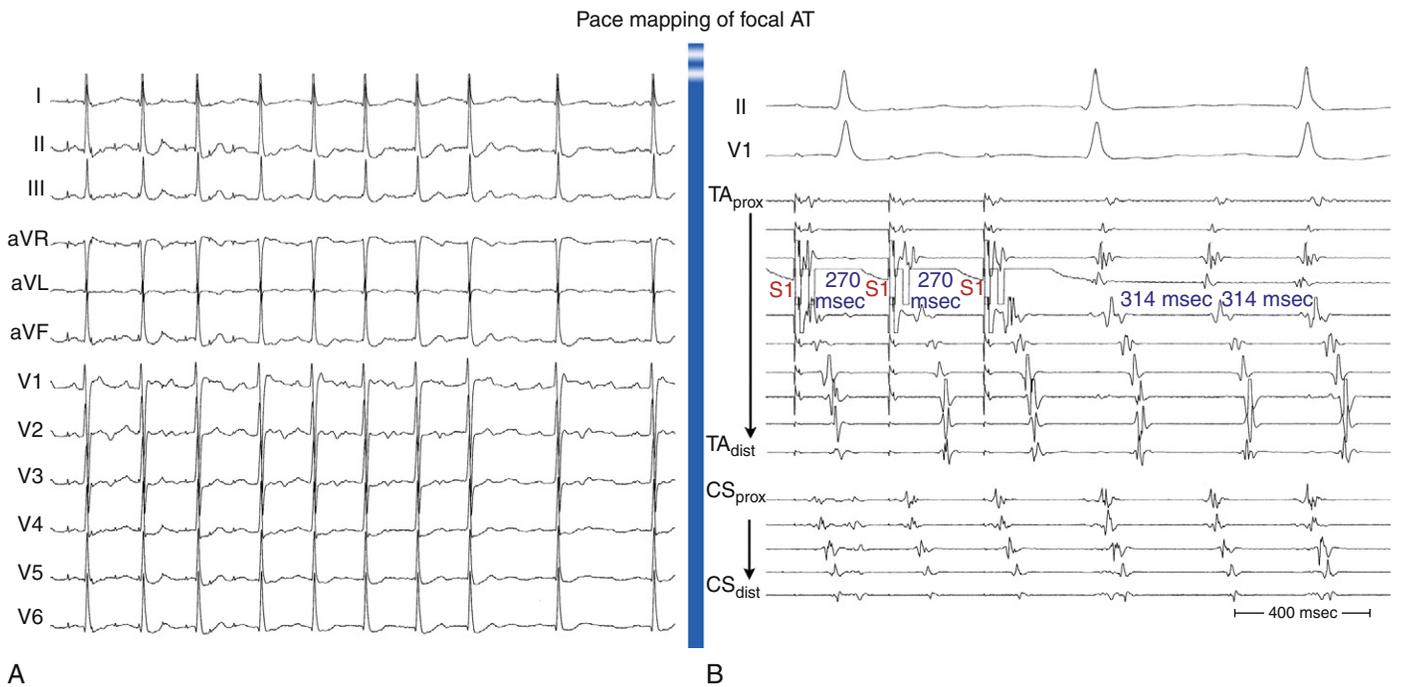

FIGURE 11-18 Surface ECG (A) and intracardiac recordings (B) demonstrating pace mapping performed during sustained focal atrial tachycardia (AT) originating from the interatrial septum. Atrial pacing (left aspect of the ECG and intracardiac recordings) is performed during the tachycardia at a cycle length (CL) of 270 milliseconds from the site of earliest activation (recorded by the Halo catheter positioned around the tricuspid annulus [TA]). Concordance between paced (at the left aspect of the ECG and intracardiac recordings) and tachycardia (at the right aspect of the ECG and intracardiac recordings) P wave morphology on the surface ECG (A), as well as an endocardial atrial activation sequence (**right panel**), suggests proximity of the pacing site to the AT focus. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

Therefore, the [PPI – AT CL] difference can be a useful adjunct to localize the AT focus and guide successful ablation sites.⁴⁶

Additionally, the [PPI – AT CL] difference can be valuable in distinguishing AT in close proximity to the sinus node from sinus tachycardia. It appears that AT foci, unlike the sinus node, have a very short perifocal conduction time, a finding suggesting that there was little “perifocal tissue” as compared with the sinus node. As a consequence, the [PPI – AT CL] difference in the setting of focal AT is determined predominantly by the distance from the focus with minimal contribution of the time required to traverse any perifocal tissue, thus explaining the finding that the [PPI – AT CL] difference approaches zero when pacing is performed directly at the AT focus. In contrast, overdrive pacing during sinus tachycardia is associated with a PPI that always exceeds (by more than 80 milliseconds) the sinus CL, even when pacing is performed directly at the origin of the sinus impulse. This finding suggests significant perinodal conduction delay. The [PPI – AT CL] difference can therefore be used to distinguish perinodal focal AT from sinus tachycardia.⁴⁶

Electroanatomical Mapping

MAPPING TECHNIQUE

Electromagnetic three-dimensional (3-D) mapping (CARTO mapping system [Biosense Webster, Diamond Bar, Calif.] or EnSite NavX system [St. Jude Medical, St. Paul, Minn.]) uses a single mapping catheter attached to a system that can precisely localize the catheter tip in 3-D space and store activation time on a 3-D anatomical reconstruction.^{5,47} Initially, selection of the reference electrogram, positioning of the anatomical reference, and determination of the window of interest are undertaken. The reference catheter is usually placed in the CS (because of its stability) by using an electrode recording a prominent atrial electrogram and ensuring that the ventricular electrogram is not the one picked up by the system.

A 4-mm-tip mapping-ablation catheter is initially positioned, using fluoroscopy, at known anatomical points that serve as landmarks for the electroanatomical map. Anatomical and EP landmarks (IVC, SVC, CS, HB, and tricuspid annulus for RA mapping and the mitral annulus and PVs for LA mapping) are tagged. The catheter is then advanced slowly around the chamber walls to sample multiple points along the endocardium, thus sequentially acquiring the location of its tip together with the local electrogram (see Fig. 11-17 and Video 10).

Activation mapping is performed to define the atrial activation sequence. A reasonable number of points homogeneously distributed in the RA or LA, or both, must be recorded (approximately 80 to 100 points). The local activation time at each site is determined from the intracardiac bipolar electrogram and is measured in relation to the fixed intracardiac electrogram obtained from the CS (reference) catheter. Points are added to the map only if stability criteria in space and local activation time requirements are met. The activation map may also be used to catalog sites at which pacing maneuvers are performed during assessment of the tachycardia (e.g., sites with good pace maps).

Activation maps display the local activation time by a color-coded overlay on the acquired 3-D geometry. The electroanatomical maps of focal ATs demonstrate radial spread of activation, from the earliest local activation site (red in CARTO, white in NavX) in all directions (a well-defined early activation site surrounded by later activation sites; see Figs. 11-17 and 6-16). In these cases, activation time—the total range of activation times, from earliest to latest—is usually markedly shorter than the tachycardia CL. Conversely, a continuous progression of colors (from red to purple in CARTO, white to purple in NavX), with close proximity of earliest and latest local activation, suggests the presence of a macroreentrant tachycardia. In these cases, total activation time is in a similar range to tachycardia CL (see Fig. 12-10).

A stepwise strategy for mapping of RA and LA focal tachycardias was described in a study using CARTO to avoid time-consuming whole-chamber maps.⁴⁷ Using this approach, mapping is started

with the acquisition of four or five anatomically defined sites at the superior and septal aspects of the tricuspid annulus, and the mapping procedure is strategically continued according to this initial activation sequence. If the initial four-point activation map shows the earliest atrial activation to be at the superior aspect of the tricuspid annulus, mapping is continued toward the free wall of the RA, including the crista terminalis. When the earliest atrial activation within the four-point area is found at the septal aspect of the tricuspid annulus, the map is expanded to the triangle of Koch and the paraseptal space. This strategy was found to differentiate reliably between ATs arising from the free wall of the RA, including the crista terminalis and RA appendage, from those arising from the triangle of Koch and paraseptal space, as well as from left-sided ATs. Once the general area of interest is identified, high-density mapping of this area is undertaken, together with conventional electrographic analysis (see earlier), to identify the site of the earliest activation within this target area. If the unipolar electrogram at the point of earliest activation at the RA septum or at the high posterior wall still shows a significant R wave, or if RF ablation at that site is unsuccessful, a left-sided AT origin is assumed, and the procedure is extended to the LA for dual-chamber maps.

ADVANTAGES

Electroanatomical mapping systems provide a highly accurate geometric rendering of the cardiac chamber with a straightforward geometric display that has the capability to determine the 3-D location and orientation of the ablation catheter accurately.

The capability of the mapping system to associate relevant EP information with the appropriate spatial location in the heart and the ability to study activation patterns (with high spatial resolution [less than 1 mm]) during tachycardia in relation to normal anatomical structures and areas of scar significantly facilitate the mapping and ablation procedure. It can suggest the mechanisms underlying the arrhythmia (distinguishing between a focal origin and macroreentrant tachycardia) and allows rapid visualization of the activation wavefront (propagation maps; Fig. 11-19), thus facilitating the identification of appropriate sites for entrainment mapping and pace mapping.

Both electroanatomical mapping systems (CARTO and NavX) provide the capability to create and tag several potential points of interest during the mapping process (e.g., double potentials and sites with good pace maps) and return to them with great precision. These features provide significant advantages over conventional techniques. The catheter can anatomically and accurately revisit a critically important recording site identified previously during the study, even if the tachycardia is no longer present or inducible and map-guided catheter navigation is no longer possible. This accurate repositioning can allow pace mapping from, or further application of, RF energy current to critically important sites that otherwise cannot be performed with a high degree of accuracy and reproducibility. Additionally, fluoroscopy time can be reduced via electromagnetic catheter navigation, and the catheter can be accurately guided to positions removed from fluoroscopic markers (see Fig. 11-17).

LIMITATIONS

The sequential data acquisition required for creation of the electroanatomical map remains time-consuming, because the process requires tagging many points, depending on the spatial details needed to analyze a given arrhythmia. Furthermore, because the acquired data are not coherent in time, multiple beats are required, and stable, sustained, or frequently repetitive arrhythmia is usually needed for creation of the activation map. Single PACs or nonsustained AT can be mapped, although at the expense of an appreciable amount of time. Unlike with the CARTO system, activation times can be acquired simultaneously by the EnSite NavX system from multiple poles on all catheters used during the study (and not just the mapping-ablation catheter).

One difficulty with current methods is that incorrect assignment of activation for a small number of electrograms can invalidate the entire activation map; manual adjustment is often required to achieve the optimal representation. Additionally, data interpolation between mapped points is used to improve the quality of the display; however, areas of unmapped myocardium are then assigned simple estimates of timing and voltage information that may not be accurate.

Additionally, the patient or intracardiac reference catheter may move, thus necessitating remapping. Although a shadow (to record original position) can be placed over this catheter to recognize displacement during the procedure, in which case the catheter can be returned to its original location, this may not always be feasible or accurate. Another limitation specific to the CARTO system is the requirement of a proprietary mapping catheter; no other catheter types can be used with this system. In contrast, the EnSite NavX system can work with most manufacturers' ablation catheters and RF or cryogenerators.

Mapping Nonsustained Focal Atrial Tachycardia

Several alternative mapping modalities can be used when AT is short-lived or cannot be reproducibly initiated, including simultaneous multisite data acquisition systems (noncontact mapping system, basket catheter, or localized high-density mapping). Moreover, the electroanatomical mapping and pace mapping techniques discussed can be used in these situations.

ENSITE NONCONTACT MAPPING SYSTEM

The EnSite 3000 noncontact mapping system (St. Jude Medical, St. Paul, Minn.) consists of a noncontact catheter with a multielectrode array surrounding a 7.5-mL balloon mounted at the distal end. Raw data detected by the multielectrode are transferred to a silicon graphics workstation via a digitalized amplifier system. The multielectrode array is used to construct a 3-D computer model of the virtual endocardium. The system is able to reconstruct more than 3000 unipolar electrograms simultaneously and superimpose them onto the virtual endocardium,

thus producing isopotential maps with a color range representing voltage amplitude. Electrical potentials at the endocardial surface some distance away are calculated. Sites of early endocardial activity, which are likely adjacent to the origin of the AT, are usually identifiable. Noncontact mapping can rapidly identify AT foci and thus delineate starting points for conventional mapping.^{48,49}

The main advantage of noncontact endocardial mapping is its ability to recreate the endocardial activation sequence from simultaneously acquired multiple data points over a few (theoretically one) tachycardia beats, without requiring sequential point-to-point acquisitions. Therefore, it can be of great value in mapping nonsustained arrhythmias, PACs, irregular ATs, and rhythms that are not hemodynamically stable.^{48,49}

TECHNIQUE. The EnSite 3000 system requires placing a 9 Fr multielectrode array and a 7 Fr conventional (roving) deflectable mapping-ablation catheter in the cardiac chamber of interest. The balloon catheter is advanced over a 0.035-inch guidewire under fluoroscopy guidance and positioned in the atrium and deployed. The balloon is positioned in the center of the atrium and does not come in contact with the atrial walls being mapped. Activated clotting time is kept at 250 to 300 seconds for right-sided and 300 to 400 seconds for left-sided mapping.

The mapping-ablation catheter is positioned in the atrium and used to collect geometry information. The mapping catheter is initially moved to known anatomical locations (IVC, SVC, CS, HB, and tricuspid annulus for RA mapping and mitral annulus and PVs for LA mapping), which are tagged. A detailed geometry of the chamber is then reconstructed by moving the mapping catheter around the atrium. Using this information, the computer creates a model of the atrium.

After the chamber geometry is determined, mapping of the arrhythmia can begin. The data acquisition process is performed automatically by the system, and all data for the entire chamber are acquired simultaneously. The system then reconstructs unipolar electrograms simultaneously and superimposes them onto the virtual endocardium, thus producing isopotential maps with a color range representing voltage amplitude. A default high-pass filter setting of 2 Hz is used to preserve components of slow conduction on the isopotential map. Color settings are adjusted so that

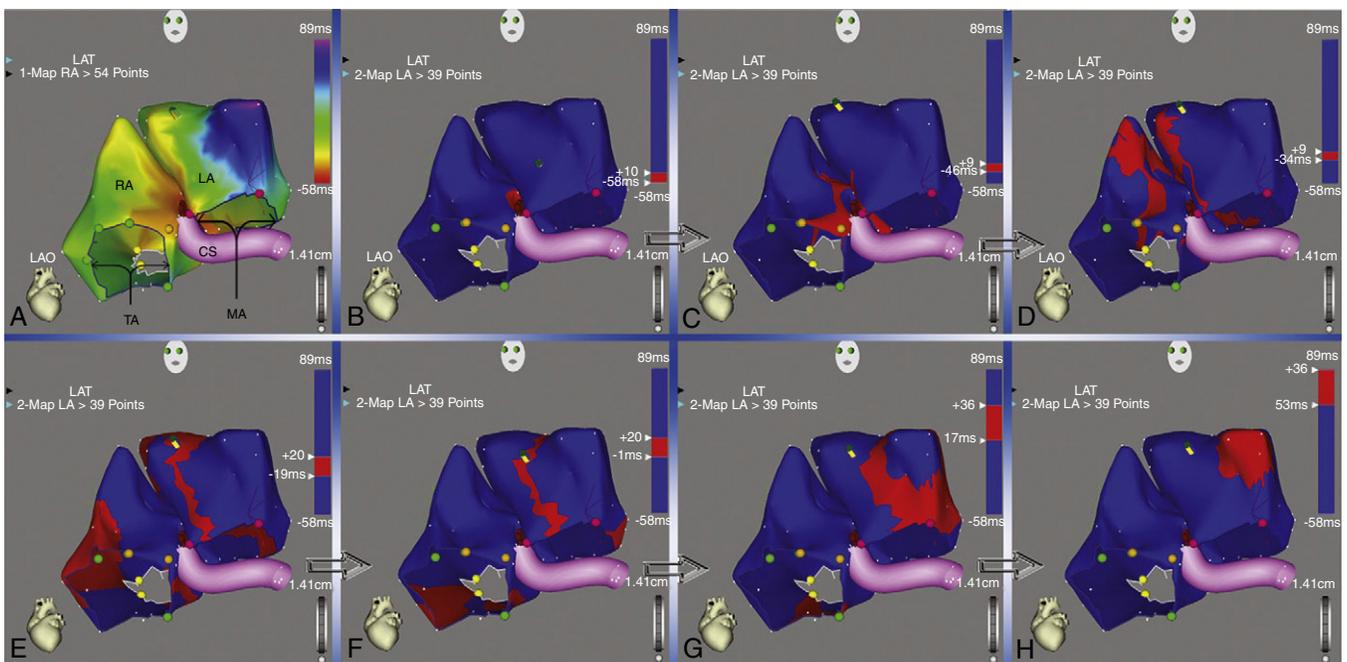

FIGURE 11-19 A, Three-dimensional electroanatomical (CARTO, Biosense Webster, Diamond Bar, Calif.) biatrial activation map in the left anterior oblique (LAO) view constructed during focal atrial tachycardia (AT) originating posterosuperior to the coronary sinus (CS) ostium. During tachycardia, the activation wavefront propagates from the earliest local activation site (red) in all directions. B to H, Biatrial propagation map during the focal AT. LAT = local activation time; MA = mitral annulus; TA = tricuspid annulus.

the color range matches 1 to 1 with the millivolt range of the electrogram deflection of interest. The color scale for each isopotential map is set so that white indicates most negative potential and blue indicates least negative potential. Activation can be tracked on the isopotential map throughout the cycle to the onset of the tachycardia beat. Virtual electrograms are then reconstructed at sites of earliest activation on the isopotential maps to look for a unipolar QS pattern. If the atrial electrograms overlap with the T wave, a VES may be delivered to accelerate ventricular depolarization and repolarization and may reveal the following atrial complex without far-field interference.

Isochronal maps can also be created. These maps represent progression of activation throughout the chamber relative to a user-defined electrical reference timing point. Contact mapping using the conventional ablation catheter may also be performed at sites of interest to supplement noncontact mapping findings, and color-coded contact activation maps can be displayed on the same 3-D geometry. Once earliest activation is identified, the site is labeled on the 3-D map, and the locator signal is used to navigate the ablation catheter to it in real time during tachycardia or during normal rhythm when sustained tachycardia is not inducible.⁴⁹

The origin of AT is defined as the earliest site showing a single spot on the isopotential map and a QS pattern on the noncontact unipolar electrogram. Early sites with an rS pattern can represent foci that are epicardial in origin or early activation sites in an adjacent structure. The earliest site that shows an rS pattern with a sudden increase of peak negative potential on the noncontact unipolar electrogram after the AT depolarizes is considered to represent the “break-out point” or “exit” from the tachycardia focus, and the path between the origin and the break-out point likely represents the preferential pathway of conduction from the origin of the AT. As such, the traditionally defined origin of focal AT (by contact mapping techniques), whereby centrifugal activation occurs, potentially represents the break-out point, rather than the real origin of the tachycardia. Ablation at the origin of tachycardia or along the proximal path to the break-out point typically eliminates the arrhythmia.⁴⁹

LIMITATIONS. Very-low-amplitude signals may not be detected, particularly if the distance between the center of the balloon catheter and the endocardial surface exceeds 40 mm, thus limiting the accurate identification of diastolic signals. Furthermore, a second catheter is still required for additional mapping and for ablation. Aggressive anticoagulation is required using this mapping modality, and special attention and care are necessary during placement of the large balloon electrode in a nondilated atrium.

MULTIELECTRODE BASKET CATHETER MAPPING

The basket catheter consists of an open-lumen catheter shaft with a collapsible, basket-shaped, distal end. The catheter is composed of 64 electrodes mounted on 8 flexible, self-expanding, equidistant metallic splines (each spline carrying 8 ring electrodes). The electrodes are equally spaced 4 or 5 mm apart, depending on the size of the basket catheter used (with diameters of 48 or 60 mm, respectively). Each spline is identified by a letter (from A to H) and each electrode by a number (from 1 to 8, with electrode 1 having the distal position on the splines). The basket catheter is constructed of a superelastic material to allow passive deployment of the array catheter and optimization of endocardial contact.

TECHNIQUE. The size of the atrium is initially evaluated (usually with echocardiography) to help select the appropriate size of the basket catheter. The collapsed basket catheter is advanced under fluoroscopy guidance through an 11 Fr long sheath into the RA or LA; the catheter is then expanded (Fig. 11-20). Electroanatomical relations are determined by fluoroscopically identifiable markers (spline A has one marker and spline B has two markers located near the shaft of the basket catheter). Additionally, the electrical signals recorded from certain electrodes (e.g., annular or HB electrograms) can help identify the location of those particular splines.

From the 64 electrodes, 64 unipolar signals and 32 to 56 bipolar signals can be recorded (by combining 1-2, 3-4, 5-6, 7-8 or 1-2,

2-3 until 7-8 electrodes are on each spline). Color-coded activation maps are reconstructed. The concepts of activation mapping discussed earlier are then used to determine the site of origin of the tachycardia. The capacity of pacing from the majority of basket electrodes allows the evaluation of activation patterns, pace mapping, and entrainment mapping. The electrograms recorded from the basket catheter can be used to monitor changes in the activation sequence in real time and thereby indicate the effects of ablation as lesions are created.

After basket catheter deployment, the conventional catheters are introduced and placed in standard positions. The ablation catheter is placed in the region of earliest activity and is used for more detailed mapping of the site of origin of the AT (see Fig. 11-20). The Astronomer (Boston Scientific, Natick, Mass.) navigation system permits precise and reproducible guidance of the ablation catheter tip electrode to targets identified by the basket catheter.

LIMITATIONS. The electrode array does not expand to provide adequate contact with the entire atrium. In addition, the system does not permit immediate correlation of activation times to precise anatomical sites. Furthermore, a second catheter is still required for additional mapping and for ablation.

LOCALIZED HIGH-DENSITY MAPPING CATHETER

The PentaRay (Biosense Webster, Diamond Bar, Calif.) is a high-density, multielectrode mapping catheter that may be used for mapping of focal AT. This 7 Fr steerable catheter (180 degrees of unidirectional flexion) has 20 electrodes distributed over 5 soft radiating spines (1-mm electrodes separated by 4-4-4 or 2-6-2 mm interelectrode spacing), allowing splaying of the catheter to cover a surface diameter of 3.5 cm. The spines have alphabetical nomenclature (A to E), with spines A and B recognized by radiopaque markers (see Fig. 6-3).⁵⁰

Localization of the atrial focus can be performed during tachycardia or atrial ectopy. Guided by the ECG appearance and previous mapping information, the catheter is sequentially applied to the endocardial surface in various atrial regions to allow rapid activation mapping. Mapping is performed to identify the earliest endocardial activity relative to the P wave or to a fixed catheter positioned within the CS, or both. By identifying the earliest site of activation around the circumference of the high-density catheter, vector mapping is performed, moving the catheter and applying it to the endocardium in the direction of earliest activation (outer bipoles) to identify the tachycardia origin and bracket activation (i.e., demonstrating later activation in all surrounding regions). Ablation is performed at the site of earliest endocardial activation relative to the P wave when tachycardia is bracketed.

The high-density mapping catheter may offer several potential advantages. Whereas basket catheter mapping has the ability to perform rapid simultaneous contact mapping of the chamber and provides a global density of mapping, its localized resolution is limited. In contrast, this newer mapping modality allows splaying of the spines against the endocardial surface to achieve high-density contact mapping to localize and characterize the origin of focal ATs accurately. Additionally, the ability to position multiple electrodes in a circumscribed part of the endocardium is particularly advantageous for use within the LA and for mapping complex focal AT.

Ablation

Target of Ablation

The site of origin (or focus) of focal AT is the target of ablation.^{31,42} Bipolar electrograms at the site of successful ablation are typically fractionated and demonstrate moderate to marked presystolic timing. Average presystolic intervals at sites of successful ablation are generally longer than 30 milliseconds (but not mid-diastolic, as in the case of macroreentrant AT). However, the key to successful mapping is finding the earliest site, because there is great variability in the presystolic interval that will be obtained

at successful ablation sites (10 to 80 milliseconds). QS unipolar electrogram morphology is highly predictive of the successful ablation site and supplements findings of bipolar mapping. Timings of the earliest bipolar and unipolar electrogram should be in agreement (see Fig. 11-11).

Focal ATs arising from the PVs can be targeted by either focal ablation or electrical isolation of the culprit PV. The latter approach can potentially limit the risk of PV stenosis, especially when targeting more distal foci within the PV.^{21,22}

Ablation Technique

RF power delivery should be adjusted to achieve a tip temperature of 55° to 65°C.^{31,42} The response of the AT focus to a successful RF application should be rapid, typically within a few seconds of RF energy delivery. The most common response to successful ablations is abrupt termination. However, in some patients, transient acceleration precedes termination; in others, gradual slowing precedes termination (Fig. 11-21). If the tachycardia is not affected within 10 to 20 seconds, RF energy application is terminated, and the catheter is repositioned slightly for a repeat attempt. Prolonged RF applications beyond 10 to 20 seconds without accompanying changes in AT rate are usually nonproductive.

Extensive ablation in one area that does not terminate AT may cause enough damage to block the spread of activation partially in the region, thus causing a change in P wave morphology (although

the actual focus may not have changed), as well as slow propagation of the tachycardia impulse away from the focus of the tachycardia to activate atrial myocardium. The latter effect can result in an increase in the interval between the presystolic electrogram at the focus and P wave onset (Fig. 11-22).

If the AT terminates or changes rate noticeably during the 10-second application, the RF application is continued for 30 to 60 seconds. However, in some patients, applications that may be just slightly off target can cause acceleration of the AT without terminating it. In these cases, the tachycardia rate usually remains accelerated as long as the RF application is in progress, and it returns immediately to the baseline rate when the RF delivery is discontinued. If adequate catheter tip temperature is achieved and good contact is ensured (which can be assessed by observing ST elevation on the unipolar recording), this probably suggests that the catheter is close to, but not exactly at, the proper target area. Continued RF application at a site that produces only acceleration (but not termination) after 15 seconds invites the possibility of transient injury to the AT focus that impedes further ablation and can result in later AT recurrence.

Ablation of focal ATs near the AVN or HB (in the triangle of Koch) requires special precautions. Titrated RF energy output should be used, starting with 5 W and increasing by 5 W every 10 seconds of energy application, up to a maximum of 40 W. Additionally, it is preferable to deliver RF energy during AT; if AT terminates during RF delivery, the RF application is continued at the same power output

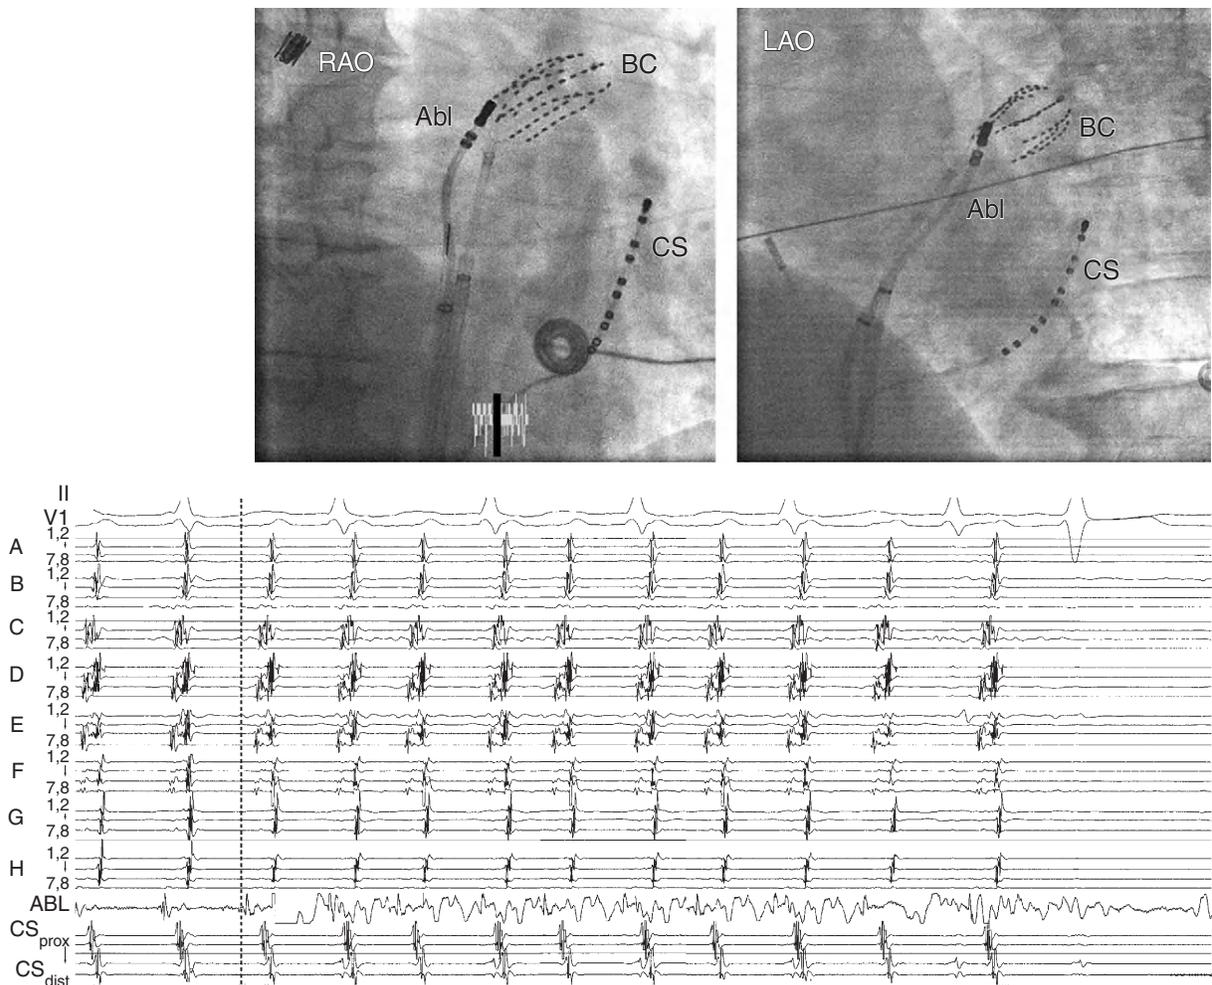

FIGURE 11-20 Basket catheter (BC) mapping of atrial tachycardia (AT). **Upper panels**, Fluoroscopic views (right anterior oblique [RAO], 30 degrees; left anterior oblique [LAO], 60 degrees) of the BC positioned at the ostium of the left superior pulmonary vein (PV). **Lower panel**, BC bipolar electrograms (1-2, 3-4, 5-6, 7-8) from the eight splines (A to H) are displayed. The earliest atrial activation during AT is recorded by the proximal electrodes of the E spline of the basket catheter. Detailed mapping obtained by the ablation catheter (Abl) recorded an even earlier activation (dashed line) at a site in the left atrial roof just outside the PV ostium. Radiofrequency energy delivery at that site resulted in termination of the tachycardia within a few seconds. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

FIGURE 11-21 Catheter ablation of focal atrial tachycardia (AT) originating from the superoanterior aspect of the mitral annulus. Four surface ECG leads and intracardiac recordings from a catheter in the coronary sinus (CS) and a 20-pole Halo catheter positioned around the tricuspid annulus (TA) are shown. Radiofrequency (RF) energy delivery at the successful ablation site resulted within a few seconds in acceleration then slowing of the tachycardia rate followed by termination of the AT and restoration of sinus rhythm. ABL_{dist} = distal ablation site; dist = distal; prox = proximal.

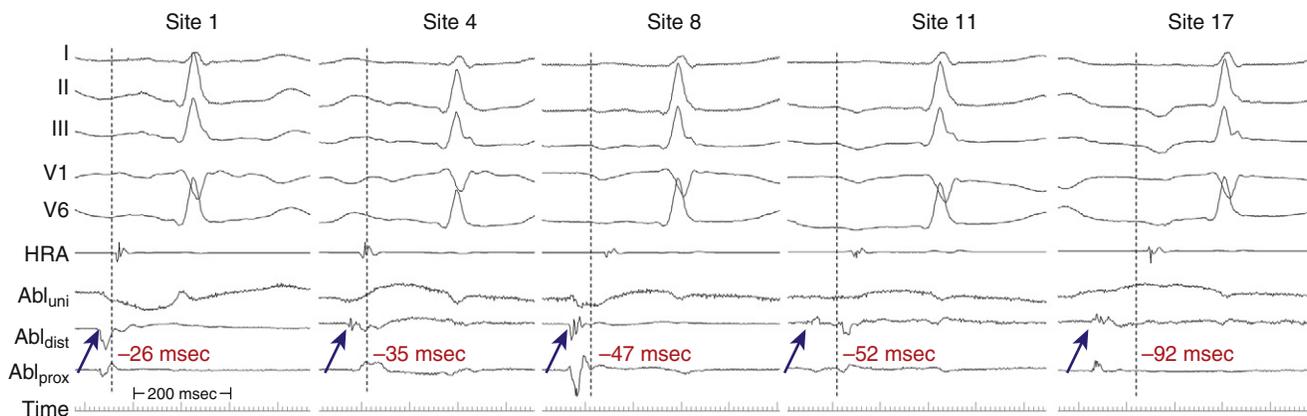

FIGURE 11-22 Recordings from focal right atrial (RA) tachycardia during progressive ablation. Examples are shown from selected ablation sites. Site 2 shows tachycardia from high RA with a site 26 milliseconds prior to the P wave onset. Ablation here changed the P wave morphology as shown in subsequent examples, and progressive ablation at sites in the lateral RA resulted in lengthening of the interval from electrogram to P wave onset (up to 92 milliseconds). Note also progressive fragmentation of the bipolar ablation recording and degradation of the unipolar recording. ABL_{dist} = distal ablation site; Abl_{prox} = proximal ablation site; Abl_{uni} = unipolar ablation site; HRA = high right atrium.

for 30 seconds and then repeated for 30 seconds or more. If the AT does not terminate with an RF output of 40 W for 30 seconds, then another site should be sought. If accelerated junctional rhythm develops after AT termination, overdrive atrial pacing should be performed to monitor AV conduction, or RF application should be stopped and other sites sought. To reduce the risk of AV block, RF delivery should be immediately discontinued when (1) impedance rises suddenly (more than 10 Ω), (2) the PR interval (during NSR, atrial pacing, or AT) prolongs, (3) AV block develops, (4) retrograde conduction block is observed during junctional ectopy, or (5) fast junctional tachycardia (CL shorter than 350 milliseconds) occurs because it may herald imminent heart block.

USE OF INTRACARDIAC ECHOCARDIOGRAPHY TO GUIDE MAPPING AND ABLATION

Intracardiac echocardiography (ICE) can be useful to provide focused real-time images of the endocardial surfaces critical for positioning of catheters, establish catheter tip-tissue contact, and monitor energy delivery in the beating heart. In particular, ICE has been used in cristal ATs. In view of the variability in the anatomical course of the crista terminalis, ICE can assist in accurate positioning of the multipolar mapping catheter and guide precise mapping along this structure with the mapping-ablation catheter (Fig. 11-23).

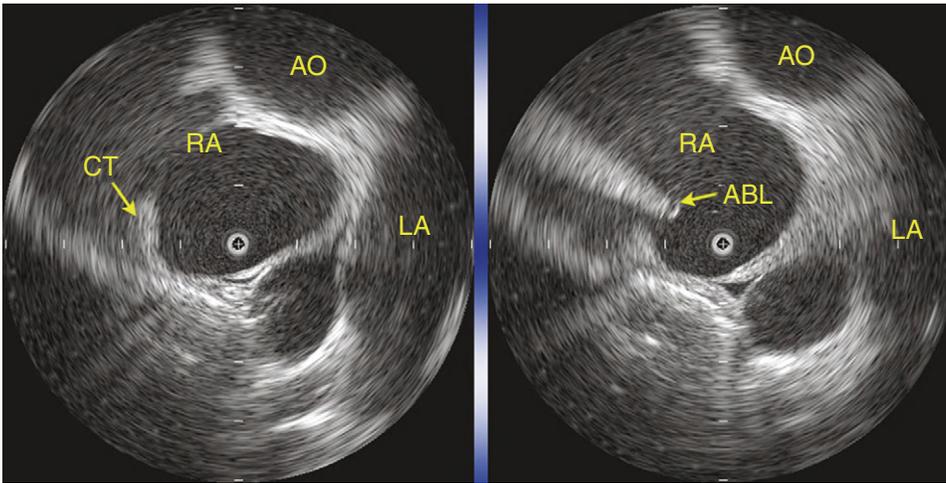

FIGURE 11-23 Intracardiac echocardiographic view (using the mechanical radial imaging system) of the high crista terminalis (CT) showing the anatomical structures and location of the ablation catheter (ABL) at the site of radiofrequency application (right panel). The ablation catheter is located on the high lateral CT. AO = aorta; LA = left atrium; RA = right atrium.

ICE can also help demonstrate the close anatomical relation between the superior crista terminalis and right upper PV and can facilitate careful and subtle mapping to determine whether a tachycardia is high crista or in the right upper PV. This is important when making a decision about the necessity to proceed with a transeptal puncture, in which case ICE can also be helpful. Echocardiographic lesion characteristics defined by ICE can provide a guide for directing additional RF lesions. The effective RF lesion has an increased or changed echo density completely extending to the epicardium, with the development of a trivial linear low-echo density or echo-free interstitial space, a finding suggesting a transmural RF lesion.

Endpoints of Ablation

TACHYCARDIA TERMINATION DURING RADIOFREQUENCY ENERGY APPLICATION. Sudden termination of a sustained AT during RF application suggests a successful ablation. However, reliance on AT termination during RF application as the sole criterion of successful ablation may be misleading because AT may terminate spontaneously or in response to PACs induced by the RF application, and AT termination may not be a result of ablation of the AT focus. Furthermore, sudden termination of the AT can be associated with catheter dislodgment from the critical site to another site, thus making it difficult to deliver additional lesions at the critical site.

NONINDUCIBILITY OF TACHYCARDIA. To use this criterion as a reliable endpoint, careful assessment of inducibility should be performed prior to ablation; the feasibility and best method of reproducible induction of the AT should be documented at baseline before ablation. In the setting of easy inducibility prior to ablation, one may consider the lack of inducibility as an indicator of successful ablation. Noninducibility of the arrhythmia is inapplicable if the original arrhythmia is noninducible at baseline or was inadvertently terminated mechanically. Inducibility should be reassessed 30 minutes after the last successful RF application.

Outcome

The short-term success rate is variable (range, 69% to 100%; mean, 91%). Complication rates range from 0% to 8% (mean, 3%). Recurrence rates range from 0% to 25% (mean, 9%). The mechanism of AT can influence outcome.

Phrenic nerve injury can occur during ablation of ATs in the right or left free wall, SVC, right superior PV, or left PVs. The ability to pace the phrenic nerve at a candidate ablation site should prompt attempting to find a slightly different site or, if this is not possible, applying RF energy at low power or for a short duration. Even when the phrenic nerve cannot be paced, intermittent fluoroscopic visualization of the ipsilateral diaphragm movement should be performed during RF application at high-risk sites, and RF delivery

should be terminated if diaphragmatic excursion decreases. An alternative approach is to position a catheter in the SVC at a site at which the phrenic nerve can be consistently captured and pace the phrenic nerve during ablation. RF energy delivery should be stopped immediately if diaphragmatic contraction becomes less vigorous or ceases.

Sinus node dysfunction can develop during ablation of ATs originating near the sinus node. The risk is usually low because of the diffuse distribution of the sinus node complex, except in older patients or in those with preexisting sinus node dysfunction.

AV block can complicate ablation of ATs originating in the anteroseptal region. When the HB potential is detectable at the ablation catheter location, titrated RF energy output and RF application for short duration should be used, coupled with overdrive atrial pacing to monitor AV conduction in case accelerated junctional rhythm occurs. Alternatively, cryoablation may be used in this region with its slightly better safety margin for AV conduction. Moreover, detailed mapping in the right and left anteroseptal regions is required, because ATs arising along the anterior and anteroseptal LA and even the right superior PV frequently have earliest RA activation at the HB region, with a normal activation pattern along the posterior LA, as recorded by the CS electrodes.

Pathophysiology

Right Atrial Anatomy

The right atrial (RA) endocardial surface is composed of many orifices and embryonic remnants, accounting for an irregular, complex surface. The RA endocardium is architecturally divided into three anatomically distinct regions; each is a remnant of embryological development. The posterior smooth-walled RA, derived from the embryonic sinus venosus, receives the superior vena cava (SVC), the inferior vena cava (IVC), and the coronary sinus (CS). It also contains the fossa ovalis, the sinus node, and the atrioventricular (AV) node (AVN). The anterolateral trabeculated “true” RA, derived from the true embryonic RA, is lined by horizontal, parallel ridges of muscle bundles that resemble the teeth of a comb (the pectinate muscle). It contains the RA appendage and free wall. The atrial septum is primarily derived from the embryonic septum primum and septum secundum.

The posterior smooth-walled RA and the anterolateral trabeculated RA are separated by the crista terminalis on the lateral wall and the eustachian ridge in the inferior aspect. The sulcus terminalis, where the sinus node is located, is a subtle groove on the epicardial surface of the heart corresponding to the crista terminalis. The crista terminalis is a C-shaped, convex, thick muscular ridge that runs from the high septum, anterior to the orifice of the SVC superiorly, and courses caudally along the posterolateral aspect of the RA. In its inferior extent, it courses anteriorly to the orifice of the IVC. As the crista reaches the region of the IVC, it is extended by the eustachian valve ridge. The eustachian valve is the remnant of the embryonic sinus venosus valve, which manifests as a flap of variable thickness and mobility along the orifice of the IVC; this valve can continue as a ridge superiorly along the floor of the RA to the ostium of the CS (CS os), to join the valve of the CS, form the tendon of Todaro, and then continue onto the interatrial septum as the inferior limbus of the fossa ovalis.¹

The SVC enters the roof of the RA between the base of the RA appendage and the superior margin of the interatrial septum. The IVC enters the posterolateral portion of the floor of the RA along the inferior margin of the interatrial septum. The CS enters the inferior aspect of the RA adjacent to the inferior margin of the interatrial septum, slightly more anterior and medial relative to the orifice of the IVC, and closer to the tricuspid annulus. On the lower third of the interatrial septum lies the fossa ovalis.

The tricuspid annulus lies anterior to the body of the RA, and its inferior portion lies a short distance (approximately 1 to 4 cm) anterior to the eustachian ridge, although its course varies among individuals.² The cavotricuspid isthmus (CTI) is the part of the RA between the ostium of the IVC and the eustachian ridge (posteriorly) and the tricuspid annulus (anteriorly). The CTI runs in an

anterolateral-to-posteromedial direction, from the low anterior RA to the low septal RA (see Fig. 17-1). Its width and muscle thickness are variable, from a few millimeters to more than 3 cm in width and more than 1 cm in depth. The CTI becomes wider in a medial-to-lateral direction, and it is thinnest in its central portion. A thick eustachian ridge (greater than 4 mm) is seen in 24% of patients. At mid-diastole, the central isthmus is straight in 8% of patients, concave in 47% of patients, and pouch-like (more than 5 mm) in 45% of patients.^{3,4} The eustachian ridge (often composed of partly or largely fibrous tissue) occurs as an elevation on the CTI. The area between the tricuspid annulus and the eustachian ridge is referred to as the subeustachian isthmus, whereas the downslope of the eustachian ridge leads to the junction of the RA and IVC. The pectinates, as they fan out from the crista terminalis or other muscle bundles on the CTI, typically spare the myocardium just atrial to the tricuspid valve. This smooth portion of the cavotricuspid annulus is referred to as the vestibular portion.¹ In the normal heart, CTI anatomy can be flat, “hilly” (from prominent eustachian ridge or pectinate muscles, or both), concave, or have a pouch-like recess.

Typical Atrial Flutter Circuit

Typical atrial flutter (AFL) is a type of macroreentrant atrial tachycardia (AT) that uses the CTI as an essential part of its circuit. The circuit boundaries are the tricuspid annulus, crista terminalis, IVC orifice, eustachian ridge, CS os, and probably fossa ovalis. These barriers (lines of conduction block) can be functional or anatomical and are necessary to provide adequate path length for the flutter reentry circuit. Whereas the anterior boundary of the tachycardia circuit has been well established as being the tricuspid ring, the posterior boundaries are more complex and not as well defined, and they occur at a variable distance from the anterior border; the posterior borders are narrowest in the region of the eustachian ridge and widest in the anterior part of the RA.^{2,5-8}

The CTI provides the protected zone of slow conduction necessary for the flutter reentry circuit. The area of slowest conduction is probably localized in the lateral aspect of the CTI in younger patients and in the medial aspect in older patients.⁹ Conduction velocity in the CTI during pacing in sinus rhythm is slower in patients with typical AFL compared with those without any history of AFL.^{3,10} The mechanism of the slower conduction velocity in the CTI, relative to the interatrial septum and RA free wall, is uncertain but can be related to the anisotropic fiber orientation. With aging or atrial dilation, intercellular fibrosis can change the density of gap junctions and produce nonuniform anisotropic conduction through the trabeculations of the CTI. Additionally, the CTI and RA in patients with typical AFL are significantly larger than those in a control population.⁶

The crista terminalis plays an important role as a functional barrier during typical AFL. Conduction delay and rate-related transverse block across the crista terminalis has been consistently observed in sinus rhythm and during pacing in humans. A line of transverse conduction block along the crista terminalis serving as a lateral boundary can be determined by the presence of double and split potentials recorded during AFL or rapid pacing from either side of the crista terminalis during electrophysiological (EP) testing. Structural characteristics of the crista terminalis influence transverse conduction; steep slope and arborization of the crista terminalis have been implicated as geometric factors in its transverse conduction block. Typical AFL is more likely to occur in the setting of a thicker and continuous crista terminalis, and these patients are more likely to exhibit transverse crista terminalis conduction block at longer cycle lengths (CLs) as opposed to controls. Similarly, the region posterior to the crista terminalis (the posterior smooth-walled RA) also has been shown to demonstrate functional transverse conduction block during AFL or rapid pacing.^{11,12}

Typical AFL is of two types: counterclockwise and clockwise.⁵ In counterclockwise AFL, the activation wavefront propagates caudocephalically up the septal side of the tricuspid annulus toward the crista terminalis and advances cephalocaudally along the lateral wall of the RA to reach the lateral tricuspid annulus, after which it propagates through the CTI ("counterclockwise" as viewed in the left anterior oblique [LAO] view from the ventricular side of the tricuspid annulus). The width of the activation wavefront in typical AFL varies considerably, determined by the distance between the anterior and posterior boundaries at any given part of the circuit. It is very

narrow inferiorly at the CTI and substantially wider moving upward. The substantial distance between anterior and posterior borders as well as the anatomical barriers superiorly, combined with variability in the completeness of the posterior border, creates conditions for substantial variability in the upper part of the circuit. Despite a relatively similar activation sequence, the active circuit (as determined by entrainment mapping) is variable. Most commonly, the reentrant wavefront courses not around the tricuspid annulus but obliquely between anterior and posterior borders away from the tricuspid annulus along any available, more rapidly conducting segments. Consequently, significant portions of the RA, including areas around the tricuspid annulus, can often be passively activated. In many subjects, the upper portions of the circuit pass behind the RA appendage and lie near or at the posterior circuit border, or they bifurcate around the SVC or RA appendage, or both. The posterior border can extend completely or partially between the IVC and the SVC.^{7,8}

The flutter circuit is entirely confined within the RA. Left atrial (LA) activation occurs as a bystander and follows transeptal conduction across the inferior CS-LA connection, Bachmann bundle, or fossa ovalis.^{2,6}

In clockwise (reverse typical) AFL, activation propagates in the direction opposite to that in counterclockwise typical AFL (Fig. 12-1). Clockwise AFL is observed in only 10% of clinical cases, despite the fact that it is easily inducible in the EP laboratory with programmed electrical stimulation. Clockwise AFL can be induced in the EP laboratory in approximately 50% of patients who clinically present with only counterclockwise AFL. The 9:1 clinical predominance of counterclockwise AFL can be related to the localization of

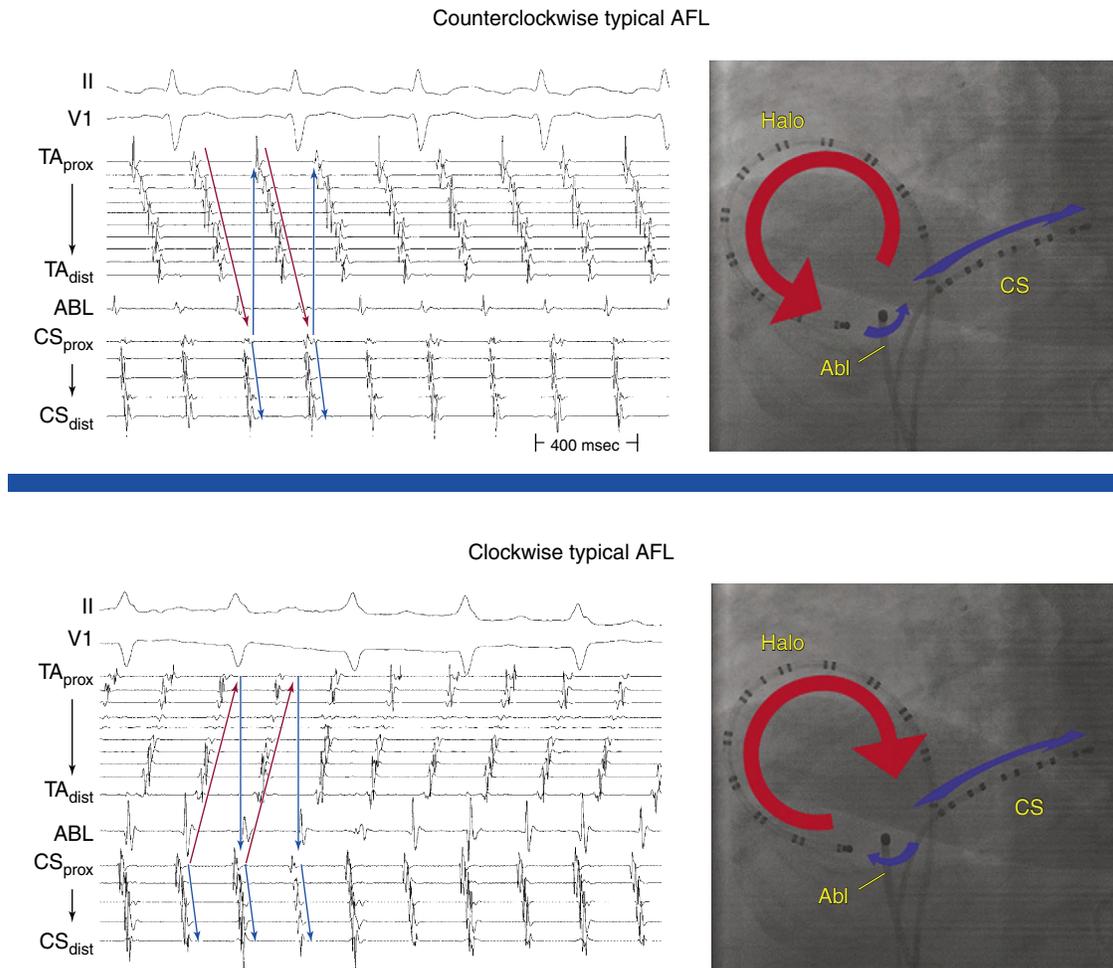

FIGURE 12-1 Endocardial activation during counterclockwise (upper panel) and clockwise (lower panel) typical atrial flutter (AFL) in the same patient. Catheter position and wavefront activation during the tachycardia are illustrated in a left anterior oblique fluoroscopic view (right side). The ablation catheter (Abl) is positioned at the cavotricuspid isthmus (CTI), and the Halo catheter is positioned around the tricuspid annulus, with the distal end at the lateral aspect of the CTI. Abl = ablation site; CS = coronary sinus; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; TA_{dist} = distal tricuspid annulus; TA_{prox} = proximal tricuspid annulus.

an area with a low safety factor for conduction in the CTI, close to the atrial septum. Additionally, counterclockwise AFL is more likely to be induced with rapid atrial pacing from the CS os. Conversely, clockwise AFL is more likely to be induced with pacing from the low lateral RA pacing. These observations may be related to the anisotropic properties of the CTI and the development of rate-dependent conduction delays and unidirectional block necessary for tachycardia induction, which may be affected by the site of stimulation.^{2,6} Spontaneous AFL initiation may be related to rapid bursts of pulmonary vein discharges (atrial fibrillation [AF]).

Double-Wave Reentry

A typical AFL circuit with a large excitable gap may allow a second excitation wave to be introduced into the flutter circuit by a critically timed atrial extrastimulus (AES), so that two wavefronts occupy the same circuit simultaneously. This type of AFL is designated double-wave reentry.

Double-wave reentry is manifest by acceleration of the tachycardia rate but with identical surface and intracardiac electrogram morphology. It can be recognized by the simultaneous activation of the superior and inferior regions of the tricuspid annulus, with all activation being sequential. This rhythm rarely lasts for more than a few beats and can serve as a trigger for AF. Because the CTI is still a necessary part of the circuit, double-wave reentry is amenable to CTI ablation.^{2,6}

Clinical Considerations

Epidemiology

It is estimated that the overall incidence of AFL in the United States is 88 per 100,000 person-years. AFL accounts for approximately 15% of supraventricular arrhythmias and frequently coexists with or precedes AF. Although in clinical practice AFL appears to be less common than paroxysmal supraventricular tachycardia, population-based data show that in the general population, AFL is diagnosed for the first time more than twice as often. Adjusted for age, the incidence of AFL in men is more than 2.5 times that of women. Paroxysmal AFL can occur in patients with no apparent structural heart disease, whereas chronic AFL is usually associated with underlying heart disease, such as valvular or ischemic heart disease or cardiomyopathy. At highest risk of developing AFL are men, older adults, and individuals with preexisting heart failure or chronic obstructive lung disease. In approximately 60% of patients, AFL occurs as part of an acute disease process, such as exacerbation of pulmonary disease, following cardiac or pulmonary surgery, or during acute myocardial infarction.¹³

Clinical Presentation

Patients with AFL may be completely asymptomatic, or they may present with a spectrum of symptoms ranging from palpitations, lightheadedness, fatigue, reduced activity tolerance, or dyspnea to acute pulmonary edema or acute coronary syndrome in susceptible patients. The severity of symptoms usually depends on the ventricular rate during the AFL, the presence of structural heart disease, and baseline left ventricular function. Some patients remain asymptomatic until they present with a thromboembolic event or with decompensated heart failure secondary to tachycardia-induced cardiomyopathy. AFL occurs in approximately 25% to 35% of patients with AF, in which case AFL may be associated with more intense symptoms because of more rapid ventricular rates.

Initial Evaluation

ECG diagnosis of typical AFL is frequently accurate, but it can occasionally be misleading (see later). Cardiac evaluation with

echocardiography is required to assess for structural heart disease. Other tests may be required to evaluate for potential substrates or triggers of AFL.

Principles of Management

ACUTE MANAGEMENT

Acute therapy for patients with AFL depends on the clinical presentation and may include cardioversion and the use of AVN blockers to slow the ventricular rate during the AFL. Cardioversion (electrical or chemical) is commonly the initial treatment of choice. Electrical cardioversion is almost always successful in terminating AFL, and it often requires relatively low energies (less than 50 J). Chemical cardioversion can be achieved with intravenous ibutilide in 38% to 76% of cases, and this agent is more effective than intravenous amiodarone, sotalol, and class IC agents. Overdrive atrial pacing (via a catheter in the esophagus or the RA) can effectively terminate typical AFL, but it can also induce conversion of AFL into AF. Anticoagulation in the pericardioversion period should be considered and is guided by the duration of the AFL and the patient's stroke risk factors, by using the same criteria as for AF (see Chap. 15).¹⁴

Rate control is typically achieved with oral or intravenous AVN blockers such as verapamil, diltiazem, beta blockers, and digoxin. Rate control tends to be more difficult to achieve during AFL than AF because of the slower and more regular atrial rate.

CHRONIC MANAGEMENT

When AFL occurs as part of an acute disease process, long-term therapy of the arrhythmia is usually not required after sinus rhythm is restored and the underlying disease process is treated. The long-term success rate of antiarrhythmic drugs to prevent AFL recurrence appears to be limited, and complete suppression of AFL can be difficult to achieve. On the other hand, ablation is highly successful at the conclusion of a relatively short and low-risk procedure. Therefore, catheter ablation of the CTI is the treatment of choice for typical AFL, whether paroxysmal or persistent, and long-term drug therapy is rarely indicated and should be reserved for unusual circumstances.²

Several antiarrhythmic drugs have demonstrated efficacy in suppression of AFL, including class IA (quinidine, procainamide, and disopyramide), class IC (flecainide and propafenone), and class III (sotalol, amiodarone, dofetilide, and dronedarone) agents. In the absence of structural heart disease, class IC agents are the drugs of choice. The use of antiarrhythmic agents should be instituted in conjunction with AVN blockers to avoid the risk of rapid ventricular rates secondary to the vagolytic effects of class I drugs and slowing of the flutter rate.¹⁴

Ablation of the AV junction and pacemaker implantation may be indicated for patients in whom curative ablation of the AFL, antiarrhythmic therapy, and rate control strategies have failed. Stroke prevention is recommended and is usually achieved with aspirin or an oral anticoagulant depending on the patient's stroke risk factors, by using the same criteria as for AF.

Electrocardiographic Features

P Waves

Flutter waves appear as atrial complexes of constant morphology, polarity, and CL. Typically, flutter waves are most prominent in the inferior leads (II, III, aVF) and lead V₁. In the inferior leads, they resemble a picket fence (sawtooth) because the leads are primarily negative. This consists of a downsloping segment, followed by a sharper negative deflection, and then a sharp positive deflection, with a positive overshoot leading to the next downsloping plateau. The relative size of each component can vary markedly.²

Counterclockwise AFL (Fig. 12-2) can be characterized by pure negative deflections in the inferior leads, negative and then positive deflections that are equal in size, or a small negative and then a larger positive deflection. Those three varieties coexist with tall positive, small positive, or biphasic P waves in lead V_1 , respectively. With progression across the precordium, the initial component rapidly becomes inverted and the second component isoelectric usually by lead V_2 to V_3 . This produces the overall impression of an upright flutter wave in lead V_1 , which becomes inverted by lead V_6 . A negative deflection always precedes the positive deflection in the inferior leads in counterclockwise AFL, and the degree of positivity in the inferior leads appears to be related to the coexistence of heart disease and LA enlargement. Lead I is low-amplitude isoelectric, and lead aVL is usually upright.¹⁵

The surface ECG appearance of clockwise typical AFL is more variable than that of counterclockwise typical AFL, but in many respects, clockwise AFL presents an inversion of the appearance in counterclockwise AFL. Clockwise AFL generally has broad positive deflections in the inferior leads, with characteristic notching (see Fig. 12-2).² However, there is an inverted component preceding the upright notched component. Depending on the amplitude of this component, the appearance can be of continuous undulation without an obviously predominant upright or inverted component. On other occasions, it may appear that the inverted component is dominant, thus superficially mimicking counterclockwise AFL. Lead V_1 is characterized by a wide negative and usually notched deflection. There is transition across the precordium to an upright deflection in lead V_6 . Lead I is usually upright, and lead aVL is low-amplitude negative and notched.¹⁵

Typical AFL usually has an atrial rate of 240 to 340 beats/min. However, AFL can be slower in patients receiving antiarrhythmic agents or after incomplete CTI ablation (Fig. 12-3), whereby flutter CLs as long as 450 milliseconds have been observed. If the ventricular response is half the atrial rate, it can be difficult to identify flutter waves “buried” within the QRS or T waves (Fig. 12-4). Close inspection of the QRS and T waves, and comparisons with ECGs obtained in normal sinus rhythm, can help identify buried flutter waves. Furthermore, vagal maneuvers and AVN blockers can slow AV conduction and unmask the flutter waves.

In patients who have undergone extensive LA ablation for treatment of AF, the P wave morphology during CTI-dependent AFL can be very different from the foregoing discussion because of alteration of intraatrial and interatrial wavefront propagation. Similarly, non-CTI-dependent macroreentrant ATs can mimic typical CTI-dependent AFL on the surface ECG. Thus, arrhythmias that appear

to be typical AFL may not be, whereas others that are actually typical AFL may not appear to be.

Atrioventricular Conduction

Most commonly, 2:1 AV conduction is present during AFL. Variable AV conduction and larger multiples (e.g., 4:1 or 6:1) are not uncommon. Slowing the atrial rate during AFL caused by antiarrhythmic drugs or following a prior incomplete CTI ablation can result in a paradoxical increase in the ventricular rate caused by better AVN conduction of the slower flutter beats (Fig. 12-5). Rapid 1:1 AV conduction is most commonly seen in patients with anterogradely conducting bypass tracts (Fig. 12-6), but it may also be present in cases of enhanced AVN conduction secondary to high sympathetic tone (e.g., exercise, sympathomimetic drugs).²

QRS Morphology

The QRS complex during AFL is often identical to that during sinus rhythm. However, flutter beats can be aberrantly conducted because of functional bundle branch block, most frequently right bundle branch block (see Fig. 12-5). Even with normal ventricular conduction, the QRS complex may be slightly distorted by temporal superimposition of flutter waves on the QRS complex. Thus, the QRS complex can appear to acquire a new or larger R, S, or Q wave.²

Electrophysiological Testing

Typically, a decapolar catheter (positioned into the CS with the proximal electrodes bracketing the CS os) and a multipolar (20 or 24 pole) Halo catheter (positioned at the tricuspid annulus) are used to map typical AFL. The distal tip of the Halo catheter is positioned at 6 to 7 o'clock in the LAO view, so that the distal electrodes will record the middle and lateral aspects of the CTI, the middle electrodes will record the anterolateral RA, and the proximal electrodes may record the RA septum (depending on the catheter used and RA size). Instead of the Halo and CS catheters, some laboratories use a single duodecapolar catheter around the tricuspid annulus, thus extending the catheter tip inside the CS. Such a catheter can straddle the CTI and provide recording and pacing from the medial and lateral aspects of the isthmus, assuming good catheter-tissue contact at these locations. In the latter arrangement, however, the body of the duodecapolar catheter crossing over the CTI can potentially hinder manipulation and

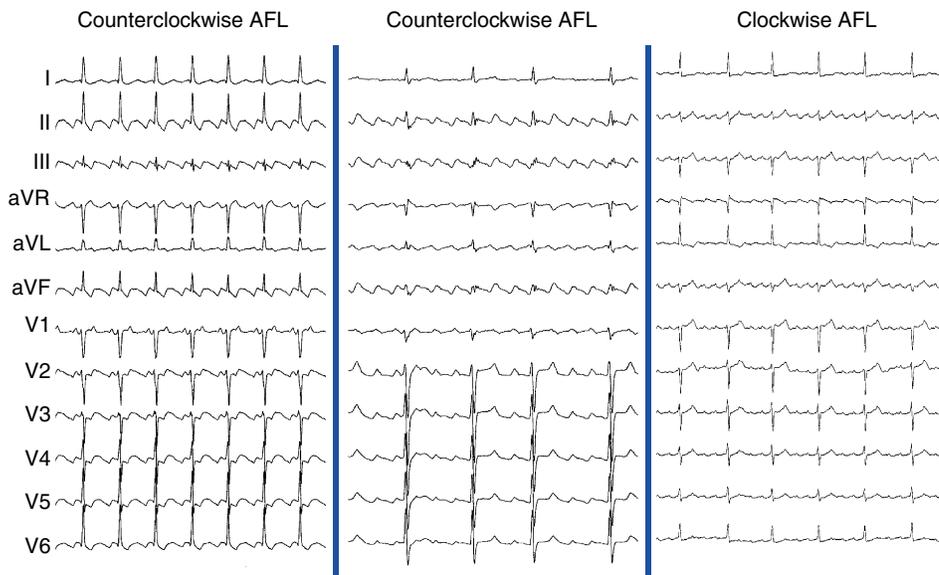

FIGURE 12-2 Surface 12-lead ECG of counterclockwise typical atrial flutter (AFL) with 2:1 atrioventricular (AV) conduction (left), counterclockwise typical AFL with variable AV conduction (middle), and clockwise typical AFL with 4:1 AV conduction (right).

positioning of the ablation catheter tip to achieve adequate tissue contact for effective ablation.

Induction of Tachycardia

Programmed electrical stimulation protocol typically involves atrial burst pacing from the high RA and CS (down to the pacing CL at which 2:1 atrial capture occurs) and single and double AESs (down to the atrial effective refractory period [ERP]) at multiple CLs (600 to 200 milliseconds) from the high RA and CS. Administration of an isoproterenol infusion (0.5 to 4 $\mu\text{g}/\text{min}$) may be required to facilitate tachycardia induction.

AFL can be induced readily with programmed electrical stimulation in most patients with a clinical history of AFL. Reproducible initiation of counterclockwise AFL is possible in more than 95% of patients.¹⁶ Rapid atrial pacing is more likely to induce AFL than a single AES, but as likely as introducing two AESs. On the other hand, the frequency of single or double AESs initiating AFL is low in patients without a history of AFL (less than 10%). Counterclockwise AFL is more likely to be induced by stimulation from the CS os; conversely, clockwise AFL is more likely to be induced with low lateral RA pacing. Induction of AFL usually occurs once unidirectional CTI block develops during pacing (Fig. 12-7). The faster the pacing rate and the shorter the AES coupling intervals, the more likely it will be that AF is induced, which is usually self-terminating but can be sustained in less than 10% of patients with no clinical history of AF. The significance of induction of AF in these patients is uncertain.

Tachycardia Features

Typical AFL is characterized by a constant CL, polarity, morphology, and amplitude of the recorded bipolar electrograms and by the presence of a single constant macroreentrant circuit with a constant atrial activation sequence. The atrial rate is very regular, with cycle-to-cycle variation of less than 2%; it is rare for AFL to display considerable variation in the CL. The atrial CL is usually between 190 and 250 milliseconds, although the atrial rate can be slower in patients receiving antiarrhythmic agents or following

a prior unsuccessful ablation of the CTI. It is not uncommon for clockwise and counterclockwise AFLs to occur in the same patient, and they often have similar rates, although clockwise AFL can have a slower rate.

As noted, AFL is usually associated with 2:1 AV conduction, but variable AV conduction and larger multiples are not uncommon. Variable AV block is the result of multilevel block; for example, proximal 2:1 AV block and more distal 3:2 Wenckebach block result in 5:2 AV Wenckebach block. It is likely that the proximal 2:1 block occurs in the upper part of the AVN, whereas Wenckebach block occurs in the lower part of the AVN. Distal Wenckebach behavior in the His bundle (HB) would result in a similar AV conduction pattern but is unlikely to occur. In most cases, the nonconducted flutter impulses block in the AVN. However, infranodal AV block can occur, especially in the presence of prolonged His-Purkinje system refractoriness caused by antiarrhythmic agents or during Wenckebach cycles in the AVN that leads to long-short cycle activation of the His-Purkinje system.

The presence of anterogradely conducting bypass tracts with a short refractory period can result in preexcited AFL with rapid 1:1 AV conduction. Infusion of isoproterenol can enhance AVN function and occasionally facilitate 1:1 AV conduction, especially when the atrial rate is relatively slow.² Adenosine increases the degree of AV block, but it also shortens atrial refractoriness and can result in the degeneration of AFL into AF.

Diagnostic Maneuvers during Tachycardia

ATRIAL EXTRASTIMULATION DURING ATRIAL FLUTTER

An AES from the high RA or CS or along the Halo catheter is introduced at a coupling CL 10 milliseconds shorter than the flutter CL, with progressive shortening of the coupling CL by 10 to 30 milliseconds.

An AES commonly results in resetting of the AFL circuit.¹⁶ The closer the site of atrial stimulation is, the easier the resetting of the AFL circuit at longer coupling intervals will be. AFL has a resetting response pattern typical of reentrant circuits with fully excitable

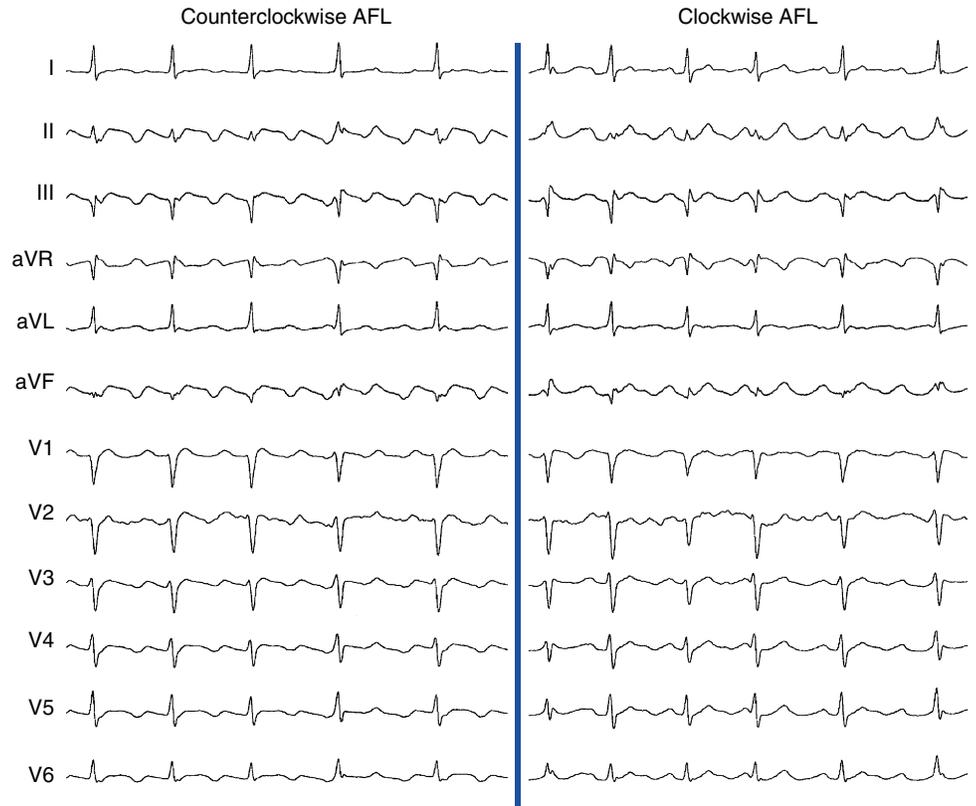

FIGURE 12-3 Surface 12-lead ECGs during counterclockwise (left) and clockwise (right) typical atrial flutter (AFL) in a patient on flecainide therapy. Note the slow flutter cycle length (approximately 350 milliseconds) secondary to the effects of flecainide.

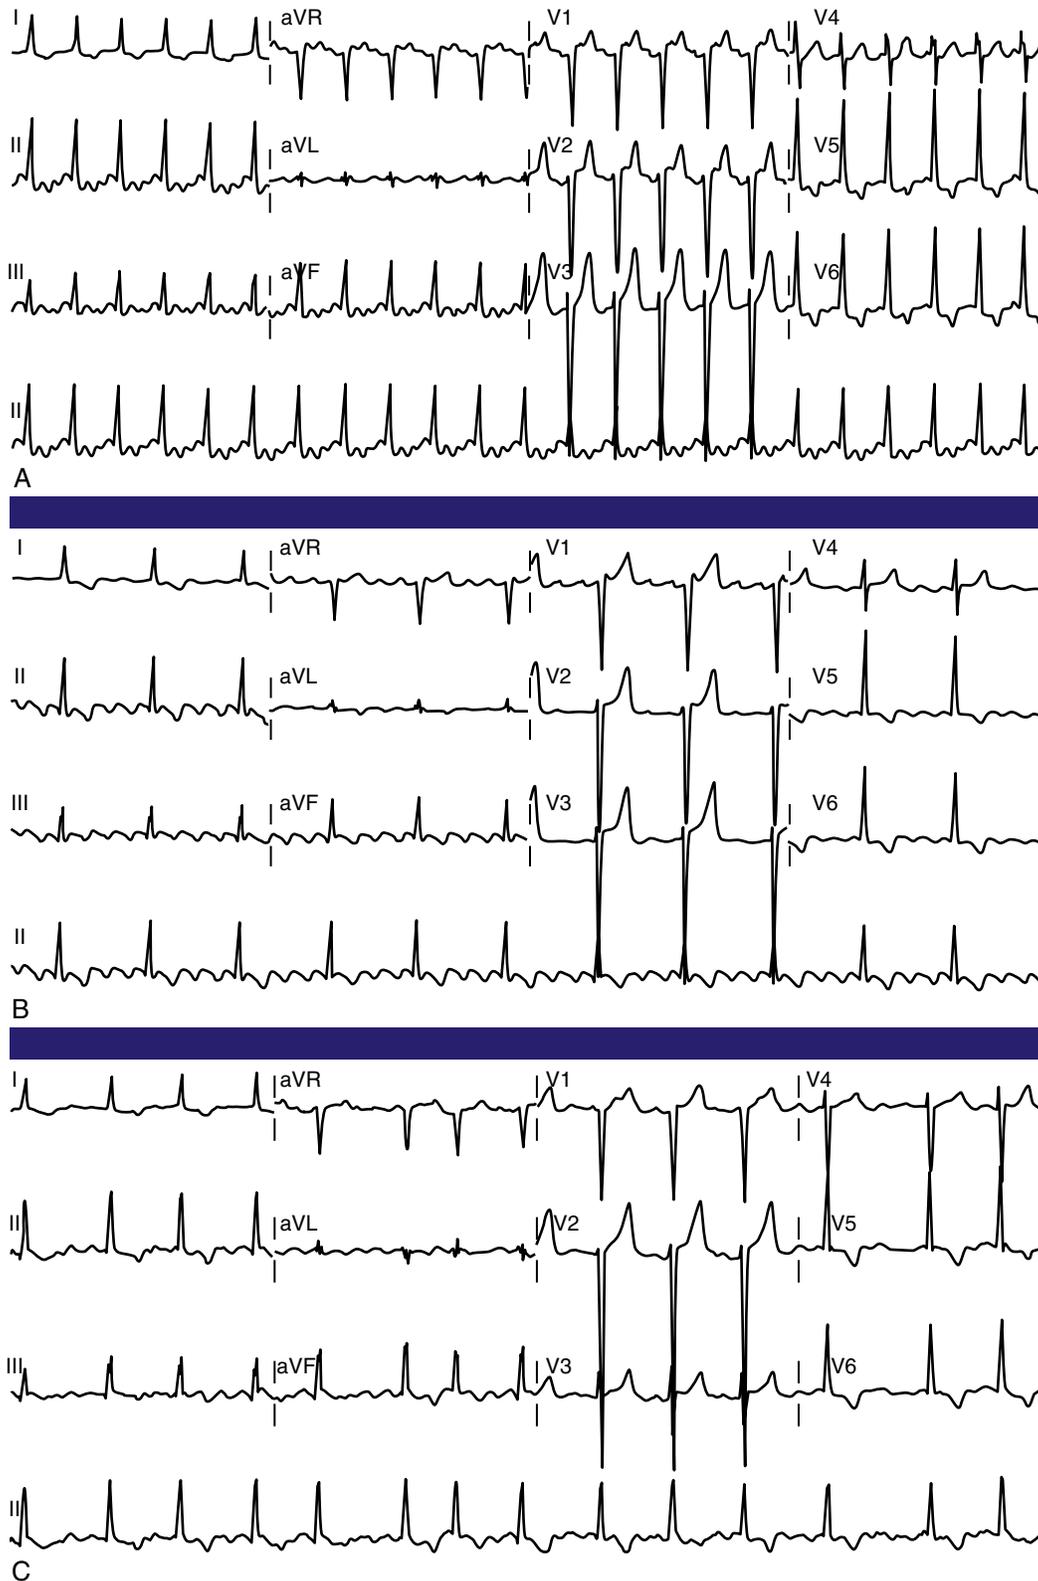

FIGURE 12-4 Surface 12-lead ECG of counterclockwise typical atrial flutter (AFL) with 2:1 atrioventricular (AV) conduction (A) and with 4:1 AV conduction (B). Note that when the ventricular response is half the atrial rate, it is difficult to identify flutter waves “buried” within the QRS or T waves (A). However, when the ventricular rate is slowed, flutter wave morphology becomes more easily visualized. C shows atrial fibrillation that developed in the same patient after ablation of the cavotricuspid isthmus. Note that fibrillation waves are coarse and can mimic flutter waves; however, close inspection reveals changes in rate and morphology of atrial activity that are inconsistent with AFL.

gaps: flat (for approximately 15% to 30% of the tachycardia CL, equal to approximately 30 to 63 milliseconds in the absence of drugs, and up to 100 milliseconds with class I antiarrhythmic agents) and then an increasing return CL with progressively shorter coupling intervals. The ability to capture the atrium without affecting (resetting)

the AFL circuit timing indicates that the pacing site is outside the AFL circuit (e.g., RA appendage or distal CS).

It is usually difficult for a single AES to terminate AFL because AFL has a sizable fully excitable gap (15% to 30% of the tachycardia CL) that makes it difficult for a single AES to penetrate the AFL

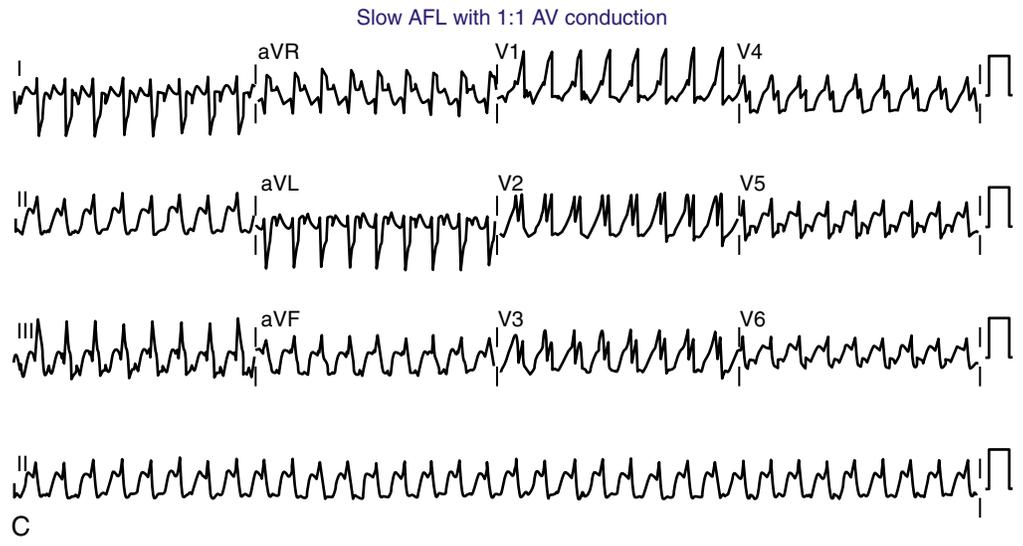

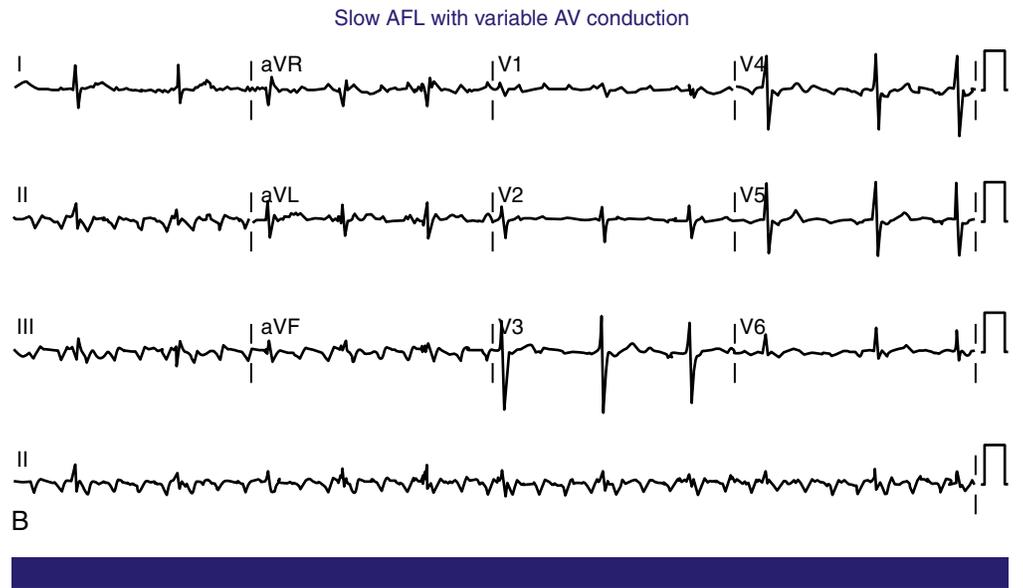

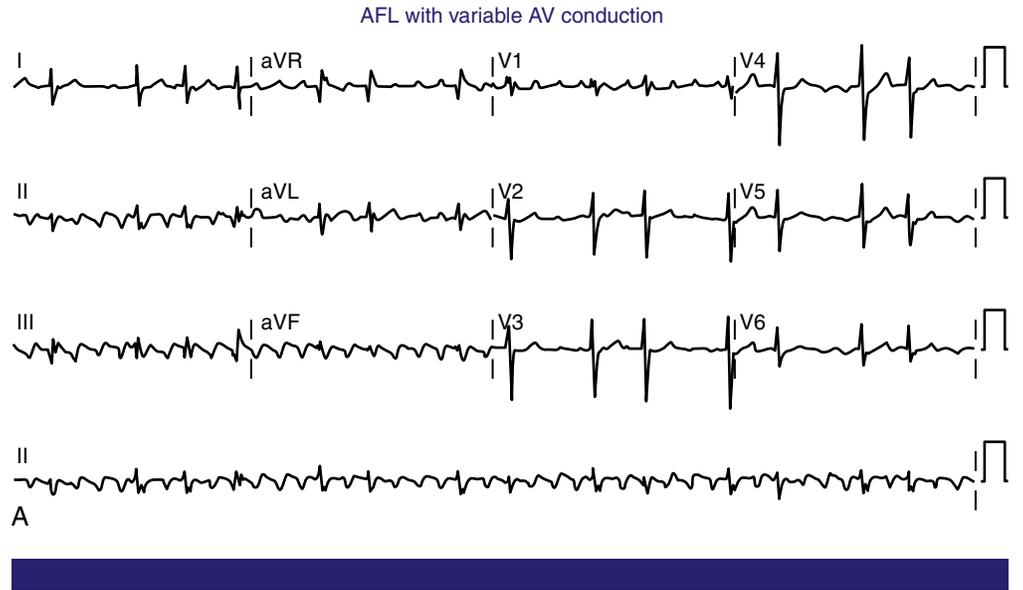

FIGURE 12-5 Effects of antiarrhythmic drugs on typical atrial flutter (AFL). Base-line surface ECG in a patient with AFL and variable atrioventricular (AV) conduction (A). Treatment with propafenone results in slowing of the atrial rate during AFL (B) and a paradoxical increase in the ventricular rate caused by better AV nodal conduction of the slower flutter beats (C). Right bundle branch block aberrancy is observed during 1:1 AV conduction.

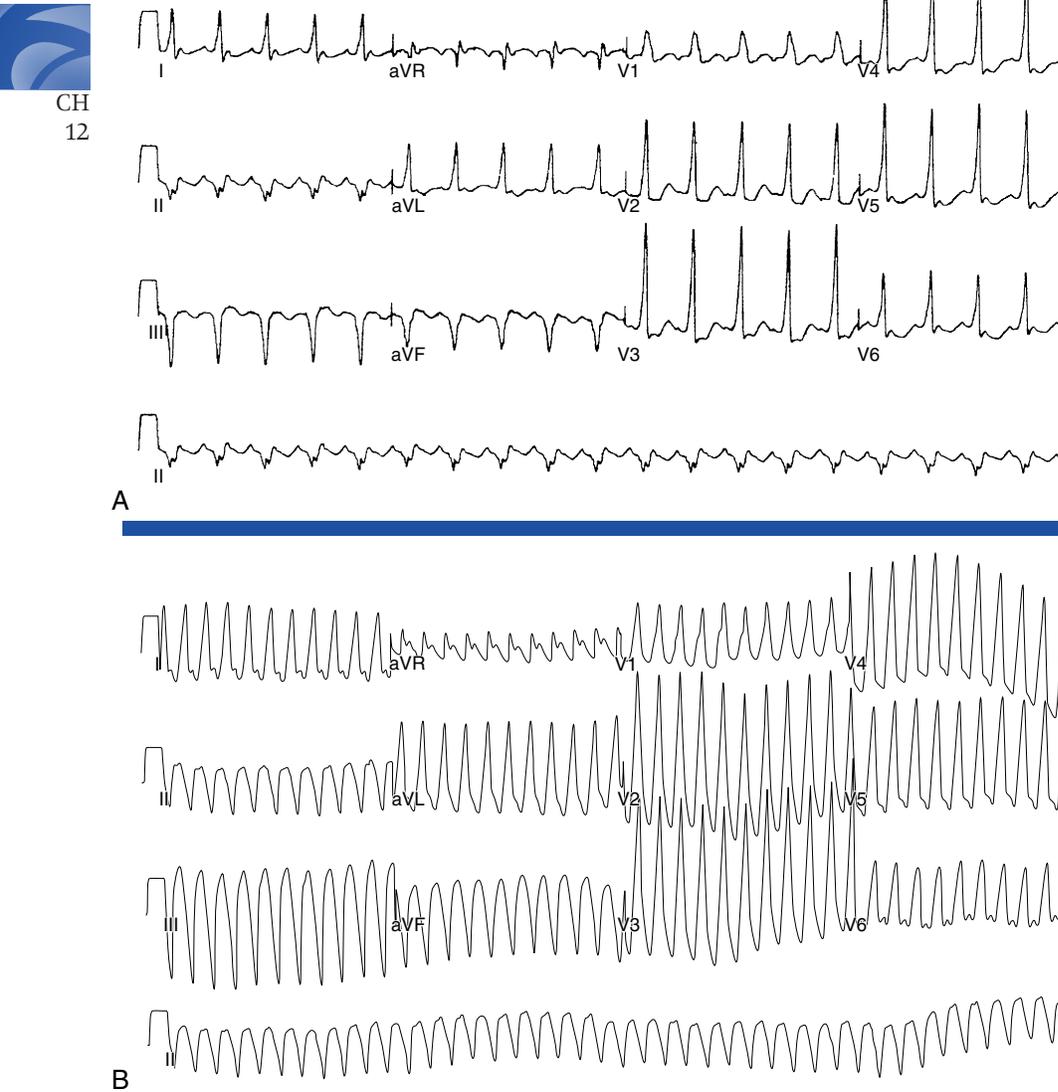

FIGURE 12-6 Surface 12-lead ECGs during clockwise typical atrial flutter in a patient with a left posteroseptal bypass tract (BT). **A**, 2:1 atrioventricular (AV) conduction with QRS fusion (secondary to conduction over both the BT and the AV node). **B**, 1:1 AV conduction over the BT with fully preexcited QRS morphology.

circuit with adequate prematurity to terminate the AFL without intervening atrial refractoriness and intraatrial conduction delays. An AES delivered in the region of the CTI has the greatest chance of terminating AFL because it can capture the isthmus tissue with a very short coupling interval (close to the ERP of this critical site), given the lack of intervening tissue between the stimulation site and isthmus. Termination of AFL always occurs because of conduction block in the CTI.

ATRIAL PACING DURING ATRIAL FLUTTER

Burst pacing from the CS or along the Halo catheter is started at a CL 10 to 20 milliseconds shorter than the flutter CL, and the pacing CL is progressively shortened by 10 to 20 milliseconds. The capture of atrial stimuli and acceleration of the atrial rate to the paced rate should be verified before analyzing the flutter response to overdrive pacing. The response of AFL to overdrive pacing is evaluated for overdrive suppression, acceleration, transformation into distinct uniform AFL morphologies or AF, entrainment, and ability and pattern of termination.

ENTRAINMENT. Overdrive atrial pacing at long CLs (i.e., 10 to 30 milliseconds shorter than the tachycardia CL) can almost always entrain typical AFL. The slower the pacing rate and the farther the pacing site from the reentrant circuit, the longer the pacing drive will need to be to penetrate and entrain the tachycardia. As discussed

in detail in [Chapter 13](#), achievement of entrainment of the AT establishes a reentrant mechanism of the tachycardia and excludes triggered activity and abnormal automaticity as potential mechanisms. However, it is important to understand that the mere acceleration of the tachycardia to the pacing rate and then resumption of the original tachycardia after cessation of pacing do not establish the presence of entrainment. After cessation of each pacing drive, the presence of entrainment should be verified by demonstrating the presence of fixed fusion of the paced complexes at a given pacing CL, progressive fusion at faster pacing CLs, and resumption of the same tachycardia morphology following cessation of pacing with a nonfused complex at a return cycle equal to the pacing CL. During entrainment of AFL, fusion of the stimulated impulse can be observed on the surface ECG, but it is easier to recognize on intracardiac recordings from the Halo and CS catheters. Entrainment with manifest fusion can be demonstrated with pacing from sites outside the CTI, such as lateral RA and CS. Conversely, pacing at the CTI results in entrainment with concealed fusion, whereby P waves (on the surface ECG and intracardiac recordings) during pacing are identical to those during the tachycardia.^{17,18}

TERMINATION. More rapid atrial burst pacing (pacing CL 20 to 50 milliseconds shorter than the AFL CL) results in termination of AFL in most cases.¹⁶ Termination of AFL during rapid pacing can be indicated by a sudden change of P wave morphology on the surface ECG and by a change of atrial activation sequence in the

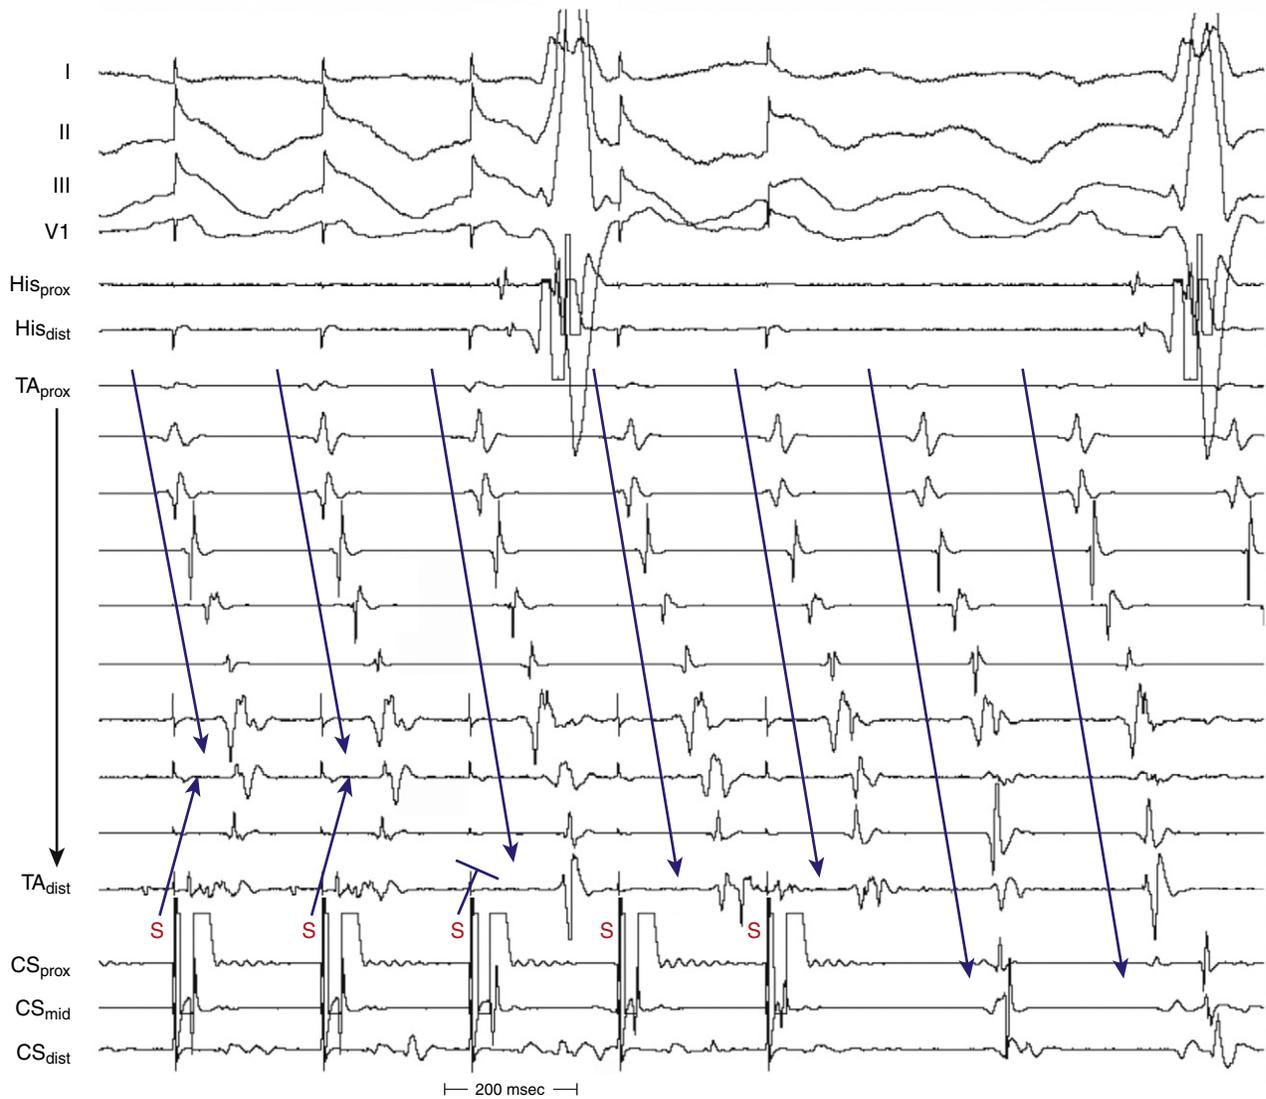

FIGURE 12-7 Surface ECG and intracardiac recordings of initiation of counterclockwise typical AFL. Burst pacing from the coronary sinus (CS) results in wavefronts proceeding in both directions around the tricuspid annulus (TA), colliding around TA 5-6 (arrows); on the third cycle, one wavefront blocks before arriving at TA 1-2 but proceeds around the TA in the opposite direction. When pacing stops, this unopposed wavefront continues around the TA as counterclockwise AFL. dist = distal; prox = proximal.

HB and CS os recordings. This is seen particularly with high RA pacing during counterclockwise AFL, whereby on termination of AFL, the negative flutter waves in the inferior leads change suddenly into upright P waves, thus reflecting a change in the atrial activation sequence to one of high RA pacing (i.e., simultaneous RA lateral and septal activation in a craniocaudal direction).⁵ However, if the pacing site is distant from the AFL circuit (e.g., distal CS), a large mass of the atrial tissue can be captured by the pacing stimulus, to produce a marked change in P wave morphology (i.e., manifest fusion) without terminating the AFL. Failure to terminate AFL with rapid pacing can be caused by any of the following: (1) a short period of pacing or pacing at a relatively long CL—the closer the pacing CL is to the tachycardia CL, the longer the pacing duration will need to be to terminate the tachycardia; (2) a pacing site distant from the AFL circuit, with the intervening atrial tissue preventing penetration of the AFL circuit; or (3) the possibility that an apparent AFL on the ECG may actually be AF with streaming of the RA activation wavefront or may be a focal nonreentrant AT.^{5,16}

OVERDRIVE SUPPRESSION. Overdrive suppression analogous to that seen with automatic AT is not expected in AFL. The post-pacing interval (PPI, measured from the last pacing stimulus that entrained the tachycardia to the next near-field recorded

electrogram at the pacing site) remains relatively stable when entrainment of AFL is performed at the same site, regardless of the length of the pacing drive. This is in contrast to overdrive suppression seen in automatic ATs, which would be associated with progressive delay of the first tachycardia beat return cycle with progressively longer overdrive pacing drives.

ACCELERATION. Acceleration by overdrive pacing refers to sustained shortening of the tachycardia CL following cessation of pacing. Atrial pacing rarely can accelerate AFL into one of two different tachycardias: double-wave reentry or lower loop reentry.¹⁶ Double-wave reentry is manifest by acceleration of the tachycardia rate but with identical surface and intracardiac electrogram morphology, and it can be recognized by having simultaneous activation of the superior and inferior regions of the tricuspid annulus, with all activation being sequential. This rhythm rarely lasts for more than a few beats and may serve as a trigger for AF. Lower loop reentry is a form of CTI-dependent AFL with a reentrant circuit around the IVC. This arrhythmia is usually transient and terminates by itself or converts spontaneously into AFL or AF (see Chap. 13).¹⁹⁻²¹

TRANSFORMATION. Rapid atrial burst pacing may convert AFL into AF. This is less likely with a slower pacing CL or pacing from sites within the AFL circuit. Induction of other forms of

atrial macroreentry can also be observed, especially with faster pacing rates.⁵

Mapping

CH
12

Activation Mapping

The simultaneous recording from endocardial sites around the tricuspid annulus (which encompasses most of the flutter macroreentrant circuit) by the Halo and CS catheters significantly facilitates activation mapping during typical AFL, and sequential point-by-point activation mapping is usually not required. The RA activation sequence during counterclockwise AFL occurs sequentially down the lateral RA wall and adjacent to the crista terminalis, across the CTI (with some delay because of slow conduction across the CTI), past the CS os, up the atrial septum, over the roof of the RA, and back to the lateral free wall of the RA (in a proximal-to-distal direction along the Halo electrodes; see Fig. 12-1). This sequence is reversed during clockwise AFL (see Fig. 12-1).

During AFL, double potentials are seen on the crista terminalis and along the eustachian ridge and indicate lines of block (fixed or functional) along those structures. Activation of the CS propagates in a proximal-to-distal direction.¹²

The atrial activation sequence in AFL is different from that during sinus rhythm or focal AT originating from the upper RA or LA, in which the activation wavefront propagates from the upper RA

(middle or proximal Halo electrodes) down both the RA septum and lateral wall in a craniocaudal direction, toward the distal and proximal-most Halo electrodes.

Occasionally, P wave morphology on the surface ECG resembles typical AFL, but intracardiac recordings show that parts of the atria (commonly the LA) have disorganized atrial activity (Fig. 12-8). Such rhythms behave more like AF than AFL, but they may be converted to true typical AFL with antiarrhythmic drugs.¹⁶

As noted, double-wave reentry is characterized by an activation sequence identical to that of typical AFL, but at a faster atrial rate and with simultaneous activation of the superior and inferior regions of the tricuspid annulus, with all activation being sequential.

Entrainment Mapping

Entrainment mapping provides information about sites of the RA or LA that are part of the reentrant circuit, those that are outside the circuit, and the critical isthmus in the macroreentrant circuit. Entrainment also qualitatively estimates how far the reentrant circuit is from the pacing site. However, before attempting to use entrainment methods for mapping, it is necessary first to demonstrate that the tachycardia can be entrained, thus providing strong evidence that it is caused by reentry rather than by triggered activity or automaticity. At sites of entrainment, there should be confirmation of consistent capture of the atrium at the pacing CL for several beats with minimal or no change in the surface

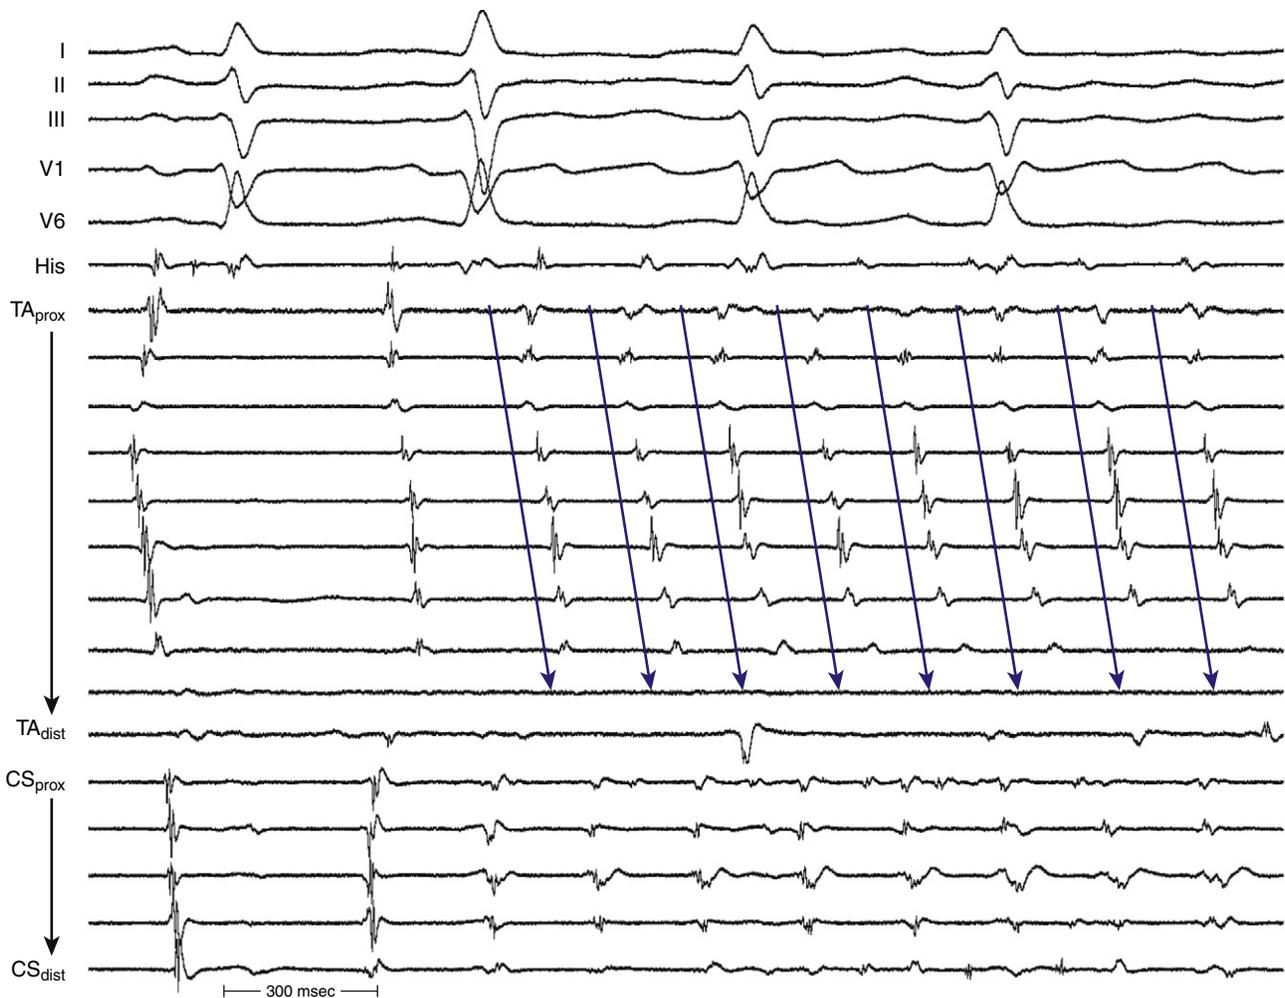

FIGURE 12-8 Surface ECG and intracardiac recordings of the onset of an episode of atrial fibrillation following cavotricuspid isthmus ablation. Activation around the tricuspid annulus (TA) follows a pattern like that in counterclockwise flutter (arrows) because of “streaming” of the wavefront between the crista terminalis and the TA. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; TA_{dist} = distal tricuspid annulus; TA_{prox} = proximal tricuspid annulus.

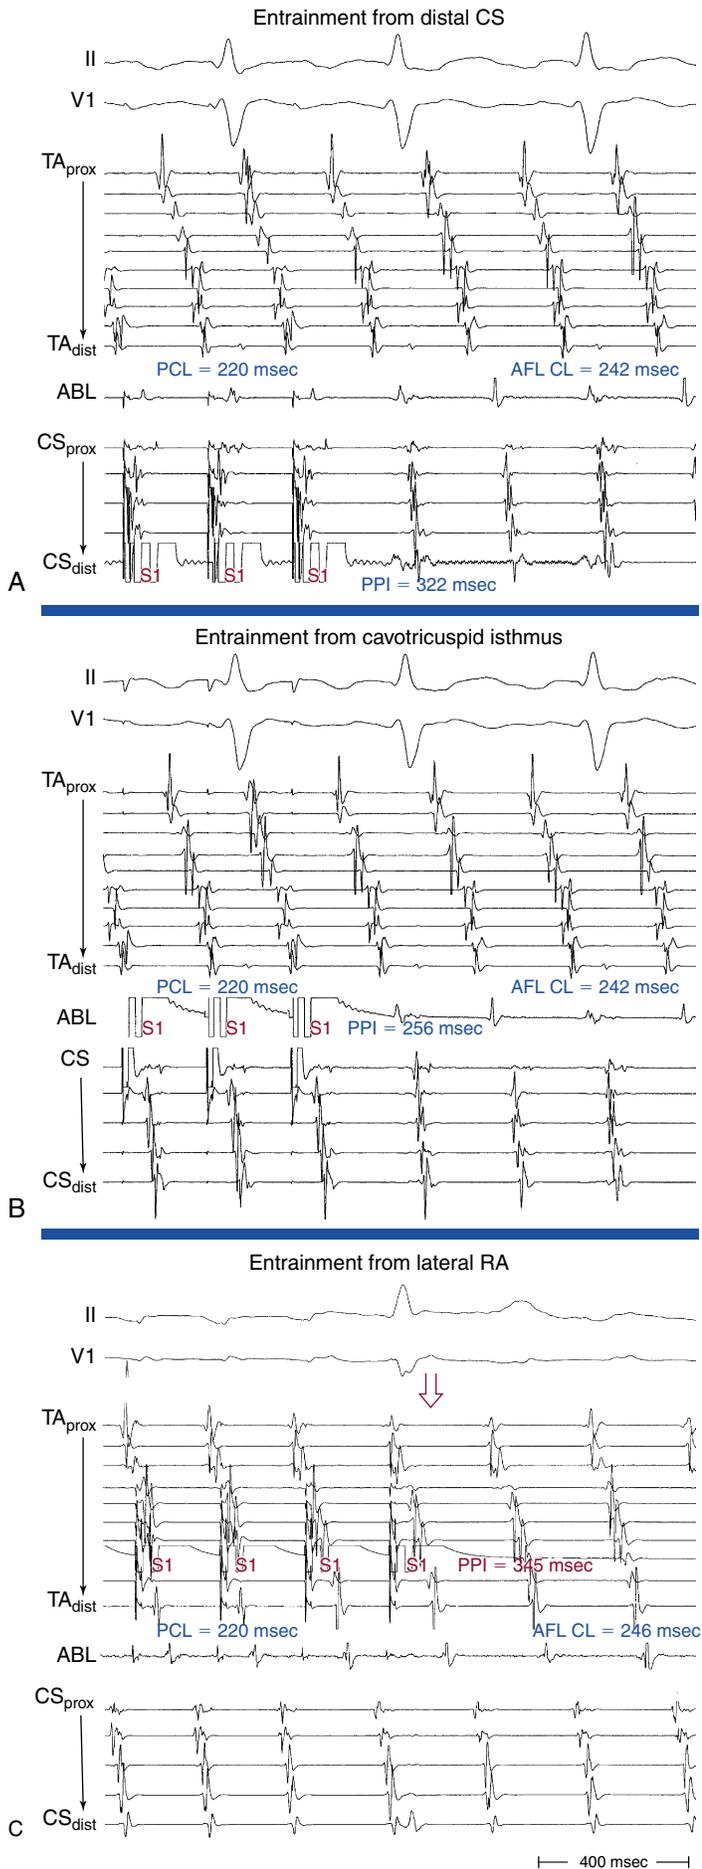

FIGURE 12-9 Entrainment of counterclockwise typical atrial flutter (AFL). **A**, Entrainment from the distal coronary sinus (CS) results in manifest atrial fusion and a long post-pacing interval (PPI; PPI – AFL cycle length [CL] = 80 milliseconds) because the distal CS is far from the reentrant circuit. **B**, Entrainment from ablation catheter positioned at the cavotricuspid isthmus (CTI) results in concealed atrial fusion with a short PPI (PPI – AFL CL = 14 milliseconds), a finding indicating that the CTI is part of the reentrant circuit. **C**, Entrainment from the lateral RA wall is attempted; however, the last paced stimulus fails to capture the atrium (open arrow); therefore, calculation of the PPI in this case is invalid and produces erroneous results. ABL = ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; PCL = pacing cycle length; TA_{dist} = distal tricuspid annulus; TA_{prox} = proximal tricuspid annulus.

morphology or intracardiac electrograms and continuation of the identical tachycardia after pacing. Evaluation of the PPI or other criteria is meaningless when the presence of true entrainment has not been established. Additionally, it is important to verify the absence of termination and reinitiation of the tachycardia during the same pacing drive.⁷

Pacing is performed from the CTI, high RA, mid-lateral RA, and proximal and distal CS, but not on the septum, to avoid the possibility of capturing the LA, which could be confusing in distinguishing RA from LA flutters.

Once the presence of entrainment is verified, several criteria can be used to indicate the relation of the pacing site to the reentrant circuit. As discussed in detail in [Chapter 13](#), the first entrainment criterion to be sought is concealed fusion. Entrainment with concealed fusion indicates that the pacing site is in a protected isthmus located within or attached to the reentrant circuit. Whether this protected isthmus is crucial to the reentrant circuit or just a bystander site needs to be verified by other criteria, mainly comparing the PPI with the tachycardia CL and the stimulus-exit interval with the electrogram-exit interval ([Fig. 12-9](#)). The diagnosis of CTI-dependent AFL is established when pacing from the CTI results in entrainment with concealed fusion and a PPI that is equal (within 20 milliseconds) to the flutter CL and an electrogram-exit interval that is equal (within 20 milliseconds) to the stimulus-exit interval. During counterclockwise AFL, a site medial to the CTI, such as the CS os, may be used to represent the exit of the reentrant wavefront. Conversely, in clockwise AFL, a site lateral to the tricuspid annulus, such as the distal Halo electrode, may be used ([Table 12-1](#)).^{17,18}

Electroanatomical Mapping

Although atrial activation sequences in the Halo and CS catheters combined with entrainment mapping techniques are usually adequate for the diagnosis of CTI-dependent typical AFL and facilitation of ablation of the CTI, electromagnetic three-dimensional (3-D) mapping (CARTO mapping system [Biosense Webster, Diamond Bar, Calif.] or EnSite NavX system [St. Jude Medical, St. Paul, Minn.]) can help distinguish between a focal origin and macroreentrant tachycardia by providing precise description of the macroreentrant circuit and sequence of atrial activation during the tachycardia and rapid visualization of the activation wavefront.

Initially, selection of the reference electrogram, positioning of the anatomical reference, and determination of the window of interest are undertaken. The reference catheter is usually placed in the CS (because of its stability), and an electrode recording a prominent atrial electrogram is selected, thus ensuring that the ventricular electrogram is not the one detected by the system.

The mapping-ablation catheter is initially positioned, using fluoroscopy, at known anatomical points that serve as landmarks for the electroanatomical map. Anatomical and EP landmarks (IVC, SVC, CS, HB, and tricuspid annulus) are tagged. A set of six specific points (three at the tricuspid annulus and three at the mouth of the IVC) is acquired to delineate the individual isthmus anatomy. The catheter is then advanced slowly around the chamber walls to sample

multiple points along the endocardium, thereby sequentially acquiring the location of its tip together with the local electrogram. Activation mapping is performed to define the atrial activation sequence. Reasonable numbers of points are homogeneously distributed in the RA, with careful mapping of endocardial sites around the

tricuspid annulus and CTI. The local activation time at each site is determined from the intracardiac bipolar electrogram and is measured in relation to the fixed intracardiac electrogram obtained from the CS (reference) catheter. The activation map may also be used to catalog sites at which pacing maneuvers are performed during assessment of the tachycardia (e.g., sites with good pace maps). Activation maps display the local activation time by a color-coded overlay on the reconstructed 3-D geometry (see Videos 11 and 16). The selected points of local activation time are color-coded.

High-density 3-D electroanatomical maps during AFL can be useful in delineating the specific features of the AFL circuit and global RA activation during AFL. The activation map typically demonstrates a continuous progression of colors (from red to purple in the CARTO system and from white to purple in the NavX system) around the tricuspid annulus with close proximity of earliest and latest local activation and an activation time in a similar range to tachycardia CL, consistent with macroreentry (Figs. 12-10 and 12-11). The activation wavefront exits the CTI as a broad wavefront, spreading anterosuperiorly around the tricuspid annulus and posterosuperiorly. Lateral spread of the posterior wavefront is blocked along the vertical line in the posterolateral RA, a region marked by double potentials that coincides with the crista terminalis. The posterior wavefront propagates cranially around the SVC to merge with the activation wavefront circulating around the tricuspid annulus. The anterolateral wall of the RA is the last to activate as the wavefront reenters the lateral aspect of the CTI.

The 3-D electroanatomical maps can also provide information about the voltage characteristics of the tissues involved in the CTI. The lower the voltage, the easier it is to achieve block in the tissue. Thus, 3-D electroanatomical mapping may help choose a path in the CTI that is easier to ablate, a path that may not necessarily be the shortest across the isthmus.

Noncontact Mapping

The EnSite 3000 noncontact mapping system (St. Jude Medical, St. Paul, Minn.) consists of a noncontact catheter with a multielectrode array surrounding a 7.5-mL balloon mounted at the distal end. The 9 Fr balloon catheter is advanced over a 0.035-inch guide-wire under fluoroscopy guidance and is positioned in the middle

TABLE 12-1 Entrainment Mapping of Typical Atrial Flutter

Pacing from sites *outside* the AFL circuit (e.g., from RA appendage or middle or distal CS) results in the following:

- Manifest atrial fusion on the surface ECG or intracardiac recordings (fixed fusion at a single pacing CL, or both, and progressive fusion on progressively shorter pacing CLs). During entrainment, any difference in atrial activation sequence compared with that during tachycardia (as determined by analysis of all available surface ECG and intracardiac recordings) is considered to represent manifest fusion.
- PPI – tachycardia CL > 20 msec
- The interval between the stimulus artifact to the onset of the flutter wave on the surface ECG is longer than the interval between the local electrogram on the pacing site to the onset of the flutter wave on the surface ECG.

Pacing from sites *inside* the AFL circuit (e.g., from the CS os or around the tricuspid annulus) results in the following:

- Manifest atrial fusion on surface ECG or intracardiac recordings (fixed fusion at a single pacing CL, or both, and progressive fusion on progressively shorter pacing CL)
- PPI – tachycardia CL < 20 msec
- The interval between the stimulus artifact to the onset of the flutter wave on the surface ECG is equal to the interval between the local electrogram on the pacing site to the onset of the flutter wave on the surface ECG.

Pacing from a protected isthmus inside the circuit (cavotricuspid isthmus) results in the following:

- Concealed atrial fusion (i.e., paced atrial waveform on the surface ECG and intracardiac recordings is identical to the AFL waveform)
- PPI – tachycardia CL < 20 msec
- The interval between the stimulus artifact to the onset of the flutter wave on the surface ECG is equal to the interval between the local electrogram on the pacing site to the onset of the flutter wave on the surface ECG.

AFL = atrial flutter; CL = cycle length; CS = coronary sinus; CS os = coronary sinus ostium; PPI = post-pacing interval; RA = right atrium.

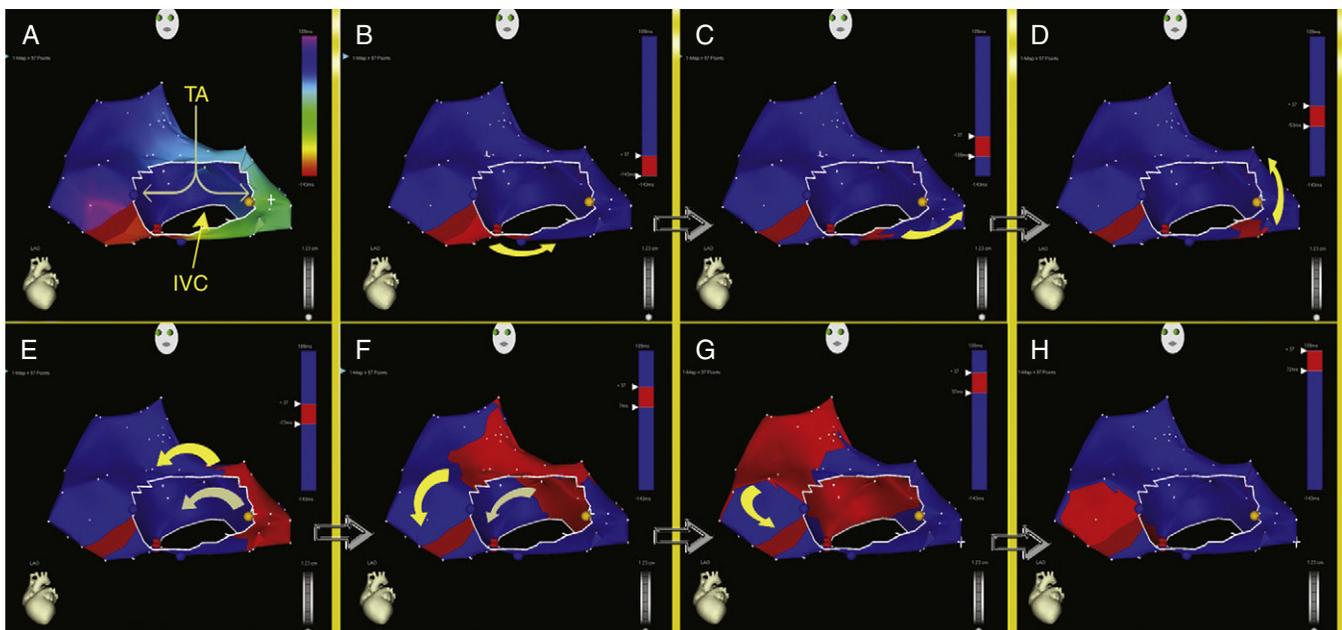

FIGURE 12-10 A, Three-dimensional electroanatomical (CARTO, Biosense Webster, Diamond Bar, Calif) activation map of the right atrium (RA) in the left anterior oblique view constructed during counterclockwise typical atrial flutter (AFL). During tachycardia, the depolarization wavefront travels counterclockwise around the tricuspid annulus (TA), as indicated by a continuous progression of colors (from red to purple) with close proximity of earliest and latest local activation (red meeting purple). B to H, Propagation map of the RA during counterclockwise typical AFL (arrows). IVC = inferior vena cava.

and lower portion of the RA. The balloon is positioned in the center of the atrium and does not come in contact with the atrial walls being mapped. Intravenous heparin is administered before balloon deployment to keep the activated clotting time at 250 to 300 seconds. A conventional mapping-ablation catheter is used to collect geometry information. The mapping catheter is initially moved to known anatomical locations (IVC, SVC, CS, HB, and tricuspid annulus), which are tagged. Detailed geometry of the chamber is then reconstructed by moving the mapping catheter around the atrium.

After the chamber geometry is determined, mapping of the arrhythmia can begin. The data acquisition process is performed automatically by the system, and all data for the entire chamber are acquired simultaneously. The system then reconstructs unipolar electrograms simultaneously and superimposes them onto the virtual

endocardium, to produce isopotential maps with a color range representing voltage amplitude (Fig. 12-12; see Video 9). A default high-pass filter setting of 2 Hz is used to preserve components of slow conduction on the isopotential map. Color settings are adjusted so that the color range matches 1 to 1 with the millivolt range of the electrogram deflection of interest. Activation can be tracked on the isopotential map throughout the tachycardia cycle. Isochronal maps can also be created that represent progression of activation throughout the chamber relative to a user-defined electrical reference timing point (see Fig. 12-12).²²

Although typical AFL is usually readily treated using standard ablation techniques, noncontact mapping can be used to confirm the anatomical location of the flutter circuit, reduce fluoroscopy time, and confirm CTI block after ablation. Noncontact mapping

FIGURE 12-11 EnSite-NavX (St. Jude Medical, St. Paul, Minn.) three-dimensional electro-anatomical activation map of the right atrium in the left anterior oblique (left) and antero-posterior (right) views constructed during counterclockwise typical atrial flutter. During tachycardia, the depolarization wavefront travels counterclockwise around the tricuspid annulus (TA), as indicated by a continuous progression of colors (from white to purple) with close proximity of earliest and latest local activation. CS = coronary sinus; IVC = inferior vena cava; SVC = superior vena cava.

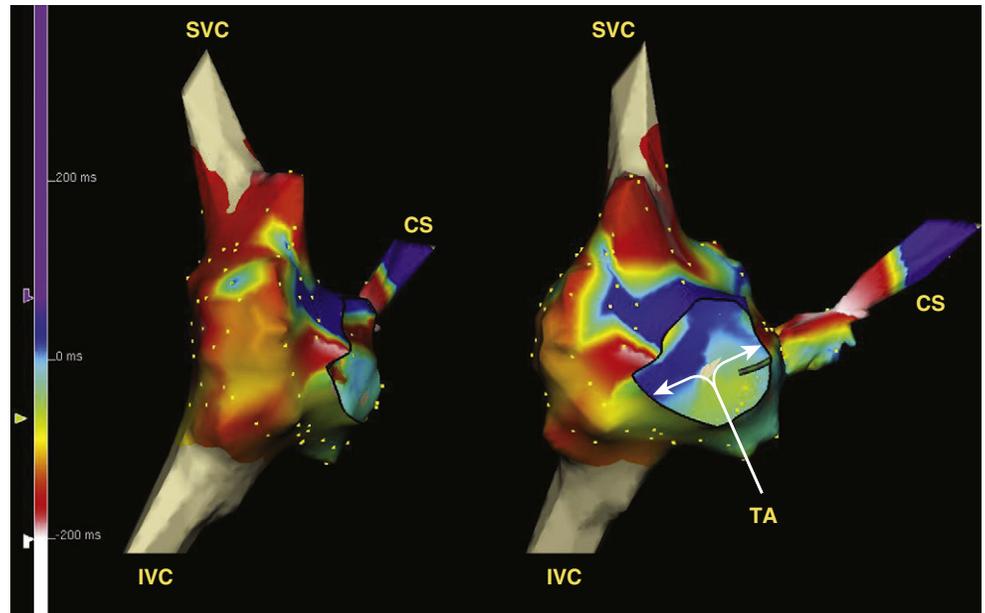

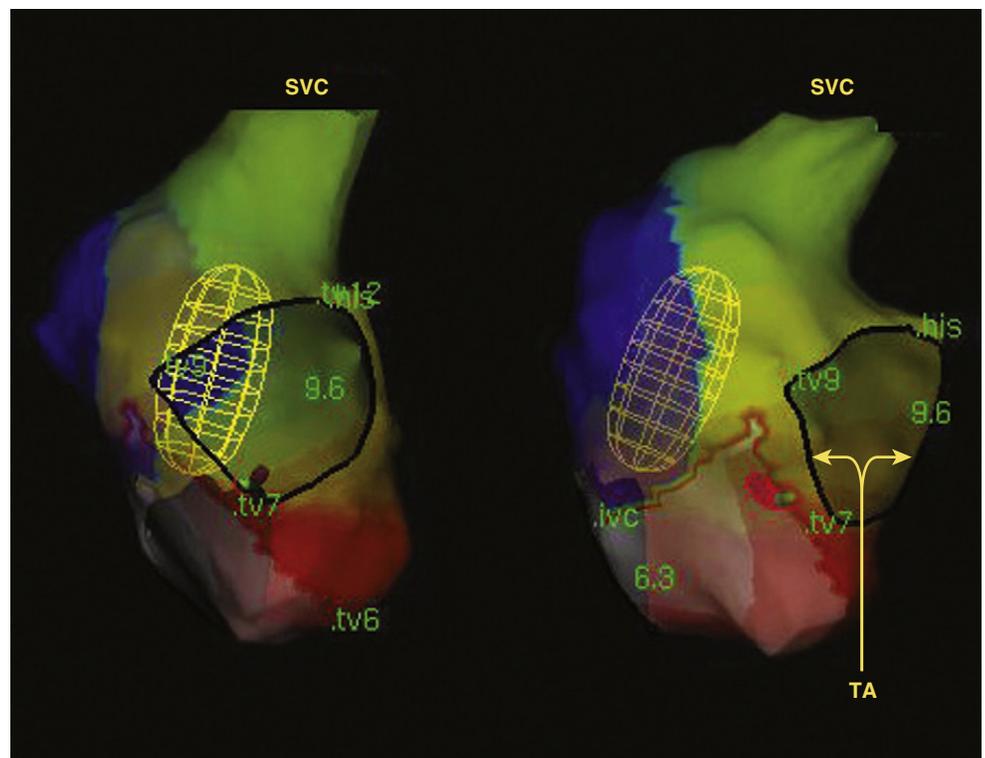

FIGURE 12-12 Noncontact mapping of typical atrial flutter (AFL). Shown are left anterior oblique and posteroanterior views of a color-coded isopotential map of right atrial activation during counterclockwise typical AFL. SVC = superior vena cava; TA = tricuspid annulus.

has also been used to identify and guide radiofrequency (RF) ablation of the site of residual conduction following incomplete linear ablation lesions at the isthmus. Because of its ability to record from multiple sites simultaneously, noncontact mapping can rapidly identify gaps in linear lesions. This is accomplished by analysis of one or more paced complexes originating adjacent to the line being assessed. This capability can be particularly helpful in patients who have recurrent AFL following a previous ablation. Because any number of maps can be superimposed on the initial geometry, bidirectional block at the ablation site can be rapidly identified during pacing following ablation. Tagging ablation areas during delivery of each RF impulse and a constantly visible ablation line offer another advantage—they ensure that no area is overlooked or ablated repeatedly.

Ablation

Target of Ablation

The CTI is the ideal target of AFL ablation because it is accessible, relatively narrow, short, safe to ablate, and essential for the AFL circuit (and not because it is the diseased area or the structure causing the AFL).²³ The central part of the isthmus (the 6 o'clock region in a fluoroscopic LAO view) appears to be the optimal target site because it is the thinner part of the isthmus (19 ± 4 mm; range, 13 to 26 mm) and therefore is less likely to resist RF ablation. Other advantages of the central isthmus are the increased distance from the paraseptal isthmus, which contains, in 10% of cases, extensions of the AVN or AVN artery, and the increased distance from the inferolateral isthmus, where the right coronary artery is in close proximity to the endocardium (less than 4 mm).^{1,24}

Alternatively, the tricuspid annulus–CS or IVC–CS isthmuses may be targeted (Fig. 12-13). However, for this approach to be successful, ablation within the CS is probably necessary. Such approaches are less successful in curing AFL.¹⁶ The paraseptal isthmus (tricuspid annulus–CS isthmus) has the thickest wall, compared with other parts of the inferior RA isthmus, although there is significant

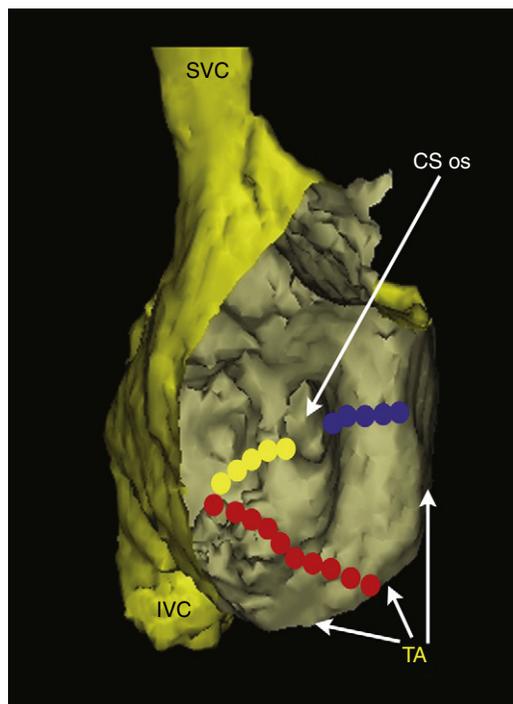

FIGURE 12-13 Computed tomography scan of the right atrium (RA; cardio-spic view) illustrating the typical location for linear ablation of the cavotricuspid isthmus (red dots), the tricuspid valve–coronary sinus (CS) isthmus (blue dots), and the CS–inferior vena cava (IVC) isthmus (yellow dots). CS os = coronary sinus ostium.

interindividual variability, and this structure is close to the arterial branch supplying the AVN and, in some cases, can contain the inferior extensions of the AVN. The inferolateral isthmus is the longest and is in closest proximity to the right coronary artery.²⁴

Ablation Technique

Periprocedural anticoagulation for catheter ablation of persistent AFL is necessary to minimize thromboembolic stroke risk. LA stunning and increased spontaneous echo contrast within the LA can occur following cardioversion or ablation of these arrhythmias. A perception of increased bleeding risks of invasive procedures undertaken while a patient is receiving therapeutic warfarin doses led many operators to adopt a “bridging” strategy of conversion to enoxaparin, to allow ablation and subsequent hemostasis to be performed during a pause in anticoagulation (a strategy also recommended by the Heart Rhythm Society/European Heart Rhythm Association/European Cardiac Arrhythmia Society expert consensus statement).²⁵ This strategy involves discontinuation of warfarin at least 3 to 5 days prior to ablation and starting heparin or enoxaparin after cessation of warfarin until the evening prior to the ablation procedure. Both enoxaparin and warfarin are then reinitiated within 4 to 6 hours after ablation and sheath removal, and enoxaparin is maintained until an optimal international normalized ratio (INR) level is achieved. However, an alternative strategy of uninterrupted periprocedure oral anticoagulation was found to be safer and more cost-effective for ablation of typical AFL. Bleeding complications were less frequent. Using this strategy, INR testing is required on the day of the procedure to confirm therapeutic anticoagulation, and transesophageal echocardiography is performed in patients with a subtherapeutic INR in the 3 weeks prior to the procedure. Another potential advantage of this strategy is the ability to reverse the effects of warfarin rapidly in the setting of a bleeding complication (e.g., pericardial bleeding) by using synthetic clotting factor concentrates or fresh frozen plasma infusion, whereas the effects of enoxaparin remain difficult to reverse; protamine has only a partial effect on its action.²⁶

CATHETER POSITIONING

A steerable ablation catheter with a distal ablation electrode of 4 or 8 mm is generally used.²⁷ The catheter’s curve size and shape can affect the ability to position the catheter on the CTI, and the use of preshaped guiding sheaths (e.g., SR0, SL1, or ramp sheath; Daig, Minnetonka, Minn.) can help stabilize the catheter position and prevent the catheter from sliding off the CTI and in and out of the right ventricle (RV).

The CTI can be localized electroanatomically. The ablation catheter is advanced to the RV under fluoroscopy (right anterior oblique [RAO] view); the tip is deflected to achieve contact with the RV inferior wall and is withdrawn progressively until the electrogram shows small atrial and large ventricular electrograms. The distal tip of the ablation catheter is then adjusted under fluoroscopy on the CTI in the LAO view until it is midway between the atrial septum and RA lateral wall (pointing toward 6 o’clock in a 45-degree LAO view; Fig. 12-14; Video 18).

The ratio of the atrial and ventricular electrogram amplitude (A/V ratio) can help localize the position of the ablation catheter; the A/V ratio is typically 1:4 or less at the tricuspid annulus, 1:2 to 1:1 at the CTI, and 2:1 to 4:1 near the IVC. The location of the catheter at the CTI can also be confirmed by demonstrating entrainment with concealed fusion during AFL.

RADIOFREQUENCY ABLATION

After positioning of the ablation catheter on or near the tricuspid annulus, the catheter is gradually withdrawn either toward the IVC during continuous energy application (50 to 70 W, 60 to 120 seconds, targeting a temperature of 55°C to 60°C), or in a stepwise manner with sequentially interrupted point-by-point application of

RF energy (50 to 70 W, 30 to 60 seconds, targeting a temperature of 55°C to 60°C). The first RF lesion is initiated from the tricuspid annulus edge with large ventricular and small atrial electrograms, and the last lesion is completed at the IVC edge. It is important that linear lesions span completely from the tricuspid annulus to the IVC (Fig. 12-15). After each RF application, the electrogram loses voltage and may become fragmented; the catheter is then withdrawn (2 to 4 mm at a time) toward the IVC until a new area of sharp atrial electrogram is reached, and the next RF application is delivered. This is repeated until the lack of atrial electrograms indicates that the catheter has reached the IVC. Before each RF application, the position of the ablation catheter is confirmed fluoroscopically, as described, or by using a 3-D mapping-navigation system.

During delivery of RF energy, AFL can terminate or its CL can increase transiently or permanently, and a gradual delay in activation of the low lateral RA wall can occur. This indicates that the ablation lesions have affected the circuit and should lead to continuation of RF delivery or extension of the lesion to ensure the achievement of complete conduction block across the CTI.

Ablation of the CTI may require more than one pass of RF delivery across the isthmus. It may be necessary to rotate the ablation catheter away from the initial line of energy application, medially or laterally in the isthmus, to create new or additional lines of block. At the time of the second pass-over, the ablation line isthmus electrograms will be fragmented, of low voltage, and often double.

A complete line of block is identified by a continuous corridor of double potentials separated by an isoelectric interval (Fig. 12-16). Further ablation is usually not needed at sites that exhibit double potentials because this finding generally indicates that local conduction block is already present. Gaps in the ablation line (i.e., sites of persistent conduction)

are characterized by single- or triple-fractionated potentials centered on or occupying the isoelectric interval of the adjacent double potential (see Fig. 12-16). These gaps should be ablated until complete CTI block is achieved. In 15% to 20% of cases, it can be extremely difficult to produce CTI block, which can be secondary to one or more of the following: (1) a very prominent eustachian ridge; (2) a thick isthmus, preventing transmural ablation; and (3) local edema, clot, or superficial damage forming a barrier for deeper penetration of subsequent RF applications.²³

MAXIMUM VOLTAGE-GUIDED TECHNIQUE

The maximum voltage-guided technique is based on the hypothesis that discrete muscle bundles in the CTI participate in the flutter circuit. Large atrial electrogram voltages identify the location of these muscle bundles along the isthmus and are selectively targeted for ablation. In effect, bidirectional CTI block is produced by the summation of a series of discrete focal ablations, rather than a continuous ablation line across the CTI.²⁸

Using this technique, the CTI is mapped in the 6 o'clock position, and bipolar atrial electrograms (during AFL or, preferably, during sinus rhythm or CS pacing) are measured from peak to peak during a continuous pull-back along the isthmus. The site of maximum voltage is noted and used as a marker for a presumed muscle bundle. The ablation catheter is positioned at this site, regardless of the location along the line, and RF ablation is performed for 40 to 60 seconds until an amplitude reduction of 50% or more is achieved. If the ablation lesion does not result in bidirectional CTI block, the line is remapped, and the next largest atrial electrogram is sequentially targeted for ablation. This is repeated until bidirectional CTI block is achieved. This technique therefore targets the signals with

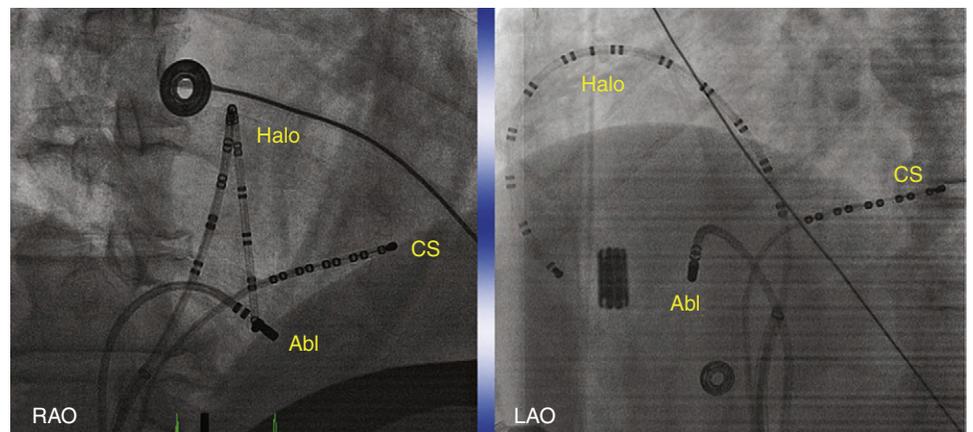

FIGURE 12-14 Fluoroscopic views (right anterior oblique [RAO] and left anterior oblique [LAO]) illustrating catheter location during ablation (Abl) of the cavotricuspid isthmus. CS = coronary sinus.

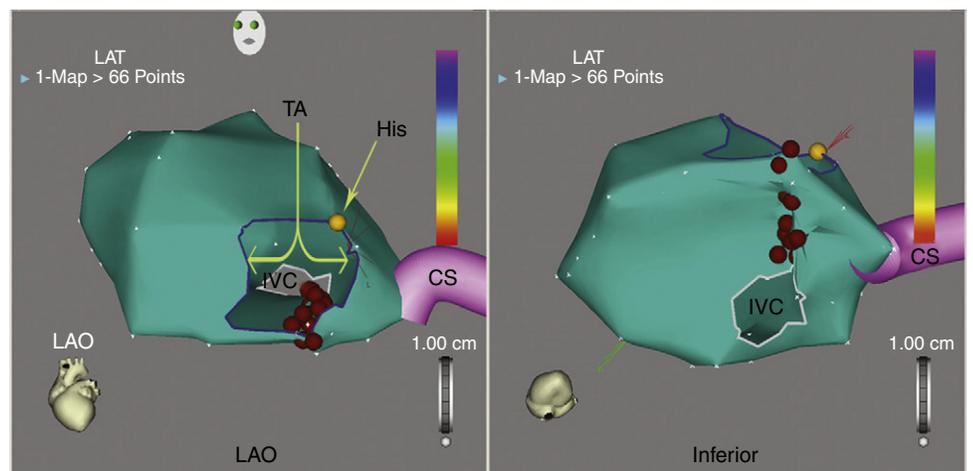

FIGURE 12-15 Ablation of the cavotricuspid isthmus (CTI) guided by CARTO (Biosense Webster, Diamond Bar, Calif.). The left anterior oblique (LAO) and inferior views of the reconstructed right atrium geometry are shown. Linear ablation (red dots) is performed across the CTI between the tricuspid annulus (TA) and inferior vena cava (IVC). CS = coronary sinus.

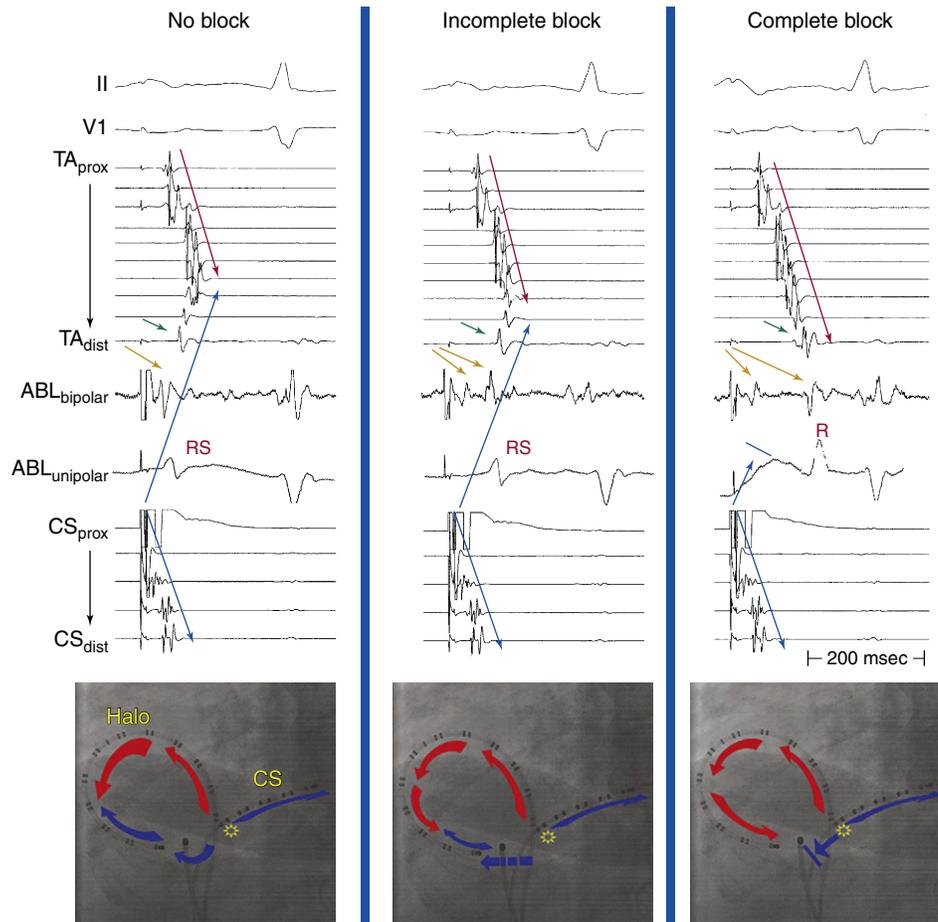

FIGURE 12-16 The use of coronary sinus (CS) pacing to verify the presence of clockwise cavotricuspid isthmus (CTI) block. **Upper panels**, Intracardiac recordings from the right atrium (RA), CS, and CTI. **Lower panels**, Left anterior oblique fluoroscopic view illustrating the position of the ablation catheter at the CTI, and the Halo catheter around the tricuspid annulus (TA), with the distal end at the lateral end of the CTI. When CTI conduction is intact (**left panel**), pacing from the coronary sinus ostium results in the collision of activation wavefronts in the lateral RA wall (red and blue arrows). **Middle panel**, The collision point moves toward the low lateral RA wall when incomplete block is present. **Right panel**, Complete clockwise CTI block is indicated by the observation of a purely descending wavefront at the lateral wall down to the CTI (proximal-to-distal Halo sequence). The bipolar electrogram recording from the CTI initially shows a single atrial potential (**left panel**, gold arrow). With partial CTI ablation, the atrial electrogram splits into two closely adjacent potentials (**middle panel**, gold arrows). Complete CTI block is indicated by the observation of double potentials separated by an isoelectric interval (**right panel**, gold arrows). Additionally, bipolar electrogram polarity reversal (**left panel**) is observed in the distal Halo and the distal ablation electrode recordings when complete CTI block is achieved (as compared with before complete CTI block is achieved in the **right** and **middle panels**), thus indicating reversal of the direction of the activation wavefront lateral to the line of block (green and gold arrows). Positive (R wave) morphology of the unipolar recording lateral to the line of block also indicates complete CTI block (in contrast to biphasic [RS] electrogram morphology when intact conduction or only incomplete block is present). ABL = ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; TA_{dist} = distal tricuspid annulus; TA_{prox} = proximal tricuspid annulus.

highest amplitude along the CTI and does not necessitate a contiguous line of ablation. This technique was found to reduce ablation times significantly compared with a purely anatomical approach; however, this did not translate into a reduction in fluoroscopy or overall procedure time.²⁸⁻³¹

ROLE OF THREE-DIMENSIONAL ELECTROANATOMICAL MAPPING NAVIGATION SYSTEMS

Electroanatomical mapping systems (CARTO or NavX) can provide precise spatial localization and tracking of the ablation catheter along the CTI that potentially help shorten fluoroscopy time. The main advantage of using this mapping system for AFL is the visibility of an ablation line as the procedure is carried out so that no area is left out or repeatedly ablated. Therefore, it facilitates the creation of ablation lines devoid of gaps across the entire isthmus (see Fig. 12-15).³²

After the usual anatomical landmarks are taken, detailed CTI mapping is performed by withdrawing the catheter at 2- to 3-mm intervals and taking several points along the line. Additionally, multiple points at the tricuspid annulus and at the mouth of the

IVC are acquired to delineate isthmus anatomy. One specific point is acquired at the most inferior point of the tricuspid annulus, whereby a small atrial electrogram and a larger ventricular electrogram are recorded. The catheter is then slightly rotated to two additional points at the tricuspid annulus, 1.5 to 2 cm septally and laterally. Three points are then acquired at the mouth of the IVC: one directly opposite to the inferior point of the tricuspid annulus and the other two points slightly lateral and medial to this point. In this way, the myocardial isthmus extension can be clearly defined and can be depicted in the 3-D space. The isthmus region forms a relatively flat rectangular surface in a caudal projection, and a side-on view is provided by the RAO projection.³³ These views allow visualization of lateral and septal displacement of the catheter tip, as well as the distance from the tricuspid annulus and the IVC. The ablation line can be planned by a trial run across the isthmus. During RF application, the line is placed to connect the most anterior and posterior points in the CTI. Each tag is approximately 4 mm in diameter, thus permitting visual estimation of the density of applications needed to produce a linear lesion during the drag. This helps avoid redundant lesion application and can identify potential gaps in the ablation line.³²

Furthermore, electroanatomical mapping also provides information about the voltage characteristics of the tissues involved in the CTI. This information can be of value in selecting ablation targets and choosing a path across the isthmus that is easier to ablate, which may not necessarily be the shortest path. Voltage mapping of the isthmus is particularly helpful in patients with recurrent AFL following previous ablation attempts; high-voltage and breakthrough sites identified during activation and voltage mapping may then be chosen as ablation targets.

Verification of CTI conduction block following ablation can also be carried out using electroanatomical mapping systems. The activation wavefront during AFL halts at the previously completed line but continues through the breakthrough site (see later).

The benefits of electroanatomical mapping compared with conventional mapping for catheter ablation have been clearly demonstrated in various arrhythmia entities, such as focal AT, macroreentrant AT (“atypical AFL”), AF, and ventricular tachycardia. These benefits include the ability of the technology for exact anatomical reconstruction, renavigation of the catheter accurately to positions removed from fluoroscopic markers, and precise electroanatomical identification of an arrhythmia origin or reentrant circuit. In the setting of typical AFL, however, the reentrant circuit and critical isthmus can be identified in most cases by using conventional mapping and fluoroscopic methods. Therefore, it is not surprising that the use of electroanatomical mapping and ablation in one report did not improve on the efficacy and the duration of the procedure as compared with the conventional technique. Nevertheless, fluoroscopy exposure time in that study was significantly reduced in the electroanatomical ablation group by almost 50%. However, this achievement was associated with an increase in the cost of the procedure.³³

APPROACH TO THE DIFFICULT CAVOTRICUSPID ISTHMUS ABLATION

Although ablation of typical AFL is successful in more than 90% of cases, occasionally inordinate difficulties can be encountered when attempting to terminate the flutter and create bidirectional conduction block across the CTI. The first step in these instances is to reconfirm the diagnosis of CTI-dependent AFL by entrainment mapping on the septal, lateral, and middle portion of the isthmus. Once the diagnosis of typical AFL is verified, other potential contributors to failure of CTI ablation should be considered, including poor catheter contact, inadequate power delivery, thick myocardium, and discontinuous ablation line, typically caused by the presence of pouches, recesses, ridges, and trabeculations within the CTI. These factors can also be responsible for recovery of CTI conduction and recurrent AFL in the follow-up after an acutely successful ablation.^{1,34,35}

RF ablation catheters with a large (8-mm) distal electrode and irrigated-tip catheters allow the creation of larger lesions in high- and low-flow regions. These catheters can facilitate ablation of the CTI by achieving a high success rate with a smaller number of RF lesions, shorter procedure times, and less fluoroscopy exposure, as compared with a standard 4-mm electrode.^{27,36,37}

When present, deep subeustachian pouches tend to be most prominent in the vestibular portion close to the septum and are typically associated with a prominent thebesian valve (which guards the CS os). The presence of a prominent subeustachian pouch can be suggested by a characteristic inferior dip of the catheter tip when the ablation catheter is dragged back across the isthmus toward the IVC. Catheter stability and power delivery for ablation within these pouches are suboptimal, and it is difficult to create a contiguous ablation line. Performing ablation relatively more laterally, particularly over the vestibular portion of the isthmus, may circumvent the problems with power delivery and potential perforation when ablating within a pouch. If linear ablation more laterally is unsuccessful because of poor catheter stability or thick myocardium, internal or external irrigation catheters may be used, with careful titration of energy delivery to avoid steam

pops. When ablation is still unsuccessful, adequate visualization of the pouch (using RA angiography or phased-array intracardiac echocardiography) can be necessary to guide ablation within or around the pouch.^{1,34,35}

Prominent pectinate muscles encroaching on the CTI can be suggested by the presence of sites with unusually high-voltage electrograms (from pectinate muscle ridges) surrounded by areas where abrupt impedance rises and minimal power delivery (likely from poor blood flow in the crevices between pectinate muscles) occurs. The thickness of prominent pectinates can prevent transmural ablation lesions and hamper adequate catheter stability. Additionally, the catheter tip can become wedged between the pectinate muscles with consequent inadequate power delivery with impedance rise, and coagulum formation may occur because of poor blood circulation. In these situations, performing ablation closer to the septum, where the pectinate muscle is less prominent, and using large-tip or irrigated-tip catheters can help achieve successful ablation.^{1,34,35}

A prominent eustachian ridge can hinder catheter manipulation to the septal aspect of the isthmus because the crest of the ridge can act as a fulcrum, directing the catheter tip laterally (instead of the expected medial rotation) when clockwise torque is applied. Additionally, when the eustachian ridge is prominent, electrode contact may be difficult to maintain on the upslope of the ridge (the portion between the crest of the eustachian ridge and the tricuspid annulus). In these situations, the use of preshaped guiding sheaths (e.g., SR0, SL1, or ramp sheath) often solves the problem.^{1,34}

DUTY-CYCLED, BIPOLAR-UNIPOLAR RADIOFREQUENCY ABLATION

A novel ablation system (GENius, Ablation Frontiers, Inc., Carlsbad, Calif.) has been developed, in which duty-cycled and alternating unipolar and bipolar RF energy is delivered using a multielectrode ablation catheter (the Tip-Versatile Ablation Catheter [TVAC], Ablation Frontiers) to create contiguous linear ablation lesions across the CTI.³⁸

The TVAC is a 9 Fr hexapolar catheter with a 4-mm tip electrode and five 2-mm band electrodes (all on 3-mm interelectrode spacing, see Fig. 7-4). The catheter has bidirectional asymmetric steering. All six electrodes contain two thermocouples, on opposite sides of the ring face, each directed toward the endocardial surface when the device is steered, to allow optimal sensing of endocardial surface temperature.

The multichannel generator delivers RF energy in a temperature-controlled, power-limited manner, but only up to a maximum of 45 W at the tip electrode and 20 W for each ring electrode. As a result of this configuration, a 30-mm-long contiguous linear lesion can be created with one RF application. The entire catheter is laid flat across the isthmus and then is pressed on the isthmus by pulling the entire catheter caudally to avoid the gaps in the ablation line. Additionally, the multielectrode catheter allows selective mapping and ablation through any or all electrodes as required.³⁹

This system is still undergoing investigation. Preliminary clinical experience has been promising. Bidirectional block across the CTI could be achieved with fewer than three RF applications, thus leading to significant decreases in procedure time, RF time, and fluoroscopy exposure.³⁹

CRYOABLATION

Complete CTI block can also be achieved by cryothermal ablation. Although there is no reason to believe that cryothermal ablation will be more effective than RF ablation of the CTI, cryothermal ablation has the advantage of being less painful. Acute success rates are comparable to those for RF ablation.⁴⁰ A prospective randomized trial comparing RF and cryothermal energy for ablation of typical AFL suggested that lesion durability from cryoablation (using an 8-mm-tip catheter [Freezor MAX, Medtronic CryoCath, Montreal]) was significantly inferior to that of RF ablation. Although acutely successful ablation rates in the cryoablation group were

comparable to those for RF ablation (89% versus 91%), persistence of bidirectional CTI block in patients treated with cryoablation reinvestigated 3 months following ablation was inferior to that in patients treated with RF ablation, as evidenced by the higher recurrence rate of symptomatic, ECG-documented AFL (10.9% versus 0%) and higher asymptomatic conduction recurrence rates (23.4% versus 15%). Additionally, compared with RF ablation, cryoablation is associated with significantly longer procedure times. This is driven mainly by differences in ablation duration, which can be attributed to the longer duration of each cryoablation (4 minutes) compared with RF ablation (up to 60 seconds).^{41,42}

Endpoints of Ablation

Ablation can be performed during AFL or CS pacing.⁴³ If ablation is carried out during AFL, the first endpoint is to terminate AFL during RF energy delivery. If AFL is terminated, programmed electrical stimulation and burst atrial pacing should be performed immediately to determine whether AFL is still reinducible. If AFL is not terminated or is reinducible, ablation should be repeated. If AFL is terminated and is not reinducible, pacing maneuvers should be performed to determine whether there is bidirectional block in the CTI. Termination of AFL during RF delivery is often not associated with complete bidirectional CTI block and should not be considered a reliable ablation endpoint by itself. Once complete bidirectional CTI block has been achieved, reconfirmation should be repeated 30 minutes after the last RF application.^{2,6}

If ablation is performed during sinus rhythm, it is usually performed during CS pacing to help monitor the activation sequence in the lateral RA wall. During ablation of the CTI, gradual delay in activation of the low lateral RA can be observed prior to achieving complete bidirectional CTI block.

CONFIRMATION OF BIDIRECTIONAL CAVOTRICUSPID ISTHMUS BLOCK

1. ATRIAL ACTIVATION SEQUENCE DURING ATRIAL PACING.

Complete bidirectional CTI block is demonstrated by pacing from the CS os and RA lateral wall and observing that sequential atrial activation terminates at the ablation line, on the contralateral side from the pacing site.

Normally, during atrial pacing at a CL of 600 milliseconds from the CS os, one wavefront propagates from the CS pacing site in a clockwise direction through the CTI to the low lateral RA. The other wavefront from the CS os ascends up the atrial septum to the high RA in a

counterclockwise direction, with resulting collision of wavefronts at the upper part of the lateral RA (the exact location of wavefront collision depends on the relative conduction velocities of the RA and the CTI) and generating an atrial activation sequence with a chevron pattern (see Fig. 12-16). Clockwise CTI block is indicated by the observation of a purely descending wavefront at the lateral wall down to the CTI (proximal-to-distal activation sequence on the Halo catheter positioned around the tricuspid annulus) when pacing from the CS os (i.e., pacing of the septal side of the ablation line; see Video 9). This block is associated with marked prolongation of the CTI conduction duration (i.e., the interval from the CS os to the low lateral RA; see Fig. 12-16). Incomplete clockwise CTI block is said to occur when a descending wavefront at the lateral RA wall still allows the lateral part of the CTI to be activated from the CS os in a clockwise direction across the CTI but at a slower conduction velocity, resulting in displacement of collision of the clockwise and counterclockwise wavefronts to the lower part of lateral RA. The distal bipole of the Halo catheter (Halo 1-2) at the lateral part of the CTI is activated slightly before or at the same time as bipole Halo 3-4, situated more laterally (see Fig. 12-16).^{2,6}

It is important to recognize that monitoring only the atrial activation sequence of the RA lateral wall recorded by the Halo catheter during CS pacing can lead to diagnostic errors in a large percentage of patients. This is because of the inability to detect very slow residual isthmus conduction that allows the wavefront propagating in an opposite direction to reach the ablation line earlier than the transisthmus conduction. Theoretically, slow but persistent isthmus conduction that can be confined within the ablation line or part of the isthmus distant from an area mapped by the multipolar catheter can therefore be misdiagnosed, no matter how closely the distal tip of the Halo catheter is placed to the ablation line, or even if the Halo catheter is positioned across the ablation line.^{2,6}

During low lateral RA pacing prior to ablation, the RA activation sequence (with intact counterclockwise CTI conduction) exhibits two ascending wavefronts (septal and lateral) leading to impulse collision at the high lateral wall. The caudocranial activation of the RA septum following counterclockwise propagation of the paced wavefront through the CTI results in atrial activation in the CS os preceding that in the HB region (Fig. 12-17). Furthermore, intact conduction through the CTI permits the paced wavefront to proceed rapidly to activate the LA from below (and CS activation propagates in a proximal-to-distal direction), thus giving rise to an inverted P wave in the inferior leads. Counterclockwise CTI block is indicated by the observation of a single ascending wavefront at the lateral wall (distal-to-proximal Halo sequence) followed by a completely descending wavefront at the septum to reach the CS os.

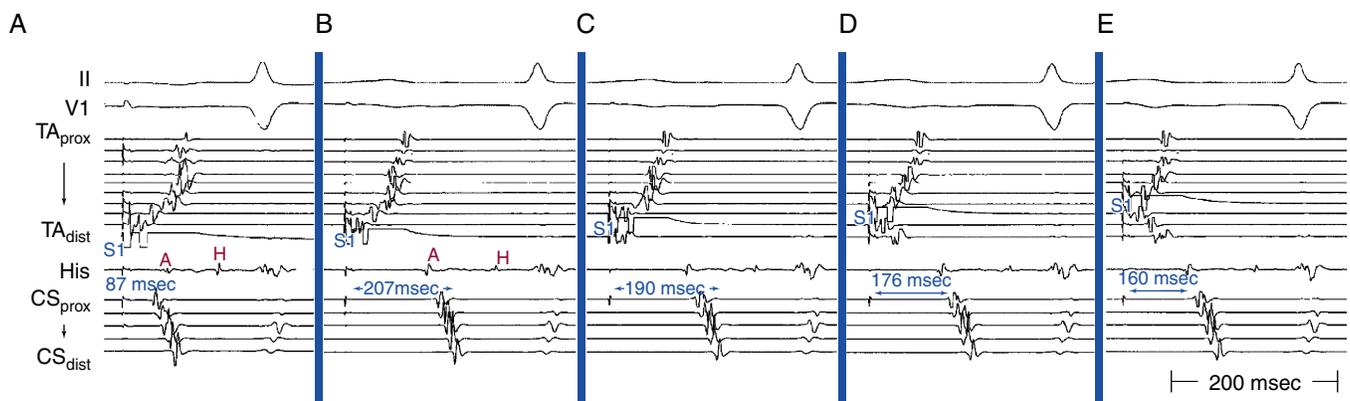

FIGURE 12-17 The use of differential pacing from the lateral right atrial (RA) wall to verify the presence of counterclockwise cavotricuspid isthmus (CTI) block. **A**, Pacing from the lateral aspect of the CTI (Halo 1,2) before CTI ablation. **B** to **E**, Pacing from different lateral RA sites along the Halo catheter after CTI ablation (**B**, pacing from Halo 3,4; **C**, pacing from Halo 5,6; **D**, pacing from Halo 7,8; **E**, pacing from Halo 9,10). When CTI conduction is intact, coronary sinus ostium (CS os) activation occurs via a counterclockwise wavefront across the CTI, and because the CS os is anatomically closer to the pacing site than the His bundle (HB), atrial activation in the CS os electrode precedes that in the HB electrode. In the presence of counterclockwise CTI block, CS os activation occurs via the wavefront propagating in a clockwise direction up the RA lateral wall, over the RA roof, and then down the septum. Consequently, CS os activation (as measured by the stimulus-to-local electrogram interval) occurs progressively earlier during pacing from more cephalic sites along the lateral RA wall (**B** to **E**). Additionally, activation of the CS os occurs after the high RA and the HB region. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; TA_{dist} = distal tricuspid annulus; TA_{prox} = proximal tricuspid annulus.

Therefore, compared with baseline, counterclockwise CTI block is associated with inversion of the direction of the septal activation from ascending to descending. Furthermore, the CS os electrogram is activated after the high RA and the HB region (see Fig. 12-17). Additionally, counterclockwise conduction block in the CTI forces the wavefront to activate the LA from above via the Bachmann bundle—and CS activation propagates in a distal-to-proximal direction—and gives rise to a different P wave morphology, with the terminal portion positive in the inferior leads.^{2,6}

2. TRANSISTHMUS CONDUCTION INTERVAL. The transisthmus conduction interval is measured during CS os or low lateral RA pacing; it is equal to the interval from the stimulus artifact from one side of the isthmus to the atrial electrogram recorded on the contralateral side. Prolongation of this interval by more than 50% (or to an absolute value of 150 milliseconds or more) suggests CTI block (see Fig. 12-16). This criterion has sensitivity and negative predictive values of 100%. However, the specificity and positive predictive values are less than 90%.

3. DOUBLE POTENTIALS. Double potentials, separated by an isoelectric interval of 30 milliseconds or longer, straddle a line of block. Double potentials along the ablation line across the CTI are generally considered the gold standard for determining complete bidirectional block (see Fig. 12-16). When there is a gap in a line of block, the isoelectric period between the double potentials shortens the closer the electrograms are to the gap. At the gap, in the line of block, double potentials are no longer present, and the electrogram is typically long and fractionated but can also be discrete. When the interval between the double potentials is more than 110 milliseconds, CTI block is present. When that interval is less than 90 milliseconds, complete bidirectional block is absent.

This technique is probably more difficult to perform than the classic activation mapping technique, mainly because of the ambiguity of electrogram interpretation along the ablation line, especially after extensive ablation attempts. When double potentials cannot be visualized, the interval between the pair of electrograms immediately on either side of the line of block (the [DP + 1] interval) when pacing immediately septal and lateral to the line of block can be used as an alternative method for verifying complete bidirectional CTI block. This technique requires positioning of a duodecapolar catheter around the tricuspid annulus while extending the catheter tip inside the CS, so that the catheter straddles the CTI and provides recording and pacing from the medial and lateral aspects of the isthmus. The [DP + 1] interval cutoff of 140 milliseconds seems to have better or equal sensitivity, specificity, and positive predictive values than other criteria. Nevertheless, it is still very difficult to distinguish incomplete block with very slow conduction from complete block. Additionally, gaps along the ablation line remote from the duodecapolar catheter would result in a [DP + 1] interval that is long in the absence of complete CTI block.⁴⁴

4. UNIPOLAR ELECTROGRAM CONFIGURATION. The morphology of the unfiltered unipolar recording indicates the direction of wavefront propagation. Positive deflections (R waves) are generated by propagation toward the recording electrode; negative deflections (QS complexes) are generated by propagation away from the electrode. During proximal CS pacing, the unfiltered unipolar signals recorded from the CTI typically demonstrate an RS configuration as the paced impulse propagates clockwise across the isthmus. In addition, because atrial depolarization along the CTI occurs sequentially in the clockwise direction, the polarity of the initial depolarization is the same from each pair of recording electrodes when using unfiltered unipolar recording on the CTI. When complete clockwise CTI block is achieved, depolarization of the electrode just medial to the line of block retains its original polarity, but its morphology changes to a single positive deflection (monophasic R wave) because the recording site becomes a dead end for impulse conduction. Conversely, atrial tissue lateral to the line of block is depolarized from the counterclockwise direction, which is opposite to the original direction of depolarization. Accordingly, the polarity of the atrial electrograms on the CTI lateral to the line of block reverses (see

Fig. 12-16). The same maneuver can be performed with pacing from the low lateral RA to evaluate counterclockwise CTI block.

Some studies have suggested that bipolar electrogram morphology could also be used for verification of the presence of CTI block. However, it is important to emphasize that bipolar recordings predominantly reflect local activation time; signal subtraction used to create a bipolar signal largely eliminates morphology information at either electrode. Nevertheless, bipolar electrogram polarity reversal can indicate a reversed wavefront direction that has been used in addition to the activation sequence for verifying bidirectional CTI block (see Fig. 12-16).

5. DIFFERENTIAL PACING. During unidirectional activation of the CTI (e.g., during low lateral RA pacing), the double electrograms recorded along the ablation line reflect activation in its immediate vicinity. The initial component reflects activation at the border ipsilateral to the pacing site, and the terminal component reflects that at the contralateral border. Pacing from another site farther away from the ablation line (e.g., midlateral RA) would obviously delay the stimulus to initial component timing, whereas the response of the terminal component would depend on the presence or absence of conduction through the ablation line. If the two components of the electrogram represent slow conduction across the isthmus ablation line, the terminal component will be delayed similar to the initial component because both components are activated by the same wavefront penetrating through the ablation line. In contrast, when complete CTI block is achieved, the two components represent two opposing activation wavefronts; the second component is advanced because it is activated by the wavefront going around, instead of through, the ablation line, given that the length of the detour is shortened by withdrawal of the pacing site.

Using the same principle, the local activation time at the CS os electrode during fixed-rate pacing performed from the low lateral and midlateral RA can be used for evaluation of counterclockwise CTI block. Normally (with intact isthmus conduction), CS os activation occurs via propagation of the paced wavefront across the CTI in a counterclockwise direction. Therefore, CS os activation occurs earlier during pacing from the low lateral RA compared with the midlateral RA because the low lateral RA is anatomically closer to the CS os. In contrast, when counterclockwise CTI block is present, CS os activation occurs via the wavefront propagating in a clockwise direction up the RA lateral wall, over the RA roof, and then down the septum (see Fig. 12-17). Consequently, CS os activation occurs earlier during pacing from the midlateral compared with the low lateral RA because the length of the detour is shortened by pacing from the midlateral RA.

6. RATE-DEPENDENT ISTHMUS BLOCK. Incomplete CTI block can mimic the activation pattern related to complete block and can produce intraatrial conduction delay at the low lateral RA. Residual CTI conduction is usually decremental and is worsened at faster pacing rates. Rate-dependent CTI block (during CS os or low lateral RA pacing) is associated with a change of the direction of impulse propagation and an increase of conduction time when the pacing rate is increased.

This maneuver helps distinguish isthmus block from long local conduction delay across the isthmus. With incomplete CTI block, activation of the low lateral RA during CS os pacing can be delayed, but activation can still occur via the CTI at the same time or just earlier than the wavefront coming to the low lateral RA from the counterclockwise direction. Increasing the pacing rate results in decremental conduction across the now diseased isthmus and causes further delay in activation of the low lateral RA (Fig. 12-18). In contrast, when complete CTI block is present, the lateral RA is activated in a counterclockwise direction across the atrial septum and RA roof. Because these atrial regions conduct nondecrementally, pacing at faster rates should not change the timing of low lateral RA activation significantly, as long as the pacing CL is longer than atrial refractoriness. The same maneuver can be performed with pacing from the low lateral RA to evaluate counterclockwise CTI block.

7. ELECTROANATOMICAL MAPPING. Electroanatomical 3-D activation mapping can be used to verify CTI block. When clockwise block in the CTI is achieved, proximal CS pacing results in an activation wavefront propagating in a counterclockwise fashion, with the latest activation in the CTI immediately lateral to the ablation line (Fig. 12-19). When conduction across the CTI is still intact, CS pacing produces an activation wavefront that propagates rapidly through the CTI, with the anterolateral RA wall activated last. Similar maps can be generated during low lateral RA pacing to confirm counterclockwise block in the CTI. Activation maps can also be evaluated for the presence of gaps in the ablation lines, as indicated by the early breakthroughs from the ablation line. However, following CTI ablation, the local electrograms at the ablation line can be complex—with double, triple,

or fragmented potentials and unclear local activation time—and electroanatomical activation mapping can be challenging.

Outcome

With the availability of precise catheter locator systems, more effective ablation tools, and accurate endpoints for ablation, the inability to create complete CTI block and to eliminate recurrences of CTI-dependent AFL successfully is unusual in contemporary practice. Acute success rate of ablation of typical AFL is higher than 90% when large-tip or irrigated RF catheters are used.^{45,46} A repeat ablation procedure is performed in 5% to 15% of patients, and the long-term success rate in preventing recurrent AFL is 97%.⁴⁵ Advances in AFL ablation technologies have had less effect on short-term success rates than

FIGURE 12-18 Surface ECG and intracardiac recordings following incomplete ablation of the cavotricuspid isthmus (CTI). The activation sequence around the tricuspid annulus (TA) during coronary sinus (CS) pacing suggests block in the CTI (continuous line, arrow); however, pacing at a faster rate at right shows a "straighter" line of activation along the TA and thus reveals that conduction had been present in the CTI at the slower paced rate. Abl = ablation site; dist = distal; mid = middle; prox = proximal.

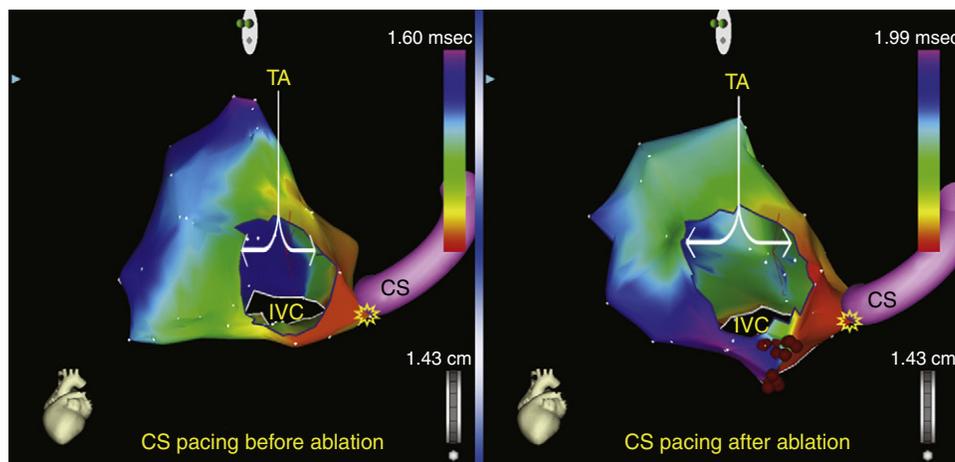

FIGURE 12-19 CARTO (Biosense Webster, Diamond Bar, Calif.) activation map of coronary sinus (CS) pacing before (left) and after (right) cavotricuspid isthmus (CTI) ablation. During CS ostium pacing (yellow star), complete CTI block in the clockwise direction is indicated by the absence of activation proceeding through the ablation line (red dots); activation of the entire tricuspid annulus (TA) remains counterclockwise, except for the small portion that is situated between the pacing site and the line of block. IVC = inferior vena cava.

on reducing AFL recurrences. On the other hand, the use of the more stringent endpoint of bidirectional block significantly reduces the AFL recurrence rate. For patients in whom typical AFL recurs after ablation, conduction through the CTI is usually responsible. Presumably, such recurrences reflect a failure to achieve bidirectional CTI block during the initial procedure, incorrect initial assessment of bidirectional block, or resumption of conduction across an initially blocked isthmus. The incidence of AFL recurrence does not increase beyond 1 to 6 months of follow-up, a finding suggesting that if recovery of isthmus conduction is going to occur, it will have done so by 6 months.⁴⁶

Serious complications associated with AFL ablation are rare (0.4%) and include AV block (most common, 0.2%), cardiac tamponade, groin hematoma, transient inferior ST segment elevation or acute occlusion of the right coronary artery,⁴⁷ thromboembolic complications, and ventricular tachycardia.⁴⁵

Following AFL ablation, AF can develop in approximately 20% to 30% (with short-term follow-up, approximately 1 year) and in up to 82% (with long-term follow-up, approximately 4 years) of patients with or without a prior history of AF.^{2,6,48} It appears that AFL is often an early marker of atrial electrical disease that frequently progresses to AF even after curative treatment for AFL. This has led some investigators to advocate ablation of AF at the same time of AFL ablation.⁴⁹ In a meta-analysis, over an average follow-up of 16 months, AF occurred in 23.1% of patients with no preablation history of AF and in 52.7% of patients with a history of AF, despite successful AFL ablation. The occurrence of AF was not influenced by the ablation technology or procedural endpoints. This finding has serious implications for patient selection, long-term arrhythmia-free success rates, postprocedure antiarrhythmic drug use, and postprocedure anticoagulation. Because AF predating ablation of AFL is very likely to recur, thus limiting the ability to discontinue antiarrhythmic medications or anticoagulation in many patients, the potential benefits of ablation of only AFL should be seriously scrutinized.⁴⁶

Pathophysiology

The term *typical atrial flutter* (AFL) is reserved for an atrial macroreentrant arrhythmia rotating clockwise or counterclockwise around the tricuspid annulus and using the cavotricuspid isthmus (CTI) as an essential part of the reentrant circuit. *Atypical AFL* is a term commonly used to describe all other *macroreentrant* atrial tachycardias (MRATs), regardless of the atrial cycle length (CL), but the former term introduces unnecessary confusion, and a mechanistic description of the tachycardia circuit is preferred.

The mechanism of MRAT is reentrant activation around a large central obstacle, generally several centimeters in diameter, at least in one of its dimensions. The central obstacle can consist of normal or abnormal structures. Additionally, the obstacle can be fixed, functional, or a combination of both. There is no single point of origin of activation, and atrial tissues outside the circuit are activated from various parts of the circuit.

A description of MRAT mechanisms must be made in relation to atrial anatomy, including a detailed description of the obstacles or boundaries of the circuit and the critical isthmuses that may be targets for therapeutic action. Typically, chronic or long-lasting atrial tachycardias (ATs) are macroreentrant. Focal ATs are more frequently responsible for irregular ATs with frequent spontaneous interruption and reinitiation than are ATs observed with macroreentry. Microreentrant ATs, by definition, use a smaller circuit and in many regards behave more like other forms of focal ATs.

Atypical Isthmus-Dependent Right Atrial Macroreentry

Lower loop reentry and intraisthmus reentry are macroreentrant circuits that are confined to the right atrium (RA) and incorporate the CTI as a critical part of the circuit. However, in contrast to typical AFL, the circuit is not peritricuspid (Fig. 13-1). Nevertheless, because the CTI is still a necessary part of the circuit, these arrhythmias are amenable to CTI ablation, as is true for patients with typical AFL.¹

LOWER LOOP REENTRY

Lower loop reentry is a form of CTI-dependent AFL with a reentrant circuit around the inferior vena cava (IVC); therefore, it is confined to the lower part of the RA (see Fig. 13-1). It often coexists with counterclockwise or clockwise typical AFL and involves posterior breakthrough across the crista terminalis. Lower loop reentry can rotate around the IVC in a counterclockwise (i.e., the impulse

within the CTI travels from the septum to the lateral wall) or clockwise fashion. A breakdown in the inferoposterior boundaries of the CTI produced by the eustachian ridge and lower crista terminalis causes the circuit to revolve around the IVC (instead of around the tricuspid annulus), across the eustachian ridge, and through the crista terminalis, with slow conduction because of transverse activation through that structure. Alternatively, the circuit can exit at the apex of Koch triangle and come behind the eustachian ridge to break through across the crista terminalis behind the IVC and then return to the CTI. This arrhythmia is usually transient and terminates by itself or converts spontaneously into AFL or atrial fibrillation (AF).¹

INTRAISTMUS REENTRY

Intraisthmus reentry is a reentrant circuit usually occurring within the region bounded by the medial CTI and coronary sinus ostium (CS os; see Fig. 13-1). Circuits in the lateral portion of the CTI can also occur but are less common. This arrhythmia can be sustained and usually occurs in patients who have undergone prior, and often extensive, ablation at the CTI. Intracardiac recordings usually resemble typical AFL. However, in this form of CTI-dependent AFL, entrainment pacing from the lateral CTI demonstrates a post-pacing interval (PPI) longer than the tachycardia CL, a finding indicating that the lateral CTI is not part of the reentrant circuit. On the other hand, pacing from the region of medial CTI or CS os demonstrates concealed entrainment with PPI equal to the tachycardia CL. Fractionated or double potentials usually can be recorded in this area and can be entrained. Although the anatomical basis of this arrhythmia remains unknown, a linear lesion across the medial CTI, usually at the site of a very prolonged electrogram, can cure the tachycardia.

Non-Isthmus-Dependent Right Atrial Macroreentry

LESIONAL RIGHT ATRIAL MACROREENTRANT TACHYCARDIA

Atrial macroreentry in the right free wall is the most common form of non-CTI-dependent RA MRAT. These circuits can propagate around a central obstacle of a low-voltage area or scar in the lateral or posterolateral RA wall, arising spontaneously or as a consequence of prior atrial surgery. The central obstacle of the macroreentrant circuit can be an atriotomy scar (in patients who have undergone surgery for congenital or valvular heart disease), a septal prosthetic patch, a suture line, or a line of fixed block secondary to

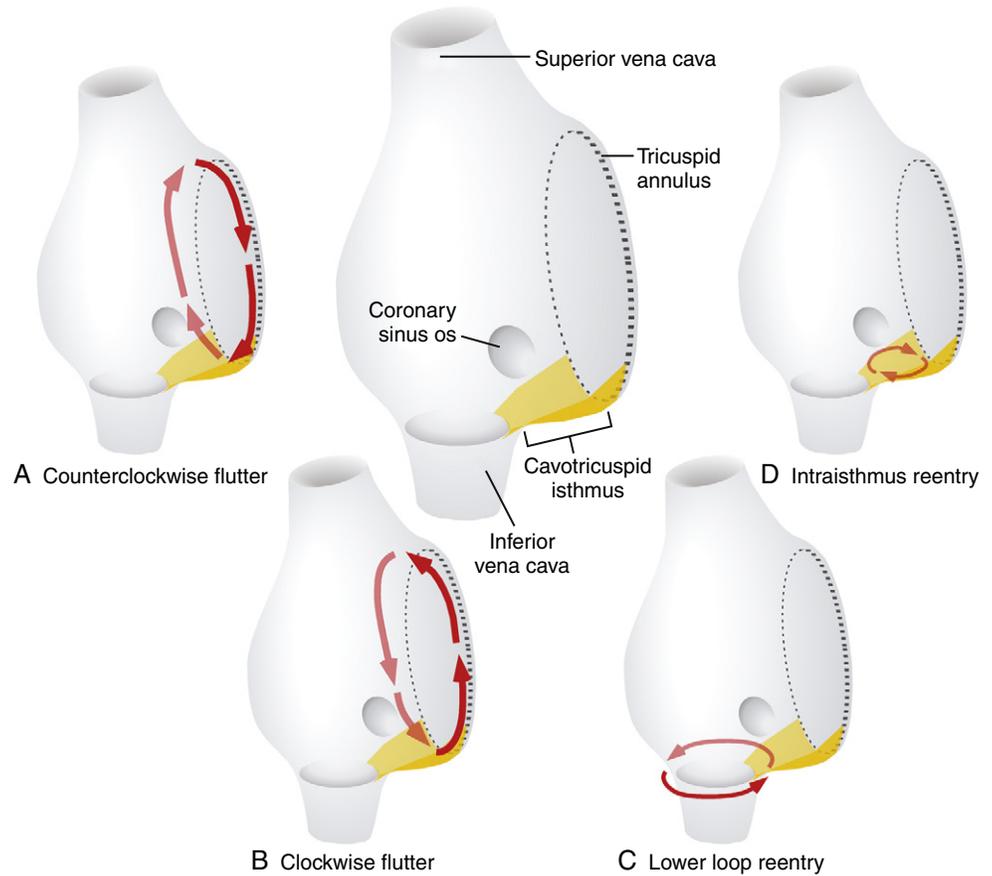

FIGURE 13-1 Anatomy of cavotricuspid-dependent atrial flutter circuits. **Top, center,** The right atrium is viewed from the right lateral aspect, with the lateral wall semitransparent. The cavotricuspid isthmus is shaded orange. **A,** Counterclockwise flutter circuit. **B,** Clockwise flutter circuit. **C,** Lower loop reentry circuit. **D,** Intraisthmus reentry circuit. See text for discussion. Os = ostium.

radiofrequency (RF) ablation. Other obstacles can also include anatomical structures located in the vicinity of the scar (superior vena cava [SVC], IVC). Occasionally, these ATs are associated with areas of electrical silence, a finding suggesting atrial scarring in patients who have not undergone prior atrial surgery. These patients have a characteristic posterolateral and lateral distribution of RA scarring and frequently have more than one tachycardia mechanism. Low-voltage electrograms characterizing areas of scar and double potentials characterizing a line of block can be observed during both normal sinus rhythm (NSR) and AT. In one study, electroanatomical mapping revealed that RA electrically silent areas (electrogram amplitude 0.03 mV or lower) were involved in the tachycardia mechanism in two thirds of the patients with non-CTI-dependent RA MRAT.^{2,3}

Patients with congenital heart disease have a high prevalence of AT, particularly after they have undergone reparative or palliative surgical procedures. For MRATs in adults with repaired congenital heart disease, three RA circuits are generally identified: lateral wall circuits with reentry around or related to the lateral atriotomy scar, septal circuits with reentry around an atrial septal patch, and typical AFL circuits using the CTI. These arrhythmias are discussed separately in [Chapter 14](#).^{1,4}

UPPER LOOP REENTRY

This type of MRAT involves the upper portion of the RA, with transverse conduction over the crista terminalis and wavefront collision occurring at a lower part of the RA or within the CTI. When upper loop reentry was first reported, it was thought to be a reentrant circuit using the channel between the SVC, fossa ovalis, and crista terminalis. Noncontact mapping studies have shown that this form of MRAT employs the crista terminalis as its functional central obstacle. The impulse rotating in the circuit can be in a counterclockwise or clockwise direction. The CTI is not an intrinsic part of

the reentrant circuit. Upper loop reentry can be abolished by linear ablation of the gap in the crista terminalis.^{5,6}

DUAL-LOOP REENTRY

Although RA MRAT (lesional RA macroreentry or upper loop reentry) can manifest as an isolated arrhythmia (single-loop reentry), it can occur in conjunction with typical clockwise or counterclockwise AFL, or both, as well as lower loop reentry. When two atrial macroreentrant circuits coexist and use neighboring anatomical structures, they create the so-called *dual-loop reentry*. Not uncommonly, ablation of one tachycardia results in transition to the other, and ablation of both circuits is necessary for clinical success. Detection of this change requires careful attention to the atrial activation sequence and ECG pattern after each RF application. The recording of multiple simultaneous electrograms, as continuous endocardial references, facilitates detection of these activation changes. Fusion between two simultaneous left atrial (LA) macroreentrant circuits is possible after prior AF ablation.⁷

Left Atrial Macroreentry

LA MRATs are less common than typical AFL and are frequently related to or coexist with AF. LA MRAT is a known complication of surgical and catheter-based therapies of AF, and it can occur in up to 50% of patients following extensive catheter ablation strategies (see [Chap. 15](#)).⁸ Additionally, cardiac surgery involving the LA or atrial septum can produce different LA macroreentrant circuits. However, LA circuits also can be found in patients without a history of atriotomy or prior ablation. Electroanatomical maps in the latter group often show low-voltage or areas of scar in the LA, which act as a central obstacle or barrier in the circuit. These areas are typically located at the posterior wall (45%), superior region (roof, 28%), or anteroseptal region (27%) of the LA. The pathogenesis of these areas

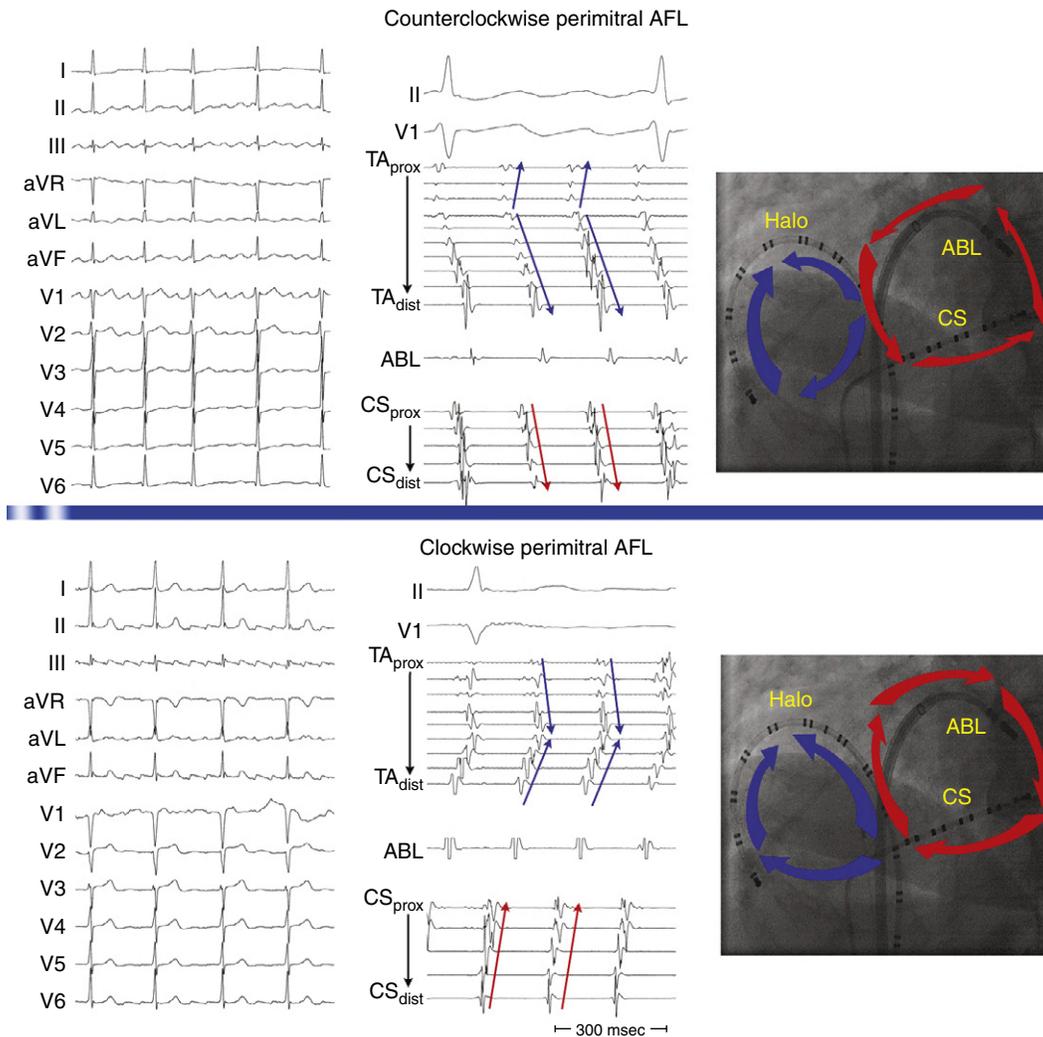

FIGURE 13-2 Surface ECGs and intracardiac recordings during clockwise (lower panel) and counterclockwise (upper panel) perimitral macroreentrant atrial tachycardia. Catheter position and wavefront activation during the tachycardia are illustrated in a left anterior oblique fluoroscopic view (right side). The ablation catheter (ABL) is positioned at the mitral isthmus, and the Halo catheter is positioned around the tricuspid annulus (TA), with the distal end at the lateral end of the cavotricuspid isthmus. AFL = atrial flutter; CS = coronary sinus; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; TA_{dist} = distal tricuspid annulus; TA_{prox} = proximal tricuspid annulus.

with no electrical signals is not well established. Potential causes include volume and pressure overload (mitral valve disease, hypertension, heart failure), ischemia (atrial branch occlusion), postinflammation scarring (after myocarditis), atrial amyloidosis, atrial dysplasia, and tachycardia-related structural remodeling. These macroreentrant circuits show considerable anatomical variability and frequently involve multiple simultaneous loops.^{1,2}

PERIMITRAL ATRIAL FLUTTER

This circuit involves reentry around the mitral annulus in a counterclockwise or clockwise fashion (Fig. 13-2, see Video 12). This arrhythmia is more common in patients with structural heart disease; however, it has been described in patients without obvious structural heart disease, but, in these patients, electroanatomical voltage mapping often shows scar or low-voltage areas on the posterior wall of the LA as a posterior boundary of this circuit. Perimitral MRAT is the most common MRAT in patients with prior LA ablation procedures for AF.

CIRCUITS INVOLVING THE PULMONARY VEINS WITH OR WITHOUT LEFT ATRIAL SCAR

Various reentrant circuits involve the pulmonary veins (PVs), especially in patients with AF or mitral valve disease and those with prior

catheter ablation of AF (particularly with linear LA ablation lesions), including reentrant circuits around two or more PVs (it is unusual for a circuit to involve one PV) and posterior scar or low-voltage areas (see Video 17).

LEFT SEPTAL CIRCUITS

Left septal circuits represent a rare form of MRAT occurring in the absence of prior cardiac surgery. These circuits involve the LA septum primum, which acts as a central obstacle for the reentrant circuit. The right PV ostia serve as its posterior boundary, whereas the mitral annulus serves as its anterior boundary. Atrial dilation and concomitant antiarrhythmic drug therapy also seem to play a role by the prolongation of left intraatrial conduction, which then allows stable macroreentry circuits to persist.² In patients with a history of surgery for atrial septal defects, scars or the patch on the septum can serve as the anatomical substrate of left septal circuits.

Clinical Considerations

Epidemiology

MRAT comprises a heterogeneous group of RA or LA macroreentrant circuits related to different anatomical and electrophysiological (EP) substrates. These arrhythmias are frequently associated

with structural heart disease, congenital cardiac defects, previous cardiac surgical procedures, or surgical or catheter ablation procedures for AF. Often, these arrhythmias coexist with AF. However, MRAT occasionally occurs in a patient with no apparent structural heart disease.⁴

Although its exact prevalence among cardiac arrhythmias is difficult to establish clinically, MRAT is not a rare arrhythmia. It seems that the incidence of MRAT is increasing. This may be related to aging of the general population, which implies progressive alteration of the atrial electrical properties with development of an arrhythmogenic substrate, as well as to the increased numbers of surgical and catheter based procedures in the atria for treatment of AF.^{4,9}

Clinical Presentation

Macroreentrant ATs are typically chronic or long lasting. As with AF and typical AFL, patients can present with symptoms related to rapid ventricular response, loss of atrioventricular (AV) synchrony, tachycardia-induced cardiomyopathy, or deterioration of preexisting cardiac disease. Additionally, typical AFL and MRAT can contribute to systemic thromboembolic complications and stroke.

Initial Evaluation

Outside typical AFL, the clinician is faced with a wide spectrum of ATs for which therapy and prognosis cannot be defined with routine noninvasive testing, and definitive diagnosis typically requires intracardiac mapping. ECG alone is frequently inadequate to distinguish MRAT from focal AT or typical AFL. Detailed evaluation of cardiac function and anatomy is typically required, especially in patients with congenital heart disease and those with previous cardiac procedures (surgical or catheter-based). Additionally, detailed knowledge of the congenital anomaly and previous surgical or ablative procedures is very important, such as location of surgical incisions and the presence and location of prosthetic patch material.

Principles of Management

Medical management of MRAT is practically similar to that for AF. Antiarrhythmic drugs (class IA, IC, and III) have been first-line therapy. Long-term anticoagulation for stroke prevention is typically recommended. Rate control versus rhythm control strategies are evaluated, depending on several factors, including severity of symptoms, response to rate-controlling medications, cardiac function, and associated noncardiac diseases.

With recent advances in the technology to visualize and modify the arrhythmia substrate, ablation of non-CTI-dependent MRAT has become increasingly successful, but it can be substantially more difficult than ablation of typical AFL. MRAT can have complex circuits that demand a thorough knowledge of atrial anatomy and a great deal of experience to correlate activation patterns with anatomical landmarks. When this type of AT is suspected, such as in patients with congenital heart disease who have had surgery, referral to an experienced center should be considered.⁴

Catheter ablation of the AV junction and pacemaker insertion should be considered if catheter ablative cure is not possible and the patient has a rapid ventricular response that is not responding to drug therapy.

Electrocardiographic Features

P wave morphology on the surface ECG is usually of limited value for precise anatomical localization of macroreentrant circuits. Analysis of the P wave can be impeded by partial or complete concealment of the P wave within the QRS complexes or T waves when the AT is associated with 1:1 or 2:1 AV conduction. Additionally, P wave morphology of a spectrum of RA and LA MRATs is highly variable. The presence of complex anatomy secondary to congenital abnormalities, prior atrial surgery, or a large low-voltage zone (secondary to underlying atrial substrate or extensive

catheter or surgical atrial ablation) can modify atrial wavefront propagation in a nonuniform manner, resulting in deviated atrial activation vectors or low amplitude P waves. Furthermore, P waves produced by different underlying substrates may appear similar if the direction of activation of the atrial septum and LA is similar. The surface ECG morphology is most characteristic (and hence predictive) for establishing a diagnosis of counterclockwise typical AFL. Nevertheless, atypical ECG patterns have been described for typical AFL after AF ablation. Although clockwise typical AFL also has a characteristic appearance, this is more variable, and it can be mimicked by various other MRATs.^{5,10} On the other hand, AFL may show distinct isoelectric intervals between P waves, especially in the presence of extensive atrial scarring or a localized macroreentrant circuit, similar to focal AT.

UPPER LOOP REENTRY. The surface ECG of upper loop reentry closely mimics that of clockwise typical AFL, with positive P waves in the inferior leads, because in most cases, both arrhythmias share a similar activation sequence of the LA, the septum, and caudocranial activation of the lateral RA. However, negative or isoelectric or flat P waves in lead I favor upper loop reentry over clockwise typical AFL. Conversely, positive P waves in lead I with an amplitude of more than 0.07 mV favor clockwise typical AFL. Additionally, the CL of upper loop reentry is usually shorter in comparison with typical AFL.^{5,6}

LOWER LOOP REENTRY. The surface morphology of lower loop reentry is highly variable and can be similar to that of counterclockwise or clockwise typical AFL, but lower loop reentry associated with higher crista terminalis breaks can produce unusual ECG patterns. Sometimes, the changes are manifested by decreased amplitude of the late positive waves in the inferior leads, probably as a result of wavefront collision over the lateral RA wall.

INCISIONAL RIGHT ATRIAL MACROREENTRANT TACHYCARDIA. The surface ECG morphology of free wall MRAT in a patient with a previous atriotomy is highly variable, depending on factors including the location of the scars and low-voltage areas, the direction of rotation, the presence of coexisting conduction block in the atrium, and the presence of a simultaneous typical AFL. The morphology of the atrial complex on the surface ECG can range from that similar to typical AFL to that characteristic of focal AT (see Fig. 14-5). Often, inverted P waves can be observed in lead V₁. Depending on the predominant direction of septal activation, RA free wall MRAT can mimic either clockwise or counterclockwise typical AFL.⁵

LEFT ATRIAL MACROREENTRANT TACHYCARDIA. The surface ECG morphology of LA MRAT caused by the different reentrant circuits is variable, and ECG findings are often similar for different underlying substrates, thus making the localization within the LA based on the ECG difficult. LA MRATs are usually associated with prominent positive P waves in lead V₁ and upright (but frequently of low amplitude) deflections in leads II, III, and aVF. However, LA MRAT can result in ECG patterns of focal AT (discrete P waves and isoelectric baseline) because of a high prevalence of generalized atrial disease and slower conduction. Infrequently, LA MRAT can mimic typical AFL on the surface ECG.⁵

PERIMITRAL ATRIAL MACROREENTRY. Most of these tachycardias show prominent forces in leads V₁ and V₂, with diminished amplitude in the inferior leads (see Fig. 13-2). It has been suggested that a posterior LA scar allows for domination by anterior LA forces. This constellation of findings may mimic counterclockwise or clockwise CTI-dependent AFL, but the decreased amplitude of frontal plane forces suggests an LA circuit. In patients with prior PV isolation procedures, the surface ECG morphology of counterclockwise perimitral MRAT can be different from that in patients without prior ablation, possibly related to varying degrees of prior LA ablation or scar. In these patients, counterclockwise perimitral MRAT demonstrates positive P waves in the inferior and precordial leads and a significant negative component in leads I and aVL. Furthermore, counterclockwise perimitral MRAT in these patients can have a morphology similar to that of left PV ATs. However, counterclockwise perimitral MRAT is suggested by

a more negative component in lead I, an initial negative component in lead V₂, and a lack of any isoelectric interval between P waves. Clockwise perimitral MRAT has limb lead morphology that is the converse of that of counterclockwise perimitral MRAT and an initial negative component in the lateral precordial leads. The positive P wave in leads I and aVL differentiates clockwise perimitral MRAT from counterclockwise CTI-dependent AFL and left PV AT.

PULMONARY VEIN CIRCUITS. Because these circuits are related to low-voltage or scar areas, the surface ECG usually shows low-amplitude or flat P waves. These tachycardias have the most variable surface ECG patterns.

LEFT SEPTAL CIRCUITS. Because the reentry circuit is on the septum, the surface ECG shows prominent, usually positive, P waves only in lead V₁ or V₂ and almost flat waves in most other leads (Fig. 13-3). This pattern can be caused by a septal circuit with anteroposterior forces projecting in lead V₁ and the cancellation of caudocranial forces. This pattern was 100% sensitive for an LA septal circuit, but the specificity of this pattern for any type of LA MRAT was only 64%.

Electrophysiological Testing

Typically, a decapolar catheter (positioned into the CS with the proximal electrodes bracketing the CS os) and a multipolar (20- or 24-pole) Halo catheter (positioned at the tricuspid annulus) are used to map typical AFL. The distal tip of the Halo catheter is positioned at 6 to 7 o'clock in left anterior oblique (LAO) view, so that the distal electrodes will record the middle and lateral aspects of the CTI, the middle electrodes will record the anterolateral RA, and the proximal electrodes may record the RA septum (depending on the catheter used). Instead of the Halo and CS catheters described, some laboratories use a single duodecapolar catheter around the tricuspid annulus while extending the catheter tip inside the CS. Such a catheter would straddle the CTI and provide recording and pacing from the medial and lateral aspects of the isthmus.

Induction of Tachycardia

The programmed electrical stimulation protocol should include atrial burst pacing from the high RA and CS—down to a pacing CL at which 2:1 atrial capture occurs—and atrial extrastimulation (AES), single and double, at multiple CLs (600 to 300 milliseconds) from the high RA and CS (down to the atrial effective refractory period). Isoproterenol infusion (0.5 to 4 µg/min) is administered as needed to facilitate tachycardia induction. The goals of EP testing in patients with MRAT are listed in Table 13-1.

Tachycardia Features

MRAT is characterized by a constant CL, P wave polarity, morphology, and amplitude of the recorded bipolar electrograms and by the presence of a single constant macroreentrant circuit with a constant atrial activation sequence. The atrial activation sequence and atrial CL depend on the origin and type of the macroreentrant circuit. However, considerable variation in the atrial CL for a single macroreentry circuit is unusual, although it can be observed in the atrium contralateral to atrium of origin of the tachycardia. In contrast, focal ATs classically exhibit alterations in CL with speeding (warm-up) and slowing (cool-down) at the onset and termination of tachycardia. Variation in the AT CL of greater than 15% has been suggested as a reliable marker of a focal AT. However, a regular AT can be either focal or macroreentrant.¹¹ Additionally, focal ATs often manifest as bursts of tachycardia with spontaneous onset and termination, although they can be incessant, and they may accelerate in response to sympathetic stimulus.⁵ Several criteria can help distinguish focal AT from MRAT (see Table 11-5).

Atrial activation during MRATs spans the whole tachycardia CL. In contrast, intracardiac mapping in the setting of focal ATs shows significant portions of the tachycardia CL without recorded atrial activity, and atrial activation time is markedly less than the tachycardia CL, even when recording from the entire

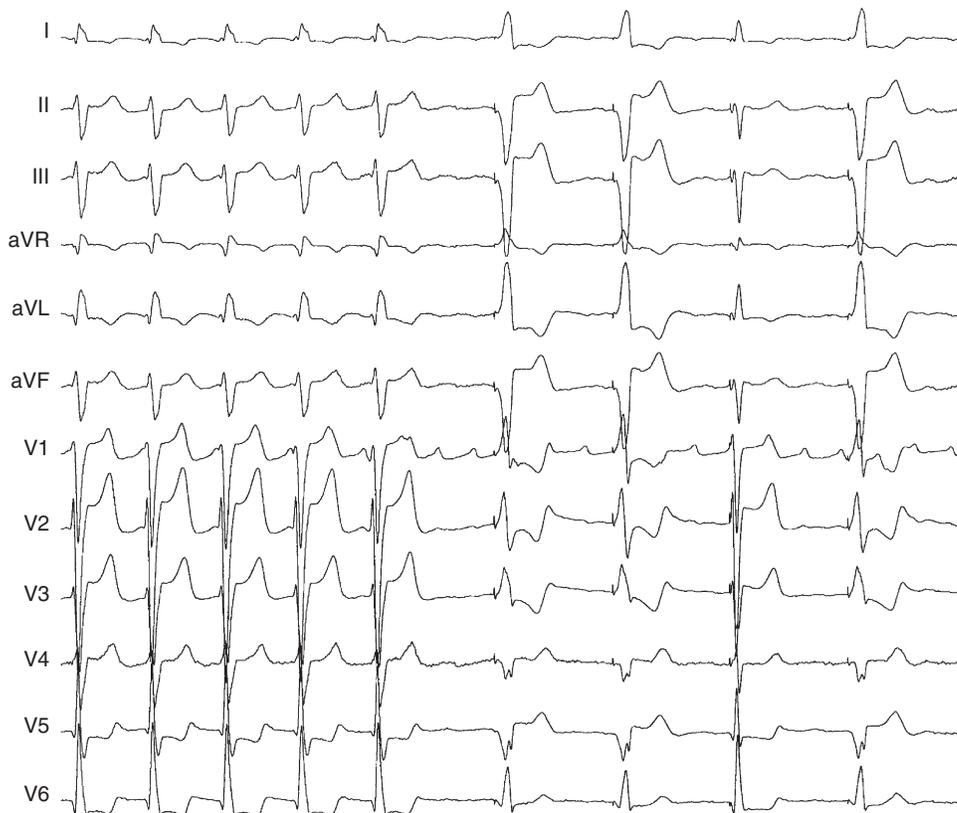

FIGURE 13-3 Surface ECG of left septal macroreentrant atrial tachycardia in a patient with tachycardia-bradycardia syndrome and permanent pacemaker implantation. The P waves are masked by the QRS and T waves during 2:1 atrioventricular (AV) conduction. Administration of adenosine results in AV block and reveals P wave morphology. Note the prominent positive P waves only in lead V₁ and almost flat waves in most of the other leads.

cardiac chamber of tachycardia origin (see Fig. 11-2). However, in the presence of complex intramyocardial conduction disturbances, activation during focal tachycardias can extend over a large proportion of the tachycardia CL, and conduction spread can follow circular patterns suggestive of macroreentrant

activation.⁵ On the other hand, long isoelectric intervals can occur between P waves during MRATs, especially when mapping is limited to only the atrium contralateral to the origin of the macroreentrant circuit or to only parts of the ipsilateral atrium; a focal activation can be observed, incorrectly suggesting a focal mechanism. This is particularly observed for LA MRATs in the presence of large areas of electrical silence. However, a *thorough* intracardiac activation mapping reveals atrial activation spanning the tachycardia CL.

Occasionally, P wave morphology on the surface ECG resembles AFL, but intracardiac recordings show that parts of the atria (commonly the LA) have disorganized atrial activity (Fig. 13-4). Such rhythms behave more like AF than AT, but they may be converted to true typical AFL with antiarrhythmic drugs.

MRAT is usually associated with 2:1 AV conduction, although variable AV conduction and larger multiples are not uncommon. Variable AV block is the result of multilevel block; for example, proximal 2:1 AV block and more distal 3:2 Wenckebach block result in 5:2 AV Wenckebach block. Macroreentrant circuits can have long CLs in the presence of extensive atrial disease and antiarrhythmic agents, in which case fast ventricular response and 1:1 AV conduction may occur.

Diagnostic Maneuvers during Tachycardia

ATRIAL EXTRASTIMULATION

A focal mechanism is defined on the basis of dissociation of almost the entire atria from the tachycardia with AES. In contrast, the MRAT circuit usually incorporates large portions of the RA

TABLE 13-1 Goals of Programmed Stimulation during Macroreentrant Atrial Tachycardia

1. To confirm that the tachycardia is an AT
 - Atrial activation spanning the tachycardia CL
 - Resetting response consistent with reentry
 - Entrainment mapping consistent with reentry
2. To confirm that the AT is a macroreentrant circuit
 - Atrial activation spanning the tachycardia CL
 - Resetting response consistent with reentry
 - Entrainment mapping consistent with reentry
3. To exclude cavotricuspid isthmus-dependent atrial flutter
 - Entrainment mapping at the cavotricuspid isthmus
4. Localization of the circuit in the RA versus LA
 - ECG morphology of the atrial complex
 - Isolated variation of the RA CL
 - RA activation time <50% of the tachycardia CL
 - Entrainment pacing from different RA sites
5. To define the tachycardia circuit
 - Activation mapping
 - Electroanatomical mapping
 - Entrainment mapping
6. To define the critical isthmus in the tachycardia circuit
 - Entrainment mapping

AT = atrial tachycardia; CL = cycle length; LA = left atrium; RA = right atrium.

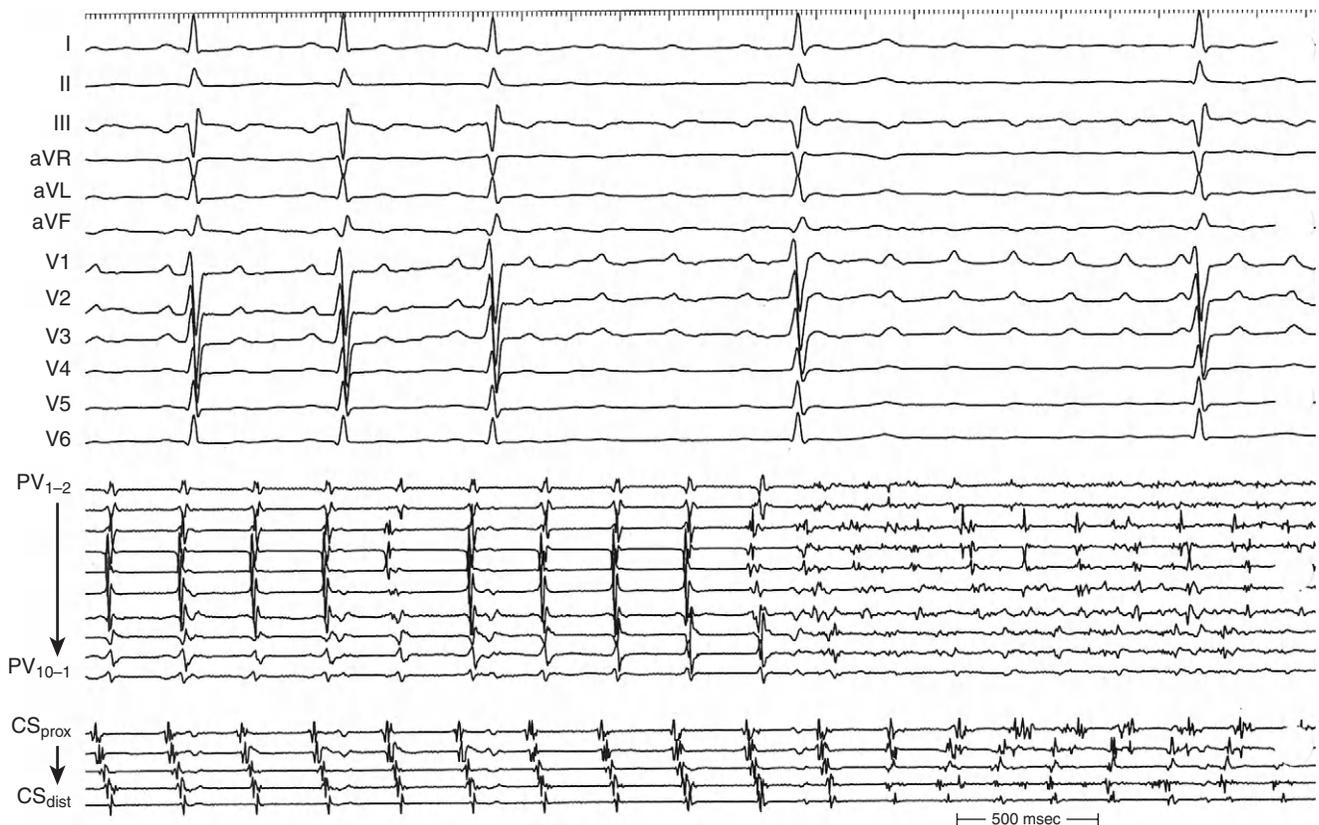

FIGURE 13-4 Surface 12-lead ECG and intracardiac recordings during left atrial tachycardia (AT) that use a small macroreentrant circuit near the ostium of the right superior pulmonary vein (PV) in a patient with prior extensive wide area circumferential PV ablation and linear ablation for atrial fibrillation (AF). On the left, P waves are separated by isoelectric intervals, mimicking focal AT, as a result of extensive scarring in the left atrium. In the middle of the recording, the AT converts spontaneously to AF. Note the intracardiac recordings demonstrate grossly irregular atrial activity during AF as compared with AT; however, on the surface ECG, atrial activity remained relatively organized, and conversion from AT into AF was manifest on the surface ECG by a change in rate and minor changes in morphology of atrial complexes. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

or LA, as demonstrated by resetting. In response to AES, MRATs typically demonstrate an increasing or mixed (flat, then increasing) resetting response. AES usually fails in terminating the AT. AES at short coupling intervals may result in transformation of the tachycardia into a different AT or AF. To minimize the risk to transform or interrupt tachycardia, atrial stimulation maneuvers during the tachycardia should be used sparingly and only when needed to confirm the diagnosis or more precisely localize the critical portion of the AT circuit as guided by the initial activation mapping.¹²

ATRIAL PACING

Burst pacing from the CS or along the Halo catheter is started at a CL 10 to 20 milliseconds shorter than the atrial CL, and then the pacing CL is progressively shortened by 10 to 20 milliseconds. The capture of atrial stimuli and acceleration of the atrial rate to the paced rate should be verified before analyzing the tachycardia response to overdrive pacing. The response of AT to overdrive pacing is evaluated for entrainment, overdrive suppression, transformation into distinct uniform AT morphologies or AF entrainment, and ability and pattern of termination.

Entrainment

Overdrive atrial pacing at long CLs (i.e., 10 to 30 milliseconds shorter than the tachycardia CL) usually can entrain MRAT. The slower the pacing rate and the farther the pacing site from the reentrant circuit, the longer the pacing drive required to penetrate and entrain the tachycardia. Achievement of entrainment of the AT establishes a reentrant mechanism of the tachycardia and excludes triggered activity and abnormal automaticity as potential mechanisms (Fig. 13-5). Entrainment can also be used to estimate qualitatively how far the reentrant circuit is from the pacing site (see later).

ENTRAINMENT CRITERIA. During constant-rate pacing, entrainment of a reentrant tachycardia results in the activation of all myocardial tissue responsible for maintaining the tachycardia at the pacing CL, with resumption of the intrinsic tachycardia morphology and rate after cessation of pacing. However, the mere acceleration of the tachycardia to the pacing rate and the subsequent resumption of the original tachycardia after cessation of pacing do not establish the presence of entrainment. After cessation of each pacing drive, the presence of entrainment should be verified by demonstrating (1) the presence of fixed fusion of the paced complexes at a given pacing CL, (2) progressive fusion at faster pacing CLs, and (3) resumption of the same tachycardia morphology following cessation of pacing with a nonfused complex at a return cycle equal to the pacing CL.

ENTRAINMENT WITH FUSION. During entrainment of MRAT, fusion of the stimulated impulse can be observed on the surface ECG, but it is easier to recognize on intracardiac recordings from the Halo and CS catheters. The stimulated impulse has hybrid morphology between the fully paced atrial impulse and the tachycardia impulse. The ability to demonstrate surface ECG fusion requires a significant mass of atrial myocardium to be depolarized by both the paced stimulus and the tachycardia. The farther the stimulation site from the reentrant circuit, the less likely entrainment will manifest ECG fusion. It is important to understand that overdrive pacing of a tachycardia of any mechanism can result in a certain degree of fusion, especially when the pacing CL is only slightly shorter than the tachycardia CL. Such fusion, however, is unstable during the same pacing drive at the same pacing CL because pacing stimuli fall on a progressively earlier portion of the tachycardia cycle, thus producing progressively less fusion and more fully paced morphology. Such phenomena should be distinguished from entrainment, and sometimes this requires pacing for long intervals to demonstrate variable degrees of fusion. Focal ATs (automatic, triggered activity, or microreentrant) cannot manifest fixed or progressive fusion during overdrive pacing. Moreover, overdrive pacing frequently results in suppression

(automatic) or acceleration (triggered activity) of focal ATs, rather than resumption of the original tachycardia with an unchanged tachycardia CL.

ENTRAINMENT WITH MANIFEST FUSION. Entrainment of MRATs commonly produces manifest fusion that is stable (fixed) during the pacing drive at a given pacing CL. Repeated entrainment at pacing CLs progressively shorter than the tachycardia CL results in different degrees of fusion, with the resultant P wave configuration looking more like a fully paced configuration.

ENTRAINMENT WITH INAPPARENT FUSION. Entrainment with inapparent fusion (also referred to as local or intracardiac fusion) is said to be present when a fully paced P morphology (with no ECG fusion) results, even when the tachycardia impulse exits the reentrant circuit (orthodromic activation of the presystolic electrogram is present). Fusion is limited to a small area and does not produce surface ECG fusion, and only intracardiac (local) fusion can be recognized.

ENTRAINMENT WITH CONCEALED FUSION. Entrainment with concealed fusion (sometimes also referred to as concealed entrainment or exact entrainment) is defined as entrainment with orthodromic capture and a surface ECG complex identical to that of the tachycardia. Entrainment with concealed fusion suggests that the pacing site is within a protected isthmus, either inside or outside but attached to the reentrant circuit (i.e., the pacing site can be in, attached to, or at the entrance to a protected isthmus that forms the diastolic pathway of the circuit).

POST-PACING INTERVAL. The PPI is the interval from the last pacing stimulus that entrained the tachycardia to the next recorded electrogram at the pacing site. The PPI should be measured to the near-field potential that indicates depolarization of tissue at the pacing site. The PPI remains relatively stable when entrainment of MRAT is performed at the same site, regardless of the length of the pacing drive.

Termination

Rapid atrial burst pacing can usually terminate MRAT. However, termination is less likely when the pacing drive is short or the pacing site is distant from the reentrant circuit.

Overdrive Suppression

Overdrive suppression analogous to that seen with automatic AT is not expected in MRAT. As noted, the PPI remains relatively stable when entrainment of MRAT is performed at the same site, regardless of the length of the pacing drive. This is in contrast to overdrive suppression seen in automatic ATs, which would be associated with progressive delay of the first tachycardia beat return cycle with progressively longer overdrive pacing drives.

Transformation

Rapid atrial burst pacing may convert an MRAT into AF, clockwise or counterclockwise typical AFL, or another type of MRAT. Detection of this change requires careful attention to the atrial activation sequence and the ECG pattern after cessation of pacing. The recording of multiple simultaneous electrograms, as continuous endocardial references, facilitates detection of these activation changes.

Mapping

Because the reentrant circuit can involve any of multiple barriers, the usual anatomically guided ablation, as performed for typical CTI-dependent AFL, is not possible. Mapping is required to determine the precise circuit and define its vulnerable segment (critical isthmus) to provide a specifically tailored ablation solution. The goals of mapping of macroreentrant circuits include localization of the tachycardia circuit (RA versus LA), identification of possible lines of block, identification of an isthmus of tissue bounded between two long barriers, and determination of whether the line of block is a critical part of the circuit.

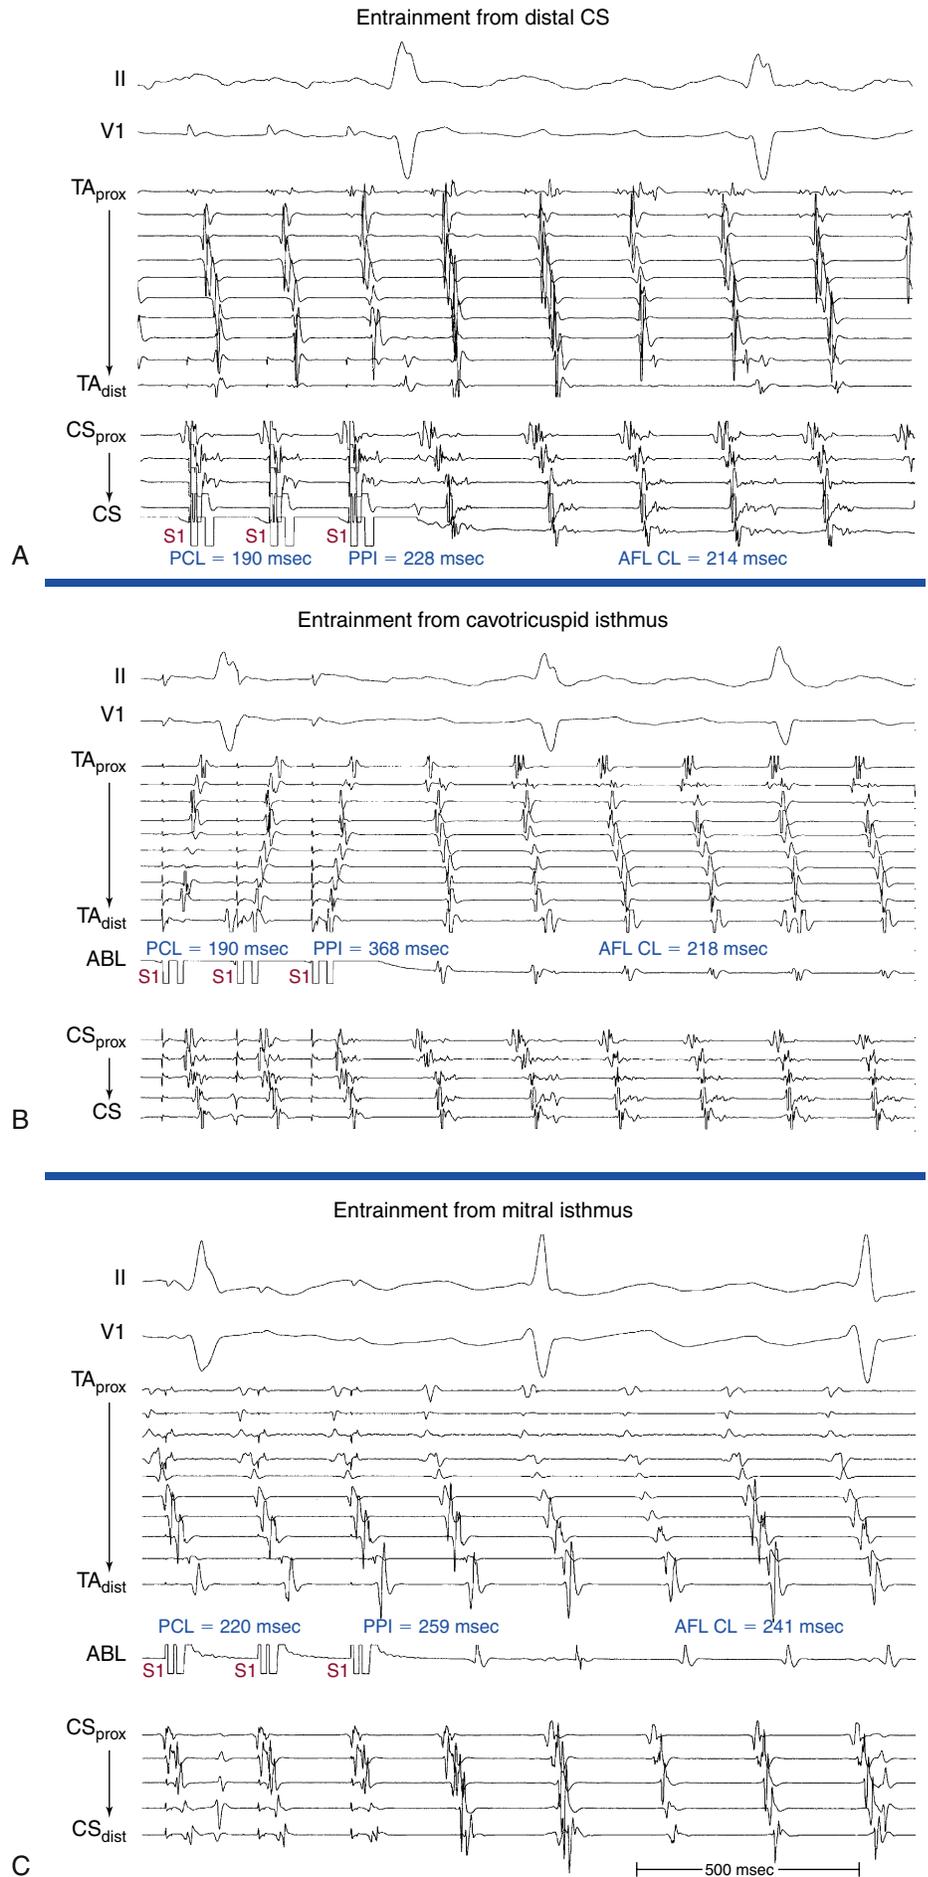

FIGURE 13-5 Entrainment of counterclockwise perimitral macroreentrant atrial tachycardia (AT). **A**, Entrainment from the distal coronary sinus (CS) results in intracardiac atrial fusion (as demonstrated in CS activation sequence) and a short post-pacing interval (PPI) [PPI – AT CL = 14 msec] because the distal CS is close to the reentrant circuit. **B**, Entrainment from the ablation catheter (ABL) positioned at the cavotricuspid isthmus (CTI) results in manifest atrial fusion with a long PPI (PPI – AT CL = 150 msec), suggesting that the CTI is not part of the reentrant circuit. **C**, Entrainment from the ablation catheter positioned at the mitral isthmus, concealed atrial fusion, and a short PPI (PPI – AT CL = 18 msec), suggesting that the mitral isthmus is the critical isthmus of the reentrant circuit. CL = cycle length; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; PCL = pacing CL; TA_{dist} = distal tricuspid annulus; TA_{prox} = proximal tricuspid annulus.

C

Detailed knowledge of the congenital anomaly and the surgical procedure, if present, is important in interpreting the results of mapping, in knowing how to access the RA, in assessing the feasibility of the transeptal puncture, and in determining whether fluoroscopy is helpful in localizing the catheters or whether intracardiac echocardiography or transesophageal echocardiography is needed.

Activation Mapping

The main goal of activation mapping of MRAT is identification of the complete reentrant circuit and its mid-diastolic critical isthmus. Unlike mapping focal AT, whereby tracking the site with the earliest presystolic local activation timing is the goal of mapping, there is no early or late region for MRAT because the wavefront is continuously propagating around the circuit. Activation can be continuously mapped, and an earlier activation time can always be found for any particular point of the circuit. Endocardial recordings often show activation during the isoelectric intervals on the surface ECG. The concept of early activation is not applicable to any particular site in the reentrant circuit. Nevertheless, for illustrative purposes, a particular reference point may be designated as the origin of activation (time 0), but it should be understood that this is always arbitrary.

The complete reentrant circuit can be defined as the spatially shortest route of unidirectional activation encompassing the complete CL of the tachycardia in terms of activation timing and returning to the site of earliest activation. Activation wavefronts that do not fulfill these conditions are bystander wavefronts and are not critical to the arrhythmia circuit. However, incomplete mapping can lead to confusion about the bystander status of a given activation wavefront or loop, and an incomplete loop can be mistaken for a complete one. High-density mapping or entrainment mapping can clarify this situation by documenting wavefront collision or a long PPI, respectively (see later). If activation recorded at different atrial locations does not cover most of the tachycardia CL, two possibilities must be considered: focal AT and small, localized reentrant circuits, which require much more detailed activation mapping to be identified.

Sometimes, it can be impossible to map the entire circuit, especially in patients with repaired congenital heart disease, because of the complex suture lines, baffles, or both. Entrainment then becomes an essential tool in these cases to confirm participation of specific areas in the circuit and to try to locate a suitable isthmus area (see later).

Identification of the tachycardia circuit barriers is very important to help understand propagation of the reentrant activation wavefront in relation to these barriers, identify the tachycardia critical isthmus, and, equally important, plan an ablation strategy to abolish the tachycardia. For RA MRAT, the tricuspid annulus often provides one important barrier. Other naturally fixed barriers (i.e., independent of the precise form of activation and present also in NSR) include the IVC, SVC, and CS os. For LA MRAT, the mitral annulus and PVs often provide important barriers. Acquired barriers include surgical incisions or patches and electrically silent regions devoid of electrical activity (of uncertain origin). A line of block can be identified by the presence of double potentials, thus reflecting conduction up one side of the barrier and down the other side, with the bipolar electrogram recording both waves of activation. Significant large areas devoid of electrical activity can be easily recognized as electrical scars, provided that catheter contact is verified. Narrow lines of block can easily be missed unless the conduction delay across them is maximized by the appropriate choice of pacing sites and CLs. Therefore, to avoid overlooking any such scar, it may be necessary to perform mapping during more than one form of activation (e.g., during both proximal CS and low lateral RA pacing).

During macroreentry, an isthmus is defined as a corridor of conductive myocardial tissue bounded by nonconductive tissue (barriers) through which the depolarization wavefront must propagate to perpetuate the tachycardia. These barriers can be scar areas or naturally occurring anatomical or functional (present only during

tachycardia, but not in sinus rhythm) obstacles. The earliest presystolic electrogram closest to mid-diastole is the most commonly used definition for the center of the isthmus of the reentrant circuit.

It is very important to ensure that the correct AT is being mapped at all points of time, and to remain vigilant to identify any change in CL or activation sequence that can result from catheter manipulation, pacing maneuvers, or ablation. Such changes can indicate transition to another tachycardia requiring reassessment. The transition may be obvious, but it is often quite subtle and sometimes imperceptible if only the CS activation is analyzed. Simultaneous recording RA activation (using a Halo catheter around the tricuspid annulus) and CS activation (using a decapolar catheter) can help rapid identification of tachycardia transformation.⁷

Variations in the tachycardia CL during MRAT can suggest variations in activation pathways resulting from circuit transformation or simply changes in conduction time; the latter is usually manifest as CL alternans. The absence of ECG alterations accompanying changes in activation sequences can occur because of an insufficient change in electromotive force, either because of distance from the recording electrodes or because of insufficient electrically active tissue. At all points of time, it is necessary to ensure that the change of activation sequence is not secondary to unintentional movement of the recording catheters. A single-loop tachycardia with a fixed barrier as its core typically remains stable and unchanged during catheter manipulation, and it may even be difficult to pace-terminate, although mechanical bump termination rendering the tachycardia noninducible suggests mechanical stimulation close to a restricted and relatively fragile isthmus.

A change in ECG morphology without a change in the tachycardia CL can occur secondary to transformation of a multiple loop tachycardia by interruption of one loop, a change in bystander activation sufficient to be visible on the surface ECG (typified by the change in CS and LA activation observed during incomplete ablation of the CTI in counterclockwise typical AFL), a change from tachycardia in one atrium to that in the other (Fig. 13-6), or activation of the same circuit in the opposite direction (the last possible only if the first AT stops at least transiently).

In addition to analyzing the RA and LA activation sequences during the tachycardia as recorded by the peritricuspid Halo catheter and CS catheter, activation mapping is started in the RA by using a roving catheter. Local activation time at each site is measured relative to a reference intracardiac electrogram (e.g., middle CS). Placing the intracardiac reference channel adjacent to the mapping catheter channel on the display allows the operator immediately to know which parts (early, middle, or late) of the cycle are being mapped by visual inspection and sequential electronic caliper measured delay. When activation from 10 evenly distributed sites in the RA (including 3 or 4 points at the tricuspid annulus) occupies less than 50% of the tachycardia CL, the arrhythmia is probably not located in the RA. The only exception is the presence of a small reentrant circuit in the RA.

During LA MRATs, in the absence of LA mapping through transeptal catheterization, long segments of the tachycardia CL may not be covered by recorded electrograms. RA mapping typically shows nonreentrant activation patterns, clearly different from typical clockwise and counterclockwise AFL. Early RA septal activation relative to other parts of the RA can suggest a focal septal origin in some cases when LA recordings are not obtained (Fig. 13-7; see Fig. 13-2). Local RA conduction disturbances, such as CTI block (from prior isthmus ablation), transverse block at the crista terminalis, or both, can result in activation of the anterior and septal RA in opposite directions that mimics reentrant RA activation of typical AFL. In these cases, entrainment mapping clarifies the location of the reentrant circuit.¹³

The CS activation sequence has frequently been suggested as a useful way to determine the chamber of interest; however, this is not without limitations. Whereas in RA MRAT the CS is frequently activated from proximal to distal, this is not always true, particularly with MRAT localized to the superior RA. Similarly, although most circuits with distal to proximal activation of the CS are caused by

FIGURE 13-6 A change in atrial activation sequence is observed during right atrial ablation during macroreentrant atrial tachycardia that interrupts one circuit while another (left atrial) circuit persists (note coronary sinus [CS] activation from distal to proximal throughout [arrows]). Abl_{dist} = distal ablation site; Abl_{prox} = proximal ablation site; CS_{dist} = distal coronary sinus; CS_{mid} = middle coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{prox} = proximal His bundle; TA_{dist} = distal tricuspid annulus; TA_{prox} = proximal tricuspid annulus.

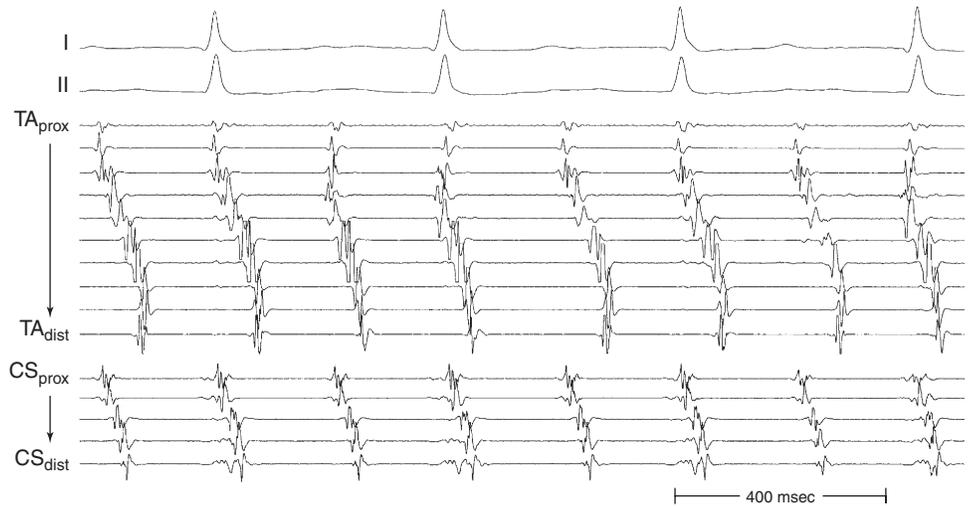

FIGURE 13-7 Surface ECG leads I and II and intracardiac recording during left atrial (LA) macroentry. Note the large spontaneous variations in the right atrial cycle length (CL) and activation sequence (as recorded by a Halo catheter around the tricuspid annulus, TA), with a constant LA CL and activation sequence (as recorded by the coronary sinus [CS] catheter). CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; TA_{dist} = distal tricuspid annulus; TA_{prox} = proximal tricuspid annulus.

LA MRAT, this sequence may also be seen in some cases of RA MRAT (see Fig. 13-2), and some LA MRATs (e.g., counterclockwise perimitral MRAT) can activate the CS proximally to distally.

For LA macroentry, identification of the complete reentrant circuit can be challenging. The initial step is activation mapping to determine whether activation of the entire tachycardia CL can be recorded within the LA. In particular, mapping should be carefully carried out around the mitral annulus because this maneuver is easy to perform and identifies a common form of LA MRAT, perimitral MRAT.

Entrainment Mapping

Entrainment mapping provides information about sites of the RA or LA that are part of the reentrant circuit, those that are outside the circuit, and the critical isthmus in the macroreentrant circuit. Entrainment also qualitatively estimates how far the reentrant circuit is from the pacing site. However, before attempting to use entrainment methods for mapping, it is necessary first to demonstrate that the tachycardia can, in fact, be entrained, thus providing strong evidence that it is

caused by reentry rather than by triggered activity or automaticity. At sites of entrainment, there should be confirmation of consistent capture of the atrium at the pacing CL for several beats, with minimal or no change in the surface morphology or intracardiac electrograms, and continuation of the identical tachycardia after pacing. Evaluation of the PPI or other criteria can be very misleading when the presence of true entrainment has not been established. Additionally, it is important to verify the absence of termination and reinitiation of the tachycardia during the same pacing drive.¹⁴

Pacing is performed from the CTI, high RA, midlateral RA, and proximal and distal CS, but not on the septum, to avoid the possibility of capturing the LA, which could be confusing in distinguishing RA from LA MRATs.

Once the presence of entrainment is verified, several criteria can be used to indicate the relation of the pacing site to the reentrant circuit. The first entrainment criterion to be sought is concealed fusion. Entrainment with concealed fusion indicates that the pacing site is in a protected isthmus located within or attached to the reentrant circuit.^{15,16}

Whether this protected isthmus is crucial to the reentrant circuit or just a bystander site needs to be verified by other criteria, mainly comparing the PPI with the tachycardia CL and the stimulus-exit interval with the electrogram-exit interval. During entrainment from sites within the reentrant circuit, the orthodromic wavefront from the last stimulus propagates through the reentry circuit and returns to the pacing site, following the same path as the circulating reentry wavefronts. The conduction time required is the revolution time through the circuit. Thus, the PPI (measured from the pacing site recording) should be equal (within 20 milliseconds) to the tachycardia CL, given that conduction velocities and the reentrant path did not change during pacing. At sites remote from the circuit, the stimulated wavefronts propagate to the circuit, then through the circuit, and finally back to the pacing site. Thus, the PPI should equal the tachycardia CL plus the time required for the stimulus to propagate from the pacing site to the tachycardia circuit and back. The greater the difference is between the PPI and the tachycardia CL (PPI – AT CL), the longer the conduction time is between the pacing site and reentry circuit, and the greater the physical distance is between the pacing site and circuit. Features of entrainment when pacing from different sites are listed in Table 13-2.^{15,16}

During entrainment of MRAT, the interval between the pacing stimulus and the onset of the P wave on the surface ECG reflects conduction time from the pacing site to the exit of the reentrant circuit (stimulus-exit interval), regardless of whether the pacing site is inside or outside the reentrant circuit, because activation starts at the pacing site and propagates in sequence to the circuit exit site. On the other hand, during tachycardia, the interval between the local electrogram at a given site and circuit exit (electrogram-exit interval) can reflect the true conduction time between those two sites if they are activated in sequence (which occurs when that particular site is located within the reentrant pathway), or can be shorter than the true conduction time if those two sites are activated in parallel (which occurs when that particular site is located outside the reentrant circuit). Because of frequent difficulty of determination of the onset of the P wave on the surface ECG, a reference intracardiac electrogram representing the exit of the circuit is usually used. Therefore, at any given pacing site, an electrogram-exit interval that is equal (± 20 milliseconds) to the stimulus-exit interval indicates that the pacing site lies within the reentry circuit and excludes the possibility that the site is a dead-end pathway attached to the circuit (i.e., not a bystander). On the other hand, pacing sites outside the reentrant circuit have an electrogram-exit interval significantly (more than 20 milliseconds) shorter than the stimulus-exit interval (see Table 13-2).

LIMITATION OF ENTRAINMENT MAPPING

Entrainment techniques can be difficult in patients with incisional AT caused by low-amplitude or absent atrial potentials

in the area of surgical incisions. Fusion is difficult to assess on the surface ECG because the pacing artifact and QRS complex frequently obscure the surface P waves, which often have low amplitude in these patients. Furthermore, methodological problems can affect the validity of the PPI. Decremental conduction during pacing increases the PPI and causes false-negative assessment results at some reentry circuit sites. The occasional presence of far-field potentials can also impair the accuracy of entrainment mapping. Additionally, it is difficult to identify exact catheter positions in relation to anatomical barriers because visualization of these barriers is not possible fluoroscopically. Spontaneous changes in the tachycardia CL in some MRATs can also make interpretation of the PPI impossible. Combining entrainment mapping with electroanatomical mapping can reduce the difficulties created by some of these limitations. Finally, reconstruction of the complete circuit can be extremely difficult to achieve, and the risk of transformation of the clinical tachycardia to another morphology or to AF is high. Therefore, it is advisable to begin with electroanatomical mapping, while pacing maneuvers are used sparingly, just to confirm the participation of precise areas in the reentry circuit and to improve understanding of the tachycardia further.

Electroanatomical Mapping

Electromagnetic three-dimensional (3-D) mapping (CARTO mapping system [Biosense Webster, Inc., Diamond Bar, Calif.] or EnSite NavX system [St. Jude Medical, St. Paul, Minn.]) can help distinguish between a focal origin and macroreentrant tachycardia by providing precise description of the macroreentrant circuit and sequence of atrial activation during the tachycardia and rapid visualization of the activation wavefront (see Videos 12 and 17). This can contribute to the understanding of the reentrant circuit in relation to native barriers and surgical scars, identification of all slow-conducting pathways and appropriate sites for entrainment mapping, planning of ablation lines, navigation of the ablation catheter, and verification of conduction block produced by RF ablation.

TABLE 13-2 Entrainment Mapping of Macroreentrant Atrial Tachycardia

Pacing from sites *outside* the AT circuit results in manifest entrainment:

1. Manifest atrial fusion on surface ECG and intracardiac recordings (fixed fusion at a single pacing CL and progressive fusion on progressively shorter pacing CLs). Any change in atrial activation sequence, compared with baseline tachycardia and that of pure pacing, as determined by analysis of all available surface and intracardiac ECG recordings, is considered to represent manifest fusion.
2. PPI – AT CL > 20 msec
3. The interval between the stimulus artifact and the onset of the P wave on the surface ECG is longer than the interval between the local electrogram on the pacing site and the onset of the P wave on the surface ECG.

Pacing from sites *inside* the AT circuit results in manifest entrainment:

1. Manifest atrial fusion on the surface ECG and intracardiac recordings (fixed fusion at a single pacing CL and progressive fusion on progressively shorter pacing CLs)
2. PPI – AT CL < 20 msec
3. The interval between the stimulus artifact and the onset of the P wave on the surface ECG equals the interval between the local electrogram on the pacing site and the onset of the P wave on the surface ECG.

Pacing from a *protected isthmus* inside the circuit results in concealed entrainment:

1. Concealed atrial fusion (i.e., paced atrial waveform on the surface ECG and intracardiac recordings is identical to the tachycardia waveform)
2. PPI – AT CL < 20 msec
3. The interval between the stimulus artifact and the onset the P wave on the surface ECG equals the interval between the local electrogram on the pacing site and the onset of the P wave on the surface ECG.

AT = atrial tachycardia; CL = cycle length; PPI = post-pacing interval.

MAPPING TECHNIQUE

Initially, selection of the reference electrogram, positioning of the anatomical reference, and determination of the window of interest are undertaken. The reference catheter is usually placed in the CS (because of its stability), by using a recording with a prominent atrial electrogram and ensuring that the ventricular electrogram is not the one detected by the system. The onset of the window of interest is usually set at the mid-diastole between two consecutive P waves with a window duration spanning 95% of the tachycardia CL. Anatomical and EP landmarks (IVC, SVC, CS, His bundle, and tricuspid annulus for RA mapping, and mitral annulus and PVs for LA mapping) are marked.

Activation mapping is performed to define the atrial activation sequence. Reasonable numbers of points homogeneously distributed in the RA or LA, or both, must be recorded (80 to 100). Each point is tagged on the 3-D map as follows: The local activation time at each site is determined from the intracardiac bipolar electrogram and is measured in relation to the fixed intracardiac electrogram obtained from the CS (reference) catheter. Points are added to the map only if stability criteria in space and local activation time are met. The end-diastolic location stability criterion is a variation of less than 2 mm, and the local activation time stability criterion is less than 2 milliseconds. Lines of block (manifest as double potentials) are tagged for easy identification because they can serve as boundaries for a subsequent design of ablation strategies. Silent areas are defined as having an atrial potential amplitude lower than 0.05 mV and the absence of atrial capture at 20 mA. Such areas and surgically related scars, such as atriotomy scars in the lateral RA or atrial septal defect closure patches, are tagged as "scar" (see Figs. 14-1 and 14-2). At sites with double potential, entrainment of the tachycardia can help evaluate which potentials are captured by the pacing stimulus. Local activation times are then reviewed, and the apparent far-field signal is excluded from the activation maps. The activation map can also be used to catalog sites at which pacing maneuvers are performed during assessment of the tachycardia.

ACTIVATION MAP

A continuous progression of colors (from red to purple in the CARTO system and from white to purple in the NavX system) around the RA (or LA), with close proximity of earliest and latest local activation, suggests the presence of an RA (or LA) macroreentrant tachycardia. In these cases, RA (or LA) activation time is in a similar range as the tachycardia CL (Fig. 13-8). Conversely, the electroanatomical maps of focal ATs demonstrate radial spreading of activation, from the earliest local activation site in all directions. In these cases, atrial activation time is markedly shorter than the tachycardia CL. When the onset of the window of interest is set at the mid-diastole between two consecutive P waves, the mid-diastolic isthmus of the reentrant circuit can be

identified by the interface of early and late activation (i.e., the region where "early meets late" on the color-coded activation map). High-density mapping is then performed in and around the isthmus to define its limits and width precisely. It is important to recognize that if an insufficient number of points is obtained in the isthmus region, it may be falsely concluded through the interpolation of activation times that the wavefront propagates from a focal source (Fig. 13-9).⁹

VOLTAGE MAP

Voltage mapping is performed to define areas of electrical scars, which can be involved in the reentrant circuit and/or can potentially serve as boundaries for the subsequent design of ablation strategies. Silent areas are defined as having an atrial potential amplitude of less than 0.05 mV and the absence of atrial capture at 20 mA.

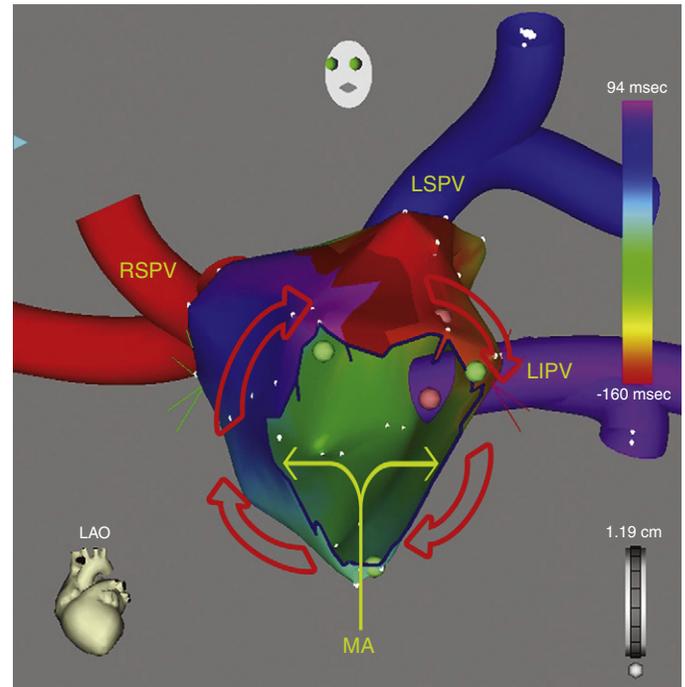

FIGURE 13-8 Three-dimensional electroanatomical (CARTO, Biosense Webster, Inc., Diamond Bar, Calif.) activation map of the left atrium in the left anterior oblique (LAO) view constructed during clockwise perimitral macroreentrant atrial tachycardia. During tachycardia, the activation wavefront travels clockwise around the mitral annulus (MA), as indicated by a continuous progression of colors (from red to purple) with close proximity of earliest and latest local activation (red meeting purple). LIPV = left inferior pulmonary vein; LSPV = left superior pulmonary vein; RSPV = right superior pulmonary vein.

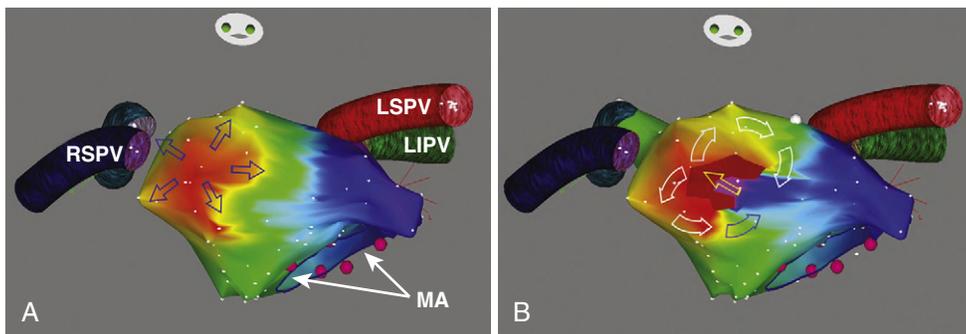

FIGURE 13-9 Left atrial electroanatomical (CARTO, Biosense Webster, Inc., Diamond Bar, Calif.) activation map in a patient with atrial tachycardia following pulmonary vein (PV) isolation for treatment of atrial fibrillation. The view is from the aspect of the right shoulder. **A**, The activation pattern suggests a focal process in the left atrium roof close with centrifugal spread of activation from the central red area. **B**, With additional detailed mapping below the red area, a small figure-of-8 macroreentrant circuit is evident. Entrainment data had already diagnosed macroreentry, but the relatively detailed activation map had missed the small area that became clear on more detailed mapping. LIPV = left inferior pulmonary vein; LSPV = left superior pulmonary vein; MA = mitral annulus; RSPV = right superior pulmonary vein.

PROPAGATION MAP

Propagation of electrical activation can be superimposed on the 3-D anatomical reconstruction of the RA or LA, thereby allowing visualization of the reentrant circuit of AT in relation to the anatomical and EP landmarks and barriers. Analysis of the propagation map may allow estimation of the conduction velocity along the reentrant circuit and identification of areas of slow conduction and may thus help locate appropriate sites for entrainment mapping and catheter ablation.

LIMITATION OF THE USE OF ELECTROANATOMICAL MAPPING

Variation of the tachycardia CL by more than 10% may prevent complete understanding of the circuit and decreases the confidence in the electroanatomical map. Similarly, electroanatomical mapping can be difficult or even impossible in patients with nonsustained AT. In these cases, 3-D mapping systems based on a single-beat analysis, such as the multielectrode basket catheter or the noncontact mapping system, may be an alternative to electroanatomical mapping technology. For unstable tachycardia with changes in morphology or CL, amiodarone infusion can help stabilize the arrhythmia.

Electroanatomical Mapping of Post-Pacing Intervals

A graphical representation of entrainment mapping can be constructed by plotting the values of the [PPI – AT CL] differences on an electroanatomical mapping system (CARTO or NavX) to generate color-coded 3-D entrainment maps (see Fig. 13-1). This approach can potentially help accurately determine and visualize the 3-D location of the entire reentrant circuit, even though the area of slow conduction of the tachycardia is not described. Because neither of the electroanatomical mapping systems (CARTO, NavX) contains an algorithm for color-coding of entrainment information, the modus for activation mapping is altered manually. At each 3-D location of the catheter tip stored on the electroanatomical mapping system, entrainment stimulation is performed, and the difference between PPI and tachycardia CL (PPI – AT CL) is calculated and entered into the electroanatomical mapping system (as if it would be an “activation time”). For that, the local electrogram stored at the 3-D location is completely disregarded. The annotation marker is manually moved into a position where the numerical timing information equaled the entrainment information (PPI – tachycardia CL). That timing information then is displayed in a color-coded fashion as if it were activation time, but, in fact, it represents information on the length of the entrainment return cycle (see Fig. 13-1). With the color range, red (in CARTO) or white (in NavX) represents points closest to the reentrant circuit (i.e., sites with smaller [PPI – AT CL] differences, approaching 0, signifying their inclusion in the reentrant circuit), and purple represents points far away from the circuit (i.e., sites with the largest [PPI – AT CL] differences).^{14,17}

Color-coded 3-D entrainment mapping allows determination of the full active reentrant circuit (versus passively activated regions of the chamber) and the obstacle around which the tachycardia is circulating, and it provides very useful information on the location of potential ablation sites. However, not all these sites terminate reentry; the final choice is determined by location of anatomical barriers and width of putative isthmuses, so that strategic ablation lines, mainly connecting to anatomical barriers, can be applied to transect the circuit and eliminate the arrhythmia.^{14,17}

Noncontact Mapping

When AT is short-lived or cannot be reproducibly initiated, simultaneous multisite data acquisition using the noncontact mapping system (EnSite 3000, St. Jude Medical, Inc., St. Paul, Minn.) can help localize the AT origin. This system can recreate the endocardial

activation sequence from simultaneously acquired multiple data points over a few tachycardia beats without requiring sequential point-to-point acquisitions.

The EnSite 3000 system requires a 9 Fr multielectrode array and a 7 Fr mapping-ablation catheter. To create a map, the balloon catheter is positioned over a 0.035-inch guidewire under fluoroscopic guidance in the cardiac chamber of interest. The balloon is then deployed, and it can be filled with a mixture of contrast and saline to be visualized fluoroscopically. The balloon is positioned in the center of the atrium and does not come into physical contact with the atrial walls being mapped. The position of the array in the chamber must be secured to avoid significant movement that would invalidate the electrical and anatomical information. The array must be positioned as closely as possible (and in direct line of sight through the blood pool) to the endocardial surface being mapped, because the accuracy of the map is sensitive to the distance between the center of the balloon and the endocardium being mapped.¹⁸

Systemic anticoagulation is critical to avoid thromboembolic complications. Intravenous heparin is usually given to maintain the activated clotting time at 250 to 300 seconds and 300 to 350 seconds for right-sided and left-sided mapping, respectively.

A conventional deflectable mapping-ablation catheter is also positioned in the chamber and used to collect geometry information. The mapping catheter is initially moved to known anatomical locations (IVC, SVC, CS, His bundle, and tricuspid annulus for RA mapping and mitral annulus and PVs for LA mapping), which are tagged. Subsequently, detailed geometry of the chamber is reconstructed by moving the mapping catheter around the atrium. Using this information, the computer creates a model, called a convex hull, of the chamber during diastole.

Once chamber geometry has been delineated, tachycardia is induced, and mapping can begin. The data acquisition process is performed automatically by the system, and all data for the entire chamber are acquired simultaneously. The system then reconstructs more than 3000 unipolar electrograms simultaneously and superimposes them onto the virtual endocardium, to produce color-coded isopotential maps that graphically depict depolarized regions. Activation can be tracked on the isopotential map throughout the tachycardia cycle, and wavefront propagation can be displayed as a user-controlled 3-D “movie.” The color range represents voltage or timing of onset. A default high-pass filter setting of 2 Hz is used to preserve components of slow conduction on the isopotential map. When conduction through gaps in a line of block is very slow, the high-pass filter may be set at 1.0 to 0.5 Hz. Color settings are adjusted so that the color range matches 1 to 1 with the millivolt range of the electrogram deflection of interest. Isochronal maps can also be created that represent progression of activation throughout the chamber relative to user-defined electrical reference timing point. If the atrial electrograms overlap with the T wave, a ventricular extrastimulus may be delivered to accelerate ventricular depolarization and repolarization and reveal the following atrial complex without far-field interference.¹⁹

In addition, the system can simultaneously display as many as 32 electrograms as waveforms. Unipolar or bipolar electrograms (virtual electrograms) can be selected (at any given interval of the tachycardia cycle) by using the mouse from any part of the created geometry and displayed as waveforms as if from point, array, or plaque electrodes. The reconstructed electrograms are subject to the same electrical principles as contact catheter electrograms because they contain far-field electrical information from the surrounding endocardium, as well as the underlying myocardial signal vector, and distance from the point where the signal is generated to the array can affect the contribution to the electrogram. The maps are particularly useful for identifying slowly conducting pathways, such as the critical slow pathways and rapid breakthrough points of MRAT. The reentry circuit can be fully identified, along with other aspects such as the slowing, narrowing, and splitting of activation wavefronts in the isthmus. The locator technology used to collect the geometry information for the convex hull can then

be used to guide an ablation catheter to the proper location in the heart. Ablation lesions can be tagged, thus facilitating performing linear ablation devoid of gaps across the tachycardia critical isthmus.¹⁹

Substrate mapping based on scar or diseased tissue, which has been introduced into noncontact mapping technology, can be of value in mapping and ablation of MRAT. Dynamic substrate mapping allows the creation of voltage maps from a single cardiac cycle and can identify low-voltage areas, as well as fixed and functional block, on the virtual endocardium through noncontact methodology. High-density voltage mapping of the atrial substrate is performed using the peak negative voltage of the reconstructed unipolar electrograms. An atrial substrate characterized by an abnormally low peak negative voltage (less than 30% of the maximal peak negative voltage) can potentially predict the slow conduction path within the protected isthmus of the MRAT. When combined with the activation sequence, substrate mapping provides essential information for guiding ablation, even when the arrhythmia is nonsustained.²⁰

LIMITATIONS OF NONCONTACT MAPPING

Very low-amplitude signals may not be detected, particularly if the distance between the center of the balloon catheter and the endocardial surface exceeds 40 mm or regions near its poles, thus limiting the accurate identification of diastolic signals. In addition, the acquired geometry with the current version of software is somewhat distorted, and multiple set points are required to establish the origin and shape of complicated structures clearly, such as the LA appendage or PVs. Otherwise, these structures may be lost in the interpolation among several neighboring points. A second catheter is still required for more detailed mapping to find the precise site to ablate, and sometimes it is difficult to manipulate an ablation catheter around the outside of the balloon, especially during mapping in the LA. Moreover, aggressive anticoagulation is required when using this system, and special attention and care are necessary during placement of the large balloon electrode in a nondilated atrium.

Practical Approach to Mapping Macroreentrant Atrial Tachycardia

EXCLUSION OF CAVOTRICUSPID ISTHMUS DEPENDENCE

Because CTI-dependent typical AFL is the most common MRAT, exclusion of the CTI as part of the reentrant circuit is an important initial step, even when the ECG pattern is not classically typical counterclockwise or clockwise AFL. In fact, typical AFL frequently manifests with an atypical 12-lead ECG appearance (so-called pseudoatypical flutter) in the setting of markedly abnormal atrial substrate. CTI-dependent AFL can be rapidly diagnosed or excluded by mapping of the tricuspid annulus and by entrainment maneuvers at the CTI. Exclusion of the CTI as part of the reentrant circuit can be established by any of the following: (1) demonstration of bidirectional activation of the CTI during AT, with resulting collision or fusion within the isthmus by activation from opposing directions (the low lateral RA and CS; see Fig. 13-2); (2) recording of double potentials separated by an isoelectric and constant interval throughout the full extent of the CTI during tachycardia; or (3) entrainment mapping from the CTI that demonstrates manifest atrial fusion with a long PPI (see Fig. 13-5).⁷

LOCALIZATION OF THE REENTRANT CIRCUIT CHAMBER (RIGHT ATRIUM VERSUS LEFT ATRIUM)

PATIENT HISTORY. A history of prior surgery or ablation within a particular atrial chamber should focus the intensity of the search for the arrhythmia substrate in that chamber. Such macroreentrant arrhythmias can occur in isolation or involve anatomical

structures to create dual- or multiple-loop or circuit reentry. In the setting of previous cardiac surgery, a right-sided location of the arrhythmia is more likely and is often seen years later in patients who had a right lateral atriotomy and who underwent surgical closure of an atrial or ventricular septal defect or valve repair. These arrhythmias can also be seen after more complex surgical correction of congenital heart disease, such as the Mustard or Senning correction of transposition of the great vessels, and also after tricuspid valve surgery. LA macroreentry is more likely in the presence of left heart disease, such as hypertrophic cardiomyopathy or mitral valve disease, and following catheter or surgical ablation of AF. In these patients, spontaneous conduction abnormalities and areas of electrical silence forming the substrate for arrhythmia have been observed.

ELECTROCARDIOGRAPHIC FINDINGS. Lead V₁ is the most useful lead for distinguishing LA from RA origin, but much overlap exists. In the absence of previous cardiac surgery or catheter ablation (particularly involving linear lesions in the LA), P waves that are completely negative or have an initial isoelectric (or inverted) component followed by an upright component in lead V₁ is more frequently associated with RA free wall circuits. Conversely, in the absence of counterclockwise typical AFL, broad-based upright (or biphasic positive-negative) P waves in lead V₁ are more frequently associated with LA circuits. LA circuits have also been reported to generate low-amplitude P waves frequently, with some of them having visible waves only in lead V₁.⁵

TACHYCARDIA CYCLE LENGTH VARIATIONS. Large spontaneous variations (30 to 125 milliseconds) or even 2:1 conduction in the RA CL with concomitant variations of less than 20 milliseconds in CS recordings suggest an LA origin of the macroreentrant circuit (see Fig. 13-7).

ACTIVATION MAPPING. As noted, when activation timing from 10 roughly evenly distributed sites in the RA, including 3 or 4 points at the tricuspid annulus, spans less than 50% of the tachycardia CL (in the absence of extensive RA scarring or prior CTI ablation), the arrhythmia is probably not located in the RA. In the setting of LA MRATs, RA mapping typically shows a nonreentrant activation pattern with early RA septal activation relative to other parts of the RA when LA recordings are not obtained (see Figs. 13-2 and 13-7). CS activation usually propagates in a proximal-to-distal direction in the setting of RA MRATs and in a distal-to-proximal direction in the setting of LA MRATs. However, this is not always true; MRATs localized to the superior RA can result in distal-to-proximal CS activation, and some LA MRATs (e.g., counterclockwise perimitral MRAT) can activate the CS in a proximal-to-distal direction (see Fig. 13-2).¹³

ENTRAINMENT MAPPING. If macroreentry has been demonstrated, a difference between the PPI and tachycardia CL of more than 40 milliseconds at three or more different points in the RA (including the CTI and RA free wall, but excluding the septum and CS) denotes an LA circuit (see Fig. 5-20).

IDENTIFICATION OF BARRIERS AND POTENTIAL LINES OF BLOCK

Identification of the tachycardia circuit barriers is very important to help understand propagation of the reentrant activation wavefront in relation to these barriers, to identify the tachycardia critical isthmus, and to plan an ablation strategy to abolish the tachycardia. For RA macroreentry, the tricuspid annulus often provides one important barrier. Other naturally fixed barriers include the IVC, SVC, and CS os. For LA macroreentry, the mitral annulus and PVs often provide important barriers. Acquired barriers include surgical incisions or patches, surgical or catheter ablation lines, and atrial regions devoid of electrical activity (electrical scars). A line of block can be identified by the presence of double potentials, thus reflecting conduction up one side of the barrier and down the other side, with the bipolar electrogram recording both waves of activation. The use of an electroanatomical mapping system (CARTO or NavX) can facilitate tagging these anatomical and EP

landmarks and understanding potential circuit routes, as well as performing voltage mapping to define areas of electrical scars.

IDENTIFICATION OF THE COMPLETE REENTRANT CIRCUIT

CH
13

Activation mapping is performed to define the atrial activation sequence. Reasonable numbers of points homogeneously distributed in the atrium of origin of the tachycardia must be recorded. Use of an electroanatomical mapping system (CARTO or NavX) can facilitate tagging each point on the 3-D map. The complete reentrant circuit is the spatially shortest route of unidirectional activation encompassing the complete CL of the tachycardia in terms of activation timing and returning to the site of earliest activation. Using electroanatomical mapping, this translates into continuous progression of colors (from red to purple in the CARTO system and from white to purple in the NavX system) around the atrium, with close proximity of earliest and latest local activation. Additionally, propagation of electrical activation superimposed on the 3-D anatomical reconstruction of the atrium can be visualized as a propagation map in relation to the anatomical and EP landmarks and barriers. For LA MRAT, activation mapping should be carefully carried out around the mitral annulus because this maneuver is easy to perform and identifies a common form of LA macroreentry, perimitral MRAT. If activation recorded at different atrial locations does not cover most of the tachycardia CL, two possibilities must be considered: focal AT and small, localized reentrant circuits (i.e., electrical activity accounting for more than 85% of the tachycardia CL is present within an area with a diameter of 3 cm or less). Identification of small circuits requires much more detailed activation mapping (see Fig. 13-9).

Additionally, entrainment mapping can be used to indicate the relation of pacing sites to the reentrant circuit, and it qualitatively estimates how far the reentrant circuit is from the pacing site. For RA MRAT, a [PPI – AT CL] difference of less than 50 milliseconds at the proximal CS distinguishes typical AFL from a lateral RA MRAT. With LA MRAT, a [PPI – AT CL] difference of less than 50 milliseconds at the proximal and distal CS distinguished perimitral MRAT from macroreentrant circuits involving the right PVs and septum.¹⁵ When entrainment does not localize the circuit in the LA or RA, a focal or small reentrant arrhythmia should be considered. Color-coded 3-D entrainment mapping can facilitate determination of the full active reentrant circuit (versus passively activated regions of the chamber) and the obstacle around which the tachycardia is circulating, and it provides very useful information on the location of potential ablation sites.

Noncontact mapping may also be used to define the atrial substrate and reentrant circuit, and it can be of significant value when the tachycardia is short-lived or cannot be reproducibly initiated.

IDENTIFICATION OF THE CRITICAL ISTHMUS

Once a scar or fixed barrier is localized, its role in supporting reentry is important in determining whether the isthmuses formed around it need ablation. Whether an isthmus is a critical part of the reentrant circuit can be determined by activation mapping during sustained stable reentry and entrainment mapping. The critical isthmus may lie between two anatomical landmarks (e.g., the mitral annulus and the left inferior PV), or it may be a relatively narrow channel bounded by sites of scar or double potentials. During electroanatomical activation mapping, when the onset of the window of interest is set at mid-diastole between two consecutive P waves, mid-diastolic isthmus of the reentrant circuit can be identified by the interface of early and late activation (i.e., the region where “early meets late” on the color-coded activation map). High-density mapping is then performed in and around the isthmus to define its limits and width precisely.⁹

For identification of the critical isthmus of the reentrant circuit, entrainment mapping is performed at selected atrial sites identified during activation mapping and propagation mapping in relation to atrial scars, barriers, and lines of block. Entrainment with

concealed fusion should be sought, to indicate that the pacing site is in a protected isthmus located within or attached to the reentrant circuit. Whether this protected isthmus is crucial to the reentrant circuit or is just a bystander site needs to be verified by comparing the PPI with the tachycardia CL and the stimulus-exit interval with the electrogram-exit interval, as outlined in Table 10-2.^{15,16}

Ablation

Target of Ablation

The choice of ablation sites should be among those segments of the reentry circuit that offer the most convenient and safest opportunity for creating conduction block. Among other factors are the isthmus size, anticipated catheter stability, and risk of damage to adjacent structures (e.g., phrenic nerve, sinus node, and AV node).

Ablation is performed by targeting the narrowest identifiable isthmus of conduction accessible within the circuit (allowing the best electrode-tissue contact along the desired line). The ablation line is chosen to transect an area critical for the circuit and, at the same time, to connect two anatomical areas of block, an electrically silent area to an anatomical zone of block (e.g., IVC, SVC, tricuspid annulus, PV, or mitral annulus), or two electrically silent areas.

In patients with incomplete maps, the ablation is guided by activation, entrainment, and voltage mapping targeting a critical isthmus or a zone of slow conduction shown to be part of the circuit by pacing maneuvers.^{9,20}

When double potentials separated by an isoelectric interval can be traced in a convergent configuration, with a progressively decreasing interpotential interval, and culminate in a fractionated continuous electrogram, this finding indicates one end of a line of block and activation through the resulting isthmus or around a pivot point at the end of the line of block. If the fractionated low-amplitude electrogram is of longer duration, this suggests a protected corridor of slow conduction, whereas single high-amplitude electrograms suggest a wider and relatively large ablation target. An electrophysiologically defined isthmus may therefore be smaller than the anatomically defined isthmus. EP guidance for determining the target site probably offers greater certitude of RF delivery at a desired location because the same tip electrodes are used for both localization and RF delivery.

Contact or noncontact voltage maps can be used to guide the choice of the ablation site. The likelihood of achieving a complete and transmural ablation line is probably greater in low-amplitude areas.^{9,20}

RIGHT ATRIAL MACROREENTRY

RA MRATs are frequently localized to the free wall of the RA, because of either previous atriotomy or a spontaneous area of conduction block. In the latter setting, the area with slow conduction (mid-diastolic isthmus, as defined by activation, entrainment, and voltage mapping) is the target of choice.

LEFT ATRIAL MACROREENTRY

IN SETTING OF PREVIOUS SURGERY OR SPONTANEOUS REGIONS OF SCAR. The goal is to localize the area with scar and extend this line of conduction block to an anatomical obstacle, or to transect the circuit by joining anatomical structures. Although this strategy is achievable in most of the atria, it is advisable to avoid attempting to connect the anterior septal region to the mitral annulus in the region of the low left septum because the thickness of the tissue prohibits complete lesions in approximately 40% of patients despite the use of irrigated-tip catheters. The exception to this is the presence of a narrow mid-diastolic isthmus (defined by activation, entrainment, and voltage mapping); this target is then preferable and usually much easier than longer linear lesions.

MACROREENTRANT ATRIAL TACHYCARDIAS FOLLOWING ABLATION OF ATRIAL FIBRILLATION. Knowledge of the type of the initial ablation procedure is critical before embarking on LA AT ablation. ATs following PV isolation procedures can often be focal, typically originating from the vicinity of a reconnected PV.⁷ Most of the ATs complicating circumferential and linear LA ablations are macroreentrant, most commonly with circuits around the mitral annulus or involving the LA roof or septum. These circuits are most often related to gaps in ablation lines or to isthmuses created between the ablation lines and other obstacles in the LA. Multiple macroreentrant circuits and multiple-loop reentrant circuits are not infrequently encountered. Additionally, localized reentrant circuits are not uncommon, and they usually arise from the vicinity of the isolated PVs or linear lesions (see Video 17).²¹

Mapping and ablation of LA MRATs following circumferential LA ablation or circumferential PV isolation are frequently challenging. Detailed mapping with a high density of points is necessary to elucidate a more complete understanding of the activation pattern during the AT. In addition, mapping of the previously performed ablation lesions is critical to determine whether the ablation lines, PV isolation, or both, are complete. When the macroreentrant circuit can be mapped, ablation lesions should be tailored to interrupt the path of the reentrant circuit (see Fig. 15-59). In the absence of complete block across the old ablation lines, the gaps must be reablated. Empirical treatment of unmappable ATs primarily involves electrical isolation of all reconnected PVs and, if needed, empirical linear lesions within the tachycardia circuit, often including a line between the mitral annulus and left inferior PV and a line between the superior PVs.²²

LEFT ATRIAL MACROREENTRY IN THE ABSENCE OF PREVIOUS SURGERY OR ATRIAL FIBRILLATION ABLATION. Spontaneous LA circuits have been observed. The circuits can propagate around spontaneous scars, frequently located in the posterior LA, but also around the mitral annulus or PVs. More recently, LA circuits have been reported to rotate around the fossa ovalis, and they are amenable to RF ablation using a linear lesion connecting the fossa ovalis to the mitral annulus.

PERIMITRAL ATRIAL MACROREENTRY. An ablation lesion connecting the mitral annulus and one other anatomical barrier (usually the left inferior PV; Fig. 13-10) or the posterior scar can eliminate this arrhythmia. Another option is to use an anterior line from the anterior mitral annulus to the ostium of the left superior PV or to a region of scar through the anterior LA.

ATRIAL MACROREENTRY AROUND THE RIGHT PULMONARY VEINS. Circuits propagating around the right PVs demonstrate colliding wavefronts along the mitral annulus and a PPI during entrainment that is much longer at the mitral isthmus than at the roof or posterior LA. This arrhythmia is observed more frequently in the current approach of wide-area atrial ablation to isolate the PVs, because the lesions performed to isolate right and

left PVs may create a narrow isthmus in the posterior LA that then forms the substrate for MRAT. A linear lesion connecting both superior PVs through the roof is the best option. This procedure is best performed along the roof, rather than the posterior wall, to avoid the potential risk of atrioesophageal fistulas.

ATRIAL MACROREENTRY AROUND THE LEFT PULMONARY VEINS. Circuits around the left PVs seem rare. They can be abolished with a linear lesion joining the left inferior PV to the mitral annulus or with a roofline connecting both superior PVs.

LEFT SEPTAL CIRCUITS. A linear lesion from right PVs to the fossa ovalis or from the mitral annulus to the fossa ovalis usually terminates the tachycardia.

UNMAPPABLE LEFT ATRIAL MACROREENTRANT TACHYCARDIAS. Some LA MRATs can show some degree of variation in their CL during mapping, in which case conventional and electroanatomical mapping is less useful. An empirical strategy that commences with ablation at the mitral isthmus and the LA roof is then justified because such ablation lines interrupt the most dominant circuits in the LA. CL variation can in some cases facilitate activation mapping by revealing when electrograms "lead" versus "follow," but it severely compromises use of entrainment mapping, which assumes that the [PPI – AT CL] differences result only from proximity of the pacing site to the circuit and not from variable conduction velocity to, from, or within the circuit.

Ablation Technique

Once the ablation target is identified, ablation involves placing a series of RF lesions to sever the critical isthmus to connect two anatomical or surgical barriers. RF energy can be delivered sequentially point by point to span the targeted isthmus or by dragging the ablation catheter tip during continuous energy administration. RF energy is maintained for up to 60 to 120 seconds until the bipolar atrial potential recorded from the ablation electrode is decreased by 80% or split into double potentials, thus indicating local conduction block. Lesion contiguity and continuity depend on ensuring the coalescence of multiple transmural lesions; this is best ensured by documenting the breakdown of the target electrogram (at each site) into double potentials and continuing RF delivery at this point for 30 to 40 seconds more to ensure a stable lesion. The documentation of electrogram breakdown into double potentials depends on the direction of activation relative to the ablation lesion and its size relative to that of the recording bipole and is maximized by activation orthogonal to the lesion's largest dimension.

During delivery of RF energy, the tachycardia can terminate, or its CL can increase transiently or permanently. These findings indicate that the lesions have affected the circuit and should lead to continuation of RF delivery or extension of the lesion to ensure the achievement of complete conduction block across the isthmus.

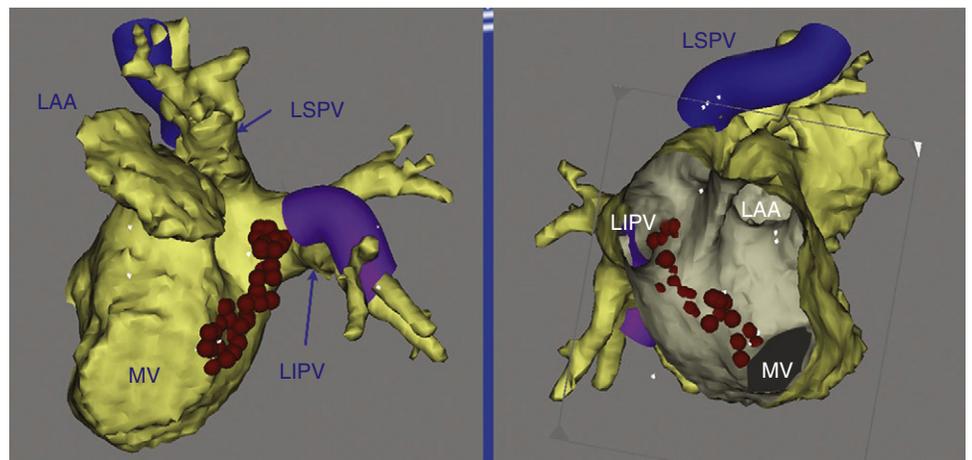

FIGURE 13-10 Integrated computed tomography (CT) and electroanatomical (CARTO, Biosense Webster, Inc., Diamond Bar, Calif.) map of the left atrium acquired during catheter ablation of the mitral isthmus. Left anterior oblique and endoscopic views of the CT scan are shown. Tubular-appearing structures are pulmonary veins; small red circles are tagged sites at which radiofrequency energy was applied across the isthmus between the annulus of the mitral valve (MV) and left inferior pulmonary vein (LIPV). LAA = LA appendage; LSPV = left superior pulmonary vein.

The coalescence of multiple RF lesions can be facilitated by any 3-D localization system (e.g., CARTO, NavX). Ablation sites may be tagged to permit visualization of the ablation line on the electro-anatomical map. CARTO is also invaluable in localizing the gaps in the scar line through which the impulse can propagate. Focal ablation of these gaps can abolish the tachycardia.^{9,20}

It is not uncommon for the arrhythmia mechanism to switch rather than terminate following successful ablation. A change in atrial activation sequence or P wave morphology or a sudden change in the atrial CL may indicate that the tachycardia that was being ablated has changed to a different loop or to a different tachycardia. In this setting, it is very important to reevaluate the mechanism and location of the new arrhythmia systematically by using activation and entrainment mapping and to move to the new target if necessary.^{12,23} However, the transition to a different loop of a tachycardia or to a different tachycardia may occur with no discernible change in the activation sequence among the atrial electrograms that are being recorded, P wave morphology, or CL. It is important to keep this in mind when ablation across an isthmus appears not to affect the tachycardia. The isthmus may have already been blocked and may no longer be participating in the tachycardia. This should be suspected if double potentials are present along the ablation line, and it is easily confirmed by entrainment mapping near the ablation line. If that site was confirmed previously to be part of the reentrant circuit (PPI – AT CL difference less than 20 milliseconds) and now it is outside the tachycardia circuit (PPI – AT CL difference more than 30 milliseconds), this finding indicates that the tachycardia circuit has changed.⁷

ABLATION OF THE MITRAL ISTHMUS

The mitral isthmus is short (2 to 4 cm), anatomically bounded by the mitral annulus, left inferior PV ostium, and superiorly by the LA appendage (see Fig. 13-10). The average thickness of the atrium along the mitral isthmus is 3.8 mm, with maximum thickness up to 7.7 mm. The CS muscle sleeve, present in up to 75% of patients, inserts into the LA inferior to the mitral isthmus and occasionally extends onto the mitral valve.^{24,25} Mitral isthmus ablation is

performed by linear ablation to join the lateral mitral isthmus to the left inferior PV.

If possible, the CS catheter is positioned to bracket the planned linear lesion between its proximal and distal bipoles. The ablation catheter, bent with a 90- to 180-degree curve and introduced through a long sheath to achieve good contact and stability, is first positioned at the ventricular edge of the lateral mitral annulus, where the A:V electrogram shows a 1:1 to 2:1 ratio, to begin ablation. The sheath and catheter are then rotated clockwise to extend the lesion posteriorly, ending at the left inferior PV ostium (Fig. 13-11). In general, ablation is commenced at about the 3- or 4-o'clock position on the mitral isthmus and reaches the 2- to 3-o'clock position at the upper end of the line. A more anterior extension to the posterior root of the LA appendage occasionally is required.

RF energy is delivered with an 8-mm-tip catheter with a target temperature of 50° to 55°C and a power of 50 to 60 W. Externally irrigated catheters are preferably used with a power of 25 to 35 W and continuous titration of flow from 5 to 60 mL/min to achieve a target temperature of 40° to 42°C. Higher-power delivery in this region carries a significant risk of cardiac perforation with tamponade because of the particular regional anatomy, as well as the catheter-tissue geometry. The stability of the catheter is monitored during RF applications by using electrogram recordings and intermittent fluoroscopy to exclude inadvertent displacement, which could result in high-energy delivery in the left inferior PV ostium or LA appendage.^{12,23}

When ablation is performed during NSR, the effect of each RF application is assessed on the local electrogram during pacing from the proximal bipole of the CS catheter located immediately posteromedial of the line, to maximize conduction delay. Splitting of the local potentials, with a resulting increase in the delay from the pacing artifact, is considered evidence of an effective local lesion. After the initial attempt to create this line, mapping is performed along the line to identify and ablate endocardial gaps, defined as sites showing the shortest delay between the pacing artifact and the local atrial potential, which can be single, narrow double, or fractionated.

Persisting epicardial conduction is suspected when the linear lesion results in adequate voltage abatement on the endocardial

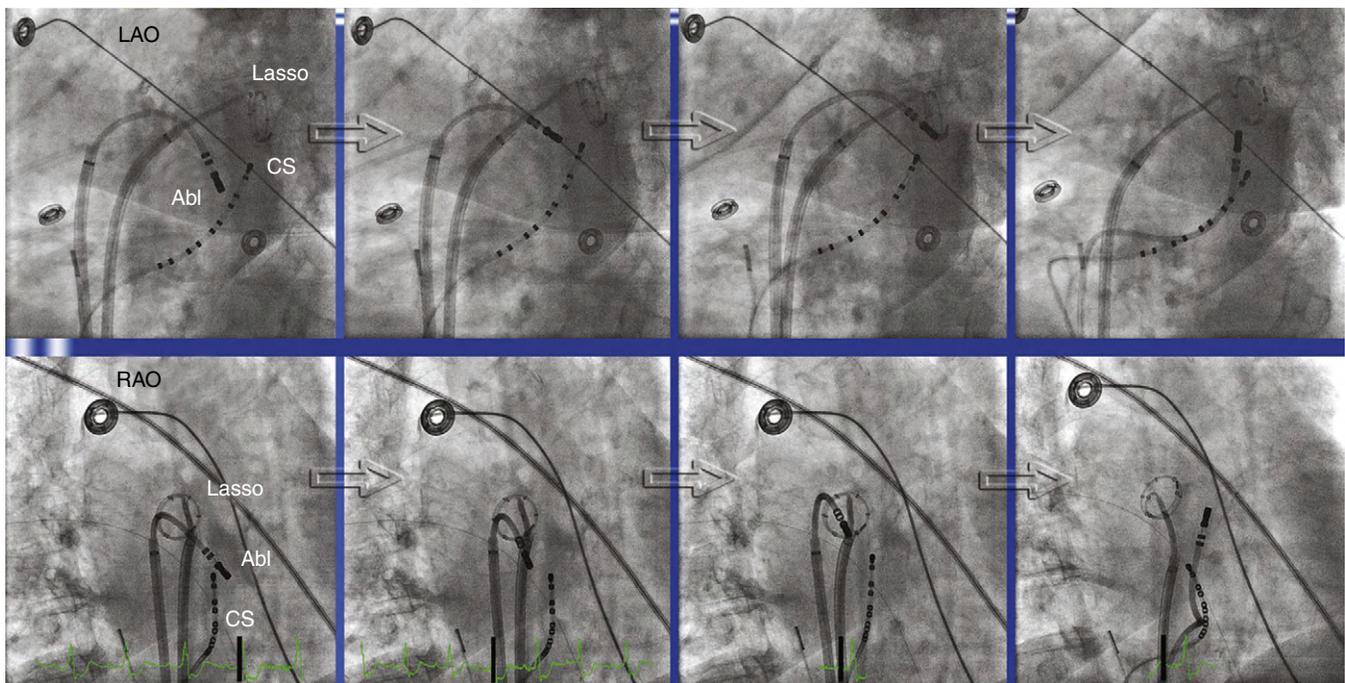

FIGURE 13-11 Right anterior oblique (RAO; upper panels) and left anterior oblique (LAO; lower panels) fluoroscopy views of catheter placement during mitral isthmus ablation. A ring catheter (Lasso) is positioned at the ostium of the left inferior pulmonary vein (PV). Ablation is started with the ablation catheter (Abl) at the ventricular edge of the mitral annulus (left panel). The catheter is then moved gradually to the midisthmus and subsequently to the junction with the ostium of the left inferior PV (middle panels). When the endocardial approach fails, epicardial ablation of the mitral isthmus is attempted through the coronary sinus (CS; right panel).

aspect and endocardial conduction delay recorded on the ablation catheter but not on the adjacent distal bipole of the CS catheter (anterolateral to the ablation line). Epicardial ablation within the CS is required to achieve block in approximately 70% of cases. The relatively low success rate of mitral isthmus block can be explained by several mechanisms. The shape and depth of the atrial myocardium vary greatly around the mitral isthmus, and the depth of the tissue (resulting from the double muscular layers of LA and CS) may be the limiting factor in achieving transmural lesion by endocardial ablation alone. Additionally, local cooling effects of blood flow in the circumflex coronary artery and the great cardiac vein (both pass in close proximity to the mitral isthmus) may act as a heat sink, preventing adequate tissue heating by RF delivery and making isthmus block difficult. Temporary displacement of the venous blood pool by using an air-filled CS balloon can potentially facilitate transmural mitral isthmus lesions during endocardial catheter ablation.^{24,26,27}

When epicardial ablation is required, the ablation catheter is withdrawn from the LA and is introduced into the CS to map the epicardial side of the isthmus and identify fractionated or early potentials suggestive of an epicardial gap. Ablation within the CS is performed using an externally irrigated-tip catheter with a power limit of 20 to 25 W, and usually maximal flow (60 mL/min) is necessary (see Fig. 13-11).^{12,23} RF application should be discontinued if there is a rapid rise or fall in impedance or a rapid rise in temperature. Sometimes a power setting of 30 to 35 W is required for successful ablation. A higher power setting should be considered when a tachycardia fails to respond to ablation with 20 to 25 W and when entrainment mapping or activation mapping indicates that the CS is still an appropriate target site.⁷

One report described an alternative approach to ablation of perimitral MRAT. Linear ablation between the anterior-anterolateral mitral annulus and the ostium of the left superior PV (modified anterior line) was found to be safe, feasible, and successful in the short term in terminating perimitral MRAT in more than 96% of cases, and in achieving bidirectional block across the ablation line in 86% of cases, without the need for RF ablation within the CS. The ablation catheter is advanced through the transeptal sheath to the anterior-anterolateral mitral annulus, and delivery of RF lesions is started when the A/V ratio is 1:2. Linear ablation is then performed with clockwise (posterior) rotation of the transeptal sheath and progressive release of the ablation catheter curve. The ablation line is extended just medial to the orifice of the LA appendage, and it ends at the ostium of the left superior PV.²⁸

Endpoints of Ablation

TACHYCARDIA TERMINATION DURING RADIOFREQUENCY ENERGY APPLICATION

Sudden termination of an incessant AT during RF application suggests that the lesion has severed a critical isthmus and that site should be targeted for additional lesions. However, reliance on AT termination during RF application as the sole criterion of a successful ablation is hazardous because such an AT can terminate spontaneously, in which case termination can be misleading. RF application itself can induce premature atrial complexes that can then terminate AT without eliminating the substrate. Moreover, the sudden termination of AT can be accompanied by catheter displacement from the critical site to another site, thus making it difficult to deliver additional energy applications at the critical site. Additionally, RF application can cause a transient but not permanent block in the critical isthmus. Such a block can last long enough to terminate the tachycardia, but it can resolve after seconds or minutes.

NONINDUCIBILITY OF TACHYCARDIA

To use the criterion of noninducibility of tachycardia as a reliable endpoint, careful assessment of inducibility should be performed prior to ablation, and the feasibility and best method of reproducible induction of the AT should be documented at

baseline before ablation. In the setting of easy inducibility prior to ablation, one can consider the lack of inducibility as an indicator of successful ablation. Noninducibility of the arrhythmia is inapplicable if the original arrhythmia is either noninducible at baseline or was inadvertently terminated mechanically. Noninducibility may also reflect conduction delay in the critical isthmus, and not stable block, or it may be secondary to changes in autonomic tone.

DOCUMENTATION OF A LINE OF BLOCK

Complete stable conduction block within the reentry path is the most useful and objective endpoint. However, achieving this endpoint can be challenging and is not as feasible as in typical AFL ablation. To confirm complete conduction block following ablation, the mapping catheter is used to retrace the same ablation line (during NSR or atrial pacing), thus showing the absence of electrograms or a complete line of block demonstrated by parallel double potentials recorded all along the line. Pacing close to the ablation line (at a site within 30 milliseconds of conduction time to the ablation lesion) and demonstration of marked delay and reversal in the direction of activation on the opposite side of the linear lesion across the isthmus indicate isthmus block, although very slow conduction can be difficult to exclude.

CONFIRMATION OF MITRAL ISTHMUS BLOCK

For perimitral MRAT, the mitral isthmus is the target of ablation. Mitral isthmus ablation has a well-defined demonstrable procedural endpoint of bidirectional conduction block analogous to CTI ablation. Validation of mitral isthmus conduction block is greatly facilitated by its proximity to the CS that allows pacing and recording on either side of the ablation line to confirm bidirectional block. Differential pacing can also be performed to exclude slow conduction through an incomplete line.

Several criteria are used to confirm the presence of bidirectional mitral isthmus block:

1. The presence of widely separated (by 150- to 300-millisecond intervals) local double potentials along the length of the ablation line during CS pacing septal of the ablation line.
2. Mapping the activation detour during pacing from either side of the ablation line. Pacing on the septal side of the line through the CS demonstrates activation toward the line both septally and laterally. Pacing lateral to the line through the ablation catheter placed endocardially demonstrates a proximal-to-distal activation sequence along the CS septal side of the line, thus confirming bidirectional conduction block (Fig. 13-12). Such an activation detour can also be determined using 3-D electroanatomical mapping.
3. Differential pacing to distinguish slow conduction across the mitral isthmus from complete block. With the distal bipole of the CS catheter placed just septal to the linear lesion, the pacing site is changed from the distal to the proximal bipole of the CS catheter without moving any of the catheters. The stimulus-to-electrogram timing at a site lateral to the ablation line is measured before and after changing the pacing site. With complete block, the stimulus-to-electrogram interval is shortened after shifting the pacing site from the distal to proximal CS bipole (Fig. 13-13; see Fig. 13-12).

CONFIRMATION OF MODIFIED ANTERIOR LINE BLOCK

The achievement of a complete block along the modified anterior line can be verified by (1) mapping of the line during pacing from the distal CS or LA appendage and verification of the presence of double potentials along its entire length, (2) electroanatomical activation mapping during LA appendage pacing with earliest LA activation lateral to the ablation line and an early-meets-late zone along the entire length of the ablation line, or (3) evaluation of the CS activation pattern during pacing just laterally and medially to

Pacing from left inferior PV

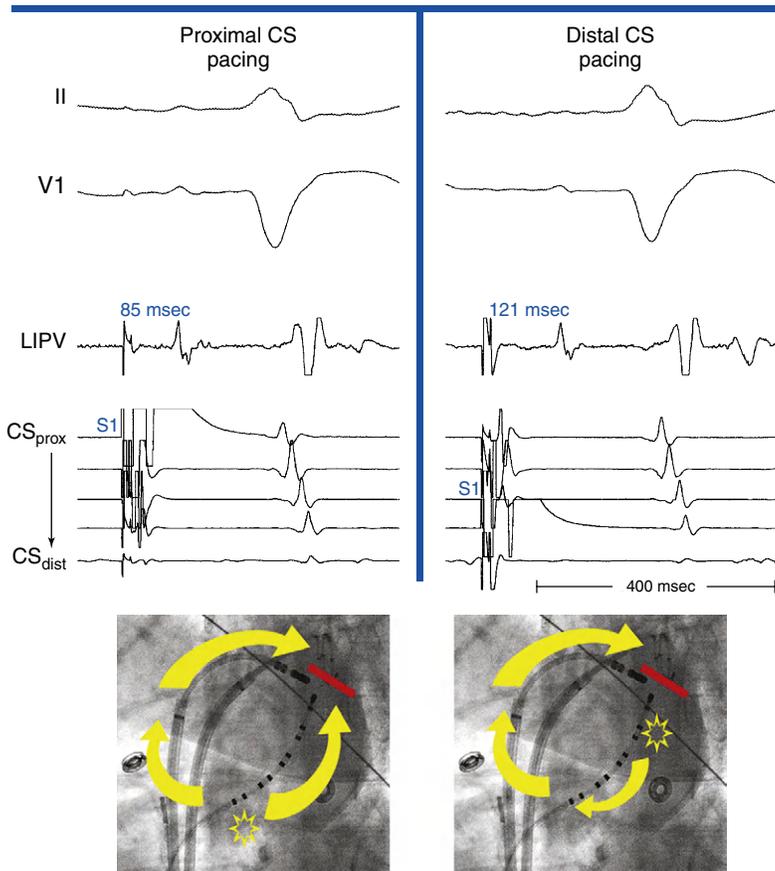

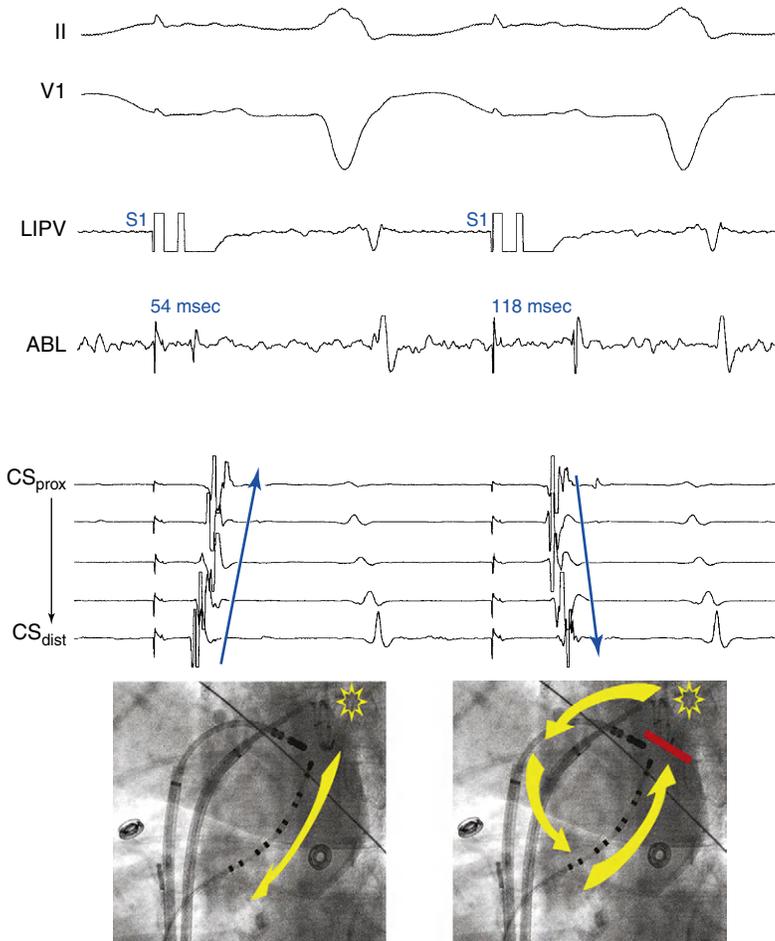

FIGURE 13-12 Verification of bidirectional mitral isthmus block. **Upper panel**, Ablation of the mitral isthmus is performed during pacing lateral to the ablation line (a Lasso catheter positioned at the ostium of the left inferior pulmonary vein [LIPV] is used in this case). With intact isthmus conduction, coronary sinus (CS) activation occurs through the wavefront propagating in the counterclockwise direction; thus, a distal-to-proximal CS activation sequence is observed. When clockwise isthmus block is achieved, CS activation occurs through the wavefront propagating in the clockwise direction; thus, reversal of the CS activation sequence is observed. The ablation catheter (ABL) is positioned at the septal aspect of the line of block. The stimulus-to-electrogram interval recorded by the ablation catheter prolongs suddenly on development of clockwise isthmus block. **Lower panels**, Differential pacing is performed from the proximal and distal CS (CS_{prox} , CS_{dist}) bipoles (both positioned at the septal aspect of the ablation line) to verify the presence of counterclockwise isthmus block. In the presence of counterclockwise block, activation lateral to the ablation line (as recorded by the Lasso catheter in the LIPV) occurs through the wavefront propagating in a clockwise direction up the left atrial (LA) septal wall and over the LA roof. Consequently, LIPV activation occurs earlier during pacing from the proximal CS (**left panel**) compared with the distal CS (**right panel**). A yellow star marks the pacing site.

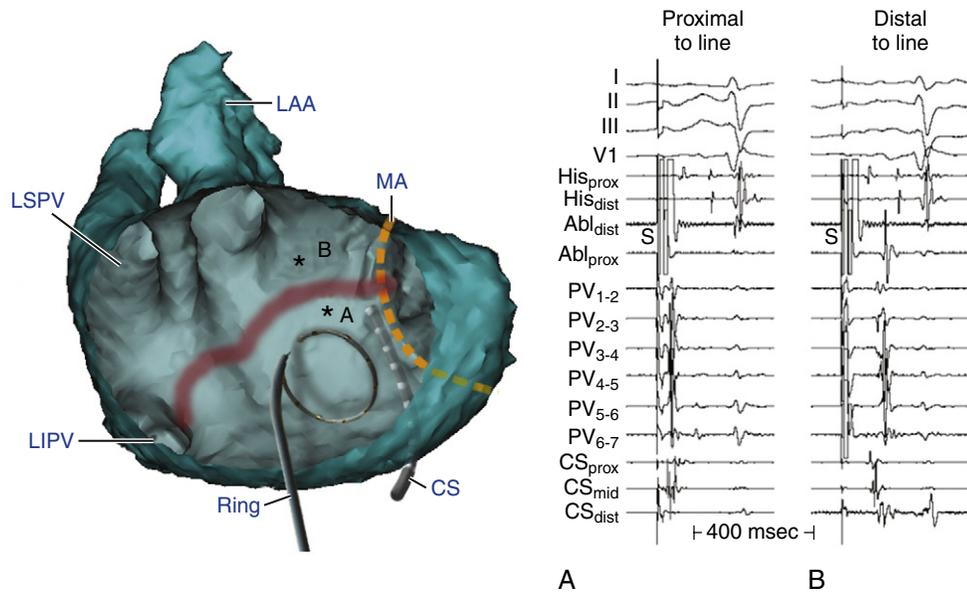

FIGURE 13-13 Endoscopic view of a CT scan of the left side of the left atrium (LA). The orifices of the left superior pulmonary vein (LSPV) and left inferior PV (LIPV) and LA appendage (LAA) are shown. An ablation line (red shading) has been made between mitral annulus (MA, orange dashes) and the LIPV orifice to transect the mitral isthmus. A multipolar ring catheter is situated on the LA endocardium as shown; the tip of the coronary sinus (CS) catheter (situated epicardial to the LA) is proximal to the ablation line. During pacing from A (asterisk), proximal to the ablation line, the ring catheter recordings appear soon after the stimulus artifact and CS electrodes are activated from distal to proximal. Pacing from B (asterisk), distal to the ablation line, shows the ring electrodes are activated much later than before, and the CS is now activated from proximal to distal, thus indicating bidirectional block at the mitral isthmus. Abl_{dist} = distal ablation site; Abl_{prox} = proximal ablation site; CS_{dist} = distal coronary sinus; CS_{mid} = middle coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{prox} = proximal His bundle; PV = pulmonary vein.

the line with the ablation catheter (translinear pacing maneuver). Complete linear block is confirmed if pacing laterally to the line results in a distal to proximal CS activation pattern, whereas after moving the catheter to the septal side of the line, the CS is activated from proximal to distal.²⁸

FAILURE OF RADIOFREQUENCY ABLATION

Atrial enlargement can interfere with RF energy delivery secondary to difficulty in achieving stable, firm catheter contact and to the probable high convective heat loss associated with the large chamber volume. In addition, targets for ablation can have low surrounding blood flow; thus, target temperature can be achieved at very low energy outputs because of inadequate cooling of the tip of a standard ablation catheter, with consequent limited energy delivery. Furthermore, some surgical repairs are associated with myocardial hypertrophy, which makes achievement of a transmural lesion difficult or impossible.

Outcome

SUCCESS

Short-term success rates are reasonably good (approximately 90%). However, recurrence rates of the same or other tachycardias are high; up to 54% of cases required repeat ablation in some studies. The long-term success rate is approximately 72%.

Despite frequent underlying structural heart disease, the incidence of AF after ablation is relatively low (9% to 21%) in patients without prior history of AF. This may be related to the presence of silent areas and lines of block (spontaneous and created by RF), which could reduce the electrically active atrial mass to less than the critical threshold for AF. In the context of MRATs propagating through incomplete lines of block delivered for AF ablation, the long-term follow-up is even better, at least in patients for whom complete block is achieved.

In patients with perimitral MRAT, block at the mitral isthmus can be achieved in 76% to 92% of patients with 20 ± 10 minutes of endocardial RF application; an additional 5 ± 4 minutes of epicardial RF application from within the CS is required in 68% of patients.

SAFETY OF ABLATION OF LEFT ATRIAL MACROREENTRANT TACHYCARDIA

Thromboembolic risk during LA ablation can be reduced by the following: (1) anticoagulation for 4 weeks prior to the procedure; (2) preprocedural transesophageal echocardiography, to exclude the presence of atrial clots; (3) perfusion of the LA sheath under pressure, to achieve a flow of approximately 2 to 4 mL/min; (4) intravenous heparin administration immediately before or immediately after transseptal puncture and throughout the LA procedure, to maintain an activated clotting time between 250 and 350 seconds; and (5) the use of irrigated-tip catheters.

Free wall perforation can occur during atrial septal puncture or during the rest of the procedure. The LA appendage is the site of the highest risk of perforation because of the very thin tissue encountered between the pectinate muscles. To prevent perforation caused by steam popping during RF delivery, it is important to limit the delivered power, especially around the PVs, posterior LA, and LA dome.

PV stenosis is another potential complication, and limiting RF power output and duration can reduce this risk. Left phrenic palsy is uncommon and is usually associated with RF delivery at the anterior LA or base of the LA appendage, or both. Right phrenic nerve injury can be observed during ablation at the anterior aspect of the right PVs.

SAFETY OF RIGHT ATRIAL MACROREENTRY ABLATION

Right phrenic nerve injury can be observed during ablation at the anterior aspect of the SVC and lateral RA. Pacing at a high output of 10 mA from the ablation catheter at the site without capture of the phrenic nerve and continuous pacing in the SVC to capture the

phrenic nerve during RA ablation are reassuring, but their efficacy has never been assessed. Early recognition of phrenic nerve injury during RF delivery, based on cough, hiccup, or reduced diaphragmatic respiratory motion, allows the immediate interruption of the application prior to the onset of permanent injury and is associated with the rapid recovery of phrenic nerve function. Furthermore, limiting the power delivered to 20 to 25 W further minimizes the risk of this complication.

Pathophysiology

Patients with congenital heart disease have a high prevalence of atrial tachycardias (ATs), particularly after they have undergone reparative or palliative surgical procedures. For macroreentrant ATs in adults with repaired congenital heart disease, three right atrial (RA) circuits are generally identified: lateral wall circuits with reentry around or related to the lateral atriotomy scar, septal circuits with reentry around an atrial septal patch, and typical atrial flutter (AFL) circuits using the cavotricuspid isthmus (CTI). Typical clockwise or counterclockwise isthmus-dependent AFL is the most common macroreentrant tachycardia in this patient population. Left atrial (LA) macroreentrant circuits are infrequent in this group of patients. Atrial macroreentry in the right free wall is the most common form of non-isthmus-dependent RA macroreentry (atypical flutter). Very complex or multiple reentry circuits can be seen after placement of an intraatrial baffle (Mustard or Senning correction for transposition of the great vessels) in an extremely dilated RA, after a Fontan procedure, and in patients with a univentricular heart.^{1,2}

Anatomical factors promoting macroreentry in patients with congenital heart disease include abnormalities of the underlying cardiac anatomy, surgically created anastomoses, and atriotomy scars, resulting in anatomical barriers to impulse propagation. Additionally, extensive cardiac surgery and hemodynamic overload result in myocardial hypertrophy and diffuse areas of atrial scarring with surviving myocardial fibers embedded within scar areas, which provide the substrate for potential reentry circuits.^{3,4}

The best characterization of macroreentrant AT caused by atriotomy is activation around an incision scar in the lateral RA wall, with a main superoinferior axis (Fig. 14-1). This is a common problem in patients who have undergone surgery for congenital or valvular heart disease. The length, location, and orientation of the atriotomy incisions, as well as potential electrical conduction gaps across the atriotomy, are important determinants of arrhythmogenicity.⁵ Typically, the reentry circuit is located in the lateral RA wall. Not only does the central obstacle include the scar, but also functional block can magnify this obstacle to include the superior vena cava (SVC). The anterior RA wall is commonly activated superoinferiorly (descending activation pattern), as in counterclockwise typical AFL. However, the septal wall frequently lacks a clear-cut inferosuperior (ascending) activation pattern. Participation of the anterior RA wall in the circuit can be confirmed with entrainment mapping. A line of double potentials can be recorded in the lateral RA, extending superoinferiorly. Double potential separation can be more marked and demonstrate a voltage lower than in typical AFL. Narrow passages (isthmuses) in the circuit can be found between the SVC and the superior end of the atriotomy scar, between the inferior vena cava (IVC) and the inferior end of the atriotomy, between the atriotomy scar and the tricuspid annulus, between the atriotomy and the crista terminalis, or even within the scar itself (Fig. 14-2). These isthmuses can be areas of slow

conduction. Stable pacing of the critical isthmus can be difficult or impossible in RA atriotomy tachycardia because of tachycardia interruption. Isthmus participation in the circuit is often proven by tachycardia interruption with catheter pressure (Fig. 14-3), as well as by tachycardia interruption and noninducibility after radiofrequency (RF) application in the area. A single, wide, fractionated electrogram can be recorded from the lower pivot point of the circuit (Fig. 14-4) in the low lateral RA, close to the IVC, and perhaps also from other isthmuses of the circuit. The line of double potentials or fractionated, low-voltage electrograms can also often be recorded in normal sinus rhythm, to allow tentative localization of the scar and the associated anatomical isthmuses.²

Typical AFL is also often associated with RA atriotomy. In fact, the single most common form of AT among patients with congenital heart disease appears to be isthmus-dependent AFL, particularly in patients with simpler anatomical lesions (e.g., tetralogy of Fallot, atrial and ventricular septal defects) (Fig. 14-5). Moreover, the CTI was found to be part of the reentrant circuit in approximately 70% of patients with postoperative intraatrial reentrant tachycardia. In one report, ablation of this isthmus alone resulted in elimination of the tachycardia in 27% of these patients. Factors such as an atriotomy or atrial fibrosis and hypertrophy serve as promoters for early development of the typical form of AFL.

Reentry circuits can also occur in the sinus node region, possibly as a result of injury related to the superior atrial cannulation site for the bypass pump. These circuits can be quite small, often manifesting as focal tachycardia in the sinus node region, and they frequently can be ablated in a single location without establishing a particular line of block.⁴

Focal mechanisms underlying postoperative AT have been rarely reported in this patient population. Nonautomatic focal ATs are predominantly found in adults, with most foci in the RA. The reasons behind this laterality are unknown. The mechanism underlying focal AT is unknown. Both triggered and microreentrant mechanisms have been suggested.⁶ Viable myocardial fibers embedded within areas of scar tissue, which play a pivotal role in the initiation and perpetuation of macroreentrant tachycardias, can also be the site of origin of a focal AT and thus play an important role in the pathogenesis of these ATs.³

Arrhythmias are also frequently observed in the early postoperative period after corrective surgery in children, occurring in 14% to 48% in the first few days after surgery. The most common arrhythmia in this period is junctional tachycardia, occurring in 5% to 10% of the operated children and usually self-limiting. Other supraventricular arrhythmias are also seen in 4%. The occurrence of early postoperative arrhythmias seems to be related to procedural factors of cardiac surgery, which are, in turn, related to the complexity of the congenital malformation. Early postoperative arrhythmias influence the long-term outcome of patients with congenital heart disease and have been found to be a predictor of late complications, such as ventricular dysfunction, late arrhythmias, and late mortality. Whether

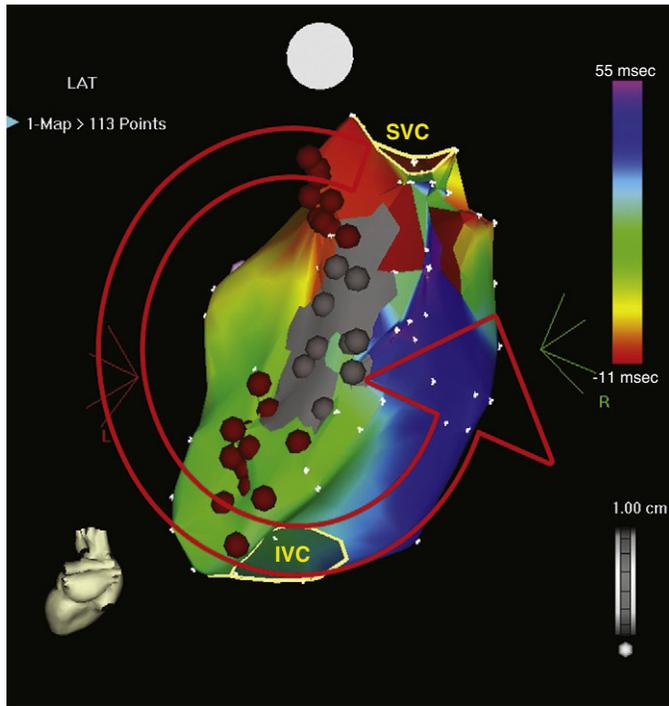

FIGURE 14-1 Three-dimensional electroanatomical (CARTO, Biosense Webster, Inc., Diamond Bar, Calif) activation map of macroreentrant atrial tachycardia in a patient with previous surgical repair of an atrial septal defect. Gray areas in the posterolateral right atrium represent areas of unexcitable scar related to previous atriotomy, characterized by very low-voltage electrograms. During tachycardia, the activation wavefront travels in a macroreentrant circuit around the atriotomy scar. Ablation lines (red dots) connecting the atriotomy scar to the inferior vena cava (IVC) and superior vena cava (SVC) successfully eliminated the tachycardia.

preventing these arrhythmias will influence the long-term survival of patients with congenital heart disease is unknown.⁷

Clinical Considerations

Epidemiology

Macroreentrant AT is the most common mechanism for symptomatic tachycardia in the adult population with congenital heart disease. Surgical incisions in the RA for repair of atrial septal defects are probably the most common causes of lesion-related reentry in adults. Usually, macroreentrant AT appears many years after operations that involved an atriotomy or other surgical manipulation. This arrhythmia can infrequently follow simple procedures, such as closure of an atrial septal defect, but the incidence is highest among patients with advanced dilation, thickening, and scarring of their RA. Other risk factors for macroreentrant AT include the severity of myocardial dysfunction, poor hemodynamic status, concomitant sinus node dysfunction, and older age at the time of heart surgery. It should be recognized, however, that typical AFL is more common than non-isthmus-dependent AFL even in this population, and typical and atypical flutter circuits often coexist in a single patient.

Interestingly, compared with patients with structurally normal hearts, the incidence of atrial fibrillation (AF) in patients with congenital heart disease is relatively low. AF is less common than one would anticipate, especially considering the often extremely dilated RA in this patient population.⁸ AF is typically associated predominantly with markers of left-sided heart disease (i.e., lower left ventricular ejection fraction and LA dilation) and is most commonly seen in patients with congenital aortic stenosis, mitral valve disease, palliated single ventricles, or end-stage heart disease.^{1,9}

The occurrence of frequent sustained tachycardia is associated with poorer clinical outcome and probably represents a specific risk factor for thrombosis and thromboembolism. It is important to

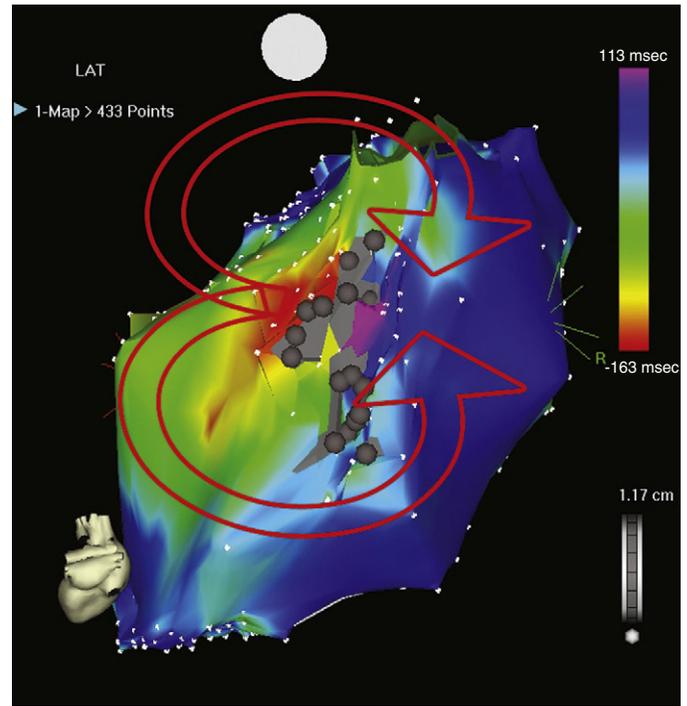

FIGURE 14-2 Three-dimensional electroanatomical (CARTO, Biosense Webster, Inc., Diamond Bar, Calif) activation map of macroreentrant atrial tachycardia in a patient with previous surgical repair of an atrial septal defect. Gray areas in the posterolateral right atrium (RA) represent areas of unexcitable scar related to previous atriotomy, characterized by very low-voltage electrograms. During tachycardia, the activation wavefront travels from the midposterior RA superiorly and inferiorly, and both counterclockwise and clockwise wavefronts return to the region proximal to the exit site (purple) to complete the circuit by propagating through a narrow isthmus bounded by two areas of unexcitable scar (figure-of-8 reentry). Radiofrequency ablation targeting the gap in the atriotomy scar successfully eliminated the tachycardia. IVC = inferior vena cava; SVC = superior vena cava.

consider the possibility that new-onset atrial arrhythmias may herald worsening ventricular function or tricuspid regurgitation, or both.

ATRIAL SEPTAL DEFECT

Macroreentrant ATs are the most frequent arrhythmias encountered in patients with secundum and sinus venosus atrial septal defects. In the absence of surgical repair, the prevalence of supraventricular arrhythmias increases with age. These arrhythmias have been reported in 20% of these patients at the age of 40 years, and typical AFL is the most common circuit. In the presence of atriotomy incisions, sutures, or patches, non-isthmus-dependent macroreentrant circuits can occur or coexist with typical AFL. Common substrates include macroreentry along the lateral RA wall and double-loop or figure-of-8 circuits. The septal patch itself is rarely a critical conduction obstacle. Surgical closure of an atrial septal defect during childhood provides a substantially lower incidence of arrhythmias. In contrast, surgical closure at adult age is far less effective; approximately 60% of these patients continue to have atrial arrhythmias during follow-up after surgery. The impact of transcatheter atrial septal defect closure on atrial arrhythmias is less clear. In one series, all patients with persistent arrhythmias remained in AF or AFL after closure.^{7,8,10}

UNIVENTRICULAR HEARTS WITH FONTAN PALLIATION

Among patients with congenital heart disease, the incidence of macroreentrant AT is highest (16% to 56%) among older patients who have undergone older-style Fontan (atriopulmonary anastomosis) operations, in which extensive suture lines and long-term hemodynamic stress result in marked atrial hypertrophy and fibrosis.⁴ The incidence of atrial tachyarrhythmias appears lower

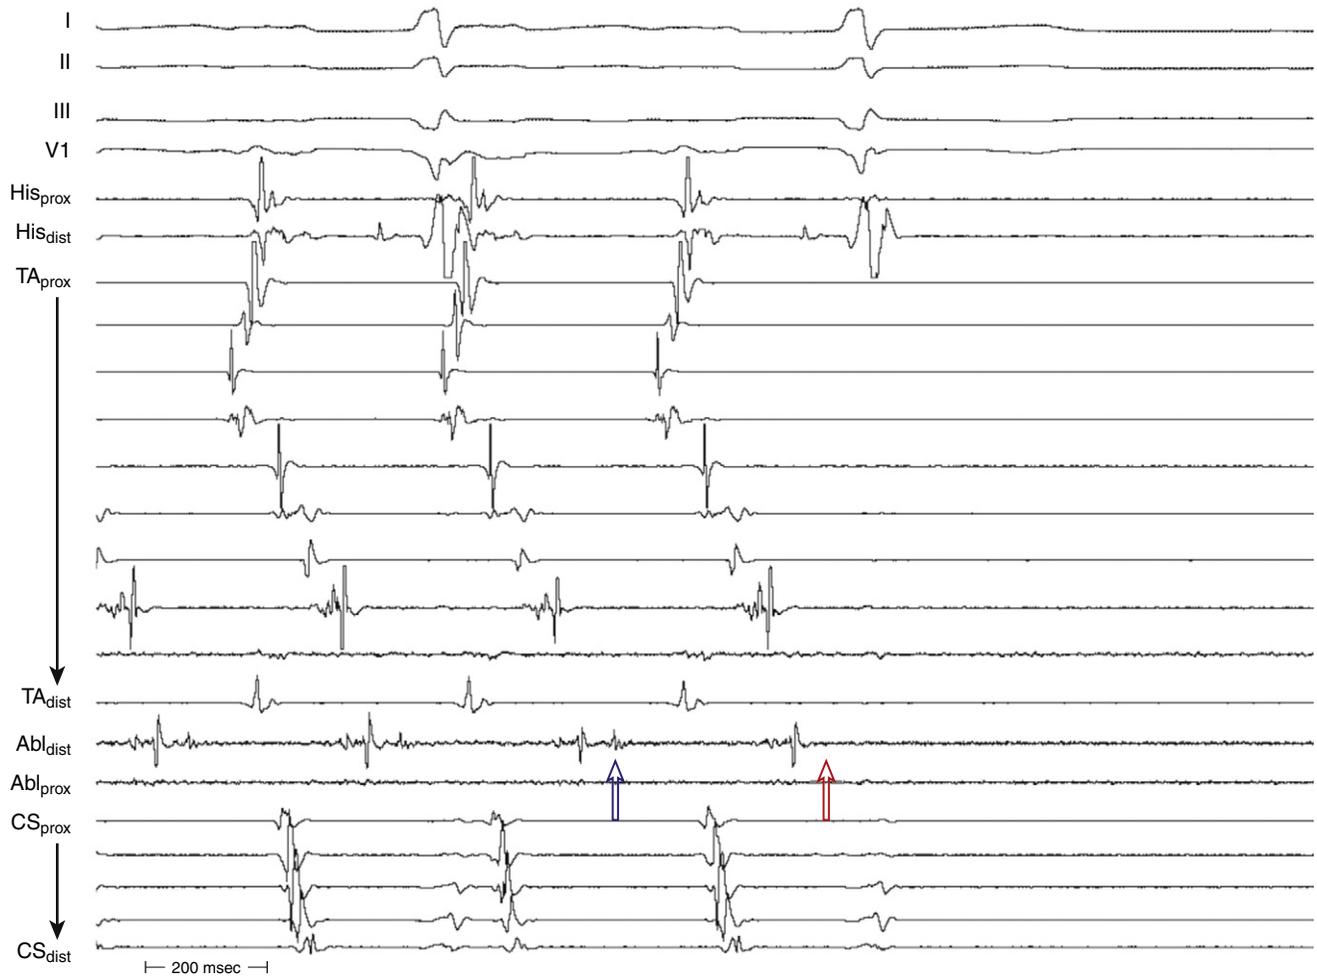

FIGURE 14-3 Catheter-induced termination of macroreentrant atrial tachycardia (AT). ECG leads and intracardiac recordings are shown during an episode of non-isthmus-dependent atrial macroreentrant AT in a patient with prior atriotomy. The episode had lasted 3 months at the time of the study, yet catheter pressure at the site from which the distal ablation site (Abl_{dist}) recording was made terminated AT twice. Note the multicomponent electrogram (blue arrow), the last portion of which is missing when AT terminates (red arrow). Abl_{prox} = proximal ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{prox} = proximal His bundle; TA_{dist} = distal tricuspid annulus; TA_{prox} = proximal tricuspid annulus.

in patients with total cavopulmonary connections in comparison with classical atriopulmonary connections. Overall, the most common arrhythmia is atrial macroreentry. Tachycardia circuits may be complex or multiple. Single circuits that are quite amenable to catheter ablation can occasionally be encountered.¹¹

TETRALOGY OF FALLOT

ATs occur commonly (12% to 34%) during extended follow-up after tetralogy of Fallot repair. The observed prevalence of atrial arrhythmias (20.1%) is modestly higher than that of ventricular arrhythmias (14.6%).¹² The most common atrial circuit is typical clockwise or counterclockwise AFL. Other circuits often involve the lateral RA wall and may be multiple, often with a double-loop type of reentry. Nonautomatic focal ATs most commonly arise adjacent to suture points, with radial spread of activation.

The prevalence of AF increases with advancing age. In the first few decades of life, AF is far less common than macroreentrant AT, but it becomes more common (more than 30%) than macroreentrant AT after 55 years of age.¹²

D-TRANSPOSITION OF THE GREAT ARTERIES

The Mustard or Senning atrial switch procedures were performed from the early 1960s until approximately 1985 as the major long-term surgical palliation procedures for young children having

D-transposition of the great arteries. Hence, there is a population of patients in their late 20s to early 50s who have undergone these operations and who are at great risk of having supraventricular arrhythmias (15% to 48%), with similar rates in patients with Mustard and Senning baffles.^{4,11} Most ATs in this patient group are typical AFL, but non-isthmus-dependent macroreentrant ATs with critical zones of slow conduction between a suture line and the SVC orifice, mitral valve annulus, and pulmonary vein orifice have all been described. Focal ATs adjacent to suture lines are also not uncommon. Currently, arterial switch surgery has supplanted atrial redirection as the procedure of choice for D-transposition of the great arteries, and it has been associated with a lower risk of arrhythmias.^{8,10}

Reports suggest that atrial tachyarrhythmias are important contributors to sudden death. Contributing factors may include longer cycle lengths (CLs) than in typical AFL (favoring 1:1 conduction), impaired atrioventricular (AV) transport with failure to augment right ventricular filling rates during tachycardia, systemic ventricular dysfunction, and subendocardial ischemia resulting from right coronary circulation irrigation of a systemic ventricle.⁸

Clinical Presentation

Macroreentrant ATs are typically chronic or long-lasting. As with AF and typical AFL, patients can present with symptoms related to rapid ventricular response, tachycardia-induced cardiomyopathy, or deterioration of preexisting cardiac disease.

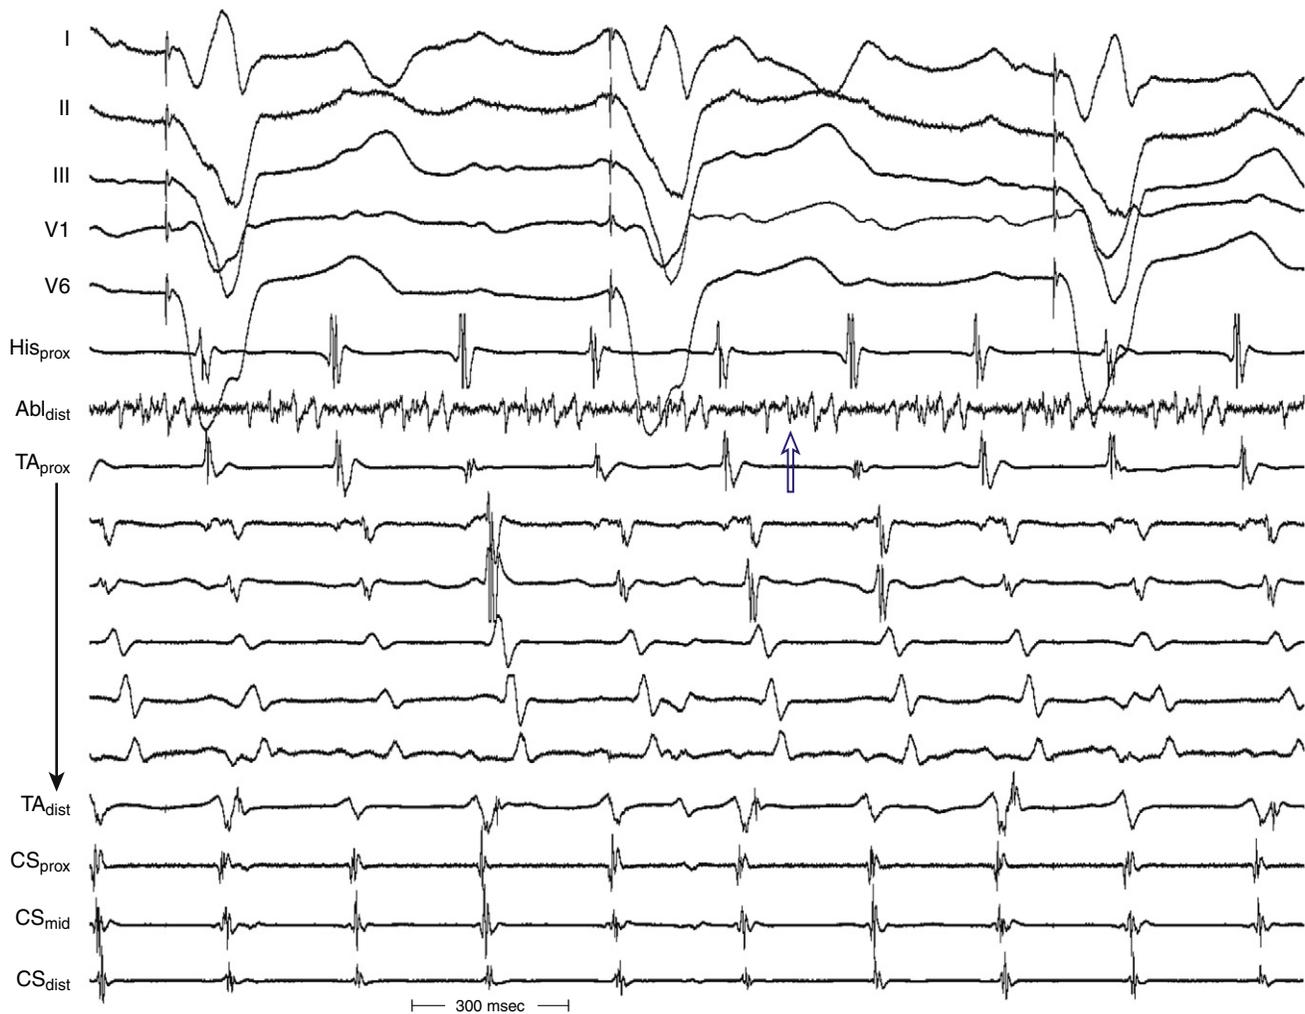

FIGURE 14-4 Postatriotomy right atrial macroreentry (atypical atrial flutter). ECG leads and intracardiac recordings are shown during non-isthmus-dependent macroreentrant atrial tachycardia (AT) in a patient with a repaired atrial septal defect. A prolonged, fractionated diastolic electrogram is observed at the ablation site. Note the repetitive recording (arrow) that nearly spans the cardiac cycle. The patient had a right atriotomy as the basis of AT and incurred complete heart block during surgery (hence the ventricular pacemaker). Abl_{dist} = distal ablation site; CS_{dist} = distal coronary sinus; CS_{mid} = middle coronary sinus; CS_{prox} = proximal coronary sinus; His_{prox} = proximal His bundle; TA_{dist} = distal tricuspid annulus; TA_{prox} = proximal tricuspid annulus.

Generally, in the adult population with congenital heart disease, macroreentrant ATs tend to be slower than typical AFL, with atrial rates in the range of 150 to 250 per minute. In the setting of a healthy AV node (AVN), such rates frequently conduct in a rapid 1:1 AV pattern and can potentially result in hypotension, syncope, or possibly circulatory collapse in patients with limited myocardial reserve. This phenomenon can potentially be compounded by ineffective atrial transport and ventricular dysfunction. Even if the ventricular response rate is well controlled, sustained macroreentrant AT can cause debilitating symptoms in some patients because of the loss of AV synchrony and can contribute to thromboembolic complications when the duration is protracted.⁹

Late-onset supraventricular arrhythmias can potentially have a major impact notably not only on morbidity but also on mortality in patients with congenital heart disease. Not only can arrhythmias be the cause of rapid hemodynamic deterioration, but also they have been linked to an increased risk of sudden death. A multicenter study of defibrillator recipients suggested that supraventricular arrhythmias can trigger ventricular arrhythmias (tachycardia-induced tachycardia). It is likely that the rapid ventricular response is not well tolerated by the impaired ventricle, thus resulting in ventricular tachycardia or fibrillation.^{7,11}

Initial Evaluation

In patients with congenital heart disease, arrhythmia onset can herald a changing hemodynamic profile and can be the first sign of deterioration. Therefore, if arrhythmias occur, a thorough evaluation of the hemodynamic status is warranted.^{7,13}

Additionally, detailed evaluation of cardiac function and anatomy and knowledge of the congenital anomaly and previous surgical procedures are very important. This evaluation can require transthoracic or transesophageal echocardiography, right or left heart catheterization, angiography of the desired cardiac chamber, and cardiac magnetic resonance imaging (MRI).

Principles of Management

Generally, short-term termination of the tachycardia can be successfully achieved with electrical cardioversion, overdrive pacing, or administration of certain class I or class III antiarrhythmic drugs. However, long-term control of the arrhythmia is far more challenging. Chronic anticoagulation for stroke prevention is typically recommended.

Although the use of antiarrhythmic agents from every class has been reported, none of these drugs have demonstrated clear long-term efficacy. Furthermore, most antiarrhythmic agents carry

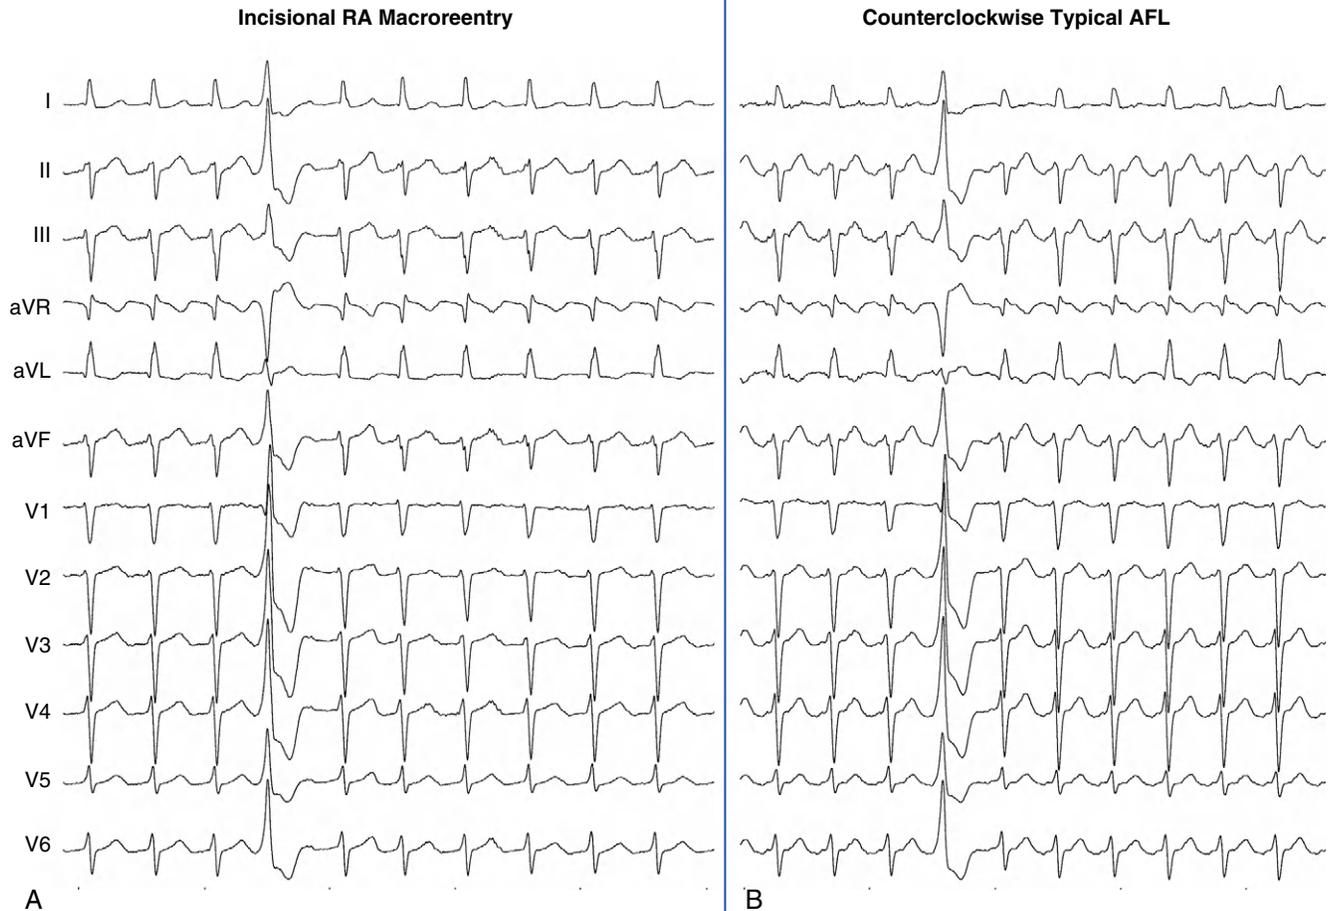

FIGURE 14-5 Surface ECGs of two types of atrial macroreentrant atrial tachycardia in a patient with previous surgical repair of atrial septal defect. **A**, A macroreentrant circuit around the atriotomy scar. **B**, Counterclockwise typical atrial flutter that developed following successful ablation of the scar-related macroreentry. Spontaneous premature ventricular complexes allow better visualization of the P wave (flutter wave) morphology. RA = right atrial; AFL = atrial flutter.

the risk of proarrhythmia, and many agents aggravate sinus node dysfunction and compromise ventricular function, thus diminishing their utility in these patients, particularly in the absence of pacemaker therapy.⁹

Because the general experience with long-term pharmacological therapy has been discouraging, catheter ablation has been adopted as an early intervention for recurrent macroreentrant AT. Catheter ablation carries short-term success rates of nearly 90%, although later tachycardia recurrence is still disappointingly common. The recurrence risk appears to be particularly high in the population of patients who have undergone Fontan procedures. These patients tend to have multiple AT circuits and the thickest and largest atrial dimensions. Nonetheless, ablation results are far superior to the extent of control obtained with medications alone.⁹ It is important to recognize that macroreentrant ATs in patients with congenital heart disease can have complex reentrant circuits, the ablation of which can be far more difficult than ablation of typical AFL. This complexity requires that the electrophysiologist be well acquainted with the details of congenital heart lesions and the types of surgical repairs. Therefore, referral to an experienced center should be considered.

Pacemaker implantation can be useful for those patients who have concomitant sinus node dysfunction as a prominent component of their clinical picture. In these patients, prevention of severe sinus bradycardia not only allows for the use of drugs necessary for rate and rhythm control but also can potentially improve the hemodynamic status and often result in marked reduction in AT frequency. Pacemakers with advanced programming features that incorporate AT detection and automatic burst pacing can also be

beneficial in select cases, but they carry the risk of accelerating the atrial rate and must thus be used cautiously in patients with rapid AV conduction.⁹

Surgical ablation (RA maze procedure) can be considered in patients with AT refractory to medical therapy and catheter ablation or in those requiring reoperation for hemodynamic reasons. This procedure is used most commonly for patients with failing Fontan procedures and the most refractory variety of macroreentrant AT and is usually combined with a revision of the Fontan connection or conversion from an older atriopulmonary anastomosis to a cavopulmonary connection. This typically includes debulking the RA, removing thrombus, excising RA scar tissue, implanting an epicardial pacemaker, performing a modified RA maze procedure, and, in patients with prior documented AF, performing a left-sided maze procedure as well.⁹ Case series with short-term follow-up report promising results, with arrhythmia recurrence rates of 13% to 30%.¹¹

It is also important to understand that although effective tachycardia therapy appears to reduce symptoms and the need for cardioversion and improves quality of life in patients with congenital heart disease, it is unclear at present that it improves survival free of major events. If the target arrhythmia is a marker, rather than a cause of poor outcome, therapy should be directed toward the suppression of symptoms while exposing the patient to minimal risk of procedure-related adverse events. Therefore, depending on the expected complexity of the arrhythmia substrate and the underlying structural heart disease, ablation may be reserved for symptomatic patients who are not responding to, or intolerant of, antiarrhythmic medications. Therapeutic decisions are made case by case.¹

Electrocardiographic Features

As noted, macroreentrant ATs in the adult population with congenital heart disease tend to have relatively slow atrial rates (in the range of 150 to 250 per minute), and can be associated with 1:1 AV conduction.

The surface ECG morphology of RA free wall macroreentry in a patient with a previous atriotomy is highly variable. The presence of complex anatomy secondary to congenital abnormalities, prior atrial surgery, or large low-voltage zones can modify P wave propagation in nonuniform manner, with resulting altered atrial activation vectors or low-amplitude P waves.¹⁴

P wave morphology on the surface ECG is usually of limited value for precise anatomical localization of macroreentrant circuits. Even typical isthmus-dependent AFL frequently manifests with an atypical 12-lead ECG appearance (so-called pseudoatypical flutter) in the setting of markedly complex congenital malformation or surgical correction, or both.

Variation in the direction of wavefront rotation, the presence of coexisting conduction block in the atrium, and the presence of simultaneous typical AFL can add to the variability of P wave morphology. Additionally, analysis of the flutter wave can be impeded by partial or complete concealment of the P wave within the QRS complexes or T waves when the AT is associated with 1:1 or 2:1 AV conduction.

The morphology of the atrial complex on the surface ECG can range from that similar to typical AFL to that characteristic of focal AT (see Fig. 14-5). Often, inverted flutter waves can be observed in lead V₁. Depending on the predominant direction of septal activation, RA free wall macroreentrant AT can mimic either clockwise or counterclockwise typical AFL.¹⁴

Mapping

Detailed knowledge of the of the patient's congenital and operative anatomy is important in the interpretation of the results of mapping, in ascertaining how to access the RA, in determining the feasibility of the transseptal puncture, and in deciding whether fluoroscopy is helpful in localizing the catheters or whether intracardiac or transesophageal echocardiography is needed. Careful preprocedural planning includes a detailed review of prior operative notes, hemodynamic catheterization reports, angiography, and other imaging studies (echocardiography, cardiac computed tomography [CT], or MRI).¹³ Table 14-1 includes those conditions that are expected to pose vascular or cardiac chamber access

challenges and methods that have been reported to allow catheter access. There is often limited opportunity to place the standard number of diagnostic electrode catheters; alternative approaches to pacing and recording may include the esophagus and hepatic veins and a retrograde approach to the atria from the ventricles.¹⁰

Exclusion of Cavotricuspid Isthmus Dependence

Exclusion of the CTI as part of the AT circuit is an important initial step because typical clockwise or counterclockwise AFL is the most common macroreentrant AT in patients with congenital heart disease (particularly in patients with simpler anatomical lesions such as the tetralogy of Fallot and atrial and ventricular septal defects), even if the P wave morphology is not characteristic for these arrhythmias. Isthmus-dependent AFL can be rapidly diagnosed or excluded by mapping of the tricuspid annulus and by entrainment maneuvers at the CTI. Exclusion of the CTI as part of the reentrant circuit can be established by any of the following: (1) demonstration of bidirectional activation of the CTI during AT, with resulting collision or fusion within the isthmus by activation from opposing directions (the low lateral RA and coronary sinus [CS]); (2) recording of double potentials separated by an isoelectric and constant interval throughout the full extent of the CTI during tachycardia; or (3) entrainment mapping from the CTI demonstrating manifest atrial fusion with a long post-pacing interval.⁴

Identification of Barriers and Potential Lines of Block

If typical AFL is excluded, attention should be directed to potential reentrant circuits anchored by a right lateral atriotomy scar or a surgical patch. Subsequently, more complex or dual- or multiple-loop reentrant circuits (especially in patients with complex congenital malformations) should be considered; these require a more comprehensive and detailed mapping approach.

Mapping of macroreentrant ATs in patients with congenital heart disease follows the same principles discussed for mapping of other types of macroreentrant ATs (see Chap. 13 for detailed discussion). Electromagnetic three-dimensional (3-D) mapping (CARTO mapping system [Biosense Webster, Inc., Diamond Bar, Calif.] or EnSite NavX system [St. Jude Medical, St. Paul, Minn.]) is typically used to help facilitate identification of the macroreentrant circuit and the sequence of atrial activation during tachycardia and rapid visualization of the activation wavefront in the context of the relevant

anatomy. Integration of preacquired cardiac CT or MRI images on the 3-D shell of the cardiac chamber created with the electroanatomical system can further facilitate the procedure. Angiography of the desired chamber may be considered.^{4,13} Noncontact mapping may also be used to define the atrial substrate and reentrant circuit, and it can be of significant value when the flutter is short-lived or cannot be reproducibly initiated.

Initially, potential tachycardia circuit barriers are identified (during sinus rhythm or tachycardia) and marked on the electroanatomical map to help understand propagation of the reentrant activation wavefront in relation to these barriers, identify potential slow-conducting pathways critical to the reentrant circuit, identify sites to target by entrainment mapping, and plan subsequent ablation strategy to abolish the tachycardia. The tricuspid annulus often provides one important barrier. Other naturally fixed barriers (i.e., independent of the precise form of activation and present also in sinus rhythm) include the IVC, SVC, and CS ostium. Acquired barriers include surgical incisions or patches, lines of block, and electrical scars. Silent areas are defined as having an atrial potential amplitude of less than 0.05 mV and the absence of atrial capture at 20 mA. Such areas and surgically related scars, such as atriotomy scars in the lateral RA or atrial septal defect closure patches, are tagged as “scar” (see Figs. 14-1 and 14-2).^{3,4,13}

Identification of the Complete Reentrant Circuit

Activation electroanatomical mapping during AT is performed to define the atrial activation sequence and identify the complete reentrant circuit and its mid-diastolic critical isthmus. Reasonable numbers of points homogeneously distributed in the atrium must be recorded. The local activation time at each site is determined from the intracardiac bipolar electrogram and is measured in relation to the fixed intracardiac electric reference (usually an electrogram obtained from the CS catheter). The complete reentrant circuit is the spatially shortest route of unidirectional activation encompassing the complete CL of the tachycardia in terms of activation timing and returning to the site of earliest activation. Using electroanatomical mapping, this translates into continuous progression of colors (from red to purple in the CARTO system and from white to purple in the NavX system) around the atrium, with close proximity of earliest and latest local activation. Additionally, propagation of electrical activation superimposed on the 3-D anatomical reconstruction of the atrium can be visualized as a propagation map in relation to the anatomical and EP landmarks and barriers.

Unlike in mapping focal AT, in which tracking the site with the earliest presystolic local activation timing is the goal of mapping, there is no early or late region for macroreentrant AT because the wavefront is continuously propagating around the circuit.

It is very important to remain vigilant during the mapping process and identify any change in CL or activation sequence, or both, that can result from catheter manipulation, pacing maneuvers, or ablation. Such changes can indicate transformation of a multiple loop tachycardia by interruption of one loop, change in bystander activation, or transition to another tachycardia, which requires reassessment. The transition may be obvious but also is often quite subtle and sometimes imperceptible if only the CS activation is analyzed. Simultaneous recording RA activation (using a Halo catheter around the tricuspid annulus) and CS activation (using a decapolar catheter) can help rapid identification of tachycardia transformation.¹⁵

Sometimes, it can be impossible to map the entire circuit, especially in patients with repaired congenital heart disease, because of the complex suture lines, baffles, or both. In this setting, a combination of activation, entrainment, and voltage mapping data is used to identify the potential isthmus or zone of slow conduction critical to the reentrant circuit, which is then targeted by catheter ablation.⁴

Identification of the Critical Isthmus

Once one or more potential isthmuses are identified during activation mapping and propagation mapping in relation to atrial scars,

barriers, and lines of block, entrainment is performed to determine their role for supporting the reentrant circuit. Entrainment with concealed fusion should be sought; this indicates that the pacing site is in a protected isthmus located within or attached to the reentrant circuit. It is important to understand, however, that in patients with complex anatomy and surgical repairs, critical corridors of slow conduction can exist anywhere in the RA mass, and multiple circuits are the rule. As a consequence, entrainment with concealed fusion is highly nonspecific for most circuits in these patients. Therefore, whether the protected isthmus is crucial to the reentrant circuit or just a bystander site needs to be verified by comparing the post-pacing interval with the tachycardia CL and the stimulus-exit interval with the electrogram-exit interval. Features of entrainment when pacing from different sites are listed in Table 13-2.^{10,16,17}

Ablation

Target of Ablation

The choice of ablation sites should be among those segments of the reentry circuit that offer the most convenient and safest opportunity for creating conduction block. Among other factors are the isthmus size, anticipated catheter stability, and risk of damage to adjacent structures (e.g., phrenic nerve, sinus node, and AVN).

Ablation is performed by targeting the narrowest identifiable isthmus of conduction accessible within the circuit (allowing the best electrode-tissue contact along the desired line). The ablation line is chosen to transect an area critical for the circuit and, at the same time, connect two anatomical areas of block, an electrically silent area to an anatomical zone of block (e.g., IVC, SVC, or tricuspid annulus), or two electrically silent areas.

Although success in most of these studies has been achieved by targeting the “slow zone” of atrial conduction presumed necessary for maintenance of the reentry, some investigators have emphasized the need for considering both the anatomy and electrophysiology simultaneously to identify a susceptible bridge of tissue, which connects two areas of electrical block. Such an approach requires careful review of the details of the atrial surgery, in addition to detailed mapping of the atria in its “usual” rhythm and during reentry.⁴

Because typical isthmus-dependent AFL is the most common mechanism underlying macroreentrant AT in the patient population with congenital heart disease, determination of the role of the CTI in supporting reentry is evaluated first, and this isthmus is targeted by ablation if it is proved to be critical to the AT circuit (see Chap. 12 for detailed discussion). Ablation of the CTI may also be reasonable in every patient with congenital heart disease, even patients presenting with non-isthmus-dependent RA macroreentry, because the CTI can support reentry in most patients with prior right atriotomy.

Successful CTI ablation can result in termination of the tachycardia and restoration of sinus rhythm, thus confirming participation of the CTI in the circuit. Alternatively, the tachycardia may transform to a different arrhythmia, as indicated by a change in activation sequence or CL, or both. Additionally, after extensive ablation and even appearance of dissociated electrograms in the CTI, AT may persist with little discernible change in CL or activation sequence. This usually indicates multiple circuits, often with a double-loop type of reentry that uses the lateral wall as well as the CTI, and is now dependent on a different isthmus (e.g., the lateral RA around or within the atriotomy scar).¹⁸

If participation of the CTI in the reentrant circuit is excluded, or if the tachycardia persists or transforms into a different tachycardia after ablation of the CTI, the participation of the lateral RA wall in the AT circuit should be assessed. Non-isthmus-dependent RA macroreentry is frequently localized to the free wall of the RA, anchored by the atriotomy scar, in which setting the ablation strategy includes any of the following: (1) to target the slow conduction area (critical isthmus of the reentrant circuit) as identified by detailed activation and entrainment mapping; (2) to extend the

atriotomy (double potential or scar) to the IVC (see Fig. 14-1); or (3) to extend the scar area to the SVC. The last approach can result in injury of the sinus node or phrenic nerve. Therefore, when possible, extending the atriotomy to the IVC is preferable. As noted, additional ablation of the CTI may be considered in these patients because these circuits are often combined with a circuit around the tricuspid annulus in a figure-of-8 reentry, such that ablation of both the CTI and one of the lateral wall options must be performed to eliminate and prevent reentrant AT.^{4,18}

Rarely, more complex circuits, such as around the right septal patch, as seen in patients with Mustard or Senning repairs, are observed. However, the approach to ablation is the same: the area with slow conduction or scar is extended to an anatomical obstacle.

Another focus for reentry circuits is the sinus node region, possibly because of injury related to the superior atrial cannulation site for the bypass pump. These circuits may be quite small, often manifesting as focal tachycardia in the sinus node region, and they can often be ablated in a single location without establishing a particular line of block.⁴

In patients with incomplete maps, a combination of activation, entrainment, and voltage mapping data is used to identify the potential isthmus or zone of slow conduction critical to the reentrant circuit, which is then targeted by catheter ablation. When limitations to this approach still exist (from poor inducibility or frequent change in morphology of the tachycardia), a stepwise ablation strategy may be employed. Because the reentrant circuit in most patients is anchored to the CTI or the atriotomy scar, or both, ablation of the CTI is initially performed. Then, if the tachycardia persists, linear ablation is carried out by targeting the isthmuses related to the lateral atriotomy scar (i.e., connecting the atriotomy to either the IVC or SVC). Additional ablation lines connecting other areas of conduction block (scar, surgical incision, septal patch, baffle, or natural barriers) may be considered based on substrate mapping findings.⁴

Ablation Technique

Once the ablation target is identified, ablation involves placing a series of RF lesions to sever the critical isthmus to connect two anatomical or surgical barriers. Because some congenital malformations and surgical repairs are associated with myocardial hypertrophy and extensive fibrotic regions, thus making the achievement of a transmural lesion difficult, ablation is performed with an irrigated (25 to 50 W) or 8-mm (target temperature, 60° to 70°C; 50 to 60 W) electrode-tip RF catheter.¹⁸

RF application is maintained for up to 60 to 120 seconds until the bipolar atrial potential recorded from the ablation electrode is decreased by 80% or split into double potentials, indicating local conduction block. The coalescence of multiple RF lesions can be facilitated by the use of an electroanatomical mapping system.

During delivery of RF energy, the tachycardia can terminate, or its CL can increase transiently or permanently. These findings indicate that the lesions have affected the circuit and should lead to continuation of RF delivery or extension of the lesion to ensure the achievement of complete conduction block across the isthmus. Alternatively, the tachycardia may transform to a different loop or to a different tachycardia (rather than terminate), as indicated by a change in activation sequence or CL, or both, in which setting reassessment of the new tachycardia mechanism and location is necessary before continued RF ablation. However, if ablation across an isthmus that was initially found to be critical to the tachycardia circuit (by entrainment mapping techniques) appears to be not affecting the tachycardia, it is important to verify whether the isthmus is still critical to the reentrant circuit by repeating entrainment mapping. Sometimes, complete isthmus block is already achieved (as suggested by the presence of double potentials along the ablation line), and the isthmus is no longer participating in the tachycardia circuit (as suggested by entrainment mapping findings), as a result of a change in the tachycardia circuit that occurred during ablation.^{15,19,20}

Ablation near the region of the superior crista terminalis and SVC can result in right phrenic nerve injury and diaphragmatic paralysis.

Pacing with a high output (10 mA at 2 milliseconds) from the ablation catheter at the target site can help identify the location of the right phrenic nerve. Additionally, suspicion of phrenic nerve injury should be considered in the case of hiccup, cough, or decrease in diaphragmatic excursion during energy delivery. Early recognition of phrenic nerve injury during RF delivery allows the immediate interruption of the application prior to the onset of permanent injury and is associated with the rapid recovery of phrenic nerve function.⁴

Endpoints of Ablation

TACHYCARDIA TERMINATION DURING RADIO-FREQUENCY ENERGY APPLICATION

Sudden termination of AT during RF application suggests that the lesion has affected a critical isthmus, and that site should be targeted for additional lesions. However, AT termination during RF application as the sole criterion of a successful ablation is hazardous because such an AT can also terminate spontaneously, secondary to premature atrial complexes induced by RF energy delivery, and by partial, rather than complete, isthmus block. Therefore, termination of AT during RF application is insufficient by itself as an endpoint.^{4,18}

NONINDUCIBILITY OF TACHYCARDIA

To use this criterion as a reliable endpoint, careful assessment of inducibility should be performed prior to ablation, and the feasibility and best method of reproducible induction of the AT should be documented at baseline before ablation. In the setting of easy inducibility prior to ablation, one can consider the lack of inducibility as an indicator of successful ablation. Noninducibility of the arrhythmia is inapplicable if the original arrhythmia either is noninducible at baseline or was inadvertently terminated mechanically. Noninducibility may also reflect conduction delay in the critical isthmus, and not stable block, or it may be secondary to changes in autonomic tone.^{4,18}

DOCUMENTATION OF A LINE OF BLOCK

Complete stable conduction block within the reentry path is the most useful and objective endpoint for ablation of macroreentrant AT. Complete conduction block following linear ablation across the isthmus can be confirmed by atrial pacing on one side of the ablation line and mapping along the line demonstrating absence of electrograms or the presence of widely separated parallel double potentials recorded all along the line with marked delay and reversal in the direction of activation on the opposite side of the linear lesion. For a vertically oriented RA free wall atriotomy, assessment of conduction block can be facilitated by the use of a multielectrode Halo-type catheter, which can document activation sequences anterior and posterior to the scar, so that when pacing close to the contiguously ablated isthmus, the absence of a wavefront penetrating the scar and isthmus is used to indicate conduction block. Additionally, assessment of electrical block across the ablation line can be facilitated by the use of the non-contact mapping system (EnSite, St. Jude Medical, St. Paul, Minn.), which allows for simultaneous mapping of the entire chamber of interest (versus sequential point-by-point mapping) during pacing on either side of the ablation line.^{4,18}

Outcome

Atrial enlargement and myocardial hypertrophy and extensive scarring in patients with congenital heart disease can interfere with RF energy delivery and limit RF lesion depth. Additionally, the complexity of anatomy, vascular access issues, and the multiplicity of circuits in some patients can render the mapping and ablation procedure very challenging. Nonetheless, the combined use of 3-D mapping and tip cooling techniques has improved acute success

rates to nearly 90%. However, high recurrence rates and the onset of new arrhythmias remain problematic (up to 30% to 45% within the first year), which may be related, at least in part, to ongoing changes in the arrhythmia substrate.⁸

Importantly, in some congenital heart malformations (e.g., AV canal defects), the AVN is displaced just anterior to the mouth of the CS. Consequently, ablating in the right inferior paraseptal region can cause AV block. Therefore, for patients with CTI-dependent macroreentry, lateral ablation lines are generally preferred, to prevent AV block.¹⁰

Pathophysiology

Classification of Atrial Fibrillation

Atrial fibrillation (AF) has been described in various ways, such as paroxysmal or persistent, lone, idiopathic, nonvalvular, valvular, or self-terminating. Each of these classifications has implications regarding mechanisms, as well as response to therapy. At the initial detection of AF, it may be difficult to be certain of the subsequent pattern of duration and frequency of recurrences. Thus, a designation of first-detected episode of AF is made on the initial diagnosis, irrespective of the duration of the arrhythmia. When the patient has experienced two or more episodes, AF is classified as recurrent. After the termination of an episode of AF, the rhythm can be classified as paroxysmal or persistent. *Paroxysmal AF* is characterized by self-terminating episodes that generally last less than 7 days. *Persistent AF* generally lasts longer than 7 days and often requires electrical or pharmacological cardioversion. *Permanent AF* refers to AF in which cardioversion has failed or AF that has been sustained for

more than 1 year, or when further attempts to terminate the arrhythmia are deemed futile. With the advent of catheter ablation interventions for AF, patients with persistent AF for longer than 1 year who are considered for ablation have been referred to as having *longstanding persistent AF*, to distinguish them from patients with permanent AF in whom attempts to restore normal sinus rhythm (NSR) were unsuccessful or have been abandoned.^{1,2}

Although useful, this arbitrary classification does not account for all presentations of AF. Paroxysmal AF often progresses to longer, non-self-terminating episodes. Additionally, the pattern of AF can change in response to treatment. AF that has been persistent can become paroxysmal with antiarrhythmic drug therapy, and AF that had been permanent may be cured or made paroxysmal by surgical or catheter-based ablation. Furthermore, the distinction between persistent and permanent AF is not only a function of the underlying arrhythmia but also a reflection of the clinical pragmatism of the patient and physician. The severity of symptoms associated with AF, anticoagulation status, and patient preference all affect the

decision of whether and when cardioversion will be attempted. This decision would then affect the duration of sustained AF and could lead to a diagnosis of persistent or permanent AF.³

Mechanism of Atrial Fibrillation

The pathogenesis of AF remains incompletely understood and is believed to be multifactorial. Two concepts of the underlying mechanism of AF have received considerable attention: factors that trigger and factors that perpetuate the arrhythmia. In general, patients with frequent, self-terminating episodes of AF are likely to have a predominance of factors that trigger AF, whereas patients with AF that does not terminate spontaneously are more likely to have a predominance of perpetuating factors. Although such a gross generalization has clinical usefulness, there is often considerable overlap of these mechanisms. The typical patient with paroxysmal AF has identifiable ectopic foci initiating the arrhythmia, but these triggers cannot be recorded in all patients. Conversely, occasional patients with persistent or permanent AF may be cured of their arrhythmia by ablation of a single triggering focus, a finding suggesting that perpetual firing of the focus may be the mechanism sustaining this arrhythmia in some cases.

Advanced mapping technologies, along with studies in animal models, have suggested the potential for complex pathophysiological substrates and modifiers responsible for AF, including the following: (1) continuous aging or degeneration of atrial tissue and the cardiac conduction system; (2) progression of structural heart disease (e.g., valvular heart disease and cardiomyopathy); (3) myocardial ischemia, local hypoxia, electrolyte derangement, and metabolic disorders (e.g., atherosclerotic heart disease, chronic lung disease, hypokalemia, and hyperthyroidism); (4) inflammation related to pericarditis or myocarditis, with or without cardiac surgery; (5) genetic predisposition; (6) drugs; and (7) autonomic effects.²

MECHANISM OF INITIATION OF ATRIAL FIBRILLATION

The factors responsible for the onset of AF include triggers that induce the arrhythmia and the substrate that sustains it. The triggers are diverse yet may not cause AF in the absence of other contributors. There are two different types of arrhythmias that can potentially play a role in generating AF: premature atrial complexes (PACs) that initiate AF (focal triggers) and focal tachycardia that either induces fibrillation in the atria or mimics AF by creating a

pattern of rapid and irregular depolarization wavefronts in the atria for as long as the focus continues to discharge.^{2,4}

The mechanism of initiation of AF is not certain in most cases and likely is multifactorial. Triggers propagating into the atrial myocardium can initiate multiple reentering wavelets and AF. In some patients with paroxysmal AF, impulses initiated by ectopic focal activity propagate into the left atrium (LA) and encounter heterogeneously recovered tissue. If reentry were assumed to be the mechanism of AF, initiation would require an area of conduction block and a wavelength of activation short enough to allow the reentrant circuits to persist in the myocardium.^{2,4}

Once triggered, AF can be self-sustained, in which case the continued firing of the focus may not be required for maintenance of the arrhythmia, and ablation of the focus may not terminate AF, but rather may prevent the reinitiation of AF. Conversely, initiation and maintenance of AF can depend on uninterrupted periodic activity of a few discrete reentrant or triggered sources localized to the LA (i.e., focal driver), emanating from such sources to propagate through both atria and interact with anatomical or functional obstacles, or both, thus leading to fragmentation and multiple wavelet formation. Factors such as wavefront curvature, sink-source relationships, and spatial and temporal organization all are relevant to the understanding of the initiation of AF by the interaction of the propagating wavefronts with such anatomical or functional obstacles. Indeed, all these factors, which differ from triggers, importantly affect the initiators of AF.

AF triggering factors include sympathetic or parasympathetic stimulation, bradycardia, PACs (which are the most common cause; Fig. 15-1), atrial flutter (AFL), supraventricular tachycardias (SVTs); especially those mediated by atrioventricular [AV] bypass tracts [BTs]; Fig. 15-2), and acute atrial stretch. Identification of these triggers has clinical importance because treatment approaches directed at elimination of the triggers (e.g., radiofrequency [RF] ablation of the initiating PACs or SVT) can be curative in selected patients.

PULMONARY VEIN TRIGGERS. Triggering foci of rapidly firing cells within the sleeves of atrial myocytes extending into the pulmonary veins (PVs) have been clearly shown to be the underlying mechanism in most cases of paroxysmal AF.⁴ Supporting this idea are clinical studies of impulses generated by single foci propagating from individual PVs or other atrial regions to the remainder of the atria as fibrillatory waves and abolition of AF by RF ablation to eliminate or isolate the venous foci.

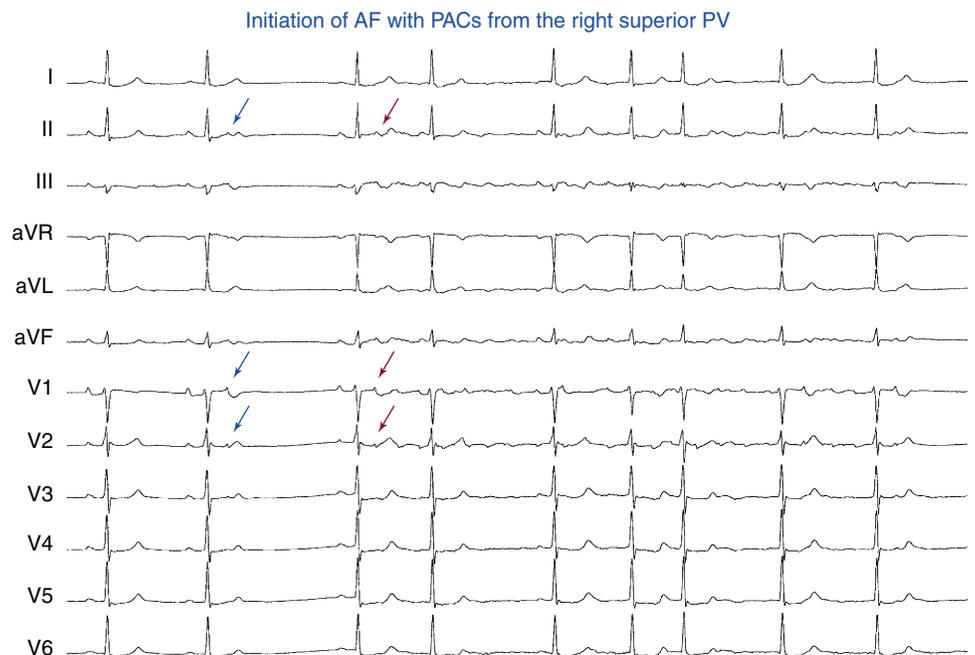

FIGURE 15-1 Atrial fibrillation (AF) induction by premature atrial complexes (PACs) originating from the right superior pulmonary vein (PV). Two monomorphic PACs (arrows) occur at short coupling intervals and are inscribed within the T wave. The second PAC (red arrows) triggers AF.

Based on several features, the thoracic veins are highly arrhythmogenic. The PV-LA junction has discontinuous myocardial fibers separated by fibrotic tissues and hence is highly anisotropic. Insulated muscle fibers can promote reentrant excitation, automaticity, and triggered activity. These regions likely resemble the juxtaposed islets of atrial myocardium and vascular smooth muscle in the coronary sinus (CS) and AV valves that, under normal circumstances, manifest synchronous electrical activity but develop delayed afterdepolarizations and triggered activity in response to catecholamine stimulation, rapid atrial pacing, or acute stretch.⁵

Furthermore, the PVs of patients with paroxysmal AF demonstrate abnormal properties of conduction so that there can be markedly reduced refractoriness within the PVs, progressive conduction delay within the PV in response to rapid pacing or programmed stimulation, and often conduction block between the PV and the LA. Such findings are much more common in patients with paroxysmal AF than in normal subjects.^{2,6} Rapidly firing foci can often be recorded within the PVs with conduction block to the LA. Administration of catecholamines such as isoproterenol can lead to shortening of the LA refractory period, thereby allowing these foci to propagate to the LA with the induction of AF.⁶ These discontinuous properties of conduction within the PV can also provide a substrate for reentry within the PV itself, although this remains to be proven.⁵

NON-PULMONARY VEIN TRIGGERS. Although more than 90% of triggering foci that are mapped during electrophysiological (EP) studies in patients with paroxysmal AF occur in the PVs, foci within the superior vena cava (SVC), small muscle bundles in the ligament of Marshall, and the musculature of the CS have been identified. Although these latter locations of triggering foci are uncommon in patients with paroxysmal AF, the common factor is that the site of origin is often within a venous structure that connects to the atrium. Other sites of initiating foci can be recorded in the LA wall or along the crista terminalis in the right atrium (RA).⁵

MECHANISM OF MAINTENANCE OF ATRIAL FIBRILLATION

Having been initiated, AF can be brief; however, various factors can act as perpetuators, thus ensuring the maintenance of AF.² One factor is the persistence of the triggers and initiators that induced the AF, which then act as an engine driving the continuation of AF. In this setting, maintenance of AF is dependent on the continued firing of the focus (the so-called focal driver). However, AF can persist even in the absence of the focal drivers. Without focal drivers, persistence of AF results from a combination of electrical and structural remodeling processes characterized by atrial dilation and shortening of atrial refractoriness (see later). These factors can be present at baseline or, alternatively, induced by the AF itself.

Several theories have been proposed to explain the EP mechanisms underlying AF, including the multiple wavelet theory, the

single circuit reentry theory, and rapidly discharging atrial focus with fibrillatory conduction.

MULTIPLE WAVELET THEORY. For many years, the most widely held theory on the maintenance of AF was the multiple wavelet hypothesis, which was a key development in our understanding of the mechanism of AF. Moe and associates noted that, “The grossly irregular wavefront becomes fractionated as it divides about islets or strands of refractory tissue, and each of the daughter wavelets may now be considered as independent offspring. Such a wavelet may accelerate or decelerate as it encounters tissue in a more or less advanced state of recovery.”⁷ Moe and associates subsequently hypothesized that AF is sustained by multiple randomly wandering wavelets that collided with each other and were extinguished, or divided into daughter wavelets that continually reexcited the atria.⁷ Those functional reentrant circuits are therefore unstable; some disappear, whereas others reform. These circuits have variable, but short, cycle lengths (CLs), resulting in multiple circuits to which atrial tissue cannot respond in a 1:1 fashion. As a result, functional block, slow conduction, and multiple wavefronts develop. It has been suggested that at least four to six independent wavelets are required to maintain AF. These wavelets rarely reenter themselves but can reexcite portions of the myocardium recently activated by another wavefront, a process called random reentry. As a result, there are multiple wavefronts of activation that can collide with each other and extinguish themselves or create new wavelets and wavefronts, thereby perpetuating the arrhythmia.

The persistence of multiple-circuit reentry depends on the ability of a tissue to maintain enough simultaneously reentering wavefronts so that electrical activity is unlikely to extinguish simultaneously in all parts of the atria. Therefore, the more wavelets are present, the more likely it is that the arrhythmia will be sustained. The number of wavelets on the heart at any moment depends on the atrial mass, refractory period, conduction velocity, and anatomical obstacles in different portions of the atria. In essence, a large atrial mass with short refractory periods and conduction delay would yield increased wavelets and would present the most favorable situation for AF to be sustained.^{2,8}

SINGLE CIRCUIT REENTRY THEORY. Studies in isolated human atrial preparations questioned the randomness of atrial activity and suggested the presence of a single source of stable reentrant activity (“mother rotor”) that serves as a periodic background focus, with break-up of emanating waves in atrial tissue of variable electrical properties and anatomical obstacles into multiple wavelets spreading in various directions. Although well represented in animal studies, rotors have not been observed in whole human atria studied at the time of thoracic surgery. More recent data using different techniques have shown that functional reentry (or anatomical reentry with a functional component), in the form of spiral waves rotating around microreentrant circuits approximately 1 cm in diameter, was suggested to be the most likely cause of AF. Other studies have shown that these dominant

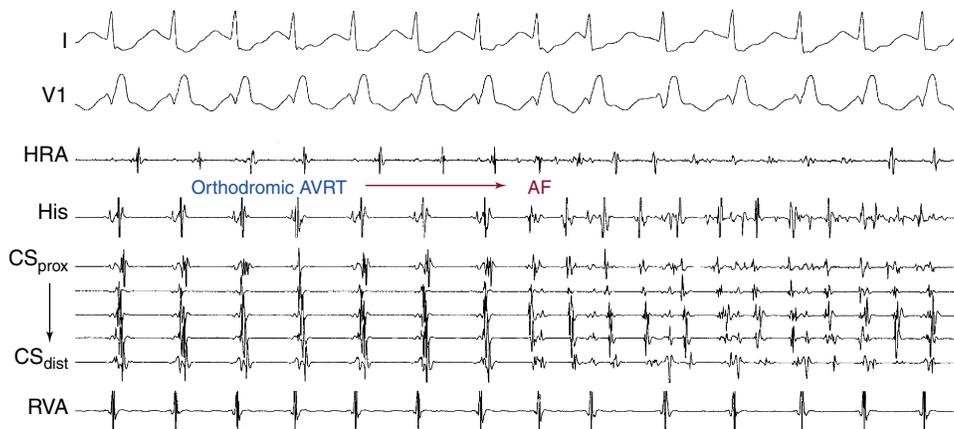

FIGURE 15-2 Atrial fibrillation (AF) induction by orthodromic atrioventricular reentrant tachycardia (AVRT). CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

rotors that drive AF invariably originate and anchor in the LA, with the RA activated passively.^{8,9}

FOCAL DRIVERS WITH FIBRILLATORY CONDUCTION. Although multiple wandering wavelets probably account for most cases of AF, occasionally a single, rapidly firing focus can be identified with EP mapping. Impulses initiated by ectopic focal activity propagate into the atria to encounter heterogeneously recovered tissue. When cardiac impulses are continuously generated at a rapid rate from any source or any mechanism, they activate the tissue of that cardiac chamber in a 1:1 manner, up to a critical rate. However, when this critical rate is exceeded, so that not all the tissue of that cardiac chamber can respond in a 1:1 fashion (e.g., because the CL of the driver is shorter than the refractory periods of those tissues), fibrillatory conduction develops. Fibrillatory conduction can be caused by spatially varying refractory periods or by the structural properties of atrial tissue, with source-sink mismatches providing spatial gradients in the response.² Thus, fibrillatory conduction is characterized by activation of tissues at variable CLs, all longer than the CL of the driver, because of variable conduction block. In that manner, activation is fragmented.² This is the mechanism of AF in several animal models in which the driver consists of a stable, abnormally automatic focus of a very short CL, a stable reentrant circuit with a very short CL, or an unstable reentrant circuit with a very short CL. It also appears to be the mechanism of AF in patients in whom activation of the atria at very short CLs originates in one or more PVs. The impulses from the PVs seem to precipitate and maintain AF. Autonomic influences (parasympathetic or sympathetic) can cause some of these rapid discharges. Of note, it has also been suggested that fibrillatory conduction caused by a reentrant driver can potentially be the cause of ventricular fibrillation (VF).

Substrate for Atrial Fibrillation

AF results from the interplay between a trigger for initiation and a vulnerable EP substrate for maintenance. The fact that most potential triggers do not initiate AF suggests some role for functional and structural substrates in most patients. However, the relative contribution of triggers versus substrate can vary with the clinical context, and the exact nature of the interaction between triggers and substrate remains to be elucidated.⁸

AF commonly occurs in the context of other cardiac or non-cardiac pathological conditions, such as valvular disease, hypertension, ischemic heart disease, heart failure, or hyperthyroidism. Depending on the type, extent, and duration of such external stressors, a cascade of time-dependent adaptive, as well as maladaptive, atrial responses develops in order to maintain homeostasis (so-called atrial remodeling), including changes at the ionic channel level, cellular level, or extracellular matrix level, or a combination of these, thus resulting in structural, functional, and electrical consequences. A hallmark of atrial structural remodeling is atrial dilation, often accompanied by a progressive increase in interstitial fibrosis. Atrial arrhythmias, especially AF, are the most common manifestations of electrical remodeling.¹⁰

Increased dispersion in atrial refractoriness and inhomogeneous dispersion of conduction abnormalities, including block, slow conduction, and dissociation of neighboring atrial muscle bundles, are key elements in the development of the substrate of AF. Importantly, different pathological conditions can be associated with a different set of remodeling responses in the atria.¹¹

Even in the setting of lone AF, whereby no structural heart disease is apparent, there is accumulating evidence that occult abnormalities (e.g., patchy fibrosis, inflammatory infiltrates, loss of myocardial voltage, conduction slowing, altered sinus node function, and vascular dysfunction) can be observed and likely represent an early stage of atrial remodeling contributing to the substrate of AF.¹²

ATRIAL ELECTROPHYSIOLOGICAL PROPERTIES

The normal atrial myocardium consists of so-called fast response tissues that depend on the rapidly activating sodium (Na^+) current

for phase 0 of the action potential. As a result, the atrium has several properties that permit the development of very complex patterns of conduction and an extremely rapid atrial rate, as seen in AF. The action potential duration is relatively short, reactivation can occur partially during phase 3 and usually completely within 10 to 50 milliseconds after return to the diastolic potential, the refractory period shortens with increasing rate, and very rapid conduction can occur.

Patients with lone AF appear to have increased dispersion of atrial refractoriness, which correlates with enhanced inducibility of AF and spontaneous episodes. Some patients have site-specific dispersion of atrial refractoriness and intraatrial conduction delays resulting from nonuniform atrial anisotropy. This appears to be a common property of normal atrial tissue, but there are further conduction delays to and within the posterior triangle of Koch in patients with induced AF, a finding suggesting an important role for the low RA in the genesis of some forms of AF.

ATRIAL FIBROSIS

Atrial fibrosis plays an important role in the pathophysiology of AF. Atrial fibrosis results from various cardiac insults that share common fibroproliferative signaling pathways. Fibrotic myocardium exhibits slow and inhomogeneous conduction, likely secondary to reduced intercellular coupling, discontinuous branching architecture, and zigzagging circuits. When combined with inhomogeneous dispersion of refractoriness within the atria, conduction block provides an ideal substrate for reentry. The greater the slowing of conduction velocity is in scarred myocardium, the shorter the anatomical circuit will need to be to sustain a reentrant wavelet. In fact, reentrant circuits need be only a few millimeters in length in discontinuously conducting tissue. Thus, atrial regions with advanced fibrosis can be local sources for AF. Such a hypothesis would not preclude the remainder of the atria from showing fibrillatory conduction or intact, functional reentrant waves, or both.^{10,13}

The normal aging process results in anatomical changes likely to yield inhomogeneous conduction that can potentially create the milieu necessary for the development of reentry. These changes are probably magnified by the presence of certain disease processes, such as hypertension, coronary artery disease, and heart failure. The strong association of sinus node dysfunction and AF (the bradycardia-tachycardia syndrome) also suggests that replacement of atrial myocytes by interstitial fibrosis likely plays an important part in the pathogenesis of AF in older adults, although in some instances the bradycardia component is a functional response to the tachycardia. Furthermore, AF itself seems to produce various alterations of atrial architecture that further contribute to atrial remodeling, mechanical dysfunction, and perpetuation of fibrillation. Longstanding AF results in loss of myofibrils, accumulation of glycogen granules, disruption in cell-to-cell coupling at gap junctions, and organelle aggregates.¹⁰

Changes in AF characteristics during evolving fibrosis also have a direct impact on why electrical or drug treatment, or both, ultimately fails to achieve conversion to NSR. In the markedly fibrotic and discontinuous atrial tissue, characterized by discontinuous anisotropy, a marked degree of gap junctional uncoupling, and fiber branching, the safety factor for propagation is higher than in normal tissue. As a consequence, blocking of the Na^+ current to the same degree as is necessary for the termination of functional reentry may not terminate reentry caused by slow and fractionated conduction in fibrotic scars of remodeled atria. Conduction in discontinuous tissue is mostly structurally determined and leads to excitable gaps behind the wavefronts. If a gap is of critical size, the effectiveness of drugs that prolong atrial refractoriness will be limited. Furthermore, scar tissue is likely to exhibit multiple entry and exit points and multiple sites at which unidirectional block occurs. This can potentially lead to activity whose appearance in local extracellular electrograms changes from beat to beat, as well as beat-to-beat CL variability. Although such regions can be expected to respond to defibrillation, AF may resume after extrasystoles or

normal sinus beats immediately after conversion, with unidirectional block recurring as a result of the presence of scar.

ATRIAL STRETCH

CH
15

Atrial stretch and dilation can play a role in the development and persistence of AF. Clinically, AF episodes occur more frequently in association with conditions known to cause elevated LA pressure and atrial stretch, such as acutely decompensated systolic or diastolic heart failure. Additionally, the echocardiographic LA volume index and restrictive transmitral Doppler flow patterns are strong predictors of the development of AF.^{8,14}

The structure of the dilated atria can potentially have important EP effects related to stretch of the atrial myocardium (so-called electromechanical feedback). Acute atrial stretch reduces the atrial refractory period and action potential duration and depresses atrial conduction velocity, potentially through a reduction of cellular excitability by the opening of stretch-activated channels or changes in cable properties (membrane resistance, capacitance, core resistance), or both. Regional stretch for less than 30 minutes turns on the immediate early gene program, thus initiating hypertrophy and altering action potential duration in affected areas. Moreover, acutely altered stress and strain patterns augment the synthesis of angiotensin II, which induces myocyte hypertrophy. By regionally increasing L-type calcium (Ca^{2+}) current (I_{CaL}) and decreasing the transient outward potassium (K^+) current (I_{to}), angiotensin II can contribute to arrhythmogenic electrical dispersion. Altered stretch of atrial myocytes also results in opening of stretch-activated channels, increasing G protein-coupled pathways. This leads to increased protein kinase A and C activity, and enhanced I_{CaL} through the cell membrane, and increased release of Ca^{2+} from the sarcoplasmic reticulum, thus promoting afterdepolarizations and triggered activity.¹⁰ Furthermore, acute stretch can promote an increase in dispersion of refractoriness and spatial heterogeneity by causing conduction block and potentially contributing to the development of AF.^{8,14,15}

INFLAMMATION AND ATRIAL FIBRILLATION

There is increasing evidence that implicates inflammation in the pathogenesis of AF. Clinically, AF occurs frequently in the setting of inflammatory states such as cardiac surgery and acute pericarditis. Additionally, the levels of inflammatory biomarkers (C-reactive protein [CRP] and interleukin-6 [IL-6]) are significantly increased in patients with AF, findings suggesting the presence of systemic inflammation in these patients. Elevation of the levels of CRP and IL-6 has been shown to predict future development, recurrence, and burden of AF.¹⁶⁻¹⁸ There is also evidence suggesting that inflammation is involved in electrical and structural atrial remodeling. Furthermore, inflammation appears to increase the inhomogeneity of atrial conduction directly, potentially via disruption of expression of connexin proteins, leading to impaired intercellular coupling.¹⁶

It is also likely that inflammation can be a consequence of AF. CRP levels decrease following restoration of sinus rhythm. Rapid atrial activation in AF results in Ca^{2+} overload in atrial myocytes that can potentially result in cell death, which induces a low-grade inflammatory response. The inflammation, in turn, can induce healing and repair that likely enhance remodeling and promote perpetuation of the arrhythmia.¹⁶

Currently, the exact role of inflammation in AF is poorly defined, and it remains unclear whether inflammation is actually involved in the mechanisms underlying AF or whether it is simply an epiphenomenon. Therapies directed at attenuating the inflammatory burden (e.g., glucocorticoids, statins, and angiotensin II inhibitors) appear promising, although early clinical trials do not support a significant benefit.¹⁹

Atrial Remodeling in Atrial Fibrillation

It is well known from clinical practice that AF is a progressive arrhythmia. Eventually, in 14% to 24% of patients with paroxysmal

AF, persistent AF will develop, even in the absence of progressive underlying heart disease. Furthermore, conversion of AF to NSR, electrically or pharmacologically, becomes more difficult when the arrhythmia has been present for a longer period. In fact, the arrhythmia itself results in a cascade of electrical and structural changes in the atria that are themselves conducive to the perpetuation of the arrhythmia ("AF begets AF"), a process known as remodeling.²⁰ Recurrent AF can potentially lead to irreversible atrial remodeling and eventually permanent structural changes that account for the progression of paroxysmal to persistent and finally to permanent AF, characterized by the failure of electrical cardioversion or pharmacological therapy, or both, to restore and maintain NSR. Even after cessation of AF, these abnormalities persist for periods that vary in proportion to the duration of the arrhythmia.^{17,21}

Changes in atrial EP features that are induced by AF can occur through alterations in ion channel activities that cause partial depolarization and abbreviation of atrial refractoriness. These changes promote the initiation and perpetuation of AF (electrical remodeling) and the modification of cellular Ca^{2+} handling, which causes contractile dysfunction (contractile remodeling), as well as atrial dilation with associated structural changes (structural remodeling). Electrical remodeling can potentially begin within a few hours after the onset of AF, whereas the structural changes are slower, likely starting after several weeks.¹⁷

Electrical remodeling results from the high rate of electrical activation. The EP changes typical of atrial myocytes during AF are shortening of the atrial refractory period and action potential duration, reduction in the amplitude of the action potential plateau, and loss of response of action potential duration to changes in rate (abnormal restitution). Whereas the normal atrial action potential duration shortens in response to pacing at shorter CLs, AF results in loss of this rate dependence of atrial action potential duration, and the atrial refractory period fails to lengthen appropriately at slow rates (e.g., with return to NSR). These changes can explain the increased duration of AF because, according to the multiple wavelet theory, a short wavelength results in smaller wavelets, which increase the maximum number of wavelets, given a certain atrial mass.^{2,20} Tachycardia-induced changes in refractoriness are spatially heterogeneous, and there is increased variability both within and among various atrial regions that may promote atrial vulnerability and AF maintenance and provide a substrate for reentry.

The mechanism for electrical remodeling and shortening of the atrial refractory period is not entirely clear. Several potential explanations exist, including ion channel remodeling, angiotensin II, and atrial ischemia. Shortening of the atrial action potential can be caused by a net decrease of inward ionic currents (Na^+ or Ca^{2+}), a net increase of outward currents (K^+), or a combination of both. The decrease of I_{CaL} seems to be responsible for shortening of the atrial action potential, whereas the decrease of I_{to} is considered to result in loss of physiological rate adaptation of the action potential. The reduction in I_{CaL} can be explained by a decreased expression of the L-type Ca^{2+} channel α_{1C} subunit, likely as a compensatory mechanism to minimize the potential for cytosolic Ca^{2+} overload secondary to increased Ca^{2+} influx during the rapidly repetitive action potentials during AF. Verapamil, an L-type Ca^{2+} channel blocker, was shown to prevent electrical remodeling and hasten complete recovery without affecting inducibility of AF, whereas intracellular Ca^{2+} overload, induced by hypercalcemia or digoxin, enhances electrical remodeling. Electrical remodeling can be attenuated by the sarcoplasmic reticulum's release of the Ca^{2+} antagonist ryanodine, a finding suggesting the importance of increased intracellular Ca^{2+} to the maladaptation of the atrial myocardium during AF. Angiotensin II may also be involved in electrical and atrial myocardial remodeling, and angiotensin II inhibitors may prevent atrial electrical remodeling. Angiotensin-converting enzyme inhibitors reduce the incidence of AF in patients with left ventricular (LV) dysfunction after myocardial infarction and in patients with chronic ischemic cardiomyopathy. Atrial ischemia is another possible contributor to electrical remodeling and shortening of the atrial refractory period via activation of the $\text{Na}^+\text{-H}^+$ exchanger.^{10,11}

Furthermore, persistent AF can result in other changes within the atria, including gap junctional remodeling, cellular remodeling, and sinus node remodeling. Gap junctional remodeling is manifest as an increase in the expression and distribution of connexin 43 and heterogeneity in the distribution of connexin 40, both of which are intercellular gap junction proteins.²⁰ Cellular remodeling is caused by the apoptotic death of myocytes with myolysis, which may not be entirely reversible. AF results in marked changes in atrial cellular substructures, including loss of myofibrils, accumulation of glycogen, changes in mitochondrial shape and size, fragmentation of sarcoplasmic reticulum, and dispersion of nuclear chromatin.²⁰

Sustained AF has also been associated with structural changes, such as myocyte hypertrophy, myocyte death, impaired atrial contractility, and atrial stretch and dilation, which act to reduce conduction velocity.²⁰ Atrial dilation increases electrical instability by shortening the effective refractory period and slowing atrial conduction.¹⁰ These structural changes, many of which probably are irreversible, appear to occur more slowly, over periods of weeks to months.

Contractile remodeling is likely caused by downregulation of I_{CaL} (resulting in reduced release of Ca^{2+} during systole), as well as myolysis (loss of sarcomeres). Contractile remodeling can potentially cause thrombus formation and atrial dilation. Contractile remodeling starts early after onset of AF, and its recovery generally takes longer than reversal of electrical remodeling, likely because of the time it takes for the atria to replace lost sarcomeres.

In addition to remodeling of the atria, the sinus node can undergo remodeling, resulting in sinus node dysfunction and bradyarrhythmias caused by reduced sinus node automaticity or prolonged sinoatrial conduction. The phenomenon of sinus node remodeling may contribute to the episodes of bradycardia seen in the tachycardia-bradycardia syndrome and may reduce sinus rhythm stability and increase the stability of AF.²⁰ As mentioned earlier, elements of the sinus bradycardia appear to be functionally reversible if the tachycardia is prevented.

Studies suggest that the PVs are more susceptible to electrical alterations resulting from AF than the atria. Although the PVs display significantly longer refractory periods at baseline than the atria, they exhibit more prominent shortening of refractoriness after a brief episode of pacing-induced AF. Moreover, the short-term presence of AF does influence PV EP features by slowing the conduction velocity without affecting the conduction times of the atria. Structural changes in the atria after remodeling, such as stretch, can also result in increased PV activity. Atrial stretch can lead to increased intraatrial pressure, causing a rise in the rate and spatiotemporal organization of electrical waves originating in the PVs. These changes imply that electrical and structural remodeling increases the likelihood of ectopic PV automaticity and AF maintenance. Therefore, rather than AF begets AF, one can vary that theme: "PV-induced paroxysmal AF begets PV-induced chronic AF."²²

Atrial tachycardia (AT)-induced remodeling can potentially underlie various clinically important phenomena, such as the tendency of patients with other forms of supraventricular arrhythmias to develop AF, the tendency of AF to recur early after electrical cardioversion, the resistance of longer duration AF to antiarrhythmic medications, and the tendency of paroxysmal AF to become persistent.²

If NSR is restored within a reasonable period of time, EP changes and atrial electrical remodeling appear to normalize gradually, atrial size decreases, and atrial mechanical function is restored. These observations lend support to the idea that the negative downhill spiral in which AF begets AF can be arrested with NSR that perpetuates NSR, and restoration of NSR may forestall progressive remodeling and the increase in duration and frequency of arrhythmic episodes by reverse remodeling.

Role of Autonomic Nervous System in Atrial Fibrillation

Cardiac function is modulated by both the extrinsic and the intrinsic cardiac autonomic nervous systems. The extrinsic (central)

system is composed of the vagosympathetic system from the brain and spinal cord to the heart. The intrinsic system is composed of a large network of autonomic cardiac ganglia buried throughout the epicardial fat within the pericardial space. Groups of several cardiac ganglia comprise plexuses that coalesce in specific locations, and different groups of ganglia have different sites of innervation throughout the heart. Atrial ganglia contain afferent neurons from the atrial myocardium and from the central autonomic nervous system, and efferent cholinergic and adrenergic neurons, with heavy innervation of the PV myocardium and the atrial myocardium surrounding the ganglionic plexuses. Additionally, an extensive array of interconnecting neurons creates a communication network among the different ganglionic plexuses, as well as between the ganglionic plexuses and the atrium and PV myocardium. The intrinsic system receives input from the extrinsic system but acts independently to modulate numerous cardiac functions, including automaticity, contractility, and conduction.^{23,24}

Several studies have suggested that both divisions of the autonomic nervous system are involved in the initiation, maintenance, and termination of AF, with a predominant role of the parasympathetic system. Electrical stimulation of autonomic nerves on the heart itself can facilitate the induction of AF. Increased vagal tone is frequently involved in the onset of AF in patients with structurally normal hearts. Parasympathetic stimulation shortens the atrial refractory period, increases the dispersion of refractoriness, and decreases the wavelength of reentrant circuits that facilitate initiation and perpetuation of AF. Long-term vagal denervation of the atria renders AF less easily inducible in animal experiments, presumably because of increased EP homogeneity. On the other hand, vagal stimulation results in maintenance of AF, and catheter ablation of the parasympathetic autonomic nerves entering the RA from the SVC prevents vagally induced AF in animal models. Sympathetic stimuli also shorten the atrial refractory period and increase the vulnerability to AF.^{23,25}

Spatial heterogeneity of refractoriness can also be produced by the heterogeneity of autonomic innervation. It has been well established that vagal innervation of the atria is heterogeneous and vagal stimulation can precipitate AF as a result of heterogeneity of atrial refractoriness. Heterogeneity of sympathetic neural inputs also plays a role in AF. In animal models, sympathetic atrial denervation facilitates sustained AF, and AF induced by rapid RA pacing is associated with nerve sprouting and a heterogeneous increase in sympathetic innervation. Enhanced sympathetic activity can promote automaticity, delayed afterdepolarization-related AT, and focal AF. Sympathetic stimulation also shortens atrial refractoriness and may facilitate the induction of AF in patients with structural heart disease, in whom possible heterogeneous sympathetic denervation leads to increased refractoriness heterogeneity.

Experimental evidence suggests that the electrical properties of the PVs are also modulated by changes in autonomic tone.⁶ Anatomical studies revealed that the LA and PVs are innervated by adrenergic and cholinergic nerve fibers. A collection of ganglia is localized on the posterior wall of the LA between the superior PVs. Subsequent studies found that ganglionated plexuses clustered at the PV entrances (within fat pads) could be stimulated without atrial excitation. For patients with PV foci, a primary increase in adrenergic tone followed by a marked vagal predominance was reported just prior to the onset of paroxysmal AF. A similar pattern of autonomic tone was reported in an unselected group of patients with paroxysmal AF and various cardiac conditions.²⁵ Activation of the ganglionic plexuses at the PV-LA junction can potentially result in conversion of PV ectopy to AF. Furthermore, ablation of the ganglionated plexuses located at the atrial entrances or antra of the PVs can potentially abolish or reduce AF inducibility.

Role of the Pulmonary Veins in Atrial Fibrillation

There is little controversy now that the PVs play a major role in triggering and maintaining AF, as established by animal and human models, especially in the setting of paroxysmal AF. First, fibrillatory

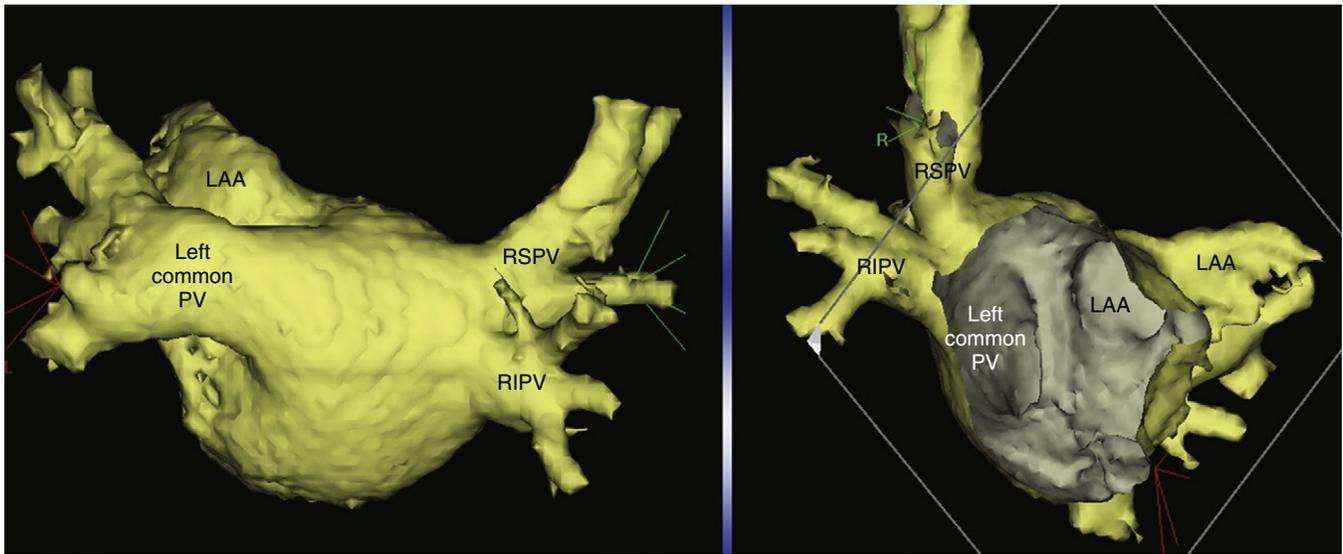

FIGURE 15-3 Cardiac CT angiogram (posteroanterior and cardioscopic views) showing a common ostium for the left pulmonary veins (PVs). LAA = LA appendage; RIPV = right inferior pulmonary vein; RSPV = right superior pulmonary vein.

conduction is likely initiated by rapid discharges from one or several focal sources within the atria; in most patients with AF (94%), the focus is in one of the PVs (Fig. 15-1). Extra-PV sites can also trigger AF, but this occurs in a few cases, likely no more than 6% to 10% of patients. AF is also perpetuated by microreentrant circuits, or rotors, that exhibit high-frequency periodic activity from which spiral wavefronts of activation radiate into surrounding atrial tissue. Conduction becomes slower and less organized with increasing distance from the rotors, likely because of atrial structural remodeling, resulting in fibrillatory conduction. Interestingly, the dominant rotors in AF are localized primarily in the junction between the LA and PVs. One study also demonstrated that the PV-LA region has heterogeneous EP properties capable of sustaining reentry (microreentry or macroreentry). Finally, vagal inputs may be important in triggering and maintaining AF, and many of these inputs are clustered close to the PV-LA junction. Thus, the PVs play a critical role in triggering and maintaining AF.

The role of PVs in the initiation and perpetuation of persistent AF seems less prominent than in the setting of paroxysmal AF, likely secondary to the electrical and structural remodeling associated with persistent AF. Non-PV triggers occur more commonly, and the reentry sites required for AF perpetuation are more often found outside the PV-LA junction in persistent AF than in paroxysmal AF.

PULMONARY VEIN ANATOMY

PVs can have variable anatomy. Most hearts examined are found to have four PVs with discrete ostia, but the remainder (approximately 25%) has a common ostium, either on the left or on the right (Fig. 15-3).⁴ The PV ostia are ellipsoid with a longer superior-inferior dimension, and funnel-shaped ostia are frequently noted in patients with AF. The right superior PV is located close to the SVC or RA, and the right inferior PV projects horizontally. The left superior PV is close to the vicinity of the LA appendage, and the left inferior PV courses near the descending aorta. PVs are larger in patients with AF than in normal subjects, in men than in women, and in persistent versus paroxysmal AF. Significant variability of PV morphologies exists, however, including supernumerary right PVs (in 8% to 29% of patients; Fig. 15-4), multiple ramification and early branching (especially of the right inferior PV), and common ostium of left-sided or, less frequently, right-sided PVs.

The PVs are covered by myocardial sleeves formed by one or more layers of myocardial fibers oriented in a circular, longitudinal, oblique, or spiral direction. These sleeves, continuing from the LA into the PV, vary from 2 to 25 mm in length, with a mean extent of

13 mm. The length of the myocardial sleeves usually has a distinctive distribution; superior PVs have longer and better developed myocardial sleeves than inferior PVs, which may explain why arrhythmogenic foci are found more often in the superior PVs than in the inferior PVs.^{4,5} It should be noted that all PVs in all individuals have such myocardial sleeves, regardless of the presence or absence of AF.

The walls of the PVs are composed of a thin endothelium, a media of smooth muscle, and a thick outer fibrous adventitia. The transition from atrial to venous walls is gradual because the myocardial sleeves from the LA overlap with the smooth muscle of the venous wall. The myocardial sleeves are thickest at the venoatrial junction (mean, 1.1 mm) and then gradually taper distally. Furthermore, the thickness of the sleeves is not uniform, with the inferior walls of the superior veins and the superior walls of the inferior veins having the thicker sleeves. Throughout the PV, and even at the venoatrial junction, there are gaps in the myocardial sleeves mainly composed of fibrous tissue. The arrangement of the myocyte bundles within the sleeves is rather complex. There appears to be a mesh-like arrangement of muscle fascicles made up of circularly oriented bundles (spiraling around the long axis of the vein) that interconnect with bundles that run in a longitudinal orientation (along the long axis of the vein). Such an arrangement, together with the patchy areas of fibrosis seen, may be relevant to the role of the PVs in the initiation of AF.⁴

ELECTROPHYSIOLOGY OF PULMONARY VEIN MUSCULATURE

As noted, the PVs play a crucial role in the initiation and maintenance of AF. However, it is not clear what makes this region so susceptible to the arrhythmia.^{4,6} There are, at present, limited data available on the ionic mechanisms that may underlie the arrhythmogenicity of PVs. Detailed mapping studies have suggested that reentry within the PVs is most likely responsible for their arrhythmogenicity, although focal or triggered activity cannot be excluded.

The EP features of the PV, with its distinct area of slow conduction, decremental conduction, nonuniform anisotropy, and heterogeneous repolarization, are potential substrates for reentry. The heterogeneous fiber orientation in the transition from the LA to the PV sleeve results in unique conduction properties in this area.^{4,6} It is possible that the complex arrangement of muscle fibers within the myocardial sleeves and the uneven distribution of interspersed connective and adipose tissue account for the greater degree of decremental conduction observed in the myocardial sleeves than in the LA and for the heterogeneity in conduction properties and

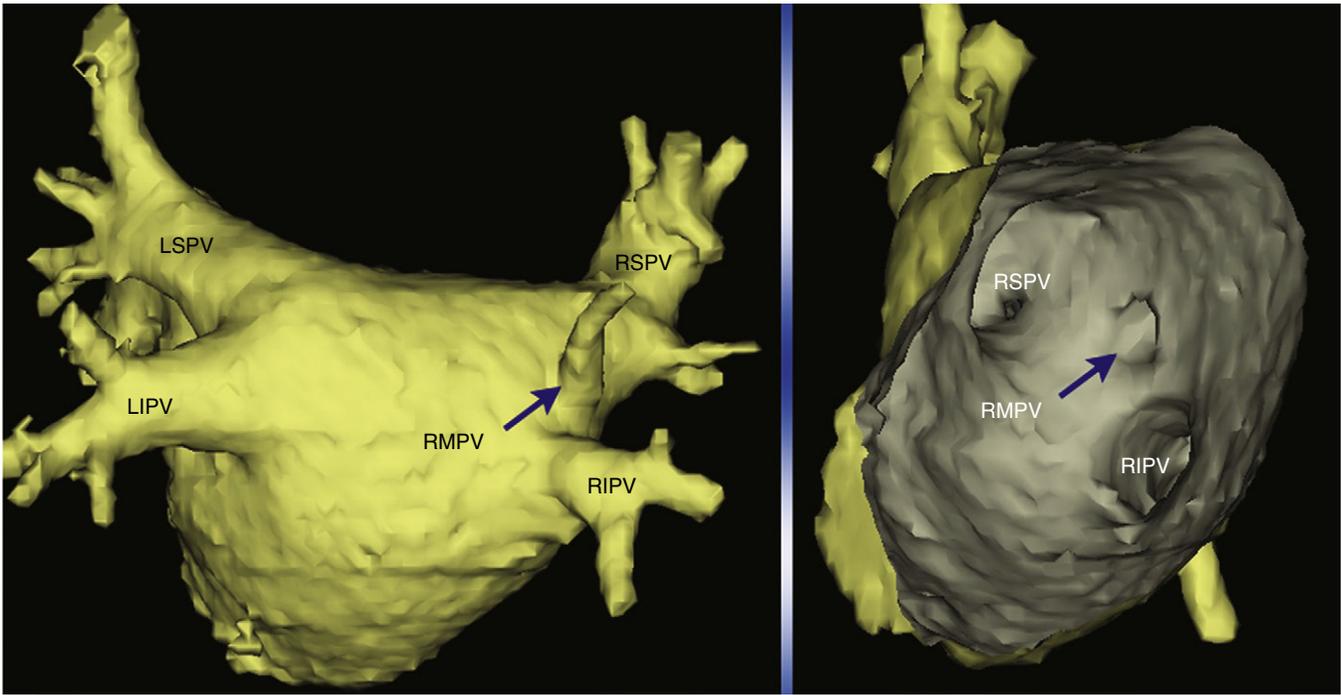

FIGURE 15-4 Cardiac CT angiogram (posteroanterior and cardioscopic views) showing the right middle pulmonary vein (RMPV). LIPV = left inferior pulmonary vein; LSPV = left superior pulmonary vein; RIPV = right inferior pulmonary vein; RSPV = right superior pulmonary vein.

refractory periods among the fascicles in the myocardial sleeves. Therefore, the fractionation of PV potentials commonly observed during premature stimulation (which usually indicates local slowing of conduction) is consistent with anisotropic properties that can be attributable to the complex arrangement of muscle fascicles within the myocardial sleeves.⁵

Several studies suggested that abnormal automaticity or triggered activity, either alone or in combination with the reentrant mechanisms described previously, can play a role in the initiation of AF. These studies suggested that the propensity of PVs to exhibit focal or triggered activity is enhanced by pathological conditions.⁴ Further work also implicated the posterior LA in the genesis of AF. Studies suggested that the PVs, together with the posterior LA, have an important role in the persistent form of AF. However, the nature of the relationship between this arrhythmogenic region and the pathological conditions that provide a substrate for AF has not been elucidated. Whether the critical region is the posterior LA, the PVs, or both, has been the source of ongoing debate.⁶

PULMONARY VEIN TACHYCARDIA VERSUS PULMONARY VEIN FIBRILLATION

In patients with paroxysmal AF originating from the PVs, a wide spectrum of atrial arrhythmias can coexist. Extensive monitoring frequently documents coexisting paroxysms of AT and AF. Furthermore, patients with paroxysmal AF usually have multiple PV foci in multiple veins, and many of these foci originate distally in those veins.

In patients whose only clinical arrhythmia is PV AT, the clinical course is more comparable to that in patients with AT from other anatomical locations than to patients with PV AF. Those patients demonstrate a largely focal process, without evidence of a more progressive and diffuse process as observed in the population with paroxysmal AF, and they have no tendency to develop further atrial arrhythmias during long-term follow-up. Notably, when patients with PV AT present with recurrence, in almost all cases this is from the original focus. In contrast, patients with paroxysmal AF have recurrences from foci in other PVs and from within the body of the LA. Importantly, in most patients with PV AT, the focus is located at the

ostium of the vein (or within 1 cm of the designated ostium), rather than from further distally (2 to 4 cm). These observations suggest that patients with focal PV AT may represent a different population from those with PV AF. PV AT patients have a discrete and focally curable process, in contrast to the more diffuse process involving multiple PVs and the LA seen in AF.

The spontaneous onset of focal AT from the PVs and its lack of inducibility with programmed stimulation suggest that this arrhythmia is more likely to be caused by abnormal automaticity or triggered activity rather than reentry. However, attempts to classify the arrhythmia mechanism of focal AT definitively in the EP laboratory are limited because of the significant overlap in the arrhythmia characteristics (initiation, response to drugs).

Clinical Considerations

Epidemiology

AF is the most common sustained arrhythmia encountered in clinical practice. It accounts for approximately one-third of hospitalizations for cardiac rhythm disturbance. AF affects 1% to 2% of the general population, and it has been estimated that 2.3 million people in the United States and 4.5 million in the European Union have paroxysmal or persistent AF. However, the true prevalence of AF is probably higher given the common occurrence of asymptomatic (silent) AF.²⁶

The prevalence of AF increases with age. AF is uncommon in childhood except after cardiac surgery. It occurs in less than 1% of individuals younger than 60 years, but in approximately 6% of those older than 65 years, and in more than 10% of those older than 80 years. The median age of patients with AF is approximately 75 years, and approximately 75% of patients with AF are 65 years of age or older.

The lifetime risk of the development of AF at age 40 years has been estimated to be approximately 25%. The age-adjusted prevalence is higher in men. Blacks have less than half the age-adjusted risk of developing AF than whites.²⁷ Given the increasing prevalence of AF with age, coupled with our aging population, the number of affected U.S. residents is expected to increase to nearly 16 million by 2050.

AF is a progressive disease. Approximately half of individuals who experience an initial episode of AF will eventually develop recurrent AF, typically within the first 2 years of follow-up. AF progresses from paroxysmal to persistent despite antiarrhythmic therapy in approximately 10% at 1 year, in 25% to 30% at 5 years, and in more than 50% beyond 10 years. Furthermore, progression from paroxysmal and persistent AF to permanent AF occurs in up to 34% of patients at 4 years after initial diagnosis. Maintenance of sinus rhythm is progressively more difficult as the duration of persistent AF increases. Only 40% to 60% of patients with persistent AF of less than 1 year's duration remain in sinus rhythm 1 year after initiation of antiarrhythmic drug therapy, despite multiple cardioversions, whereas patients with persistent AF of more than 3 year's duration have only a 15% likelihood of long-term sinus rhythm. Increased age, diabetes, and heart failure are among potential predictors of progression to permanent AF. Lone AF is less likely to progress.²⁸

AF is associated with an increased long-term risk of stroke, heart failure, hospitalization, and all-cause mortality, especially in women, even after controlling for CHADS₂ score and other covariables. The mortality rate of patients with AF is approximately double that of patients in NSR and is linked to the severity of underlying heart disease.^{27,29}

Clinical Risk Factors Predisposing to Atrial Fibrillation

As noted, AF can be related to a transient reversible cause, such as thyrotoxicosis, acute myocardial infarction, acute pericarditis, recent cardiac surgery, acute pulmonary disease, alcohol intake, or electrocution. In these cases, AF is generally eliminated by treatment of the underlying precipitating condition.

AF is thought to be secondary to underlying structural heart disease in more than 70% of patients and is the final arrhythmic expression of a diverse family of diseases. AF derives from a complex continuum of predisposing factors that appear to involve disease processes that contribute to the triggering of AF (e.g., sympathetic and parasympathetic nervous systems [neurogenic AF], predisposing arrhythmias, ectopic foci in PVs), increase atrial distention (e.g., valvular heart disease, hypertension, and heart failure), decrease the ratio of atrial myocyte to fibrotic tissue, possibly including an increased rate of apoptotic cell death (e.g., hypertension and ischemic heart disease), disrupt transmyocyte communications (e.g., pericarditis and edema), increase inflammatory mediators (e.g., pericarditis and myocarditis), or alter energy and redox states that modulate the function of ion channels and gap junctions.

The most frequent causes of acute AF are myocardial infarction (5% to 10% of patients with infarct) and cardiothoracic surgery (up to 50% of patients). The most common clinical settings for permanent AF are hypertension and ischemic heart disease, with the subset of patients having congestive heart failure most likely to experience the arrhythmia. In the developing world, hypertension and rheumatic valvular (usually mitral) and congenital heart diseases are the most commonly related conditions.³⁰

Heart failure is present in 34% of patients with AF, and AF develops in up to 42% of patients with heart failure. AF and heart failure have a grim prognosis, with a 1-year mortality of 9.5% and worsening of heart failure in almost 25%.³¹ In patients with heart failure who are undergoing defibrillator implantation, a history of AF at time of procedure identifies additional risk of heart failure and death, and the new detection of AF afterward is associated with even higher rates of death.³²

There is accumulating evidence demonstrating an independent association between sleep apnea and AF, likely related to the effects of sleep apnea and nocturnal hypoxemia on LA electrical remodeling, fibrosis, and chamber enlargement. AF occurs in 5% of persons with severe sleep apnea and only 1% of those without sleep apnea. The prevalence of at least moderate sleep apnea was reported in up to 32% of patients with lone AF. Furthermore, cross-sectional studies demonstrated that patients with AF had a significantly higher risk of obstructive sleep apnea than matched

controls (49% versus 33%), and multivariate analysis demonstrated a strong independent association between sleep apnea and AF (odds ratio, 2.2). Additionally, several prospective studies showed that obstructive sleep apnea predicts the occurrence of future AF. Untreated obstructive sleep apnea was associated with a remarkably high rate of AF recurrence at 1 year compared with patients with unknown sleep apnea status (83% versus 53%). The presence of sleep apnea can also predict a higher rate of early recurrence of PV conduction and AF following catheter ablation of AF.³³ Several investigations identified obesity (found in approximately 25% of patients with AF) as a risk factor for the development of AF, and there exists a linear association between the body mass index and AF risk. Obesity is associated with increased LA size and impaired LV diastolic function, which can potentially explain its predisposition to AF.³⁴

The presence of sinus node dysfunction also predicts an increased risk for AF. Atrial high-rate episodes lasting longer than 5 minutes were noted in 29% of the patients receiving pacemakers for sinus node dysfunction but with no prior history of AF.

In younger patients, approximately 30% to 45% of paroxysmal cases and 20% to 25% of persistent cases of AF occur in the absence of any chronic or acute risk factors for the arrhythmia, a condition referred to as lone AF. Adrenergic and vagotonic forms of paroxysmal AF are uncommon. Nonetheless, patients with lone AF often have attacks against the background of parasympathetic predominance, whereas paroxysms in patients with structural heart disease more usually occur in a sympathetic setting.

Clinical Presentation

AF can be symptomatic or asymptomatic, even in the same patient. Asymptomatic, or silent, AF occurs frequently. In patients with paroxysmal AF; up to 90% of episodes can be unrecognized by the patient, including some lasting more than 48 hours. On the other hand, continuous monitoring with a pacemaker with dedicated functions for AF detection and electrogram storage showed that as many as 40% of patients experienced AF-like symptoms in the absence of AF, whereas 38% of patients with a history of AF had episodes of AF lasting more than 48 hours noted at the time of interrogation even though these patients were asymptomatic. In more than 10% to 25% of patients, however, AF is discovered in the absence of symptoms or after a complication attributable to AF.

Symptoms associated with AF vary, depending on the ventricular rate, the underlying functional status, the duration of AF, the presence and degree of structural heart disease, and the individual patient's perception. The hemodynamic consequences of AF are related to loss of coordinated atrial contraction, irregularity of ventricular response, and fast heart rate, as well as long-term consequences such as atrial and ventricular cardiomyopathy. Loss of effective atrial contraction can potentially reduce cardiac output by 15% to 20%. These consequences are magnified in the presence of impaired diastolic ventricular filling, hypertension, mitral stenosis, LV hypertrophy, and restrictive cardiomyopathy. Irregularity of the cardiac cycle, especially when accompanied by short coupling intervals, and rapid heart rates in AF can lead to reduction in diastolic filling, stroke volume, and cardiac output.²⁷

Most patients with AF complain of palpitations, chest discomfort, dyspnea, generalized fatigue, or dizziness. Although palpitation, or awareness of the irregularity of the heartbeat, is prominent in more than half of patients with AF, its correlation with documented arrhythmia is unimpressive.³⁵ Furthermore, AF with a chronically rapid heart rate (more than 120 to 130 beats/min) can lead to tachycardia-mediated cardiomyopathy and heart failure. Syncope is an uncommon complication of AF that can occur on conversion in patients with sinus node dysfunction or because of rapid ventricular rates in patients with hypertrophic cardiomyopathy, in patients with valvular aortic stenosis, or in patients with ventricular preexcitation over an accessory pathway. The first presentation of asymptomatic AF can be catastrophic—an embolic complication or acute decompensation of heart failure.^{27,35}

In some patients, paroxysmal AF can be classified as either *vagal* or *adrenergic*, depending on the types of triggers and the temporal distribution of the arrhythmic episodes. Vagal AF typically occurs in young male patients without structural heart disease and characteristically develops during sleep or postprandial. In contrast, patients with adrenergic AF are usually older, often with evidence of underlying heart disease, and the episodes of AF usually occur during the day and are associated with physical or emotional stress. In patients with paroxysmal AF, the prevalence of vagal AF probably ranges between 6% and 25%, whereas that of adrenergic AF ranges between 7% and 16%. Approximately 12% of patients with paroxysmal AF exhibit features of mixed vagal and adrenergic patterns.²⁵

Many patients with persistent or permanent AF have one or more comorbid conditions that can considerably contribute to specific complaints and to overall quality of life. Therefore, it is important to establish a correlation between any symptoms and AF, as well as ventricular response rates. The effect of regulation of ventricular rate during persistent AF or conversion to NSR on a patient's symptoms and quality of life can help assess the relative contribution of AF to the patient's complaints. The Canadian Cardiovascular Society Severity in Atrial Fibrillation (CCS-SAF) scale is a simple, five-point semiquantitative scale (Table 15-1) that has been proposed for use at the bedside to assess the functional consequences of symptoms during AF and can provide objective assessment of the patient's subjective state (analogous to the New York Heart Association [NYHA] congestive heart failure functional class and the CCS angina severity class).³⁵

Risk of Thromboembolism

AF is a major risk factor for thromboembolism, causing approximately 15% of the ischemic strokes in the United States and up to 25% of those in patients older than 80 years. In the Framingham Heart Study, patients with rheumatic heart disease and AF had a 17-fold increased risk of stroke compared with age-matched controls, and the attributable risk was 5 times greater than in those with nonrheumatic AF. For nonvalvular AF, the risk of stroke is estimated to be 2 to 7 times that of subjects without arrhythmia, thus resulting in an average incidence of stroke of 5% per year. This rate may increase to 7% per year when silent cerebral ischemic events and transient ischemic attacks are taken into account.²⁷ Patients with paroxysmal and persistent AF appear to have a stroke risk similar to that in patients with permanent AF.

Although patients with AF in the setting of rheumatic valvular disease are accepted to be at high risk of stroke, stroke risk in nonvalvular AF is not homogeneous across the various subgroups of patients. The risk ranges from less than 1.5% per year in patients with lone AF who are less than 59 years old to more than 10% per year in older patients, especially when AF is associated with specific conditions or comorbidities. Prior history of stroke, transient ischemic attack, or thromboembolism, age, gender, hypertension, diabetes, coronary artery disease, peripheral artery disease, cardiomyopathy, and heart failure are important risk factors. Also, smoking was identified on multivariate analysis in one study as a significant predictor of thromboembolism.³⁶⁻³⁸ The presence of moderate to severe LV systolic dysfunction on transthoracic echocardiography is the only independent echocardiographic risk factor for stroke on multivariable analysis. On transesophageal echocardiography (TEE), the presence of an LA thrombus (relative risk, 2.5), complex aortic plaques (relative risk, 2.1), spontaneous echo contrast (relative risk, 3.7), and low LA appendage velocities (up to 20 cm/sec; relative risk, 1.7) are independent predictors of stroke and thromboembolism.³⁶ Limited data suggest that large LA appendage dimensions on magnetic resonance imaging (MRI) may predict a higher risk of thromboembolism.³⁹

Several prominent risk stratification schemes have been developed to help distinguish those patients with AF who are at high risk of ischemic stroke and other systemic thromboembolism from those with a risk sufficiently low that anticoagulation may not be beneficial when considering the associated bleeding risks. Two

schemes were developed from multivariable analyses of pooled data from randomized trial participants: the Atrial Fibrillation Investigators (AFI) and the Stroke Prevention in Atrial Fibrillation (SPAF) risk schemes. The CHADS₂ index, named for a combination of clinical risk factors (Congestive heart failure, Hypertension, Age 75 years or more, Diabetes mellitus, and prior Stroke or transient ischemic attack), was subsequently developed using data from the AFI and SPAF studies and was validated in a retrospective cohort of hospitalized patients with AF. The CHADS₂ score assigns two points to a history of prior cerebral ischemia and one point for the presence of congestive heart failure, hypertension, age 75 years or more, or diabetes mellitus. The CHADS₂ score has been associated with higher rates of thromboembolic stroke in a linear fashion for patients, both those taking anticoagulants and those not receiving anticoagulation. The stroke rate per 100 patient-years without antithrombotic therapy increases by a factor of approximately 1.5 for each one-point increase in the CHADS₂ score: from 1.9% for a score of 0 to 18.2% for a score of 6.⁴⁰

TABLE 15-1 Canadian Cardiovascular Society Severity of Atrial Fibrillation Scale

Step 1: Symptoms

Identify the presence of the following symptoms:

- Palpitation
- Dyspnea
- Dizziness, presyncope, or syncope
- Chest pain
- Weakness or fatigue

Step 2: Association

Is AF, when present, associated with the foregoing symptoms? For example: Ascertain whether any of the foregoing symptoms are present during AF and are likely caused by AF (as opposed to some other cause).

Step 3: Functionality

Determine whether the symptoms associated with AF (or the treatment of AF) affect the patient's functionality (subjective QOL).

CCS-SAF Class Definitions

Class 0	Asymptomatic with respect to AF
Class 1	Symptoms attributable to AF have <i>minimal</i> effect on patient's general QOL <ul style="list-style-type: none"> • Minimal and/or infrequent symptoms, or • Single episode of AF without syncope or heart failure
Class 2	Symptoms attributable to AF have <i>minor</i> effect on patient's general QOL <ul style="list-style-type: none"> • Mild awareness of symptoms in patients with persistent or permanent AF, or • Rare episodes (e.g., less than a few per year) in patients with paroxysmal or intermittent AF
Class 3	Symptoms attributable to AF have a moderate effect on patient's general QOL <ul style="list-style-type: none"> • Moderate awareness of symptoms on most days in patient with persistent or permanent AF, or • More common episodes (e.g., more than every few months) or more severe symptoms, or both, in patients with paroxysmal or intermittent AF
Class 4	Symptoms attributable to AF have a severe effect on patient's general QOL <ul style="list-style-type: none"> • Very unpleasant symptoms in patients with persistent or paroxysmal AF and/or • Frequent and highly symptomatic episodes in patients with paroxysmal or intermittent AF, and/or • Syncope thought to result from AF, and/or • Congestive heart failure secondary to AF

AF = atrial fibrillation; CCS = Canadian Cardiovascular Society; QOL = quality of life; SAF = severity of atrial fibrillation.

From Dorian P, Guerra PG, Kerr CR, et al: Validation of a new simple scale to measure symptoms in atrial fibrillation: the Canadian Cardiovascular Society Severity in Atrial Fibrillation (CCS-SAF) scale. *Circ Arrhythm Electrophysiol* 2:268-275, 2009.

The CHADS₂ score was compared with four other risk stratification schemes to predict thromboembolism in persons with non-valvular AF. No risk scheme was superior, and all of them had relatively poor ability to predict thromboembolism. Nonetheless, the CHADS₂ scheme remains the most widely used because of its simplicity and ease, and it is useful for assessment of when a patient has sufficiently high risk (CHADS₂ score of 2 or higher) to warrant anticoagulation. However, the CHADS₂ scheme does not incorporate other stroke risk factors and can lead to inadequate discrimination of risk. In fact, many patients (more than 60%) are classified as having intermediate risk, for whom the ideal thromboprophylaxis strategy is uncertain.⁴⁰

A newer scheme (the CHA₂DS₂-VASc score or Birmingham 2009 schema) incorporates additional risk factors, including vascular disease, female gender, and age 65 to 74 years (Table 15-2). This scheme showed a modest improvement of thromboembolic risk stratification over the CHADS₂ score and classified a much smaller proportion of patients (15.1%) into the intermediate risk category than the original CHADS₂ score (61.9%), hence allowing less uncertainty regarding treatment decisions. Also, those in the low-risk category in the CHA₂DS₂-VASc system were truly at low risk, with a 0% rate of thromboembolic events at 1 year, in contrast to the subjects classified as low risk using the CHADS₂ schema (i.e., a score of 0) who still had an annual event rate of 1.4%.³⁸

The CHA₂DS₂-VASc score was validated in a cohort of more than 1000 patients with nonvalvular AF followed during 1 year without anticoagulation, as well as in a large anticoagulated clinical trial cohort (Table 15-3).^{37,38} The risk of thromboembolism for patients with a CHA₂DS₂-VASc score of 1 who were not receiving anticoagulation was 0.6% in the first year, but in those with a score of 0, no thromboembolic events were observed. Nonetheless, it is important to recognize that all the available clinical prediction tools have only modest predictive ability.³⁶

In patients with AF who are undergoing implantation of a dual-chamber pacemaker, risk stratification for thromboembolic events can be improved by combining the CHADS₂ score with data on the presence and duration of AF episodes detected by the pacemaker. Patients with a CHADS₂ score of 2 or less who have no or only very short (less than 5 minutes' duration) episodes of AF, those with a CHADS₂ score of 1 or less who have AF episodes lasting between 5 minutes and 24 hours, and those with a CHADS₂ score of 0 regardless of the duration of AF episodes all appear to exhibit a low risk of stroke (0.8% per year).⁴¹

Importantly, the assessment of stroke risk is independent of the type of AF (i.e., paroxysmal, persistent or permanent). Although current guidelines consider patients with paroxysmal AF as having a stroke risk similar to those with persistent or permanent AF, in

RISK FACTOR	SCORE
Congestive heart failure or left ventricular dysfunction	1
Hypertension	1
Age ≥75 yr	2
Diabetes mellitus	1
Stroke, transient ischemic attack, or thromboembolism	2
Vascular disease (prior myocardial infarction, peripheral artery disease, or aortic plaque)	1
Age 65-74 yr	1
Sex category (i.e., female gender)	1

CHA₂DS₂-VASc = updated version of the CHADS₂ (congestive heart failure, hypertension, age, diabetes, and stroke [doubled]) system, with additional risk factors.

From Lip GY, Nieuwlaar R, Pisters R, et al: Refining clinical risk stratification for predicting stroke and thromboembolism in atrial fibrillation using a novel risk factor-based approach, *Chest* 137:263-272, 2010.

the presence of risk factors, the threshold burden of paroxysmal AF required to justify chronic anticoagulant therapy has not been clearly defined. In patients with AF who have implanted pacemakers or defibrillators, the risk for thromboembolism appears to be quantitatively linked to AF burden as quantified by the implanted devices. An AF burden for more than 5.5 hours on any day in the most recent 30 days seems to confer a doubling of the risk of thromboembolism compared with an AF burden of less than 5.5 hours, even after adjusting for baseline stroke risk factors and antithrombotic therapy. Further research is necessary to identify precisely the amount of AF burden associated with a significantly increased risk of stroke.^{36,42}

It is still unclear how to assess the risk of thromboembolism and guide antithrombotic therapy in patients with implanted pacemakers or defibrillators (but no prior clinical history of AF) in whom atrial high-rate episodes consistent with AF have been detected by the implanted devices. Limited data suggest that any strategy of anticoagulation therapy should take into consideration not only the duration of the atrial arrhythmias but also the individual's risk factor profile according to the previously mentioned risk stratification schemes.²⁶ Importantly, episodes detected by the device and designated as indicative of AF must be validated because some detection algorithms are overly sensitive and diagnose AF episodes when apparent rapid atrial recordings are, in fact, caused by atrial noncapture during NSR, erroneous counting of far-field R waves, or other phenomena.

Initial Evaluation

The initial evaluation of a patient with suspected or documented AF includes characterizing the pattern of the arrhythmia (e.g., paroxysmal or persistent), determining underlying causes (e.g., heart failure, pulmonary problems, hypertension, or hyperthyroidism), defining associated cardiac and extracardiac conditions, and identifying potential complications of AF. Additionally, a thorough history should be obtained to estimate of the risk of stroke (using the CHADS₂ or CHA₂DS₂-VASc schemes) and quantify AF-related

CHA ₂ DS ₂ -VASc SCORE	Cohort of Patients on Anticoagulation		Cohort of Patients off Anticoagulation

*Theoretical thromboembolism rates without anticoagulation therapy: assuming that warfarin provides a 64% reduction in thromboembolic risk. Data from Lip GY, Frison L, Halperin JL, Lane DA: Identifying patients at risk of stroke despite anticoagulation, *Stroke* 41: 2731-2738, 2010.

†Theoretical thromboembolism rates without antiplatelet therapy: assuming that aspirin provides a 22% reduction in thromboembolic risk. Data from Lip GY, Nieuwlaar R, Pisters R, et al: Refining clinical risk stratification for predicting stroke and thromboembolism in atrial fibrillation using a novel risk factor-based approach, *Chest* 137:263-272, 2010.

CHA₂DS₂-VASc = updated version of the CHADS₂ (congestive heart failure, hypertension, age, diabetes, and stroke [doubled]) system, with additional risk factors.

symptoms (e.g., CCS-SAF score). A careful history results in a well-planned focused work-up that serves as an effective guide to therapy.

The physical examination can suggest AF on the basis of irregular pulse, irregular jugular venous pulsations, and variation in the intensity of the first heart sound. Examination can also disclose associated valvular heart disease, myocardial abnormalities, or heart failure.

Exercise testing is often used to assess the adequacy of rate control with exercise in permanent AF, to reproduce exercise-induced AF, and to evaluate for associated ischemic heart disease. Although ischemic heart disease is not a common cause of AF, identifying underlying coronary artery disease is particularly important if the use of a class IC antiarrhythmic drug is being considered. Ambulatory cardiac monitoring can also be required for documentation of AF, its relation to symptoms, and evaluation of the adequacy of heart rate control.²⁷

Assessment for hyperthyroidism is indicated for all patients with a first episode of AF, when the ventricular response to AF is difficult to control, or when AF recurs unexpectedly after cardioversion. Serum should be obtained for measurement of thyroid-stimulating hormone (TSH) and free thyroxine (T₄), even if there are no symptoms suggestive of hyperthyroidism, because the risk of AF is increased up to threefold in patients with subclinical hyperthyroidism.

Rarely, EP testing can be required, especially in patients with wide QRS complex tachycardia or a possible predisposing arrhythmia, such as AFL or paroxysmal SVT. Hints to the presence of paroxysmal SVT include a history of episodes of regular rapid palpitations dating from teenage or early adult years (unusual for AF to occur de novo in this age group) and termination of episodes of palpitations with vagal maneuvers or adenosine (which should not occur with AF).

Principles of Management

Management of AF should be aimed at identifying and treating underlying causes of the arrhythmia, as well as reducing symptoms, improving quality of life, and preventing cardiovascular morbidity and mortality associated with AF. There are two main issues that must be addressed in the treatment of AF: (1) prevention of systemic embolization, and (2) control of symptoms related to AF, typically involving rate or rhythm control. The choice of therapy is influenced by patient preference, associated structural heart disease, severity of symptoms, and whether the AF is recurrent paroxysmal, recurrent persistent, or permanent. In addition, patient education is critical, given the potential morbidity associated with AF and its treatment. For control of symptoms, a safety-driven approach is of paramount importance because most treatments (drug, surgery, ablation) have the capacity to produce significant morbidity and even mortality.²⁷

PREVENTION OF SYSTEMIC EMBOLIZATION

As noted, AF significantly increases the risk of stroke, and the stroke risk appears to be equivalent in paroxysmal and persistent AF and equivalent with a rate control or rhythm control management strategy.

ANTIPLATELET THERAPY. Aspirin is associated with only modest (22%) reduction in the incidence of stroke, corresponding to an absolute stroke risk reduction of 1.5% per year as compared with placebo. Thus, except in the lowest risk patients, aspirin alone is not a viable treatment option for stroke prevention. The combination of aspirin plus clopidogrel is superior to aspirin therapy alone (28% relative risk reduction), but it is associated with a significantly increased risk of major bleeding (2.0% versus 1.3% per year) to levels generally similar to those associated with warfarin therapy.

VITAMIN K ANTAGONISTS. Oral anticoagulation therapy with vitamin K antagonists (warfarin) reduces stroke risk by approximately 64%, corresponding to an absolute annual risk reduction

in all strokes of 2.7% as compared with placebo. Warfarin is superior to aspirin, with relative risk reduction of 39% for stroke and 29% for cardiovascular events. However, warfarin increases the risk of major bleeding by approximately 70% compared with aspirin. Although the risk of intracranial hemorrhage is doubled with adjusted-dose warfarin compared with aspirin, the absolute risk increase appears to be small (0.2% per year). Furthermore, randomized clinical trials have shown that warfarin is superior to the combination of aspirin plus clopidogrel for prevention of vascular events in patients with AF at high risk of stroke (relative risk reduction of 40%), with similar risks for major bleeding events. Combinations of warfarin (international normalized ratio [INR], 2.0 to 3.0) with antiplatelet therapy offer no incremental benefit in stroke risk reduction while they increase the risk of bleeding.^{36,43,44}

The reduction in ischemic stroke with warfarin in patients with paroxysmal AF is probably similar to that in patients with persistent or permanent AF. The benefit of warfarin is greatest for patients at higher risk of stroke, and there appears to be little benefit for those with no risk factors. The true efficacy of warfarin is likely to be even higher than suggested by trial results because many of the strokes in the warfarin-treated groups occurred in patients who were noncompliant at the time of the stroke.²⁷ It has been found that if a patient's INR is not maintained in the therapeutic range at least 65% of the time, the advantage of taking warfarin over aspirin is nullified.

Warfarin therapy, however, has several problems that limit the enthusiasm of patients and clinicians: a narrow therapeutic window that requires periodic INR monitoring and frequent dose adjustments, multiple drug and dietary interactions, genetic variability in response (accounting for 39% to 56% of the variability in the warfarin dose), long half-life (36 to 42 hours), and slow onset of action. In several trials, more than one-third of the patients refused warfarin therapy, largely because of the life-style changes required, the inconvenience of INR monitoring, and concern about bleeding risk. These issues have contributed to the underutilization of anticoagulation therapy in patients who can stand to derive benefit from it. In fact, it is estimated that less than 50% of eligible patients are being treated with warfarin. Additionally, more than one-third of patients taking warfarin are not maintained in the therapeutic range, thus exposing them to increased risk of either stroke or bleeding.

Furthermore, it is estimated that up to 44% of patients with AF have one or more absolute or relative contraindications for long-term oral anticoagulation therapy, most commonly related to increased risk of bleeding. The estimated annual incidence of bleeding associated with oral anticoagulation is 0.6% for fatal bleeding, 3.0% for major bleeding, and 9.6% for major or minor bleeding. The risk of bleeding appears to be especially high during the first year of treatment. Notably, the risk of major bleeding in older patients (at least 80 years of age) receiving warfarin therapy, although higher than younger patients, is acceptably low (2.5% per year), and these patients can still benefit from warfarin prophylaxis when a good quality of anticoagulation is obtained.⁴² The risk of falling and intracranial bleeding should be considered but not overstated, because a patient may need to fall almost 300 times per year for the risk of intracranial hemorrhage to outweigh the benefit of warfarin therapy in stroke prevention.

DIRECT THROMBIN INHIBITORS. Dabigatran, an oral direct thrombin inhibitor, was compared with warfarin therapy in a large (18,113 patients) randomized controlled trial in patients with nonvalvular AF and a mean CHADS₂ score of 2. Dabigatran was superior to warfarin for stroke prevention, with similar risk of bleeding at a higher dabigatran dose (150 mg twice daily). A lower dose (110 mg twice daily) of dabigatran was associated with stroke rates similar to those seen with warfarin, with lower bleeding risk.

Disadvantages of dabigatran include lack of long-term safety data, twice-daily dosing, tolerability issues secondary to dyspepsia, lack of an antidote, and when compared with warfarin, a trend toward increased incidence of myocardial infarction and higher

cost. Bleeding with dabigatran remains a hazard and increases over time, out to 2.5 years of follow-up, albeit at a lower rate than with warfarin.

Dabigatran was approved by the U.S. Food and Drug Administration (FDA) for stroke prevention in nonvalvular AF and is likely to improve compliance by obviating the need for dietary restrictions and frequent blood monitoring required for warfarin therapy.⁴⁵

FACTOR Xa INHIBITORS. Several oral factor Xa inhibitors are being considered. Rivaroxaban was shown to be noninferior to warfarin in stroke prevention in patients with AF and two or more stroke risk factors, and it seems to be associated with a lower risk of intracranial and fatal bleeding.⁴⁶ In patients for whom vitamin K-antagonist therapy was considered unsuitable, apixaban was found more than 50% superior to aspirin for the prevention of stroke or systemic embolism, with a similar risk of bleeding.⁴⁷ Also, when compared with warfarin for stroke prevention in patients with AF with one or more additional stroke risk factors, apixaban was found superior to warfarin for stroke and systemic embolism in patients with AF with one or more additional stroke risk factors, thus reducing the risk, with less risk of major bleeding and lower mortality.⁴⁸

NONPHARMACOLOGICAL INTERVENTIONS. Given that the LA appendage is the most common site of thrombi in patients with nonvalvular AF, several approaches have targeted exclusion of the LA appendage from the systemic circulation to help prevent systemic thromboembolism. These approaches can potentially become important clinical options in many patients, given the fact that up to 44% of patients with AF have one or more absolute or relative contraindications for chronic oral anticoagulation therapy, most commonly related to increased risk of bleeding.^{49,50}

Open surgical LA appendage amputation, suture ligation, or stapling is commonly performed in patients with AF who are undergoing valvular or coronary artery bypass surgery or as an adjunct to the maze procedure. LA excision appears more efficacious than ligation or stapling, largely because achieving complete LA appendage closure with suture ligation or stapling is quite challenging and operator dependent.⁵⁰

Additionally, various minimally invasive thoracoscopic LA appendage exclusion techniques (LA appendage excision, stapling, and clipping) have emerged as isolated surgical procedures or in conjunction with minimally invasive maze procedures for ablation of AF. However, data are still limited regarding its efficacy and safety.⁵¹

Percutaneous catheter-based closure of the LA appendage using various closure devices (e.g., the Watchman device [Atritech, Plymouth, Minn.], PLAATO implant [ev3 Endovascular, Inc., North Plymouth, Minn.], or Amplatzer cardiac plug [AGA Medical Corporation, Golden Valley, Minn.]) is an emerging approach. The feasibility, safety, and efficacy of these interventions have been demonstrated in experimental and clinical studies; however, further evaluation is required to demonstrate long-term efficacy.^{49,50}

RECOMMENDATIONS FOR LONG-TERM STROKE PREVENTION. The choice of therapy (oral anticoagulation versus aspirin) varies with the estimated thromboembolic risk. Patients with valvular AF (those with mitral stenosis or valvular prosthesis) should be managed with oral anticoagulation. For nonvalvular AF, the CHADS₂ (Table 15-4) and CHA₂DS₂-VASc (see Tables 15-2 and 15-3) scoring systems are currently the best validated and most clinically useful for risk stratification. Patients with a CHADS₂ score of 2 or higher are at high risk and should be managed with oral anticoagulation therapy, unless contraindicated. Most patients with AF, however, have a CHADS₂ score of less than 2, and a more comprehensive risk factor-based approach, such as the CHA₂DS₂-VASc scheme, can be used for better risk assessment. Patients with a CHA₂DS₂-VASc score higher than 1 should be considered for oral anticoagulation, whereas patients with a score of 0 have very low risk and can be managed with aspirin therapy (75 to 325 mg daily). Patients

5	18.2 (10.5-27.4)	6

*Not treated with anticoagulation.

†The adjusted stroke rate was derived from multivariate analysis assuming no aspirin usage. CHADS₂ = congestive heart failure, hypertension, age, diabetes, and stroke (doubled); CI = confidence interval.

From Gage BF, Waterman AD, Shannon W, et al: Validation of clinical classification schemes for predicting stroke: results from the National Registry of Atrial Fibrillation, *JAMA* 285: 2864-2870, 2010.

with a score of 1 probably represent an intermediate-risk category and can be managed with either aspirin or oral anticoagulation. When possible, patients at intermediate risk should be considered for oral anticoagulation rather than for aspirin because undertreatment is more harmful than overtreatment. Importantly, those recommendations apply to all patients with AF irrespective of the type of AF.^{27,38}

An INR between 2.0 and 3.0 is recommended for most patients with AF who receive warfarin therapy. The risk of stroke doubles when the INR falls to 1.7, and values up to 3.5 do not convey an increased risk of bleeding complications.²⁷ A higher goal (INR between 2.5 and 3.5) is reasonable for patients at particularly high risk for embolization (e.g., prior thromboembolism, rheumatic heart disease, prosthetic heart valves). Similarly, in patients who sustain ischemic stroke or systemic embolism during treatment with therapeutic doses of warfarin (INR, 2.0 to 3.0), raising the intensity of anticoagulation to a higher INR range of 3.0 to 3.5 should be considered. This approach is probably preferable to adding an antiplatelet agent because an appreciable risk in major bleeding is seen with warfarin only when the INR is greater than 3.5 and is likely to be less than that associated with combination therapy.

Oral anticoagulation is associated with increased risk of bleeding; therefore, an assessment of bleeding risk should be part of the patient assessment before starting anticoagulation. At therapeutic INR levels, the rates of intracerebral hemorrhage are typically between 0.1% and 0.6%, with no increment in bleeding risk with INR values between 2.0 and 3.0 compared with lower INR levels. However, an appreciable increase in bleeding risk is observed with higher INR values (more than 3.5 to 4.0). The risk of bleeding should be weighed against the potential benefit of stroke prevention in individual patients considered for anticoagulation therapy. Various bleeding risk scores have been validated for bleeding risk in anticoagulated patients. Among those is the HAS-BLED score, which was found to correlate well with the risk of major bleeding, hospitalization, or death (Table 15-5). Patients are categorized as low, intermediate, and high bleeding risk according to HAS-BLED scores 0 to 1, 2, and 3 or higher, respectively. A score higher than 2 suggests a risk of major bleeding of 1.9% per year, whereas a score of 5 is associated with a risk of major bleeding of up to 12.5% per

**TABLE 15-5 Clinical Characteristics Comprising the HAS-BLED Bleeding Risk Score**

LETTER	CLINICAL CHARACTERISTIC*	POINTS AWARDED
H	Hypertension	1
A	Abnormal renal and liver function (1 point each)	1 or 2
S	Stroke	1
B	Bleeding	1
L	Labile INR	1
E	Older patients (e.g., age >65 years)	1
D	Drugs or alcohol use (1 point each)	1 or 2
		Maximum 9 points

*Hypertension is defined as systolic blood pressure higher than 160 mmHg. Abnormal kidney function is defined as the presence of long-term dialysis or renal transplantation or serum creatinine concentration of at least 200 $\mu\text{mol/liter}$. Abnormal liver function is defined as chronic hepatic disease (e.g., cirrhosis) or biochemical evidence of significant hepatic derangement (e.g., bilirubin more than twice the upper limit of normal, in association with aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase more than three times the upper limit of normal). Bleeding refers to previous bleeding history or predisposition to bleeding, or both (e.g., bleeding diathesis, anemia). Labile INRs refers to unstable or high INRs or poor time in therapeutic range (e.g., less than 60%). Drugs or alcohol use refers to concomitant use of drugs (e.g., antiplatelet agents, nonsteroidal antiinflammatory drugs, or alcohol abuse).

INR = international normalized ratio.

From Pisters R, Lane DA, Nieuwlaat R, et al: A novel user-friendly score (HAS-BLED) to assess 1-year risk of major bleeding in patients with atrial fibrillation: the Euro Heart Survey, *Chest* 138:1093-1100, 2010.

year.⁵² One report also proposed a simple 5-variable risk score for quantifying the risk of warfarin-associated hemorrhage, including anemia (3 points), severe renal disease (3 points), age 75 years or more (2 points), prior bleeding (1 point), and hypertension (1 point). Major bleeding annual rates were 0.8% for the low-risk group (0 to 3 points), 2.6% for the intermediate-risk group (4 points), and 5.8% for the high-risk group (5 to 10 points).⁵³

In high-risk patients who cannot be treated with oral anticoagulation because of poor tolerance or noncompliance issues or because of strong patient preference, dual antiplatelet therapy (aspirin plus clopidogrel) can be used. However, dual antiplatelet therapy is not an alternative to oral anticoagulation in patients at high bleeding risk because the risk of major bleeding associated with dual antiplatelet therapy is broadly similar to that with oral anticoagulation. In the latter group, aspirin monotherapy is associated with lesser bleeding risk, although at the expense of less protection from systemic thromboembolism.^{36,43,44} Percutaneous LA appendage exclusion procedures may become an important therapeutic alternative to long-term antithrombotic therapy in these patients.³⁶

The new antithrombotic agents have many potential advantages over the vitamin K antagonists, including their rapid onset of action, predictable therapeutic effect, less complex pharmacodynamics, and limited dietary and drug interactions. These advantages will likely promote greater use of anticoagulants, enhance patients' compliance, allow for routine therapy without monitoring, and possibly eliminate the need for anticoagulation with parenteral agents such as heparin ("bridge therapy"). However, warfarin will remain the mainstay of treatment for patients with valvular AF and those with mechanical heart valves because studies in this population have not been started. Warfarin may also hold favor with patients who are considered noncompliant with therapy and as an option for those patients who "fail" or develop an event while taking one of the new agents.

ANTICOAGULATION IN PATIENTS WITH CORONARY ARTERY DISEASE. The combined use of antiplatelet and anticoagulant drugs can be required in patients with AF and coronary artery disease. In these patients, it is a common practice to add low-dose aspirin therapy in conjunction with warfarin. Although this strategy appears to be appropriate in patients with acute coronary syndromes, it is important to recognize that in patients with AF with

stable coronary, carotid artery disease, or peripheral artery disease, adding aspirin to warfarin does not reduce the risk of stroke, systemic embolism, or myocardial infarction, but it substantially increases the risk of major bleeding (3.9% per year versus 2.3% per year).⁵⁴

After percutaneous coronary interventions, dual antiplatelet therapy with aspirin plus clopidogrel is superior to aspirin alone, warfarin alone, or warfarin plus aspirin, for reduction of the risk for myocardial infarction and cardiovascular death. On the other hand, the omission of warfarin therapy in eligible patients with AF following percutaneous coronary interventions can result in increased rates of mortality and ischemic stroke, a finding suggesting the importance of maintaining anticoagulation in this population. Importantly, triple therapy (aspirin plus clopidogrel plus warfarin) has been associated with major bleeding rates as high as 7% per year.

In the absence of randomized trials, antithrombotic therapy should be individualized, taking into account the risks of bleeding, thromboembolism, and stent thrombosis. It appears reasonable to resume anticoagulation as soon as feasible after percutaneous coronary interventions and to use triple therapy (aspirin [75 to 100 mg] plus clopidogrel [75 mg] plus warfarin) in patients with AF with moderate or high stroke risk in the initial period following an acute coronary syndrome (3 to 6 months) and following placement of coronary stents (4 weeks for a bare-metal stent, 6 to 12 months for a drug-eluting stent), especially in patients with low risk of serious bleeding. Afterward, warfarin is continued in addition to a single antiplatelet agent (either aspirin or clopidogrel). During triple therapy, it is advisable to target a lower INR (approximately 2.0), limit the duration of triple therapy to the period required for stent endothelialization, consider prophylactic proton pump inhibition, and follow patients closely to help minimize the high risk of bleeding. Additionally, it is advisable to avoid drug-eluting stents (which are associated with delayed endothelialization and an apparently higher incidence of late stent thrombosis) in patients requiring anticoagulation to reduce the need for prolonged triple therapy.^{36,54}

ANTICOAGULATION IN THE PERICARDIOVERSION PERIOD. Patients without a contraindication to oral anticoagulation who have been in AF for more than 48 hours should receive 3 to 4 weeks of warfarin prior to and after cardioversion. This approach is also recommended for patients with AF who have valvular disease, evidence of LV dysfunction, recent thromboembolism, or AF of unknown duration.²⁷

The rationale for anticoagulation prior to cardioversion is based on observational studies showing that more than 85% of LA thrombi resolve after 4 weeks of warfarin therapy. Thromboembolic events have been reported in 1% to 7% of patients who did not receive anticoagulation before cardioversion. The recommended target INR is 2.0 to 3.0. It has been suggested that it may be prudent to aim for an INR greater than 2.5 before cardioversion to provide the greatest protection against embolic events. Probably more important is to document that the INR has consistently been higher than 2.0 in the weeks before cardioversion.²⁷

An alternative approach that eliminates the need for prolonged anticoagulation prior to cardioversion, particularly in low-risk patients who would benefit from earlier cardioversion, is the use of TEE-guided cardioversion. Cardioversion is performed if TEE excludes the presence of intracardiac clots. Anticoagulation after cardioversion, however, is still necessary.

After cardioversion, it is recommended to continue warfarin therapy for at least 4 weeks, with a target INR of 2.5 (range, 2.0 to 3.0). This recommendation deals only with protection from embolic events related to the cardioversion period. Subsequently, the long-term recommendations for patients who have been cardioverted to NSR but are at high risk for thromboembolism are similar to those for patients with chronic AF, even though the patients are in NSR.²⁷

A different approach with respect to anticoagulation can be used in low-risk patients (no mitral valve disease, severe LV dysfunction, or history of recent thromboembolism) in whom there is reasonable certainty that AF has been present for less than 48 hours. Such patients have a low risk of clinical thromboembolism

if converted early (0.8% in one study), even without screening TEE. The American College of Cardiology/American Heart Association guidelines do not recommend long-term anticoagulation prior to cardioversion in such patients, but they do recommend heparin use at presentation and during the pericardioversion period. The optimal therapy after cardioversion in this group is uncertain. A common practice is to administer aspirin for a first episode of AF that converts spontaneously and warfarin for at least 4 weeks to all other patients. Aspirin should not be considered for patients with AF of less than 48 hours' duration if there is associated rheumatic mitral valve disease, severe LV dysfunction, or recent thromboembolism. Such patients should be treated the same as patients with AF of longer duration: 3 to 4 weeks of oral anticoagulation with warfarin or shorter term anticoagulation with screening TEE prior to elective electrical or pharmacological cardioversion, followed by prolonged warfarin therapy after cardioversion.²⁷

RATE CONTROL

Rate control during AF is important to prevent hemodynamic instability or symptoms such as palpitations, heart failure, lightheadedness, and poor exercise capacity and, over the long-term, to prevent tachycardia-mediated cardiomyopathy and improve quality of life. Beta blockers (e.g., atenolol or metoprolol), diltiazem, and verapamil are recommended for rate control during rest and exercise. Digoxin is not effective during exercise but can be used in patients with heart failure or hypotension or as a second-line agent.

Adequacy of rate control should be assessed at rest and with exertion. However, parameters for optimal rate control in AF remain controversial. It appears reasonable to target a resting heart rate of 60 to 80 beats/min and 90 to 115 beats/min during moderate exercise. Additionally, ambulatory monitoring can help assess adequacy of rate control; goals of therapy include a 24-hour average heart rate lower than 100 beats/min and no heart rate higher than 100% of the maximum age-adjusted predicted exercise heart rate. Also, a maximum heart rate of 110 beats/min during a 6-minute walk test is a commonly used target.^{27,47}

Nevertheless, one study found that a more lenient rate control (resting heart rate less than 110 beats/min) is not inferior to strict rate control (heart rate less than 80 beats/min at rest and less than 110 beats/min during moderate exercise). Such an approach can be more convenient in clinical practice and may be considered especially in asymptomatic patients with permanent AF and no significant structural heart disease, but periodic monitoring of LV function is necessary to evaluate for the potential risk of tachycardia-mediated cardiomyopathy.^{47,55} Of note, lenient rate control does not seem to increase the risk of adverse atrial or ventricular remodeling.

In some patients with tachycardia-bradycardia syndrome, pacemaker implantation can be required to protect from severe bradycardia while allowing the use of AV nodal (AVN) blockers for adequate control of fast ventricular rates during AF (see Fig. 8-4).

AVN ablation and permanent pacemaker implantation are highly effective means of improving symptoms in patients with AF who experience symptoms related to a rapid ventricular rate during AF that cannot be adequately controlled with antiarrhythmic or AVN blockers. AV junction ablation is especially useful when excessive ventricular rates induce a tachycardia-mediated decline in LV systolic function, despite appropriate medical therapy. Additionally, in patients with AF and advanced heart failure requiring cardiac resynchronization therapy, AVN ablation can potentially improve long-term survival, NYHA class, and LV systolic function, even in patients with mean ventricular rates lower than 100 beats/min during AF. In these patients, AVN ablation ensures a high percentage of resynchronized QRS complexes and attenuates cardiac output impairment resulting from R-R interval variability.⁵⁶

RHYTHM CONTROL

Restoration and maintenance of sinus rhythm in patients with AF can have several potential benefits, including relief of symptoms,

improved functional status and quality of life, prevention of systemic thromboembolism, and avoidance of cardiomyopathy. Reduction in atrial remodeling and retardation of progression of AF, and improvement in LV function also have been described. The impact of rhythm control on mortality, however, remains to be determined.²¹

Unfortunately, complete restoration of sinus rhythm (100% freedom from AF recurrence) often is unachievable with current drug therapies and remains an impractical treatment goal. It has been estimated that the average 1-year recurrence rate associated with amiodarone approximates 35%, and the recurrence rate for other currently available antiarrhythmic drug therapies is even higher (approximately 50%). However, it is likely that individuals with AF can derive benefit from even partial restoration of sinus rhythm, including improvements in symptoms and attenuation of electrical and structural atrial remodeling associated with AF and hence retardation of progression of AF.²¹

REVERSION TO NORMAL SINUS RHYTHM. When rhythm control is chosen, both electrical and pharmacological cardioversion methods are appropriate options. The timing of attempted cardioversion is influenced by the duration of AF. As noted, in patients with AF of a duration longer than 48 hours or unknown duration, cardioversion should be delayed until the patient has been anticoagulated at appropriate levels for 3 to 4 weeks or TEE has excluded atrial thrombi.²⁷

Electrical cardioversion is indicated for patients with rapid ventricular rates not responding promptly to medical therapy and ongoing myocardial ischemia, hypotension, acute heart failure, or ventricular preexcitation. In stable patients in whom spontaneous reversion caused by correction of an underlying condition is not likely, electrical or pharmacological cardioversion can be performed. Electrical cardioversion is usually preferred because of greater efficacy and a low risk of proarrhythmia; however, it requires conscious sedation or anesthesia. Importantly, electrical cardioversion is contraindicated in patients with ongoing toxic reactions from digitalis or patients with hypokalemia.⁵⁷

The overall success rate of electrical cardioversion (at any level of energy) for AF is 75% to 93% and is related inversely to the duration of AF and LA size. Occasionally, electrical cardioversion can fail to terminate AF, or AF recurs shortly after transient restoration of sinus rhythm. When AF fails to terminate, using higher energy levels, applying external pressure on the cardioversion patches, and performing cardioversion during exhalation can improve effectiveness. When AF recurs early after a successful cardioversion, pretreatment with amiodarone, dofetilide, flecainide, ibutilide, propafenone, or sotalol can facilitate successful electrical cardioversion.^{57,58} It is important to distinguish failure to terminate AF with a certain shock energy (the solution for which is higher energy shock) from successful termination of AF with nearly immediate recurrence (for which repeated shocks at any energy are unlikely to have greater benefit). Sinus pauses or transient sinus arrest after successful cardioversion are common; rarely, several-second pauses result from sinus node dysfunction and the effect of sedation. Almost all external defibrillators have the capability of back-up bradycardia pacing through the defibrillation patches, which can be used transiently if needed. The need for more prolonged pacing after cardioversion is rare.

Certain antiarrhythmic drugs have been found to be more effective than placebo for chemical cardioversion of AF, by converting 30% to 60% of patients. Evidence of efficacy from randomized trials has been best established for dofetilide, ibutilide, flecainide, propafenone, amiodarone, and quinidine. The benefit from specific antiarrhythmic drugs varies with the duration of AF: dofetilide, flecainide, ibutilide, propafenone or, to a lesser degree, amiodarone if less than 7 days' duration; and dofetilide or, to a lesser degree, amiodarone or ibutilide if AF is more prolonged. Flecainide and propafenone should be avoided in patients with abnormal LV function and ischemia.⁵⁷

Rate control with an AVN blocker (beta blockers, diltiazem, verapamil, digoxin) should be attained before instituting a class IA or

IC drug because of possible conversion to AFL and a very rapid ventricular rate.²⁷ Importantly, continuous cardiac monitoring is required (to detect sinus node dysfunction, AV block, ventricular arrhythmias, and conversion into AFL) for an interval that is dependent on the agent used (usually approximately half the drug elimination half-life). Once the safety of pharmacological conversion with propafenone or flecainide has been established, repeat patient-administered cardioversion using oral propafenone (450 to 600 mg) or flecainide (200 to 300 mg) may be appropriate on an outpatient basis ("pill-in-the-pocket" approach).^{36,57}

MAINTENANCE OF NORMAL SINUS RHYTHM. Only 20% to 30% of patients who are successfully cardioverted maintain NSR for more than 1 year without chronic antiarrhythmic therapy. This is more likely to occur in patients with AF for less than 1 year, no enlargement of the LA (less than 4.0 cm), and a reversible cause of AF, such as hyperthyroidism, pericarditis, pulmonary embolism, or cardiac surgery. It has been thought that the drugs most likely to maintain NSR suppress triggering ectopic beats and arrhythmias and affect atrial EP properties to diminish the likelihood of AF. There is therefore a strong rationale for prophylactic antiarrhythmic drug therapy in patients who have a moderate to high risk of recurrence, provided that the therapy is effective and that toxic and proarrhythmic effects are low. Prophylactic drug treatment is seldom indicated in patients with a first-detected episode of AF and can also be avoided in patients with infrequent and well-tolerated paroxysmal AF.²⁷

Evidence of efficacy from randomized trials is best for amiodarone, propafenone, disopyramide, sotalol, flecainide, dofetilide, dronedarone, and quinidine. Amiodarone is the most effective agent but is associated with substantial noncardiac toxic effects. The relative efficacy of the other antiarrhythmic drugs for the management of AF remains unknown. Drug selection is largely driven by the safety profile. The presence and extent of concomitant cardiovascular disease have to be carefully considered. A safer, although possibly less efficacious, drug is usually

recommended before resorting to more effective but less safe therapies (Fig. 15-5).³⁶

In patients with AF with and minimal or no heart disease (lone AF), flecainide, propafenone, sotalol, and dronedarone are preferred. In patients with adrenergically mediated AF, beta blockers represent first-line treatment, followed by sotalol. The anticholinergic activity of long-acting disopyramide makes it a relatively attractive choice for patients with vagally mediated AF. In contrast, propafenone is not recommended in vagally mediated AF because its (weak) intrinsic beta-blocking activity may aggravate this type of paroxysmal AF. In patients with lone AF, amiodarone should be chosen later in the sequence of drug therapy because of its potential toxicity.³⁶

In patients with substantial LV hypertrophy (LV wall thickness greater than 1.4 cm), sotalol is thought to be associated with an increased incidence of proarrhythmia. It is also reasonable to avoid flecainide and propafenone because of concern of increased proarrhythmic risk. Dronedarone, although not specifically tested in this population, is likely to be safe. Amiodarone is usually considered when symptomatic AF recurrences continue to affect the quality of life of these patients.^{27,36}

Flecainide and propafenone are contraindicated in patients with coronary artery disease. Sotalol, dofetilide, or dronedarone are recommended as first-line therapy. Amiodarone is considered the drug of last resort in this population because of its potential toxicity.³⁶

Dronedarone, dofetilide, and amiodarone are the only agents available for patients with AF with concomitant heart failure; other antiarrhythmic agents can be associated with substantial toxicity and proarrhythmia. Dronedarone is contraindicated in patients with NYHA Class III to IV or recently (within the previous month) decompensated heart failure, especially when the LV ejection fraction is 35% or lower. In such patients, dofetilide and amiodarone are preferred. Importantly, concerning results emerged from a study (the Permanent Atrial fibrillation Outcome Study Using

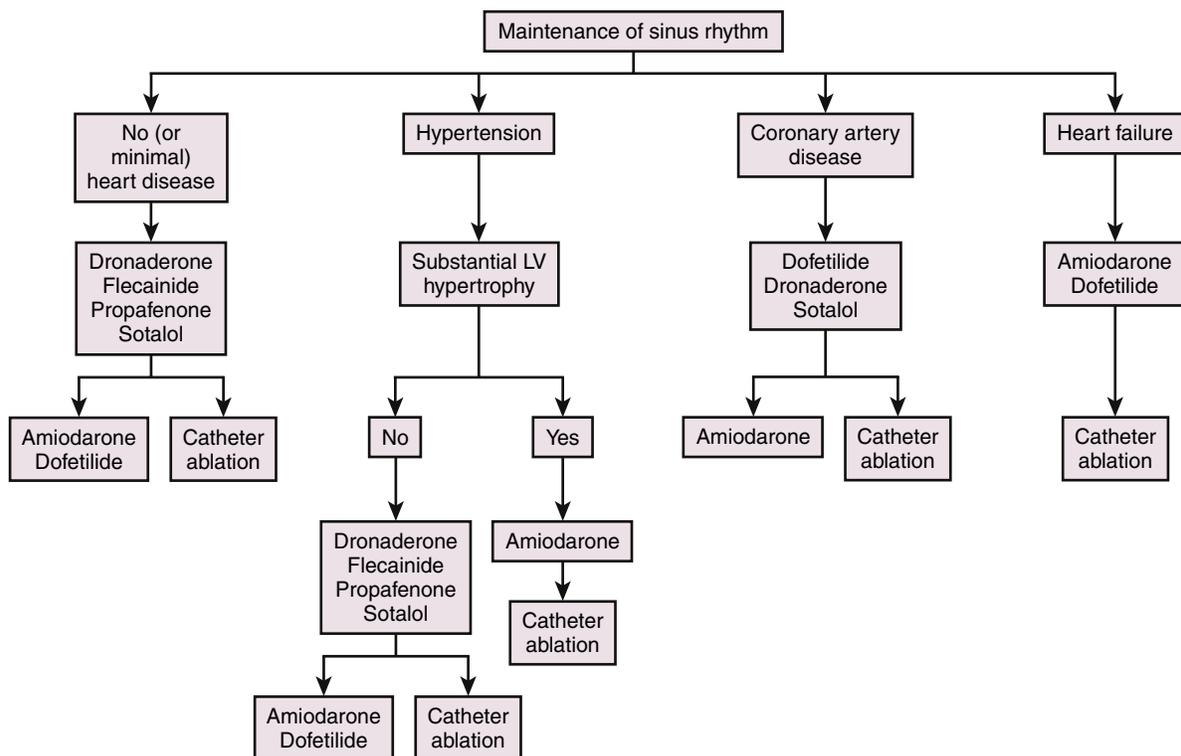

FIGURE 15-5 Therapy to maintain sinus rhythm in patients with recurrent paroxysmal or persistent atrial fibrillation. Drugs are listed alphabetically and not in order of suggested use. The seriousness of heart disease progresses from left to right, and selection of therapy in patients with multiple conditions depends on the most serious condition present. LV = left ventricle. (With permission from Wann LS, Curtis AB, January CT, et al: 2011 ACCF/AHA/HRS Focused update on the management of patients with atrial fibrillation [updating the 2006 guideline], *Heart Rhythm* 8:157-176, 2011.)

Dronedronarone on Top of Standard Therapy [PALLAS]) conducted to assess the potential clinical benefit of dronedronarone in patients more than 65 years of age with permanent AF in the reduction of major cardiovascular events (stroke, systemic arterial embolism, myocardial infarction, or cardiovascular death), or unplanned cardiovascular hospitalization or death from any cause. The study was stopped early because of a twofold increase in death, as well as twofold increases in stroke and hospitalization for heart failure in patients receiving dronedronarone compared with patients taking a placebo. These data currently are being reviewed by the FDA to determine whether those results apply to patients who use dronedronarone for the approved indications in nonpermanent (paroxysmal or persistent) AF.

Although amiodarone is associated with organ toxicity, it appears to have a lower risk of proarrhythmia than other agents. Class IC agents can be associated with substantial toxicity in patients with heart failure because of their proarrhythmic and negative inotropic effects.³⁶

Quinidine is associated with increased mortality, likely the result of ventricular proarrhythmia secondary to QT interval prolongation. Hence, this drug has largely been abandoned for AF therapy.

When treatment with a single drug fails, combinations of antiarrhythmic drugs can be tried. Useful combinations include a beta blocker, sotalol, or amiodarone, in addition to a class IC agent.²⁷ When AF recurrences are infrequent and tolerated, patients experiencing breakthrough arrhythmias may not require a change in antiarrhythmic drug therapy.

UPSTREAM THERAPY. Given the limited effectiveness and marked risks of serious complications associated with currently available antiarrhythmic drug therapy, the role of therapies targeting the atrial substrate underlying AF (“upstream therapy”) is of particular clinical interest. The goal of this approach is attenuation and reversal of atrial structural remodeling. Given the role of fibrosis and inflammation in the pathogenesis of AF, drugs that suppress fibrosis, as well as antiinflammatory and antioxidative drugs, are being investigated both alone and in combination with traditional antiarrhythmic drugs. Among these drugs are several angiotensin-converting enzyme inhibitors, angiotensin II type 1 receptor blockers, antialdosterone agents, statins (3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors), and omega-3 polyunsaturated fatty acids. These agents seem to reduce atrial fibrosis and were found potentially to reduce structural remodeling and AF susceptibility in various AF models. Nonetheless, current evidence does not support the routine use of these agents for the sole purpose of preventing or treating AF.^{13,16,59,60}

RHYTHM CONTROL VERSUS RATE CONTROL

In the past, many physicians preferred rhythm control to rate control. Reversion of AF and maintenance of NSR restores normal hemodynamics and had been thought to reduce the frequency of embolism. However, two major clinical trials—AFFIRM (Atrial Fibrillation Follow-Up Investigation of Rhythm Management) and RACE (RATE Control versus Electrical Cardioversion for Persistent Atrial Fibrillation)—compared rhythm and rate control and found that embolic events occurred with equal frequency, regardless of whether a rate control or rhythm control strategy was pursued, and this occurred most often after warfarin had been stopped or when the INR was subtherapeutic. Both studies also showed an almost significant trend toward a lower incidence of the primary endpoint with rate control. There was no difference in the functional status or quality of life. Thus, both rhythm control and rate control are acceptable approaches, and both require long-term anticoagulation for stroke prevention. The trials provided supportive evidence for the rate control option in most patients. The AF-Congestive Heart Failure (AF-CHF) study demonstrated similar results among patients with AF with concomitant heart failure.⁶¹

In a worldwide, prospective, observational survey of management of AF in unselected, community-based patients, clinical outcomes were not influenced by the choice of rhythm control versus

rate control. Major cardiovascular outcomes were driven mainly by hospitalizations for arrhythmia or proarrhythmia and other cardiovascular causes and were more dependent on comorbidity than the choice of cardiac rhythm management. Nevertheless, patients receiving rhythm control progressed less rapidly to permanent AF.

However, it would be incorrect to extrapolate that NSR offers no benefit over AF and that effective treatments to maintain NSR need not be pursued. First, these trials were not comparisons of NSR and AF. They compared a rate control strategy to a rhythm control strategy that attempted to maintain NSR but fell short. The failure of AFFIRM and RACE in showing any difference between rate and rhythm control is not so much a positive statement for rate control but rather a testimony to the ineffectiveness of the rhythm control methods used. Failure of rhythm control to demonstrate superiority over rate control is caused by failure to achieve maintenance of NSR over the long term. Several trials demonstrated that the success of antiarrhythmic therapy in maintaining NSR is borderline, at best, with increasing failure rates over time. When the data from these trials were analyzed according to the patient’s actual rhythm (as opposed to his or her treatment strategy), the benefit of NSR over AF became apparent: the presence of NSR was found to be one of the most powerful independent predictors of survival, along with the use of warfarin, even after adjustment for all other relevant clinical variables. Patients in NSR are almost half as likely to die compared with those with AF. This benefit, however, is offset by the use of antiarrhythmic drug therapy, which increases the risk of death.^{21,61,62}

Achieving and maintaining sinus rhythm remain viable and important treatment goals. However, because currently available antiarrhythmic agents commonly fail to suppress AF completely and have safety profiles that are less than ideal, it is reasonable to reserve it to the populations of patients likely to derive the greatest benefit from rhythm control. The selection of appropriate rhythm control or rate control strategies should be individualized and take into consideration the nature, intensity, and frequency of symptoms, patient preferences, comorbid conditions, and the risk of recurrent AF. According to analyses of available data, these groups may include young patients and those with newly diagnosed AF, significant symptoms, poorly controlled ventricular response, or tachycardia-mediated cardiomyopathy. On the other hand, asymptomatic or mildly symptomatic patients, especially those older than 65 years, and women with persistent AF who have hypertension or other underlying heart diseases may be better suited for rate control therapy.^{21,61,62}

NONPHARMACOLOGICAL APPROACHES FOR RHYTHM CONTROL

CATHETER ABLATION OF ATRIAL FIBRILLATION. Currently, the mainstay of nonpharmacological rhythm control is catheter ablation of AF, which can help maintain NSR without the risk associated with long-term antiarrhythmic therapy and has been shown to significantly improve symptoms, exercise capacity, quality of life, and LV function, even in the presence of concurrent heart disease and when ventricular rate control has been adequate before ablation. Because no mortality benefit of catheter ablation of AF has so far been demonstrated, the procedure is currently reserved for patients with symptomatic AF.

Several studies have found catheter ablation superior to medical therapy for the control of AF. In a meta-analysis of 6 randomized, controlled trials with a total of 693 patients with AF that compared catheter ablation (PV isolation) and medical therapy, the efficacy of PV isolation for the maintenance of NSR was more than twofold greater than that of antiarrhythmic drug therapy (77% versus 29% at 12 months of follow-up). The benefit of PV isolation was even greater in patients with paroxysmal AF. Moreover, catheter ablation was associated with a two-thirds reduction in hospitalization for cardiovascular causes, with a relatively small (2.6%) risk of major procedural complications.²⁵ Nonetheless, in the absence of large, well-designed, multicenter randomized trials of catheter ablation

as a first-line therapy for AF in symptomatic or asymptomatic patients, a history of symptoms, despite therapeutic doses of antiarrhythmic medication (type IA, IC, or III), is widely accepted as the minimum qualifying criterion for catheter ablation. With improved efficacy of ablation techniques, however, the threshold for ablation will continue to fall.

Catheter ablation was also found to be associated with better quality of life, higher rates of freedom from both AF and antiarrhythmic medications, and lower rates of AF progression when compared with AVN ablation and biventricular pacing in symptomatic patients with AF and cardiomyopathy (LV ejection fraction 40% or less).⁶³

SURGICAL ABLATION OF ATRIAL FIBRILLATION. The classic Cox-maze procedure involves creating a series of incisions in both the left and right atria that were originally designed to direct the propagation of the sinus impulse through both atria while interrupting the multiple macroreentrant circuits thought to be responsible for AF. This procedure is the most effective means of curing this arrhythmia, eliminating AF in 75% to 95% up to 15 years after surgery. Improvements and simplifications culminated in the Cox-maze III procedure, which became the gold standard for the surgical treatment of AF. Nonetheless, because of its complexity, technical difficulty, and risk of mortality and other complications, the maze procedure did not gain widespread acceptance.⁶⁴

To simplify the procedure, the standard cut-and-sew surgical technique has been replaced with linear epicardial ablation using unipolar or bipolar RF ablation, cryoablation, laser, high-frequency ultrasound, and microwave energy. Most surgical epicardial ablation procedures have been performed in conjunction with mitral valve surgery; the combination of mitral valve repair and cure of AF can enable selected patients to avoid life-long anticoagulation.^{64,65}

Current surgical instrumentation now enables minimally invasive approaches to be performed epicardially on the beating heart through mini-thoracotomies with video assistance. However, despite elimination of the need for median sternotomy and cardiopulmonary bypass, these procedures are still relatively invasive. To minimize the invasiveness of the procedure further, a totally thoracoscopic approach has been developed. Bipolar RF is the predominant energy source used, and bilateral PV isolation is the most common lesion set, with some approaches adding ganglionic plexus ablation, as well as exclusion of the LA appendage. Although multiple series described high success rates for paroxysmal AF (89% at 12 months of follow-up), success has been limited in patients with persistent and longstanding persistent AF (25% to 87%).^{64,65} Limited follow-up has left uncertainty about overall results.

More extensive ablation lines, in addition to PV antral isolation and ganglionic plexus ablation, as well as documentation of complete PV isolation by demonstration of EP entrance or exit block, conduction block across ablation lines, and the detection and

confirmation of ablation of the parasympathetic component of the ganglionic plexuses, are being evaluated to improve outcome. Some series reported a single procedure success rate of 86% at 1 year without the use of antiarrhythmic drugs.^{66,67}

Currently, stand-alone surgical epicardial AF ablation may be considered for symptomatic patients with AF who were refractory to one or more attempts at catheter ablation or who are not candidates for catheter ablation (e.g., patients not candidates for long-term anticoagulation and those with an LA thrombus). There have been no randomized studies comparing surgical and catheter ablation of AF. Hence, the decision to recommend surgical AF ablation before considering catheter ablation for patients with symptomatic AF refractory to drug therapy and no other indication for cardiac surgery remains controversial, and it should be based on each institution's experience with both techniques, the relative outcomes and risks of each in the individual patient, and patient preference.^{64,65} Given the degree of patient discomfort, longer hospitalizations and recovery times, and the risk of bleeding following LA appendage excision, most patients prefer catheter to surgical ablation.⁶⁸

DEVICE THERAPY. Atrial defibrillators and pacemakers have demonstrated poor efficacy in treating AF. Burst atrial pacing can effectively convert AT or AFL but fails to terminate or minimize AF. Atrial defibrillators can terminate AF with high acute success rates, but the need for repeated shocks and the resulting patient discomfort often render this option intolerable. Similarly, dual-site atrial pacing has failed to demonstrate any consistent reduction in AF burden or improvement in AF symptoms.

Electrocardiographic Features

Atrial Activity

AF is characterized by rapid and irregular atrial fibrillatory waves (f waves) and a lack of clearly defined P waves, with an undulating baseline that may alternate between recognizable atrial activity and a nearly flat line (Fig. 15-6). Atrial fibrillatory activity is generally best seen in lead V₁ and in the inferior leads. Less often, the f waves are most prominent in leads I and aVL.

The rate of the fibrillatory waves is generally between 350 and 600 beats/min. With up to 600 pulses generated every minute, syncytial contraction of the atria is replaced by irregular atrial twitches. Therefore, the fibrillating atria look like a bag of worms in that the contractions are very rapid and irregular. The f waves vary in amplitude, morphology, and intervals, thus reflecting the multiple potential types of atrial activation that may be present at the same time at different locations throughout the atria. The f waves can be fine (amplitude less than 0.5 mm on ECG) or coarse (amplitude more than 0.5 mm). On occasion, the f waves can be inapparent on the standard and precordial leads, which is most likely to occur

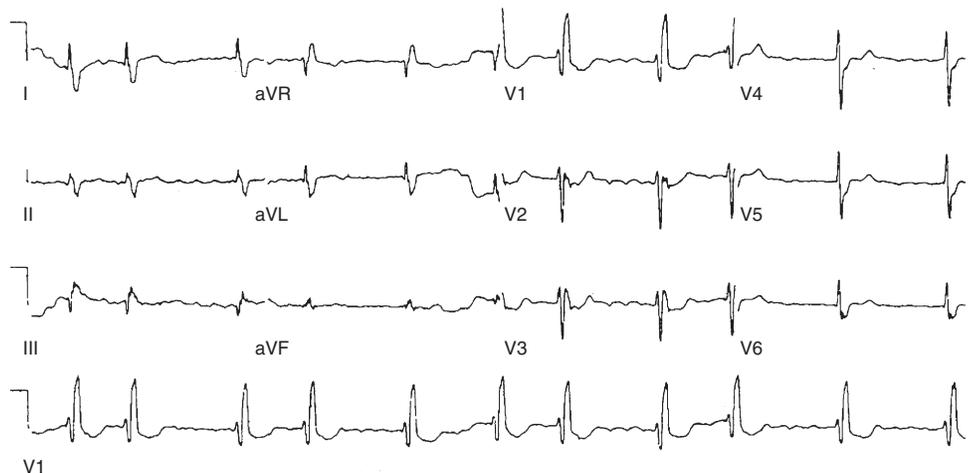

FIGURE 15-6 Surface ECG of atrial fibrillation with chronic right bundle branch block.

in permanent AF. It was initially thought that the amplitude of the f waves correlated with increasing atrial size; however, echocardiographic studies have failed to show a correlation among the amplitude of the f waves, the size of the atria, and the type of heart disease. The amplitude, however, may correlate with the duration of AF.

AF should be distinguished from other rhythms in which the R-R intervals are irregularly irregular. These include multifocal AT (see Fig. 11-1), wandering atrial pacemaker, multifocal PACs, and AT or AFL with varying AV block (see Fig. 12-4). In general, distinct (although often abnormal and possibly variable) P (or flutter) waves are present during these arrhythmias, in contrast to AF. Patients with rheumatic mitral stenosis often demonstrate large-amplitude fibrillatory waves in the anterior precordial leads (V_1 and V_2), which can be confused with AFL. However, careful examination of the fibrillatory waves reveals them to have a varying CL and morphology. The distinction between AF and AFL can also be confusing in patients who demonstrate a transition between these arrhythmias. Thus, AF may organize to AFL or AFL may degenerate to AF (Fig. 15-7). Occasionally, extracardiac artifacts (e.g., 60 cycle/min muscle tremors, as in parkinsonism) can mimic f waves.

Intracardiac recordings demonstrate variability in the atrial electrogram morphology, amplitude, and CL from beat to beat. The different patterns of conduction during AF may be reflected in the morphology of atrial electrograms recorded with mapping during induced AF. Single potentials usually indicate rapid uniform conduction, short intervals between double potentials may indicate collision, long intervals between double potentials are usually indicative of conduction block, and fragmented potentials and complex fractionated atrial electrograms (CFAEs) are markers for pivoting points or slow conduction.

Atrioventricular Conduction during Atrial Fibrillation

The ventricular response in AF is typically irregularly irregular, and the ventricular rate depends on multiple factors, including the EP properties of the AVN, the rate and organization of atrial inputs to the AVN, the level of autonomic tone, the effects of medications that act on the AV conduction system, and the presence of preexcitation over an AV BT.

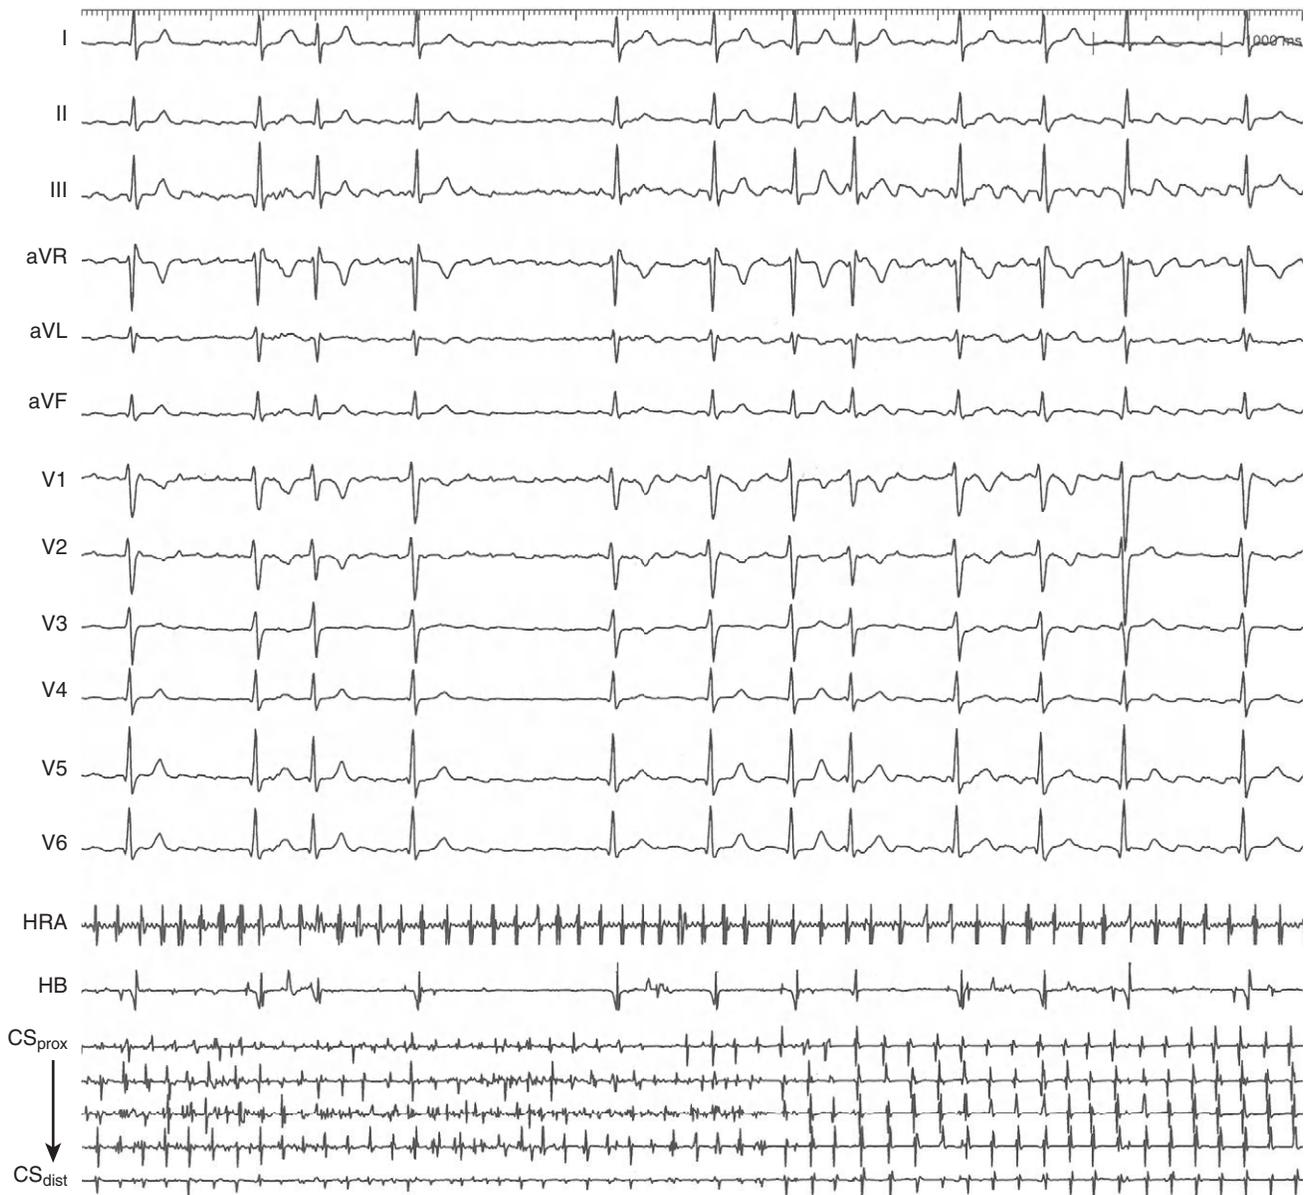

FIGURE 15-7 Surface ECG and intracardiac recordings demonstrating spontaneous conversion of atrial fibrillation (at left) into typical atrial flutter (right). CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HB = His bundle = HRA = high right atrium.

The ventricular rate in untreated patients usually ranges from 90 up to 170 beats/min. Ventricular rates that are clearly outside this range suggest some concurrent problem. Ventricular rates slower than 60 beats/min are seen with AVN disease and can be associated with the sick sinus syndrome, drugs that affect conduction, and high vagal tone, as can occur in a well-conditioned athlete. The ventricular rate in AF can become rapid (more than 200 beats/min) during exercise, with catecholamine excess (Fig. 15-8), parasympathetic withdrawal, thyrotoxicosis, or preexcitation (Fig. 15-9). The ventricular rate can be very rapid (more than 300 beats/min) in patients with the Wolff-Parkinson-White syndrome, with conduction over AV BTs having short anterograde refractory periods.

The compact AVN is located anteriorly in the triangle of Koch. There are two distinct atrial inputs to the AVN, anteriorly via the interatrial septum and posteriorly via the crista terminalis. Experiments in a rabbit AVN preparation demonstrated that propagation of impulses during AF through the AVN to the His bundle (HB) is critically dependent on the relative timing of activation of septal inputs to the AVN at the crista terminalis and interatrial septum. Other investigators showed that the ventricular response also depends on atrial input frequency.

Concealed conduction likely plays the predominant role in determining ventricular response during AF. The constant bombardment of atrial impulses into the AVN creates substantial and varying degrees of concealed conduction, with atrial impulses that enter the AVN but do not conduct to the ventricle, thus leaving a wake of refractoriness encountered by subsequent impulses. This also accounts for the irregular ventricular response during AF. Although the AVN would be expected to conduct whenever it recovers excitability after the last conducted atrial impulse, which would then be at regular intervals, the ventricular response is irregularly irregular because of the varying depth of penetration of the numerous fibrillatory impulses approaching the AVN, leaving it refractory in the face of subsequent atrial impulses.

Alterations of autonomic tone can have profound effects on AVN conduction. Enhanced parasympathetic and sympathetic tone have negative and positive dromotropic effects, respectively, on AVN conduction and refractoriness. An additional factor is the use of AVN blocking agents such as digoxin, Ca^{2+} channel blockers, or beta blockers. There also may be a circadian rhythm for both AVN refractoriness and concealed conduction that accounts for the circadian variation in ventricular rate.

PREEXCITATION DURING ATRIAL FIBRILLATION. The presence of a grossly irregular, very rapid ventricular response (more than 250 beats/min) with QRS longer than 120-millisecond duration during AF rarely results from conduction over the AVN and strongly implies conduction over an AV BT, with rare exceptions (see Fig. 15-9). At very fast heart rates, there is usually a tendency toward regularization of the R-R intervals; therefore, distinguishing the preexcited AF from ventricular tachycardia (VT) or preexcited SVT can be difficult. However, careful measurement always discloses definite irregularities. Moreover, very rapid and irregular VTs are usually unstable and quickly degenerate into VF. Thus, when a rapid, irregular wide QRS complex tachycardia is noted in a patient who has a reasonably stable hemodynamic state, preexcited AF is the most likely diagnosis.

The ability to conduct rapidly over an AV BT is determined primarily by the intrinsic conduction and refractoriness properties of the AV BT. However, as with AVN conduction, factors such as spatial and temporal characteristics of atrial wavefronts during AF, autonomic tone, and concealed conduction influence activation over the AV BT. Very rapid AV conduction during AF can occur in the presence of AV BTs with very short refractoriness, especially when normal conduction through the AVN and His-Purkinje system (HPS) is blocked (as occurs with AVN blocking drugs) and ventricular activation occurs only via the rapidly conducting BT, which would then eliminate retrograde concealment into the BT. This would result in extremely rapid ventricular rates, possibly more than 300 beats/min, which may occasionally degenerate into VF.

REGULAR VENTRICULAR RATE DURING ATRIAL FIBRILLATION. Regular ventricular rate during AF indicates associated abnormalities. A regular, slow ventricular rhythm during AF suggests a junctional, subjunctional, or ventricular rhythm, either as an escape mechanism with complete AV block or as an accelerated pacemaker activity with AV dissociation (see Fig. 9-27). Rarely, the R-R interval can be regularly irregular and show group beating with the combination of complete heart block and a lower nodal pacemaker with a Wenckebach type of exit block. Patients with severe underlying heart disease may develop the combination of AF and VT, leading to a rapid, regular, wide QRS complex tachycardia.

EFFECT OF DIGITALIS TOXICITY ON THE VENTRICULAR RESPONSE. With increasing degrees of digitalis toxicity, high-grade but not complete AV block during AF initially leads to single junctional, subjunctional, or ventricular escape beats.

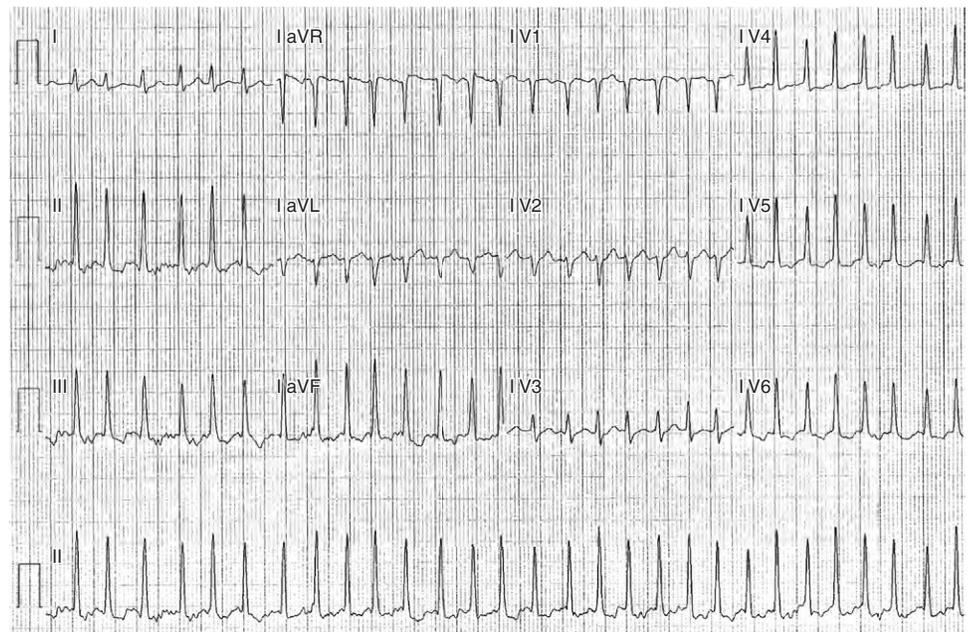

FIGURE 15-8 Surface ECG of atrial fibrillation with rapid ventricular response (207 beats/min) in a patient with septic shock on dopamine infusion.

Higher degrees of AV block result in so few atrial impulses being conducted that the lower pacemaker takes over, thus leading to an escape junctional, subjunctional, or ventricular rhythm with a regular R-R interval for two or more cycles. On occasion, the junctional rate can increase, possibly because of digitalis-induced triggered activity, and it is called nonparoxysmal junctional tachycardia. Increasing digitalis toxicity can result in a Wenckebach exit block and give the appearance of an irregular ventricular rhythm with restoration of AF conduction, but the rhythm shows repetitive group beating as a result of the exit block. Complete AV block is marked by a regular escape rhythm with no conducted beats, a finding that may lead to the erroneous assumption that the patient has converted to NSR. Infrequently, impulses from the lower pacemaker travel alternately down the right and left bundle branches or alternate fascicles of the left bundle branch, resulting in a bidirectional tachycardia. This arrhythmia, which is also frequently a reflection of marked digitalis toxicity, may appear to be ventricular bigeminy. In true bigeminy, however, the ventricular beat in the bigeminal pattern is premature. In comparison, the R-R interval is regular with a bidirectional tachycardia, because all the beats arise from a single pacemaker.

QRS Morphology

The QRS complexes during AF are narrow and normal unless AV conduction is abnormal because of functional (rate-related) aberration, preexisting bundle branch block (BBB; see Fig. 15-6), or pre-excitation over an AV BT (see Fig. 15-9).

Aberrant conduction commonly occurs during AF. Aberrancy is caused by the physiological changes of the conduction system refractory periods that are associated with sudden changes in heart rate. The refractoriness of the HPS tissue is directly related to the preceding R-R interval. Thus, there can be aberrant conduction as the result of a long R-R interval followed by a short cycle. In this scenario, the refractory period of the bundles increases during the long R-R interval (long cycle). The QRS complex that ends the long pause will be conducted normally but is followed by a prolonged refractory period of the bundle branches. If the next QRS complex occurs after a short coupling interval, it can be conducted aberrantly because one of the bundle branches is still refractory as a result of a lengthening of the refractory period (the Ashman phenomenon). The gross irregularity of ventricular response during AF yields an abundance of different R-R intervals; therefore, the long-short cycle sequence occurs commonly, and the Ashman phenomenon is seen frequently during AF. Right BBB (RBBB) aberrancy is more common than left BBB (LBBB) aberrancy, because the right bundle branch has a longer refractory period at slower heart rates. The left anterior fascicle is also frequently involved, often in combination with RBBB. In contrast, functional aberration is uncommon in the HB, the left posterior fascicle, or the main left bundle. Moreover, CLs preceding the pause may also affect the chance for aberrancy after the pause.

The aberrancy caused by the Ashman phenomenon can be present for one beat and have a morphology that resembles a premature ventricular complex (PVC), or it can involve several sequential complexes, suggesting VT. The persistence of aberrancy may reflect a time-dependent adjustment of refractoriness of the

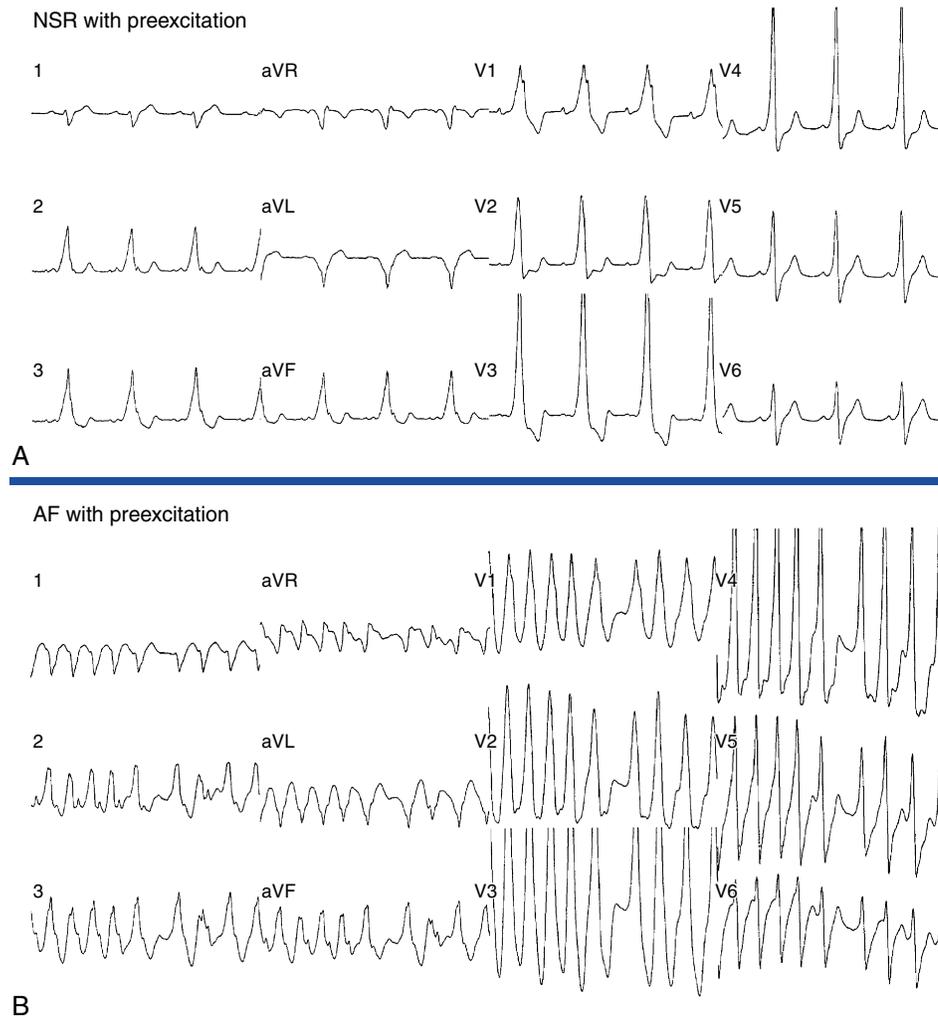

FIGURE 15-9 Preexcited atrial fibrillation (AF). **A**, ECG showing normal sinus rhythm (NSR) with a Wolff-Parkinson-White pattern and pre-excitation using a left lateral bypass tract (BT). **B**, ECG showing preexcited AF (i.e., AF with conduction over the BT).

bundle branch to an abrupt change in CL, or it may be the result of concealed transseptal activation.

Although functional BBB is common in AF, PVCs are even more frequent, and it is important to differentiate between aberrant ventricular conduction and VT when repetitive wide QRS complexes occur during AF. The presence or absence of a long-short cycle sequence may not be helpful in differentiating aberration from ectopy for two reasons. Although a long cycle (pause) sets the stage for the Ashman phenomenon, it also tends to precipitate ventricular ectopy. Moreover, concealed conduction occurs frequently during AF, and therefore it is never possible to determine exactly when a bundle branch is activated from the surface ECG.

The proper diagnosis of aberrant conduction is a continuing challenge, but it can usually be accomplished by careful analysis of the rhythm strip and application of certain criteria. An aberrantly conducted beat caused by BBB generally has the pattern of a classic bundle branch or fascicular block. A PVC is usually followed by a longer R-R cycle, indicating the occurrence of a compensatory pause, the result of retrograde conduction into the AVN and anterograde block of the impulse originating in the atrium. The presence of long R-R cycles after the wide QRS complex that have identical CLs also suggests a ventricular origin (see Fig. 10-3). Furthermore, the absence of a long-short cycle sequence associated with the wide or aberrant QRS complex suggests that it is of ventricular origin. Aberrancy is not present if, with inspection of a long ECG rhythm strip, there are R-R interval combinations that are longer and shorter than those associated with the wide QRS complex. Also, a ventricular origin is likely if there is a fixed coupling interval between the normal and wide QRS complexes (Fig. 15-10).

Catheter Ablation of Atrial Fibrillation

Evolution

Since 1990, catheter ablation for the treatment of AF has evolved from an investigational procedure to one that is now performed on thousands of patients annually in many medical centers worldwide. The growing acceptance of this procedure has been brought

about by a steadily increasing number of reports showing the safety and efficacy of catheter ablation of AF targeting the PVs and posterior LA.

CATHETER ABLATION OF ATRIAL FIBRILLATION: SUBSTRATE MODIFICATION

Cox and colleagues developed a series of techniques for the surgical disruption of AF. The final iteration, the maze III procedure, was based on a model of AF in which maintenance of the arrhythmia requires persistence of a critical number of circulating wavelets of reentry, each of which requires a critical mass of atrial tissue to sustain it. The concept behind the maze III, in which a series of complete, transmural incisions are made in the left and right atria, was that by dividing the atria into small enough electrically isolated compartments, reentrant activity was no longer possible and maintenance of AF could be prevented, regardless of the mode of initiation. However, application of the maze III operation has been limited by the morbidity and risk associated with sternotomy-thoracotomy and cardiopulmonary bypass, as well as by limited adoption by cardiothoracic surgeons. With the success of the Cox-maze procedure, multiple variations of the procedure have been performed, most of which have involved the use of a smaller lesion set. The LA lesion set was found to be fairly adequate to prevent AF, whereas RA lesions were required to prevent the development of AFL. Isolation of the PVs and posterior LA was a feature common to all successful iterations of the maze procedure. Therefore, this and other similar compartmentalization procedures have evolved over time and now predominantly involve the LA. In general, all these approaches have lower success rates than the maze III procedure.^{64,65}

The success of surgical linear lesions led to the development of the catheter-based approach to perform linear ablation. Initial attempts at delivering long lines of RF ablation aimed at mimicking the lines of the surgical maze. Schwartz and associates reported recreation of the maze III lesion set in a small series of patients by using specially designed sheaths and standard RF catheters.⁶⁹ Although the efficacy was modest, complication rates were high, and procedure and fluoroscopy times were exceedingly long, this

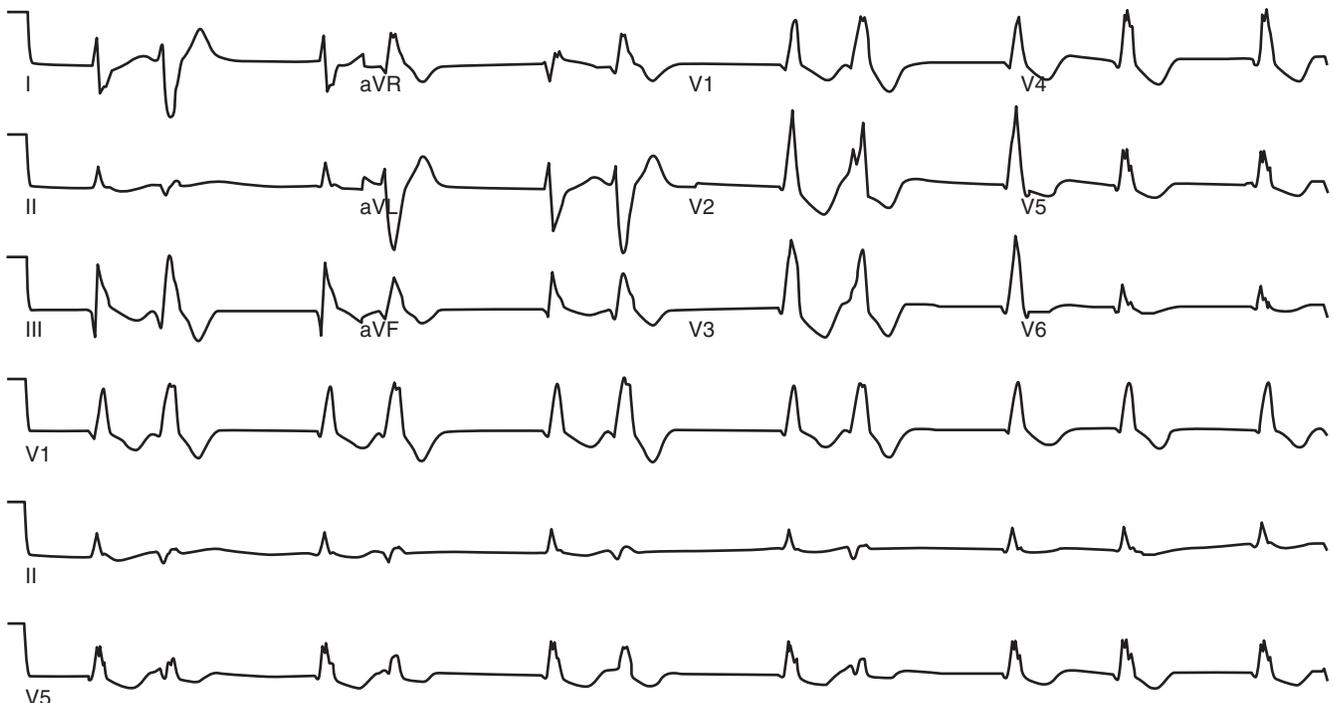

FIGURE 15-10 Surface ECG of atrial fibrillation with right bundle branch block. Ventricular bigeminy is present. Note the fixed coupling interval of the premature ventricular complexes (PVCs). Also, QRS morphology during PVCs is different from that during conducted AF complexes and is inconsistent with aberration.

report demonstrated a proof of concept that led others to try to improve the catheter-based approach. Further refinement of the linear catheter ablation technique involved creating a series of ablation lesions using RF catheters to create specific lesion sets in the RA (two lines) and LA (three or four lines). The RA lesion sets consisted of an intercaval line along the interatrial septum and a cavotricuspid isthmus line to prevent AFL. LA lesions were designed to connect the four PVs to each other and to the mitral annulus. As increasing evidence emerged regarding the importance of the LA in the maintenance of AF, ablation targets became limited to the LA.

In the late 1990s, Pappone and coworkers developed the wide-area circumferential ablation approach using three-dimensional (3-D) electroanatomical mapping.⁷⁰ RF ablation was performed circumferentially around ipsilateral PVs, with the endpoint of ablation being the absence or marked reduction (80%) in the amplitude of electrical signals within the encircling lesions (Fig. 15-11). Despite lack of evidence showing that PVs treated in this way are electrically isolated from the LA, this group began reporting results for paroxysmal AF which were just as good as or better than those working with the ostial segmental PV isolation approach (see later). Furthermore, patients with persistent or permanent AF treated with the Pappone approach achieved freedom from AF almost as good as in patients with paroxysmal AF and far better than reports of patients treated with segmental PV isolation. Further improvements have required a strategy closer to the surgical maze—that is, lines to connect the ipsilateral pairs of the PVs and a line to link the left PV encircling lesion to the mitral annulus, which can be described as the *catheter maze*. Such lines further improved the outcomes of paroxysmal AF and have produced good results for ablation of longstanding persistent AF as well. It became clear that

producing lines with proven transmural conduction block leads to a lower rate of recurrence of AF. However, achieving this is technically challenging and requires long, arduous procedures. Also, gaps in these lines could promote macroreentrant AT.⁷¹

More recently, fractionated electrograms and autonomic responses have been used to guide substrate modification for AF ablation (see Fig. 15-11).⁷²⁻⁷⁴ The ablation of all fractionated electrograms in the RA and LA was based on the hypothesis that these are consistent sites where fibrillating wavefronts turn or split. By ablating these areas, the propagating random wavefronts are progressively restricted until the atria can no longer support AF. Other studies have also provided strong presumptive evidence that hyperactivity of the intrinsic autonomic nervous system constitutes a dysautonomia that can lead to a greater propensity for AF, both paroxysmal and sustained forms. Targeting autonomic nerves at a few specific sites on the heart that are directly related to arrhythmia formation may help limit the extent of damage to healthy myocardium while curtailing the ability to induce or maintain AF.^{75,76}

CATHETER ABLATION OF ATRIAL FIBRILLATION: ELIMINATION OF TRIGGERS

FOCAL ABLATION OF TRIGGERS. The landmark publication of Haissaguerre and colleagues in 1998 demonstrated that paroxysmal episodes of AF are consistently initiated by spontaneous triggers or atrial extrasystoles.⁴ Remarkably, 94% of those triggers originated within the PVs, most within 2 to 4 cm of the ostium. The EP basis of these focal sources appeared to be the sleeves of LA muscle investing the PVs. One or more veins developed abnormal, paroxysmal, rapid automaticity, triggering AF as a result. AF was initiated with a burst of rapid firing from the foci and was abolished with RF ablation at the site of origin. The initial technique was to identify and ablate the culprit focus within the PV, but this approach was limited by the complication of PV stenosis and the recognition that multiple veins are involved in most patients, which leads to frequent recurrences after a “successful” procedure. Moreover, it is frequently difficult to elicit PV arrhythmia in the EP laboratory to allow adequate mapping and ablation.⁴

PULMONARY VEIN ISOLATION. Recognition of major limitations of focal ablation has led to the development of the PV electrical isolation technique. Recognizing that PV musculature conducts to LA musculature by discrete connections has allowed investigators to target those connections using multipolar catheters shaped into rings or baskets. Ablation is performed with a separate roving catheter at the site of earliest activation sequentially until PV electrical activity disappears or becomes dissociated from the LA activity (see Fig. 15-11). Using this strategy, between 20% and 60% of the PV circumference is targeted by ablation. PV isolation has the additional advantage of simultaneously treating all triggering foci within the vein, thereby obviating the need to elicit and map those foci individually. For the same reason, investigators were soon led to attempt to isolate as many PVs as possible at the initial ablation session. Comparative case series ultimately demonstrated that empirical isolation of the four PVs led to superior outcomes over isolating fewer veins.^{36,37}

It was subsequently found that by ablating at or just outside the PV ostia, the incidence of PV stenosis could be reduced significantly. Using this approach, ablation is performed circumferentially around the antrum of each of the four PVs (see Fig. 15-11). In patients in whom the inferior and superior veins were closely spaced or shared a common ostium, a single large circumferential RF lesion set was performed.^{77,78}

With further research, it was also observed that non-PV foci were an important source of AF in some patients, although percentages varied among different groups. Among the sources identified are the vein of Marshall, the CS, and the SVC, all of which are, like the PVs, thoracic veins. Targeting those triggers by electrical isolation of the involved thoracic veins has been attempted in selected patients.⁷⁹

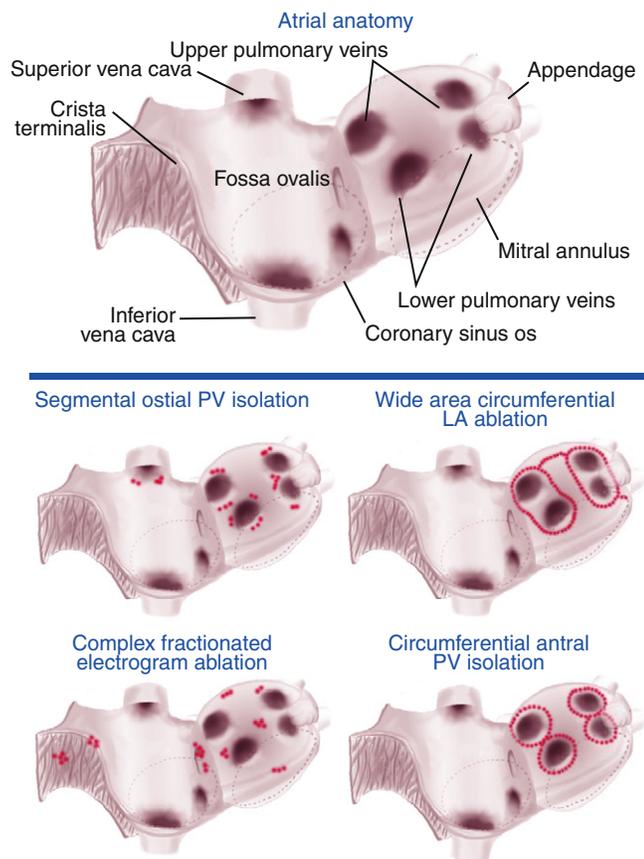

FIGURE 15-11 Catheter ablation of atrial fibrillation (AF). Atrial anatomy is shown at top; both atria are opened and viewed from the front. Various procedures for catheter ablation of AF are shown (red dots are ablation lesions). See text for further discussion. LA = left atrium; PV = pulmonary vein.

Periprocedural Management

ANTIARRHYTHMIC AGENTS

Antiarrhythmic medications are frequently stopped more than 5 days (more than five half-lives) before the ablation procedure because they can suppress spontaneous firing and fractionation of the electrograms that can be used to guide ablation. However, a longer period (approximately 6 months) is required for amiodarone, which may not be practical. Hence, amiodarone may be continued or discontinued before or after ablation.

One report suggested that, in patients with persistent AF, it may be reasonable to attempt electrical cardioversion and maintenance of sinus rhythm using antiarrhythmic medications as a prelude to ablation. Restoration of sinus rhythm, even for a relatively short time, can potentially result in reverse electrical atrial remodeling and hence improve the outcome of the ablation procedure.⁸⁰

Continuing antiarrhythmic drug therapy after ablation can potentially reduce the incidence of early recurrences of symptomatic atrial arrhythmias and the need for cardioversion or hospitalization for arrhythmia management. However, this strategy does not seem to improve long-term freedom from AF. Therefore, it seems unnecessary to continue antiarrhythmic drug therapy following ablation with a view to the prevention of long-term arrhythmia recurrences. Nonetheless, the early short-term prophylactic use of antiarrhythmic drugs may be reasonable to help reduce morbidity.⁸¹ Alternatively, antiarrhythmic treatment can be initiated in select patients, such as those with incomplete or unsuccessful ablation procedures and patients with early recurrences of AF or AFL after ablation.

In patients discharged with antiarrhythmic drug therapy, such therapy is usually discontinued after 1 to 3 months if no recurrence of AF is observed. In patients discharged without antiarrhythmic drug therapy who develop recurrent AF, antiarrhythmic drug therapy is initiated unless the patient is satisfied with the extent of symptomatic improvement or elects to undergo a repeat ablation procedure.

ANTICOAGULATION

Patients with a high risk of thromboembolism are anticoagulated with warfarin (INR, 2 to 3) for more than 4 to 6 weeks before the ablation procedure. Warfarin is usually stopped 2 to 5 days before the procedure, and replaced with enoxaparin or intravenous heparin once the INR is lower than 2.0. Enoxaparin is stopped 12 to 24 hours and heparin is stopped 4 to 6 hours before ablation (because transeptal catheterization is frequently required).

An alternative strategy is the continuation of warfarin at a therapeutic INR at the time of ablation without the use of heparin or enoxaparin for bridging. This approach appears to be a safe and efficacious periprocedural anticoagulation strategy and a potentially better alternative to strategies that use bridging with heparin or enoxaparin. The reasons are that it eliminates a period of inadequate anticoagulation immediately following the ablation procedure (a critical period for thromboembolic risk as a result of the inflammation and irritation associated with ablation), and it potentially reduces the risk of acute bleeding complications by obviating the need for heparin or enoxaparin therapy after ablation. Furthermore, a therapeutic INR at the time of the ablation procedure is associated with lower heparin requirements to achieve the target activated clotting time (ACT) and more consistent maintenance of a goal ACT value during the ablation procedure.^{82,83}

Notably, continuation of warfarin through the ablation procedure was not associated with an increase in the incidence of cardiac tamponade. However, patients who developed pericardial effusion are likely to have a larger amount of blood removed from their pericardium for stabilization and require more blood transfusion units, but without an increase in the need to undergo emergency surgical exploration as compared with patients with normal INR levels. Nevertheless, this approach has been predominantly used

by experienced operators, and the transeptal puncture is typically performed under the guidance of intracardiac echocardiography (ICE). Using this approach, warfarin is started (or continued) several weeks before ablation, and the INR is maintained at therapeutic levels. On the day of ablation, an INR of 2.0 to 4.0 is considered acceptable. TEE is performed in patients with a subtherapeutic INR in the 3 weeks prior to ablation. The procedure is cancelled in patients with an INR greater than 4.0.⁸²⁻⁸⁵

Once vascular access is achieved, intravenous heparin (bolus of 100 units/kg, then infusion of 10 units/kg/hr) is administered to all patients during the ablation procedure, even those fully anticoagulated with therapeutic INR at the time of the procedure. During the initial experience with AF ablation, anticoagulation with heparin was delayed until after the LA access had been achieved because of fear of complications with the transeptal puncture. Later, it became evident that such a strategy can allow thrombus formation on sheaths, catheters, and high-profile wires in the RA before transeptal puncture, and these thrombi could potentially travel to the LA. More recently, experienced operators have favored complete heparinization after vascular access, and clearly before transeptal puncture. The ACT should be checked at 10- to 15-minute intervals during the procedure and the heparin dose is adjusted to achieve an ACT of 300 to 400 seconds; then the ACT is checked at 30-minute intervals. To reduce the risk of bleeding complications, it is preferable to avoid antiplatelet therapy (especially glycoprotein IIb/IIIa receptor blockers and clopidogrel) if possible.³

At the conclusion of the ablation procedure, sheath removal requires interruption of anticoagulation to achieve adequate hemostasis. Heparin infusion can be discontinued and the sheaths removed when the ACT is less than 200 seconds. Alternatively, protamine can be administered to reverse heparin effects (1 mg of protamine for every 100 units of heparin received in the previous 2 hours). Warfarin is restarted after the procedure and is continued for a minimum of 2 to 3 months in all patients, regardless of stroke risk factors. Intravenous heparin (therapeutic loading doses) or subcutaneous enoxaparin (0.5 mg/kg twice daily) is administered 4 to 6 hours after sheath removal and continued until the INR reaches therapeutic levels. In patients undergoing the ablation procedure while fully anticoagulated with warfarin, no heparin or enoxaparin is required following ablation as long as INR levels are maintained in the therapeutic range.⁸⁴ In patients who have not taken warfarin before the procedure, it may be initiated the day of the procedure or even the day before, because the INR will not increase immediately. Bridging its effect with enoxaparin is routine in these cases. Alternatively, some centers use dabigatran at therapeutic doses starting at the time of sheath removal to minimize the duration of suboptimal anticoagulation. There are as yet no data on the safety and efficacy of the latter strategy.

When cardiac perforation or major bleeding occurs, protamine is administered intravenously to reverse the effects of heparin. For patients with therapeutic INR levels, fresh frozen plasma, vitamin K, and higher doses of protamine can be required for reversal of anticoagulation. Activated factor VII also can be used to reverse the effects of warfarin. Type and crossmatch for packed red blood cells and fresh frozen plasma should be universally performed and readily available to be infused, along with cardiothoracic surgical back-up if emergency interventions are needed.^{84,85}

Decisions regarding the use of warfarin more than 2 to 3 months following ablation should be based on the patient's risk factors for stroke and not on the presence or absence of AF. Discontinuation of warfarin therapy after ablation is generally not recommended in patients who have a CHADS₂ score of 2 or higher.³ Although one study showed that discontinuation of warfarin therapy 3 months after successful catheter ablation can be safe over medium-term follow-up in some subsets of patients, this was never confirmed by a large prospective randomized trial and therefore remains unproven.³ Even when discontinuation of warfarin therapy is being considered, recurrences of AF should be excluded with confidence. Reliance only on symptoms as an indicator for AF recurrence or ambulatory monitoring can be misleading and can

underestimate the incidence of recurrence. With transtelephonic ECGs, the rate of recurrent AF is much higher (28% versus 14% with serial ECG and Holter monitoring in one report). Moreover, a high rate of asymptomatic AF episodes, with some lasting more than 48 hours, has also been noted in patients with paroxysmal AF, even in patients who were significantly symptomatic before the ablation procedure. Therefore, without reliable documentation of the absence of AF recurrences, patients should be anticoagulated according to the guidelines for other patients with AF. The CHADS₂ or CHA₂DS₂-VASc score is recommended for risk stratification to determine which patients require long-term warfarin and which patients can be treated with aspirin. One exception is that patients who would be treated with aspirin receive warfarin anticoagulation for 2 to 3 months after the ablation procedure. In high-risk patients with previous stroke or other indications for anticoagulation, warfarin should be continued indefinitely. Some investigators have also suggested continuation of anticoagulation therapy if significant PV stenosis (more than 50%) is detected.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

TEE is performed in most patients undergoing AF ablation to screen for LA thrombus. Although it is optional in patients with paroxysmal AF and no structural heart disease, preablation TEE is often performed in patients who are in AF at the time of the procedure, regardless of the anticoagulation status prior to ablation. The presence of intracardiac thrombus should prompt cancellation of the procedure and mandate 4 to 8 more weeks of anticoagulation, followed by another TEE. The technique of 64-slice computed tomographic (CT) scanning has been used to identify LA thrombus, but TEE remains the gold standard.

Some reports suggested that a TEE may not be necessary in patients receiving warfarin therapy if therapeutic INR is present on the day of the procedure and has been verified every week in the 4 weeks preceding the ablation.⁸⁴ However, other studies reported a substantial prevalence of LA appendage clots (up to 3.6%) among patients with full anticoagulation and in those with paroxysmal AF and suggested that TEE should be performed in all patients prior to ablation. Therefore, until more data are available, the risk of a thromboembolic event must be weighed against relatively low risk of moderate sedation and TEE, by taking into consideration the type of AF (paroxysmal versus persistent), anticoagulation status, CHADS₂ score, LA diameter, and LV function. At this time, it may be reasonable to perform TEE in all patients, with the possible exception of those with paroxysmal AF and a CHADS₂ score of 0.^{86,87}

CARDIAC MONITORING

Patients are generally hospitalized the night after the procedure, with cardiac monitoring, and discharged home the following day. After discharge, patients who report symptoms compatible with an arrhythmia should undergo ambulatory cardiac monitoring. Because early recurrences of atrial arrhythmias are common during the first 1 to 3 months following ablation and many of them resolve spontaneously, arrhythmia monitoring to assess the efficacy of the ablation procedure is typically delayed for at least 3 months following ablation. Periodic Holter monitoring to screen for asymptomatic occurrences of atrial arrhythmias can be considered. Event monitoring, even in asymptomatic patients, can also help screen for recurrent episodes of AF. The patient is encouraged to activate the event monitor whenever he or she develops symptoms and randomly a few times a day. Patients are also encouraged to take their pulse periodically and monitor for irregularity. Twelve-lead ECGs should be obtained at all follow-up visits.³

PULMONARY VEIN IMAGING

MRI or contrast-enhanced, multislice CT scanning of the LA with 3-D reconstruction is performed to define the anatomy of the PVs before the procedure (see Figs. 15-3 and 15-4). After ablation, CT or

MRI is important to evaluate for evidence of PV stenosis in patients in whom there is a clinical suspicion. Although many investigators recommend routine follow-up imaging for detection of asymptomatic PV stenosis 3 to 4 months after ablation of AF, it is unknown whether early diagnosis and treatment of asymptomatic PV stenosis provide any long-term advantage to the patient.⁸⁸ Nevertheless, follow-up PV imaging should be considered during the initial experience of a new AF ablation procedure for quality assurance.

Technical Aspects Common to Different Methods of Ablation

SEDATION DURING ABLATION

In most patients, conscious sedation or general anesthesia is used; the choice is determined by the institutional preference and also by assessment of the patient's suitability for conscious sedation. General anesthesia is typically used for patients at risk of airway obstruction, those with history of sleep apnea, and those at increased risk of pulmonary edema. General anesthesia may also be used electively in healthy patients to improve patient tolerance of the procedure.³

LEFT ATRIAL ACCESS

Mapping and ablation in the LA are performed through a transeptal approach. A search for a patent foramen ovale is initially performed. If one is absent, a transeptal puncture is performed (see detailed discussion in Chap. 4). Generally, one or two transeptal punctures are performed under fluoroscopic (with or without ICE) guidance, and one or two long vascular sheaths (SR0, SL1, or Mullins sheath, St. Jude Medical, Minnetonka, Minn.) are introduced into the LA. The long sheaths are flushed with heparinized saline at a low infusion rate during the entire procedure, whether or not they are withdrawn into the RA during the LA mapping and ablation portion of the procedure.

IDENTIFICATION OF THE PULMONARY VEINS

Initial approaches of focal ablation targeting arrhythmic foci within the PVs were associated with high incidences of PV stenosis. To avoid this serious complication, the ablation procedure has evolved over time to an increasingly proximal ablation, first at the venous ostium or venoatrial junction and most recently proximal to the PV to encompass the antral region. However, the more proximal ablation approaches require correct identification of the ostia and PV-LA junction, and given the marked variation in PV anatomy, assessment of the number of PVs and anatomy of the ostia is essential when planning an ablation strategy. Various imaging techniques have been developed in an attempt to identify the PV ostium more accurately, but exact localization of this structure remains difficult, and the exact definition of the PV ostium varies, depending on the imaging modality used. Ultimately, however, the choice of imaging modality is dictated by local availability.

FLUOROSCOPY. Entry into the PV is clearly identified as the catheter leaves the cardiac shadow on fluoroscopy and electrical activity disappears; however, the ostium is located more proximally. The inferior portion of the PV ostia can be localized by advancing the catheter into the PV with downward deflection of the tip and then dragging back while fluoroscopically monitoring the drop off the ostial edge of the catheter.

IMPEDANCE MAPPING. Impedance monitoring can be used to identify the LA-PV junction. With catheter entry into the PV, the impedance usually rises to more than 140 to 150 Ω . At the PV ostium, the impedance typically is more than 4 Ω higher than the mean LA impedance.

PULMONARY VEIN ANGIOGRAPHY. PV angiography can be used at the time of catheter ablation to detail PV anatomy. Selective PV angiography is performed using a 5- to 10-mL hand

injection of contrast medium through a long sheath (for angiography of right superior, left superior, and left inferior PVs) or NIH catheter (for angiography of right inferior PV; Fig. 15-12). Alternatively, PV angiography is performed by injecting contrast in the left and right pulmonary arteries or the pulmonary trunk; PVs are then assessed during the venous phase of pulmonary arteriography. A third technique used for PV angiography involves contrast injection in the body of the LA or at the roof of the right or left superior PV ostium immediately after administration of an adenosine intravenous bolus to induce AV block; the contrast medium will fill the LA body, PV antrum, and proximal part of the PV during the phase of ventricular asystole. An important limitation of PV angiography is that it images only the tubular portion and does not adequately define the full posterior extension of the PV. Studies of PV anatomy from pathological specimens and 3-D CT scans have shown that the PV is funnel-shaped, with a tube that fans out into a proximal cup that blends into the posterior atrial wall, referred to as the antrum. Furthermore, the PV antrum connects to the LA wall at an oblique angle. The posterior aspect of each PV is more proximal, whereas the anterior segments of the PVs are more distal.

INTRACARDIAC ECHOCARDIOGRAPHY. Phased-array ICE can be used to visualize the antrum and ostium of the PVs (see detailed discussion in Chap. 6). ICE has the advantage of providing real-time imaging of the PVs. In contrast to angiography, ICE can define the proximal edge of the PV antrum (see Fig. 6-22).

ELECTROANATOMICAL MAPPING. The CARTO (Biosense Webster, Inc., Diamond Bar, Calif.) and EnSite NavX (St. Jude Medical, St. Paul, Minn.) electroanatomical mapping systems have been used to construct a 3-D shell of the LA and identify the PVs. However, definition of the true PV ostium using these systems alone can be difficult because of variants in 3-D vein morphology.

COMBINING ELECTROANATOMICAL MAPPING SYSTEMS WITH CARDIAC CT OR MRI. Cardiac CT and MRI provide critical information regarding the number, location, and size of the PVs, which is needed in planning the ablation and selecting appropriately sized mapping and ablation devices. In addition, preacquired CT and MRI scans have the advantage of allowing full integration with 3-D mapping systems and real-time catheter navigation on a 3-D CT or MRI image, which can facilitate identification of PV ostia and ablation targets (see detailed discussion in Chap. 6).

CATHETERIZATION OF THE PULMONARY VEINS

In the anteroposterior fluoroscopic view, the PV ostia are situated on both sides of the spine. Clockwise rotation of the catheter

inside the LA directs its tip posteriorly and toward the PVs. It is frequently necessary to apply clockwise torque to both the catheter and its long sheath. For catheterization of the left PVs, the catheter should be directed anteroposteriorly in the right anterior oblique (RAO) view and to the left in the left anterior oblique (LAO) view. Care must be taken to avoid advancing the catheter into the LA appendage, in which case the catheter is directed to the right (anteriorly) in the RAO view and not anteroposteriorly. Advancing a catheter into the LA appendage results in an increase in electrogram amplitude (rather than decreasing amplitude, when advancing into a PV). For catheterization of the right PVs, the catheter is rotated further clockwise and is directed to the right in the RAO view and anteroposteriorly in the LAO view. An alternative method for reaching the ostia of the right PVs is to loop the catheter around the lateral, inferior, and then septal LA walls, laying the catheter down along the wall, and dragging the catheter by withdrawing it along the posterior right ostia. Forming a tight loop with maximal deflection of the catheter and using rotational movements can provide greater stability during ablation, particularly at the anterior aspect of the PVs. Counterclockwise rotation of the catheter inside the LA would lead the catheter into the LV. Care must be taken not to allow the circular (Lasso) catheter to cross the mitral annulus because it can then become trapped with the mitral valve apparatus. Usually, reversal of the catheter movement (clockwise torque) that resulted in this situation helps correct it.

Focal Ablation of Pulmonary Vein Triggers

Rationale

There are two different types of arrhythmias that can play a role in generating AF, and both may be addressed by focal ablation. One type is a PAC (or runs of PACs) that triggers self-sustained AF (focal triggers). Ablation of a focal trigger does not terminate AF but prevents its reinitiation (see Fig. 15-1).^{4,70} A second type is a focal tachycardia that either induces fibrillation in the atria or mimics AF by creating a pattern of rapid and irregular depolarization wavefronts in the atria. Such a tachycardia acts as a focal driver and is necessary for the continuation and maintenance of AF. Ablation of a focal driver results in the termination of AF and prevention of its reinitiation. Focal tachycardias that initiate or mimic AF can be recognized in the EP laboratory because they are frequently associated with exit block between the site of origin of the tachycardia and the rest of the atria (Fig. 15-13).⁴

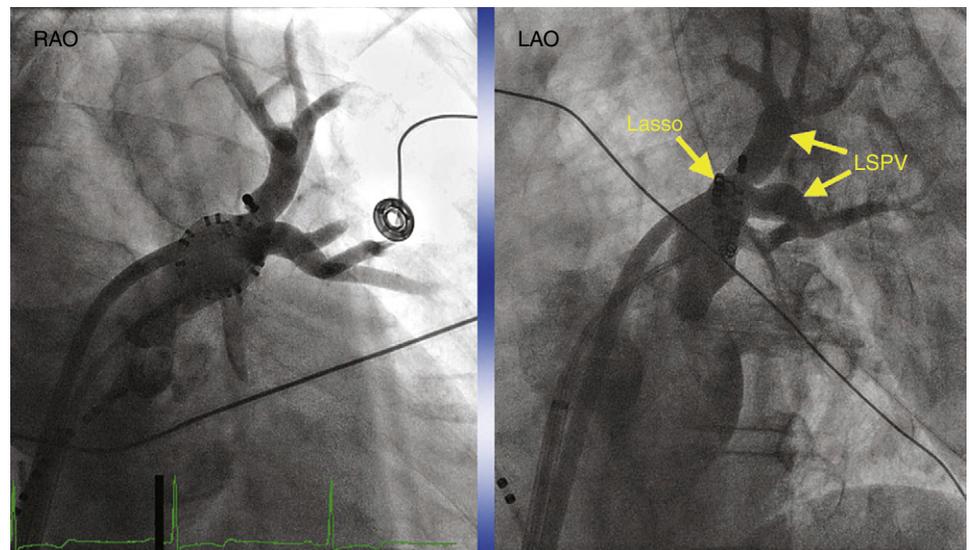

FIGURE 15-12 Pulmonary vein (PV) angiography. Fluoroscopic (right anterior oblique [RAO] and left anterior oblique [LAO]) views of the left superior PV (LSPV). The ring catheter is positioned at the PV ostium.

Several observations have provided evidence that the electrical activity that arises in the PVs plays a role in the maintenance of AF. By analyzing surface ECG and 24-hour Holter recordings, studies have shown that most paroxysmal AF episodes are initiated by a single PAC.⁷⁰ Although focal sources of AF may be found in the RA, LA, CS, SVC, or vein of Marshall, 94% of foci are located within a PV. It is possible that intermittent bursts of PV tachycardia serve to perpetuate AF in the same fashion as

aconitine-induced rapid firing or bursts of rapid atrial pacing (see Fig. 15-13).⁴

There may be a subset of patients with focally induced AF in whom ablation of a single dominant focus can result in cure, without the need for empirical isolation of all PVs. A more limited ablation approach requires shorter procedure and fluoroscopy times and may be safer. These are important considerations in a relatively young patient population.

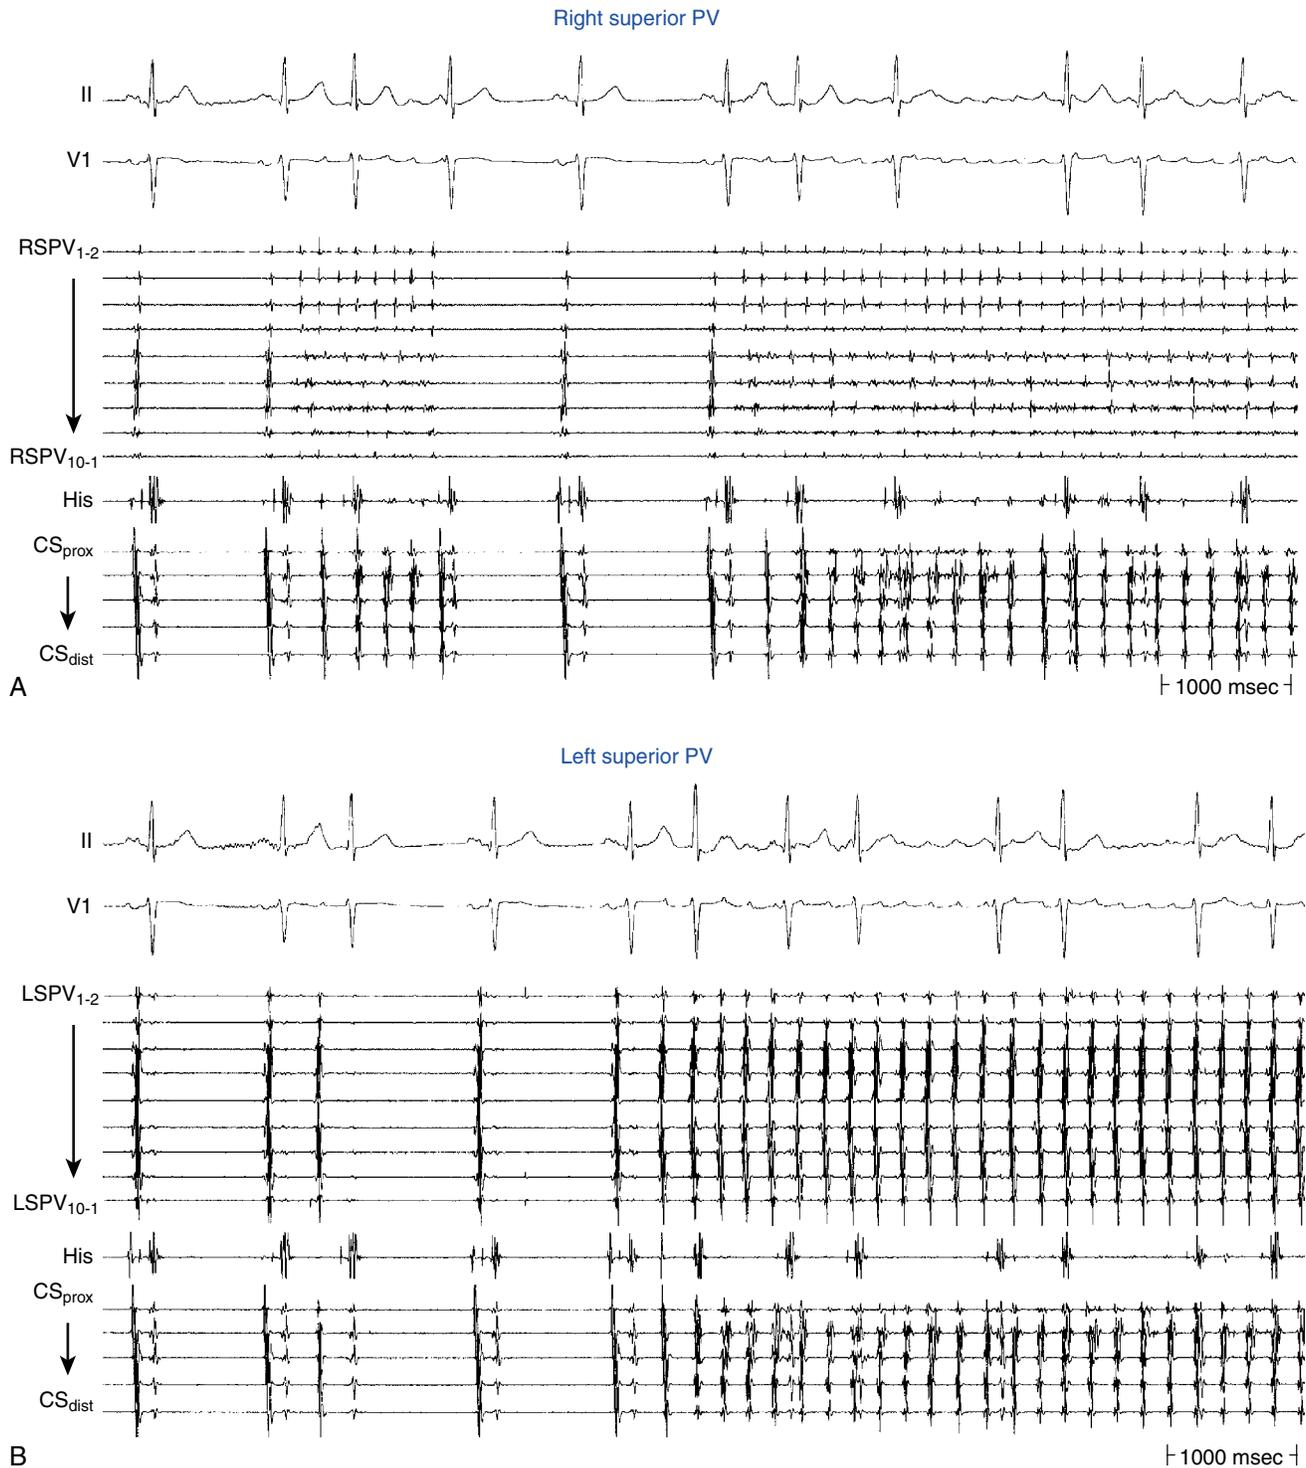

FIGURE 15-13 Atrial fibrillation (AF) initiation from the right superior pulmonary vein (RSPV). **A**, A burst of nonsustained PV tachycardia followed by a second sustained episode. Note that the local cycle length (CL) in the ring catheter recordings from the RSPV is significantly shorter than atrial CL recorded in the coronary sinus (CS) during AF, indicating that this PV is most probably the source and driver of AF. **B**, Recording from the left superior PV (LSPV) in the same patient during spontaneous initiation of AF showing LSPV activity with a CL similar to the atrial CL, a finding suggesting that this PV is activated passively. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

Identification of Arrhythmogenic Pulmonary Veins

DEFINITION OF AN ARRHYTHMOGENIC PULMONARY VEIN

An arrhythmogenic PV is defined by single or multiple ectopic discharges originating from the vein, with or without conduction to the LA. During ectopy from an arrhythmogenic PV, there is a reversal in activation sequence, from the distal PV trunk (source) to the ostium and LA (exit), with the PV potential preceding the LA potential (Figs. 15-14 and 15-15). Conversely, if the explored PV is not the origin of ectopy, it is passively activated, as in NSR, with a proximal-to-distal sequence and a PV potential after or fusing with the LA potential.⁸⁹

Ectopic discharges with a short coupling interval may not be conducted to the LA, thus producing isolated PV potentials confined within the PV. These can be recognized as a PV potential coincident with or just after the ventricular electrogram and can be distinguished from a potential of ventricular origin by their spontaneous disappearance (intermittent PV potential) or suppression during atrial pacing.

During an episode of AF, rapid rhythms arising in the PVs (variably referred to as rapid focal activity, repetitive rapid activity, intermittent PV tachycardia, or paroxysmal CL shortening) are common and can play an important role in the maintenance of AF or may be markers of an arrhythmogenic PV that triggers AF during NSR. The CL of local activity within the arrhythmogenic PV is shorter than that of the atrium. In contrast, the local CL in passively activated PVs is similar to or longer than that of the atrium (see Fig. 15-13).

PROVOCATION OF PULMONARY VEIN ECTOPY

If PV ectopy does not spontaneously develop during EP monitoring or is not sufficiently sustained, one or a combination of several provocative maneuvers can be tried to induce the arrhythmia, including physiological procedures (e.g., Valsalva maneuvers, carotid sinus massage, or deep breathing), pharmacological agents (isoproterenol, 1 to 8 $\mu\text{g}/\text{min}$; and adenosine, rapid intravenous injection, 12 mg and then 18 mg, up to 20 to 60 mg), and slow-rate atrial pacing (bursts of 3 to 10 stimuli at 100 to 200 beats/min for postpause ectopy). Additionally, in patients who present with AF at the time of ablation, electrical cardioversion of AF can reproducibly induce PACs from the same location as spontaneous PACs, and those PACs that follow cardioversion may reinitiate AF. In fact, there is a high degree of correlation between spontaneous and postcardioversion PACs or PACs inducing AF. If AF is not present at baseline, rapid burst atrial pacing to induce AF, followed by electrical cardioversion, may also be attempted to identify early postcardioversion PV triggers.⁸⁹

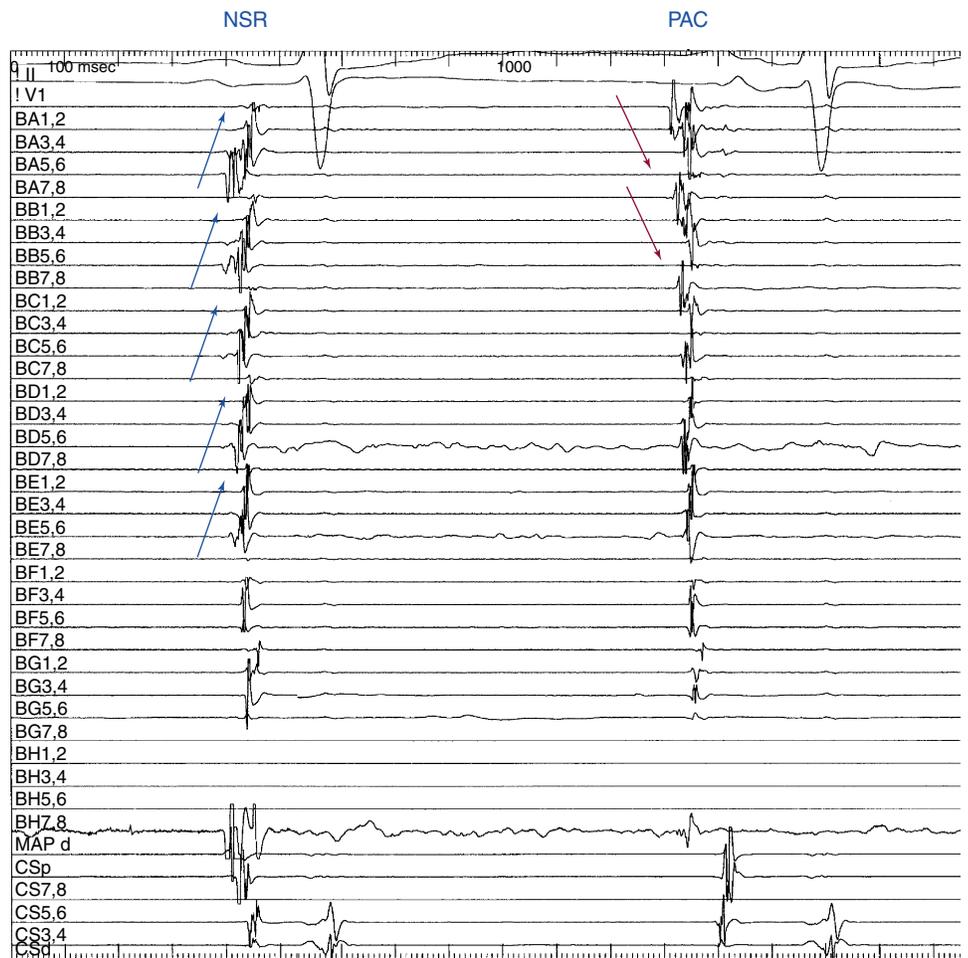

Mapping of Pulmonary Vein Ectopy

ECG LOCALIZATION OF PULMONARY VEIN ECTOPY

ATs arising from the PVs are characterized by entirely positive P waves in lead V_1 in 100% of cases, isoelectric or negative in aVL in 86%, and negative in lead aVR in 96%; lead aVL can be biphasic or positive in right-sided PV ATs (Fig. 15-16).⁹⁰

Left PV ATs have several characteristics (as compared with right PV ATs), including positive notching in the P waves in two or more surface leads, isoelectric or negative P wave in lead I, P wave

FIGURE 15-14 Mapping of pulmonary vein (PV) ectopy using a basket catheter. The basket catheter is positioned in the left superior PV. Bipolar recordings are obtained from the eight electrodes (1-2, 3-4, 5-6, 7-8) on each of the eight splines (BA through BH) of the basket catheter. **Left**, During normal sinus rhythm (NSR), PV activation propagates from proximal (ostial) to distal, as reflected by earlier activation timing on the proximal basket electrodes than the distal ones (blue arrows). **Right**, In contrast, during a premature atrial complex (PAC) originating from this PV, activation occurs earliest deep in the vein and progressively later toward the ostium and the left atrial (LA) exit, resulting in distal to proximal venous activation on the basket catheter recordings (red arrows). Note that the PV potentials precede the onset of the P wave on the surface ECG during PV ectopy, but they occur late after P wave onset during NSR.

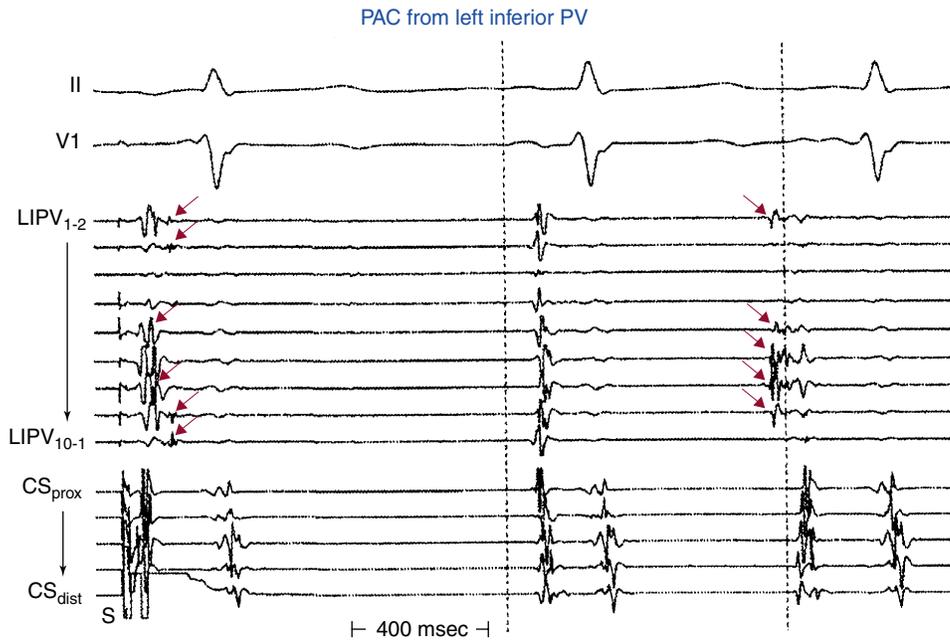

FIGURE 15-15 Mapping pulmonary vein (PV) ectopy using a ring catheter. The ring catheter is positioned at the ostium of the left inferior PV (LIPV). **Left**, During pacing from the distal coronary sinus (CS) (at left), PV potentials (red arrows) follow the left atrium (LA) potentials. During normal sinus rhythm (NSR; middle complex), LA and PV potentials overlap, and they occur in the second half of the P wave. **Right**, During a premature atrial complex (PAC) originating from the LIPV, reversal of the electrogram sequence in the ring catheter recording is observed, with the PV potentials (red arrows) preceding the LA potentials and occurring well before the onset of the P wave on the surface ECG (dashed line). CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

amplitude in the lead III/II ratio greater than 0.8, and broad P waves in lead V1 (see Fig. 15-16).

ATs arising from superior PVs have larger amplitude P waves in inferior leads than those in ATs arising from inferior PVs (see Fig. 15-16). However, P wave morphology generally is of greater accuracy in distinguishing right-sided from left-sided veins, in contrast to superior from inferior.

During right superior PV ATs, the P waves are narrow, positive in inferior leads, of equal amplitude in leads II and III, biphasic or slightly positive in lead V₁, and isoelectric in lead I (see Fig. 15-16). The right superior PV is a common site of origin for LA ATs. It is only a few centimeters from the sinus node. Activation rapidly crosses the septum via the Bachmann bundle to activate the RA in a fashion similar to NSR, thus explaining the similarities in P wave morphology. However, whereas the P wave is biphasic in lead V₁ during NSR, it is positive in that lead during right superior PV AT (see Fig. 15-16).⁹⁰

ENDOCARDIAL ACTIVATION MAPPING

Initially, the PV of interest is identified based on earliest activation of triggers in the CS and RA catheters. If no sharp bipolar activity is recorded in the RA at least 10 milliseconds before the onset of the ectopic P wave, the ectopic beats are considered to have originated in the LA. Following initial identification, the ablation catheter is placed and maneuvered to the appropriate PV.

Activation mapping within the PV is performed during ectopy. It is important to have adequate frequency of PACs from each focus, to be able to acquire enough points and identify the earliest activation sequence. Electroanatomical mapping or multielectrode mapping catheters, such as the ring catheter (a decapolar catheter with a distal ring configuration) or basket catheter positioned in the PV, can be of value in mapping the source of ectopy (Fig. 15-17). The ectopic focus is localized inside the selected PV according to the earliest atrial activity relative to the reference electrogram or the onset of the ectopic P wave. PV depolarization during ectopy is marked by a spike (an electrogram of sharp onset and short duration) preceding the onset of the ectopic P wave by 106 ± 24 milliseconds (range, 40 to 160 milliseconds; see Figs. 15-14 and 15-15). The spike is typically localized, and its amplitude rapidly decreases when the catheter tip is turned or moved a few millimeters. Bystander or far-field activity from contiguous branches can be distinguished by temporal delay or lower amplitude. The spike occurs earliest deep in the vein and progressively later toward the ostium and LA exit, thus resulting in distal-to-proximal venous

activation during multipolar recordings (see Fig. 15-14). A second electrogram component with a slow deflection (depolarization rate [dV/dt] of less than 0.5 mV/msec), reflecting later LA activation, is temporally distinct from the spike inside the vein and then approaches and becomes continuous with the spike at the ostium.

Mechanically induced beats can be prevented by avoiding manipulation of the catheters during the recordings. These beats are excluded by comparing the ECG pattern and intracardiac activation sequence with the confirmed spontaneous ectopic beats.

If still insufficient spontaneous or induced ectopy is present, focal mapping and ablation of AF can become difficult. In these cases, the use of a multielectrode basket catheter mapping (see Fig. 15-14) or noncontact mapping (EnSite) system can map a single beat and help identify the origin of spontaneously occurring PACs and PACs induced following the cardioversion of spontaneous or induced AF.

Following successful ablation of the initially targeted PV triggers, a second PV is usually targeted if there are either significant spontaneous isolated PACs (at least five per minute), at least two separate PACs inducing AF, or PACs originating from the same PV inducing AF following cardioversion on at least two occasions.

Target of Ablation

The site showing the earliest atrial activity relative to the reference electrogram or onset of the ectopic P wave is targeted by ablation. If more than one PV is arrhythmogenic, the PV producing the most repetitive ectopy and/or AF-triggering ectopy is targeted first. If ablation of the ectopic focus fails, electrical isolation of the arrhythmogenic PV should be considered (see later). In addition, ablation may be performed at sites with catheter-induced repetitive ectopy, manifesting as a burst of rapid PACs starting on touching the wall, sustained irritability while at the site, and acute termination of rapid activity on release of the catheter.⁸⁹

Ablation Technique

RF energy is delivered using a 4-mm-tip catheter with a target temperature of 45°C to 50°C and a maximal power output of 25 to 30 W to reduce the risk of PV stenosis. At successful ablation sites, a rapid burst of PACs originating from that site often develops during RF energy delivery, or an abrupt disappearance of triggering PACs is observed.⁸⁹ Cryoablation has also been used to target these sites although the precision of mapping is less (6-mm catheter tip).

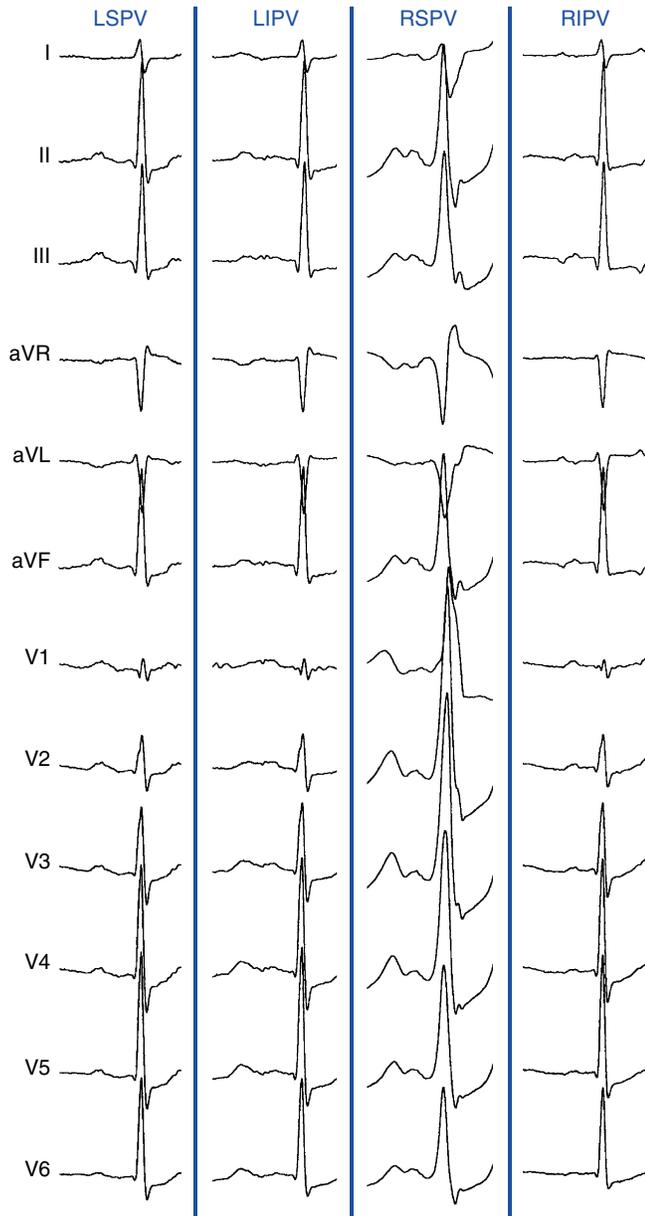

FIGURE 15-16 Surface ECG of spontaneous premature atrial complexes originating from the pulmonary veins. LIPV = left inferior pulmonary vein; LSPV = left superior pulmonary vein; RIPV = right inferior pulmonary vein; RSPV = right superior pulmonary vein.

Endpoints of Ablation

The endpoint is elimination of ectopy, spontaneous or induced by provocative maneuvers (using both the same provocative maneuvers and defibrillation protocols as before the ablation). Elimination or dissociation of PV potentials from atrial activity is also a satisfactory endpoint.

Outcome

Early experience with the focal ablation of PV arrhythmias has indicated that the recurrence rate is high and the success rate is only modest, even in experienced laboratories. The suboptimal results can be attributed to the limitations of the technique. Many patients have multiple foci in the same PV or in multiple PVs. Multiple arrhythmogenic PVs are usually associated with older age, longer AF duration, and larger atrial dimensions. In addition, there may be a paucity of spontaneous or inducible arrhythmias during the procedure. The spontaneous occurrence of ectopic

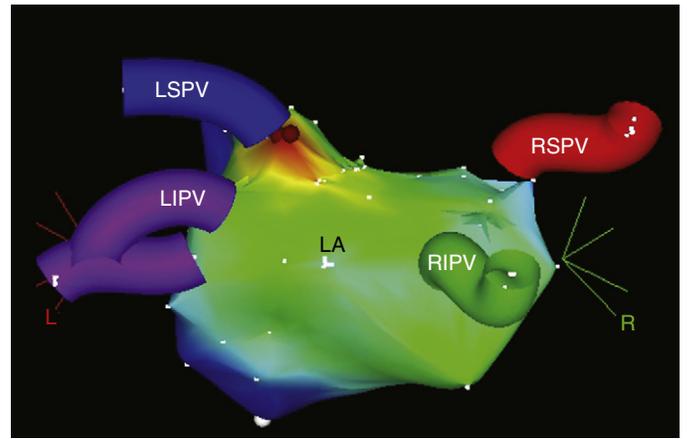

FIGURE 15-17 CARTO (Biosense Webster, Inc., Diamond Bar, Calif.) activation map of the left atrium (LA) (posteroanterior view) during premature atrial complexes (PACs) originating from the left superior pulmonary vein (LSPV). Focal ablation (red dots) at the PV ostium eliminated those PACs. LIPV = left inferior pulmonary vein; RIPV = right inferior pulmonary vein; RSPV = right superior pulmonary vein.

beats and paroxysms of AF is unpredictable, and provocative procedures are not consistently effective. Mapping can also be made difficult by frequent recurrences of persistent AF requiring multiple cardioversions. Furthermore, after a successful procedure, new foci may emerge. Remapping usually shows new foci in the ablated vein or in other veins, rather than recurrence of the original focus.

It is also important to recognize that RF ablation inside the PVs carries a significant risk of PV stenosis, which limits the amount of RF energy that can be safely delivered within a PV. Some degree of PV stenosis was detected by increased PV flow velocity on TEE in 42% of cases in one report. An increased risk of PV stenosis has been associated with the use of RF power more than 45 W.

Focal ablation has been successful only in highly selected patients with frequently recurring paroxysmal AF. Reported rates of a positive outcome using a focal ablation approach to eliminate AF triggers have varied from 38% to 80%. AF recurrences appear to be related to recovery of initially targeted foci or emergence of new nontargeted ones in the same or in a different PV. Because of these safety and efficacy limitations, this method is generally not used currently.

Segmental Ostial Pulmonary Vein Isolation

Rationale

ELECTRICAL ISOLATION OF PULMONARY VEINS

On the basis of the knowledge of the AF initiation mechanism by focal discharges in the PVs, electrical disconnection at the PV ostium seemed to be a better ablative technique than focal ablation to inactivate focal triggers of AF. Ablation guided by mapping focal ectopy has a high recurrence rate and low long-term success and is limited by unpredictability, inconsistent inducibility, and the risk of inducing AF requiring cardioversion multiple times during the procedure. Moreover, the appearance of multiple sources of AF triggers and the high recurrence rate argue for more extensive ablation strategy. PV isolation has been introduced to address these issues.

PV potentials identify muscular sleeves that extend from the LA into the PVs. These muscular bands are responsible for transmitting triggering impulses from the vein to the LA. The myocardial fibers that envelop the PVs may not be present along the entire circumference of the PV ostia. Therefore, to eliminate conduction

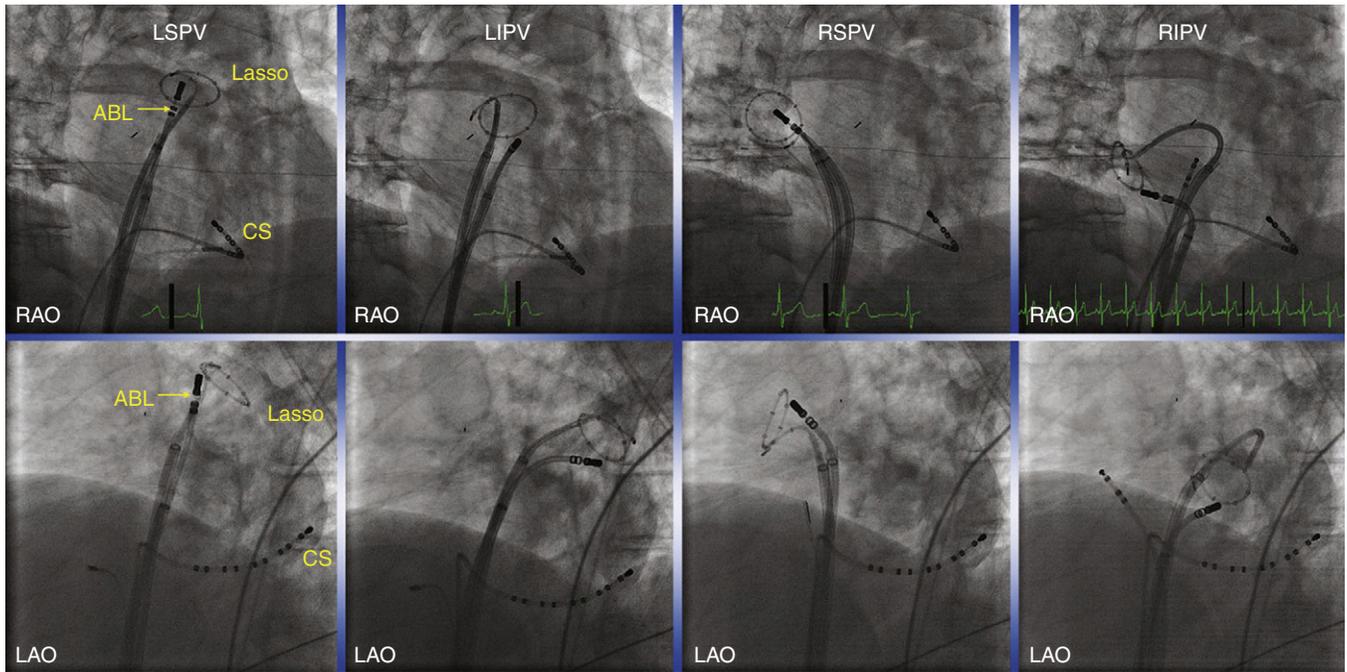

FIGURE 15-18 Fluoroscopy views (right anterior oblique [RAO] and left anterior oblique [LAO]) of the ring catheter positioned at the ostium of the four pulmonary veins (PVs). Panels from left to right, Left superior PV (LSPV), left inferior PV (LIPV), right superior PV (RSPV), and right inferior PV (RIPV). Note that during ablation, the ablation catheter (ABL) is always positioned at the atrial side of the ring catheter. CS, coronary sinus.

in and out of a PV, ablation along the entire circumference of the ostium may not be necessary. Instead, RF energy can be targeted to the segments of the ostium at which muscle fibers are present, which typically involves RF application to 30% to 80% of the circumference of the PVs. These sites are identified by the presence of high-frequency depolarizations, which likely represent PV muscle potentials.⁸⁹

The major advantages of this technique are that it eliminates the need for detailed mapping of all PV foci and that there is a clear-cut endpoint of ablation, even when spontaneous arrhythmias are absent, and PV stenosis is far less likely to occur (although it is still possible).

WHICH PULMONARY VEINS TO ISOLATE

ONLY ARRHYTHMOGENIC PULMONARY VEINS. Focal ablation deep in a PV carries a risk of PV stenosis. Restricting RF delivery to the ostium of the arrhythmogenic PV, as in segmental ostial PV isolation, may help reduce this risk. Furthermore, a more limited ablation approach (as compared with isolation of all PVs) requires shorter procedure and fluoroscopy times and can potentially be safer.⁸⁹

ALL FOUR PULMONARY VEINS. PV isolation of only the arrhythmogenic PV was shown to have a limited success rate. Furthermore, identification of the arrhythmogenic PV can be difficult and time consuming, because focal activity can be difficult to observe or induce during the ablation procedure. Additionally, the prevalence of multiple arrhythmogenic PVs is high (greater than 70%).⁸⁹ Therefore, isolation of only the culprit PV identified during the procedure may allow the emergence of focal ectopy from other PVs, which can potentially cause AF recurrence after the procedure. Moreover, electrical disconnection may not be achieved by ostial ablation to only the targeted PV in patients with electrical connections between the PVs (i.e., across the carina between left PVs).

Evidence has suggested that almost all PVs are capable of generating the premature depolarizations that trigger AF, and the upper PVs are responsible for most AF triggers (the left superior PV is the vein with the longest muscular sleeve). Only a few (0% to 30%) foci have been identified in the inferior PVs (the right inferior PV

is the least important source of triggers). The relatively infrequent importance of the right inferior PV in patients with AF is consistent with prior anatomical studies demonstrating that the muscle sleeves around the right inferior PV are less prominent than the muscle sleeves that surround the other PVs. Although cannulation of the right inferior PV with a distal ring catheter electrode can be challenging in some patients, in most patients this vein can be successfully isolated with little prolongation in the total PV isolation procedural time. Therefore, unless no PV potentials are present at its ostium (a rare finding), all four PVs should be targeted, whenever feasible.

Circumferential Mapping of Pulmonary Vein Potentials

LASSO CATHETER MAPPING

A deflectable decapolar catheter with a distal ring configuration (Lasso catheter) is advanced sequentially into each PV and is used for ostial mapping (Fig. 15-18). The ring catheter enables circumferential mapping of the PV ostia perpendicular to the axis of the vein. Lasso catheters are of different sizes. The selection of a 15-, 20-, or 25-mm-diameter Lasso catheter is guided by the estimated size of the PVs angiographically and/or with CT (see Fig. 15-12). Because of the highly variable sizes of PV ostia, fixed-diameter catheters may not always achieve catheter stability and optimal electrogram recordings. In some cases, suboptimal positioning, poor wall contact, and poor stability of an inappropriately sized circumferential catheter underestimate the number of PV potentials and can result in failure to isolate the PV completely because of undetected residual PV-atrial electrical connections. Some of those issues can be addressed by using an expandable 15- to 25-mm-diameter ring catheter. The expandable ring catheter is introduced into each PV and withdrawn to the most proximal stable position, with optimal wall contact ensured by progressive loop expansion. These catheters may enable more proximal and stable placement and optimal wall contact at the PV ostia. This is important because the ablation target is not within the ostia, but in the atrial tissue proximal to the LA-PV junction.

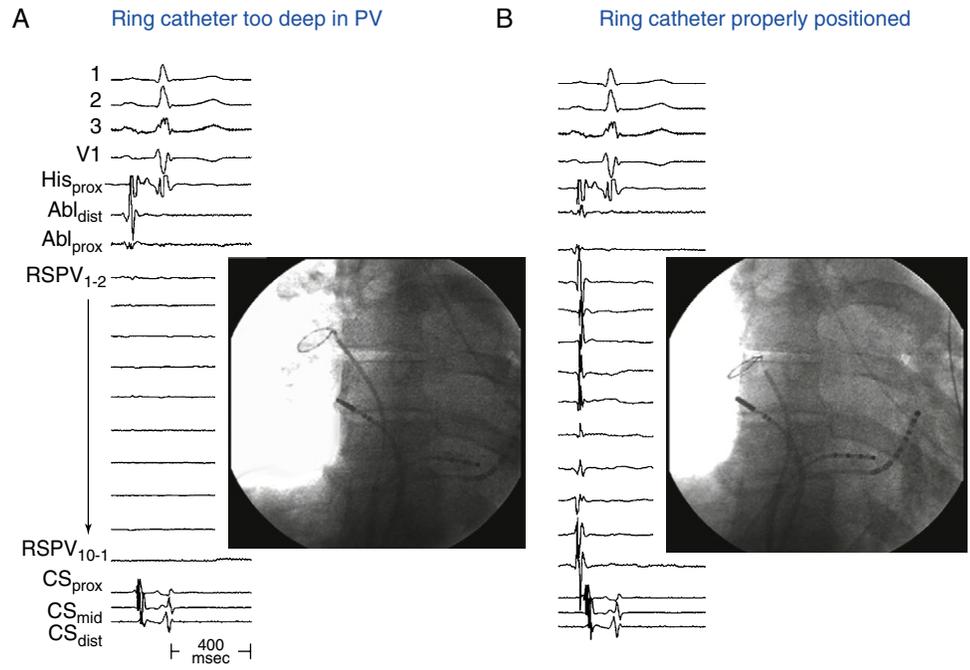

FIGURE 15-19 Recordings from a ring catheter in the right superior pulmonary vein (RSPV). **A**, The ring catheter is situated too deep in the vein; recordings suggest no pulmonary vein (PV) potentials. **B**, The ring catheter pulled back 1.5 cm, showing abundant PV potentials. Abl_{dist} = distal ablation site; Abl_{prox} = proximal ablation site; CS_{dist} = distal coronary sinus; CS_{mid} = middle coronary sinus; CS_{prox} = proximal coronary sinus; His_{prox} = proximal His bundle.

The ring catheter is positioned in the left superior PV, left inferior PV, and right superior PV. If accessible, the right inferior PV is usually mapped last because of the technical difficulty and the risk of dislodgment of the mapping catheters from the LA to the RA. The ring catheter is positioned within a PV and gradually withdrawn to within 5 mm of the ostium. It is important to position the ring catheter at the ostium of the PV; when it is positioned too deeply in the PV, PV potentials can be missed (Fig. 15-19). Subsequently, circumferential mapping of the PV is performed by obtaining 10 bipolar electrograms (1-2, 2-3, up to 10-1 electrode pairs) with the circular arranged electrodes of the ring catheter. The band-pass settings for the bipolar recordings are 30 to 500 Hz. Pacing from each pair of electrodes from the ring catheter has been used by some to ensure appropriate ring catheter sizing (80% of electrode pairs resulting in capture) and to demonstrate conduction from the veins to the atrium before ablation.

Ring catheters with 20 poles are also available and can offer higher resolution circumferential mapping and improve the differentiation of PV from LA potentials. The conventional wide bipolar electrograms record the PV potentials, as well as the larger LA potentials, which can obscure or mimic the PV potentials. In contrast, the high-resolution electrograms minimize the extent of far-field electrogram detection and display very small or completely absent LA potentials. In the context of PV isolation during sustained AF, improved discrimination between atrial and PV potentials can facilitate the recognition of complete PV disconnection and possibly limit the number of unnecessary RF applications. On the other hand, when a ring catheter and closely spaced electrodes make poor contact with the PV wall or are placed deep within the PV, near-field potentials may not be seen, which leads to under-detection of PV potentials.

The use of a navigational system (CARTO-3 or EnSite NavX) in ostial segmental PV isolation provides accurate nonfluoroscopic visualization of multiple catheter tips and curves (including the ring catheter) and allows a real-time assessment of wall contact and catheter stability, as well as assessment of the spatial relationship between ablation and ring catheters. Furthermore, the NavX technology enables taking a shadow of the stable position of the ring catheter and, hence, accurate repositioning of the catheter in the case of displacement to its original location. Also, the system enables labeling the electrodes on the ring catheters, thus allowing precise navigation of the ablation catheter to the labeled pole of the ring catheter without the assistance of fluoroscopy.

MAPPING DURING NORMAL SINUS RHYTHM

It is preferable to perform PV mapping during NSR or atrial pacing whenever possible because AF reduces PV potential amplitude and makes PVs more difficult to identify. Therefore, if the patient is in AF, electrical cardioversion is usually performed to restore NSR. Ibutilide (1 mg) or amiodarone (300 mg) may also be administered intravenously to prevent immediate recurrences of AF after cardioversion.

PV mapping during NSR typically shows double or multiple potentials that are usually recorded in a progressively later temporal sequence, synchronous with the first (right PVs) or second (left PVs) half of the sinus P wave (Fig. 15-20). The first low-frequency potential reflects activation of the adjacent LA. The latest high-frequency electrograms indicate PV potentials.

IDENTIFICATION OF PULMONARY VEIN POTENTIALS USING PACING MANEUVERS. PV potentials often are fused with the far-field LA electrograms but can be identified by their high-frequency appearance. Not uncommonly, an isoelectric interval separates the far-field LA electrogram and the near-field PV potential. The basis for this separation is unclear; however, evidence has suggested that there is an area of slow conduction at the proximal PV. The interval between the far-field electrogram and the PV potential may differ based on the site of pacing. The reasons for this phenomenon may be related to fiber orientation (anisotropy), which can make it easier to enter the vein from certain wavefront directions or because the far-field electrogram is not actually coming from the LA but is arising from a neighboring structure. Therefore, pacing from different atrial sites (most commonly high RA or distal CS) can help separate PV potentials from far-field atrial signals (Fig. 15-21; see Fig. 15-20). Furthermore, incremental rate atrial pacing and premature atrial stimulation from the same atrial site can sometimes result in conduction delay between the LA and PV at the PV ostium, which often exhibits decremental conduction properties (Fig. 15-22). Thus, if a complex electrogram is seen on a PV mapping catheter and, with faster or premature pacing, one of the potentials is seen to occur later after the far-field atrial electrogram, the delayed signal likely is a PV potential.

Right-sided PVs are typically mapped during NSR or RA pacing. For left PVs, the ostial PV potentials are sometimes not obvious during NSR because of the superimposed LA potential; therefore, pacing from the distal CS (at a CL of 500 to 600 milliseconds) allows

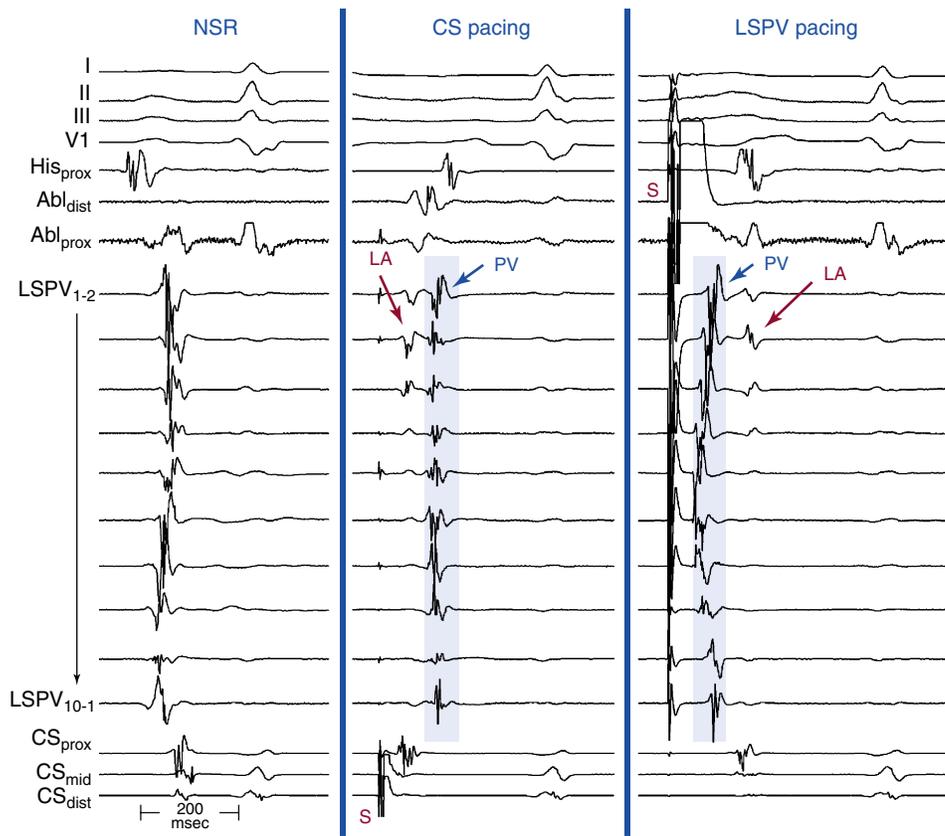

FIGURE 15-20 Differential atrial pacing to identify pulmonary vein (PV) potentials. **Left panel**, During normal sinus rhythm (NSR), the atrial and left superior PV (LSPV) potentials are superimposed and distinction of PV potentials from left atrial (LA) electrograms is difficult, if not impossible. **Middle panel**, During coronary sinus (CS) pacing, PV potentials (shaded area) are delayed relative to LA potentials and are thus readily discerned. **Right panel**, Pacing from within the LSPV also shows a clear delineation of PV versus LA potentials; in this case, PV potentials precede LA potentials. Abl_{dist} = distal ablation site; Abl_{prox} = proximal ablation site; CS_{dist} = distal coronary sinus; CS_{mid} = middle coronary sinus; CS_{prox} = proximal coronary sinus; His_{prox} = proximal His bundle.

their separation and easy recognition of PV potentials (see Fig. 15-20). However, even during CS pacing, the atrial and PV potentials still can overlap in approximately 50% to 60% of left PVs (see Fig. 15-22). The separation can be less evident in the posterior PV antrum, which is closer to the CS. Pacing from the LA appendage can help in this situation.

Because of the anatomical proximity of the PVs to several other structures that are electrically active, complex signals may be recorded by a catheter placed in the PV. For example, a catheter placed in the left superior PV may record electrical activity in the LA, LA appendage, ipsilateral PV, and ligament of Marshall. Similarly, a mapping catheter placed in the right superior PV may record electrical activity in the right middle PV, right inferior PV (particularly a superior branch), RA, LA, and SVC (Fig. 15-23). When a typical PV potential is recorded in a left PV, the far-field electrogram usually is coming from the LA. When mapping catheters are placed in the right-sided PV, often the main far-field electrogram is the RA electrogram, and the second far-field electrogram, if seen, is the LA electrogram.⁹¹ In general, only the PV potential itself is near-field; all other structures picked up by the antenna of the mapping catheter are blunted and far-field. However, this criterion alone is insufficient for identifying the true PV potential. For example, if a catheter is deep within the left superior PV, where no PV musculature is present, the LA appendage electrograms will appear relatively near-field. Similarly, when RF ablation has already been performed, edema near the PV os and inadvertent ablation within the PV (more frequent than generally realized) will cause PV potentials to be less sharp and less near-field in character.⁹¹ Various pacing maneuvers can differentiate from among these possibilities and can help exclude or prove a relationship of various components of the electrogram recorded from a PV to anatomical structures surrounding that particular PV. An important feature of far-field potentials is that they should be seen only on electrodes that “face” the structure in question; for instance, with a catheter in the left superior PV, signals that are recorded on electrodes adjacent to the LA appendage may represent far-field recordings from that structure, whereas signals visible only on electrodes at

the posterior aspect of the left superior PV cannot be far-field LA appendage potentials (Fig. 15-24).

One pacing maneuver commonly used when complex electrograms are recorded on a mapping catheter placed in a PV is pacing at specific sites likely to be responsible for the components of the electrogram. The premise of such a maneuver is that pacing from a particular site causes the electrogram originating from that site to occur earlier, close to the pacing stimulus. For example, because of the proximity of the LA appendage to the left PVs (especially the left superior PV), far-field LA appendage potentials can be recorded in these PVs, and PV potentials can be confused with LA appendage potentials. These potentials are distinguished from PV potentials by differential pacing from the distal CS and LA appendage. If a pacing catheter is placed in the LA appendage and LA appendage capture is documented, the LA appendage component of the complex electrogram will occur early and will be drawn toward the pacing artifact (Fig. 15-25). Thus, the electrogram that moves the closest to the pacing stimulus can be diagnosed as originating from the LA appendage. Similar reasoning can be applied when pacing in an ipsilateral PV—if a component of the electrogram recorded in the left superior PV is, in fact, a left inferior PV potential—or when pacing in the SVC and vein of Marshall.⁹¹

LA electrograms, particularly when fragmented secondary to partial ablation, can also be mistaken for a PV potential, and pacing from a site in the LA close to, but not within, the PV (perivenous pacing) can help define the LA electrogram component of a complex PV recording. When pacing from a perivenous location, the LA signal will occur very close to, and often will merge with, the saturation artifact related to the pacing spike. However, because pacing is being performed proximal to the site of ostial delay, the PV potential remains unchanged or may occur with slightly more delay. The shift of the LA signal, which now is being captured by perivenous pacing, toward the pacing spike indicates the origin of that component of a complex signal. Differentiation of RA, LA, and PV potentials recorded within right-sided PVs can also be achieved using similar maneuvers (Fig. 15-26).⁹¹

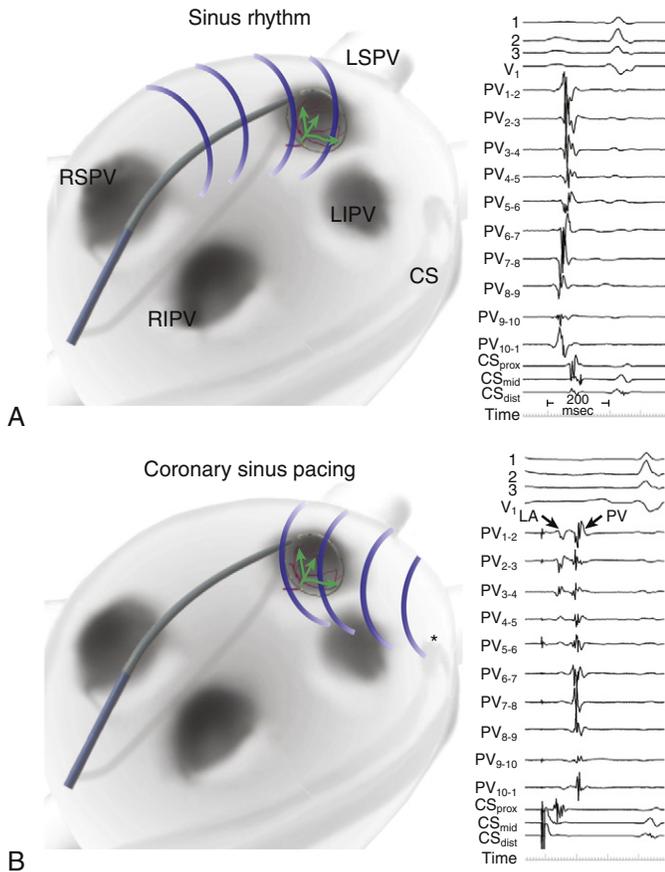

FIGURE 15-21 Depiction of differential activation of left atrial (LA) and pulmonary vein (PV) potentials. The LA is opened from the front, showing orifices of PVs; a ring catheter is in the left superior PV (LSPV). Red strands indicate a muscular PV fascicle extending into the LSPV; green arrows indicate propagation into the PV over the fascicle. **A**, During sinus rhythm, the wavefront propagates as indicated by blue curved lines and activates LA tissue around the PV and the PV fascicle at almost the same time, yielding a summated electrogram at right. **B**, During pacing from the coronary sinus (CS, at asterisk), the wavefront approaches from a different direction and activates LA muscle well before the PV fascicle is entered, accounting for the delay in PV potential inscription at right. CS_{dist} = distal coronary sinus; CS_{mid} = middle coronary sinus; CS_{prox} = proximal coronary sinus; LIPV, left inferior pulmonary vein; RIPV, right inferior pulmonary vein; RSPV, right superior pulmonary vein.

Multisite simultaneous pacing is an extension of the basic concept that pacing from a particular site will cause earlier occurrence of the electrogram arising from that site. For example, pacing from the CS alone is compared with simultaneous pacing from both the CS and LA appendage, with specific attention paid to the transition in the recorded electrogram between single-site (e.g., CS only) and dual-site (e.g., CS and LA appendage) pacing, which can help immediate distinction of the various components of a complex signal recorded within the PV.⁹¹

ABLATION TARGET SITES. Target sites for ablation are selected by identifying the earliest bipolar PV potentials or the unipolar electrograms with the most rapid (sharpest) intrinsic deflection on high-speed recordings (150 to 200 mm/sec) that have equivalent or earlier activation relative to the earliest PV potential recorded on the adjacent ring catheter recording sites (Fig. 15-27).

Electrogram polarity reversal can also be used as an additional indicator of breakthroughs from the LA to the PVs and identify potential ablation targets. *Polarity reversal* is defined as a sudden change in the main deflection of the PV potential. The reversal occurs as the wavefront of activation propagates radially in the PV from its connection with the LA, thus reaching contiguous bipolar recording electrodes in opposing directions (Fig. 15-28; see also Fig. 15-27).

MAPPING DURING ATRIAL FIBRILLATION

Although segmental ostial PV isolation is accomplished most efficiently during NSR, maintenance of NSR during an ablation procedure may not be readily achievable, particularly in patients with chronic AF. During an ongoing episode of AF, PV potentials can be obscured during the chaotic electrical activity of AF. Nevertheless, segmental ostial PV isolation was found to be as feasible and successful during AF as during NSR. An advantage of mapping during AF is that it obviates the need for the administration of antiarrhythmic drugs and for multiple electrical cardioversions in patients with immediately recurrent AF after cardioversion. Two approaches have been described for PV isolation during AF: the first uses intermittent bursts of PV tachycardia to guide PV isolation, and the second uses organized PV potentials during AF to guide PV isolation.

INTERMITTENT PULMONARY VEIN TACHYCARDIA. Prior studies demonstrated that rapid rhythms arising in the PVs (intermittent PV tachycardia) are common during AF (recorded during AF in 90% to 97% of PVs) and can play an important role in the maintenance of AF, or they can be a marker of an arrhythmogenic PV that triggers AF. Those intermittent bursts of PV tachycardia indicate the presence of an underlying arrhythmogenic muscular fascicle near the ostial recording sites and therefore can be used to guide segmental ostial ablation to isolate the PVs during AF.

During AF, the PVs are sequentially mapped with the ring catheter to assess the presence of intermittent PV tachycardia, defined as a PV rhythm that intermittently has a CL shorter than the AF CL recorded in the adjacent LA. When intermittent PV tachycardia is recorded by several electrodes, the ostial site corresponding to the most rapid intrinsic deflection of the unipolar electrogram should be targeted by RF applications. If PV tachycardia is not observed, ostial sites that display a high-frequency bipolar PV potential or rapid unipolar intrinsic deflection during AF, or both, can alternatively be targeted for ablation.

If AF terminates during ablation, PV potentials are then assessed during NSR and atrial pacing. If there is evidence of residual conduction over a PV fascicle, RF energy is delivered at these ostial sites during NSR or atrial pacing. On the other hand, if AF is still present after isolation of a PV, electrical cardioversion is performed. If AF recurs, other PVs are isolated during AF and, if NSR is maintained, the remaining PVs are isolated during NSR or atrial pacing.

ORGANIZATION OF PULMONARY VEIN POTENTIALS. PV potentials are classified at baseline as organized (have a consistent activation sequence for more than 10 seconds) or disorganized (activation sequence on the ring catheter varies from beat to beat). Approximately 37% of PVs have organized PV potentials (more for inferior than superior PVs—53% versus 26%; Fig. 15-29). When the PV activation pattern is organized (from the beginning or after some anatomically guided RF applications), the area showing the earliest activation or demonstrating polarity reversal on the ring catheter is targeted.

For disorganized PV potentials, ablation is performed circumferentially around the ring catheter on the ostial side of the PV. The top and bottom segments of the PV are targeted first because of the high prevalence of LA-PV breakthroughs at these sites. In most cases, initial RF applications result in organization of PV activity. This activity is probably secondary to progressive reduction of LA-PV breakthroughs that diminishes the mass of fibrillatory conduction within the PV and channels the electrical activity through the last remaining fascicles connecting the LA to the PV, thereby activating the PV in an organized fashion. This consequently enables EP-guided PV isolation.

Organized PV activity can represent fewer LA-PV connections and therefore may require fewer RF applications than PVs with disorganized activity. This may explain the greater frequency of organized activity in the inferior PVs, presumably because of the presence of less extensive muscular sleeves in these veins as demonstrated by pathological studies.

BASKET CATHETER MAPPING

The basket catheter (Constellation, Boston Scientific, Natick, Mass.) is composed of 64 electrodes mounted on 8 flexible, self-expanding splines (see Fig. 4-4). Each spline is identified by a letter (from A to H) and each electrode by a number (distal 1 to

proximal 8). The 32 bipolar electrograms provide 3-D mapping of PV activation.

BASKET CATHETER POSITIONING. After transeptal access is gained, an 8.5 Fr soft-tipped guiding sheath with a 90- or 120-degree curve or, preferably, a deflectable sheath, is introduced into the PVs. A steerable ablation catheter can help introduce the sheath

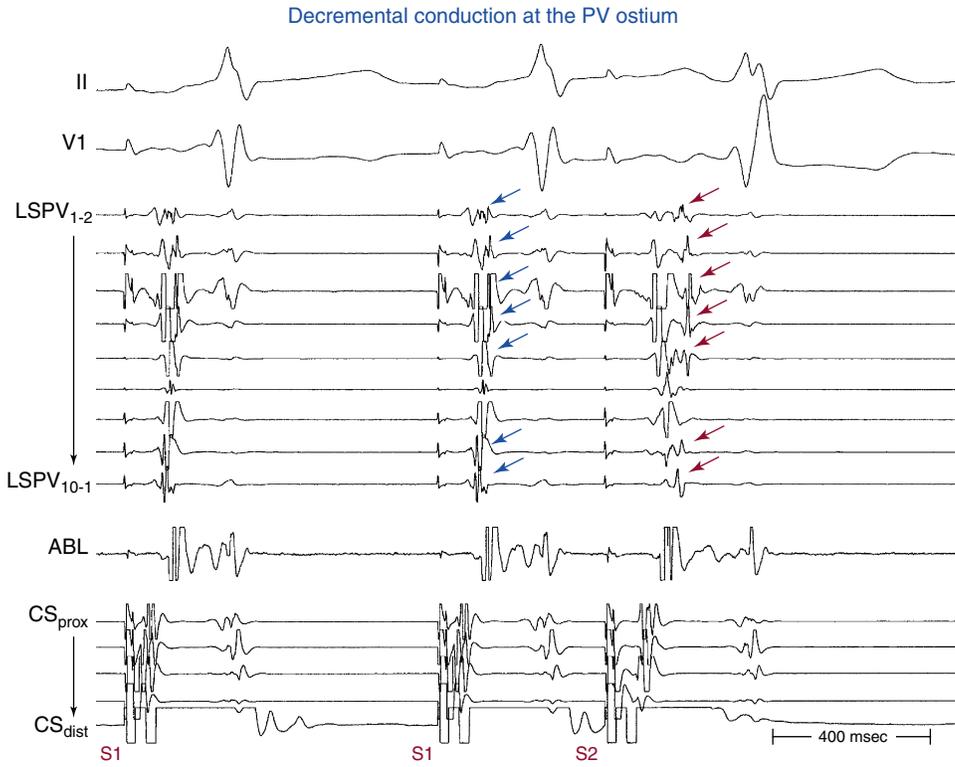

FIGURE 15-22 Decremental conduction at the pulmonary vein (PV) ostium. During coronary sinus (CS) drive pacing, complex electrograms (blue arrows) are recorded by the ring catheter positioned at the ostium of the left superior PV (LSPV). An atrial extrastimulus from the distal CS results in conduction delay between the left atrium (LA) and the PV at the PV ostium. Therefore, PV potentials (red arrows) become delayed and separated from atrial electrograms. ABL = ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

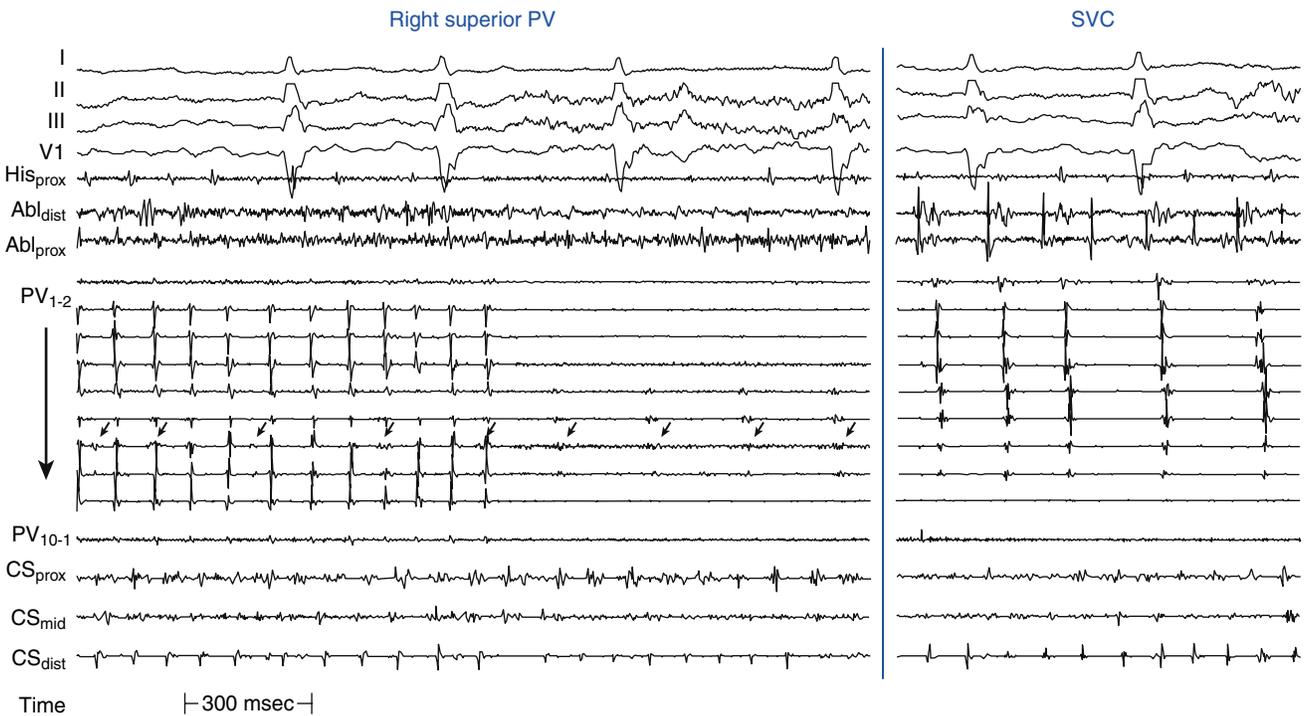

FIGURE 15-23 Superior vena cava (SVC) activity recorded in the right superior pulmonary vein (PV). **Left panel**, Recordings from a ring catheter positioned at the ostium of the right superior PV showing high-amplitude PV potentials that disappear midway through the recording because of isolation of the vein with radiofrequency ablation. Another set of lower amplitude signals (arrows) remains and was present prior to PV isolation. **Right panel**, These potentials represent far-field SVC recordings, shown as sharp near-field recordings after the ring catheter is positioned in the SVC. Abl_{dist} = distal ablation site; Abl_{prox} = proximal ablation site; CS_{dist} = distal coronary sinus; CS_{mid} = middle coronary sinus; CS_{prox} = proximal coronary sinus; His_{prox} = proximal His bundle.

into the PVs (especially the inferior PVs). The ablation catheter is introduced through the sheath, and once it is engaged in the PV, the sheath is advanced over the ablation catheter. Once the sheath is in place in the PV, the steerable catheter is removed and is replaced by the basket catheter. The basket catheter is introduced into the sheath so that the tip of the basket catheter reaches the tip of the sheath; the sheath is then pulled back to allow expansion of the basket catheter (Fig. 15-30). Alternatively, the basket catheter is inserted directly into the PVs directly with

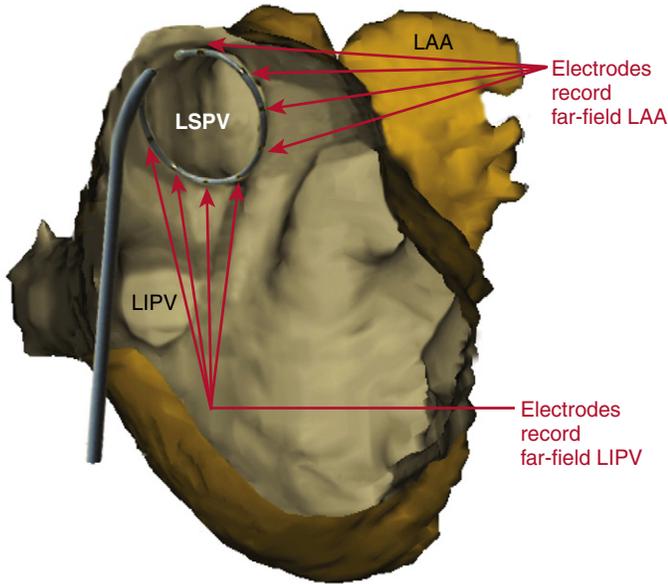

FIGURE 15-24 Left pulmonary veins versus left atrial appendage (LAA). Cutaway view of the left atrium showing the inside of the lateral aspect. A ring catheter is depicted in the left superior pulmonary vein (LSPV). Far-field recordings can be made from adjacent structures on certain electrodes of the ring catheter as indicated, such as LAA or left inferior pulmonary vein (LIPV).

the sheath positioned in the LA. However, although this technique was found to be safe because of the very flexible splines of the basket catheter, extreme caution is required to avoid venous perforation by the stiff catheter tip.

A basket catheter with a diameter of 31 mm is chosen when the diameter of the main PV trunk is 26 mm or smaller, and a basket catheter with a diameter of 38 mm is used when the PV diameter is greater than 26 mm or when there is a common ostium. The PV diameter is determined by preacquired MRI, CT scanning, or PV angiography. The position of the basket catheter in relation to the PV ostium can be determined by PV angiography (Fig. 15-31). If necessary, the basket catheter is retracted to obtain optimal contact to the main trunk and ostium of the PV.

BASKET CATHETER MAPPING. The basket catheter is deployed within the target PV with its most proximal electrodes positioned at the PV ostium, as determined by selective PV angiography. PV activation can be followed during NSR or CS pacing propagating through the four levels of bipolar electrograms from proximal ostial (7/8) to distal (1/2) inside the PV. During ectopic beats or initiation of AF, the activation can be followed from the source of ectopy to its exit to the LA (see Fig. 15-14).⁹¹

A computerized 3-D mapping system (QMS2, CathData Inc., Toronto, Canada) has been introduced to construct a 3-D color isochronal or isopotential map from a total of 56 bipolar electrograms recorded by the basket catheter. This 3-D mapping system has been found useful for identifying a preferential electrical connection and determining its elimination accurately because it enables not only a visualization of the activation sequence of the PV potentials but also an adequate evaluation of the activation sequence between the splines. An animation of a 3-D potential map, which can reflect a series of electrical activations, is used to reveal the style of breakthrough, distribution of the PV musculature, and activation pattern within the PV. A color setup with a gradation that corresponds to the relative size of the potential amplitude can be arranged variously on the QMS map. For example, in the detection of an AF focus, the color setup needs to be arranged to emphasize the small PV potentials triggering the AF. In contrast, for PV isolation, it is essential to minimize the low-amplitude LA potentials and emphasize the

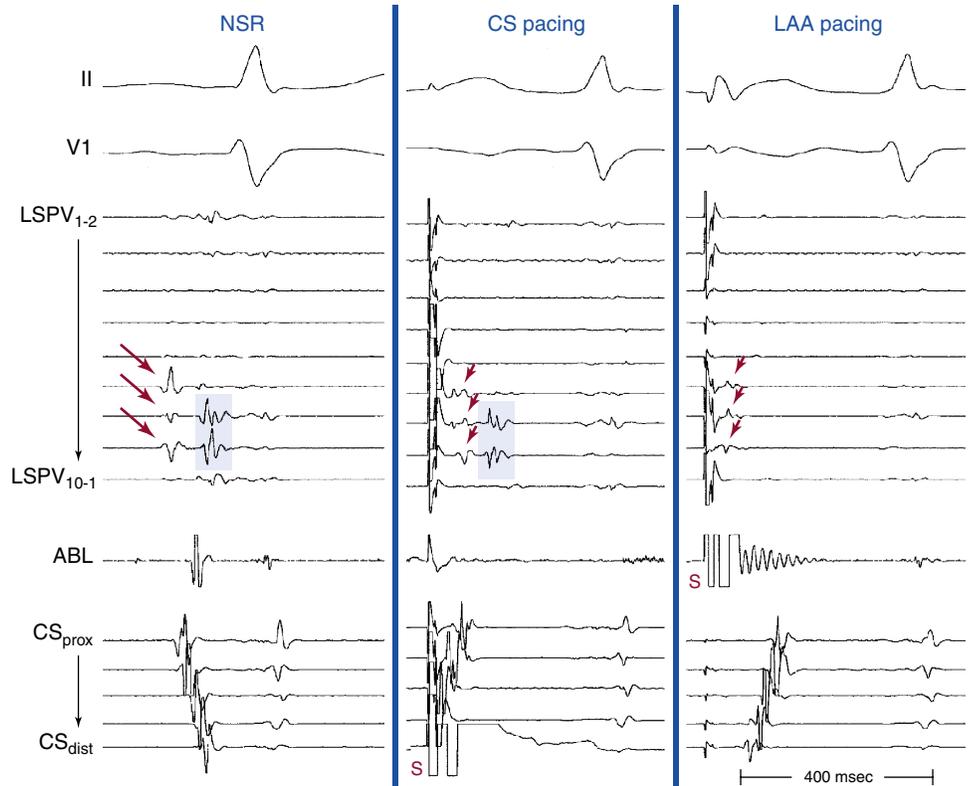

FIGURE 15-25 Differential pacing for identification of pulmonary vein (PV) potentials. During electrical isolation of the left superior PV (LSPV) in normal sinus rhythm (NSR), residual electrograms were persistent despite multiple radiofrequency (RF) applications. The initial electrograms (red arrows) were consistent with left atrial (LA) far-field activity. However, the late electrograms (shaded area) were suggestive of PV activity. Pacing from the distal coronary sinus (CS) resulted in anticipation of both early and late electrograms. Pacing via the ablation catheter (ABL) positioned in the LA appendage (LAA) resulted in disappearance of the late electrograms (i.e., those electrograms merged with the saturation artifact related to the pacing spike), a finding suggesting that those electrograms in fact represented LAA activity. Therefore, the presence of PV potentials was excluded, and no further RF ablation was necessary. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

high-amplitude PV potentials to construct a clear 3-D map of the PV potentials. When the small potentials need to be emphasized, the color threshold is decreased to 30% of the largest amplitude of all the related potentials. The short stay of the activation wavefront near the outer frame of the 3-D PV potential map before the longitudinal propagation, which reflects a conduction delay, indicates the LA-PV junction where continuous fractionated potentials connecting the LA potentials and PV potentials are observed. The serial activation patterns moving around the outer frame of the 3-D PV isopotential map before the longitudinal propagation are defined to indicate the LA-PV junction. The onset of a centrifugal activation on the LA-PV junction is identified as an electrical connection.

BASKET CATHETER-GUIDED PULMONARY VEIN ISOLATION.

With a multipolar basket catheter, ostial PV isolation can be performed by RF application to the breakthrough site identified by the 3-D PV potential map. The Astronomer system (Boston Scientific) is used for navigation of the ablation catheter inside the basket catheter.⁹² Ablation is performed at the junction between the PV and the LA, as ostial as catheter stability allows, at the site of earliest PV potential recording or shortest atrial-PV potential delay. The location of the ostium is determined by electrogram morphology and by noting the shape of the basket catheter because it conforms to the PV, and ostial anatomy can be confirmed by angiography. The QMS recording is performed after

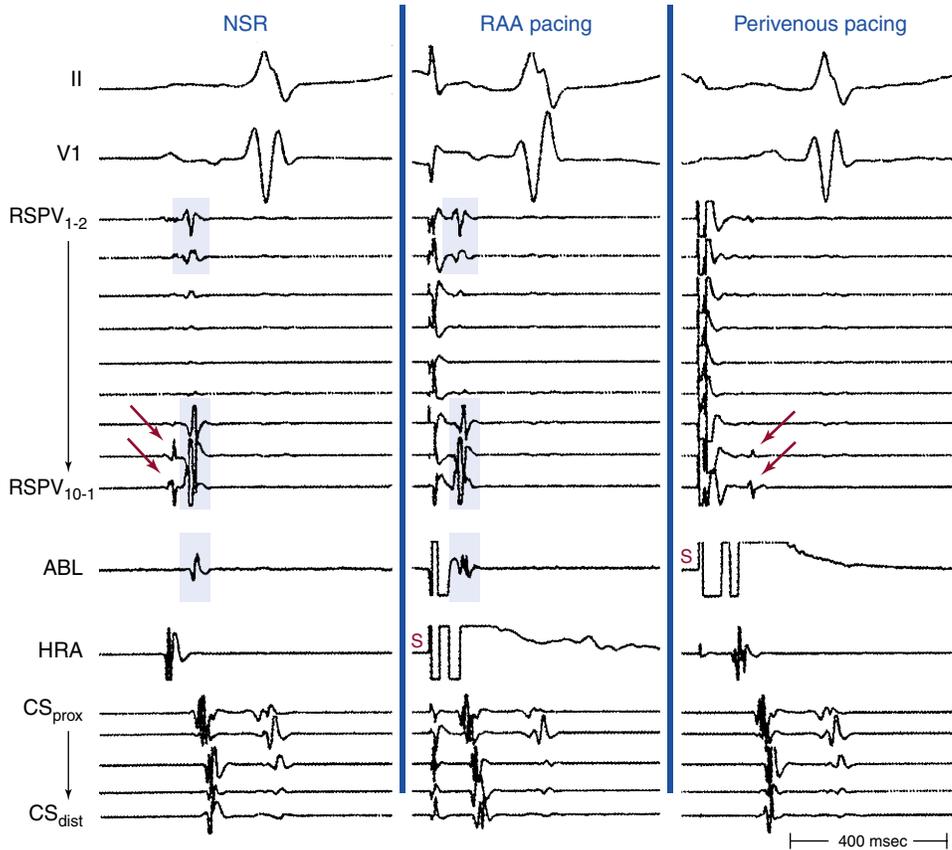

FIGURE 15-26 Differential pacing for identification of pulmonary vein (PV) potentials. During electrical isolation of the right superior PV (RSPV) in normal sinus rhythm (NSR), residual electrograms (blue shaded area and red arrows) were persistent despite multiple radiofrequency (RF) applications. Pacing from the right atrial (RA) appendage (RAA) resulted in disappearance of the earlier electrograms (red arrows; i.e., those electrograms merged with the saturation artifact related to the pacing spike), a finding suggesting that those electrograms in fact represented RA activity. During pacing just outside the ostium of the RSPV (using the ablation catheter), the second set of electrograms (shaded area) disappeared, whereas the RA electrograms (red arrows) persisted in the ring catheter recordings, indicating that the second set of electrograms in fact represented left atrial (LA) activity. Therefore, the presence of PV potentials was excluded, and no further radiofrequency ablation was necessary. ABL = ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium.

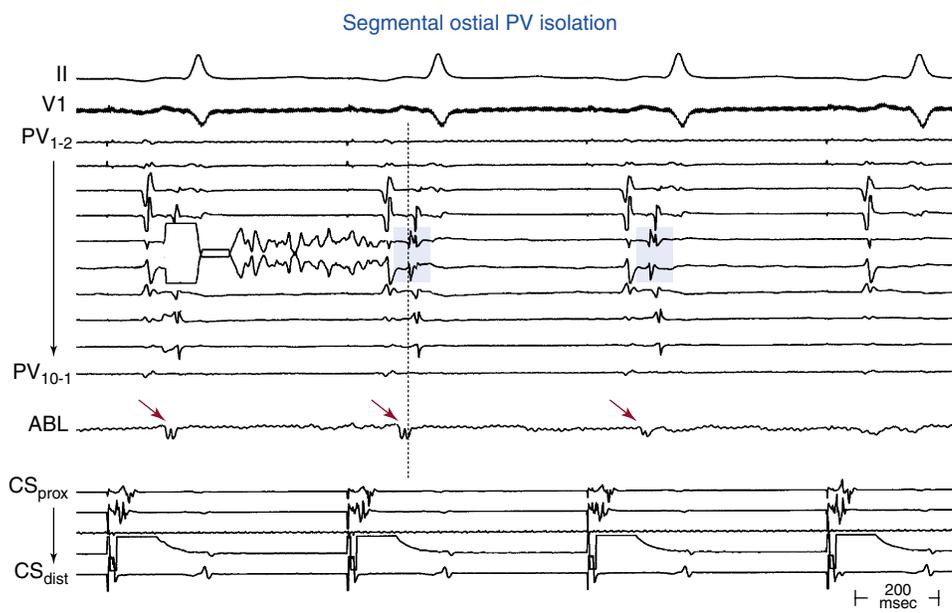

FIGURE 15-27 Segmental ostial pulmonary vein (PV) isolation. During circumferential ostial PV mapping using a ring catheter, electrical connections between the left atrium (LA) and the PV (target sites for ablation) are identified by recording the earliest bipolar PV potentials with electrogram polarity reversal on adjacent poles (shaded electrograms). Note that the distal bipoles of the ablation catheter record even an earlier sharp PV potential (arrows). The presence of ablation artifact on the recording from a specific ring catheter pole confirms the pole the catheter is on and that the catheter is in the same plane as the ring catheter. Catheter ablation at that site results in complete elimination of PV potentials and LA-PV block (last complex). ABL = ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

every RF application and, if the elimination of a target breakthrough is confirmed, another breakthrough is identified and ablated.

ADVANTAGES OF THE BASKET CATHETER. The basket catheter is currently the mapping tool with the highest resolution available for endovascular mapping of the LA-PV junction in humans. In addition, the basket catheter provides information about the anatomy of the PV, such as exact ostium localization, because the basket catheter takes the shape of the PV (see Fig. 15-31) and allows 3-D reconstruction of the PV activation from the ostium to deep inside the PV.

The Astronomer navigation system permits precise and reproducible guidance of the ablation catheter tip to areas identified as LA to PV conduction pathways and thereby allows efficient PV isolation. The distal poles of the basket catheter can be used to

monitor changes in the activation sequence in real time and to demonstrate the effects of ablation at the ostium as lesions are created. They also provide an immediate indication of successful PV isolation by the disappearance of the distal PV potentials. The system also helps identify areas near the PV ostium with fragmented potentials and with discharging ostial foci, which can be localized in a single beat.

The risk of PV stenosis seems to be low (1.2%) with the use of basket catheter-guided PV isolation. This technology can potentially minimize the risk of PV stenosis, first by reducing the number of RF applications and second by avoiding ablation inside the PV, because the basket catheter allows localization of the PV ostium during the entire procedure. Thus, the use of complementary navigation systems or ICE appears to be nonessential when using the basket catheter for PV isolation.
