DISADVANTAGES OF THE BASKET CATHETER. Carbonizations can form after ablation on the splines of the basket catheter, which can potentially cause embolism. Carbonizations, which appear as dark material attached to the basket catheter electrodes or splines, are thought to be caused by the concentration of RF energy on the thin splines that results in very high local temperatures that induce denaturation of serum proteins. However, carbonization can be greatly diminished with the use of an irrigated-tip catheter as opposed to conventional ablation catheters.

Another disadvantage is that the basket catheter is nondeflectable and has limited maneuverability, and it requires a special sheath with a limited number of preshaped curves. Sometimes, it can be challenging to introduce a basket catheter into the inferior PVs. The use of a deflectable transeptal sheath can facilitate catheterization of the PVs.

Additionally, the splines may contact one another when the basket catheter is positioned within a relatively small PV, thereby inducing electrical artifact (see Fig. 15-31). Similarly, the splines may not always be equally spaced relative to the circumference of the PV. As a result, areas in which several splines are clustered may be densely mapped, whereas other regions are less densely recorded.

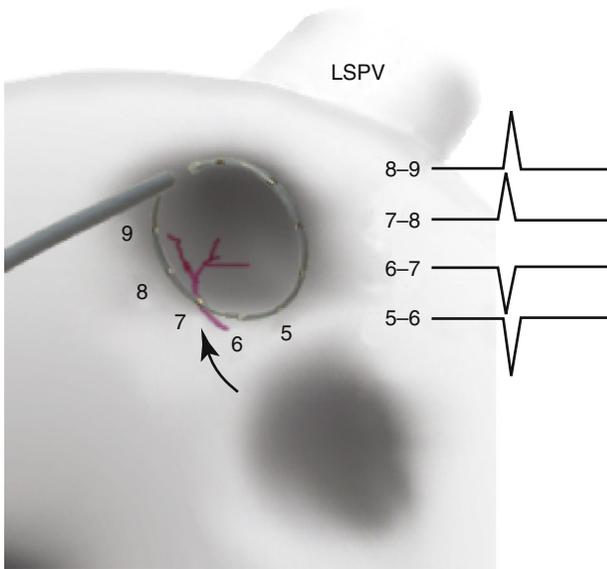

FIGURE 15-28 Bipolar electrogram polarity reversal. The ring electrode catheter (electrodes numbered) is situated in the ostium of the left superior pulmonary vein (LSPV); a strand of atrial muscle crosses from the left atrium (LA) to the PV (red) and branches within the vein. The arrow indicates propagation of the wavefront of activation from the LA to the PV. The strand crosses at electrode 7; recordings from surrounding bipoles indicate the direction of propagation away from (negative deflection) or toward (positive deflection) the bipole. The point at which the polarity reverses from positive to negative is where the strand crosses into the PV.

Target of Ablation

The objective of the mapping and ablation procedure is to identify PV potentials along the circumference of the PV ostium and ablate to eliminate these potentials completely. Isolation of all PVs is performed without attempting to identify the PVs demonstrating arrhythmogenicity. RF ablation is targeted to the ostial portion of the breakthrough segments (electrical connections) connecting the LA to the PV, which are identified as the earliest PV potentials recorded from the ring catheter. The PV potential reflects

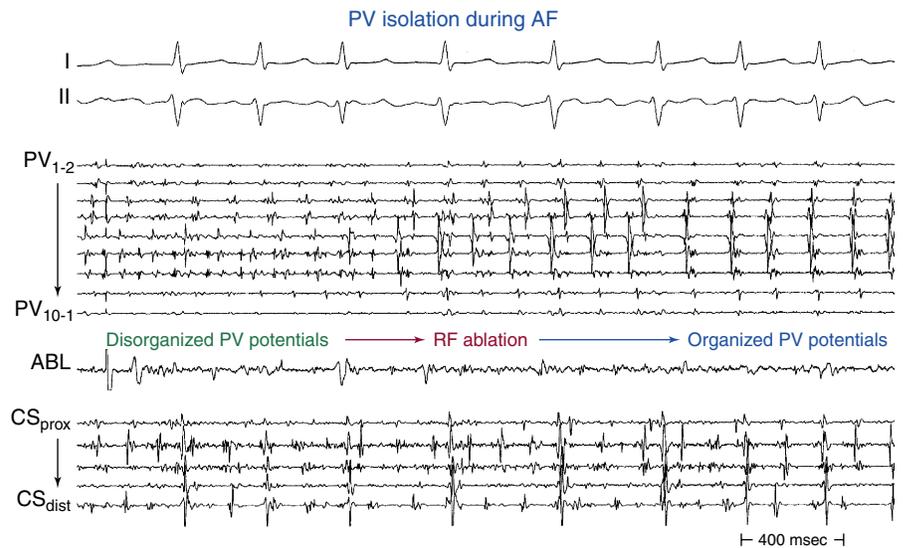

FIGURE 15-29 Pulmonary vein (PV) isolation during atrial fibrillation (AF). Initially (at left), PV potentials are disorganized. During radiofrequency (RF) application at the PV ostium, the PV potentials become organized. See text for discussion. ABL = ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

the activation of muscular LA bands extending into the PV with longitudinal, oblique, or complex courses and ending in a cul-de-sac or even looping back in the LA. The source, its course within the PV, and its exit into the LA may all be considered appropriate individual targets for ablation. The PV potential is recorded over a broader area proximally, but with great variability. Therefore, a few seconds of energy application may be sufficient at some proximal sites to eliminate downstream PV muscle activity, whereas wide or repeated RF applications may have been required in others.

Once the presence of the PV potentials along the PV circumference is defined on the ring catheter, target sites for ablation are selected by identifying the earliest bipolar PV potentials or the unipolar electrograms with the most rapid (sharpest) intrinsic deflection on high-speed recordings (150 to 200 mm/sec) that had equivalent or earlier activation relative to the earliest PV potential recorded on the adjacent ring catheter recording sites (see Fig. 15-27). The ablation catheter then is maneuvered to a position adjacent to the target electrode pair of the ring catheter and withdrawn to the edge of the ostium (the ostial side of the ring catheter). RF ablation is performed within 5 to 15 mm of the PV ostium; the exact

location usually depends on catheter stability. This is safer (regarding the risk of PV stenosis) than more distal applications, especially in smaller veins.

Several PV potential electrogram characteristics predict a successful ablation site: (1) timing of the (unipolar and bipolar) PV potential electrogram recorded by the ablation catheter equal to or earlier than the earliest PV potential recorded by the ring catheter (see Fig. 15-27); (2) larger (unipolar and bipolar) electrogram amplitude; (3) steeper intrinsic deflection of the unipolar electrogram; and (4) identical morphologies of the unipolar electrograms recorded by the ablation catheter and by the contiguous electrode of the ring catheter.

Ablation Technique

A temperature-controlled, 4- or 8-mm-tip deflectable catheter or a 3.5-mm irrigated-tip ablation catheter can be used. For 8-mm-tip catheters, RF ablation is performed with the maximum temperature set at 45°C to 55°C, the power set at 70 W or lower, and for a duration of 20 to 60 seconds. Power limit is usually reduced to 25 W

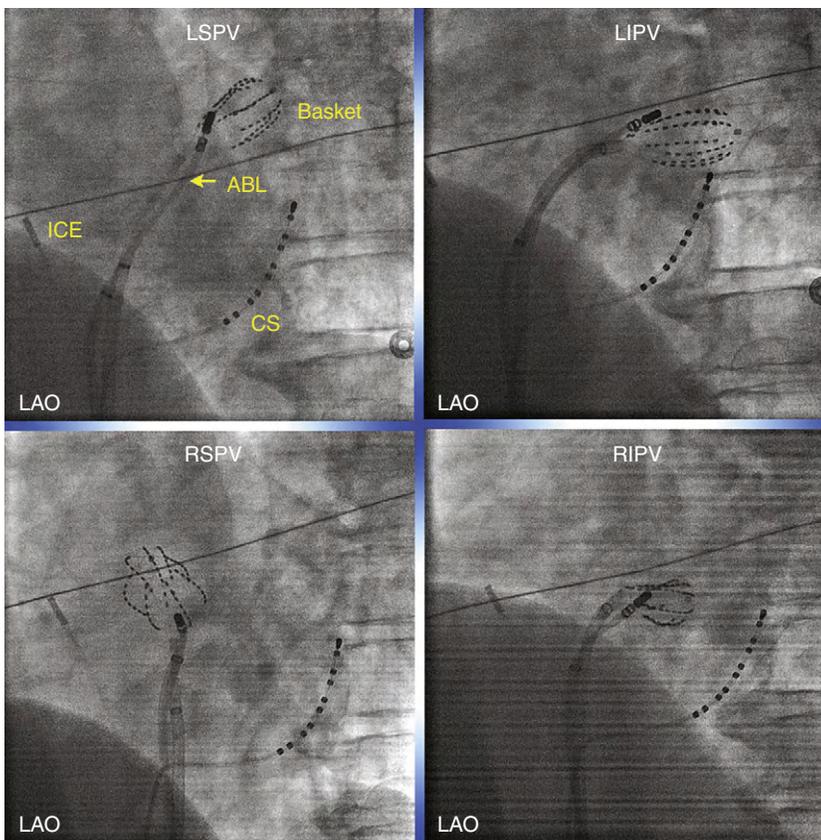

FIGURE 15-30 Left anterior oblique (LAO) fluoroscopic views of basket catheter positioned in the four pulmonary veins (PVs). A long deflectable sheath is used to help position the basket catheter in the different PVs. CS = coronary sinus; ICE = intracardiac echocardiography; LIPV = left inferior pulmonary vein; LSPV = left superior pulmonary vein; RIPV = right inferior pulmonary vein; RSPV = right superior pulmonary vein.

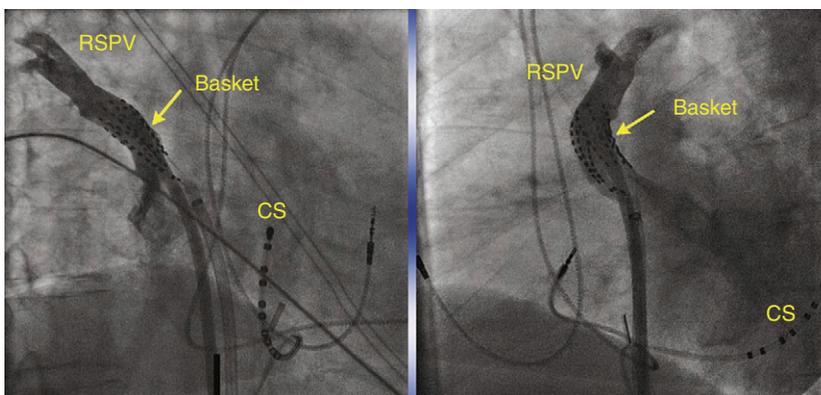

FIGURE 15-31 Fluoroscopic right anterior oblique (RAO) and left anterior oblique (LAO) views of angiography of the right superior pulmonary vein (RSPV) with a basket catheter positioned in the vein. Note that the basket catheter takes the shape of the PV and provides anatomical information about the location of the ostium and size of the PV. CS = coronary sinus.

for the case of a left inferior PV and to 20 W if the PV diameter is less than 15 mm. For irrigated-tip catheters, power is set at 50 W or lower and temperature at 40°C or lower. Ablation lesions are delivered for a maximum of 60 seconds to achieve an impedance drop of 5 to 10 Ω at the ablation site. RF application may be repeated or prolonged when a change occurs in activation or morphology of the PV potentials, or both, as determined by circumferential mapping recorded downstream. Additional ostial applications targeting fragmented electrograms are performed after PV isolation to eliminate any ostial PV potentials, thus reducing the risk of recurrence caused by ostial foci. The presence of high-amplitude electrical artifact on the recording from a specific ring catheter pole confirms the pole with which the ablation catheter is in contact and that the catheter is in the same plane as the ring catheter (see Fig. 15-27).

A successful ablation site is defined as a site at which an application of RF energy results in elimination of a PV potential at more than one ring catheter recording sites or delay (shift) of a PV potential by at least 10 milliseconds at more than two ring catheter recording sites (Fig. 15-32). Once a shift or elimination of PV potentials at some ring catheter poles is achieved, the ablation catheter is adjusted to target the new ring catheter pole recording the now earliest PV potential. This maneuver is repeated until the whole PV is electrically isolated. Complete electrical isolation of the PV is defined as complete entrance block into the PV during AF and elimination or dissociation of all ostial PV potentials during NSR and atrial pacing (see Fig. 15-32), as well as exit block from the vein (see later).

The extent of the circumference ablated is variable among PVs. When ablation is performed proximally to the PV ostium or during AF, more circumferential ablation is often required to achieve PV isolation. Occasionally, electrical connections exist between ipsilateral PVs, and elimination of these connections is important only when isolation of one PV is the goal of the ablation procedure. The electrical connections between PVs are defined as the identification of the earliest activation at the ostium of an untargeted PV during pacing inside the targeted PV; thus, ablation

is performed at this untargeted PV ostium to achieve electrical disconnection.

When a multielectrode basket catheter is used for PV mapping, it is recommended to use an irrigated-tip catheter at a maximum temperature of 45°C, maximum power of 30 W, and flow rate during ablation of 17 mL/min.

CRYOABLATION

Although RF energy has become the gold standard for catheter ablation in most cardiac arrhythmias, PV isolation by heating has potential limitations. RF energy produces tissue disruption, which increases the risk of perforation and thromboembolism. Moreover, RF energy induces inhomogeneous, dense fibrosis and shrinking of the tissue, leading to PV stenosis. Cryothermal energy is an alternative energy source that may overcome these limitations. Cryothermal energy creates minimal endothelial and endocardial disruption and preserves the underlying tissue architecture. Therefore, the lesions are minimally thrombogenic and arrhythmogenic, and cryoablation of the PV should have a low risk of PV stenosis.

Initial experiences of EP-guided segmental ostial PV isolation by using cryothermal energy application with a 10.5 Fr (CryoCor, San Diego, Calif.) or 7 Fr (Freezor, CryoCath Technologies, Montreal, Canada) focal ablation catheter showed that PV isolation is feasible with a comparable number of applications and clinical outcome with regard to RF ablation. Importantly, the early cryoablation experience has not evidenced, so far, development of PV stenosis following ablation. On the other hand, cryothermal injury is sensitive to surrounding thermal conditions. The high flow of the PVs can present a considerable heat load to cryothermal technologies, which can limit the size and depth of the lesion produced by cryothermal energy at the PV ostium and thus limit the ability of achieving complete and permanent PV isolation. Additionally, the longer application times (2.5 to 5.0 minutes) required when cryothermal energy is used may relevantly reflect on the procedure duration, thus limiting the clinical use of this theoretically optimal energy source.

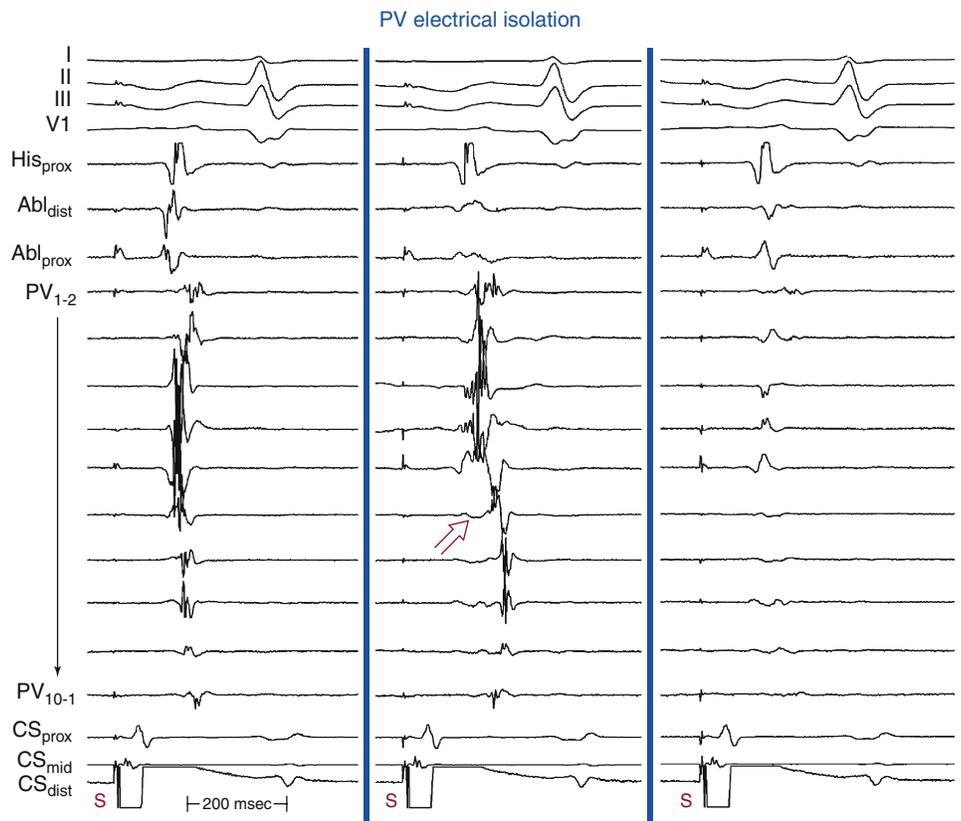

FIGURE 15-32 Electrical isolation of the right superior pulmonary vein (PV). **Left panel**, Baseline recordings from a ring catheter situated at the PV ostium. During coronary sinus (CS) pacing, left atrial (LA) and PV potentials overlap. **Middle panel**, After some encircling ablation, some of the PV potentials are shifted to a later time (arrow) and become separated from far-field LA electrograms. **Right panel**, On completion of isolation, no PV potentials are visible (entrance block into the PV). Endpoints of Ablation

ELECTRICAL DISCONNECTION OF THE PULMONARY VEIN

CH
15

Complete PV electrical disconnection is verified by (1) complete entrance block into the PV during AF and the elimination or dissociation of all ostial PV potentials recorded by the ring catheter during NSR and atrial pacing (i.e., LA-PV conduction block) (Fig. 15-33; see also Fig. 15-32) and (2) complete exit block from the PV to the PV ostium and LA during intra-PV pacing (i.e., PVLA conduction block; Fig. 15-34).⁹³ Evidence suggests that demonstration of only entrance block is an insufficient endpoint. In one report, less than 60% of PVs demonstrated exit block after achieving entrance block (Fig. 15-35). The fact that tachycardias can be induced in isolated PV segments highlights the importance of achieving PV exit block. PV pacing is performed from multiple sites in as circumferential a manner as possible by using the bipoles of the ring catheter or mapping-ablation catheter and with the minimal output that constantly captures the PV potential. This maneuver also can unmask electrical connections between ipsilateral PVs, which manifest as intact LA conduction during intra-PV pacing after elimination of all potentials in that PV, thus indicating unidirectional block. This is relevant when only one (and not all) PV is targeted for isolation.

Early PV reconnection can be observed in up to 93% of patients and 50% of PVs, with 33% of the PVs demonstrating a first recurrence at 30 minutes and 17% showing a first recurrence at 60 minutes. Notably, recovery of PV conduction is more frequently observed in the left superior PV as compared with the other PVs. Therefore, reconfirmation of PV isolation after a 30- or even 60-minute waiting period after initial PV isolation or pharmacological provocation with adenosine (20 to 30 mg rapid intravenous bolus) or isoproterenol (20 μ g/min intravenous infusion) has been suggested to

improve outcome. Incorporation of shorter waiting time (20 to 30 minutes) in conjunction of adenosine administration may also be reasonable. Of note, each of those methods seems to have unique features in uncovering PV reconnection, and the results of the different methods may not be in agreement. In other words, PV reconnection may be unmasked only after a waiting period but not by administration of adenosine, and vice versa. Even the sites of PV reconnection uncovered by one method can be different from those uncovered by the other methods.⁹³⁻⁹⁵

INABILITY TO ISOLATE A PULMONARY VEIN

More than 90% of PVs can be electrically isolated from the LA by conventional applications of RF energy along segments of the ostia, guided by PV potentials. The inability to abolish the arrhythmogenic PV potential or its recovery (even in a very discrete area and with a prolonged conduction time) is associated with a higher AF recurrence rate.

The inability to disconnect the PV has been demonstrated in 3% to 24% of targeted PVs in previous studies and may be attributable to anatomical variations in the geometry of the ostia that could limit optimal recording of PV potentials with the ring catheter. Using an expandable ring catheter or using ICE to guide positioning of the ring catheter aids in stabilizing the mapping catheter. Additionally, some fascicles can be too thick to be ablated with conventional RF energy, and the use of high-power output or an irrigated-tip ablation catheter, which creates deeper lesions than a conventional ablation catheter, can be required to isolate those PVs. Also, the inability to isolate a PV can be caused by the presence of electrical connections between PVs. Approximately 14% of the patients have electrical connections between ipsilateral PVs. In these patients, ostial ablation of an untargeted PV is required for successful disconnection of the targeted PV. Recognition of

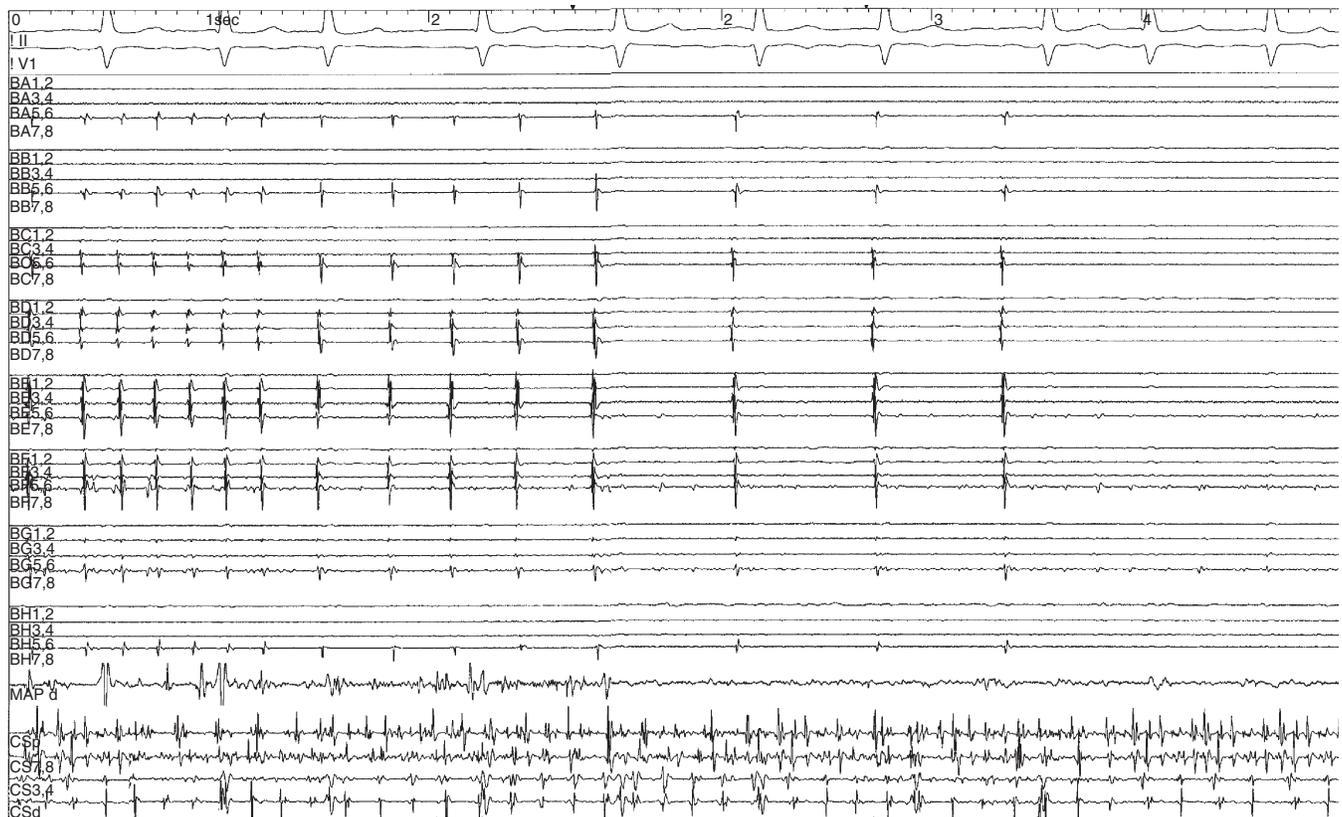

FIGURE 15-33 Pulmonary vein (PV) isolation during atrial fibrillation (AF) using a basket catheter. Bipolar recordings from the eight electrodes (1-2, 3-4, 5-6, 7-8) on each of the eight splines (BA through BH) of the basket catheter positioned in the left superior PV initially show sharp PV potentials. Radiofrequency ablation during AF results in gradual slowing and then disappearance of all PV potentials and persistence of residual low-amplitude, far-field, left atrial (LA) electrograms, consistent with LA-PV entrance block. AF continues in the coronary sinus (CS) recordings.

electrical connections between PVs during ostial ablation of PVs prevents unnecessary or excessive RF applications that probably produce postablation PV stenosis. Occasionally, the proximity of a targeted PV to an important extracardiac structure (esophagus, phrenic nerve) limits the ability to isolate the vein fully.

Outcome

Segmental ostial PV isolation represents an important advance in catheter treatment of AF and was found more efficacious than

focal ablation for the control of paroxysmal AF. As compared with focal ablation, PV isolation eliminates the need for detailed mapping of spontaneous ectopy, and there is a clear-cut endpoint of ablation, even when spontaneous arrhythmias are absent. Importantly, the risk of PV stenosis is less than that with focal PV ablation.

On the other hand, the benefit of empiric isolation of all PVs over the identification and selective isolation of arrhythmogenic veins is less clear. Previous comparative case series demonstrated that empirical all-PV isolation led to superior outcomes over isolating fewer veins, which is expected given that most (up to 71%) patients

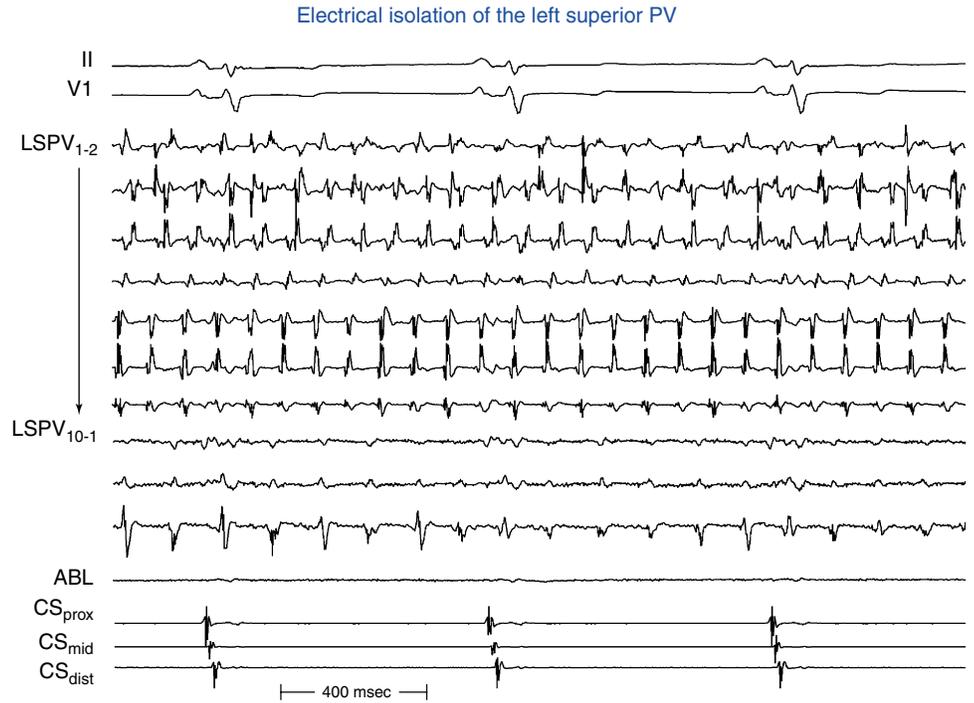

FIGURE 15-34 Electrical isolation of the left superior pulmonary vein (LSPV). Complete electrical isolation of the LSPV resulted in termination of atrial fibrillation (AF) and conversion to normal sinus rhythm (NSR) on the surface ECG and coronary sinus (CS) recordings, whereas AF continued in the LSPV (PV–left atrial exit block). ABL = ablation site; CS_{dist} = distal coronary sinus; CS_{mid} = middle coronary sinus; CS_{prox} = proximal coronary sinus.

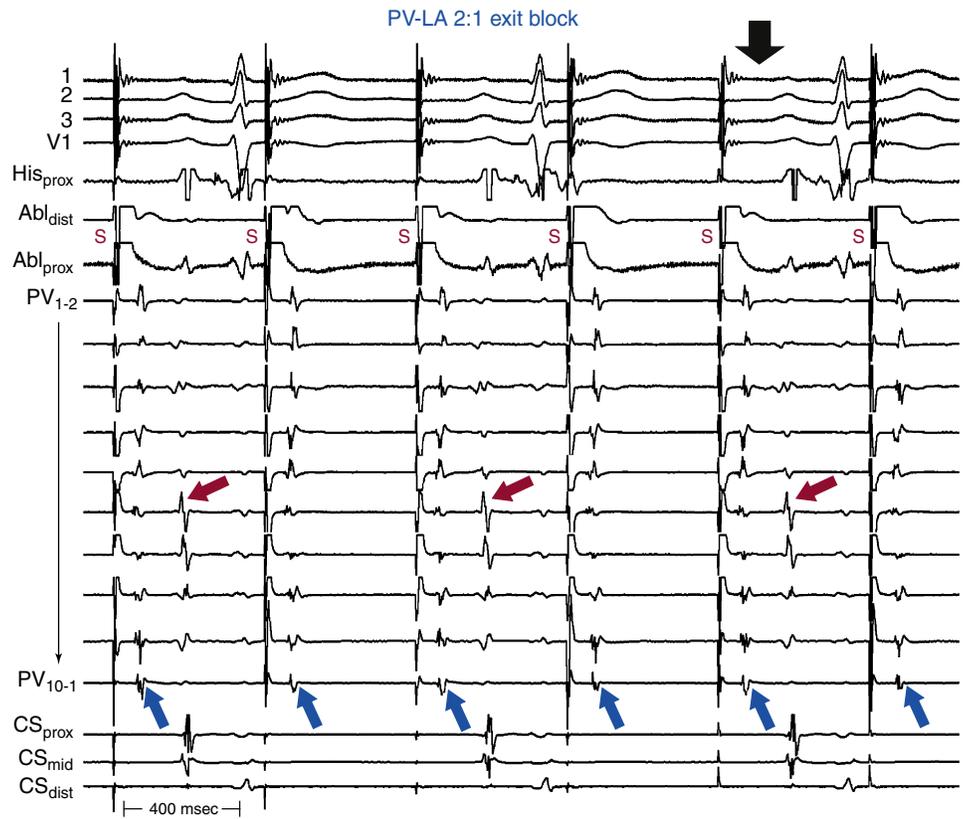

FIGURE 15-35 Pulmonary vein (PV)–left atrium (LA) 2:1 exit block. The ring catheter is positioned at the ostium of the left superior PV. During pacing using the ablation catheter positioned more distally in the vein, consistent capture of PV potentials is shown (blue arrows) but only every other PV potential conducts to LA (red arrows). Note very long delay between the stimulus and the P wave of the conducted complex (black arrow). Abl_{dist} = distal ablation site; Abl_{prox} = proximal ablation site; CS_{dist} = distal coronary sinus; CS_{mid} = middle coronary sinus; CS_{prox} = proximal coronary sinus; His_{prox} = proximal His bundle.

prove to have three or more arrhythmogenic PVs.⁸⁹ Nevertheless, in a study in patients with predominantly paroxysmal AF, isolation of arrhythmogenic veins identified using a comprehensive stimulation protocol was found as effective as empiric isolation of all PVs in achieving long-term arrhythmia control after a single ablation procedure. Of interest, limiting ablation to the arrhythmogenic PV did not yield any significant benefit over isolation of all PVs in terms of serious adverse events or procedure and fluoroscopy times.^{89,93}

Reconnection of previously isolated PVs (caused by recovery of conduction through inadequately ablated fascicles in the muscle sleeves surrounding the PVs) is probably the most common reason for recurrent AF after PV isolation, at least among patients with paroxysmal AF. Other causes include ectopy from PVs not targeted or that could not be isolated at the initial procedure and the presence of non-PV triggers. In one study on the recurrence of AF following PV electrical isolation, most triggers were found to originate from previously targeted PVs (54%), whereas one-third of recurrent triggers (32%) originated from PVs that were not ablated during the initial session. Notably, 61% of previously isolated PVs in that series had evidence of recovered PV potentials. Therefore, successful PV isolation does not confer permanent disconnection of the PV musculature from the LA, and in most isolated PVs residual conduction remains or recurs with time.

Predictors of early recurrence of AF include older age (65 years or more), the presence of associated cardiovascular disease, the presence of multiple AF foci, the presence of AF foci from LA free wall, LA enlargement, and longstanding persistent AF. Predictors of late recurrence of AF include the presence of early recurrence of AF and the presence of multiple AF foci.

In most reports, a successful outcome was defined as the absence of any symptomatic atrial arrhythmias beyond the first 2 to 3 months after ablation without the use of antiarrhythmic drugs. Medium-term success has reportedly been achieved in up to 70% of patients with paroxysmal AF but in only 30% of patients with persistent AF. This finding suggests that intervention with PV isolation in patients with drug-refractory paroxysmal AF should not be postponed until the AF becomes persistent. Once AF has become persistent, it is likely that PV isolation will have to be supplemented by some other type of ablation procedure directed at the atrial myocardium. The less satisfactory outcome of PV isolation in persistent AF suggests that the PVs play a less critical role in generating AF once the AF has become persistent. It is possible that the EP and anatomical remodeling that occurs during persistent AF often allows the atria to continue fibrillating independently of the PVs. The overall major complication rate is 6.3%, including stroke (0.7%), pericardial tamponade (1.2%), and significant PV stenosis (4.3%).

Circumferential Antral Pulmonary Vein Isolation

Rationale

The muscular sleeves of the PVs extend proximally to the antral-LA junction and are not restricted to the tubular portion of the PV. This finding is not surprising, because embryologically the PVs originate from the posterior LA wall, so that a continuum exists between the atrial wall and PVs. Therefore, it is likely that the PV antrum also has an arrhythmogenic potential similar to that of the tubular portion of the PVs. Furthermore, the PV antrum can potentially harbor ganglionated plexuses that have been implicated in the genesis of AF, as well as high-frequency activity or rotors that are thought to have anchor points necessary for perpetuation of AF. Hence, ablation at the antrum not only is effective to isolate PVs electrically, but also it can eliminate certain potential mechanisms of AF. Additionally, a large area of the posterior LA is included inside the ablation lines and a considerable amount of atrial debulking (approximately 25% to 30%) may occur after antral PV isolation.

Circumferential antral PV isolation has several additional advantages over segmental ostial PV isolation. This technique does not

rely on localizing the sites of electrical breakthroughs into the PV, and thus it is easier to perform during AF. Furthermore, this approach reduces the risk of PV stenosis because ablation is performed in the LA, away from the PV ostia (Fig. 15-36). In addition, in some patients with PV anatomical variations, this approach can be more favorable. One such variation is the presence of a common ostium of the left PVs, occurring in up to 32% of patients undergoing PV isolation. Such common ostia typically are too large to allow a stable position of the ring catheter (see Fig. 15-3). Another anatomical variation is the presence of a right middle PV, present in up to 21% of patients, which typically is separated from the right superior PV and right inferior PV by a narrow rim of atrial tissue (see Fig. 15-3). This would predispose to sliding of the ablation catheter into the PV during ablation. Another anatomical finding that renders extraostial PV isolation more favorable is a PV ostial diameter of less than 10 mm. RF application at a small ostium carries a higher risk of PV stenosis.

Circumferential antral PV isolation has been shown to be more effective in preventing AF recurrence than segmental ostial PV isolation, and this procedure has become a preferred ablation strategy in patients with paroxysmal and persistent AF. The preferred ablation target is the outmost atrial side of the PV ostium.

Identification of Pulmonary Vein Antra

The objective of the mapping and ablation procedure is to identify PV potentials along the perimeter of the PV antrum and ablate to eliminate these potentials completely. Reliable definition of the anatomy of PV antra is crucial to provide an effective set of lesions. A navigation system is used to provide 3-D anatomical images that allow safe maneuvering of the ablation catheter to complete the lesions at the antrum and eliminate conduction to PVs. However, the use of these systems does not replace the use of circumferential mapping and an EP endpoint to the procedure. More importantly, none of these systems can exclude the risk of RF delivery within the PVs and therefore the risk of PV stenosis.

RING CATHETER MAPPING

The ring catheter is used for circumferential ostial mapping of PV potentials, as described for segmental ostial PV isolation. However, the breakthrough segments (electrical connections) connecting

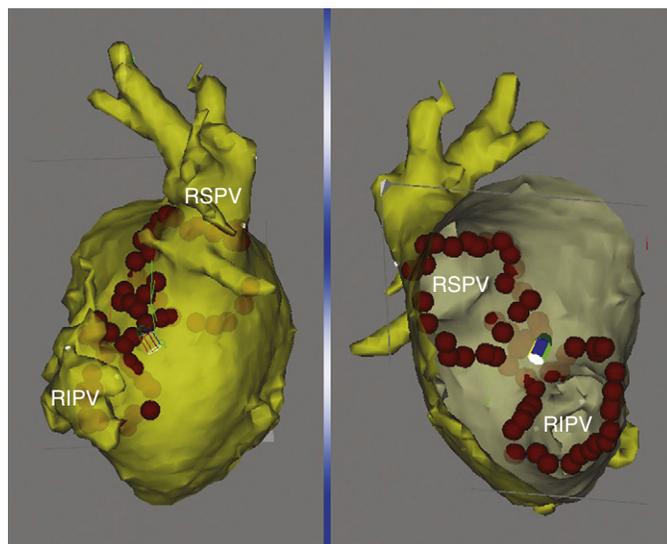

FIGURE 15-36 Circumferential antral pulmonary vein (PV) isolation. Registered three-dimensional surface reconstructions of the left atrium (LA; right lateral and cardioscopic views) during circumferential antral PV isolation of the right PVs are illustrated. Contiguous radiofrequency lesions are deployed in the LA proximal to the ostia of the PVs, creating a circumferential line around each PV ostium. RIPV, right inferior pulmonary vein; RSPV, right superior pulmonary vein.

the LA to the PV, identified as the earliest PV potentials recorded from the ring catheter, are not specifically mapped or targeted. Instead, the entire perimeter of the PV ostium is the target for the ablation procedure. Using the ring catheter enables circumferential mapping of the PV ostia perpendicular to the axis of the vein and serves as a landmark for the PV ostium around which RF lesions are delivered. In addition, the ring catheter is vital for confirming complete electrical isolation of the PV, an important endpoint of this ablation strategy.

BASKET CATHETER MAPPING

The technique of positioning the basket catheter into the PVs is described earlier in this chapter (see Fig. 15-30). For antral PV isolation, the basket catheter is introduced toward the distal PV under fluoroscopy guidance and then is pulled back as proximally as possible without dislodgment until its most proximal electrodes are positioned at the PV antrum, which is identified by selective angiography. The basket catheter can help identify the true junction between the PVs and LA anatomically and electrically. Because the basket catheter conforms to the shape of the PV, it provides information about the anatomy of the PV.⁹²

Furthermore, longitudinal mapping with a basket catheter can help identify the transition zone between the PV and LA potentials. Far-field LA potentials are normally recorded almost simultaneously all over the PV, whereas the activation sequence of the PV potentials is from proximal to distal when the activation propagates from the LA to the distal PV. Consequently, the interval between the LA potentials and PV potentials is shorter at the proximal PV than at the distal PV. At the transition zone, total fusion of the PV and LA potentials occurs (Fig. 15-37). Therefore, the potential recorded at the transition zone may reflect the activation of the PV antrum. A transverse activation pattern, indicated by simultaneous activation recorded by some neighboring electrode pairs along the spline, sometimes occurs around the LA-PV junction before the longitudinal activation pattern within the PVs. This pattern may reflect the activation of the circle of myocardium at the PV antrum.⁹²

On the basis of these findings, PV antrum potentials are defined as single sharp potentials formed by the total fusion of the PV and LA potentials around the PV ostium or single sharp potentials with a transverse activation pattern around the PV ostium (see Fig. 15-37). Targeting those potentials by RF ablation would target the transition zone between the PV ostium and LA. When potentials conforming to the definition of PV antrum potentials are observed

from some electrode pairs on the same spline, the antrum potential recorded from the most proximal electrode pair is targeted. RF applications are also delivered to the gap between the targeted electrode pairs on the neighboring splines to produce a continuous RF lesion at the PV antrum.⁹²

ELECTROANATOMICAL MAPPING

Different navigation tools, such as the EnSite NavX and CARTO systems, have been used to facilitate circumferential PV isolation. These systems can provide a high-resolution reconstruction of the LA and defining PV ostia and antra and allow real-time visualization of the ablation catheter within the reconstructed 3-D geometry. Additionally, ablation lesions can be tagged, thus facilitating creation of lines of block with considerable accuracy by serial RF lesion placement and allowing verification of the continuity of ablation line.

CARTO. The CARTO-3 system, the third-generation platform from Biosense Webster, allows visualization of up to five catheters (with and without the magnetic sensors) simultaneously with clear distinction of all electrodes. Unlike point-by-point electroanatomical mapping required in the older CARTO versions, volume data can be collected with Fast Anatomical Mapping (FAM), which permits rapid creation of anatomical maps by movement of a sensor-based catheter throughout the cardiac chamber (Fig. 15-38, see Video 15). Proprietary catheters besides the ablation catheter (e.g., the Lasso catheter) can further enhance the collection of points and increase the mapping speed.

ENSITE NAVX. Similar to the CARTO system, the EnSite NavX system can provide a high-resolution reconstruction of the PV antrum and its anatomical variations. NavX-guided procedures are performed using the same catheter setup as conventional approaches, and the system does not need any special catheter. The system also works with most manufacturers' ablation catheters and RF or cryogenerators. The NavX system allows real-time visualization of the position of up to 64 electrodes on up to 8 standard EP catheters. Any electrode can be used to gather data, create static isochronal and voltage maps, and perform ablation procedures. A shadow can be displayed on the catheters of interest (e.g., the reference CS catheter and the ring catheter) to record the catheter's spatial position to realize displacement during the procedure. In case of displacement, the catheter can be returned easily to its original location under the guidance of NavX.

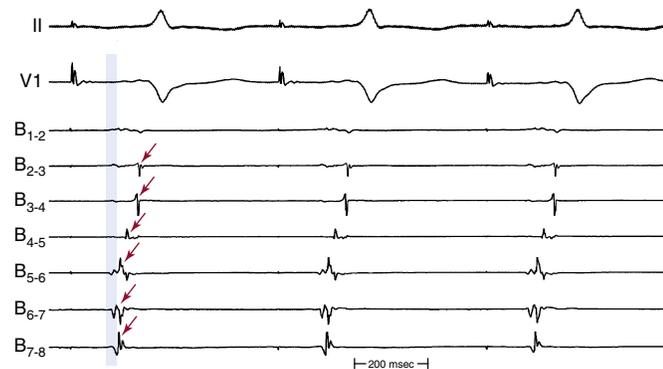

FIGURE 15-37 Identification of the pulmonary vein (PV) antrum using the basket catheter. The basket catheter is positioned in the left superior PV. Shown are seven bipolar recordings obtained from the eight electrodes (1-2, 2-3, to 7-8) on one of the eight splines (B1-2 through B7-8) of the basket catheter. During coronary sinus pacing, far-field left atrial (LA) potentials are normally recorded almost simultaneously all over the PV (shaded area). In contrast, PV activation propagates from proximal (ostial) to distal, and the interval between the LA potentials and the PV potentials is shorter at the proximal PV than at the distal PV. At the transition zone (PV antrum), a total fusion of the PV and LA potentials occurs (B7-8).

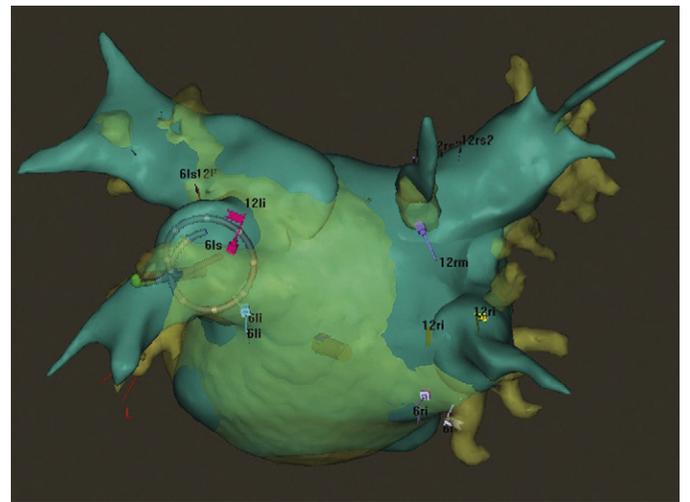

FIGURE 15-38 Three-dimensional reconstruction of the left atrium (LA, posterior view) using the CARTO-3 (Biosense Webster, Inc., Diamond Bar, Calif.) electroanatomical system (fast anatomical mapping [FAM]) and integration with preacquired computed tomography. The ring catheter is visualized in the left inferior pulmonary vein.

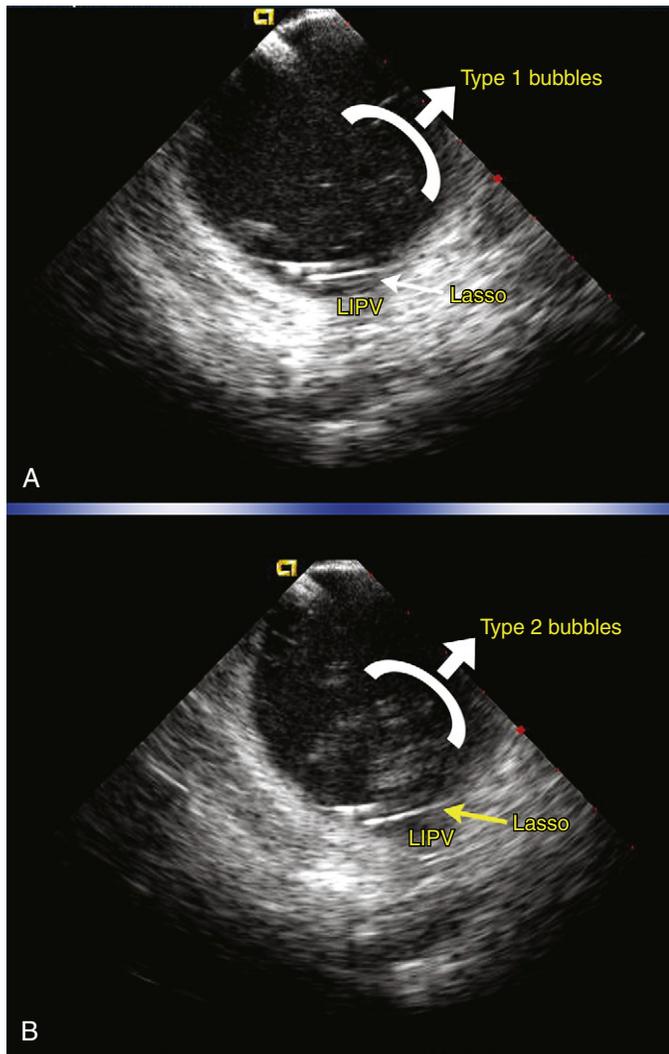

FIGURE 15-39 Intracardiac echocardiography (ICE)-guided radiofrequency (RF) energy delivery (microbubble monitoring). These are phased-array ICE views of the left atrium (LA) across the interatrial septum with the ring (Lasso) catheter positioned at the ostium of the left inferior pulmonary vein (LIPV). **A**, Localized microbubbles (type 1 bubbles) are observed during radiofrequency (RF) delivery. **B**, Showers of dense microbubbles extending to the LA cavity (type 2 bubbles) are observed during RF delivery. See text for discussion.

Using either the CARTO or NavX system, the 3-D shell representing the LA and PVs is constructed using the ablation or ring catheter, or both. Initially, fixed anatomical points are acquired at the four PV ostia, the LA appendage is demarcated, and three locations are recorded along the mitral isthmus to tag the valve orifice (Fig. 15-39; see Fig. 15-36). To acquire the PVs, entry into the vein is clearly identified as the catheter leaves the cardiac shadow on fluoroscopy, the impedance usually rises to more than 140 to 150 Ω , and electrical activity disappears. Because of the orientation of some veins and the limitations of catheter shape, it can be difficult to enter deeply into some veins, but the impedance still rises when the catheter is in the mouth of the vein. To differentiate between PVs and LA more clearly, voltage criteria (fractionation of local bipolar electrogram) and impedance (rise more than 4 Ω higher than the mean LA impedance) can be used to define the PV ostium. Mapping of each PV is performed by placing the mapping catheter 2 to 4 cm inside the PV and slowly pulling it back to the LA under fluoroscopy guidance. Care should be taken to reconstruct each PV ostium and the transition toward the LA (antrum), posterior free wall, mitral isthmus, and left interatrial septum. Subsequently, the system is allowed to create the geometry automatically while the ablation (or ring) catheter is moved throughout the LA. Sequential positioning of a

catheter at multiple sites along the endocardial surface of the LA establishes that chamber's geometry.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

CT and MRI provide critical information regarding the number, location, and size of PVs, as needed for planning the ablation and selecting appropriately sized ablation devices. Resulting images also identify branching patterns of potentially arrhythmogenic PVs, disclose the presence of fused superior and inferior veins into antral structures, and clarify the potentially confounding origins of far-field electrograms that masquerade as PV potentials.

Furthermore, the segmented CT/MRI volumes can be downloaded on the CARTO and NavX platforms. The 3-D electroanatomical maps can be simultaneously displayed side-by-side with CT/MRI segmented cardiac scans to confirm cardiac structures and guide ablation. These systems also enable registration of the preacquired 3-D CT/MRI images of LA reconstructions on the real-time 3-D electroanatomical maps reconstructed from multiple endocardial locations. This allows real-time visualization of the location and orientation of the catheter tip within the registered CT/MRI anatomical framework and can potentially improve the quality of lesion sets, reduce complications, and shorten procedure and fluoroscopy times (see Video 13 and Figs. 15-39 and 3-45).

A novel application (EP Navigator prototype, Philips Healthcare, Best, The Netherlands) has been developed to superimpose a preacquired segmented 3-D CT image of the LA over a real-time fluoroscopy system (CT overlay), to help in guiding ablation of AF.

The process of image integration—preprocedural CT and MRI image acquisition, image segmentation and extraction, and image registration—is discussed in Chapter 6.

INTRACARDIAC ECHOCARDIOGRAPHY

Phased-array ICE has been used in AF ablation procedures for several purposes: to assist with transseptal puncture, to identify the number and position of PVs, to identify the true border of the PV antrum, to determine the branching patterns of the right PVs needed for total PV isolation, to guide the positioning of the ring and ablation catheters at the antrum of the PV, to verify ablation catheter tip to tissue contact, to assess the degree of PV occlusion during balloon-based ablative interventions, and to detect procedural complications (e.g., pericardial effusion, LA thrombus, and PV stenosis).

For ICE imaging, a 10 or 8 Fr 64-element phased-array ultrasound catheter is positioned in the middle of the RA via an 11 or 9 Fr left femoral venous access. The ICE catheter remains in the RA for the entire procedure to guide transseptal puncture, define PV anatomy, and monitor for microbubble formation during RF ablation. A 7.5- or 8.5-MHz imaging frequency optimizes visualization of LA structures and PVs beyond the interatrial septum. PV imaging is uniformly possible by first visualizing the membranous fossa from a middle to low RA catheter tip position. From this view, clockwise catheter rotation allows visualization of the LA appendage, followed by long-axis views of the left superior and inferior PVs (see Figs. 4-13 and 6-22). Further clockwise rotation of the catheter brings the orifice of the right superior and inferior PVs into view. The LA ostia of these veins are typically viewed en face, to yield an owl's eye appearance at the vein's orifice.

As the operator images each vein, the ring and ablation catheters can be positioned at the antral-LA interface for ablation. Because the PV antrum is a large-diameter structure, its circumference cannot be mapped using a stationary ring catheter fixed in one position. Instead, the ring catheter must be sequentially positioned along each segment of the antral circumference to look for PV potentials. ICE can identify the true border of the PV antrum and guide positioning of the ring and ablation catheters. Therefore, the ring catheter is a roving catheter in this procedure. An operator's assistant often must hold the ring catheter in position around the antrum

because the ring catheter is not wedged into the tubular ostium for stability. When mapping the anterior segments of the left PVs or septal segments of the right PVs, the ring catheter must be advanced slightly because of the oblique nature of the antral-LA interface.

Additionally, ICE can help with the registration process of the CT/MRI image with the electroanatomical mapping system. Furthermore, the CARTOSound Image Integration Module (Biosense Webster, Inc.) allows for 3-D reconstruction of the LA using real-time ICE and incorporates the electroanatomical map to the map derived from ICE (see Chap. 6 and Video 14).

Target of Ablation

The ablation procedure is based on electrical isolation of all PVs. The objective is to identify PV potentials along the circumference of the PV antrum and ablate to eliminate these potentials completely. However, unlike segmental ostial PV isolation, the ostial portion of the breakthrough segments (electrical connections) connecting the LA to the PV, identified as the earliest PV potentials recorded from the ring catheter, is not the sole target of ablation. Complete encirclement of each PV antrum with ablation lesions is the goal of the ablation procedure, which would consequently result in PV isolation (see Fig. 15-36). All PVs are targeted.

Ablation lines consist of contiguous focal lesions deployed in the LA at a distance 5 mm or more proximal to the ostia of the PVs, to create a circumferential line of conduction block around each PV (see Fig. 15-36). PV isolation is performed 1 cm from the ostium of the right PVs, as well as for the posterior and superior aspects of the left PVs, to enhance efficacy and prevent PV stenosis. However, ablation at the anterior portions of the left PVs usually requires energy be delivered less than 5 mm from the ostium of the PV to achieve catheter stability. Ablation is started randomly in the right or left PVs and is performed individually.

When two or three ipsilateral PV ostia are coalescent, en bloc encirclement of those ostia is performed (i.e., one encirclement for the right-sided or left-sided PVs), and no line between the ipsilateral PVs is deployed (Fig. 15-40). The use of two ring catheters within the ipsilateral PVs may be considered in such an approach. With this double-Lasso technique, electrical isolation of ipsilateral PVs occurs simultaneously in most (more than 80%) cases. The simultaneous use of two ring catheters provides insights into the electrical interactions of the ipsilateral PVs and helps identify conduction gaps in the complete circumferential ablation lines in case of redoing the ablation procedure for recurrent AF. However, this approach involves obtaining a third transeptal access, which rendered its use uncommon. Importantly, single encirclement of ipsilateral PVs predisposes to breakthrough conduction of both ipsilateral PVs in case of a single gap in the en bloc circle. Furthermore, one report found that AF triggers originate frequently from the carina region of the PVs; hence, ablation in this area between ipsilateral PVs, in addition to being frequently necessary for complete electrical isolation of PVs, can be effective for targeting the source of the PV triggers.⁹⁶

Ablation Technique

Several ablation technologies have been used for circumferential PV isolation. Most commonly, RF ablation is performed with an irrigated-tip ablation catheter. Alternatively, an 8-mm-tip standard ablation catheter can be used. Technological evolution is now aimed at developing new catheter designs for circumferential ablation of the PVs as an alternative for the conventional point-by-point RF ablation. A novel ablation system using duty-cycled and alternating unipolar and bipolar RF energy is currently undergoing clinical evaluation. Furthermore, balloon-based ablation devices using different energy sources (e.g., cryothermal energy, laser energy, RF energy [“hot balloon” and mesh technologies], and high-intensity focused ultrasound [HIFU]) have been evaluated. The cryoballoon has proven feasibility, safety, and efficacy in the treatment of AF. The laser balloon is currently undergoing

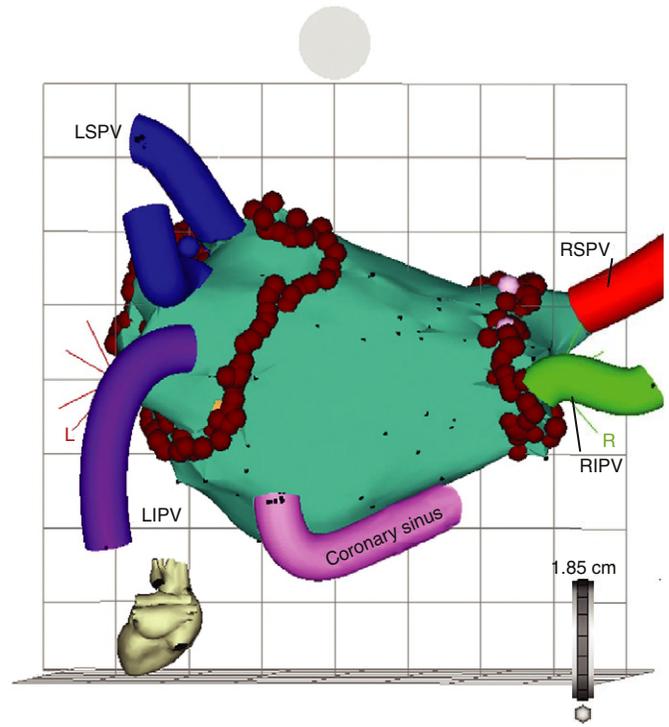

FIGURE 15-40 Circumferential antral pulmonary vein (PV) isolation. This posterior view of the electroanatomical map of the left atrium (LA) at the conclusion of the PV isolation procedure shows closely spaced red dots denoting locations at which radiofrequency ablation was performed. En bloc encirclement of the PV ostia (one encirclement for the right-sided and a second encirclement of left-sided PVs) was performed without ablation lines between the ipsilateral PVs. LIPV = left inferior pulmonary vein; LSPV = left superior pulmonary vein; RIPV = right inferior pulmonary vein; RSPV = right superior pulmonary vein.

evaluation, and preliminary clinical results are promising. Because of severe complications in the form of atrioesophageal fistula, the HIFU balloon is no longer in clinical use (see Chap. 7). The clinical evaluation of the RF hot balloon catheter is still in its initial stages. Another novel ablation catheter system delivers RF energy through a flexible mesh electrode (C.R. Bard, Inc., Billerica, Mass.) that is deployed in the PV ostium. This system is undergoing investigation for PV isolation.⁹⁷⁻⁹⁹

CONVENTIONAL RADIOFREQUENCY ABLATION

Ablation is started at the posterior wall of each PV, usually fluoroscopically facing the border of the spine in the anteroposterior projection, and continued around the venous perimeter. The posterior wall of the right PV is reached by counterclockwise torque of the catheter and the left PV by clockwise torque. For ablation at the anterior portions of the left PVs, energy must usually be delivered within a few millimeters of the vein (because of a relatively narrow border between the left PVs and the LA appendage, and the difficulty to balance the catheter tip on the narrow rim of tissue separating these structures) to achieve effective disconnection. RF ablation sites are tagged on the reconstructed 3-D map. This tagging helps ensure coalescence of the ablation lesions to ensure continuity of the ablation line (see Fig. 15-36).

RF energy is delivered using an irrigated-tip catheter, with power output limited to 25 to 30 W (or even less) on the posterior LA wall where the atrial wall is thin and esophageal proximity presents potential danger, and 30 to 50 W on the left PV-LA appendage ridge and anterior LA wall, and a target temperature of less than 41°C and irrigation rates of 5 to 20 mL/min (0.9% heparinized saline). Alternatively, ablation may be performed using an 8-mm-tip conventional ablation catheter, with a maximum power of up to 70 W and a target temperature of 50°C to 55°C.

RF energy is delivered for 30 to 60 seconds at each point, until the maximal local electrogram amplitude is decreased by 50% to 90% or double potentials are observed or to achieve an impedance drop of 5 to 10 Ω at the ablation site. RF application is prolonged for 1 to 2 minutes when a change occurs in the activation or morphology, or both, of the PV potentials, as determined by circumferential mapping recorded downstream on the ring catheter. Additional ostial applications targeting fragmented electrograms may be performed after PV isolation to eliminate any ostial PV potentials, thus reducing the risk of recurrence because of ostial foci.

Alternatively, short RF applications (for 2 to 5 seconds) at a higher power (50 W, irrigation rate 30 mL/min, maximum temperature 43°C) can be employed. The latter approach results in momentarily higher LA tissue temperatures and allows the tip to be set at a high power to injure the superficial tissue while minimizing time-dependent deep heating through excessive heat transfer. Typically, the ablation catheter is dragged continuously in small increments every 2 to 5 seconds during continuous RF delivery, and ablation is repeated at each site, if required, for many times throughout the procedure until the local atrial electrogram is completely eliminated. It is probably reasonable to allow at least 2-minute time intervals before returning to ablate a previously ablated site to allow for heat dissipation, especially when ablating at the LA posterior wall, to avoid excessive esophageal heating.¹⁰⁰

Adequate and stable catheter tip-tissue contact is critical to ensure effective ablation lesions. The use of steerable transeptal sheaths facilitates more stable catheter positioning and access to all desired ablation targets for PV isolation. Additionally, ICE can provide detailed anatomical information and real-time information of the location of the tip electrode of the ablation catheter and can help confirm catheter stability. Real-time measurements of the contact force of the ablation tip have been introduced using different technologies, especially in conjunction with robotic navigation systems.

INTRACARDIAC ECHOCARDIOGRAPHY-GUIDED ABLATION

INTRACARDIAC ECHOCARDIOGRAPHY-GUIDED CATHETER POSITIONING. The ring and ablation catheters are positioned at the antral-LA interface for ablation. The ring catheter is then sequentially positioned along each segment of the antral circumference (guided by ICE) to look for PV potentials. As the ring catheter is moved from one segment of the LA-antral interface to the next, ablation is performed at the poles demonstrating PV potentials. The ablation catheter is moved to the target pole on the ring catheter, while care is taken to keep the catheter in the same plane as the ring catheter. Ablation is performed only along the specific antral segment that the ring catheter is mapping. Because the PV antrum is a large structure, multiple movements of the ring catheter around the PV antrum are needed. After all segments of a PV are ablated, the ring catheter is used to again map the vein's interface with the LA to confirm the absence of PV potentials at the antral-LA interface. During NSR or CS pacing, the ring catheter is advanced deep into the PV tube to confirm an absence of electrogram recordings, which represents entrance block into the PV.

Using ICE to define the PV antrum and guide RF ablation, the anatomical region within the ablation circles typically encompasses the entire posterior wall, LA roof, and anteroseptal extension of the right PVs.

INTRACARDIAC ECHOCARDIOGRAPHY-GUIDED RADIOFREQUENCY ENERGY DELIVERY (MICROBUBBLE MONITORING). ICE can help visualize evolving lesions during RF energy delivery and image microbubble formation during tissue heating. The latter is important because microbubble formation during ablation can indicate excessive tissue heating, which could lead to thrombus or char formation, tissue disruption, or PV stenosis.

Observation by ICE of microbubbles during ablation was previously proposed as a method of titrating RF power delivery. Two types of bubble patterns are seen with ICE: scattered microbubbles

(type 1) and a brisk shower of dense microbubbles (type 2) (see Fig. 15-39). It has been hypothesized that type 1 microbubbles indicate early tissue overheating (i.e., subcritical heating of the myocardium with imminent risk of steam pop formation), whereas type 2 microbubbles indicate excessive heating. Microbubbles seen on ICE directly correlate with cerebral microembolic events detected by transcranial Doppler, tissue disruption, and char formation. Restricting power output to avoid microbubble formation on ICE increases the efficacy of antral PV isolation while minimizing severe PV stenosis and cerebroembolic complications. Absolute temperature and impedance readings do not correlate with microbubbles and cannot reliably predict tissue disruption and cerebroembolic events.

By using these principles, RF energy is initially set at 30 W and 55°C using a nonopen irrigated ablation catheter. Subsequently, RF power is titrated up to a maximum of 70 W by 5-W increments every few seconds while monitoring for microbubble formation on ICE. When type 1 (scattered) microbubbles are seen, energy is titrated down by 5-W decrements every 5 seconds until microbubble generation has subsided. Energy delivery is terminated immediately when type 2 (dense showers) microbubbles are seen. The operator should aggressively avoid any microbubble formation. Ablation is continued in one spot until no more PV potentials are seen. Each lesion typically lasts 30 to 50 seconds.

Microbubble formation, however, is not a straightforward surrogate for tissue heating. Experimental animal studies revealed that, particularly with the use of an irrigated ablation electrode, the abrupt occurrence of steam popping can occur without prior development of any bubbles on ICE. Thus, caution is warranted in interpretation of the absence of bubble formation on ICE as an indicator of inadequate intramyocardial heating. The absence of microbubble formation does not indicate that tissue heating is inadequate or that the power level should be increased, nor does the presence of scattered microbubbles indicate safe tissue heating. This marker is fairly specific for tissue heating as judged by tissue temperatures, but it is not routinely sensitive. Specifically, scattered microbubbles are noted to occur over the entire spectrum of tissue temperatures, whereas dense showers of microbubbles occur only at tissue temperatures higher than 60°C. Scattered microbubbles may represent an electrolytic phenomenon, whereas dense showers of microbubbles suggest steam formation, with associated tissue disruption and impedance rises. Furthermore, it must be recognized that bubbles are typically present during open-irrigated ablation and can also be seen during high-output pacing and infusion of saline through the transeptal sheath side port.

DUTY-CYCLED BIPOLAR AND UNIPOLAR RADIOFREQUENCY CATHETER ABLATION

A novel ablation system (GENius, Medtronic Inc., Minneapolis, Minn.) has been developed for AF ablation, in which duty-cycled and alternating unipolar and bipolar (between adjacent electrodes) nonirrigated RF energy is used to create contiguous ablation lesions in the PV antrum using a circular multielectrode PV ablation catheter (PVAC, Ablation Frontiers, Inc., Carlsbad, Calif.) (Figs. 7-4 and 7-5).

The PVAC is a circular decapolar 9 Fr bidirectional over-the-wire catheter with a 25-mm diameter array at the distal tip, 3-mm-long platinum electrodes, and interelectrode spacing of 3 mm. The multielectrode catheter allows selective mapping, pacing, and ablation through any or all electrodes as required. Each electrode is supplied with a thermocouple, and a software algorithm modulates power to reach the user-defined target temperature (usually 60°C), but it limits power to a maximum of 8 W per electrode when using the PVAC in a 4:1 power setting or 10 W in all other settings.¹⁰¹

The PVAC is advanced over a guidewire into the LA via a steerable transeptal sheath. Initially, the PVAC itself is maneuvered within each PV to map PV potentials. Once the region of interest is localized and good contact of the PVAC with antral tissue is achieved (as indicated by local electrogram interpretation and

enhanced fluoroscopy), RF energy is delivered in a combination of one or more of the five bipolar channels. When ablating large common PV ostia, some electrode pairs that have no or suboptimal contact to the atrial tissue are deactivated to avoid ineffective energy delivery. Bipolar and unipolar RF delivery is typically set in a 4:1 configuration (i.e., 80% bipolar and 20% unipolar), to create a 3- to 4-mm wide and deep lesion. After several RF applications over all electrode pairs, the PVAC is rotated around the PV ostium to look for the earliest PV potential to isolate the vein completely.

ADVANTAGES. The PVAC represents a reasonable alternative for point-by-point circumferential PV isolation. Preliminary studies found the PVAC system very successful in achieving complete PV isolation in most patients and veins, and it was associated with shorter procedure and fluoroscopy times. The short-term and intermediate-term efficacy is comparable to that of a conventional antral ablation technique. This system is still undergoing investigation. One advantage of the PVAC system is the simultaneous application of RF energy across the electrode array, thus creating contiguous lesions.^{101,102}

LIMITATIONS. This system has several limitations. The PVAC diameter is unadjustable; large vein ostia can be difficult to isolate. Additionally, it is not feasible to monitor PV potentials during RF energy delivery. The PVAC is primarily designed for PV isolation, and mapping of extra-PV triggers usually requires a second ablation catheter. Other catheter designs, which use the same multi-channel duty-cycled RF generator, also have been developed for ablation of fractionated electrograms in the LA (MAAC, Ablation Frontiers), septal ablation (MASC, Ablation Frontiers), as well as linear ablation (TVAC, Ablation Frontiers) (see Fig. 7-4).^{101,102} Ablation with the PVAC has been associated with a high incidence of subclinical cerebral microemboli detected by MRI in a small number of patients, compared with other technologies (37% of cases, versus 7% for standard irrigated RF and 4% for cryoablation). The significance of this finding remains to be determined.

CRYOBALLOON ABLATION

Clinical studies indicate an acceptable efficacy rate of PV isolation using the cryoballoon, with 1-year freedom from AF demonstrated in 73% in patients with paroxysmal AF and in 45% for those with persistent AF. Further studies, including direct comparison with conventional RF ablation, are ongoing and will provide important insight into long-term efficacy and safety.^{103,104}

The cryothermal balloon ablation system (CryoCath Technologies) consists of a nondeflectable, over-the-wire, 10 Fr two-lumen catheter with double inner-outer cooling balloons (outer balloon maximum diameter, 23 mm; total length, 20 mm; see Fig. 7-11). The refrigerant nitrous oxide (N₂O) is delivered under pressure from the console into the inner balloon chamber via a lumen within 2 mm of the catheter tip, where it undergoes a liquid to gas phase change, resulting in inner balloon cooling to temperatures of -80°C or lower. During cryotherapy, temperature is monitored via a thermocouple located at the inner balloon.¹⁰³

The deflated cryoballoon is advanced via a steerable transeptal sheath over either an extrarigid 0.032-mm guidewire or a small six-pole microcircular mapping catheter placed inside of each PV. Initially, PV angiography is performed to delineate PV anatomy and guide balloon positioning. The cryoballoon is inflated outside of the PV (to avoid any mechanical damage) and then is advanced into the PV to occlude the vein. Achieving complete mechanical occlusion of the PV is important to prevent the heating effect of residual PV flow during freezing. In fact, the degree of PV occlusion at the tip of the inflated balloon has been correlated with electrical isolation. Complete PV occlusion is confirmed by the lack of contrast medium runoff into the LA during contrast injection into the distal lumen of the cryoballoon or the disappearance of flow on color Doppler obtained by ICE or TEE. If PV occlusion is not achieved, the device can be turned clockwise and counterclockwise or even slightly withdrawn until PV flow disappears. Also, the guidewire can be positioned in a different PV branch to change

the orientation of the balloon at the PV ostium. Among the other maneuvers used to facilitate PV occlusion by the cryoballoon is the “hockey stick technique,” which allows for an optimized tissue contact at the inferior circumference of the inferior PVs. This technique involves advancing the sheath via a guidewire placed in the PV with a maximal bend to the superoposterior LA and pushing the balloon into the inferior part of the PV ostium. The “pull-down technique” is used if angiography indicates perfect contact of the balloon only at the superior circumference of the PV but not at the lower PV circumference. The pull-down involves waiting for the balloon to adhere to the superior aspect of the targeted vein (generally after 60 seconds), followed by catheter and shaft deflection to pull the frozen balloon downward to achieve contact with the inferior portion of the vein and thereby eliminate the inferior gap.^{103,104}

After confirmation of PV occlusion by contrast injection, the 5-minute freezing cycle is initiated. During ablation of the right superior PV, maintenance of phrenic nerve activity is ensured by continuous monitoring of spontaneous breathing or by continuous pacing of the right phrenic nerve from a catheter positioned in the SVC. In case of loss of capture or weakening of right hemidiaphragmatic movements, freezing should be immediately stopped.

After two freezing cycles, the balloon is deflated, and a conventional circular mapping catheter is inserted into the PV to assess for isolation. Although a small six-pole microcircular mapping catheter can be introduced through the lumen of the cryoballoon and can help with real-time PV mapping during freezing, this catheter often lacks the mechanical support needed for adequate mapping and confirmation of complete PV isolation.¹⁰⁴

If PV isolation is not achieved, the cryoballoon is repositioned, and additional freezes are applied. If remnant ostial potentials are still recorded, electrical isolation is segmentally completed by focal cryoablation using an 8-mm cryoablation catheter (Freezor Max, CryoCath Technologies).

ADVANTAGES. Cryoablation can offer several potential advantages, including elimination of coagulum formation, which should reduce stroke risk, and absence of coagulative necrosis of the ablated tissue, which can potentially reduce the risk of tamponade, PV stenosis, and pericarditis. Although the highly variable anatomy of the PVs provides a significant challenge for any balloon-based technology (it requires the shaft of the catheter to be directed coaxially to the PV), the cryothermal balloon overcomes this problem because the entire balloon can freeze and adhere to the adjacent tissue. As such, the perimeter of the balloon in closest apposition to the vein becomes the source of ablation, irrespective of the orientation in the vein. Also, compared with other balloon-based ablation technologies (HIFU and endoscopic laser), the cryoballoon is less direction dependent, because the refrigerant jet inside the balloon is directed to produce the lowest ablation temperatures in a large circular zone on the anterior third of the balloon. As such, cryoballoon ablation may be expected to isolate the muscular PV sleeves, as well as the PV antrum.

LIMITATIONS. Cryoablation of the right inferior PV remains challenging. The most important complication of cryoballoon ablation is phrenic nerve palsy, which occurs in up to 11.2% of patients, even with close monitoring of phrenic movement. Phrenic nerve palsy is transient, with complete resolution observed within 1 year in most cases. It has become evident that cryoballoon ablation can be associated with PV stenosis (the rate of symptomatic PV stenosis or PV stenosis requiring intervention was 0.17%). A distal position of the cryoballoon with respect to the PV ostium, especially when using the smaller 23-mm balloon, can potentially increase the risk of these complications. It is possible that using the big (28-mm) cryoballoon for all veins can help direct cryothermal lesions proximal to the PV ostium at the antral level and thereby reduce the risk of phrenic nerve injury and PV stenosis.¹⁰⁴

LASER ABLATION

The laser ablation catheter technology (CardioFocus, Inc., Marlborough, Mass.) is still in clinical trials. The initial clinical experience

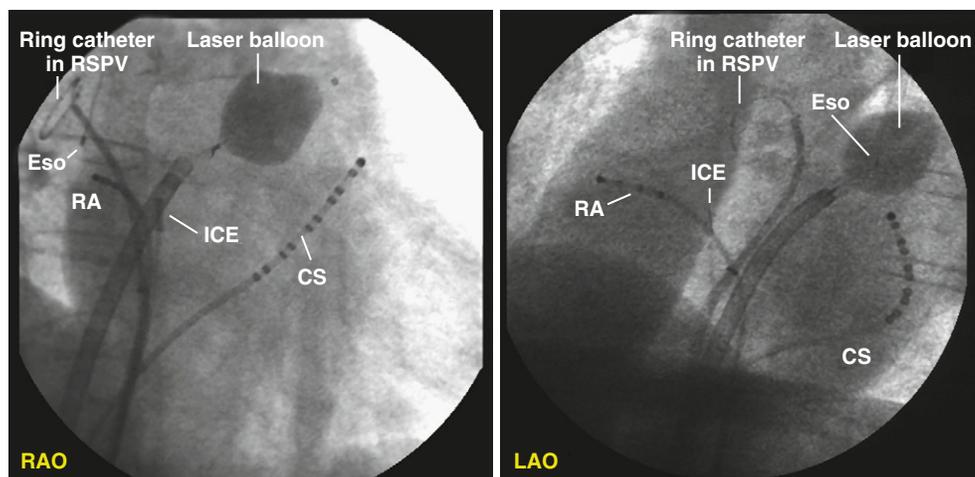

FIGURE 15-41 Pulmonary vein (PV) isolation using the laser balloon technology. The laser balloon is inflated in the left superior PV. The ring catheter is positioned in the right superior PV (RSPV) during balloon inflation. CS = coronary sinus catheter; Eso = esophageal temperature probe; ICE = phased-array intracardiac echocardiography catheter; RA = right atrial catheter.

with this technology suggests the ability to create discrete point-by-point ablation and a configurable ablation line design and achieve reliable and lasting circumferential PV electrical isolation in patients with highly variable PV shapes and sizes.^{98,99}

The endoscopic ablation system consists of a nonsteerable, compliant balloon catheter with an adjustable diameter that allows treatment of PVs of 9 to 32 mm in diameter. The laser balloon is inserted at the PV antrum through a steerable 12 Fr transseptal sheath. Selective PV angiography or ICE, or both, can be used to verify appropriate position of the balloon. The balloon is filled with a mixture of contrast and deuterium dioxide (D₂O) and is irrigated internally at 20 mL/min to minimize absorption of laser energy.

The efficacy of the laser balloon ablation depends on good contact around the balloon circumference. Hence, the laser ablation catheter system incorporates a 2 Fr fiberoptic endoscope positioned at the proximal end of the balloon that, once the balloon is deployed, enables direct visualization of the face of the balloon at the targeted PV antrum and monitoring for the intrusion of blood into the space between the balloon and the tissue.

The arc generator consists of an optical fiber located within the central shaft that projects a 30-degree arc of light onto regions of balloon-tissue contact guided by an endoscopic view of the PV antrum (areas of balloon-tissue contact are visualized as blanched white, whereas contact with blood is visualized as red). This arc serves as an aiming beam for laser delivery. It can be steered along the balloon face with endoscopic visualization, independently of the balloon itself, thus facilitating individual lesion application in an anatomically flexible lesion design that adapts to the highly variable PV anatomy. Once the proper location is identified, a diode laser is used to deliver laser energy at 980 nm. The laser fiber can be advanced or withdrawn to shift the site of lasing along the longitudinal axis of the catheter. Lesions are deployed in a point-by-point fashion. Each individual ablation lesion covers 30 degrees of a circle, and lesions are overlapped by 30% to 50% to minimize gaps between adjacent lesions. Rotating and advancing and retracting the aiming beam, and consequently the laser beam, facilitate individual lesion application and individual line design. The balloon inflation pressure and diameter can be adjusted to optimize sealing of the PV antrum and maximize tissue exposure to the laser arc. Laser energy is delivered at power output of 5.5 to 18 W for 20 to 30 seconds, depending on the thickness of tissue or the proximity of the esophagus, or both. Because the catheter shaft obscures one-fifth of the circumference, catheter rotation is required to complete ablation at a particular PV.⁹⁸

Importantly, the laser balloon does not have the capability of simultaneous mapping and ablation. Mapping of PV potential is performed using a ring catheter before and after ablation. Initially, the ring catheter should not be left in the same PV while the laser

balloon is deployed and during circumferential ablation because its shaft can impede balloon-tissue contact (Fig. 15-41). After completion of the ablation circle, the balloon is deflated, and the ring catheter is inserted into the PV to assess for electrical isolation. However, if PV isolation is incomplete after a single ablation, the ring catheter may be placed distally to the inflated laser balloon to visualize PV electric activity online during laser energy application. However, the shaft of the ring catheter is positioned opposite to the presumed electrical gap to avoid incomplete PV sealing at the targeted ablation site.

Preliminary studies of PV isolation using the laser ablation catheter technology in patients with paroxysmal AF found the short-term and 1-year success rates similar to those of other ablation techniques and other ablation energies (Fig. 15-42). Procedure times also were comparable with those of established balloon-based ablation systems. No PV stenosis has been observed. The incidence of phrenic nerve palsies after laser ablation seems to be moderate compared with other balloon-based ablation systems, but it needs further investigation. Larger studies evaluating the long-term efficacy and safety of this system are required.^{98,99}

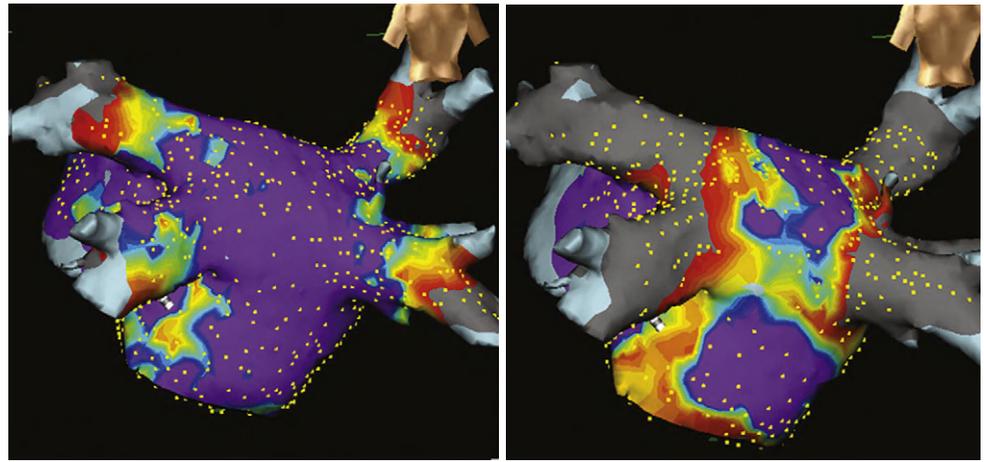

ADVANTAGES. An advantage of the laser balloon system is the ability to visualize the substrate for ablation directly, thus superseding the need for additional imaging. Additionally, in comparison with the cryoballoon and HIFU balloon, the size of the laser balloon is adjustable to the individual PV anatomy in a broad range, which allows for treatment of virtually any PV with a single device. The laser arc of 30 degrees allows for very discrete lesions, and the laser energy is titratable, to enable flexible lesion deployment and freedom to create the preferred ablation line design. Moreover, unlike the cryoballoon and HIFU balloon systems in which energy titration is not possible, the ability to titrate laser energy can potentially decrease injury to adjacent structures.⁹⁸

LIMITATIONS. One of the limitations of the laser balloon system is an observed trend toward higher esophageal temperatures, resulting in more severe mucosal damage, as known from other energy sources, although no atrioesophageal fistula has been reported. Therefore, esophageal temperature monitoring is essential with the use of this system. However, the optimal esophageal cutoff temperature is still not known. Additionally, defining the appropriate laser energy setting will require further investigation. Because the laser balloon system is not designed as an over-the-wire system, it is sometimes challenging to direct and stabilize the balloon catheter within the LA or the respective PV.⁹⁹

Endpoints of Ablation

Common intraprocedural endpoints of circumferential antral PV isolation include electrical isolation of all PVs, noninducibility of

FIGURE 15-42 Three-dimensional electro-anatomical voltage map of the left atrium before (left) and after (right) circumferential pulmonary vein isolation using the laser balloon. Sites with voltage lower than 0.5 mV are red on the map, and those with voltage higher than 1.5 mV are purple, with interpolation of color for intermediate amplitudes. The gray area denotes no detectable signal (scar). Note the voltage abatement at the level of the antrum of each of the pulmonary veins, indicating the level of ablation achieved using the laser balloon catheter system. (Courtesy of CardioFocus, Inc., Marlborough, Mass.)

AF, and elimination of residual potentials inside the circumferential ablation lines. Importantly, these endpoints, even when successfully achieved during the procedure, often do not persist over time, both in patients with and in those without AF recurrences. Nevertheless, there is a consensus on the importance of the complete bidirectional electrical isolation of all PVs as a procedural endpoint. On the other hand, less agreement exists on the value of the other endpoints.¹⁰⁵

ELECTRICAL DISCONNECTION OF ALL PULMONARY VEINS

The endpoint of ablation is complete bidirectional electrical isolation of all four PVs, as described earlier for segmental ostial PV isolation.

NONINDUCIBILITY OF ATRIAL FIBRILLATION

Induction of sustained AF is thought to indicate the presence of a potential atrial substrate capable of maintaining AF; however, its value as a predictor for clinical outcome remains controversial. Elimination of PV potentials correlates with clinical success better than the acute suppression of AF inducibility. However, a successful outcome is sometimes observed without complete PV potential elimination, and some supposedly unsuccessfully treated patients experience remarkable improvement with a previously ineffective drug.

Different pacing protocols and definitions of inducibility of AF have been employed in different studies. Aggressive pacing protocols can decrease the specificity, yet more conservative pacing protocols can potentially decrease the predictive value. In fact, aggressive atrial pacing (at CLs shorter than 180 milliseconds) can induce AF in up to 26% of patients without a history of AF. Further investigation is needed to optimize the specificity of using AF induction as an endpoint for AF ablation.¹⁰⁶

Commonly, induction of AF is attempted by burst pacing at a CL of 250 milliseconds with sequential decrement down to 200 milliseconds (as long as 1:1 capture is maintained) for 5 to 10 seconds at least three times from the CS and then repeated from the RA. If AF is not inducible, isoproterenol (10 to 20 $\mu\text{g}/\text{min}$ intravenous infusion) is then administered, and atrial pacing is repeated. Also, AF induction by a 30-joule external biphasic shock delivered during the vulnerable period of atrial refractoriness (i.e., synchronized to the R wave) may predict recurrent AF after PV isolation. This predictor of AF recurrence can provide additive information over inducibility with burst atrial pacing alone.¹⁰⁷

Many (up to 57%) patients with paroxysmal AF have no inducible AF after PV isolation. This subset can represent a group that can potentially benefit from PV isolation alone and do not require additional substrate modification. Induction of AF should prompt reconfirmation of PV isolation in all veins. If AF remains inducible

despite complete PV isolation, additional substrate-based atrial ablation may be considered (see later discussion).

ELIMINATION OF RESIDUAL POTENTIALS INSIDE THE CIRCUMFERENTIAL ABLATION LINES

The value of complete voltage abatement (i.e., reduction of the atrial electrogram amplitude by >80% or a decrease to less than 0.1 mV as determined by local electrogram analysis and voltage mapping) inside the circumferential ablation lines in preventing the recurrence of AF remains controversial and requires further investigation. Some studies suggested that the elimination of residual potentials inside the LA-PV junctions or carina after PV isolation offer an incremental benefit on the recurrence of AF. In contrast, other studies showed no additional benefit of this approach.^{93,108}

Outcome

Circumferential antral PV isolation offers a better outcome compared with ostial segmental PV isolation for paroxysmal AF (approximately 71% versus 64%). The incremental clinical benefit of adjuvant linear LA ablation or CFAE ablation, or both, in patients with paroxysmal AF has been controversial and is likely to be small or negligible. For patients with persistent AF, the success rates of circumferential antral PV isolation (approximately 50% to 70%) are less than for paroxysmal AF but are still better than those achieved by ostial segmental PV isolation, and adjuvant substrate modification seems to offer additional benefit in AF control, although this remains controversial.^{78,109,110}

Circumferential Left Atrial Ablation

Rationale

Attempts to replicate the results of the maze procedure in the EP laboratory have consisted of the creation of linear lesions in the LA or RA, or both. In the past, multiple catheters with coil electrodes positioned against the atrial wall were used to create the linear lesions without having to reposition the catheter repeatedly. Currently, linear ablation lesions are created with individual contiguous applications of RF energy on a point-by-point basis. RF ablation is performed circumferentially around the ipsilateral PVs, with the endpoint of ablation being the absence or marked reduction (80%) in the amplitude of electrical signals within the encircling lesions.

Whereas the efficacy of PV isolation depends on complete and lasting PV disconnection from the LA, the efficacy of circumferential LA ablation does not. This finding highlights the fact that circumferential LA ablation (also referred to as wide-area LA ablation or circumferential PV ablation) eliminates AF by mechanisms other than complete PV isolation. Several mechanisms of action can be involved. First, there is substrate modification by LA compartmentalization.

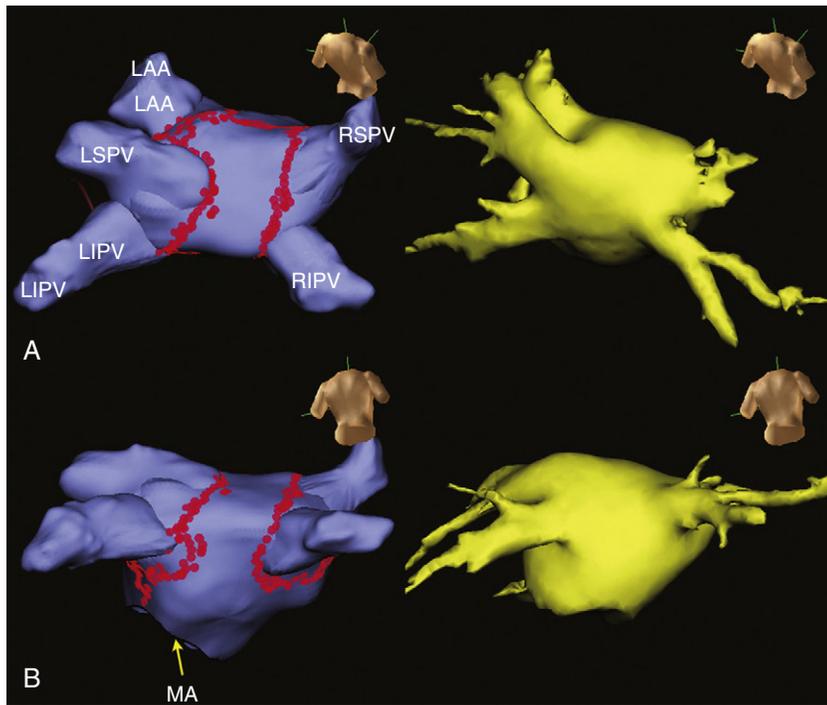

FIGURE 15-43 Wide-area circumferential left atrial (LA) ablation. Shown are cephalic (A) and caudal (B) posteroanterior views of three-dimensional (3-D) reconstruction of the LA and pulmonary veins (PVs) using EnSite NavX (St. Jude Medical, Austin, Tex.; left) and synchronized 3-D reconstruction of the LA and PVs using cardiac CT angiography (right). Red dots indicate the sites of ablation, with circumferential LA ablation in addition to the LA roof and mitral isthmus lines. LAA = left atrial appendage; LIPV = left inferior pulmonary vein; LSPV = left superior pulmonary vein; MA, mitral annulus; RIPV = right inferior pulmonary vein; RSPV = right superior pulmonary vein.

Approximately 25% to 30% of the LA myocardium is excluded by the encircling lesions, thereby limiting the area available for circulating wavelets needed to perpetuate AF. The ablation lines can also eliminate anchor points for rotors or mother waves that drive AF and make reentry pathways unsuitable. Autonomic denervation by ablation of vagal inputs to the posterior LA wall is another potential mechanism. Furthermore, the Marshall ligament or Bachmann bundle, which can be involved in the initiation and maintenance of AF, may be excluded by the circumferential ablation lines. The ligament of Marshall, which inserts in close proximity to the left superior PV and can be a source of triggers for AF, can potentially be eliminated by the ablation line that encircles the left-sided PVs. Additionally, promotion of atrial electroanatomical remodeling involving the LA posterior wall may result, to the point that the substrate for AF is no longer present. Modification of PV arrhythmogenic activity can also be operative. By encircling the PVs, LA ablation can potentially eliminate the triggers and driving mechanisms of paroxysmal AF that arise in the PVs. Although complete conduction block across the encircling lesions may not be achieved, decremental conduction can occur, particularly at shorter CLs, and it may impede the conduction of PV tachycardias to the LA.^{111,112}

There are several differences between circumferential LA ablation and PV isolation strategies. From a mechanistic standpoint, segmental ostial ablation electrically isolates the PVs, thereby eliminating the arrhythmogenic activity in the PVs that triggers or perpetuates episodes of paroxysmal AF. However, sources of AF that do not originate in the PVs and the substrate that supports the maintenance of AF are not addressed by PV isolation. From a technical aspect, segmental ostial and circumferential antral PV isolation techniques require the insertion of two catheters into the LA, whereas linear LA ablation requires only a single catheter in the LA. Also, although PV isolation requires the identification of PV potentials, which can be difficult to distinguish from atrial electrograms, circumferential LA ablation is primarily an anatomical approach to ablation. Furthermore, the risk of PV stenosis, which is a major concern during ostial PV isolation, is minimized during circumferential LA ablation because most ablation sites are more than 1 cm away from PV ostia.^{111,112}

Electroanatomical Mapping

The ablation catheter is advanced into the LA through a transseptal puncture. A ring or basket catheter is unnecessary; therefore,

only one transeptal puncture is required. A nonfluoroscopic 3-D electroanatomical CARTO or NavX navigation system is used for generating and validating the continuity of the circular ablation lines (Fig. 15-43). Integration of CT and MRI scans into the electroanatomical mapping system improves visualization of complex LA geometries and can potentially improve the safety and success of catheter ablation for AF (see Fig. 15-39). CT/MRI integration offers the added benefit of displaying the atrial configuration, thus allowing completion of a ring of ablation lesions that follows the patient's own anatomy rather than empirical encirclement.¹¹¹

The ostium of each PV is identified based on the results of selective biplane PV angiography (if performed) and fluoroscopic visualization of the catheter tip entering the cardiac silhouette, with a simultaneous decrease in impedance and appearance of the atrial potential (see previous discussion).

If validation of the circumferential lesions around PVs and the completeness of conduction block across the ablation lines are to be used as endpoints for the ablation procedure, propagation maps have to be created before and after RF ablation. Additionally, the collected data can be displayed as voltage maps, which can be useful to define scar areas and electrically diseased tissues. In patients in NSR at the beginning of the procedure, maps are acquired during pacing from the CS or RA at a CL of 600 milliseconds. In patients in AF at the end of the mapping procedure, electrical cardioversion to restore NSR is performed to allow stimulation maneuvers.

Target of Ablation

The ablation lines are typically created with encircling lesions around the left- and right-sided PVs, 1 to 2 cm from the PV ostia. The circumferential ablation lines may surround each of the PVs, or, instead of encircling each PV, one big circle is placed around the PVs of each side (Fig. 15-44; see also Fig. 15-43). An ablation line is also created across the LA roof to connect the two circumferential ablation lines and often another ablation line across the mitral isthmus between the inferior portion of the left-sided encircling lesion and the lateral mitral annulus (see later discussion). In some patients, additional ablation lines are created in the septum and anterior wall that extend from the roof line to the mitral isthmus. At present, the number and location of LA linear lesions should be tailored to the individual patient. The ideal configuration would combine technical ease and safety with long-term control of AF.^{111,112}

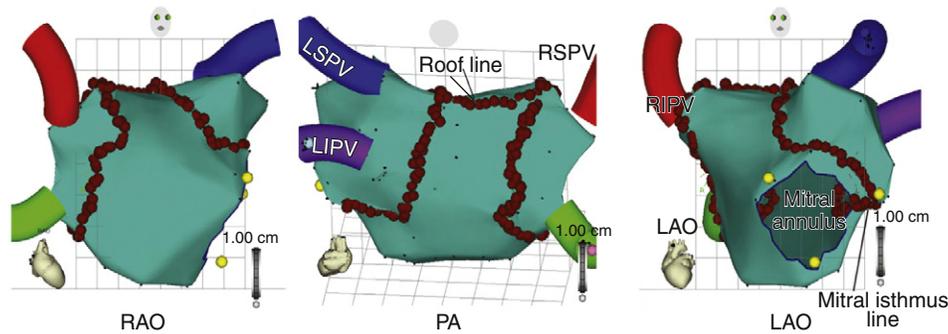

FIGURE 15-44 Wide-area circumferential left atrial (LA) ablation. Shown are multiple (right anterior oblique [RAO], posteroanterior [PA], and left anterior oblique [LAO]) views of anatomical “shell” rendering of the LA anatomy and pulmonary veins (PVs) using CARTO (Biosense Webster, Inc., Diamond Bar, Calif.). Red dots indicate sites of ablation. LA roof and mitral isthmus lines, connecting anatomical barriers, are as shown. LIPV = left inferior pulmonary vein; LSPV = left superior pulmonary vein; RIPV = right inferior pulmonary vein; RSPV = right superior pulmonary vein.

Ablation Technique

Once an electroanatomical map of the main PVs and LA has been adequately reconstructed, RF ablation is performed 1 to 2 cm from the PV ostia to encircle the left- and right-sided PVs. However, because there is a narrow rim of atrial tissue between the anterior aspect of the left superior PV and the LA appendage in approximately 50% of patients, ablation within 1 cm of the ostium of this vein sometimes is required.

Circumferential ablation lines are usually created starting at the lateral mitral isthmus and withdrawing the ablation catheter tip posteriorly and then anteriorly to the left-sided PVs, passing between the left superior PV and the LA appendage before completing the circumferential line on the posterior wall of the LA. The ridge between the left superior PV and the LA appendage can be identified by fragmented electrograms caused by collision of activity from the LA appendage and left superior PV-LA. The LA appendage is identifiable by a significantly higher impedance (more than 4Ω higher than the LA mean), a high-voltage local bipolar electrogram, with characteristically organized activity in fibrillating patients. The right PVs are ablated in a similar fashion. Ablation sites are tagged on the model of the LA created with the electroanatomical mapping system, and that system is used for generating and validating the continuity of circular lines.

An irrigated 3.5- to 4-mm-tip catheter is typically used with power settings of 20 to 30 W on the posterior wall, 35 to 40 W elsewhere, with a temperature limit of less than 42°C . Alternatively, a solid 8-mm-tip ablation catheter may be used, with RF energy set to a target temperature of 55°C to 65°C and a power limit of 70 to 100 W. The power and temperature limits are reduced in the posterior LA wall to 50 W and 55°C to minimize the risk of injury to the surrounding structures. A series of RF applications is delivered until the maximum local bipolar electrogram amplitude decreases by 80% to 90% or to less than 0.05 to 0.1 mV, or to a maximum RF duration of 40 milliseconds, whichever comes first. Alternatively, RF energy is applied continuously on the planned circumferential ablation lines as the catheter is gradually dragged along the line, with repositioning of the catheter tip every 10 to 20 seconds. Continuous catheter movement, often in a to-and-fro fashion over a point, helps keep the catheter tip temperature down as a result of passive cooling.

Power, impedance, and electrical activity are monitored continuously during navigation and ablation. Impedance can increase suddenly if a thrombus forms on the catheter tip. A much more useful indicator is a 40% to 50% reduction in the power delivered to reach target temperature. If thrombus formation is suspected, catheter withdrawal from the LA without advancing the transseptal sheath can be necessary to avoid stripping any thrombus present on the catheter tip as the catheter is withdrawn into the sheath, which can result in systemic embolization.

RF application should be immediately terminated when the catheter position deviates significantly from the planned line or

falls into a PV, when impedance rises suddenly, or when the patient develops cough, burning pain, or severe bradycardia.

After completion of the circular lesions around the left- and the right-sided PVs, the area within the ablation lines is explored with the ablation catheter. RF energy is applied at sites that have a local electrogram amplitude greater than 0.1 mV. In addition, when AF is still present, sites inside the encircling ablation lines where the CL is shorter than the atrial CL in the CS also are ablated.

Endpoints of Ablation

To date, circumferential LA ablation for AF has stood apart from most other types of ablation procedures in that a clear-cut EP endpoint has not been defined. The only endpoint of ablation used in most studies has been voltage abatement. Although one study suggested that complete block across the ablation lines is a useful EP endpoint, this was not confirmed in two other studies.

VOLTAGE MAPPING. The primary endpoint for circumferential ablation is the reduction in voltage within the isolated regions by more than 80% to 90% or the recording of low (less than 0.05 to 0.1 mV) peak-to-peak bipolar potentials inside the lesion, as determined by local electrogram analysis and voltage mapping (Fig. 15-45).

Postablation voltage mapping is performed using the preablation map for the acquisition of new points (on the existing LA geometry) to permit accurate comparison of preablation and postablation bipolar voltage maps. After completion of the circular lesions around the left- and right-sided PVs, the area within the ablation lines is explored with the ablation catheter, and RF energy is applied at sites that have a local electrogram amplitude greater than 0.1 mV. As an anatomy-based ablation strategy, this may be the only required endpoint.

ACTIVATION MAPPING. Another endpoint used for lesion validation requires the acquisition of two activation-propagation maps during CS and RA pacing for left- and right-sided PVs, respectively. The rationale behind this setting is to pace from a site close to the lesions and shorten conduction time to the ablation site, thereby allowing detection of delayed activation inside the circular line.

Several criteria are used to define line continuity: (1) low peak-to-peak bipolar potentials (less than 0.1 mV) inside the lesion, as determined by local electrogram analysis and voltage mapping; (2) local activation time delay of more than 30 milliseconds between contiguous points lying in the same axial plane on the external and internal sides of the line, as assessed by activation mapping; and (3) gaps in the ablation lines, defined as breakthroughs in an ablated area and identified by sites with single potentials and by early local activation. Changes in activation spread are also evaluated with propagation mapping. Incomplete block is revealed by impulse propagation across the line; in this case, further RF applications are given to complete the line of block.

Importantly, the only predictive criterion for a successful ablation seems to be the amount of postablation low-voltage encircled area.

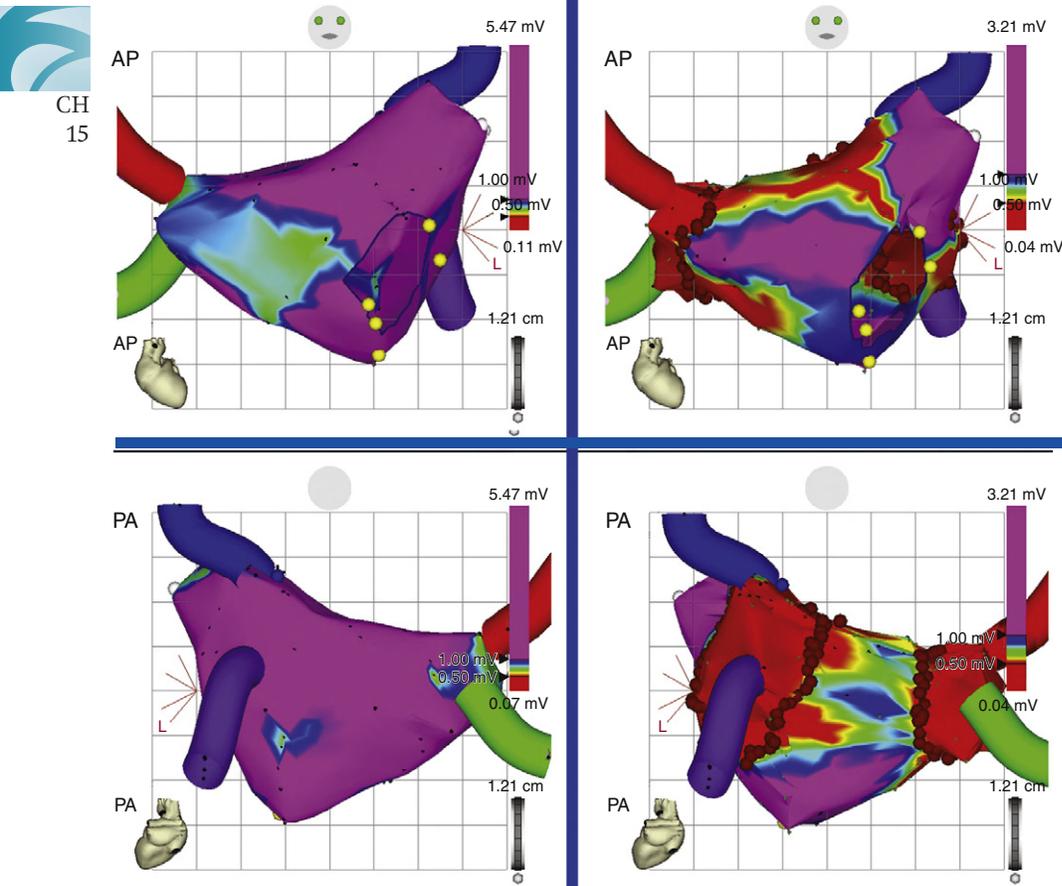

FIGURE 15-45 CARTO (Biosense Webster, Inc., Diamond Bar, Calif.) voltage map after wide-area circumferential left atrial (LA) ablation. Anteroposterior (AP) and posteroanterior (PA) views of electroanatomical voltage maps before (left) and after (right) wide-area circumferential LA ablation depict peak-to-peak bipolar electrogram amplitude. Red represents lowest voltage, and purple represents the highest voltage. In postablation maps, areas within and around the ablation lines, involving to some extent the LA posterior wall, show low-amplitude (less than 0.5 mV) electrograms.

Therefore, validation of the circumferential lesions around PVs by pacing maneuvers, the completeness of conduction block across the ablation lines, and the search for gaps in the ablation lines are not routinely performed.

PULMONARY VEIN ISOLATION. Controversial data have been published regarding the influence of PV disconnection during circumferential LA ablation. Several reports showed that complete electrical isolation of the PVs is not necessary for a successful outcome. Hence, complete PV isolation is not required as an endpoint for circumferential LA ablation.¹¹² In fact, this ablation strategy typically is associated with incomplete PV isolation. Nonetheless, although PV potentials were still present in one or more PVs in 80% of patients, there usually is a conduction delay between the LA and PVs, and the prevalence of PV tachycardias is markedly reduced after circumferential LA ablation.

Of interest, conduction gaps in the ablation lines and LA-PV connection sites can be characterized by multicomponent electrograms without isoelectric lines during sinus rhythm and by multicomponent electrograms or continuous activity during AF. In one report, targeting those sites with ablation was shown to increase the PV disconnection rate during circumferential LA ablation to more than 85% of PVs, which can potentially improve clinical outcome.¹¹¹

TERMINATION OF PERSISTENT ATRIAL FIBRILLATION. Termination of AF during the procedure occurs in approximately one-third of patients. If AF does not terminate during RF, transthoracic cardioversion is performed at the conclusion of ablation. If AF recurs immediately after the cardioversion, the completeness of the lines is reassessed, and additional ablation lines should be considered. Additional ablation consists of ablation lines created along the LA septum, roof, posterior mitral isthmus, or anterior wall, on the basis of the presence of fractionated or rapid atrial activity (see later discussion).

ORGANIZED ATRIAL ARRHYTHMIAS. When LA ablation is performed during an ongoing episode of AF, the AF converts to NSR or to a more organized type of atrial tachyarrhythmia in approximately 20% to 30% of patients. LA ablation can create macroreentrant circuits in the LA, thus mediating conversion of AF into AT. The most common type of macroreentry is mitral isthmus–dependent AT. Additionally, macroreentrant circuits (single or multiple-loop reentry as well as small-loop reentry) can be created by gaps in the ablation lines that encircle the PVs, mostly located on the ridge between the LA appendage and the left superior PV. Entrainment and activation mapping should be performed during organized ATs, and detailed online mapping to search for gaps in the ablation lines should be performed. RF applications at the gaps in the circumferential ablation lines or linear ablation across the lateral mitral isthmus or LA roof can be required for elimination of those ATs.¹¹³

NONINDUCIBILITY OF ATRIAL FIBRILLATION. Whether non-inducibility of AF can be used as a clinical endpoint of ablation in patients with AF who have undergone circumferential LA ablation is still controversial. Some reports found that inducibility of AF after ablation was an independent predictor of recurrent AF. One study suggested performing additional ablation when AF is still inducible after the initial procedure. Circumferential LA ablation renders AF noninducible by rapid atrial pacing in approximately 40% of patients with paroxysmal AF. With additional LA ablation lines, the percentage of patients in whom AF was rendered non-inducible increases to approximately 90%, and such an endpoint is associated with a better clinical efficacy than when AF was still inducible. Conversely, other reports showed a rather low predictive accuracy of the postablation stimulation test that prohibited its use as a reliable procedural endpoint for individual patients; these reports suggested that continuation of ablation caused by a

positive stimulation test or AF persistence may lead to overtreatment in a substantial proportion of patients.¹⁰⁶

Outcome

In multiple reports, long-term success was achieved in approximately 74% of patients with paroxysmal AF and in 49% of patients with persistent or permanent AF.

One study suggested that circumferential LA ablation to encircle the PVs is preferable to segmental ostial PV isolation as the first approach in patients with symptomatic paroxysmal AF. In contrast, another prospective randomized study comparing the two strategies showed the opposite results. Not unexpectedly, the opposite results in the two studies were obtained because of the large variability in the success rate observed in patients undergoing circumferential LA ablation (88% versus 47%), whereas the success rates in patients undergoing segmental ostial PV isolation were similar (67% versus 71%).

Although some studies reported that PV electrical isolation was not related to the success of the procedure, more recent studies found that rigorously achieving complete PV electrical isolation improved the success of circumferential LA ablation as compared with the purely anatomical endpoint of abatement of electrical activity by the ablation catheter recording within the encircled regions.^{112,114} Currently, the Heart Rhythm Society's consensus statement on AF ablation strongly urges demonstration of PV isolation with whatever ablation strategy used.

Linear Atrial Ablation

Linear ablation lesions in the LA in conjunction with circumferential LA ablation were proposed to improve the clinical outcome of AF ablation by modifying the atrial substrate. Additionally, linear atrial ablation can potentially reduce the risk of postablation macroreentrant ATs. Ablation strategies may involve the LA roof line, the LA mitral isthmus line, and the RA cavotricuspid isthmus line in conjunction with circumferential LA ablation or PV isolation.⁹³

Left Atrial Roof Line

RATIONALE

Although the exact mechanism by which the LA roof supports the fibrillatory process is unclear, evidence has implicated this region in the substrate for AF. In addition, the LA roof represents a region demonstrating highly fragmented electrograms, perhaps indicating the presence of substrate capable of sustaining localized reentry or focal activity that may maintain fibrillation, and it also has the potential for supporting macroreentry around the PVs using the LA roof.

Ablation at the LA roof was found to have a direct effect on the fibrillation process, by prolonging the fibrillatory CL and terminating the arrhythmia in some patients and rendering AF noninducible in patients with inducible or sustained arrhythmia after PV isolation. This finding implicated the LA roof in the substrate maintaining AF after PV isolation.¹¹⁵

Linear ablation was previously performed posteriorly or anteriorly across the LA. However, a posterior ablation line between the two superior PVs carries a higher risk of atriopharyngeal fistula. Transection of the anterior LA results in significantly delayed activation of the lateral LA during NSR, which has potentially deleterious hemodynamic consequences. Therefore, these lines are currently substituted with the LA roof line (see Fig. 15-44).¹¹⁵

ABLATION TECHNIQUE

LA roof ablation is performed after circumferential LA ablation or circumferential antral PV isolation. Commencing at the encircling lesion at the left superior PV, the sheath and catheter assembly are rotated clockwise posteriorly and are dragged toward the right

superior PV. To achieve stability along the cranial LA roof, the catheter may be directed toward the left superior PV and the sheath rotated to face the right PVs, or vice versa. Two alternative methods can also be used to reach the LA roof for ablation. First, the catheter can be looped around the lateral, inferior, septal, and then cranial walls, then laying the catheter down along the cranial wall of the LA to allow dragging of the catheter by withdrawal from the left to the right superior PV ostia. Second, the catheter can be maximally deflected to form a tight loop near the left superior PV, with the tip facing the right PVs. Releasing the curve positions the catheter tip adjacent to the right superior PV ostia and allows dragging back to the left PV.¹¹⁵

The stability of the catheter is monitored during RF applications with the use of the proximal electrograms, intermittent fluoroscopy, or a navigation system to recognize inadvertent displacement of the catheter. Electroanatomical mapping is used for real-time monitoring and to tag the ablation sequence. RF energy is delivered for 60 to 120 seconds at each point while the local atrial electrograms are monitored. Local potential elimination or formation of double potentials during pacing or AF signifies the effectiveness of ablation locally.

ENDPOINTS OF ABLATION

The EP endpoint of ablation is the demonstration of a complete line of block joining the two superior PVs. Following the restoration of NSR, complete linear block is defined by point-by-point mapping of an online corridor of double potentials along the entire length of the LA roof during pacing from the anterior LA (from the LA appendage or the distal CS) or during NSR and by demonstration of an activation detour circumventing the right and left PVs to activate the posterior wall caudocranially (instead of the craniocaudal activation typically observed during NSR and LA appendage pacing), with no conduction through the LA roof. When residual conduction is demonstrated, detailed mapping is performed to identify and ablate gaps in the linear lesion.¹¹⁶

OUTCOME

Ablation of the LA roof in conjunction with circumferential antral PV isolation was shown in one study to affect results significantly. The clinical outcome was improved compared with PV isolation alone in patients with paroxysmal AF. Additional roof line ablation with complete conduction block was associated with 87% of patients being arrhythmia-free without antiarrhythmic medications compared with 69% undergoing PV isolation alone. The clinical benefit was similar to other described lines (e.g., mitral isthmus line); however, the roof line could be achieved with shorter RF application and procedural durations. With a mean of 12 ± 6 minutes of RF energy, complete block at the LA roof could be achieved in 96% of cases.

Although the addition of a complete line of block at the LA roof can potentially improve efficacy for the suppression of atrial arrhythmia compared with PV isolation alone, this requires additional ablation and can be associated with a proarrhythmic risk. Whether such linear ablation should be empirically performed in all patients with AF or applied selectively on the basis of clinical or procedural variables, notably persistent inducibility after PV isolation, remains to be determined prospectively.

Left Atrial Posterior Wall Isolation (Box Isolation)

RATIONALE

The role of the LA posterior wall in initiation and perpetuation of AF has been suggested by both human and animal studies. Focal discharges from the posterior LA are important in the initiation of AF as non-PV foci. Furthermore, the LA posterior wall can harbor rotors that can participate in maintaining AF. Several

studies suggested that deployment of linear lesions along the LA to exclude the LA posterior wall in addition to PV ablation was shown to improve the success rate. Electrical isolation of the LA posterior wall after PV isolation was shown to result in further prolongation of the AF CL with termination of longstanding AF achieved in approximately 20%. After isolation of this region, the LA posterior wall demonstrates automatic activity, independent of the PVs, in up to 30% of patients.^{117,118}

ABLATION TECHNIQUE

Following circumferential PV ablation, isolation of the LA posterior wall is achieved by an ablation line joining the two superior PVs (roof line) and a second ablation line joining the two inferior PVs (inferior line). The lateral boundaries of the box isolation are formed by the contiguous lesions previously created by circumferential PV ablation (Fig. 15-46).^{117,118}

Ablation of the LA roof is performed as described earlier. Following the roof line, a contiguous line of ablation lesions joins the inferior PVs to isolate the LA posterior wall. Commencing at the lesion at the left inferior PV, the sheath and catheter are rotated clockwise posteriorly and dragged toward the right inferior PV. RF power output is limited to 20 to 30 W to minimize the risk of atrioesophageal fistula.^{117,118}

During ablation, the slowing of LA posterior wall activity with progressive completion of the posterior LA rectangle and termination of AF can be observed in some patients. Complete linear block can be verified by the demonstration of no conduction through the LA roof and inferior lines by point-by-point sequential mapping either conventionally or by electroanatomical mapping. Persistent conduction across to the posterior wall should prompt meticulous online mapping to identify and ablate gaps in the linear lesions.¹¹⁸

ENDPOINTS OF ABLATION

The endpoints of box isolation are the demonstration of the absence or dissociation of electrical activity within the ablated zone (i.e., entrance block), as well as failure to capture the LA outside the isolated region (i.e., exit block) during pacing from the posterior LA and all PVs (after the restoration of NSR).¹¹⁷⁻¹¹⁹

OUTCOME

Initial studies showed that exclusion of the LA posterior wall is feasible and results in incremental improvement to the effect of PV isolation. In patients with longstanding AF, box isolation resulted in further prolongation of the fibrillatory CL (independent of PV isolation) with termination of AF in approximately 20%. At 2 years following ablation, 63% of these patients with longstanding persistent

AF have remained in NSR.¹¹⁷ However, one prospective randomized study showed that isolation of the LA posterior wall did not offer additional benefit over a single LA roof line with respect to the risk of arrhythmia recurrence after circumferential PV ablation. This finding suggests that the benefits demonstrated in previous reports may represent a general debulking of the atria rather than a specific role of electrical isolation of the posterior wall.¹¹⁹

Left Atrial Mitral Isthmus Line

Emerging evidence has implicated regions of conduction slowing and block associated with atrial remodeling in the substrate predisposing to AF. In the LA, studies demonstrated preferential propagation that is closely correlated with muscle fiber orientation along the posterior LA and circumferentially around the mitral annulus. Such preferential propagation occurring in response to functional or anatomical conduction block (perhaps exacerbated by AF or conditions predisposing to AF) is capable of facilitating reentry using the mitral isthmus, as recognized with common forms of LA macroreentry, and thus can have a role in the milieu that maintains AF.

Because of the contiguity with the left PVs and LA appendage, ablation of the mitral isthmus results in a long (functional) line of conduction block that transects the lateral LA from the mitral isthmus to the roof. Its EP consequences can be considered analogous to those produced by cavotricuspid isthmus ablation, in which a short line is amplified by the crista terminalis to result in a long line of functional conduction block. It is thus likely that ablation of the mitral isthmus, as an adjunct to other ablation strategies for AF, helps modify a large region of the LA substrate for AF by eliminating anatomical or functional reentry involving the mitral isthmus or PVs. Additionally, it can eliminate arrhythmogenic triggers arising from the ligament of Marshall.

LA macroreentrant ATs can develop following catheter ablation of AF in up to 50% of cases. The most common type of macroreentry is mitral isthmus-dependent AT, and it seems more likely that this type of AT is a direct result of LA ablation. The potential of this complication underscores the importance of an ablation line across the mitral isthmus. Ablation of the mitral isthmus is discussed in detail in Chapter 13.

In one report, the outcome of 100 consecutive patients with paroxysmal AF undergoing circumferential PV isolation alone was compared with that of an equal number of consecutive patients undergoing circumferential PV isolation and mitral isthmus ablation. Mitral isthmus block was achieved in 92% of patients after 20 ± 10 minutes of endocardial RF application (additional 5 ± 4 minutes of epicardial RF application from within the CS was required in 68%). One year after the last procedure, 87% of patients with mitral isthmus ablation and 69% without ablation ($p = 0.002$) were arrhythmia-free in the absence of antiarrhythmic drugs. Another study showed a significant improvement of

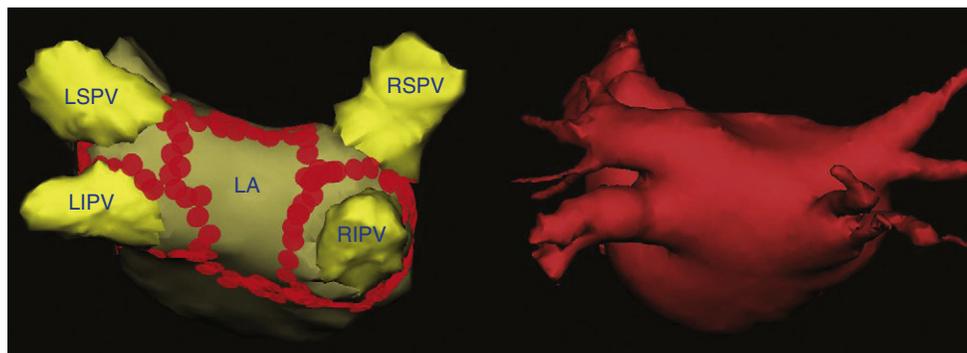

FIGURE 15-46 Three-dimensional reconstruction of the left atrium (LA, posterior view) using ESI EnSite NavX (St. Jude Medical, Austin, Tex.) electroanatomical system (left) and computed tomography (right). Small red circles are tagged sites at which radiofrequency energy was applied to isolate the pulmonary veins (PVs). Electrical isolation of the LA posterior wall (box isolation) is performed by an ablation line joining the two superior PVs (roofline) and a second ablation line joining the two inferior PVs (inferior line). LIPV = left inferior pulmonary vein; LSPV = left superior pulmonary vein; RIPV = right inferior pulmonary vein; RSPV = right superior pulmonary vein.

long-term sinus rhythm maintenance with the combination of bidirectional block along the left mitral isthmus and circumferential PV isolation in patients with both paroxysmal (76% versus 62%) and persistent (74% versus 36%) AF.

Importantly, continuous linear lesions are difficult to achieve, even under direct visualization during intraoperative ablation. It has been shown that creating transmural permanent lines of block across the mitral isthmus line in particular is technically challenging and sometimes requires ablation deep within the CS. Gaps within the ablation lines, whether secondary to areas of recovery or areas missed initially, can produce areas of slow conduction and a substrate for macroreentry. Therefore, when linear LA ablation is applied, complete bidirectional conduction block across the ablation lines should be verified to reduce the risk of development of macroreentrant ATs related to gaps in the ablation lines.

Right Atrial Cavotricuspid Isthmus Line

AF and AFL frequently coexist in the same patient. Clinical AFL occurs in more than one-third of patients with AF. AF often precedes the onset of AFL and can also develop after the successful catheter ablation of AFL. AFL, usually induced either by atrial pacing or by AF, can be observed in up to two-thirds of patients undergoing PV isolation for AF. Approximately 80% of these episodes are typical AFL.

Although typical AFL and AF frequently coexist, their precise interrelationship is unclear. It may be that the same premature depolarizations that trigger AF also trigger AFL, or the EP and structural remodeling that accompany AF may also promote the occurrence of AFL, or vice versa. Evidence suggests that AF plays an important role in the genesis of typical AFL. Commonly, spontaneous or induced typical AFL does not start immediately after a premature beat or burst rapid atrial pacing; rather, its onset is generally preceded by a transitional rhythm (AF) of variable duration.¹²⁰ AF can promote the formation of an intercaval functional line of block in the RA, which can be critical for the initiation of AFL. Also, class IC and IA antiarrhythmic drugs and amiodarone used to suppress AF commonly promote AFL.

On the other hand, it is also possible that at least some episodes of AFL can degenerate into AF. AFL with a short CL can result in fibrillatory conduction. Additionally, AFL can induce atrial electrical remodeling that predisposes to development of AF.

Catheter ablation techniques targeting the cavotricuspid isthmus for typical AFL or the initiating triggers within the PVs for AF were independently shown to offer a potential cure for the two arrhythmias. However, more recent studies suggested that successful ablation of typical AFL does not improve the natural history of AF. The occurrence rates of AF following ablation of typical AFL alone have been shown to range from 38% to 50% when preprocedural AFL is the dominant arrhythmia over AF to 86% when AF is the dominant arrhythmia. In most patients, AF develops within the first year after AFL ablation.¹²¹ These observations suggest that AFL may be initiated by bursts of AF and that in the absence of AFL substrate the AF continues to progress, or, alternatively, the atrial electrical remodeling caused by AFL can provide the substrate for subsequent AF development. Hence, some investigators have proposed additional PV isolation at the time of cavotricuspid isthmus ablation in patients with AFL but no documented AF before ablation to help improve long-term freedom of AF recurrences. Although small studies suggested some value of this approach, this strategy cannot be recommended for general adoption before confirmation by larger studies because of the increased risk and procedure duration when PV isolation is added.^{121,122}

In patients with AF and no known history of AFL, ablation of the cavotricuspid isthmus at the time of AF ablation was proposed in some studies to reduce the risk of subsequent typical AFL, as well as AF, after ablation. However, as was shown in one study, although cavotricuspid isthmus ablation can potentially reduce early recurrences of AFL, those early recurrences do not represent a long-term problem in most patients and require only short-term therapy.

Additionally, the potential benefit of adjunctive cavotricuspid isthmus ablation on risk of recurrence of AF after PV isolation has not been confirmed by large studies. Therefore, routinely performing typical AFL ablation in all patients undergoing AF ablation may not provide added clinical benefit but can potentially add time, cost, and risk.¹²³

In patients with paroxysmal AF who had periods of typical AFL, the effect of PV isolation alone on the risk of recurrence of AFL remains controversial. It has been reported that ablation of AF in these patients, although not interrupting the reentrant circuit in typical AFL, can potentially control both arrhythmias, a finding suggesting that AF initiated by PV triggers can be the precursor rather than the consequence of AFL. This is consistent with the observation that AFL commonly starts after a transitional rhythm of variable duration, usually AF. However, these findings were not confirmed by other studies that showed no benefit of PV isolation on the risk of recurrence of typical AFL. Therefore, in patients undergoing AF ablation, it is likely beneficial to ablate the cavotricuspid isthmus whenever typical AFL is observed clinically. Additionally, the occurrence of typical AFL in the course of a catheter ablation procedure aimed at elimination of AF was shown to be predictive of symptomatic AFL during follow-up after PV isolation, even in patients who had no prior clinical history of AFL, a risk that was lowered by combining AF and AFL ablation in those patients. Thus, supplementary cavotricuspid isthmus ablation in conjunction with AF ablation seems reasonable in these patients.¹²³

Ablation of Complex Fractionated Atrial Electrograms

Rationale

Evaluation of the complexity and frequency of intracardiac electrograms can help in understanding the pathophysiology of AF. Atrial electrograms during sustained AF have three distinct patterns: single potentials, double potentials, and complex fractionated potentials. Continuous propagation of multiple wavelets in the atria and wavelets as offspring of atrial reentry circuits has been suggested as the mechanism by which AF can be perpetuated without continuous focal discharge. Fractionated and continuous electrical activity has been assumed to indicate the presence of wave collision, slow conduction, or pivot points where the wavelets turn around at the end of the arcs of functional blocks. Thus, areas of CFAEs during AF can potentially represent continuous reentry of the fibrillation waves into the same area or overlap of different wavelets entering the same area at different times, although the mapping resolution to discern whether such rotors even exist in human AF is still limited.^{124,125}

Such complex electrical activity has a relatively short CL and heterogeneous temporal and spatial distribution. A relatively short CL may indicate the presence of a driver, analogous to the frequency gradient from the drivers or rotors to the rest of the atria observed in experimental models of AF, in which the central core of these rotors can have high-frequency electrical activity, whereas the periphery of the rotors can display complex electrograms because of wave break and fibrillatory conduction. Importantly, regions of CFAEs have been shown to remain spatially and temporally stable in individual patients, particularly when these regions were measured over several seconds, a surprising finding considering the earlier observation that the underlying mechanism for AF is random reentry and that the reentrant wavelets are expected to meander.^{124,125}

Data have suggested that areas of CFAEs are critical sites for AF perpetuation and can serve as target sites for AF ablation. It has been proposed that once CFAEs are eliminated by ablation, AF can no longer be sustained because the random reentry paths are altered or eliminated so that the fibrillation wavelets can no longer reenter the ablated areas.¹²⁶ Whereas PV isolation targets the triggering foci, ablation of CFAEs targets the substrate for AF. However,

some connections between both approaches probably exist. Data indicate that PVs are the key areas where CFAEs are located; these areas need to be ablated to achieve conversion of AF to NSR. It is thus very likely that many patients may respond to ablation in the PV regions because of both trigger elimination and substrate modification.^{124,126}

Mapping of Complex Fractionated Atrial Electrograms

Mapping of CFAEs is performed during AF. In patients in NSR at the time of study, AF is induced by isoproterenol infusion or rapid atrial pacing. In patients with persistent AF or with induced AF sustained for more than 5 minutes, biatrial electroanatomical (CARTO or NavX) mapping is performed.¹²⁶ The CS or RA appendage recording is used for electrical reference during mapping. Atrial CLs are monitored and recorded from the reference and mapping catheters. Electroanatomical mapping systems enable the operator to associate areas of CFAEs with the anatomy of both atria. Sites with CFAEs can be tagged and associated with the atrial geometry created by the electroanatomical mapping system and thereby serve as target sites for ablation. During AF, the local activation time of the arrhythmia is of no value in guiding activation sequence mapping.

The definition of CFAEs has not been consistent. Initially, CFAEs were defined as: (1) atrial electrograms that are fractionated and composed of at least two deflections and/or have a perturbation of the baseline with continuous deflection of a prolonged activation complex over a 10-second recording period; or (2) atrial electrograms with a very short CL (up to 120 milliseconds) averaged over a 10-second recording period (Fig. 15-47). More recently, CFAEs have been defined as having any of the following: (1) a magnitude of less than 0.5 mV; (2) a duration longer than 50 milliseconds with multiple deflections from the isoelectric line (more than three deflections); or (3) continuous electrical activity without an isoelectric line, verified visually. Some investigators, using unipolar mapping, defined fragmented potentials as electrograms exhibiting two or more negative deflections within 50 milliseconds. The limit of 50 milliseconds was based on the assumption that the atrial refractory period during AF and the interval between two successive fibrillation waves were 50 milliseconds or more.^{124,125,127}

An important limitation of this approach is that the visual appearance of CFAEs is variable, and they are often of very low amplitude (less than 0.25 to 0.5 mV); therefore, their identification by visual inspection can be challenging and is highly subjective and investigator dependent (Fig. 15-48). To improve the accuracy of CFAE mapping, custom software was developed with algorithms that enable automated detection and tagging of areas of CFAEs with the anatomical shell of both atria. This software offers valuable advantages in the detection, quantification, and regionalization of CFAEs.

Currently, the automatic algorithms are variable and are dependent on the recording technology (NavX and CARTO). With CARTO, the CFAE complex is identified using an algorithm that quantifies the CFAE phenomenon in two parameters. First is the "interval confidence level," which characterizes the repetitiveness of the electrogram peaks within the recorded intracardiac signal. The assumption is that the more repetitions are recorded in a given time duration (2.5 milliseconds), the more confident is the categorization of a site as harboring CFAEs. The second parameter is either the "shortest complex interval," which is the shortest interval found in milliseconds out of all the intervals identified between consecutive CFAE complexes, or the "average complex interval," which is the average of all the intervals identified between consecutive CFAE complexes for each 2.5-second electrogram. CFAE areas are displayed on the whole-chamber map in a color-coded manner according to the degree of fractionated signals and their CLs for easier identification (Fig. 15-49). The algorithm allows the operator to exclude both noise and high-voltage signal from the analysis (default values, 0.05 mV and 0.15 mV).¹²⁸

With the NavX system, CFAEs are characterized using the "CFAE-mean" contact mapping tool. The CFAE-mean is defined as the average time duration between consecutive deflections ($-dV/dt$) in a local AF intracardiac bipolar electrogram recorded over a specified length of time (at least 5 seconds). The mean interdeflection time interval (i.e., the mean CL) is then projected onto the LA anatomical shell as a color-coded display. The shorter the mean CL is, the more rapid and fractionated the local electrogram will be. Regions with mean CLs shorter than 120 milliseconds are considered to correspond to CFAE. To optimize algorithm accuracy, bipolar recordings are filtered at 30 to 500 Hz, and electrogram width

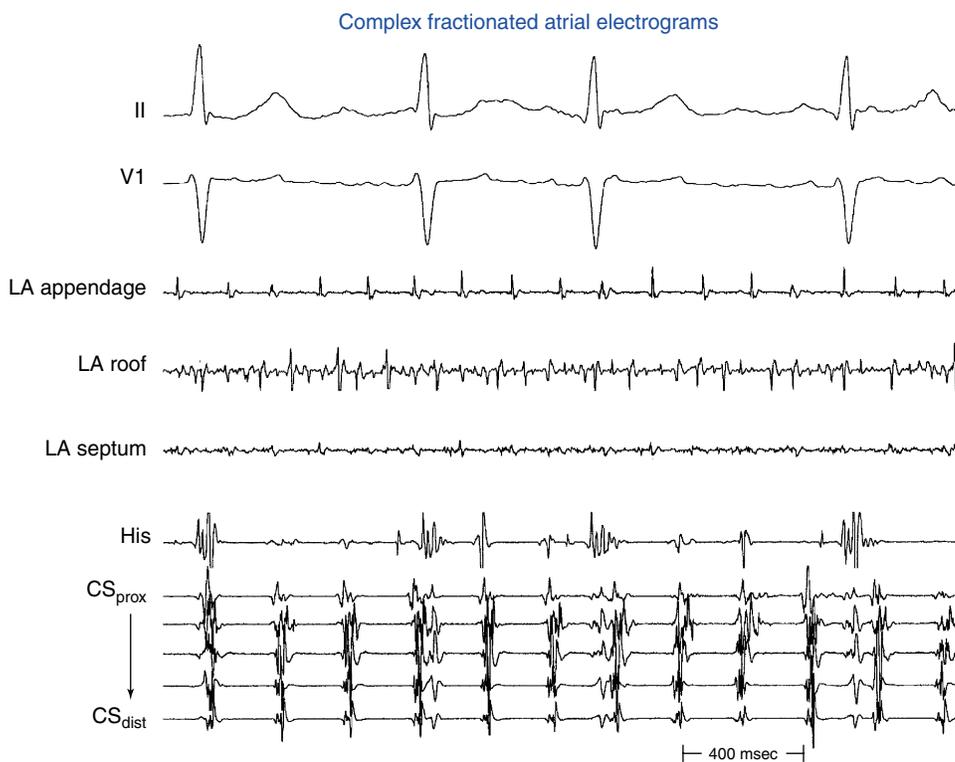

FIGURE 15-47 Examples of complex fractionated atrial electrograms. Fractionated atrial electrograms with a very short cycle length, compared with the rest of the atria, were recorded in the left atrial (LA) roof. In the LA septum, fractionated electrograms with continuous prolonged activation complex were observed. See text for discussion. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

and “refractory” period are typically set at 10 to 20 milliseconds and 30 to 50 milliseconds, respectively, to avoid multiple detections on a single deflection or counting of ventricular far-field signals. Additionally, the baseline signal noise level is determined, and the peak-to-peak electrogram amplitude detection limit is set just higher than the noise level (typically, 0.03 to 0.05 mV) to minimize noise detection while allowing detection of CFAEs, which are

typically of very low amplitude (less than 0.5 mV). This algorithm is probably most analogous to the “average complex interval” map from the CARTO software. Advantages of the NavX system include an adjustable duration of recording from 1 to 8 seconds and the ability to record electrograms from multiple poles of several catheters simultaneously, which can potentially occupy a significant proportion of local AF CL.^{124,129}

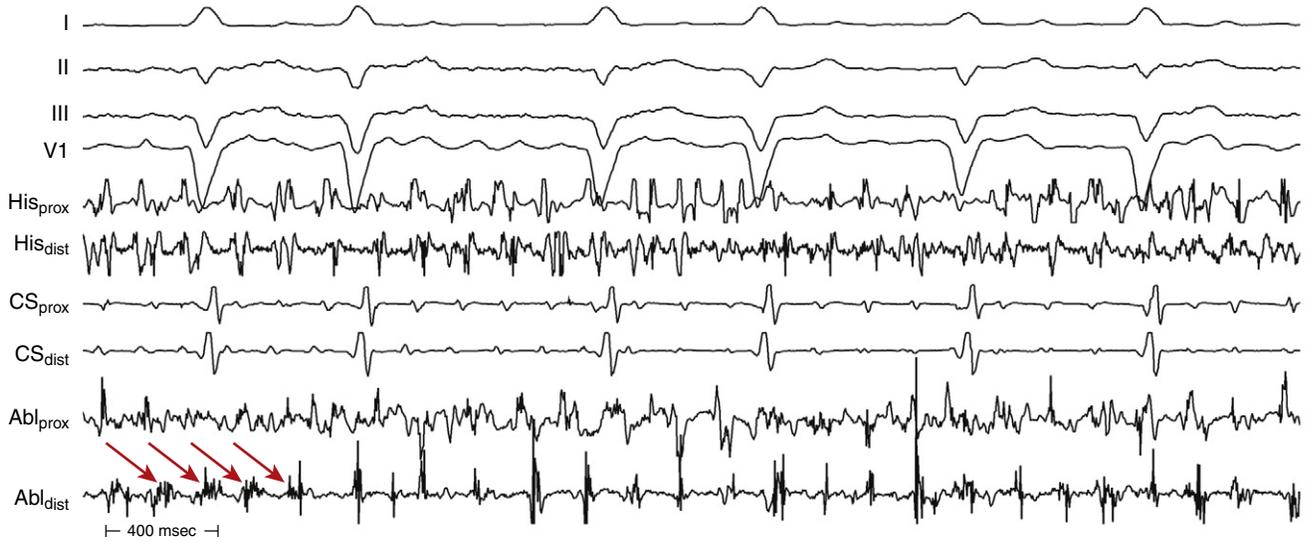

FIGURE 15-48 Recordings from near ligament of Marshall (Abl) showing complex fragmented atrial electrograms (high-frequency, somewhat repetitive spikes [arrows]); these are not consistently present over the duration of the recording, whereas similar activity is intermittently seen in the His recordings (right atrial). Abl_{dist} = distal ablation site; Abl_{prox} = proximal ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{prox} = proximal His bundle.

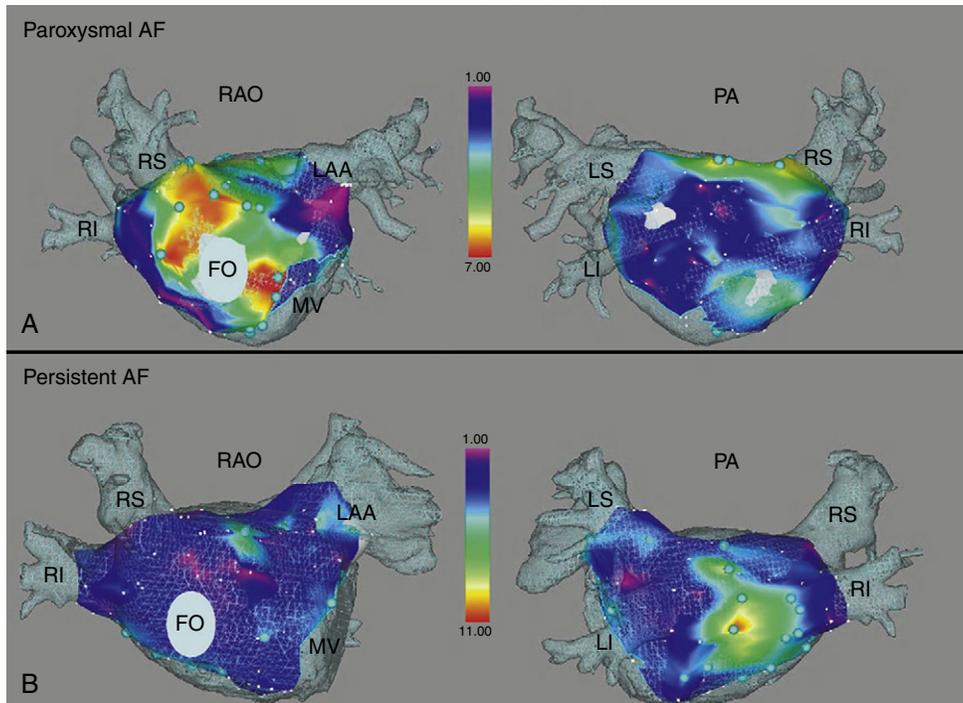

FIGURE 15-49 CARTO (Biosense Webster, Inc., Diamond Bar, Calif.) maps of complex fractionated atrial electrograms (CFAEs). CFAE maps with registered left atrial (LA) CT surface reconstruction (shown as wire frame), shown in right anterior oblique (RAO) view (left-sided images) and posteroanterior (PA) view (right-sided images), in patients with paroxysmal atrial fibrillation (AF) (A) and persistent AF (B). The CFAE maps are color-coded, with red representing the highest interval confidence level (ICL) and purple representing the lowest ICL. Highly repetitive CFAE sites (ICL ≥ 5) are tagged with light blue dots on the CFAE maps. As shown in this example, the highly repetitive CFAE sites are more likely located at the pulmonary vein (PV) ostia, interatrial septum, and mitral annulus area in patients with paroxysmal AF, whereas patients with persistent AF have highly repetitive CFAE sites predominantly identified on the LA posterior wall. FO = fossa ovalis; LAA = left atrial appendage; LI = left inferior pulmonary vein; LS = left superior pulmonary vein; MV = mitral valve; RI = right inferior pulmonary vein; RS = right superior pulmonary vein. (From Scherr D, Dalal D, Cheema A, et al: Automated detection and characterization of complex fractionated atrial electrograms in human left atrium during atrial fibrillation, *Heart Rhythm* 4:1013, 2007.)

Importantly, assessment of fractionated electrograms during AF requires a recording duration of at least 5 seconds at each site to obtain a consistent fractionation and accurate analysis. A small mapping catheter tip (4 mm), good atrial contact, and stable mapping catheter positions for several seconds while mapping at each location are important to obtain high-quality recordings.¹²⁴

CFAEs usually can be identified in most (80%) areas of the LA, but they appear to be predominantly located in the interatrial septum, LA roof, posterior wall, mitral annulus, and PV ostia. Less commonly, CFAEs are located in the RA, involving the septal region, crista terminalis, and cavotricuspid isthmus, as well as the CS os. Notably, patients with paroxysmal AF appear to have more CFAE sites identified around the PV ostia, whereas CFAEs detected in patients with persistent AF appear to be more evenly distributed over all areas of the LA. However, these findings have not been consistent across studies using different CFAE detection methods.¹²⁴

Target of Ablation

Atrial ablation is performed at all sites displaying continuous electrical activity, complex and fractionated electrograms, regions with a gradient of activation (significant electrogram offset between the distal and proximal recording bipoles on the map electrode), or regions with shorter CL activity compared with the LA appendage. CFAE regions with the shortest CL and highest degrees of fractionation are the regions of most interest; sites displaying a greater percentage of continuous activity or a temporal activation gradient are more likely to be associated with slowing or termination of AF after local ablation.¹²⁷ The atrial septum, followed by the regions of the PVs, is the most common site for CFAEs. The most common localizations for termination and regularization of AF during CFAE ablation are the regions of the PV ostia, the interatrial septum, and the LA anterior wall close to the roof of the LA appendage.

After ablation of CFAEs in the LA, those in the CS and RA are targeted. RA ablation aimed at termination of AF can potentially offer a clinical benefit in patients with longstanding persistent AF, but it does not seem to improve outcome in patients with persistent AF of shorter durations.¹³⁰

Ablation Technique

The ablation typically begins at sites at which CFAEs have the shortest interval and preferably also have a high interval confidence level. RF energy is applied using an 8-mm-tip or, preferably, an irrigated-tip catheter. Lower power output is applied in the CS and along the posterior LA.

A mean of 64 ± 36 RF applications was required in one study. In a second study, the mean duration of RF energy application was 36 ± 13 minutes. When the areas with CFAEs are completely eliminated, but the arrhythmia organizes into AFL or AT, the atrial tachyarrhythmias are mapped and ablated (occasionally in conjunction with ibutilide, 1 mg infused over 10 minutes). If the arrhythmias are not successfully terminated by ablation or ibutilide, external cardioversion is performed.

Endpoints of Ablation

The ablation endpoints when targeting CFAEs are uncertain. In most studies, the primary endpoints were complete elimination of the areas with CFAEs or organization slowing of local electrograms, conversion of AF to NSR (either directly or first to an AT) for patients with persistent AF, or noninducibility of AF (with isoproterenol and atrial pacing) for patients with paroxysmal AF.¹²⁶ When areas with CFAEs are completely eliminated, but arrhythmias continue as organized AFL or AT, those arrhythmias are mapped and ablated.

However, arrhythmia termination (conversion to AT or NSR) in patients with persistent AF can potentially be a challenging endpoint to achieve and generally requires very long procedure times. Reports demonstrated the limited ability of CFAE ablation to

terminate persistent AF. Furthermore, although AF termination during ablation can potentially predict the mode of recurrence (AT versus AF), its correlation with long-term success is still controversial. AF recurrence rates of more than 50% were observed even in patients in whom AF was terminated during CFAE ablation. Thus, ablation of all areas displaying the electrogram of interest in the LA and CS can be a reasonable alternative endpoint when ablation fails to terminate AF.¹³⁰⁻¹³⁴

Preliminary reports suggested the clinical utility of monitoring dominant frequency in real time to guide catheter ablation of AF. A critical decrease (11% or higher, measured in lead V₁ and the CS) of dominant frequency following CFAE ablation can potentially indicate adequate elimination of drivers of AF and is associated with clinical efficacy that is as high as when AF is terminated by ablation. However, these findings require validation in prospective studies.¹³⁵

Outcome

Although initial single-center studies using CFAE ablation as a stand-alone strategy for ablation of AF showed high success rates (up to 92% freedom from AF at 1 year follow-up after one or two ablation procedures), these results were not reproducible, and several more recent trials achieved only modest short-term efficacy. These findings suggest that CFAE ablation alone is not a sufficient strategy for successful treatment of AF.^{72-74,125,128}

On the other hand, CFAE ablation can potentially be of value as an adjunct strategy in combination with PV isolation, particularly in patients with persistent AF whose response to other ablation strategies is suboptimal, as well as in patients with recurrent AF who are undergoing a second ablation procedure. Nonetheless, different studies produced conflicting results, partly because of variability of mapping techniques, the inconsistencies in CFAE electrogram interpretations, differences in the type and size of the mapping-ablation electrode, and differences in the accompanying lesion set. Whether ablating sites with CFAEs in paroxysmal AF has any additional effect on long-term outcome is even less clear. A meta-analysis (7 controlled trials with a total of 622 patients) found that, as compared with PV antral isolation alone, additional CFAE ablation after the PV isolation procedure slightly increased the rate of sinus rhythm maintenance in patients with persistent or longstanding persistent AF but did not show benefit in patients with paroxysmal AF.^{136,137}

The benefits of AF substrate ablation have to be balanced against the potential risks in individual patients, especially given that CFAE ablation involves additional ablation lesions that can encompass extensive amounts of the atrial surface area, which can potentially compromise long-term atrial contractile function, produce arrhythmogenic atrial scarring, prolong procedure and radiation times, and increase risks of acute procedural complications. When adjunctive CFAE ablation is planned, it may be reasonable to target CFAEs after, rather than before, PV electrical isolation because that latter strategy can itself reduce the burden of CFAEs and minimize the consequent need for extensive LA ablation.^{124,138}

In its current iteration, the CFAE ablation approach is limited by uncertainties regarding the mechanistic significance, efficacy, and endpoint of the ablation strategy. The lack of standardization in CFAE definition and differences in mapping technologies and electrogram measurements, especially given the lack of comparative information for the current technologies, adds to the challenge. Furthermore, although multiple studies have found that ablation at sites of CFAEs could prolong the CL or terminate AF, their true significance in the pathophysiology of AF remains to be determined, and the sensitivity and specificity of CFAEs in identifying sites critical to perpetuation of AF are uncertain. The mechanistic relevance of all sites of CFAEs in specific clinical contexts and in individual patients can potentially differ. Some CFAE sites can simply result from passive atrial activation and reflect shortening in the AF CL, random collision of fibrillatory waves, wave disruption adjacent to rapidly firing foci or rotors, or nonuniform anisotropic conduction.

In fact, significant spatiotemporal variability of CFAEs exists across studies for uncertain reasons. Whether all CFAE sites need to be targeted for catheter ablation is still not known, and reliable criteria to distinguish active from passive electrogram patterns and define optimal ablation targets are lacking.^{124,127}

In addition to the time-domain (fractionation) mapping method, which involves scanning the atrium for CFAEs, the electrical substrate during AF can be described using the frequency mapping method. Frequency-domain (spectral) analysis of the atrial electrograms uses the fast Fourier transform algorithm to break down the AF signals into their different frequency components, distill the local activation frequency from highly complex electrograms, and determine the dominant frequency of the signal. Experimental evidence suggests that sites with high dominant frequencies can potentially be more specific than CFAEs at identifying the rotor regions driving the fibrillation process. Additionally, monophasic action potentials can identify local activation and repolarization in AF and help exclude CFAEs resulting from far-field signals that may be less attractive ablation sites. However, the clinical role of targeting the sites with high dominant frequency or monophasic action potentials by ablation is still under investigation.^{124,139}

Pulmonary Vein Denervation

Rationale

Experimental and clinical data suggest that the autonomic nervous system plays a critical role in the initiation and maintenance of AF.¹²⁶ High-frequency stimulation of epicardial autonomic plexuses can induce triggered activity from the PVs and potentially shorten the atrial refractory periods to provide a substrate for the conversion of PV firing into sustained AF. Clinical studies found that ablation of the ganglionated plexuses located at the antra of the PVs (by specifically targeting the ganglionated plexuses or inadvertently during standard PV ablation procedures) can potentially reduce the risk of recurrence of AF.^{25,93,140}

Localization of Ganglionated Plexuses

Autonomic inputs to the heart converge at several locations; these convergence points are typically embedded in the epicardial fat pads and form ganglionated plexuses that contain autonomic ganglia and nerves. In the LA, there are four major ganglionated plexuses located around the antral regions of the PVs and in the crux. The superior left ganglionated plexus is located on the roof of the LA, medial to the left superior PV, and often extends to the medial aspect of LA appendage. The anterior right ganglionated plexus is located just anterior to the right superior PV and often extends inferiorly, to the region anterior to the right inferior PV. The inferior left ganglionated plexus is located at the inferior aspect of the posterior wall of the LA, 1 to 3 cm below the left inferior PV. The inferior right ganglionated plexus is also located at the inferior aspect of the posterior wall of the LA below the right inferior PV and may extend toward the area adjacent to the crux of the heart, where another atrial ganglionated plexus (the crux ganglionated plexus) is located.^{24,76}

High-frequency electrical nerve stimulation allows for precise determination of the location, threshold, and predominance of the parasympathetic or sympathetic response of the ganglionated plexuses. The distal electrode of the mapping-ablation catheter is used to deliver high-frequency stimulation (1200 beats/min [20 Hz], at 12 to 24 V and pulse width 1 to 10 milliseconds) using a Grass stimulator (S88X dual output square pulse stimulator, Grass Instruments Division, Astro Med Inc., Warwick, R.I.). Tolerance of the conscious patient to the stimulation still must be determined, because most reports have described use of this approach in deeply sedated patients.^{75,76,141}

High-frequency stimulation of a ganglionated plexus can elicit both parasympathetic and sympathetic responses. A parasympathetic response is typically elicited immediately (within to

4 seconds) following stimulation, but a sympathetic response requires longer stimulation durations (8 to 10 seconds). A predominant efferent parasympathetic response is defined as induction of sinus bradycardia (slower than 40 beats/min), AV block (second- or third-degree AV block during sinus rhythm or a 50% or higher increase in mean R-R interval during AF), and/or hypotension (20 mm Hg or greater reduction of systolic blood pressure), following a 5-second application of high-frequency stimulation, with return to baseline values on cessation of stimulation. The sites of positive parasympathetic responses to high-frequency stimulation are marked on the electroanatomical map. If no response occurs, the catheter is positioned at adjacent sites. It is important to limit high-frequency stimulation to only 2 to 5 seconds, to avoid eliciting a sympathetic response that can otherwise mask or attenuate the parasympathetic response (e.g., by facilitating AV conduction and increasing blood pressure).^{75,76}

Before applying high-frequency stimulation to inferior ganglionated plexuses, it is important to ensure that the catheter tip is not close to the ventricle to avoid induction of VF. When high-frequency stimulation is applied during NSR, AF generally occurs and usually terminates within seconds or minutes. Repeated stimulation usually results in sustained AF, at least in patients with a clinical history of AF.⁷⁶

Alternatively, ganglia identification and ablation can be accomplished by a purely anatomical technique without the need for specific ganglionated plexus identification with high-frequency stimulation. The suboptimal sensitivity of high-frequency stimulation in identifying *all* LA ganglionated plexuses can result in partial and nonhomogeneous atrial denervation. Additionally, high-frequency stimulation commonly requires general anesthesia and carries the risk of induction of AF. The anatomical approach is based on studies in humans demonstrating that the largest accumulation of PV-related cardiac neural structures is localized to the inferior and posterior surface of the roots of both left and right inferior PVs, as well as on the anterior surface of the root of the right superior PV.^{75,140}

Target of Ablation

During ablation of AF, the LA ganglionated plexuses are specifically targeted by ablation, as identified by high-frequency stimulation or on an anatomical basis, as described previously.

Ablation Technique

High-frequency stimulation is performed in the LA adjacent to the antral region of the PVs and the region of the LA crux. Once identified, the location of a ganglionated plexus is tagged on the electroanatomical map. Generally, the four major LA ganglionated plexuses can be identified and localized using high-frequency stimulation in the majority of patients; though, it is not uncommon that one or more ganglionated plexuses cannot be identified, especially in patients with persistent AF. RF is delivered after all ganglionated plexus sites have been identified.⁷⁶

RF ablation is usually performed using an irrigated-tip catheter (25 to 35 W for 40 to 60 seconds). RF power and duration are reduced at sites close to the esophagus (15 to 20 W for 20 to 30 seconds). After each RF application, high-frequency stimulation is repeated immediately at the same site. If a positive parasympathetic response is still elicited, RF applications are repeated until a positive parasympathetic response is no longer elicited. Notably, RF energy delivery does not usually elicit a parasympathetic response, even at sites with positive response to high-frequency stimulation. Thus, the absence of an autonomic response should not prompt termination of RF application.^{75,76,140} Because there is experimental evidence that ablation of the inferior right ganglionated plexus can potentially attenuate the parasympathetic response of other ganglionated plexuses to high-frequency stimulation and hence render subsequent localization of other ganglionated plexuses challenging,

Vagal reflex during PV isolation

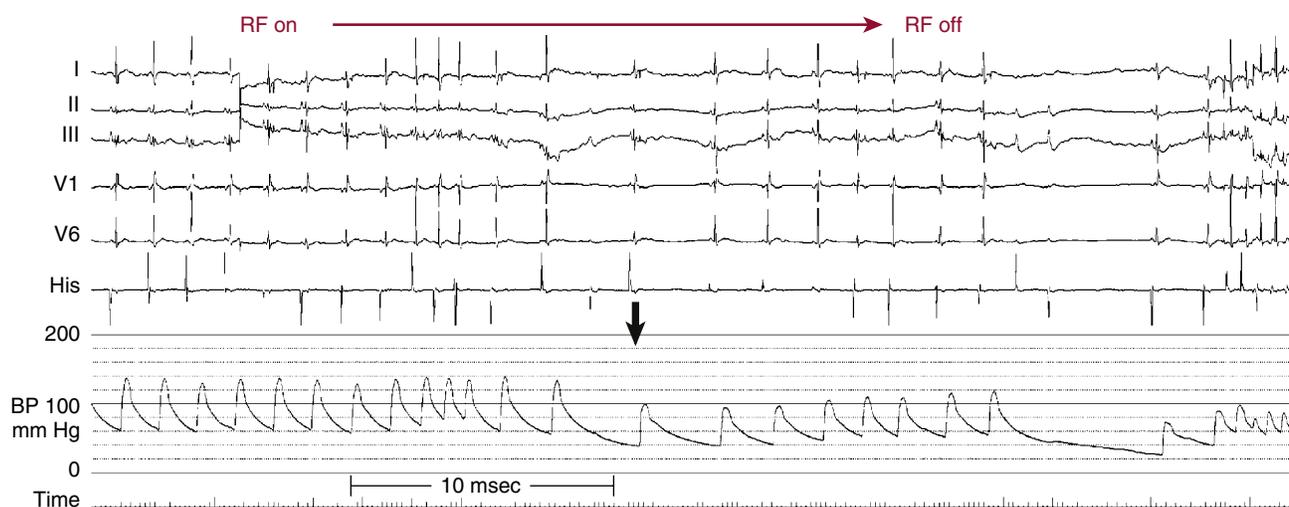

CH
15

FIGURE 15-50 Vagal reflex during pulmonary vein (PV) isolation. Sinus rhythm is present at the beginning of the tracing; when radiofrequency (RF) energy is applied ("RF on"), blood pressure (BP) and heart rate decrease markedly (sinus bradycardia and nonconducted P wave). After energy is stopped ("RF off"), a short episode of atrial fibrillation ensues.

it is preferred to stimulate and ablate the inferior right ganglionated plexus last.

When using an anatomical approach for localization of the ganglionated plexuses, the presumed ganglionated plexus clusters near the PV antra are targeted by RF ablation. Because the exact anatomical borders of ganglionated plexus clusters are unknown and their location can vary slightly in different patients, a relatively extensive regional ablation is performed by delivering RF energy at multiple sites in and around the presumed anatomical location of each ganglionated plexus. Using this approach, vagal reflexes can be observed in at least one-third of patients, typically within a few seconds of the onset of RF application (Fig. 15-50). When a vagal reflex is observed during RF application, RF energy should be delivered until these reflexes are abolished, or for up to 30 seconds. It is important to recognize that the specificity and sensitivity of eliciting such vagal responses during RF application are not known. Similar responses can be triggered by pericardial pain during RF energy delivery. Additionally, as noted previously, vagal responses are not usually observed during RF ablation directly over the location of the ganglionated plexuses identified by high-frequency stimulation or even while applying RF energy to the plexuses during epicardial surgical ablation.^{75,76,140}

Endpoints of Ablation

The endpoint of ablation is the abolition of all vagal reflexes evoked by high-frequency stimulation over the ganglionated plexus sites marked on the electroanatomical map. For anatomically guided atrial autonomic denervation, the endpoint of the ablation procedure is elimination of electrical activity (peak-to-peak bipolar electrogram less than 0.1 mV) in the specified areas and abolition of any vagal effects during RF energy delivery.⁷⁵

Outcome

At present, no reports have suggested that targeting of ganglionated plexuses as a stand-alone procedure will consistently terminate AF or prevent its reinitiation. On the other hand, several studies incorporating ganglionated plexus mapping and ablation with PV-based ablation procedures for the treatment of AF have produced promising but variable results. Although modification of LA autonomic ganglia by epicardial or endocardial ablation has been proposed as an adjunctive procedure in association with PV-directed

ablation procedures for the treatment of AF, only limited data have been available on the long-term benefit of vagal denervation, and the effectiveness of LA ganglionated plexus ablation requires more evaluation. Because the ganglionated plexuses are predominantly located near the PV antra, regions that are typically targeted by the different AF ablation strategies, whether the clinical benefits of ablation in these regions are related to selective ganglionated plexus modification and parasympathetic denervation, as opposed to interference with other AF-related mechanisms, is not known. On the other hand, some type of atrial denervation is likely to be inadvertently achieved after PV-based ablation procedures, which can potentially underlie, at least in part, the efficacy of these procedures.⁷⁶ Approximately 10% of patients undergoing PV isolation have subacute (weeks to months) acceleration of the sinus rate (to 80 to 95 beats/min) following ablation, a finding suggesting at least some effect on ganglionated plexuses.

Given the limitations of high-frequency stimulation in identifying all neural cardiac elements, some investigators have proposed that expanded regional LA ablation at the anatomical sites of the LA ganglionated plexuses can promote a more homogeneous and complete autonomic atrial denervation and can potentially offer higher clinical efficacy as compared with ablation guided by high-frequency stimulation.⁷⁵

Ablation of Non-Pulmonary Vein Triggers

Rationale

Although the PVs are the major site of ectopic foci initiating AF, evidence has demonstrated the important role of non-PV ectopic beats initiating AF. Investigators have debated the frequency of the non-PV sources, with an incidence ranging from 3.2% to 47%; the incidence was found to be higher in chronic AF. The non-PV ectopic beats can arise from the SVC (most common, especially in female patients), LA posterior free wall (especially in patients with LA enlargement), crista terminalis, CS, ligament of Marshall, interatrial septum, or rarely, a persistent left SVC. Additionally, SVTs such as AVN reentrant tachycardia (AVNRT) and AV reentrant tachycardia (AVRT) can be identified in up to 4% in unselected patients referred for AF ablation and can serve as a triggering mechanism for AF (see Fig. 15-2).⁷⁹

Additionally, the presence of non-PV ectopic beats can play an important role in the recurrence of AF after PV isolation. Several investigators have reported focal AT originating from the LA after isolating all four PVs or circumferential LA ablation in up to 3% to 10% of patients. The locations of focal ATs were around the PV ostium, LA appendage, or LA free wall. Those findings support the concept that non-PV triggers actually exist before the AF ablation, and that they become the drivers of the AF or AT after part of the LA tissue is ablated or the LA-PV conduction is interrupted. Previous studies have also shown that wide-area circumferential LA ablation may be more effective than simple PV isolation, in part because some LA posterior free wall foci may be eliminated and/or isolated during circumferential ablation.

At the present time, most PV ablation procedures are performed anatomically by isolating all PV ostia. However, it is currently unclear whether an attempt should be made before and after PV isolation to observe the spontaneous or provoked ectopic beats initiating AF to evaluate for non-PV sources of this ectopy during initial and repeat ablation procedures.

Mapping of Non–Pulmonary Vein Triggers

PROVOCATION OF ECTOPY

The initial step is to locate the spontaneous onset of ectopic beats initiating AF in the baseline state or after infusion of isoproterenol (up to 4 to 8 $\mu\text{g}/\text{min}$ for 5 minutes). If spontaneous AF does not develop, intermittent atrial pacing (8 to 12 beats) with a CL of 200 to 300 milliseconds from the high RA or CS is used to facilitate spontaneous initiation of AF after a pause in the atrial pacing. If spontaneous AF does not occur, burst pacing from the high RA or CS is used to induce sustained AF. After an episode of pacing-induced AF is sustained for 5 to 10 minutes, external cardioversion is attempted to convert the AF to NSR and observe the spontaneous reinitiation of AF. A bolus of high-dose adenosine (24 to 84 mg) may also be used to provoke the spontaneous onset of AF.

The onset pattern of spontaneous AF is analyzed, and the earliest ectopic site is considered to be the initiating focus of AF. The method used to provoke spontaneous AF is repeated at least twice to ensure reproducibility.

LOCALIZATION OF ECTOPY

Mapping of endocardial atrial activation sequences from the high RA, HB, and CS catheters can predict the location of AF initiation foci. The difference in the time interval between the high RA and HB atrial activation obtained during sinus beats and PACs is a good method to identify whether the ectopic focus is from the RA or LA. When the difference in the time interval is less than 0 millisecond, the accuracy for discriminating RA from LA ectopy approximates 100%.

If the initiating focus of the AF is considered to be from the RA, a duodecapolar catheter is placed along the crista terminalis, so that it would reach to the top of the SVC. The polarity of the P wave of the ectopic beat in the inferior leads is a useful method to differentiate the location of the ectopic beats. Ectopy from the SVC and upper crista exhibits upright P waves in the inferior leads, whereas ectopy from the coronary sinus ostium (CS os) exhibits a negative P wave polarity in the inferior leads and ectopy from the midcrista exhibits biphasic P waves. During RA ectopy, the P wave can be biphasic or positive in lead V_1 , whereas it is predominantly positive in the case of right superior PV ectopy.

If the RA ectopy cannot be confirmed by the activation time, P wave morphology on the surface ECG, or intracardiac signals, transeptal access is obtained and two multipolar catheters are placed in the right superior PV and at the LA posterior wall simultaneously. Unusual ectopy from the RA septal region also requires biatrial mapping to confirm the location, especially in cases with a shorter activation time (less than 15 milliseconds) preceding

P wave onset or a monophasic, narrow, and positive P wave in lead V_1 during ectopy. Multielectrode basket catheter, balloon catheter (EnSite noncontact mapping), and 3-D electroanatomical mapping systems can be of value in localization of the origin of AF triggers, especially in patients with infrequent PACs.

Mapping and Ablation of the Ligament of Marshall

The ligament of Marshall is an epicardial vestigial fold that marks the location of the embryological left SVC; it contains the nerve, vein (vein of Marshall), and muscle tracts, and it encompasses portions of the embryonic sinus venosus and left cardinal vein, running between the left superior and left inferior PVs along the left side of the parietal pericardium. The ligament of Marshall leads to the earliest tributaries of the CS and the transition from a ligamentous structure to a vein occurs in the region between the left superior PV and base of the LA appendage. The proximal portions of the muscle tracts connect directly to the CS myocardial sleeves. The connecting point is the landmark that separates the great cardiac vein from the CS (the origin of the ligament of Marshall often corresponds to the location of the tip of a CS catheter advanced to the wedge position as far distally as possible in the CS). The distal portions of the muscle tracts extend upward into the PV region.

Studies demonstrated electrical activity within the ligament of Marshall, and the two terminal ends of this atrial tract can have insertions into the LA musculature and CS. Also, more recently, the ligament of Marshall was shown to have electrically active myocardial tissue capable of generating focal automatic activity and can potentially contribute to the development of AF. It seems that isoproterenol infusion is usually required to provoke ectopy or bursts of AF originating from the ligament of Marshall.

Several attributes of the ligament of Marshall have been proposed to explain its mechanistic role in AF. Multiple connections among the Marshall bundle, LA, and CS can potentially create paths for reentrant excitation, leading to more complex and rapid activations. In fact, electrograms recorded from the ligament of Marshall during AF often exhibit short CLs, high dominant frequency, and CFAEs. Furthermore, rich innervation of the ligament of Marshall, predominantly by sympathetic fibers at its PV junction and parasympathetic ganglia at its CS junction, has been observed.

The ligament of Marshall should be considered as a source of paroxysmal AF, especially in young patients with a history compatible with adrenergic AF. Additionally, whenever an ectopic beat is mapped to the region around the posterolateral mitral annulus or a left-sided PV ostium, an origin from the ligament of Marshall should be considered. The P wave morphology associated with vein of Marshall ectopic activity is characterized by an isoelectric P wave in leads I and aVL, positive in leads III, aVF, and V_2 to V_5 , and it is similar to that seen with ectopic beats arising from the left PVs. The P waves can be biphasic or negative in lead II.⁷⁹

MAPPING OF THE LIGAMENT OF MARSHALL

The ligament of Marshall can be mapped epicardially or endocardially. The endocardial approach involves cannulation of the CS (preferably via an internal jugular venous access) with a 7 Fr luminal decapolar CS catheter. A venogram of the CS is obtained in the RAO 30-degree view to visualize the vein of Marshall and its ostium inside the CS. A 7 Fr luminal CS catheter is then directly engaged into the ostium of the vein of Marshall, and a 1.4 Fr mapping catheter is inserted into the inner lumen of the CS catheter and advanced toward the vein of Marshall.⁷⁹

However, cannulation of the vein of Marshall is not always successful because of various anatomical and technical reasons. In patients whose vein of Marshall either is not visible on a CS venogram or is visible but cannot be cannulated, the percutaneous (subxiphoid) epicardial approach may result in successful mapping and ablation (Fig. 15-51). This latter approach has the advantage of free catheter movement and is not limited by the size of the

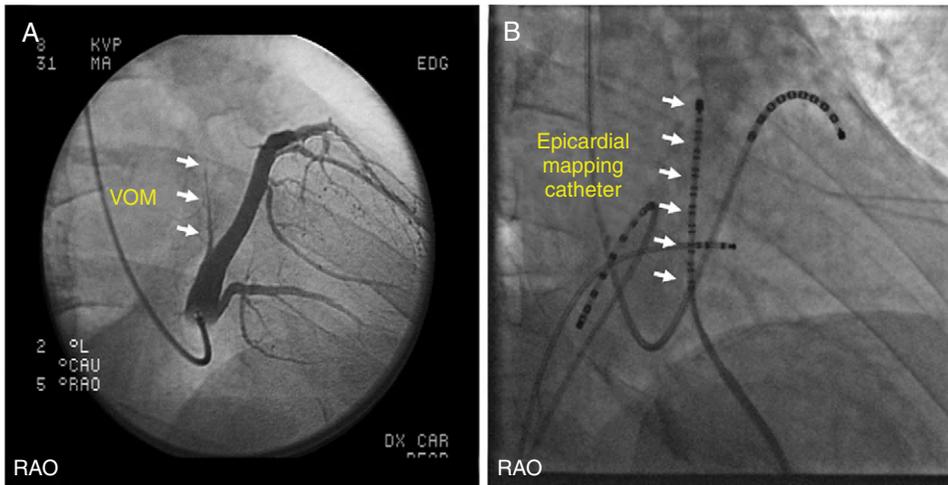

FIGURE 15-51 Two different approaches to mapping of the ligament of Marshall, right anterior oblique (RAO) views. **A**, Vein of Marshall (VOM) visualized by balloon occlusion coronary sinus (CS) angiogram. A 1.5 Fr mapping catheter can be inserted via the CS into this VOM for endocardial mapping. **B**, Epicardial mapping catheter inserted via a subxiphoid pericardial puncture. (From Hwang C, Fishbein MC, Chen P: How and when to ablate the ligament of Marshall, *Heart Rhythm* 3:1505, 2006.)

vein of Marshall. However, the endocardial approach is the best method for differentiating ligament of Marshall ectopy from other sources.

Certain observations and pacing maneuvers can indicate vein of Marshall activation, including (1) unexpected PV activation sequence during NSR, (2) unexpected PV activation sequence during low-output CS pacing, and (3) unexpectedly early exit from PV ectopy.⁷⁹

During NSR, PV activation spreads from proximal (PV ostium) to distal. If earlier activation is seen in the middle or distal PV electrodes than near the ostium, a bypass of the ostium with direct activation of the middle or distal PV is likely. One explanation is epicardial activation via the myocardial tissue within the vein of Marshall.

With high-output pacing in the mid-CS, there is capture of both the myocardium of the CS itself and the adjacent LA. With lower-output pacing, in most cases there will be capture of the myocardium of the CS only, with the LA activated from the CS through a CS-to-LA connection. In some patients, the CS-to-LA connection is small and discrete and, if the connection is not close to the site of pacing within the CS, there can be considerable delay between the CS myocardial electrograms and adjacent LA tissue electrograms (Fig. 15-52). This observation can be used to determine whether PV activation is occurring via the vein of Marshall. During low-output CS pacing, the LA is not directly activated. Because PV activation depends on LA activation, in most cases, when the LA electrogram is delayed, PV potentials also are delayed. When the time from stimulus to PV potential remains fixed regardless of whether direct capture of the LA occurs, PV activation is dependent only on CS muscular activation and a vein of Marshall connection very likely is present (see Fig. 15-52).

Because the ligament of Marshall can have multiple insertion sites in the LA posterior free wall or near the PV ostium, it can be difficult to differentiate ligament of Marshall ectopy from PV or LA posterior free wall ectopy. Ectopy or rapid tachycardias arising from the PV typically demonstrate an early near-field potential on catheters placed within the PV and a late far-field electrogram consistent with LA activation. Often, the exit delay (interval between the early near-field potential and late far-field potential) exceeds the entrance delay seen in sinus rhythm with activation from the LA to the PV. Despite this exit delay, however, the earliest atrial activation should be in the perivenous area. If earlier activation is noted in the CS rather than the perivenous LA, direct conduction from the PV to the CS through the musculature of an atrial epicardial vein, usually the vein of Marshall, is likely (Fig. 15-53).

Furthermore, the possibility of ligament of Marshall ectopy should be considered when the so-called triple potentials (a discrete sharp potential preceding the LA and PV potentials) are recorded around the PV ostium. Furthermore, in patients with ectopic beats from the ligament of Marshall, double potentials are

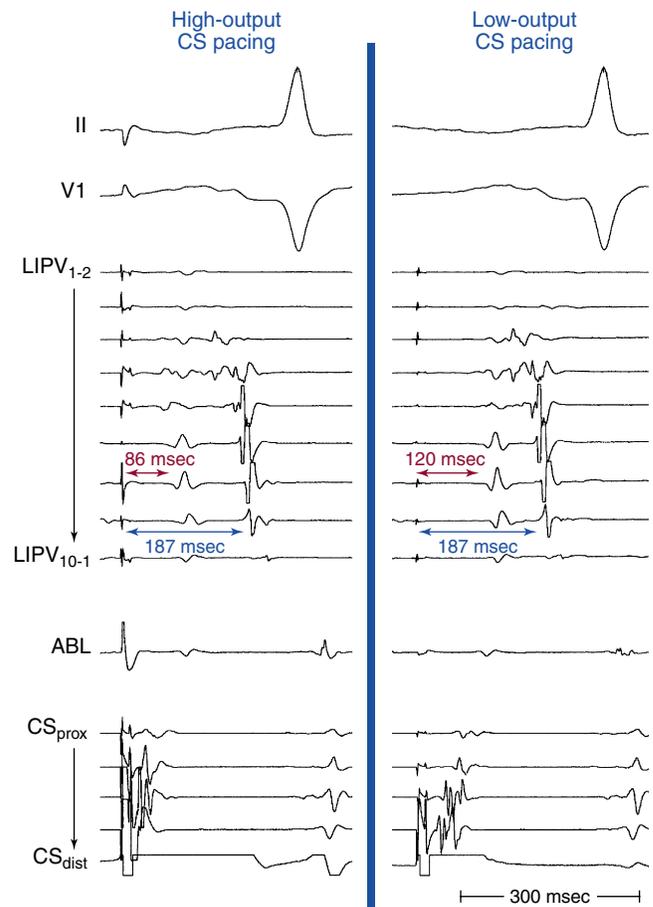

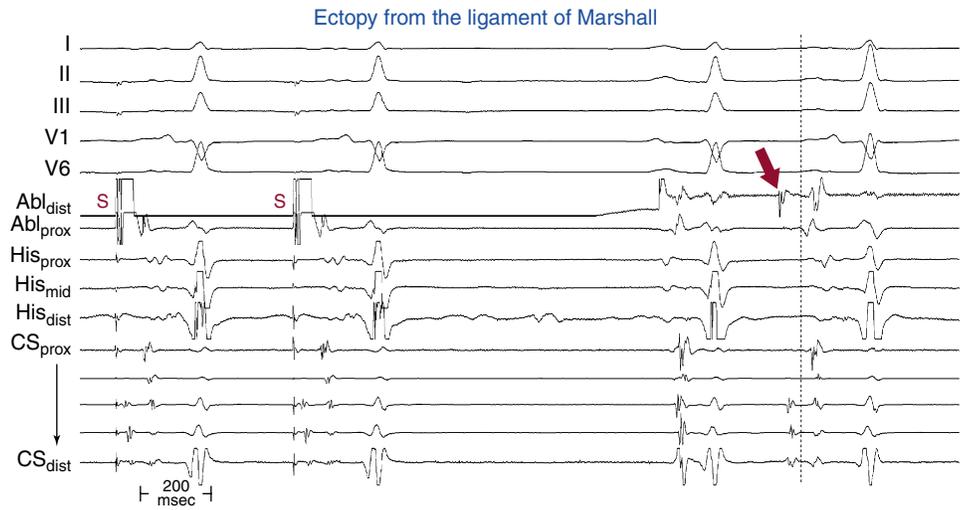

FIGURE 15-52 Identification of vein of Marshall activation using differential-output coronary sinus (CS) pacing. **Left panel**, During high-output CS pacing, both the left atrium (LA) and CS musculature are captured directly. **Right panel**, During low-output CS pacing, only the CS musculature is captured directly; the LA is activated from the CS through a CS to LA connection. In this case, the CS-LA connection is not close to the site of pacing within the CS; therefore, considerable delay is observed between the CS myocardial electrograms and the adjacent LA tissue electrograms. Despite the delay in LA activation (as reflected by the interval between the pacing artifact and the LA electrograms) during low-output versus high-output CS pacing, the timing of left inferior pulmonary vein (LIPV) activation remains constant (as reflected by the fixed interval between the pacing artifact and the PV potentials in both cases), thus indicating that PV activation is occurring via the vein of Marshall and is independent of LA activation. ABL = ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

FIGURE 15-53 Ectopy from the ligament of Marshall (LOM). The recordings are from a patient with atrial fibrillation caused by ectopy from the region of the LOM. **Right**, Sinus complex and premature atrial complex from the LOM with a very early potential recorded by the ablation catheter in this area. Note the same potential occurring in coronary sinus (CS) recordings. **Left**, Pace mapping replicates the atrial activation sequence during the ectopy complex. Abl_{dist} = distal ablation site; Abl_{prox} = proximal ablation site; CS_{dist} = distal coronary sinus; CS_{mid} = middle coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle.

present at the orifice of or inside the left PVs, and distal CS pacing can help differentiate the ligament of Marshall potential from the PV musculature potential. If the second deflection of double potentials is attributable to the activation of the ligament of Marshall, the interval between the CS os and the second deflection will be shorter during distal CS pacing compared with NSR. In contrast, if the second deflection is attributable to activation of the PV musculature, the interval between the CS os and the second deflection will be longer during distal CS pacing compared with NSR.

Finally, the persistence of ectopic triggers of AF consistent with origins from the left-sided PVs despite complete electrical isolation of those veins should alert the operator to the ligament of Marshall as the source of ectopy.⁷⁹

ABLATION OF THE LIGAMENT OF MARSHALL

Cannulation of the vein of Marshall and direct recording of the ligament of Marshall potentials from the vein of Marshall can be used as the anatomical targets for endocardial ablation and to confirm successful elimination of the ligament of Marshall potentials. Even when cannulation of the vein of Marshall is not feasible, obtaining a CS venogram to visualize the vein of Marshall can be used as an indirect method to trace the possible route of the ligament of Marshall to help guide ablation (see Fig. 15-51).⁷⁹

The site having the shortest distance from the LA endocardium to the ligament of Marshall is located at the inferior region of the left antrum, just under the left inferior PV ostium. RF energy application from the endocardium to this region eliminates ligament of Marshall potentials in more than 90% of the cases, as confirmed by the mapping catheter inside the vein of Marshall. The elimination of ligament of Marshall electrograms along the entire length of the ligament and the presence of exit block between the ligament of Marshall and the LA during pacing from multiple sites within the vein of Marshall help confirm successful ablation.⁷⁹

To simplify the procedure, a large-diameter (20 to 25 mm) ring catheter can be placed at the antrum of the left inferior PV to guide and then confirm simultaneous isolation of the antrum and ligament of Marshall. Complete isolation or disconnection of the entire left PV and antrum can be confirmed by pacing from the inside of the left PV. If PV potentials are dissociated from the LA potentials, these findings will confirm elimination of all connections to the LA, including the left PVs and ligament of Marshall.

Infrequently, endocardial ablation alone cannot eliminate all connecting fibers, as evidenced by the ability to still record ligament of Marshall potentials. In these situations, most of the remaining connections are located in the ridge between the anterior border of the left PVs and the posterior wall of the appendage. In some patients, the ridge can be as thick as 10 mm. Even using an

irrigated-tip catheter and a high-power setting, complete isolation still may not be possible. In these difficult cases, a combined endocardial and epicardial approach can be used to ablate ligament of Marshall ectopy initiating AF and is associated with a higher success rate. Cannulation of the vein of Marshall can be used to guide epicardial ablation sites.

Electrical Isolation of the Superior Vena Cava

RATIONALE

The proximal SVC contains cardiac muscle fibers connected to the RA, and atrial excitation can propagate into the SVC. SVC cardiomyocytes can acquire pacemaker activity, and enhanced automaticity and afterdepolarization play a role in the arrhythmogenic activity of SVC (Fig. 15-54). The SVC myocardial extension harbors most (up to 55%) non-PV triggers of AF (especially in female patients), and elimination of SVC triggers is associated with improved long-term maintenance of sinus rhythm after AF ablation. Of interest, a long SVC sleeve greater than 30 mm long and a large SVC potential greater than 1.0 mV were proposed in one report to indicate an SVC source of AF triggers.

Electrical isolation of SVC from the RA can be a better strategy than focal ablation of ectopy inside SVC. It obviates the need for detailed mapping of the exact origin of the ectopy focus, as well as the need for RF ablation inside the SVC, which may carry the risk of SVC stenosis. Nevertheless, injury to the sinus node and phrenic nerve remains a concern. The value of empirical isolation of the SVC as an adjunctive strategy for AF ablation needs further evaluation.¹⁴²

MAPPING OF SUPERIOR VENA CAVA ECTOPY

To localize the accurate site of SVC ectopy, 3-D electroanatomical, ring catheter, or basket catheter mapping can be useful (Fig. 15-55). During NSR or atrial pacing, the intracardiac recordings from inside the lower level of the SVC (near the SVC-RA junction) frequently exhibit a blunted far-field atrial electrogram followed by a sharp and discrete SVC potential. At a more cranial level of the SVC, the SVC potential precedes the atrial electrogram during the SVC ectopic beat (Fig. 15-56). Furthermore, the intracardiac recordings in the higher SVC frequently exhibit double potentials. The first potential represents the SVC potential, and the second potential represents the far-field right superior PV potential. Simultaneous recordings from the right superior PV also exhibit a double potential during SVC ectopy. The recording from the right superior PV shows that the first potential is a far-field potential from the SVC, and the second potential is true activation of the right superior PV.

Focal AT originating from the SVC

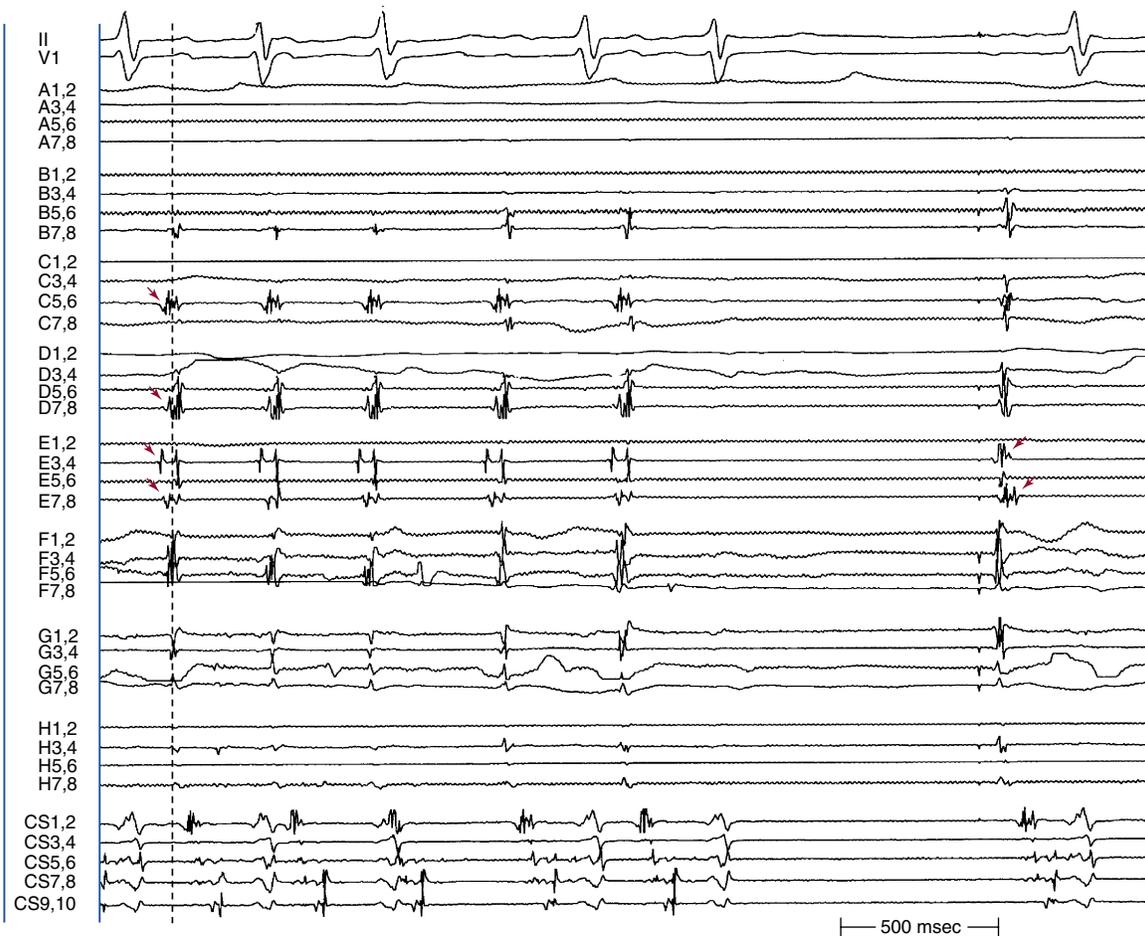

FIGURE 15-54 Focal atrial tachycardia (AT) originating from the superior vena cava (SVC). The basket catheter is positioned in the SVC–right atrial (RA) junction. Bipolar recordings are obtained from the eight electrodes (1-2, 3-4, 5-6, 7-8) on each of the eight splines (A through H) of the basket catheter. During AT (at left), SVC potentials (arrowheads) precede RA potentials and also precede P wave onset on the surface ECG (dashed line). During RA pacing (at right), SVC potentials overlap with or follow RA potentials.

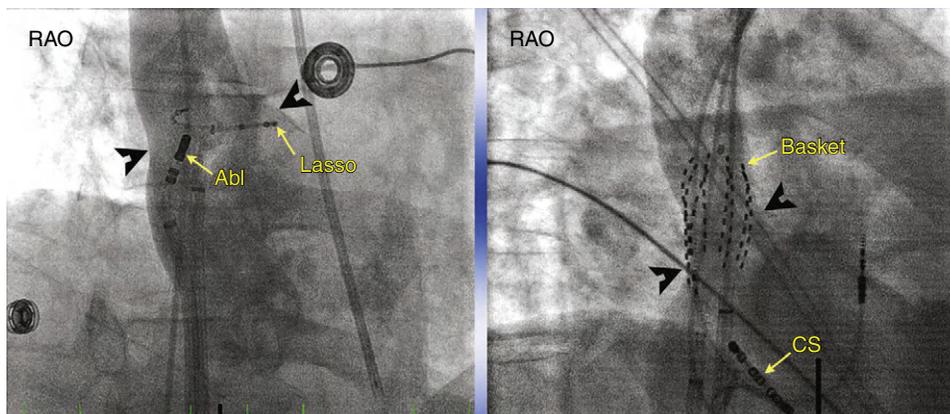

FIGURE 15-55 Superior vena cava (SVC) angiogram. Fluoroscopic right anterior oblique (RAO) views of SVC angiography with the ring (Lasso) catheter (at left) and basket catheter (at right) positioned at the SVC–right atrial (RA) junction (black arrowheads). Note that the size of the ring catheter is usually smaller than the circumference of the SVC, and repositioning of the ring catheter is typically required for circumferential mapping and electrical isolation of the SVC. Abl = ablation site; CS = coronary sinus.

ABLATION TECHNIQUE

The SVC is isolated using the same technique and endpoint as used for segmental ostial PV isolation. The SVC-RA junction (defined as the point below which the cylindrical SVC flares into the RA) can be confirmed by SVC venography (see Fig. 15-55), ICE (Fig. 15-57), or by the electrical signals. SVC venography can be performed by placing a pigtail catheter at the top of the SVC and using a contrast injector (a total of 40 mL of contrast medium over 2 seconds) and biplane fluoroscopic views (RAO, 30 degrees; LAO 60 degrees). The

overlapping of the anterior wall of the SVC and RA appendage is near the level of the SVC-RA junction. The ring catheter is placed just above the RA-SVC junction at the level of the lower border of the pulmonary artery, as seen by ICE (see Fig. 15-57). The size of the ring catheter is usually smaller than the circumference of the SVC, and repositioning of the ring catheter is typically required for circumferential mapping and electrical isolation of the SVC (see Fig. 15-55).

Compared with PV isolation, it is easier to interrupt the conduction between the RA and the SVC. Most patients exhibit only two

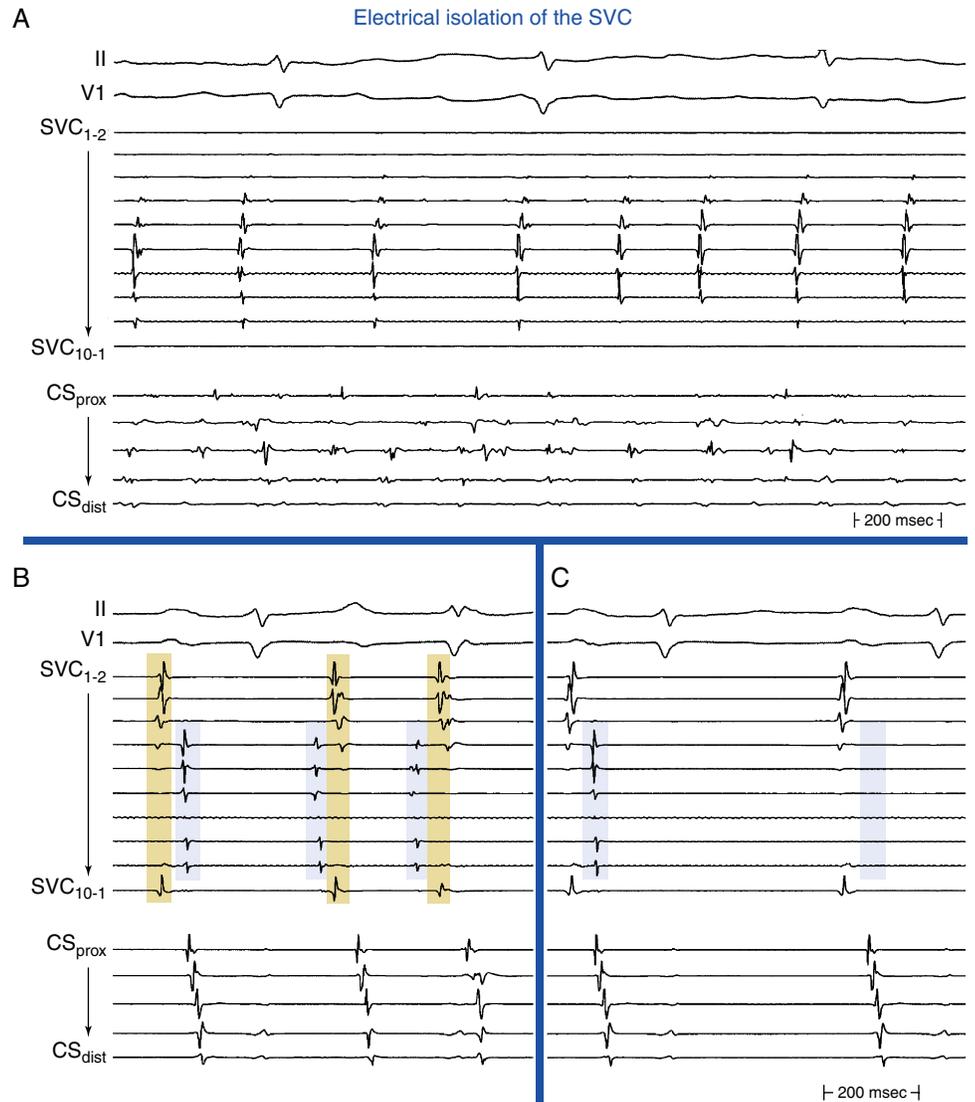

FIGURE 15-56 Electrical isolation of the superior vena cava (SVC). This recording was obtained from a ring catheter positioned at the SVC–right atrium (RA) junction during electrical isolation of the SVC. **A**, During atrial fibrillation, SVC potentials are observed at a cycle length (CL) longer than the atrial CL observed in the coronary sinus (CS) recordings. **B**, The first complex is normal sinus, during which SVC potentials (blue shading) are observed following RA potentials (orange shading). The second and third complexes are premature atrial complexes originating from the SVC, during which SVC potentials precede RA potentials. **C**, Radiofrequency energy application at a single site results in the disappearance of SVC potentials (at right) and complete SVC entrance block. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

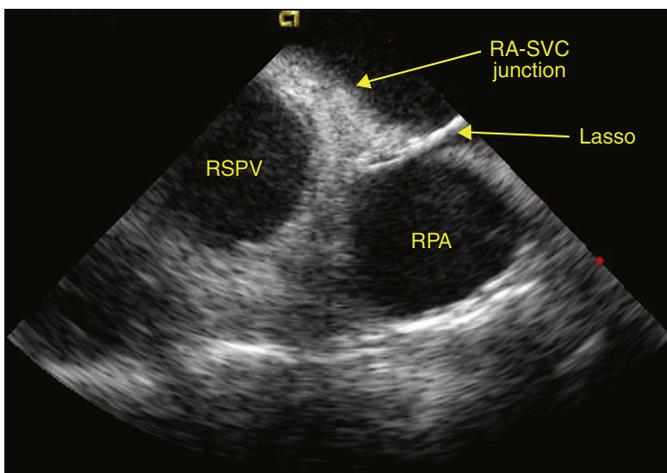

FIGURE 15-57 Electrical isolation of the superior vena cava (SVC). The intracardiac echocardiography catheter positioned in the high right atrium (RA) is used to guide positioning of the ring catheter at the RA-SVC junction (at the level of the lower border of the right pulmonary artery [RPA]). RSPV = right superior pulmonary vein.

breakthrough sites. A ring or basket catheter can be used for mapping SVC potentials (see Fig. 15-56). The SVC-RA junction exhibits an eccentric, not a round, shape; thus, the basket or ring catheter may not contact the wall well. Therefore, one needs to manipulate the catheter to contact the whole SVC-RA circumference to confirm the presence or disappearance of SVC potentials. The circumference of the SVC-RA junction is mapped to determine the region of earliest activation during NSR characterized by an initial negative rapid deflection or fusion, or both, of the major atrial electrogram and the SVC muscular potential. Those regions are then targeted by RF ablation.

RF energy should be applied at the level approximately 5 mm below the entire circumference of the SVC-RA junction. Although application of RF energy inside the SVC makes it easier to interrupt the SVC-RA myocardial sleeve, it carries a higher risk of SVC narrowing or stenosis. RF energy is set at a power setting of 45 to 55 W, targeting a temperature of 50°C to 55°C and applied for a duration of 20 to 40 seconds. Acceleration of the sinus rate during RF delivery is a sign that heat injury to the sinus node is occurring and should prompt discontinuation of RF application.

The phrenic nerve often courses posterolaterally at the level of the SVC-RA junction. Pacing prior to ablation along the circumference of this vein at an output between 5 and 10 mA is mandatory before energy delivery. The patient should not receive a paralytic agent if general anesthesia is to be used, and both mechanical palpation for diaphragmatic stimulation and fluoroscopy of an

Electrical isolation of the CS

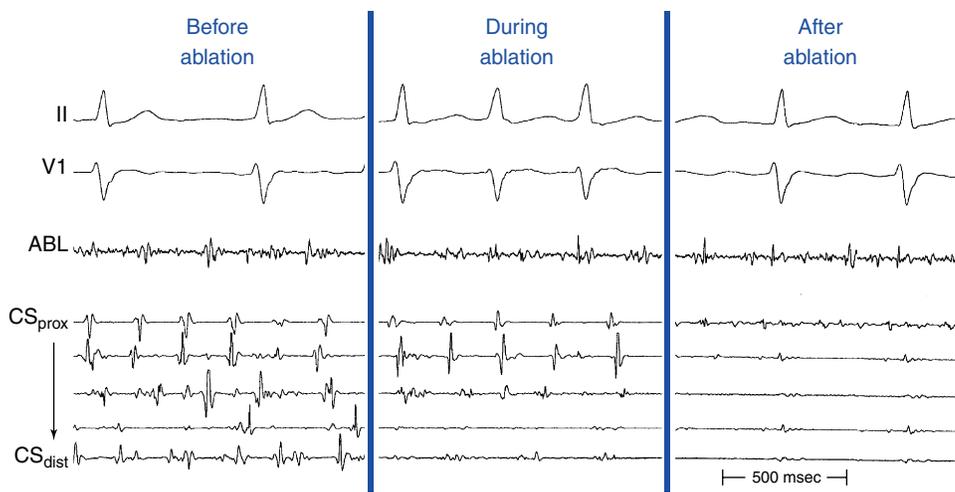

FIGURE 15-58 Electrical isolation of the coronary sinus (CS). Intracardiac recordings illustrating CS electrograms during atrial fibrillation before, during, and after successful electrical isolation of the CS. Following complete electrical isolation, the local sharp potentials within the CS are eliminated. ABL = ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus.

entire respiratory cycle should be performed during pacing so that the absence of phrenic nerve stimulation can be determined with certainty. The maneuver should be repeated at each ablation site, and during ablation the catheter should not be moved to sites more than a few millimeters away. If the patient is in AF during the attempted isolation of the SVC, the pacing maneuver still should be performed, but with asynchronous pacing from the ablation catheter.

Electrical Isolation of the Coronary Sinus

RATIONALE

The muscular tissue in the wall of the CS appears to be electrophysiologically active, capable of spontaneous depolarization and mediating slow conduction, which can potentially contribute to initiation or perpetuation of AF. The venous wall of the CS is surrounded by a continuous sleeve of atrial myocardium that extends for 25 to 51 mm from the CS os. This muscle is continuous with the RA myocardium proximally, but it is usually separated from the LA by adipose tissue. This separation can be bridged by muscular strands producing electrical continuity between the CS musculature and the LA. These connections are targeted by RF ablation for electrical isolation of the CS from the LA.¹⁴³

ABLATION TECHNIQUE

Isolation of the CS is commenced along the endocardial aspect and completed from within the CS, as required. The ablation catheter is dragged along the endocardium of the inferior LA after looping the catheter to position it parallel to the CS catheter. After achieving a 360-degree loop in the LA, the catheter is gradually withdrawn initially along the septal area anterior to the right PVs and ablation commenced at the inferior LA along the posterior mitral annulus from a site adjacent to the CS os progressing to the lateral LA (at the 4-o'clock position in the LAO projection). The endpoint is elimination of local endocardial electrograms bordering the mitral isthmus in an attempt to eliminate or prolong the CL of sharp potentials present within the CS (Fig. 15-58). Ablation within the CS is started distally (at the 4-o'clock position in the LAO projection) and pursued along the CS up to the ostium by targeting local sharp potentials at individual sites or as a continuous drag. During AF, ablation within the CS is performed at all sites showing persistent or intermittent rapid activity, either continuous electrograms or discrete electrograms displaying CLs shorter than the CL measured in the LA appendage. Finally, additional RF applications are continued around the CS orifice from the RA. CS disconnection

is confirmed by the dissociation or abolition of sharp potentials in its first 3 cm.

Electrical Isolation of the Left Atrial Appendage

RATIONALE

Following extensive LA ablation, some patients have focal or reentrant tachycardias arising in the region of the LA appendage (base or more deeply in the appendage). Some operators have advocated isolation of the appendage as a means of eliminating these arrhythmias without entering the deeper part of the appendage, which typically turns back medially toward the midline (limiting catheter reach) and where muscle is very thin. The appendage is occasionally inadvertently isolated during roof or mitral isthmus line ablation.

ABLATION TECHNIQUE

The ring catheter may be carefully situated in the mouth of the appendage, with ablation targeting earliest sites of propagation into or out of the appendage (similar to selective ostial isolation of PVs). Alternatively, anatomically based ablation around the ostium or the appendage can be performed, guided by a mapping system, because much of the line will have already been made with prior ablation.

Outcome

The success rate of AF elimination varies, depending on the site of ectopy. A higher success rate is noted when the triggering foci are located in the RA, including the SVC and crista terminalis. The LA posterior free wall has a higher recurrence rate because of anatomical limitations and multiple ectopic foci. The success rate of curing ligament of Marshall ectopy initiating AF is low when ablation is limited only to the endocardial area. A combined endocardial and epicardial approach to ablate ligament of Marshall ectopy has a higher success rate (60% to 70%). Isolation of the LA appendage, resulting in an akinetic or competitively contracting structure (if it retains an automatic rhythm), has not been associated with adverse hemodynamic outcomes although data are limited.

Non-PV foci triggering AF appear to be the mechanism of recurrences of AF after PV isolation procedures in only a small proportion (approximately 10%) of patients undergoing repeat ablation. Given the fact that inducing those triggers is usually challenging and time consuming, it is unclear whether to incorporate a routine search for these triggers into an initial ablation procedure.

Outcome of Catheter Ablation of Atrial Fibrillation

Success Rates

There are several hypothetical benefits of ablation of AF and restoration of sinus rhythm: improvement in quality of life, reduction of stroke risk, reduction in heart failure risk, and improved survival. Several randomized trials demonstrated the benefit of ablation in the reduction of the burden of AF and improvement in quality of life. However, no studies demonstrated that these findings translate into reduction in overall mortality. Therefore, the primary justification for an AF ablation procedure at this time is the presence of symptomatic AF.

Interestingly, the quality of life improvement after AF ablation is not entirely dependent on efficacy of the procedure. In fact, up to 65% of patients with documented recurrences of AF after ablation exhibit improvement of symptoms during the AF episodes and report significant improvement of the physical component of the quality of life.^{144,145} Reduction of symptomatic episodes after ablation may arise from a placebo effect or autonomic denervation.

With time, operator experience, and greater consistency in the technique, AF ablation has proved itself to be a very effective treatment for symptomatic AF. Reportedly, current techniques of RF catheter ablation can achieve a 60% to 90% improvement in selected patients with medically refractory AF, with similar success rates being reported by several different groups. Although success rates are not perfect, they are two- to threefold better than anything achievable by antiarrhythmic medications. Furthermore, successful control of AF by ablation seems to be durable, given the long follow-up (almost 3 years) reported by some groups and the observation that most recurrences tend to occur early in the follow-up period, and they only infrequently occur late after ablation.

Variations in success rates for similar procedural techniques for catheter ablation of AF reported by different centers can potentially arise from several factors, including variation in study design, different patient population characteristics (age, cardiac disease, LA size), different types of AF (paroxysmal versus persistent versus longstanding), differences in follow-up duration and strategy, and differences in definition of success (complete freedom from all atrial arrhythmias versus AF versus symptomatic arrhythmias, with or without antiarrhythmic agents). Also, the efficacy of AF ablation can be largely influenced by the operator's experience and the volume of ablations.¹³¹

Consideration also needs to be given to the adoption of a subclassification of AF based on clinical criteria if the magnitude of the therapeutic impact of catheter ablation on patients' quality of life is to be meaningfully assessed. For a patient whose condition is transformed from a predominant pattern of highly symptomatic persistent AF, with occasional spontaneous terminations before ablation, to a pattern of asymptomatic or symptomatic short-lived episodes of transient AF (lasting a few minutes) after ablation, the procedure could be deemed clinically successful. In contrast, a binary outcome analysis limited to whether a patient has any recurrence of AF at any time or is free of AF recurrence would classify the ablation as a failed procedure, and any clinical benefit to the patient would not be recognized.

ABLATION OF PAROXYSMAL ATRIAL FIBRILLATION. In the setting of paroxysmal AF, RF ablation of AF (generally PV isolation with little to no adjuvant ablation) was found superior to antiarrhythmic drug therapy in several studies, with a success rate of approximately 77% over 12 months. In many of these studies, a single repeat ablation procedure was required in 10% to 25% of patients. Circumferential antral PV isolation appears more effective than segmental ostial PV isolation. The role of adjunctive substrate-based ablation techniques (linear ablation, CFAE ablation, and vagal denervation) is controversial, but these approaches appear to have little value, if any, over antral PV isolation alone in patients with paroxysmal AF.^{78,109,110}

ABLATION OF NONPAROXYSMAL ATRIAL FIBRILLATION. In patients with persistent AF, segmental ostial PV isolation is inadequate for arrhythmia control, with single-procedure, drug-free success rates of approximately 22%, and multiple-procedure success rates lower than 55%. In contrast, circumferential antral PV isolation offers better success rates (32% to 44% after a single procedure and 59% to 77% after multiple procedures). Several studies found an incremental benefit of adding LA linear ablation (LA roof line and mitral isthmus ablation) to antral PV isolation, especially in patients with longstanding AF. The data are not convincing regarding the additive benefit of posterior wall isolation. Importantly, linear LA ablation can be proarrhythmic, increasing the risk of LA macroreentrant ATs, especially if the presence of bidirectional block across the ablation lines has not been verified. The role of CFAE ablation is more controversial. Although some studies achieved higher success rates with PV isolation when combined to CFAE ablation, other studies showed no incremental benefit. CFAE ablation as a stand-alone strategy appears inadequate for successful treatment of AF (pooled success rate of only 26%). Purely anatomical techniques of PV ablation (with or without adjunctive CFAE ablation) have been found to be inferior to techniques that rigorously confirm complete PV electrical isolation (single procedure success rate of 27% versus 57% at 2 years of follow-up). Importantly, regardless of the ablation strategy, multiple procedures appear to be required in nearly half of patients with persistent AF. Prospective, randomized trials comparing ablative strategies are much needed.^{74,78,146,147}

A stepwise ablation strategy has been proposed for patients with persistent AF, whereby antral PV isolation is followed by CFAE ablation and linear ablation until AF termination. This approach results in a single-procedure success rate of 25% to 62%. More than half of all patients undergo at least one repeat ablation procedure, and when all are complete the success rate is approximately 70% to 88%.^{78,131,148}

Recurrence of Atrial Fibrillation

Recurrences of AF are common and can be observed in more than 50% of patients within the first 3 months following catheter ablation, regardless of the ablation technique. The incidence of recurrent AF seems to be higher in patients with persistent AF (47%) as compared with paroxysmal AF (33%), in patients older than 65 years (48%) versus patients younger than 65 years (28%), and in patients with structural heart disease (47% to 74%) versus patients without structural heart disease (29% to 50%).³ Less consistent predictors of AF recurrence include the presence of comorbidities such as hypertension, sleep apnea, and diabetes. Gender and obesity do not appear to predict AF recurrence.^{105,149,150}

The incidence of AF recurrences increases with increasing follow-up duration and intensity. Considering the intermittent nature of the arrhythmia and the inconsistency of symptoms, the exclusive reliance on patient reporting of symptomatic recurrences results in an underestimation of recurrence of the arrhythmia. To obtain reliable information about the success of AF ablation, repeated ambulatory monitoring with automatic detection of arrhythmias is necessary.¹⁵¹

Most recurrences occur within the first 12 months, and most patients who remain free of AF at 1 year after ablation are likely to remain in NSR at long-term follow-up. Among patients who develop recurrent AF, approximately 76% do so within the first 6 months after ablation, 86% by 12 months, and 92% by 24 months. Although there continues to be an ongoing risk of recurrent AF, new recurrences of AF are infrequent beyond 12 to 24 months following ablation.¹⁵²

EARLY RECURRENCES. Early (within 3 months after ablation) AF recurrences peak within the first few weeks and then gradually decrease to lower levels in the period of 3 months after ablation. The mechanism of early postablation AF is unclear but seems to be different from that of the patient's preablation arrhythmia. Several mechanisms have been implicated, including local inflammation

in response to RF thermal injury or pericarditis, systemic inflammation, heightened adrenergic tone, changes in medicines, fluid and electrolyte imbalances, and a delayed therapeutic effect of RF ablation likely attributable to lesion growth or maturation. Additionally, failure to identify and modify AF triggers (e.g., failure to isolate the PVs) can manifest with early AF recurrences.^{153,154}

LATE RECURRENCES. Beyond the early postablation period, recurrent AF following ostial segmental or circumferential antral PV isolation is predominantly caused by PV ectopy originating from previously isolated PVs rather than non-PV foci. Recurrence of PV-LA conduction is almost universal (more than 80%), and reisolation of the PVs is recommended in these patients. However, additional linear LA ablation, substrate modification, or targeting non-PV foci should also be considered. Additionally, a significant subset of recurrences can be iatrogenic, resulting from macroreentry secondary to gaps in ablation lines or tissue recovery, or both.¹⁵⁵

VERY LATE RECURRENCES. The incidence of very late AF recurrences after long-lasting (more than 12 months) arrhythmia-free intervals following catheter ablation is approximately 4% to 10%. These recurrences appear still to be triggered by foci from reconnected PVs in most cases; however, non-PV triggers can play a more dominant role in AF initiation in this setting. The insidious and progressive arrhythmogenic substrate formation during a period of apparent AF elimination is also a likely cause. Most studies have reported that patients in whom an initial attempt at ablation fails and who undergo a repeat ablation procedure demonstrate recurrent conduction in previously isolated PVs, rather than new arrhythmogenic foci from nontargeted PVs or outside the PVs. In patients with AF caused by reconnection from the PVs, reisolation of the PV is frequently sufficient. Other patients may require targeting non-PV triggers or ablation strategies directed at the AF substrate, including additional linear ablation lesions or ablation of CFAEs.^{105,155}

Late recurrences of AF after initial arrhythmia-free intervals argue against AF ablation as a curative procedure and also suggest that a decision regarding discontinuation of anticoagulation after AF ablation should be based on the stroke risk stratification rather than the apparent efficacy of the AF ablation procedure.¹⁴⁷

MANAGEMENT OF RECURRENT ATRIAL FIBRILLATION. As noted previously, administration of antiarrhythmic drug therapy to patients who undergo catheter ablation for AF can decrease early recurrence of atrial arrhythmias. However, the long-term risk of AF recurrence does not seem to be affected by early, prophylactic, short-term use of antiarrhythmic drugs.⁸¹ Nonetheless, because early recurrences of AF are common and do not necessarily predict long-term recurrences, some operators choose to treat all patients with suppressive antiarrhythmic drugs during the first 1 to 3 months following ablation, a strategy that can potentially help decrease morbidity related to symptomatic arrhythmia episodes and the need for cardioversion or hospitalization. Typically, a class IC agent, sotalol, dofetilide, or amiodarone, is used. In patients discharged with antiarrhythmic drug therapy, such therapy is discontinued if no recurrence of AF is observed after 1 to 3 months.

In patients discharged without antiarrhythmic drug therapy who develop paroxysmal episodes of AF, antiarrhythmic drug therapy is initiated unless the patient is satisfied with the extent of symptomatic improvement. Catheter ablation of AF can be partially effective and allow a patient with AF that was previously refractory to antiarrhythmic drug therapy to become responsive to drugs. Therefore, if AF recurs following discontinuation of antiarrhythmic medications, it is common practice to reinstate the antiarrhythmic drug. For persistent AF, the early restoration of sinus rhythm can improve the likelihood of long-term maintenance of sinus rhythm, regardless of when the arrhythmia first recurs after the ablation procedure.¹⁵⁴

Although early recurrence of AF carries an independent risk for ablation failure, its occurrence should not prompt immediate reablation attempts because many patients experiencing recurrences within the first months after ablation will not have any further

arrhythmias during long-term follow-up. Repeat ablation procedures should be deferred for at least 3 months following the initial procedure, except in patients with poorly tolerated atrial arrhythmias refractory to medical therapy.³ Many patients with satisfactory control of AF with drugs prefer to continue antiarrhythmic drug therapy rather than undergo a repeat ablation procedure, in which case drug therapy is an acceptable long-term management strategy. However, in other patients it is desirable to eliminate all arrhythmias and possibly eliminate antiarrhythmic drug therapy; hence, repeat ablation may be considered in the setting of AF recurrence following the initial procedure. In general, recurrences of AF or AT after an initial AF ablation procedure lead to a reablation procedure in 20% to 40% of patients.

Atrial Tachycardia and Flutter Following Ablation of Atrial Fibrillation

LA tachycardia or flutter is a known complication of surgical and catheter-based therapies of AF. Originally reported in association with LA scar following mitral valve or maze surgical procedures, several reports demonstrated focal and macroreentrant ATs occurring after linear LA ablation and circumferential and segmental PV isolation, with an incidence ranging between 2% and 50%. The incidence seems to be lower following segmental ostial PV isolation than circumferential PV isolation and much higher following circumferential or linear LA ablation (more than 30%). Targeting CFAEs without linear lesions or PV isolation is associated with a moderate risk (8.3%) of postablation ATs. Following stepwise approaches of catheter ablation incorporating extensive lesions in the LA and RA to terminate persistent AF, ATs can be observed in more than 50% of patients.^{156,157} Although typical AFL should be considered in the differential diagnosis of regular tachycardias (even in the presence of atypical ECG patterns) observed following AF ablation, most of these arrhythmias arise from the LA and can be focal or macroreentrant.¹⁵⁸

LA tachycardias tend to occur at variable time intervals after AF ablation procedures. AT (macroreentrant or focal) can develop in the course of the ablation procedure or up to 1 year after the procedure, but the most common timing appears to be 1 to 2 months after ablation.^{159,160} This time course suggests that healing of ablation lines likely contributes to the substrate for atrial reentry. The occurrence of ATs early after ablation is common and potentially, but not necessarily, predicts later recurrences of both AT and AF.^{159,160} These tachycardias can be problematic because they frequently are incessant and are associated with rapid ventricular rates, and they are more likely to require electrical cardioversion when compared with the episodes of AF prior to ablation.

The three predominant catheter-based techniques for AF ablation appear to be associated with different rates and types of post-procedure ATs. Segmental ostial PV isolation is associated with a lower incidence of atrial tachyarrhythmias (less than 5%). When they do occur, these arrhythmias tend to be focal ATs, often originating from ostial segments of reconnected PVs. Reisolation of the PV and ablation of non-PV foci are usually sufficient to treat this proarrhythmia. Macroreentrant ATs (LA flutters) have been reported after segmental PV isolation, but this situation appears to be significantly less common. Most reentrant circuits use the ablated zone as a central obstacle, resulting in perimitral or peri-PV reentry, with the latter more prevalent in patients with larger atria.

Circumferential antral PV isolation has also been complicated by LA tachyarrhythmias, both focal and macroreentrant, and PV-LA conduction recovery is frequently a critical element in these arrhythmias. The area of recovery within an ablated region of the antrum can potentially create a region of slow conduction and the substrate for reentry (Fig. 15-59). When this area is a critical limb of the macroreentry circuit, reisolation of the PVs by ablation within the antrum terminates the tachycardia. In some cases, it is also possible that the recovered PV conduction allows PV triggers to induce a tachycardia that does not involve the PV antra. These patients also benefit from PV reisolation and elimination of PV triggers.

Macroreentrant AT after AF ablation

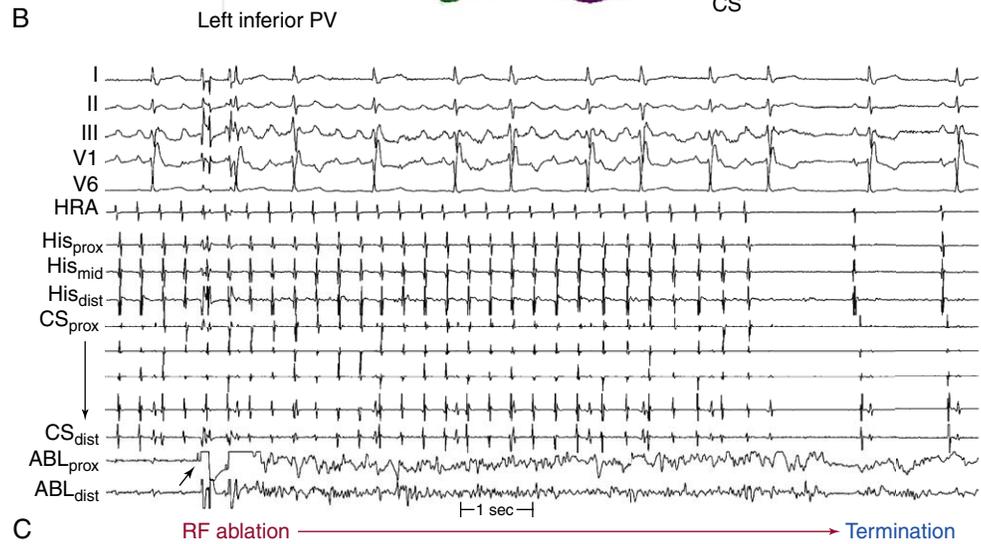

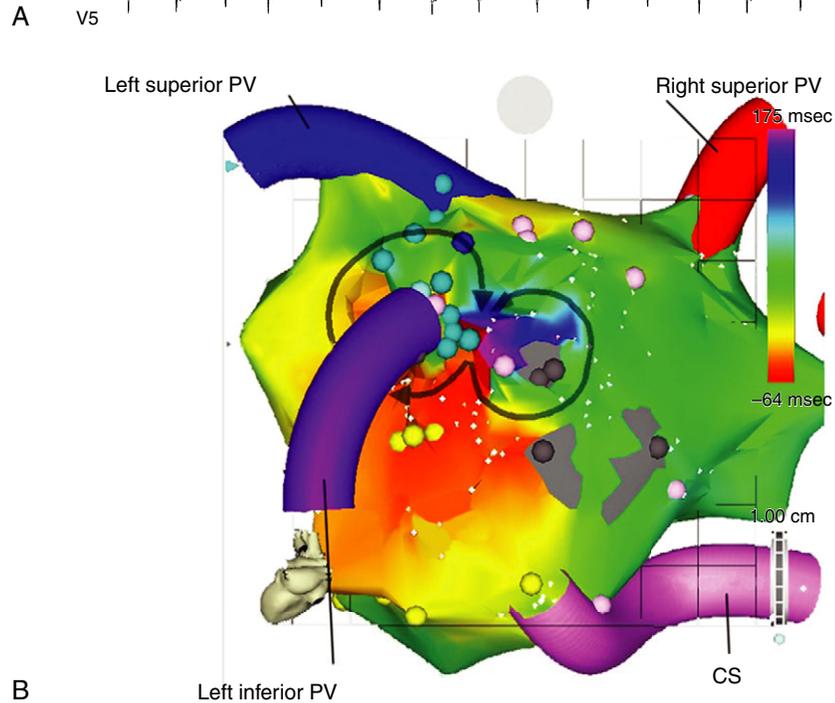

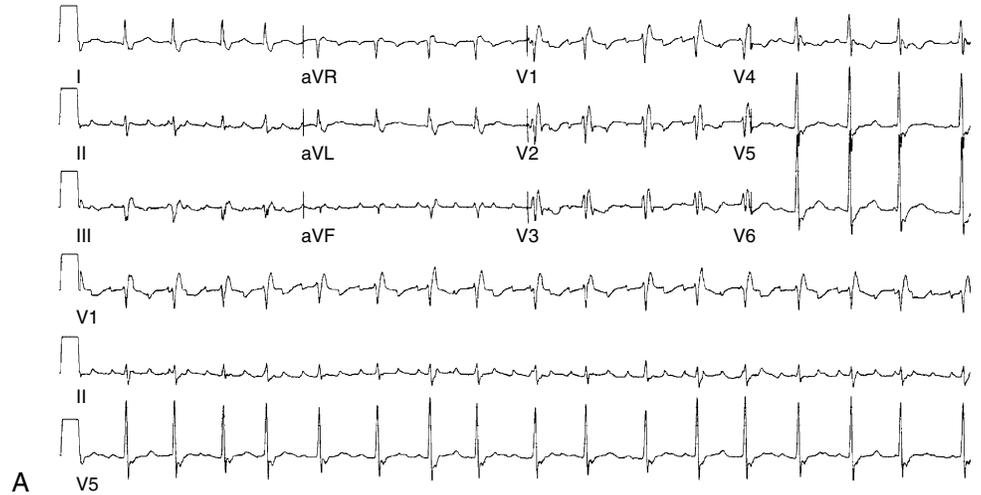

FIGURE 15-59 Macroreentrant atrial tachycardia (AT) after atrial fibrillation ablation. **A**, ECG of incessant AT occurring months following circumferential antral pulmonary vein (PV) isolation. **B**, Electroanatomical activation map (posterolateral view) of the same AT. Figure-of-8 reentry is seen involving the orifice of the left inferior PV and scar tissue (gray patches) resulting from the prior ablation. **C**, Intracardiac recordings during the AT. A single radiofrequency application at the site of the diastolic potential terminates the AT within a few seconds after onset of power delivery. Abl_{dist} = distal ablation site; Abl_{mid} = middle ablation site; Abl_{prox} = proximal ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle.

Wide-area circumferential LA ablation is frequently complicated by LA macroreentrant ATs. Most of those ATs are related to gaps in prior ablation lines, a finding that implies that most postablation ATs are avoidable, either by limiting the amount of linear ablation and/or by confirming complete conduction block across linear lesions.¹⁶¹ Not infrequently, multiple (three to four) different tachycardias occur in individual patients. The long linear lesions required in this approach to prevent AF also create new fixed obstacles to propagation, adjacent areas of block, and slow conduction, and eventual discontinuities represent ideal substrates for large reentrant circuits. Perimitral macroreentrant AT traversing the mitral isthmus is the most common, accounting for approximately 40% of macroreentrant ATs, and macroreentrant circuits traversing the LA roof account for approximately 20%. Less common sites of macroreentry involve the LA septum, the cavotricuspid isthmus, and the base of the LA appendage.¹⁵⁷ Focal ATs also have been reported following circumferential LA ablation, but macroreentrant ATs are much more common.

Modification of the original circumferential LA ablation technique has involved the addition of linear ablation connecting the superior PVs (roof line) and connecting the left inferior ablation line to the mitral annulus (mitral isthmus line). Whereas some studies demonstrated a reduction in the incidence of postprocedure LA tachycardias, others actually raised concern that the addition of linear lesions, if incomplete, could lead to an increased rather than decreased incidence of this problem. As noted, even when complete conduction block across the linear lesions is achieved, the ablation lines can potentially promote reentry by providing conduction obstacles and protected isthmuses with adjacent anatomical structures in the LA.¹¹⁰ Therefore, these additional ablation lines can actually contribute to, rather than prevent, macroreentry, and further studies are needed to define their role in the ablation strategy.¹⁶²

Importantly, LA macroreentry can be induced in a large percentage (38%) of patients immediately after circumferential LA ablation for AF; however, such inducibility does not seem to predict those patients who subsequently develop clinical episodes of LA tachycardias. Also, the lack of inducibility of such arrhythmias after ablation is not a good predictor of long-term clinical success. Therefore, mapping and ablation of LA macroreentry induced during catheter ablation for AF do not seem necessary.

MANAGEMENT OF ATRIAL TACHYCARDIAS FOLLOWING ABLATION OF ATRIAL FIBRILLATION. There is currently no well-defined standard treatment strategy for ATs following AF ablation procedures, and treatment should be tailored to the potential arrhythmia mechanism. It is important to recognize that many of these arrhythmias are self-limited and resolve spontaneously in up to two-thirds of patients within the first 3 to 6 months of follow-up. Therefore, efforts should be focused at suppressing these arrhythmias with antiarrhythmic medications or controlling the ventricular response with AVN blocking drugs. Despite the often more severe symptoms associated with these arrhythmias, ablation for LA macroreentrant ATs should be postponed for approximately 3 to 4 months after diagnosis.³

Understanding the initial lesion set is critical before embarking on AT ablation. For focal ATs following PV isolation procedures, most of the foci are located in a PV or in the antrum of a PV, and reisolation of all reconnected PVs appears to be sufficient in most cases. The septal aspect of ablation lines encircling the right PVs and the area anterior to the left superior PV are particularly vulnerable to recovery of conduction after circumferential PV isolation, thus predisposing patients to the development of LA tachycardia. Particular attention should be paid at these sites to ensure continuous transmural lesions. If the PVs are excluded as the site of origin of a focal AT, mapping then should focus on the other most likely sites of origin, including the posterior LA, mitral annulus, CS, SVC, and crista terminalis.¹⁵⁷ Nonetheless, PV isolation is still appropriate if there is evidence of PV conduction, even if the focal AT is not arising in the PV, to minimize the possibility of recurrent AF.¹⁶³

Mapping and ablation of LA macroreentry following circumferential LA ablation or circumferential antral PV isolation are frequently challenging. Detailed mapping with a high density of points is necessary to elucidate the mechanism of the arrhythmias (see Chap. 13). Current treatment of macroreentrant ATs primarily involves electrical isolation of all reconnected PVs and, if needed, empirical linear lesions within the AT circuit, often including a line between the mitral annulus and left inferior PV and a line between the superior PVs. However, when the macroreentrant circuit can be mapped, ablation lesions should be tailored to interrupt the path of the reentrant circuit (see Fig. 15-59). The mitral isthmus, LA roof, and septum account for 75% of the ablation target sites for macroreentrant ATs from the LA. Successful catheter ablation has been reported in approximately 85% of macroreentrant ATs arising in the LA in highly experienced laboratories; however, ablation of macroreentrant ATs occurring in the septal wall is challenging and less successful.^{161,163}

Multiple macroreentrant circuits and multiple-loop reentrant circuits are not infrequently encountered after catheter ablation of AF, especially following extensive ablation strategies. Transition from one tachycardia to another tachycardia incorporating a different loop of the same circuit or using a different circuit can be encountered during mapping or after successful ablation of the initial tachycardia.^{157,161} Additionally, localized reentrant circuits are not uncommon, especially following ablation of longstanding AF. These small circuits usually arise from the vicinity of the isolated PVs or linear lesions.¹⁶⁴

Impact on Cardiac Structure and Function

Restoration of sinus rhythm is expected to improve atrial mechanical function as compared with AF; however, the impact of catheter ablation of AF on LA transport function is still under investigation. Several studies demonstrated an increase in the LA voltage and a decrease in the LA volume following AF ablation. Reversal of atrial electrical remodeling following restoration of NSR can happen within 1 week, and reverse structural remodeling has been demonstrated by imaging studies during long-term follow-up after successful AF ablation.¹⁶⁵

On the other hand, extensive ablation of atrial tissue replaces myocardium with scar and prolongs intraatrial conduction, which can potentially result in asynchronized contraction of the LA, possibly attenuating atrial contractile performances. The decline in LA systolic function appears to be strongly correlated with the volume of RF ablation scar.¹⁶⁶ Furthermore, extensive septal ablation can potentially damage the Bachmann bundle and delay LA activation, attenuating LA contribution to LV filling, especially when the latest activity in the LA occurs after the QRS, because of closure of the mitral valve before completion of LA contraction.¹⁶⁷ It is likely that the smaller the surface area occupied by scar tissue, the greater the probable benefit for atrial contractile function. One report described pulmonary hypertension with LA diastolic dysfunction with preserved atrial systolic function (so-called stiff LA syndrome) occurring in 1.4% of patients following AF ablation. Patients with extensive atrial scarring, small LA (45 mm or less), diabetes mellitus, obstructive sleep apnea, and high LA pressure seem to be more prone to develop this syndrome. Symptomatic patients manifest with dyspnea and congestive heart failure and experience symptomatic improvement after diuretic therapy. Further refinement of techniques to identify sites crucial for maintenance of AF or subsequent AT on an individual basis is therefore necessary to minimize the extent of LA injury and to maximize the mechanical benefit of catheter ablation therapy for AF.

In patients with heart failure and an LV ejection fraction of less than 45%, AF ablation was shown to produce significant improvement in LV function, LV dimensions, exercise capacity, symptoms, and quality of life. However, larger studies are needed to determine exactly which component of this improvement in LV function results from improvement in rate control as compared with restoration of sinus rhythm per se. Of note, restoration of NSR by AF

ablation was found to improve LV function even in patients with preserved LV ejection fraction.¹⁶⁸

Complications of Catheter Ablation of Atrial Fibrillation

Catheter ablation of AF is one of the most complex interventional EP procedures, and the risk associated with such a procedure is higher than for the ablation of most other arrhythmias. Complications include local vascular complications, cardiac perforation, valvular injury, systemic embolism, esophageal injury, PV stenosis, and proarrhythmia resulting from reentrant tachycardias arising from incomplete ablative lesions.

Numerous studies have reported complication rates following catheter ablation for AF ranging from 3.9% to 6%. A voluntary worldwide survey of AF ablation in 8745 patients (181 centers) collected in 2002 to 2003 reported an overall complication rate of 6%, including both early and late complications, and an updated survey from 2003 to 2006 (32,569 patients undergoing 45,115 procedures in 262 centers) reported a complication rate of 4.5% and an overall mortality rate of approximately 1 per 1000. The most frequent causes of mortality were tamponade (25%), stroke (16%), and atrioesophageal fistula (16%).¹⁶⁹⁻¹⁷¹ A more recent Italian multicenter registry reported a lower complication rate of 3.9%.¹⁷² In an analysis of Medicare claims data for fiscal years 2001 to 2006, the annual probability of an in-hospital complication increased significantly from 6.7% to 10.1% during this time interval, driven mainly by the occurrence of vascular access complications and cardiac perforation/tamponade. Baseline demographic and clinical variables and hospital procedural volume had relatively little impact on the overall risk of complications. However, an association between hospital procedural volume and in-hospital death was observed.¹⁷³

PULMONARY VEIN STENOSIS

PV stenosis after AF ablation has been reported with a wide range of incidence (0% to 42%), depending on the ablation technique, the operator's experience, and the method for detection of PV stenosis (see Fig. 32-7). Focal ablation and then ostial PV ablation carry the highest risk for PV stenosis. Circumferential LA ablation, with ablation limited to atrial tissue outside the PV orifice, seems to have the lowest rates of PV stenosis, whereas the use of an individual encircling lesion set that requires RF ablation between the ipsilateral PVs carries a higher risk. Stenosis seems to be more common in the left-sided PVs. Delivery of energy inside the PV during ablation, although undesirable, is more likely in the left PVs because the ablation catheter moves easily into them when patients breathe.⁸⁸

The prevalence of this complication has decreased because of various factors, including abandonment of in-vein ablation at the site of the AF focus, limiting of ablation to the extraostial portion of the PV or PV antrum, use of advanced imaging techniques to guide catheter placement and RF application, reduction in target ablation temperature and energy output, and increased operator experience. Nonetheless, PV stenosis remains an important complication, affecting approximately 1.0% to 1.4% of procedures (see Chap. 32 and Videos 24, 25, and 26).^{174,175}

Although PV angiography, electroanatomical mapping, and impedance monitoring have been used in an attempt to avoid delivery of RF energy to the PV ostia or within the PVs, these techniques are still imperfect. Electroanatomical mapping, for example, relies on the patient's position remaining unchanged throughout the procedure. With patient movement, the 3-D electroanatomical reconstruction of the LA and PVs may not accurately reflect true, contemporaneous anatomy. Similarly, PV angiography is typically performed immediately prior to the start of PV ablation. Not only does this provide a crude two-dimensional representation of true PV anatomy, but patient movement later in the procedure can also result in misalignment of the true PV anatomy with that reflected by the PV angiograms. Although impedance monitoring provides online feedback to the location of the ablation catheter relative

to the PV, one study found no significant difference in impedance between PV ostial and LA sites. Therefore, it is possible for movement of the ablation catheter into the PV ostia to be missed.⁸⁸

Cryothermal ablation has unique characteristics that may prove to be desirable when lesions are required within the PV. Specifically, there is less endothelial disruption, maintenance of extracellular collagen matrix without collagen denaturation, and no collagen contracture related to thermal effects. These characteristics may translate into a reduction in PV stenosis as compared with RF ablation. Nonetheless, cryoballoon ablation for PV isolation still can be associated with PV stenosis (the rate of symptomatic PV stenosis or PV stenosis requiring intervention was 0.17%). A distal position of the cryoballoon with respect to the PV ostium, especially when using the smaller 23-mm balloon, can potentially increase the risk of these complications.¹⁰⁴

ATRIOESOPHAGEAL FISTULA

The formation of an atrioesophageal fistula is the most feared complication of catheter ablation of AF (see Fig. 32-9 and Video 27). Although rare (with an incidence estimated at 0.03% to 0.2%), this complication is highly fatal, accounting for 15.6% of cases with fatal outcome, the second leading cause of mortality following AF ablation, following cardiac tamponade (see Chap. 32).¹⁷⁰⁻¹⁷²

On the other hand, esophageal mucosal changes consistent with thermal injury are much more common, reported in up to 47% of the patients following AF ablation, and esophageal ulcerations confirmed by esophagogastroscopy or capsule endoscopy can be observed in 14% to 18%.^{176,177}

The risk of esophageal injury likely is enhanced by increasing magnitude and duration of local tissue heating (i.e., the total ablation energy delivered to cardiac tissue near the esophagus), which is related to catheter tip size, contact pressure, catheter orientation, and energy power output and duration. Additionally, ablation strategies incorporating extensive ablation in the LA posterior wall, the type of AF (persistent more than paroxysmal AF, possibly because of the additional linear ablation lesions), the use of nasogastric tubes, and general anesthesia have been associated with an increased rate of esophageal ulcerations.^{178,179}

Cryoballoon ablation commonly causes significant decreases in esophageal temperature in most patients, especially during cryoablation of the inferior PVs, resulting in esophageal ulcerations. Although no instances of atrioesophageal fistula formation after cryoballoon PV isolation have yet been reported, the total number of cryoballoon ablation cases performed is relatively small to detect this rare complication reliably. Furthermore, esophageal ulcerations have been observed following cryoballoon ablation at a rate similar to those seen with RF ablation (17% of patients). Factors associated with ulcerations were the mean nadir and the cumulative decrease of luminal esophageal temperature, as well as the number of lesions with an observed esophageal temperature lower than 30°C. Although there is no definitive proof that esophageal ulcer formation is predictive of fistulas, it is reasonable to assume that esophageal ulcerations can represent the first step on the way to atrioesophageal fistula. Therefore, cryoballoon ablation should not be considered completely safe with regard to atrioesophageal fistula formation.¹⁸⁰

PV electrical isolation with HIFU ablation can cause excessive esophageal heating. Studies showed that power modulation did not prevent esophageal temperature to exceed levels higher than 40°C at the end of the ablation. In fact, elevated esophageal temperature prompting cessation of energy delivery occurred in 9% of PVs. Despite use of the safety algorithm, the occurrence of esophageal thermal damage and lethal atrioesophageal fistula could not be prevented, which occurred in 1 of 28 patients. PV isolation with HIFU has proven to be successful but is not yet safe for clinical use.¹⁸¹

Various strategies can be used to avoid the development of an atrioesophageal fistula. However, because of the rarity of this complication, it remains unproven whether the use of these approaches lowers or eliminates the risk of esophageal perforation or fistula

formation, and the optimal technique has not yet been determined. Therefore, it appears prudent to apply a combination of these preventive techniques during AF ablation.¹⁸²

AVOIDING ABLATION IN THE VICINITY OF THE ESOPHAGUS. The most effective measure to prevent atrioesophageal fistula formation is to avoid ablation in the LA posterior wall at sites close to the esophagus. However, effective treatment of AF and PV isolation typically require ablation at those sites, and complete avoidance of the LA posterior wall usually is not feasible. Nonetheless, inclusion of a linear lesion connecting the PV encirclements in the posterior LA wall is no longer advised. If such a connection is thought to be clinically necessary, it should be performed superiorly in the dome of the LA instead of the posterior wall.

ASSESSMENT OF THE ESOPHAGUS POSITION. Newer imaging techniques have been used to visualize the anatomical relationship between the esophagus and the LA during AF catheter ablation. Esophageal imaging is not part of the usual CT or MRI of the LA and PVs. Visualization of the esophagus can be achieved during the CT angiography by the use of barium sulfate or Gastrografin and swallowing instructions, which help the contrast substance to lodge in the middle and distal esophagus, rather than in the stomach (Fig. 15-60). Visualization of the esophagus during CT or MRI can also be achieved by combining the barium sulfate paste with gadolinium diglutamate. The barium cream helps the gadolinium lodge in the esophagus. However, these approaches have several limitations. The esophagus is a mobile structure, and CT and MRI scans of the esophagus are static and not real-time images, acquired on a previous session; therefore, these images may be an unreliable guide to the position of the esophagus during the ablation procedure. This may be particularly true for procedures performed while the patient is under conscious sedation, when esophageal peristalsis is likely to occur. Furthermore, the image of the esophagus is obtained with a barium sulfate paste, and the real dimensions of the esophagus depend on the volume of contrast media injected. During ablation, the esophagus is empty, and the real dimension and probably the exact location can be misinterpreted.^{178,182} The use of 3-D mapping systems that allow the integration of preacquired 3-D CT scans or MRI of the LA, PVs, and esophagus provides a visualization tool that permits a rapid understanding of complex cardiac anatomical relationships. The location of the esophagus can also be tagged by the electroanatomical system (CARTO or NavX). A nasogastric tube is inserted into the esophagus, and the mapping catheter is coated with lubricant and passed down the nasogastric tube under fluoroscopy guidance. Alternatively, a special catheter (EsophaStar, Biosense Webster) is currently available for esophageal mapping combined with the CARTO system. Acquisition of the catheter tip location is made during pull-back of the catheter out of the nasogastric tube; these data points are saved as a separate map in the electroanatomical mapping system. After LA chamber reconstruction is made, the esophageal map is displayed in 3-D space in relation to the LA reconstruction (see Fig. 15-60). The EsophaStar catheter can be left in the esophagus and used as a fluoroscopic guide to esophageal location during the ablation procedure (see Fig. 15-60). It is important to recognize, however, that the catheter used for tagging can be positioned eccentrically in the esophageal lumen, thus providing misleading information.¹⁸²

Phased-array ICE has been evaluated as a diagnostic tool for rapid real-time localization of the esophageal location in relation to the posterior LA wall (Fig. 15-61). The location of the esophagus determined by ICE during the ablation procedure was found to correlate well with the location determined by MRI before the procedure.¹⁷⁸ This technique has the advantage of providing real-time information on the location of the esophagus, especially when movement occurs.

Another strategy to limit the risk of esophageal injury is real-time imaging of the anatomical course of the esophagus during the ablation procedure by placement of a radiopaque esophageal monitoring probe or use of a viscous radiopaque contrast paste. Orally

administered barium provides a simple, inexpensive, and safe way to keep track of the esophagus accurately during an ablation procedure (Fig. 15-62). In most patients, barium paste coats the wall of the esophagus, and residual barium often allows visualization of the esophagus for 1 to 2 hours after the initial barium swallow. However, to avoid the risk of aspiration, patients should receive little or no sedation before swallowing the barium. The ablation procedure can also be performed with the patient under general anesthesia with orotracheal intubation and esophagography during the procedure. General anesthesia guarantees enough esophageal immobilization because the swallow reflex is abolished. Placement of an orogastric tube to allow esophageal localization is carried out before anticoagulation to avoid any risk of trauma and bleeding. At the end of the procedure, the contrast is totally removed. This technique allows visualization of the esophagus position in real

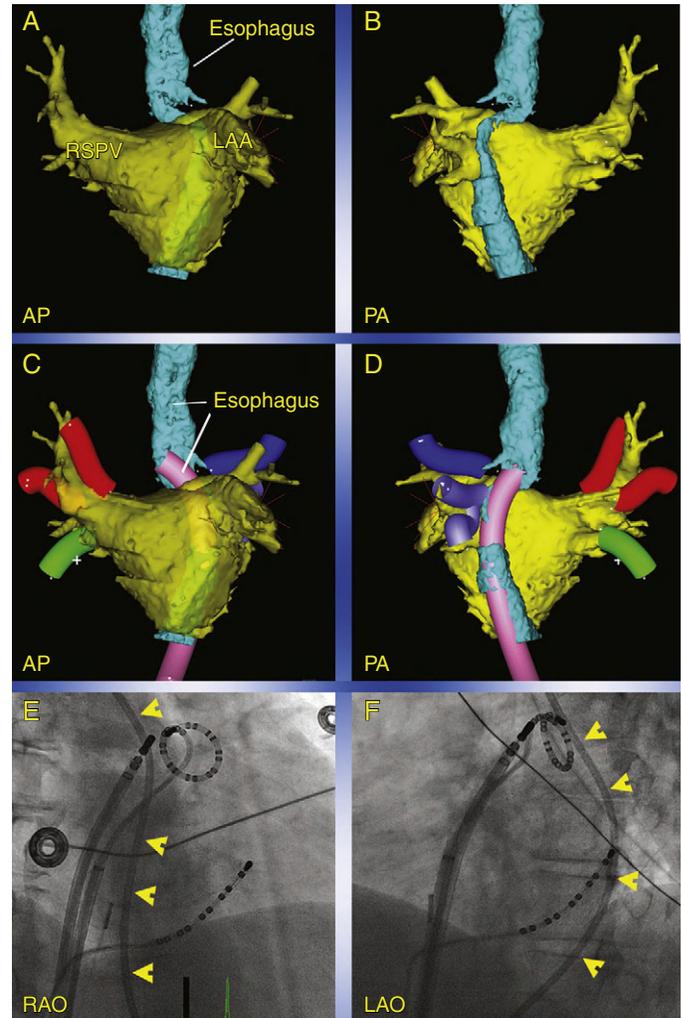

FIGURE 15-60 Esophageal imaging. A and B, Anteroposterior (AP) and posteroanterior (PA) views of a CT image of the left atrium and esophagus. The esophagus is visualized during CT scanning by the use of Gastrografin (contrast medium). Note that the real dimensions of the midsegment are not very clear because of peristaltic movements and inadequate filling of the esophagus. C and D, AP and PA views of integrated CT image and electroanatomical mapping system (CARTO, Biosense Webster, Inc., Diamond Bar, Calif.). The esophagus is tagged by passing the esophageal mapping catheter (EsophaStar) through the esophagus. Note that the position of the esophagus during the ablation procedure (as marked by the CARTO system) correlates well with the position on the preacquired CT image. Note the close proximity of the esophagus to the ostia of the left pulmonary veins (PVs). E and F, Fluoroscopic (right anterior oblique [RAO] and left anterior oblique [LAO]) views in the same patient with the esophageal mapping catheter (arrowheads) left in the esophagus during the ablation procedure to provide a real-time guide to the location of the esophagus. LAA = left atrial appendage; RSPV = right superior pulmonary vein.

time. The operator visualizes any subsequent esophageal movement immediately. Nonetheless, the use of nasogastric tubes can potentially increase the risk by pressing the anterior esophageal wall against the LA posterior wall.

MECHANICAL DISPLACEMENT OF THE ESOPHAGUS. When ablation cannot be performed in certain LA regions because of proximity of the ablation site to the esophagus, mechanical displacement of the esophagus to the contralateral side from the ablation catheter by an endoscope has been suggested to facilitate safe energy delivery. However, the risk of esophageal perforation by the endoscope should be recognized, and the safety of this strategy needs to be determined before implementation into clinical practice. Furthermore, apparent displacement of the esophagus with an endoscope can potentially represent mere distortion rather than anatomical displacement, in which setting the esophagus can be rendered more vulnerable to injury. Additionally, the presence of the endoscope probe can increase the diameter of the esophagus and increase its contact with the posterior LA wall.¹⁸³

ESOPHAGEAL TEMPERATURE MONITORING. Thermal monitoring of the esophagus during ablation can be of value.¹⁰⁰ Measurement of esophageal temperature involves the placement of a monotherm temperature probe, which is advanced under fluoroscopy guidance to the lower third of the esophagus directly posterior to the LA. This technique requires general anesthesia to allow tolerability of the esophageal probe. Adjustment of the position of the temperature probe during ablation to keep the probe

in close vicinity to the ablation catheter tip is crucial to obtain reliable information on the real current esophageal temperature. The probe is used to identify the general location of the esophagus in relation to the posterior LA and PVs based on a 3°C to 4°C rise in temperature from baseline and assuming a linear degree of heating from the external esophagus relative to the lumen. However, discrepancies between the temperatures of the external and internal esophagus and thermal latency in heat transfer from the atrium to the esophagus can limit the utility of esophageal temperature monitoring. Also, because the esophagus is broad, a lateral position of the temperature probe may not align with the ablation electrode. The possibility of heating of the esophageal wall without recording a change in central luminal esophageal temperature can be harmful by providing a false sense of safety.^{178,182} It is important to note that esophageal temperature can continue to increase for several seconds after discontinuation of RF delivery; thus, energy application must be stopped as soon as there is any increase in esophageal temperature.

Although studies demonstrated the absence of esophageal lesions in patients with a maximal esophageal luminal temperature lower than 41.8°C, the safety zone of temperature rise from baseline has not been validated.¹⁸⁴

LIMITING ABLATION ENERGY. Modification of RF application parameters at sites close to the esophagus is the most widely utilized strategy to avoid atrioesophageal fistula formation. Limitation of power and duration of RF applications, particularly in the posterior LA, even if a significant reduction in bipolar electrogram amplitude is not recorded, can be the most important safety considerations for the avoidance of fistula formation. Although no data exist on which to make specific recommendations, there is widespread agreement that prolonged RF applications in the posterior LA are to be avoided and that low power settings should be used. When standard RF energy is to be applied close to the esophagus, the RF power is typically reduced to 20 to 30 W and 55°C for no more than 20 seconds. Also, direct perpendicular orientation of the ablating electrode and forward pressure against the posterior LA wall should be avoided, particularly if an 8-mm or irrigated electrode is used. It is preferable to maintain frequent movements of the ablation catheter when RF energy is applied at the posterior LA wall in the vicinity of the esophagus. Open irrigation RF ablation may be associated with less risk of esophageal injury compared with standard RF ablation using an 8-mm-tip catheter. When using open-irrigated RF ablation, lower energy outputs (15 W compared with 25 W) were found to be associated with a decreased rate of esophageal ulcerations.¹⁷⁹

The value of limiting the duration of RF application without energy output reduction for prevention of ulcerations remains to be evaluated.¹⁷⁹ Although many investigators recommend the use of lower power settings for longer periods of time (25 W for 20 to 30 seconds), some investigators suggest that short RF applications

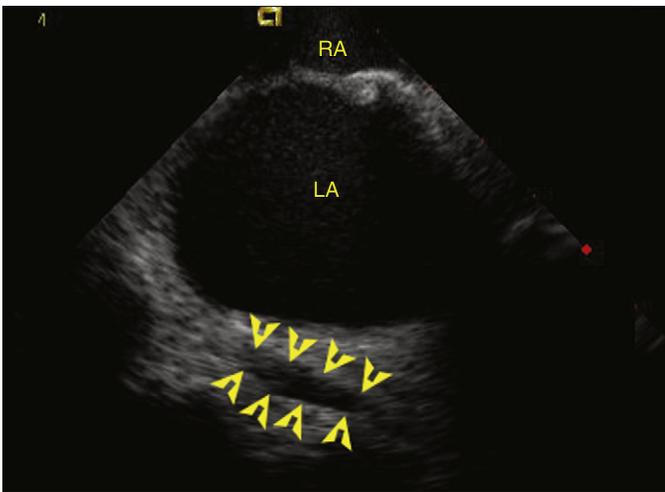

FIGURE 15-61 Intracardiac echocardiography (ICE) imaging of the esophagus. This phased-array ICE image with the transducer placed in the right atrium (RA) showing the esophagus (between arrowheads). Note that the left atrial (LA) posterior wall is contiguous with the esophagus.

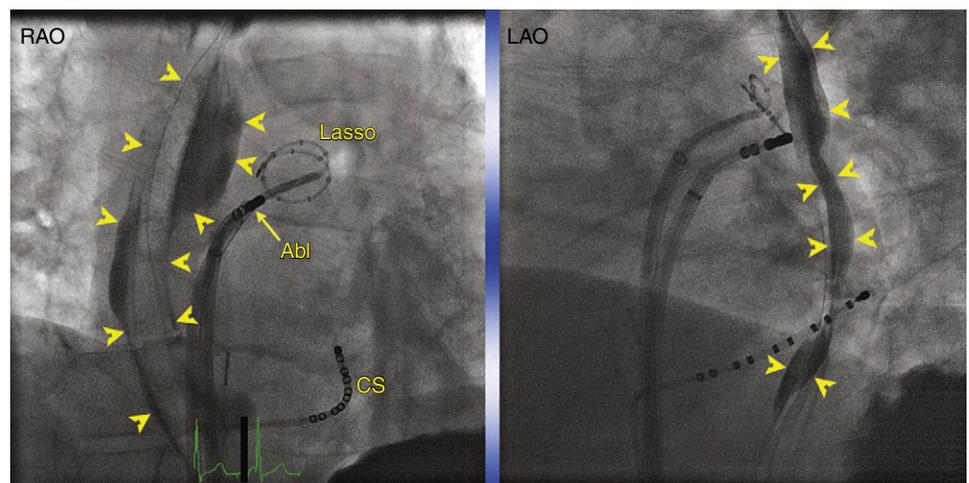

FIGURE 15-62 Esophageal imaging. Fluoroscopic (right anterior oblique [RAO] and left anterior oblique [LAO]) views of the esophagus during catheter ablation of atrial fibrillation. Barium paste was given to the patient just before initiation of sedation for real-time visualization of the esophagus (arrowheads) during the ablation procedure. The ring (Lasso) and ablation (Abl) catheters are positioned at the ostium of the left superior pulmonary vein. CS = coronary sinus.

(for 2 to 5 seconds) at a higher power (50 W, irrigation rate 30 mL/min, maximum temperature 43°C) result in momentarily higher LA tissue temperatures and allow the tip to be set at a high power to injure the superficial tissue while minimizing time-dependent deep heating through excessive heat transfer. The latter approach can compromise lesion efficacy because the time-dependent variable of “total heat transferred” is decreased. Typically, the ablation catheter is dragged continuously in small increments every 2 to 5 seconds during continuous RF delivery, and ablation is repeated at each site, if required, for many times throughout the procedure until the local atrial electrogram is completely eliminated. It is probably reasonable to allow at least 2-minute time intervals before returning to ablate a previously ablated site to allow for heat dissipation and complete cooling of potential esophageal heating.¹⁰⁰

Importantly, using light conscious sedation during the procedure can allow the use of pain as an indicator for potential esophageal injury; RF application should be interrupted promptly and the catheter moved to a different site on the development of significant or sharp pain during energy delivery.

PROPHYLACTIC PROTON PUMP INHIBITORS. The value of routine prophylactic administration of proton pump inhibitors after AF ablation to reduce the risk of fistula formation is unknown. However, this therapy is commonly offered to patients in whom esophageal lesions are detected by endoscopy or capsule endoscopy following the procedure. Because fistula tracts develop over the first 2 to 4 weeks after the procedure, when the patient is already home and recovering in other regards, it is important that patients be aware of and report symptoms of dysphagia, fever, stroke-like symptoms, new chest discomfort, or gastrointestinal bleeding. Early diagnosis of atri-esophageal fistula is critical to give the best chance for survival and recovery.

CARDIAC TAMPONADE

The risk of pericardial tamponade during AF ablation (averaging 0.8% to 2.9% and up to 6% in some reports) is higher than that associated with other EP procedures, likely secondary to the common need for two or more transseptal punctures, extensive intracardiac catheter manipulation and ablation, and prolonged high-dose heparinization during the procedure. Cardiac tamponade is the most common cause of death following AF ablation.^{175,185}

Several factors can affect the risk of developing cardiac tamponade. High RF power output may increase the risk of cardiac perforation. An audible pop associated with an abrupt rise in impedance is heard in many patients who develop tamponade. Popping occurs because of tissue boiling causing endocardial tissue rupture, and it is increased by irrigated-tip ablation, high tissue-catheter interface flow, poor or unstable tissue contact, and high catheter tip temperature. Notably, the atrial dome is susceptible to perforation injury during transitioning the catheter tip between the left and right superior PVs. Mechanical perforation can also occur from inadvertent movement of the catheter inside the LA appendage while it is being positioned during left superior PV or mitral isthmus ablation. In one report, pericardial effusion developed in 20% of patients undergoing antral PV isolation using an irrigated-tip ablation catheter at high power (50 W), but no cases were reported when lower power (35 W) or a standard 8-mm-tip catheter was used.^{175,185}

Although the use of ICE can potentially limit the risk of cardiac perforation by guiding transseptal puncture and visualizing microbubbles in the LA during RF ablation, perforations remain relatively common. New anatomical approaches, such as linear LA ablation or ablation of sites of highly fractionated electrograms that maintain the catheter in the muscular atrium, may affect perforation rates. The thickness of the atrium averages 4 mm, but decreases from 3.7 to 2.5 mm at the venoatrial junction. The PV further decreases in thickness by 1 to 2 mm outside the PV orifice. However, one report showed a higher risk of tamponade during linear LA ablation strategies as compared with PV isolation.^{175,185}

Although most perforations occur in the LA, few (13.3% in one report) require surgical closure. Percutaneous pericardiocentesis effectively restores hemodynamic function in the majority of cases. The LA dome seems to be especially susceptible to perforation that may not be responsive to conservative therapy. The atrial dome may be more susceptible to persistent bleeding because the pericardium is not closely adherent to the atrium, and a tight seal of these structures is difficult to achieve by applying negative pressure through the percutaneous pigtail catheter.¹⁷⁵

As noted previously, continuation of warfarin through the ablation procedure does not appear to increase the risk of cardiac tamponade. Although patients with therapeutic INR levels who develop cardiac perforation are likely to have a larger amount of blood removed from their pericardium for stabilization and require more blood transfusion units, the need to undergo emergency surgical exploration is not increased as compared with patients with normal INR levels.^{82,83}

The occurrence of cardiac perforation is associated with short-term recurrent AF in most patients, in part because the ablation procedure is interrupted by the complication prior to achieving electrical endpoints. Other patients probably have a higher rate of arrhythmia recurrence because of pericardial inflammation, but in most patients this appears to be transient. Most patients with completed ablations have favorable long-term rates of AF elimination, although still lower than expected with uncomplicated cases.

THROMBOEMBOLISM

Systemic thromboembolism is a serious complication of AF ablation, with a reported incidence of 0.5 to 2.8%. In a worldwide report, the rate of stroke was approximately 0.25% and that of transient ischemic attacks was 0.66%. Prior history of stroke or transient ischemic attack is the most potent individual risk factor for cerebrovascular accidents complicating AF ablation; patients with a history of cerebrovascular accidents had a ninefold increased risk of periprocedural stroke. Additionally, the incidence of periprocedural stroke increases in a stepwise fashion with an increasing CHADS₂ score.¹⁸⁶

Thromboembolic events typically occur within 24 hours of the ablation procedure, with the high-risk period extending for the first 2 weeks following ablation. Cerebral thromboembolism is most common, but emboli can also involve the coronary, abdominal, or peripheral vascular circulations. Although silent cerebral thromboembolism has been reported, its incidence is unknown.

Potential sources of emboli include thrombus formation on the LA catheters and sheaths, char formation at the tip of the ablation catheter or at the site of ablation, endocardial disruption from the ablation lesions, embolization of air, dislodgment of a preexisting LA thrombus by catheter manipulation, development of thrombi in the LA appendage after conversion of AF to sinus rhythm, or thrombus formation over the disrupted endothelium.¹⁸⁶

Careful attention to anticoagulation before, during, and after the ablation procedure is critical to minimize the risk of stroke. TEE should be considered in most patients undergoing AF ablation to screen for LA thrombus. Aggressive intraprocedural anticoagulation, including early heparin administration (preferably before the transseptal puncture), is followed by continuous infusion to maintain the ACT above 300 seconds.¹⁸⁶ Anticoagulation with warfarin should be started before and continued for at least 2 to 3 months after ablation. Furthermore, continuation of warfarin at a therapeutic INR at the time of AF ablation can potentially be a better alternative to strategies that use bridging with heparin or enoxaparin because this approach eliminates a period of inadequate anticoagulation immediately following the ablation procedure. This period is critical for thromboembolic risk as a result of the inflammation and irritation inherently associated with ablation.^{82,83} Additionally, meticulous attention to sheath management is paramount to prevent thrombus formation and air embolization, with visualized aspiration and flushing whenever catheters are inserted into the sheaths and continuous flushing of transseptal

sheaths with heparinized saline.⁷¹ Open irrigated-tip RF ablation catheters or cryoablation can potentially decrease the formation of char and thrombus at the tip of the ablation catheter. Also, the use of ICE can enable detection of intracardiac thrombi and accelerated bubble formation consistent with endocardial tissue disruption with RF application.¹⁸⁶

AIR EMBOLISM

The most common cause of air embolism is introduction of air into the transeptal sheath. Although air can be introduced through the infusion line, air embolism can also occur with suction when catheters are removed. Careful sheath management, including constant infusion of heparinized saline and air filters, should be observed. Whenever catheters are removed, they need to be withdrawn slowly to minimize suction effects and the fluid column within the sheath should be aspirated simultaneously. The sheath should then be aspirated and irrigated to ascertain that neither air nor blood has collected in the sheath.^{3,175}

Arterial air emboli can distribute to almost any organ, but they have devastating clinical sequelae when they enter the end arteries (see Chap. 32). This situation can lead to the hypoxic manifestations of myocardial injury and cerebrovascular accidents. A common presentation of air embolism during AF ablation is acute inferior ischemia or heart block. This reflects preferential downstream migration of air emboli into the right coronary artery. Air embolism to the cerebral vasculature can be associated with altered mental status, seizures, and focal neurological signs. The central nervous system dysfunction is attributable to both mechanical obstruction of the arterioles and thrombotic-inflammatory responses of air-injured endothelium.³

CATHETER ENTRAPMENT IN THE MITRAL VALVE APPARATUS

There are several reports of the ring catheter becoming entrapped in the mitral valve apparatus during AF ablation, resulting in valve injury that required thoracic surgery and valve replacement. The risk of this complication can be minimized by preventing anterior displacement of the ring catheter during the ablation. Catheter position can be monitored by using a combination of orthogonal fluoroscopy (ensuring that the ring catheter remains behind the CS on the RAO view) and ICE, as well as by paying close attention to the characteristics of the electrograms recorded on the catheter.^{71,187}

Catheters entangled in the valve apparatus may be difficult to free by clockwise and counterclockwise rotation of the shaft, especially after significant tugging has occurred. To prevent this, prior to pulling on the catheter, one may consider advancing the catheter toward the LV apex. Advancing the sheath over the catheter may facilitate the effort further and is also recommended so that the catheter can be withdrawn into the sheath and the whole assembly withdrawn to the LA.^{71,187}

Forcible traction of the catheter may damage the valve and ultimately lead to mitral valve replacement. Therefore, when gentle manipulation and moderate traction are unsuccessful, removing the catheter by thoracic surgery may be preferable.¹⁸⁷

RADIATION EXPOSURE

Catheter ablation of AF is associated with markedly prolonged fluoroscopy duration (60 to 100 minutes of fluoroscopy exposure delivered to patients in both the RAO and LAO projections), which exceeds that of patients undergoing catheter ablation of AFL or AVNRT by approximately fourfold.^{3,71} The use of CT scanning before and after AF ablation procedures further increases patient exposure to radiation.

During AF ablation, the patient tissue receiving the greatest radiation dose is the skin area of the back at the entrance point of the x-ray beam, which can cause skin injuries (see Chap. 32).^{188,189}

The estimated lifetime risk of a fatal malignant disease after PV ablation using a modern low-frame pulsed fluoroscopy system is relatively low (0.15% for female patients and 0.21% for male patients in one report), and it is higher than, although within the range of, previously reported risk to result from the ablation of standard types of supraventricular arrhythmias (0.03% to 0.26%). It has been estimated that for every 60 minutes of fluoroscopy, the mean total lifetime excess risk of a fatal malignant disease is 0.03% to 0.065%.

One study found that patient body mass index is a more important determinant of the effective radiation dose than total fluoroscopy time, and obese patients receive more than twice the effective radiation dose of normal-weight patients during AF ablation procedures. Therefore, obesity needs to be considered in the risk-to-benefit ratio of AF ablation and should prompt further measures to reduce radiation exposure.

The use of 3-D mapping systems can significantly reduce fluoroscopy time. The use of remote navigation systems also is likely to reduce fluoroscopy exposure to the patient and certainly to the operator.^{188,189}

PHRENIC NERVE INJURY

Fortunately, phrenic nerve injury has been an infrequent complication of AF catheter ablation. Injury to the right phrenic nerve can occur during ablation in and around the right superior PV and electrical isolation of the SVC. The reported incidence of phrenic nerve injury secondary to AF ablation varies from 0% to 0.48%. Although it is much less common, left phrenic nerve injury can also occur during RF delivery at the proximal aspect of the roof of the LA appendage.^{24,190}

The use of a non-RF source of energy is unlikely to prevent this complication because phrenic nerve injury has been reported with ultrasound, laser, and cryotherapy. Furthermore, phrenic nerve injury occurs independently of the strategy of AF ablation used (PV isolation versus wide-area circumferential LA ablation). Fortunately, phrenic nerve injury has been an infrequent complication of AF catheter ablation. Complete or partial recovery of diaphragmatic function was observed in most patients (more than 80%).^{24,190} Diaphragmatic paralysis may develop 1 to 2 days following the procedure despite normal function at the end of the ablation protocol; this may reflect inflammation rather than direct injury to the phrenic nerve.

Studies indicated that transient phrenic nerve injury occurs early and uniformly before permanent injury. Therefore, in areas at high risk of phrenic nerve injury (inferoanterior part of right PV ostium, posteroseptal part of the SVC, and proximal LA appendage roof) that require ablation, high-output pacing should be performed before energy delivery. When diaphragmatic stimulation is observed, energy application at this site should be avoided. Early suspicion of phrenic nerve injury should be considered in the case of hiccup, cough, or decrease in diaphragmatic excursion during energy delivery. Early recognition of phrenic nerve injury during RF delivery allows the immediate interruption of the application prior to the onset of permanent injury, which is associated with the rapid recovery of phrenic nerve function.^{24,190}

Diaphragmatic electromyography during continuous pacing of the right phrenic nerve with a catheter in the SVC has been used for monitoring phrenic nerve integrity during ablation. A progressive decline in compound motor action potential amplitude heralded phrenic nerve palsy, with a 30% decrease yielding the best predictive value, preceding hemidiaphragmatic paralysis. The clinical application of this approach to prevent phrenic nerve palsy induced by cryoballoon ablation of the right superior PV is still in its preliminary stages, and further evaluation is required to validate and optimize this approach.

OTHER COMPLICATIONS

Vagal denervation, resulting in gastroparesis, has been rarely reported. This is usually transient, resolving over the course of 1 to 3

weeks following the procedure. Sinus node dysfunction and heart block are rare but can occur sporadically. The stiff LA syndrome, characterized by LA diastolic dysfunction and pulmonary hypertension, is also uncommon and seems associated with more extensive ablation.

Recommendations and Controversies

Determination of Candidates for Catheter Ablation

The ideal candidate for catheter ablation of AF has symptomatic episodes of paroxysmal or persistent AF, has not responded to one or more class I or III antiarrhythmic drugs, does not have severe comorbid conditions or severe structural heart disease, has an LA diameter smaller than 50 to 55 mm, and, for those with longstanding AF, has had AF for less than 5 years. Catheter ablation of AF is likely to be of little or no benefit in patients with end-stage cardiomyopathy or massive enlargement of the LA (more than 60 mm), or in patients who have severe mitral regurgitation or stenosis and are deemed inappropriate candidates for valvular intervention.

The introduction into clinical practice of the various techniques described earlier has contributed to the expansion of inclusion criteria for catheter ablation of AF. Expanded indications at many centers now include patients with permanent AF and those with cardiomyopathy. It is controversial whether patient preference to discontinue anticoagulation should be considered an indication for AF catheter ablation; however, it is important to recognize that there are still no randomized controlled data demonstrating that a patient's stroke risk is reduced by ablation. It is currently recommended to continue long-term anticoagulation with warfarin in all patients with a CHADS₂ score of 2 or higher, even those with a successful catheter ablation procedure.³ Nonetheless, it is probably reasonable to consider ablation in patients in whom anticoagulation is indicated secondary to AF but who cannot tolerate, or whose occupations or activities preclude, long-term anticoagulation.

Several reports attempted to identify preprocedural markers of the extent of pathological atrial tissue remodeling and predictors of success (e.g., quantification of atrial fibrosis and scar burden on MRI and severity of LA enlargement) that may help improve selection criteria. Although the LA size and duration of longstanding AF, among other markers, can potentially predict lower procedure success rates, most of these markers do not adequately distinguish subjects in whom ablation should categorically be avoided. The question of how to identify patients in whom structural remodeling and scarring have become irreversible and it is too late to intervene remains unanswered, although preliminary data from cardiac MRI, assessing the degree of LA scarring, hold promise. Nonetheless, it is now well recognized that intervention relatively early in the course of persistent AF helps achieve a better outcome.¹⁹¹

Complications of catheter ablation can have catastrophic outcomes in certain patients, including those with severe obstructive carotid artery disease, cardiomyopathy, aortic stenosis, nonvascularized left main or three-vessel coronary artery disease, severe pulmonary arterial hypertension, or hypertrophic cardiomyopathy with severe LV outflow obstruction. Another relative contraindication is a history of major lung resection because of the severe impact of potential PV stenosis. Furthermore, because the risk of thromboembolic events during the procedure and in the early postoperative period, patients who cannot be anticoagulated during and for at least 2 months after the ablation procedure should not be considered for catheter ablation of AF. Also, catheter ablation should not be performed in patients with an LA appendage thrombus or a recently implanted LA appendage closure device.

It is also important to realize that surgical intervention can be lifesaving should a severe mechanical complication, such as rupture or massive cardiac perforation or catheter entrapment, occur. Therefore, catheter ablation of AF should not be performed,

particularly in higher risk patients, if surgical back-up is not readily available. In addition, catheter ablation of AF should not be performed in patients who are scheduled to undergo cardiac surgery for another indication when surgical ablation of AF also can be performed.

At the current time, criteria for selection of patients for AF ablation should include weighing risks and potential benefits associated with the procedure, as well as consideration of other factors such as severity of symptoms, quality of life, presence and severity of structural heart disease and other comorbidities, and availability of other reasonable treatment options. Additionally, the projected ablation success rate with the operator's own experience and the tools available to him or her should be taken into consideration.

Whether catheter ablation will provide a more effective approach than antiarrhythmic therapy as a primary strategy for control of AF, and reduce attendant morbidity and mortality, is the subject of a 3000-patient multicenter trial, CABANA (Catheter Ablation versus Antiarrhythmic Drug Therapy for Atrial Fibrillation). A similar study, CASTLE-AF (Catheter Ablation versus Standard Conventional Treatment in Patients with Left Ventricular Dysfunction and AF), is under way in Europe.

Importantly, recurrence of AF after the initial ablation procedure should not prompt automatic reablation. Because improvement in quality of life and reduction of symptoms are the main goals of ablation, the mere recurrence of AF after the initial ablation procedure should not be the only basis for recommending reablation. Reassessment of the degree of improvement the patient experienced following the initial procedure, the severity of symptoms during AF recurrences, the burden of AF, and the potential response to antiarrhythmic drugs should all be taken into consideration before recommending a redo ablation. For example, some patients experience a substantial palliative effect of ablation whereby AF recurrences cause minor or no symptoms, whereas others achieve satisfactory control with antiarrhythmic drugs that previously failed in the treatment of AF. Those patients may benefit from noninvasive management without the need for further ablation procedures.

Determination of the Necessity of Pulmonary Vein Electrical Isolation

Several investigators addressed this issue and came to differing conclusions. There is evidence that short-term efficacy can occasionally be observed in the presence of conduction recurrence across all previously disconnected PVs. In these cases, it is possible that the extent of conduction delay developed in response to the changes induced by chronic lesions prevents, at least for some time during follow-up, the occurrence of arrhythmia relapses. Conversely, patients with recurrence of AF invariably show restored conduction across one or more previously disconnected PVs, and reisolation of the reconnected PVs was found to be an effective treatment strategy. More recent reports strongly suggest that achievement of complete PV isolation improves outcome with the circumferential LA ablation approach.^{112,114}

In conclusion, although the importance of achieving isolation of the PVs remains unclear, it is acknowledged that electrical isolation of the PVs should be at least as effective as not achieving isolation. Furthermore, it is clear that if wide-area circumferential ablation is performed, complete PV isolation is also the most desirable endpoint. As long as PV stenosis is avoided, there are no deleterious effects of complete PV isolation as an additional endpoint in wide-area circumferential LA ablation techniques.

Currently, PV electrical isolation is considered central to any AF ablation strategy, and most centers performing AF ablation are empirically isolating all four PVs, without mapping or specific targeting of the trigger of the focus causing the arrhythmia. Furthermore, most groups are ablating outside the tubular portion of the PV (i.e., antral ablation as opposed to ostial ablation) to avoid the risk of PV stenosis and improve the efficacy of the procedure. The antrum blends into the posterior wall of the LA, and, on the

posterior wall, there is little space between adjacent antra. Therefore, to encompass as much of the PV structure as possible, ablation needs to be performed around the entire antrum, along the posterior LA wall. Although different groups may refer to ablation in this region by different names, such as wide-area LA ablation, circumferential antral PV ablation, or extraostial isolation, the lesion sets produced by the procedures are all similar. There is less consensus, however, on the distance from the PV ostia at which the optimal circumferential lesions should be placed. The greater the distance is, the greater the number of applications and density of lesions will be required to achieve isolation, but the lower the likelihood of PV stenosis. Furthermore, the greater the distance is from the ostia, the larger will be the area encircled and the greater the potential impact of the lesion set on atrial rotors and sites within the posterior LA, which can potentially contribute to the maintenance of AF. However, it is clear that wide-area circumferential LA ablation minimizes the risk of PV stenosis, but at the cost of a higher incidence of macroreentrant ATs and more extensive LA ablation with possible deleterious hemodynamic effects.

Determination of the Necessity of Adjunctive Substrate Modification

While elimination of PV triggers appears to be an adequate initial ablation strategy for patients with paroxysmal AF, atrial substrate modification takes on a more important role in the setting of persistent AF. However, current techniques of substrate modification (linear ablation, CFAE ablation, vagal denervation) are technically challenging and lack robust procedural endpoints to determine when enough ablation has been performed to modify the atrial substrate sufficiently. Additionally, these approaches involve more extensive ablation that can potentially increase the risk of complications, impair LA mechanical properties, and predispose to the development of LA macroreentry. Therefore, to balance efficacy and safety, it may not be advisable to use such an approach for all patients. A rational approach that targets a particular patient profile, rather than a unified strategy used for all patients, may be advisable.

For paroxysmal AF, circumferential antral electrical isolation of all PVs is the procedure of choice. If a focal trigger is identified outside the PVs, it should be targeted if possible. The clinical value of adjunctive substrate-based techniques has not been definitively proven, and these approaches are likely unnecessary, especially during the initial ablation procedure.^{78,93,152}

Circumferential antral isolation of all PVs also is recommended as the cornerstone of most ablation procedures in patients with persistent AF. In addition to elimination of the most common AF triggers, this technique incorporates substrate modification by considerable debulking of the atrium as well as elimination of CFAEs, rotors, and ganglionated plexuses commonly located within the circumferential ablation lesions around the PV antra. Nevertheless, adjunctive substrate-based ablation techniques can potentially play an important role in improving ablation efficacy. Supplementary linear LA ablation (roof and mitral isthmus lines) or CFAE ablation can be considered especially in patients with longstanding persistent AF or during redo ablation after failure of an initial PV-based ablation procedure. If additional linear ablation lesions are applied, complete bidirectional block across the ablation lines should be verified by mapping and pacing maneuvers to reduce the risk of proarrhythmias. Also, when CFAE ablation is being considered, it is reasonable to target CFAEs after, rather than before, PV electrical isolation, because that latter strategy can itself reduce the burden of CFAEs and minimize the consequent need for extensive LA ablation. The role of ablation of ganglionated plexuses in patients with AF remains to be determined in well-designed future studies, and it has not yet been adopted as a routine strategy in the treatment of patients with persistent AF.^{93,112,138}

In patients with longstanding AF, several stepwise or tailored approaches have implemented increasing ablation lesions until persistent AF is terminated by ablation or until AF is rendered

noninducible by rapid atrial pacing or infusion of isoproterenol or adenosine. A common approach involves starting with circumferential antral PV isolation, which is then followed by linear ablation across the LA roof, CS isolation, ablation of CFAEs, mitral isthmus ablation, and RA-SVC ablation in a stepwise fashion whereby each step is started if AF still persists after completion of earlier steps. It should be recognized, however, that despite the best efforts with various combinations of several ablation strategies, converting chronic AF to sinus rhythm solely by ablation may not occur in most patients. Hence, an endpoint of acute termination of chronic AF may not be practical. Moreover, whether acute termination of chronic AF by RF ablation is a predictor of long-term clinical efficacy remains to be evaluated.^{78,131,148}

Importantly, substrate-based ablation techniques are typically used in conjunction with PV isolation. Their use as a stand-alone procedure for either paroxysmal or persistent AF without any attempt to isolate the PVs electrically has been associated with high rates of recurrence, and this approach has been abandoned by many centers.

Atrioventricular Junction Ablation

Rationale

AF may not be amenable to ablation procedures and may require multiple pharmacological agents for management. In some of these patients, medical therapy is poorly tolerated or unsuccessful. In these cases, AVN ablation combined with permanent pacemaker implantation (the “ablate and pace” approach) is a possible treatment strategy, with rate control as the goal. The pacemaker may be single-chamber (VVI) for permanent AF, dual-chamber (DDD) for paroxysmal or recurrent persistent AF, or biventricular for patients with LV dysfunction. This procedure is successful in almost 100% of cases, and late recovery of AV conduction is rare. However, this procedure still mandates anticoagulation and possibly requires antiarrhythmic therapy to control the AF.

The timing of AVN ablation in relation to pacing is debatable, mainly in the setting of paroxysmal AF. In most EP laboratories, permanent pacemaker implantation is performed prior to the ablation procedure. Long-term pacemaker function does not seem to be affected by RF ablation; however, the pacemaker may develop a transient unpredictable response during RF application in up to 50% of patients, including inhibition, switching to back-up mode, oversensing, undersensing, loss of capture, exit block, and electromechanical interference. These responses may argue for the use of an external pacemaker during the ablation procedure. In patients with paroxysmal AF, a dual-chamber pacemaker may be implanted first, and the need for AV junction ablation is reassessed after 1 to 3 months of intensification of medical therapy (i.e., AVN blocking drugs).

Target of Ablation

The target site of this approach is located closer to the compact AVN than the HB in the anterosuperior region of the triangle of Koch. This approach selectively ablates the AVN, and not the HB. This ensures ablation of the proximal part of the AV junction to preserve underlying automatism and to avoid complete pacemaker dependency. Occasionally, when ablation of the AVN is unsuccessful, RF ablation of the HB may be performed using a right- or left-sided approach.

Ablation Technique

A 4- or 8-mm-tip ablation catheter is initially positioned at the AV junction to obtain the maximal amplitude of the bipolar His potential recorded from the distal pair of the electrodes. The catheter is then withdrawn while maintaining clockwise torque on the catheter to maintain septal contact until the His potential becomes small or barely visible, or disappears while recording a relatively

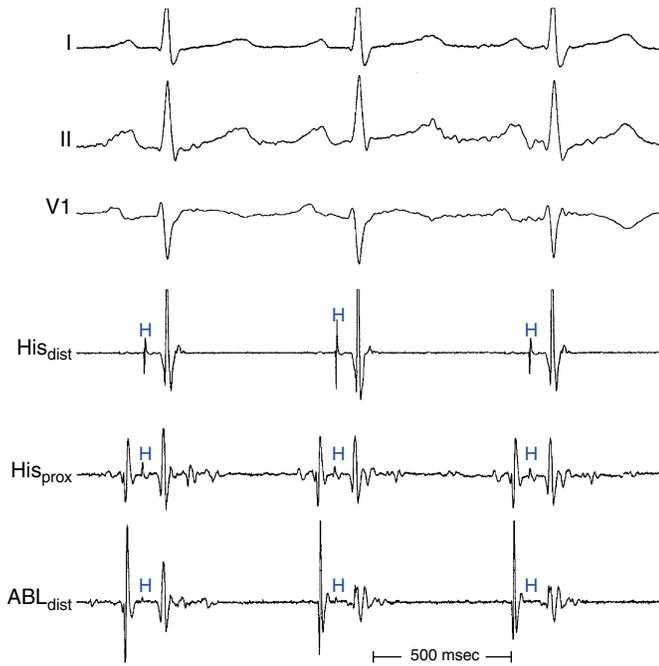

FIGURE 15-63 Optimal ablation site for atrioventricular junction ablation during normal sinus rhythm. The distal ablation electrodes (Abl_{dist}) record a small His potential and a large atrial electrogram [atrial-ventricular (A/V) ratio greater than 1]. More prominent His potentials, such as recorded by the proximal or distal His bundle catheter bipoles, suggest inappropriate site for ablation. His_{dist} = distal His bundle; His_{prox} = proximal His bundle.

large atrial electrogram (A/V ratio greater than 1) or, in patients with AF, until the His potential disappears under the fibrillatory waves (Fig. 15-63).

An alternative approach is to position a quadripolar catheter at the HB position. The tip of the ablation catheter is then withdrawn to approximately 2 cm below and to the left of the tip of the HB catheter in the RAO view (Fig. 15-64). Occasionally, in 5% to 15% of patients, when the right-sided approach is undesirable or unsuccessful, a left-sided approach to ablate the HB may be used. The ablation catheter is advanced retrogradely through the aorta into the LV, withdrawn so that the catheter tip lies against the membranous septum just below the aortic valve, and records a large HB electrogram and small atrial electrogram (Fig. 15-65). Often, no atrial electrogram is seen. A large atrial electrogram suggests that the catheter tip is close to the LA above the aortic valve; ablation should not be attempted at this site. The left-sided approach typically requires fewer RF applications than the right-sided approach.

One report described the feasibility of AV junction ablation performed from the axillary vein concurrent with the implantation of a dual-chamber pacemaker.¹⁹² This approach involves placing two separate introducer sheaths into the axillary or subclavian vein. The first sheath is used for implantation of the pacemaker ventricular lead, which is then connected to the pulse generator or a temporary pacemaker. Subsequently, a standard ablation catheter is introduced through the second venous sheath and used for ablation of the AV junction. The ablation catheter is advanced into the right ventricle (RV) and is positioned near the HB region by deflection of the tip superiorly to form a J shape; the catheter is then withdrawn so that it lies across the superior margin of the tricuspid annulus (Fig. 15-66). Alternatively, the catheter can be looped in the RA (figure-of-6) and the body of the loop advanced in the RV so

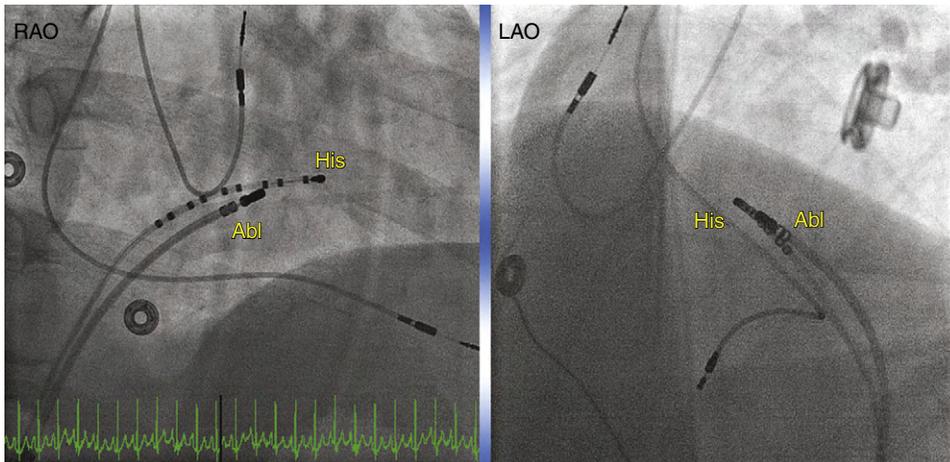

FIGURE 15-64 Fluoroscopic (right anterior oblique [RAO] and left anterior oblique [LAO]) views of the ablation catheter position (Abl) in relation to the His bundle (HB) catheter at the optimal site of atrioventricular junction ablation. The distal ablation electrode is positioned just proximal and inferior to the proximal HB electrodes.

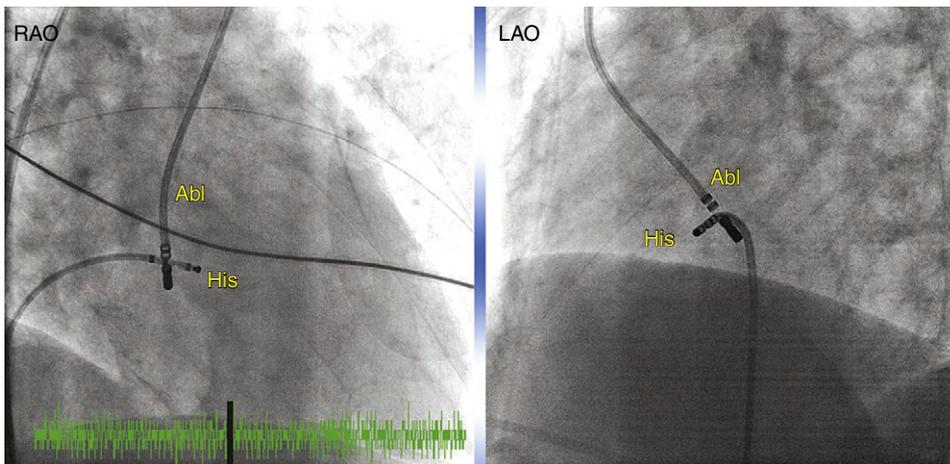

FIGURE 15-65 Fluoroscopic (right anterior oblique [RAO] and left anterior oblique [LAO]) views of the ablation catheter introduced via a transaortic approach in relation to the His bundle (HB) catheter at the optimal site for atrioventricular junction ablation (Abl). The distal ablation electrode is positioned just inferior to the aortic cusp in the left ventricular outflow tract, opposite the HB catheter in the right ventricle.

that the tip of the catheter is pointing toward the RA and lying on the septal aspect of the RA. Gentle withdrawal of the catheter can increase the size of the loop and allow the catheter tip to rest on the HB location (see Fig. 15-66). After successful ablation, the ablation catheter is withdrawn, and the atrial pacing lead is advanced through that same sheath.¹⁹²

RF energy is delivered with a power output of 50 W, targeting a temperature of 60°C to 70°C, and for a duration of 30 to 120 seconds. AV block may appear immediately or after several RF applications. Typically, at good ablation sites, an accelerated junctional rhythm is induced during RF application (Fig. 15-67).

Endpoints of Ablation

The endpoint of ablation is achieving complete AV block. It is preferable to achieve AVN block with a junctional escape rhythm to avoid pacemaker dependency; however, sometimes this is difficult to achieve, and HB ablation with fascicular or no escape rhythm is the end result (see Fig. 15-67).

Outcome

Complete AV block can be achieved in almost 100% of patients, with a 3% risk of recurrence of AV conduction. Achieving complete AVN block specifically, however, is less successful (80% to 90%). Ablation of the AV junction may be difficult to achieve in patients with atrial enlargement or hypertrophy, as seen with longstanding heart failure or hypertension.

Most patients who undergo RF ablation of the AV junction are pacemaker dependent after the procedure, as defined by lack of an escape rhythm that is faster than 40 beats/min. Following AV junction ablation, an escape rhythm develops in 70% to 100% of cases, and the absence of escape rhythm immediately after ablation seems to be the only predictor for long-term pacemaker dependency. Although the appearance of an escape rhythm does

not obviate the need for pacing, it may provide reassurance in case of pacemaker failure.

Malignant ventricular arrhythmias and sudden cardiac death have been observed in the early phase following AV junction ablation. Polymorphic VTs are related to electrical instability caused by an initial prolongation and then slow adaptation of repolarization caused by changes in the heart rate and activation sequence. Most polymorphic VTs, VF, and torsades de pointes that have been reported seem to be consistent with a pause or bradycardia-dependent mechanism. Anomalous dynamics of the paced QT intervals have been observed until the second day after AV junction ablation in patients with rapid refractory AF, resulting in prolongation of the QT interval when the heart rate is less than 75 beats/min. This finding may explain the ventricular arrhythmias occurring after AV junction ablation and may also explain the beneficial effects of temporary relatively rapid pacing. On the other hand, bradycardia may not be the sole factor. Sympathetic tone augmentation following AV junction ablation has been described in patients paced at 60 beats/min, thus causing prolongation of action potential duration and RV refractoriness, whereas sympathetic tone was reduced in patients paced at 90 beats/min. Such an increase in sympathetic activity and prolongation in action potential duration may favor early afterdepolarization and triggered activity, which may mediate torsades de pointes and polymorphic VT. To reduce the risk of these arrhythmias, routine pacing at 80 beats/min has been recommended following AV junction ablation. Patients with high-risk factors for arrhythmias, such as congestive heart failure or impaired LV function, may require pacing at higher rates (e.g., at 90 beats/min for 1 to 3 months) as well as in-hospital monitoring for at least 48 hours. Adjustment of the pacing rate, although rarely to less than 70 beats/min, is usually undertaken after 1 week in most patients, preferably after an ECG evaluation for repolarization abnormalities at the lower rate.

Another adverse effect of the ablate and pace approach is ventricular dyssynchrony induced by RV pacing, which may result in impairment of LV systolic function. Positioning the ventricular

FIGURE 15-66 Fluoroscopic (right anterior oblique) views of the ablation (Abl) catheter introduced via the left axillary vein. Implantation of the pacemaker ventricular lead is initially performed. The ablation catheter is positioned near the His bundle region by deflection of the tip superiorly to form a J shape and then withdrawing the catheter so that it lies across the superior margin of the tricuspid annulus (left), or by looping the catheter in the right atrium (RA; figure-of-6) and then advancing the body of the loop into the right ventricle so that the tip of the catheter is pointing toward the RA and lying on the septal aspect of the RA (right). LAO = left anterior oblique; RAO = right anterior oblique; RV = right ventricle.

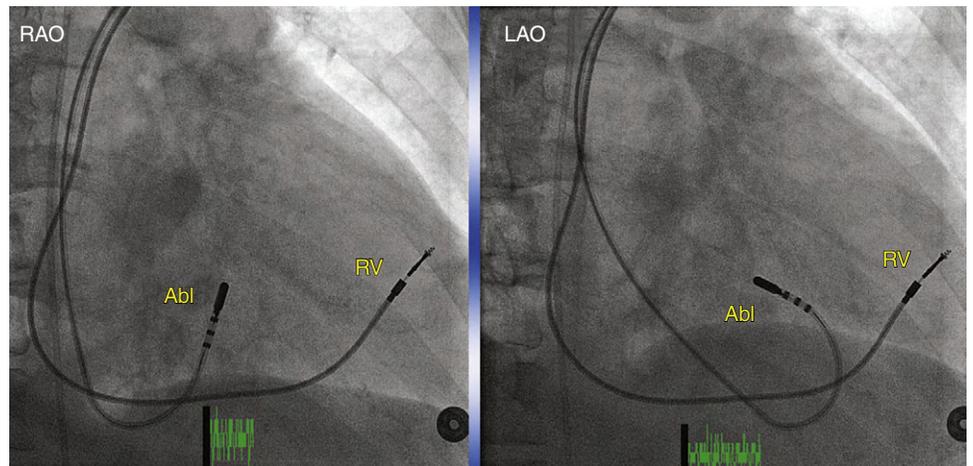

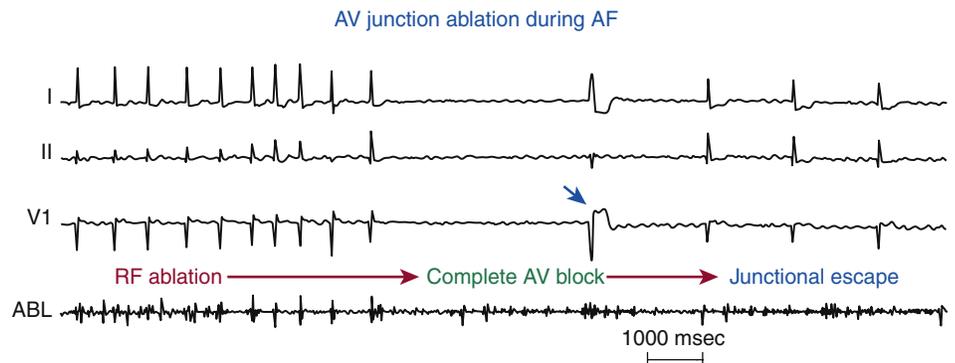

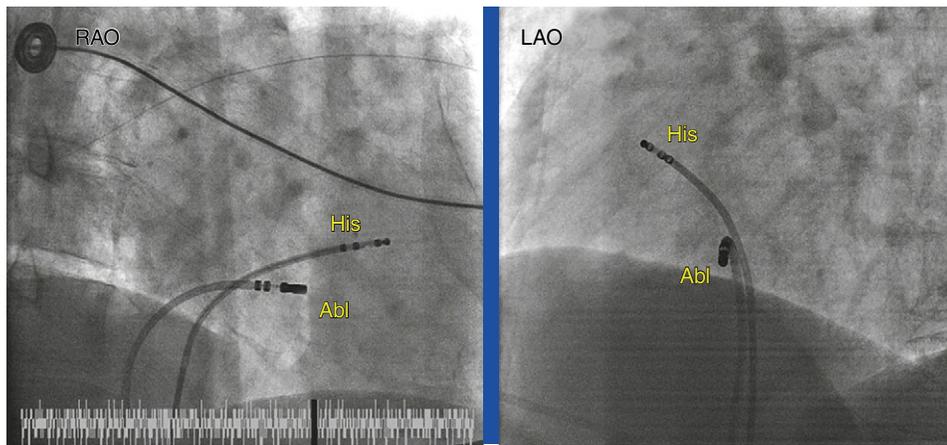

FIGURE 15-67 Atrioventricular (AV) junction ablation (ABL) during atrial fibrillation (AF). A ventricular pacemaker was implanted prior to ablation and programmed to VVI pacing mode at 30 beats/min. Radiofrequency (RF) application results in complete AV block with an escape ventricular paced complex (blue arrow) followed by the emergence of a junctional escape rhythm at 35 beats/min.

AVN modification during AF

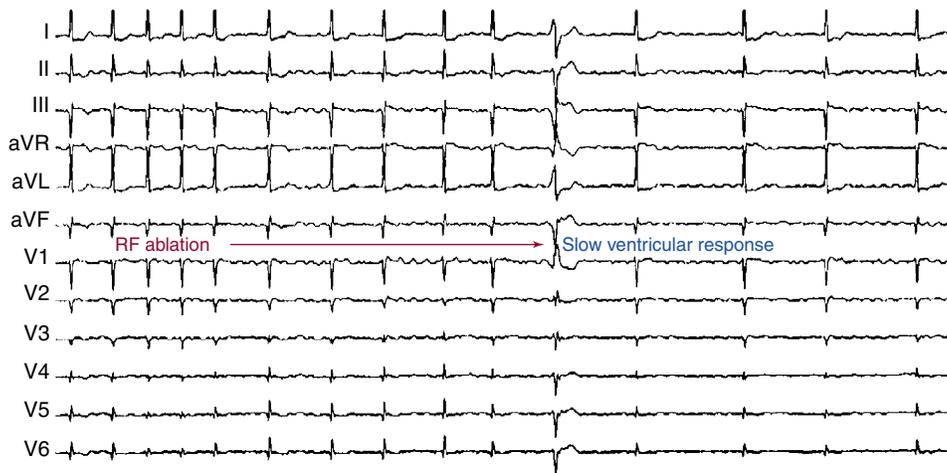

FIGURE 15-68 Atrioventricular node (AVN) modification during atrial fibrillation (AF). **Upper panel**, Fluoroscopic (right anterior oblique [RAO] and left anterior oblique [LAO]) views of the ablation catheter position (Abl) in relation to the His bundle (HB) catheter at the optimal site of AVN modification. The distal ablation electrode is positioned in the posteroseptal or midatrial septum near the tricuspid annulus, close to the coronary sinus ostium. **Lower panel**, AF with rapid ventricular response is initially observed (at left). Radiofrequency (RF) application results in slowing of the ventricular rate (at right) but not complete AV block, as indicated by irregularity of the rhythm.

pacing electrode over the RV septum, HB pacing, and biventricular pacing are being evaluated to reduce the impact of this potential problem.

Atrioventricular Nodal Modification

Rationale

AVN modification is performed to injure the AVN to reduce the ventricular rate during AF without producing complete heart block. As compared with ablation of the AV junction, AVN modification has the advantage in that it results in adequate control of the ventricular rate in most patients while obviating the need for a permanent pacemaker. Therefore, it may be appropriate to attempt first to modify AV conduction in patients with AF and rapid ventricular rates who are appropriate candidates for ablation of the AV junction. Because the risk of inadvertent complete AV block is approximately 20%, the use of the procedure should be limited at present to patients with AF who are symptomatic enough for ablation of the AV junction and implantation of a permanent pacemaker to be justified.

Target of Ablation

The right posteroseptal area along the tricuspid annulus extending from the CS os to the recording site of the HB can be divided into three regions: posterior, medial, and anterior. The conventional technique for ablation of the AV junction uses sites located anteriorly and superiorly on the tricuspid annulus. In contrast, with the technique used to modify AV conduction, the target sites are located inferiorly and posteriorly near the tricuspid annulus close to the CS os (i.e., in the posterior or midatrial septum) (Fig. 15-68).

In the presence of dual AVN physiology, the slow AVN pathway is targeted, as described for ablation of AVNRT.

Ablation Technique

Two quadripolar-electrode catheters are inserted into a femoral vein and positioned at the HB and in the RV. An ablation catheter with a 4-mm tip is used. In patients with no demonstrable dual AVN physiology, RF energy is delivered during AF under continuous infusion of isoproterenol (4 $\mu\text{g}/\text{min}$) to permit immediate assessment of the effect of each RF application. The ventricular rate during AF, obtained after administration of isoproterenol, is presumed to simulate the maximal rate of clinical AF. If NSR is present, AF is induced by rapid atrial pacing before the delivery of RF energy. The ablation catheter is initially positioned against the posterior RA septum, at the level of or lower than the CS os, to record a stable electrogram for at least 10 seconds, with a maximal A/V electrogram amplitude ratio of 0.5 or lower.

RF energy is delivered for 20 seconds at 30 W. If there is no change in the ventricular rate or no accelerating junctional rhythm within 20 seconds, higher energy (an increment of 5 W every 20 seconds, up to 40 W) is delivered to the same site. Whenever there is an abrupt lengthening of the R-R interval or appearance of an accelerated junctional rhythm, the application of energy is immediately discontinued (see Fig. 15-68). If the ventricular rate is still higher than the endpoint ventricular rate (i.e., more than 130 beats/min), higher energy is delivered to the effective site, or the ablation site is changed and the catheter is repositioned in progressively upward (more superior and anterior) positions along the tricuspid annulus until the endpoint is achieved. RF energy should not be delivered at the upper third of the atrial septum, where a HB potential is visible.

If the endpoint ventricular rate could not be achieved after RF application to the posterior and midatrial septum, a decision should be made about whether to attempt complete ablation of AVN. In the presence of dual AVN physiology, RF energy is delivered during NSR to eliminate a slow AVN pathway. The ablation technique is similar to that described for ablation of AVNRT.

Endpoints of Ablation

The endpoint of the procedure is an average ventricular rate of 120 to 130 beats/min or 70% to 75% of the maximum ventricular rate during infusion of isoproterenol (4 µg/min).

Outcome

SHORT-TERM RESULTS

The immediate success of AVN modification to control the ventricular rate without inducing pathological AV block is approximately 75% to 92%.

LONG-TERM RESULTS

In one report, 92% of patients with paroxysmal AF and uncontrolled ventricular rates refractory to antiarrhythmic drugs achieved adequate slowing of the ventricular rate and were free of symptoms without any antiarrhythmic drug or the need for a permanent pacemaker. The mean resting, ambulatory, and minimal ventricular rates during AF usually remained stable during an interval from 2 days to 3 months after the modification procedure. However, the mean maximal ventricular rate tended to increase (by up to 25%) during this period, which may reflect partial recovery of AV conduction from the immediate effects of RF energy. Nevertheless, the mean maximal ventricular rate during exercise or isoproterenol infusion at 3 months of follow-up remained approximately 25% lower than at baseline, a degree of attenuation adequate to result in the persistent resolution of symptoms.

ATRIOVENTRICULAR BLOCK

Inadvertent complete AV block occurs in approximately 20% to 25% of patients. Of those patients who develop transient AV block during RF application, approximately two-thirds develop persistent AV block within the first 36 to 72 hours after the procedure. It may be that transient thermal injury to the AV conduction system results in an inflammatory reaction responsible for the delayed occurrence of permanent injury. Regardless of the mechanism, if transient AV block occurs during an attempt to modify AV conduction, continuous ECG monitoring on an inpatient basis is appropriate for 3 to 4 days to watch for a recurrence of AV block.

LIMITATIONS

The AVN modification approach is applicable only to patients who do not have symptoms caused by irregular heart rhythm. An irregular rhythm may be hemodynamically less efficient than a regular paced rhythm. Additionally, at least 25% of patients in whom AVN modification is attempted develop inadvertent complete AV block that necessitates implantation of a permanent pacemaker.

Pathophysiology

Sinus tachycardia is a physiological response to sympathetic activation and/or parasympathetic withdrawal, such as during exercise, anxiety, pain, hypovolemia, orthostatic hypotension, fever, infections, hyperthyroidism, hypoglycemia, anemia, myocardial infarction, heart failure, pericarditis, diabetes-related autonomic dysfunction, drug abuse, catecholamine infusions, anticholinergic drugs, tobacco, caffeine, alcohol, and beta-blocking agent withdrawal. Inappropriate sinus tachycardia (IST) is a nonparoxysmal tachyarrhythmia characterized by a persistent increase in resting sinus rate unrelated to, or out of proportion with, the level of physical, emotional, pathological, or pharmacological stress or an exaggerated heart rate response to minimal exertion or a change in body posture.¹ IST is neither a response to a pathological process (e.g., heart failure, hyperthyroidism, or drug effects) nor a result of physical deconditioning.

The underlying mechanism of IST remains poorly understood. Several potential mechanisms have been suggested, including enhanced automaticity of the sinus node, altered sinus nodal intrinsic regulation, disorder of autonomic responsiveness of the sinus node, and sympathovagal imbalance, with excessive sympathetic drive or reduced vagal influence on the sinus node, or both. A primary abnormality of sinus node function has been suggested, as evidenced by a higher intrinsic heart rate (after muscarinic and beta-receptor blockade) than that found in normal controls or a blunted response to adenosine with less sinus cycle length prolongation than in control subjects (with and without autonomic blockade).^{2,3} In addition, beta-adrenergic receptor hypersensitivity, alpha-adrenergic receptor hyposensitivity, M₂ muscarinic receptor abnormalities, brain stem dysregulation, depressed efferent cardiovagal reflex, and impaired baroreflex control are likely explanations. Chronic beta-receptor stimulation by autoantibodies and autonomic neuritis or autonomic neuropathy can play a role in some cases. The extent to which each of these mechanisms contributes to tachycardia and associated symptoms is unknown, but the underlying mechanisms are likely multifactorial and complex.^{4,7}

In some patients, there can be an overlap between IST and disorders such as chronic fatigue syndrome and neurocardiogenic syncope, and other patients can have a psychological component of hypersensitivity to somatic input.⁸ Other groups with similar or overlapping laboratory findings and clinical course include patients with hyperadrenergic syndrome, idiopathic hypovolemia,⁹ orthostatic hypotension, and mitral valve prolapse syndrome.^{2,3}

Clinical Considerations

Epidemiology

Almost all patients afflicted with IST are young women (mean age, 38 ± 12 years), and many of them are hypertensive. IST affects people working in health care in disproportionate numbers. The explanation for these findings is lacking.^{3,10} The prevalence of IST

in a middle-aged population (up to 1.16% in one report) appears to be higher than previously assumed. Despite the chronic nature of the disorder and long-lasting symptoms, the natural course and prognosis of IST are benign.¹⁰

Clinical Presentation

The most prominent symptoms are palpitations, fatigue, and exercise intolerance. IST can also be associated with a host of other symptoms, including chest pain, dyspnea, lightheadedness, dizziness, presyncope, and syncope. The clinical presentation of the arrhythmia is highly variable, ranging from totally asymptomatic patients identified during routine medical examination to those with paroxysmal short episodes of palpitations to individuals with chronic, incessant, and incapacitating symptoms.^{2,10} The risk of tachycardia-induced cardiomyopathy in untreated patients is unknown but is likely to be low.^{1,10,11}

Initial Evaluation

IST is an ill-defined clinical syndrome with diverse clinical manifestations. There is no gold standard to make a definitive diagnosis of IST, and the diagnosis remains a clinical one after exclusion of other causes of symptomatic tachycardia. Clinical examination and routine investigations allow elimination of secondary causes for the tachycardia but are generally not helpful in establishing the diagnosis of IST.¹⁻³

The syndrome of IST is characterized by the following: (1) a relative or absolute increase in sinus rate out of proportion to the physiological demand (there can be an increased resting sinus rate of more than 100 beats/min or an exaggerated heart rate response to minimal exertion or change in body posture); (2) P wave axis and morphology during tachycardia that are similar or identical to those noted during normal sinus rhythm; (3) lack of secondary causes of sinus tachycardia; and (4) markedly distressing symptoms of palpitations, fatigue, dyspnea, and anxiety during tachycardia, with an absence of symptoms during normal sinus rates.^{1-4,12}

Ambulatory Holter recordings characteristically demonstrate a mean heart rate of more than 90 to 95 beats/min (Fig. 16-1). However, some patients have either a physiological or normal heart rate at rest (less than 85 beats/min) with an inappropriate tachycardia response to a minimal physiological challenge or a moderately elevated resting heart rate (more than 85 beats/min) with an accentuated (inappropriate) heart rate response to minimal exertion.^{2,3,13} However, this quantitative definition of inappropriate is arbitrary, and validation of the reproducibility of the heart rate and activity correlation can be challenging.^{12,14}

Exercise ECG testing typically shows an early and excessive increase of heart rate in response to minimal exercise (heart rate greater than 130 beats/min within 90 seconds of exercise; Bruce protocol). This heart rate response is differentiated from physical deconditioning by chronicity and the presence of associated symptoms.²

Isoproterenol provocation helps demonstrate sinus node hypersensitivity to beta-adrenergic stimulation. Isoproterenol is

FIGURE 16-1 A 24-hour trend of the long-term ECG showing inappropriate sinus tachycardia throughout usual activity and on awakening.

administered as escalating intravenous boluses at 1-minute intervals, starting at 0.25 μg , with doubling of the dose every minute, until a target heart rate increase of 35 beats/min higher than baseline or a maximum heart rate of 150 beats/min is reached. In patients with IST, the target heart rate is reached with an isoproterenol dose of $0.29 \pm 0.1 \mu\text{g}$ (versus $1.27 \pm 0.4 \mu\text{g}$ in normal controls).²

Invasive electrophysiological (EP) testing may be considered when other arrhythmias are suspected or when a decision to proceed with catheter ablation is undertaken. It is important to recognize that sinus node modification to target IST is a clinical decision, and it must be made prior to the invasive EP study itself. The diagnosis of IST and the treatment approach have to be established before the patient is brought to the EP laboratory.^{2,3}

IST shares several characteristics with postural orthostatic tachycardia syndrome (POTS), and it is sometimes challenging to differentiate between the two conditions. POTS is characterized by the presence of symptoms of orthostatic intolerance (i.e., the provocation of symptoms on standing that are relieved by recumbence) associated with a heart rate increase of 30 beats/min (or a rate that exceeds 120 beats/min) that occurs within the first 10 minutes of standing or upright tilt and is not associated with other chronic debilitating conditions such as prolonged bed rest or the use of medications known to diminish vascular or autonomic tone. Patients with POTS tend to display a more pronounced degree of postural change in heart rate than do those with IST. Additionally, in the supine position, the heart rate in patients with POTS rarely exceeds 100 beats/min, whereas in IST the resting heart rate is often higher than 100 beats/min. Patients with IST do not display the same degree of postural change in norepinephrine levels as do patients with hyperadrenergic POTS. The distinction between IST and POTS is important because catheter ablation of the sinus node rarely improves, and can even worsen, symptoms in patients with POTS.¹⁵

Principles of Management

The treatment of IST is predominantly symptom driven. Medical management remains the mainstay of therapy. Beta-blockers can be useful and should be prescribed as first-line therapy for most patients. Nondihydropyridine calcium channel blockers (verapamil and diltiazem) can also be effective.¹ However, pharmacological therapy for IST has been limited by the poor long-term tolerance to the drugs and the disappointing long-term outcome.

Ivabradine is a novel selective inhibitor of cardiac pacemaker I_f ion current, which is highly expressed in the sinus node and contributes to sinus node automaticity. Ivabradine selectivity induces heart rate reduction in humans and animals without any modification in cardiac contractility and atrioventricular and intraventricular conduction times. Blockade of the I_f current induced by ivabradine is dose and heart rate dependent, resulting in greater effects during fast heart rates and limiting the risk of symptomatic bradycardia. This agent is commonly used to relieve pain in patients affected by chronic stable angina. Preliminary data suggest that orally administered ivabradine lowers the mean daily and maximal heart rates in patients with IST, improves symptoms, enhances exercise-stress tolerance, and markedly improves quality of life, even in patients refractory to beta-blocking therapy. This pharmacological treatment could be considered a second-line therapy in patients

refractory to and intolerant of beta-blockers and nondihydropyridine calcium channel blockers. However, more large-cohort studies are needed to confirm these preliminary results.^{11,16,17}

Despite advances in ablation technologies, the long-term success of catheter ablation for IST remains disappointing. Nevertheless, sinus node modification by catheter ablation remains a potentially important therapeutic option in the most refractory cases of IST.^{1,2}

Electrophysiological Testing

The goals of EP testing in patients with IST are to exclude other tachycardias that can mimic sinus tachycardia, such as atrial tachycardia (AT) originating near the superior aspect of the crista terminalis or right superior pulmonary vein, and to ensure that the tachycardia occurring spontaneously or, more likely with isoproterenol infusion, acts in a manner consistent with an exaggeration of normal sinus node physiology.^{2,3}

For activation sequence mapping, a multipolar (20-pole) crista catheter is placed along the crista terminalis in addition to the catheters used for a routine EP evaluation (coronary sinus, His bundle, and right ventricular apex). The crista catheter is positioned on the crista terminalis from the superomedial aspect originating at the junction of the superior vena cava (SVC) and right atrial (RA) appendage, with continuation along the crista toward the junction of the inferior vena cava and RA inferolaterally. Catheter contact with the crista terminalis can be enhanced by using a long sheath (Fig. 16-2). Intracardiac echocardiography (ICE) may also be used to identify the crista terminalis and guide mapping catheter positioning as well as radiofrequency (RF) ablation (see later).^{2,3}

Induction of Tachycardia

Programmed electrical stimulation is performed before and after isoproterenol infusion. Isoproterenol infusion is started at 0.5 to 1.0 $\mu\text{g}/\text{min}$ and titrated every 3 to 5 minutes to a maximum of 6 $\mu\text{g}/\text{min}$. Atropine (1 mg) can also be administered to assess maximum sinus cycle length. It is important to document failure to induce AT and other supraventricular tachycardias during programmed stimulation. IST cannot be initiated with atrial rapid pacing or extrastimulation, but it can be induced by adrenergic stimulation. Initiation of IST is associated with a gradual increase of the sinus rate, with a gradual shift of the earliest atrial activation site up the crista terminalis.

EP phenomena such as dual atrioventricular nodal physiology or atrioventricular nodal echo beats should be cautiously evaluated in patients in whom the only documented symptomatic tachycardia appears to have a sinus mechanism. The relevance of these phenomena should be carefully assessed.

Tachycardia Features

The atrial activation sequence during IST is characterized by a craniocaudal activation sequence along the crista, with the site of earliest atrial activation shifting up the crista at faster rates and down the crista at slower rates. The earliest atrial activation site always occurs along the crista terminalis (as confirmed by the multipolar catheter placed on the crista) despite a changing tachycardia rate or autonomic modulation (isoproterenol and atropine).

In contrast focal AT, IST is characterized by a gradual increase and decrease in heart rate with changes in autonomic tone or at the initiation and termination of the tachycardia. Additionally, adrenergic stimulation reproducibly causes an increase in IST rate and a cranial shift in atrial activation along the crista terminalis, whereas vagal stimulation causes slowing of the IST rate with caudal shift.

Exclusion of Other Arrhythmia Mechanisms

Both sinus node reentrant tachycardia and focal AT have to be excluded. Sinus node reentry is easily and reproducibly initiated with atrial extrastimulation, and AT can be initiated with atrial extrastimulation, burst pacing, or adrenergic stimulation, whereas IST cannot

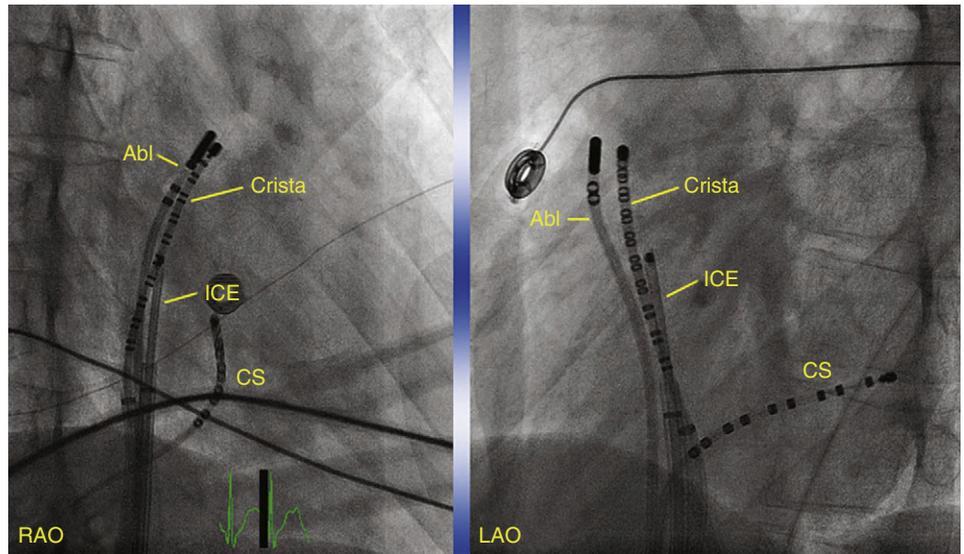

FIGURE 16-2 Right anterior oblique (RAO) and left anterior oblique (LAO) fluoroscopic view during sinus node modification. Multipolar (crista) catheter is placed along the crista terminalis with intracardiac echocardiography (ICE) guidance. Abl = ablation; CS = coronary sinus.

FIGURE 16-3 A 12-lead ECG showing perinodal focal atrial tachycardia (or sinus node reentrant tachycardia) with abrupt termination and restoration of normal sinus rhythm. Note the similarities between the tachycardia and sinus P wave morphology.

be initiated with programmed electrical stimulation. Furthermore, AT and the sinus node reentrant tachycardia rate can shift suddenly at initiation, although AT can then warm up over a few beats, as opposed to the gradual increase of the IST rate over seconds to minutes.

The atrial activation sequence shifts suddenly at the onset of AT or sinus node reentrant tachycardia, as opposed to a gradual cranial shift of the earliest atrial activation up the crista terminalis with adrenergic stimulation as the sinus rate increases during IST. Although the rate of focal AT can continue to increase with continued adrenergic stimulation, this is not associated with a further shift in the atrial activation sequence.

Sinus node reentry is easily and reproducibly terminated with programmed stimulation, whereas IST cannot be terminated with programmed stimulation. Termination of focal AT and sinus node

reentry is sudden, as opposed to gradual slowing (cooldown) of the IST rate (Fig. 16-3). Vagal maneuvers result in abrupt termination of sinus node reentry and in either no effect or abrupt termination of AT, as opposed to gradual slowing and inferior shift down the crista terminalis of the site of origin of IST. Abrupt termination of the tachycardia with a single RF application suggests AT, because IST originates from a widespread area involving the superior crista terminalis.

Ablation

Target of Ablation

Understanding the anatomy and physiology of the sinus node (see Chap. 8) is critical for identifying the target of ablation for sinus node

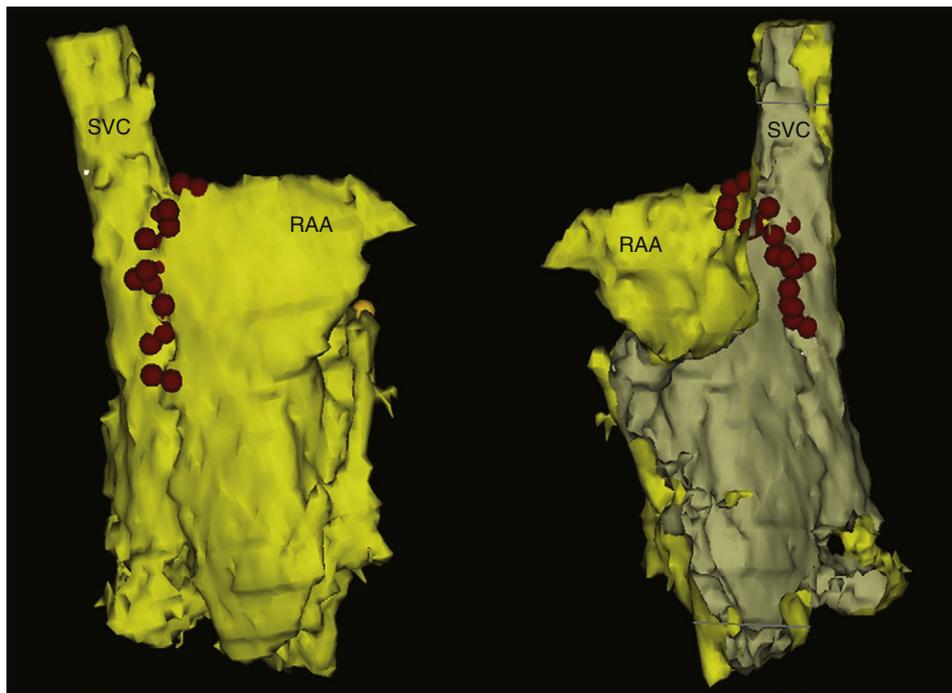

FIGURE 16-4 Integrated computed tomography (CT) and electroanatomical (CARTO) map of the right atrium acquired during sinus node modification. Right anterior oblique and cardioscopic views of the CT scan are shown. Note the area targeted by radiofrequency ablation (red dots) starting cranially at the medial portion of the crista as it courses in front of the superior vena cava (SVC). RAA = right atrial appendage.

modification. The sinus node region is a distributed complex characterized by rate-dependent site differentiation (i.e., there is anatomical distribution of impulse generation with changes in sinus rate), which allows for targeted ablation to eliminate the fastest sinus rates while maintaining some degree of sinus node function.¹⁸

Sinus node modification targets the site of most rapid discharge, generally at the superior aspect of the crista terminalis. One must recognize, however, that sinus node modification is not a focal ablation, but requires complete abolition of the cranial portion of the sinus node complex (Fig. 16-4). Ideally, this procedure eliminates the areas of the sinus node responsible for rapid rates while preserving some chronotropic competence.

Because of the possibility of unsatisfactory results of ablation (see later), it is important to have an understanding with the patient and family about likely outcomes and implications (needing a pacemaker or repeat ablation procedure, persistence of symptoms despite good heart rate control) prior to an ablation procedure.

Ablation Technique

The crista terminalis is not visible on fluoroscopy and has a varied course among patients. Therefore, some operators prefer using ICE to help identify the crista, position the tip of the ablation catheter with firm contact on the crista, and assess the RF lesion (see Fig. 11-23).^{19,20}

A three-dimensional mapping system (CARTO, NavX) can also help delineate relevant anatomical structures (SVC, boundaries of atrium), define the extent of the earliest site of activation during IST, delineate the course of the phrenic nerve (sites at which pacing stimulates the diaphragm), and catalog sites of ablation.^{21,22}

A multipolar catheter is placed along the crista terminalis (with or without ICE guidance; see Fig. 16-2). A standard ablation catheter with a 4- or 8-mm-tip or an irrigated-tip catheter is used for RF application. RF power is adjusted to achieve a tip temperature of 50° to 60°C or an impedance drop of 5 to 10 Ω, or both. RF lesions are applied as guided by the earliest atrial activation time, usually along superior regions of the crista terminalis using the guidance of the crista catheter. The local endocardial activation time recorded by the ablation catheter at successful sites typically precedes the onset of the surface P wave during the tachycardia by 25 to 45 milliseconds (Fig. 16-5).

RF ablation is performed under maximal adrenergic stimulation with isoproterenol (with or without parasympathetic blockade

with atropine) to reveal the superior portions of the crista terminalis as the earliest sites of atrial activation. The medial portion of the crista as it courses in front of the SVC is usually the site of earliest activation for the fastest sinus rates; this portion of the crista should be targeted by RF ablation first. Progressively inferior portions of the crista are then ablated until target heart rate reduction is achieved. This technique often requires ablating an estimated area of $12 \pm 4 \times 19 \pm 5$ mm.²¹

RF energy delivery at any one site should probably be limited to 30 seconds because these are usually closely spaced applications, which carry the risk of char formation with longer applications. Pacing from the ablation catheter tip at high output (5 to 10 mA) before each RF application to verify the absence of diaphragmatic stimulation is necessary to avoid phrenic nerve injury. Rarely, pericardial access with epicardial ablation has been necessary. Then, avoidance of the phrenic nerve can be even more problematic and require instilling saline into the pericardial space or placing a balloon catheter through a second pericardial access to separate the phrenic nerve physically from the ablation zone.^{2,3,20,22}

Acceleration of the sinus rate followed by a marked subsequent rate reduction or the appearance of a junctional rhythm during ablation is an indicator of successful ablation sites, and thereafter delivery of RF energy should be continued for at least 60 to 90 seconds. Most patients demonstrate a stepwise reduction in sinus rate during the course of ablation, associated with migration of the site of earliest atrial activation in a craniocaudal direction along the crista terminalis (see Fig. 16-5). However, it is not uncommon to observe an abrupt reduction in the sinus rate in response to RF ablation at a focal site of earliest atrial activation (Fig. 16-6).²² Echocardiographic lesion characteristics using ICE can also provide a guide for directing additional RF lesions. The effective RF lesion has an increased or changed echodensity completely extending to the epicardium with the development of a trivial linear low-echodensity or echo-free interstitial space, which suggests a transmural RF lesion.²³

Endpoints of Ablation

Acute procedural success is defined as the following: (1) abrupt reduction of the sinus rate by 30 beats/min or more during RF delivery or a 30% decline in maximum heart rate during infused isoproterenol and atropine; (2) persistence of a reduced sinus rate; (3) maintenance of a superiorly directed P wave (negative P wave in lead

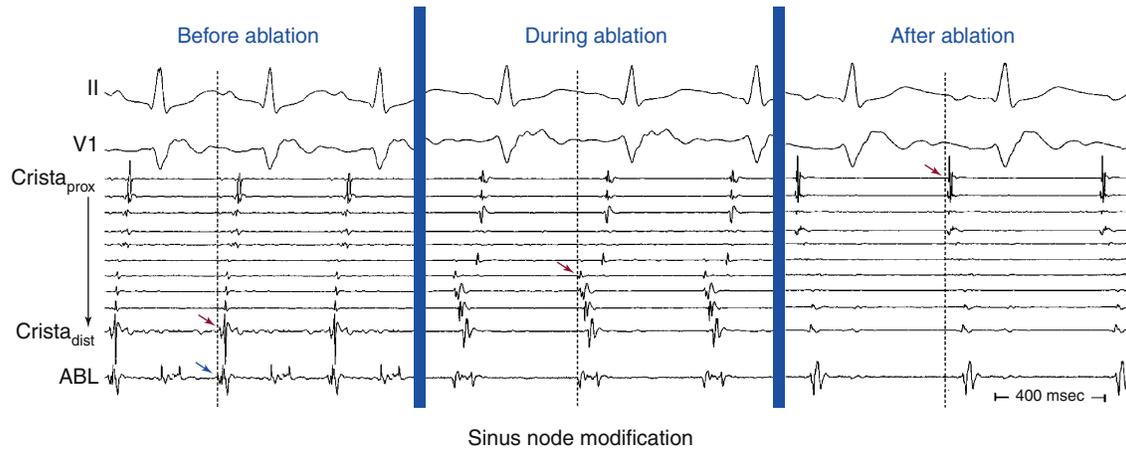

FIGURE 16-5 Intracardiac recordings during sinus node modification. **Left panel**, Before ablation (ABL) and under adrenergic stimulation, sinus tachycardia is observed, with the earliest local activation (red arrows) recorded by the most distal (cranial) electrodes of the crista catheter, just anterior to the superior vena cava–right atrial junction. Note that local activation recorded by the ablation catheter (blue arrow) precedes the onset of the P wave (indicated by the vertical dashed line) by 20 to 30 milliseconds. **Middle panel**, Following ablation of the most cranial part of the sinus node, the sinus rate becomes slower, and the activation sequence shifts toward more proximal (caudal) electrodes 7 to 8 on the crista catheter. **Right panel**, Following successful sinus node modification, the sinus rate (under constant adrenergic stimulation) is reduced by more than 30%, and the atrial activation sequence shifts to the most proximal (caudal) crista catheter electrodes. Note the P wave is now inverted in lead II. dist = distal; prox = proximal.

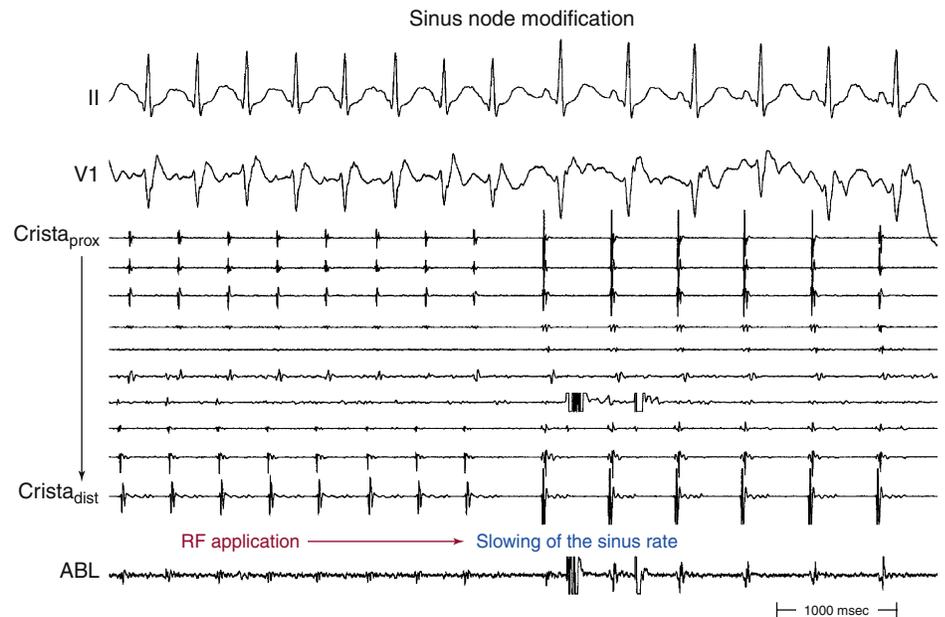

FIGURE 16-6 Intracardiac recordings during sinus node modification. An abrupt reduction in the sinus rate is observed in response to radiofrequency (RF) ablation (ABL) at a focal site of earliest atrial activation. dist = distal; prox = proximal.

III); and (4) inferior shift of the site of earliest atrial activation down the crista terminalis, even with maximal adrenergic stimulation.^{2,3,22}

RF ablation of IST often is difficult and requires multiple RF applications; a mean of 12 RF applications (range, 6 to 92) was required in one study (see Fig. 16-4).¹⁹ The resilience of the sinus node to endocardial catheter ablation can be explained, in part, by the architectural features of the node—the dense matrix of connective tissue in which the specialized sinus node cells are packed; the cooling effect of the nodal artery; the subepicardial nodal location; and the thick terminal crest, particularly in relation to the nodal portion caudal to the sinus node artery. Additionally, the length of the sinus node, the absence of an insulating sheath, the presence of nodal radiations, and caudal fragments offer a potential for multiple breakthroughs of the nodal wavefront.¹⁸

Outcome

Prior to undertaking ablation of the sinus node for IST, the physician and patient should have realistic expectations and understanding

of the goals of ablation and potential outcomes. Relatively few patients will achieve the desired combination of relief of symptoms and normal resting heart rate and chronotropic response without the need for implantation of a permanent pacemaker. In some patients, symptoms persist despite an acceptable technical result.^{2,3}

RF ablation is at best only a modestly effective technique for managing patients with IST. The long-term success rate is variable, ranging between 23% and 83%.⁸ Complete ablation of the sinus node resulting in junctional rhythm has better long-term success (72%) but requires pacemaker insertion. Most recurrences occur 1 to 6 months after the procedure and are typically related to tachycardia recurrence after an initially successful procedure. A repeat procedure may be necessary in patients with intolerable symptoms. Symptomatic recurrence or persistence of symptoms in the absence of documented IST and despite persisting evidence of a successful EP outcome has been observed in some cases. Persistent symptoms despite heart rate reduction may be suggestive of a more global dysautonomia that also happens to affect the sinus node.^{2,3,20-22}

Complications of sinus node modification include cardiac tamponade, SVC syndrome, diaphragmatic paralysis, and sinus node dysfunction.²⁴ Cardiac tamponade is rare and is usually caused by penetration of an unattended right ventricular catheter in a thin female patient with rapid and vigorous heart action because of high-dose isoproterenol infusion. Transient SVC syndrome can develop because of extensive lesion creation and edema at the SVC-RA junction. This can rarely cause permanent SVC stenosis. More targeted ablation using ICE may help avoid this complication. Diaphragmatic paralysis secondary to damage to the right phrenic nerve should be minimized if ablative lesions are confined to the crista itself or placed just anterior to it. Using ICE to guide ablation makes this complication unlikely because the phrenic nerve is a posterior structure. Pacing with a high output of 10 mA from the ablation catheter at the target site without capture of the phrenic nerve and continuous pacing in the SVC to capture the phrenic nerve during RA ablation are reassuring, but their efficacy has never been assessed. Additionally, suspicion of phrenic nerve injury should be considered in the case of hiccup, cough, or decrease in diaphragmatic excursion during energy delivery. Early recognition of phrenic nerve injury during RF delivery allows the immediate interruption of the application prior to the onset of permanent injury and is associated with rapid recovery of phrenic nerve function. Persistent junctional rhythm requiring pacemaker insertion is rare. Such junctional rhythm usually disappears with the return of sinus rhythm within several days.^{2,3,22}

Pathophysiology

Anatomy and Physiology of the Atrioventricular Node

The atrioventricular (AV) junction is a complex structure, located within an area called the triangle of Koch (Fig. 17-1).¹ The triangle of Koch is bounded by the coronary sinus ostium (CS os) posteriorly, the tricuspid annulus (the attachment of the septal leaflet of the tricuspid valve) inferiorly, and the tendon of Todaro anteriorly and superiorly. The triangle of Koch is septal in location and constitutes the right atrial (RA) endocardial surface of the muscular AV septum. The compact AV node (AVN) lies just beneath the RA endocardium, at the apex of the triangle of Koch, anterior to the CS os, and directly above the insertion of the septal leaflet of the tricuspid valve, where the tendon of Todaro merges with the central fibrous body. Slightly more anteriorly and superiorly is where the His bundle (HB) lies. The mean distances from the HB electrogram recording site to the upper and lower lips of the CS os are 10 mm (range, 0 to 23 mm), and 20 to 25 mm (range, 9 to 46 mm), respectively. However, the contour of the Koch triangle may be small or even horizontal in some patients.²⁻⁴

Functionally, based on activation times during anterograde or retrograde propagation, or both, and on the action potential characteristics from microelectrode recordings in the rabbit AV junction, the cells of the AVN region are frequently described as AN (atrionodal), N (nodal), and NH (nodal-His). The transition from one cell area to the other is gradual, with intermediate cells exhibiting intermediate action potentials with great changes related to the autonomic tone.²⁻⁶

The AN region corresponds to the cells in the transitional zone, which are activated shortly after the atrial cells. The transitional cell zone represents the inferior, more open portion of the AVN into which atrial bands gradually merge (i.e., the approaches from the working atrial myocardium to the AVN). Transitional cells are histologically distinct from both the cells of the compact AVN and the working atrial myocytes. Transitional cells are not insulated from the surrounding myocardium but tend to be separated from one another by thin fibrous strands. The connections between atrial and transitional cells are so gradual that no clear anatomical demarcations can be detected.⁷ Transitional cells do not represent conducting tracts, but rather a bridge funneling of atrial depolarization into the compact AVN through discrete AVN inputs (approaches). In humans and animals, two such inputs are commonly recognized in the right septal region: the anterior (superior) approaches, which travel from the anterior limbus of the fossa ovalis and merge with the AVN closer to the apex of the triangle of Koch, and the

posterior (inferior) approaches, located in the inferoseptal RA and which serve as a bridge with the atrial myocardium at the CS os. Although both inputs have traditionally been assumed to be RA structures, growing evidence supports the AV conduction apparatus as a transeptal structure that reaches both atria. A third, middle group of transitional cells has also been identified to account for the nodal connections with the septum and left atrium (LA).^{2,5,8-12}

The N region corresponds to the compact AVN, the region where transitional cells merge with midnodal cells. The N cells represent the most typical of the nodal cells because they are characterized by a less negative resting membrane potential and low action potential amplitude (mediated by the L-type calcium [Ca^{+2}] current), slow rates of depolarization and repolarization, few intercellular connections such as gap junctions, and reduced excitability compared with surrounding cells. The N cells in the compact AVN appear to be responsible for the major part of AV conduction delay. Sodium channel density is lower in the midnodal zone of the AVN than in the AN and NH cell zones, and the inward L-type Ca^{2+} current is the basis of the upstroke of the N cell action potential. Therefore, conduction is slower through the compact AVN than through the AN and NH cell zones.^{1,6} Fast pathway conduction through the AVN apparently bypasses many of the N cells by transitional cells, whereas slow pathway conduction traverses the entire compact AVN. Importantly, the recovery of excitability after conduction of an impulse is faster for the slow pathway than for the fast pathway for reasons that are unclear.^{5,6,13}

The NH region corresponds to the lower nodal cells, typically distal to the site of Wenckebach block, connecting to the insulated penetrating portion of the HB. The action potentials of the NH cells are closer in appearance to the fast-rising and long action potentials of the HB.

When traced inferiorly, toward the base of the triangle of Koch, the compact AVN area separates into two extensions, usually with the artery supplying the AVN running between them. The prongs bifurcate toward the CS os and tricuspid annulus (right posterior extension) and toward the mitral annulus (left posterior extension). The right posterior nodal extension has been implicated as the anatomical substrate for the so-called slow pathway in the AVN reentrant tachycardia (AVNRT) circuit. The tachycardia circuit may seldom involve the left posterior nodal extension (see later). The fast pathway is less well defined from an anatomical and structural standpoint. The probable anatomical substrate of this pathway consists of the transitional cell layers located around the compact AVN at the interface between the compact node and transitional cells.^{3,4,12,14} The HB connects with the distal part of the compact AVN and passes through the fibrous core of the central fibrous body in a leftward direction (away from the RA endocardium and

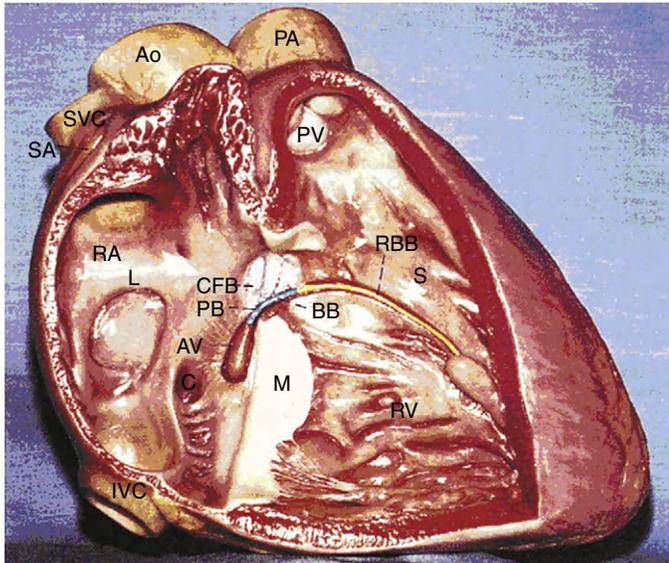

FIGURE 17-1 Right lateral view of the right atrium (RA). Ao = aorta; AV = atrioventricular node; BB = bundle of His, branching portion; C = coronary sinus; CFB = central fibrous body; IVC = inferior vena cava; L = limbus of the fossa ovalis; M = medial (septal) leaflet of the tricuspid valve; PA = pulmonary artery; PB = bundle of His, penetrating portion; PV = pulmonic valve; RBB = right bundle branch; RV = right ventricle; S = septal band of the crista supraventricularis; SA = sinoatrial node; SVC = superior vena cava. (From Saffitz J, Zimmerman F, Lindsay B. In Braunwald E, McManus BM, editors: *Atlas of cardiovascular pathology for the clinician*, Philadelphia, 2000, Wiley-Blackwell, p 21.)

toward the ventricular septum). The HB then continues through the annulus fibrosus, where it is called the nonbranching portion as it penetrates the membranous septum, along the crest of the left side of the interventricular septum, for 1 to 2 cm and then divides into the right bundle branch (RB) and left bundle branch (LB). The HB is insulated from the atrial myocardium by the membranous septum and from the ventricular myocardium by connective tissue of the central fibrous body.¹ Viewed from the left ventricle (LV), the HB is marked by the area of fibrous continuity between the aortic and mitral valves adjacent to the membranous septum. Viewed from the aorta, the HB passes beneath the part of the membranous septum that adjoins the interleaflet fibrous triangle between the right and noncoronary sinuses.¹²

Tachycardia Circuit

The concept of AVN reentry is related, but not identical, to the so-called dual pathway electrophysiology. It is well established that dual AVN physiology is the underlying substrate for AVNRT; however, it is important to recognize that dual AVN physiology characterizes the normal AVN electrophysiology, and the presence of dual (or multiple) AVN pathways is not necessarily indicative of the existence of functional reentry, although it is required to maintain the reentry circuit. Nevertheless, the presence of dual AVN physiology provides the natural substrate for the occurrence of AVN reentry. In the absence of an animal model, however, the exact pathophysiological substrate for AVNRT remains uncertain.⁴

The AVNRT circuit does not involve the ventricles, but whether the circuit is confined to the compact AVN (subatrial) or involves a component of perinodal atrial myocardium is controversial. There is good evidence that the distal junction of the slow and fast pathways is located in the AVN, with the existence of a region of AVN tissue extending between the distal junction of the two pathways and the HB (called the lower common pathway), at least in a subset of patients (Table 17-1). However, the nature of the proximal link between these pathways is unclear, and the existence of an upper common pathway is still a matter of controversy (Tables 17-2 and 17-3). Based on rare cases of dissociation of atrial activation

TABLE 17-1 Evidence against the Necessity of Ventricle in Reentrant Circuit*

VA Wenckebach CL during ventricular pacing longer than the tachycardia CL
HA interval during ventricular pacing at the tachycardia CL longer than that during AVNRT
AV block occurring without interruption of AVNRT
AES during AVNRT resulting in changes in the relative activation of HB and atrium (i.e., varying HA intervals)
VES during AVNRT prematurely depolarizing the HB without affecting the tachycardia

*Supporting the presence of a lower common pathway.

AES = atrial extrastimulation; AV = atrioventricular; AVNRT = atrioventricular nodal reentrant tachycardia; CL = cycle length; HA = His bundle–atrial; HB = His bundle; VA = ventriculoatrial; VES = ventricular extrastimulation.

TABLE 17-3 Evidence against the Necessity of Atrium in Reentrant Circuit*

Initiation of AVNRT in the absence of an atrial echo
AV Wenckebach CL during atrial pacing longer than the tachycardia CL
AH interval during atrial pacing at the tachycardia CL longer than that during AVNRT
Retrograde VA block occurring without interruption of AVNRT
AVNRT occurrence in the presence of AF
Depolarization of the atria surrounding the AVN without affecting the tachycardia
Resetting of the tachycardia by ventricular stimulation in the absence of atrial activation
Heterogeneous atrial activation during AVNRT that is incompatible with atrial participation
Changing VA relationship with minimal or no change in the tachycardia CL (suggesting that atrial activation is determined by the functional output to the atrium from the tachycardia and not causally related to it)

*Supporting the presence of an upper common pathway.

AF = atrial fibrillation; AH = atrial–His bundle; AV = atrioventricular; AVN = atrioventricular node; AVNRT = atrioventricular nodal reentrant tachycardia; CL = cycle length; VA = ventriculoatrial.

From Josephson ME: Supraventricular tachycardias. In Josephson ME, editor: *Clinical cardiac electrophysiology*, ed 3, Philadelphia, 2002, Lippincott Williams & Wilkins, pp 168-271.

from the tachycardia (e.g., persistence of AVNRT during different patterns of VA block) and on similarities between fast-slow AV conduction and longitudinal-transverse conduction in nonuniform anisotropy, early studies proposed that AVNRT results from reentry within the compact AVN because of functional longitudinal

TABLE 17-4 Functional Differences between Fast and Slow Atrioventricular Node Pathways

The fast pathway forms the normal physiological conduction axis, and the AH interval during conduction over the fast pathway is usually no longer than 220 msec. Longer AH intervals can be caused by conduction over the slow pathway.

Anterograde ERP of the fast pathway is usually longer than that of the slow pathway. However, many exceptions exist.

Adrenergic stimulation tends to shorten the anterograde and retrograde ERP of the fast pathway to a greater extent than that of the slow pathway. Conversely, beta blockers tend to prolong ERP of the fast pathway more than that of the slow pathway.

The earliest atrial activation site during retrograde conduction over the fast pathway is in the anterior apex of the triangle of Koch at the same site recording the proximal His potential (although some studies showed the earliest site of atrial activation occurring in the anterior interatrial septum above the tendon of Todaro, outside the triangle of Koch), whereas that over the slow pathway is in the base of the triangle of Koch.

AH = atrial–His bundle; ERP = effective refractory period.

dissociation within the AVN into fast and slow pathways and suggested the presence of an upper common pathway, at least in a subset of patients.^{13,15}

Current evidence, derived from multielectrode recordings and optical mapping studies, supports the role of perinodal tissue and suggests that the fast and slow pathways involved in the reentrant circuit of AVNRT represent conduction over different atrionodal connections, thus making at least a small amount of atrial tissue a necessary part of the reentrant circuit (Video 19). As noted, the compact AVN is surrounded by transitional cells whose structure and function are intermediate between those of atrial and compact nodal cells. If one considers the compact AVN and the surrounding transitional cells as a functional AVN unit, which implies that the AVN tissue occupies the bulk of the triangle of Koch, then the AVN reentrant circuit may be considered as confined to the AVN. Therefore, much of the disagreement on the presence or absence of an upper common pathway and the role of the atrium in the genesis of the reentrant circuit may, in part, be related to the definition of the extent of the AVN.¹⁶

Nevertheless, the understanding of the AVN as having superior (anterior) and inferior (posterior) inputs that form the fast and slow pathways, respectively, is a simple conceptual framework that seems to enable the clinician to confront most cases. Reentry occurring along these pathways is the basic mechanism for the various subtypes of AVNRT. The proximal atrial insertions of the fast and slow pathways are anatomically distinct during retrograde conduction, and several important functional differences exist between the two pathways (Table 17-4).^{13,14}

Multiple slow pathways (as demonstrated by multiple discontinuities in the AVN function curves; see later) are present in up to 14% of patients with AVNRT, although not all these pathways are involved in the initiation and maintenance of AVNRT. Whether these pathways represent discrete anatomically distinct circuits or are functionally present because of nonuniform anisotropy is unclear. Frequently, multiple slow pathways are in close proximity within the triangle of Koch, and elimination of multiple slow pathways with radiofrequency (RF) ablation at one site is observed in approximately 42% of cases. Slow pathways with longer conduction times have a more inferior location in the triangle of Koch when compared with locations producing a shorter atrial–HB (AH) interval.

Types of Atrioventricular Nodal Reentry

SLOW-FAST (TYPICAL, COMMON) ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

Typical AVNRT accounts for 90% of AVNRTs. The reentrant circuit uses the slow AVN pathway anterogradely and the fast pathway retrogradely. The earliest atrial activation during typical AVNRT is

usually in the apex of the triangle of Koch; however, retrograde atrial activation over the fast pathway is heterogeneous and may be found at the CS os or on the left side of the septum in up to 9% of patients (Fig. 17-2).^{8,13,17,18}

During typical AVNRT, atrial and ventricular activations occur almost simultaneously. The AH interval is relatively long (more than 200 milliseconds) and the HA interval is relatively short (less than 70 milliseconds), resulting in a short RP tachycardia.

The presence of a lower common pathway in typical AVNRT remains controversial. Although some studies suggested the existence of a lower common pathway in most patients with typical AVNRT, others demonstrated that most patients with AVNRT without evidence of a substantial lower common pathway had typical AVNRT (i.e., the lower turnaround is within the proximal HB), and the presence of a lower common pathway was strongly associated with the atypical variants of AVNRT. Nevertheless, it is recognized that the lower common pathway in typical AVNRT, if present, is very short (as assessed by the degree of HB prematurity required for a ventricular extrastimulus [VES] to reset the tachycardia, and by comparing the HB–atrial (HA) interval during AVNRT with that during ventricular pacing at the tachycardia cycle length [CL]).⁸

FAST-SLOW (ATYPICAL, UNCOMMON) ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

In this variant of AVNRT, the reentrant circuit uses the fast AVN pathway anterogradely and the slow pathway retrogradely. Although fast-slow AVNRT is thought of as using the same circuit as typical AVNRT but in the reverse direction, two previous studies reported different anatomical sites for the anterograde and retrograde slow pathways, and the fast-slow form of AVNRT may not be exactly the reverse form of the slow-fast form of AVNRT in some patients.

The earliest retrograde atrial activation during fast-slow AVNRT is usually in the inferoposterior part of the triangle of Koch. The AH interval is shorter than the HA interval (30 to 185 milliseconds versus 135 to 435 milliseconds), resulting in long RP tachycardia. The lower common pathway is relatively long.^{8,19}

SLOW-SLOW (POSTERIOR-TYPE) ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

In slow-slow AVNRT, the reentrant circuit uses a slow or an intermediate pathway anterogradely and a second slow pathway retrogradely. The earliest retrograde atrial activation occurs along the roof of the proximal CS or, less commonly, at the inferoposterior part of the triangle of Koch.

The AH interval is long (more than 200 milliseconds). The HA interval is often short, but it has a much wider range than that in typical AVNRT (–30 to 260 milliseconds, usually more than 70 milliseconds). The ventriculoatrial (VA) interval (as measured from the onset of ventricular activity to the onset of atrial activity by whichever electrode recorded the earliest interval) may be prolonged, ranging from 76 to 168 milliseconds. The AH/HA ratio, however, remains greater than 1. Therefore, this type is sometimes called slow-intermediate AVNRT. The lower common pathway is significantly longer than that in typical AVNRT, a finding that explains the short HA interval seen in many patients with slow-slow AVNRT. These patients often exhibit multiple AH interval jumps during atrial extrastimulus (AES) testing, consistent with multiple slow pathways.⁸

LEFT VARIANT OF ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

It has been known for some time that the slow pathway may be composed of both rightward and leftward posterior nodal extensions. The rightward extensions travel anatomically in the triangle of Koch between the tricuspid annulus and the CS os. The leftward extensions travel within the myocardial coat of the proximal CS

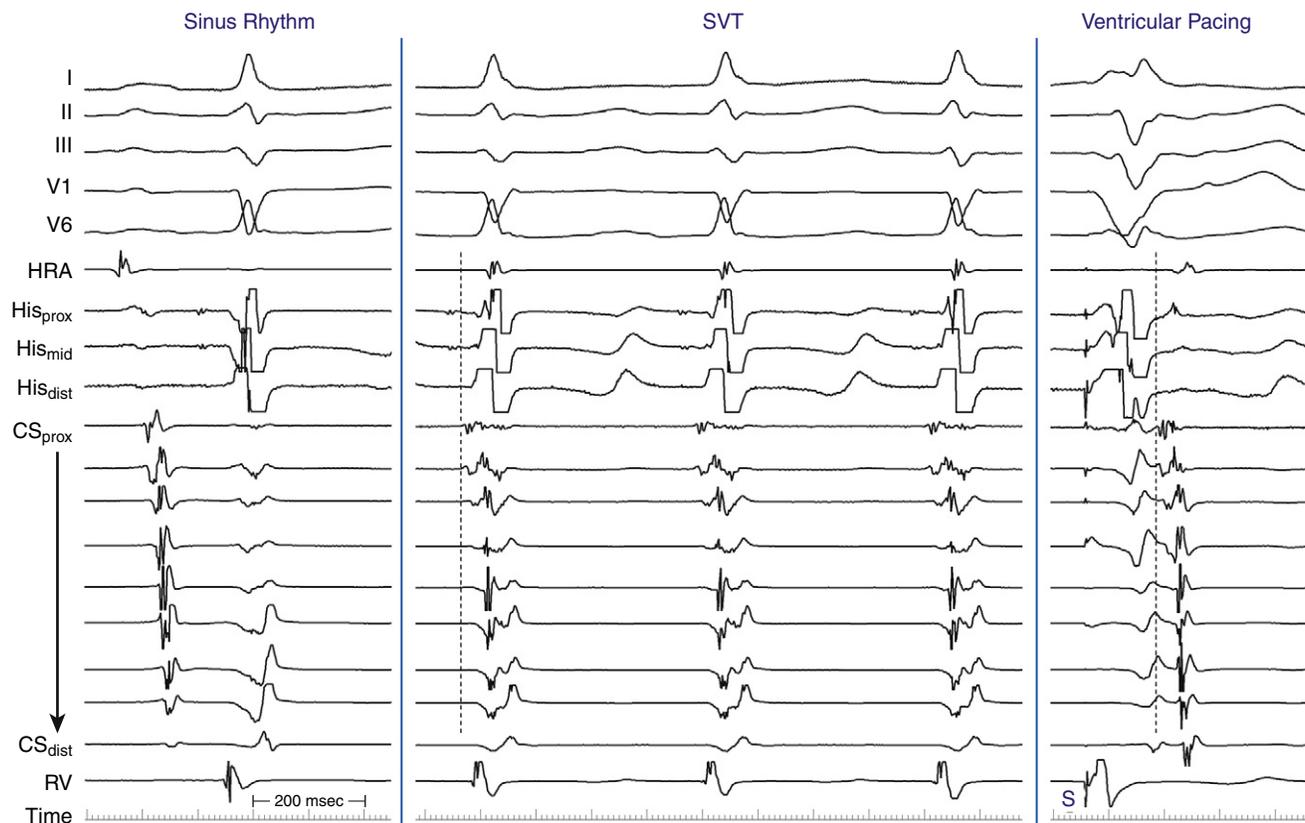

FIGURE 17-2 Atrioventricular nodal reentrant tachycardia (AVNRT) with early atrial activation in the coronary sinus (CS) ostium region. Sinus rhythm is shown on the left, slow-fast AVNRT is shown in the center, and ventricular pacing during sinus rhythm appears on the right. The dashed line denotes earliest atrial activation (proximal CS, near ostium), significantly before the His bundle atrial activation (most visible during ventricular pacing). CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; RV = right ventricle.

leftward (transseptally) toward the left inferoseptal region and mitral annulus. These leftward extensions can then connect with the rightward extensions in the triangle of Koch anterior to the CS os. The leftward inferior extension can provide an LA input to the AVN, as suggested by functional studies showing preferential access to the AVN from the left inferior septum. Clinically, the leftward inferior nodal extension can behave as the slow pathway and lead to AVNRT. In the typical (slow-fast) form of AVNRT, this would render ablation in the usual inferoseptal RA ineffective and lead to the necessity of ablating inside the CS or on the posterior mitral annulus.⁸ In atypical forms of AVNRT, if the leftward inferior extension serves as the slow pathway conducting retrogradely, then the earliest atrial activation would be recorded in the LA, thus leading to eccentric CS activation.⁹

Eccentric retrograde atrial activation sequences that are suggestive of leftward atrionodal extensions of the slow AVN pathway have been described in AVNRT, but the exact incidence is unknown. Various reports have shown a higher incidence of the eccentric CS activation pattern among patients with atypical (14% to 80%) than those with typical (0% to 8%) forms of AVNRT.^{8,18,20,21} However, even in the presence of eccentric retrograde atrial activation during AVNRT, the significance of such leftward extensions to the AVNRT circuit has been debated. Whether the retrograde left-sided atrionodal connection constitutes the critical component of the reentrant circuit or is only an innocent bystander in atypical AVNRT with the eccentric CS activation pattern is controversial. It may be possible for both the leftward and rightward extensions, either together or separately, to participate in nodal reentry. Right-sided ablation is probably sufficient for most of these patients. However, in some patients, the slow pathway participating in the reentrant circuit cannot be ablated from the posteroseptal RA or the CS os, but it can be eliminated by ablation along the roof of the

CS, as much as 5 to 6 cm from the CS os, or mitral annulus. In one report, direct left-sided ablation to the earliest retrograde activation site inside the CS (without ablation at the conventional site of the slow pathway) rendered the tachycardias noninducible in all 18 patients, a finding suggesting that the left-sided slow pathway constituted critical parts of the reentrant circuit.^{8,22}

SUPERIOR VARIANT OF ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

The superior variant of AVNRT uses a slowly conducting retrograde pathway with a superoseptal atrial exit as a retrograde limb and is associated with evidence of a lower common pathway. The anterograde limb of the circuit is likely the fast pathway. The superior variant of atypical AVNRT has been observed in 3% of all forms of AVNRT, and it is characterized by a shorter AH and longer HA interval during the tachycardia, a longer HA interval during ventricular pacing, and earliest retrograde atrial activation in the superoseptal RA. Whereas classical slow pathway ablation in the inferoseptal RA or proximal CS is highly successful in eliminating most types of AVNRT, it is inefficient in eliminating the superior variant of AVNRT. Instead, the tachycardia was eliminated in most patients in one report by ablation in the midseptal RA (where no His potential is recorded). Those observations suggest that the entire components of the tachycardia circuit in the superior type of atypical AVNRT may be localized to the superior part of the Koch triangle as compared with those in the inferior type. The mechanism by which ablation in the midseptal RA, not in the superoseptal RA where the earliest retrograde atrial activation was recorded, modified the retrograde slow pathway conduction properties and eliminated the tachycardia inducibility of the superior type is unclear.²³

Clinical Considerations

Epidemiology

AVNRT is the most common form of paroxysmal supraventricular tachycardia (SVT). The absolute number of patients with AVNRT and its proportion of paroxysmal SVT increase with age. The reason may be related to the normal evolution of AVN physiology over the first two decades of life, as well as to age-related changes in atrial and nodal physiology observed in later decades.²⁴ AVNRT is unusual in children less than 5 years of age, and it typically initially manifests in early life (e.g., in the teens). Conversely, atrioventricular reentrant tachycardia (AVRT) manifests earlier, with an average of more than 10 years separating the time of clinical presentation of AVRT and that of AVNRT. There is also a striking 2:1 predominance of AVNRT in women, in whom symptoms start at a significantly younger age.^{24,25} In fact, female sex and older age (i.e., teens versus newborns or young children) favor the diagnosis of AVNRT over AVRT.²⁶ Gender differences in the anterograde and retrograde AVN electrophysiological (EP) properties have been observed and may contribute to the pathogenesis of AVNRT.²⁵

Clinical Presentation

Patients with AVNRT typically present with the clinical syndrome of paroxysmal SVT. This is characterized as regular rapid tachycardia of abrupt onset and termination. Patients commonly describe palpitations and dizziness. Rapid ventricular rates can be associated with complaints of dyspnea, weakness, angina, or even frank syncope and can at times be disabling. Episodes can last from seconds to several hours. Patients often learn to use certain maneuvers such as carotid sinus massage or the Valsalva maneuver to terminate the arrhythmia, although many require pharmacological treatment. There is no significant association of AVNRT with other types of structural heart disease.

About half of patients with typical AVNRT report experiencing a pounding sensation in the neck during tachycardia, which is caused by simultaneous contraction of the atria and ventricles against closed mitral and tricuspid valves. The physical examination correlate of this phenomenon is continuous pulsing cannon A waves in the jugular venous waveform (described as the “frog” sign). This clinical feature has been reported to distinguish paroxysmal SVT resulting from AVNRT from that caused by orthodromic AVRT. Although atrial contraction during AVRT occurs against closed AV valves, the longer VA interval results in separate ventricular and then atrial contraction and a relatively lower RA and venous pressure; therefore, the presence of palpitations in the neck is experienced less commonly (about 17%) in patients with AVRT.²⁶

Initial Evaluation

History, physical examination, and 12-lead ECG constitute an appropriate initial evaluation. In patients with brief, self-terminating episodes, an event recorder is the most effective way to obtain ECG documentation. An echocardiographic examination should be considered in patients with documented sustained SVT to exclude the possibility of structural heart disease.²⁷ Further diagnostic studies (e.g., cardiac stress testing) are indicated only if there are signs or symptoms that suggest structural heart disease.⁸

The diagnosis of AVNRT as the mechanism of SVT can be strongly suspected based on the surface ECG but is often difficult to confirm, especially when only single-lead rhythm strips are available during the SVT. EP testing, however, is not indicated unless a decision to proceed with catheter ablation is undertaken.

Principles of Management

ACUTE MANAGEMENT

Because maintenance of AVNRT is dependent on AVN conduction, maneuvers or drugs that slow AVN conduction can be used to

terminate the tachycardia. Initially, maneuvers that increase vagal tone (e.g., Valsalva maneuvers, gagging, carotid sinus massage) are used.²⁷ When vagal maneuvers are unsuccessful, termination can be achieved with antiarrhythmic drugs whose primary effects increase refractoriness and/or decrease conduction (negative dromotropic effect) over the AVN. Adenosine is the drug of choice and is successful in almost 100% of cases.²⁷ Verapamil, diltiazem, and beta blockers also can terminate AVNRT and prevent induction. Digoxin, which has a slower onset of action than the other AVN blockers, is not favored for the acute termination of AVNRT, except if there are relative contraindications to the other agents. Class IA and IC sodium channel blockers can also be used in treating an acute event of AVNRT, a strategy that is rarely used when other regimens have failed. If AVNRT cannot be terminated with intravenous drugs, electrical cardioversion can always be used. Energies in the range of 10 to 50 J are usually adequate.⁸

CHRONIC MANAGEMENT

Because AVNRT is generally a benign arrhythmia that does not influence survival, the primary indication for its treatment relates to its impact on a patient's quality of life. Factors that contribute to the therapeutic decision include the frequency and duration of tachycardia, tolerance of symptoms, the effectiveness and tolerance of antiarrhythmic drugs, the need for lifelong drug therapy, and the presence of concomitant structural heart disease. Patients who develop a highly symptomatic episode of paroxysmal SVT, particularly if it requires an emergency room visit for termination, can elect to initiate therapy after a single episode. In contrast, a patient who presents with minimally symptomatic episodes of paroxysmal SVT that terminate spontaneously or in response to Valsalva maneuvers may elect to be followed clinically without specific therapy.^{8,27}

Once it is decided to initiate treatment for AVNRT, the question arises whether to initiate pharmacological therapy or to use catheter ablation. Because of its high efficacy (greater than 95%) and low incidence of complications, catheter ablation has become the preferred therapy over long-term pharmacological therapy and can be offered as an initial therapeutic option. It is reasonable to discuss catheter ablation with all patients suspected of having AVNRT. However, patients considering RF ablation must be willing to accept the risk, albeit low, of AV block and pacemaker implantation. For patients in whom ablation is not desirable or available, long-term pharmacological therapy may be effective.²⁷

Most pharmacological agents that depress AVN conduction (including beta blockers and calcium channel blockers) can reduce the frequency of recurrences of AVNRT. If those agents are ineffective, class IA, IC, or III antiarrhythmic agents may be considered. In general, drug efficacy is in the range of 30% to 50%.⁸

Outpatients can use a single dose of verapamil, propranolol, or flecainide to terminate an episode of AVNRT effectively. This so-called pill in the pocket approach (i.e., administration of a drug only during an episode of tachycardia for the purpose of termination of the arrhythmia when vagal maneuvers alone are not effective) is appropriate to consider for patients with infrequent episodes of AVNRT that are prolonged but well tolerated, and it obviates exposure of patients to long-term and unnecessary therapy between rare arrhythmic events. This approach necessitates the use of a drug that has a short onset of action (i.e., immediate-release preparations).²⁷ Candidate patients should be free of significant LV dysfunction, sinus bradycardia, and preexcitation. Single-dose oral therapy with diltiazem (120 mg) plus propranolol (80 mg) has been shown to be superior to both placebo and flecainide in terminating AVNRT.^{8,27}

Electrocardiographic Features

P Wave Morphology

In typical (slow-fast) AVNRT, the P wave is usually not visible because of the simultaneous atrial and ventricular activation. The P wave can distort the initial portion of the QRS (mimicking a q wave

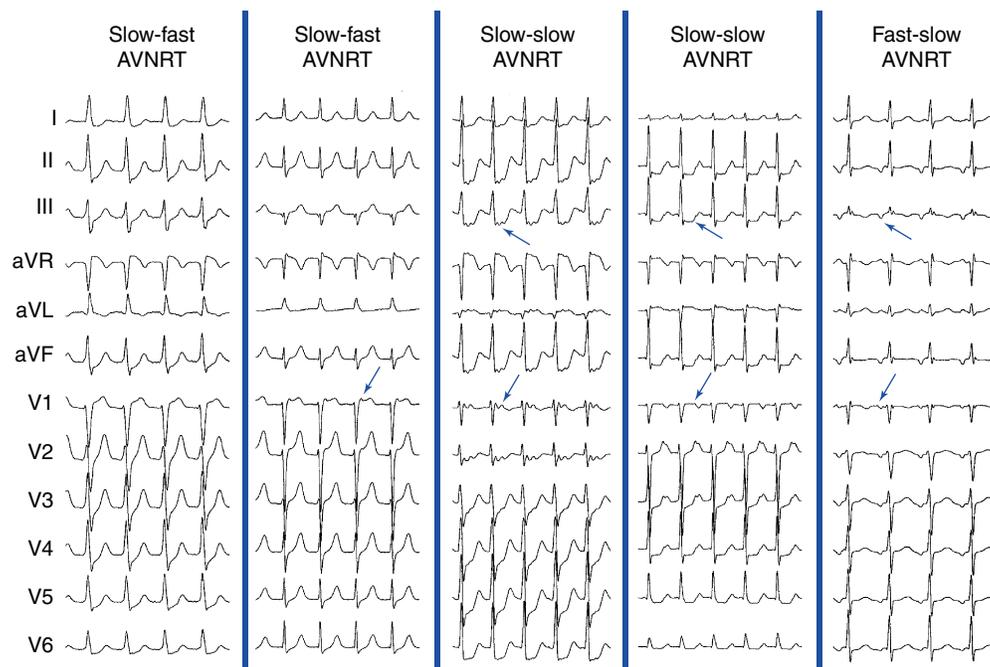

FIGURE 17-3 Surface ECG of the different types of atrioventricular nodal reentrant tachycardia (AVNRT). Arrows mark the P waves. In slow-fast (typical) AVNRT, the P wave may lie within the QRS (invisible, **first panel**) or distort the terminal portion of the QRS (mimicking an r wave in V_1 , **second panel**). In slow-slow AVNRT, the P wave lies outside the QRS in the ST-T wave, and the RP interval is longer than that in slow-fast AVNRT. In fast-slow AVNRT, the P wave lies before the QRS with a long RP interval. In all varieties of AVNRT, the P wave is relatively narrow, negative in the inferior leads, and positive in V_1 .

in the inferior leads), lie just within the QRS (inapparent), or distort the terminal portion of the QRS (mimicking an s wave in the inferior leads or an r wave in lead V_1) (Fig. 17-3).⁸ When apparent, the P wave is significantly narrower than the sinus P wave and is negative in the inferior leads, findings consistent with concentric retrograde atrial activation over the fast AVN pathway.⁸ In atypical (fast-slow) AVNRT, the P wave is relatively narrow, negative in the inferior leads, and positive in lead V_1 (see Fig. 17-3).⁸

QRS Morphology

QRS morphology during AVNRT is usually the same as in normal sinus rhythm (NSR). The development of prolonged functional aberration during AVNRT is uncommon, and it usually occurs following induction of AVNRT by ventricular stimulation more frequently than by atrial stimulation, or following resumption of 1:1 conduction to the ventricles after a period of block below the tachycardia circuit.⁸ At times, alternans of QRS amplitude can occur when the tachycardia rates are rapid. Occasionally, AVNRT can coexist with ventricular preexcitation over an AV bypass tract (BT), whereby the BT is an innocent bystander.⁸

P-QRS Relationship

In typical (slow-fast) AVNRT, the RP interval is very short (–40 to 75 milliseconds). Variation of the P-QRS relationship with or without block can occur during AVNRT, especially in atypical or multiple-form tachycardias.⁸ This phenomenon usually occurs when the conduction system and the reentry circuit are unstable during initiation or termination of the tachycardia, likely secondary to decremental conduction in the lower common pathway. The ECG manifestation of P-QRS variations with or without AV block during tachycardia, especially at the initiation of tachycardias or in cases of nonsustained tachycardias, should not be misdiagnosed as atrial tachycardias (ATs); these variations may represent atypical or, rarely, typical forms of AVNRT. Moreover, the variations can be of such magnitude that long RP tachycardia can masquerade for brief periods of time as short RP tachycardia.

Usually, the A/V ratio during AVNRT is equal to 1; however, 2:1 AV block can be present because of block below the reentry circuit (usually below the HB and, infrequently, in the lower common pathway). In such cases, narrow, inverted P wave morphology in the inferior leads inscribed exactly between QRS complexes strongly

suggests AVNRT (Fig. 17-4). The incidence of reproducible sustained 2:1 AV block during induced episodes of AVNRT is approximately 10%. Rarely, VA block can occur because of block in an upper common pathway.⁸

In atypical (fast-slow) AVNRT, the RP interval is longer than the PR interval. In slow-slow AVNRT, the RP interval is usually shorter than, and sometimes equal to, the PR interval. Occasionally, the P wave is inscribed in the middle of the cardiac cycle, thus mimicking atrial flutter or AT with 2:1 AV conduction (Fig. 17-5).¹⁹ Slow-slow AVNRT can be associated with RP intervals and P wave morphology similar to that during orthodromic AV reentrant tachycardia (AVRT) using a posteroseptal AV BT. However, although both SVTs have the earliest atrial activation in the posteroseptal region, conduction time from that site to the HB region is significantly longer in AVNRT than in orthodromic AVRT. The results are a significantly longer RP interval in lead V_1 and a significantly larger difference in the RP interval between lead V_1 and inferior leads during AVNRT. Therefore, Δ RP interval ($V_1 - III$) of more than 20 milliseconds suggests slow-slow AVNRT (sensitivity, 71%; specificity, 87%).

Electrophysiological Testing

EP testing is used to study the inducibility and mechanism of the SVT and to guide catheter ablation. Typically, three quadripolar catheters are positioned in the high RA, the right ventricular (RV) apex, and the HB region, and a decapolar catheter is positioned in the CS (see Fig. 4-7).

Baseline Observations during Normal Sinus Rhythm

ATRIAL EXTRASTIMULATION AND ATRIAL PACING DURING NORMAL SINUS RHYTHM

ANTEROGRADE DUAL ATRIOVENTRICULAR NODAL PHYSIOLOGY. Demonstration of anterograde dual AVN pathway conduction curves requires a longer effective refractory period (ERP) of the fast pathway than the slow pathway ERP and atrial functional refractory period (FRP), as well as a sufficient difference in conduction times between the two pathways. Dual AVN physiology can be diagnosed by demonstrating the following: (1) a “jump” in the AH interval in response to progressively more premature AES; (2) two ventricular responses to a single atrial impulse;

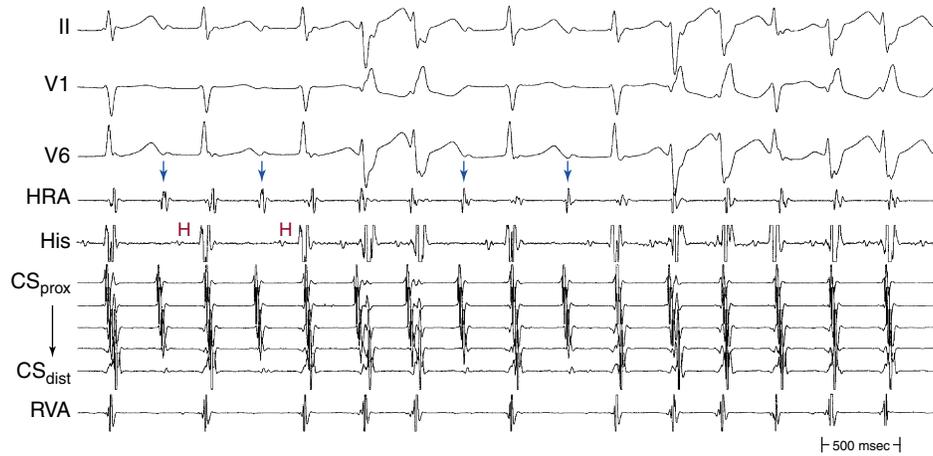

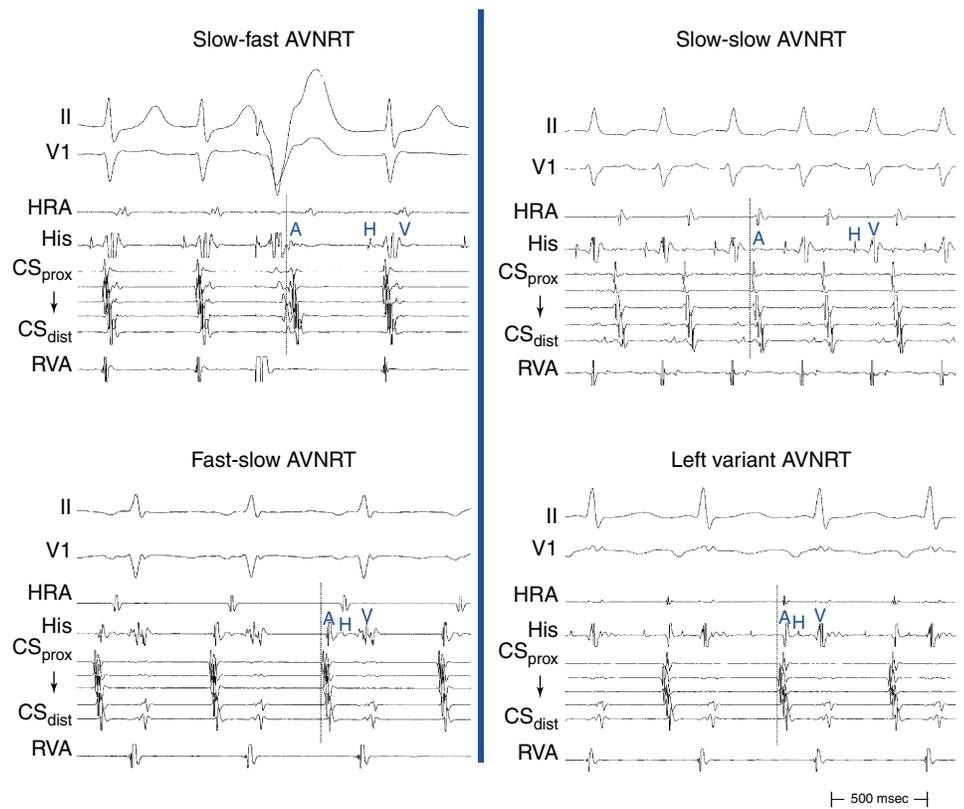

FIGURE 17-4 Typical atrioventricular nodal reentrant tachycardia (AVNRT) with intermittent 2:1 AV block. His potential (H) is observed following conducted atrial impulses, but not after blocked atrial impulses, thus indicating AV block in the lower common pathway or in the portion of the His bundle proximal to the recording site. Note that intermittent AV block results in long-short cycle sequences associated with a right bundle branch block (RBBB) pattern during complexes conducted following a short cycle. RBBB is also observed intermittently during supraventricular tachycardia with 1:1 AV conduction. Note the lack of effect of RBBB on the tachycardia cycle length (A-A interval) or ventricular-atrial (VA) interval. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

FIGURE 17-5 Surface ECG leads II and V₁ and endocardial recordings of the different types of atrioventricular nodal reentrant tachycardia (AVNRT). The dashed line marks the site with the earliest atrial activation. In slow-fast (typical) AVNRT, the initial site of atrial activation is usually recorded in the His bundle (HB) catheter. In slow-slow AVNRT, the P wave lies outside the QRS in the ST-T wave, and the RP interval is longer than that in slow-fast AVNRT. The earliest retrograde atrial activation is usually in the inferoposterior part of the triangle of Koch. Slow pathways with longer conduction times have a more inferior location in the triangle of Koch. In fast-slow AVNRT, the earliest site of retrograde atrial activation is usually recorded at the base of the triangle of Koch or coronary sinus ostium (CS os). An eccentric retrograde atrial activation sequence with the earliest retrograde activation site inside the CS can be observed in the left variant of AVNRT, more common in atypical than typical forms of AVNRT. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

(3) a PR interval exceeding the R-R interval during rapid atrial pacing; and/or (4) different PR or AH intervals during NSR or fixed-rate atrial pacing.²⁸

ATRIAL-HIS INTERVAL JUMP. In contrast to the normal pattern of AVN conduction, in which the AH interval gradually lengthens in response to progressively shorter AES coupling intervals, patients with dual AVN physiology usually demonstrate a sudden increase (jump) in the AH interval at a critical AES (A₁-A₂) coupling interval (Fig. 17-6). Conduction with a short PR or AH interval reflects fast pathway conduction, whereas conduction with a long PR or AH interval reflects slow pathway conduction. The AH interval jump signals block of anterograde conduction of the progressively premature AES over the fast pathway (once

the AES coupling interval becomes shorter than the fast pathway ERP) and anterograde conduction over the slow pathway (which has an ERP shorter than the AES coupling interval), with a longer conduction time (i.e., longer A₂-H₂ interval). A jump in the A₂-H₂ (or H₁-H₂) interval of 50 milliseconds or more in response to a 10-millisecond shortening of either the A₁-A₂ interval (i.e., AES coupling interval) or the A₁-A₁ interval (i.e., pacing CL) is defined as a discontinuous AVN function curve and is considered evidence of dual anterograde AVN pathways (see Fig. 4-23).⁸

1:2 RESPONSE. Rapid atrial pacing or AES can result in two ventricular complexes to a single paced atrial impulse. The first ventricular complex is caused by conduction of the atrial

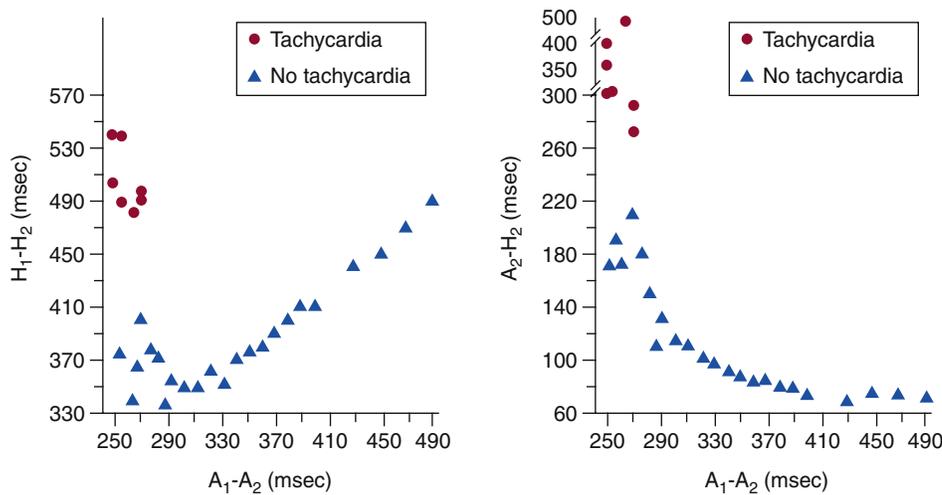

FIGURE 17-6 Dual atrioventricular node (AVN) physiology. H₁-H₂ intervals (left) and A₂-H₂ intervals (right) are at various A₁-A₂ intervals, with a discontinuous AVN curve. At a critical A₁-A₂ interval, the H₁-H₂ and A₁-H₂ intervals increase markedly. At the break in the curves, atrioventricular nodal reentrant tachycardia is initiated. (From Olgin JE, Zipes DP: *Specific arrhythmias: diagnosis and treatment*. In Libby P, Bonow RO, Mann DL, Zipes DP, editors: *Braunwald's heart disease: a textbook of cardiovascular medicine*, ed 7, Philadelphia, 2008, Saunders, p 880.)

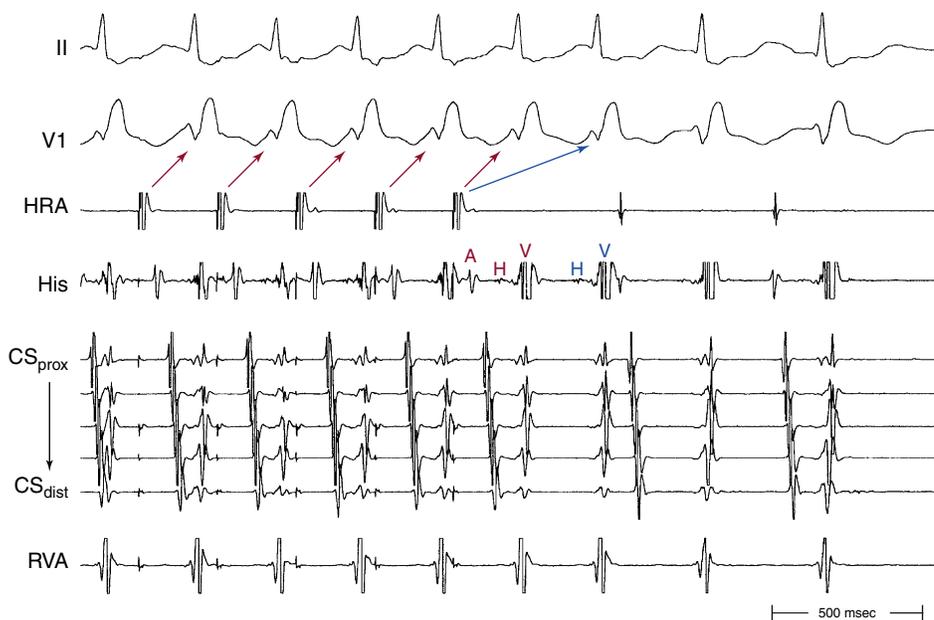

FIGURE 17-7 Rapid atrial pacing during normal sinus rhythm (NSR). Each paced atrial impulse conducts anterogradely over the fast atrioventricular node (AVN) pathway (red arrows). The last paced impulse, however, conducts anterogradely over both the fast (red arrow) and slow (blue arrow) pathways, resulting in two His bundle and ventricular responses. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

impulse over the fast AVN pathway, and the second complex is caused by conduction over the slow AVN pathway (Fig. 17-7). This response requires unidirectional retrograde block in the slow AVN pathway. Typically, in the presence of dual AVN pathways, conduction propagates simultaneously over both fast and slow AVN pathways. However, the wavefront conducting down the fast pathway reaches the distal junction of the two pathways before the impulse conducting down the slow pathway, and, subsequently, it conducts retrogradely up the slow pathway to collide with the impulse conducting anterogradely down that pathway. Thus, the anterograde impulse conducting down the slow pathway does not have the opportunity to reach the HB and ventricle. Rarely, the slow pathway conducts anterogradely only or has a very long retrograde ERP. In this setting, the wavefront traveling anterogradely down the fast pathway blocks (but does not conceal) in the slow pathway retrogradely and fails to retard the impulse traveling anterogradely down that pathway. Consequently, the wavefront traveling down the slow pathway can reach the HB and ventricle to produce a second His potential and QRS in response to a single atrial impulse. Because retrograde block in the slow pathway is a prerequisite to a 1:2 response, when such a phenomenon is present, it indicates that the slow pathway cannot support reentrant tachycardia using the slow pathway as the retrograde limb (i.e., atypical AVNRT

cannot be operative). The 1:2 response should be differentiated from pseudo-simultaneous fast and slow pathway conduction, which is a much more common phenomenon during rapid atrial pacing. In the latter case, all paced atrial impulses block anterogradely in the fast pathway and conduct exclusively down the slow pathway with prolonged AH intervals (with PR intervals longer than atrial pacing CL), so that the last paced atrial impulse falls before the His potential caused by conduction of the preceding paced atrial impulse. Thus, the last paced atrial impulse is followed by two His potentials and two ventricular complexes. The last response may then be followed by induction of AVN echo beats or AVNRT, mimicking simultaneous fast and slow pathway conduction (Fig. 17-8).^{8,29}

PR INTERVAL LONGER THAN PACING CYCLE LENGTH DURING ATRIAL PACING. The PR interval gradually prolongs as the atrial pacing rate increases. When a critical pacing rate is reached, the PR interval typically exceeds the R-R interval, with all AVN conduction over the slow AVN pathway (see Fig. 17-8). This manifests as *crossing over* of the pacing stimulus artifacts and QRSs; that is, the paced atrial complex is conducting not to the QRS immediately following it, but rather to the next QRS, because of a very long PR interval. There should be consistent 1:1 AV conduction that remains stable over the span of several cycles for this observation to be interpreted (i.e., without Wenckebach

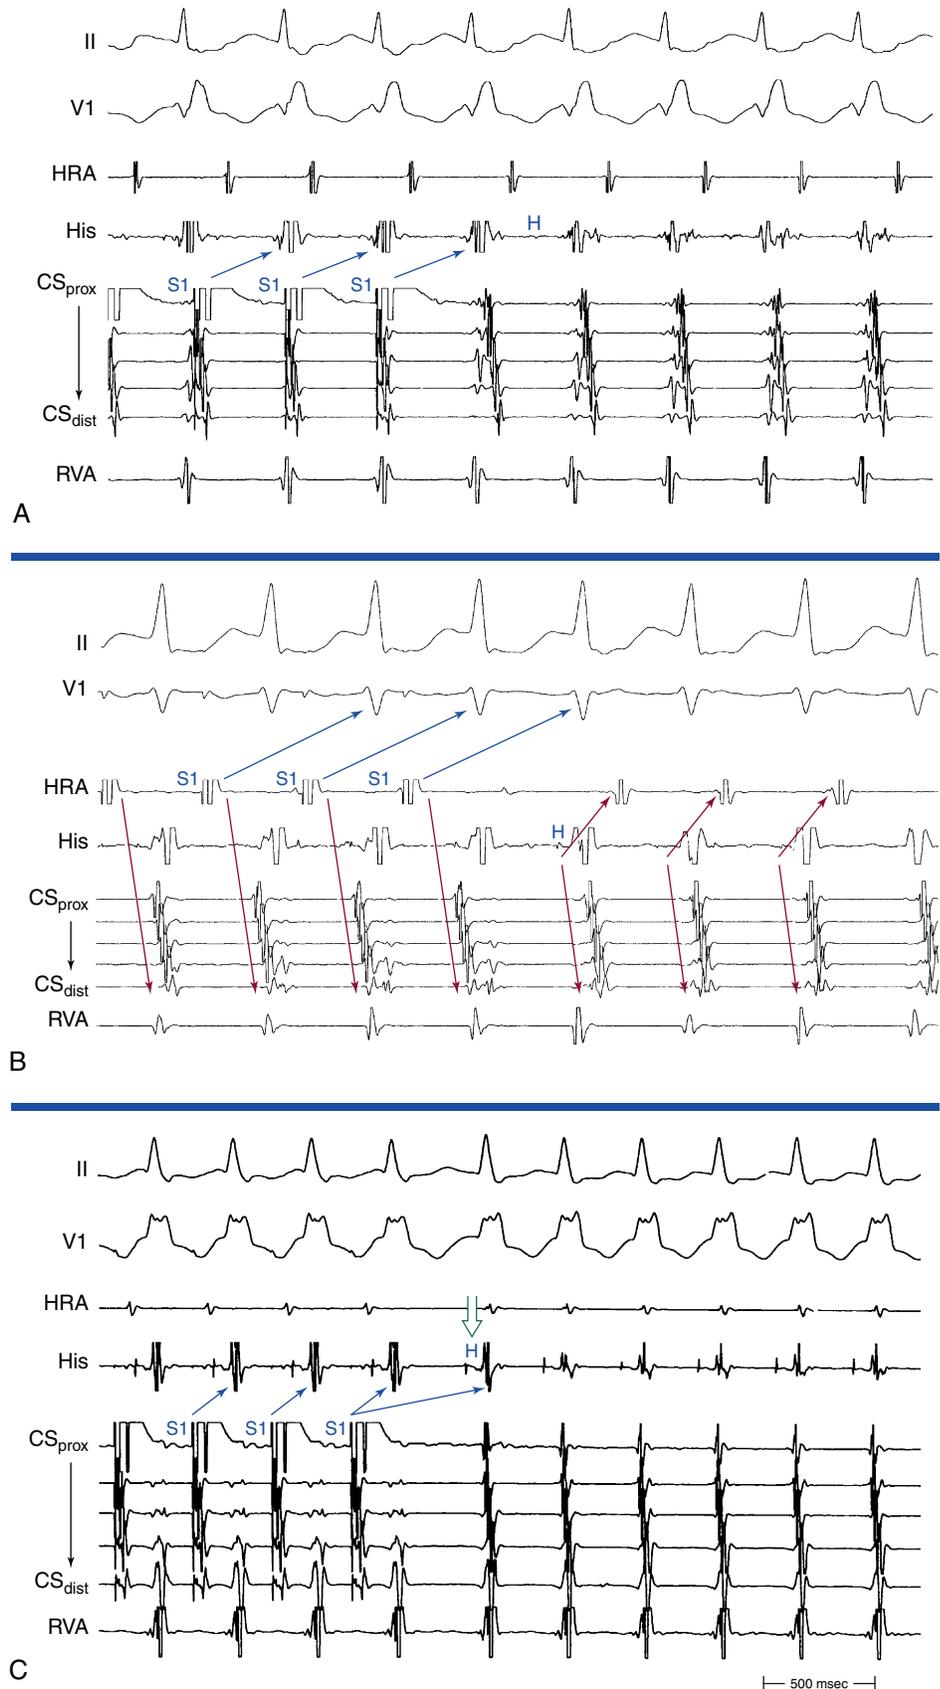

FIGURE 17-8 Induction of typical atrioventricular nodal reentrant tachycardia (AVNRT) with atrial pacing. **A**, Each of the atrial paced impulses (S1) conducts anterogradely over the slow AVN pathway. The last paced impulse, following anterograde conduction down the slow pathway, also conducts retrogradely up the fast AVN pathway to initiate typical AVNRT with right bundle branch block (RBBB). **B**, Each of the atrial paced impulses conducts anterogradely over the slow AVN pathway with a long PR interval (blue arrows); this is longer than the pacing cycle length (CL), resulting in crossing over, which can mimic a 1:2 AV response caused by anterograde conduction over both the fast and slow AVN pathways. Following anterograde conduction down the slow pathway, the last paced impulse also conducts retrogradely over the fast pathway, initiating typical AVNRT. Red arrows illustrate atrial activation sequence during atrial pacing versus AVNRT. **C**, Atrial pacing from the coronary sinus ostium (CS os) induces typical AVNRT. Each of the atrial paced impulses (S1) conducts over the fast AVN pathway except for the last paced impulse, which conducts over both the fast and slow AVN pathways (blue arrows), resulting in a 1:2 response (i.e., 2 ventricular responses); this is followed by induction of typical AVNRT with RBBB. The possibility of conduction of the paced atrial beats over the slow AVN pathway with a long atrial–His bundle (AH) interval (longer than the paced CL) is unlikely because the His potential preceding the first tachycardia complex (indicated by the green arrow) occurs later (i.e., at a longer AH interval) than what would be expected if that His potential was actually a result of conduction of the last atrial stimulus (as compared with the previous AH intervals). CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

block). Such slow AVN conduction is seen only when conduction propagates over a slow AVN pathway, and it is not seen in the absence of dual AVN physiology. This phenomenon is diagnostic of the presence of dual AVN physiology, even in the absence of an AH interval jump and therefore is very helpful in patients with

smooth AVN function curves. In fact, 96% of patients with AVNRT and smooth AVN function curves have a PR interval/RR interval ratio greater than 1 (i.e., PR interval longer than pacing CL) during atrial pacing at the maximal rate with consistent 1:1 AV conduction (versus 11% in controls).

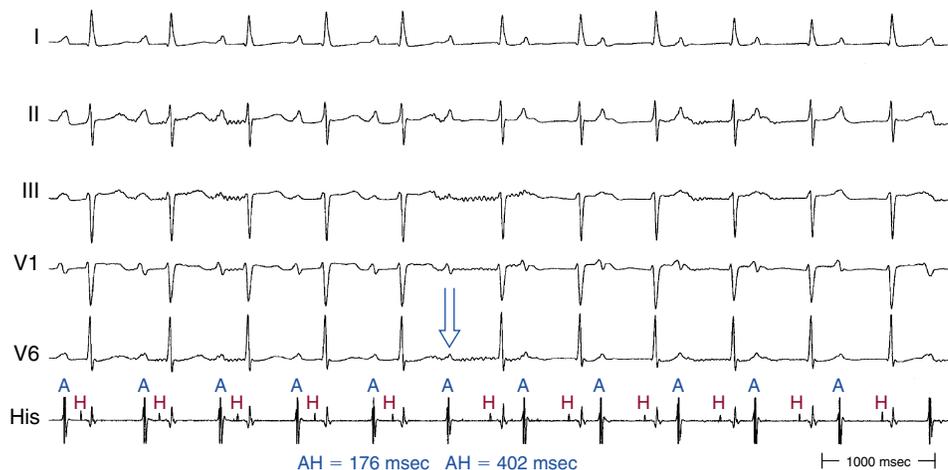

FIGURE 17-9 Dual atrioventricular node (AVN) physiology manifesting as two different PR intervals during normal sinus rhythm. Note that the shift in AV conduction from the fast to the slow AVN pathway (arrow) occurs without any changes in the sinus cycle length (CL) (680 milliseconds). This phenomenon indicates that the fast pathway anterograde effective refractory period is long relative to the sinus CL.

DIFFERENT PR OR AH INTERVALS DURING NORMAL SINUS RHYTHM OR AT IDENTICAL ATRIAL PACING CYCLE LENGTHS. This phenomenon can occur when the fast pathway anterograde ERP is long relative to the sinus or paced CL (Fig. 17-9). Such a phenomenon also requires a long retrograde ERP of the fast pathway. Otherwise, AVN echo beats or AVNRT would result, because once the impulse blocks anterogradely in the fast pathway and is conducted down the slow pathway, it would subsequently conduct retrogradely up the fast pathway if the ERP of the fast pathway were shorter than the conduction time (i.e., shorter than the AH interval) over the slow pathway.⁸

MULTIPLE ATRIOVENTRICULAR NODAL PATHWAYS. Multiple AH interval “jumps” in response to AES, a finding suggesting the presence of multiple AVN pathways, can be observed in up to 14% of patients with AVNRT. These phenomena are characterized by multiple AH interval jumps of 50 milliseconds or more in response to an increasingly premature AES. In these patients, a single AES may initiate multiple jumps in only 68%, whereas double AESs or atrial pacing is required in 32%. Such patients can have AVNRT with longer tachycardia CLs and longer ERP and FRP of the AVN. It is uncommon for multiple AVNRTs with different tachycardia CLs and P-QRS relationships to be present in the same patient.

PREVALENCE OF DUAL ATRIOVENTRICULAR NODAL PHYSIOLOGY. The presence of dual AVN pathways can usually be demonstrated by using a single AES or atrial pacing in 85% of patients with clinical AVNRT. In 95% of patients, the presence of dual AVN pathways can be shown by using multiple AESs, multiple-drive CLs (typically 600 and 400 milliseconds), and multiple pacing sites (typically high RA and CS). Failure to demonstrate dual AVN physiology in patients with AVNRT can be caused by similar fast and slow AVN pathway ERPs. Dissociation of refractoriness of the fast and slow AVN pathways may then be required. This can be achieved by any of the following: introduction of an AES at a shorter pacing drive CL; introduction of multiple AESs; burst atrial pacing; or administration of drugs such as beta blockers, verapamil, or digoxin. In general, if fast pathway conduction is suppressed in the baseline (as evidenced by a long AH interval at all atrial pacing rates or VA block during ventricular pacing), isoproterenol infusion (and occasionally atropine) usually facilitates fast pathway conduction. In contrast, if the baseline ERP of the fast pathway is very short, conduction over the slow pathway can be difficult to document. Increasing the degree of sedation or infusion of esmolol can prolong the fast pathway ERP and allow recognition of slow pathway conduction.

Another potential reason for the inability to demonstrate dual AVN physiology is block in the fast AVN pathway at the pacing drive CL (i.e., pacing drive CL is shorter than fast pathway ERP). Additionally, atrial FRP can limit the prematurity of the AES. Consequently, AVN activation cannot be adequately advanced to produce block in the fast pathway because a more premature AES would result in

TABLE 17-5 Programmed Stimulation Protocol for Electrophysiology Testing of Atrioventricular Nodal Reentrant Tachycardia

Atrial burst pacing from the RA and CS (down to AV Wenckebach CL)
Single and double AESs at multiple CLs (600-400 msec) from the high RA and CS (down to atrial ERP)
Ventricular burst pacing from the RV apex (down to VA Wenckebach CL)
Single and double VESs at multiple CLs (600-400 msec) from the RV apex (down to ventricular ERP)
Administration of isoproterenol infusion as needed to facilitate tachycardia induction (0.5-4 µg/min)

AES = atrial extrastimulus; AV = atrioventricular; CL = cycle length; CS = coronary sinus; ERP = effective refractory period; RA = right atrium; RV = right ventricle; VA = ventriculoatrial; VES = ventricular extrastimulus.

more intraatrial conduction delay and less premature stimulation of the AVN. This obstacle can be overcome by the introduction of an AES following a shorter pacing drive CL, introduction of multiple AESs, burst atrial pacing, or stimulation from multiple atrial sites. A typical programmed electrical stimulation protocol used for EP testing in patients with AVNRT is outlined in Table 17-5.²⁸

VENTRICULAR EXTRASTIMULATION AND VENTRICULAR PACING DURING NORMAL SINUS RHYTHM

RETROGRADE DUAL ATRIOVENTRICULAR NODAL PHYSIOLOGY. Demonstration of retrograde dual AVN pathway conduction curves requires a longer retrograde ERP of the fast pathway than slow pathway ERP and ventricular and His-Purkinje system (HPS) FRP, as well as a sufficient difference in conduction times between the two pathways. In a pattern analogous to that of anterograde dual AVN physiology, ventricular stimulation can result in discontinuous retrograde AVN function curves, manifesting as a jump in the H₂-A₂ (or A₁-A₂) interval of 50 milliseconds or more in response to a 10-millisecond decrement of the VES coupling interval (V₁-V₂) or ventricular pacing CL (V₁-V₁). This finding must be distinguished from sudden VA prolongation caused by VH interval (but not HA interval) prolongation related to retrograde functional block in the RB and transeptal activation of HB through the LB (see Fig. 4-27). A 1:2 response (i.e., two atrial responses to a single ventricular stimulus) can also be observed.²⁸

Failure to demonstrate retrograde dual AVN physiology in patients with atypical AVNRT can be caused by similar fast and slow AVN pathway ERPs. Dissociation of refractoriness of the fast and slow AVN pathways may be required and usually can be achieved by any of the following: introduction of VESs at a shorter

pacing drive CL; introduction of multiple VESs; burst ventricular pacing; or administration of drugs such as beta blockers, verapamil, or digoxin. In addition, retrograde block in the fast AVN pathway at the pacing drive CL (i.e., the pacing CL is shorter than the fast pathway ERP) and ventricular or HPS FRP interval limiting the prematurity of the VES can also account for such failure.²⁸

Induction of Tachycardia

INITIATION BY ATRIAL EXTRASTIMULATION OR ATRIAL PACING

TYPICAL (SLOW-FAST) ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA. Clinical AVNRT almost always can be initiated with an AES that blocks anterogradely in the fast pathway, conducts down the slow pathway, and then conducts retrogradely up the fast pathway. Only when anterograde conduction down the slow pathway is slow enough (critical AH interval) to allow for recovery of the fast pathway to conduct retrogradely does reentry occur (see Fig. 17-6). This critical AH interval is not a fixed interval. It can change with changes in pacing drive CL, changes in autonomic tone, or after drug administration, thus reflecting changes in the fast pathway retrograde ERP.²⁸

There is a zone of AES coupling intervals (A_1 - A_2) associated with AVNRT induction called the tachycardia zone. This zone usually begins at coupling intervals associated with marked prolongation of the AH intervals. This AVN conduction delay (AH interval prolongation), and not the AES coupling interval, is of prime importance for the genesis of AVNRT.

Atrial pacing can initiate AVNRT at pacing CLs associated with sufficient AVN conduction delay (see Fig. 17-8), especially during the atypical Wenckebach periodicity, when anterograde block occurs in the fast pathway and conduction shifts to the slow pathway.

Rarely, AES or atrial pacing can produce a 1:2 response with anterograde conduction over both the fast and slow pathways, as explained earlier (see Fig. 17-8).²⁹ Such a response predicts easy induction of slow-fast AVNRT by ventricular stimulation because poor slow pathway retrograde conduction would increase the opportunity for the ventricular stimulus to block in the slow pathway and conduct up the fast pathway to return down the slow pathway and initiate AVNRT.

The site of atrial stimulation can affect the ease of inducibility of AVNRT, probably because of different atrial inputs to the AVN or different atrial FRPs. Therefore, it is important to perform atrial stimulation from both the high RA and CS.

Atrial echoes and AVNRT usually occur at the same time that dual pathways are revealed (see Fig. 4-23). In 20% of patients, the dual AVN pathway AH interval jump occurs without concurrent occurrence of echo beats or AVNRT because of failure of retrograde conduction up the fast pathway. This failure can be caused by the absence of a distal connection between the two AVN pathways, a long retrograde ERP of the fast AVN pathway, or concealment of the AES anterogradely into the fast AVN pathway (i.e., the AES propagates some distance into the fast pathway before being blocked). The last event results in anterograde postdepolarization refractoriness, which would consequently make the fast pathway refractory to the wavefront invading it in the retrograde direction. The latter phenomenon can be diagnosed by demonstrating that the AH interval following the AES that fails to produce an echo beat is longer than the shortest ventricular pacing CL with 1:1 retrograde conduction. Such a pacing CL is a marker of the fast pathway retrograde ERP. This finding implies that an AES blocking in the fast pathway and conducting over the slow pathway, with an AH interval exceeding fast pathway ERP and still not conducting retrogradely over the fast pathway, is caused by anterograde concealment (and not just block) into the fast pathway.²⁸

Markers of poor retrograde conduction over the fast AVN pathway predict low inducibility of AVNRT. These markers include the absence of VA conduction, poor VA conduction (manifest as

retrograde AVN Wenckebach CL longer than 500 milliseconds), and retrograde dual pathways (indicative of long retrograde ERP of the fast pathway, which must exceed the refractoriness of the slow pathway for retrograde dual pathways to be demonstrable). In fact, retrograde fast AVN pathway characteristics (i.e., ERP) are the major determinant of whether reentry (AVN echoes or AVNRT, or both) occurs, whereas conduction delay anterogradely over the slow pathway (i.e., "critical AH interval") determines when reentry is to occur.

Although isolated AVN echoes can occur as long as VA conduction is present, the ability to initiate sustained AVNRT also requires the capability of the slow pathway to sustain repetitive anterograde conduction. In other words, sustenance of AVNRT requires that the tachycardia CL be longer than the ERP of all components of the circuit. Typically, for AVN reentry to occur, the fast pathway should be able to support 1:1 VA conduction at a ventricular pacing CL shorter than 400 milliseconds (i.e., retrograde Wenckebach CL shorter than 400 milliseconds), and the slow pathway should be able to support 1:1 AV conduction at an atrial pacing CL shorter than 350 milliseconds (i.e., anterograde Wenckebach CL shorter than 350 milliseconds). The shorter the AH interval during anterograde conduction over the fast pathway, the better the retrograde conduction over the same pathway (i.e., the shorter the HA interval), and the better the inducibility of AVNRT. Nevertheless, it is important to recognize that during EP testing, these criteria are dependent on the cardiac autonomic tone at that moment, and they can change dramatically by changing the level of patient sedation or the use of isoproterenol or by prolonged periods of rapid pacing (particularly ventricular) that cause hypotension and a reflex increase in adrenergic tone, which then affect inducibility of AVNRT.²⁸

ATYPICAL (FAST-SLOW) ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA. Anterograde dual AVN physiology is usually not demonstrable in patients with atypical AVNRT. Additionally, as noted, the presence of a 1:2 response to AES predicts noninducibility of atypical AVNRT because it indicates failure of the slow pathway to support retrograde conduction, a prerequisite for the atypical AVNRT circuit.¹⁹

When atypical AVNRT is initiated with atrial stimulation, it is usually with modest prolongation of the AH interval over the fast pathway and anterograde block in the slow pathway, followed by retrograde slow conduction over the slow pathway (Fig. 17-10). Therefore, a critical AH interval delay is not obvious.¹⁹

INITIATION BY VENTRICULAR EXTRASTIMULATION OR VENTRICULAR PACING

TYPICAL (SLOW-FAST) ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA. Ventricular stimulation induces typical AVNRT by different mechanisms. The most common mechanism involves retrograde block of the ventricular stimulus in the slow pathway and retrograde conduction up the fast pathway, followed by anterograde conduction down the slow pathway. This occurs when the retrograde ERP of the slow pathway exceeds that of the fast pathway. This means that induction occurs without the demonstration of retrograde dual AVN physiology, and no critical VA or HA interval is required for induction. Occasionally, an interpolated premature ventricular complex (PVC) can block in the slow pathway retrogradely and penetrate into the fast pathway and cause concealment, so that the fast pathway will be refractory when the next sinus beat occurs. The sinus beat would then block in the fast pathway and conduct down the slow pathway and initiate typical AVNRT. This mechanism is uncommon. Retrograde VA conduction over the fast AVN pathway is usually good, and VA block rarely occurs in patients with typical AVNRT initiated by ventricular stimulation.²⁸

Ventricular stimulation is less effective than atrial stimulation in inducing typical AVNRT (success rate is approximately 10% with VES and 40% with ventricular pacing), whereas atypical AVNRT can be induced almost as frequently by ventricular stimulation as

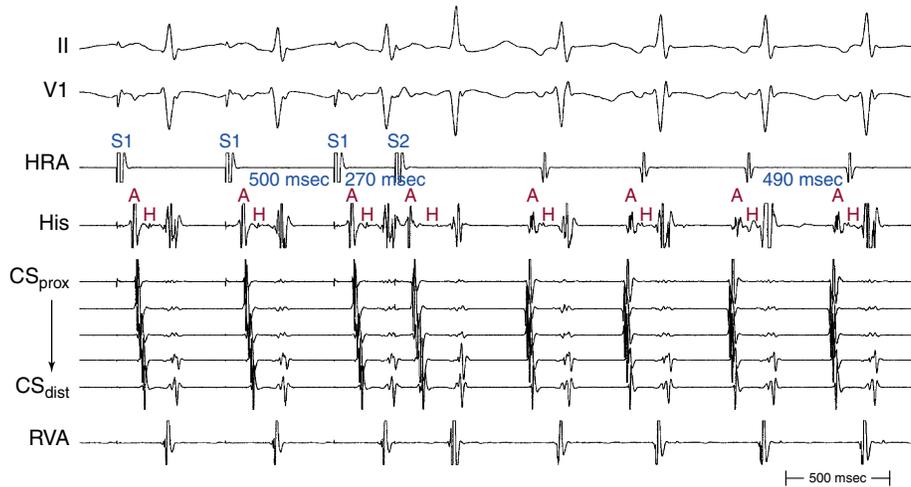

FIGURE 17-10 Induction of atypical atrioventricular nodal reentrant tachycardia (AVNRT) with atrial extrastimulation (AES). AES delivered from the high right atrium (HRA) at a coupling interval of 270 milliseconds after a drive cycle length (CL) of 500 milliseconds initiated atypical AVNRT with a CL of 490 milliseconds. Note that the AES conducted with only a modest prolongation of the atrial–His bundle (AH) interval. Additionally, comparing the AH interval between atrial drive pacing and that during the SVT (because the tachycardia CL approximates the pacing CL) reveals that ΔAH ($AH_{\text{pacing}} - AH_{\text{SVT}}$) is more than 40 milliseconds, thus favoring AVNRT over atrial tachycardia and orthodromic atrioventricular reentrant tachycardia. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; RVA = right ventricular apex.

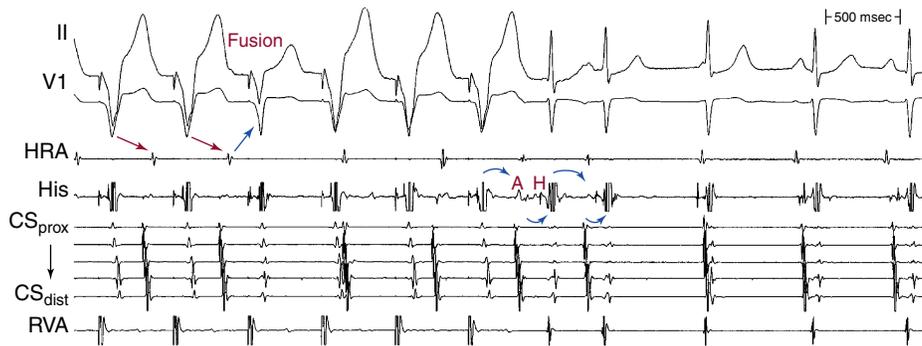

FIGURE 17-11 Ventricular pacing inducing atrioventricular nodal (AVN) echo beats. Note that ventriculoatrial conduction during ventricular pacing is occurring up the slow AVN pathway (red arrows). This results in AVN echo beats caused by anterograde conduction over the fast pathway, which results in occasional QRS fusion (i.e., fusion between the echo beat and the paced impulse) during the pacing drive. Cessation of ventricular pacing is followed by double AVN echo beats (blue arrows). CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

by atrial stimulation. It is difficult for VES to induce typical AVNRT because the prematurity with which the VES arrives at the AVN can be limited by conduction delay in the HPS or in the lower common pathway. The ERP of the HPS may exceed that of the slow AVN pathway. This limitation can usually be overcome by the introduction of multiple VESs, use of a shorter drive CL, or ventricular pacing, which results in adaptation and shortening of the HPS ERP. Additionally, the anterograde ERP of the slow pathway may exceed the ventricular pacing CL so that the slow pathway is incapable of anterograde conduction of the ventricular impulse conducting retrogradely over the fast pathway. Similar retrograde ERPs of the slow and fast pathways also can limit the successful initiation of AVNRT by ventricular stimulation. As noted, manipulation of the autonomic tone with vagal maneuvers or drugs can facilitate dissociation of those ERPs. Another explanation for the lower success rate of AVNRT induction by ventricular stimulation is that the ventricular stimulus can penetrate (and not just block) in the slow pathway retrogradely, thus causing concealment that renders that pathway refractory and incapable of anterograde conduction of the ventricular impulse traveling retrogradely over the fast pathway.²⁸

Burst ventricular pacing can overcome many of the problems imposed by HPS refractoriness in the induction of typical AVNRT (Fig. 17-11). During ventricular pacing, the AVN is the primary site of conduction delay. However, block in the lower common pathway and repetitive concealment (not just block) in the slow AVN

pathway can still limit the success of ventricular pacing in inducing typical AVNRT.

Of note, a VES that initiates an SVT with an HA interval longer than the HA (or VA) interval during the SVT, even though the H-H interval following that particular VES is longer than the H-H interval during the SVT, indicates that the SVT is AVNRT and not orthodromic AVRT. The reason is that both the HA interval during orthodromic AVRT and that following the VES represent sequential conduction duration from the HB up the lower common pathway and fast pathway to the atrium (Fig. 17-12). In contrast, during AVNRT, the HB and the atrium are activated in parallel, resulting in a shortened HA interval.²⁸

ATYPICAL (FAST-SLOW) ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA. Ventricular stimulation can induce atypical AVNRT by different mechanisms. The ventricular impulse can block in the fast pathway and conduct retrogradely over the slow pathway, with a long HA interval, thus allowing for recovery of the fast pathway and subsequent anterograde conduction down this pathway, initiating atypical AVNRT (see Fig. 17-12). This requires the retrograde ERP of the fast pathway to exceed that of the slow pathway. In this case, dual retrograde AVN pathways would be demonstrated with ventricular stimulation. Both VES and ventricular pacing are equally effective in inducing atypical AVNRT by this mechanism. Occasionally, a VES can conduct over both AVN pathways, to produce a 1:2 response, which is

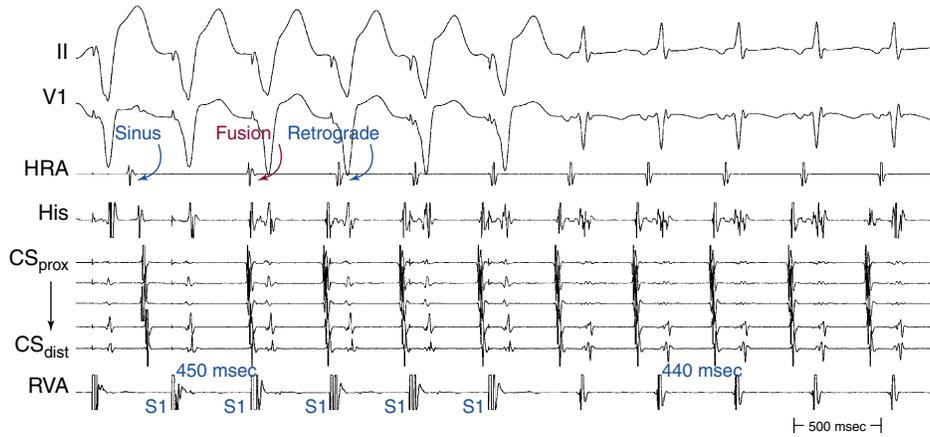

FIGURE 17-12 Induction of atypical atrioventricular nodal reentrant tachycardia (AVNRT) with ventricular pacing. Right ventricular apical (RVA) pacing (cycle length [CL] = 450 milliseconds) induces atypical AVNRT (CL = 440 milliseconds). Retrograde atrial activation sequence during ventricular pacing is similar to that during the supraventricular tachycardia (SVT), and the ventriculoatrial (VA) interval during ventricular pacing is longer than during the SVT; both criteria favor AVNRT over orthodromic atrioventricular reentrant tachycardia. Note that the first atrial complex on the left of the tracing is actually a sinus P wave, and the second is a fusion between retrograde VA conduction and a sinus impulse; a pure retrograde atrial activation sequence is observed only after the third ventricular stimulus. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium.

subsequently followed by the induction of atypical AVNRT. Ventricular pacing can initiate atypical AVNRT at pacing CLs associated with sufficient retrograde AVN conduction delay, especially during Wenckebach cycles, when retrograde block occurs in the fast pathway and conduction shifts to the slow pathway.¹⁹

Inducibility of atypical AVNRT is mostly determined by the retrograde slow pathway conduction. The reason is that the anterograde fast pathway conduction is usually sufficiently fast and its ERP is sufficiently short to allow anterograde conduction of the impulse arriving from the slow pathway.²⁸

Tachycardia Features

TYPICAL (SLOW-FAST) ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

ATRIAL ACTIVATION SEQUENCE. The initial site of atrial activation is usually recorded in the HB catheter at the apex of the triangle of Koch. In general, the shorter the HA interval is, the more likely the earliest atrial activation is to be recorded in the HB electrograms. As the HA interval prolongs, the earliest atrial activation moves closer to the base of the triangle of Koch or in the CS. However, significant heterogeneity in atrial activation exists, with multiple breakthrough points (unlike AT or orthodromic AVRT). In addition, in approximately 60% of patients, retrograde atrial activation during typical AVNRT can be slightly discordant quantitatively and qualitatively from that during ventricular pacing. Subsequently, the wave of atrial activation propagates radially cephalad and laterally to activate both atria (i.e., concentric atrial activation). This results in a relatively narrow P wave. In fact, the narrowest P wave during any arrhythmia is seen when the atrial activation begins at the apex of the triangle of Koch. The site of earliest atrial activation is not always obvious during AVNRT because of superimposition of atrial and ventricular electrograms. Delivering a VES that advances ventricular activation but does not reset atrial activation usually helps unmask the atrial activation sequence.⁸

ATRIAL-VENTRICULAR RELATIONSHIP. The onset of atrial activation appears before or coincides with the onset of the QRS in approximately 70% of cases. The RP interval is very short (−40 to 75 milliseconds); however, variation of the A/V relationship (with changes in AH, HA, and AH/HA interval ratio) can occasionally occur during initiation or termination of the tachycardia, likely because of decremental conduction in the lower common pathway. Usually, the A/V ratio equals 1. However, AV block can be present because of block below the reentry circuit (usually below the HB and infrequently in the lower common pathway), which

can occur especially at the onset of the SVT, during acceleration of the SVT, and following a PVC or VES. Moreover, Wenckebach-type block can occur in the lower common pathway and can result in a changing relationship between the His potential and the atrial electrogram (i.e., retrograde atrial electrogram moves closer to or actually precedes the His potential, until block occurs with no His potential apparent). Reproducible, sustained 2:1 AV block during induced episodes of AVNRT can be observed in approximately 10% of cases (see Fig. 17-4). The His potential is absent in blocked beats in approximately 40% of patients who have 2:1 AV block. In the remaining patients, the His potential can range from being rudimentary to large in amplitude. However, irrespective of whether a His potential is present in blocked beats, the AV block persists after the administration of atropine, a finding suggesting that the site of block is not in the AVN. In addition, a VES introduced during the 2:1 AV block consistently results in 1:1 conduction, indicating that the AV block is functional and that the level of block is infranodal. Therefore, what was previously thought to be 2:1 AVN block in the lower common pathway of the AVNRT circuit (because of the absence of visible His potentials) is more likely to be intra-Hisian block. Rarely, VA block can occur during AVNRT because of block in the upper common pathway (see Fig. 17-11).^{8,15}

OSCILLATION IN THE TACHYCARDIA CYCLE LENGTH. When CL variability is observed during typical AVNRT, it is generally caused by changes in anterograde conduction over the slow AVN pathway. Because retrograde conduction through the fast AVN pathway generally is much less variable, the changes in the ventricular CL that result from variability in anterograde AVN conduction precede the subsequent changes in the atrial CL (Fig. 17-13), and changes in the atrial CL do not predict changes in the subsequent ventricular CL, as is the case in orthodromic AVRT.³⁰

EFFECT OF BUNDLE BRANCH BLOCK. The development of prolonged functional aberration during AVNRT is uncommon, and it usually occurs at initiation of the tachycardia or after resumption of 1:1 AV conduction after a period of block in the HB or lower common pathway (see Fig. 17-4). When BBB does occur during AVNRT, it does not influence the tachycardia CL (A-A or H-H intervals) because the ventricles are not required for the tachycardia circuit.

TERMINATION AND RESPONSE TO PHYSIOLOGICAL AND PHARMACOLOGICAL MANEUVERS. The tachycardia CL is correlated best to the conduction time down the slow pathway. Spontaneous or pharmacologically mediated changes in the tachycardia CL are also more closely associated with changes in slow pathway conduction. Spontaneous termination of typical AVNRT occurs because of block in the fast or the slow pathway. However, the better the retrograde fast pathway conduction is, the less likely it is to

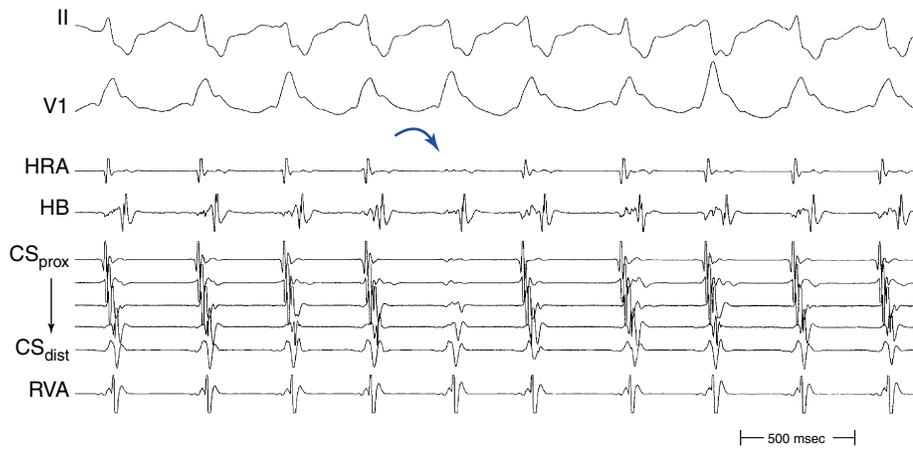

FIGURE 17-13 Typical atrioventricular nodal reentrant tachycardia (AVNRT) with right bundle branch block. Intermittent ventriculoatrial (VA) block is observed (arrow) secondary to block in an upper common pathway. Oscillation of the tachycardia cycle length (CL) is observed before the block. Note the changes in the H-H and V-V intervals preceding similar changes in the A-A interval. Both atrial tachycardia and orthodromic atrioventricular reentrant tachycardia are excluded by the fact that the atrium is not necessary for continuation of the tachycardia. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

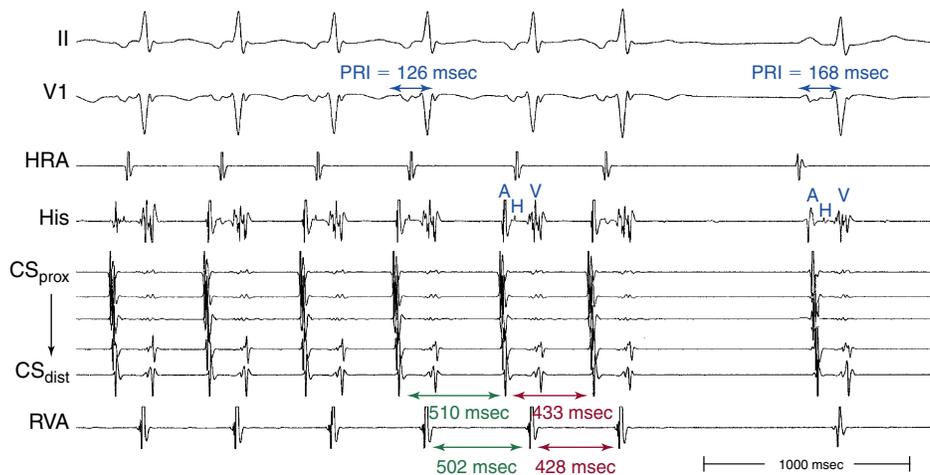

FIGURE 17-14 Atypical (fast-slow) atrioventricular nodal reentrant tachycardia (AVNRT) terminating spontaneously. Oscillation of the tachycardia cycle length (CL) is observed just before termination. Note that changes in the atrial CL predict changes in the subsequent ventricular CL because CL variability during atypical AVNRT is usually caused by changes in retrograde conduction over the slow AVN pathway, whereas anterograde conduction occurs over the more stable fast AVN pathway and is less subject to variability. Additionally, the PR interval (PRI) and atrial–His bundle (AH) interval are shorter during AVNRT than those during normal sinus rhythm (NSR) because both the atrium and the ventricle are activated in parallel with simultaneous conduction up an upper common pathway and down the anterograde fast pathway in atypical AVNRT but in sequence during NSR. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

be the site of block. Carotid sinus massage and vagal maneuvers can terminate typical AVNRT with gradual anterograde slowing and then block in the slow pathway, whereas block in the fast pathway is uncommon. AVN blockers (digoxin, calcium channel blockers, and beta blockers) prolong the refractoriness of the fast and slow pathways to similar or different degrees. Such effects mediate termination of AVNRT. However, they can occasionally help dissociate the ERP of the fast and slow pathways and unmask dual AVN physiology, and they can also facilitate inducibility of the AVNRT. Adenosine blocks the slow pathway and terminates AVNRT, but it does not affect the fast pathway. Class IA and IC agents and amiodarone affect both the fast and the slow pathways.²⁸

ATYPICAL (FAST-SLOW) ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

The earliest site of retrograde atrial activation during atypical AVNRT is usually recorded at the base of the triangle of Koch or CS os, and CS breakthrough is observed in most patients. The CS breakthrough is likely part of or very close to the reentry circuit, as demonstrated by entrainment mapping.²¹

The RP interval during atypical AVNRT is longer than the PR interval. Additionally, the PR and AH intervals are shorter during AVNRT than during NSR because the atrium and ventricle are activated in parallel with simultaneous conduction up the upper

common pathway and down the anterograde fast pathway in atypical AVNRT, but in sequence during NSR (Fig. 17-14).

Usually, the A/V ratio equals 1, as is the case for typical AVNRT. BBB can occur but does not influence the tachycardia CL. In contrast to typical AVNRT, CL variability during atypical AVNRT is usually caused by changes in retrograde conduction over the slow AVN pathway. Anterograde conduction occurs over the more stable fast AVN pathway and is less subject to variability (see Fig. 17-14). Therefore, during atypical AVNRT, changes in the atrial CL predict changes in the subsequent ventricular CL (as is the case in AT).³⁰ Carotid sinus massage, vagal maneuvers, adenosine, and AVN blockers (e.g., digoxin, calcium channel blockers, and beta blockers) generally terminate atypical AVNRT by gradual slowing and then block in the retrograde slow pathway (see Fig. 17-14). Termination of atypical AVNRT with adenosine can also result from block in the fast AVN pathway; however, the value of this observation in distinguishing between atypical AVNRT and orthodromic AVRT using a slow retrograde BT is questionable.

Diagnostic Maneuvers during Tachycardia

ATRIAL EXTRASTIMULATION AND ATRIAL PACING DURING SUPRAVENTRICULAR TACHYCARDIA

A late-coupled AES usually fails to reach the AVN with adequate prematurity and thus fails to affect the tachycardia, and a full

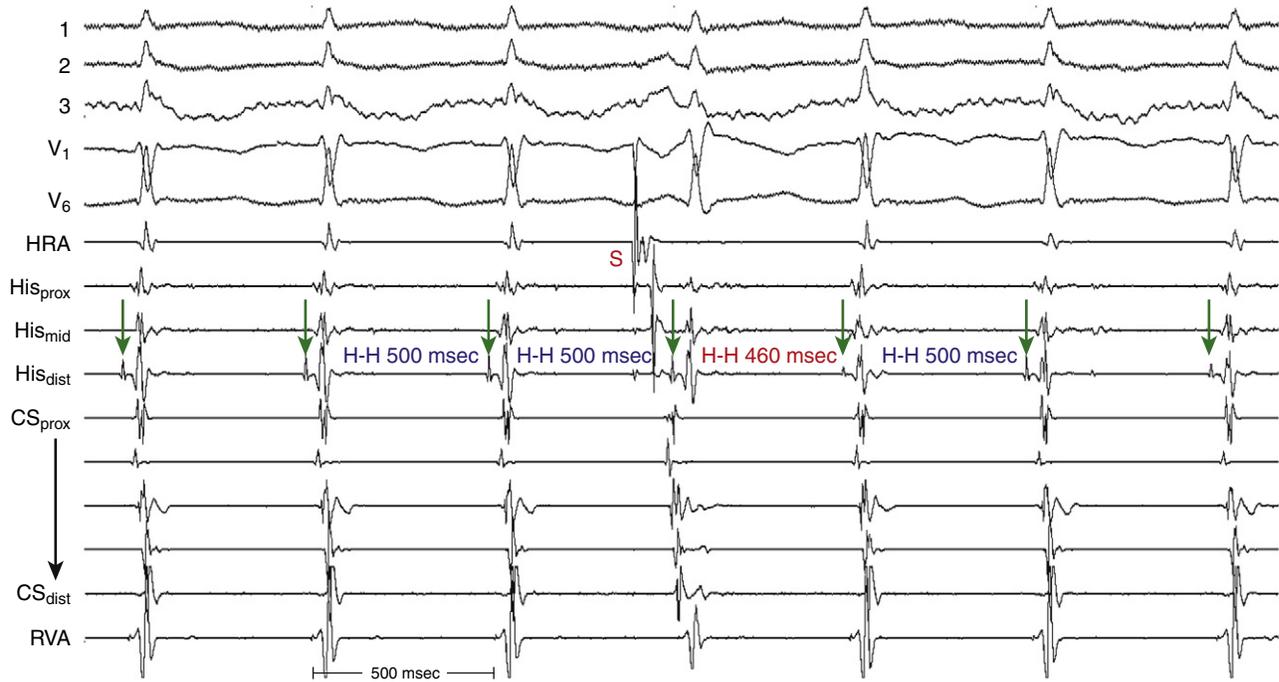

FIGURE 17-15 Atrial extrastimulus during atrioventricular nodal reentrant tachycardia has no effect on the timing of the immediately following His potential (H-H interval = 500 milliseconds) but advances the timing of the following His potential (H-H interval = 460 milliseconds). Arrows mark His potentials. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; RVA = right ventricular apex.

compensatory pause results. However, the AES can anterogradely conceal in the upper common pathway, thereby retarding conduction of the impulse traveling retrogradely up the fast pathway and resulting in a delay in the timing of the next atrial activation. This is usually manifested by an AES that delays the subsequent atrial activation but without affecting the timing of HB and ventricular activation.²⁸

In typical AVNRT, an early-coupled AES frequently penetrates the AVN and resets the reentry circuit, with a resulting compensatory pause that is less than, equal to, or greater than a full compensatory pause, depending on the degree of anterograde conduction delay that the AES encounters down the slow pathway (because of the decremental conduction properties of the AVN). The AES orthodromically propagates through the anterograde slow pathway, with a resulting alteration of the subsequent H-H' interval, whereas it antidromically collides with the preceding tachycardia wavefront traveling retrogradely up the fast pathway (Fig. 17-15). Progressively premature AESs encounter progressive anterograde conduction delay in the slow pathway, and an increasing resetting response pattern occurs. Theoretically, the degree of conduction delay in the slow pathway can exactly compensate for the prematurity of the AES, thus producing a pause that is equal to a full compensatory pause. To verify whether that pause was fully compensatory because the AES failed to penetrate the AVN or because the degree of anterograde conduction delay in the AVN was exactly sufficient to compensate for the prematurity of the AES, the return cycles are evaluated after delivery of additional AESs with different coupling intervals. Similarly, a delay in the slow pathway causes delay in the subsequent His potential timing, and such a delay can be equal to, greater, or smaller than what is needed to compensate for the prematurity of the AES. Therefore, the His potential following an AES can occur early, late, or on time relative to the expected tachycardia His potential. An early-coupled AES can also impinge on the relative refractory period of the lower common pathway and can cause slowed conduction and delay in the timing of the next His potential (i.e., longer A_2-H_2 than the baseline tachycardia A_1-H_1). This can occur even without affecting the timing of the next atrial activation, if conduction delay occurs only in the lower common

pathway but not in the slow pathway.²⁸ In atypical AVNRT, an early-coupled AES can reset the SVT in a fashion that that seen in typical AVNRT. However, the delay in conduction that the AES will engender is mainly in the retrograde limb of the circuit (i.e., the slow pathway). An AES that accelerates the next His potential and resets tachycardia is indicative of focal junctional tachycardia (Fig. 17-16).

Resetting with fusion (a hallmark of macroreentrant tachycardias) cannot be demonstrated in AVNRT. For atrial fusion (i.e., fusion of atrial activation from both the tachycardia wavefront and the AES) to occur, the AES should be able to enter the reentrant circuit, while at the same time the tachycardia wavefront should be able to exit the circuit. This requires spatial separation between the entry and exit sites to the reentrant circuit, a condition that seems to be lacking in the setting of AVNRT. Once the tachycardia wavefront exits the reentry circuit to activate the atrium, any AES delivered beyond that time and resulting in atrial fusion is not capable of reaching the reentry circuit because the entry-exit site is already refractory in response to activation by the exiting wavefront, and the AES has no alternative way of reaching the circuit. Similarly, once an AES is capable of reaching the reentry circuit, the shared entry-exit site is made refractory and incapable of allowing a simultaneous exit of the tachycardia wavefront.

During typical AVNRT, a very early-coupled AES can block anterogradely in the slow pathway, and it usually collides with a retrograde wavefront in the fast pathway to terminate the SVT. However, if the tachycardia CL is sufficiently long, with a wide fully excitable gap, and the AES is appropriately timed, the AES can block anterogradely in the slow pathway and still conduct down the fast pathway to capture the HB and ventricle and terminate the SVT before the SVT wavefront traveling down the slow pathway reaches the lower turnaround point. Therefore, the last HB and ventricular electrograms before termination are advanced and premature, in contrast to termination secondary to an AES blocking anterogradely in the slow and fast pathways, whereby the last HB and ventricular electrograms of the SVT occur on time. This phenomenon occurs more commonly in atypical AVNRT.²⁸ In atypical AVNRT, a very early-coupled AES can conduct down the fast pathway during retrograde slow pathway activation and block retrogradely in

FIGURE 17-16 Atrial extrastimulus during focal junctional rhythm advances the timing of the immediately following His potential (H-H interval = 830 milliseconds) and resets the timing of the following His potential (H-H interval = 860 milliseconds). CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle; RV = right ventricle.

the slow pathway. In this case, the AES results in a premature HB and ventricular activation, and the AVNRT is terminated before the expected atrial activation.

TERMINATION. The ability of an AES to terminate AVNRT depends on the following: (1) the tachycardia CL (AVNRT with a CL shorter than 350 milliseconds is rarely terminated by a single AES, unless atrial stimulation is performed close to the AVN); (2) the distance of the site of atrial stimulation from the AVN (which would influence the ability of the AES to arrive to the AVN with adequate prematurity); (3) the refractoriness of the intervening atrial tissue (which can be overcome by delivery of multiple AESs); (4) atrial conduction velocity resulting from the AES; and (5) the size of the excitable gap in the reentrant circuit.²⁸

ENTRAINMENT. Atrial pacing at a CL approximately 10 to 30 milliseconds shorter than the tachycardia CL is usually able to entrain AVNRT. In contrast to orthodromic AVRT, entrainment with atrial fusion cannot be demonstrated during AVNRT, a finding suggesting that the reentrant circuit in AVNRT does not have widely separate atrial entry and exit sites. Therefore, during entrainment of AVNRT by atrial pacing, the atrial activation sequence and P wave morphology are always those of pure paced morphology. The inability to demonstrate entrainment with manifest atrial fusion suggests a purely intranodal location of the AVNRT circuit. On the other hand, one study showed orthodromic capture of the atrial electrogram at the HB recording site (i.e., the bipolar HB electrogram morphology is identical to that during the tachycardia and is unaffected by pacing, and the first post-pacing interval [PPI] is identical to the pacing CL) during entrainment from the CS os region, a finding consistent with intracardiac atrial fusion. This suggests the absence of an upper common pathway between a reentrant circuit and atrial tissue surrounding the AVN and supports the concept that the reentrant circuit in AVNRT incorporates the atrial tissue surrounding the AVN. The AH interval during entrainment is usually longer than that during AVNRT because the atrial and the His electrograms are activated in parallel during AVNRT and in sequence

during atrial pacing entraining the AVNRT (in response to the presence of intervening atrial tissue and, potentially, an upper common pathway separating the site of atrial stimulation from the reentry circuit).²⁸

VENTRICULOATRIAL LINKING The initial atrial complex following cessation of atrial pacing entraining typical AVNRT is *linked* to, and cannot be dissociated from, the last captured ventricular complex. As a consequence, the post-pacing VA intervals are fixed and similar to those during tachycardia (with less than 10 milliseconds variation) after different attempts at SVT entrainment, regardless of the site, duration, or CL of the entraining atrial pacing drive. VA linking occurs in the setting of typical AVNRT because the timing of atrial activation is dependent on ventricular activation and is the result of retrograde VA conduction over the AVN fast pathway, which is relatively fixed and constant. VA linking can also be observed in orthodromic AVRT. In contrast, in the setting of AT, the first atrial return cycle following cessation of pacing is dependent on the distance between the AT origin and pacing site, the atrial conduction properties, and the mode of the resetting response of the AT, and it is not related to the preceding ventricular activation. Hence, the post-pacing VA intervals following different attempts at entrainment can vary especially when pacing at different rates or durations or from different atrial sites.^{31,32}

VENTRICULAR EXTRASTIMULATION AND VENTRICULAR PACING DURING SUPRAVENTRICULAR TACHYCARDIA

RESETTING. For a VES to reset the AVNRT circuit, it needs to advance (prematurely activate) the HB timing by a degree that is dependent on the following: (1) the tachycardia CL, (2) the local ventricular ERP, (3) the time needed for the VES to reach the HB, and (4) the length of the lower common pathway. The longer the lower common pathway is, the more the timing of HB activation must be advanced so that the VES will be able to activate the AVNRT circuit prematurely. Therefore, in slow-fast and slow-slow

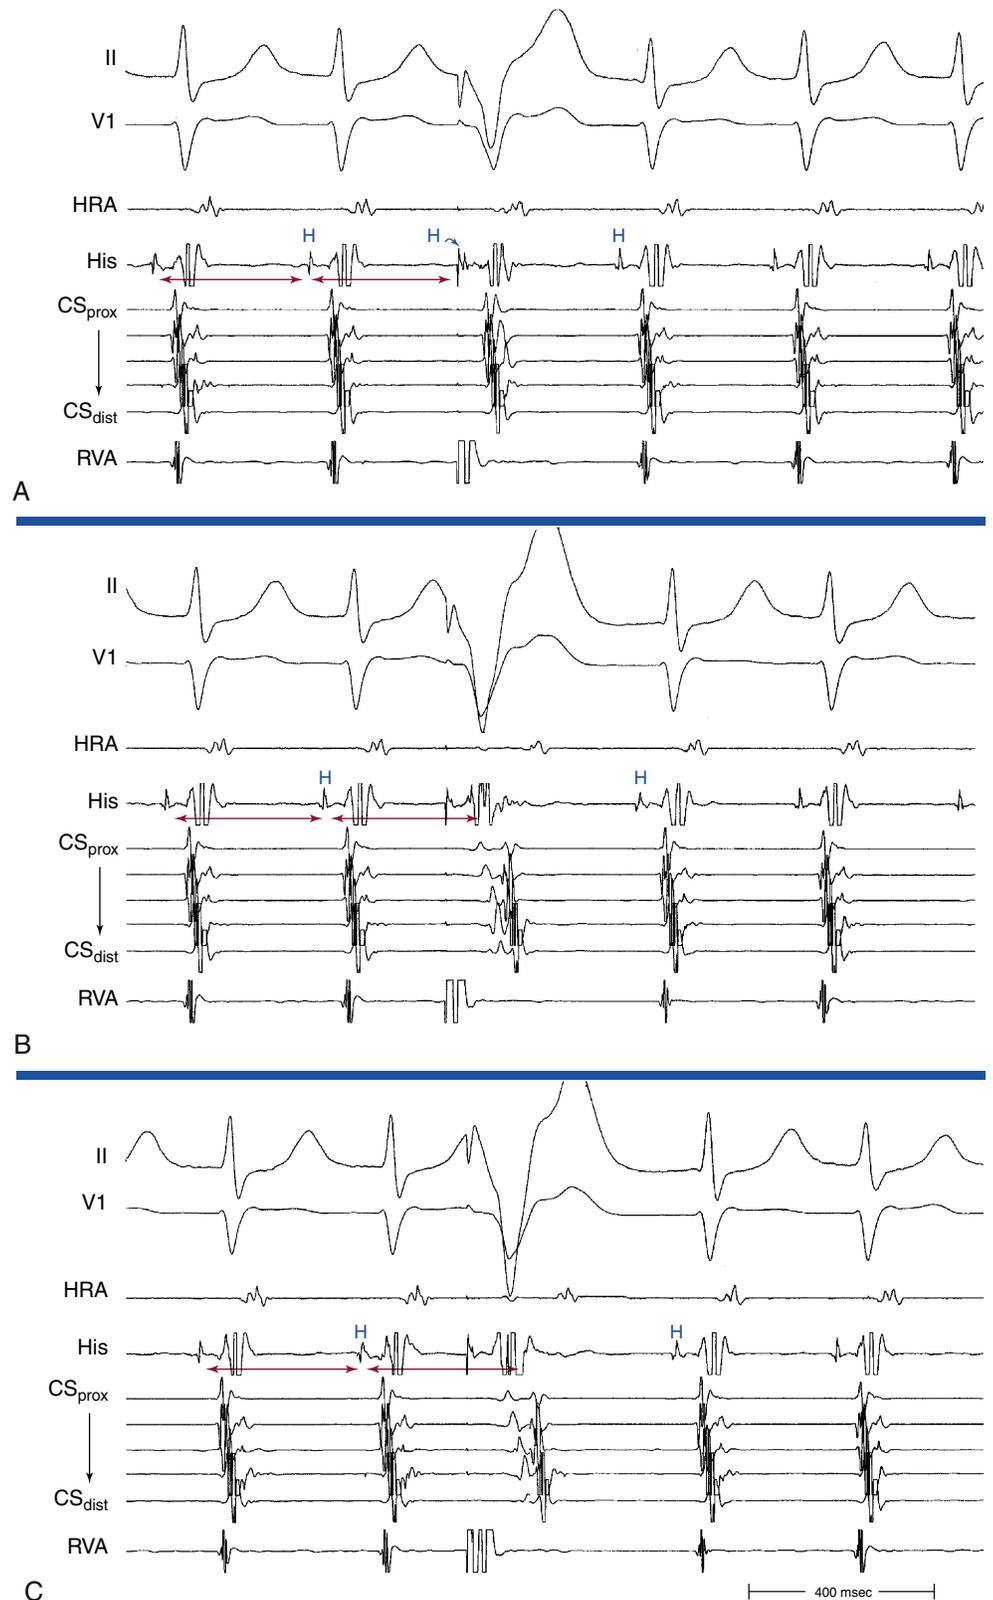

FIGURE 17-17 Resetting of atrioventricular nodal reentrant tachycardia (AVNRT) with ventricular extrastimulation (VES) at different coupling intervals. **A**, Late-coupled VES delivered when the His bundle is refractory fails to reset the AVNRT. In fact, the antero- grade His potential (H) is visualized shortly after the pacing artifact (arrow), occurring at the expected timing (the tachycardia cycle length is indicated by the red lines). **B**, An early VES delivered well before the expected time of the antero- grade His potential fails to reset the supraventricular tachycardia (SVT). The fact that this VES advances ventricular activation at all recorded sites by approximately 70 milliseconds and still fails to reset the SVT excludes orthodromic atrioventricular reentrant tachycardia. **C**, Earlier VES results in resetting of the SVT, as indicated by earlier timing of the following atrial activation. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

AVNRT, which typically has a long lower common pathway, the HB activation must be advanced by more than 30 to 60 milliseconds. In contrast, in slow-fast AVNRT, the lower common pathway is shorter, and the tachycardia is typically reset by the VES as soon as the HB activation is advanced.²⁸

A late-coupled VES may block in the HPS or lower common pathway and may not affect the SVT (Fig. 17-17A). A late-coupled VES

that resets the SVT without first retrogradely activating the HB (i.e., VES delivered at, after, or within 50 milliseconds of the expected inscription of the antero- grade His potential) excludes AVNRT.

An early-coupled VES can reset AVNRT, especially when the tachycardia CL is relatively long (more than 350 milliseconds). The resetting VES antegradely collides with the preceding tachycardia wavefront traveling antegradely and is conducted through

the retrograde pathway to reset the tachycardia (see Fig. 17-17). Resetting of AVNRT with fusion of the QRS cannot be demonstrated because of the shared entry-exit site from the ventricle to the circuit, as discussed earlier.

A VES can reset the AVNRT circuit without resulting in subsequent atrial activation (i.e., advances the subsequent His potential and QRS and blocks in the upper common pathway). This latter phenomenon excludes AT and orthodromic AVRT as the mechanism of SVT, because it proves that the atrium is not part of the SVT circuit.

TERMINATION. Termination of AVNRT with VES is difficult (more so than termination with AES) and is rare when the tachycardia CL is shorter than 350 milliseconds. Such termination favors the diagnosis of orthodromic AVRT. In typical AVNRT, when termination occurs, it is usually caused by block of the VES in the anterograde or retrograde limb of the AVNRT circuit. The slower the SVT is, the more likely the block will be to occur in the anterograde slow pathway. Ventricular pacing can terminate AVNRT more easily than VES because rapid ventricular pacing can modulate and overcome the refractoriness of the intervening HPS. VES always terminates atypical AVNRT by blocking retrogradely in the slow pathway.²⁸

ENTRAINMENT. Ventricular pacing at a CL approximately 10 to 30 milliseconds shorter than the tachycardia CL is usually able

to entrain AVNRT. Visualization of the His potential before atrial activation during entrainment helps differentiate AVNRT from orthodromic AVRT. If the His potential cannot be visualized during ventricular pacing, two other parameters can be helpful to distinguish AVNRT from orthodromic AVRT: the VA interval during ventricular pacing and the PPI. The VA interval during ventricular pacing is significantly longer than that during AVNRT ($\Delta VA [VA_{\text{pacing}} - VA_{\text{SVT}}]$ is usually more than 85 milliseconds) because both the ventricle and the atrium are activated in parallel during AVNRT but in sequence during ventricular pacing entraining the AVNRT (Figs. 17-18 and 17-19).

The PPI after entrainment of AVNRT from the RV apex is significantly longer than the tachycardia CL (the $[PPI - SVT CL]$ difference is usually more than 115 milliseconds) because the reentrant circuit in AVNRT (confined above the HB and does not involve the ventricle) is far from the pacing site. In AVNRT, the PPI reflects the conduction time from the pacing site through the RV muscle and HPS, once around the reentry circuit and back to the pacing site. Therefore, the difference between the PPI and tachycardia CL reflects twice the sum of the conduction time through the RV muscle, the HPS, and the lower common pathway. In orthodromic AVRT using a septal BT, the PPI reflects the conduction time through the RV to the septum, once around the reentry circuit and back. In other words, the difference between the PPI and tachycardia CL reflects

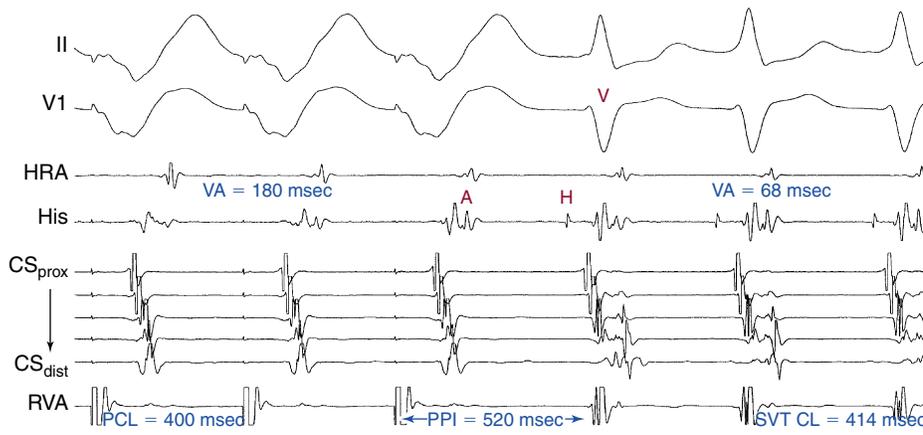

FIGURE 17-18 Entrainment of typical atrioventricular nodal reentrant tachycardia (AVNRT) with right ventricular (RV) apical pacing. The post-pacing interval (PPI) minus supraventricular tachycardia (SVT) cycle length (CL) ($PPI - SVT CL$) is more than 115 milliseconds, and the ΔVA interval (ventriculoatrial $[VA_{\text{pacing}} - VA_{\text{SVT}}]$) is more than 85 milliseconds. The atrial activation sequence during ventricular pacing is identical to that during AVNRT. No QRS fusion is observed. Cessation of ventricular pacing is followed by an AV response. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; PCL = pacing CL; RVA = right ventricular apex.

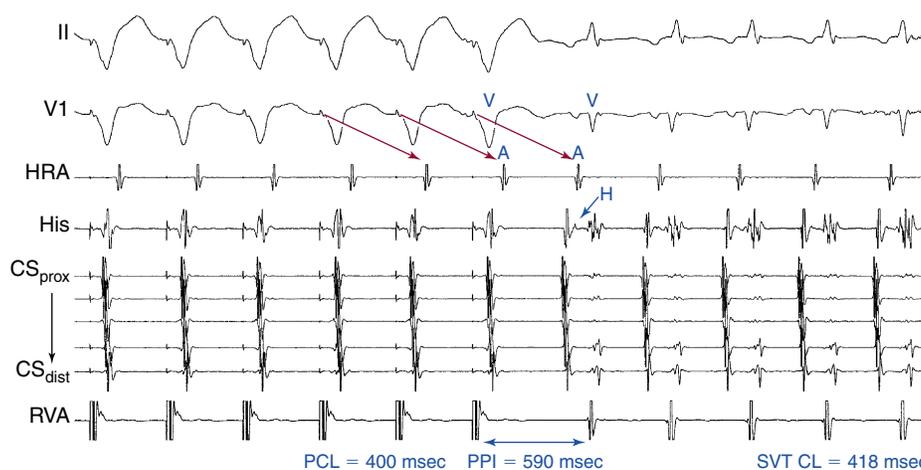

FIGURE 17-19 Entrainment of atypical atrioventricular nodal reentrant tachycardia (AVNRT) with right ventricular (RV) apical pacing. The post-pacing interval (PPI) minus supraventricular tachycardia (SVT) cycle length (CL) ($PPI - SVT CL = 172$ milliseconds) is long, and the ΔVA ($VA_{\text{pacing}} - VA_{\text{SVT}}$) interval is also long (188 milliseconds); both criteria favor AVNRT over orthodromic atrioventricular reentrant tachycardia. Note that the atrial activation sequence during RV pacing is similar to that during the SVT, again favoring AVNRT over other types of SVT. Additionally, a pseudo-A-A-V response is observed following cessation of ventricular pacing because retrograde conduction occurs through the slow pathway during ventricular pacing with a long VA interval (red arrows), longer than the pacing CL (PCL); hence, the last ventricular paced impulse is followed first by the P wave conducted slowly from the previous paced QRS and then by the P wave resulting from the last paced QRS, thus mimicking an A-A-V response. This is confirmed by the observation that the last atrial activation resulting from conduction of the last paced ventricular complex follows the preceding P wave with an A-A interval equal to the ventricular PCL. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

twice the conduction time from the pacing catheter through the ventricular myocardium to the reentry circuit. Because the ventricle is an essential component of the AVRT circuit, the RV apex is closer to the tachycardia circuit. Therefore, the PPI more closely approximates the SVT CL in orthodromic AVRT using a septal BT ([PPI – SVT CL] difference is usually less than 115 milliseconds) compared with AVNRT. This maneuver was studied specifically for differentiation between atypical AVNRT and orthodromic AVRT using a septal BT, but the principle also applies to typical AVNRT (see Figs. 17-18 and 17-19). For borderline values, ventricular pacing at the RV base can help exaggerate the difference between the PPI and tachycardia CL in the case of AVNRT, but without significant changes in the case of orthodromic AVRT. The reason is that the site of pacing at the RV base is farther from the AVNRT circuit than the RV apex (the paced wavefront has to travel first to near the RV apex before engaging the HPS and conducting retrogradely to the AVN), but it is still close to an AVRT circuit using a septal BT (and in fact is closer to the ventricular insertion of the BT).³³

However, there are several potential pitfalls to those criteria. The tachycardia CL and VA interval are often perturbed for a few cycles after entrainment. For this reason, care should be taken not to measure unstable intervals immediately after ventricular pacing. In addition, spontaneous oscillations in the tachycardia CL and VA intervals can be seen. The discriminant points chosen may not apply when the spontaneous variability is more than 30 milliseconds. In addition, it is possible to mistake isorhythmic VA dissociation for entrainment if the pacing train is not sufficiently long or the pacing CL is too close to the tachycardia CL. Finally, those criteria may not apply to BTs with significant decremental properties, although small decremental intervals are unlikely to provide a false result.

Additionally, overdrive ventricular pacing during entrainment can induce decremental anterograde AVN conduction. Subtracting the increment in AVN conduction time in the first PPI (post-pacing AH interval – prepacing AH interval) from the [PPI – SVT CL] difference (“corrected” [PPI – SVT CL]) has been found to improve the accuracy of this criterion. The difference between the AV intervals (post-pacing AV interval – prepacing AV interval) can be taken for the latter adjustment when a clear His deflection is lacking. A corrected [PPI – SVT CL] of less than 110 milliseconds was found to be highly accurate in identifying orthodromic AVRT from AVNRT.^{34,36}

Again, no QRS fusion is manifest during ventricular entrainment of AVNRT, and QRS morphology is that of pure paced morphology. Fusion during resetting or entrainment of AVNRT with ventricular stimulation would require the paced ventricular wavefronts to enter the circuit propagating through the HB at the time that impulses are exiting through this structure. The HB is also the site of exit of the tachycardia circuit to the ventricular tissue. Therefore, collision of the antidromic wavefront and the orthodromic wavefront from the preceding beat occurs in AVN tissue and not in the ventricle. Under such circumstances, constant fusion during entrainment is almost impossible (unless a second connection exists between the atria and ventricles; i.e., an innocent bystander BT). Manifest ventricular fusion during entrainment of SVT indicates that the reentrant circuit includes ventricular tissue (diagnostic of AVRT), thus excluding both AVNRT and AT.

DIFFERENTIAL RIGHT VENTRICULAR ENTRAINMENT. Differential-site RV entrainment (from RV apex versus RV base) can help distinguish AVNRT from orthodromic AVRT. Because the reentrant circuit in AVNRT is confined above the HB and does not involve the ventricle, the base of the RV is electrically more distant (although anatomically closer) than the RV apex to the tachycardia circuit, given that the His-Purkinje network directly inserts in the RV apex. Consequently, the PPI after entrainment of AVNRT from the RV base is longer than that following entrainment from the RV apex. The difference in PPI from RV base versus RV apex is largely composed of the extra time required to reach the circuit from the base versus the apex (approximately 30 milliseconds). Conversely, in orthodromic AVRT, in which the ventricles are an obligatory part of the circuit, the basal pacing site

relative to the RV apex is variably related to the circuit, closer than the RV apex with septal BTs and equidistant with free wall BTs, but the paced wavefront from either RV apex or RV base tends to have, on average, approximately equal access and EP proximity to the reentrant circuit involved in orthodromic AVRT. Therefore, the time taken to reach the circuit (and hence the PPI) tends to be similar, irrespective of the location of the BT.

As noted, decremental conduction can occur during entrainment of either AVNRT or orthodromic AVRT, and most commonly it occurs during conduction through the AVN, especially the AVN slow pathway. The degree of decrement is dependent on both the pacing rate and the functional refractory properties of the AVN. Therefore, the PPI will prolong if decrement occurs, but the degree of decrement is not expected to be materially different from basal rather than apical pacing as long as the pacing rates are the same or similar. To avoid potential error introduced by decremental conduction within the AVN, correction of the PPI is preferred, and it is obtained by subtracting any increase in the AV interval of the return cycle beat (as compared with the AV interval during SVT). In one study, a differential corrected [PPI – SVT CL] of more than 30 milliseconds after transient entrainment was observed in all cases of AVNRT (i.e., corrected PPI following pacing from the RV base was consistently at least 30 milliseconds longer than that following pacing from the RV apex), and corrected [PPI – SVT CL] of less than 30 milliseconds was observed in all cases of orthodromic AVRT. Additionally, differential VA interval (ventricular stimulus-to-atrial interval during entrainment from RV base versus RV septum) of more than 20 milliseconds was consistent with AVNRT, whereas a differential VA interval of less than 20 milliseconds was consistent with orthodromic AVRT.³⁷

LENGTH OF PACING DRIVE REQUIRED FOR ENTRAINMENT. Careful analysis of the beginning of RV pacing during the SVT can aid in the tachycardia diagnosis. Assessing the timing and type of response of SVT to RV pacing also can help differentiate orthodromic AVRT from AVNRT with high positive and negative predictive values. In the setting of orthodromic AVRT, ventricular tissue is the only intervening tissue between the pacing wavefront and the ventricular insertion site of the BT. Therefore, once ventricular capture is achieved during RV pacing, the paced wavefront propagates to the ventricular insertion site of the BT quickly and resets the tachycardia. Consequently, RV pacing results in a faster response of resetting the tachycardia. In the setting of AVNRT, on the other hand, the pacing wavefront has to penetrate the HPS and AVN tissue prior to resetting the tachycardia. This results in delayed resetting of the tachycardia compared with orthodromic AVRT. After initiation of synchronized RV pacing during SVT at a CL 10 to 40 milliseconds shorter than the tachycardia CL, once constant-appearing paced RV complexes (either pure capture or fixed fusion) are observed (as evidenced by fixed pacing morphology of the surface ECG), the number of RV paced beats required to accelerate the SVT to the pacing CL is determined. The first atrial capture beat accelerated to the pacing CL is identified by demonstrating a fixed ventricular stimulus-to-atrial capture interval. One report demonstrated that using a cutoff of one beat to accelerate the SVT to the pacing CL could identify all orthodromic AVRT cases and essentially exclude all cases of AVNRT with high accuracy. On the contrary, if two beats are required to accelerate SVT to the pacing CL, this can distinguish AVNRT from orthodromic AVRT with very high confidence as well. The major advantage of this method is its independence of tachycardia continuation after cessation of pacing. However, it is likely that these criteria may not be applicable at faster pacing CLs because resetting of the tachycardia may occur earlier in AVNRT in response to a greater degree of penetration into the tachycardia circuit. In addition, these findings may not apply in cases in which AVNRT occurs in the setting of a bystander BT because SVT may be reset using the bystander BT.³⁸

ATRIAL RESETTING DURING THE TRANSITION ZONE. On initiation of RV pacing trains during the SVT at a rate slightly faster than the SVT CL, there is a transition zone during which the

acing train fuses with anterograde ventricular activation (i.e., the zone in which the paced QRS complexes show progressive fusion with the SVT complexes) until stable QRS morphology is observed (either completely paced or constantly fused). In patients with AVNRT or AT, acceleration of the timing of atrial activation cannot occur through the AVN during the transition zone. The reason is that the HB is expected to be refractory, as indicated by at least some ventricular activation still occurring by anterograde conduction over the HPS, similar to the concept of entrainment with manifest fusion discussed previously. If perturbation of atrial timing occurs during the transition zone, it indicates the presence of a retrogradely conducting BT, which can be an integral part of the SVT circuit (i.e., orthodromic AVRT) or a bystander. In one report, these criteria showed excellent diagnostic accuracy and could be applied regardless of whether entrainment was achieved or whether the SVT terminated during pacing. Perturbation of atrial timing for 15 milliseconds or longer or a fixed S-A interval measured from last beat of the transition zone was seen in all the patients with orthodromic AVRT and in none of the patients with AVNRT or AT.³⁹

ATRIAL AND VENTRICULAR ELECTROGRAM SEQUENCE FOLLOWING CESSATION OF VENTRICULAR PACING. Following ventricular entrainment of typical AVNRT, an “A-V” electrogram sequence is observed after the last paced QRS (see Fig. 17-18). In contrast, following overdrive ventricular pacing (1:1 VA conduction) during AT, retrograde conduction occurs through the AVN. In this setting, the last retrograde P wave resulting from ventricular pacing is unable to conduct back to the ventricle because the AVN is still refractory to anterograde conduction, and the result is an A-A-V response (as discussed in detail in Chap. 11). Importantly, this maneuver is not useful when 1:1 VA conduction during ventricular pacing is absent (see Fig. 11-14). Additionally, a pseudo-A-A-V response can occur during atypical AVNRT because retrograde conduction during ventricular pacing occurs through the slow pathway. This can result in a VA interval that is longer than the pacing CL; hence, the last ventricular paced impulse is followed first by the P wave conducted slowly from the previous paced QRS and then by the P wave resulting from the last paced QRS, thus mimicking an A-A-V response (see Fig. 17-19). Careful identification of the last atrial electrogram that resulted from VA conduction during ventricular pacing avoids this potential pitfall. The last atrial activation resulting from conduction of the last paced ventricular complex follows the preceding P wave with an A-A interval equal to the ventricular pacing CL. A pseudo-A-A-V response can also occur during typical AVNRT with long HV intervals or short HA intervals, or both, in which atrial activation precedes ventricular activation. In the latter setting, using HB activation instead of ventricular activation (i.e., characterizing the response as A-A-H or A-H instead of A-A-V or A-V, respectively) can be more accurate and can help eliminate the pseudo-A-A-V response.⁴⁰

Diagnostic Maneuvers during Normal Sinus Rhythm after Tachycardia Termination

ATRIAL PACING AT THE TACHYCARDIA CYCLE LENGTH

Atrial pacing at the tachycardia CL can result in an AH interval during atrial pacing that is longer than the AH interval during AVNRT. The AH interval during AVNRT can appear artificially shortened because both the atrium and the HB are activated in parallel with simultaneous conduction up an upper common pathway (if present) and down the anterograde AVN pathway (the slow pathway in typical AVNRT and the fast pathway in atypical AVNRT). In contrast, during AT and orthodromic AVRT, the atrium and HB are activated in sequence, and, consequently, the AH interval during SVT approximates that during atrial pacing.

Under comparable autonomic tone status, 1:1 AV conduction over the AVN may or may not be maintained during atrial pacing

at the tachycardia CL. AV block can occur during atrial pacing but not during AVNRT because of anterograde block in an upper common pathway. Retrograde conduction properties of the upper common pathway may allow 1:1 conduction from the AVNRT circuit up to the atrium, but the anterograde conduction properties may not allow 1:1 anterograde conduction from the atrium down to the ventricle during atrial pacing at a similar CL. In contrast, 1:1 AV conduction, under comparable autonomic tone status, is typically maintained during atrial pacing at the tachycardia CL in the case of AT and orthodromic AVRT.²⁸ Typically, atrial pacing at the tachycardia CL yields an AH shorter than that during AVNRT as a result of preferential conduction over the fast pathway. To compare slow pathway conduction intervals between AVNRT and atrial pacing more directly, one may have to initiate pacing at a CL less than the tachycardia CL to block in the fast pathway, engage the slow pathway, and then increase the pacing CL to the tachycardia CL.

VENTRICULAR PACING AT THE TACHYCARDIA CYCLE LENGTH

Ventricular pacing at the tachycardia CL results in HA and VA intervals that are longer during pacing than those during AVNRT when assessed with standard 5-mm spacing quadripolar catheters in the His position. With more closely spaced His recording electrodes, the HA interval during pacing (HA_{pacing}) may be less than that during tachycardia (HA_{SVT}), a finding implying that part of the proximal HB is part of the AVNRT circuit. Whether or not the HA interval during pacing is longer than that during tachycardia thus depends in large part on how proximal an HB recording is made. The ΔHA interval ($HA_{\text{pacing}} - HA_{\text{SVT}}$) is typically more than -10 milliseconds, because the HA interval during AVNRT is shortened by parallel activation of both the HB and the atrium during the tachycardia, whereas the HB and atrium are activated sequentially during ventricular pacing (Fig. 17-20). The ΔHA interval is even more pronounced in atypical AVNRT, which has a lower common pathway that is longer than that in typical AVNRT. In focal junctional tachycardia, the ΔHA interval is typically close to 0 (see Fig. 17-20).²⁸

When pacing the atrium or ventricle at the tachycardia CL, it is important that the autonomic tone be similar to its state during the tachycardia because alterations of autonomic tone can independently influence AV or VA conduction. Under comparable autonomic tone, 1:1 VA conduction over the AVN may or may not be maintained during ventricular pacing at the tachycardia CL because of possible retrograde block in the lower common pathway. Anterograde conduction properties of the lower common pathway may allow 1:1 conduction from the AVNRT circuit down to the ventricle, but its retrograde conduction properties may not allow 1:1 retrograde conduction from the ventricle up to the atrium during ventricular pacing at a CL similar to the tachycardia CL. When VA block is present, orthodromic AVRT is excluded, and AT or AVNRT with lower common pathway physiology is more likely.

The atrial activation sequence during ventricular pacing is similar to that during AVNRT. A different atrial activation sequence suggests the presence of a retrogradely conducting BT, which may or may not be related to the SVT.

PARA-HISIAN PACING

Para-Hisian pacing helps exclude the presence of a septal AV BT, which can mediate an orthodromic AVRT with a retrograde atrial activation sequence similar to that during AVNRT. In the absence of a BT, para-Hisian pacing results in a shorter S-A interval when the HB-RB is captured ($S-H = 0$ and $S-A = HA$) than the S-A interval when only the ventricle is captured ($S-A = S-H+HA$) with no change in the atrial activation sequence or HA interval. This response to para-Hisian pacing is termed *pattern 1* or *AVN/AVN pattern*.²⁸

A change in the retrograde atrial activation sequence with loss of HB-RB capture indicates the presence of a retrogradely conducting BT. Similarly, an S-A (VA) interval that is constant

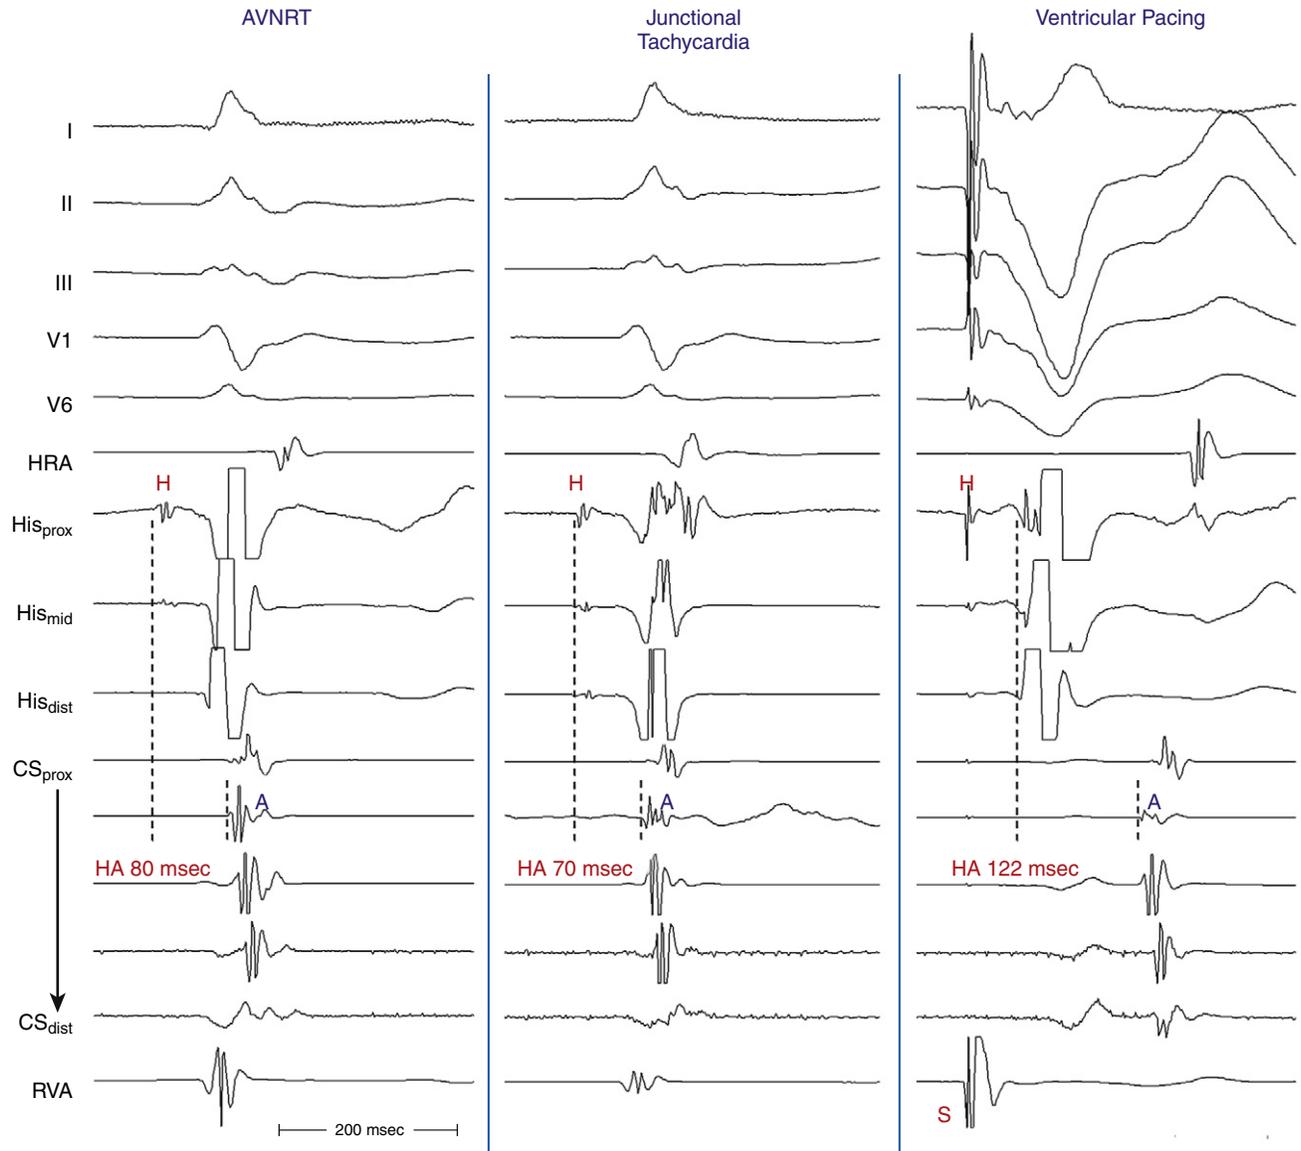

FIGURE 17-20 HA intervals during atrioventricular nodal reentrant tachycardia (AVNRT) (**left**), junctional tachycardia during radiofrequency application (**center**), and ventricular pacing at tachycardia cycle length in the same patient (**right**), measured from His potential onset to onset of atrial activation (near-proximal coronary sinus) as indicated by dashed lines. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{mid} = middle His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; RVA = right ventricular apex.

regardless of whether the HB RB is being captured indicates the presence of a BT, whereas prolongation of the S-A (VA) interval on loss of HB capture, compared with that during HB capture, excludes the presence of a retrogradely conducting BT, except for slowly conducting and far free-wall BTs. Please refer to [Chapter 18](#) for a more detailed discussion of para-Hisian pacing.²⁸

DIFFERENTIAL RIGHT VENTRICULAR PACING

The response to differential RV pacing can be evaluated by comparing two variables between RV basal and RV apical pacing: the VA interval and atrial activation sequence. In the absence of a septal AV BT, pacing at the RV apex results in rapid access of the paced wavefront to the RB, HB, and AVN, and in a shorter VA interval compared with pacing at the RV base. In the presence of a retrogradely conducting septal AV BT, pacing at the RV base allows the wavefront to access the BT rapidly and activate the atrium with a shorter VA interval than during RV apical pacing, which is farther from the BT ventricular insertion site.²⁸

Occurrence of RB block (RBBB) (but not LB block [LBBB]) can alter the significance of the VA interval criterion, especially when VA conduction propagates over the HPS-AVN. In the presence of retrograde RBBB, VA conduction occurs over the LB-HB. Therefore, the VA interval depends on the distance between the pacing site and the LB rather than the RB, and access of the paced wavefront to the LB can be faster for RV basal or septal pacing compared with pacing from the RV apex ([Fig. 17-21](#)).

The atrial activation sequence is similar during RV apical and RV basal pacing in the absence of a retrogradely conducting AV BT because the atrium is activated over the AVN in both cases. In contrast, in the presence of a septal AV BT, the atrial activation sequence may or may not be similar during pacing from the RV apex versus RV base. Atrial activation may propagate only over the AV BT in both situations, or it may propagate over the AV BT during RV basal pacing and over the AVN (or a fusion of conduction over both the AVN and AV BT) during RV apical pacing. Please refer to [Chapter 18](#) for a more detailed discussion on differential RV pacing.

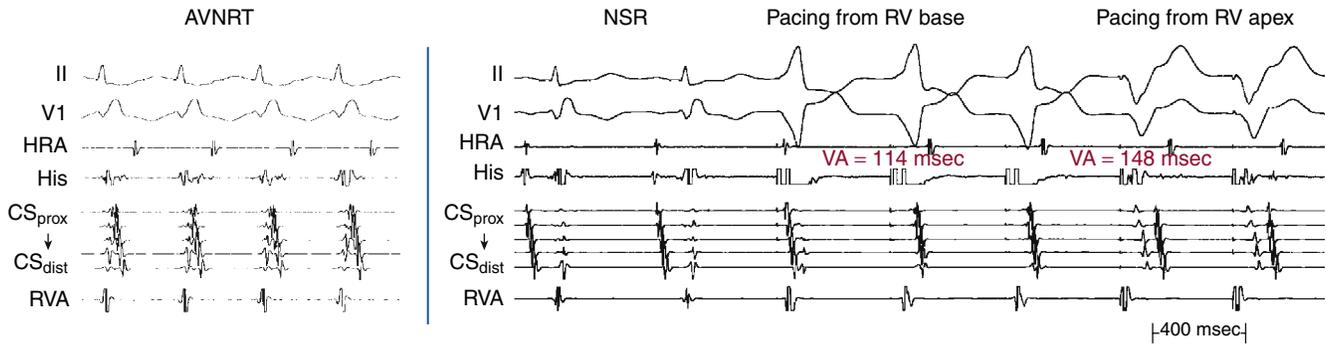

FIGURE 17-21 Comparison between right ventricular (RV) basal versus apical pacing during normal sinus rhythm (NSR, right panel) in a patient with typical atrioventricular nodal reentrant tachycardia (AVNRT) and right bundle branch block (RBBB, left panel) but no bypass tracts (BTs). RBBB is also observed during NSR (beginning of right panel). In the absence of a retrogradely conducting BT, pacing from the RV apex is expected to result in a shorter ventriculoatrial (VA) interval than pacing from the RV base. However, in this case, the presence of RBBB produces misleading results because retrograde VA conduction occurs over the left bundle branch (LB)–His bundle, and the VA interval depends on the distance between the pacing site to the LB, as opposed to the right bundle branch. CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

Exclusion of Other Arrhythmia Mechanisms

ATs arising from the anteroseptal region and orthodromic AVRT using superoparaseptal BTs can mimic typical AVNRT. Additionally, ATs arising from the posteroseptal region and orthodromic AVRT using posteroseptal BTs can mimic atypical AVNRT. The various EP testing maneuvers used to exclude these tachycardias are outlined in Tables 17-6 and 17-7.

VA block during SVT is a rare phenomenon. As noted, VA block can rarely occur during AVNRT because of block in an upper common pathway (see Fig. 17-13). Other potential mechanisms of SVT with VA block include automatic junctional tachycardia with retrograde VA block and orthodromic AVRT using a nodofascicular or nodoventricular BT for retrograde conduction.⁴¹ Intra-Hisian reentry is another potential mechanism, but it is a theoretical entity whose clinical occurrence has not convincingly been demonstrated. All these tachycardias are associated with a concentric atrial activation sequence, mimicking AVNRT. Nonetheless, several criteria can distinguish AVNRT from the other SVT mechanisms. Automatic junctional tachycardia typically cannot be induced or terminated by programmed stimulation; initiation of the tachycardia is usually spontaneous with absence of a critical AH delay and often requires catecholamines. Additionally, automatic junctional tachycardia is characterized by a gradual increase in tachycardia rate (warm-up) following initiation, marked CL variation, and slow decrease in tachycardia rate (cool-down), rather than an abrupt termination. The presence of nodofascicular (nodoventricular) tachycardia should be suspected when intermittent anterograde preexcitation is recorded, when AES fails to capture the tachycardia circuit, and when the SVT can be initiated with a single AES producing two ventricular complexes (mimicking the 1:2 response observed in patients with dual AVN physiology) or by a VES without a retrograde His deflection. Orthodromic AVRT can be diagnosed by demonstrating changes in the tachycardia CL with the development of BBB, and resetting or termination of the SVT by a late-coupled VES delivered when the HB is refractory.^{15,42}

Ablation

Target of Ablation

Ablation of the slow pathway is indicated in patients with documented AVNRT during EP testing, but it also can be performed in patients with documented SVT that is morphologically consistent with AVNRT on preprocedure ECG or rhythm strip but in whom only dual AVN physiology (but not tachycardia) is demonstrated during an EP study. Slow pathway ablation may also be considered at the discretion of the physician when sustained (more than

Oscillations in SVT CL	<ul style="list-style-type: none"> Changes in atrial CL that are predicted by the change in the preceding ventricular CL argue against AT. Spontaneous changes in tachycardia CL accompanied by constant VA interval (VA linking) exclude AT.
VES delivered during SVT	<ul style="list-style-type: none"> VES that terminates the SVT without atrial activation excludes AT. VES that delays the next atrial activation excludes AT.
Overdrive ventricular pacing during SVT	<ul style="list-style-type: none"> The presence of A-V electrogram sequence following cessation of pacing is consistent with AVNRT and generally excludes AT.
Overdrive atrial pacing during SVT	<ul style="list-style-type: none"> An ΔAH interval ($AH_{\text{pacing}} - AH_{\text{SVT}}$) >40 msec excludes AT. If the VA interval following the last entrained QRS is reproducibly constant (with <10 msec variation), despite pacing at different CLs or for different durations (VA linking) and similar to that during SVT CL, AT is unlikely. If the VA interval following the last entrained QRS is reproducibly constant (with <14-msec variation), despite pacing at different atrial sites (VA linking), AT is unlikely.
Atrial pacing during NSR at tachycardia CL	<ul style="list-style-type: none"> An ΔAH interval ($AH_{\text{pacing}} - AH_{\text{SVT}}$) >40 msec excludes AT. AV block during atrial pacing argues against AT.
SVT termination	<ul style="list-style-type: none"> Reproducible termination of the SVT (spontaneous or with adenosine) with a P wave not followed by a QRS excludes AT.

AH = atrial–His bundle; AT = atrial tachycardia; AV = atrioventricular; A-V = atrium–ventricle; AVNRT = atrioventricular nodal reentrant tachycardia; CL = cycle length; NSR = normal sinus rhythm; SVT = supraventricular tachycardia; VA = ventriculoatrial; VES = ventricular extrastimulus.

30 seconds) AVNRT is induced incidentally during an ablation procedure directed at a different clinical tachycardia.

Historically, the initial approach of RF ablation of AVNRT was modification of AVN conduction by lesions created near the anterosuperior aspect of the triangle of Koch (fast pathway ablation or the “anterior approach”). However, because the fast pathway constitutes the physiological conduction axis and is located in close proximity to the compact AVN and HB, this procedure was associated with an unacceptable risk of AV block or unphysiologically long PR intervals and was consequently abandoned. Since the early 1990s, selective ablation of the slow AVN pathway by lesions created near the posteroinferior base

of the triangle of Koch between the CS os and tricuspid annulus (the “posterior approach”) has proved to be a more successful and safer procedure. Additionally, in patients with multiple slow pathways, ablation of the fast pathway can be associated with persistently inducible AVNRT with anterograde conduction

over a second slowly conducting pathway. In contrast, successful ablation of the slow pathway can eliminate all variants of AVNRT.^{43,44}

The target for the posterior approach is the site of the slow pathway. This target can be defined by one of two approaches: a purely anatomical approach and an electroanatomical approach. Despite the lack of precise knowledge of the pathophysiological substrate for AVNRT, ablation procedures have fortunately been successful.

ANATOMICAL APPROACH

The target of ablation is the isthmus of tissue between the tricuspid annulus and the CS os (Fig. 17-22).²⁸ The sequence of ablation sites chosen for RF delivery is related to the probability of successful slow pathway ablation at each site and the risk of impairing AV conduction. The most common site for effective and safe ablation is along the tricuspid annulus immediately anterior to the CS os; this site has a success rate of 95%. Occasionally, successful ablation can require the catheter positioned along the tricuspid annulus inferior to the CS os. If ablation is not successful at these locations, the catheter is then moved more cephalad along the tricuspid annulus superior to the CS os. Finally, if those sites are unsuccessful, RF delivery at more superior sites (more than halfway between the CS os and HB) can be considered only if the risk of complete AV block can be justified by the severity of clinical symptoms.²⁸

If slow pathway ablation cannot be achieved in the inferoseptal RA, it may be worthwhile to deliver RF energy at sites within the proximal CS, close to the os, with the ablation catheter pointing toward the LV with counterclockwise torque. Rarely, successful slow pathway ablation may require an application of energy on the left side of the posterior septum, along the mitral annulus.^{28,43}

Catheter-induced AVN block occasionally occurs during mapping (approximately 2%). This may indicate the presence of a relatively small compact AVN that may be more susceptible to heart block during ablation. Catheter-induced AV block typically resolves after seconds to minutes. Careful catheter positioning to avoid sites at which catheter-induced block occurs generally results in successful ablation without AV block.

ELECTROANATOMICAL APPROACH (SLOW PATHWAY POTENTIALS)

The electroanatomical approach is guided by the identification of slow pathway potentials in conjunction with anatomical landmarks. These potentials have been used by some to define the site of the slow pathway within the triangle of Koch, and they can be used effectively as a guide to target ablation.²⁸

It has been suggested that activation of the slow pathway is associated with inscription of discrete electrical potentials, often referred to as slow pathway potentials. The origin of these potentials is uncertain. Whether they represent nodal tissue activation, anisotropic conduction through muscle bundles in various sites in the triangle of Koch, or a combination of both is unclear. The electrogram morphology of the slow potentials has been variously described as sharp and rapid (representing the atrial connection to the slow pathway; see Fig. 17-22), or slow and broad with low amplitude (representing slow potentials; see Fig. 17-22). The timing of slow potentials during NSR was reported to follow closely (within 10 to 40 milliseconds) local atrial activation near the CS os or to span the AH interval (it can occur as late as the His potential). However, such potentials are specific neither to the triangle of Koch nor to patients with AVNRT and can be recorded near the tricuspid annulus at sites distant from the slow pathway. Despite these observations, the probability of recording putative slow potentials at the site of effective slow ablation is more than 90%.²⁸ For ablation of slow-slow and fast-slow AVNRT, the slow pathway used for retrograde conduction during the tachycardia should be targeted by ablation, and this target can be different from the slow AVN pathway used for

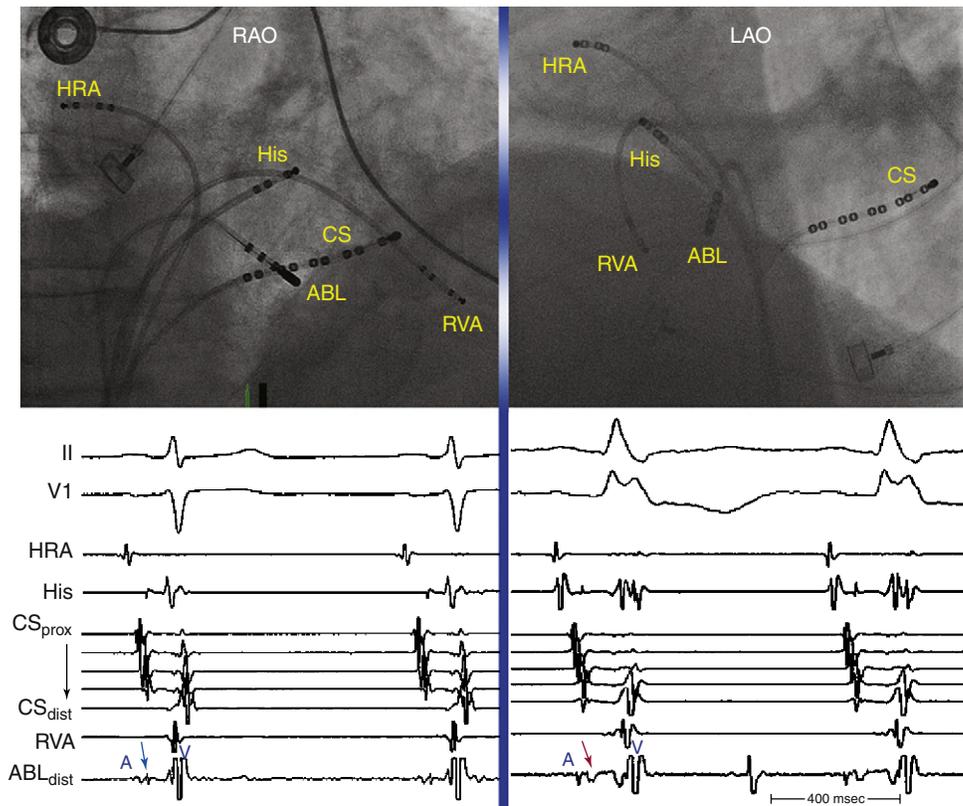

FIGURE 17-22 Ablation of the slow atrioventricular node (AVN) pathway. **Upper panel**, Right anterior oblique (RAO) and left anterior oblique (LAO) fluoroscopic views of a typical catheter setup during atrioventricular nodal reentrant tachycardia (AVNRT) ablation. The ablation catheter (ABL) is positioned at the slow pathway location in the lower portion of the triangle of Koch, away from the His bundle (His) and anterior to the coronary sinus (CS) (those landmarks are defined by the His bundle and CS catheters, respectively). **Lower panel**, Intracardiac recordings during ablation of the slow pathway. Note the sharp (blue arrow, left lower panel) and broad (red arrow, right lower panel) potentials recorded between the atrial and ventricular electrograms at the ablation sites. Those potentials were suggested to reflect activation of the slow pathway (slow pathway potentials). ABL_{dist} = distal ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

anterograde conduction. Therefore, ablation can be guided by the site of earliest retrograde atrial activation during AVNRT or ventricular pacing, which is usually localized to the isthmus of tissue between the tricuspid annulus and the CS os in fast-slow AVNRT and along the anterior aspect of the CS in slow-slow AVNRT (Fig. 17-23).^{44,45}

Ablation Technique

For slow pathway ablation, a quadripolar, 4-mm-tip, deflectable ablation catheter is advanced through a femoral vein. Rarely, a superior vena caval approach (through the internal jugular or subclavian vein) is required because of inferior vena caval obstruction or barriers, and one report demonstrated the feasibility of this approach.⁴⁶ The target site can be mapped using the anatomical or electroanatomical approach. Large-tip and irrigated-tip catheters have no role in catheter ablation of the slow pathway because the larger lesions they create can increase the risk of AV block.

ANATOMICAL APPROACH

As noted, the target of slow pathway ablation is the isthmus of tissue between the tricuspid annulus and the CS os.²⁸ Using the right anterior oblique fluoroscopy view, which best displays the triangle of Koch in profile, the ablation catheter is advanced into the RV, moved inferiorly so that it lies anterior to the CS os, and then withdrawn until the distal pair of electrodes records small atrial and large ventricular electrograms (with an A/V electrogram amplitude ratio during NSR of 0.1 to 0.5). Gentle clockwise torque is maintained to keep the catheter in contact with the low atrial septum. This positions the catheter along the tricuspid annulus immediately anterior to the CS os (see Fig. 17-22). Positioning is best performed during NSR, rather than AVNRT, because the atrial and ventricular electrograms at the tricuspid annulus are more easily discerned. The catheter often slips into the CS when one applies even a small amount of torque because the CS is large in many of these patients. If the catheter does not easily reach far enough into the ventricle, yielding an A/V ratio of only 1:1, or if catheter stability

is inadequate or falls into the CS repeatedly, a long sheath with a slight septal angulation can be helpful. Moreover, some ablation catheters have asymmetrical bidirectional deflection curves, an option that can prove to be of value for catheter reach and stability in some cases.⁴³

ELECTROANATOMICAL APPROACH

The target site is identified by slow pathway potentials (see Fig. 17-22).²⁸ Initially, the triangle of Koch is mapped from the apex (where the HB is recorded) and then moved toward the CS os. This approach also helps evaluate the extension of the zone recording a His potential. Slow pathway potentials are usually recorded at the midanteroseptal position, where they are located in the middle of the isoelectric line connecting the atrial and ventricular electrograms. Moving the mapping catheter inferiorly, the slow pathway potential moves toward the atrial electrogram, and when the optimal site for slow pathway ablation is reached, it merges with the atrial electrogram. Because electrograms with these characteristics can be recorded near the tricuspid annulus at sites distant from the slow pathway, the region explored with the ablation catheter should be limited to the posterior septum, near the CS os.²⁸ In the left anterior oblique fluoroscopy view, using the HB and CS os positions (as defined by the HB and CS catheters) as landmarks, the most common area where the slow potentials are recorded is in the posterior third of the line connecting those two landmarks.⁴⁵

Validation of slow pathway potentials can be useful and can be achieved by demonstrating that they represent slow and decremental conduction properties. Typically, brief runs of incremental atrial pacing or AES produce a decline in the amplitude and slope, an increase in the duration, and a separation of the slow potential from the preceding atrial electrogram until disappearance of any consistent activity. This is especially helpful in the presence of a sharp slow pathway potential, to distinguish it from a proximal HB recording (Fig. 17-24). Catheter-induced junctional ectopy, when present, indicates that the catheter tip is at a good ablation site. In patients with slow-slow and slow-fast AVNRT, mapping during

FIGURE 17-23 Ablation site in atypical (fast-slow) atrioventricular nodal reentrant tachycardia; a small spike (arrow) precedes the earliest atrial electrogram. ABL_{dist} = distal ablation site; ABL_{prox} = proximal ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; RVA = right ventricular apex.

AVNRT often shows a discrete potential 20 to 40 milliseconds prior to the earliest atrial electrogram; this may indicate the slow pathway and signify a good target site.⁴⁵

RADIOFREQUENCY ENERGY DELIVERY

Catheter stability should be optimized before starting RF energy application, to avoid inadvertent AV block. This may require cessation of isoproterenol infusion if hyperdynamic contractility is present. Additionally, good positioning of the other EP catheters defining the anatomical landmarks demarcating the triangle of Koch and the location of HB is mandatory.

Ablation should be performed during NSR, when it is easier to maintain a stable catheter position. When ablation is carried out during AVNRT, sudden termination of the tachycardia during RF delivery can result in any combination of dislodgment of the ablation catheter, inadvertent AV block, or an incomplete RF lesion.²⁸

Typical RF settings consist of a maximum power of 50 W and a maximum temperature of 55° to 60°C, continued for 30 to 60 seconds, or until the junctional rhythm extinguishes (see later).²⁸ Impedance and ECG should be carefully monitored throughout RF application. However, in the case of slow pathway ablation, the decrement in impedance associated with successful

energy applications is usually small (approximately 2.5 Ω); such a small change precludes the clinical usefulness of impedance monitoring.

JUNCTIONAL RHYTHM

An accelerated junctional rhythm typically develops within a few seconds of RF delivery at the effective ablation site (Fig. 17-25). The mechanism of this rhythm is unclear but is likely to be secondary to enhanced automaticity in AVN tissue because of thermal injury. Accelerated junctional rhythm during RF ablation is usually associated with subtle changes in retrograde atrial activation sequence (compared with that during AVNRT). Occurrence of this rhythm is strongly correlated with and sensitive to successful ablation sites; it occurs more frequently (94% versus 64%) and for a longer duration (7.1 versus 5.0 seconds) during successful compared with unsuccessful RF applications. Such a rhythm is, however, not specific for slow pathway ablation and is routinely observed during intentional fast pathway and AVN ablation. More rapid junctional tachycardia, on the other hand, is probably caused by thermal injury of the HB and heralds impending AV block (Fig. 17-26).^{44,47,48}

When an accelerated junctional rhythm occurs, careful monitoring of VA conduction during this rhythm is essential, and

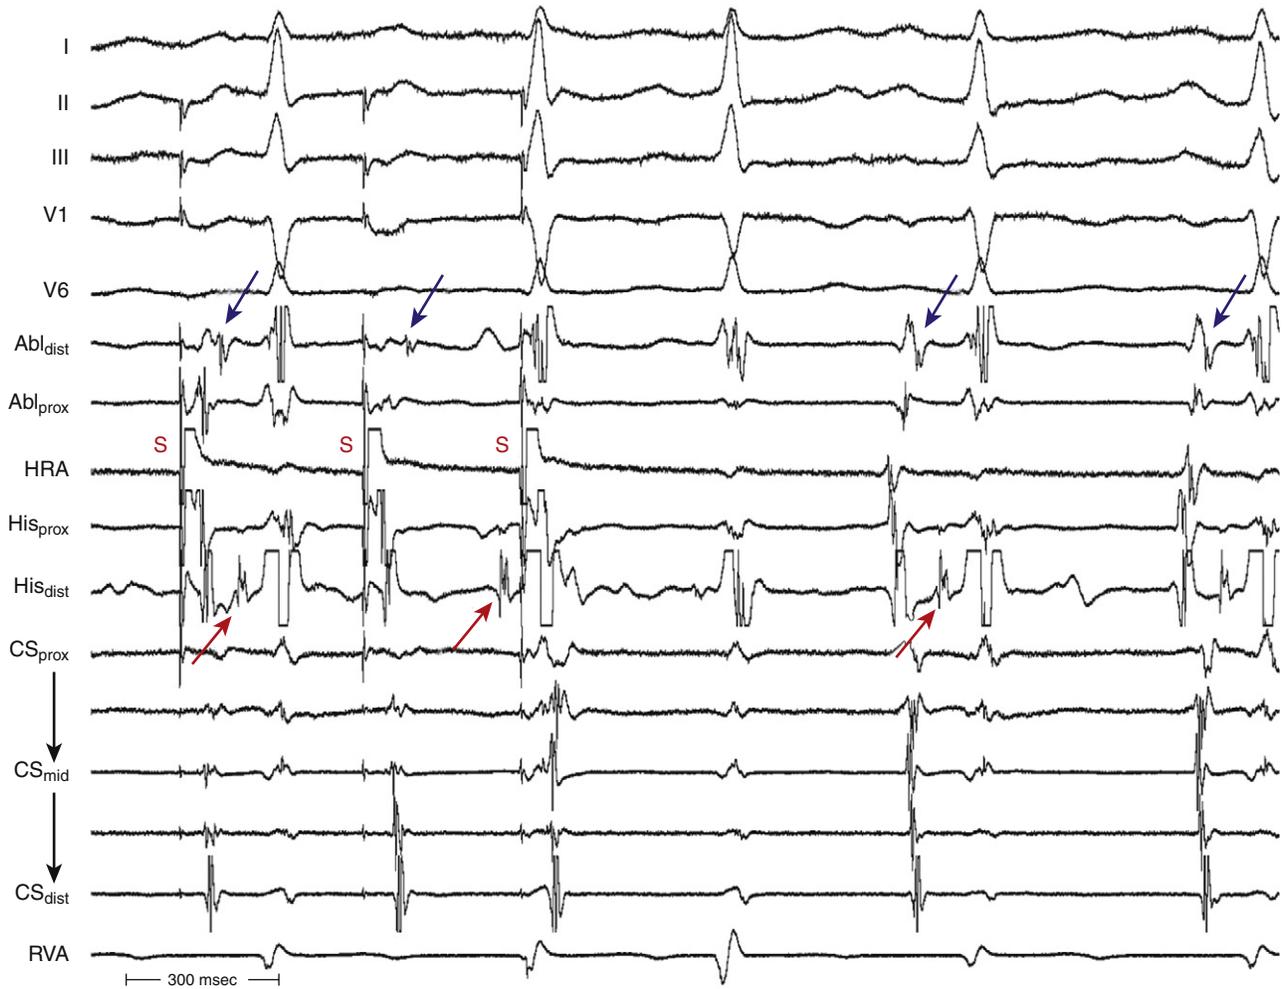

FIGURE 17-24 A putative slow pathway potential (blue arrows) is validated as being distinct from the His bundle potential (red arrows) by a burst of atrial stimulation. ABL_{dist} = distal ablation site; ABL_{prox} = proximal ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{prox} = proximal His bundle; HRA = high right atrium; RVA = right ventricular apex; S = stimulus.

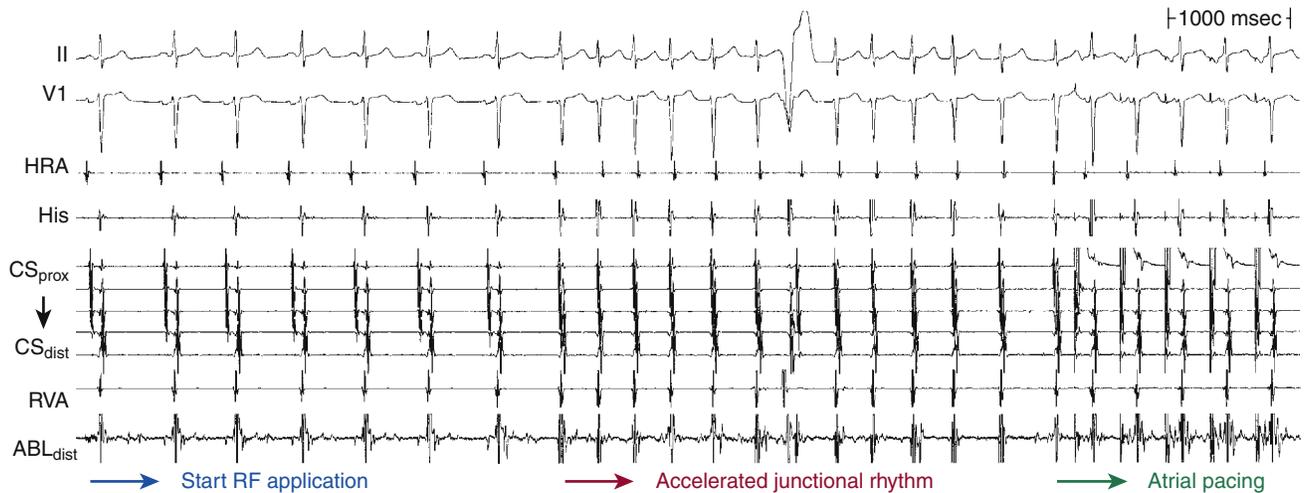

FIGURE 17-25 Catheter ablation of the slow atrioventricular nodal pathway. Radiofrequency (RF) energy delivery during normal sinus rhythm results in accelerated junctional rhythm with intact ventriculoatrial conduction. Overdrive atrial pacing at a rate faster than the junctional rhythm rate was started and confirmed intact atrioventricular conduction. This observation can indicate a good ablation site, with no injury to the fast pathway. ABL_{dist} = distal ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; HRA = high right atrium; RVA = right ventricular apex.

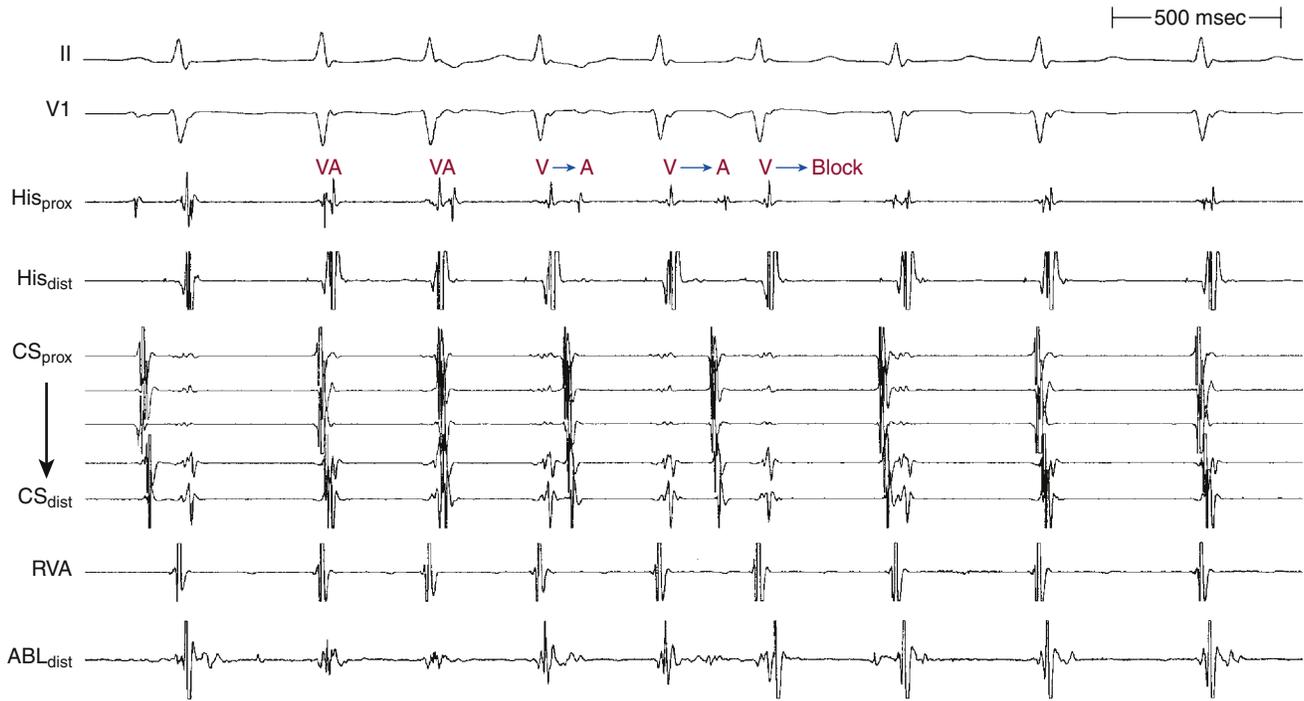

FIGURE 17-26 Junctional tachycardia observed during slow pathway ablation. Wenckebach ventriculoatrial (VA) block is observed during the junctional rhythm, a sign that heralds injury to the His bundle and should prompt immediate termination of radiofrequency application. ABL_{dist} = distal ablation site; CS_{dist} = distal coronary sinus; CS_{prox} = proximal coronary sinus; His_{dist} = distal His bundle; His_{prox} = proximal His bundle; RVA = right ventricular apex.

override atrial pacing may be performed to ensure maintenance of 1:1 anterograde AV conduction (see Fig. 17-25). Occasionally, atrial pacing at a rate sufficiently fast to override the junctional rhythm results in AV Wenckebach block at baseline, even before the onset of RF energy delivery. In this case, isoproterenol can be used to shorten the AV block CL and maintain 1:1 AV conduction during pacing.⁴⁸

The absence of junctional rhythm during RF application corresponds to an unsuccessful ablation site. When an accelerated junctional rhythm does not develop within 10 to 20 seconds of RF delivery, RF application should be stopped, and the catheter tip should be repositioned to a slightly different site or until better contact is verified, and a new RF application is attempted. Nevertheless, a junctional rhythm may not occur in several situations, including atypical forms of AVNRT (fast-slow and slow-slow) and some cases of typical (slow-fast) AVNRT undergoing repeat ablation.

After an RF application that results in an accelerated junctional rhythm, programmed electrical stimulation (atrial and ventricular stimulation) is performed to determine the presence or absence of slow pathway conduction, AVN echoes, or inducible AVNRT. If the result is unsatisfactory, the catheter is moved to a slightly different site (usually a few millimeters anteriorly), and RF is reapplied.^{44,48}

Several observations should prompt immediate discontinuation of RF application, including sudden impedance rise (more than 10 Ω), prolongation of the PR interval (during NSR or atrial pacing), development of AV block, fast junctional tachycardia (CL shorter than 350 milliseconds), and retrograde conduction block during junctional ectopy (see Fig. 17-26). Although the last observation may herald anterograde AV block in the case of typical AVNRT and necessitates immediate discontinuation of RF delivery, retrograde block over the fast pathway is a common occurrence in patients with atypical AVNRT, even before ablation. In this setting, the occurrence of junctional rhythm with no VA conduction may not be such an ominous sign; in fact, such an occurrence may indicate successful ablation of the slow pathway and thus should prompt ongoing RF delivery.²⁸ As noted earlier, atrial pacing at a rate sufficient to override junctional rhythm allows monitoring of anterograde fast pathway conduction and helps ensure safe RF application.

Endpoints of Ablation

The optimal endpoint for slow pathway ablation is the complete elimination of slow pathway conduction and dual AVN physiology without impairing the fast pathway. This is evidenced by loss of conduction over the slow pathway (i.e., disappearance of discontinuous AV conduction curves), alteration of Wenckebach CL (shorter or longer), an increase in the ERP of the AVN, and preservation of intact anterograde and retrograde AVN (fast pathway) conduction.⁴⁹ In many cases, the ERP of the fast pathway can actually shorten, likely secondary to the withdrawal of electrotonic inhibition imposed on the fast pathway by the slow pathway. For atypical AVNRT, elimination of retrograde fast pathway conduction (i.e., complete VA block) is an important additional endpoint.^{43,44}

However, elimination of all evidence of slow pathway conduction is not a necessary requirement for a successful slow pathway ablation procedure.²⁸ It suffices to eliminate inducibility of AVNRT and 1:1 anterograde conduction over the slow pathway, with and without isoproterenol infusion. Complete elimination of all anterograde slow conduction is not essential for clinical success and is actually associated with a slightly higher risk of AV block. In patients with a successful slow pathway ablation procedure, 40% to 50% will still have dual AVN physiology, and 75% of those patients will have single AVN echoes, but AVNRT is not inducible (these patients are said to have undergone slow pathway modification). In most patients who no longer have inducible AVNRT after ablation in the slow pathway region, residual discontinuous AVN function curves and single AVN echoes do not predict an increased risk of AVNRT recurrence.

Therefore, noninducibility of AVNRT (with and without isoproterenol infusion), with residual evidence of dual AVN pathways (AH interval jump) and single AVN echoes with an echo zone shorter than 30 milliseconds, is an acceptable endpoint. However, double AVN echoes or single echoes produced over a wide range of coupling intervals usually predict inducibility of AVNRT with the addition of isoproterenol or atropine, as well as late clinical recurrence of SVT. Therefore, additional RF applications are recommended.⁴³ When AVNRT or dual AVN physiology, or both, is rarely inducible at baseline, it may not be possible to confirm the efficacy of RF ablation. In this case, other parameters can be indicative of a successful

ablation, including the disappearance of a PR/RR ratio greater than 1 during rapid atrial pacing with 1:1 AV conduction, prolongation of the Wenckebach CL, and a decrease in fast pathway ERP.^{8,28,43} If isoproterenol was required for initiation of SVT prior to ablation, isoproterenol should be discontinued during ablation and readministered afterward to assess the efficacy of ablation adequately. If isoproterenol was not necessary for SVT initiation prior to ablation, it need not be used for postablation testing. However, if the presence of single AVN echoes is accepted as an endpoint, isoproterenol infusion is then required during postablation testing to verify noninducibility of double echoes or AVNRT.^{43,44}

Reassessment of tachycardia inducibility is typically repeated 30 minutes after the last successful RF application. However, there are no data supporting the hypothesis that such a waiting period leads to reduced recurrence rates following acutely successful ablation. In fact, one report demonstrated that a procedure-prolonging waiting period may be omitted without compromising the patient's long-term outcome results.⁵⁰

Outcome

Acute success rates of AVNRT ablation using the posterior approach are approximately 97% to 99%, and they are similar whether the ablation is guided anatomically or electroanatomically.⁴⁹ The recurrence rate after apparently successful ablation is approximately 2% to 5%. In 40% of patients with AVNRT recurrences, slow pathway conduction recovers after initial evidence of its abolition. Most AVNRT recurrences take place within the first days to months after ablation.^{44,49}

The most important complication of AVNRT ablation is AV block. AV block occurs in approximately 0.2% to 0.8% of patients who undergo slow pathway ablation using the posterior approach, it generally occurs during RF delivery or within the first 24 hours after ablation, and it is almost always preceded by junctional ectopy with VA block. The level of block is usually in the AVN. Predictors of AV block include proximity of the anatomical ablation site to the compact AVN, the occurrence of fast junctional tachycardia (CL shorter than 350 milliseconds) during RF application, the occurrence of junctional rhythm with VA block, the number of RF applications (related to the amount of tissue damage), and significant worsening of anterograde AV conduction during the ablation procedure.^{49,51}

Palpitations occur in 20% to 30% of patients following ablation of AVNRT. These are generally transient and usually are not caused by recurrent AVNRT. Most are caused by premature atrial or ventricular complexes, which subside spontaneously and require no treatment other than reassurance. Inappropriate sinus tachycardia can develop in some patients after AVNRT ablation, a finding suggesting disruption of the parasympathetic or sympathetic inputs into the sinus node and AVN.

Subclinical activation of the coagulation system (e.g., elevated plasma levels of the D-dimer) is common during RF ablation. Nevertheless, clinically detectable embolic events are uncommon (0.7%). Aspirin is usually recommended for 6 to 8 weeks following ablation, to minimize the risk of thrombus formation in the RA or vena cavae. Other complications include cardiac tamponade (in 0.2% of patients), hematoma (in 0.2%), and femoral artery pseudoaneurysm (in 0.1%).⁴⁴

There are several advantages of selective slow pathway ablation over fast pathway ablation, including a significantly lower risk of AV block and avoidance of a long postablation PR interval, which can cause symptoms similar to those of the pacemaker syndrome. Furthermore, in patients with multiple slow pathways, as demonstrated by AVN function curves, ablation of the fast pathway can be associated with persistently inducible AVNRT, with anterograde conduction over a second slowly conducting pathway.⁴⁴

Selective slow pathway ablation can be technically challenging in several clinical situations. For example, in patients with evidence of impaired fast pathway conduction (usually older patients with tachycardia CL longer than 400 milliseconds), ablation of the slow pathway can result in mandatory conduction through the impaired fast

pathway, and Wenckebach block during rest can develop. Whether the fast pathway should be targeted by ablation instead of the slow pathway in these patients is controversial. Similarly, some patients with AVNRT have a markedly prolonged PR interval during NSR, a finding suggesting the possibility of absent anterograde fast pathway conduction and a high risk of complete AV block if the slow pathway is ablated. However, in such patients, the fast pathway can be affected by an electrotonic interaction with the slow pathway, and elimination of this effect by slow pathway ablation often shortens the ERP of the fast pathway. In fact, in many of these patients, the AH interval remains stable or even shortens after slow pathway ablation. Another challenging situation may be experienced in patients with prior unsuccessful attempts at fast pathway ablation, with persistent AVNRT. Slow pathway ablation may then result in high-degree AV block because of impairment of the fast pathway related to the prior ablation attempt. In such patients, it may be wise to confine further ablation efforts to the pathway originally targeted for ablation.^{43,44}

It is also important to know that in some cases of typical AVNRT, the fast pathway can have a more posterior location, and the earliest atrial activation site during the tachycardia is near the CS os. In such cases, ablation should be performed with caution because RF application at the usual slow pathway anatomical site can result in PR interval prolongation or heart block. Cryoablation can be of advantage in these situations.

Fast Pathway Modification (Anterior Approach)

TARGET OF FAST PATHWAY ABLATION

The target site of this approach is located closer to the compact AVN and HB in the anterosuperior region of the triangle of Koch. The anterior approach selectively ablates or modifies fast pathway retrograde conduction; however, it can also cause damage to fast or slow pathway anterograde conduction.^{43,44} Fast pathway ablation is hardly ever the treatment of choice, with the rare exception of patients with clear AVNRT who have a long PR in sinus rhythm (i.e., slow pathway conduction) and no evidence of anterograde fast pathway conduction.

FAST PATHWAY ABLATION TECHNIQUE

The ablation catheter is initially positioned at the AV junction to obtain the maximal amplitude of the bipolar His potential recorded from the distal pair of electrodes. The catheter is then withdrawn while a firm clockwise torque is maintained until the His potential becomes small or barely visible or disappears while recording a relatively large atrial electrogram (with an A/V electrogram amplitude ratio greater than 1; see Fig. 15-63). At the optimal ablation site, retrograde atrial activation timing occurs earlier or simultaneously with the atrial electrogram in the catheter at the HB position. At this point, the ablation catheter is held steadily, and RF energy is applied (starting at low power outputs of 5 to 10 W) until one of the following events occurs: impedance rise, transient high-grade AV block, prolongation of the PR interval by more than 30% to 50%, or appearance of very rapid junctional rhythm associated with retrograde conduction block. Overdrive atrial pacing may be performed to monitor AV conduction in case a junctional escape rhythm occurs during RF application.^{43,44}

ENDPOINTS OF FAST PATHWAY ABLATION

The endpoint of ablation is noninducibility of AVNRT or development of AV block. Frequently, fast pathway ablation is associated with retrograde VA block over both the slow and fast pathways. Occasionally, dual AVN physiology can still be present.

OUTCOME OF FAST PATHWAY ABLATION

Short-term success rates are greater than 95%. However, the anterior approach has a small safety margin and is associated with a

higher risk of inadvertent complete AV block (approximately 10%, but ranging from 2% to 20%). Careful monitoring of AV conduction during RF application and prompt discontinuation of energy delivery on evidence of AV block are the keys to minimize the incidence of AV block.

Cryoablation of the Slow Pathway

TARGET OF CRYOABLATION

The target of ablation is the region of the slow pathway, and it is identified anatomically or electroanatomically, as described for standard RF ablation. The target site should be identified during NSR whether cryoablation is to be performed during NSR or AVNRT, because the A/V ratio and electrogram morphology usually are obscured during AVNRT.

CRYOABLATION TECHNIQUE

Cryomapping

Cryomapping (ice mapping) is designed to verify that ablation at the chosen site will have the desired effect (i.e., block in the slow pathway) and to reassure the absence of complications (i.e., AV block). Cryomapping is performed at a temperature of -30°C . At this temperature, the cryolesion is reversible (for up to 60 seconds), and the catheter is stuck to the atrial endocardium within an ice ball that includes the tip of the catheter (cryoadherence). Formation of an ice ball at the catheter tip and adherence to the underlying myocardium are signaled by the appearance of electrical noise recorded from the ablation catheter's distal bipole. In the cryomapping mode, the temperature is not allowed to drop to less than -30° , and the duration of energy application is limited to 60 seconds. Once an ice ball is formed, various pacing protocols are performed to test the modification or disappearance of slow pathway conduction.⁵²

Cryomapping is usually performed during NSR in patients with discontinuous anterograde dual AVN conduction curve. For patients without a clear discontinuity in the AVN conduction curve, cryomapping may be performed during AVNRT, which is feasible without the risk of catheter dislodgment on termination of the tachycardia (because of cryoadherence).⁵²

During cryoablation of the slow pathway, no junctional rhythm is observed. Thus, other parameters must be used to validate the potential effectiveness of the ablation site. In fact, the absence of junctional rhythm can be advantageous because it allows the maintenance of NSR during ablation and enables monitoring of the PR interval throughout the procedure. Additionally, the maintenance of NSR during cryoablation allows various pacing maneuvers to be performed during ongoing cryoenergy application, to evaluate the effect of the ablation on slow pathway conduction. Disappearance of the dual AVN physiology, noninducibility of AVNRT, and modification of the fast pathway ERP predict a successful ablation site. When cryoablation is performed during AVNRT, progressive AH interval lengthening followed by termination of AVNRT indicates slow pathway block.⁵²

Slow pathway block usually occurs quickly (within 10 to 20 seconds) at the optimal target site. If cryomapping does not yield the desired result within 20 to 30 seconds or causes unintended AV conduction delay or block, the cryomapping procedure is interrupted. After a few seconds, to allow the catheter to thaw and become dislodged from the tissue, the catheter is moved to a different site, and cryomapping is repeated.⁵²

Cryoablation

When sites of successful cryomapping are identified by demonstrating satisfactory slow pathway block or modification with no modification of the basal anterograde AV conduction, the cryoablation mode is activated, during which a target temperature lower than -75°C is sought (a temperature of approximately -75° to -80°C is generally achieved). The application is then continued

for 4 minutes, to create an irreversible lesion. If the catheter tip is in close contact with the endocardium, a prompt drop in catheter tip temperature should be seen as soon as the cryoablation mode is activated. A slow decline in temperature or a very high flow rate of refrigerant during ablation suggests poor catheter tip tissue contact; in such cases, cryoablation should be interrupted and the catheter repositioned.⁵²

The successful site for cryomapping and cryoablation of the slow pathway frequently is found in the midseptal region of the Koch triangle, more superiorly than the usual site of successful RF ablation. Rarely, AV block does not appear during cryomapping at a particular site but occurs during cryoablation at the same site. Fortunately, this resolves quickly if the cryoablation is interrupted promptly.

ENDPOINTS OF CRYOABLATION

The goal of cryoablation is the complete elimination of slow pathway function. This usually requires delivery of several cryoapplications at closely adjacent sites. If a discontinuity in the anterograde AVN conduction curve and single AVN echoes persist despite multiple cryoapplications, this is still a reasonable endpoint, provided that multiple echoes or SVT are not inducible, even during isoproterenol infusion. If acute procedural success cannot be achieved with a standard 4-mm-tip catheter, a 6-mm-tip catheter can be used, which can help yield larger and deeper cryolesions.⁵²

OUTCOME OF CRYOABLATION

Previously published reports with cryoablation of AVNRT in pediatric patients demonstrated procedural success rates of 83% to 97% and recurrence rates ranging from 0% to 20%. Although the use of bonus cryoapplications to consolidate the acutely successful cryoablation and the choice of larger-tip cryocatheters (8-mm and 6-mm versus 4-mm tips) to create larger lesions have been associated with fewer recurrences on long-term follow-up without compromising safety, the overall procedural success rate has remained consistently lower than that of RF ablation.^{51,53-56}

The safety of cryoablation is indisputable. Not a single case of persistent AV block has been reported, even when using large-tip cryocatheters, despite the fact that transient AV block occurs in up to 11% of patients during cryomapping at -30°C or during cryoablation at -75°C .

ADVANTAGES OF CRYOABLATION

One of the distinct advantages of cryothermal technology is the ability to demonstrate loss of function of tissue with cooling reversibly (ice mapping or cryomapping), thereby demonstrating the functionality of prospective ablation sites without inducing permanent injury. Furthermore, once the catheter tip temperature is reduced to less than 0°C , progressive ice formation at the catheter tip causes adherence to the adjacent tissue (cryoadherence), which maintains stable catheter contact at the site of ablation and minimizes the risk of catheter dislodgment during changing cardiac rhythm.⁵² A disadvantage of cryoablation is that the cryocatheter is not yet as steerable as the conventional RF catheter, and this can potentially limit proper positioning of the catheter tip.⁵² The procedure is also slightly longer than standard RF ablation.

Cryoablation can be of particular advantage in patients with AVNRT with posterior displacement of the fast pathway or AVN, and those with a small space in the triangle of Koch between the HB and the CS os, when ablation must be performed in the midseptum. However, given the high success rate and low risk of RF slow pathway ablation, it may be difficult to demonstrate a clinical advantage of cryoablation over RF ablation of unselected AVNRT cases. Therefore, the use of cryoablation may be recommended in specific circumstances in which the use of RF can be more likely to cause AVN damage. These circumstances include patients with unusual cardiac anatomy that makes safe RF delivery difficult, those with

evidence of impaired AV conduction at baseline, those who need ablation in the close vicinity of the compact AVN following unsuccessful RF ablation at more posterior sites, pediatric patients, and patients in whom even the small risk of AV block associated with RF ablation is considered unacceptable.⁵¹⁻⁵³

Types of Bypass Tracts

Bypass tracts (BTs) are remnants of the atrioventricular (AV) connections caused by incomplete embryological development of the AV annuli and failure of the fibrous separation between the atria and ventricles. There are several types of BTs. Atrioventricular BTs are strands of working myocardial cells connecting atrial and ventricular myocardium across the electrically insulating fibrofatty tissues of the AV junction bypassing the atrioventricular node–His-Purkinje system (AVN-HPS). In the older literature, these BTs were called Kent bundles, although incorrectly (Kent described AVN-like tissue in the right atrial [RA] free wall that did not connect to the ventricle). Thus, the use of the term *bundle of Kent* should be discouraged.¹ Atrionodal BTs connect the atrium to the distal or compact AVN. They have been called James fibers and are of uncertain physiological significance. Atrio-Hisian BTs connect the atrium to the His bundle (HB); these BTs are rare.^{2,3} Atypical BTs include various types of Hisian-fascicular BTs, which connect the atrium (atriofascicular pathways), AVN (nodofascicular pathways), or HB (fasciculoventricular) to distal Purkinje fibers or ventricular myocardium, in addition to slowly conducting short atrioventricular BTs and long atrioventricular BTs. These atypical BTs are sometimes collectively referred to as Mahaim fibers, a term to be discouraged because it is more illuminating to name the precise BT according to its connections.

Types of Preexcitation Syndromes

Several patterns of preexcitation can occur, depending on the anatomy of the BT and the direction in which impulses are conducted. Conduction from the atria to the ventricles normally occurs via the AVN-HPS. Patients with preexcitation have an additional or alternative pathway, the BT, which directly connects the atria and ventricles and bypasses the AVN. The term *syndrome* is used when the anatomical variant is responsible for tachycardia.

In the Wolff-Parkinson-White (WPW) syndrome, AV conduction occurs, partially or entirely, through an AV BT, which results in earlier activation (preexcitation) of the ventricles than if the impulse had traveled through the AVN.¹ In the setting of Lown-Ganong-Levine (LGL) syndrome, preexcitation purportedly occurs via atrio-Hisian

BTs or, alternatively, no BT is present and enhanced AVN conduction accounts for the electrocardiographic (ECG) findings. The net effect is a short PR interval without delta wave or QRS prolongation. It is important to stress, however, that LGL is not a recognized syndrome with an anatomical basis, but only an ECG description, and the use of the term should be discouraged.^{2,3} The so-called Mahaim variant of preexcitation does not typically result in a delta wave, because these pathways, which usually terminate in the conducting system or in the ventricular myocardium close to the conducting system, conduct slowly, and the AVN-HPS has adequate time to activate most of the ventricular muscle mass. Concealed AV BTs refer to AV BTs that do not manifest anterograde conduction and therefore do not result in ventricular preexcitation. Because they do not result in alteration of the QRS complex in the ECG, they cannot be detected by inspection of the surface ECG; they are called *concealed*. However, the concealed BT can conduct in a retrograde fashion, thereby creating a reentrant circuit with impulses traveling from the atrium to the AVN, HPS, ventricle, and then back to the atrium via the BT.

Pathophysiology

Wolff-Parkinson-White Syndrome

WPW pattern refers to the constellation of ECG abnormalities related to the presence of an AV BT (short PR interval, delta wave) in asymptomatic patients.¹ *WPW syndrome* refers to a WPW ECG pattern associated with tachyarrhythmias.

Because the AV BT typically conducts faster than the AVN, the onset of ventricular activation is earlier than if depolarization occurred only via the AVN, resulting in a shortened PR (P-delta) interval. Additionally, because the BT exhibits practically nondecremental conduction, the early activation (and P-delta interval) remains almost constant at all heart rates. Preexcited intraventricular conduction in WPW propagates from the insertion point of the AV BT in the ventricular myocardium via direct muscle-to-muscle conduction. This process is inherently slower than ventricular depolarization resulting from rapid HPS conduction. Thus, although the initial excitation of the ventricles (via the BT) occurs earlier, it is followed by slower activation of the ventricular myocardium than

occurs normally. The net effect is that the QRS complex consists of fusion between the early ventricular activation caused by preexcitation with the later ventricular activation resulting from impulse propagation through the AVN and HPS to the ventricles. The initial part of ventricular activation resulting in the upstroke of the QRS complex is slurred because of slow muscle-to-muscle conduction; this is termed a *delta wave*. The more rapid the conduction along the BT in relation to the AVN, the greater the amount of myocardium depolarized via the BT, resulting in a more prominent or wider delta wave and increasing prolongation of the QRS complex duration.

Atrioventricular Bypass Tracts

The AV junctions are the areas of the heart where the atrial musculature connects to the annuli of the mitral and tricuspid valves. The AVN-HPS, which lies in the septal component of the AV junction, is the only normal electrical connection between the atria and the ventricles. The fibrous skeleton and AV valvular annuli act as an insulator to prevent electrical impulses from getting into the ventricles by any other route. The main function of the AVN is modulation of atrial impulse transmission to the ventricles, thereby coordinating atrial and ventricular contractions; it receives, slows down, and conveys atrial impulses to the ventricles.

AV BTs are aberrant muscle bundles that connect the atria to the ventricles outside of the normal AV conduction system. AV BTs are found most often in the parietal AV junctional areas, including the paraseptal areas. They breach the insulation provided by the fibrofatty tissues of the AV groove (sulcus tissue) and the hinge lines (fibrous annulus) of the valves. They are rarely found in the area of fibrous continuity between the aortic and mitral valves because in this area, there is usually a wide gap between the atrial myocardium and ventricular myocardium to accommodate the aortic outflow tract.^{4,5} The remainder of the AV groove may be divided into quadrants consisting of the left free wall, right free wall, and posteroseptal and anteroseptal spaces. The distribution of BTs within these regions is not homogeneous—46% to 60% of BTs are found within the left free wall space; 25% are within the posteroseptal space; 13% to 21% of BTs are within the right free wall space; and 2% are within the right superoparaseptal (formerly called anteroseptal) space (Fig. 18-1).

BTs are usually very thin muscular strands (rarely thicker than 1 to 2 mm) but can occasionally exist as broad bands of tissue. The AV BT can run in an oblique course rather than perpendicular to the transverse plane of the AV groove. As a result, the fibers can have an atrial insertion point that is transversely from less than one to several centimeters removed from the point of ventricular attachment.⁶ Some posteroseptal pathways insert into coronary

sinus (CS) musculature rather than atrial myocardium and can be associated with the coronary venous system or diverticula from a CS branch vein.

Multiple AV BTs occur in 5% to 10% of patients. BTs are defined as multiple when they are separated by more than 1 to 3 cm. The most common combination of widely spaced multiple BTs is posteroseptal and right free wall BTs. The incidence of multiple BTs is particularly high in patients with antidromic atrioventricular reentrant tachycardia (AVRT) (50% to 75%), patients in whom AF resulted in ventricular fibrillation (VF), and patients with Ebstein anomaly.

Although the majority (approximately 60%) of AV BTs conduct both anterogradely and retrogradely (i.e., bidirectionally), some AV BTs are capable of propagating impulses in only one direction. BTs that conduct only in the anterograde direction are uncommon (<5%), often cross the right AV groove, and frequently possess decremental conduction properties.³ On the other hand, BTs that conduct only in the retrograde direction occur more frequently, accounting for 17% to 37% of all BTs. When the BT is capable of anterograde conduction, ventricular preexcitation is usually evident during normal sinus rhythm (NSR), and the BT is referred to as *manifest*. BTs capable of retrograde-only conduction are referred to as *concealed*.

Because working myocardial cells make up the vast majority of AV BTs, conduction over those BTs is mediated by the rapid inward sodium current, similar to normal His-Purkinje tissue and atrial and ventricular myocardium. Therefore, AV BTs have rather constant anterograde and retrograde conduction at all rates until the refractory period is reached, at which time conduction is completely blocked (nondecremental conduction). Thus, conduction over AV BTs usually behaves in an all-or-none fashion. In contrast, the AVN, which depends on the slow inward calcium current for generation and propagation of its action potential, exhibits what has been called *decremental conduction*, in which the conduction time of the impulse propagating through the AVN prolongs as the atrial cycle length (CL) shortens. Thus, AV conduction is more rapid through the AV BT than through the AVN, a difference that is increased at a fast heart rate. This difference has potentially great clinical importance. A primary function of the AVN is to limit the number of impulses conducted from the atria to the ventricles, which is particularly important during fast atrial rates (e.g., AF or atrial flutter [AFL]) when only a fraction of impulses are conducted to the ventricles, whereas the remainder are blocked in the AVN. However, in the presence of nondecrementally conducting AV BTs with short refractory periods, these arrhythmias can lead to very fast ventricular rates that can degenerate into VF.

Atrioventricular Reentry

AVRT is a macroreentrant tachycardia with an anatomically defined circuit that consists of two distinct pathways, the normal AV conduction system and an AV BT, linked by common proximal (atrial) and distal (ventricular) tissues. If sufficient differences in conduction time and refractoriness exist between the normal conduction system and the BT, a properly timed premature impulse of atrial or ventricular origin can initiate reentry. AVRTs are the most common (80%) tachycardias associated with the WPW syndrome. AVRT is divided into orthodromic and antidromic according to the direction of conduction in the AVN-HPS (Fig. 18-2). Orthodromic indicates normal direction (anterograde) of conduction over AVN-HPS during the AVRT.

ORTHODROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA

In orthodromic AVRT, the AVN-HPS serves as the anterograde limb of the reentrant circuit (i.e., the pathway that conducts the impulse from the atria to the ventricles), whereas an AV BT serves as the retrograde limb (see Fig. 18-2). Approximately 50% of BTs

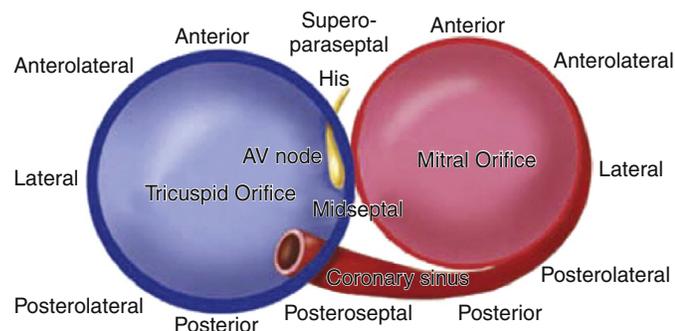

FIGURE 18-1 Locations of atrioventricular bypass tracts (AV BTs) by anatomical region. Tricuspid and mitral valve annuli are depicted in a left anterior oblique view. Locations of the coronary sinus, AV node, and His bundle are shown. AV BTs may connect atrial to ventricular myocardium in any of the regions shown. (From Miller JM, Zipes DP: *Therapy for cardiac arrhythmias*. In Libby P, Bonow R, Mann DL, Zipes DP, editors: *Braunwald's heart disease: a textbook of cardiovascular medicine*, ed 8, Philadelphia, 2007, WB Saunders, pp 779-830.)

ATRIAL FIBRILLATION

Paroxysmal AF occurs in 50% of patients with WPW, and is the presenting arrhythmia in 20%. Chronic AF, however, is rare in these patients.³ Spontaneous AF is most common in patients with anterograde conduction through the BT. Patients with antidromic AVRT, multiple BTs, and BTs that have a short anterograde effective refractory period (ERP) are more liable to develop AF.³ In individuals with WPW, AF is often preceded by AVRT that degenerates into AF.

The frequency with which intermittent AF occurs in patients with the WPW syndrome is striking because of the low prevalence of coexisting structural heart disease, which is a major predisposing factor for AF in subjects without a BT. This observation suggests that the AV BT itself can be related to the genesis of AF.

The mechanisms by which AVRT precipitates AF are not well understood. The rapid atrial rate can cause disruption in atrial activation and reactivation, creating an electrophysiological substrate conducive to AF. The observation that most patients with BT and AF who undergo BT ablation are cured of both AVRT and AF is compatible with this hypothesis. Another possibility is that the complex geometry of networks of BTs predisposes to AF by fractionation of the activation wavefronts. Localized reentry has been recorded in some patients, using direct recordings of the activation of the BTs. Hemodynamic changes, atrial stretch caused by atrial contraction against closed AV valves during ventricular systole, can also play a role. Ablation of the BT can cure AF in more than 90% of patients; however, vulnerability to AF persists in up to 56%, and the response to atrial extrastimulation (AES) is also unaltered by ablation.

ATRIAL FLUTTER

AFL is the most common (60%) regular preexcited tachycardia in patients with WPW syndrome. AFL is caused by a reentrant circuit within the RA and therefore exists independently of the BT, and AFL does not have the same causal association to AV BTs as AF. In some patients with WPW syndrome who develop AFL, AVRT is the initiating event. This relationship can be mediated by contraction-excitation feedback into the atria during the AVRT.

AFL, like AF, can conduct anterogradely via a BT causing a preexcited tachycardia. Depending on the various refractory periods of the normal and pathological AV conduction pathways, AFL potentially can conduct 1:1 to the ventricles during a preexcited tachycardia, making the arrhythmia difficult to distinguish from ventricular tachycardia (VT; see Fig. 12-6).

VENTRICULAR FIBRILLATION AND SUDDEN CARDIAC DEATH

The mechanism of sudden cardiac death (SCD) in most patients with WPW is likely the occurrence of AF with a very rapid ventricular rate that leads to VF. Although the frequency with which AF having rapid AV conduction via a BT degenerates into VF is unknown, the incidence of SCD in patients with WPW syndrome is rather low, ranging from 0% to 0.39% annually in several large case series. The trigger for AF in this population of patients (who usually are otherwise healthy individuals and are expected to have a low rate of AF) is generally an episode of SVT. In fact, most patients who have been resuscitated from VF secondary to preexcitation have previous history of AVRT, AF, or both (although in some patients, SCD may be the presenting symptom), and induction of SVT during EP testing is also predictive of clinical symptoms in some asymptomatic individuals.⁷⁻¹¹

Several factors can help identify the patient with WPW who is at increased risk for VF, including symptomatic SVT, septal location of the BT, presence of multiple BTs, and male gender.⁸ Nonetheless, it is clear that the most important factor for the occurrence of VF in these patients is the ability of the BT to conduct rapidly to the ventricles. This is best measured by determining the shortest and average preexcited intervals during AF or alternatively by measuring the anterograde ERP of the BT. If the BT has a very short

anterograde effective refractory period (ERP <250 milliseconds), a rapid ventricular response can occur with degeneration of the rhythm to VF. A short preexcited R-R interval during AF (≤ 220 milliseconds) appears to be a sensitive clinical marker for identifying patients at risk for SCD in children, although its positive predictive value in adults is only 19% to 38%.^{9,10,12}

Drug therapy can be an additional determinant of the risk of VF in patients with preexcitation. As an example, intravenous verapamil can increase the ventricular response to AF and has resulted in VF in some patients. Several mechanisms are probably involved; hypotension produced by verapamil-induced vasodilation is followed by a sympathetic discharge that enhances BT conduction. Furthermore, verapamil slows AVN conduction directly and increases AVN refractoriness, resulting in less concealed penetration of the BT by normally conducted beats. Additionally, the increased rate, irregular rate, hypotension, and sympathetic discharge probably result in fractionation of the ventricular wavefront and VF. For these reasons, intravenous verapamil is contraindicated for the acute treatment of AF in patients with WPW. Other intravenous drugs that block the AVN also should be avoided, including beta blockers, adenosine, diltiazem, and digoxin. Both oral and intravenous digoxin has been associated with the degeneration of AF into VF in patients with preexcitation syndromes. Some of these patients had a history of previously benign AF. How digitalis might promote the development of VF is uncertain. One possible mechanism is that shortening of the atrial and BT ERP, plus increasing AVN block, results in decreased concealed retrograde penetration of the BT by normally conducted beats, thereby preventing its inactivation.

Intravenous adenosine, given appropriately to treat orthodromic AVRT, can also precipitate AF episodes. This is unusual and should not be viewed as a contraindication to adenosine use, but one should be prepared for emergency cardioversion before administering adenosine to SVT patients. Lidocaine, for reasons that are unclear, has also been associated with degeneration of AF into VF. It is occasionally used in patients with WPW who have a wide QRS complex tachycardia that might be misinterpreted as VT.

VENTRICULAR TACHYCARDIA

Coexisting VT is uncommon because patients with WPW syndrome infrequently have structural heart disease. Naturally, older patients are subject to coronary artery and other diseases that can cause VT.

Clinical Considerations

Epidemiology of Wolff-Parkinson-White Syndrome

WOLFF-PARKINSON-WHITE PATTERN

The prevalence of WPW pattern on the surface ECG is 0.15% to 0.25% in the general population. The prevalence is increased to 0.55% among first-degree relatives of affected patients, suggesting a familial component. The yearly incidence of newly diagnosed cases of preexcitation in the general population was substantially lower, 0.004% in a diverse population of residents from Olmsted County, Minnesota, 50% of whom were asymptomatic.¹² The incidence in men is twice that in women and highest in the first year of life, with a secondary peak in young adulthood.

The WPW pattern on the ECG can be intermittent and can even permanently disappear (in up to 40% of cases) over time. Intermittent and/or persistent loss of preexcitation may indicate that the BT has a relatively longer baseline ERP, which makes it more susceptible to age-related degenerative changes and variations in autonomic tone. Consistent with this hypothesis is the observation that, compared with patients with a persistent WPW pattern, those in whom anterograde conduction via the BT disappeared were older (50 versus 39 years) and had a longer ERP of the BT at initial EP study (414 versus 295 milliseconds). The lifetime risk of mortality related to this in asymptomatic individuals can never be

accurately known but has been estimated at 0.1% annual risk, with the majority of patients identified between the ages of approximately 10 and 40 years.

In a recent report, about 90% of 293 adults who were asymptomatic at the time of diagnosis of WPW ECG pattern had no arrhythmic events, remaining totally asymptomatic over a median follow-up of 67 months, and 30% of them had disappearance of preexcitation. Only a minority of young adult patients (10%) developed a first arrhythmic event, which was potentially life-threatening in approximately 5%, but no one died. Compared with patients who experienced potentially life-threatening events, those who did not showed a characteristic EP profile (older age, lower tachyarrhythmia inducibility, longer anterograde refractory ERP of BTs, and low likelihood of baseline retrograde BT conduction or multiple BTs).¹⁰

In a similar report in 184 children (8 to 12 years of age) with WPW ECG pattern who were totally asymptomatic at the time of diagnosis (which was made incidentally in the majority of cases either at a routine medical examination or on a screening ECG before admission to sports), during a median follow-up of 57 months, no child lost preexcitation, more than 70% had no arrhythmic events, and about 30% developed a first arrhythmic event, which was potentially life-threatening in 10%. Compared with children who experienced potentially life-threatening tachyarrhythmias, those who did not showed a characteristic electrophysiological profile (lower tachyarrhythmia inducibility, longer anterograde refractory period of BTs, and low likelihood of baseline retrograde AP conduction or multiple BTs).⁹

WOLFF-PARKINSON-WHITE SYNDROME

The prevalence of the WPW syndrome is substantially lower than that of the WPW ECG pattern. In a review of 22,500 healthy aviation personnel, the WPW pattern on surface ECG was seen in 0.25%; only 1.8% of these patients had documented arrhythmias. In another report of 228 subjects with WPW ECG pattern followed for 22 years, the overall incidence of arrhythmia was 1% per patient-year. The occurrence of arrhythmias is related to the age at the time preexcitation was discovered. In the Olmsted County population, one-third of asymptomatic individuals younger than 40 years at the time of diagnosis of WPW eventually had symptoms, compared with none of those who were older than 40 years at diagnosis. In a recent report, of 293 asymptomatic adults with the WPW ECG pattern who underwent EP testing without ablative intervention, almost 90% remained asymptomatic over a median follow-up of 67 months, whereas 31 patients had an arrhythmic event, and 17 had a “potentially” life-threatening event (AF with mean rate of 250 beats/min or faster).¹⁰ In another report, of 188 asymptomatic children (between 8 and 12 years of age) with the WPW ECG pattern who underwent EP testing without ablative intervention, 72% remained asymptomatic over a median follow-up of 57 months, whereas 31 patients had an arrhythmic event.⁹ Symptomatic arrhythmias developed more commonly in initially asymptomatic patients with a WPW ECG pattern who had inducible SVTs in the EP laboratory compared with those with no inducible tachycardias. In one report, less than 4% of patients developed clinical SVT over a 37.7-month follow-up period, compared with 67% of those with inducible SVT on EP testing.

A recent report demonstrated that women more commonly had right-sided BTs compared with men and that Asians had right free wall BTs substantially more frequently than other races. These relationships may suggest a potential inherited component of development of the AV annuli.¹³

ASSOCIATED CARDIAC ABNORMALITIES

Most patients with AV BTs do not have coexisting structural cardiac abnormalities, except for those that are age-related. Associated congenital heart disease, when present, is more likely to be right-sided than left-sided in location. Ebstein anomaly is the congenital lesion

most strongly associated with the WPW syndrome. As many as 10% of such patients have one or more BTs; most of these are located in the right free wall and right posteroseptal space. An association between mitral valve prolapse and left-sided BTs has also been reported. However, this association may simply reflect the random coexistence of two relatively common conditions.

FAMILIAL WOLFF-PARKINSON-WHITE SYNDROME

Among patients with the WPW syndrome, 3.4% have first-degree relatives with a preexcitation syndrome. A familial form of WPW has infrequently been reported and is usually inherited as an autosomal dominant trait. The genetic cause of a rare form of familial WPW syndrome has been described.^{14,15} The clinical phenotype is characterized by the presence of preexcitation on the ECG; frequent SVTs, including AF; progressive conduction system disease; and cardiac hypertrophy. Patients typically present in late adolescence or the third decade with syncope or palpitations. Premature SCD occurred in 10% of patients. Paradoxically, by the fourth decade of life, progression to advanced sinus node dysfunction or AV block (with the loss of preexcitation) requiring pacemaker implantation was common. Approximately 80% of the patients older than 50 years had chronic AF. Causative mutations in the *PRKAG2* gene were identified in these families. The *PRKAG2* gene encodes the gamma-2 regulatory subunit of the adenosine monophosphate (AMP)-activated protein kinase, which is a key regulator of metabolic pathways, including glucose metabolism. The penetrance of the disease for WPW syndrome was complete, but the expression was variable. The described phenotype of this syndrome is similar to the autosomal recessive glycogen storage disease, Pompe disease. Given the function of the AMP-activated protein kinase and this similarity, the *PRKAG2* syndrome is likely a cardiac-specific glycogenosis syndrome. This syndrome thus belongs to the group of genetic metabolic cardiomyopathies, rather than to the congenital primary arrhythmia syndromes.

CONCEALED BYPASS TRACTS

The true prevalence of concealed BTs is unknown because, unlike the situation with the WPW ECG pattern, these BTs are concealed on the surface ECG and are only expressed during AVRT; only symptomatic patients undergo EP testing. As noted, orthodromic AVRT accounts for approximately 95% of AVRTs and 35% of all paroxysmal SVTs, and 50% of the BTs that participate in orthodromic AVRT are concealed. SVTs using a concealed BT have no gender predilection and tend to occur more frequently in younger patients than in those with AVNRT; however, significant overlap exists. PJRT most often occurs in early childhood, although clinically asymptomatic patients presenting later in life are not uncommon.

Clinical Presentation

Most patients with preexcitation are asymptomatic and are discovered incidentally on an ECG obtained for unrelated reasons. When symptomatic arrhythmias occur in the WPW patient, the disorder is called the WPW syndrome. The two most common types of arrhythmias in the WPW syndrome are AVRT and AF. Patients with AVRT experience symptoms characteristic of paroxysmal SVT with sudden onset and termination, including rapid and regular palpitations, chest pain, dyspnea, presyncope, and rarely, syncope. Symptoms are usually mild and short-lived and terminate spontaneously or with vagal maneuvers. However, occasionally patients present with disabling symptoms, especially in the presence of structural heart disease. Of note, clinical symptoms are not usually helpful in differentiating AVRT from other forms of paroxysmal SVTs.

An AVRT that in general is well tolerated by the patient when additional heart disease is absent can deteriorate into AF. AF can be a life-threatening arrhythmia in the WPW syndrome if the BT has a short anterograde ERP, resulting in very fast ventricular rates, with possible deterioration into VF and SCD.

The incidence of SCD in patients with the WPW syndrome has been estimated to range from 0.15% to 0.39% over a 3- to 10-year follow-up. It is unusual for cardiac arrest to be the first symptomatic manifestation of WPW syndrome. Conversely, in about 50% of cardiac arrest cases in WPW patients, it is the first manifestation of WPW.

PJRT commonly presents as a frequently recurring or incessant tachycardia that is refractory to drug therapy and can lead to cardiomyopathy and congestive heart failure symptoms.

Initial Evaluation

History, physical examination, and 12-lead ECG constitute an appropriate initial evaluation. In patients with brief, self-terminating episodes of palpitations, an event recorder is the most effective way to obtain ECG documentation. Echocardiographic examination is often useful to exclude structural heart disease.

Several other noninvasive tests have been proposed as useful for evaluating symptomatic patients and risk-stratifying patients for SCD risk. However, the sensitivity and specificity of noninvasive testing have been shown to be limited. Invasive EP testing may be considered in patients with arrhythmias and those with a WPW ECG pattern when noninvasive testing does not lead to the conclusion that the anterograde ERP of the BT is relatively long.

EP testing can help risk-stratify asymptomatic patients with WPW pattern for developing symptoms and SCD secondary to preexcitation. As noted, inducibility of AVRT, a shorter BT ERP (<250 milliseconds), a shorter preexcited R-R interval during induced AF (<220 milliseconds), the presence of multiple pathways, and septal and right-sided pathway locations appear to identify a higher risk group.⁹⁻¹¹ However, a strategy to perform an EP study for all asymptomatic patients with the WPW ECG pattern for the purpose of risk stratification is still controversial and not widely accepted.¹⁶

METHODS FOR EVALUATION OF BYPASS TRACT REFRACTORY PERIOD

DEMONSTRATION OF INTERMITTENT PREEXCITATION. Observation of intermittent loss of the preexcitation pattern in a Holter monitor or serial ECGs is generally correlated with a long BT ERP and essentially ensures that the BT has a low “margin of safety” for conduction and hence is likely to block during AF, resulting in a slower ventricular response. Intermittent preexcitation, however, has to be distinguished from inapparent preexcitation (see later) and from a bigeminal ventricular rhythm with a long coupling interval.

ASSESSING ABILITY OF ANTIARRHYTHMIC AGENTS TO PRODUCE ANTEROGRADE BLOCK IN BYPASS TRACTS. When, during NSR, the intravenous injection of ajmaline (1 mg/kg over 3 minutes) or procainamide (10 mg/kg over 5 minutes) results in complete block of the BT, a long anterograde ERP (>270 milliseconds) of the BT is likely. The shorter the BT ERP, the less likely it would be blocked by these drugs. Furthermore, the amount of ajmaline required to block conduction over the BT correlates with the duration of the anterograde ERP of the BT. However, the incidence of BT block in response to these drugs is low and, although the occurrence of block predicts a long ERP of the BT, failure to produce block does not necessarily suggest a short ERP. Moreover, pharmacological testing is carried out at rest and therefore does not indicate what effect the drug will have on the BT ERP during sympathetic stimulation, such as exercise, emotion, anxiety, and recreational drug use.^{8,17,18}

RESPONSE OF PREEXCITATION TO EXERCISE. Demonstration of a sudden loss of preexcitation (indicated by abrupt loss of the delta wave associated with prolongation of the PR interval and normalization of the QRS) during exercise is consistent with block in the BT and is indicative of a long BT ERP (>300 milliseconds). This is a good predictor that the patient is not at risk for VF, even during sympathetic stimulation. However, the frequency of block in the BT during exercise is low (approximately 10%), and thus sensitivity of this test is poor.

EVALUATION OF VENTRICULAR RESPONSE DURING ATRIAL FIBRILLATION. During spontaneous or induced AF, the propensity for rapid AV conduction can be judged by the interval between consecutively preexcited QRS complexes. A mean preexcited R-R interval of more than 250 milliseconds and a shortest preexcited R-R of more than 220 milliseconds predict low risk for SCD, with a negative predictive value of more than 95%; however, the positive predictive value is low (20%).

RESPONSE OF PREEXCITATION TO TRANSESOPHAGEAL ATRIAL STIMULATION. There is good correlation between the value of the anterograde ERP of the BT obtained during single-test programmed atrial stimulation and atrial pacing at increasing rates and the ventricular rate during AF. Programmed electrical stimulation of the atrium can be performed by the transesophageal route and the value of the anterograde ERP of the BT can be determined.

ELECTROPHYSIOLOGICAL TESTING. Programmed atrial stimulation is used to evaluate the BT ERP. Because BT refractoriness shortens with decreasing pacing CL, the ERP should be determined at multiple pacing CLs (preferably ≤ 400 milliseconds). Additionally, atrial stimulation should be performed close to the BT atrial insertion site to obviate the effect of intraatrial conduction delay. Incremental rate atrial pacing is performed to determine the maximal rate at which 1:1 conduction over the BT occurs. Induction of AF should be performed to determine the average and the shortest R-R interval during preexcited AF. Atrial and ventricular stimulation is also performed to evaluate inducibility of AVRT as well as the number and location of BTs.

Principles of Management

MANAGEMENT OF ASYMPTOMATIC PATIENTS WITH PREEXCITATION

The role of EP testing and catheter ablation in asymptomatic patients with preexcitation is still controversial. Guidelines of the American College of Cardiology and European Society of Cardiology on the management of asymptomatic WPW patients suggest restricting catheter ablation of BTs to those in high-risk occupations (e.g., school bus drivers, police, and pilots) and professional athletes.¹⁹ Catheter ablation in asymptomatic preexcitation was classified as a class IIA indication with a B level of evidence. This means essentially that it is “reasonable” to offer ablation in selected patients but is not mandated in all patients. According to the North American Society of Pacing and Electrophysiology (NASPE; now the Heart Rhythm Society [HRS]) Expert Consensus Conference, asymptomatic WPW pattern on the ECG without recognized tachycardia is a class IIB indication for catheter ablation in children older than 5 years and a class III indication in younger children.²⁰

This approach has several justifications; one-third of asymptomatic individuals younger than 40 years when preexcitation was identified eventually developed symptoms, whereas no patients in whom preexcitation was first uncovered after the age of 40 years developed symptoms. Additionally, most patients with asymptomatic preexcitation have a good prognosis; cardiac arrest is rarely the first manifestation of the disorder. The positive predictive value of invasive EP testing is considered to be too low to justify routine use in asymptomatic patients.

Some studies, however, have questioned the approach discussed above.^{8,17,18} Those studies have shown that in the asymptomatic WPW population, a negative EP study with no AVRT or AF inducibility identifies subjects at very low risk for the development of spontaneous arrhythmias. Inducibility of sustained preexcited AF with a fast ventricular response, particularly in the presence of multiple BTs, may help select asymptomatic WPW subjects at definite risk for dying suddenly, and catheter ablation of the BT(s) appears to be required to prevent SCD. Because extensive studies have reported extremely rare complications from EP testing and radiofrequency (RF) ablation in experienced centers, it has been suggested that all asymptomatic patients with WPW pattern should

undergo EP testing for risk stratification, and those with inducible AVRT or AF or who have a short BT ERP should be considered for catheter ablation of the BT, whereas patients who are noninducible and have a long BT ERP may be followed without treatment.^{8-10,21} This argument is further supported by the fact that assessment of the future VF risk in an asymptomatic patient with WPW is not easy. Noninvasive markers of lower risk such as intermittent loss of pre-excitation, sudden loss of BT conduction on exercise stress testing, and loss of BT conduction after treatment with antiarrhythmic drugs are limited by inadequate sensitivity or specificity and the low incidence of future adverse events. With this approach, prophylactic ablation of BTs in high-risk subjects may be justified but is not an acceptable option for low-risk individuals. The physician involved needs to use special care and discretion in making the decision to proceed to ablation and must especially consider his or her own success and complication rates for ablation of the specific location of the BT identified.

In summary, the potential value of EP testing in identifying high-risk patients who may benefit from catheter ablation must be balanced against the approximately 2% risk of a major complication associated with catheter ablation.²² If RF catheter ablation were a totally risk-free procedure, one would logically advise such a procedure to the asymptomatic WPW patient with a short anterograde ERP. However, complications such as AV block, stroke, tamponade, and even death have been reported. It is not difficult to envision a small potential mortality benefit, if present, erased or eclipsed by a small complication rate if thousands of patients with BTs in various locations undergo ablation.¹⁶ Although complications of a diagnostic EP study are minor and non-life-threatening and are less common than those of catheter ablation, if routine EP testing of all asymptomatic WPW patients were considered, many patients would proceed immediately to RF ablation and, in others, there would be a strong temptation to ablate when catheters are in place (regardless of predicted SCD risk), especially given the fact that the criteria for ablation usually will not be black or white. This greatly increases the risk to the patient. Furthermore, invasive EP assessment has drawbacks, because no single factor has both a high sensitivity and specificity for identifying at-risk individuals. For example, a shortest preexcited R-R interval of less than 250 milliseconds during sustained induced AF is a very sensitive but not specific marker of the risk of VF in WPW patients, because approximately one-third of patients will have a shortest R-R interval of less than 250 milliseconds during induced AF. In fact, the addition of isoproterenol to the baseline study may shorten the ERP of the accessory pathway to levels of potential concern in the majority of individuals with WPW. In view of those considerations, prudence dictates that noninvasive testing with a Holter monitor and (if the Holter monitor does not show intermittent preexcitation) exercise testing should be considered before the EP study to identify the low-risk patient because of a long anterograde ERP of the BT.^{21,22}

For the low-risk patient, it may be appropriate to pursue a strategy of follow-up with ECGs and reevaluation at selected intervals with a high degree of suspicion for new arrhythmia symptoms. This strategy is supported by recent prospective studies of asymptomatic patients with WPW pattern; although “potentially” life-threatening arrhythmias were observed during follow-up, no patients had actually died. This observation implies that patient education about the potential risks associated with preexcitation and about the symptoms of arrhythmias that should prompt them to seek attention can prove very important at reducing the risk of mortality without necessarily exposing the patient to the risks of catheter ablation.^{10,16} It is also advisable to give the patient a copy of his or her ECG and a short note about the fact that the WPW pattern is present to prevent the misdiagnosis of myocardial infarction (MI) and to explain the basis of cardiac arrhythmias in case they develop later. Patients should also be encouraged to seek medical expertise whenever arrhythmia-related symptoms occur.

In patients not showing block in their BT during noninvasive studies, esophageal pacing may be performed to determine the anterograde ERP of the BT and the ability to induce sustained

arrhythmias. This procedure is neither pleasant for patients nor often definitive, but if arrhythmias can be induced, the benefits and risk of an invasive investigation and catheter ablation should be based on individual considerations such as age, gender, occupation, and athletic involvement. This should be discussed with the patient or, in the case of a child, with the parents. Because knowledge about the success and complication rate at the EP center plays a major role in decision making, that information should be made available so that the appropriate place for invasive diagnosis and treatment can be selected. If an EP study is performed for risk stratification, the combination of inducible AVRT and a shortest preexcited R-R interval during AF of less than 250 milliseconds provides the most compelling indications for ablation. The key is a clear understanding by the patient of the relative merits of each strategy. The well-informed patient needs to choose between a very small risk of potentially life-threatening arrhythmia over a long period of time and a one-time small procedural risk associated with EP testing and catheter ablation. Certain patients such as athletes and those in higher risk occupations will generally choose ablation. Others, especially patients older than 30 years, may prefer the small risk of a conservative strategy.^{10,16,21,22}

MANAGEMENT OF SYMPTOMATIC PATIENTS

ACUTE MANAGEMENT. Patients with AVRT are treated in a similar fashion as those with paroxysmal SVT. In patients with orthodromic and antidromic AVRT, drug treatment can be directed at the BT (ibutilide, procainamide, flecainide) or at the AVN (beta blockers, diltiazem, verapamil) because both are critical components of the tachycardia circuit. Adenosine should be used with caution because it can induce AF with a rapid ventricular rate in patients with preexcited tachycardias.¹⁹

AVN blocking drugs are ineffective in patients with antidromic AVRT who have anterograde conduction over one BT and retrograde conduction over a separate BT because the AVN is not involved in the circuit.¹⁹ Additionally, caution is advised against AVN blocking agents for the treatment of preexcited tachycardias occurring in patients with AT, AFL, or AF with a bystander BT. Antiarrhythmic drugs such as ibutilide, procainamide, or flecainide, which prevent rapid conduction through the bystander pathway, are preferable, even if they may not convert the atrial arrhythmia. When drug therapy fails or hemodynamic instability is present, electrical cardioversion should be considered.

CHRONIC MANAGEMENT. The NASPE policy statement on catheter ablation states that catheter ablation is considered first-line therapy (class I) and the treatment of choice for patients with the WPW syndrome—that is, patients with manifest preexcitation along with symptoms.²⁰ It is curative in more than 95% of patients and has a low complication rate. It also obviates the unwanted side effects of antiarrhythmic agents. For patients with preexcitation who are not candidates for ablation, antiarrhythmic drugs to block BT conduction should be used, such as sodium or potassium channel blockers.²³ However, there have been no controlled trials of pharmacological therapy in patients with AVRT, but small nonrandomized trials have reported the safety and efficacy of drug therapy. Despite the absence of data from clinical trials, chronic oral beta blocker therapy can be used for the treatment of patients with WPW syndrome, particularly if their BT has been demonstrated during EP testing to be incapable of rapid anterograde conduction. Verapamil, diltiazem, and digoxin, on the other hand, generally should not be used as the sole long-term therapy for patients with BT that might be capable of rapid conduction during AF.

Catheter ablation is also considered first-line therapy (class I) for patients with paroxysmal SVT involving a concealed BT. However, because concealed BTs are not associated with an increased risk of SCD in these patients, catheter ablation can be presented as one of a number of potential therapeutic approaches, including pharmacological therapy and clinical follow-up alone.¹⁹ When pharmacological therapy is selected for patients with concealed BTs,

it is reasonable to consider a trial of beta blocker therapy, calcium channel blockers, or a class IC antiarrhythmic agent.

Electrocardiographic Features

Electrocardiography of Preexcitation

Anterogradely conducting AV BTs produce the classic WPW ECG pattern characterized by a fusion between conduction via the BT and the normal AVN-HPS: (1) short PR (P-delta) interval (<120 milliseconds); (2) slurred upstroke of the QRS (delta wave); and (3) wide QRS (>120 milliseconds) (Fig. 18-4).

The degree of preexcitation depends on several factors, including conduction time over the AVN-HPS, conduction time from the sinus node to the atrial insertion site of the BT (which depends on the distance, conduction, and refractoriness of the intervening atrial tissue), and conduction time through the BT (which depends on the length, thickness, and conduction properties of the BT).

Pharmacological and/or physiological maneuvers (e.g., carotid sinus massage, Valsalva maneuvers, adenosine, beta blockers) that alter AVN conduction can be used to alter the degree of preexcitation, thereby confirming the diagnosis of the presence of an AV BT.

The ECG pattern displayed by some patients with the WPW syndrome can simulate the pattern found in other cardiac conditions

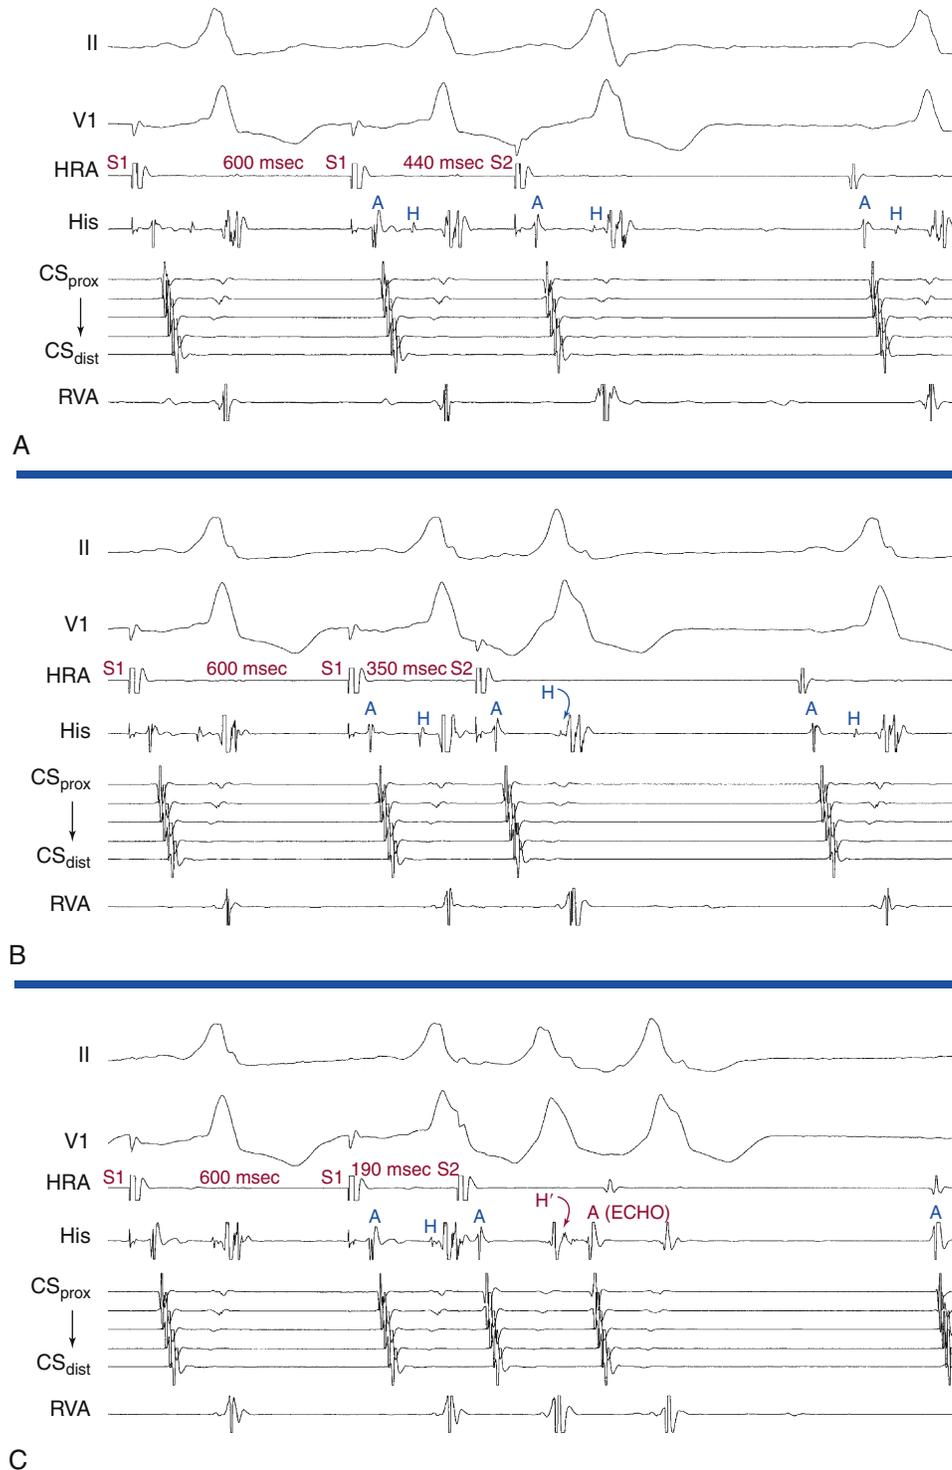

FIGURE 18-4 Effect of atrial extrastimulation (AES) on preexcitation. **A**, Preexcitation is manifest during normal sinus rhythm (NSR) and atrial pacing associated with a short His bundle-ventricular (HV) interval (−11 milliseconds). AES produces decremental conduction over the atrioventricular node (AVN) (with prolonged atrial-His bundle [AH] interval) but not over the bypass tract (constant P-delta interval), increasing the degree of preexcitation with the His potential inscribed within the QRS (HV interval of −64 milliseconds). **B**, An earlier coupled AES produces more pronounced preexcitation and an HV interval of −93 milliseconds. **C**, A more premature AES produces full preexcitation with the HB activated retrogradely (H'), followed by ventriculoatrial conduction over the AVN and an echo beat (atrioventricular reentry).

and can alter the pattern seen in the presence of other cardiac disease. A negative delta wave (presenting as a Q wave) can mimic an MI pattern. Conversely, a positive delta wave can mask the presence of a previous MI. Intermittent WPW can also be mistaken for frequent premature ventricular complexes (PVCs; Fig. 18-5). If the WPW pattern persists for several beats, the rhythm can be misdiagnosed as an accelerated idioventricular rhythm. The WPW pattern is occasionally seen on alternate beats and may suggest ventricular bigeminy. An alternating WPW and normal pattern can occasionally suggest electrical alternans. On the other hand, late-coupled PVCs (Fig. 18-6) and ventricular pacing (Fig. 18-7) with inapparent pacing artifacts can occasionally mimic ventricular preexcitation.

INAPPARENT VERSUS INTERMITTENT PREEXCITATION

INAPPARENT PREEXCITATION. With inapparent preexcitation, preexcitation is absent on the surface ECG despite the presence of an anterogradely conducting AV BT, because conduction over the AVN-HPS reaches the ventricle faster than that over the BT. In this setting, the PR interval is shorter than what the P-delta interval would be if preexcitation were present. Therefore, when preexcitation becomes inapparent, the PR interval becomes shorter, reflecting the now better AVN-HPS conduction.³

Inapparent preexcitation is usually caused by (1) enhanced AVN conduction, so that it is faster than conduction over the BT; (2) prolonged intraatrial conduction from the site of atrial stimulation to the atrial insertion site of BT (most often left lateral), favoring anterograde conduction over the AVN-HPS; and/or (3) prolonged conduction over the BT, so that it is slower than AVN-HPS conduction.

INTERMITTENT PREEXCITATION. Intermittent preexcitation is defined as the presence and absence of preexcitation on the same tracing (Fig. 18-8). True intermittent preexcitation is characterized by an abrupt loss of the delta wave (independently of how fast or slow is AVN conduction), with prolongation (normalization)

of the PR interval (reflecting the loss of the faster BT conduction, and the subsequent conduction over the slower AVN-HPS), and normalization of the QRS in the absence of any significant change in heart rate.

Intermittent preexcitation is usually caused by (1) phase 3 (i.e., tachycardia-dependent) or phase 4 (i.e., bradycardia-dependent) block in the BT (see Chap. 10); (2) anterograde or retrograde concealed conduction produced by PVCs, premature atrial complexes (PACs), or atrial arrhythmias; (3) BTs with long ERP and the gap phenomenon in response to PACs; and/or (4) BTs with long ERP and supernormal conduction.

Intermittent preexcitation is generally a reliable sign that the AV BT has a relatively long anterograde ERP and is not capable of excessively rapid impulse conduction, such as during AF. Maneuvers that slow AVN conduction (e.g., carotid sinus massage, AVN blockers) would unmask inapparent preexcitation but would not affect intermittent preexcitation.

Preexcitation alternans is a form of intermittent preexcitation in which a QRS complex manifesting a delta wave alternates with a normal QRS complex (see Fig. 18-5). *Concertina preexcitation* is another form of intermittent preexcitation in which the PR intervals and QRS complex durations show a cyclic pattern; that is, preexcitation becomes progressively more prominent over a number of QRS complex cycles followed by a gradual diminution in the degree of preexcitation over several QRS cycles, despite a fairly constant heart rate.

Differentiation between intermittent preexcitation and inapparent preexcitation on an ECG showing QRS complexes with and without preexcitation can be achieved by comparing the P-delta interval during preexcitation and the PR interval when preexcitation is absent. Loss of preexcitation associated with a PR interval longer than the P-delta interval is consistent with intermittent preexcitation (see Fig. 18-8), whereas loss of preexcitation associated with a PR interval shorter than the P-delta interval is consistent with inapparent preexcitation.

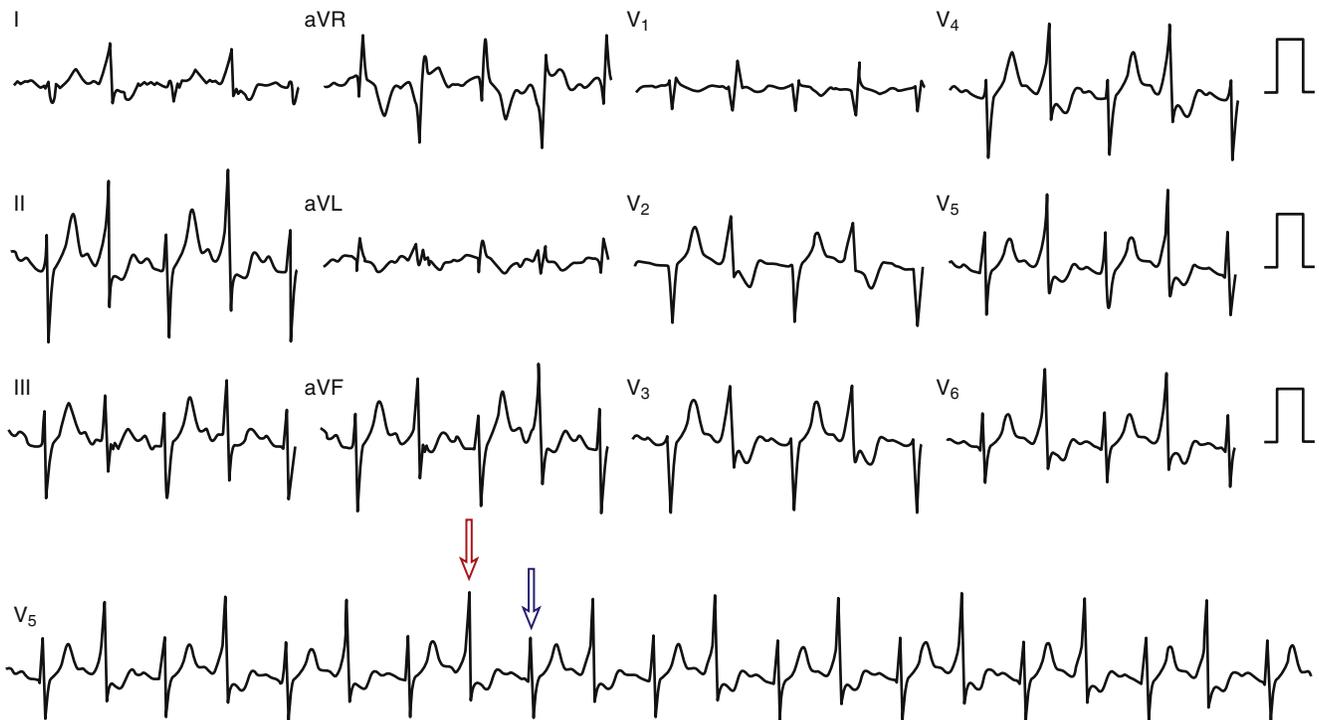

FIGURE 18-5 Preexcitation alternans. Surface ECG during sinus tachycardia demonstrating intermittent preexcitation in which a QRS complex manifesting a delta wave (red arrow) alternates with a normal QRS complex (blue arrow) (i.e., preexcitation alternans). Note the intermittent abrupt loss of delta wave associated with prolongation of the PR interval and the presence of a stable sinus rate, indicating that loss of preexcitation is secondary to anterograde block in the bypass tract (i.e., intermittent preexcitation) rather than enhanced atrioventricular nodal conduction.

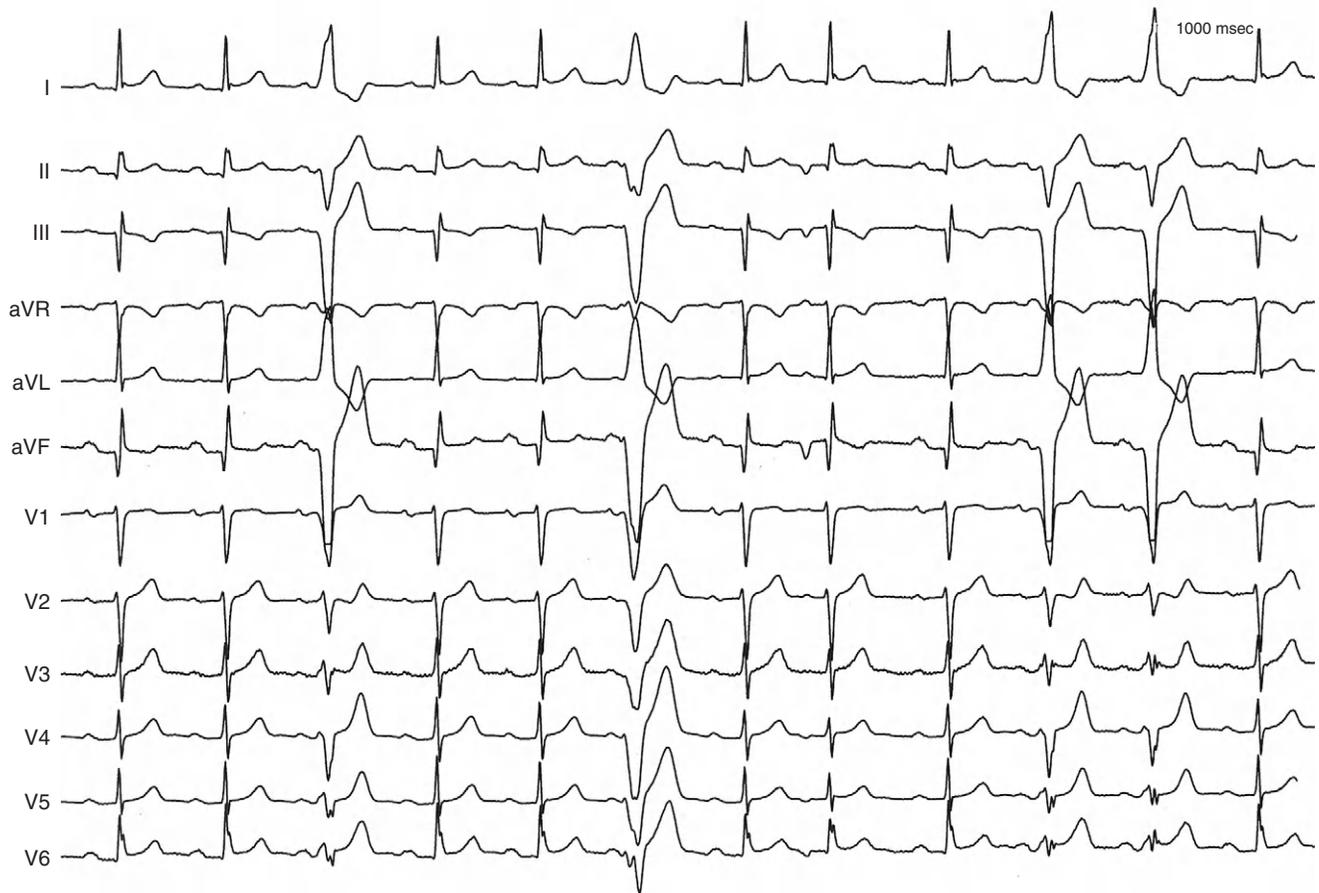

FIGURE 18-6 Surface ECG of normal sinus rhythm with late-coupled premature ventricular complexes, which are inscribed shortly after the sinus P waves, resulting in a short PR interval and wide QRS complexes mimicking intermittent ventricular preexcitation. Note that the degree of widening of the QRS and the variability of the QRS morphology and the varying relationship to the preceding P waves all argue against ventricular preexcitation.

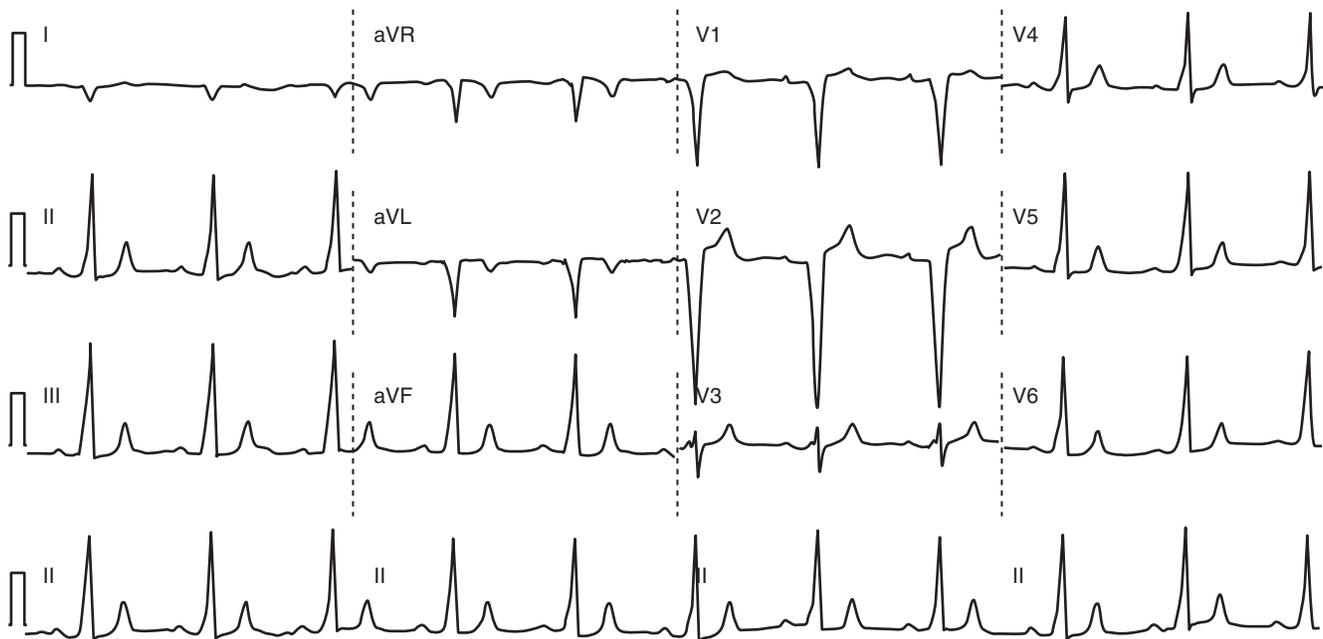

FIGURE 18-7 Surface ECG of normal sinus rhythm with atrial-tracking ventricular pacing. The QRS complexes are the result of fusion from ventricular pacing and conduction over the normal atrioventricular conduction axis, resulting in a pseudo-delta wave, mimicking a Wolff-Parkinson-White ECG pattern. The pacing artifacts are very small, but careful inspection reveals those artifacts most clearly in lead III.

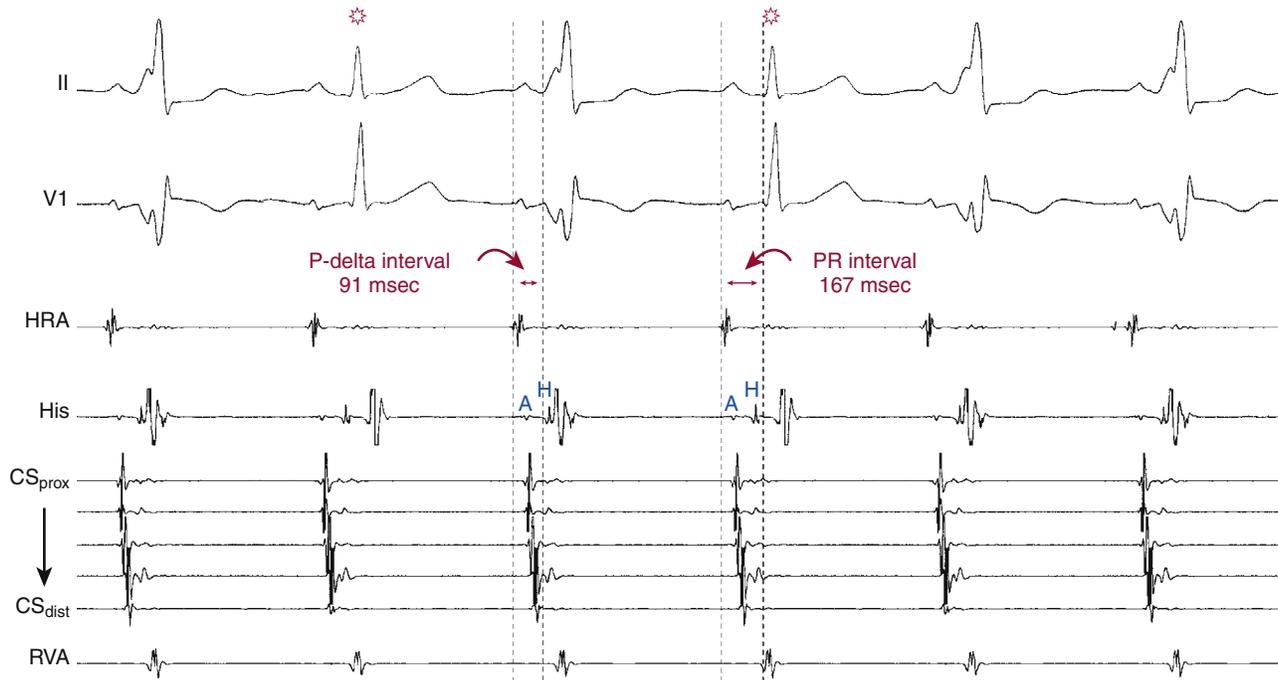

FIGURE 18-8 Intermittent preexcitation. Surface ECG leads II and V₁ and intracardiac recordings in a patient with Wolff-Parkinson-White syndrome and a right anterior bypass tract (BT). Note the intermittent abrupt loss of delta wave (stars) associated with prolongation of the PR interval and normalization of the His bundle-ventricular (HV) interval, despite the presence of a constant atrial-His bundle (AH) interval (atrioventricular node [AVN] conduction) and a stable sinus rate, indicating that loss of preexcitation is secondary to anterograde block in the BT (i.e., intermittent preexcitation) rather than enhanced AVN conduction.

Supraventricular Tachycardias Associated with Wolff-Parkinson-White Syndrome

ORTHODROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA

The ECG during orthodromic AVRT shows P waves inscribed within the ST-T wave segment with an RP interval that is usually less than half of the tachycardia R-R interval (i.e., RP interval < PR interval) (Fig. 18-9). The RP interval remains constant, regardless of the tachycardia CL, because it reflects the nondecremental conduction over the BT. QRS morphology during orthodromic AVRT is generally normal and not preexcited, even when preexcitation is present during NSR (Fig. 18-10). Functional bundle branch block (BBB) can be observed frequently during orthodromic AVRT (see Fig. 18-9). The presence of BBB during SVT in a young person (<40 years) should raise the suspicion of orthodromic AVRT incorporating a BT ipsilateral to the blocked bundle, because the longer conduction time through the involved ventricle engendered by the BBB facilitates orthodromic reentry by enabling all portions of the circuit enough time to recover excitability from the prior cycle. This is particularly true with left bundle branch block (LBBB), which is very uncommon in younger patients.

Orthodromic AVRT tends to be a rapid tachycardia, with rates ranging from 150 to more than 250 beats/min. A beat-to-beat oscillation in QRS amplitude (QRS alternans) is present in up to 38% of cases and is most commonly seen when the rate is very rapid. The mechanism for QRS alternans is not clear but can partly result from oscillations in the relative refractory period of the distal portions of the HPS.

Ischemic-appearing ST segment depression also can occur during orthodromic AVRT, even in young individuals who are unlikely to have coronary artery disease. An association has been observed between repolarization changes (ST segment depression or T wave inversion) and the underlying mechanism of the tachycardia, because such changes are more common in orthodromic AVRT than AVNRT (57% versus 25%). Several factors can contribute to ST segment depression in these arrhythmias, including changes

in autonomic tone, intraventricular conduction disturbances, a longer ventricular-atrial (VA) interval, and a retrograde P wave of longer duration that overlaps into the ST segment. The location of the ST segment changes can vary with the location of the BT; ST segment depression in leads V₃ to V₆ is almost invariably seen with a left lateral BT, whereas ST segment depression and a negative T wave in the inferior leads is associated with a posteroseptal or posterior BT. A negative or notched T wave in leads V₂ or V₃ with a positive retrograde P wave in at least two inferior leads suggests an anteroseptal BT. However, ST segment depression occurring during orthodromic AVRT in an older patient mandates consideration of possible coexisting ischemic heart disease.

ANTIDROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA

Antidromic AVRT is characterized by a wide (fully preexcited) QRS complex, usually regular R-R intervals, and ventricular rates of up to 250 beats/min. The width of the preexcited QRS complex and the amplitude of the ST-T wave segment usually obscure the retrograde P wave on the surface ECG. When the P waves can be identified, they are inscribed within the ST-T wave segment with an RP interval that may be more than half of the tachycardia R-R interval because retrograde conduction occurs slowly via the AVN-HPS. The PR (P-delta) interval remains constant, regardless of the tachycardia CL, because it reflects nondecremental conduction over the BT.

PERMANENT JUNCTIONAL RECIPROCATING TACHYCARDIA

PJRT tends to be incessant, stopping and starting spontaneously every few beats without initiating PACs or PVCs. The heart rate is usually between 120 and 200 beats/min and the QRS duration is generally normal. Slow retrograde conduction over the BT causes the RP interval during PJRT to be long, usually more than half of the tachycardia R-R interval (Fig. 18-11). The P waves resulting from retrograde conduction are easily seen on the ECG and are inverted in leads II, III, aVF, and V₃ to V₆.

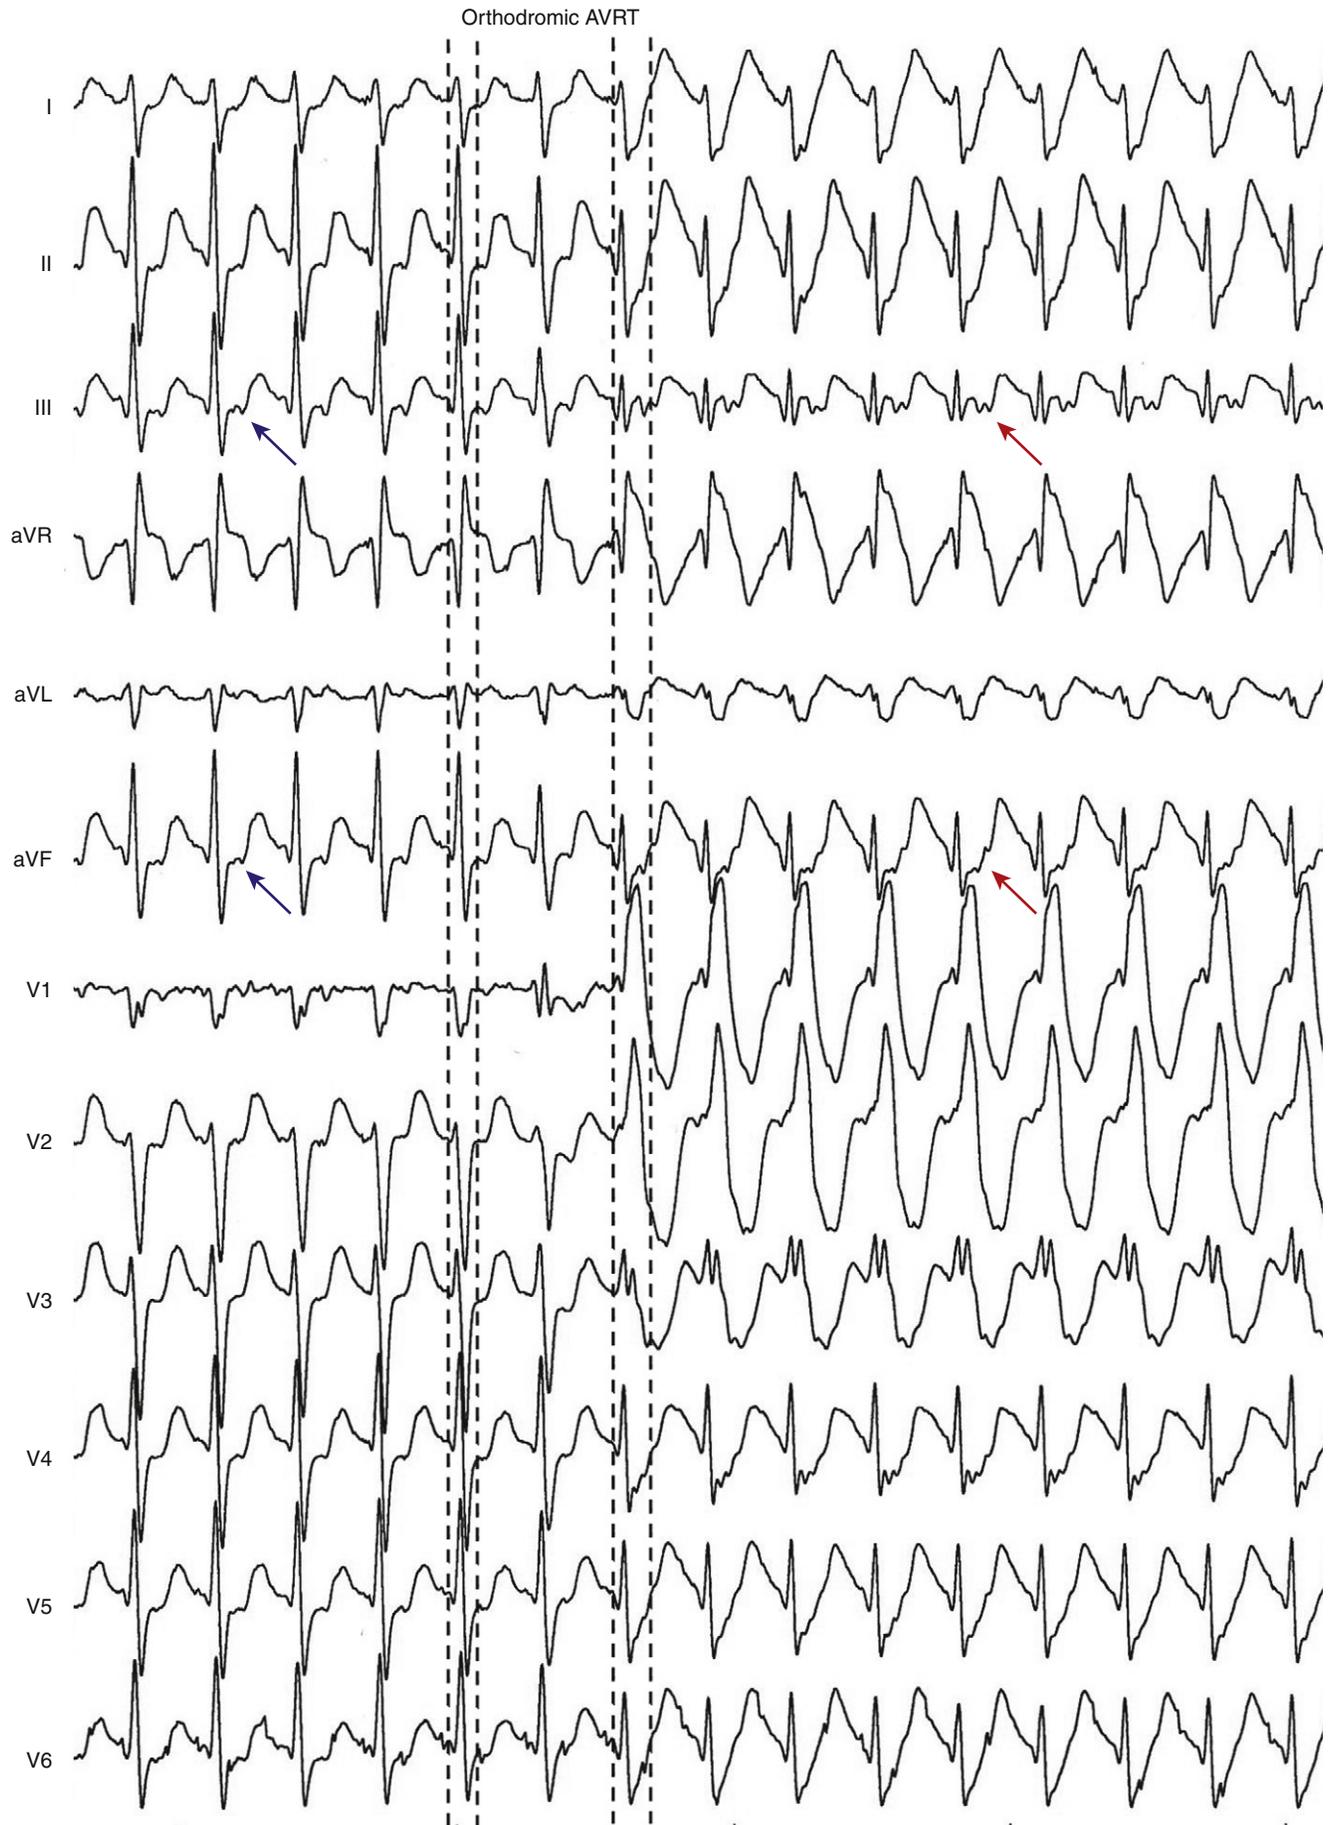

FIGURE 18-9 Surface ECG of orthodromic atrioventricular reentrant tachycardia (AVRT) using a concealed superoparaseptal bypass tract (BT). Note the P waves (arrows) inscribed within the ST-T wave segment (short RP interval). Ischemic-appearing ST segment depression is also observed. Functional right bundle branch block occurs in the right side of the tracing, with prolongation of the RP (ventriculoatrial [VA]) interval, suggesting that retrograde VA conduction during the supraventricular tachycardia is mediated by a right-sided BT. The dashed lines denote the QRS onset and P wave onset.

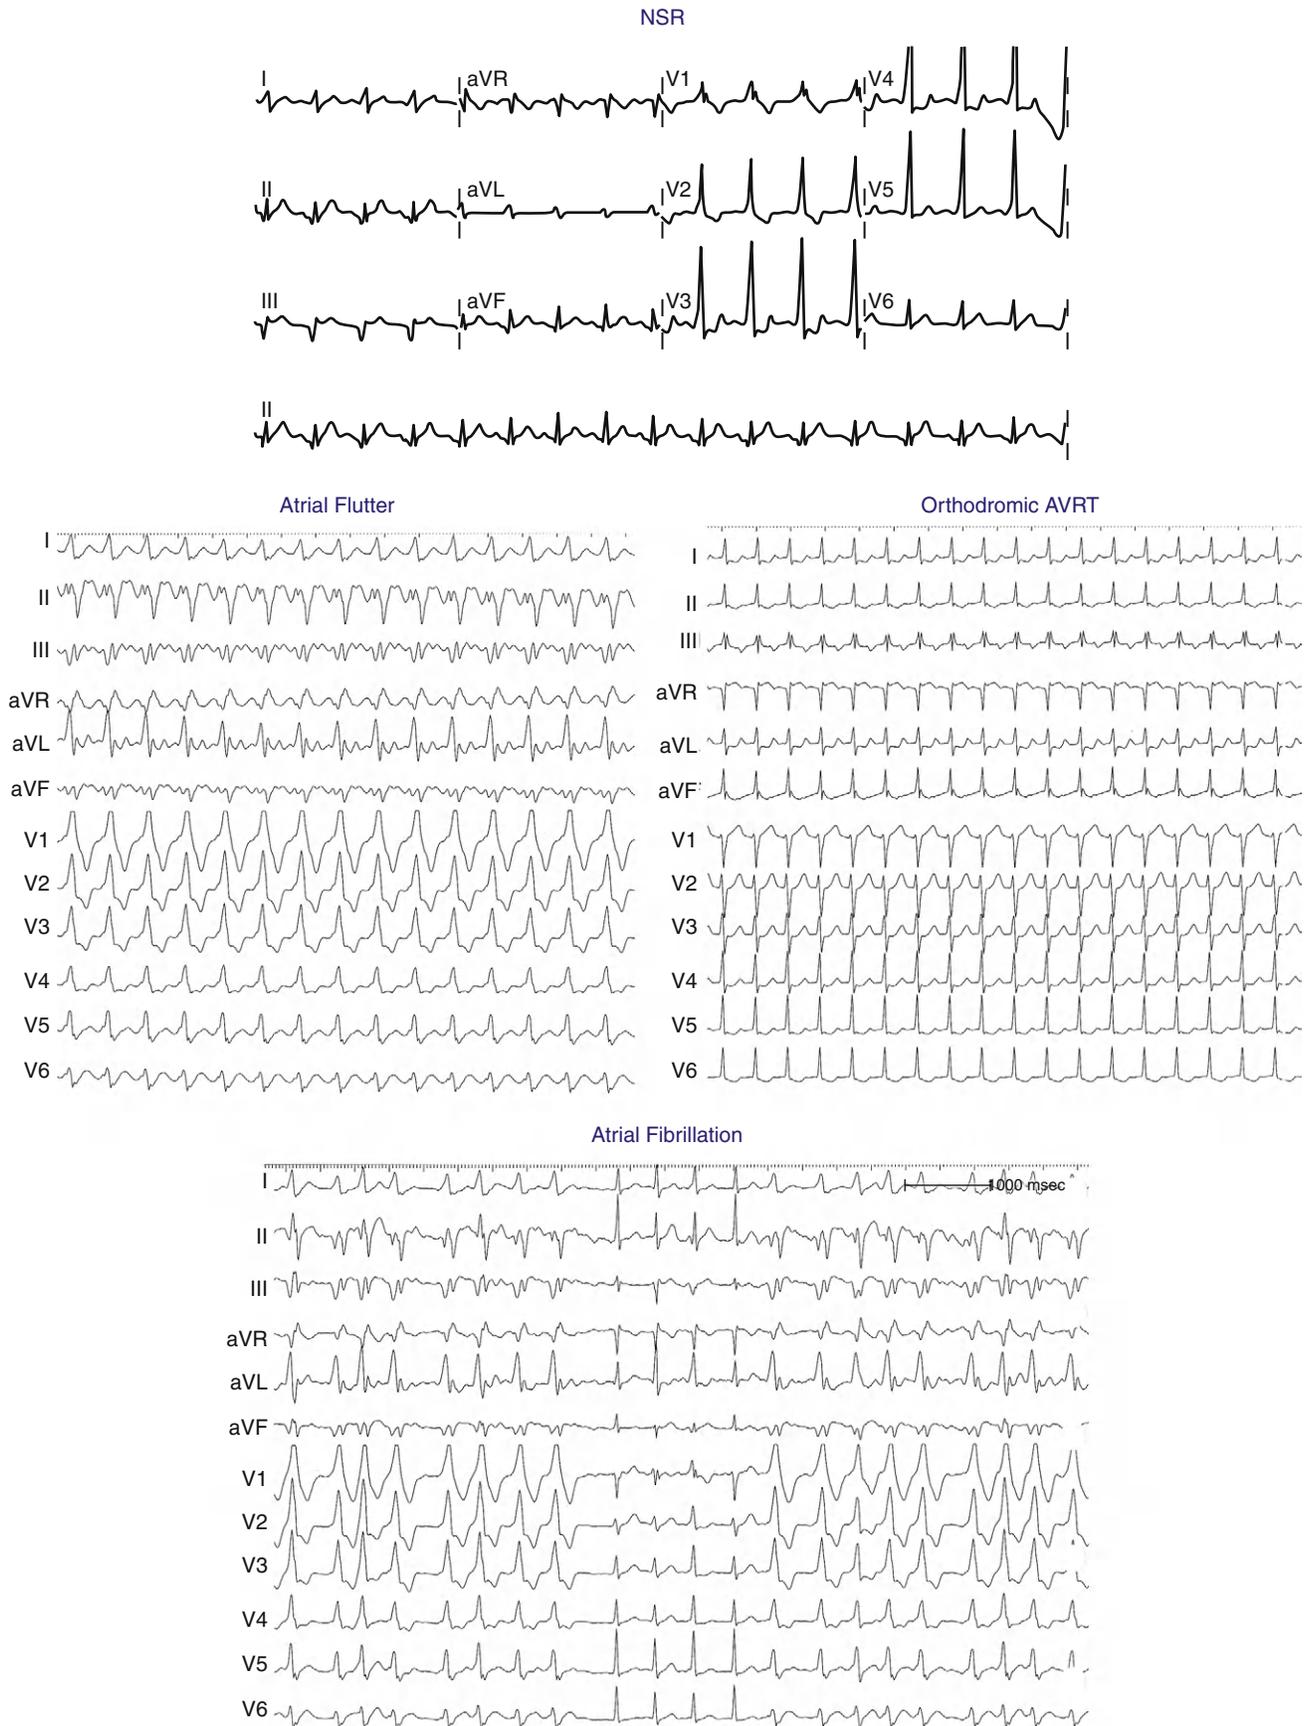

FIGURE 18-10 Surface ECG of multiple supraventricular arrhythmias in a patient with a bidirectional left posteroseptal bypass tract (BT). Ventricular preexcitation is evident during normal sinus rhythm (NSR). Atrial flutter with 2:1 atrioventricular (AV) conduction over the BT results in a wide complex tachycardia. The narrow complex tachycardia represents orthodromic atrioventricular reentrant tachycardia (AVRT) using the BT as the retrograde limb of the reentrant circuit. Atrial fibrillation results in an irregularly irregular rhythm with “clumping” of the preexcited (wide) and normal QRS complexes.

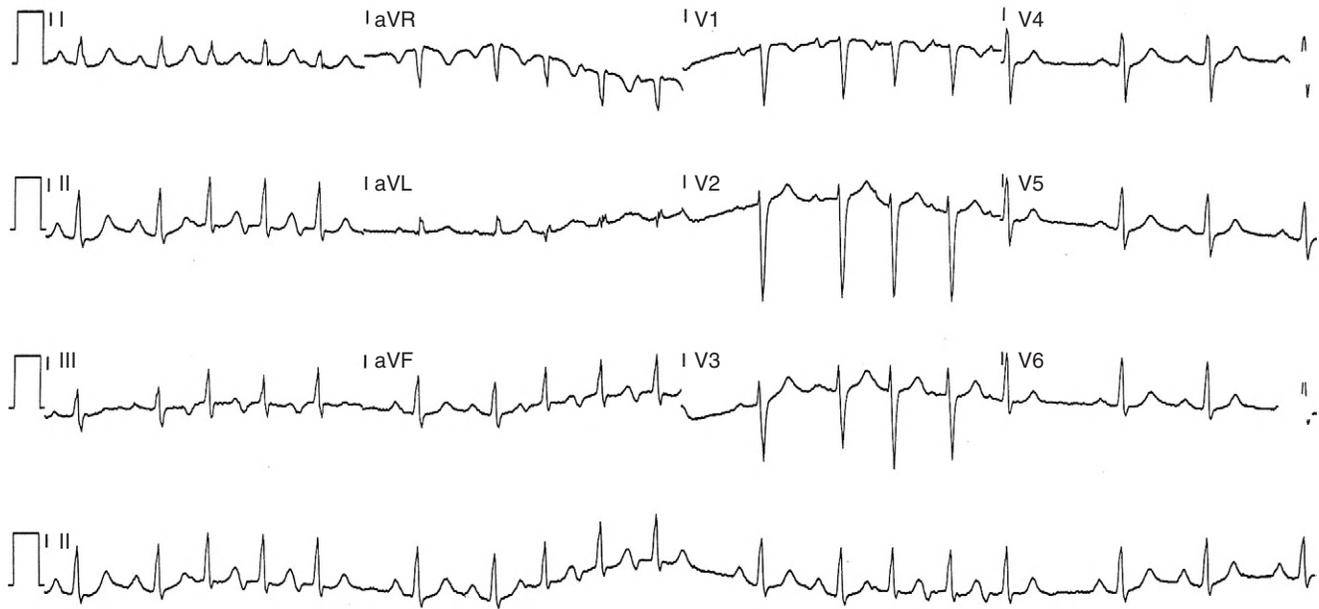

FIGURE 18-11 Surface ECG of permanent junctional reciprocating tachycardia (PJRT). Note the incessant nature of the arrhythmia, stopping and starting spontaneously every few beats without initiating atrial or ventricular ectopic beats. Slow retrograde conduction over the bypass tract causes the RP interval during PJRT to be long (long RP tachycardia). The P waves resulting from retrograde conduction are easily seen on the ECG and are inverted in the inferior leads.

ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA AND ATRIAL TACHYCARDIA

Both AVNRT and AT can be associated with partially or fully preexcited QRS complex secondary to anterograde conduction to the ventricles over the bystander BT. When AVNRT occurs in the WPW syndrome, the arrhythmia can be difficult to distinguish from orthodromic AVRT without EP testing.

ATRIAL FIBRILLATION

There are several characteristic findings on the ECG in patients with AF conducting over a BT, so-called preexcited AF (see Fig. 18-10). The rhythm is irregularly irregular, and can be associated with very rapid ventricular response caused by the nondecremental anterograde AV conduction over the BT. However, a sustained rapid ventricular rate of more than 180 to 200 beats/min will often create pseudo-regularized R-R intervals when the ECG is recorded at 25 mm/sec. Although the QRS complexes are conducted aberrantly, resembling those during preexcited NSR, their duration can be variable and they can become normalized. This is not related to the R-R interval (i.e., it is not a rate-related phenomenon), but rather is related to the variable relationship between conduction over the BT and AVN-HPS. Preexcited and normal QRS complexes often appear “clumped” (see Fig. 18-10). This can result from concealed retrograde conduction into the BT or the AVN.

The QRS complex during preexcitation is a fusion between the impulse that preexcites the ventricles caused by rapid conduction through a BT and the impulse that takes the usual route through the AVN. The number of impulses that can be transmitted through the BT and the amount of preexcitation depend on the refractoriness of both the BT and AVN. The shorter the anterograde ERP of the BT, the more rapid is anterograde impulse conduction and, because of more preexcitation, the wider the QRS complexes. Patients who have a BT with a very short ERP and rapid ventricular rates represent the group at greatest risk for development of VF.

Anterograde block in the BT abolishes retrograde conduction into the AVN, which in turn allows the AVN to recover its excitability and conduct anterogradely. These conducted impulses through the AVN can result in retrograde concealment into the BT, causing anterograde block of the BT, thereby slowing the ventricular rate.

ATRIAL FLUTTER

AFL, like AF, can conduct anterogradely via a BT resulting in a preexcited tachycardia (see Fig. 18-10). Depending on the various refractory periods of the normal and pathological AV conduction pathways, AFL potentially can conduct 1:1 to the ventricles during a preexcited tachycardia, making the arrhythmia difficult to distinguish from VT (see Fig. 12-6).

Electrocardiographic Localization of the Bypass Tract

LOCALIZATION USING THE DELTA WAVE

Careful analysis of the preexcitation pattern during sinus rhythm can potentially allow an accurate approximation of the location of the BT. This provides the electrophysiologist with important information that can guide patient counseling with regard to risks and benefits of ablation, in particular, providing some guidance about the proximity of the BT to the normal conduction system and the subsequent risk of AV block associated with an ablation attempt, as well as the need for left heart catheterization and atrial septal puncture and their potential complications. Additionally, it can also allow planning the subsequent catheter ablation, such as the use of cryoablation for septal BTs or the need for special equipment for atrial septal puncture for left-sided BTs.²⁴

The delta wave vector is helpful in approximating BT location, especially when maximal preexcitation is present. However, during NSR, only partial ventricular preexcitation is usually present, which limits the accuracy of ECG localization of the BT. Additionally, the degree of preexcitation may vary in an individual, depending on heart rate, autonomic tone, and AVN function, as well as BT location and EP characteristics. Therefore, it is important first to assess the degree of preexcitation visible throughout the entire ECG and then use only the delta wave polarity for localization (the first 40 milliseconds of the QRS in most cases, unless fully preexcited) rather than the overall QRS polarity, which may vary from each other.²⁵⁻²⁹

Several algorithms have been developed to precisely locate a BT to a specific anatomic location, using the delta wave polarity (Table 18-1; Figs. 18-12 and 18-13).^{25,26} Although these algorithms

TABLE 18-1 Delta Wave Characteristics during Preexcitation According to Bypass Tract Location***Left Lateral/Left Anterolateral BTs**

- A. $R/S \geq 1$ in V_2 and positive delta in III, or $R/S < 1$ in V_2 and positive delta in III and V_1
- B. RS transition $\leq V_1$ and > 2 positive delta in the inferior leads or $S > R$ in aVL
- C. QS or QR morphology in aVL and no negative QRS in III and V_1

Left Posterior/Left Posterolateral BTs

- A. $R/S \geq 1$ in V_1 and V_2 , no positive delta in III and positive delta in V_1
- B. R/S transition $\leq V_1$, no ≥ 2 positive delta in the inferior leads, no $S > R$ in aVL, in lead I $R < (S \text{ } 0.8 \text{ mV})$, and the sum of the inferior delta is not negative
- C. Positive QRS in aVL and an equiphasic QRS or positive in V_1 and no negative QRS in III

Left Posteroseptal BTs

- A. $R/S \geq 1$ in V_2 , no positive delta in III, and positive delta and $R/S < 1$ in V_1
- B. R/S transition $\leq V_1$, no ≥ 2 positive delta in the inferior leads, no $S > R$ in aVL, in lead I $R < (S \text{ } 0.8 \text{ mV})$, and the sum of the inferior delta is negative
- C. Negative QRS in III, V_1 , and aVF, tallest precordial R wave in V_2 - V_4 and R wave width in $V_1 > 0.06$ msec

Midseptal BTs

- A. $R/S < 1$ in V_2 , no positive delta in III, and negative delta in V_1
- B. R/S transition between V_2 and V_3 or between V_3 and V_4 but the delta amplitude in lead II ≥ 1.0 mV (septal location), and the sum of delta polarities in inferior leads is $-1, 0,$ or $+1$ mV
- C. Negative QRS in leads III, V_1 , and aVF, tallest precordial R in leads V_2 - V_4 and R wave width in $V_1 < 0.06$ msec

Right Posteroseptal BTs

- A. $R/S \geq 1$ in V_2 and no positive delta in III and V_1
- B. The sum of delta polarities in inferior leads is less than or equal to -2 mV
- C. Negative QRS in leads III, V_1 , and aVF and tallest precordial R in V_5 or V_6

Right Posterior/Right Posterolateral BTs

- A. $R/S < 1$ in V_2 , no positive delta in III and no negative delta in V_1 , and negative delta polarity in aVF
- B. R/S transition between V_3 and V_4 with delta amplitude in lead II < 1.0 mV or $\geq V_4$ and the delta axis is < 0 degrees and the R in lead III is ≤ 0 mV
- C. Positive QRS in III, negative in V_1 , and RS morphology in aVL

Right Lateral/Right Anterolateral BTs

- A. $R/S < 1$ in V_2 , no positive delta in III and no negative delta in V_1 and negative or biphasic delta in aVF
- B. R/S transition between leads V_3 and V_4 with delta amplitude in lead II < 1.0 mV or $\geq V_4$ and the delta axis is < 0 degrees and the R amplitude in lead III is < 0 mV
- C. Positive QRS in leads aVL and III and negative in V_1

Right Anterior/Right Superoparaseptal BTs

- A. $R/S < 1$ in V_2 , positive delta in III and no positive delta in V_1
- B. The sum of delta polarities in inferior leads is ≥ 2
- C. Positive QRS in aVF and negative in leads III and V_1

BT = bypass tract; R/S = R-S wave ratio.

From Katsouras CS, Grekas GF, Goudevenos JA, et al: Localization of accessory pathways by the electrogram, *Pacing Clin Electrophysiol* 27:189, 2004.

facilitate prediction of the location of a BT, they are inherently limited by biological variability in anatomy (e.g., rotation of the heart within the thorax), variable degree of preexcitation and QRS fusion, the presence of more than one manifest BT, intrinsic ECG abnormalities (such as prior myocardial infarction and ventricular hypertrophy), as well as technical variability in ECG acquisition and electrode positioning. These factors can subject all algorithms to exceptions and inaccuracies.²⁴

No single published algorithm offers extremely high sensitivity and specificity for all BT locations, particularly when differentiating septal BTs. Therefore, it may be more realistic to initially identify a general area in which the BT is located, and then to apply

more subtle criteria from one or more of the algorithms to attempt a more precise localization.

The mere presence and the degree of preexcitation can sometimes help in predicting the location of the BT. In fact, an apparently normal ECG does not fully rule out anterograde conducting left lateral BTs or rate-dependent or decremental BTs. Posteroseptal and right-sided BTs tend to be associated with a prominent degree of preexcitation because of the proximity to the sinus node, whereas left lateral BTs are often associated with subtle preexcitation. Nevertheless, when preexcitation is prominent, the accuracy of surface ECG localization of manifest BTs tends to be higher for the diagnosis of left free wall BTs than for BTs in other locations. The presence of multiple manifest BTs may result in fusion of preexcitation patterns or predominance of right-sided conduction.²⁴

LOCALIZATION USING POLARITY OF THE RETROGRADE P WAVE DURING ORTHODROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA

The polarity of the retrograde P waves during orthodromic AVRT is dependent on the location of the atrial insertion of the BT, and is helpful to localize the BT. However, the P wave is usually inscribed within the ST segment and its morphology may not be easily determined.^{3,30,31}

In general, P wave morphology in leads I and V_1 and in the inferior leads is most helpful. Negative P wave vector in lead I is highly suggestive of left free wall BTs, whereas a positive P wave is suggestive of right free wall BTs. On the other hand, a negative P wave in lead V_1 is highly suggestive of right-sided BTs. P wave polarity in the inferior leads, positive or negative, suggests superior or inferior location of the BT, respectively.^{3,30,31}

Posteroseptal BTs have positive P waves in leads V_1 , aVR, and aVL and negative P waves in the inferior leads. Left posterior BTs also have negative P waves in the inferior leads, but the P waves are more negative in lead II than in lead III and are more positive in lead aVR than in lead aVL, which is often isoelectric. Left lateral BTs have negative P waves in leads I and aVL, with a tendency for more positive P waves in lead III than in leads II and aVF as the location of the BT moves more superiorly.^{3,30,31}

Electrophysiological Testing

EP testing is used to study the features, location, and number of BTs and the tachycardias, if any, associated with them (Table 18-2). Typically, three quadripolar catheters are positioned in the high RA, right ventricle (RV) apex or septum, and HB region, and a decapolar catheter is positioned in the CS (see Fig. 4-7). If a right-sided BT is suspected, a duo-decapolar (Halo; Biosense Webster, Diamond Bar, Calif.) catheter along the tricuspid annulus can be helpful.

Baseline Observations during Normal Sinus Rhythm

Preexcitation is associated with a short His bundle–ventricular (HV) or H-delta interval during NSR. The HV interval can even be negative or the His potential can be buried in the local ventricular electrogram (see Fig. 18-4). The QRS is a fusion between conduction over the BT and that over the AVN-HPS. The site of earliest ventricular activation is near the ventricular insertion site of the BT (i.e., near the tricuspid annulus or mitral annulus at the base of the heart). Slowing of conduction in the AVN by carotid sinus massage, AVN blockers, or rapid atrial pacing unmasks and increases the degree of preexcitation, because these maneuvers do not affect the conduction over the BT. Dual AVN pathways are present in 8% to 40% of patients.

ATRIAL PACING AND ATRIAL EXTRASTIMULATION DURING NORMAL SINUS RHYTHM

In the presence of a manifest AV BT, atrial stimulation from any atrial site can help unmask preexcitation if it is not manifest during

- Demonstration of the BT role in the tachycardia
- Evaluation of other tachycardias not dependent on the presence of the BT
- Termination of the tachycardias

NSR because of fast AVN conduction. Incremental rate atrial pacing and progressively premature AES produce decremental conduction over the AVN (but not over the BT), increasing the degree of preexcitation and shortening the HV interval, until the His potential is inscribed within the QRS. The His potential is still activated anterogradely over the AVN until anterograde block in the AVN occurs; the QRS then becomes fully preexcited, and the His potential becomes retrogradely activated (see Fig. 18-4).

Atrial stimulation close to or at the AV BT insertion site results in maximal preexcitation and the shortest P-delta interval because of the lack of intervening atrial tissue whose refractoriness may otherwise limit the ability of atrial stimulation to activate the AV BT as early (Fig. 18-14). The failure of atrial stimulation to increase the amount of preexcitation can be caused by markedly enhanced AVN conduction, the presence of another AV BT, a pacing-induced block in the AV BT because of a long ERP of the BT (longer than that of the AVN), total preexcitation already present at the basal state caused by prolonged or absent AVN-HPS conduction, and/or decremental conduction in the BT. Atrial pacing can reveal the presence of multiple BTs (Fig. 18-15). Rare cases of catecholamine-dependent BTs have been reported that require isoproterenol infusion to manifest preexcitation that is absent at baseline.

VENTRICULAR PACING AND VENTRICULAR EXTRASTIMULATION DURING NORMAL SINUS RHYTHM

In the presence of a retrogradely conducting AV BT (whether manifest or concealed), ventricular extrastimulation (VES) during NSR can result in VA conduction over the BT, AVN, both, or neither (Fig. 18-16). Conduction over the BT alone is the most common pattern at short pacing CLs or short VES coupling intervals. In this setting, the VA conduction time is fairly constant over a wide range of pacing CLs and VES coupling intervals, in the absence of intraventricular conduction abnormalities or additional BTs. On the other hand, retrograde conduction over the BT and HPS-AVN is especially common when RV pacing is performed in the presence of a left-sided BT at long pacing CLs or long VES coupling intervals. This occurs because it is easier to engage the right bundle branch (RB) and conduct retrogradely through the AVN than it is to reach a distant left-sided BT. In this setting, the atrial activation pattern depends on the refractoriness and conduction times over both pathways and usually exhibits a variable degree of fusion. In addition, VA conduction can proceed over the HPS-AVN alone, resulting in a normal pattern of VA conduction, or can be absent because of block in both the HPS-AVN and BT, which is especially common with short pacing CLs and very early VES.

Ventricular stimulation during NSR also helps prove the presence of a retrogradely conducting AV BT. Ventricular stimulation resulting in retrograde VA conduction not consistent with normal conduction over the AVN (i.e., eccentric atrial activation sequence; see Fig. 18-16) and a VES delivered when the HB is refractory that results in atrial activation are indicators of the presence of a retrogradely conducting AV BT. However, if a VES delivered when the HB is refractory does not result in atrial activation, this does not necessarily exclude the presence of a retrogradely conducting AV BT, because

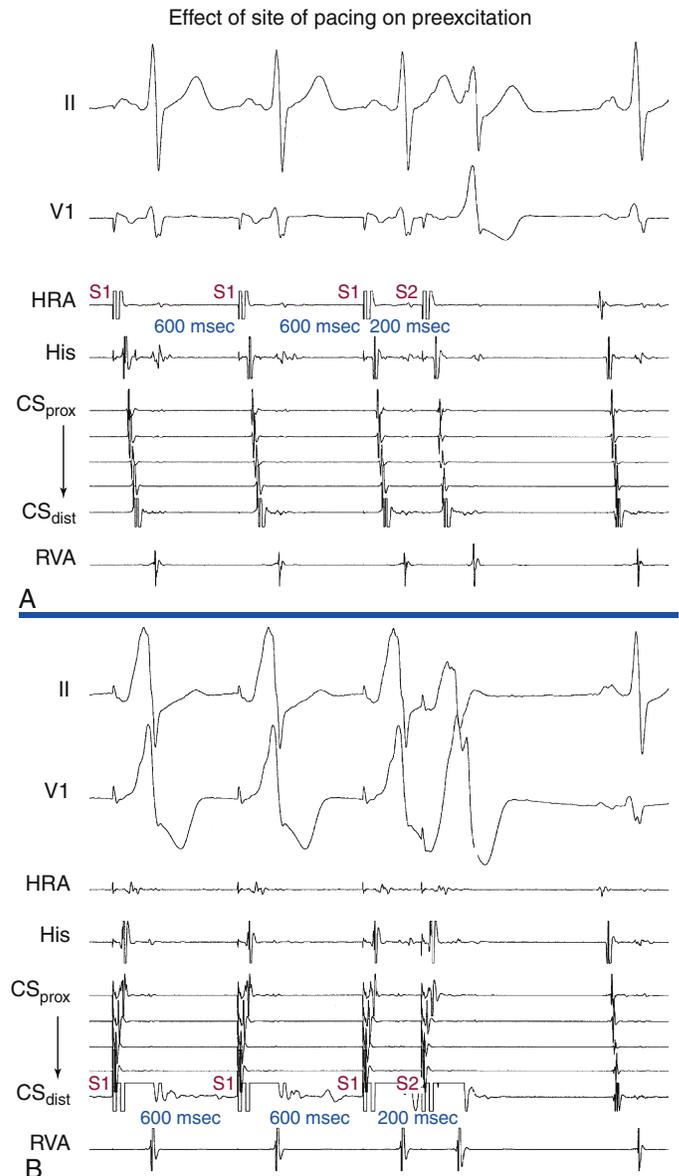

FIGURE 18-14 Effect of site of pacing on preexcitation. **A**, In the presence of a manifest left lateral bypass tract (BT), pacing from the high right atrium at a cycle length (CL) of 600 milliseconds produces minimal preexcitation. The degree of preexcitation increases with premature stimulation because of delay in atrioventricular nodal conduction. **B**, In the same patient, pacing at the same CLs from the distal coronary sinus (CS), close to or at the BT insertion site, results in a larger degree of preexcitation and shorter P-delta interval because of the lack of intervening atrial tissue whose refractoriness might otherwise limit the ability of atrial stimulation to activate the BT as early.

such a VES can be associated with retrograde block in the BT itself (see Fig. 18-16). Additionally, the lack of such a response does not exclude the presence of unidirectional (anterograde-only) AV BTs. A VES that conducts to the HB and results in an atrial activation that either precedes HB activation (Fig. 18-17) or is associated with an apparent His bundle–atrial (HA) interval shorter than that during drive complexes indicates the presence of a BT. Ventricular pacing can also reveal the presence of multiple BTs (Fig. 18-18).

During the delivery of progressively premature single VESs, an abrupt increase in the VA conduction interval is often observed. This may be due to a variety of reasons including a change in activation from a BT block to the AVN or a change from fast to slow pathway conduction; or it may be the result of an abrupt change when the refractory period of the RB has been reached. Retrograde right bundle branch block (RBBB) occurs frequently during VES testing,

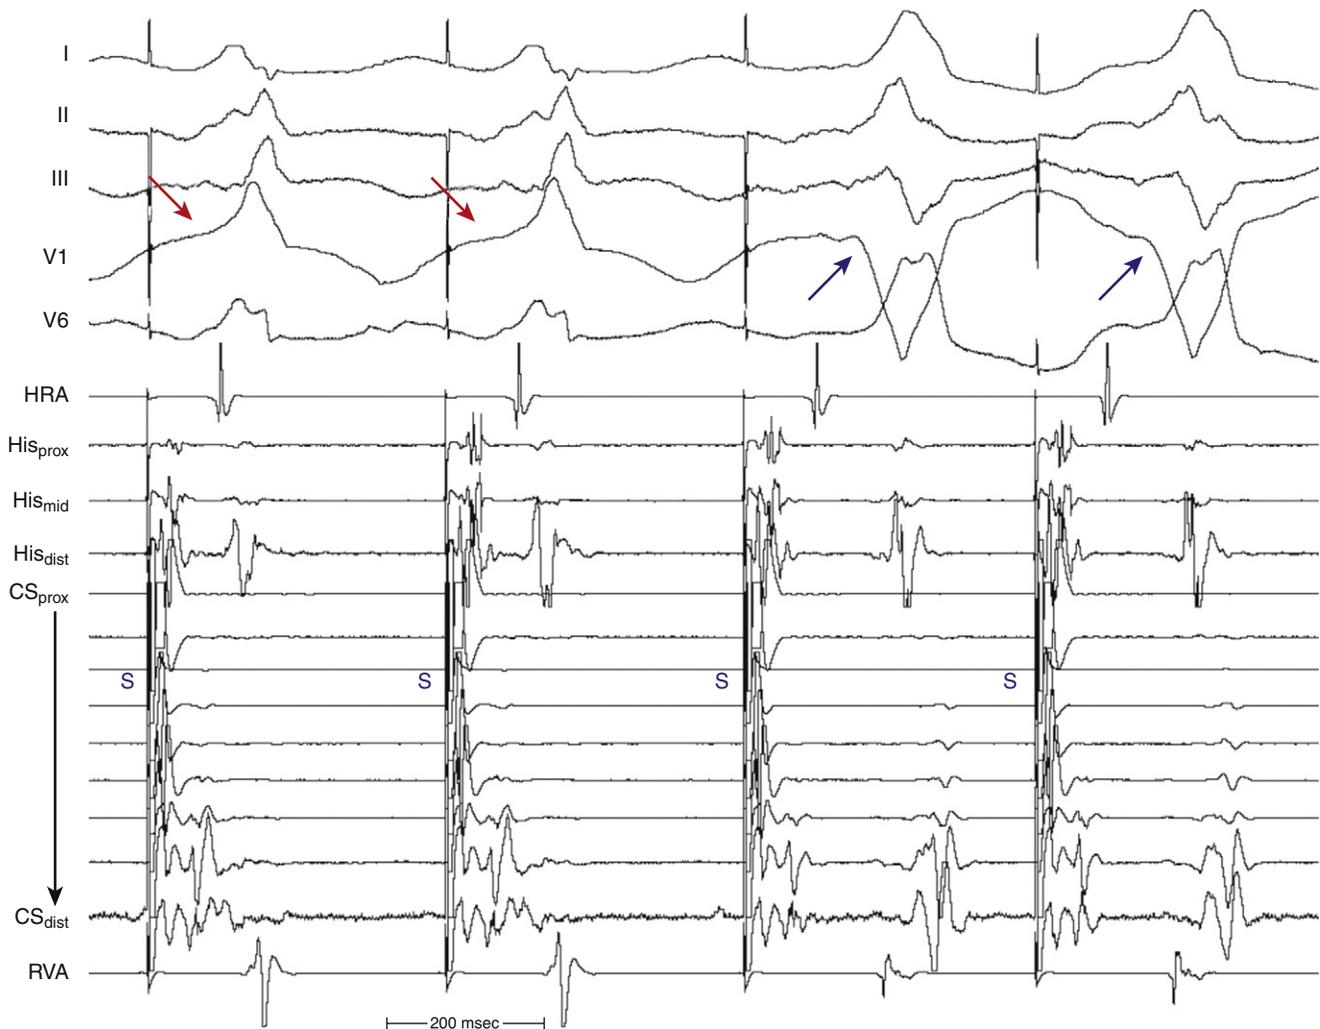

FIGURE 18-15 Surface ECG and intracardiac recordings during coronary sinus (CS) pacing (S) in a patient with both right and left lateral BTs. The first two complexes show a left lateral preexcitation pattern (red arrows), whereas this pathway fails to conduct on the last two complexes, which show a right lateral preexcitation pattern (blue arrows).

and can be diagnosed by observing the retrograde His potential during the drive train and its abrupt delay following the VES. Often, however, it is difficult to visualize the retrograde His potential during the pacing train; nevertheless, the sudden appearance of an easily distinguished retrograde His potential, separate from the ventricular electrogram following the VES, may be sufficient to recognize retrograde RBBB. Prolongation of the V-H interval is observed on development of retrograde RBBB, because conduction must traverse the interventricular septum (which requires approximately 60 to 70 milliseconds in normal hearts), enter retrograde via the left bundle branch (LB), and ascend to reach the HB. Although an increase in the V-H interval necessarily occurs with retrograde RBBB, whether a similar increase occurs in the VA interval depends on the nature of VA conduction. Measurement of the effect of retrograde V-H and VA intervals on the development of retrograde RBBB during VES can help the distinction between retrograde AVN and BT conduction. In the absence of a BT, the AVN can be activated in a retrograde fashion only after retrograde activation of the HB; as a consequence, VA activation will necessarily be delayed with retrograde RBBB, and the increase in the VA interval will be at least as much as the increase in the V-H interval. On the other hand, when retrograde conduction is via a BT, there will be no expected increase in the VA interval when retrograde RBBB is induced. Thus, the increase in the VA interval is minimal and always less than the increase in the V-H interval.³²

During retrograde conduction over the BT, the VA interval may increase slightly in response to incremental rate ventricular pacing or progressively premature VES. At short ventricular pacing

CLs or VES coupling intervals, intramyocardial conduction delay can occur, resulting in prolongation in the VA interval; however, the local VA interval at the BT location remains unchanged. Furthermore, short ventricular pacing CLs or VES coupling intervals can encroach on the BT refractoriness, causing some decremental conduction, with a consequent increase in total and local VA intervals. The VA interval can also change with changing the site of ventricular stimulation, because the VA interval represents the sum of conduction time over the BT and conduction time through the ventricular tissue intervening between the site of stimulation and ventricular insertion site of the BT. BTs with retrograde decremental conduction properties can also exhibit prolongation of conduction time and VA interval with ventricular pacing or VES.

The absence of VA conduction (at long pacing CLs) or the presence of decremental VA conduction at baseline makes the presence of a retrogradely conducting BT unlikely, except for the rare catecholamine-dependent BTs that require isoproterenol infusion for demonstration.

Induction of Tachycardia

INITIATION BY ATRIAL EXTRASTIMULATION OR ATRIAL PACING

ORTHODROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA: MANIFEST ATRIOVENTRICULAR BYPASS TRACT. In the presence of a manifest AV BT, initiation of orthodromic AVRT with an AES requires the following: (1) anterograde block in the AV BT; (2) anterograde conduction over the AVN-HPS; and (3) slow

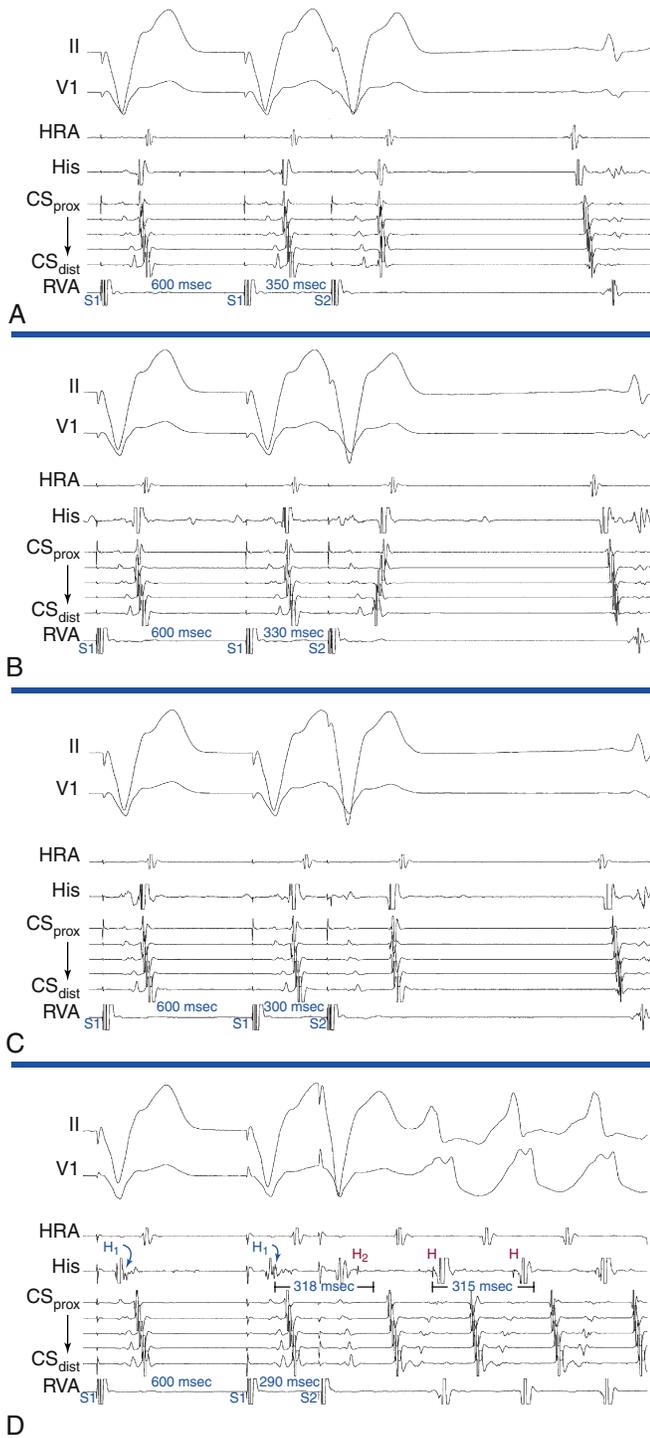

FIGURE 18-16 Retrograde conduction during ventricular extrastimulation (VES) in a patient with a bidirectional left lateral bypass tract (BT). **A**, The ventricular pacing drive is conducted retrogradely over the atrioventricular node (AVN) with a concentric atrial activation sequence. The VES is conducted over both the AVN and BT (atrial fusion). **B**, An earlier VES encounters delay in the His-Purkinje system (HPS)-AVN and conducts solely over the BT with an eccentric atrial activation sequence. **C**, An early-coupled VES blocks retrogradely in the BT and conducts solely over the AVN. **D**, The VES conducts only over the HPS-AVN with more pronounced ventriculoatrial (VA) delay, which allows recovery of the BT and anterograde conduction, initiating antidromic atrioventricular reentrant tachycardia (AVRT). The VA delay is provided by conduction delay, not only within the AVN but also within the HPS. Note that the VES encounters retrograde block in the right bundle branch (RB), and His bundle (HB) activation is mediated by retrograde conduction over the left bundle branch (LB). Consequently, the His potential is visible after the ventricular electrogram. Note that despite the fact that the H_1 - H_2 interval following VES approximates the H-H interval during supraventricular tachycardia (SVT), the His bundle-atrial (HA) interval following the initiating VES is shorter than that during the SVT, which favors antidromic AVRT over preexcited atrioventricular nodal reentrant tachycardia (AVNRT) as the mechanism of the SVT.

conduction over the AVN-HPS, with adequate delay to allow for the recovery of the atrium and AV BT and subsequent retrograde conduction over the BT (see Fig. 3-10).³ The reason this occurs is that, whereas the BT conducts more rapidly than the AVN, it has a longer ERP, so the early atrial impulse blocks anterogradely in the BT but conducts over the AVN. The site of AV delay is less important; it is most commonly in the AVN, but it can occur also in the HB, bundle branches, or ventricular myocardium. Because the coupling intervals of the AES required to achieve anterograde block in the BT are usually short, sufficient AVN delay is usually present so that orthodromic AVRT is initiated once anterograde BT block occurs. The presence of dual AVN physiology can facilitate the initiation of orthodromic AVRT by providing adequate AV delay by mediating anterograde conduction over the slow AVN pathway. BBB ipsilateral to the AV BT provides an additional AV delay that can facilitate tachycardia initiation.

Induction of orthodromic AVRT is easier with atrial stimulation at a site in close proximity to the AV BT insertion site; the closer the stimulation site to the BT, the easier it is to encroach on the refractory period of the BT and achieve block, because it is not limited by the refractoriness of intervening atrial tissue. Furthermore, the earlier the atrial insertion of the BT is activated, the more likely it will recover before arrival of the retrograde atrial activation wavefront to the BT atrial insertion site, thereby facilitating reentry. Thus, one may actually require less anterograde AV delay if recovery of excitability is shifted earlier in time. In addition, different sites of atrial stimulation can produce different AVN conduction velocities and refractoriness (even at the same AES coupling intervals).

If SVT induction fails, the use of multiple AESs, rapid atrial pacing, and pacing closer to the BT would achieve block in the BT and produce adequate AV delay.

AES can also result in a 1:2 response caused by conduction over both the AV BT and the AVN-HPS (i.e., a single AES resulting in two ventricular complexes; the first is fully preexcited and the second is normal). For this response to occur, significant delay in AVN-HPS conduction should be present to allow for recovery of the ventricle after its activation via the BT. AES can also produce sinus nodal or AVN echo beats that in turn may block in the BT and achieve adequate AV delay to initiate orthodromic AVRT.

ORTHODROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA: CONCEALED ATRIOVENTRICULAR BYPASS TRACT.

Orthodromic AVRT in patients with concealed BTs is identical to that in patients with WPW. The only difference is that in patients with concealed BTs anterograde block in the BT is already present. Consequently, the only condition needed to induce orthodromic AVRT is adequate AV delay (in the AVN or HPS) to allow for recovery of the atrium and atrial insertion site of the AV BT. Therefore, orthodromic AVRT initiation requires less premature coupling intervals of the AESs in patients with concealed BTs than in patients with WPW.

ORTHODROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA: SLOWLY CONDUCTING CONCEALED ATRIOVENTRICULAR BYPASS TRACT (PERMANENT JUNCTIONAL RECIPROCATING TACHYCARDIA).

PJRT is usually incessant and is initiated by spontaneous shortening of the sinus CL, without a triggering PAC or PVC. The tachycardia can be transiently terminated by PACs or PVCs but usually resumes after a few sinus beats (Fig. 18-19). This phenomenon has three potential mechanisms: a rate-related decrease in the retrograde ERP of the BT, a rate-related decrease in atrial refractoriness that allows the impulse to reactivate the atrium retrogradely over the BT, or a concealed Wenckebach block with block at the atrial-BT junction terminating the Wenckebach cycle, relieving any anterograde concealed conduction that may have prevented retrograde conduction up the BT. The latter is the most likely mechanism, because such slow BTs actually demonstrate decremental conduction at rapid rates and, in most cases, the atrial ERP at the atrial-BT junction is shorter than the RP (VA) interval. Thus, some sort of anterograde concealment during NSR in the BT must be operative, preventing tachycardia from always occurring.³ Late-coupled AESs can also readily initiate PJRT.

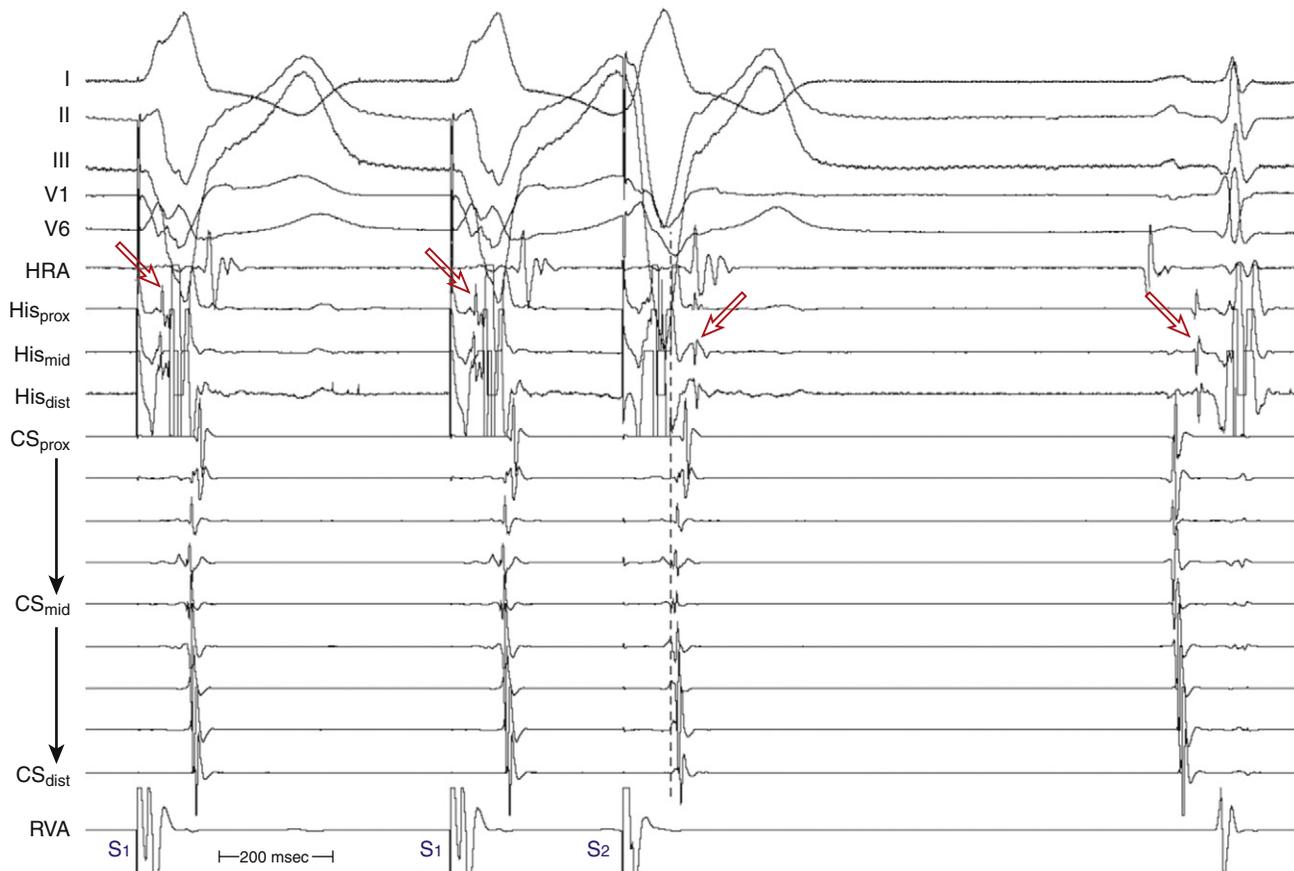

FIGURE 18-17 Ventricular pacing with a single ventricular extrastimulus (S_2) showing the presence of a bypass tract (BT). A retrograde His potential is present on both drive complexes (S_1) as well as following the extrastimulus (arrows); although atrial activation also follows each stimulus, it occurs (dashed line) before the inscription of the His potential on the extrastimulus complex. Thus, a BT is present because atrial activation is not dependent on His bundle–atrioventricular (HB–AVN) activation.

ANTIDROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA. The initiation of classic antidromic AVRT by an AES requires the following: (1) intact anterograde conduction over the BT; (2) anterograde block in the AVN or HPS; and (3) intact retrograde conduction over the HPS–AVN once the AVN resumes excitability following partial anterograde penetration (see Fig. 18-4). The latter is usually the limiting factor for the initiation of antidromic AVRT. A delay of more than 150 milliseconds between atrial insertion of the BT and HB is probably required for the initiation of antidromic AVRT.³

Several mechanisms of antidromic AVRT initiation can be operative.³ The AES may block in the AVN with anterograde conduction down the BT and subsequent retrograde conduction over the HPS–AVN. In this setting, ventricular–His bundle (V–H) delay is required to allow recovery of the AVN. Because antidromic AVRTs have relatively short VA intervals, this mechanism of initiation is probably uncommon, except with left-sided BTs, which would potentially provide sufficient V–H delay to allow retrograde conduction. Tachycardia initiation can be facilitated by a short retrograde AVN ERP, a common finding in patients with these SVTs. Alternatively, the AES may block in the AVN, with anterograde conduction down the BT and subsequent retrograde conduction over a different BT. Subsequent complexes can conduct retrogradely over the AVN–HPS or the second BT. Changing tachycardia CL (and VA interval) may relate to whether retrograde conduction proceeds over the AVN–HPS or the second BT. A third potential mechanism for the initiation of antidromic AVRT involves AES conduction over the BT and simultaneously over the slow pathway of a dual AVN pathway situation, with anterograde block in the fast AVN pathway. Conduction beyond the HB to the ventricle is not possible because of ventricular refractoriness, yet an AVN echo to the atrium may occur, which in turn may conduct anterogradely over the BT, when the ventricle

would have recovered excitability, and subsequently back up the now-recovered AVN, initiating antidromic AVRT. AVN reentry may not persist or may be preempted by retrograde conduction up the fast AVN pathway because of the premature ventricular activation over the BT. In this scenario, the location of the His potential will depend on whether or not it was anterograde or retrograde.

In general, if atrial stimulation induces antidromic AVRT, multiple BTs are often operative. Whether or not they are operative throughout the SVT depends on the relative retrograde activation times over the additional BTs and HPS–AVN and the varying degree of anterograde and/or retrograde concealment into the additional BTs, HPS–AVN, or both during the SVT.

The site of atrial stimulation plays an important role in inducibility of AVRT, and can also determine the type of AVRT initiated in patients with bidirectional BTs. The closer the stimulation site to the BT, the more likely anterograde block in the BT will occur and orthodromic AVRT will result. Conversely, antidromic AVRT is more likely to occur with atrial stimulation close to the AVN.

INITIATION BY VENTRICULAR EXTRASTIMULATION OR VENTRICULAR PACING

ORTHODROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA: MANIFEST OR CONCEALED ATRIOVENTRICULAR BYPASS TRACT. Ventricular stimulation is usually able to induce orthodromic AVRT (inducibility rate of 60% with VES and 80% with ventricular pacing), and is similar in patients with manifest or concealed BTs (Fig. 18-20). Initiation of orthodromic AVRT by ventricular stimulation requires the following: (1) retrograde block of the ventricular impulse in the HPS–AVN; (2) retrograde conduction only over the AV BT; and (3) adequate VA conduction delay to allow for recovery of the AVN–HPS from any concealment

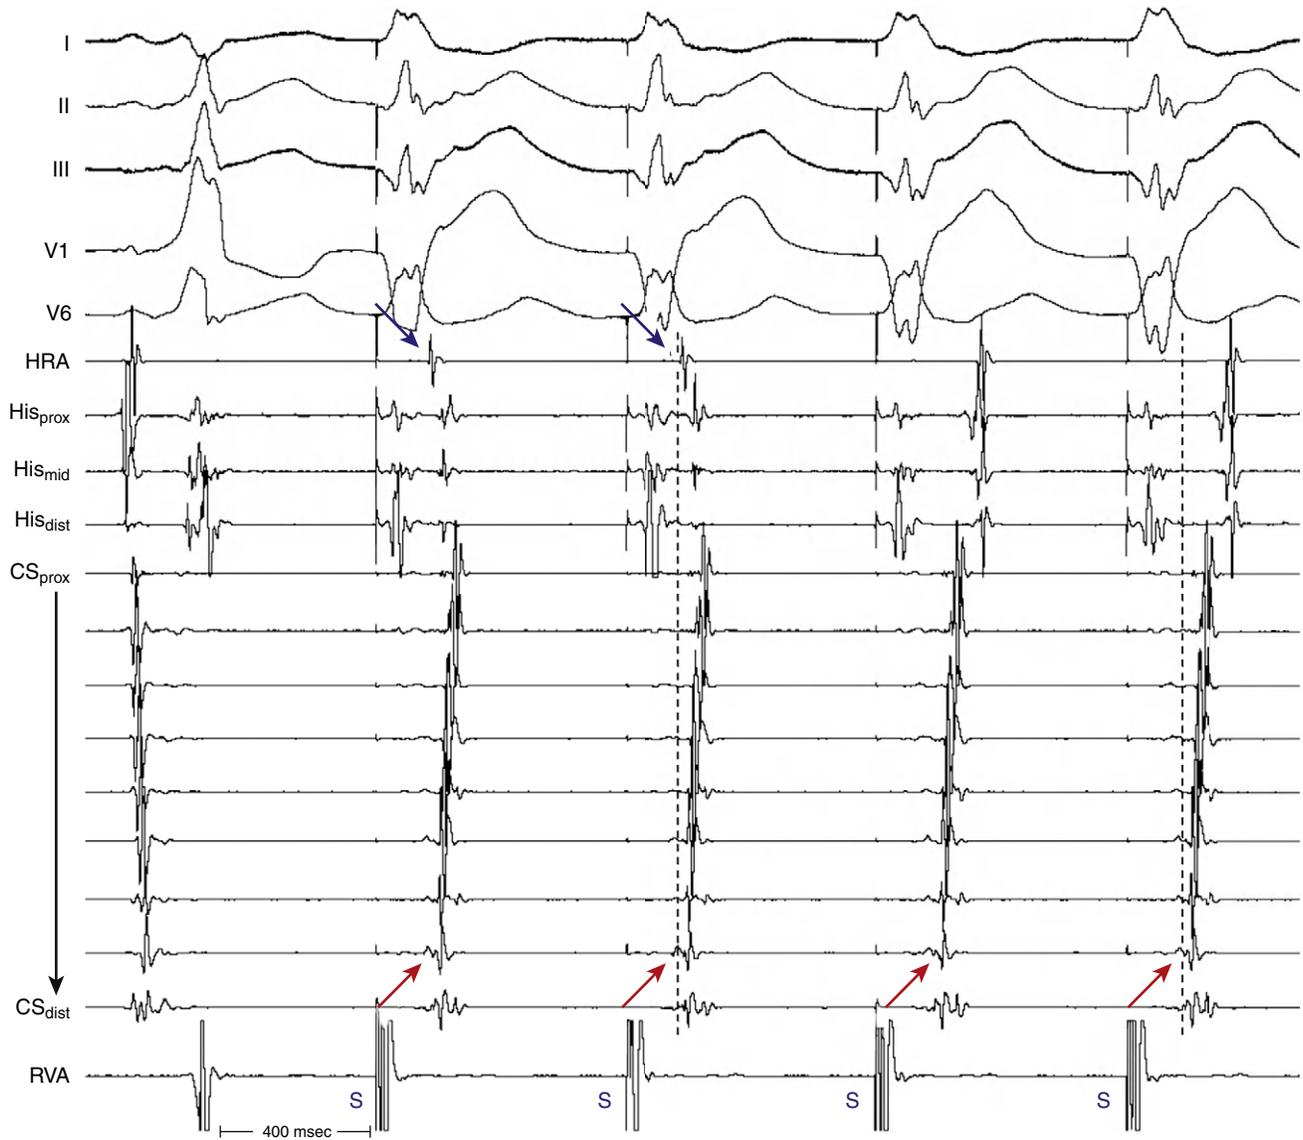

FIGURE 18-18 Surface ECG and intracardiac recordings in a patient with both right and left free wall bypass tracts (BTs). The first complex shows sinus rhythm with preexcitation, showing a left free wall pattern. Four complexes of right ventricular pacing follow, the first two of which show fusion of retrograde activation over both a left lateral BT (red arrows), which is present in each complex, as well as a right lateral BT (blue arrows) that is present in the first two paced complexes but fails to conduct on the last two complexes. Dashed lines aid in comparison of activation sequences.

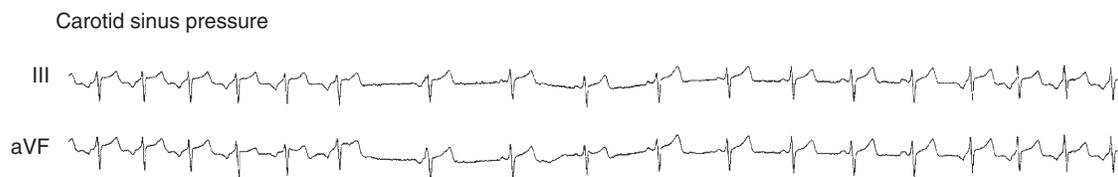

FIGURE 18-19 Two surface ECG leads are shown during permanent junctional reciprocating tachycardia. Carotid sinus pressure is applied at left, resulting in termination of supraventricular tachycardia (SVT) caused by block in the bypass tract (the SVT terminates with a QRS). Several escape and sinus complexes follow, and then the SVT resumes. This phenomenon gives rise to the use of the term *permanent* or *incessant*.

produced by ventricular stimulation, so it can support anterograde conduction of the reentrant impulse. Because the BT retrograde ERP is usually very short, the prime determinant of orthodromic AVRT initiation is the extent of retrograde conduction and/or concealment in the HPS-AVN.³

Multiple modes of initiation of orthodromic AVRT can be present, depending on the pacing CL or VES coupling interval, conduction velocities, and refractoriness of the HPS-AVN and BT, as well as the site of ventricular stimulation.³ Ventricular pacing at a CL or a VES

with a coupling interval shorter than the ERP of the AVN but longer than that of the HPS and AV BT would block retrogradely in the AVN and conduct over the AV BT to initiate orthodromic AVRT. Block in the AVN, which is more likely to occur with rapid ventricular pacing or VES delivered after a short pacing drive CL, can cause concealment and subsequent delay in anterograde conduction of the first SVT impulse over the AVN, resulting in longer AH and PR intervals of the first SVT beat compared with subsequent beats (see Fig. 18-20). On the other hand, a VES with a coupling interval or ventricular

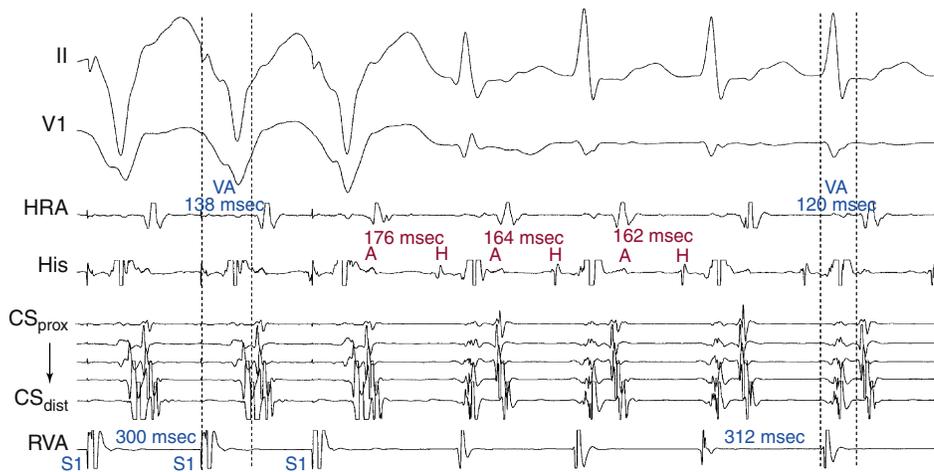

FIGURE 18-20 Induction of an orthodromic atrioventricular reentrant tachycardia (AVRT) using a concealed posteroseptal bypass tract with ventricular pacing. Note that although the ventricular pacing cycle length (CL) approximates the supraventricular tachycardia (SVT) CL, the ventriculoatrial (VA) interval (dashed lines) during ventricular pacing is only slightly longer than that during SVT, which favors orthodromic AVRT over atrioventricular nodal reentrant tachycardia (AVNRT) as the mechanism of the SVT. Additionally, the atrial–His bundle interval of the first SVT complex is longer than that of subsequent beats, indicating retrograde concealment in the AVN produced by the last ventricular stimulus.

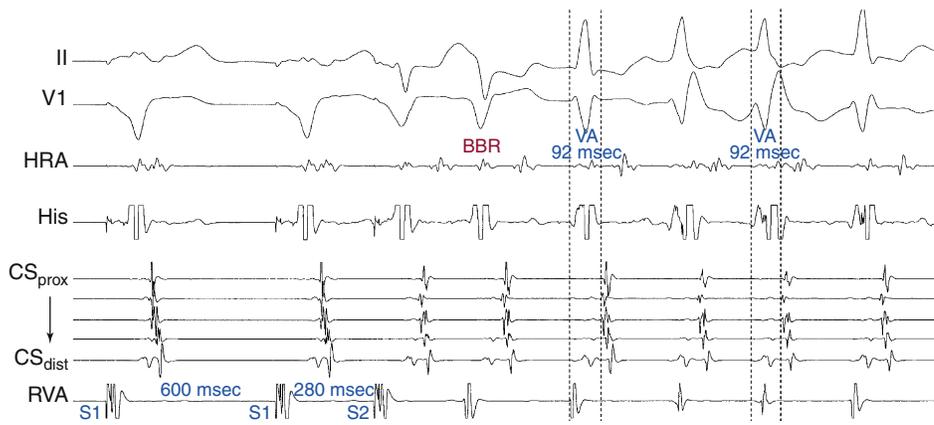

FIGURE 18-21 Induction of an orthodromic atrioventricular reentrant tachycardia (AVRT) using a concealed left posteroseptal bypass tract (BT) with ventricular extrastimulation (VES). The VES conducts retrogradely over the BT, but also results in a bundle branch reentrant (BBR) beat, which in turn conducts to the atrium over the BT and initiates orthodromic AVRT. Note that right bundle branch block (RBBB) develops shortly after initiation of the SVT; however, the ventriculoatrial (VA) interval (dashed lines) remains constant, regardless of the presence or absence of RBBB, because the BT is in the contralateral ventricle.

pacing at a CL shorter than the ERP of the HPS, but longer than that of the AV BT, would block retrogradely in the HPS and conduct over the AV BT to initiate orthodromic AVRT. When block occurs in the HPS, which is more likely to occur with a VES delivered during NSR or after a long pacing drive CL, the first SVT beat will approach a fully recovered AVN and conduct with short AH and PR intervals equal to subsequent SVT beats. In this case, adequate prolongation of the HV interval may be required to allow for the recovery of ventricular refractoriness for the ventricle to be activated and support reentry, because AVN delay may have not been sufficient. When HV interval prolongation is required to initiate orthodromic AVRT, it is almost invariably associated with LBBB. A short-coupled VES, especially following a pacing drive with a long CL, that blocks retrogradely in both the AV BT and RB and conducts transeptally and then retrogradely over the LB, can result in a bundle branch reentrant (BBR) beat that conducts to the ventricle down the RB, and then retrogradely to the atrium over the AV BT, mediating the initiation of orthodromic AVRT. The long HV interval often associated with BBR beats, plus the LBBB pattern, facilitate the induction of orthodromic AVRT using a left-sided BT (Fig. 18-21).

ORTHODROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA: SLOWLY CONDUCTING CONCEALED ATRIOVENTRICULAR BYPASS TRACT (PERMANENT JUNCTIONAL RECIPROCATING TACHYCARDIA). Ventricular stimulation is less effective in initiating PJRT because of the already impaired conduction in the BT, such that an early VES produces block in the BT. A late-coupled VES (when the HB is refractory) can initiate SVT in some cases.

ANTIDROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA. Initiation of classic antidromic AVRT by ventricular pacing and VES requires the following: (1) retrograde block in the BT; (2) retrograde conduction over the AVN or HPS; and (3)

adequate VA delay to allow for recovery of the atrium and BT so it can support subsequent anterograde conduction (see Fig. 18-16).³

When induction of the SVT is achieved by ventricular pacing at a CL similar to the tachycardia CL or by a VES that activates the HB at a coupling interval (i.e., H_1-H_2 interval) similar to the H-H interval during the SVT, the HA interval following the initiating ventricular stimulus is always equal to or shorter than that during the antidromic AVRT. This is because the His potential and atrium are activated in sequence during antidromic AVRT and in parallel during ventricular stimulation. Therefore, an HA interval of the initiating ventricular stimulus longer than the HA interval during SVT favors AVNRT and excludes antidromic AVRT (see Fig. 18-16). Moreover, because the AVN usually exhibits greater decremental conduction with repetitive engagement of impulses than to a single impulse at a similar coupling interval, the more prolonged the HA interval with the initiating ventricular stimulus, the more likely that the SVT is AVNRT.

Tachycardia Features

ORTHODROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA: MANIFEST OR CONCEALED ATRIOVENTRICULAR BYPASS TRACT

ATRIAL ACTIVATION SEQUENCE. The initial site of atrial activation during orthodromic AVRT depends on the location of the AV BT, but is always near the AV groove and without multiple breakthrough points. The atrial activation sequence during orthodromic AVRT should be identical to that during ventricular pacing at comparable CLs when VA conduction occurs exclusively over the AV BT. However, retrograde conduction during ventricular pacing may proceed over the AVN or over both the BT and AVN, resulting in fusion of atrial activation, depending on the site of

Spontaneous termination of orthodromic AVRT

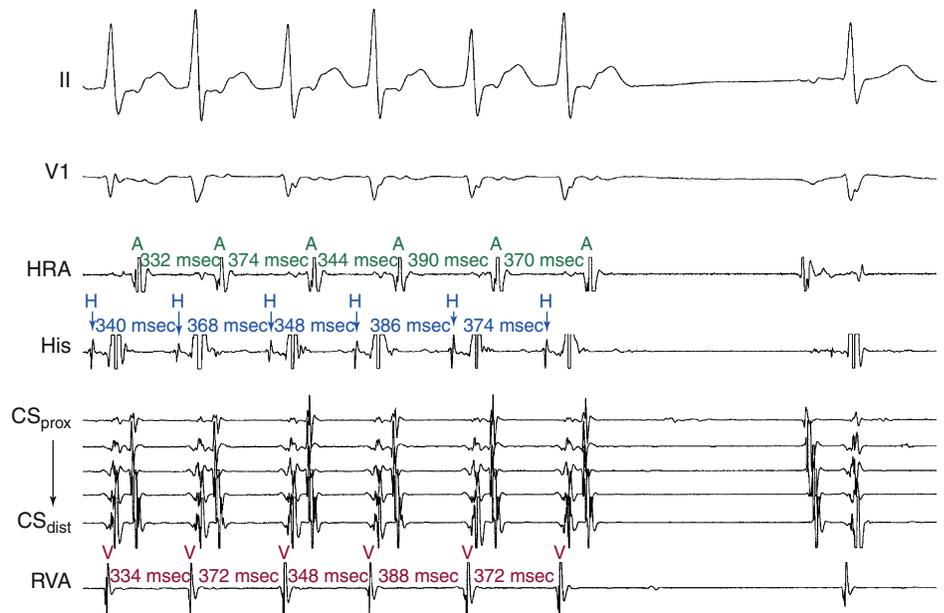

FIGURE 18-22 Spontaneous termination of orthodromic atrioventricular reentrant tachycardia (AVRT) using a concealed superoparaseptal bypass tract. Note that the supraventricular tachycardia (SVT) terminates with an atrial complex not followed by a QRS, consistent with anterograde block in the atrioventricular node (AVN). Also, note the oscillation in the SVT cycle length (CL) preceding termination. Changes in H-H and V-V intervals precede the subsequent changes in A-A intervals, and the ventriculoatrial (VA) interval remains constant despite oscillation of the CL. This indicates that the variability in the tachycardia CL is secondary to changes in the anterograde conduction over the AVN, whereas VA conduction over the retrograde limb of the reentrant circuit (the bypass tract) remains constant.

ventricular stimulation relative to the BT and HPS, and on retrograde conduction and refractoriness of the HPS-AVN.

ATRIAL-VENTRICULAR RELATIONSHIP. Conduction time over the classic (fast) BTs is approximately 30 to 120 milliseconds. Therefore, the RP interval during orthodromic AVRT is short, but longer than that during typical AVNRT, because in the setting of orthodromic AVRT the wavefront has to activate the ventricle before it reaches the AV BT ventricular insertion site at the AV groove and subsequently conduct to the atrium. Consequently, a very short VA interval (<70 milliseconds) or V-high RA interval (<95 milliseconds) largely excludes orthodromic AVRT, and is consistent with typical AVNRT.³³ The RP and VA intervals remain constant during orthodromic AVRT regardless of oscillations in tachycardia CL from whatever cause or changes in the PR interval (AH interval); as a consequence, the tachycardia CL is most closely associated with the PR interval (i.e., anterograde slow conduction) and the RP/PR ratio may vary (Fig. 18-22).

A 1:1 A-V relationship is a prerequisite for maintenance of AVRT, because parts of both the atrium and the ventricle are essential components of the reentrant circuit. If an SVT persists despite the presence of AV block, orthodromic AVRT is excluded.

When dual AVN pathways are present, the slow AVN pathway functions in most cases as the anterograde limb during orthodromic AVRT. An AH interval of more than 180 milliseconds during orthodromic AVRT suggests a slow AVN pathway mediating the anterograde limb of the reentrant circuit, whereas an AH interval of less than 160 milliseconds suggests a fast AVN pathway mediating anterograde conduction. Obviously, orthodromic AVRT using the slow pathway will have a longer tachycardia CL.

Slow-slow AVNRT is associated with an RP interval and P wave morphology similar to that during orthodromic AVRT using a posteroseptal AV BT. However, although both SVTs have the earliest atrial activation in the posteroseptal region, conduction time from that site to the HB region is significantly longer in AVNRT than in orthodromic AVRT, resulting in a significantly longer RP interval in lead V₁ and a larger difference in the RP interval between lead V₁ and the inferior leads. Therefore, a Δ RP interval (V₁ – III) longer than 20 milliseconds suggests slow-slow AVNRT with a sensitivity of 71%, specificity of 87%, and positive predictive value of 75%.

EFFECTS OF BUNDLE BRANCH BLOCK. The presence of BBB during SVT is much more common in orthodromic AVRT than AVNRT or AT (90% of SVTs with sustained LBBB are orthodromic AVRTs). Two reasons have been proposed to explain why prolonged aberration occurs less commonly during AVNRT than

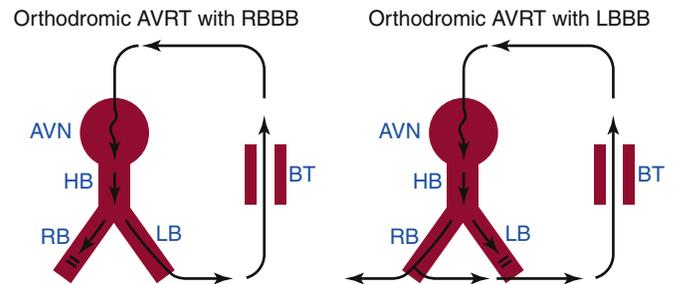

FIGURE 18-23 Schematic illustration of the effect of bundle branch block (BBB) on the reentrant circuit during orthodromic atrioventricular reentrant tachycardia (AVRT) using a left-sided bypass tract (BT). Block in the left bundle branch (LB) (ipsilateral to the BT) results in prolongation of the reentrant pathway and, therefore, prolongation of the ventriculoatrial interval. In contrast, block in the right bundle branch (RB) (contralateral to the BT) has no effect on the reentrant circuit. AVN = atrioventricular node; HB = His bundle; LBBB = left bundle branch block; RBBB = right bundle branch block.

orthodromic AVRT. First, the induction of AVNRT requires significant AVN delay, which makes the H₁-H₂ interval longer and makes aberration unlikely, whereas in orthodromic AVRT, AVN conduction need not be slow, resulting in a shorter AH interval and an impulse encroaching on HPS refractoriness, in turn resulting in BBB. Second, LBBB facilitates the induction of orthodromic AVRT when a left-sided AV BT is present.³⁴

BBB is more common when AVRT is initiated by an AES that is delivered during NSR or after long-drive CLs, whereby HPS refractoriness is longest and AVN conduction and refractoriness are shortest. When AVRT is induced by atrial stimulation, RBBB is more common than LBBB (2:1). In contrast, when AVRT is induced by ventricular stimulation, LBBB is much more common than RBBB (because of concealment in the LB). Additionally, the incidence of BBB is more common in AVRTs induced by ventricular stimulation than those induced by atrial stimulation (75% versus 50%).

BBB ipsilateral to the AV BT results in prolongation of the surface VA interval because more time is needed for the impulse to travel from the AVN down the HB and contralateral bundle branch, and transeptally to the ipsilateral ventricle to reach the AV BT and then activate the atrium (Fig. 18-23). However, the local VA interval (measured at the site of BT insertion) remains constant. On the other hand, the tachycardia CL usually increases in concordance with the increase in the surface VA interval as a result of ipsilateral BBB,

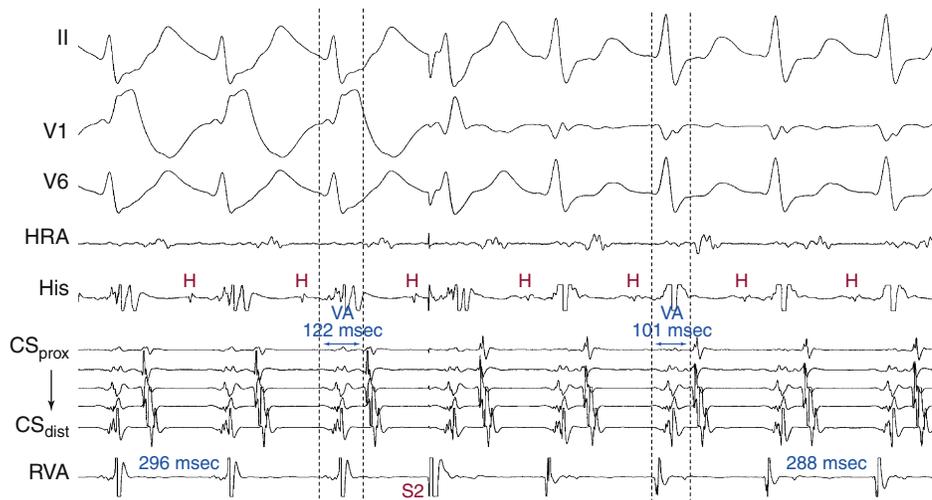

FIGURE 18-24 Effect of right bundle branch block (RBBB) on orthodromic atrioventricular reentrant tachycardia (AVRT). RBBB is initially present during an orthodromic AVRT using a concealed superoparaseptal bypass tract (BT). Introduction of a ventricular extrastimulus (S_2) from the right ventricular apex during the tachycardia is followed by resolution of RBBB (peeling of refractoriness). Note that the loss of RBBB is associated with shortening of the ventriculoatrial (VA) interval (by 21 milliseconds) and a milder degree of shortening of the tachycardia cycle length (by 8 milliseconds), indicating the presence and participation of a septal BT in the reentrant circuit.

because of the now larger tachycardia circuit; however, because the time the wavefront spends outside the AVN is now longer, AVN conduction may improve, resulting in shortening of the AH interval (PR interval), which can be sufficient to overcome the prolongation of the VA interval. This can consequently result in shortening of the tachycardia CL. Thus, the surface VA interval and not the tachycardia CL should be used to assess the effects of BBB on the SVT (Fig. 18-24; and see Fig. 18-23).

Prolongation of the surface VA interval during SVT in response to BBB by more than 35 milliseconds compared to that with normal QRS or contralateral BBB indicates that an ipsilateral free wall AV BT is present and is participating in the SVT (i.e., diagnostic of orthodromic AVRT). On the other hand, prolongation of the surface VA by more than 25 milliseconds suggests a septal AV BT (postero-septal AV BT in association with LBBB, and superoparaseptal AV BT in association with RBBB; see Fig. 18-24). In contrast, BBB contralateral to the AV BT does not influence the VA interval or tachycardia CL (because the contralateral ventricle is not part of the reentrant circuit; see Figs. 18-21 and 18-23). Prolongation of the VA interval by more than 45 milliseconds in response to RV pacing entraining the orthodromic AVRT is also diagnostic of a left-sided BT, whereby RV pacing results in effects analogous to those created by LBBB and, as a consequence, VA interval prolongation.

OSCILLATIONS IN THE TACHYCARDIA CYCLE LENGTH. Oscillation of the tachycardia CL during orthodromic AVRT can occur and generally is caused by changes in the anterograde conduction over the AVN (see Fig. 18-22). Because retrograde conduction through the BT is much less variable, the changes in ventricular CL that result from variability in the anterograde AVN conduction precede the subsequent changes in atrial CL, and changes in atrial CL do not predict changes in subsequent ventricular CL (similar to observations during typical AVNRT). Contrariwise, changes in atrial CL predict the changes in subsequent ventricular CL during atypical AVNRT and AT.³⁵

Additionally, orthodromic AVRT in the presence of dual AVN physiology can be associated with anterograde conduction alternating over the slow and fast AVN pathways, resulting in a regular irregularity of the tachycardia CL (alternating long and short cycles). Alternatively, the presence of dual AVN pathways can lead to two separate stable tachycardia CLs. In either setting, the RP interval during the SVT remains constant.

QRS ALTERNANS. Alternans of the QRS complex amplitude during relatively slow SVTs is almost always indicative of orthodromic AVRT (Fig. 18-25). On the other hand, although QRS alternans during fast SVTs is most commonly seen in orthodromic AVRT, it can also be seen with other types of SVTs.

TERMINATION AND RESPONSE TO PHYSIOLOGICAL AND PHARMACOLOGICAL MANEUVERS. Spontaneous termination of orthodromic AVRT is usually caused by gradual slowing

and then block in the AVN (see Fig. 18-22), sometimes causing initial oscillation in the tachycardia CL, with alternate complexes demonstrating a Wenckebach periodicity before block. However, termination with block in the AV BT without any perturbations of the tachycardia CL can occur during very rapid AVRT or following a sudden shortening of the tachycardia CL.

Carotid sinus massage can terminate orthodromic AVRT by gradual slowing and then block in the AVN. Adenosine, digoxin, calcium channel blockers, and beta blockers terminate orthodromic AVRT by block in the AVN; therefore, the SVT terminates with a P wave not followed by a QRS. Verapamil rarely produces block in the AV BT and, when it does, block is usually preceded by oscillation in the tachycardia CL produced by changes in AVN conduction, leading to long-short sequences. Class IA and IC antiarrhythmic agents can produce block in the AV BT with variable effect on the AVN-HPS. Amiodarone can terminate AVRT by block in the AVN, HPS, or AV BT. Sotalol affects the AVN with little or no effect on the AV BT.

ORTHODROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA: SLOWLY CONDUCTING CONCEALED ATRIOVENTRICULAR BYPASS TRACT (PERMANENT JUNCTIONAL RECIPROCATING TACHYCARDIA)

ATRIAL ACTIVATION SEQUENCE. The initial site of atrial activation is most often in the posteroseptal part of the triangle of Koch near the CS os, similar to that in atypical AVNRT (Fig. 18-26).

ATRIAL-VENTRICULAR RELATIONSHIP. Because the retrograde limb of the reentry circuit is the slow BT (which conducts more slowly than the AVN), the RP interval is longer than the PR interval, similar to atypical AVNRT (see Figs. 18-11 and 18-26). In contrast to the classic fast BTs, the RP interval during PJRT is not fixed, because the BT serving as the retrograde limb of the reentrant circuit has decremental properties. Similar to all types of AVRTs, a 1:1 A-V relationship is a prerequisite to sustenance of the tachycardia.

OSCILLATIONS IN THE TACHYCARDIA CYCLE LENGTH. The tachycardia rate typically fluctuates (100 to 220 beats/min) in response to autonomic tone and physical activity, and the rate changes result from modulation of the PR and RP intervals. The tachycardia CL is often just longer than the shortest CL at which the BT can conduct retrogradely.

EFFECTS OF BUNDLE BRANCH BLOCK. BBB affects PJRT in a manner analogous to that described for orthodromic AVRT.

TERMINATION AND RESPONSE TO PHYSIOLOGICAL AND PHARMACOLOGICAL MANEUVERS. Carotid sinus massage and AVN blockers (adenosine, digoxin, calcium channel blockers, and beta blockers) usually terminate PJRT by block in the AVN (two-thirds) or in the BT (one-third) (see Fig. 18-19). Although the mode of tachycardia termination by adenosine has

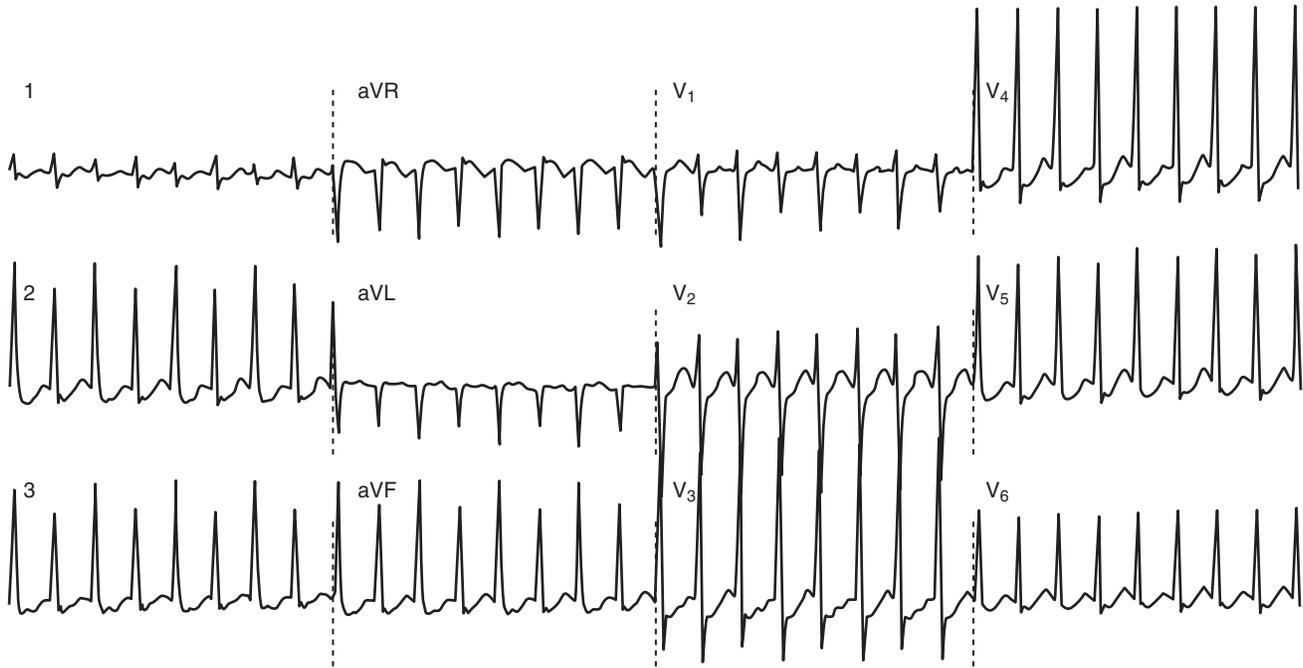

FIGURE 18-25 Surface 12-lead ECG of orthodromic atrioventricular reentrant tachycardia showing QRS alternans in multiple ECG leads.

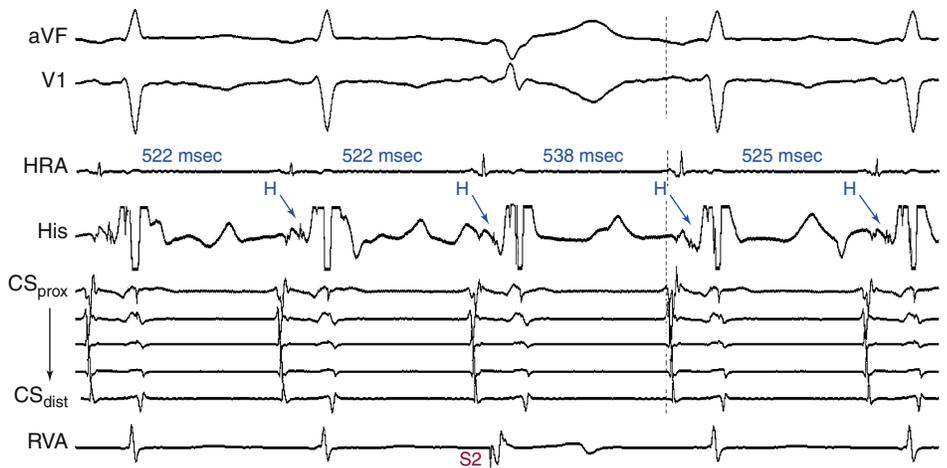

FIGURE 18-26 Ventricular extrastimulation (VES) during permanent junctional reciprocating tachycardia. The supraventricular tachycardia has a stable baseline cycle length (522 milliseconds). A single VES (S_2) introduced during His bundle refractoriness retards the timing of the next atrial complex (538 milliseconds) (postexcitation). The anticipated timing of the high RA electrogram is indicated by the dashed line.

been suggested to distinguish between PJRT and atypical AVNRT, one report has shown that termination of atypical AVNRT with adenosine can also result from block in the fast AVN pathway and therefore its value in distinguishing between atypical AVNRT and PJRT is questionable.

ANTIDROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA

ATRIAL ACTIVATION SEQUENCE. The initial site of atrial activation in classic antidromic AVRT is consistent with retrograde conduction over the AVN. If the antidromic AVRT is using a second BT for retrograde conduction, then the atrial activation sequence will depend on the location of that BT (see Fig. 18-3). Additionally, ventricular activation precedes HB activation during classic antidromic AVRT. Therefore, during preexcited SVT, a positive HV interval or a V-H interval not more than 10 milliseconds, especially when the HA interval is not more than 50 milliseconds, favors preexcited AVNRT over antidromic AVRT.

ATRIAL-VENTRICULAR RELATIONSHIP. Conduction time over classic (fast) BTs is approximately 30 to 120 milliseconds. Therefore, the PR is short and fixed, regardless of oscillations in

the tachycardia CL from whatever cause. Similar to all types of AVRT, the A/V ratio is always equal to 1. If the SVT persists in the presence of AV block, antidromic AVRT is excluded.

OSCILLATIONS IN THE TACHYCARDIA CYCLE LENGTH. Antidromic AVRT can be irregular. Tachycardia CL changes are usually caused by changes in retrograde conduction over different fascicles of the HPS with different VA intervals (regardless of the type and degree of changes in the V-H or HA intervals), retrograde conduction over dual AVN pathways (with different HA intervals), different routes of anterograde conduction (with different AV intervals), and/or retrograde conduction over different BTs (with different VA intervals). When the change in the tachycardia CL can be ascribed to a change in the V-H interval and/or the subsequent HA interval, it suggests that retrograde conduction occurs over the HPS and AVN and not over a second BT.

The tachycardia CL tends to be shorter during classic antidromic AVRT than orthodromic AVRT when these arrhythmias occur in the same patient. This may be explained by the fact that antidromic AVRT uses the fast AVN pathway (of a dual AVN physiology) retrogradely, whereas orthodromic AVRT uses the slow pathway anterogradely or, in the absence of dual AVN physiology, this may be merely supportive evidence that retrograde conduction during

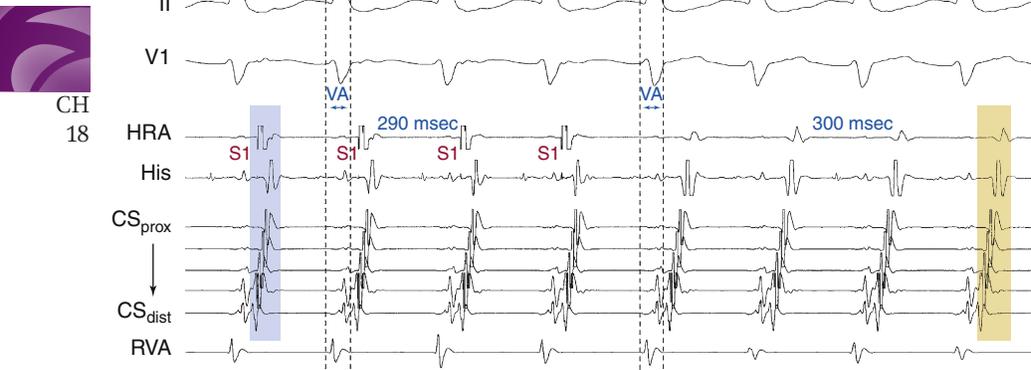

FIGURE 18-27 Atrial entrainment of orthodromic atrioventricular reentrant tachycardia (AVRT) using a left lateral bypass tract (BT). Atrial fusion (between the paced and tachycardia wavefronts; compare shaded areas) is observed during entrainment, which is consistent with AVRT and excludes both focal atrial tachycardia and atrioventricular nodal reentrant tachycardia. Note that the ventriculoatrial (VA) interval (dashed lines) of the return cycle after cessation of atrial pacing is similar to that of the supraventricular tachycardia (V-A linking), because retrograde VA conduction of the last entrained QRS is mediated by the BT.

antidromic AVRT uses another fast BT instead of the slower AVN. On the other hand, antidromic AVRTs using two or more BTs may have longer tachycardia CLs than orthodromic AVRT or classic antidromic AVRT because the two BTs are typically in opposite chambers and are incorporated in a larger reentrant circuit than one involving a midline AVN.³

EFFECTS OF BUNDLE BRANCH BLOCK. Retrograde BBB affects antidromic AVRT in a manner analogous to that described for orthodromic AVRT.

TERMINATION AND RESPONSE TO PHYSIOLOGICAL AND PHARMACOLOGICAL MANEUVERS. Various physiological and pharmacological maneuvers affect the AV BT and AVN during antidromic AVRT in a fashion similar to that described for orthodromic AVRT. Carotid sinus massage and adenosine terminate classic antidromic AVRT after ventricular activation, secondary to retrograde block up the AVN. In contrast, preexcited typical AVNRT terminates after atrial activation, secondary to anterograde block down the slow AVN pathway.

Termination or prolongation of the VA (and V-H) interval and tachycardia CL with transient RBBB, caused by mechanical trauma or introduction of VES, is diagnostic of antidromic AVRT using a right-sided or septal BT and excludes preexcited AVNRT. Continuation of an SVT at the same tachycardia CL, despite anterograde block in the BT (by drugs, mechanical trauma caused by catheter manipulation, or ablation), excludes antidromic AVRT.

Diagnostic Maneuvers during Tachycardia

ATRIAL EXTRASTIMULATION AND ATRIAL PACING DURING SUPRAVENTRICULAR TACHYCARDIA

ORTHODROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA. Atrial pacing at a CL slightly shorter than the tachycardia CL generally can entrain orthodromic AVRT (Fig. 18-27). If the P waves on the surface ECG can be seen, which usually is not the case, they may appear to be fusion beats resulting from intraatrial collision of the impulse propagating from the paced site with the one emerging from the BT. In general, when pacing is initiated orthodromically to the zone of slow conduction (the AVN in this case), conduction time within the area of slow conduction is long enough to allow a wide atrial antidromic wavefront to generate surface ECG fusion (see Fig. 18-27).

The initial atrial complex following cessation of atrial pacing entraining orthodromic AVRT is *linked* to, and cannot be dissociated from, the last captured ventricular complex. As a consequence, the VA intervals of the return cycle after cessation of atrial pacing are fixed and similar to those during tachycardia (with <10 milliseconds of variation) after different attempts at SVT entrainment (see Fig. 18-27). The post-pacing VA intervals typically remain constant regardless of the site, duration, or CL of the entraining atrial pacing drive because retrograde VA conduction of the last entrained QRS is mediated by the BT, which is fixed and constant. VA linking can also be observed in typical AVNRT but not AT.^{33,36}

It is difficult for AES not to affect the SVT because of the large size and large excitable gap of the reentrant circuit. However, this can be influenced by the distance between the site of atrial stimulation and the atrial region incorporated in the AVRT circuit (i.e., atrial myocardium between the BT and the AVN). Because only parts of the atrium ipsilateral to the BT are requisite components of the orthodromic AVRT circuit, AES delivered in the contralateral atrium may not affect the circuit, whereas AESs delivered at sites in close proximity to the BT or the AVN have the highest success at resetting the reentrant circuit.

AES over a wide range of coupling intervals can reset orthodromic AVRT via conduction down the AVN-HPS. In this setting, atrial activation is a fusion of the AES and the SVT impulse traveling retrogradely up the AV BT. The next QRS can be early or late, depending on the degree of slowing of conduction of the AES anterogradely down the AVN (i.e., the degree of prolongation of the A₂-H₂ interval).

An early-coupled AES can terminate the SVT, usually by block in the AVN-HPS. In this setting, the SVT terminates with an AES not followed by a QRS (i.e., AV block). Alternatively, the AES can render the atrium refractory to the SVT impulse traveling retrogradely up the AV BT, in which case the SVT terminates with an AES followed by a QRS (i.e., VA block). The AES can also anterogradely penetrate the AV BT and collide with the retrogradely traveling SVT wavefront (VA block). Lastly, the AES can conduct down the AVN-HPS and advance the next QRS, which then blocks in the still-refractory AV BT or atrium (VA block).

ANTIDROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA. AES is of value in distinguishing antidromic AVRT from preexcited AVNRT. A late-coupled AES, delivered close to the BT atrial insertion site during SVT when the AV junctional atrium is refractory (i.e., when the atrial electrogram is already manifest in the HB recording at the time of AES delivery) that advances (accelerates) the timing of both the next ventricular activation as well as the subsequent atrial activation, proves that the SVT is an antidromic AVRT using an AV BT anterogradely, and excludes preexcited AVNRT (Fig. 18-28A). Because the AV junctional atrium is refractory at the time of the AES, the AES cannot penetrate the AVN, and resetting of the SVT by such an AES is therefore incompatible with AVNRT.

Also, an AES delivered during the SVT that advances ventricular activation and does not influence the VA interval excludes preexcited AVNRT and is diagnostic of antidromic AVRT (see Fig. 18-28A). The VA interval should change in the setting of preexcited AVNRT because the AES penetrates the AVN, producing slower conduction down the AVN before resumption of the tachycardia, which, in the presence of a fixed AV interval (caused by conduction down the BT) in response to the AES, would lead to a longer VA interval. In addition, the advanced QRS could invade and capture the HB retrogradely and conduct up the fast AVN pathway and reset the AVN circuit. Then the V-H interval of the advanced QRS plus the HA interval in response to this QRS

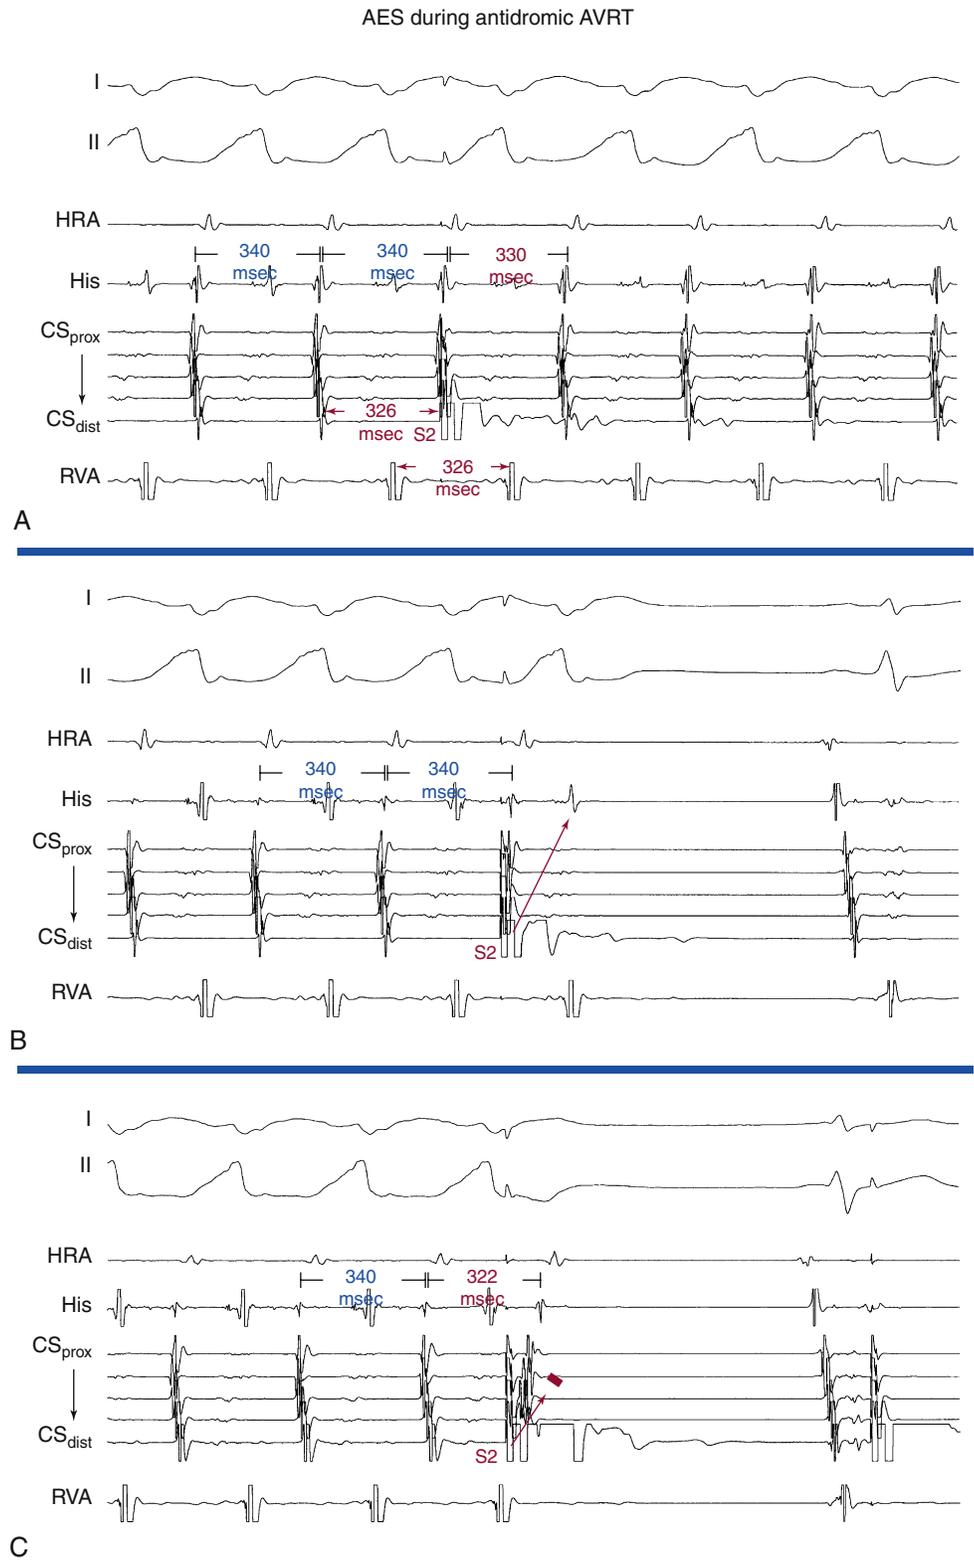

FIGURE 18-28 Atrial extrastimulation (AES) during antidromic atrioventricular reentrant tachycardia (AVRT) using a left lateral bypass tract (BT). **A**, A late-coupled AES delivered when the atrioventricular (AV) junction is refractory (as indicated by lack of advancement of the timing of the local atrial electrogram recording by the His bundle catheter) resets both the next ventricular activation and the subsequent atrial activation. This proves that the supraventricular tachycardia (SVT) is an antidromic AVRT using an AV BT anterogradely, and excludes preexcited atrioventricular nodal reentrant tachycardia (AVNRT). Additionally, the reset ventricular activation occurs at a coupling interval identical to the AES coupling interval (i.e., exact coupling phenomenon), and the ventriculoatrial (VA) interval following the AES remains similar to that during SVT, which is consistent with antidromic AVNRT. **B**, Late-coupled AES delivered when the AV junction is refractory advances the subsequent QRS and terminates the SVT by retrograde block in the His-Purkinje system–atrioventricular node. **C**, An earlier AES terminates the SVT without conduction to the ventricle (i.e., anterograde block in the BT). The AES advances the timing of AV junctional atrial activation.

should add up to the same VA interval on an undisturbed AVNRT, which is clearly unlikely.

Exact atrial and ventricular capture by an AES delivered when the AV junction is depolarized excludes AVNRT (see Fig. 18-28A). An AES that captures the ventricle at the same coupling interval as that of the AES indicates that the atrial stimulation site is inside the reentrant circuit, because if there were intervening atrial tissue between the stimulation site and the tachycardia circuit (as is the case during AVNRT), the AV interval would increase, and consequently, the V-V interval would exceed the AES coupling interval.³

The presence of a fixed and short VH interval during entrainment of the SVT with atrial pacing suggests antidromic AVRT, and makes AVNRT unlikely (but does not exclude AVNRT). Moreover, failure of entrainment by atrial pacing to influence the VA interval during SVT excludes preexcited AVNRT.

An early-coupled AES can terminate the SVT by retrograde block in the AVN-HPS (the SVT terminates with an AES followed by a QRS; i.e., VA block; Fig. 18-28B) or by anterograde block in the BT (the SVT terminates with an AES not followed by a QRS; i.e., AV block; Fig. 18-28C).

VENTRICULAR EXTRASTIMULATION AND VENTRICULAR PACING DURING SUPRAVENTRICULAR TACHYCARDIA

ORTHODROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA: MANIFEST OR CONCEALED ATRIOVENTRICULAR BYPASS TRACT.

VES and ventricular pacing can easily reset, entrain, and may terminate orthodromic AVRT (Fig. 18-29).³³ However, the ability of the VES to affect the SVT depends on the distance between the site of ventricular stimulation to the ventricular insertion site of the BT and on the VES coupling interval. Because only parts of the ventricle ipsilateral to the BT are requisite components of the orthodromic AVRT circuit, a VES delivered in the contralateral ventricle may not affect the circuit.

The preexcitation index analyzes the coupling interval of the VES (delivered from the RV) that resets orthodromic AVRT as a percentage of the tachycardia CL. A relative preexcitation index (the ratio of the coupling interval to the tachycardia CL) more than 90% of a VES that advances atrial activation during orthodromic AVRT suggests that the BT is close to the site of ventricular stimulation (i.e., RV or septal BT). An absolute preexcitation index (tachycardia CL minus VES coupling interval) of at least 75 milliseconds suggests a left free wall BT, an index of less than 45 milliseconds suggests a septal BT, and an index of 45 to 75 milliseconds is indeterminate.

RESETTING AND/OR ENTRAINMENT WITH MANIFEST VENTRICULAR FUSION. The relative proximity (conduction time) of the pacing site, the site of entrance to a reentrant circuit, and the site of exit from the circuit to the paced chamber is critical for the occurrence of fusion during resetting and/or entrainment. A requirement for the presence of fusion, independent of the pacing site, is spatial separation between the sites of entrance to and exit from the reentrant circuit. In orthodromic AVRT, the entrance and exit of the reentrant circuit (to and from ventricular tissue) are separated from each other, the entrance being from the HPS and the exit being at the ventricular insertion site of the BT. Therefore, pacing at a site closer to the BT ventricular insertion site (e.g., left ventricular [LV] pacing in the setting of left free wall BTs, and RV pacing in the setting of right-sided or septal BTs) than the entrance of the reentrant circuit to ventricular tissue (i.e., the HPS) would result in fusion of QRS morphology between baseline morphology during orthodromic AVRT and that of fully paced QRS (Fig. 18-30). Manifest ventricular fusion during entrainment is proof that the ventricle is a part of the SVT circuit because fusion is due to collision of the antidromic stimulated wavefront with the orthodromic wavefront from the preceding beat occurring within ventricular myocardium. On the other hand, such phenomena cannot occur during AVNRT because of the lack of spatial separation of the entrance and exit to the AVNRT circuit and because the ventricles are not an obligatory part of the AVNRT circuit.

ENTRAINMENT BY RIGHT VENTRICULAR APICAL PACING. This technique can help differentiate orthodromic AVRT with a right lateral or septal BT from AVNRT. The VA interval during ventricular pacing is compared with that during SVT. The ventricle and atrium are activated in sequence during orthodromic AVRT and during ventricular pacing, whereas during AVNRT the ventricle and atrium are activated in parallel. Therefore, the VA interval during orthodromic AVRT approximates that during ventricular pacing. On the other hand, the VA interval during AVNRT is much shorter than that during ventricular pacing (see Fig. 18-30). Therefore, a Δ VA interval (VA interval during ventricular pacing minus VA interval during SVT) of more than 85 milliseconds is consistent with AVNRT, whereas a Δ VA interval of less than 85 milliseconds is consistent with orthodromic AVRT. In addition, evaluation of the post-pacing interval (PPI) versus the tachycardia CL is of value. In AVNRT (typical or atypical), the PPI reflects conduction time from the RV pacing site through the RV muscle and HPS, once around the reentry circuit and back. Therefore, the [PPI – tachycardia CL] difference represents twice the sum of the conduction time through the RV muscle and HPS. In orthodromic AVRT using a septal BT, the PPI reflects the conduction time through the RV to the septum, once around the reentry circuit and back. Hence,

the PPI more closely approximates the tachycardia CL in orthodromic AVRT using a septal BT compared with AVNRT (see Fig. 18-30). Therefore, a [PPI – tachycardia CL] difference of more than 115 milliseconds is consistent with AVNRT, whereas a [PPI – tachycardia CL] difference of less than 115 milliseconds is consistent with orthodromic AVRT. For borderline values, ventricular pacing at the RV base can help exaggerate the difference between the PPI and tachycardia CL in the setting of AVNRT, but without significant changes in the setting of orthodromic AVRT, because the site of pacing at the RV base is farther from the AVNRT circuit than the RV apex, but is still close to an AVRT circuit using a septal BT (and in fact is closer to the ventricular insertion of the BT).³⁷

However, there are several potential pitfalls to the criteria discussed above. The tachycardia CL and VA interval are often perturbed for a few cycles after entrainment. For this reason, care should be taken not to measure unstable intervals immediately after ventricular pacing. In addition, spontaneous oscillations in the tachycardia CL and VA intervals can be seen. The discriminant points chosen may not apply when the spontaneous variability is greater than 30 milliseconds. Also, it is possible to mistake isorhythmic VA dissociation for entrainment if the pacing train is not long enough or the pacing CL is too close to the tachycardia CL. Furthermore, this test is less reliable and should be used with caution in patients with left lateral BTs. Additionally, these criteria may not apply to BTs with significant decremental properties, although small decremental intervals are unlikely to provide a false result.

A relatively common phenomenon encountered during entrainment of orthodromic AVRT by ventricular pacing is the prolongation of the AH interval because of either decremental conduction properties of the AVN or (in the presence of dual AVN physiology) a jump of anterograde conduction from the fast pathway to the slow pathway. The prolonged AH interval on the last entrained beat will contribute to prolongation of the PPI that is not reflective of the distance of the pacing site from the circuit. Thus, the [PPI – SVT CL] differences obtained after entrainment of orthodromic AVRT employing a septal BT can actually overlap with those observed after entrainment of AVNRT. Subtracting the increment in AVN conduction time in the first PPI (post-pacing AH interval minus pre-pacing AH interval) from the [PPI – SVT CL] difference (“corrected” [PPI – SVT CL]) has been found to improve the accuracy of this criterion. The difference between AV intervals (post-pacing AV interval minus pre-pacing AV interval) can be taken for the latter adjustment when a His deflection is not clearly visible (assuming the HV interval remains constant). In a study of patients with both typical and atypical forms of AVNRT, as well as orthodromic using septal and free wall BTs, a corrected [PPI – SVT CL] difference of less than 110 milliseconds was found more accurate in identifying orthodromic AVRT from AVNRT than the uncorrected [PPI – SVT CL] difference. The use of change in the VA interval is of course not influenced by prolongation of the AV interval during pacing and does not require correction.³⁸⁻⁴⁰

DIFFERENTIAL RIGHT VENTRICULAR ENTRAINMENT. As discussed in Chapter 17, differential-site RV entrainment (from RV apex versus RV base) can help distinguish AVNRT from orthodromic AVRT. In orthodromic AVRT, in which the ventricles are an obligatory part of the circuit, the basal pacing site relative to the RV apex is variably related to the circuit, being closer than the RV apex with septal BTs and equidistant with free wall BTs, but the paced wavefront from either RV apex or RV base tends to have, on average, approximately equal access and proximity (electrophysiologically) to the reentrant circuit involved in orthodromic AVRT and, therefore, the time taken to reach the circuit (and hence the PPI) tends to be similar, irrespective of the location of the BT. Conversely, the base of the RV is electrically more distant than the RV apex (where the His-Purkinje network directly inserts) from the AVNRT circuit. Hence, following ventricular entrainment of AVNRT, the difference in PPI from RV base versus RV apex will largely be composed of the extra time required to reach the circuit from the base versus the apex (approximately 30 milliseconds).

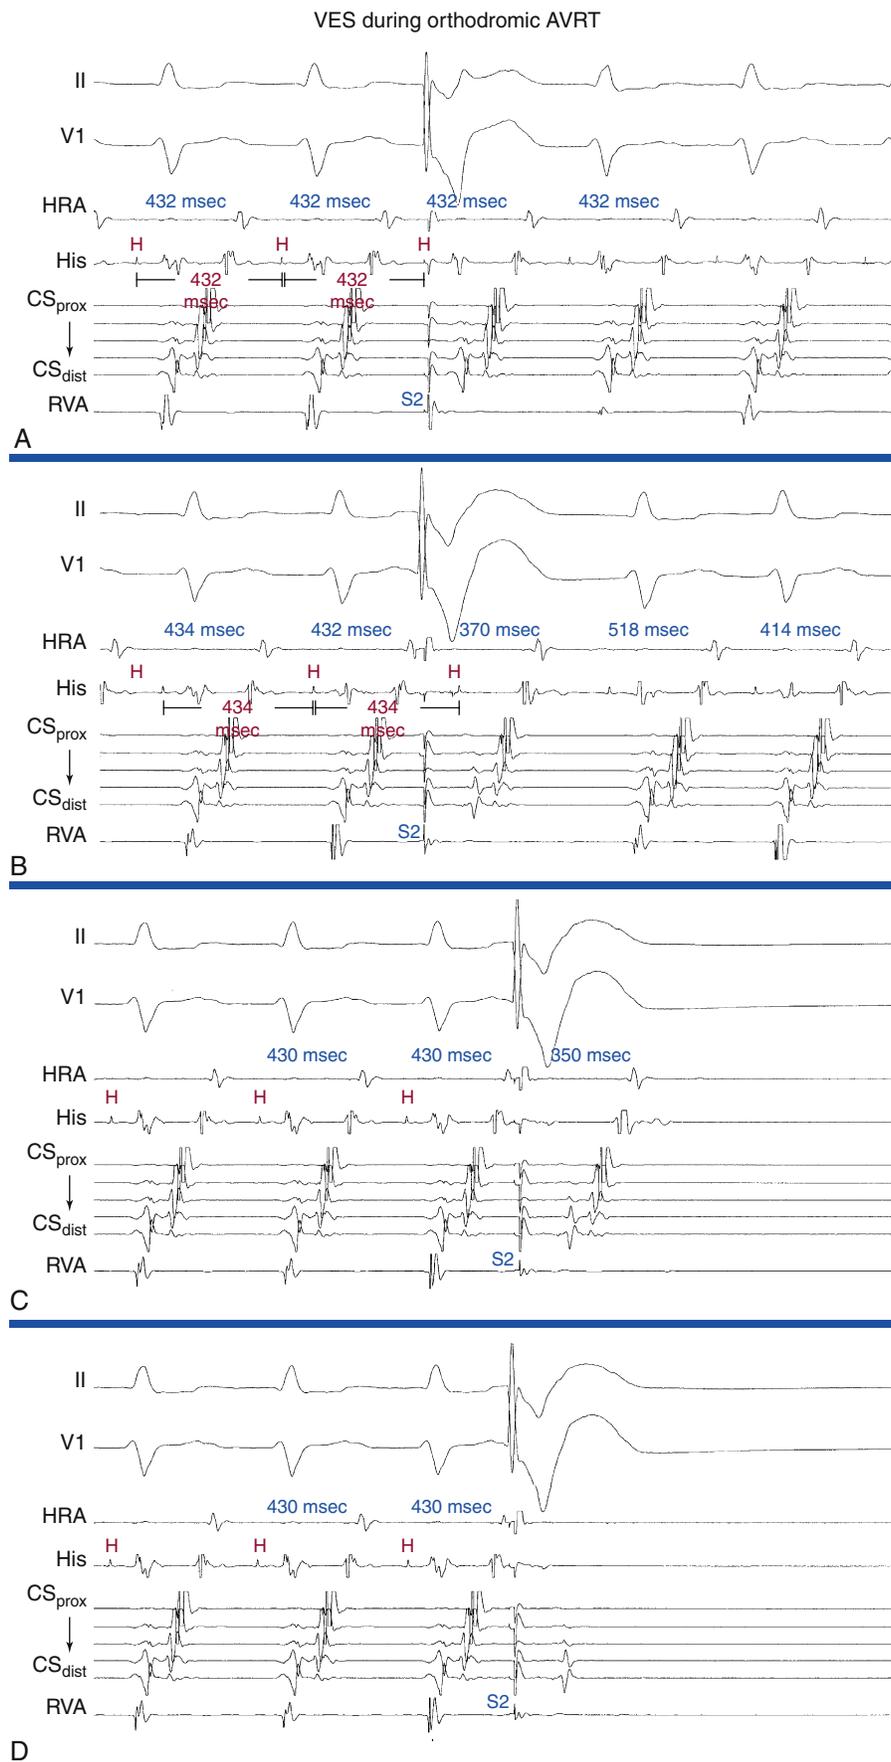

FIGURE 18-29 Ventricular extrastimulation (VES) during orthodromic atrioventricular reentrant tachycardia (AVRT) using a left lateral bypass tract (BT). **A**, A late-coupled VES delivered when the His bundle (HB) is refractory, as indicated by lack of advancement of the timing of the His potential, fails to reset the supraventricular tachycardia (SVT). **B**, An earlier VES fails to advance the timing of the HB but advances the subsequent atrial activation, indicating orthodromic AVRT and excluding atrioventricular nodal reentrant tachycardia (AVNRT). Note that the reset atrial impulse is followed by a prolonged atrial–His bundle (AH) interval caused by decremental anterograde conduction in the atrioventricular node (AVN). However, the local ventriculoatrial (VA) interval (retrograde BT conduction) remains constant. **C**, An earlier VES delivered before the HB is refractory resets the subsequent atrial activation and terminates the SVT by anterograde atrioventricular (AV) block in the AVN. **D**, A more premature VES terminates the SVT by retrograde VA block in the BT, excluding atrial tachycardia (AT), but can still occur in AVNRT because the VES is delivered before anterograde activation of the HB and could potentially penetrate the AVN.

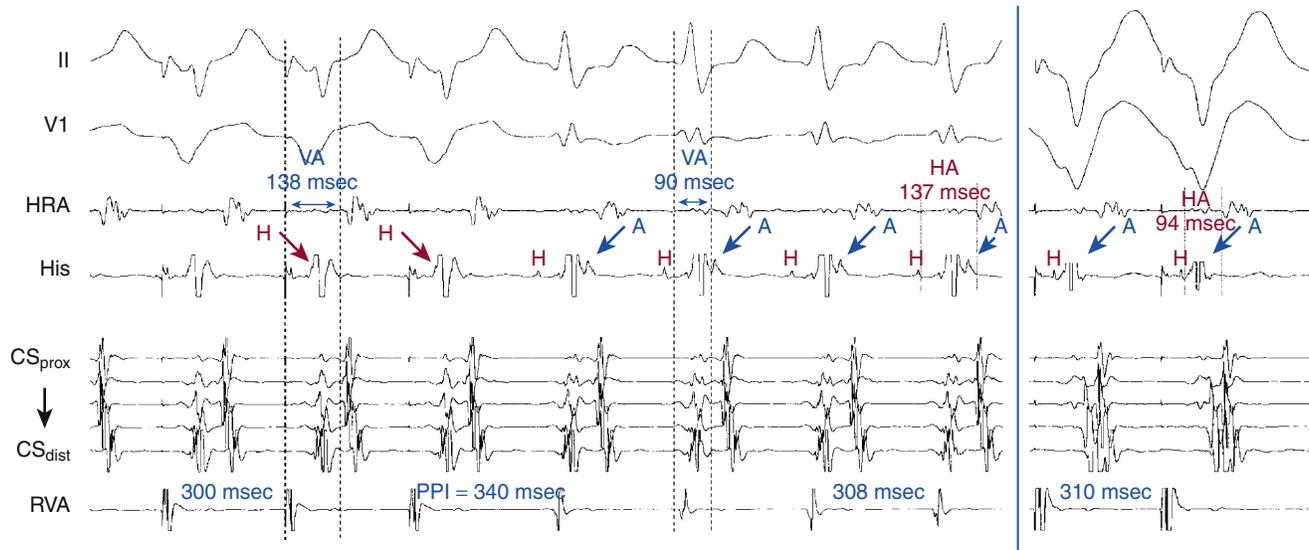

FIGURE 18-30 Ventricular entrainment of an orthodromic atrioventricular reentrant tachycardia (AVRT) using a concealed superoparaseptal bypass tract. Note that the Δ VA interval (ventriculoatrial interval during ventricular pacing minus VA interval during supraventricular tachycardia [SVT]) is less than 85 milliseconds and the post-pacing interval minus SVT cycle length [PPI – SVT CL] is less than 115 milliseconds, both of which favor orthodromic AVRT over atrioventricular nodal reentrant tachycardia (AVNRT). Additionally, ventricular fusion (between the paced and tachycardia wavefronts) is observed during entrainment (right, pure paced QRS morphology), which is consistent with AVRT and excludes AVNRT. Comparing the His bundle–atrial (HA) interval during the SVT (left) with that during ventricular pacing during normal sinus rhythm at the tachycardia CL (right) demonstrates that the Δ HA interval (HA interval during ventricular pacing minus HA interval during SVT) is -43 milliseconds, which favors orthodromic AVRT over AVNRT; the HA interval is measured from the end of the His potential to the atrial electrogram in the high RA.

Correction of the PPI (to avoid potential error introduced by decremental conduction within the AVN during ventricular pacing) increases the accuracy of this method. The “corrected PPI” is obtained by subtracting any increase in the AV interval of the return cycle beat (as compared with the AV interval during SVT). A differential corrected [PPI – SVT CL] difference of more than 30 milliseconds after transient entrainment was found to be consistent with AVNRT (i.e., corrected [PPI – SVT CL] difference following pacing from the RV base was consistently at least 30 milliseconds longer than that following pacing from the RV apex), and a corrected [PPI – SVT CL] difference of less than 30 milliseconds was observed in all cases of orthodromic AVRT. Additionally, a differential VA interval (ventricular stimulus-to-atrial interval during entrainment from RV base versus RV septum) of more than 20 milliseconds was consistent with AVNRT, whereas a differential VA interval of less than 20 milliseconds was consistent with orthodromic AVRT.⁴¹

LENGTH OF PACING DRIVE REQUIRED FOR ENTRAINMENT. As discussed in Chapter 17, assessing timing and type of response of SVT to RV pacing also can help differentiate orthodromic AVRT from AVNRT with high positive and negative predictive values. In the setting of orthodromic AVRT, once ventricular capture is achieved during RV pacing, the paced wavefront propagates to the ventricular insertion site of the BT quickly and resets the tachycardia. In the setting of AVNRT, on the other hand, where the pacing wavefront has to penetrate the HPS followed by AVN tissue prior to resetting the tachycardia, resetting of the tachycardia is delayed as compared with orthodromic AVRT. When resetting of the SVT occurs after a single paced beat orthodromic AVRT is suggested and AVNRT is generally excluded. On the contrary, if resetting occurs only after at least two beats AVNRT is suggested.⁴²

ATRIAL RESETTING DURING THE TRANSITION ZONE. Similar to the concept discussed earlier for entrainment with manifest QRS fusion, perturbation (at least 15 milliseconds) of atrial timing during “transition zone” on initiation of RV pacing (the zone during which the pacing train fuses with anterograde ventricular activation) indicates the presence of a retrogradely conducting BT,

and cannot occur in AT or AVNRT unless a bystander retrogradely conducting BT is present (see Chap. 17).⁴³

TERMINATION. Termination of orthodromic AVRT by VES can occur secondary to block of the VES retrogradely in the AV BT, conduction of the VES retrogradely over the AVN-HPS with or without conduction up the BT, or retrograde conduction of the VES up the BT and preexcitation of the atrium and subsequent anterograde block in the AVN-HPS (the most common mechanism) (see Fig. 18-29). Termination of SVT with a single VES strongly suggests orthodromic AVRT as the mechanism of SVT in three settings: when the VES is late-coupled (>80% of tachycardia CL), when the tachycardia CL is less than 300 milliseconds, and when the VES is delivered during HB refractoriness and is associated with no atrial activation.

MANEUVERS TO PROVE PRESENCE OF AN ATRIOVENTRICULAR BYPASS TRACT. When VES or ventricular pacing results in eccentric atrial activation sequence, the presence of a BT is strongly suggested. A VES delivered when the HB is refractory (i.e., when the His potential is already manifest or within 35 to 55 milliseconds before the time of the expected His potential) that advances (accelerates) the next atrial activation is diagnostic of the presence of a retrogradely conducting BT. Such a VES has to conduct and advance atrial activation via an AV BT because the HPS-AVN is already refractory and cannot mediate retrograde conduction of the VES to the atrium (see Fig. 18-29). Although such an observation excludes AVNRT, it does not exclude AT or prove orthodromic AVRT, and the preexcited atrial activation can reset or even terminate an AT, whereby the AV BT is an innocent bystander. However, if this VES advances atrial activation with an activation sequence identical to that during the SVT, this suggests that the SVT is orthodromic AVRT and the AV BT is participating in the SVT, although it does not exclude the rare case of an AT originating at a site close to the atrial insertion site of a bystander AV BT. Furthermore, a VES delivered when the HB is refractory may not affect the next atrial activation if the ventricular stimulation site is far from the BT. Conduction from the ventricular stimulation site to the BT, local ventricular refractoriness, and the tachycardia

CL all determine the ability of a VES to reach the reentrant circuit before ventricular activation over the normal AVN-HPS.³³

MANEUVERS TO PROVE PRESENCE AND PARTICIPATION OF ATRIOVENTRICULAR BYPASS TRACT IN THE SUPRAVENTRICULAR TACHYCARDIA. One maneuver is a VES delivered when the HB is refractory that delays the next atrial activation. Although such a VES can advance atrial activation during AT through fast retrograde conduction over a bystander BT, it should not be able to delay an AT beat by conduction over the AV BT. Such delay indicates that the VES was conducted with some delay over the AV BT and that the next atrial activation was dependent on this slower conduction; thus, the AV BT is participating in the SVT, proving orthodromic AVRT as the mechanism of the tachycardia. Similarly, a VES delivered when the HB is refractory that terminates the SVT without atrial activation is diagnostic of AVRT. Furthermore, entrainment of the SVT by ventricular pacing that results in prolongation in the surface VA interval indicates that the SVT is orthodromic AVRT mediated by an AV BT in the ventricle contralateral to the site of ventricular pacing; this is analogous to the influence of ipsilateral BBB on the VA interval during orthodromic AVRT (see Fig. 18-30). Exact and paradoxical capture phenomena are also diagnostic of AVRT. VES that captures the atrium at the same coupling interval as that of the VES (exact capture phenomenon) indicates that the ventricular stimulation site is inside the reentrant circuit, because if there were intervening tissue involved, the VA interval would increase and, subsequently, the A-A interval would exceed the VES coupling interval. Similarly, a VES that captures the atrium at a shorter coupling interval than that of the VES (paradoxical capture phenomenon) indicates that the ventricular stimulation site is not only inside the reentrant circuit but also closer to the ventricular insertion site of the AV BT than the initial site of ventricular activation over the AVN-HPS during the SVT, so that the VA interval following the VES is shorter than that during the SVT. This is easier to demonstrate with RV apical pacing during orthodromic AVRT mediated by a right-sided BT.³

ORTHODROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA: SLOWLY CONDUCTING CONCEALED ATRIOVENTRICULAR BYPASS TRACT (PERMANENT JUNCTIONAL RECIPROCATING TACHYCARDIA). A VES delivered during PJRT can produce decremental conduction in the BT and prolongation of the VA interval, resulting in possible delay of the next atrial activation (i.e., postexcitation or delay of excitation; see Fig. 18-26). Such a response excludes AT, and when this occurs in response to a VES delivered when the HB is refractory, it is diagnostic of orthodromic AVRT, and excludes both AT and AVNRT. Additionally, a late-coupled VES introduced when the HB is refractory frequently blocks retrogradely in the BT and reproducibly terminates the tachycardia without reaching the atrium, again excluding both AT and AVNRT.

The ability to preexcite the atrium with a VES introduced when the HB is refractory is difficult to demonstrate in PJRT because of the long conduction time over the BT, the decremental conduction properties of the BT, and the fact that the tachycardia CL is just longer than the shortest length at which the BT is capable of retrograde conduction. This can be facilitated by introduction of the PVC at a site closer to the BT ventricular insertion.

ANTIDROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA. Failure of entrainment by ventricular pacing to influence the surface VA interval during SVT excludes AVNRT. In addition, when a VES introduced during the SVT results in retrograde RBBB (i.e., blocks retrogradely in the RB), such RBBB will not change the timing of the next atrial activation in the setting of AVNRT. However, in antidromic AVRT using a right-sided BT, such RBBB will increase the size of the reentrant circuit, because the impulse cannot reach the HB through the RB and has to travel transeptally and then retrogradely over the LB. This results in prolongation in the VA interval and delay in the timing of the next atrial activation. The increment in the VA interval is caused by prolongation of the V-H interval and, if RBBB persists, the SVT will have a long V-H interval.

Antidromic AVRT usually can be terminated by ventricular pacing. Termination occurs by retrograde invasion and concealment in the BT, resulting in anterograde block over the BT following conduction to the atrium through the AVN.

Diagnostic Maneuvers during Normal Sinus Rhythm after Tachycardia Termination

ATRIAL PACING AT THE TACHYCARDIA CYCLE LENGTH

Under comparable autonomic tone, 1:1 AV conduction over the AVN should be maintained during atrial pacing at a CL similar to the tachycardia CL. If AV block develops during atrial pacing, AT and orthodromic AVRT are less likely, and AVNRT is the likely mechanism of the SVT. Additionally, the PR and AH intervals during atrial pacing at a CL similar to the tachycardia CL should be comparable to those during orthodromic AVRT. These findings are also observed in the setting of AT. In contrast, the AH and PR intervals during atrial pacing would be longer than those during tachycardia in the setting of AVNRT, assuming the slow pathway has been engaged.

VENTRICULAR PACING AT THE TACHYCARDIA CYCLE LENGTH

Under comparable autonomic tone status, 1:1 VA conduction over the AVN should be maintained during ventricular pacing at a CL similar to the tachycardia CL. If VA block develops during ventricular pacing, orthodromic AVRT is unlikely, and AT and AVNRT are favored.

It is important to recognize that the atrial activation sequence during ventricular pacing can be mediated by retrograde conduction over the BT, over the AVN, or a fusion of both, and consequently it can be similar to or different from that during orthodromic AVRT.

Ventricular pacing during NSR at a CL similar to the tachycardia results in HA and VA intervals that are shorter than those during orthodromic AVRT, because the HB and atrium are activated sequentially during orthodromic AVRT but in parallel during ventricular pacing (see Fig. 18-30). To help distinguish between orthodromic AVRT and AVNRT, the HA interval is measured from the *end* of the His potential (where the impulse leaves the HB to enter the AVN) to the atrial electrogram in the high RA recording and the Δ HA interval (HA interval during ventricular pacing minus HA interval during SVT) is calculated. In the setting of orthodromic AVRT the Δ HA interval is typically less than -10 milliseconds. In contrast, in the setting of AVNRT the Δ HA interval is more than -10 milliseconds. This criterion has 100% specificity and sensitivity and positive predictive accuracy for differentiation between AVNRT and orthodromic AVRT. The main limitation of the Δ HA interval criterion is the ability to record the retrograde His potential during ventricular pacing. Retrograde His potential generally appears before the local ventricular electrogram in the HB tracing, and can be verified by the introduction of a VES that causes the His potential to occur after the local ventricular electrogram. Moreover, pacing from different sites (e.g., midseptum) may allow earlier penetration into the HPS and facilitate observation of a retrograde His potential. When the retrograde His potential is not visualized, using the Δ VA interval instead of the Δ HA interval is not as accurate in discriminating orthodromic AVRT from AVNRT. Another limitation is that VA conduction during ventricular pacing may not occur over the BT but propagates preferentially over the HPS-AVN, leading to earlier atrial activation over this pathway than over the BT. If this were the case, the HA interval during ventricular pacing would be shorter than that observed if the atrium were activated via the BT. This would yield a more negative Δ HA interval.

PARA-HISIAN PACING DURING NORMAL SINUS RHYTHM

TECHNIQUE. Ideally, two quadripolar catheters (one for pacing and one for recording) or a single octapolar catheter (for both

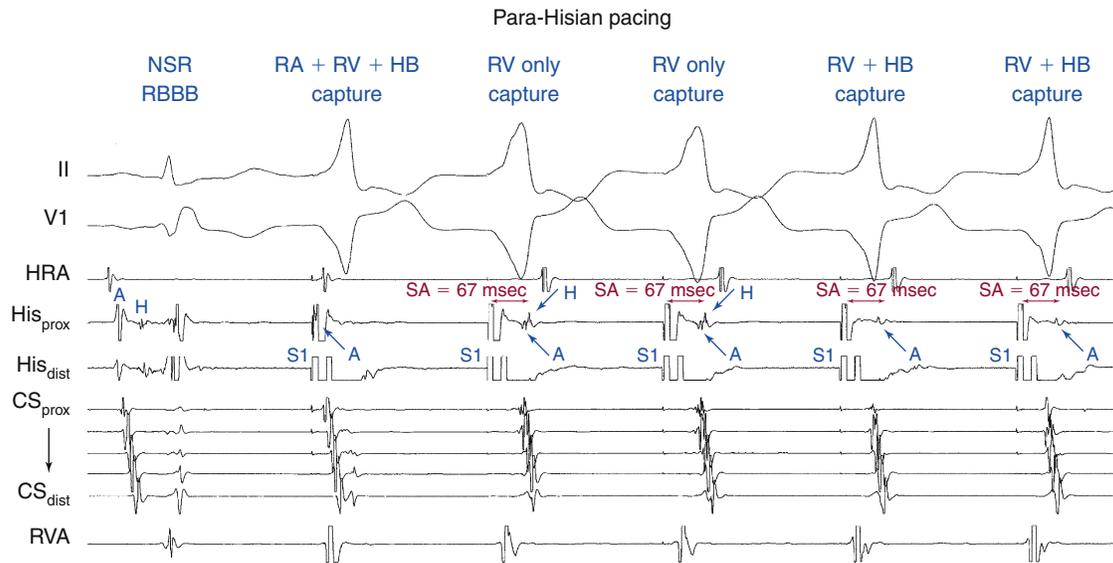

FIGURE 18-31 Para-Hisian pacing in a patient with concealed midseptal bypass tract and right bundle branch block (RBBB). The first complex is a sinus beat with RBBB. The second complex shows capture of the atrium, ventricle, and His bundle–right bundle branch (HB–RB). Atrial capture is indicated by immediate inscription of atrial electrogram following the pacing artifact. It is important to identify this occurrence to avoid erroneous interpretation of the results of para-Hisian pacing. The third and fourth complexes show right ventricle (RV)–only capture, and the last two complexes show RV and HB–RB capture but without atrial capture. Note that the atrial activation sequence and stimulus–atrial (SA) intervals remain unchanged, regardless of whether HB–RB capture occurs, because retrograde ventriculoatrial (VA) conduction occurs over the bypass tract in either case. During RV-only capture, the HB activation occurs after atrial activation, indicating that VA conduction is independent of the atrioventricular node (AVN). Note that para-Hisian pacing could be performed successfully even in the presence of RBBB if capture of the HB–RB is achieved proximal to the site of block. NSR = normal sinus rhythm.

pacing and recording) is placed at the distal His bundle–right bundle branch (HB–RB) region. Alternatively, a single quadripolar HB catheter (which is typically used during a diagnostic EP study) is used, taking into account that such an approach would limit the ability to record the retrograde His potential and HA interval.⁴⁴

Overdrive ventricular pacing is performed (from the pair of electrodes on the HB catheter that records activation of the distal HB–RB) at a long pacing CL (>500 milliseconds) and high output. During pacing, direct HB–RB capture is indicated by narrowing of the paced QRS width. The pacing output and pulse width are then decreased until the paced QRS widens, which is associated with a delay in the timing of the retrograde HB potential, indicating loss of HB–RB capture. The pacing output is increased and decreased to gain and lose HB–RB capture, respectively, while local ventricular capture is maintained. Occasionally, the HB can be captured uniquely (without myocardial capture), resulting in a QRS identical to the patient’s normally conducted QRS.⁴⁴

CONCEPT OF PARA-HISIAN PACING. The para-Hisian pacing site is unique because it is anatomically close but electrically distant from the HB. Para-Hisian pacing at high output simultaneously captures the HB or proximal RB, as well as the adjacent ventricular myocardium. At lower output, direct HB–RB capture is lost and retrograde activation of the HB is delayed because the HB and RB are insulated from the adjacent myocardium and the peripheral inputs to the Purkinje system are located far from the para-Hisian pacing site. By maintaining local ventricular capture while intermittently losing HB–RB capture, retrograde VA conduction can be classified as dependent on the timing of local ventricular activation (BT), HB activation (AVN), or both (fusion).

Para-Hisian pacing can result in capture of the ventricle (indicated by a wide paced QRS), the atrium (indicated by atrial activation in the HB region immediately following the pacing artifact), the HB (indicated by narrow paced QRS), or any combination of these (Fig. 18-31).⁴⁴ Careful attention must be given to minimize the atrial signal seen on the recording from the pacing electrode pair to ensure that local atrial capture does not occur during pacing.

RESPONSE TO PARA-HISIAN PACING. When the ventricle and HB are captured simultaneously, the wavefront activates the ventricles over the HPS and results in a relatively narrow QRS. The

wavefront can also travel retrogradely over the AVN to activate the atrium with an S–A interval (i.e., the interval from the pacing stimulus to the atrial electrogram) that represents conduction time over the proximal part of the HB and AVN (i.e., S–A interval = HA interval) because the onset of ventricular activation occurs simultaneously to that of HB activation (i.e., S–H interval = 0).

When the ventricle is captured but not the atrium or HB, the wavefront activates the ventricles by muscle-to-muscle conduction, resulting in a wide QRS with LBBB morphology caused by pacing in the RV. Once the wavefront reaches the RV apex, it conducts retrogradely up the RB and then over the HB and AVN to activate the atrium. In this setting, the S–A interval represents the conduction time from the RV base to the HB (S–H interval) plus the conduction time over the HB and AVN (HA interval). Thus, normally (in the absence of a retrogradely conducting BT), para-Hisian pacing results in a shorter S–A interval when the HB (or HB plus RV) is captured than the S–A interval when only the ventricle is captured (because of the delayed conduction of the impulse to the HB [i.e., S–H interval] when only the RV is captured).

In the presence of a septal AV BT, the S–A interval usually remains fixed regardless of whether or not the HB is being captured, because in both situations the paced impulse travels retrogradely over the AV BT, with constant conduction time to the atrium as long as local ventricular myocardium is being captured. Atrial activation in this setting can be secondary to activation over the BT, especially when only the ventricle is captured, or a result of fusion of conduction over both the AV BT and AVN, especially when both the ventricle and the HB are captured. Nevertheless, because VA conduction time over the BT is faster than that over the AVN, the timing of the earliest atrial activation remains constant (i.e., the S–A and local VA intervals), regardless of whether or not HB–RB capture occurs and regardless of whether or not atrial activation occurs exclusively over the AV BT or as a fusion of conduction over both the AV BT and AVN.

Seven patterns of response to para-Hisian pacing can be observed (Table 18-3 and Fig. 18-32; and see Fig. 18-31). In patients with retrogradely conducting AV BTs, in whom retrograde conduction occurs over both the AVN and BT during para-Hisian pacing, the amount of atria activated by each of the two pathways (atrial

TABLE 18-3 Response Patterns to Para-Hisian Pacing**Pattern 1 (AVN/AVN Pattern)**

- Retrograde conduction occurs exclusively over the AVN regardless of whether the HB-RB is captured.
- Loss of HB-RB capture results in an increase in the S-A interval in all electrograms equal to the increase in the S-H interval, with no change in the atrial activation sequence. The HA interval remains essentially the same.
- This response indicates that retrograde conduction is dependent on HB activation and not on local ventricular activation.
- This pattern is observed in all patients with AVNRT and is not observed in any patient with a septal or right free wall BT. However, this pattern can be observed in some patients with a left free wall BT or PJRT, in which case retrograde AVN conduction masks the presence of retrograde BT conduction.

Pattern 2 (BT-BT Pattern)

- Retrograde conduction occurs exclusively over a single BT.
- The S-A interval is identical during HB-RB capture and noncapture, indicating that retrograde conduction is dependent on local ventricular activation and not on HB activation.
- This pattern does not exclude the presence of retrograde conduction over the AVN with longer conduction time or a second BT with longer conduction time or located far from the pacing site.

Pattern 3 (BT-BT_L Pattern)

- Retrograde conduction occurs exclusively over a BT.
- Loss of HB-RB capture is associated with a delay in the timing of ventricular activation close to the BT. This results in an increase in the S-A interval in all electrograms, with no change in the atrial activation sequence. The local VA interval, recorded close to the BT, remains approximately the same. The increase in S-A interval is less than the increase in the S-H interval. Therefore, the HA interval is shortened with loss of HB-RB capture, indicating that retrograde conduction cannot be occurring over the AVN. Two mechanisms have been identified accounting for the delay in timing of ventricular activation close to the BT.
- Activation of the HPS results in earlier ventricular activation near some BTs located far from the para-Hisian pacing site, such as left lateral or anterolateral BTs.
- Decreasing the pacing output to lose HB-RB capture occasionally results in a small delay in ventricular activation close to the pacing site.
- Pattern 3 is referred to as the BT-BT_L pattern, where BT_L refers to a lengthening of the S-A interval with loss of HB-RB capture.

Pattern 4 (AVN-BT Pattern)

- Loss of HB-RB capture is associated with atrial activation exclusively over the BT.
- Loss of HB-RB capture results in an increase in S-A and local VA intervals in all electrograms, with the least increase occurring in the electrogram closest to the BT.
- The HA interval shortens, indicating that the atrium near the AVN is activated by the BT before retrograde conduction over the AVN is complete.

Pattern 5 (AVN-Fusion Pattern)

- Loss of HB-RB capture results in activation of part of the atria by the AVN and part by the BT.
- Loss of HB-RB capture is associated with an increase in S-A and local VA intervals in all electrograms.
- The HA interval remains constant, indicating that part of the atria was still activated by the AVN.

Pattern 6 (Fusion-BT Pattern)

- Loss of HB-RB capture results in atrial activation exclusively over the BT.
- Loss of HB-RB capture is associated with no change in the S-A or local VA intervals recorded near the BT.
- In the HB electrogram, the S-A interval increases, but not as much as the S-H interval, leading to a decrease in the HA interval. This indicates that the atrial myocardium in that region is no longer activated by the AVN.

Pattern 7 (Fusion-Fusion Pattern)

- The atria continue to be activated by both the AVN and the BT during loss of HB-RB capture, with more of the atria activated by the BT than during HB-RB capture.
- Like pattern 6, loss of HB-RB capture is associated with minimal change in the S-A or local VA intervals recorded close to the BT; however, the HA interval remains essentially the same, indicating that part of the atria is still activated by the AVN.

AVN = atrioventricular node; AVNRT = atrioventricular nodal reentrant tachycardia; BT = bypass tract; HA = His bundle–atrial; HB-RB = His bundle–right bundle branch; HPS = His-Purkinje system; PJRT = permanent junctional reciprocating tachycardia; S-A = stimulus–atrial; S-H = stimulus–His bundle; VA = ventriculoatrial.

fusion) is dependent on four variables: (1) the magnitude of delay in retrograde activation of the HB (i.e., S-H interval); (2) retrograde conduction time over the AVN (HA interval); (3) intraventricular conduction time from the para-Hisian pacing site to the ventricular end of the BT (S-V_{BT}); and (4) retrograde conduction time over the BT (V-A_{BT}). The first two variables (S-H plus HA) form the S-A interval resulting from retrograde VA conduction over the AVN, and the latter two variables (S-V_{BT} plus V-A_{BT}) form the S-A interval resulting from retrograde VA conduction over the BT. The amount of the atria activated by the AVN is greater during HB-RB capture, secondary to a minimal S-H interval (i.e., S-A interval = HA interval). Loss of HB-RB capture results in prolongation of the S-H interval and, therefore, an increase in the amount of atria activated by the BT, resulting in a change in the retrograde atrial activation sequence. Consequently, a change in the retrograde atrial activation sequence with loss of HB-RB capture always indicates the presence of retrograde conduction over both the BT and AVN. There are four such patterns (patterns 4 through 7). In patterns 4 and 5, HB-RB capture is associated with activation of the atria exclusively by retrograde conduction over the AVN. In patterns 6 and 7, HB-RB capture results in atrial activation over both the AVN and the BT.⁴⁴

INTERPRETATION OF RESULTS OF PARA-HISIAN PACING. The response to para-Hisian pacing can be determined by comparing the following four variables between HB-RB capture and noncapture while maintaining local ventricular capture and no atrial capture: (1) atrial activation sequence, (2) S-A interval, (3) local VA interval, and (4) HA interval (see Figs. 18-31 and 18-32).

The S-A interval is defined as the interval between the pacing stimulus and atrial electrogram. It should be recorded at multiple sites, including close to the site of earliest atrial activation during SVT.

The local VA interval is defined as the local ventricular to atrial electrogram interval in the electrode position with the earliest retrograde atrial activation time. For the local VA to be relied on, it actually has to be measured at the site of earliest atrial activation (this requires positioning a catheter at the site of earliest atrial activation recorded during SVT). The high RA catheter, for example, may not be satisfactory for evaluation of the local VA interval in the presence of a septal BT.

The HA interval is recorded in the HB electrogram; however, this measurement can be obtained only if two catheters are placed

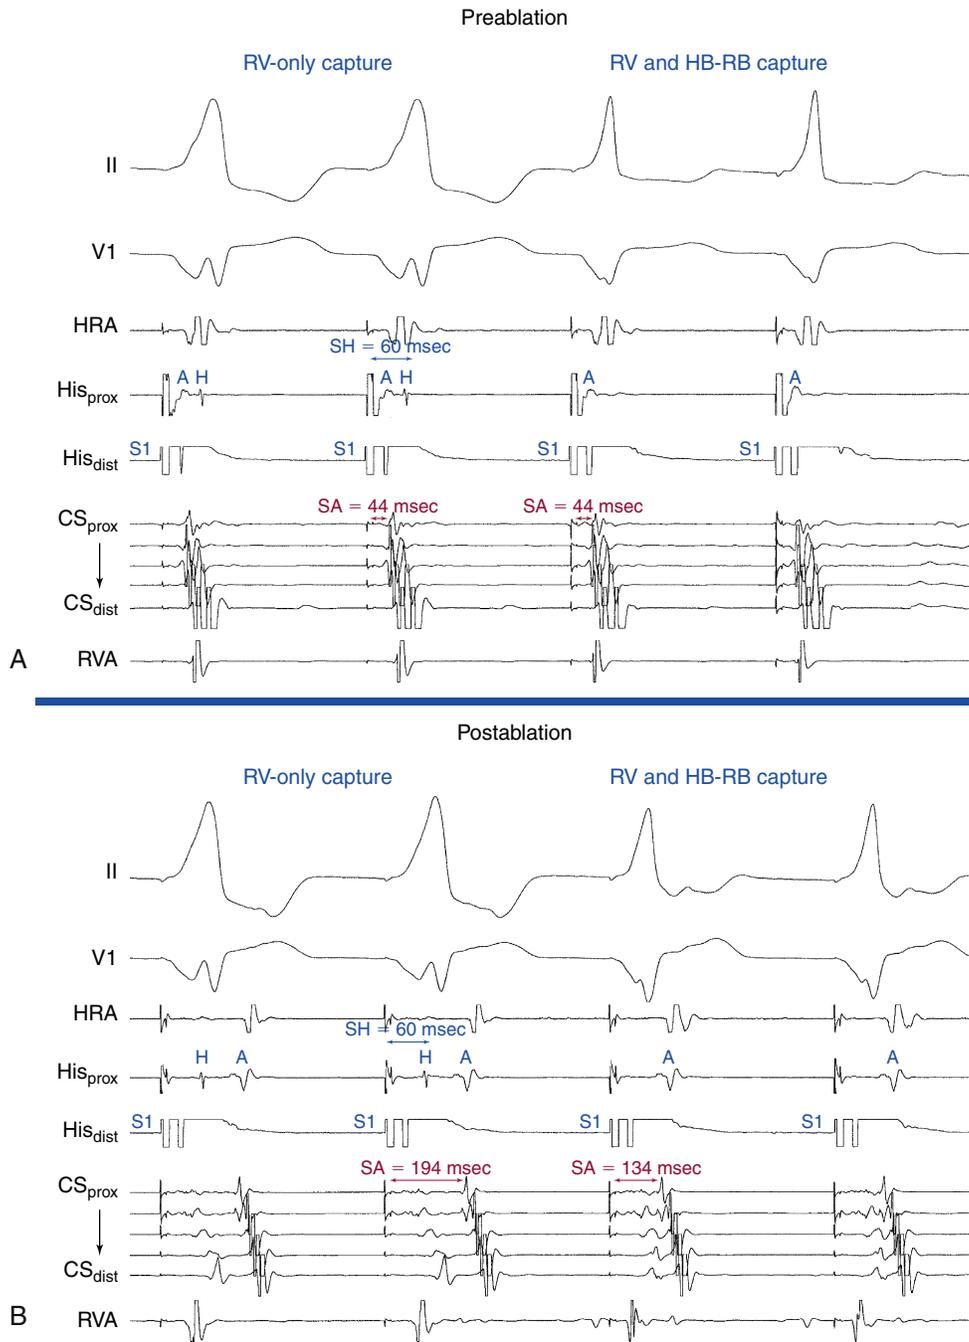

FIGURE 18-32 Para-Hisian pacing in a patient with a concealed superoparaseptal bypass tract (BT). In each panel, the first two complexes show right ventricle (RV)-only capture, and the last two complexes show RV and His bundle–right bundle branch (HB-RB) capture. The loss of HB-RB capture is identified by delay in the HB activation (S-H interval = 60 milliseconds) and widening of the QRS. The His potential is not visible during HB-RB capture. **A**, Para-Hisian pacing is performed before ablation of the BT, and the S-A interval remains unchanged regardless of whether HB-RB capture occurs, because retrograde ventriculoatrial (VA) conduction occurs over the BT in either case. In fact, during RV-only capture, the S-A interval is shorter than the S-H interval, indicating that VA conduction is independent of the atrioventricular node (AVN). **B**, Para-Hisian pacing is performed after successful ablation of the BT; the S-A interval is longer than before ablation, and it prolongs further on loss of HB-RB capture, concomitant with delay in HB activation (i.e., prolongation in the S-H interval) and a constant HA interval, indicating that VA conduction is mediated only by the AVN. Note that the activation sequence before ablation (VA conduction occurring over the BT) is slightly different from after ablation (VA conduction occurring over the AVN). However, in each case, the atrial activation sequence occurs over the same pathway and remains constant, regardless of whether HB-RB occurs.

in the HB position (one for pacing and one for recording) or if an octapolar catheter is used for pacing and sensing around the HB. The use of a single quadripolar HB catheter, which is typically used during a diagnostic EP study, negates the ability to record the retrograde His potential and HA interval during pacing. However, the combination of the S-A and local VA intervals is sufficient to identify the presence of retrograde BT.

If the S-A (and local VA) interval at any site remains fixed, regardless of whether or not HB-RB capture occurs, while the HA interval shortens, retrograde conduction is occurring only over an AV BT. In this setting, the HA interval shortens on loss of HB-RB capture because the HB and atrium are activated in parallel and HB activation is delayed because of prolongation of the S-H interval, while atrial activation timing remains unchanged because it results from retrograde conduction over the AV BT and is independent of timing of HB activation. On the other hand, if the S-A (and local VA) interval increases in all electrograms (including the electrode recording the earliest atrial activation) coincident with loss of

HB-RB capture, while the HA interval remains essentially the same, retrograde conduction is occurring only over the AVN.

An identical retrograde atrial activation sequence during HB-RB capture and noncapture indicates that retrograde conduction is occurring over the same system (either the BT or AVN) and does not help prove or exclude the presence of a BT (especially a septal BT; see Fig. 18-32). A change in retrograde atrial activation sequence with loss of HB-RB capture, however, indicates the presence of retrograde conduction over both a BT and the AVN. Morphological change in the atrial electrogram recorded at the AV junction without overlapping the ventricular electrogram also seems to have diagnostic significance, indicating the presence of both BT and AVN conduction.

LIMITATIONS OF PARA-HISIAN PACING. The location of the BT, as well as retrograde conduction time over the BT, must be taken into account when interpreting the results of para-Hisian pacing. For superoparaseptal BTs, the S-V_{BT} interval is short. For BTs located progressively farther from the para-Hisian pacing site,

the $S-V_{BT}$ increases progressively. This is not a significant factor for midseptal, posteroseptal, or most right free wall BTs. However, for left free wall BTs, which are located far from the pacing site, the $S-V_{BT}$ interval can be sufficiently long to have the entire atria activated by the AVN, even during loss of HB-RB capture. In this setting, para-Hisian pacing can produce an AVN retrograde conduction pattern, regardless of whether or not the HB-RB is captured (pattern 1: AVN-AVN), failing to identify the presence of retrograde BT conduction (because of the long $S-V_{BT}$). However, a left lateral BT should not be a diagnostic challenge because of the obvious eccentric retrograde atrial activation sequence during orthodromic AVRT, and para-Hisian pacing is performed mainly to investigate the presence of a septal BT. Additionally, for BTs located far from the para-Hisian pacing site, it is important to record atrial activation close to the suspected site of the BT. Otherwise, without recording electrograms near the BT, the change in atrial activation sequence may not be identified, incorrectly suggesting that retrograde conduction is occurring over just the AVN. This is most likely to occur in patients with short retrograde AVN conduction (short HA interval) and a BT located far from the pacing site.

Para-Hisian pacing may fail to identify retrograde conduction over a slowly conducting BT (e.g., PJRT) because of the long $V-A_{BT}$ interval. Performing para-Hisian entrainment or resetting during SVT can help in these situations (see later). Additionally, although para-Hisian pacing during NSR can help prove the presence of an AV BT, it does not show whether that BT is operative during the SVT.

In patients with very proximal retrograde RBBB, RB capture may fail to produce early retrograde activation of the HB, limiting the use of para-Hisian pacing in these patients. This observation suggests that HB-RB capture actually represents capture of the proximal RB and not HB capture. This is supported by the observation that, during HB-RB capture, the HB potential is often recorded 10 to 20 milliseconds after the pacing stimulus. Importantly, para-Hisian pacing has been performed successfully in many patients with more distal RBBB (see Fig. 18-31).

Assurance of lack of atrial capture by the pacing stimulus is important to interpret the results of para-Hisian pacing. Atrial capture is indicated by a very short S-A interval in the electrodes just proximal to the pacing electrodes. It is sometimes helpful to withdraw the para-Hisian pacing catheter until atrial capture alone is seen; if the S-A interval in the presence of ventricular capture is not longer than this, atrial capture was also present and the test should be repeated at a more distal pacing site.

PARA-HISIAN PACING DURING SUPRAVENTRICULAR TACHYCARDIA (PARA-HISIAN ENTRAINMENT OR RESETTING)

TECHNIQUE. Entrainment of the tachycardia is performed by pacing at the para-Hisian region using the HB catheter, as described previously, at a pacing CL 10 to 30 milliseconds shorter than the tachycardia CL. Entrainment is confirmed when the atrial CL accelerates to the pacing CL, without a change in the atrial activation sequence, and the tachycardia continues after pacing is discontinued.⁴⁵

Para-Hisian entrainment is performed by alternately pacing at high-energy output for HB-RB capture or lower energy output for HB-RB noncapture. Entrainment with HB-RB capture is recorded separately from that without HB-RB capture. The S-A and local VA intervals during HB-RB capture and noncapture are then examined.⁴⁵

One must be cautious about performing the para-Hisian entrainment maneuver by simply decreasing the pacing energy output during the same run to achieve HB-RB noncapture. That is, even though the SVT may have been entrained during HB-RB capture, on loss of HB-RB capture, the initial paced complexes typically do not entrain the SVT. This initial failure of entrainment occurs because of the sudden increase in the distance from the pacing site to the actual reentrant circuit. During HB-RB capture of AVNRT,

the pacing site is near the circuit (the HB-RB); however, the pacing site (the basal RV myocardium) is well outside the circuit during HB-RB noncapture. This limitation would not apply if HB-RB noncapture is performed *prior* to HB-RB capture. That is, if the pacing output is increased while the SVT is being entrained during HB-RB noncapture, the circuit almost certainly will be entrained on HB-RB capture (unless the SVT terminates).

If para-Hisian entrainment cannot be performed because of repetitive termination of the tachycardia during entrainment attempts, isoproterenol infusion may be used to help sustain the rhythm. Alternatively, single or double VESs can be given to reset the tachycardia (para-Hisian resetting). These VESs are delivered at progressively shorter coupling intervals until the first VES that reliably advances or resets the tachycardia. This is performed alternately with high- or low-energy outputs to achieve HB-RB capture and noncapture, respectively. As with para-Hisian entrainment, the retrograde atrial activation sequence and timing are compared during para-Hisian resetting to characterize the response.

INTERPRETATION OF RESULTS OF PARA-HISIAN ENTRAINMENT OR RESETTING. In AVNRT (typical or atypical), the AVN-AVN pattern is observed in response to para-Hisian entrainment/resetting. Both the S-A and the local VA intervals increase during HB-RB noncapture compared with HB-RB capture.⁴⁵

In orthodromic AVRT, the BT-BT pattern or BT-BT_L pattern is observed. In the setting of a BT-BT pattern, the S-A and local VA intervals are usually not significantly different between HB-RB capture and noncapture. Conversely, in the case of a BT-BT_L pattern, the S-A interval increases on HB-RB noncapture, but without significant change in the local VA interval.⁴⁵

A $\Delta S-A$ interval of less than 40 milliseconds was found to be a reasonable guide to separating the AVN-AVN from the BT-BT response; patients with AVNRT uniformly have a $\Delta S-A$ interval of greater than 40 milliseconds, and only rare patients with AVRT (with a left lateral BT) have a $\Delta S-A$ interval less than 40 milliseconds. However, the Δ local VA interval is a more accurate parameter.

An AVN-AVN or fusion pattern during para-Hisian entrainment or resetting has not been observed in patients with AVNRT, a potential advantage over para-Hisian pacing during NSR in identifying the presence of a BT. Because retrograde VA conduction can only proceed over a single route during entrainment of the SVT (assuming that a complex scenario such as multiple BTs is not present), the various forms of retrograde fusion that might be seen during para-Hisian pacing during NSR cannot occur during para-Hisian entrainment or resetting.⁴⁵

DIFFERENTIAL RIGHT VENTRICULAR PACING

The response to differential-site RV pacing can be evaluated by comparing the VA interval and atrial activation sequence during pacing at the RV base versus the RV apex (Fig. 18-33). The RV apex, although anatomically more distant from the atrium than the RV base, is nonetheless electrically closer because of the proximity of the distal RB to the pacing site. Consequently, in the absence of a retrogradely conducting septal AV BT, pacing at the RV apex allows entry into the rapidly conducting HPS and results in a shorter stimulus-to-atrial (S-A) interval during pacing from the apex than from the base. Pacing from the RV base requires the paced wavefront to travel a longer distance by muscle-to-muscle conduction to reach the RV apex and then propagate retrogradely through the RB and HB. In other words, the V-H interval is shorter with pacing at the RV apex versus the RV base. In the presence of a septal AV BT, pacing at the RV base allows the wavefront to access the AV BT rapidly and activate the atrium with a shorter S-A interval than during pacing at the RV apex, which is distant from the ventricular insertion site of AV BT (i.e., because the V-BT interval is shorter with pacing at the RV base versus the RV apex).

In the absence of a retrogradely conducting AV BT, atrial activation sequence will be similar during pacing both at the RV apex and at the RV base because the atrium is activated over the AVN in both settings. On the other hand, if a septal AV BT is present,

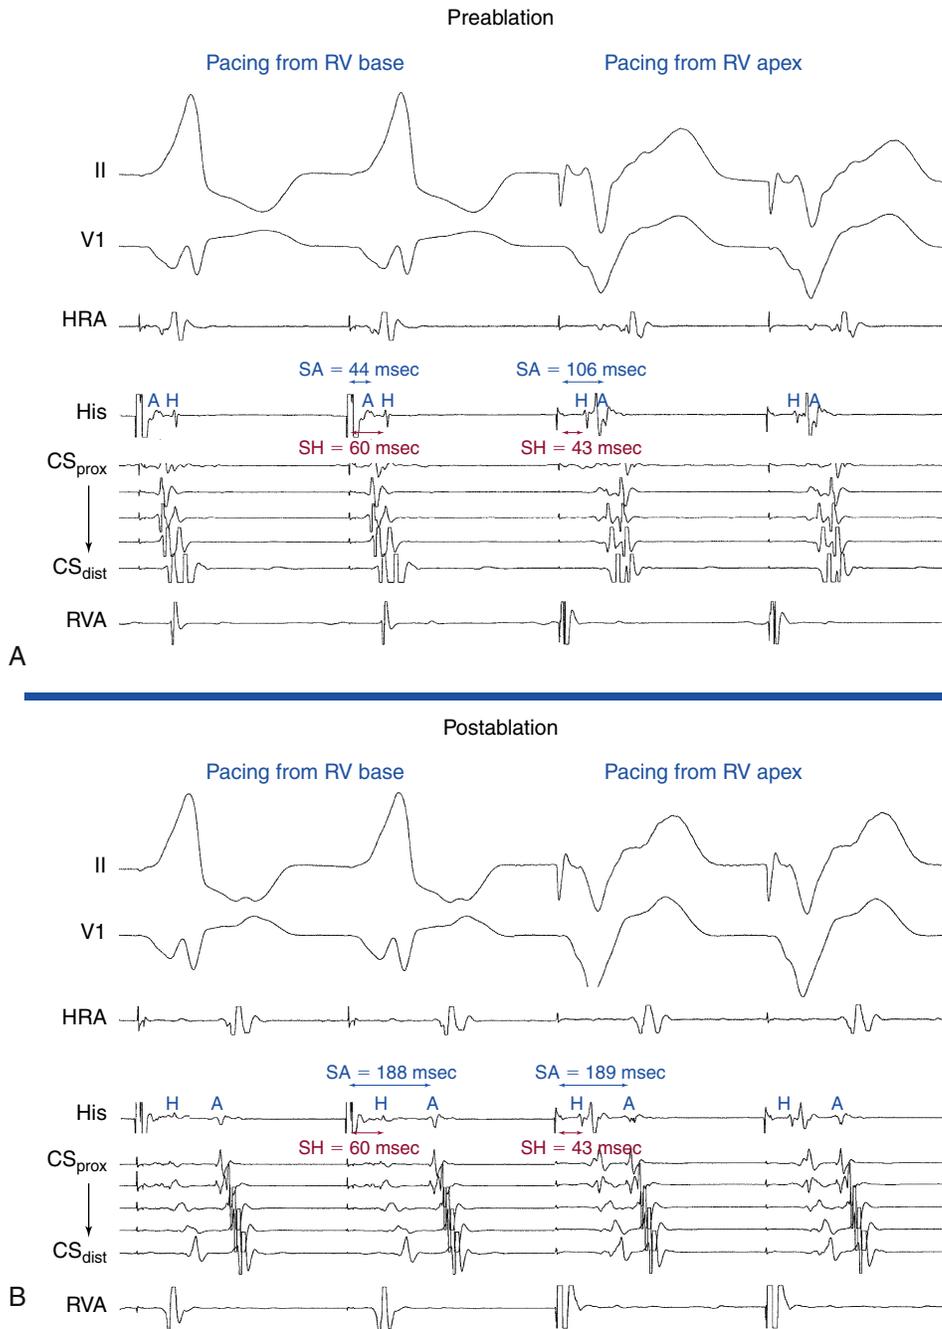

FIGURE 18-33 Differential-site right ventricular (RV) pacing in a patient with concealed superoparaseptal bypass tract (BT). In each panel, the first two complexes show RV basal-septal pacing, and the last two complexes show RV apical pacing. **A**, RV pacing is performed before ablation of the BT. The S-A (ventriculoatrial [VA]) interval is shorter during pacing at the RV base than during pacing at the RV apex, suggesting VA conduction occurring over a BT. Note that atrial activation occurs even before His bundle (HB) activation during pacing from the RV base, suggesting that VA conduction is independent of the AVN. **B**, RV pacing is performed after successful ablation of the BT. During pacing from the RV apex, the S-A interval is longer than before ablation, and it prolongs further by pacing at the RV base, consistent with the occurrence of VA conduction exclusively over the AVN. Note that in both panels the S-H (V-H) interval during RV apical pacing is shorter than that during RV basilar pacing because of the faster access of the paced wavefront to the right bundle branch–His bundle (RB–HB) during pacing at the RV apex. However, when VA conduction occurs over a BT (upper panel), the S-A interval remains constant; in contrast, in the absence of a BT (lower panel), the S-A interval shortens, coinciding with shortening of the S-H interval during pacing at the RV apex compared with pacing at the RV base.

atrial activation results from VA conduction over the AV BT during pacing at the RV base, and over either the AVN, the AV BT, or a fusion of both during pacing at the RV apex. Therefore, a variable retrograde atrial activation sequence in response to differential RV pacing (RV base versus RV apex) is indicative of the presence of an AV BT, but a constant atrial activation sequence is not helpful in excluding the presence of an AV BT.

This maneuver, however, does not exclude the presence of a distant right or left free wall AV BT, because the site of pacing is far from the AV BT; as a consequence, pacing from the RV apex or RV base may result in preferential VA conduction exclusively over the AVN and a constant atrial activation sequence. Similarly, this maneuver does not exclude the presence of a slowly conducting BT. The VA interval criterion identifies the actual route of VA conduction and therefore the fastest path of this conduction; hence, a slowly conducting BT would be missed in the presence of fast VA conduction over the HPS-AVN.

Conflicting results can also occur if conduction occurs simultaneously over a BT and HPS-AVN or, alternatively, over these two routes, depending on the pacing site. To help in these situations, calculation of the VA interval should be performed at several pacing CLs (the VA index should be independent of the pacing rate and, consequently, different values of the index at different rates would suggest more than one conducting path), after verapamil infusion (which would block the AVN and allow preferential VA conduction over the BT, if one is present), or during entrainment of the SVT (which would then ensure that VA conduction is occurring over the same path as that during the SVT).

The occurrence of RBBB (but not LBBB) also can alter the significance of the VA interval criterion, especially when VA conduction propagates over the HPS-AVN. In the presence of retrograde RBBB, VA conduction occurs over the LB–HB; therefore, the VA interval depends on the distance between the pacing site and the LB rather than the RB, and access of the paced wavefront to the LB can be

faster for RV basilar or septal pacing compared with pacing from the RV apex (see Fig. 17-21).

DUAL-CHAMBER SEQUENTIAL EXTRASTIMULATION

Although the various ventricular pacing maneuvers described previously can expose an eccentric or nondecremental atrial activation pattern that suggests retrograde conduction over a BT rather than the AVN, in certain circumstances, these maneuvers may not be adequate to confirm the presence or absence of BT conduction, especially when the BT has an ERP, retrograde atrial activation pattern, and conduction time similar to the AVN. In particular, identification, mapping, and verification of success of ablation of BT function can be challenging in the setting of septal BTs with a retrograde activation pattern similar to retrograde AVN conduction, slowly conducting BTs, as well as BTs with decremental properties.⁴⁶

Dual-chamber sequential extrastimulation is a useful maneuver for identifying concealed slowly conducting BTs not revealed with standard pacing maneuvers. This maneuver relies on concealed AVN conduction during a critically timed AES to cause transient retrograde AVN blockade at the time a VES is delivered, thereby allowing the BT to become manifest with the VES (analogous to delivering a VES during SVT while the HB is refractory).⁴⁶

The dual-chamber sequential extrastimulation maneuver consists of an eight-beat drive train of simultaneous atrial and RV pacing at 600 milliseconds, followed by an AES (A_2) delivered at a coupling interval equal to the AVN ERP, followed by a VES (V_2) delivered at a coupling interval equal to the drive train CL (600 milliseconds). Repeat drives are then performed with decrements of 10 milliseconds for V_2 until VA block is observed.⁴⁶

The critically timed A_2 prolongs the AVN refractory period via concealed anterograde conduction, causing V_2 to block in the AVN when it would have conducted had A_2 not been delivered. If a BT is present, V_2 conducts back to the atrium while the AVN remains refractory, resulting in a retrograde atrial activation pattern consistent with exclusive BT conduction. Although there can also be some degree of concealed anterograde conduction into the BT during A_2 stimulation, the more pronounced decremental properties of AVN tissue should prolong AVN refractoriness to a greater degree than that of the BT, allowing exclusive retrograde conduction over the BT to remain intact during V_2 stimulation.⁴⁶

This maneuver has several potential limitations. First, atrial ERP may exceed anterograde AVN ERP. Additionally, local atrial ERP at the site of BT insertion can render the atrium refractory to the wavefront traveling retrogradely over the BT. Therefore, atrial pacing during this maneuver ideally should be performed at a site in close proximity to the atrial insertion of the BT if possible. Furthermore, the AES may cause anterograde concealed conduction in the BT, potentially resulting in BT conduction block during delivery of V_2 . The success of this pacing maneuver relies on the differential effects of concealed conduction into the AVN and BT, with greater extension of refractoriness in the former than the latter.⁴⁶

EXCLUSION OF OTHER ARRHYTHMIA MECHANISMS

AVNRT and AT arising near the AV groove can mimic orthodromic AVRT and, in the presence of a manifest BT, those tachycardias can be associated with ventricular preexcitation mimicking antidromic AVRT, whereby the BT is functioning as an innocent bystander. Therefore, EP testing is required, not just to identify the presence of a BT, but also to define its role in any clinical or inducible arrhythmia. Tables 18-4 and 18-5 summarize the EP findings indicative of the presence of a BT and its potential participation in an inducible SVT. Exclusion of other SVT mechanisms is necessary, because the mere presence of a BT is not adequate to make a diagnosis and a treatment strategy (Tables 18-6, 18-7, and 18-8).

Furthermore, the presence of multiple BTs is not infrequent, and careful EP testing is required to evaluate this possibility. Several clinical and EP findings are indicative of the presence of multiple BTs (Table 18-9 and Fig. 18-34; and see Fig. 18-3). However, despite

TABLE 18-4 Electrophysiological Findings Indicating Presence of Retrograde Atrioventricular Bypass Tract Function

- Eccentric atrial activation sequence during ventricular pacing
- RV apical pacing producing longer VA interval and/or different atrial activation sequence compared with that during RV basilar pacing
- Para-Hisian pacing producing similar VA interval with and without HB capture or producing different atrial activation sequence depending on whether the HB is captured
- VES delivered when the HB is refractory advances the next atrial activation during SVT

HB = His bundle; RV = right ventricle; SVT = supraventricular tachycardia; VA = ventriculoatrial; VES = ventricular extrastimulus.

TABLE 18-5 Electrophysiological Findings Indicating Presence and Participation of Atrioventricular Bypass Tract in Supraventricular Tachycardia

- VES delivered during SVT when the HB is refractory terminates the SVT without atrial activation.
- VES delivered during SVT when the HB is refractory delays the next atrial activation.
- VES during SVT captures the atrium at the same coupling interval as that of the VES (exact capture phenomenon).
- VES delivered during SVT captures the atrium at a shorter coupling interval than that of the VES (paradoxical capture phenomenon).
- VA interval (with or without concomitant prolongation in tachycardia CL) prolonged during the SVT secondary to the development of BBB.
- Entrainment of the SVT by ventricular pacing results in prolongation of the VA interval ($VA_{\text{pacing}} > VA_{\text{SVT}}$).

BBB = bundle branch block; CL = cycle length; HB = His bundle; SVT = supraventricular tachycardia; VA = ventriculoatrial; VES = ventricular extrastimulus.

these various methods, many BTs are not identified until after catheter ablation of the first BT. Failure to detect the presence of multiple BTs during EP testing has been reported in as many as 5% to 15% of patients. This may be explained by the fact that changes in the preexcitation pattern can be subtle in shifting from one BT to another. Furthermore, one BT can preferentially conduct during atrial pacing or participate in preexcited tachycardias while another BT can be responsible for the retrograde limb during orthodromic AVRT or ventricular pacing. Additionally, there may be fusion of BT conduction, anterograde or retrograde. Repetitive concealed conduction into the BT during AVRT also may preclude identification of that BT before ablation of the first BT.

Localization of the Bypass Tract

Pacing from Multiple Atrial Sites

The closer the pacing site to the BT atrial insertion, the more rapidly the impulse will reach the BT relative to the AVN and thus the greater is the degree of preexcitation and the shorter is the P-delta interval. This method is especially helpful when the BT cannot conduct retrogradely, prohibiting localization with atrial mapping during SVT or ventricular pacing.

Preexcitation Index

As noted, the preexcitation index analyzes the coupling interval of the VES (delivered from the RV) that resets orthodromic AVRT as a percentage of the tachycardia CL. A relative preexcitation index (the ratio of coupling interval to the tachycardia CL) of more than 90% of a VES that advances atrial activation during orthodromic AVRT suggests that the BT is close to the site of ventricular stimulation (i.e., RV or septal BT). An absolute preexcitation index (tachycardia CL minus VES coupling interval) of at least 75 milliseconds suggests a left free wall BT, an index of less than 45 milliseconds suggests a septal BT, and an index of 45 to 75 milliseconds is indeterminate.

TABLE 18-6 Exclusion of Atrial Tachycardia**Effects of BBB**

- Prolongation of surface VA interval during SVT (with or without tachycardia CL prolongation) on development of BBB excludes AT.

Oscillations in SVT CL

- Spontaneous changes in tachycardia CL accompanied by constant VA interval (VA linking) exclude AT.
- Changes in atrial CL that are predicted by the change in the preceding ventricular CL argue against AT.

VES Delivered during SVT

- VES that terminates the SVT without atrial activation excludes AT.
- VES that delays next atrial activation excludes AT.
- VES during SVT that captures the atrium at the same coupling interval as that of the VES (exact capture phenomenon) excludes AT.
- VES delivered during SVT that captures the atrium at a shorter coupling interval than that of the VES (paradoxical capture phenomenon) excludes AT.
- Ventricular fusion during resetting indicates AVRT and excludes AT.

Overdrive Ventricular Pacing during SVT

- If atrial activation sequence during ventricular entrainment is similar to that during the SVT, AT is less likely.
- Presence of A-V electrogram sequence at cessation of ventricular pacing generally excludes AT.
- Ventricular fusion during entrainment indicates AVRT and excludes AT.

Overdrive Atrial Pacing during SVT

- If the VA interval following the last entrained QRS is reproducibly constant (with <10-msec variation), despite pacing at different CLs or for different durations (VA linking) and similar to that during SVT CL, AT is unlikely.
- If the VA interval following the last entrained QRS is reproducibly constant (with <14-msec variation), despite pacing at different atrial sites (VA linking), AT is unlikely.

Atrial Pacing during NSR at Tachycardia CL

- If the VA interval following the last entrained QRS is reproducibly constant (with <10-msec variation), despite pacing at different CLs or for different durations (VA linking) and similar to that during SVT CL, AT is unlikely.
- If the VA interval following the last entrained QRS is reproducibly constant (with <14-msec variation), despite pacing at different atrial sites (VA linking), AT is unlikely.

Ventricular Pacing during NSR at Tachycardia CL

- If retrograde atrial activation sequence during ventricular pacing is similar to that during SVT, AT is less likely.

AT = atrial tachycardia; AVRT = atrioventricular reentrant tachycardia; BBB = bundle branch block; CL = cycle length; NSR = normal sinus rhythm; SVT = supraventricular tachycardia; VA = ventriculoatrial; VES = ventricular extrastimulus.

Effects of Bundle Branch Block during Orthodromic Atrioventricular Reentrant Tachycardia

Prolongation of the tachycardia CL and, more importantly, the surface VA interval by more than 35 milliseconds following the development of BBB is diagnostic of AVRT using a free wall BT ipsilateral to the BBB (LBBB with left-sided BT, and RBBB with right-sided BT).^{33,34} Superoparaseptal and posteroseptal BTs are associated with a lesser degree of prolongation of the VA interval (approximately 5 to 25 milliseconds) on the development of BBB (RBBB with superoparaseptal BT, and LBBB with posteroseptal BT). In an analogous fashion, entrainment of the SVT by ventricular pacing that results in prolongation of the VA interval ($VA_{\text{pacing}} > VA_{\text{SVT}}$) suggests that the SVT is orthodromic AVRT mediated by an AV BT in the ventricle contralateral to the site of ventricular pacing.

TABLE 18-7 Exclusion of Atrioventricular Nodal Reentrant Tachycardia**Atrial Activation Sequence**

- Eccentric atrial activation sequence during the SVT excludes AVNRT (with the exception of left variant AVNRT).

Effects of BBB

- Prolongation of VA interval or tachycardia CL on development of BBB excludes AVNRT.

Oscillations in SVT CL

- Spontaneous changes in tachycardia CL accompanied by constant VA interval (VA linking) make AVNRT unlikely.

VES Delivered during SVT

- VES delivered during SVT when the HB is refractory that resets or terminates the SVT excludes AVNRT.
- VES during SVT that conducts to the atrium at the same coupling interval as that of the VES (exact capture phenomenon) excludes AVNRT.
- VES delivered during SVT that conducts to the atrium at a shorter coupling interval than that of the VES (paradoxical capture phenomenon) excludes AVNRT.

Entrainment of SVT by Atrial Pacing

- $AH_{\text{pacing}} - AH_{\text{SVT}} < 20$ msec excludes AVNRT.

Entrainment of SVT by Ventricular Pacing

- $VA_{\text{pacing}} - VA_{\text{SVT}} < 85$ msec argues against AVNRT.
- $PPI - SVT CL < 115$ msec argues against AVNRT.
- Corrected $PPI - SVT CL < 110$ msec argues against AVNRT.
- Manifest ventricular fusion during entrainment indicates AVRT and excludes AVNRT.
- Acceleration of the SVT to the pacing CL occurring after a single captured paced RV complex is consistent with orthodromic AVRT and essentially excludes AVNRT.
- A differential corrected $PPI - SVT CL$ of <30 msec after transient entrainment from the RV apex versus the RV base is consistent with orthodromic AVRT and excludes AVNRT.
- A differential VA interval (ventricular stimulus-to-atrial interval during entrainment from RV base versus RV septum) of <20 msec is consistent with orthodromic AVRT and excludes AVNRT.

Atrial Pacing during NSR at Tachycardia CL

- $AH_{\text{pacing}} - AH_{\text{SVT}} < 20$ msec excludes AVNRT.

Ventricular Pacing during NSR at Tachycardia CL

- If $HA_{\text{pacing}} - HA_{\text{SVT}}$ is less than -10 msec, the SVT excludes AVNRT.

Differential RV Pacing

- If the atrial activation sequence changes during pacing at the RV apex versus pacing at the RV base, AVNRT is less likely.
- If the S-A interval is shorter with pacing from the base than from the apex, AVNRT is less likely.

Para-Hisian Pacing

- Para-Hisian pacing producing similar VA interval, regardless of whether HB capture occurs, and/or different atrial activation sequence, depending on whether HB capture occurs, makes AVNRT unlikely.

AH = atrial-His bundle; AVNRT = atrioventricular nodal reentrant tachycardia; AVRT = atrioventricular reentrant tachycardia; BBB = bundle branch block; CL = cycle length; HA = His bundle-atrial interval; HB = His bundle; NSR = normal sinus rhythm; PPI = post-pacing interval; RV = right ventricle; SVT = supraventricular tachycardia; VA = ventriculoatrial; VES = ventricular extrastimulus.

Earliest Ventricular Activation Site during Anterograde Bypass Tract Conduction

During ventricular preexcitation (preexcited sinus or atrial paced rhythm, or antidromic AVRT), the surface ECG lead with the earliest onset of the delta wave, preferably with a relatively sharp delineation of its onset, should be selected and used as the timing reference during mapping (Fig. 18-35). The site of earliest ventricular activation (preceding the onset of the delta wave) along the tricuspid and

TABLE 18-8 Differentiation Between Antidromic AVRT and Preexcited AVNRT**SVT Features**

- $HA_{SVT} < 70$ msec excludes antidromic AVRT.
- Positive HV or V-H interval ≤ 10 msec (especially when HA interval is ≤ 50 msec) suggests AVNRT.

Termination of SVT

- Continuation of the SVT at the same tachycardia CL, despite anterograde block in the BT (by drugs, mechanical trauma, or ablation), is diagnostic of AVNRT and excludes antidromic AVRT.
- Block of the BT by drugs and subsequent induction of narrow-complex SVT with the same tachycardia CL, HA interval, and retrograde atrial activation sequence as that of the preexcited SVT induced before the BT block is diagnostic of preexcited AVNRT and excludes antidromic AVRT.
- Termination of SVT in response to carotid sinus massage or adenosine:
 - AVNRT terminates after atrial activation (secondary to anterograde block down the slow pathway).
 - Classic antidromic AVRT terminates after ventricular activation (secondary to retrograde block up the AVN).

Effects of BBB

- Prolongation of VA interval or tachycardia CL on development of BBB excludes AVNRT.

SVT Induction with Ventricular Stimulation

- Induction of the SVT by ventricular pacing at a pacing CL similar to the tachycardia CL or by a VES that advances the timing of the His potential by a coupling interval (i.e., H_1 - H_2 interval) similar to the H-H during the SVT, the HA interval following such a VES is compared with that during the SVT:
 - $HA_{VES \text{ or ventricular pacing}} > HA_{SVT}$ is diagnostic of AVNRT and excludes antidromic AVRT.
 - $HA_{VES \text{ or ventricular pacing}} \leq HA_{SVT}$ is diagnostic of antidromic AVRT and excludes AVNRT.

AES Delivered during SVT

- Late-coupled AES is delivered close to the BT atrial insertion site during SVT when the AV junctional atrium is refractory. If it advances the timing of both the next ventricular activation and the subsequent atrial activation, it proves that the SVT is antidromic AVRT using an AV BT anterogradely, and excludes preexcited AVNRT.
- AES during the SVT that advances ventricular activation and does not affect VA interval excludes AVNRT and is diagnostic of antidromic AVRT.
- Exact atrial and ventricular capture by AES delivered when the AV junction is depolarized excludes AVNRT.

Entrainment of SVT by Atrial Pacing

- Failure of entrainment by atrial pacing to influence the VA interval during SVT excludes AVNRT.
- The presence of a fixed short V-H interval during entrainment of the SVT with atrial pacing suggests antidromic AVRT, and makes AVNRT unlikely (but does not exclude AVNRT).

Entrainment of SVT by Ventricular Pacing

- Failure of entrainment by ventricular pacing to influence the VA interval during SVT excludes AVNRT.

Ventricular Pacing during NSR at the Tachycardia CL

- Pacing at the RV apex at tachycardia CL is performed, and the HA interval during RV pacing is compared with the HA interval during SVT. (It is important to verify that VA conduction occurred only over the AVN and not over the BT for this analysis to be valid.)
- $HA_{pacing} > HA_{SVT}$ is diagnostic of AVNRT and excludes antidromic AVRT.
- $HA_{pacing} \leq HA_{SVT}$ is diagnostic of antidromic AVRT and excludes AVNRT.
- VA block during RV apical pacing excludes antidromic AVRT.

AES = atrial extrastimulus; AV = atrioventricular; AVNRT = atrioventricular nodal reentrant tachycardia; AVRT = atrioventricular reentrant tachycardia; BBB = bundle branch block; BT = bypass tract; CL = cycle length; HA = His bundle-atrial; HV = His bundle-ventricular; NSR = normal sinus rhythm; RV = right ventricle; SVT = supraventricular tachycardia; VA = ventriculoatrial; VES = ventricular extrastimulus; V-H = ventricular-His bundle.

TABLE 18-9 Electrophysiological Findings Indicating Presence of Multiple Atrioventricular Bypass Tracts**During Preexcited Rhythms (NSR, PACs, Spontaneous or Induced AF, RA, and LA Pacing)**

- Changing anterograde delta wave (i.e., variations in preexcited QRS morphology). Atrial pacing from different sites (high RA and CS) may accentuate preexcitation over one BT and not the other, help unmask the changes in the delta wave
- Atypical pattern of preexcitation (i.e., does not conform to an expected QRS morphology for a given location)
- Changing anterograde delta wave following antiarrhythmic agents (e.g., amiodarone or class I agents) that may block one BT and not the other or following ablation of one BT

During Ventricular Pacing at Different CLs and from Multiple Pacing Sites

- Evidence of multiple routes of retrograde atrial activation:
 - Changing P wave morphology or atrial activation sequence
 - Multiple atrial breakthrough sites
 - Changing VA interval
- Evidence of mismatch of site of anterograde preexcitation and site of retrograde atrial activation observed during ventricular pacing

During Orthodromic AVRT

- Evidence of multiple routes of retrograde atrial activation:
 - Changing P wave morphology or atrial activation sequence
 - Multiple atrial breakthrough sites
 - Changing VA interval
 - Failure to delay atrial activation at all sites with the development of BBB ipsilateral to the BT
- Evidence of multiple routes of anterograde ventricular activation:
 - Intermittent anterograde fusion (preexcited) complexes
 - Evidence of mismatch of site of anterograde preexcitation and site of retrograde atrial activation observed during orthodromic AVRT

During Antidromic AVRT

- Eccentric atrial activation sequence
- Varying degrees of anterograde fusion
- Changing V-H interval without any change in the tachycardia CL or atrial activation sequence (suggesting that the HPS is not part of the reentrant circuit)
- Tachycardia CL during antidromic AVRT slower than orthodromic AVRT in the same patient (in absence of dual AVN pathways)
- Anterograde ventricular activation over posteroseptal BT
- The mere presence of antidromic AVRT

AF = atrial fibrillation; AVN = atrioventricular node; AVRT = atrioventricular reentrant tachycardia; BBB = bundle branch block; BT = bypass tract; CL = cycle length; CS = coronary sinus; HPS = His-Purkinje system; LA = left atrium; NSR = normal sinus rhythm; PAC = premature atrial complex; RA = right atrium; VA = ventriculoatrial.

mitral annuli identifies the BT ventricular insertion site. Both bipolar and unipolar recordings on the ablation catheter should be used for mapping (Fig. 18-36). Bipolar electrograms display electrogram components and timing and may demonstrate a BT potential. The unfiltered (0.05 to ≥ 300 Hz) unipolar signal morphology should show a monophasic QS complex with a rapid negative deflection if the site was at the origin of impulse formation in the ventricle (i.e., BT insertion site). Concordance of the timing of the onset of the bipolar electrogram with that of the filtered or unfiltered unipolar electrogram (with the rapid downslope of the S wave of the unipolar QS complex coinciding with the initial peak of the bipolar signal) helps ensure that the tip electrode, which is the ablation electrode, is responsible for the early component of the bipolar electrogram. If only bipolar recordings are used, one does not know which of the two poles is responsible for the earliest component of the bipolar electrogram.⁶

Earliest Atrial Activation Site during Retrograde Bypass Tract Conduction

During orthodromic AVRT or during ventricular pacing with retrograde conduction over the BT, the site of earliest atrial activation

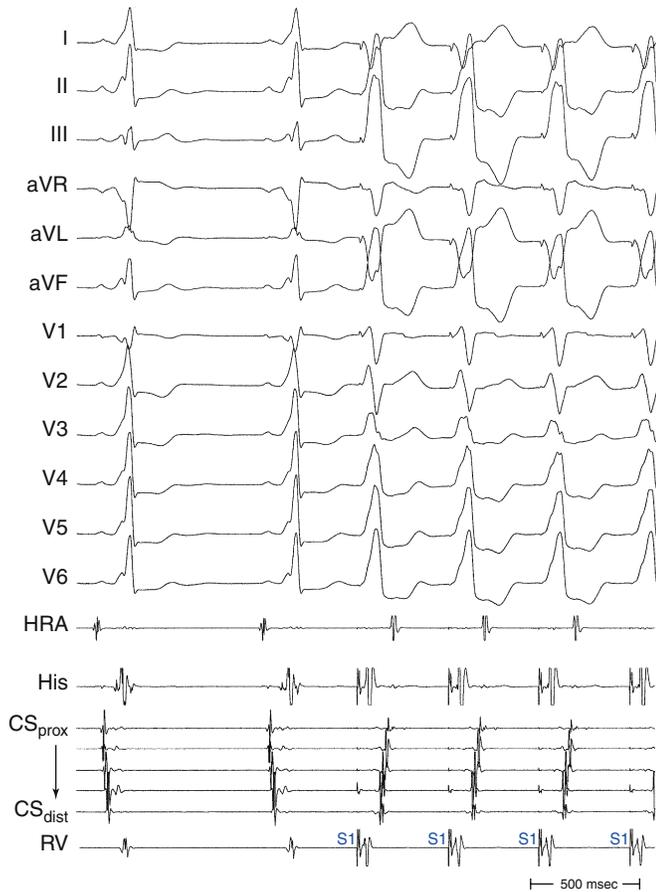

FIGURE 18-34 The presence of multiple bypass tracts (BTs) is indicated by the mismatch of sites of anterograde preexcitation during normal sinus rhythm (the delta wave morphology is consistent with anterograde conduction over a right anterior BT) and site of retrograde atrial activation observed during ventricular pacing (the atrial activation sequence is consistent with VA conduction over a left lateral BT).

along the tricuspid and mitral annuli identifies the BT atrial insertion site. When mapping is performed during ventricular pacing, fusion of atrial activation, caused by simultaneous retrograde conduction over both the AVN and the BT, has to be considered, because it can affect the accuracy of mapping. This can be an issue in the setting of septal BTs whereby retrograde atrial activation sequence over the BT may not be very different from that over the AVN. Dissociation of retrograde conduction over the BT from that over the AVN is required in these situations, and can usually be achieved with ventricular stimulation from sites closer to the BT and with the use of AVN blockers (e.g., adenosine) to ensure preferential retrograde conduction over the BT.³ As with ventricular mapping, both bipolar and unipolar recordings on the distal ablation electrode should be used for atrial mapping (Fig. 18-37). Determining what components of a complex ablation electrode recording is atrial versus ventricular can be facilitated by either rapid burst ventricular pacing that does not conduct 1:1 retrogradely (Fig. 18-38) or introduction of a VES that does not conduct retrogradely during fixed rate ventricular pacing (Fig. 18-39). In either case, the principle is to compare the electrogram that is known to have no atrial component with the electrogram in question (with some atrial component), any difference being due to the contribution of the atrial electrogram.

Mapping Atrial Electrogram Polarity Reversal during Retrograde Bypass Tract Conduction

The morphology and amplitude of the bipolar electrograms are influenced by the orientation of the bipolar recording axis to the

direction of propagation of the activation wavefront. Although the direction of wavefront propagation cannot be reliably inferred from the morphology of the bipolar signal, a change in morphology can be a useful finding, and the unfiltered bipolar electrogram with the electrodes oriented parallel to the axis of the annulus can be used to localize the atrial insertion site of the BT.

During retrograde BT conduction (orthodromic AVRT or ventricular pacing), BT atrial insertion is identified as the site where the polarity of the atrial potential reverses. Because the site of BT atrial insertion is usually discrete, atrial activation propagates in two opposite directions along the annulus from the insertion site. Consequently, an RS configuration electrogram will be present on one side of the BT, where the wavefront is propagating from the distal electrode toward the proximal electrode, and a QR morphology electrogram on the other side, where the wavefront is propagating from the proximal electrode toward the distal electrode (see Fig. 5-5).

This technique is typically used for localization of left free wall BTs via the transeptal approach, which allows an electrode orientation parallel with atrial activation along the mitral annulus. As the ablation catheter is moved along the mitral annulus during retrograde BT conduction, the amplitude and polarity of the atrial electrogram are examined. With the tip electrode negative, and the catheter lying on the mitral annulus from anterior to posterior, an upright atrial electrogram indicates a catheter position anterior to the insertion site, whereas a negative electrogram indicates positions posterior to the insertion site. When the bipole approaches and then passes directly over the atrial insertion site, the atrial electrogram becomes diminished in amplitude, isoelectric, and fractionated. As the catheter moves from one side of the insertion site to the other side, reversal of the atrial electrogram polarity is observed. This maneuver has a sensitivity of 97%, specificity of 46%, and positive predictive value of 75%.²³ For BTs at other locations, mapping can be facilitated by using a multipolar catheter positioned in the CS or around the tricuspid annulus (e.g., Halo catheter); the site of the BT atrial insertion is enclosed between the two adjacent bipoles, demonstrating atrial electrogram polarity reversal.

Direct Recording of Bypass Tract Potential

The BT potential manifests as a sharp narrow spike on both unipolar and bipolar recordings 10 to 30 milliseconds before the onset of the delta wave during anterograde preexcitation or between the ventricular and atrial electrograms at the earliest site of retrograde atrial activation during orthodromic AVRT or ventricular pacing. The BT potential amplitude averages 0.5 to 1 mV at successful ablation sites (see Figs. 18-36 and 18-37). Similar electrical signals, however, can be a component of the atrial or ventricular electrogram, and proof that an electrical signal actually is a BT potential is difficult, because it needs to be dissociated from the local atrial and ventricular electrograms.

DISSOCIATION OF BYPASS TRACT POTENTIAL FROM LOCAL ATRIAL POTENTIAL

During orthodromic AVRT or ventricular pacing, introduction of a VES may cause retrograde block near the BT-atrial interface. This would result in loss of the atrial potential while maintaining the BT potential, providing evidence that this potential is not a component of the atrial electrogram. Additionally, during ventricular pacing, introduction of a late-coupled AES can advance the timing of the local atrial potential without affecting the retrograde BT potential, providing evidence that the BT potential is not related to atrial activation. Alternatively, during atrial pacing, introduction of a late-coupled VES may advance ventricular and BT activation without affecting atrial activation, providing additional evidence that the BT potential is not related to atrial activation (Fig. 18-40).

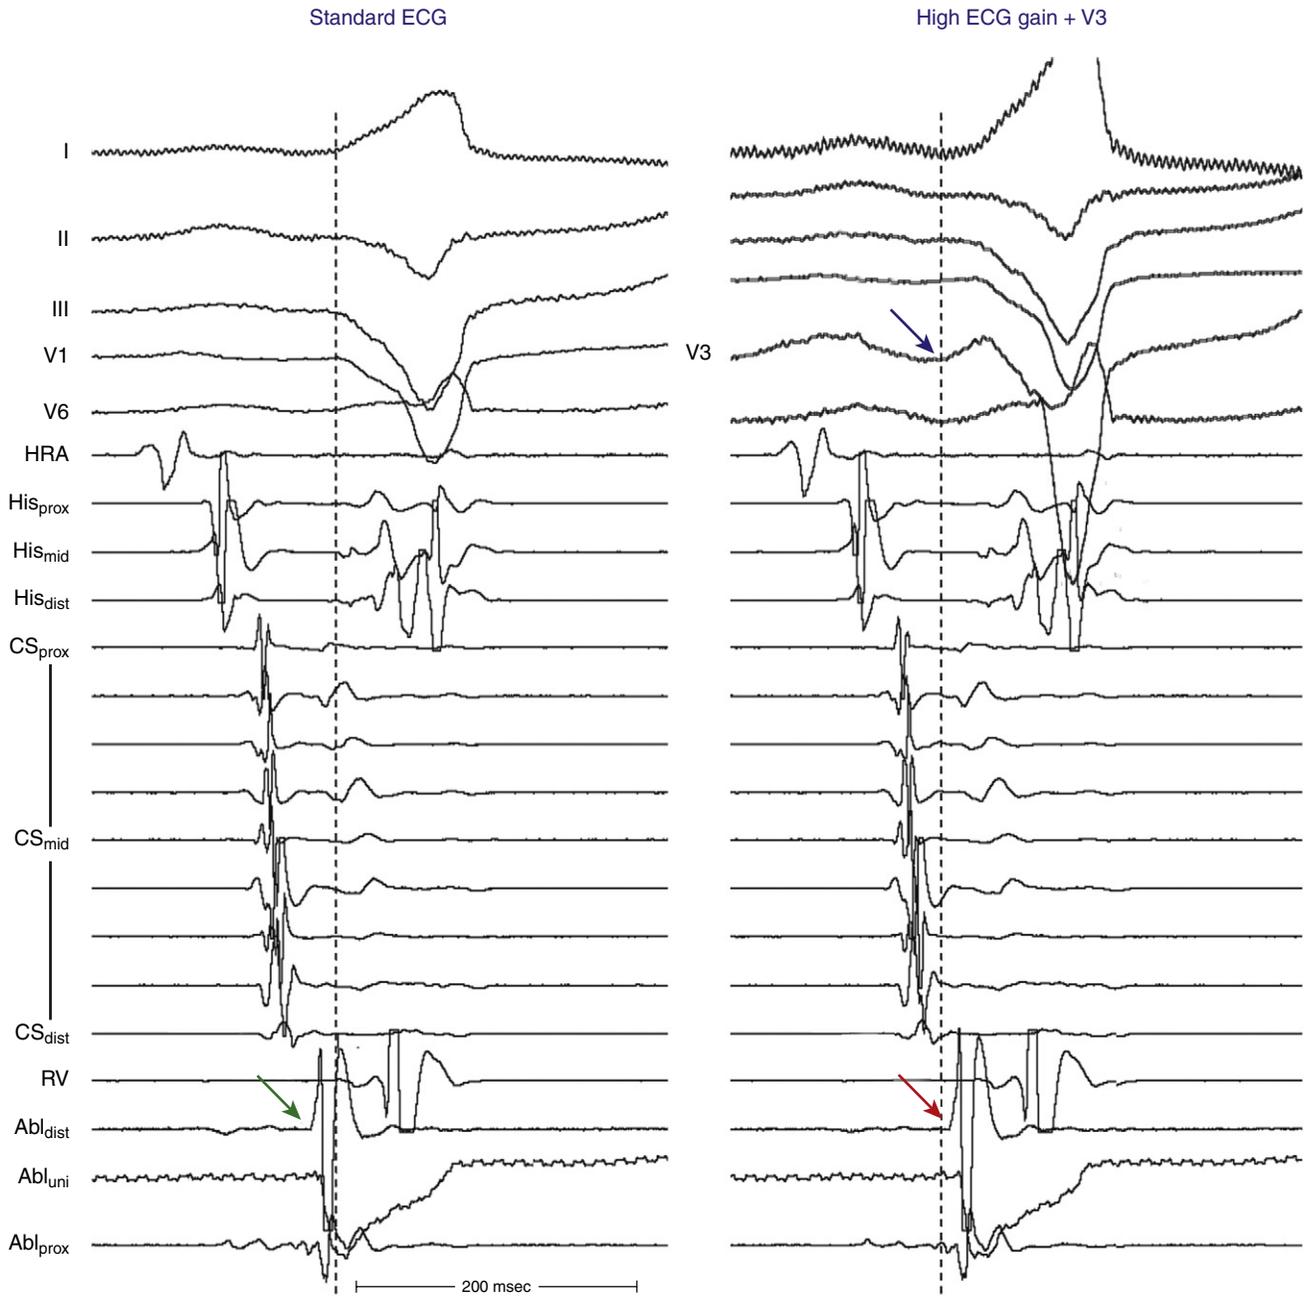

FIGURE 18-35 Surface ECG and intracardiac recordings of possible ablation site. On the left, with standard ECG recordings, the features of the ablation site electrograms (Abl) suggest this would be a good ablation site (green arrow) because they occur well before the onset of the delta wave (dashed line). However, on the right, the very same complex is shown, but with increased gain on surface ECG leads as well as an addition of lead of V₃ (showing sharp delineation of delta wave onset, blue arrow). Now, the dashed line that denotes the true onset of surface preexcitation reveals that the putative ablation site is not attractive (red arrow).

DISSOCIATION OF BYPASS TRACT POTENTIAL FROM LOCAL VENTRICULAR POTENTIAL

During AVRT or ventricular pacing, introduction of a late-coupled VES may block retrogradely in the BT near the ventricular-BT interface. This would result in loss of the BT potential while maintaining the ventricular potential, providing evidence that the BT potential is not related to ventricular activation. Additionally, during pre-excited atrial pacing, introduction of a late-coupled VES (occurring at the time of the anterograde BT potential) that advances the local ventricular electrogram but does not alter the BT potential dissociates this potential from local ventricular activation. Moreover, during ventricular pacing, introduction of a critically timed AES may anterogradely activate the BT, advancing the timing of the BT potential without affecting the timing or morphology of

the ventricular potential, providing evidence that the BT potential does not result from atrial activation (Fig. 18-41).

However, these criteria for validation of BT potentials are often difficult to achieve. Therefore, validation of BT potentials by programmed electrical stimulation is often not practical in clinical settings; instead, such a potential is called *possible* or *probable* BT potential.

Targeting an isolated BT potential has been associated with the highest frequency of ablation success. The usefulness of this criterion, however, has been limited by difficulty in locating or validating a BT potential. The difficulty in identifying the BT potential is often related to the oblique course of the BT. A ventricular or atrial wavefront propagating concurrently with the BT can overlap and mask the BT potential. Pacing from the site producing the shorter

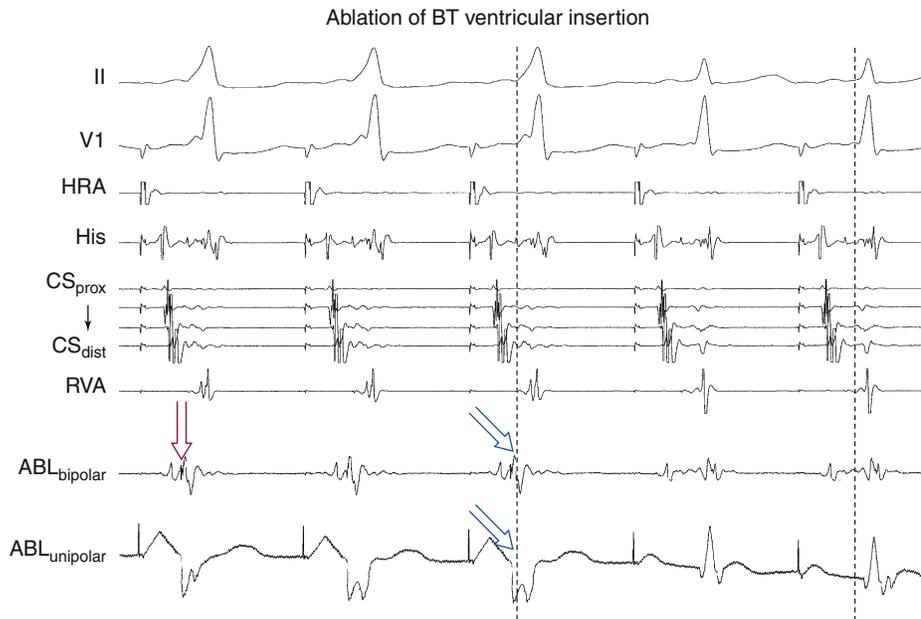

FIGURE 18-36 Catheter ablation of a left anterolateral bypass tract (BT) during anterograde conduction. Ablation is performed during preexcited atrial pacing. Preexcitation is observed during the first three complexes. The dashed line indicates the onset of the delta wave. Note the sharp negative deflection (QS morphology) in the unipolar recording. Also, note the concordance of the timing of the unipolar and bipolar electrograms (blue arrows), which precedes the onset of the delta wave by 10 to 15 milliseconds. A sharp potential (possible BT potential, red arrow) is recorded between the atrial and ventricular electrograms. RF application at this site successfully eliminated preexcitation (last two complexes).

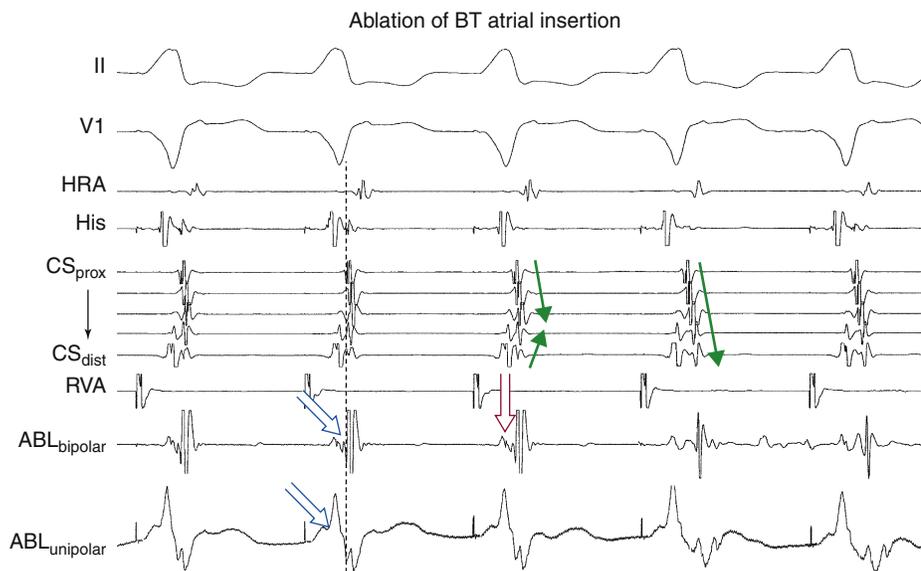

FIGURE 18-37 Catheter ablation of a left lateral bypass tract (BT) during retrograde conduction. Ablation is performed during ventricular pacing with atrial fusion (ventriculoatrial conduction occurring over both the BT and atrioventricular node [AVN]). The dashed line indicates the onset of the earliest atrial activation. Note the sharp negative deflection (QS morphology) in the unipolar recording. The timing of the unipolar electrogram coincides with the bipolar electrogram (blue arrows) and precedes the delta wave by 5 to 10 milliseconds. The atrial and ventricular electrograms merge together, and the true morphology of the ventricular electrogram is unmasked after successful ablation (last two complexes). A sharp potential (possible BT potential, red arrow) is recorded between the two electrograms. After successful elimination of the BT function, atrial activation occurs exclusively over the AVN (last two complexes, green arrows).

local VA or local AV intervals helps identify the BT potential in most of these cases.

Local Atrioventricular (or Ventriculoatrial) Interval

Although the site of the shortest local VA interval during retrograde BT conduction and the site of the shortest local AV interval during anterograde BT conduction are often considered the optimal target for BT ablation, the reliability of this criterion has been debated and can be misleading in the setting of oblique BTs.^{3,6} Short local VA intervals can occur at sites along the valve annulus distant from the BT because atrial and ventricular activation wavefronts can propagate circumferentially along the annulus, and the timing of local atrial and ventricular activation can be close to one another at multiple sites along the annulus (Fig. 18-42). Furthermore, with oblique BTs, the shortest local VA interval can be shifted away from the BT in the direction of the ventricular wavefront if the velocity of the ventricular wavefront along the annulus is less than the velocity of the atrial wavefront. Similarly, the site of the shortest local AV interval can be shifted away from the BT in the direction of the

atrial wavefront if the atrial wavefront is slower than the ventricular wavefront.

With an oblique course, the local VA and AV intervals at the site of earliest ventricular activation varies by reversing the direction of the paced ventricular and atrial wavefronts, respectively.⁶ During ventricular pacing, a ventricular wavefront propagating from the direction of the ventricular end (concurrently with BT activation) produces a short local VA interval, because activation along the BT propagates to the site of earliest atrial activation concomitant with the ventricular wavefront. Contrariwise, a ventricular wavefront propagating in the opposite (countercurrent) direction produces a longer local VA interval because the ventricular wavefront must pass the site of earliest atrial activation before reaching the ventricular end of the BT (Fig. 18-43). This has important implications for localizing oblique AV BTs. With a concurrent wavefront, the ventricular potential may overlap and mask the BT potential and overlap the atrial potential, masking the site of earliest atrial activation. If the velocity of the ventricular wavefront along the annulus were slower than the BT and atrial wavefronts, the shortest local VA interval would be shifted away from the BT. A countercurrent wavefront should expose the atrial activation sequence and BT potential.

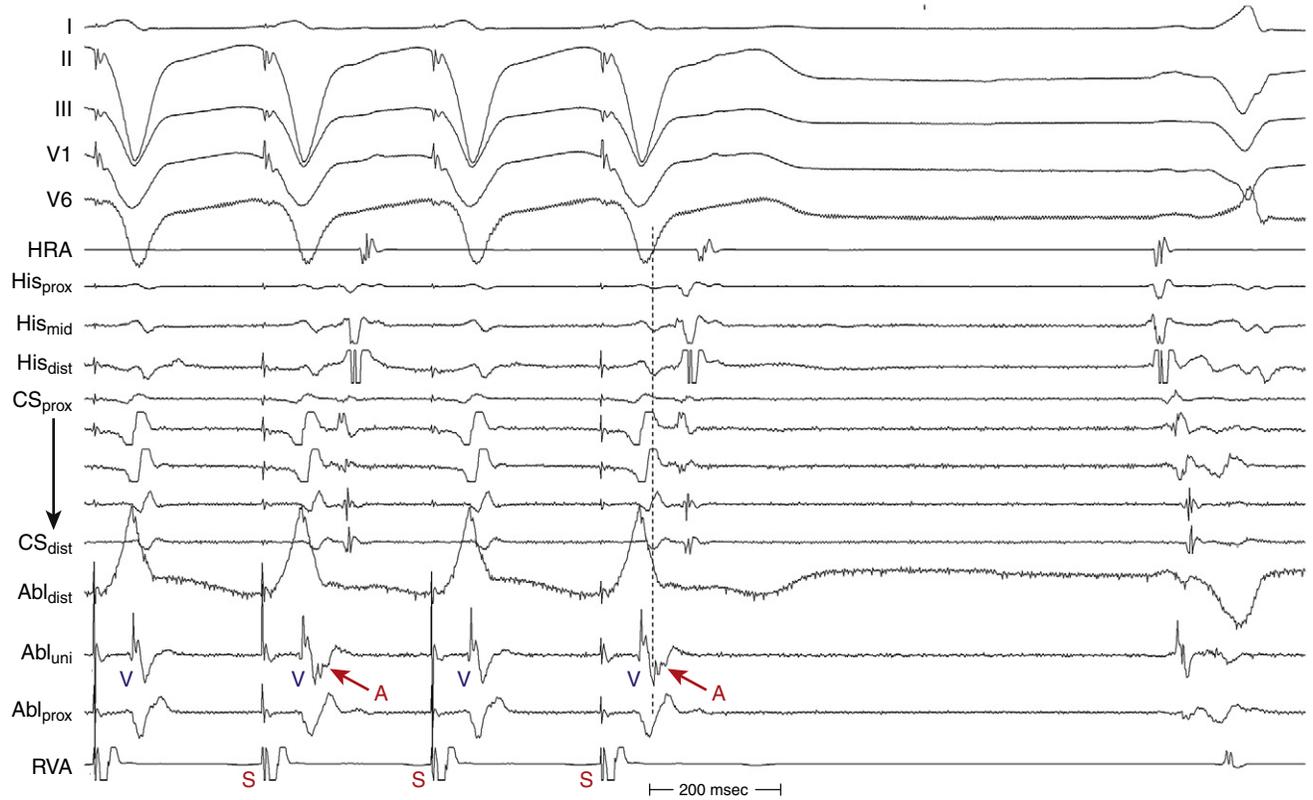

FIGURE 18-38 Using ventricular pacing to evaluate ablation site electrogram components. Burst ventricular pacing is shown at a rate that produces 2:1 retrograde conduction over the bypass tract (BT). This facilitates determination of what portion of the ablation site recording is atrial versus ventricular, because whatever is present in recordings on cycles during which retrograde conduction is present, but absent when retrograde conduction fails, is the atrial (or BT plus atrial) recording (red arrows).

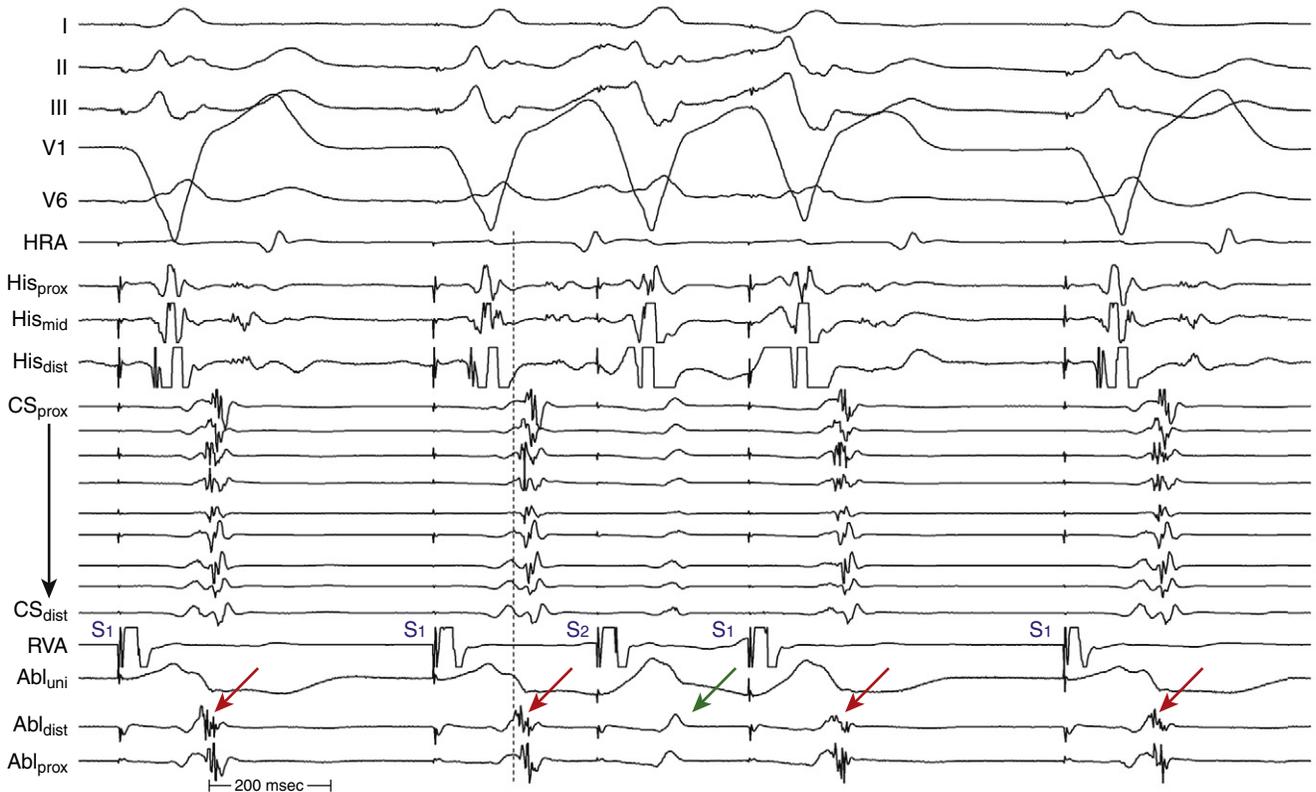

FIGURE 18-39 Using ventricular extrastimuli to evaluate ablation site electrogram components. Determining what part of a complex ablation site recording is atrial or bypass tract (BT) is aided by introducing an extrastimulus (S₂) during a fixed-rate drive, which fails to conduct retrogradely while drive complexes do conduct. The portion of the electrogram that is absent on this complex (green arrow), but present on others (red arrows), is the atrial (±BT) component.

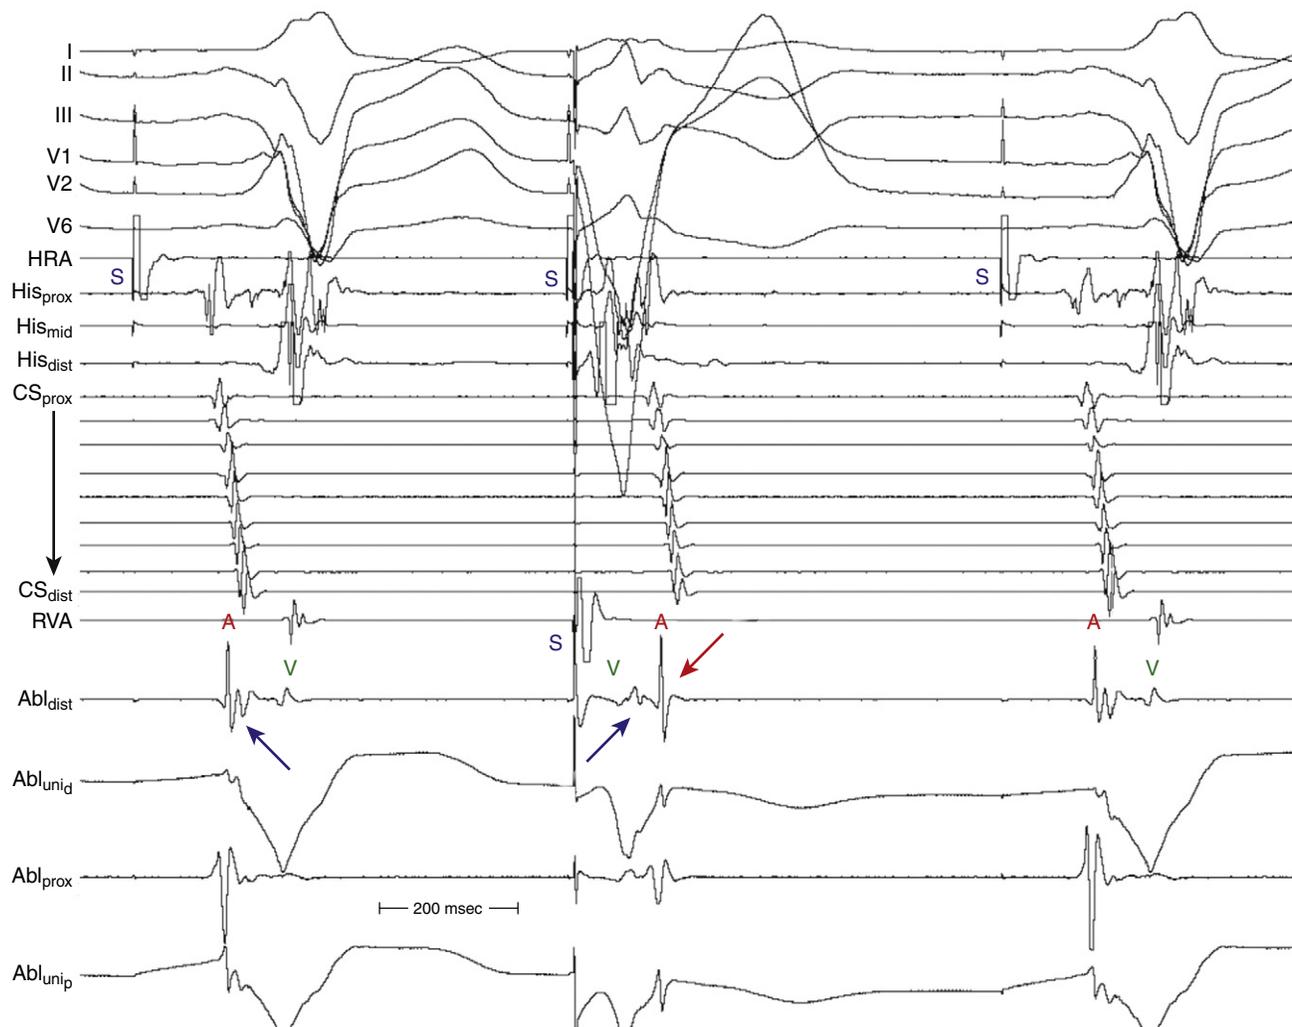

FIGURE 18-40 Dissociation of bypass tract (BT) potential from local atrial potential. Surface ECG and intracardiac recordings evaluate possible BT potential. Fixed-rate atrial pacing is present on all three complexes shown. On the first complex, a blue arrow points to a possible BT potential following the sharp atrial potential (A). This same sharp atrial potential is seen at the same rate as atrial pacing on all three complexes. On the middle complex, a single ventricular extrastimulus is delivered almost simultaneously with the atrial drive stimulus (S). Here, the blue arrow shows that the putative BT potential does not follow the sharp atrial recording (red arrow indicates its absence), and thus is not part of the atrial electrogram.

Similarly, during atrial pacing, a concurrent atrial wavefront would shorten the local AV interval at the site of earliest ventricular activation (local AV) and could mask the BT potential and site of earliest ventricular activation. A countercurrent wavefront should lengthen the local AV and expose the BT potential and ventricular activation sequence (see Fig. 18-43).

Reversing the paced ventricular or atrial wavefronts increases the local VA or local AV interval, respectively, by at least 15 milliseconds in more than 85% of patients, which suggests that most BTs have an oblique course. The increase in the local VA or local AV intervals may facilitate identification of the BT potential.⁶ An anterograde or retrograde BT potential can be recorded in more than 85% of patients with oblique BTs, which is much more frequent than that with nonoblique BTs, because fusion of the atrial, BT, and ventricular potentials may be expected with nonoblique BT.

During retrograde BT conduction, the earliest atrial activation may be recorded 3 to 5 mm (or possibly more) from the actual BT insertion. Ablation is likely to be successful if the electrode is located 3 to 5 mm from the atrial insertion in the direction of the ventricular insertion and unsuccessful if located in the opposite direction. During anterograde BT conduction, ablation at a site recording earliest ventricular activation is likely to be successful,

even if the electrode is located 3 to 5 mm from the ventricular end but in the direction of the atrial insertion and unsuccessful if located in the opposite direction. This explains the 40% ablation success for the criterion of local ventricular activation preceding the onset of the delta wave by less than 0 millisecond during anterograde BT conduction, even though ventricular activation usually can be recorded as much as 30 milliseconds before the delta wave in right-sided BTs and 15 to 20 milliseconds in left-sided BTs.

Ablation

Target of Ablation

The BT is the target of ablation. The best site of ablation of a BT is where it crosses the annulus. Localization of the BT can be achieved with different mapping methods, as described earlier. Ablation should be performed at the same side of the annulus to the one being mapped (i.e., ablation on the atrial side during mapping of the atrial insertion site during retrograde BT conduction, and ablation on the ventricular side during mapping of the earliest ventricular activation during anterograde BT conduction). This is especially important in the presence of oblique BTs, whereby

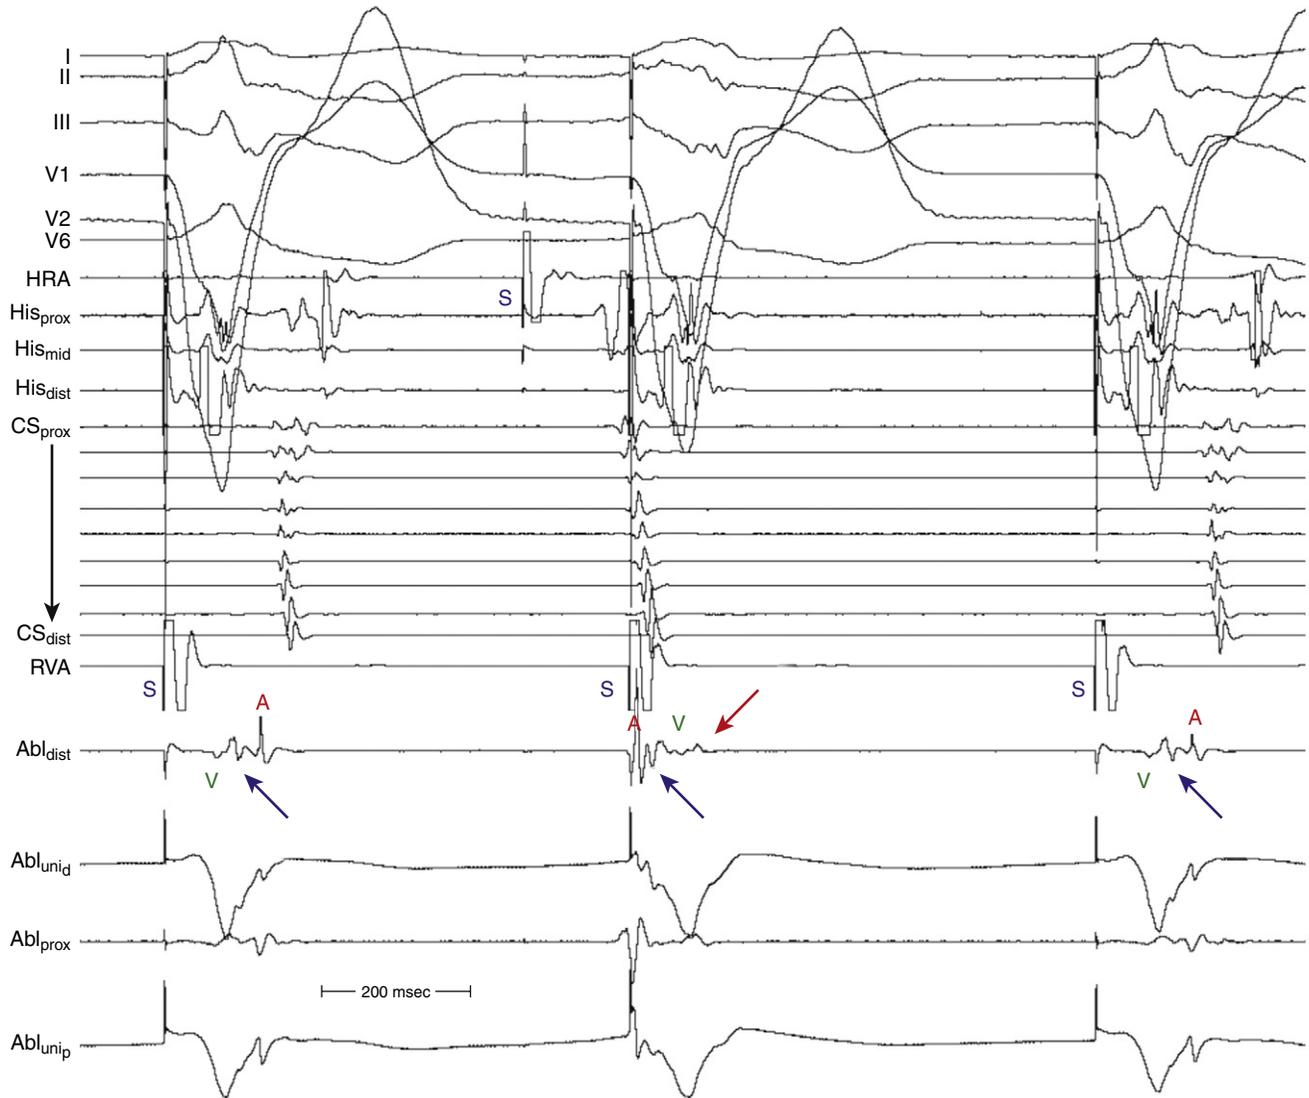

FIGURE 18-41 Dissociation of bypass tract (BT) potential from local ventricular potential. Surface ECG and intracardiac recordings evaluate possible BT potential in the same patient as in Figure 18-40. Fixed-rate ventricular pacing is shown in all three complexes, with a single atrial extrastimulus (AES) introduced during the middle complex. The blue arrow in the first complex points to a putative BT potential between ventricular (V) and atrial (A) electrograms. In the middle complex, the AES is timed such that the BT potential follows the atrial electrogram (blue arrow), and not the ventricular recording (red arrow). Thus, it is not part of the ventricular electrogram.

the earliest ventricular activation site during anterograde BT conduction from the atrial aspect of the annulus can be distant from the atrial insertion site of the BT, and ablation would not then be successful.

Although BT conduction can be eliminated by ablation anywhere between the atrial and ventricular ends, RF applications targeted to the atrial end (site of earliest atrial activation during retrograde BT conduction) or ventricular end (site of earliest ventricular activation during anterograde BT conduction) can occasionally fail. This observation suggests that the recording range of the 4-mm electrode (unipolar or bipolar configuration) commonly used for RF ablation is greater than the RF lesion radius.

Criteria of successful ablation sites during anterograde or retrograde activation mapping of BTs are presented in Table 18-10 (and see Figs. 18-36 and 18-37).

Ablation Technique: General Considerations

Some investigators have advocated a simplified approach to ablation using one or two catheters. Although often successful, 10% of patients with preexcitation have multiple arrhythmias, and 10% to

20% of such patients have multiple BTs that can result in a very complex procedure. Because it is difficult to know beforehand in any given patient whether the procedure will be straightforward or complex, the single-catheter approach to ablation of arrhythmias should be discouraged.

For most free wall BTs, complete bidirectional block can be achieved with a conventional 4-mm-tip ablation catheter, using a power setting of 50 W and targeting a temperature of 60°C. If BT conduction block is transient, permanent BT block can usually be obtained with better and more consistent contact at the same site. It is rare that an 8-mm- or irrigated-tip ablation catheter is necessary, except when ablating in small branches of the CS, at which time irrigated-tip catheters can be helpful, because power delivery with a standard 4-mm electrode is limited because of less passive cooling in small vessels.

RADIOFREQUENCY ENERGY DELIVERY

A temperature of 55°C to 60°C should be sought. Transient loss of BT function is seen at roughly 50°C, and permanent loss of function occurs at 60°C. Therefore, sites with favorable electrogram

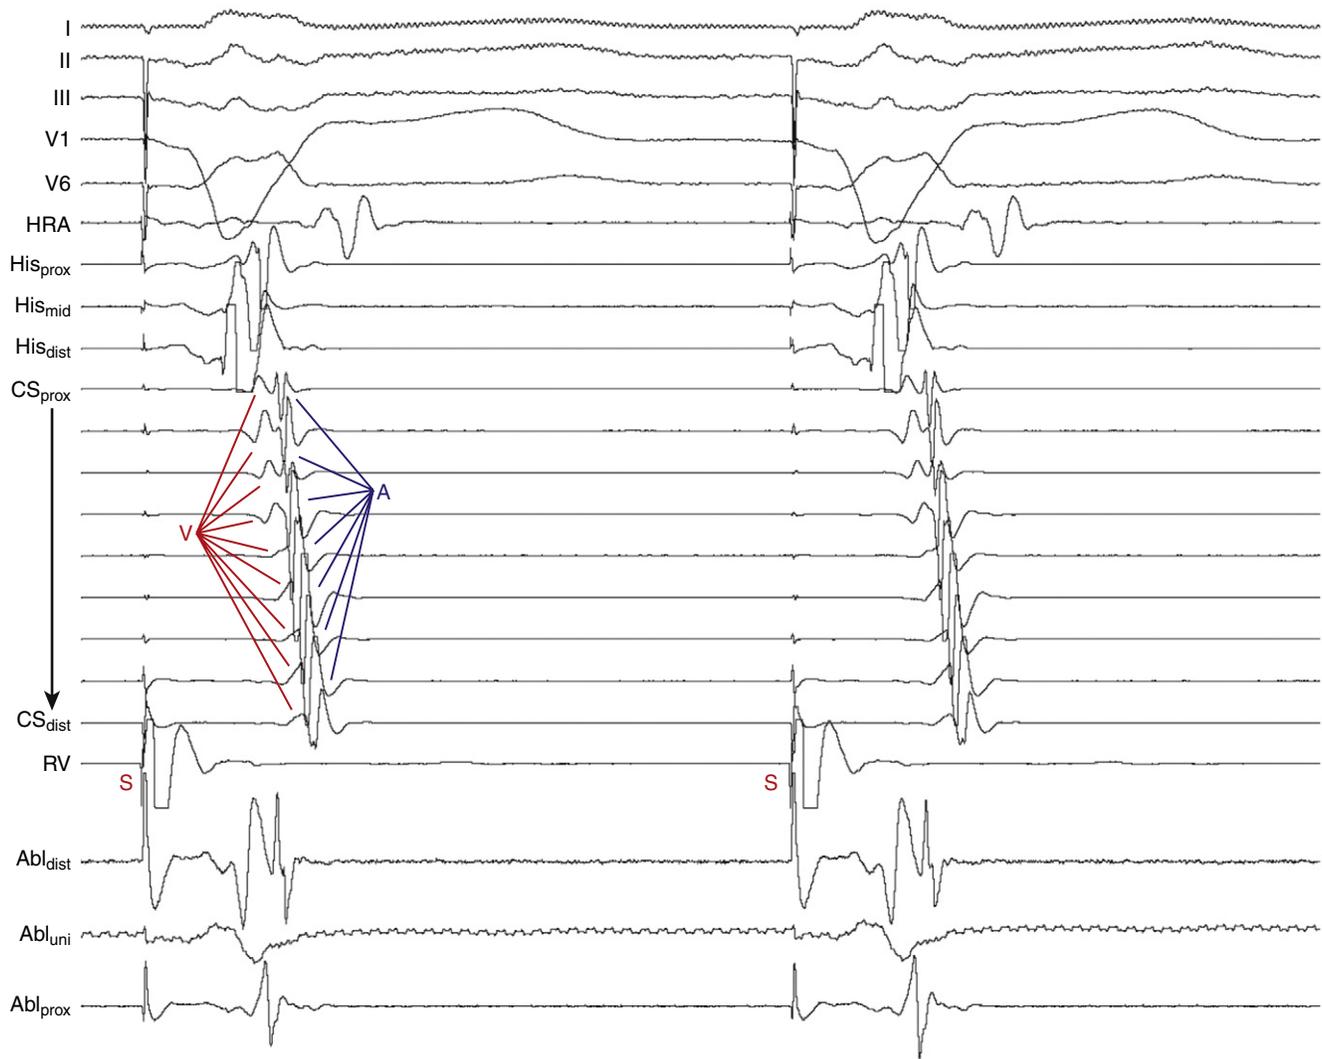

FIGURE 18-42 Two ventricular paced complexes with retrograde conduction are shown. Ventricular (V) and atrial (A) recordings are as designated by lines. Of the recordings indicated, the earliest atrial electrogram is at CS_{prox} (proximal coronary sinus), whereas the shortest local VA interval is far more distal in the coronary sinus recordings; in fact, in CS_{dist} (distal coronary sinus), the VA interval is negative.

characteristics should not be abandoned until a temperature higher than 50°C to 55°C is reached. Conversely, repeated energy applications at the same location after achieving a temperature of 55°C or higher are unlikely to succeed.⁴⁷

Loss of BT conduction is expected within 1 to 6 seconds of RF application (once the target temperature and power delivery have been reached) for most successful lesions. If no effect is seen after 15 seconds of RF delivery, energy delivery should be discontinued because it is unlikely to be beneficial, and mapping criteria and catheter contact should be reexamined. If BT conduction is eliminated during the application, RF delivery should be continued for up to 60 seconds. BT conduction may be eliminated in one direction only (most typically loss of anterograde but persistence of retrograde conduction). Thus, testing for conduction in each direction is mandatory after what appears to be a successful RF application.

If preexcitation is present, ablation should be performed during NSR or, preferably, atrial pacing. For concealed BTs, RF energy is delivered during ventricular pacing, which usually allows for detection of an altered retrograde atrial activation sequence. RF energy delivery during AVRT should be avoided because of potential catheter dislodgment from its critical position on abrupt tachycardia termination. This event can be associated with transient loss of conduction over the BT for a variable period of time without resulting in permanent damage to the BT caused by premature

interruption of the RF application. Occasionally, BT conduction may resume hours to days after the procedure; therefore, one may not find a suitable target to complete the RF lesion if not addressed adequately during the initial attempt. Ablation during continuous pacing prevents this problem. For incessant AVRT, energy may be delivered during ventricular pacing entraining the tachycardia. Also, the use of an electroanatomical mapping system can obviate this problem by tagging the initial site of ablation, allowing precise return to that site.⁴⁷

If BT function is not eliminated at a site with apparent favorable electrographic features, catheter contact with the tissue may be inadequate. Adequacy of catheter contact can be verified by evaluating the electrode temperature, catheter stability on fluoroscopy, electrogram stability, and ST elevation on the unipolar electrogram (Fig. 18-44). If the electrode temperature is consistently more than 50°C with more than 25 W of energy delivered to the tissue during the RF application, good catheter contact is likely; however, if electrode temperature reaches more than 50°C but with very low power (<10 W), coagulum may have formed at the catheter tip. Also, catheter “shimmering” on fluoroscopy suggests poor contact. Similarly, changing electrographic amplitudes before or during ablation suggest inadequate catheter contact. Furthermore, ablation-related injury usually yields ST elevation on the unipolar electrogram; if absent, inadequate tissue heating is likely.⁴⁷

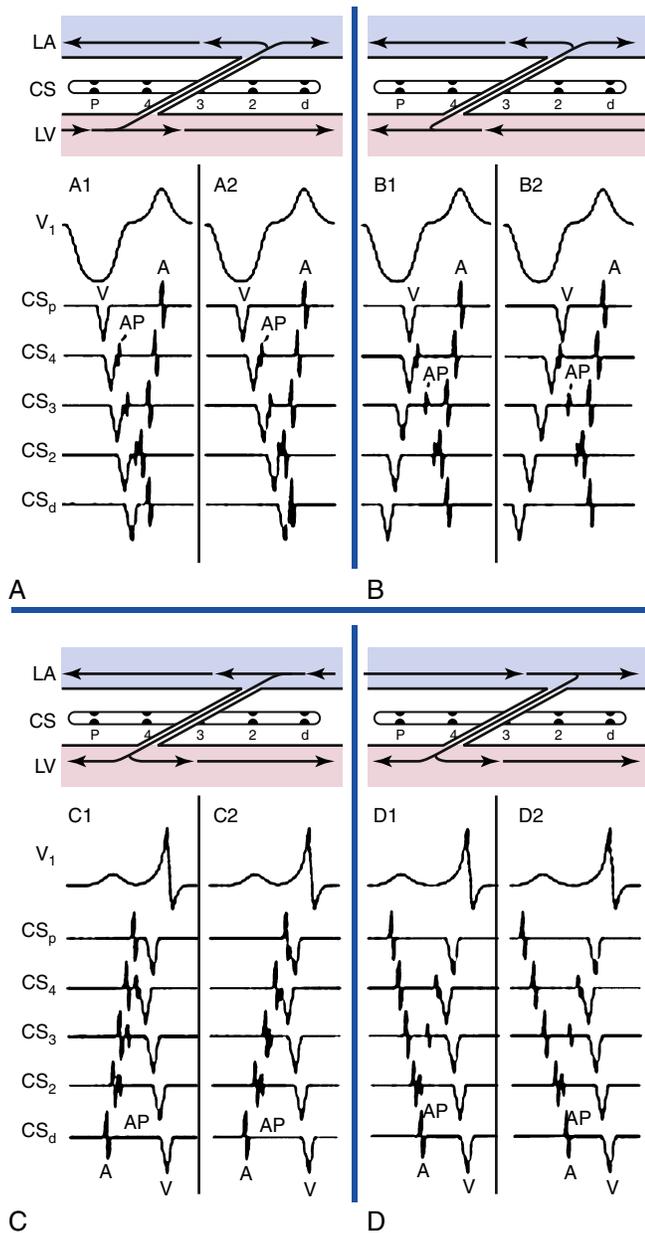

FIGURE 18-43 Schematic representation of anterograde and retrograde activation of a left free wall bypass tract. The oblique course illustrates change in electrogram timing with the reversal of the paced ventricular wavefront (A and B) and reversal of the paced atrial wavefront (C and D). AP = accessory pathway potential; p = proximal; d = distal. (From Otomo K, Gonzalez MD, Beckman KJ, et al: Reversing the direction of paced ventricular and atrial wavefronts reveals an oblique course in accessory AV pathways and improves localization for catheter ablation, *Circulation* 104:550, 2001.)

Ablation of Left Free Wall Bypass Tracts

ANATOMICAL CONSIDERATIONS

Although the atrial insertion of the BT is typically discrete in size (1 to 3 mm) and close to the mitral annulus, the ventricular insertion site tends to ramify over the region of tissue and can be displaced a small distance away from the mitral annulus, toward the ventricular apex.⁴⁸ Additionally, most left free wall BTs cross the mitral annulus obliquely, with the atrial insertion typically 4 to 30 mm proximal (posterior) to the more distal (anterior) ventricular insertion site (as mapped from within the CS).⁶

Conduction at the insertion sites of the BT is markedly anisotropic because of almost horizontal orientation of the atrial and ventricular

TABLE 18-10 Electrophysiological Criteria of Successful Bypass Tract Ablation Sites

Criteria of Successful Ablation Sites during Anterograde Activation Mapping

- Stable catheter position, as confirmed fluoroscopically and by observing a stable electrogram (<10% change in amplitude in atrial and ventricular electrograms over 5-10 beats).
- Atrial electrogram amplitude >0.4 mV, or A/V ratio >0. Both atrial and ventricular electrogram components should be recorded from the ablation (tip) electrode. When ablating from the atrial aspect of the annulus, the atrial electrogram is usually equal to or larger than the ventricular electrogram. Sometimes, the two can merge and it may be difficult to determine whether both components are present. Rapid atrial or ventricular pacing resulting in block in the BT can help eliminate ventricular or atrial electrogram (respectively) so that the exact morphology of the other component can be visualized.
- Local AV interval on the ablation catheter is usually short (25-50 msec, except for previously damaged, slowly conducting, oblique, or epicardial BTs).
- The local ventricular electrogram on the ablation catheter should precede the onset of the delta wave on the ECG by a mean of 0-10 msec for left-sided BTs and 10-30 msec for right-sided BTs (the local ventricular electrogram is measured from the peak of the bipolar electrogram or the maximal dV/dT in the unipolar electrogram).
- QS (or, less preferably, rS) morphology of the unipolar electrogram. Right-sided BTs usually have unipolar recordings that show more pronounced (rapid and deeper) QS configuration than left-sided BTs.
- Continuous electrical activity (defined as isoelectric interval of <5 msec between ventricular and atrial electrograms).
- Presence of BT potential.

Criteria of Successful Ablation Sites during Retrograde Activation Mapping

- Stable catheter position, as confirmed fluoroscopically and by observing a stable electrogram (<10% change in amplitude in atrial and ventricular electrograms over 5-10 beats).
- Local VA interval during retrograde activation of the BT is short (25-50 msec, except for previously damaged, slowly conducting, oblique, or epicardial BTs), usually resulting in inscription of the atrial electrogram on the ascending portion of the terminal ventricular electrogram. The "pseudo-disappearance" of the atrial electrogram within the terminal portion of the ventricular electrogram (forming a W sign) during orthodromic AVRT is a manifestation of an extremely short local VA interval, which correlates with successful ablation sites.
- Surface QRS to local atrial electrogram interval ≤ 70 msec (during orthodromic AVRT).
- The local VA interval remains constant regardless of which direction the ventricular wavefront engaging the BT is traveling (i.e., despite pacing from different ventricular sites). If one uses the ventricular approach to ablate a concealed BT, the ventricular insertion site can be identified as one that maintains a constant local VA interval, despite differences in direction of activation to the ventricular site.
- Continuous electrical activity (defined as isoelectric interval <5 msec between ventricular and atrial electrograms).
- Presence of BT potential.

A/V = atrium to ventricle; AVRT = atrioventricular reentrant tachycardia; BT = bypass tract; VA = ventriculoatrial.

fibers as they insert into the mitral annulus. In addition, the atrial fibers run parallel to the annulus, giving rise to rapid conduction away from the insertion site, parallel to the annulus, and slow conduction to the free wall of the atrium, perpendicular to the annulus.

Although the CS is useful as a guide for mapping the mitral annulus in the left anterior oblique (LAO) fluoroscopy view, it has a variable relationship to the mitral annulus. The CS lies 2 cm superior to the annulus as it empties into the RA. Anterolaterally, the CS frequently overrides the LV. Thus, depending on the distance from the ostium, the CS can lie above the mitral annulus and be associated with the left atrium (LA), or can cross over the LV side of the mitral annulus. Therefore, electrograms recorded from the CS can only provide a reference for atrial and/or ventricular insertion sites of the BT and can only be used to guide the ablation catheter to areas in which more detailed mapping needs to be performed.⁴⁸

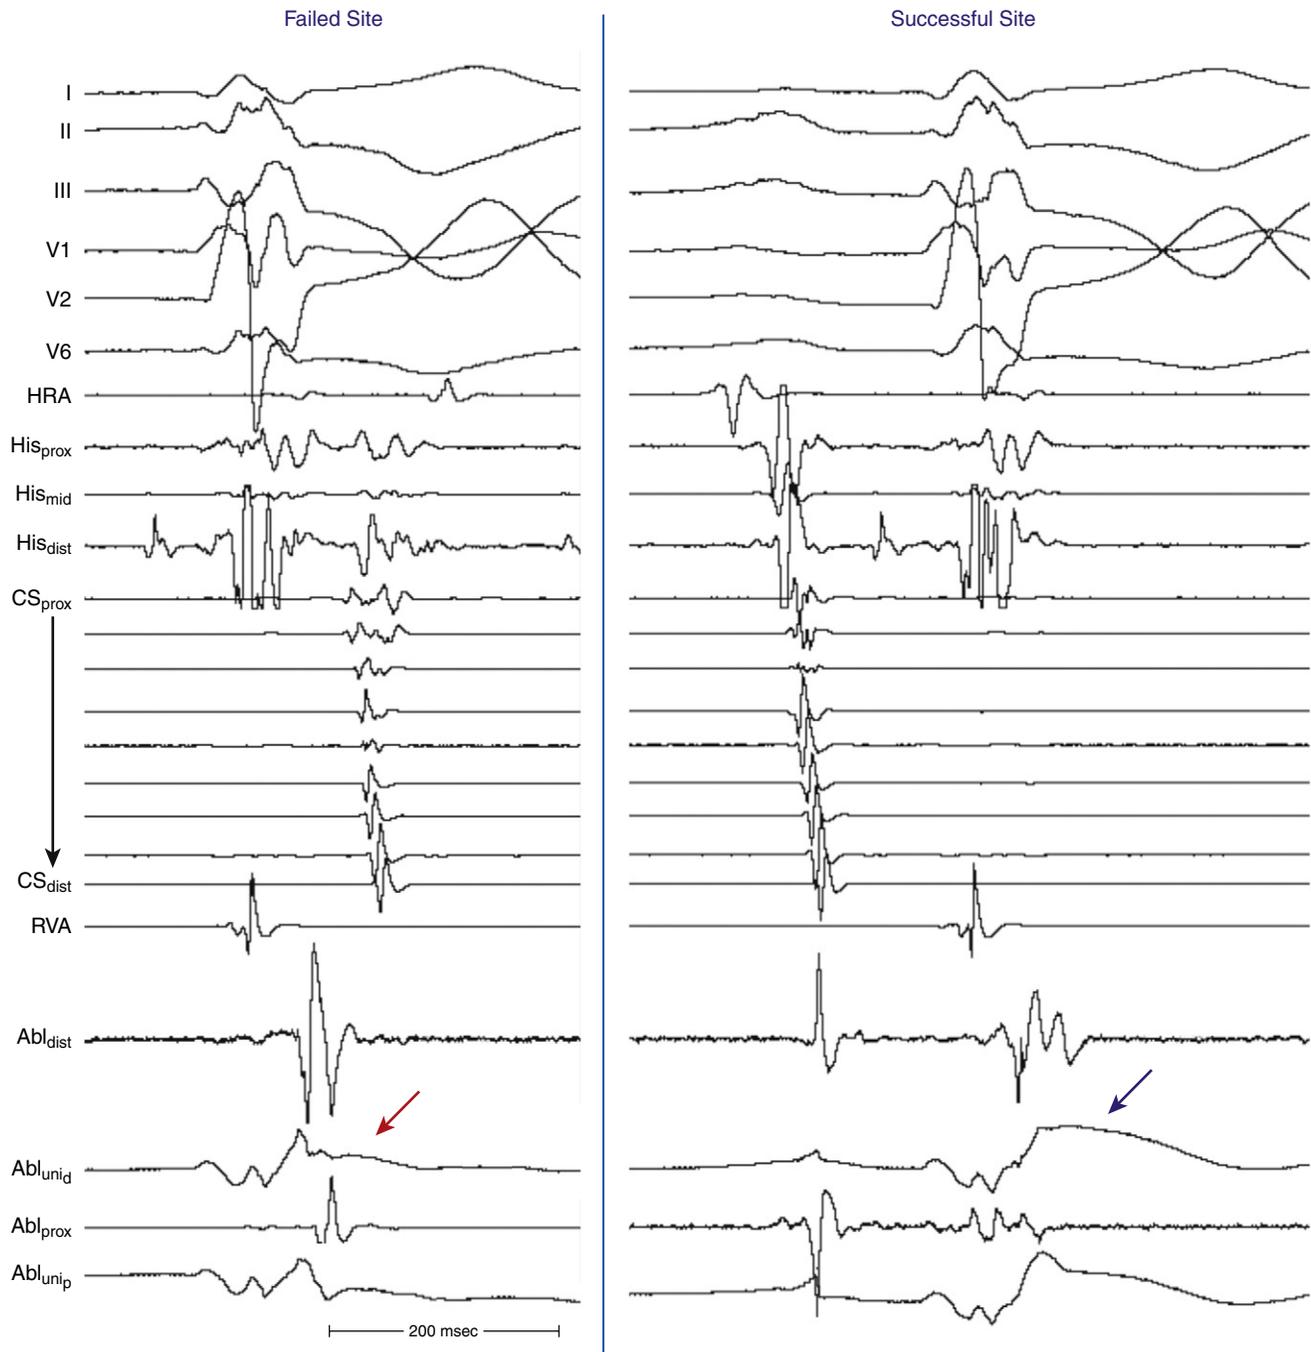

FIGURE 18-44 Effect of ablation on unipolar ST segment. On the **left** ("Failed Site"), recordings during orthodromic atrioventricular reentrant tachycardia are shown following an unsuccessful ablation attempt. The distal ablation unipolar (Abl_{unid}) recording shows minimal, if any, ST segment shift in the ventricular recording (red arrow). On the **right** ("Successful Site"), a single complex of sinus rhythm is shown with significant ST elevation (blue arrow), indicating injury has occurred at that site.

TECHNICAL CONSIDERATIONS

TRANSAORTIC (RETROGRADE) APPROACH. The right femoral artery is the most commonly used access for the transaortic approach. A long vascular sheath may provide added catheter stability, although with a possibly increased risk of thromboembolism. Anticoagulation is started before the LV is accessed (with heparin, 5000 U IV bolus, followed by 1000 U/hr infusion), to maintain the activated clotting time (ACT) between 250 and 300 seconds. The ablation catheter is advanced to the descending aorta and, in this position, a tight J curve is formed with the catheter tip before passage to the aortic root to minimize catheter manipulation in the arch. In the right anterior oblique (RAO) fluoroscopy view, the curved catheter is advanced through the aortic

valve with the J curve opening to the right, so the catheter passes into the LV oriented anterolaterally. The straight catheter tip must never be used to cross the aortic valve, because of the risk of leaflet perforation. Once in the LV, and while maintaining a tight curve, the catheter is rotated counterclockwise and withdrawn in the LA as the tip turns posteriorly. By opening the J curve slightly, the tip can easily map the mitral annulus; clockwise torque moves the tip anteriorly (distally along the CS), and counterclockwise torque returns the tip posteriorly (proximally along the CS). Alternatively, after crossing the aortic valve, the catheter can be straightened and steered directly under the mitral annulus to the BT location or withdrawn in the LV outflow tract, rotated posteriorly with a slight curve, and then advanced under the posterior

mitral annulus for left paraseptal or posterior BTs. When the ablation catheter is approximated along the mitral annulus, the catheter tip is simultaneously withdrawn and straightened slightly to slip under the annulus for fine manipulation. For left lateral and anterior BTs, extended-reach catheters may be required.⁴⁸

Catheter positions beneath the annulus between the ventricular myocardium and mitral leaflet are most stable for ablation of the BT ventricular insertion, but manipulation can be constrained by the chordae. Catheter positions above or along the annulus provide more freedom to map along the mitral annulus but are sometimes too unstable for successful energy delivery. Initial mapping is performed with the ablation electrode on the annulus. From this general area, the catheter is then positioned beneath the mitral annulus for more precise mapping. Catheter tip positions beneath the mitral annulus are suggested by proximity to the CS catheter, motion concomitant with the CS catheter, and an A/V electrogram ratio of less than 1.

Because the transaortic approach targets the ventricular insertion site of the BT, it is best suited for mapping anterograde BT activation (i.e., preexcitation). Mapping retrograde activation from the subannular position is more difficult than for anterograde mapping because of obscuration of the low-amplitude atrial electrogram following the large ventricular electrogram.

Although BT locations are commonly defined by mapping along the CS catheter, this only approximates localization of the subannular ablation site because of the oblique course of left free wall BTs, displacement of the CS above the mitral annulus, variable basal-apical ventricular insertion of the BT, and BT location beyond the distal CS electrode.

TRANSEPTAL APPROACH. Transseptal and transaortic approaches are equally effective for ablation of left free wall BTs.⁴⁹ However, the transseptal approach is primarily used for mapping of the BT atrial insertion site during retrograde BT conduction (orthodromic AVRT or ventricular pacing). On the other hand, ventricular mapping of manifest BTs (during preexcitation) using the transseptal approach is limited.⁴⁷

The transseptal approach has several advantages over the transaortic approach.⁴⁹ The transseptal approach provides better access to far lateral and anterolateral BT locations, easier catheter maneuverability in the LA, and less risk of coronary injury. Additionally, no arterial access is required with the transseptal approach, and vascular recovery is therefore shorter. However, the transseptal approach provides less catheter stability and is associated with a higher risk of cardiac perforation and air embolism. Furthermore, the transseptal approach entails higher cost if intracardiac echocardiography is used.⁴⁹

Before introducing the standard transseptal sheath, its curvature can be modified according to BT location. The curve is left intact for left posterior BTs. The sheath is progressively withdrawn toward the RA for lateral BT locations, and it is almost entirely withdrawn toward the RA for anterior BTs. Alternatively, preformed or deflectable sheaths may be used. Ablation catheters with bidirectional asymmetric deflections also can be of value.

Once the ablation catheter is positioned on the mitral annulus in a 30-degree RAO view, mapping is performed in the LAO view. In the absence of preformed septal sheaths, gentle clockwise torque is needed to maintain the catheter on the posterior mitral annulus. No torque is needed for lateral positions. As the catheter is moved anteriorly, counterclockwise torque is necessary to keep the catheter tip on the annulus. In the anterior positions, the catheter tip can dislodge into the LA appendage or LV, and attention to intracardiac electrograms is necessary when mapping anterior regions, because the CS catheter rarely provides an accurate fluoroscopic reference in this setting. The goal is to maintain the catheter tip on the atrial aspect of the mitral annulus, so that the mitral annulus can be easily mapped by advancing and withdrawing the catheter, causing it to slide along the mitral annulus freely in parallel to the CS catheter. Advancing the catheter moves the tip posteriorly; withdrawing it moves the tip anteriorly. The ventricular aspect of the mitral annulus can be mapped by passing the catheter tip across the mitral valve and deflecting the tip toward the annulus.

The transeptal approach facilitates mapping of the atrial aspect of the mitral annulus. Catheter position on the atrial aspect of the annulus can be verified by recording a bipolar A/V electrogram amplitude ratio of greater than 1, and a unipolar electrogram PR segment displacement from baseline without ST segment displacement. The stability of the catheter can be assessed by PR segment elevation (confirming good atrial tissue contact), consistent local electrographic amplitudes, and concordant motion of the CS and ablation catheters.

Because of the mobility of the ablation catheter and the electrode orientation parallel with atrial activation along the mitral annulus, a unique vectorial mapping technique is possible with the transeptal approach. As noted, using the unfiltered bipolar electrogram with the electrodes oriented parallel to the axis of the mitral annulus, the BT atrial insertion can be identified as the site at which the polarity of the atrial potential reverses.

Ablation of Right Free Wall Bypass Tracts

ANATOMICAL CONSIDERATIONS

Unique features of the tricuspid annulus and important anatomic differences as compared with the mitral annulus have often rendered ablation of right-sided BTs more challenging than that of left free wall BTs. Additionally, transient interruption of BT conduction during RF delivery, with subsequent resumption of conduction within seconds or minutes, and recurrence rates over the first few weeks after initially successful BT ablation, are more common with right-sided BTs compared with left-sided BTs.

A significantly larger endocardial area is present along the tricuspid ring because of the larger circumference compared with the mitral ring (12 versus 10 cm). Additionally, BTs may occur anywhere around the tricuspid annulus whereas the mitral ring has an area of fibrous continuity with the left and posterior leaflets of the aortic valve (the aortomitral continuity) where BTs are rarely found. Despite these facts, right-sided BTs are much less common than left-sided BTs (12% versus 59%).

In contrast to the mitral valve, which attaches to its fibrous annulus at a right angle, the tricuspid valve attaches to its annulus at an acute angle oriented toward the RV, making it more difficult to wedge an ablation catheter underneath the tricuspid valve. Additionally, unlike left parietal AV BTs, which tend to pass close to the hinge line of the mitral valve, the AV groove between the RA and RV is much deeper than on the left side. The deep groove can allow the RA wall to fold over onto the RV wall, and the BT muscle bundles can cross at any depth.⁴ Hence, the right-sided BTs can be somewhat removed from the tricuspid annulus. In fact, atrial insertion of the BT can be as far as 1 cm away from the annulus in the folded-over atrial sac. The folded-over atrium and the bizarre angle required for mapping of the inferior and posterolateral aspect of the RA by a catheter passed through the RA from the inferior vena cava (IVC) can make it difficult to achieve a stable catheter position at the tricuspid annulus because of a tendency of the catheter to fall into the folded-over sac. Thus, sometimes the superior vena cava (SVC) approach is required to allow full exploration of the folded-over atrial sac and the inferior-inferolateral positions around the tricuspid annulus. The standard IVC approach, however, is usually adequate to map the superior aspects of the tricuspid annulus. If the IVC approach is used, a guiding sheath can be especially helpful for better catheter stability and tissue contact. The use of a multipolar (Halo) catheter positioned around the tricuspid annulus can provide good regional localization to guide the ablation catheter.

Furthermore, closely adjacent but anatomically discrete sites of catheter ablation can be necessary to eliminate anterograde and retrograde BT conduction in up to 10% of patients—the incidence is highest (18.6%) with right free wall BTs. The explanation for this phenomenon is not clear but probably relates to the complexity of fiber orientation, possibly branching over 1 to 2 cm along the annulus. This factor emphasizes the importance of identifying and targeting both the atrial and the ventricular BT insertion sites.⁵⁰ Right-sided

AV BTs are associated with higher incidences of anatomic variations and congenital abnormalities along the tricuspid annulus. Ebstein anomaly is an abnormality of the tricuspid valve in which the septal leaflet and often the posterior leaflet are displaced a variable distance into the RV and the anterior leaflet is usually malformed, excessively large, and abnormally attached or adherent to the RV free wall. Thus, a portion of the RV is “atrialized” in that it is located on the atrial side of the tricuspid valve, and the remaining functional RV is small. The atrialized portion of the RV is morphologically and electrically ventricular but functionally atrial. Right-sided BTs have been reported in 10% to 30% of patients with Ebstein anomaly, and they often are multiple. The BTs bridge the true anatomical tricuspid annulus, regardless of where the valve is located, and ablation can be challenging as electrical signals recorded from the atrialized portion of the RV can be complex and fractionated, and identification of the true AV groove, along which BTs are targeted, can be difficult. Coronary angiography or insertion of a thin multielectrode catheter in the right coronary artery may be necessary to help identify the true AV groove. Ablation is usually accomplished at the true tricuspid annulus, above the displaced valve leaflet, although some patients may undergo successful ablation from the ventricular side of the tricuspid annulus (but still above the valve leaflet).⁵⁰

TECHNICAL CONSIDERATIONS

Characteristics of successful ablation sites for right-sided BTs include the following: the local AV interval is shorter than that for BTs elsewhere, the local ventricular electrogram precedes the onset of the delta wave by an interval longer than that for BTs elsewhere (18 ± 10 milliseconds for right-sided BTs versus 0 ± 5 milliseconds for left-sided BTs), and the unipolar recording shows more pronounced (rapid and deeper) QS configuration.

Most commonly, ablation of the BT is approached from the atrial aspect. The optimal site of ablation is the earliest atrial activation site during retrograde BT conduction (during orthodromic AVRT or ventricular pacing), preferably with a BT potential present. The earliest site of atrial activation is identified using a roving catheter or a multipolar (Halo) catheter along the tricuspid annulus. If mapping is performed during ventricular pacing, conduction over both the BT and AVN can occur, resulting in atrial fusion, which can interfere with localization of the BT. Ventricular pacing performed close to the BT ventricular insertion site can accentuate atrial activation over the BT.⁵⁰

Occasionally, the BT may be better approached from the ventricular side. Ventricular activation mapping is performed during preexcited NSR, atrial pacing, preexcited SVT, or antidromic AVRT.⁵⁰ The site of the earliest ventricular activation during preexcitation, preferably with a BT potential present, would be the optimal site. The earliest onset of ventricular activation recorded on the ablation catheter (using unipolar or bipolar electrograms) should precede the onset of the delta wave by at least 10 to 25 milliseconds. For concealed BTs, the ventricular insertion site cannot be determined by ventricular activation mapping because of the lack of preexcitation. In this setting, recording of a BT potential can be especially useful to help guide ablation.

The tricuspid annulus is usually mapped in the LAO fluoroscopy view. The right posterior, posterolateral, and lateral regions are usually best mapped from the IVC approach. The right anterior and anterolateral regions can also often be ablated using the IVC approach, but the SVC approach can offer more stable and better catheter-tissue contact in these areas. The catheter can be prolapsed across the tricuspid valve to help stabilize the tip on the tricuspid annulus. In the LAO view, the HB is located at about 1 o'clock and the CS at 5 o'clock; right free wall BTs span from approximately 6 to 12 o'clock. Right anterior BTs are at the most superior aspect of the tricuspid annulus, right superoparaseptal BTs are located near the HB catheter, and right posterior free wall BTs are located at the most posterior aspect of the tricuspid annulus, whereas right posteroseptal BTs are located near the CS.⁵⁰ Although the location of the mitral annulus is reasonably indicated by the CS catheter, the location of the tricuspid annulus is not as easily discerned because

there is no analogous venous structure to mark with a catheter. Furthermore, because the mitral and tricuspid annuli are not always in the same plane, the CS catheter is only a rough guide to the location of the tricuspid annulus in the RAO view.

Attempts at providing an endocardial reference catheter along the tricuspid annulus have been made using a 20-pole Halo catheter. This approach has had limited success, as the catheter often does not position directly on the AV groove. Introducing the Halo catheter through a preformed sheath can provide better catheter stability along the tricuspid annulus. Occasionally, a fine angioplasty wire may be passed into the right coronary artery to delineate the location of the tricuspid annulus. The latter approach, however, has not been widely adopted, possibly in part because of concerns of prolonged instrumentation of the right coronary artery during the procedure. Another approach is to create a three-dimensional electroanatomical map (EnSite-NavX; St. Jude Medical, St. Paul, Minn.) of the right coronary artery. After right coronary artery angiography, a 2.3 French (Fr) octapolar microcatheter (Cardima Inc., Fresno, Calif.) is inserted in the right coronary artery. The EnSite NavX system is used because it is nonproprietary with respect to catheter recognition. Mapping and acquisition of the bipolar electrograms recorded by the microcatheter are performed during anterograde or retrograde BT conduction. This map allows for early removal of the catheter from the coronary artery while continuously displaying electroanatomic information to assist with mapping of the BT.⁵¹

To target the ventricular aspect of the tricuspid annulus, the catheter is introduced across the tricuspid valve and looped back on itself in the RV underneath the valve until a small atrial electrogram and a larger ventricular electrogram are recorded, confirming adequate proximity to the tricuspid annulus. A long sheath may be used to stabilize the body of the catheter and direct the catheter to several different locations along the tricuspid annulus.

RF energy may be delivered during NSR, atrial pacing, or ventricular pacing. Delivery during AVRT can result in sudden termination of the SVT, which can cause dislodgment of the ablation catheter, resulting in an inadequate RF application. Therefore, if retrograde mapping during orthodromic AVRT is used to determine the optimal atrial ablation site, especially for concealed BTs, it is preferable to entrain the orthodromic AVRT with ventricular pacing at a slightly shorter CL so that block in the BT and termination of the SVT during RF energy delivery will be followed by ventricular pacing at a rate similar to that of the SVT, minimizing catheter movement. If BT function does not disappear despite good catheter stability, adequate catheter-tissue contact, and good temperature rise ($>50^\circ\text{C}$), the catheter is probably located at the wrong site. Although transient interruption of BT conduction during RF delivery, with subsequent reappearance of conduction within seconds or minutes after energy delivery is completed, is more common with right than left free wall BTs, the use of multisite “insurance lesions” is discouraged, and the use of one or two ablation sites should be the goal, which requires careful mapping to achieve.

Three-dimensional electroanatomical mapping can help ablation of right-sided BTs, and is especially useful in the presence of multiple BTs or complicated anatomy. An electroanatomical color-coded activation map along the tricuspid annulus can be constructed, either along the atrial side, during orthodromic AVRT or ventricular pacing, or along the ventricular side, during anterograde preexcitation. Sites of interest can be tagged for further reference, so that the ablation catheter can be returned to any of them with precision. Information with regard to catheter stability and movement can also be provided.

Ablation of Posteroseptal (Inferoparaseptal) Bypass Tracts

ANATOMICAL CONSIDERATIONS

The posteroseptal region corresponds to a complex anatomic region where the four cardiac chambers reach their maximal

proximity posteriorly (i.e., the crux), and incorporates the converging segments of the AV rings as well as the CS with its proximal branches. The posteroseptal region spans the area between the central fibrous body (superiorly), the interventricular septum (anteriorly), the right posterior paraseptal (right lateral border), and the left posterior paraseptal (left lateral border) regions. Posteroseptal BTs may be located in a relatively wide area either at an epicardial site around the proximal CS or the middle cardiac vein or at an endocardial site along the tricuspid ring in the immediate vicinity of the CS os or along the posteromedial ventricular aspect of the mitral annulus. Because the posteroseptal region is actually posterior to the septum and not a septal structure, posteroseptal BTs are more appropriately referred to as right- or left-sided inferoparaseptal or posterior paraseptal BTs.^{52,53}

Because the interatrial sulcus is displaced to the far left of the interventricular sulcus, and because the AV valves are not isoplanar (the attachment of the septal leaflet of the tricuspid valve into the most anterior part of the central fibrous body is displaced a few millimeters apically relative to the attachment of the septal leaflet of the mitral valve), the true septal part of the AV junction (the RA-LV sulcus) actually separates the inferomedial RA from the posterior superior process of the LV. The undersurface of the CS is about 1 cm above the mitral annulus, and the CS os abuts the superior margin of the RA-LV sulcus.⁴⁸ The right margin of the posteroseptal space includes the area surrounding the CS os and the inferior portion of the triangle of Koch; the left margin (the junction of the posterior septum and left free wall) lies as far as 2 to 3 cm from the CS os. The epicardial dimension of the posteroseptal space at the level of the valve annuli extends a mean of 3.4 ± 0.5 cm. BTs can be located anywhere within this relatively large space or in the adjacent right or left free walls. BTs located close to the edges of the septum can be ablated from the adjacent atrial or ventricular cavity, but BTs located deep within the posteroseptal space or near the epicardial aspect require ablation from within the CS or cardiac veins. BTs located in the proximal 1.5 cm of the CS are almost always in the posterior septum. Those located between 1.5 and 3 cm from the CS os can be in the left free wall or posterior septum, and those located more than 3 cm from the CS os are almost invariably in the left free wall.⁴⁸ Most posteroseptal BTs are believed to be RA-to-LV BTs, with the ventricular insertion attaching onto the posterior superior process of the LV, but some posteroseptal BTs are considered to be left paraseptal (connecting the LA to the LV) or right paraseptal (connecting the RA to the RV).⁵³⁻⁵⁵

Although epicardial BTs can be found at any location, they are most common in the posteroseptal and left posterior paraseptal regions.⁴⁹ Approximately 20% of all posteroseptal BTs and 40% of those in patients referred after a failed ablation procedure are epicardial. One hypothesis for this predilection is that those BTs connect the myocardial coat of the CS, which is connected anatomically and electrically to both the RA and LA, and to the LV (see later discussion).

TECHNICAL CONSIDERATIONS

Ablation of posteroseptal BTs usually is more difficult than other BT locations because of the complexity of the anatomical structures involved.⁴⁸ Mapping and ablation may be required at either the mitral or the tricuspid annulus, or inside the CS or its proximal branches. Therefore, the ability to discriminate—without instrumentation of the left heart—BTs amenable to ablation from the right side (on the tricuspid ring or inside the coronary venous system) from those requiring ablation on the mitral ring can potentially have great impact on procedure outcome and safety by reducing procedural and fluoroscopy times, reducing the number of unsuccessful RF applications, as well as avoiding unnecessary left atrial access and its potential complications.^{54,55}

Generally, a right-sided endocardial approach is initially adopted for mapping and ablation of BTs in the posteroseptal region. The posteroseptal tricuspid annulus, including the CS os and its most

proximal part, and inferomedial RA are carefully mapped. If the ablation site fails or no appropriate ablation site can be obtained, the left posteroseptal area is mapped (with a transaortic or transseptal approach, as described for left-sided BTs). A primary left-sided approach can also be considered if multiple ECG and EP features suggest a left-sided location of the BT. If endocardial mapping fails, an epicardial approach via the CS is then considered (see later).

Prediction of the site of successful ablation of posteroseptal BTs into either the right or the left heart has been attempted by the analysis of the preexcitation pattern on the surface ECG. In addition to the obvious limitation of the surface ECG in the case of concealed BTs (47.5% in a recent report), reports on the accuracy of surface ECG features to differentiate BTs associated with the three compartments of the inferior paraseptal space have been conflicting.

Previous reports found that, in patients with preexcitation, a negative delta wave polarity in lead V_1 and positive polarity in lead V_2 favors right-sided localization of a posteroseptal BT, whereas left posteroseptal BTs were associated with biphasic or positive delta wave polarity in leads V_1 and V_2 . Recent reports, however, have questioned the predictive value for such a criterion. The vast majority of posteroseptal BTs can be successfully ablated at the tricuspid annulus or within the proximal CS although the delta wave polarity on the ECG suggests a left ventricular origin. This phenomenon can be explained by the fact that many posteroseptal BTs are “RA-to-LV” fibers and an RA approach would suffice even though the delta wave polarity in lead V_1 is suggestive of left posteroseptal BTs.^{54,55}

On the other hand, the R/S ratio in lead V_1 was found to be an accurate ECG parameter to predict the site of successful posteroseptal BT ablation. This finding might be related to the observation that the ventricular insertion of “RA-to-LV” posteroseptal BTs attaches onto the posterosuperior process of the LV, resulting in earlier activation of the posterobasal LV with positive delta wave and predominantly negative QRS morphology (R/S ratio <1) in lead V_1 . In contrast, the ventricular insertion of “LA-to-LV” BTs attaches to the posteromedial aspect of the mitral annulus, resulting in a positive delta wave and a predominantly positive QRS morphology (R/S ratio >1) in lead V_1 .⁵⁵

Invasive EP findings also have been used to predict the successful ablation site of manifest or concealed posteroseptal BTs. The prolongation of the VA interval in response to the development of LBBB during orthodromic AVRT has been regarded as suggestive of a left-sided BT. However, many posteroseptal BTs associated with this phenomenon can be ablated from the right side, sometimes even when the prolongation is more than 30 milliseconds.⁵⁴

Additionally, measurement of the Δ VA interval during orthodromic AVRT (the difference in VA intervals measured at the HB catheter and the site of earliest atrial activation in the CS) was found to be useful for predicting the successful approach. A Δ VA interval greater than or equal to 25 milliseconds suggests a left endocardial BT, whereas a Δ VA interval less than 25 milliseconds favors a right endocardial BT. This suggests that atrial activation is relatively early in the HB region during retrograde conduction through both right endocardial and CS-associated BTs, compared with left endocardial ones.⁵⁴

Furthermore, a previous report found that a VA interval less than 50 milliseconds recorded at the left posteroseptal region during RV pacing identified 71% of patients with left posteroseptal BTs, with 100% specificity. In patients with a VA interval greater than or equal to 50 milliseconds, a difference in the VA intervals of less than 20 milliseconds recorded at the HB region and left posteroseptal region during RV pacing predicted right posteroseptal BT with a sensitivity of 97%, a specificity of 85%, and a positive predictive value of 91%.⁵²

PJRT is usually caused by a slowly conducting BT, commonly located in the posteroseptal region. Although the mere presence of a long-RP AVRT has been suggested to favor a right endocardial BT, in 50% of cases, such BTs can be located in the left posterior or free wall (>4 cm inside the CS). In the remaining 50%, it is located

between the base of the pyramidal space formed by the points of pericardial deflection that contact the posterior RA and LA. None have been reported in the anteroseptal region.⁵⁴

An earliest atrial activation during orthodromic AVRT in the middle CS favors a left endocardial ablation site. However, recent studies found that a large proportion (more than one-third) of patients with an earliest site distal at or distal to the mid-CS required ablation inside the CS after a failed left endocardial approach, and 35% of all BTs ablated from the right side produced such an eccentric retrograde atrial activation.⁵⁴ Therefore, the ability of the site of earliest atrial activation during AVRT to predict the successful approach seems very limited, mainly because CS-associated BTs can produce a very much eccentric retrograde atrial activation sequence.

“Atrial” electrograms recorded from inside the proximal CS originate not only from LA myocardium, but also from activation of the CS myocardial coat. This results in “fragmented” or double potentials, with a low-amplitude, blunt “far field” LA component and a larger, sharp “near field” signal from the CS musculature. The sequence of LA and CS myocardial coat activation at the earliest “atrial” electrograms in the CS recorded during retrograde BT conduction by a catheter placed inside the CS can guide mapping of these BTs into right- or left-sided compartments of the inferoparaseptal space. An activation wavefront traveling from the posteroseptal RA toward the left (e.g., by pacing posterior to the CS os) will first activate the muscle coat covering the proximal CS, producing a large, sharp signal recorded by the electrodes inside the CS. Discrete connections of the CS musculature with the LA will activate the LA myocardium, producing a lower amplitude, blunt, “far field” signal on the CS electrodes. Thus two-component “fragmented” or double potentials will be recorded in the proximal CS, with the sharp component preceding the blunt signal (sharp/blunt sequence). The same sequence (sharp/blunt) of potentials is expected to happen when a retrogradely conducting right-sided “endocardial” BT first activates RA myocardium as well as when a BT inserts directly into the CS musculature (as is the case with epicardial CS-associated BTs). Contrariwise, when pacing is performed from the lateral LA, the sequence is the opposite (blunt/sharp), with CS musculature activation following activation of LA myocardium. This sequence should be produced if a BT connects to LA myocardium (i.e., left-sided “endocardial” AV BTs), the first signal recorded in the CS being a “far field” potential followed by later activation of the CS musculature resulting in a blunt/sharp sequence of potentials. Different conduction velocities of LA myocardium and CS musculature can cause the sequence of potentials to change farther away from the insertion site of the BT, explaining the importance of analyzing the electrograms recorded at the earliest site. The recording of double potentials inside the CS has been found to be especially common during retrograde conduction through posteroseptal BTs.⁵⁴

Ablation of Superparaseptal and Midseptal Bypass Tracts

ANATOMICAL CONSIDERATIONS

The midseptum is the only true muscular septal area between the offset attachments of the mitral and tricuspid valves, and it corresponds roughly to the location of the triangle of Koch. The triangle of Koch is bounded by the CS os posteriorly, the tricuspid annulus (the attachment of the septal leaflet of the tricuspid valve) inferiorly, and the tendon of Todaro anteriorly and superiorly. The compact AVN is located anteriorly at its apex, where the tendon of Todaro merges with the central fibrous body. Slightly more anteriorly and superiorly is where the HB penetrates the AV junction through the central fibrous body and posterior aspect of the membranous AV septum (see Fig. 17-1). The triangle of Koch constitutes the RA endocardial surface of the muscular AV septum. BTs with an atrial insertion in the floor of the triangle of Koch, posteroinferior to the compact AVN and HB and above the anterior portion of the

CS os, have been labeled as midseptal; these BTs are the only truly septal BTs; hence, they can be referred to simply as septal BTs.⁵⁶

The previously named anteroseptal and posteroseptal areas are not septal but are parts of the parietal AV junction that are anterior and posterior to the true septum. Anterosuperior to the AV septum and compact AVN and HB, the tricuspid annulus diverges laterally away from membranous part of the septum to course along the supraventricular crest of the RV (crista supraventricularis). This muscular structure interposes between the attachments of the leaflets of the tricuspid and pulmonic valves in the roof of the RV. BTs in this area (at the apex of the triangle of Koch) are labeled anteroseptal, but they must be considered “superparaseptal” right free wall BTs, because anatomically they do not belong to the septum. There is no atrial septum in the region anterior to the HB recording site; the aortic root separates the right and left atrial walls here.⁵³

TECHNICAL CONSIDERATIONS

BTs are classified as superparaseptal if the BT potential and His potential are simultaneously recorded from the diagnostic catheter placed at the HB region. The precise location of the BT is verified by mapping this space in a 30-degree LAO fluoroscopy view using the ablation catheter, advanced via the right internal jugular vein or IVC. The use of a long vascular sheath may help stabilize the catheter tip during mapping and ablation in the superparaseptal region. The optimal site of ablation is one from which the atrial and ventricular electrograms are recorded in conjunction with a BT potential, but with no or only a tiny His potential (<0.1 mV).⁵⁷ Preferably, the ventricular insertion site of the BT is targeted with ablation to minimize the risk of damage to the AVN. Rarely, ablation is required in the presence of a marked (>0.1 mV) His potential recorded through the ablation catheter (true para-Hisian BTs).

BTs are classified as midseptal if ablation is achieved through the mapping-ablation catheter located in an area bounded superiorly by the electrode recording the His potential, and posteroinferiorly by the CS os, as marked by the vortex of curvature in the CS catheter. The optimal site of ablation for a right midseptal BT is one from which atrial and ventricular electrograms are recorded simultaneously with a BT potential in between. Ablation is first attempted from the right side. If it is ineffective or early recurrence occurs after termination of RF application, then the left-sided approach is attempted. The combination of a negative delta wave in lead V₁ and R-S transition in leads V₃-V₄ suggests right-sided midseptal BT, whereas a biphasic delta wave in lead V₁ and earlier QRS transition (in leads V₁-V₂) suggest a left-sided location of the midseptal BT.⁵⁸ Midseptal BTs can be differentiated from superparaseptal and para-Hisian BTs by a negative delta wave in lead III and a biphasic delta wave in lead aVF.^{26,57}

Ablation in the region of the triangle of Koch is associated with a 5% incidence of AV block and, to decrease this risk, such BTs should be ablated with the catheter placed on the tricuspid annulus or on the ventricular side of the tricuspid annulus, preferably with the use of lower RF power. Titrated RF energy output can be used for true para-Hisian BTs, starting with 5 W, and increasing by 5 W every 10 seconds of energy application, up to a maximum of 40 W. For other superparaseptal BTs, ablation can be started at 30 W, targeting a temperature of 50°C to 60°C. During RF ablation within the triangle of Koch, the occurrence of junctional tachycardia is not uncommon and is associated with loss of preexcitation; this should not be misinterpreted as successful ablation leading to continuing RF energy delivery. Instead, overdrive atrial pacing should be performed to monitor AV conduction or RF application should be stopped and other sites sought (Fig. 18-45).⁵⁷ RF application should be stopped after 10 to 15 seconds if no block in the BT is achieved to minimize potential damage to the AVN-HB.

For manifest BTs, RF application is performed during NSR or atrial pacing. In the setting of concealed para-Hisian BTs, it is challenging to assess the success of RF application and monitor AV conduction simultaneously, an important parameter when performing RF ablation near the HB. When RF delivery is performed during ventricular

FIGURE 18-45 Junctional tachycardia during radiofrequency (RF) ablation of a superoparaseptal bypass tract. The first few complexes demonstrate normal sinus rhythm with preexcitation. A few seconds after starting RF energy delivery, junctional tachycardia develops, with loss of preexcitation. This prompted immediate termination of RF application, after which preexcitation resumed.

spacing, monitoring the success of RF application is not possible because the retrograde atrial activation sequence during ventricular pacing can be similar with BT and AVN conduction. Although atrial pacing during RF delivery helps monitor AV conduction and override junctional rhythms that may occur during RF delivery, it is not helpful for assessing the efficacy of RF application because the BT is retrograde only. RF delivery during orthodromic AVRT is an option; however, this will certainly have the potential for catheter dislodgment on SVT termination, as stated earlier, and such dislodgment can endanger the AVN-HB. Moreover, application of RF energy during orthodromic AVRT will not allow monitoring of AV conduction. In this setting, monitoring of the mode of termination of orthodromic AVRT during RF delivery is essential. Termination of orthodromic AVRT with an atrial electrogram signifies potential damage to the anterograde limb of the SVT circuit (i.e., the AVN), and therefore RF delivery should be immediately stopped. On the other hand, termination of orthodromic AVRT with a ventricular electrogram suggests successful block in the retrograde limb of the SVT circuit (i.e., the BT), and therefore RF delivery should be continued, with careful monitoring of AV conduction during NSR following termination of the SVT. Another valuable option is RF delivery during atrial-entrained orthodromic AVRT with manifest atrial fusion. This technique enables continuous monitoring of effects of RF application on BT function and also obviates a sudden change in ventricular rate on termination of the SVT. In addition, this technique allows monitoring of AV conduction during RF application once the orthodromic AVRT is terminated, and therefore reduces the risk of damage to the AVN-HB. During successful RF application, termination of orthodromic AVRT will be indicated by transformation from the tachycardia P wave morphology and atrial activation sequence into a fully paced atrial activation sequence at the same rate.

To reduce the risk of AV block, RF delivery should be immediately discontinued when the following occur: (1) the impedance rises suddenly ($>10 \Omega$); (2) the PR interval (during NSR or atrial pacing) prolongs; (3) AV block develops; (4) retrograde conduction block is observed during junctional ectopy; or (5) fast junctional tachycardia (tachycardia CL <350 milliseconds) occurs, which may herald imminent heart block.

CRYOABLATION OF SUPEROPARASEPTAL AND MIDSEPTAL BYPASS TRACTS

Cryothermal ablation of BTs in the superoparaseptal and mid-septal areas, both at high risk of complete permanent AV block when standard RF energy is performed, is extremely safe and successful. Cryoablation can also be successfully and safely used to ablate selected cases of epicardial left-sided BTs within the CS, well beyond the middle cardiac vein, once attempts using the transseptal and transaortic approaches have failed. The experience with cryoablation in unselected BTs, however, is more limited and less satisfactory; this is likely related to multiple factors, including the learning curve and the smaller size of the lesion produced by cryoablation. In addition, all the peculiarities of cryothermal energy, which are optimal for septal ablation, are less important or even useless for ablation of BTs located elsewhere.^{59,60}

CRYOMAPPING. Cryomapping, or ice mapping, is designed to verify that ablation at the chosen site will have the desired effect (i.e., block in the BT) and to ensure the absence of complications (i.e., AV block). Cryomapping is performed at -30°C in the selected site. At this temperature, the lesion is reversible (for up to 60 seconds) and the catheter is “stuck” to the endocardium in an ice ball that includes the tip of the catheter (cryoadherence). This permits programmed electrical stimulation to test the disappearance of BT conduction during ongoing ablation and also allows ablation to be performed during AVRT without the risk of catheter dislodgment on tachycardia termination.

In the cryomapping mode, the temperature is not allowed to drop below -30°C , and the time of application is limited to 60 seconds. Formation of an ice ball at the catheter tip and adherence to the underlying myocardium are signaled by the appearance of electrical noise recorded from the ablation catheter’s distal bipole. Once an ice ball is formed, programmed electrical stimulation is repeated to verify that the BT has been blocked. If cryomapping does not yield the desired result within 30 seconds or results in unintended AV conduction delay or block, cryomapping is interrupted and, after a few seconds, allowing the catheter to thaw and become dislodged from the tissue, the catheter can be moved to a different site and cryomapping repeated. Alternatively, if the test application is unsuccessful, after rewarming, further 30-second

applications are tested, decreasing the temperature by 10°C for every step of the application, up to the last application at -70°C. This is because the amount of cryothermal energy required for permanent ablation is individualized, ranging from an application of -40°C for 40 seconds to one of -75°C for 480 seconds; limiting test applications to only -30°C can limit the applicability of cryoablation for these patients. Additionally, the use of cryothermal energy at temperatures lower than -30°C should be considered safer than RF energy at these critical sites.

CRYOABLATION. When sites of successful cryomapping are identified by demonstrating BT block with no modification of basal AVN conduction, the cryoablation mode is activated, in which a target temperature below about 75°C is sought (a temperature of -75°C to -80°C is generally achieved). The application is then continued for up to 480 seconds, creating an irreversible lesion. If the catheter tip is in close contact with the endocardium, a prompt drop in catheter tip temperature should be seen as soon as the cryoablation mode is activated. A slow decline in temperature or very high flow rates of refrigerant during ablation suggests poor catheter tip tissue contact and, in such a case, cryoablation is interrupted and the catheter is repositioned.

ADVANTAGES OF CRYOABLATION. One of the distinct advantages of cryothermal technology is the ability to demonstrate loss of function of tissue reversibly with cooling (cryomapping), thereby demonstrating the functionality of prospective ablation sites without inducing permanent injury. Furthermore, once the catheter tip temperature is reduced below 0°C, progressive ice formation at the catheter tip causes adherence to the adjacent tissue (cryoadherence). A disadvantage of cryoablation is that the cryocatheter is not yet as steerable as the conventional RF catheter, which can potentially limit proper positioning of the catheter tip. In addition, the larger electrodes decrease the specificity of mapping.

OUTCOME OF CRYOABLATION. In recent series, the acute success rate of cryoablation of BTs in the superoparaseptal and midseptal regions exceeded 90%; however, resumption of BT conduction with palpitation recurrences can occur in up to 20% of patients, and overall success rates have been lower than those of AVNRT cryoablation. Nevertheless, whereas RF ablation of some superoparaseptal and midseptal BTs may otherwise be abandoned because of a prohibitive risk of AV block, cryoablation is a viable, and often successful, option to eliminate those BTs. Although transient modifications of the normal AVN conduction pathways can be observed during cooling, no permanent modifications have been observed. RBBB has occurred on occasion, but inadvertent AV block has yet to be reported. In fact, immediate discontinuation of cryothermal energy application at any temperature on observation of modification of conduction over normal pathways results in return to baseline conditions soon after discontinuation.⁶⁰

Ablation of Epicardial Bypass Tracts

ANATOMICAL CONSIDERATIONS

As noted, epicardial BTs can be found at any location, but they are most common in the posteroseptal and left posterior regions.⁴⁹ Epicardial BTs also account for 4% of left lateral ablation cases and 10% of those in patients referred after a failed ablation attempt.

Embryologically, the CS develops from the sinus venosus, together with the smooth part of the RA. As a remnant of sinus venosus musculature, a cuff of striated muscle covers the proximal CS, continuous with RA myocardium at the CS os. The CS muscle coat has electrical connections with both the right and the left atria and may extend for several millimeters over the necks of the middle cardiac vein and posterior coronary vein in 3% and 2% of hearts, respectively. Additionally, myocardial cords extending around the AV groove branch of the distal left circumflex coronary artery can be found in 6% of hearts. These myocardial sleeves or cords do not usually extend into the ventricular myocardium. In variations, where a continuation into the epicardial surface of the ventricle

is formed, however, an AV BT (referred to as an “epicardial” BT) is formed in the posteroseptal and left posterior region.^{61,62} In some cases, the muscle creating this connection is found in the neck of a CS diverticulum. The prevalence of CS-associated epicardial BTs is approximately 22% to 36% among patients with posteroseptal or left posterior BTs, and is up to 47% among patients with a previous failed ablation attempt. This highlights the difficulty of localizing these BTs.^{54,63} Other types of unusual BTs that cannot be ablated with a standard endocardial approach at the annulus have been described. These include BTs that connect an atrial appendage to its respective ventricle, which can be successfully ablated using a transcatheter pericardial approach or endocardial ablation over a large area. Another example is BTs closely associated with the ligament of Marshall, which can be ablated by targeting this ligament.

TECHNICAL CONSIDERATIONS

ECG predictors of epicardial posteroseptal BTs include the following: (1) steep negative delta wave in lead II; (2) steep positive delta wave in aV_R; and (3) deep S wave in V₆. A negative delta wave in lead II has highest sensitivity and a positive delta in aV_R has highest specificity for prediction of the presence of epicardial (i.e., requiring ablation within the CS and its branches) versus endocardial posteroseptal BTs.⁵⁵

An epicardial location of the BT is suggested if the earliest site of endocardial ventricular activation does not precede the onset of the delta wave, and if a very large BT potential can be easily recorded on the CS electrodes.

Additionally, as noted previously, the CS activation sequence can be of value in distinguishing between CS-associated epicardial BTs from left-sided “endocardial” AV BTs. During retrograde conduction either over a CS-associated BT (which inserts directly into the CS musculature) or over a right-sided “endocardial” BT, the CS muscular coat is activated prior to the LA myocardium, and the high-frequency component precedes the low-frequency component. Thus, a sharp/blunt sequence in the CS electrogram indicates that the BT can be ablated using a right-sided approach. In contrast, with left-sided “endocardial” BTs, the impulse activates the LA before the CS and the low-frequency, far-field signal from the LA will precede the sharp, CS component.⁵⁴

During anterograde conduction over a CS-ventricular BT, ventricular activation within a branch of the CS precedes endocardial activation, and CS muscle extension potentials usually are recorded in the venous branch, producing a pattern similar to a BT potential.⁴⁹ The closer proximity of these BTs to the CS than the mitral annulus results in large BT potentials recorded within the CS and susceptibility to ablation from within the CS. Such large BT potentials usually exceed the local atrial and/or ventricular electrogram amplitude. Furthermore, the earliest endocardial anterograde ventricular activation (as indicated by a rapid downstroke on the unfiltered unipolar electrogram) may be recorded more than 15 milliseconds after the onset of the far-field ventricular potential and at a site 1 to 3 cm apical to the mitral and tricuspid annuli. Elimination of these requires ablation of the ventricular end at the insertion of the middle cardiac vein or posterior coronary vein into the CS, because ablation at the site of earliest retrograde atrial activation often produces only a shift in the site of earliest atrial activation (mimicking multiple BTs) because of the multiple connections of the CS myocardial coat to both atria.^{54,63} BTs in the inferior pyramidal space can be approached through the CS and also the middle cardiac vein, but proximity to important structures must be borne in mind. This is an important issue, particularly given the close proximity of the right coronary artery with the middle cardiac vein in the vast majority of individuals.

The CS provides a useful route for mapping and ablation of left-sided AV BTs around the mitral valve and those traversing the inferior pyramidal space, the inferior BTs. Epicardial BTs resulting from connections between the muscular coat of the CS and ventricle are generally ablatable only within a branch of the CS, most commonly the middle cardiac vein, on the floor of the CS at the orifice

of a venous branch, or within a CS diverticulum. Nevertheless, BTs located very close to the hinge of the mitral valve may be difficult to ablate because the CS is some distance away. Rarely, a transcatheter approach is required to ablate epicardial BTs that are posteroseptal or right-sided.^{61,62}

The middle (or “posterior interventricular”) cardiac vein is a well-established site for posterior epicardial BTs, and is useful for approaching AV BTs located in the inferior pyramidal space. This vein courses with the posterior descending coronary artery in the posterior interventricular groove and enters the CS close to the RA orifice or, rarely, enters directly into the RA apical to the septal attachment of the tricuspid valve. At its junction with the CS, the venous entrance is very occasionally dilated, forming a venous diverticulum. The proximity and crossover relationship of the middle cardiac vein with the right coronary artery and its branch to the AVN should be appreciated to avoid inadvertent damage to these structures.^{61,62}

CS venography is typically required to help delineate its anatomy and guide ablation. Also, coronary angiography should be performed before delivering RF energy near or within a branch of the CS to determine whether there are any branches of the right or left coronary artery in proximity to the ablation site. If there is a branch of the right coronary artery within 2 mm of the ablation site, there may be a high risk of coronary artery injury if RF energy is delivered. In this situation, cryoablation can be performed with little or no risk of coronary artery injury.

A 4-mm-tip, 7 Fr (for CS), or 6 Fr (for CS branches), ablation catheter is generally used. However, a conventional ablation catheter may completely occlude a branch of the CS, preventing cooling of the ablation electrode and resulting in high impedance when RF energy is delivered. This markedly reduces the amount of power that can be delivered and may result in adherence of the ablation electrode to the wall of the vein. An external saline-cooled ablation catheter allows more consistent delivery of RF energy, with less heating at the electrode-tissue interface.

RF energy of 20 to 30 W and a temperature of 55°C to 60°C for 30 to 60 seconds is delivered at sites within the CS, with the ablation catheter tip directed toward the ventricle within the CS (by maintaining a gentle counterclockwise torque on the ablation catheter). RF energy is stopped if impedance rises significantly (>130 to 140 Ω).

Epicardial posteroseptal BTs are most successfully ablated from the terminal segment of the middle cardiac vein or posterior coronary vein at the site recording the largest, sharpest unipolar BT potential. If ablation is unsuccessful, the catheter can be withdrawn slightly to a more proximal part of the vein. This is relevant in that RF application in a small vein may occlude it at that point, precluding advancement of the catheter to more distal portions of the vein if the RF application was unsuccessful and further mapping is needed. However, the distal right (or left) coronary artery is frequently located within 2 mm of the ideal ablation site, increasing the risk of acute arterial injury.

Causes of Failed Bypass Tract Ablation

Technical difficulties are the most common cause of failed BT ablation. These difficulties are typically related to catheter manipulation and stability (Fig. 18-46) or inability to access the target site, and are occasionally caused by inability to deliver sufficient energy to the optimal target site. They are more common with right-sided BTs because of the smooth atrial aspect of the tricuspid annulus. Such difficulties can be overcome by using preformed guiding sheaths to help stabilize the catheter, using different catheter curvatures and shaft stiffness, changing the approach for ablation (e.g., from transeptal to transaortic, or from IVC to SVC), or changing the ablation modality. Cryoablation can help achieve better catheter stability and target sites that might otherwise be avoided because of the risk of damage to neighboring structures. Large (8-mm) ablation electrodes and cooled RF ablation can also help generate large RF lesions. However, other causes of ablation failure should be considered first before shifting to those approaches, which are only rarely

required for BT ablation because the target tissue (BT) is generally a thin strand, ablation of which should not require a large amount of damage.

Mapping errors are the second most common cause of ablation failure. Mapping pitfalls are largely related to inaccurate localization of a BT that has an oblique course. This is more likely to occur when retrograde atrial activation mapping is performed with the ablation catheter positioned at the ventricular side of the annulus; because of the oblique course of the BT, the site of earliest atrial activation recorded from the ventricular aspect of the annulus does not correspond to the ventricular insertion site. Similar situations can occur when the ablation catheter is positioned on the atrial aspect of the annulus and RF applications are delivered where the earliest ventricular activation is recorded. In these situations, mapping for the earliest atrial activation site with the catheter on the atrial side of the annulus, or mapping for the earliest ventricular activation site with the catheter on the ventricular side of the annulus, should be undertaken. Occasionally, ablation at an atrial site proximal to the BT's actual atrial insertion site can cause a substantial shift in atrial activation sequence simulating the presence of a second BT.

Failure to recognize that a posteroseptal BT is left-sided rather than right-sided, and epicardial location of a left-sided or a posteroseptal BT, are other potential causes of failed ablation of those BTs. Detailed mapping in the CS should be considered in such situations. Furthermore, some BTs insert in the ventricle at a distance from the annulus, in which case a search for a presumed BT potential within the ventricle adjacent to the region of the earliest ventricular activation recorded at the annulus can be helpful. Unusual BTs (e.g., atriofascicular BTs) and anatomical abnormality (e.g., congenital heart disease) also account for some failures in BT ablation.

Catheter-induced trauma to the BT also can lead to ablation failure. Catheter-induced BT trauma is often persistent, leading to discontinuation of the mapping and ablation procedure in many cases, and the long-term risk for recovery of BT function is high. Superoparaseptal and atriofascicular BTs exhibit the highest susceptibility to mechanical trauma, followed by left free wall BTs. The outcome can still be improved in these situations by close observation of the ECG recordings to recognize catheter-induced trauma of a BT promptly and, whenever conduction block in the BT does not resolve within 1 minute, by immediate application of RF energy, provided that the catheter has not moved from the site of presumed trauma.

Endpoints of Ablation

Confirmation of complete loss of BT function, and not just non-inducibility of tachycardias, is essential. Confirmation of loss of anterograde BT function using AES and atrial pacing is achieved by demonstrating lack of preexcitation and marked prolongation of the local AV interval at the ablation site. Atrial stimulation should be performed at sites and rates that were associated with preexcitation before ablation. It is possible to have loss of anterograde conduction with persistence of retrograde conduction (less commonly the opposite). Care must be taken to ensure bidirectional conduction block.

Confirmation of complete loss of retrograde BT function using VES and ventricular pacing is achieved by demonstrating concentric and decremental retrograde atrial activation, consistent with VA conduction over the AVN, VA dissociation, and/or marked prolongation of the local VA interval at the ablation site. Ventricular stimulation should be performed at sites and rates that were associated with retrograde VA conduction over the BT before ablation. Para-Hisian pacing and RV apical versus RV basilar pacing can also help confirm the absence of septal and paraseptal BTs.

Outcome

RF ablation is a highly effective and curative treatment for AVRT (>95%). Initially successful RF ablation is persistent and late recurrence of BT conduction after ablation is rare (4%).⁴⁹ Short runs of

FIGURE 18-46 Poor choice of ablation sites because of unstable recordings. In the distal ablation bipolar (Abl_{dist}) recording, the atrial and ventricular electrograms have constantly changing amplitudes, signifying unstable electrode contact with tissue. Ablation should not be performed until the recordings are stable.

palpitations are frequent, usually caused by isolated or short runs of PACs or PVCs and not by recurrence of BT conduction, and can be easily managed with symptomatic treatment without further investigation. Recurrence of BT-mediated tachycardia is usually observed during the first month after ablation, whereas later symptoms (palpitations appearing more than 3 months after the ablation) are highly suggestive of SVTs not related to the ablated BT and justify a thorough evaluation (e.g., event monitoring, long-term ECG monitoring, new EP study).

In a survey of 6065 patients, the long-term success rate was 98% and a repeat procedure was necessary in 2.2% of cases. Serious complication (e.g., cardiac tamponade, AV block, coronary artery injury, retroperitoneal hemorrhage, stroke) occurred in 0.6% of patients, with one fatality (0.02%).⁴⁹ Therefore, the one-time risk of catheter ablation appears to be considerably lower than the cumulative annual risk associated with the WPW syndrome. It is clear that the treatment of choice for patients with the WPW syndrome who may be at risk for life-threatening arrhythmias is catheter ablation. In addition, the highly favorable risk-benefit ratio justifies the use of catheter ablation as first-line therapy for any patient with BT-dependent tachycardia requiring treatment.

Success rates and risk of complications vary with different BT locations. Ablation of right free wall BT is associated with a success rate of 93% to 98%, a recurrence rate of 21%, and a complication rate less than that with other BT locations. Ablation of posteroseptal BTs is also associated with a high success rate (98%) and a recurrence rate of 12%. With ablation of superoparaseptal BTs, the reported success rate is up to 97%, with a risk of RBBB in 5% to

10% of cases. Similarly, ablation of midseptal BTs is associated with a success rate of 98%, with an incidence of first-degree AV block in 2% and second-degree AV block in 2%. Although with superoparaseptal BT ablation RF energy is frequently applied at locations with visible His potential, the risk of high-grade AV block is higher for ablation of midseptal BTs because the compact AVN is located in the midseptum. In contrast to the well-insulated HB, the compact AVN is fragile and more vulnerable to damage during ablation.⁵³

The immediate success rate of transaortic ablation of left free wall BTs is 86% to 100% (highest with anterograde BT activation), and the recurrence rate is 2% to 5%, less frequent than for BTs at other locations. Complications of this approach include vascular complications (50% of all complications: groin hematoma, aortic dissection, and thrombosis), cardiac tamponade, stroke, coronary dissection (from direct catheter trauma), injury to the left circumflex coronary artery (from subannular RF application), valvular damage, and systemic embolism (from aortic atherosclerosis, catheter tip coagulum, or ablation site thrombosis). The transseptal approach, on the other hand, is associated with a success rate of 85% to 100%, a recurrence rate of 3% to 6.6%, and a complication rate of 0% to 6%. Such complications include coronary spasm, cardiac tamponade, systemic embolization (0.08%), and death (0.08%).

The ablation of epicardial BTs (within the CS) is associated with a success rate of 62% to 100% and a complication rate of 0% to 6%. Complications associated with this approach include CS spasm, cardiac tamponade, pericarditis, and right coronary artery spasm or occlusion. The overall incidence of coronary artery injury is low (0.1%) and it can present immediately or several weeks after ablation.⁶⁴

Variants of Preexcitation (Atypical Bypass Tracts)

A working definition of an atypical bypass tract (BT) is a conduction pathway that bypasses all or part of the normal conduction system but is not a rapidly conducting pathway connecting atrium and ventricle near the mitral or tricuspid annulus. Thus, pathways that connect the atrium to the His bundle (HB), the atrioventricular node (AVN) to the His-Purkinje system (HPS) or the ventricle, or the HPS to the ventricle fit into this designation (Fig. 19-1).

“Mahaim Fibers”

In 1937, during pathological examination of the heart, Mahaim and Benatt identified islands of conducting tissue extending from the HB into the ventricular myocardium. These fibers were called Mahaim fibers or fasciculoventricular fibers.^{1,3} This description was subsequently expanded to include connections between the AVN and the ventricular myocardium (nodoventricular fibers). Later, it was recognized that BTs could arise from the AVN and insert into the right bundle branch (RB; nodofascicular fibers).^{2,3} This classification for Mahaim fibers persisted until evidence suggested that the anatomical substrate of tachycardias with characteristics previously attributed to nodoventricular and nodofascicular fibers is actually atrioventricular (AV) and atriofascicular BTs with decremental conduction properties (i.e., conduction slows at faster heart rates) (see Fig. 19-1). Although these BTs are sometimes collectively referred to as “Mahaim fibers,” the use of this term is discouraged because it is more illuminating to name the precise BT according to its connections. In this chapter, these BTs are referred to as *atypical* BTs to differentiate them from the more common (*typical*) rapidly conducting AV BTs that result in the Wolff-Parkinson-White (WPW) syndrome.⁴

“Mahaim Tachycardia”

The term *Mahaim tachycardia* is used to describe the typical constellation of electrophysiological (EP) features that characterize the unusual form of reentrant tachycardia using an atypical BT, without implication about the underlying anatomical cause. It should be noted that, because the term was originally applied to an anatomical finding and subsequently (incorrectly) applied to physiology that matched what would be expected from this anatomy, it has given rise to more confusion than understanding. Hence, the use of the term *Mahaim tachycardia* should generally be discouraged; instead, one should simply describe the physiological characteristics of the tachyarrhythmia.⁵

Types of Atypical Bypass Tracts

LONG DECREMENTALLY CONDUCTING ATRIOVENTRICULAR AND ATRIOFASCICULAR BYPASS TRACTS

These BTs comprise the majority (80%) of atypical BTs; their atrial insertion site is in the right atrial (RA) free wall.^{6,7} These BTs tend

(84%) to cross the tricuspid annulus in the lateral, anterolateral, or anterior region. They extend along the right ventricular (RV) free wall to the region where the moderator band usually inserts at the apical third of the RV free wall, inserting into the distal part of the RB (atriofascicular BT) or into the ventricular myocardium close to the RB (long decrementally conducting AV BT). These BTs are functionally similar to the normal AV junction, with an AVN-like structure leading to a His bundle (HB)-like structure. In essence, those BTs function as an auxiliary conduction system parallel to the normal conduction system (AVN-HPS). Similar to the normal AVN, these BTs demonstrate decremental conduction (related to the slow rate of recovery of excitability) and Wenckebach-type block in response to rapid atrial pacing and are sensitive to adenosine. The conduction delay in these BTs has been localized to the intraatrial portion of the BT (the AVN-like portion), whereas the interval from the inscription of the BT potential at the tricuspid annulus and the onset of ventricular activation (BT-V interval) remains constant.^{4,6,8,9}

SHORT DECREMENTALLY CONDUCTING ATRIOVENTRICULAR BYPASS TRACTS

These BTs are analogous to decrementally conducting concealed BTs responsible for the permanent form of junctional reciprocating tachycardia (PJRT; see Chap. 18) in that they bridge the AV rings and insert proximally into ventricular myocardium in close proximity to the AV annulus.^{7,10} These BTs primarily arise from the RA free wall, but can also arise from the posterior or septal region. Left-sided BTs with decremental conduction characteristics have rarely been described. Although these BTs demonstrate decremental conduction and Wenckebach-type block in response to rapid atrial pacing, they do not consistently appear to be responsive to adenosine, which suggests that their structure is not composed of AVN-like tissue.¹⁰

NODOVENTRICULAR AND NODOFASCICULAR BYPASS TRACTS

Nodoventricular BTs arise in the normal AVN and insert into ventricular myocardium near the AV junction.⁷ Nodofascicular BTs arise in the normal AVN and insert into the RB. These BTs are sensitive to adenosine, probably because of their AVN connection.⁵

FASCICULOVENTRICULAR BYPASS TRACTS

Fasciculoventricular BTs are the rarest form of preexcitation (1.2% to 5.1% of atypical BTs). These BTs have different features from the other atypical BTs, and are discussed separately (see later).⁵

Arrhythmias Associated with Atypical Bypass Tracts

Atypical BTs in patients with clinical arrhythmias have the following characteristics: (1) unidirectional (anterograde-only) conduction (with rare exceptions); (2) long conduction times; and (3) decremental conduction (i.e., cycle length [CL]-dependent slowing of conduction).

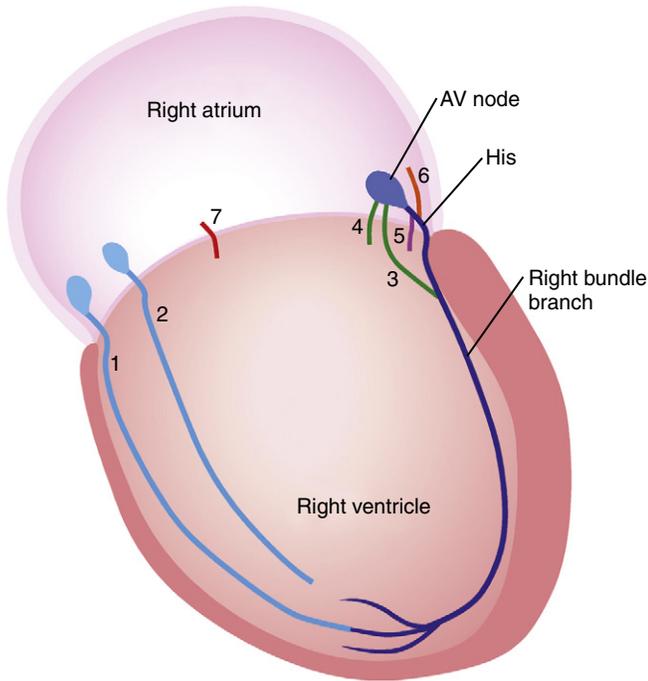

FIGURE 19-1 Variants of preexcitation. Right atrium and ventricle are depicted. 1, Atriofascicular bypass tract (BT); 2, long atrioventricular BT; 3, nodofascicular BT; 4, nodoventricular BT; 5, fasciculoventricular BT; 6, atrio-Hisian BT; 7, typical short atrioventricular BT.

Atypical BTs comprise 3% to 5% of all BTs. The incidence is slightly higher (6%) in patients presenting with supraventricular tachycardia (SVT) with a left bundle branch block (LBBB) morphology.⁷ Multiple BTs occur in 10% of patients with atypical BTs. In some cases, a typical, rapidly conducting AV BT can mask the presence of an atypical BT, which only becomes apparent after ablation of the typical BT. Dual AVN pathways or multiple BTs occur in 40% of patients with atypical BTs. Atypical BTs can also be associated with Ebstein anomaly.

SUPRAVENTRICULAR TACHYCARDIAS REQUIRING AN ATRIOVENTRICULAR BYPASS TRACT FOR INITIATION AND MAINTENANCE

Antidromic atrioventricular reentrant tachycardia (AVRT) can use the atypical BT anterogradely and the HPS-AVN retrogradely. Antidromic AVRT can also use the atypical BT anterogradely and a second AV BT retrogradely. In the latter case, the AVN can participate as an innocent bystander mediating anterograde or retrograde fusion. Because these atypical BTs almost always conduct anterogradely only, they cannot mediate orthodromic AVRT, but can mediate antidromic AVRT or can be an innocent bystander during other SVTs (e.g., atrioventricular nodal reentrant tachycardia [AVNRT]). However, they can coexist with typical rapidly conducting AV BTs. AVRTs using a nodoventricular or nodofascicular BT as the anterograde limb generally use a second AV BT as the retrograde limb of the reentrant circuit.⁵ Right free wall atriofascicular BTs capable of both anterograde and retrograde conduction that participate in both antidromic and orthodromic AVRT have rarely been reported.¹¹

SUPRAVENTRICULAR TACHYCARDIAS NOT REQUIRING AN ATRIOVENTRICULAR BYPASS TRACT FOR INITIATION AND MAINTENANCE

AVNRT, atrial tachycardia (AT), atrial flutter (AFL), or atrial fibrillation (AF) can coexist with atypical BTs, in which case the atypical BTs function as bystanders, wholly or partly responsible for ventricular activation during the tachycardia.

Electrocardiographic Features

NORMAL SINUS RHYTHM

During normal sinus rhythm (NSR), the ECG shows normal QRS or minimal preexcitation in most patients with atypical BTs. Subtle preexcitation can be suspected by the absence of the normal septal forces (small q waves) in leads I, aVL, V₅, and V₆ and the presence of an rS complex in lead III in the setting of a narrow QRS.¹² The degree of preexcitation depends on the relative conduction time over the AVN and BT. Maneuvers that prolong conduction over the AVN (e.g., atrial pacing, vagal maneuvers, or drugs) to a greater degree than BT conduction will increase the degree of preexcitation. Because atypical BTs exhibit decremental conduction, increasing the atrial pacing rate results in prolongation of the P-delta interval. In contrast, in the setting of typical rapidly conducting AV BTs, the P-delta interval remains relatively constant regardless of the degree of preexcitation; whereas prolonging the AVN conduction time results in more preexcitation. The P-delta interval remains constant or exhibits mild prolongation because conduction over the typical BT displays less decrement than does the AVN.^{5,7,12-14}

PREEXCITED QRS MORPHOLOGY

For atriofascicular and nodofascicular BTs, the QRS is relatively narrow (133 ± 10 milliseconds), and its morphology is classic for typical LBBB with a QRS axis between 0 and -75 degrees and a late precordial R/S transition zone (at V₄ or V₅, and sometimes V₆). However, for long decrementally conducting AV BTs, the QRS is relatively wider (166 ± 26 milliseconds) and the LBBB pattern is less typical (with broad initial R in V₁). The QRS is even wider and the LBBB pattern is less typical with nodoventricular and decrementally conducting short AV BTs than that with atriofascicular or long decrementally conducting AV BTs.^{5,12,14}

SUPRAVENTRICULAR TACHYCARDIAS

Arrhythmias associated with atypical BTs are associated with an LBBB pattern and, most often, in the setting of long decrementally conducting AV and atriofascicular BTs, left axis deviation on the surface ECG (Fig. 19-2). There are several ECG features that suggest (although are not diagnostic of) atypical BTs as the cause of an SVT with LBBB pattern. These include (1) QRS axis between 0 and -75 degrees, (2) QRS duration of 150 milliseconds or less, (3) R wave in lead I, (4) rS complex in lead V₁, and (5) precordial R wave transition in lead V₄ or later.^{5,12,14}

Electrophysiological Testing

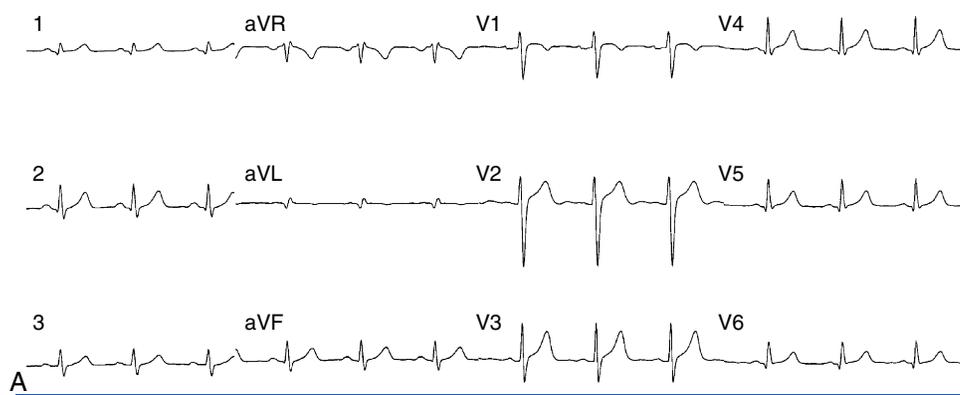

BASELINE OBSERVATIONS DURING NORMAL SINUS RHYTHM

In the baseline state, minimal or no preexcitation can be present; thus, the His bundle–ventricular (HV) interval is normal or slightly short.

Atrial Pacing and Atrial Extrastimulation during Normal Sinus Rhythm

Progressively shorter atrial pacing CLs or atrial extrastimulus (AES) coupling intervals produce decremental conduction in both the atypical BT and, to a greater degree, the AVN (Fig. 19-3).¹² Consequently, the atrial–His bundle (AH) interval increases, the QRS morphology gradually shifts to a more preexcited LBBB morphology, and the AV (A-delta) interval increases. However, the AV (A-delta) interval increases to a lesser degree than the AH interval. This is in contrast to the setting of typical rapidly conducting AV BTs, in which the AV (A-delta) interval remains constant despite prolongation of the AH interval and exaggeration of the degree of preexcitation, because the A-delta interval represents conduction time over the BT. Typical AV BTs maintain constant conduction time during

NSR

Antidromic AVRT

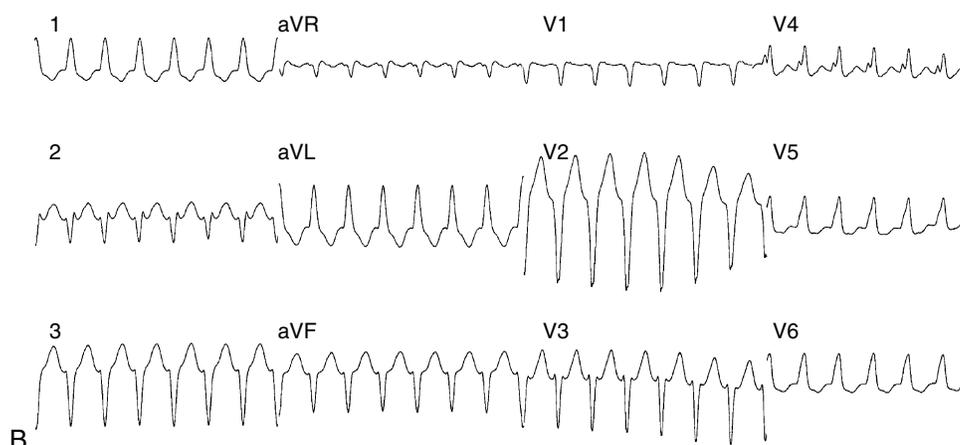

FIGURE 19-2 Atriofascicular bypass tracts (BTs). **A**, Normal sinus rhythm (NSR) with no evidence of preexcitation. **B**, Antidromic atrioventricular reentrant tachycardia (AVRT) using an atriofascicular BT. QRS morphology during tachycardia resembles left bundle branch block aberration because of anterograde activation over the atriofascicular BT. Retrograde P waves can be seen after the end of the QRS.

different pacing rates and AES coupling intervals—that is, nondecremental conduction.⁵

With progressively shorter atrial pacing CLs or AES coupling intervals, the HV interval decreases as the His potential becomes progressively inscribed into the QRS (usually within the first 5 to 25 milliseconds after the onset of the QRS). The His potential eventually becomes activated retrogradely as the wavefront travels anterogradely down the BT and then retrogradely up the RB to the HB (see Fig. 19-3). When the His potential is lost within the QRS, it is unclear whether anterograde AV conduction continues to propagate over the HB or block has occurred.⁷

At the point of maximal preexcitation, the AV (A-delta) interval continues to prolong with more rapid pacing because of the decremental conduction properties of the BT, and the His potential-QRS relationship remains unaltered because the HB is activated retrogradely until block in the BT occurs. The fixed ventricular-His bundle (VH) interval, despite shorter pacing CLs or AES coupling intervals, suggests that the BT inserts into or near the distal RB at the anterior free wall of the RV with retrograde conduction to the HB. Whenever the VH interval is less than 20 milliseconds, insertion into the RB (i.e., atriofascicular or nodofascicular BT) is likely. On the other hand, with long decrementally conducting AV BTs, which insert into the ventricular myocardium close to the RB, the VH interval approximates the HV interval minus the duration of the His potential (because the His potential is activated retrogradely).^{5,7}

For short decrementally conducting BTs, the HB is activated anterogradely, and retrograde conduction to the HB is only seen following AV block or during antidromic AVRT. Decremental conduction (progressive prolongation of the AV interval) and Wenckebach-type block develop in the BT. The conduction delay in these BTs is localized to the intraatrial portion of the BT; the interval from the inscription of the BT potential at the tricuspid annulus to the onset of ventricular activation (BT-V interval) remains constant.⁵

Dual AVN physiology is common in patients with atypical BTs. Sometimes, during AES, a jump from the fast to the slow AVN pathway prolongs the AH interval to a degree sufficient to unmask preexcitation over the BT, at which time the His potential becomes inscribed within the QRS.

The site of the earliest ventricular activation during preexcitation is at the RV apex for long, decrementally conducting AV BTs and atriofascicular BTs, but adjacent to the annulus near the base of the RV for short, decrementally conducting AV BTs.

The site of atrial stimulation does not influence the degree of preexcitation in the setting of nodofascicular and nodoventricular BTs. Contrariwise, preexcitation becomes more prominent when atrial stimulation is performed closer to the atrial insertion site of AV or atriofascicular BTs.

Ventricular Pacing and Ventricular Extrastimulation during Normal Sinus Rhythm

Because these BTs rarely have retrograde conduction, ventricular stimulation cannot help in mapping of the BT location. VA conduction during ventricular pacing should propagate over the HPS-AVN with concentric atrial activation sequence and decremental properties in response to progressively shorter ventricular pacing CLs or ventricular extrastimulation (VES) coupling intervals. If rapid and fixed VA conduction is present, a separate retrogradely and rapidly conducting AV BT should be excluded. Retrograde dual AVN pathways may be present.

Effects of Adenosine

Adenosine produces conduction delay in most atypical BTs except for short decrementally conducting AV BTs. The conduction delay has been localized to the intraatrial portion of the BT; the interval from the inscription of the BT potential at the tricuspid annulus and the onset of ventricular activation remains constant.^{7,13} When

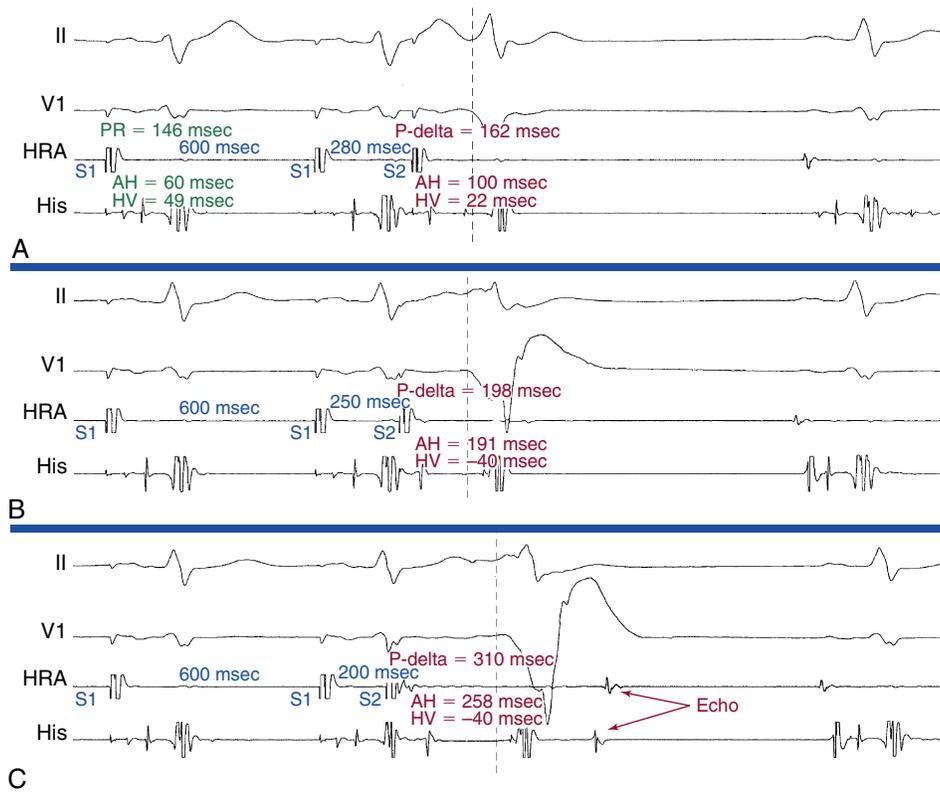

FIGURE 19-3 Effect of atrial extrastimulation (AES) on preexcitation via a long atrioventricular (AV) bypass tract (BT). No preexcitation is observed during normal sinus rhythm and during the pacing drive at a cycle length of 600 milliseconds (normal PR and His bundle–ventricular [HV] intervals). **A**, AES produces decremental conduction in the atrioventricular node (AVN) with prolongation of the atrial–His bundle (AH) interval (from 60 to 100 milliseconds), associated with manifest preexcitation and shortening of the HV interval (from 49 to 22 milliseconds). **B** and **C**, Progressively shorter AES coupling intervals produce decremental conduction in the BT and, to a greater degree, in the AVN. Consequently, the AH interval prolongs, the QRS morphology gradually shifts to a more preexcited left bundle branch block morphology, and the AV (P-delta) interval prolongs. However, the P-delta interval prolongs to a lesser degree than the AH interval. The HV interval decreases (becomes negative) but remains fixed (**B** and **C**) although the P-delta interval continues to prolong with more premature AES because of decremental conduction over the BT. The fixed ventricular–His bundle (VH) interval, despite shorter AES coupling intervals, suggests that the BT inserts into or near the distal right bundle branch (RB) at the anterior free wall of the right ventricle, with retrograde conduction to the His bundle (HB). However, because the VH interval is modestly long (40 milliseconds), a long decrementally conducting AV BT inserting into the ventricle close to the RB is more likely than an atriofascicular BT. **C**, AV reentrant echo complex (red arrows) secondary to anterograde conduction over the BT and retrograde conduction over the AVN.

adenosine administration slows AVN conduction, an increase in the degree of preexcitation is noted in all types of BTs (as long as adenosine does not block the BT).

INDUCTION OF TACHYCARDIA

Initiation by Atrial Extrastimulation or Atrial Pacing

Initiation of antidromic AVRT by an AES requires the following: (1) intact anterograde conduction over the BT; (2) anterograde block in the AVN or HPS; and (3) intact retrograde conduction over the HPS–AVN once the AVN resumes excitability following partial anterograde penetration. Whereas the latter is usually the limiting factor for the initiation of antidromic AVRT using typical rapidly conducting AV BTs, it is readily available in the setting of atypical BTs. This is because of the slow decremental conduction anterogradely over the atypical BT, providing adequate delay for full recovery of the HPS–AVN.

As noted, progressively shorter atrial pacing CLs (especially from the RA) result in progressive AV (A-delta) interval prolongation and a greater degree of preexcitation until maximal. Often, once maximal preexcitation has been achieved, cessation of pacing is followed by preexcited SVT. Progressively shorter AES coupling intervals similarly result in progressive AV (A-delta) interval prolongation and a greater degree of preexcitation until maximal. When anterograde AVN conduction fails but conduction persists over the BT, the HPS–AVN can be activated retrogradely to initiate antidromic AVRT.⁷

The sudden appearance of preexcitation associated with a “jump” from the fast to the slow AVN pathway with a His potential

inscribed before ventricular activation or with a VH interval of less than 10 milliseconds strongly favors AVNRT. Although a slowly conducting atriofascicular BT that becomes manifest with a jump to the slow AVN pathway cannot be excluded, a consistent pattern of dual pathway dependence and an HV relationship too short to be retrograde from the distal RB would be unlikely.⁷ Induction of AVNRT with AES is almost always associated with a dual pathway response, which may not be seen if the impulse conducts anterogradely over the BT and captures the HB before it is activated by the impulse traversing the slow AVN pathway anterogradely. In other cases, a jump can be seen so that the anterograde His potential follows the QRS with a typical AVN echo to initiate SVT, analogous to 1:2 conduction initiating antidromic AVRT.

Initiation by Ventricular Extrastimulation or Ventricular Pacing

Initiation of antidromic AVRT by ventricular pacing or VES requires the following: (1) retrograde block in the BT, which is almost always available, because the atypical BTs are usually unidirectional (anterograde only); (2) retrograde conduction over the HPS–AVN; and (3) adequate VA delay to allow for recovery of the atrium and BT so it can support subsequent anterograde conduction.

Ventricular pacing can initiate SVT in 85% of cases. Initiation is almost always associated with retrograde conduction up a relatively fast AVN pathway, followed by anterograde conduction down a slow pathway, which is associated with preexcitation. The anterograde slow pathway can be a BT (i.e., antidromic AVRT) or a slow AVN pathway (i.e., AVNRT with an innocent bystander BT). During induction of the SVT by ventricular pacing at a CL similar to the

tachycardia CL or by a VES that advances the His potential by a coupling interval similar to the H-H interval during the SVT, the His bundle–atrial (HA) interval following the ventricular stimulus is compared with that during the SVT—an HA interval that is longer with ventricular pacing or VES initiating the SVT than that during the SVT suggests AVNRT. This occurs despite the fact that the H-H interval of the VES (i.e., the interval between the His potential activated anterogradely by the last sinus beat to the His potential activated retrogradely by the VES initiating the SVT) exceeds the H-H interval during the SVT. Because the AVN usually exhibits greater decremental conduction with repetitive engagement of impulses than in response to a single impulse at a similar coupling interval, the more prolonged the HA with the initiating ventricular stimulus, the more likely the SVT is AVNRT. If the SVT uses the BT for anterograde conduction, the HA interval during ventricular pacing or the VES initiating the SVT, at a comparable coupling interval as the tachycardia CL, should have the same HA interval as during the SVT.

TACHYCARDIA FEATURES

Antidromic Atrioventricular Reentrant Tachycardia Using an Atypical Bypass Tract Anterogradely

SITE OF EARLIEST VENTRICULAR ACTIVATION. In the setting of atriofascicular, nodofascicular, and long decrementally conducting AV BTs, the earliest ventricular activation occurs at or near the RV apex. In contrast, for nodoventricular and short decrementally conducting AV BTs, the earliest ventricular activation occurs adjacent to the tricuspid annulus.

VENTRICULAR–HIS BUNDLE INTERVAL. For atriofascicular and nodofascicular BTs, the VH interval is short (16 ± 5 milliseconds), much shorter than the nonpreexcited HV interval and also shorter than the VH interval during ventricular pacing, because the BT inserts into the RB, hence, the HB and ventricle are activated in parallel, not in sequence. Conduction time to the distal RB is short ($V\text{-RB} = 3 \pm 5$ milliseconds).¹³ For long decrementally conducting AV BTs, the VH interval is short (37 ± 9 milliseconds) but longer than that of atriofascicular BTs because the ventricle and HB are activated in sequence, not in parallel. However, the VH interval is still shorter than the nonpreexcited HV interval. In this setting, the VH interval approximates the HV interval minus the duration of the His potential, because the BT inserts close to the RB and the His potential is activated retrogradely. In the presence of long decrementally conducting AV BTs, conduction time to the distal RB ($V\text{-RB} = 25 \pm 6$ milliseconds) is longer than that for atriofascicular BTs. During antidromic AVRT using a nodoventricular or a short decrementally conducting AV BT, intermediate VH intervals are observed, whereby the His potential is inscribed within the QRS. The VH interval during the AVRT is longer than the nonpreexcited HV interval and than the VH interval during RV apical pacing, exceeding it by the time it takes the impulse to travel from the ventricular insertion site of the BT at the RV base to the distal RB (i.e., because of the long V-RB interval).^{7,13} When antidromic AVRT occurs in the presence of retrograde right bundle branch block (RBBB), the VH interval is long (the His potential is inscribed after the QRS and the VH interval is longer than the nonpreexcited HV interval). Retrograde block over the RB results in anterograde conduction over the distal RB (in the setting of atriofascicular BTs) or RV and transseptal impulse propagation with subsequent retrograde conduction over the left bundle branch (LB) into the HB and AVN. This results in an antidromic AVRT with a macroreentrant circuit incorporating the LB retrogradely and either an atriofascicular, a long decrementally conducting, or a short decrementally conducting AV BT anterogradely.^{7,13}

ATRIAL-VENTRICULAR RELATIONSHIP. For atriofascicular BTs, long decrementally conducting AV BTs, and short decrementally conducting AV BTs, a 1:1 A-V relationship is a prerequisite for the maintenance of antidromic AVRT, because parts of both the RA and the RV are incorporated in the reentrant circuit. However, in the setting of nodofascicular and nodoventricular BTs, the atrium is neither part of nor required for the reentrant circuit, and

AV block or dissociation can (although rarely) be present without disrupting the SVT.^{7,13}

RESPONSE TO DRUGS. These SVTs are very responsive to and terminate easily with adenosine, calcium channel blockers, and beta blockers.

CHANGES IN TACHYCARDIA CYCLE LENGTH. Changes in the rate of antidromic AVRT using an atriofascicular or a long AV BT as the anterograde limb of the circuit can occur secondary to changes in the VA conduction time, due to either retrograde RBBB or shift of retrograde conduction over a fast AVN pathway to conduction over a slow AVN pathway. The prolongation of the tachycardia CL will be in the VH interval in the former setting, but in the HA interval in the latter setting. Additionally, VA conduction over the HB-AVN axis changing into VA conduction over a second BT can alter the tachycardia CL. When this occurs, the change in the tachycardia CL will depend on the location of the ventricular end of the second BT and the conduction properties of that BT. Therefore, there may be a shortening or a prolongation of the CL. The behavior of the V-RB and VH interval in that situation will depend on where the block is located in the bundle branch–HB-AVN axis.¹⁵

Preexcited Atrioventricular Nodal Reentrant Tachycardia Using an Atypical Bypass Tract as an Innocent Bystander

The site of earliest ventricular activation depends on the type of the atypical BT mediating preexcitation (see previous discussion). A positive HV interval or VH interval of 10 milliseconds or less (especially when the HA interval is 50 milliseconds or less) is characteristic of AVNRT, because the HB is usually activated anterogradely. However, the HB can become activated retrogradely when conduction over the anterograde slow AVN pathway is very slow; then the VH interval will depend on the type of the atypical BT mediating preexcitation (see earlier).^{7,13}

DIAGNOSTIC MANEUVERS DURING TACHYCARDIA

Atrial Extrastimulation and Atrial Pacing during Tachycardia

To prove the presence of a BT and its participation in the SVT, a late-coupled AES is delivered from the lateral RA (close to the BT) when the AV junctional portion of the atrium is refractory, so that the AES does not penetrate the AVN, as indicated by the lack of advancement of local atrial activation in the HB or coronary sinus ostium (CS os) recording. Therefore, such an AES cannot conduct to the ventricle over the AVN; this maneuver is analogous to the introduction of VES when the HB is refractory during orthodromic AVRT. If this AES advances (or delays) the timing of the next ventricular activation, it indicates that an anterogradely conducting AV or atriofascicular BT is present, and excludes nodoventricular and nodofascicular BTs. If the AES advances (or delays) the timing of the next ventricular activation and the advanced (or delayed) QRS morphology is identical to that during the SVT, this proves that the AV or atriofascicular BT also mediates preexcitation during the SVT, either as an integral part of the SVT circuit or as an innocent bystander. On the other hand, if the AES advances the timing of both the next ventricular activation and subsequent atrial activation, it proves that the SVT is an antidromic AVRT using an AV or atriofascicular BT anterogradely, and excludes preexcited AVNRT (Fig. 19-4). Advancement of both ventricular and atrial activation by such an AES requires anterograde conduction over the BT followed by retrograde conduction over the AVN. This can occur during antidromic AVRT but not in AVNRT, because in the setting of AVNRT the HB would be refractory because of anterograde activation by the time the advanced ventricular impulse invades the HPS retrogradely, with subsequent failure of the advanced ventricular activation to penetrate the HPS-AVN and affect the timing of subsequent atrial activation.^{7,13}

During entrainment of the SVT by atrial pacing at a CL slightly shorter than the tachycardia CL, the presence of a fixed short VH interval suggests antidromic AVRT, but does not exclude AVNRT. Atrial pacing can usually terminate the SVT; whereby anterograde block is always produced in the AVN, with or without block in the BT. A short-coupled AES can block in the BT, terminating the SVT

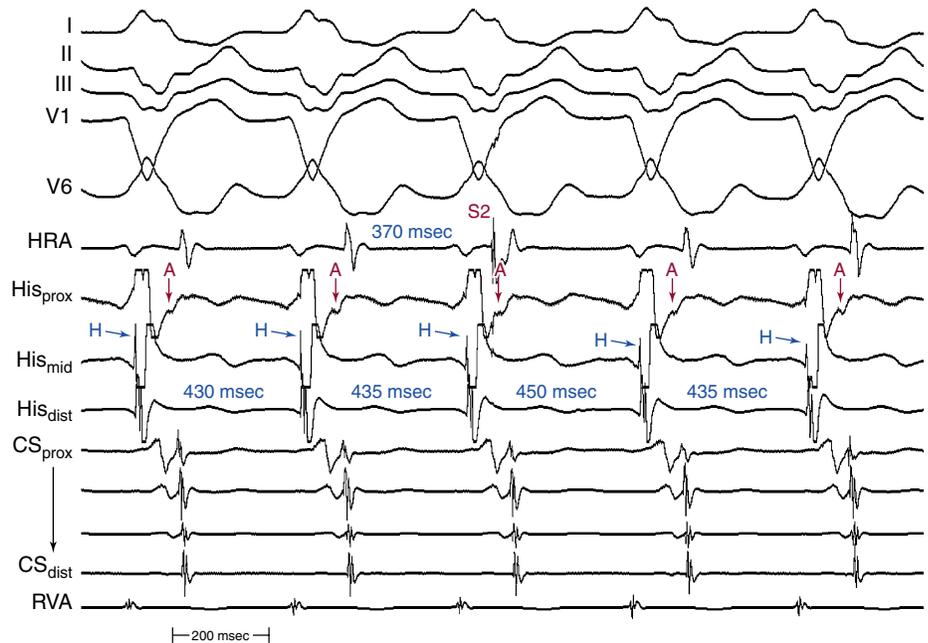

FIGURE 19-4 Atrial extrastimulation (AES) during antidromic atrioventricular reentrant tachycardia (AVRT) using an atriofascicular bypass tract. A late-coupled AES (S_2) delivered from the right atrium (RA) when the AV junctional atrium is refractory (as evidenced by the failure of the AES to affect the timing of atrial activation recorded by the proximal His bundle and proximal coronary sinus electrodes) results in a delay in the timing of the next QRS (“postexcitation”), as well as a delay in the timing of the following atrial activation. This confirms the diagnosis of antidromic AVRT and excludes preexcited atrioventricular nodal reentrant tachycardia and ventricular tachycardia as potential mechanisms of this wide QRS complex tachycardia.

(in the setting of antidromic AVRT) or changing the SVT to a narrow QRS complex SVT at the same CL and same HA interval (in the setting of preexcited AVNRT).

Ventricular Extrastimulation and Ventricular Pacing during Tachycardia

Introduction of a VES during the SVT that results in RBBB can be of diagnostic value. During AVNRT, such RBBB will not change the time of the next atrial activation, because the ventricle and HPS are not parts of the AVNRT circuit. Conversely, during antidromic AVRT, retrograde block in the RB increases the size of the reentrant circuit, because the impulse cannot reach the HB through the RB, and it has to travel transeptally and then retrogradely over the LB. This results in prolongation in the VA interval and delay in the timing of the next atrial activation. The increment in the VA interval occurs because of prolongation of the VH interval, and, if RBBB persists, the SVT will have a long VH interval.

Ventricular pacing can usually terminate the SVT. Termination occurs by retrograde invasion and concealment in the BT, resulting in anterograde block over the BT following conduction to the atrium through the AVN.

DIFFERENTIAL DIAGNOSIS

The goals of programmed electrical stimulation during SVT are evaluation of the relationship among the His potential, the QRS, and the VH interval during atrial pacing and during SVT and differentiation between the different types of atypical BTs (Table 19-1). In addition, exclusion of a separate BT is necessary, especially if a rapid and fixed VA interval exists during incremental rate ventricular pacing. Furthermore, it is important to differentiate between antidromic AVRT using the BT anterogradely and preexcited AVNRT, in which the BT is an innocent bystander (Table 19-2).

Localization of the Bypass Tract

Mapping principles for typical AV BTs—searching for sites with the earliest atrial activation during retrograde BT conduction and earliest ventricular activation during anterograde BT conduction—are largely inapplicable in the case of atypical BTs because of their unusual course and conduction properties. Therefore, different approaches are used.

Mapping of the ventricular insertion site of atriofascicular and long decrementally conducting AV BTs is difficult because of the

long intracardiac course and distal insertion of these BTs, which shows extensive arborization over a wide area of ventricular muscle, with a diameter of up to 0.5 to 2 cm. A propensity to temporary loss of conduction of the atypical BT because of catheter trauma further complicates ventricular mapping.⁵

Mapping of the atrial insertion site can be performed by (1) P-delta interval mapping by stimulation at different atrial sites, (2) recording of the BT potential at the tricuspid annulus, and (3) AES from the RA during antidromic AVRT.⁸

Careful mapping of the tricuspid annulus and the anterior free wall of the RV typically demonstrates discrete potentials with complexes comparable to those recorded at the AV junction. The BT potential is analogous to the His potential. Atrial pacing, AES, and adenosine produce delay proximal to BT potential with a constant BT potential to QRS (BT-V) interval. Faster atrial pacing produces Wenckebach block proximal to the BT potential.¹³

MAPPING THE ATRIAL INSERTION SITE

Mapping the Shortest Atrial Stimulus to Delta (S-V) Interval

The mapping catheter is advanced from site to site along the atrial aspect of the tricuspid annulus while pacing from its distal tip. The resulting interval between the stimulus and the onset of the delta wave (S-V interval) should decrease progressively as the BT atrial insertion site is approached, and increase as it is passed. Thus, the atrial pacing site associated with the shortest S-V interval is the site closest to the BT atrial insertion site. It is essential that pacing at different sites be performed at a constant CL to avoid rate-dependent conduction slowing in the BT as a reason for changing the S-V interval. This method is rarely used because of several limitations: (1) a constant distance of the mapping-pacing catheter from the tricuspid annulus must be maintained to reduce the influence of the time spent traversing intervening atrial tissue; (2) catheter manipulation during pacing can result in initiation of tachycardia, which must then be terminated to continue mapping; (3) optimal sites can be overlooked if they cannot be consistently paced because of unstable catheter contact; and (4) this method cannot be applied in the setting of incessant tachycardia or when AF is present.¹³

Atrial Extrastimulation Mapping during Supraventricular Tachycardias

The BT atrial insertion site is close to the site from which the longest coupled AES delivered during preexcited tachycardia advances the timing of the next ventricular activation. Alternatively, the BT

atrial insertion site is close to the site from which the greatest amount of advancement of the next ventricular activation occurs when using a fixed AES coupling interval. This method is rarely used because of several limitations: (1) it is time-consuming, and cannot be used if the SVT is difficult to initiate or nonsustained; (2) it is not particularly useful in cases of true nodofascicular BTs; (3) a constant distance of the mapping-pacing catheter from the tricuspid annulus must be maintained to reduce the influence of the time spent traversing intervening atrial tissue; and (4) optimal sites can be overlooked if they cannot be consistently paced because of unstable catheter contact.¹³

MAPPING THE VENTRICULAR INSERTION SITE

Mapping the Distal Fascicular Insertion Site (for Atriofascicular Bypass Tracts)

The distal insertion site of atriofascicular BTs can be localized by careful mapping along the lateral RV wall toward the apex, seeking the earliest site of ventricular activation during anterograde BT conduction. A distal RB recording is usually present at this site. This

method can be used to map any rhythm during which consistent preexcitation is present (atrial pacing, AF, and preexcited SVT). However, seeking the distal insertion is less precise because a distal RB recording may be localized, but not the portion into which the atriofascicular fiber inserts. It is most useful if the course of the atriofascicular BT can be traced from the tricuspid annulus to its insertion into the RB. Additionally, ablation at the distal site offers no advantage unless catheter stability is better at that location as opposed to the tricuspid annulus. If the RB is ablated rather than the BT, RBBB will result. Not only will this fail to eliminate the BT function, but it can also facilitate induction and maintenance of the SVT by increasing the reentrant circuit size.^{8,13}

Mapping the Distal Ventricular Insertion Site (for Slowly Conducting Atrioventricular Bypass Tracts)

Mapping is performed in the same fashion as for typical rapidly conducting AV BTs—seeking the ventricular site with the earliest unipolar or bipolar ventricular electrogram recording. However, there is evidence that a variable degree of arborization of the distal insertion site occurs in some patients. This feature makes the

TABLE 19-1 Differentiation among Different Types of Atypical Bypass Tracts

Preexcited QRS Morphology

- **Atriofascicular BTs:** The QRS is relatively narrow (133 ± 10 msec), and is classic for typical LBBB morphology.
- **Long decrementally conducting AV BTs:** The QRS is wider (166 ± 26 msec) and the LBBB pattern is less typical (with broad initial R in V_1) than that with atriofascicular BTs.
- **Nodofascicular BTs:** Same as for atriofascicular BTs.
- **Nodoverricular BTs:** The QRS is significantly wider and the LBBB pattern is less typical than that with atriofascicular or long decrementally conducting AV BTs.
- **Short decrementally conducting AV BTs:** The QRS is significantly wider and the LBBB pattern is less typical than that with atriofascicular or long decrementally conducting AV BTs.

Site of Earliest Ventricular Activation

- **Atriofascicular BTs:** The earliest ventricular activation occurs at or near the RV apex.
- **Long decrementally conducting AV BTs:** The earliest ventricular activation occurs at or near the RV apex.
- **Nodofascicular BTs:** The earliest ventricular activation occurs at or near the RV apex.
- **Nodoverricular BTs:** The earliest ventricular activation occurs adjacent to the tricuspid annulus.
- **Short decrementally conducting AV BTs:** The earliest ventricular activation occurs adjacent to the tricuspid annulus.

Influence of Site of Atrial Stimulation

- **Atriofascicular BTs:** Preexcitation increases when atrial stimulation is performed closer to the atrial insertion site.
- **Long decrementally conducting AV BTs:** Preexcitation increases when atrial stimulation is performed closer to the atrial insertion site.
- **Nodofascicular BTs:** The degree of preexcitation is not influenced by the site of atrial stimulation.
- **Nodoverricular BTs:** The degree of preexcitation is not influenced by the site of atrial stimulation.
- **Short decrementally conducting AV BTs:** Preexcitation increases when atrial stimulation is performed closer to the atrial insertion site.

AES Delivered from Lateral RA During Antidromic AVRT when AV Junctional Atrium Is Refractory

- **Atriofascicular BTs:** The AES can advance or delay the next ventricular activation.
- **Long decrementally conducting AV BTs:** The AES can advance or delay the next ventricular activation.
- **Nodofascicular BTs:** The AES cannot advance the next ventricular activation.
- **Nodoverricular BTs:** The AES cannot advance the next ventricular activation.
- **Short decrementally conducting AV BTs:** The AES can advance or delay the next ventricular activation.

VH Interval during Maximal Preexcitation or Antidromic AVRT

- **Atriofascicular BTs:** The VH interval is short (VH interval = 16 ± 5 msec and V-RB interval = 3 ± 5 msec; VH interval < HV interval and < VH interval during RV pacing).
- **Long decrementally conducting AV BTs:** The VH interval is short but longer than that with atriofascicular BTs (VH interval = 37 ± 9 msec and V-RB interval = 25 ± 6 msec).
- **Nodofascicular BTs:** The VH interval is short, as for atriofascicular BTs.
- **Nodoverricular BTs:** The VH interval is intermediate (His potential is inscribed in the QRS, VH interval \geq HV interval; VH interval > HV interval and > VH interval during RV pacing).
- **Short decrementally conducting AV BTs:** The VH interval is intermediate, as for nodoverricular BTs.
- **Antidromic AVRT in presence of retrograde RBBB:** The VH interval is long (His potential is inscribed after the QRS, VH interval > HV interval).

Presence of VA Block or AV Dissociation

- VA block or AV dissociation during the SVT excludes atriofascicular, short decrementally conducting AV BTs, and long decrementally conducting AV BTs, but does not exclude nodofascicular and nodoverricular BTs.

Effects of Adenosine

- Adenosine produces conduction delay in most atypical BTs (except for short decrementally conducting BTs).
- When adenosine administration slows AVN conduction but not the BT, an increase in the degree of preexcitation is noted in all types of BTs except for fasciculo-ventricular BTs, whereby the degrees of preexcitation and HV interval remain fixed.

TABLE 19-2 Differentiation between Antidromic AVRT and Preexcited AVNRT Using an Atypical BT

SVT Induction

- Induction of the SVT by ventricular pacing at a CL similar to the tachycardia CL, or by a VES that advances the His potential by a coupling interval similar to the H-H interval during the SVT—the HA interval following such a ventricular stimulus is compared with that during the SVT:
 - $HA_{VES} > HA_{SVT}$ is diagnostic of AVNRT and excludes antidromic AVRT.
 - $HA_{VES} \leq HA_{SVT}$ is diagnostic of antidromic AVRT and excludes AVNRT.

Features of the SVT

- Positive HV interval or VH interval ≤ 10 msec (especially when HA interval is ≤ 50 msec) suggests AVNRT.
- Continuation of the SVT at the same tachycardia CL, despite anterograde block in the BT (by extrastimuli, drugs, mechanical trauma caused by catheter manipulation, or ablation), is diagnostic of AVNRT and excludes antidromic AVRT.
- Termination of the SVT or prolongation of the VA (and VH) interval and tachycardia CL with transient RBBB (caused by mechanical trauma or introduction of VES) is diagnostic of antidromic AVRT and excludes AVNRT.

AES Delivered from Lateral RA when AV Junction Is Refractory

- If the AES advances the timing of both the following ventricular activation and the subsequent atrial activation, it proves that the SVT is an antidromic AVRT using an AV or atriofascicular BT anterogradely, and excludes preexcited AVNRT.

Entrainment of the SVT with Atrial Pacing

- The presence of a fixed short VH interval during entrainment of the SVT with atrial pacing suggests antidromic AVRT and makes AVNRT unlikely (but does not exclude AVNRT).

RV Apical Pacing during NSR

- RV apical pacing at the tachycardia CL is performed, and the HA interval during RV apical pacing versus the HA interval during SVT are compared:
 - $HA_{SVT} < HA_{pacing}$ is diagnostic of AVNRT and excludes antidromic AVRT.
 - $HA_{SVT} \geq HA_{pacing}$ is diagnostic of antidromic AVRT and excludes AVNRT.

AES = atrial extrastimulation; AV = atrioventricular; AVNRT = atrioventricular nodal reentrant tachycardia; AVRT = atrioventricular reentrant tachycardia; BT = bypass tract; CL = cycle length; HA = His bundle–atrial; NSR = normal sinus rhythm; RA = right atrium; RBBB = right bundle branch block; RV = right ventricle; SVT = supraventricular tachycardia; VA = ventriculoatrial; VES = ventricular extrastimulation; VH = ventricular–His bundle.

ventricular insertion site a less attractive ablation target because of the potential of requiring ablation of a relatively large amount of ventricular myocardium to be effective.¹³

MAPPING THE BYPASS TRACT POTENTIAL

Direct recording of the BT potential at the tricuspid annulus is the most precise and preferred method of localizing the atypical BT. The BT potential is usually a low-amplitude, high-frequency recording made at the tricuspid annulus, which resembles a His potential (Fig. 19-5). Only the annular and subannular portions of the BT have been successfully recorded; attempts to record potentials from the atrial portion (corresponding to nodal-like tissue) have been unsuccessful. Distinct atrial, BT, and ventricular potentials can be found at the BT atrial insertion site. Recording a BT potential can be successful during NSR, atrial pacing, or preexcited SVT. However, recording of a BT potential along the tricuspid annulus may not be successful in up to 48% of cases. Furthermore, because of the low amplitude of the BT potential, it is difficult or impossible to record it during AF. Additionally, this technique presents the risk of producing mechanical block in the BT. Nevertheless, this method is less time-consuming and more precise than the previous ones.^{8,13}

MAPPING SITES OF MECHANICALLY INDUCED LOSS OF PREEXCITATION

Atypical BTs are particularly sensitive to mechanical trauma, and catheter manipulation along the tricuspid annulus during mapping of the BT may result in loss of BT function, even as a result of gentle pressure from the catheter tip. When mapping is performed during preexcited atrial pacing or SVT, damage to the BT is indicated by a sudden, transient loss of preexcitation. This phenomenon can be used to localize the BT precisely (bump mapping). Conduction block typically occurs while a BT potential is still recorded; thus, conduction is interrupted within the ventricular course of the BT. Block usually lasts from a few beats to a few minutes but can last for hours, after which preexcitation resumes. This method can be used during any consistently preexcited rhythm (atrial pacing, AF, and antidromic AVRT). However, if it occurs during antidromic AVRT, termination of the tachycardia may result in catheter displacement and loss of the exact location of the BT. Additionally, interruption of BT conduction can occur as the catheter is passing the area, and

Ablation of atriofascicular BT

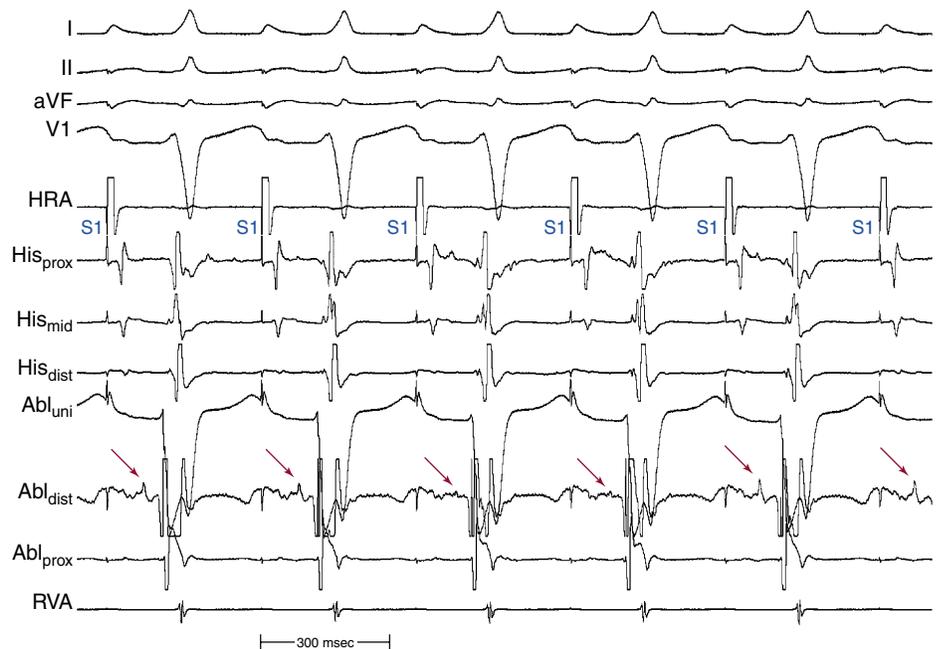

FIGURE 19-5 Ablation of an atriofascicular bypass tract (BT). A discrete potential (arrows) is shown in the ablation recording during atrial pacing, with a small His potential occurring just after the onset of the preexcited QRS. Ablation at this site eliminated this BT in 2 seconds.

where the catheter comes to rest may not be the same site as where loss of BT function occurred; in this situation, the target cannot be relocated until BT conduction resumes. Delivery of radiofrequency (RF) energy at a site at which catheter pressure caused loss of preexcitation may successfully eliminate conduction in the BT; however, it is best to wait to deliver energy until preexcitation resumes, because of the possibility that the catheter position may have changed. Electroanatomical mapping (e.g., CARTO, NavX) can help tag sites of interest, facilitating precise relocation of the ablation catheter to these sites if it has been determined that they are a good ablation target. Atriofascicular BTs are more susceptible to mechanically induced block, probably suggesting that these BTs are composed of thinner strands or are located closer to the endocardium.¹³

Ablation

TARGET OF ABLATION

Direct recording of the BT potential at the tricuspid annulus is the most precise and preferred method of localizing the BT and serves as the target of ablation (see Fig. 19-5).^{7,13} Ablation at the ventricular insertion site of the BT offers no advantage over targeting the atrial insertion site because there is evidence that a variable degree of arborization of the distal insertion site occurs in some patients, with the potential of requiring ablation of a relatively large amount of ventricular myocardium to be effective.^{5,8}

However, when a BT potential along the tricuspid annulus cannot be recorded, ablation of the distal insertion sites of atriofascicular BTs becomes an alternative and has been found to be highly effective, but is commonly (57%) associated with the development of RBBB. Ablation of the RB can carry a proarrhythmic effect and facilitate induction of the SVT or cause incessant tachycardia; however, this is not a concern as long as the BT itself is also successfully ablated.^{8,13}

Using these methods, the locations of successful ablation of atypical BTs are found to be mostly along the lateral tricuspid annulus, with a minority along the septal aspect of the tricuspid annulus or within the ventricle. Atriofascicular and long decrementally conducting AV BTs tend (84%) to cross the tricuspid annulus in a lateral, anterolateral, or anterior region, whereas short decrementally conducting AV BTs are roughly equally distributed between these and a posterior or septal region.

ABLATION TECHNIQUE

Once an appropriate target site for ablation has been identified, RF energy may be applied during NSR, atrial pacing, or antidromic AVRT. Atrial pacing is preferred to ensure that adequate preexcitation is evident (unlike NSR) to be able to assess the efficacy of ablation, and that the rhythm remains the same after elimination of preexcitation (unlike antidromic AVRT) to prevent catheter dislodgment.^{5,8}

The use of long curved sheaths can help achieve good catheter positioning and stability along the tricuspid annulus. Typical RF settings consist of a maximal power of 50 W and a maximal temperature of 55°C to 60°C, continued for 30 to 60 seconds after elimination of the BT function (i.e., after disappearance of preexcitation). During RF energy delivery, an accelerated preexcited rhythm is often observed. This so-called *Mahaim automatic tachycardia* is analogous to the accelerated junctional rhythm observed during AVN modification, and is presumably secondary to heating-related automaticity of nodal-like tissue of the BT. Accelerated automatic beats during RF ablation have been considered a marker of a successful result, and RF energy delivery should be continued for a sufficient duration after termination of this rhythm.¹³ Heat-induced automaticity during RF ablation is observed less commonly in short decrementally conducting AV BTs as compared with atriofascicular BTs (50% versus 91%).^{16,17}

ENDPOINTS OF ABLATION

Complete loss of BT function, not just noninducibility of tachycardias, is an essential endpoint. BT block is confirmed by demonstrating

loss of preexcitation with atrial pacing and AES and noninducibility of AVRT. Atrial stimulation should be performed at sites and rates that were associated with preexcitation before ablation.¹³

OUTCOME

The acute success rate is approximately 90% to 100%, and the short-term recurrence rate is less than 5%.¹³

Fasciculoventricular Bypass Tracts

General Considerations

Fasciculoventricular BTs are the rarest form of preexcitation (1.2% to 5.1% of atypical BTs). They connect the HB to ventricular myocardium in the anteroseptal location. These fibers do not give rise to any reentrant tachycardia, and appear to be only an ECG and EP curiosity. Even during AF and AFL, a rapid ventricular response is not expected in the presence of a normal AVN proximal to the BT. However, it is important to distinguish fasciculoventricular BTs from superoparaseptal BTs to avoid unnecessary invasive EP procedures and potential harm to the AVN-HB if such a BT is mistakenly targeted by ablation, because this form of preexcitation does not require treatment.⁷

Electrocardiographic Features

In patients with fasciculoventricular BTs, preexcitation is always present during NSR. The ECG preexcitation pattern can mimic that of manifest WPW pattern, especially that of superoparaseptal AV BTs, with a normal frontal plane axis between 0 and 75 degrees and precordial RS transitional zone in leads V₂-V₃. With fasciculoventricular BTs, the PR interval is normal despite the presence of preexcitation (Fig. 19-6). This is in contrast to superoparaseptal AV BTs, which result in the WPW pattern with significant shortening of the PR interval because of the relative proximity of the BT location to the sinus node.

Several ECG findings in lead V₁ favor fasciculoventricular BTs as the cause of preexcitation, including: (1) PR interval greater than 110 milliseconds; (2) R wave width less than 35 milliseconds; (3) S wave amplitude less than 20 mm; (4) flat or negative delta wave; and (5) notching in the descending limb of the S wave (see Fig. 19-6).¹⁸

Electrophysiological Testing

With fasciculoventricular BTs, preexcitation is present during NSR with a normal AH interval and short HV interval. The earliest ventricular activation occurs at the HB region (Table 19-3).

Progressively shorter atrial pacing CLs or AES coupling intervals produce progressive prolongation of the PR and AH intervals but with a fixed degree of preexcitation, a constant and short HV interval, and a fixed relationship between the His potential and RB potential (Fig. 19-7). AVN Wenckebach block can develop, which is then associated with a fixed degree of preexcitation and a constant, short HV interval. The loss of AV conduction is associated with loss of preexcitation. AES can result in block in the fasciculoventricular BT, producing a sudden loss of preexcitation and prolongation of the HV interval to normal values (see Fig. 19-7).

HB pacing normalizes the HV interval and eliminates preexcitation in all types of BTs except for fasciculoventricular BTs, in which a fixed degree of preexcitation and a constant short HV interval remain unchanged during HB pacing (see Fig. 19-6).

When adenosine administration slows AVN conduction, an increase in the degree of preexcitation is noted in all types of BTs, as long as adenosine does not block the BT, except for fasciculoventricular BTs, in which the degree of preexcitation and HV interval remain fixed. Moreover, adenosine administration can be associated with complete AV block and junctional escape beats and, in the setting of fasciculoventricular BTs, these beats are associated with the same degree of preexcitation and the same HV interval as during NSR, even when these ectopic beats are associated with retrograde VA block and no atrial depolarization.

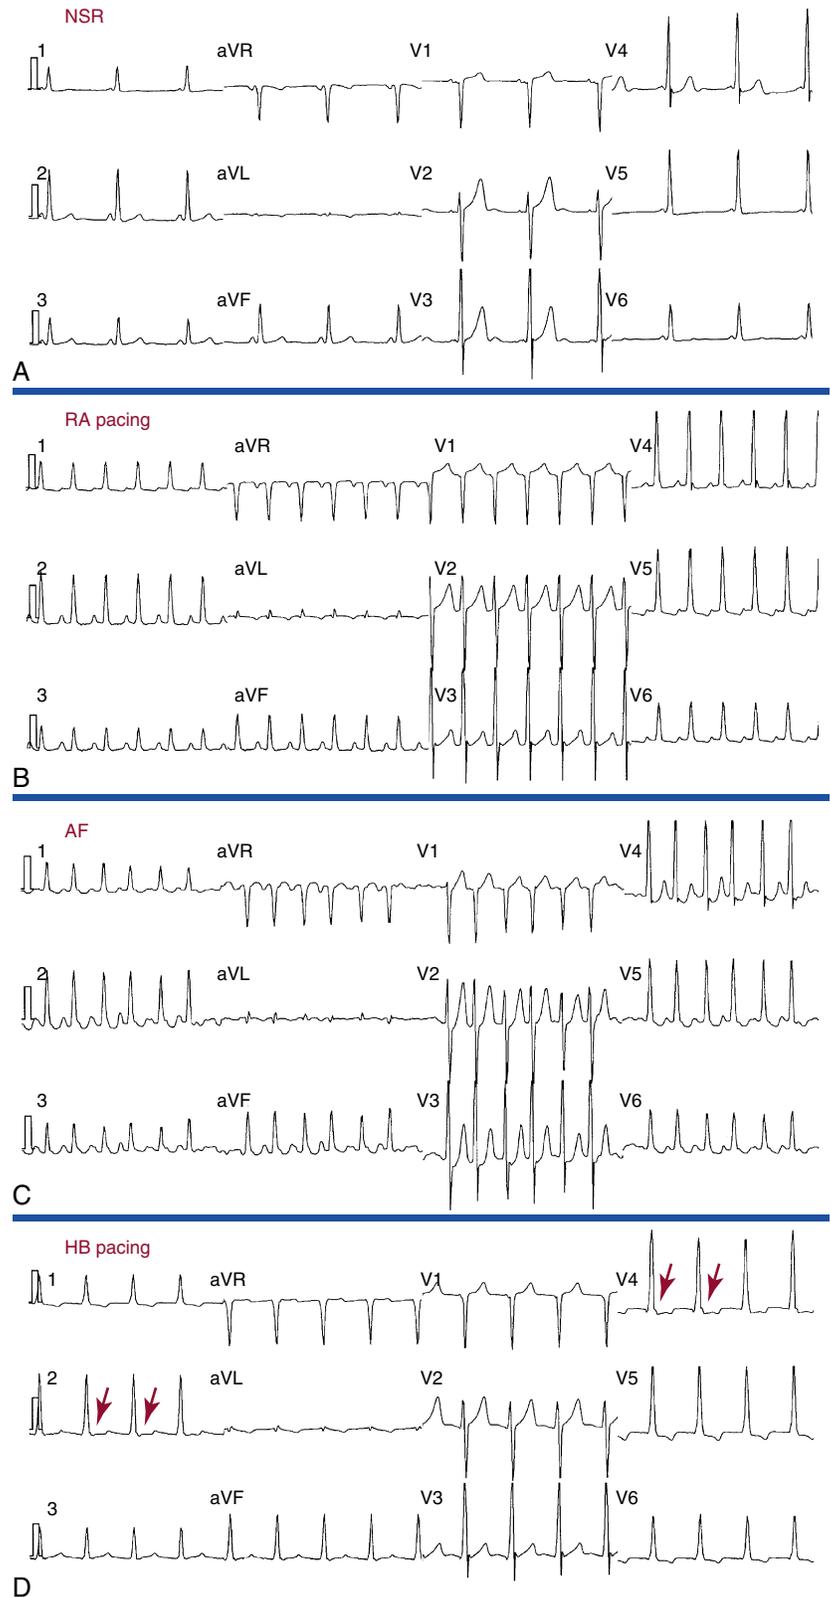

FIGURE 19-6 ECG of fasciculoventricular bypass tracts. **A**, Surface ECG of normal sinus rhythm (NSR) with preexcitation over a fasciculoventricular pathway. Note the short PR and slight slurring of the QRS upstroke in several leads. **B**, Pacing from the right atrium (RA) at the shortest cycle length associated with 1:1 atrioventricular (AV) conduction results in no change in the mild degree of preexcitation compared with NSR despite atrioventricular nodal conduction delay (longer PR interval). **C**, Atrial fibrillation (AF) is present, with no change in the mild degree of preexcitation compared with NSR regardless of the R-R interval. **D**, Surface ECG during His bundle (HB) pacing in the same patient. The same degree of preexcitation persists as in NSR. Retrograde P waves are visible (arrows), deforming the end of QRS complexes.

Atrio-Hisian Bypass Tracts

General Considerations

Patients with palpitations who had a short PR interval but normal QRS complex in the resting ECG were first described in 1938 and then further evaluated by Lown and colleagues in 1952.¹⁹ The latter report consisted of a retrospective examination of 13,500 ECGs and identified short PR intervals in a mixed group of 200 subjects,

most of whom had a normal QRS complex (Fig. 19-8). The authors described a “syndrome” characterized by short PR interval, narrow QRS complex, and recurrent paroxysmal SVTs. They initially ascribed this syndrome to the presence of an AV nodal BT.^{7,19} A variety of explanations were later offered to account for the short PR interval.

Although the incidence of palpitations was significantly higher in these patients with short PR intervals when compared with a control group with a normal PR interval (17% versus 0.5%), most

PR interval. In contrast, the tachycardia CL of orthodromic AVRT tends to be much shorter in these patients compared with patients with normal PR intervals, which is expected because the circuit of orthodromic AVRT uses the fast AVN pathway for anterograde conduction. In fact, in any SVT with a tachycardia CL shorter than 250 milliseconds enhanced AVN conduction and orthodromic AVRT should be suspected. In such patients, bundle branch block (BBB) is common during SVT, resulting in wide complex tachycardia.⁷

PATIENTS WITH ATRIO-HISIAN BYPASS TRACTS

These patients primarily present with AF and AFL with a rapid ventricular response, and do not develop reentrant SVTs using the AV junction as one limb.⁷ Rapid ventricular response during AF depends on refractoriness of the tissue responsible for AV conduction (i.e., AVN or BT) and not on the site of insertion for that tissue.

Electrophysiological Testing

BASELINE OBSERVATIONS DURING NORMAL SINUS RHYTHM

Enhanced AVN conduction is characterized by a short AH interval (<60 milliseconds) and normal HV interval.⁷ In rare cases in which the AVN is completely bypassed by an atrio-Hisian BT, the HV interval is short. The HV interval in these cases is artifactually short because the proximal HB and the ventricle are activated in parallel since the atrio-Hisian BT inserts into the distal HB (i.e., the proximal HB is activated retrogradely).

ATRIAL PACING AND ATRIAL EXTRASTIMULATION

Patients with Enhanced Atrioventricular Node Conduction

The AH interval prolongs with progressively shorter atrial pacing CLs and AES coupling intervals.⁷ The prolongation in the AH interval is smooth, continuous, and blunted, with a maximal increase in the AH interval of 100 milliseconds or less during pacing at a CL of 300 milliseconds compared with the value measured during NSR. The maximal AH interval (at any pacing rate) is rarely longer than 200 milliseconds and 1:1 conduction typically is maintained to pacing rates greater than 200 beats/min.

The AH interval response can be characteristic of dual AVN physiology, with an initial blunted small prolongation in the AH interval followed by a significant jump at a critical pacing CL or AES coupling interval, while maintaining 1:1 conduction at a pacing rate greater than 200 beats/min. In such patients, the maximal AH interval can be greater than 200 milliseconds, and the maximal prolongation in the AH interval can be greater than 100 milliseconds.⁷ Atrial pacing from the CS is associated with shorter AH intervals, shorter Wenckebach CLs, and shorter AVN effective refractory periods, suggesting a preferential input into the AVN.

Patients with Atrio-Hisian Bypass Tracts

The AH interval remains short with no or minimal prolongation in response to progressively shorter atrial pacing CLs and AES coupling intervals. Block in the BT, which can usually be achieved by antiarrhythmic agents or occasionally by the induction of AF, is associated with a simultaneous increase in the PR and AH intervals and normalization of the HV interval.⁷

VENTRICULAR PACING AND VENTRICULAR EXTRASTIMULATION

Patients with Enhanced Atrioventricular Node Conduction

Retrograde AVN conduction is extremely rapid in these patients. In general, the HA interval is shorter than the AH interval at comparable pacing CLs. The HA interval typically remains relatively short with little prolongation in response to progressively shorter

ventricular pacing CLs and VES coupling intervals.⁷ A concealed AV BT mediating retrograde VA conduction should be excluded, which can be achieved by a variety of pacing maneuvers (see Chap. 18).

Patients with Atrio-Hisian Bypass Tracts

VA conduction is unpredictable in these patients. In many cases, VA conduction is absent and, even when present, it is not as good as AV conduction.⁷

RESPONSE TO PHARMACOLOGICAL AND PHYSIOLOGICAL MANEUVERS

Patients with Enhanced Atrioventricular Node Conduction

The AH interval prolongs in response to beta blockers, verapamil, digoxin, carotid sinus massage, and vagal maneuvers. Complete autonomic blockade results in increases in the AH interval and AVN functional refractory period, but a minimal change in the AVN effective refractory period (suggesting sympathetic tone predominance in these patients, in contrast to individuals with normal AVN conduction in whom vagal tone predominates).⁷

Patients with Atrio-Hisian Bypass Tracts

AV conduction over the atrio-Hisian BT is not affected by autonomic modulation. Conduction block in the BT requires class IA or IC agents or amiodarone. Conduction block is associated with an immediate, sudden, and marked prolongation of the AH and HV intervals to normal values.

PRACTICAL APPROACH TO ELECTROPHYSIOLOGICAL

DIAGNOSIS OF SUPRAVENTRICULAR TACHYCARDIA, 495

REFERENCES, 498

Clinical Considerations

A “supraventricular” origin of a tachycardia implies the obligatory involvement of one or more cardiac structures above the bifurcation of the His bundle (HB), including the atrial myocardium, the atrioventricular node (AVN), the proximal HB, the coronary sinus (CS), the pulmonary veins (PVs), the venae cavae, or abnormal atrioventricular (AV) connections other than the HB (i.e., bypass tracts, BTs).¹

Epidemiology

Narrow QRS complex supraventricular tachycardia (SVT) is a tachyarrhythmia with a rate greater than 100 beats/min and a QRS duration of less than 120 milliseconds. Narrow QRS complex SVTs include sinus tachycardia, inappropriate sinus tachycardia, sinoatrial nodal reentrant tachycardia, atrial tachycardia (AT), multifocal AT, atrial fibrillation (AF), atrial flutter (AFL), junctional ectopic tachycardia, nonparoxysmal junctional tachycardia, atrioventricular nodal reentrant tachycardia (AVNRT), and atrioventricular reentrant tachycardia (AVRT).

Narrow QRS complex tachycardias can be divided into those that require only atrial tissue for their initiation and maintenance (sinus tachycardia, AT, AF, and AFL), and those that require the AV junction (junctional tachycardia, AVNRT, and AVRT).

Paroxysmal SVT is the term generally applied to intermittent SVT other than AF, AFL, and multifocal AT. The major causes are AVNRT (approximately 50% to 60% of cases), AVRT (approximately 30% of cases), and AT (approximately 10% of cases).

Paroxysmal SVT with sudden onset and termination is relatively common; the estimated prevalence in the normal population is 2.25/1000, with an incidence of 35/100,000 person-years. Paroxysmal SVT in the absence of structural heart disease can present at any age but most commonly first presents between ages 12 and 30 years. Women have a twofold greater risk of developing this arrhythmia than men.

The mechanism of paroxysmal SVT is significantly influenced by both age and gender. In a large cohort of patients with symptomatic paroxysmal SVT referred for ablation, as patients grew older there was a significant and progressive decline in the number of patients presenting with AVRT, which was the predominant mechanism in the first decade, and a striking increase in AVNRT and AT (Fig. 20-1). These trends were similar in both genders, although AVNRT replaced AVRT as the predominant mechanism much earlier in women.² The early predominance of AVRT is consistent with the congenital nature of the substrate and with the fact that symptom onset occurs earlier in patients with AVRT than AVNRT, most commonly in the first two decades of life. However, a minority of patients have relatively late onset of symptoms associated with AVRT and thus continue to account for a small proportion of

ablations in older patients. Men account for a higher proportion of AVRT at all ages.

AVNRT is the predominant mechanism overall in patients undergoing ablation and after the age of 20 years accounts for the largest number of ablations in each age group. AVNRT is unusual in children under 5 years of age, and typically initially manifests in early life, often in the teens. AVRT presents earlier, with an average of more than 10 years separating the time of clinical presentation of AVRT versus AVNRT. There is a striking 2:1 predominance of women in the AVNRT group, which remains without clear physiological or anatomical explanation. Female sex and older age, that is, teens versus early childhood years, favor the diagnosis of AVNRT over AVRT.³

ATs comprise a progressively greater proportion of those with paroxysmal SVT with increasing age, accounting for 23% of patients older than 70 years. Although there is a greater absolute number of women with AT, the proportion of AT in both genders is similar. Age-related changes in the atrial electrophysiological (EP) substrate (including cellular coupling and autonomic influences) can contribute to the increased incidence of AT in older individuals.

Clinical Presentation

The clinical syndrome of paroxysmal SVT is characterized as a regular rapid tachycardia of abrupt onset and termination. Episodes can last from seconds to several hours. Patients commonly describe palpitations and dizziness. Dizziness can occur initially because of hypotension, but it then disappears when the sympathetic response to the SVT stabilizes the blood pressure. Rapid ventricular rates can be associated with complaints of dyspnea, weakness, angina, or even frank syncope, and can at times be disabling. Neck pounding can occur during tachycardia because of simultaneous contraction of the atria and ventricles against closed mitral and tricuspid valves. The latter is more common in patients with typical AVNRT, occurring in approximately 50% of patients.

Patients often learn to use certain maneuvers such as carotid sinus massage or the Valsalva maneuver to terminate the arrhythmia, although many require pharmacological treatment to achieve this. In patients without structural heart disease, the physical examination is usually remarkable only for a rapid, regular heart rate. At times, because of the simultaneous contraction of atria and ventricles, cannon A waves can be seen in the jugular venous waveform (described as the “frog” sign). This clinical feature has been reported to distinguish paroxysmal SVT resulting from AVNRT from that caused by orthodromic AVRT. Although the atrial contraction during AVRT will occur against closed AV valves, the longer VA interval results in separate ventricular and then atrial contraction and a relatively lower right atrial (RA) and venous pressure; therefore, the presence of palpitations in the neck is experienced less commonly (up to 17%) in patients with AVRT.³ In patients with an

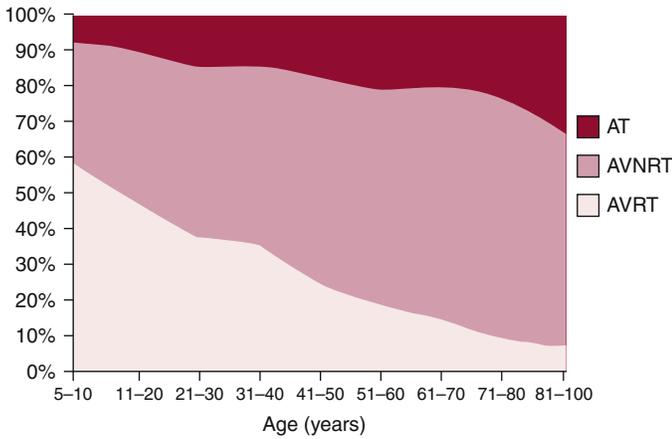

FIGURE 20-1 Proportion of paroxysmal supraventricular tachycardia mechanisms by age. AT = atrial tachycardia; AVNRT = atrioventricular nodal reentrant tachycardia; AVRT = atrioventricular reentrant tachycardia. (From Porter MJ, Morton JB, Denman R, et al: Influence of age and gender on the mechanism of supraventricular tachycardia, *Heart Rhythm* 1:393, 2004.)

AT exhibiting AV block, usually of the Wenckebach type, the ventricular rate is irregular.

Initial Evaluation

History, physical examination, and an electrocardiogram (ECG) constitute an appropriate initial evaluation of paroxysmal SVT. However, clinical symptoms are not usually helpful in distinguishing different forms of paroxysmal SVT. A 12-lead ECG during tachycardia can be helpful for defining the mechanism of paroxysmal SVT. Ambulatory 24-hour Holter recording can be used for documentation of the arrhythmia in patients with frequent (i.e., several episodes per week) but self-terminating tachycardias. A cardiac event monitor is often more useful than a 24-hour recording in patients with less frequent arrhythmias. Implantable loop recorders can be helpful in selected cases with rare episodes associated with severe symptoms of hemodynamic instability (e.g., syncope).

An echocardiographic examination should be considered in patients with documented sustained SVT to exclude the possibility of structural heart disease. Exercise testing is rarely useful for diagnosis unless the arrhythmia is clearly triggered by exertion. Further diagnostic studies are indicated only if there are signs or symptoms that suggest structural heart disease.

Transesophageal atrial recordings and stimulation can be used in selected cases for diagnosis or to provoke paroxysmal tachyarrhythmias if the clinical history is insufficient or if other measures have failed to document an arrhythmia. Esophageal stimulation is not indicated if invasive EP investigation is planned. Invasive EP testing with subsequent catheter ablation may be used for diagnosis and therapy in cases with a clear history of paroxysmal regular palpitations. It may also be considered in patients with preexcitation or disabling symptoms without ECG documentation of an arrhythmia.

Principles of Management

ACUTE MANAGEMENT

Most episodes of paroxysmal SVT require intact 1:1 AVN conduction for continuation and are therefore classified as AVN-dependent. AVN conduction and refractoriness can be modified by vagal maneuvers and by many pharmacological agents and thus are the weak links targeted by most acute therapies. Termination of a sustained episode of SVT is usually accomplished by producing transient block in the AVN.

Vagal maneuvers such as carotid sinus massage, Valsalva maneuvers, or the dive reflex are usually used as the first step and generally

terminate the SVT. Valsalva is the most effective technique in adults, but carotid sinus massage can also be effective. Facial immersion in water is the most reliable method in infants. Vagal maneuvers are less effective once a sympathetic response to paroxysmal SVT has become established, so patients should be advised to try them soon after onset of symptoms. Vagal maneuvers present the advantage of being relatively simple and noninvasive, but their efficacy seems to be lower compared with pharmacological interventions, with the incidence of paroxysmal SVT termination ranging from 6% to 22% following carotid sinus massage.

When vagal maneuvers are unsuccessful, termination can be achieved with antiarrhythmic drugs whose primary effects increase AVN refractoriness, decrease AVN conduction (negative dromotropic effect), or both. These drugs can have direct (e.g., verapamil and diltiazem block the slow inward calcium current of the AVN) or indirect effects (e.g., digoxin increases vagal tone to the AVN). In most patients, the drug of choice is either adenosine or verapamil.

The advantages of adenosine include its rapid onset of action (usually within 10 to 25 seconds via a peripheral vein), short half-life (<10 seconds), and high degree of efficacy. The effective dose of adenosine is usually 6 to 12 mg, given as a rapid bolus. Doses up to 12 mg terminate over 90% of paroxysmal SVT episodes. Sequential dosing can be given at 60-second intervals because of adenosine's rapid metabolism. In AVNRT, termination is usually caused by block in the anterograde slow pathway. In AVRT, termination occurs secondary to block in the AVN. Termination can also occur indirectly, that is, because of adenosine-induced premature atrial complexes (PACs) or premature ventricular complexes (PVCs). Adenosine shortens the atrial refractory period, and atrial ectopy can induce AF. This can be dangerous if the patient has a BT capable of rapid anterograde conduction, and sometimes subsequently requires immediate electrical cardioversion. Because adenosine is cleared so rapidly, reinitiation of paroxysmal SVT after initial termination can occur. Either repeated administration of the same dose of adenosine or substitution of a calcium channel blocker will be effective.

The AVN action potential is calcium channel-dependent, and the non-dihydropyridine calcium channel blockers verapamil and diltiazem are effective for terminating AVN-dependent paroxysmal SVT. The recommended dosage of verapamil is 5 mg intravenously over 2 minutes, followed in 5 to 10 minutes by a second 5- to 7.5-mg dose. The recommended dose of diltiazem is 20 mg intravenously followed, if necessary, by a second dose of 25 to 35 mg. Paroxysmal SVT termination should occur within 5 minutes of the end of the infusion, and over 90% of patients with AVN-dependent paroxysmal SVT respond. As with adenosine, transient arrhythmias, including atrial and ventricular ectopy, AF, and bradycardia, can be seen after paroxysmal SVT termination with calcium channel blockers. Hypotension can occur with calcium channel blockers, particularly if the paroxysmal SVT does not terminate. Adenosine and verapamil have been reported to have a similar high efficacy in terminating paroxysmal SVT, with a rate of success ranging from 59% to 100% for adenosine and from 73% to 98.8% for verapamil, according to the dose and mode of administration. However, data also suggest that the efficacy of adenosine and verapamil is affected by the arrhythmia rate. Increasing SVT rates are significantly associated with higher percentages of sinus rhythm restoration following treatment with adenosine. In contrast, the efficacy of verapamil in restoring sinus rhythm was inversely related to the rate of paroxysmal SVT.⁴

Intravenous beta blockers including propranolol (1 to 3 mg), metoprolol (5 mg), and esmolol (500 µg/kg over 1 minute and a 50-µg/kg/min infusion) are also useful for acute termination. Digoxin (0.5 to 1.0 mg) is considered the least effective of the four categories of drugs available, but is a useful alternative when there is a contraindication to the other agents.

AVN-dependent paroxysmal SVT can present with a wide QRS complex in patients with fixed or functional aberration, or if a BT is used for anterograde conduction. Most wide complex tachycardias, however, are caused by mechanisms that can worsen after

intravenous administration of adenosine and calcium channel blockers. Unless there is strong evidence that a wide QRS tachycardia is AVN-dependent, adenosine, verapamil, and diltiazem should not be used.

Limited data are available on the acute pharmacological therapy of ATs. Automatic or triggered tachycardias and sinus node reentry should respond to adenosine, verapamil, diltiazem, or beta-adrenergic blockers. Other ATs can respond to class I or III antiarrhythmic drugs given orally or parenterally.

CHRONIC MANAGEMENT

Because most paroxysmal SVTs are generally benign arrhythmias that do not influence survival, the main reason for treatment is to alleviate symptoms. The threshold for initiation of therapy and the decision to treat SVT with oral antiarrhythmic drugs or catheter ablation depends on the frequency and duration of the arrhythmia, severity of symptoms, and patient preference. The threshold for treatment will also reflect whether the patient is a competitive athlete, a woman considering pregnancy, or someone with a high-risk occupation. Catheter ablation is an especially attractive option for patients who desire to avoid or are unresponsive or intolerant to drug therapy.

For patients requiring therapy who are reluctant to undergo catheter ablation, antiarrhythmic drug therapy remains a viable alternative. For AVN-dependent paroxysmal SVT, calcium channel blockers and beta blockers will improve symptoms in 60% to 80% of patients. A comparison of verapamil, propranolol, and digoxin has shown equivalent efficacy in a small group of patients. However, in general, calcium channel blockers and beta blockers are preferred to digoxin. In patients who do not respond, class IC and III drugs can be considered. Flecainide and propafenone affect the AVN and BTs and reduce SVT frequency. Sotalolol, dofetilide, and amiodarone are second-line agents. Because sympathetic stimulation can antagonize the effects of many antiarrhythmic agents, concomitant therapy with a beta blocker can improve efficacy.

Patients with well-tolerated episodes of paroxysmal SVT that always terminate spontaneously or with vagal maneuvers do not require chronic prophylactic therapy. Selected patients may be treated only for acute episodes. Outpatients may use a single oral dose of verapamil, propranolol, or propafenone to terminate an episode of AVRT or AVNRT effectively. This so-called “pill in the pocket” or “cocktail therapy” is a reasonable treatment option for patients who have tachycardia episodes that are sustained but infrequent enough that daily preventive therapy is not desired. Oral antiarrhythmic drug tablets are not reliably absorbed during rapid paroxysmal SVT, but some patients can respond to self-administration of crushed medications.

Pharmacological management of ATs has not been well evaluated in controlled clinical trials. Depending on the mechanism responsible for the arrhythmia, beta blockers, calcium channel blockers, and class I or III antiarrhythmic drugs may reduce or eliminate symptoms.

Electrocardiographic Features

Assessment of Regularity of the Supraventricular Tachycardia

Most SVTs are associated with a regular ventricular rate. If the rhythm is irregular, the ECG should be scrutinized for discrete atrial activity and for any evidence of a pattern to the irregularity (e.g., grouped beating typical of Wenckebach periodicity). If the rhythm is irregularly irregular (i.e., no pattern can be detected), the mechanism of the arrhythmia is either multifocal AT or AF (Fig. 20-2). Multifocal AT is an irregularly irregular atrial rhythm characterized by more than three different P wave morphologies, with the P waves separated by isoelectric intervals and associated with varying P-R, and PR intervals (see Fig. 11-1). On the other hand,

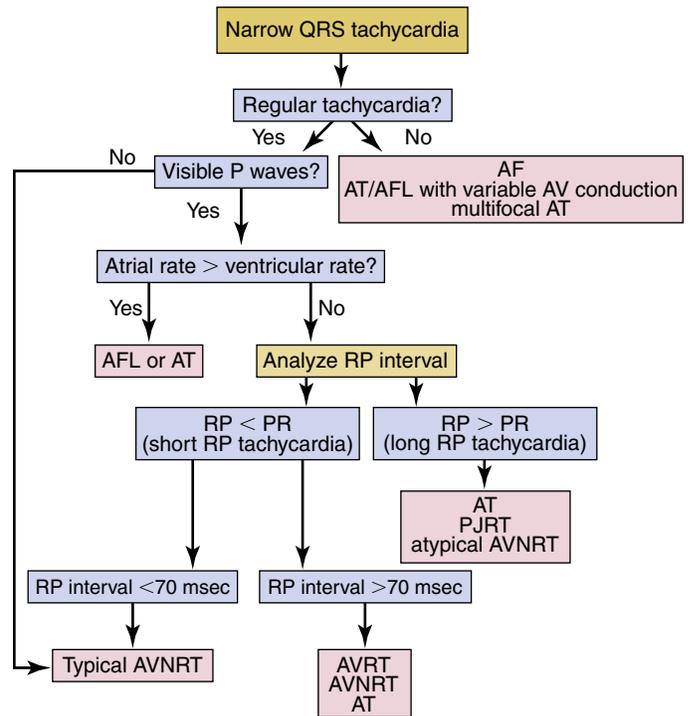

FIGURE 20-2 Differential diagnosis of narrow QRS tachycardia. AF = atrial fibrillation; AFL = atrial flutter; AT = atrial tachycardia; AV = atrioventricular; AVNRT = atrioventricular nodal reentrant tachycardia; AVRT = atrioventricular reentrant tachycardia; PJRT = permanent junctional reciprocating tachycardia. (From Blomström-Lundqvist C, Scheinman MM, Aliot EM, et al: American College of Cardiology; American Heart Association Task Force on Practice Guidelines; European Society of Cardiology Committee for Practice Guidelines [Writing Committee to Develop Guidelines for the Management of Patients with Supraventricular Arrhythmias]; ACC/AHA/ESC guidelines for the management of patients with supraventricular arrhythmias—executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and the European Society of Cardiology Committee for Practice Guidelines [Writing Committee to Develop Guidelines for the Management of Patients with Supraventricular Arrhythmias], *Circulation*;108:1871, 2003.)

AF is characterized by rapid and irregular atrial fibrillatory activity and, in the presence of normal AVN conduction, by an irregularly irregular ventricular response. P waves cannot be detected in AF, although coarse fibrillatory waves and prominent U waves can sometimes give the appearance of P waves. At times, the fibrillatory activity is so fine as to be undetectable.

Atrial Activity

IDENTIFICATION

If the patient's rhythm is regular or has a clearly discernible pattern, the ECG should next be assessed for P waves (atrial activity).⁵ The P waves may be easily discernible; however, frequently, comparison with a normal baseline ECG is needed and can reveal a slight alteration in the QRS, ST segment, or T waves, suggesting the presence of the P wave. If the P waves cannot be clearly identified, carotid sinus massage or the administration of intravenous adenosine may help clarify the diagnosis. These maneuvers may also terminate the SVT.

Carotid Sinus Massage

Carotid sinus massage can result in one of four possible effects: (1) temporary decrease in the atrial rate in patients with sinus tachycardia or automatic AT; (2) slowing of AVN conduction and AVN block, which can unmask atrial electrical activity—that is, reveal P waves or flutter waves in patients with AT or AFL by decreasing the number of QRS complexes that obscure the electrical baseline; (3) with some SVTs that require AVN conduction, especially AVNRT

and AVRT, the transient slowing of AVN conduction can terminate the arrhythmia by interrupting the reentry circuit; less commonly, carotid sinus massage can cause some ATs to slow and terminate; or (4) in some cases, no effect is observed.

Adenosine Administration

Adenosine results in slowing of the sinus rate and AVN conduction. In the setting of SVT, the effects of adenosine are similar to those seen with carotid sinus massage described earlier. For intravenous adenosine administration, the patient should be supine and should have ECG and blood pressure monitoring. The drug is administered by rapid intravenous injection over 1 to 2 seconds at a peripheral site, followed by a normal saline flush. The usual initial dose is 6 mg, with a maximal single dose of 12 mg. If a central intravenous access site is used, the initial dose should not exceed 3 mg and may be as little as 1 mg. Adenosine can precipitate AF and AFL because it shortens atrial refractoriness. In patients with Wolff-Parkinson-White (WPW) syndrome and AF, adenosine can result in a rapid ventricular response that can degenerate into VF. However, this problem has not been observed frequently, and the use of adenosine for diagnosis and termination of regular SVTs, including AVRT, is appropriate as long as close patient observation and preparedness to treat potential complications, such as with immediate electrical cardioversion/defibrillation, are maintained.

Termination of the Arrhythmia

Carotid sinus massage or adenosine can terminate the SVT, especially if the rhythm is AVNRT or AVRT. A continuous ECG tracing should be recorded during these maneuvers, because the response can aid in the diagnosis.⁵ Termination of the tachycardia with a P wave after the last QRS complex is most common in AVRT and typical AVNRT and is rarely seen with AT (see Fig. 18-22), whereas termination of the tachycardia with a QRS complex is more common with AT, atypical AVNRT, and permanent junctional reciprocating tachycardia (PJRT; see Fig. 18-19). If the tachycardia continues despite development of AV block, the rhythm is almost certainly AT or AFL; AVRT is excluded and AVNRT is very unlikely.

CHARACTERIZATION

Atrial Rate

An atrial rate greater than 250 beats/min is usually caused by AFL. However, overlap exists, and AT and AVRT can occasionally be faster than 250 beats/min. AVRT tends to be faster than AVNRT and AT; again, significant overlap exists and this criterion does not usually help in distinguishing among different SVTs.

P Wave Morphology

A P wave morphology identical to sinus P wave suggests sinus tachycardia, inappropriate sinus tachycardia, sinoatrial nodal reentrant tachycardia, or AT arising close to the region of the sinus node. An abnormal P wave morphology can be observed during AVNRT (P wave is concentric; see Fig. 17-3), AVRT (P wave can be eccentric or concentric; see Fig. 18-9), AT (P wave can be eccentric or concentric), and AFL (lack of distinct isoelectric baselines between atrial deflections is suggestive of AFL, but can also be seen occasionally in AT; see Fig. 12-2).⁵

The P waves may not be discernible on ECG, which suggests typical AVNRT or, less commonly, AVRT (especially in the presence of bundle branch block [BBB] contralateral to the BT).

CHARACTERIZATION OF THE P/QRS RELATIONSHIP

RP/PR Intervals

SVTs are classified as short or long RP interval SVTs (see Fig. 20-2). During short RP SVTs, the ECG will show P waves inscribed within the ST-T wave with an RP interval that is less than half the tachycardia R-R interval. Such SVTs include typical AVNRT (most common), orthodromic AVRT, AT with prolonged AV conduction, and slow-slow AVNRT. A very short RP interval (<70 milliseconds) excludes AVRT.^{5,6}

In typical AVNRT, the P wave is usually not visible because of the simultaneous atrial and ventricular activation. The P wave may distort the initial portion of the QRS (mimicking a q wave in inferior leads) or lie just within the QRS (inapparent) or distort the terminal portion of the QRS (mimicking an s wave in inferior leads or r' in V₁; see Fig. 17-3).

Long RP SVTs include AT, atypical (fast-slow) AVNRT, and AVRT using a slowly conducting AV BT (e.g., PJRT). If the PR interval during the SVT is shorter than that during normal sinus rhythm (NSR), AT and AVRT are very unlikely, and atypical AVNRT, which is associated with an apparent shortening of the PR interval, is the likely diagnosis. ATs originating close to the AV junction are also a possibility.

Atrial-Ventricular Relationship

SVTs with an A/V ratio of 1 (i.e., equal number of atrial and ventricular events) include AVNRT, AVRT, and AT. On the other hand, an A/V ratio during the SVT of greater than 1 indicates the presence of AV block and that the ventricles are not required for the SVT circuit, thereby excluding AVRT and suggesting either AT (most common; see Fig. 11-2) or AVNRT (rare; see Fig. 17-4). AV dissociation (i.e., complete AV block) can be observed during AT (most common) or AVNRT (rare).

QRS Morphology

The QRS morphology during SVT is usually the same as in NSR. However, functional aberration can occur at rapid rates. Functional aberration occurs frequently in AF, AFL, and AVRT, is less common in AT, and is very uncommon in AVNRT.

Electrophysiological Testing

Discussion in this section will focus on differential diagnosis of narrow QRS complex paroxysmal SVTs, including AT, orthodromic AVRT, and AVNRT. The goals of EP testing in these patients include the following: (1) evaluation of baseline cardiac electrophysiology; (2) induction of SVT; (3) evaluation of the mode of initiation of the SVT; (4) definition of atrial activation sequence during the SVT; (5) definition of the relationship of the P wave to the QRS at the onset and during the SVT; (6) evaluation of the effect of BBB on the tachycardia cycle length (CL) and ventriculoatrial (VA) interval; (7) evaluation of the SVT circuit and requirement for the atria, His bundle (HB), and/or ventricles in the initiation and maintenance of the SVT; (8) evaluation of the SVT response to programmed electrical stimulation and overdrive pacing from the atrium and ventricle; and (9) evaluation of the effects of drugs and physiological maneuvers on the SVT.

Baseline Observations during Normal Sinus Rhythm

The presence of preexcitation during NSR suggests AVRT as the likely diagnosis; however, it does not exclude other causes of SVT during which the AV BT is an innocent bystander. Furthermore, the absence of preexcitation during NSR does not exclude the presence of an AV BT or the diagnosis of AVRT mediated by either a concealed or a slowly conducting BT. The presence of intraatrial conduction delay suggests AT, but does not exclude other types of SVTs.

Programmed Electrical Stimulation during Normal Sinus Rhythm

The programmed stimulation protocol should include (1) ventricular burst pacing from the right ventricular (RV) apex (down to pacing CL at which VA block develops); (2) single and double ventricular extrastimuli (VESs, down to the ventricular effective refractory period, ERP) at multiple CLs (600 to 400 milliseconds) from the RV apex; (3) atrial burst pacing from the high right atrium (RA) and coronary sinus (CS; down to the pacing CL at which 2:1 atrial capture

occurs); (4) single and double atrial extrastimuli (AESs, down to the atrial ERP) at multiple CLs (600 to 400 milliseconds) from the high RA and CS; and (5) administration of isoproterenol infusion (0.5 to 4 $\mu\text{g}/\text{min}$) as needed to facilitate tachycardia induction.

ATRIAL EXTRASTIMULATION AND ATRIAL PACING DURING NORMAL SINUS RHYTHM

Dual Atrioventricular Nodal Physiology

Although the demonstration of dual AVN physiology during programmed atrial stimulation favors AVNRT as the mechanism of SVT, it is not an uncommon finding in patients with other types of SVTs. Furthermore, failure to demonstrate dual AVN physiology does not exclude the possibility of AVNRT, and might be related to similar fast and slow AVN pathway ERPs. Dissociation of refractoriness of the fast and slow AVN pathways can then be necessary (see Chap. 17).

Ventricular Preexcitation

Atrial stimulation can help unmask preexcitation if it is not manifest during NSR because of fast AVN conduction, slow BT conduction, or both. AES and atrial pacing from any atrial site result in slowing of AVN conduction and, consequently, unmask or increase the degree of preexcitation over the AV BT (see Fig. 18-14). Moreover, atrial stimulation close to the AV BT insertion site results in maximal preexcitation and the shortest P-delta interval because of the ability to advance the activation of the AV BT down to its ERP from pacing at this site caused by the lack of intervening atrial tissue, whose conduction time and refractoriness can otherwise limit the ability of the AES to stimulate the BT prematurely (see Fig. 18-14).

Failure of atrial stimulation to increase the amount of preexcitation can occur because of markedly enhanced AVN conduction, the presence of another AV BT, or pacing-induced block in the AV BT due to the long ERP of the BT (longer than that of the AVN). It can also occur because total preexcitation is already present in the basal state as a result of prolonged AVN/His-Purkinje system (HPS) conduction.

Extra Atrial Beats

AES and atrial pacing can trigger extra atrial beats or echo beats. Those beats can be caused by different mechanisms.

INTRAATRIAL REENTRANT BEATS. These beats usually occur at short coupling intervals, and can originate anywhere in the atrium. Therefore, the atrial activation sequence depends on the site of origin of the beat. The more premature the AES, the more likely it will induce nonspecific intraatrial reentrant beats and short runs of irregular AT or AF.

CATHETER-INDUCED ATRIAL BEATS. These beats usually have the earliest activation site recorded at that particular catheter tip and have the same atrial activation sequence as the atrial impulse produced by pacing from that catheter. Portions of the catheter proximal to the tip usually do not elicit mechanically induced ectopic impulses.

ATRIOVENTRICULAR NODAL ECHO BEATS. These beats occur in the presence of anterograde dual AVN physiology (see Fig. 4-23). Such beats require anterograde block of the atrial stimulus in the fast AVN pathway, anterograde conduction down the slow pathway, and then retrograde conduction up the fast pathway. AVN echo beats have several features: they appear reproducibly after a critical AH interval; the atrial activation sequence is consistent with retrograde conduction over the fast pathway, with the earliest atrial activation site in the HB; and the VA interval is very short, but it can be longer if the atrial stimulus causes anterograde concealment (and not just block) in the fast pathway.

ATRIOVENTRICULAR ECHO BEATS. AV echo beats occur secondary to anterograde conduction of the atrial stimulus over the AVN-HPS and retrograde conduction over an AV BT (concealed or bidirectional BT). If preexcitation is manifest during atrial stimulation, the last atrial impulse inducing the echo beat will demonstrate loss of preexcitation because of anterograde block in the

AV BT, and atrial activation sequence and P wave morphology of the echo beat will depend on the location of the BT (see Fig. 3-10). These beats have a relatively short VA interval, but always longer than 70 milliseconds. Moreover, the VA interval of the AV echo beat remains constant, regardless of the varying coupling interval of the AES triggering the echo beat (VA linking). Alternatively, AV echo beats can occur secondary to anterograde conduction of the atrial stimulus over a manifest AV BT and retrograde conduction over an AVN, in which setting the last paced beat is associated with anterograde block in the AVN and fully preexcited QRS complex.

VENTRICULAR EXTRASTIMULATION AND VENTRICULAR PACING DURING NORMAL SINUS RHYTHM

Retrograde Dual Atrioventricular Nodal Physiology

Demonstration of retrograde dual AVN physiology during programmed ventricular stimulation suggests AVNRT (occurring most commonly during atypical AVNRT), but it can also be observed with other SVTs.⁷ Importantly, failure to demonstrate retrograde dual AVN physiology in patients with AVNRT can be the result of similar fast and slow AVN pathway ERPs, in which setting dissociation of refractoriness of the fast and slow AVN pathways is required (see Chap. 17).

VA block at a ventricular pacing CL greater than 600 milliseconds or decremental VA conduction during ventricular pacing makes the presence of a retrogradely conducting BT unlikely, except for decrementally conducting BTs and the rare catecholamine-dependent BTs. In addition, development of VA block during ventricular pacing in response to adenosine suggests the absence of BT.

Retrograde Atrial Activation Sequence

VA conduction over the AVN produces a classic concentric atrial activation sequence starting in the anteroseptal or posteroseptal region of the RA because of retrograde conduction over either the fast or the slow AVN pathways, respectively. In the presence of a retrogradely conducting AV BT, atrial activation can result from conduction over the AV BT, over the AVN, or a fusion of both (see Fig. 18-16). An eccentric atrial activation sequence in response to ventricular stimulation suggests the presence of an AV BT mediating VA conduction (see Fig. 18-16). The presence of a concentric retrograde atrial activation sequence, however, does not exclude the presence of a retrogradely conducting BT that could be septal in location or located far from the pacing site, allowing for preferential VA conduction over the AVN.

Extra Ventricular Beats

Ventricular stimulation can trigger extra ventricular beats or echo beats. These beats can be caused by different mechanisms.

BUNDLE BRANCH REENTRANT BEATS. During RV stimulation at close coupling intervals, progressive retrograde conduction delay and block occur in the right bundle branch (RB), so that retrograde HB activation occurs via the left bundle branch (LB). At this point, the His potential usually follows the local ventricular electrogram. Further decrease in the coupling interval produces an increase in retrograde HPS conduction delay. When a critical degree of HPS delay (S_2 - H_2) is attained, the impulse can return down the initially blocked RB and result in a QRS of similar morphology to the paced QRS at the RV apex—specifically, it will look like a typical left bundle branch block (LBBB) pattern with left axis deviation because ventricular activation originates from conduction over the RB. The His bundle–ventricular (HV) interval of the bundle branch reentrant (BBR) beat is usually longer than or equal to the HV interval during NSR. Retrograde atrial activation, if present, follows the His potential (see Fig. 4-27).

ATRIOVENTRICULAR NODE ECHO BEATS. These beats are caused by reentry in the AVN in patients with retrograde dual AVN physiology (see Fig. 17-11). The last paced beat conducts retrogradely down the slow AVN pathway and then anterogradely down the fast pathway to produce the echo beat. AVN echoes appear reproducibly after a critical H_2 - A_2 interval (or V_2 - A_2 interval, when

the His potential cannot be seen), and manifest as extra beats with a normal anterograde QRS morphology and atrial activity preceding the His potential before the echo beat. This phenomenon can occur at long or short coupling intervals and depends only on the degree of retrograde AVN conduction delay. In most cases, this delay is achieved before the appearance of a retrograde His potential beyond the local ventricular electrogram (i.e., before retrograde block in the RB).

ATRIOVENTRICULAR ECHO BEATS. These beats occur secondary to retrograde block in the HPS-AVN and VA conduction over an AV BT, followed by anterograde conduction over the AVN, or secondary to retrograde block in the AV BT and VA conduction over the AVN-HPS, followed by anterograde conduction over the AV-BT. In the latter setting, the echo beat is fully preexcited (see Fig. 18-16).

INTRAVENTRICULAR REENTRANT BEATS. This response occurs most commonly in the setting of a cardiac pathological condition, especially coronary artery disease, and usually occurs at short coupling intervals. It can have any QRS morphology, but more often right bundle branch block (RBBB) than LBBB in patients with prior myocardial infarction (MI). These responses are usually nonsustained (1 to 30 complexes) and typically polymorphic. In patients without prior clinical arrhythmias, such responses are of no clinical significance.

CATHETER-INDUCED VENTRICULAR BEATS. Such beats usually have the earliest ventricular activation site recorded at that particular catheter tip and have the same QRS morphology as the QRS produced by pacing from that catheter.

Right Bundle Branch Block during Ventricular Extrastimulation

During the delivery of progressively premature single VESs, an abrupt increase in the VA conduction interval is often seen. This may be due to a variety of reasons including a change in activation from a BT block to the AVN or a change from fast to slow pathway conduction, or it may be the result of an abrupt change when the refractory period of the RB has been reached.

Retrograde RBBB occurs frequently during VES testing, and can be diagnosed by observing the retrograde His potential during the drive train and its abrupt displacement with the VES. Often, however, it is difficult to visualize the retrograde His potential during the pacing train; even then, the sudden appearance of an easily distinguished retrograde His potential, separate from the ventricular electrogram, may be sufficient to recognize retrograde RBBB.

The VH interval prolongation occurs because, following RBBB, conduction must traverse the interventricular septum (which requires approximately 60 to 70 milliseconds in normal hearts), enter retrogradely via the LB, and ascend to reach the HB. Although an increase in the VH interval necessarily occurs with retrograde RBBB, whether a similar increase occurs in the VA interval depends on the nature of VA conduction. Measurement of the retrograde VH and VA intervals on development of retrograde RBBB during VES can help the distinction between retrograde AVN and BT conduction.

In the absence of a BT, the AVN can be activated in a retrograde fashion only after retrograde activation of the HB; as a consequence, VA activation will necessarily be delayed with retrograde RBBB, and the increase in the VA interval will be at least as much as the increase in the VH interval. In contrast, when retrograde conduction is via a BT, there will be no expected increase in the VA interval when retrograde RBBB is induced. Thus, the increase in the VA interval is minimal and always less than the increase in the VH interval.⁸

Induction of Tachycardia

INITIATION BY ATRIAL EXTRASTIMULATION OR ATRIAL PACING

Inducibility

All types of paroxysmal SVTs can be inducible with atrial stimulation (except automatic AT). SVT initiation that is reproducibly

dependent on a critical AH interval is classic for typical AVNRT (see Fig. 17-8). Atypical AVNRT is usually initiated with modest prolongation of the AH interval along the fast pathway with anterograde block in the slow pathway, followed by retrograde slow conduction over the slow pathway. Therefore, a critical AH interval delay is not obvious (see Fig. 17-10). AT initiation also can be associated with AV delay, but that is not a prerequisite for initiation. Orthodromic AVRT usually requires some AV delay for initiation; however, the delay can occur anywhere along the AVN-HPS axis. In patients with baseline manifest preexcitation, initiation of orthodromic AVRT is usually associated with anterograde block in the AV BT and loss of preexcitation following the initiating atrial stimulus, which would then allow that BT to conduct retrogradely during the SVT.⁹ Initiation may require catecholamines (isoproterenol) with any type of SVT, and this observation does not help for differential diagnosis.

Warm-Up

Progressive shortening of the tachycardia CL for several beats (warm-up) before its ultimate rate is achieved is characteristic of automatic AT, but may occur in other SVTs as well.

Ventriculoatrial Interval

If the VA interval of the first tachycardia beat is reproducibly identical to that during the rest of the SVT, AT is very unlikely, and such "VA linking" is suggestive of typical AVNRT and orthodromic AVRT.

INITIATION BY VENTRICULAR EXTRASTIMULI OR VENTRICULAR PACING

Inducibility

Ventricular stimulation commonly induces AVRT, typical and atypical AVNRT, and less frequently AT.

His Bundle–Atrial Interval

During induction of the SVT by ventricular pacing at a CL similar to the tachycardia CL or by a VES that advances the His potential by a coupling interval (i.e., H_1-H_2) similar to the H-H interval during the SVT (i.e., similar to the tachycardia CL), the His bundle–atrial (HA) or VA interval following the initiating ventricular stimulus then is compared with that during the SVT. During AVNRT, the HA interval of the ventricular stimulus initiating the SVT is longer than that during the SVT, because both the HB and atrium are activated in sequence during ventricular stimulation and in parallel during AVNRT. This is even exaggerated by the fact that the AVN usually exhibits greater decremental conduction with repetitive engagement of impulses than to a single impulse at a similar coupling interval. Therefore, the more prolonged the HA interval with the initiating ventricular stimulus, the more likely the SVT is AVNRT. On the other hand, if the SVT uses an AV BT for retrograde conduction, the HA interval during the initiating ventricular stimulus (at a coupling interval comparable to the tachycardia CL) should approximate that during the SVT, because the atrium and ventricle are activated in sequence in both scenarios (see Fig. 18-16).⁹

Tachycardia Features

ATRIAL ACTIVATION SEQUENCE

During typical AVNRT, the initial site of atrial activation is usually recorded in the HB catheter at the apex of the triangle of Koch.¹⁰ In contrast, the initial site of atrial activation during atypical AVNRT is usually recorded at the base of the triangle of Koch or coronary sinus ostium (CS os) (see Fig. 17-5).¹⁰ On the other hand, in orthodromic AVRT, the initial site of atrial activation depends on the location of the AV BT, but is always near the AV groove, without multiple breakthrough points. It is comparable to that during ventricular pacing when VA conduction occurs exclusively over the AV BT. The atrial activation sequence during AT depends on the origin of the AT, and can simulate that of other types of SVTs. In summary, eccentric atrial activation during SVT excludes typical and atypical

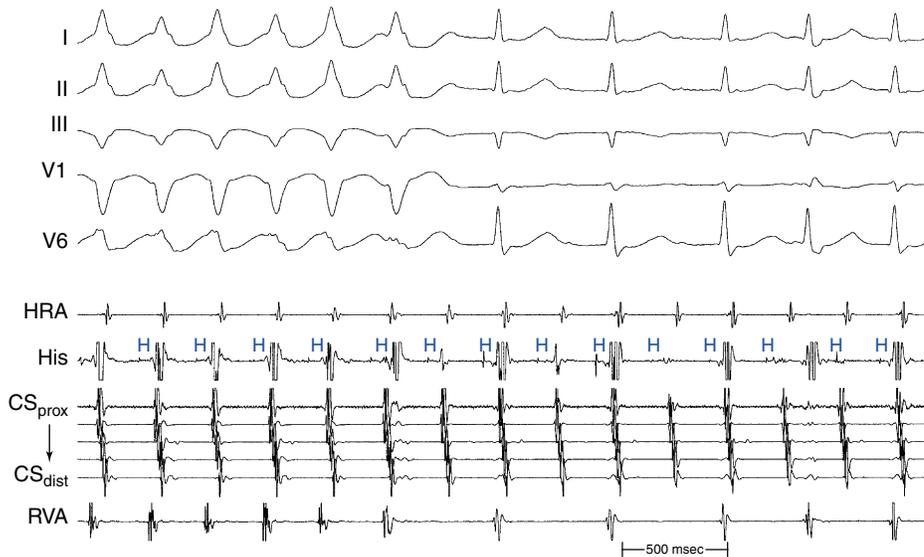

FIGURE 20-3 Supraventricular tachycardia (SVT) with concentric atrial activation sequence and intermittent atrioventricular (AV) block. At left, a wide complex tachycardia with left bundle branch block (LBBB) pattern and 1:1 AV ratio is shown. Simultaneous atrial and ventricular activation is observed, excluding atrioventricular reentrant tachycardia (AVRT) as the mechanism of the tachycardia, and favoring typical atrioventricular nodal reentrant tachycardia (AVNRT) or atrial tachycardia (AT) with a long PR interval. At right, 2:1 AV block is observed without disruption of the tachycardia. Normalization of QRS morphology is observed during the period of 2:1 AV block, suggesting that wide QRS morphology during 1:1 AV conduction was a result of functional LBBB. The development of AV block with continuation of the tachycardia confirms that the ventricle is not part of the tachycardia circuit and, thus, excludes AVRT. The presence of His potentials, even during the blocked beats, suggests that the block is infra-Hisian. The observation of AV block favors AT, but does not exclude AVNRT. The ventriculoatrial (VA) interval remains constant following both the narrow and wide QRS complexes, which suggests AVNRT. Other pacing maneuvers confirmed that this SVT was in fact typical AVNRT.

AVNRT, except for the left variant of AVNRT, during which the earliest atrial activation occurs in the proximal or mid-CS. Moreover, an eccentric atrial activation sequence that originates away from the AV rings is diagnostic of AT and excludes both AVNRT and AVRT.⁹

ATRIAL-VENTRICULAR RELATIONSHIP

PR/RP

During AT, the PR interval is appropriate for the AT rate and is usually longer than that during NSR. The faster the AT rate, the longer the PR interval. Thus, the PR interval can be shorter, longer, or equal to the RP interval. The PR interval can also be equal to the R-R and the P wave can then fall within the preceding QRS, mimicking typical AVNRT. During typical AVNRT, the RP interval is very short (−40 to 75 milliseconds); in contrast, during atypical AVNRT, the RP interval is longer than the PR interval. On the other hand, during orthodromic AVRT, the RP interval is short but longer than that in typical AVNRT (>70 milliseconds), because the wavefront has to activate the ventricle before it reaches the AV BT and subsequently conduct retrogradely to the atrium. Thus, the ventricle and atrium are activated in sequence, in contrast to AVNRT, during which the ventricle and atrium are activated in parallel, resulting in abbreviation of the VA interval.⁶

Atrioventricular Block

The presence of AV block during SVT excludes AVRT, is uncommon during AVNRT, and strongly favors AT (Fig. 20-3). AV block occurs commonly during AT, with either Wenckebach periodicity or fixed-ratio block. AV block may also occur during AVNRT because of block below the reentry circuit, usually below the HB and infrequently in the lower common pathway, which can occur especially at the onset of the SVT, during acceleration of the SVT, and following a PVC or a VES (see Fig. 17-4).

Ventriculoatrial Block

VA block during SVT is a rare phenomenon, and may occasionally be observed in infraatrial SVTs, including junctional ectopic tachycardia, orthodromic AVRT using a nodofascicular or nodoventricular BT for retrograde conduction, as well as infra-atrial AVNRT. VA

block can rarely occur during AVNRT because of block in an upper common pathway (see Fig. 17-13). Intra-Hisian reentry is another potential mechanism, but it is a theoretical entity whose clinical occurrence has not been convincingly demonstrated.^{1,11-13}

Variation of the P/QRS Relationship

Spontaneous changes in the PR and RP intervals with fixed A-A interval favor AT and exclude orthodromic AVRT (Fig. 20-4, see Fig. 11-13). On the other hand, spontaneous changes in tachycardia CL accompanied by constant VA interval suggest orthodromic AVRT (see Fig. 18-22). During orthodromic AVRT, the RP interval remains fixed, regardless of oscillations in tachycardia CL from whatever cause or changes in the PR (AH) interval. Thus, the RP/PR ratio may change, and the tachycardia CL is most closely associated with the PR interval (i.e., anterograde slow conduction). Variation of the P/QRS relationship (with changes in the AH interval, HA interval, and AH/HA ratio), with or without block, can occur during AVNRT, especially in atypical or slow-slow AVNRT. This phenomenon usually occurs when the conduction system, the reentry circuit, or both are unstable during initiation or termination of the tachycardia or in cases of nonsustained tachycardias. The ECG manifestation of P/QRS variations, with or without AV block during tachycardia, should not be misdiagnosed as AT; they can be atypical or, rarely, typical forms of AVNRT. Moreover, the variations could be of such magnitude that a long RP tachycardia can masquerade for brief periods of time as short RP tachycardia.

OSCILLATION IN TACHYCARDIA CYCLE LENGTH

Analysis of tachycardia CL variability can provide useful diagnostic information that is available even when episodes of SVT are nonsustained. SVT CL variability of at least 15 milliseconds in magnitude was found to occur in up to 73% of paroxysmal SVTs and was equally prevalent in AT, AVNRT, and orthodromic AVRT. Changes in atrial CL preceding similar changes in subsequent ventricular CL strongly favor AT or atypical AVNRT (see Fig. 17-14). In contrast, when the change in atrial CL is predicted by the change in preceding ventricular CL, typical AVNRT or orthodromic AVRT is the most likely mechanism (see Fig. 18-22).

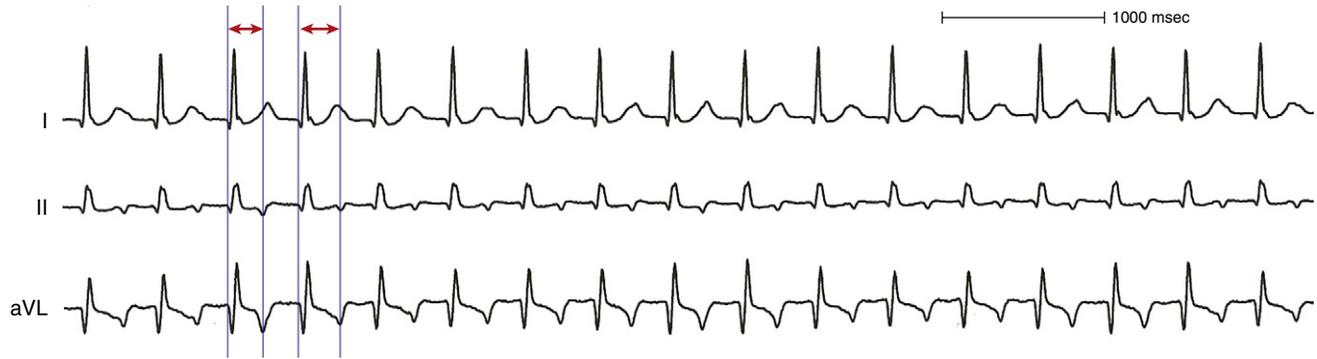

FIGURE 20-4 Narrow complex supraventricular tachycardia (SVT) with variable RP intervals. Three surface ECG leads are shown. The P waves are inscribed within the T waves, and are more discernible with negative polarity in lead aVL. Note that the RP interval varies during the SVT (arrows) with constant A-A intervals, consistent with atrial tachycardia as the mechanism of the SVT and excludes orthodromic atrioventricular reentrant tachycardia.

The AVN participates either actively or passively in all types of SVTs and the AV interval can vary depending on the preceding atrial CL and autonomic tone. A change in anterograde or retrograde AVN conduction can result in tachycardia CL variability in AVNRT or orthodromic AVRT. In contrast, CL variability in AT is a result of changes in the CL of the atrial reentrant or focal tachycardia, or changes in AVN conduction. Therefore, when there is CL variability in both the atrium and ventricle, changes in atrial CL during AT would be expected to precede and predict the changes in ventricular CL. However, ventricular CL variability can be caused by changes in AV conduction instead of changes in the CL of an AT, in which case ventricular CL variability may not be predicted by a prior change in atrial CL during AT. Nevertheless, because there is no VA conduction during AT, ventricular CL variability by itself would not be expected to result in atrial CL variability during AT.

In contrast to AT, typical AVNRT and orthodromic AVRT generally have CL variability because of changes in anterograde AVN conduction. Because retrograde conduction through a fast AVN pathway or a BT generally is much less variable than anterograde conduction through the AVN, the changes in ventricular CL that result from variability in anterograde AVN conduction would be expected to precede the subsequent changes in atrial CL. This explains why the change in atrial CL does not predict the change in subsequent ventricular CL in typical AVNRT and orthodromic AVRT. On the other hand, in atypical AVNRT, anterograde conduction occurs over the more stable fast AVN pathway and retrograde conduction is more subject to variability. This explains the finding that changes in atrial CL predict the changes in subsequent ventricular CL in atypical AVNRT, as was the case in AT.

EFFECTS OF BUNDLE BRANCH BLOCK

The development of BBB during SVT that neither influences the tachycardia CL (A-A or H-H interval) nor the VA interval is consistent with AT, AVNRT (see Fig. 17-4), and orthodromic AVRT using a BT in the ventricle contralateral to the BBB (see Fig. 18-21), but excludes orthodromic AVRT using a BT ipsilateral to the BBB.

BBB ipsilateral to the AV BT mediating orthodromic AVRT results in prolongation of the surface VA interval because of the extra time required for the impulse to travel from the AVN down the HB and contralateral bundle branch, and transseptally to the ipsilateral ventricle to reach the AV BT and then activate the atrium (see Fig. 18-23). However, the local VA interval (measured at the site of BT insertion) remains constant. Additionally, the tachycardia CL usually increases in concordance with the increase in the surface VA interval as a result of ipsilateral BBB, because of the now-larger tachycardia circuit; however, because the time the wavefront spends outside the AVN is now longer, AVN conduction may improve, resulting in shortening in the AH interval (PR interval), which can be of a magnitude sufficient to overcome the prolongation of the VA interval. This can consequently result in shortening in the tachycardia CL. Thus, the surface VA interval and not the

tachycardia CL should be used to assess the effects of BBB on the SVT (see Fig. 18-9).

Prolongation of the VA interval during SVT in response to BBB by more than 35 milliseconds indicates that an ipsilateral free wall AV BT is present and is participating in the SVT (i.e., diagnostic of orthodromic AVRT). On the other hand, prolongation of the surface VA by more than 25 milliseconds suggests a septal AV BT (postero-septal AV BT in association with LBBB, and superoparaseptal AV BT in association with RBBB; see Fig. 18-24). In contrast, BBB contralateral to the AV BT does not influence the VA interval or tachycardia CL because the contralateral ventricle is not part of the reentrant circuit (see Figs. 18-21 and 18-23).

Since the occurrence of BBB during SVT is much more common in orthodromic AVRT than AVNRT or AT (90% of SVTs with sustained LBBB are orthodromic AVRTs), the mere presence of LBBB aberrancy during SVT is suggestive of orthodromic AVRT, but can still occur in other types of SVTs.^{6,9}

QRS ALTERNANS

QRS alternans during relatively slow SVTs is almost always consistent with orthodromic AVRT. However, QRS alternans during fast SVTs is most commonly seen in orthodromic AVRT but can also be seen with other types of SVTs as well.

TERMINATION AND RESPONSE TO PHYSIOLOGICAL AND PHARMACOLOGICAL MANEUVERS

Spontaneous Termination

Spontaneous termination of orthodromic AVRT usually occurs because of anterograde gradual slowing and then block in the AVN, sometimes causing initial oscillation in the tachycardia CL, with alternate complexes demonstrating a Wenckebach periodicity before block. However, termination with retrograde block in the AV BT can occur without any perturbations of the tachycardia CL during very rapid orthodromic AVRT or with sudden shortening of the tachycardia CL. Spontaneous termination of AVNRT occurs because of block in the fast or slow pathway. However, the better the retrograde fast pathway conduction, the less likely that it is the site of block. Spontaneous termination of AT is usually accompanied by progressive prolongation of the A-A interval, with or without changes in AV conduction. During AT with 1:1 AV conduction, the last beat of AT is conducted to the ventricle. Spontaneous termination of SVT with a P wave not followed by a QRS practically excludes AT, except coincidentally or in the case of a nonconducted PAC terminating the AT (neither of which will be reproducible).⁹

Termination with Adenosine

The mere termination of SVT in response to adenosine is usually not helpful in differentiating SVTs. However, the pattern of SVT termination can be helpful in two situations: First, reproducible

FIGURE 20-5 Termination of supraventricular tachycardia (SVT) with adenosine. Administration of adenosine during an SVT with concentric atrial activation sequence and short RP interval results in termination of the SVT with an atrial complex not followed by a QRS, which is inconsistent with atrial tachycardia. Following termination of the SVT, complete atrioventricular (AV) block during sinus rhythm is observed; however, ventricular pacing is associated with intact ventriculoatrial (VA) conduction and retrograde atrial activation sequence identical to that during the SVT, which suggests that VA conduction is not mediated by the atrioventricular node (AVN) but by an AV bypass tract (BT). The SVT is in fact an orthodromic atrioventricular reentrant tachycardia using a concealed septal BT, and termination with adenosine was the result of block in the AVN. Retrograde conduction over the BT was not affected by adenosine.

termination of the SVT with a QRS not followed by a P wave excludes orthodromic AVRT using a rapidly conducting AV BT as the retrograde limb (adenosine blocks the AVN and not the BT), is unusual in typical AVNRT (adenosine blocks the slow pathway but does not affect the fast pathway), and is consistent with AT, PJRT, or atypical AVNRT. Second, reproducible termination of the SVT with a P wave not followed by a QRS excludes AT, because it occurs in AT only if adenosine terminates the AT at the same moment it causes AV block, which is an unlikely coincidence (Fig. 20-5). Most ATs (50% to 80%) can be terminated by adenosine, typically (80%) prior to the onset of AV block. Response to adenosine does not help differentiate between atypical AVNRT and PJRT.

Termination with Vagal Maneuvers

Carotid sinus massage and vagal maneuvers reproducibly slow or terminate up to 25% of ATs. Orthodromic AVRT usually terminates with gradual slowing and then block in the AVN. Typical AVNRT usually terminates with gradual anterograde slowing and then block in the slow pathway; block in the fast pathway is uncommon. Additionally, carotid sinus massage and vagal maneuvers terminate atypical AVNRT by gradual slowing and then block in the retrograde slow pathway.⁹

Diagnostic Maneuvers during Tachycardia

ATRIAL EXTRASTIMULATION DURING SUPRAVENTRICULAR TACHYCARDIA

Resetting

An AES can reset AT, AVNRT, and orthodromic AVRT, and demonstration of resetting by itself is not helpful in distinguishing among the different types of SVTs. However, resetting with manifest atrial fusion can be demonstrated only in orthodromic AVRT and macroreentrant AT, but not with AVNRT or focal AT. For atrial fusion (i.e., fusion of atrial activation from both the tachycardia wavefront and the AES) to occur, the AES should be able to enter the reentrant circuit while at the same time the tachycardia wavefront should be able to exit the circuit. This requires spatial separation between the entry and exit sites to the reentrant circuit, a condition that seems to be lacking in the setting of AVNRT and focal AT.

Additionally, the resetting curve can help differentiate the different subtypes of SVT. Reentrant AT, AVNRT, and orthodromic AVRT are characterized by an increasing or mixed response curve, whereas triggered activity AT exhibits a decreasing resetting response curve and automatic AT exhibits an increasing resetting response curve. It is difficult for an AES not to affect orthodromic AVRT because of the large size of the reentrant circuit, and an AES

over a wide range of coupling intervals can reset the SVT via conduction down the AVN-HPS. However, for AVNRT, more premature AESs are needed to demonstrate resetting.⁹

Termination

Termination of SVT with an AES is not usually helpful for the differential diagnosis. An AES can reproducibly terminate reentrant AT, AVNRT, and orthodromic AVRT, but not automatic AT. Termination of triggered activity AT is less reproducible.⁹

ATRIAL PACING DURING SUPRAVENTRICULAR TACHYCARDIA

Entrainment

Overdrive atrial pacing can entrain reentrant AT, AVNRT, and orthodromic AVRT but not triggered activity or automatic ATs. Entrainment with manifest fusion, on the other hand, can be seen only in AVRT and macroreentrant AT, but not with AVNRT or focal AT (see Fig. 18-27). However, it is important to understand that overdrive pacing of focal AT and AVNRT can result in a certain degree of fusion, especially when the pacing CL is only slightly shorter than the tachycardia CL. Such fusion, however, is unstable during the same pacing drive at a constant CL, because the pacing stimuli fall on a progressively earlier portion of the tachycardia cycle, producing progressively less fusion and more fully paced morphology. Such phenomena should be distinguished from entrainment, and sometimes this requires pacing for long intervals to demonstrate variable degrees of fusion.

During entrainment at a pacing CL close to the tachycardia CL, the AH interval during entrainment is longer than that during AVNRT because the atrium and HB are activated in parallel during AVNRT and in sequence during atrial pacing entraining the AVNRT (because of the presence of an upper common pathway). In contrast, in the setting of AT and orthodromic AVRT, the AH interval is comparable during SVT and entrainment with atrial pacing.⁹

Acceleration

Overdrive pacing during triggered activity AT generally produces acceleration of the tachycardia CL.

Overdrive Suppression

Automatic AT cannot be entrained by atrial pacing; however, rapid atrial pacing results in overdrive suppression of the AT rate, with the return CL following the pacing train prolonging with increasing the duration and/or rate of overdrive pacing, in contrast to constant return cycles following entrainment of reentrant circuits, regardless of the length of the pacing drive. The AT resumes following

cessation of atrial pacing but at a slower rate, gradually speeding up (warming up) back to pre-pacing tachycardia CL.⁹

Termination

Termination of SVT with atrial pacing is not usually helpful for differential diagnosis. Atrial pacing can reproducibly terminate reentrant AT, AVNRT, and orthodromic AVRT, but not automatic AT. Termination of triggered activity AT is less reproducible.

Ventriculoatrial Linking

On cessation of overdrive atrial pacing, if the VA interval following the last entrained QRS is reproducibly constant (<10 milliseconds in variation), despite pacing at different CLs or for different durations ("VA linking") and is similar to that during SVT, AT is unlikely. If no VA linking is demonstrable, AT is more likely than other types of SVTs (see Fig. 18-27).⁶ VA linking occurs in the setting of typical AVNRT and orthodromic AVRT because the timing of atrial activation is dependent on the preceding ventricular activation and is the result of retrograde VA conduction over the AVN fast pathway (during typical AVNRT) or the AV BT (during orthodromic AVRT), which is relatively fixed and constant. Contrariwise, following cessation of overdrive pacing (with 1:1 AV conduction) during focal AT, the VA interval can vary significantly from the VA interval during AT, because the timing of the tachycardia atrial return cycle is not related to the preceding QRS.^{2,6}

Differential-Site Atrial Pacing

As discussed in Chapter 11, differential site atrial pacing can help distinguish AT from other mechanisms of SVT. When the Δ VA interval (i.e., the maximal difference in the post-pacing VA intervals following cessation of pacing from the high RA and proximal CS) is more than 14 milliseconds, AT is suggested. On the other hand, in orthodromic AVRT and AVNRT, the initial atrial complex following cessation of atrial pacing entraining the SVT is *linked* to, and cannot be dissociated from, the last captured ventricular complex; hence, the Δ VA interval is typically less than 14 milliseconds.¹⁴

VENTRICULAR EXTRASTIMULATION DURING SUPRAVENTRICULAR TACHYCARDIA

Resetting

During orthodromic AVRT, a VES can usually reset the SVT. However, the ability of the VES to affect the SVT depends on the distance between the site of ventricular stimulation to the ventricular insertion site of the BT and on the VES coupling interval. Because only parts of the ventricle ipsilateral to the BT are requisite components of the orthodromic AVRT circuit, a VES delivered in the contralateral ventricle may not affect the circuit (see Fig. 18-29). On the other hand, the inability of early single or double VESs to reset the SVT despite advancement of all ventricular electrograms (including the local electrogram in the electrode recording the earliest atrial activation during the SVT, which would be close to the potential BT ventricular insertion site) by more than 30 milliseconds excludes orthodromic AVRT. Several other findings can help confirm the presence of BT function and whether it is participating in the SVT or is only a bystander (see Tables 18-4 and 18-5).

For AVNRT, the ability of a VES to affect the SVT depends on its ability to activate the HB prematurely and penetrate the AVN, which in turn depends on the tachycardia CL, local ventricular ERP, and the time needed for the VES to reach the HB. Even when HB activation is advanced by the VES, the ability of the paced impulse to invade the AVN will depend on the length of the lower common pathway; the longer the lower common pathway, the more the timing of HB activation must be advanced. In fast-slow or slow-slow AVNRT, which typically has a long lower common pathway, the HB activation must be advanced by more than 30 to 60 milliseconds. In contrast, in slow-fast AVNRT, the lower common pathway is shorter and the tachycardia is typically reset by the VES as soon as the HB activation is advanced. Therefore, a late VES, delivered when the HB is refractory, would not be able to penetrate the AVN and

reset AVNRT. During AT, a VES can advance the next atrial activation when given the chance to conduct retrogradely and prematurely to the atrium. However, it would never be able to delay the next AT beat.

Although resetting the SVT by a VES is not diagnostic by itself of a specific type of SVT, it can be helpful in certain situations. First, the ability of a late VES delivered while the HB is refractory (i.e., when the anterograde His potential is already manifest or within 35 to 55 milliseconds before the time of the expected His potential) to affect (reset or terminate) the SVT excludes AVNRT, because such a VES would not have been able to penetrate the AVNRT circuit (Fig. 20-6; and see Fig. 18-29). It also excludes AT, except for cases of AT associated with the presence of innocent bystander BT, in which case the presence of such a BT is usually easy to exclude with ventricular pacing during NSR. Second, the ability of a VES to delay the next atrial activation excludes AT (see Fig. 18-26). Third, the ability of a VES to reset the SVT without atrial activation (i.e., the VES advances the subsequent His potential and QRS and blocks in the upper common pathway) excludes AT and orthodromic AVRT, because it proves that the atrium is not part of the SVT circuit. Fourth, failure of early single or double VESs to reset the SVT, despite advancement of ventricular electrograms in the electrode recording the earliest atrial activation by more than 30 milliseconds, excludes orthodromic AVRT. Fifth, resetting with manifest QRS fusion can be observed during orthodromic AVRT, especially during pacing at a site closer to the BT ventricular insertion site than the entrance of the reentrant circuit to ventricular tissue (i.e., the HPS). Such a phenomenon, on the other hand, cannot occur during AVNRT or focal AT because of the lack of spatial separation of the entrance and exit to the tachycardia circuit. Sixth, retrograde atrial activation sequence following a VES that resets the tachycardia is usually similar to that during SVT in the setting of AVNRT and orthodromic AVRT, because it should conduct over the tachycardia retrograde limb (except in the presence of a bystander retrogradely conducting AV BT). In contrast, a retrograde atrial activation sequence during the VES is usually different from that during AT, except for ATs originating close to the AV junction.

Termination

Termination of AVNRT with a single VES is difficult and occurs rarely when the tachycardia CL is less than 350 milliseconds; such termination favors the diagnosis of orthodromic AVRT, which can usually be readily terminated by single or double VESs. Termination of the SVT with a VES delivered when the HB is refractory excludes AVNRT (see Fig. 20-6). It also excludes AT, except for cases of AT associated with the presence of an innocent bystander BT mediating VA conduction. Reproducible termination of the SVT with a VES not followed by atrial activation excludes AT (see Fig. 18-29) and, if this occurs with a VES delivered while the HB is refractory, it excludes both AT and AVNRT (see Fig. 20-6).

VENTRICULAR PACING DURING SUPRAVENTRICULAR TACHYCARDIA

Ventricular pacing is performed at a CL 10 to 30 milliseconds shorter than the tachycardia CL; the pacing CL is then progressively reduced by 10 to 20 milliseconds in a stepwise fashion with discontinuation of ventricular pacing after each pacing CL to verify continuation versus termination of the SVT. The presence of ventricular capture during ventricular pacing should be verified. Additionally, the presence of 1:1 VA conduction and acceleration of the atrial rate to the pacing CL should be carefully examined (Fig. 20-7). It is also important to verify the continuation of the SVT following cessation of ventricular pacing and whether SVT termination, with or without reinduction of the SVT, has occurred during ventricular pacing.

Ventriculoatrial Dissociation

When overdrive ventricular pacing during SVT fails to accelerate the atrial CL to the pacing CL (i.e., the ventricles are dissociated

FIGURE 20-6 Ventricular extrastimulation (VES) during supraventricular tachycardia (SVT). VESs were delivered at progressively shorter coupling intervals during a narrow complex SVT with concentric atrial activation sequence. Timing of the anticipated anterograde His bundle (HB) activation is indicated by the blue arrows. The first VES is delivered during HB refractoriness and fails to reset the tachycardia, a phenomenon that does not help in the differential diagnosis. The second VES is delivered slightly earlier but still during HB refractoriness, and it does accelerate the following atrial activation. Atrial activation sequence during the reset atrial complex is identical to that during SVT. This observation excludes atrioventricular nodal reentrant tachycardia (AVNRT), and favors orthodromic atrioventricular reentrant tachycardia (AVRT), but does not exclude the rare example of atrial tachycardia (AT) with a bystander bypass tract (BT) with atrial insertion close to the AT focus. The third VES is delivered during HB refractoriness (within 40 milliseconds before the anticipated anterograde HB activation) and it terminates the tachycardia without conducting to the atrium. This observation, when reproducible, excludes both AVNRT and AT, and proves that the tachycardia is an orthodromic AVRT.

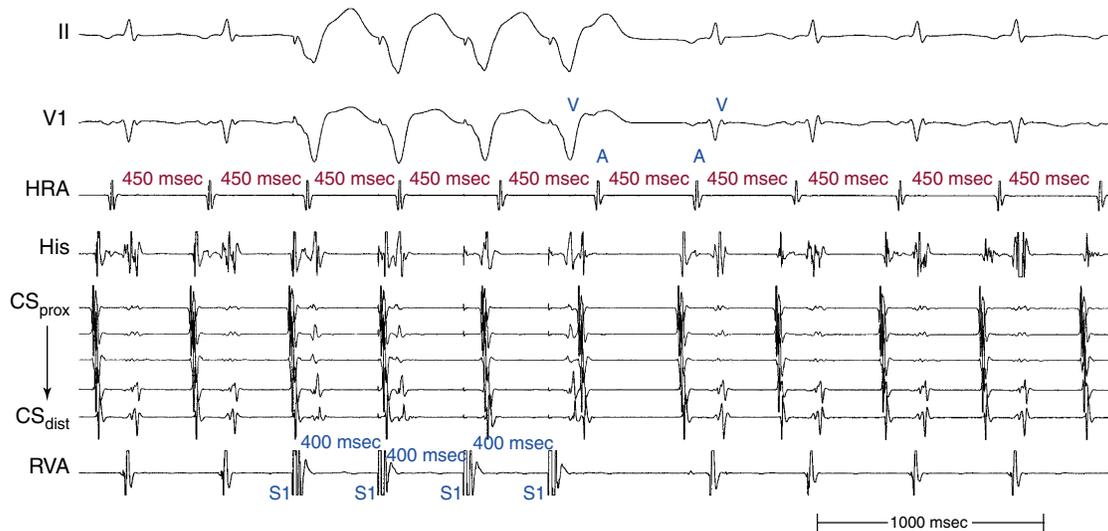

FIGURE 20-7 Overdrive ventricular pacing during supraventricular tachycardia (SVT). The SVT has a long RP interval and concentric atrial activation sequence, which favors atypical atrioventricular nodal reentrant tachycardia (AVNRT), atrial tachycardia (AT) originating close to the AV junction, or orthodromic AVRT using a slowly conducting septal bypass tract. Overdrive ventricular pacing during the tachycardia fails to entrain the tachycardia or capture the atrium (no ventriculoatrial [VA] conduction), because the tachycardia atrial cycle length (CL; 450 milliseconds) remains stable and unaltered by the faster ventricular pacing CL (400 milliseconds). Therefore, analysis of the post-pacing interval or VA interval during pacing versus SVT is invalid. Analysis of the response sequence following cessation of pacing (A-V versus A-A-A-V response) is also invalid in view of the lack of 1:1 VA conduction during ventricular pacing (resulting in a pseudo-A-A-V response). Nonetheless, the fact that ventricular pacing has dissociated the atrium from the ventricle excludes AVRT. However, other pacing maneuvers are required for differentiation between atypical AVNRT and AT.

from the tachycardia), AVRT is excluded, AT is the most likely diagnosis, but AVNRT is still possible.

Atrial Activation Sequence

As noted, the retrograde atrial activation sequence during ventricular pacing during the SVT is usually similar to that during the SVT in the setting of AVNRT and orthodromic AVRT, because

it should conduct over the tachycardia retrograde limb. On the other hand, the retrograde atrial activation sequence during ventricular pacing is usually different from that during AT, except for ATs originating close to the AV junction. A pitfall of this criterion is the presence of a bystander AV BT, which can provide another retrograde route capable of mediating retrograde conduction during ventricular pacing without being part

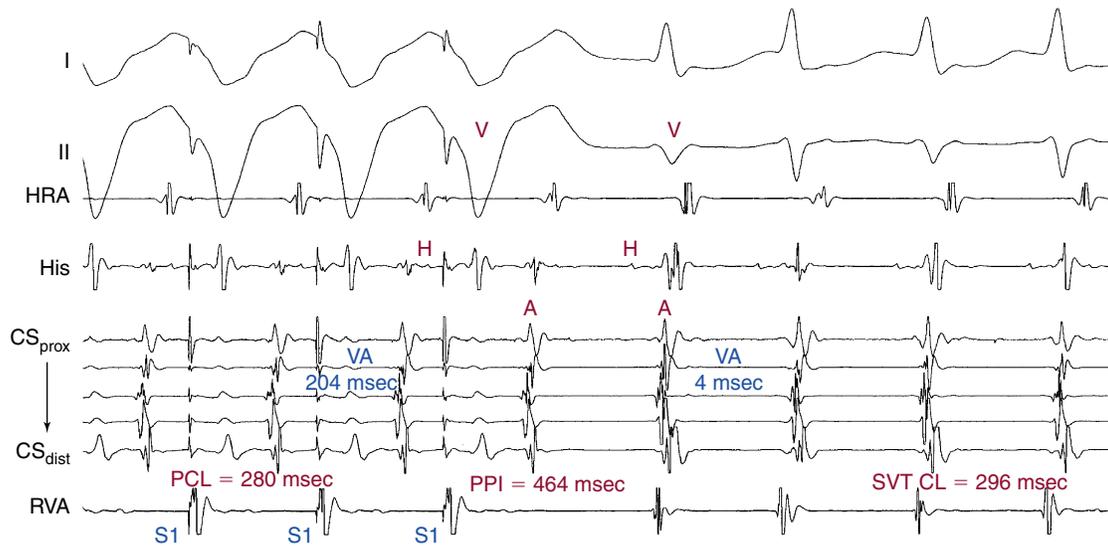

FIGURE 20-8 Entrainment of narrow QRS supraventricular tachycardia (SVT) with right ventricular (RV) apical pacing. Several features in this tracing can help in the differential diagnosis of the SVT. First, atrial and ventricular activation occur simultaneously during the SVT, which excludes atrioventricular reentrant tachycardia (AVRT). Second, atrial activation during the SVT is eccentric, with earliest activation in the mid-coronary sinus (CS), which favors atrial tachycardia (AT) over AVNRT. Third, the atrial activation sequence during ventricular pacing is identical to that during SVT, which favors AVNRT and AVRT over AT. Fourth, following cessation over ventricular pacing, the post-pacing interval (PPI) minus SVT cycle length (CL), [PPI – SVT CL], is more than 115 milliseconds, and the Δ VA interval ($VA_{\text{pacing}} - VA_{\text{SVT}}$) is more than 85 milliseconds, which favors AVNRT over AVRT. Fifth, although characterization of the activation sequence following cessation of ventricular pacing (A-A-V versus A-V response) is unclear (because of the simultaneous occurrence of atrial and ventricular activation in the first tachycardia complex, replacing ventricular activation with HB activation [i.e., characterizing the response as A-A-H or A-H instead of A-A-V or A-V, respectively]) reveals an A-H response, which favors AVRT and AVNRT over AT. In summary, AVRT can be reliably excluded by the simultaneous atrial and ventricular activation. AT is excluded by the A-H response following cessation of ventricular pacing and by the identical atrial activation sequence during the SVT and ventricular pacing. The left variant of typical AVRT (with an eccentric atrial activation sequence) is the mechanism of the SVT.

of the SVT circuit. In this setting, ventricular pacing can result in a retrograde atrial activation sequence different from that of AVNRT or orthodromic AVRT. The presence of such an AV BT, however, is generally easy to verify with ventricular stimulation during NSR.

Entrainment

Ventricular pacing is almost always able to entrain AVNRT and orthodromic AVRT and, if 1:1 VA conduction is maintained, reentrant AT. Entrainment of the SVT by RV pacing can help differentiate orthodromic AVRT from AVNRT by evaluating the VA interval during SVT versus that during pacing, and also by evaluating the post-pacing interval (PPI). The ventricle and atrium are activated in sequence during orthodromic AVRT and during ventricular pacing, but in parallel during AVNRT. Therefore, the VA interval during orthodromic AVRT approximates that during ventricular pacing (see Fig. 18-30). In contrast, the VA interval during AVNRT would be much shorter than that during ventricular pacing (see Fig. 17-18). In general, a difference in the VA interval (Δ VA [$VA_{\text{pacing}} - VA_{\text{SVT}}$]) greater than 85 milliseconds is consistent with AVNRT, whereas a Δ VA of less than 85 milliseconds is consistent with orthodromic AVRT (Fig. 20-8).

Additionally, the PPI after entrainment of AVNRT from the RV apex is significantly longer than the tachycardia CL (the [PPI – SVT CL] difference is usually >115 milliseconds), because the reentrant circuit in AVNRT is above the ventricle and far from the pacing site (see Fig. 17-18). In AVNRT, the PPI reflects the conduction time from the pacing site through the RV muscle and HPS, once around the reentry circuit and back to the pacing site. Therefore, the difference between the PPI and the SVT CL [PPI – SVT CL] reflects twice the sum of the conduction time through the RV muscle, the HPS, and any lower common pathway (see Fig. 20-8). In orthodromic AVRT using a septal BT, the PPI reflects the conduction time through the RV to the septum, once around the reentry circuit and back. In other words, the [PPI – SVT CL] reflects twice the conduction time from the pacing catheter through the

ventricular myocardium to the reentry circuit. Therefore, the PPI more closely approximates the SVT CL in orthodromic AVRT using a septal BT, compared with AVNRT (see Fig. 18-30). This maneuver was studied specifically for differentiation between atypical AVNRT and orthodromic AVRT, but the principle also applies to typical AVNRT. In general, a [PPI – SVT CL] difference greater than 115 milliseconds is consistent with AVNRT, whereas a [PPI – SVT CL] difference greater than 115 milliseconds is consistent with orthodromic AVRT. For borderline values, ventricular pacing at the RV base can help exaggerate the difference between the PPI and tachycardia CL in the setting of AVNRT, but without significant changes in the setting of orthodromic AVRT, because the site of pacing at the RV base is farther from the AVNRT circuit than the RV apex (because the paced wavefront has to travel first to the RV apex before engaging the HPS and conducting retrogradely to the AVN), but is still close to an AVRT circuit using a septal BT (and, in fact, it is closer to the ventricular insertion of the BT).^{15,16}

However, there are several potential pitfalls to the criteria discussed above. The tachycardia CL and VA interval are often perturbed for a few cycles after entrainment. For this reason, care should be taken not to measure unstable intervals immediately after ventricular pacing. In addition, spontaneous oscillations in the tachycardia CL and VA intervals can be seen. The discriminant points chosen may not apply when the spontaneous variability is more than 30 milliseconds. Also, it is possible to mistake isorhythmic VA dissociation for entrainment if the pacing train is not long enough or the pacing CL is too close to the tachycardia CL. Finally, those criteria may not apply to BTs with significant decremental properties, although small decremental intervals are unlikely to provide a false result.

Another limitation is that the [PPI – SVT CL] difference does not account for potential decremental anterograde AVN conduction that may be induced by overdrive pacing, which can significantly affect diagnostic interpretations of the PPI. The prolonged AH interval on the last entrained beat will contribute to prolongation of the PPI that is not reflective of the distance of the pacing

site from the circuit. Thus, [PPI – SVT CL] differences obtained after entrainment of orthodromic AVRT employing a septal BT can actually overlap with those observed after entrainment of AVNRT. Correction of the [PPI – SVT CL] difference for the degree of decrement in the AVN (by subtracting the difference in AH [or AV] interval during tachycardia and on the return cycle from the [PPI – SVT CL]) has been shown to improve the accuracy of this criterion for distinction between AVNRT and orthodromic AVRT. In a study of patients with both typical and atypical forms of AVNRT, as well as orthodromic using septal and free wall BTs, a corrected [PPI – SVT CL] difference of less than 110 milliseconds was found more accurate in identifying orthodromic AVRT from AVNRT than the uncorrected [PPI – SVT CL] difference. The use of change in VA interval is of course not influenced by prolongation of the AV interval during pacing and does not require correction.^{15,17,18}

Differential Right Ventricular Entrainment

Differential-site RV entrainment (from RV apex versus RV base) can help distinguish AVNRT from orthodromic AVRT. As discussed in Chapter 17, after entrainment of AVNRT, the PPI following entrainment from the RV base is longer than that post entrainment from the RV apex. Conversely, in orthodromic AVRT, the PPI tends to be similar, irrespective of the site of RV pacing.¹⁹ To avoid potential errors introduced by decremental conduction within the AVN during RV pacing, it is preferable to perform correction of the PPI (by subtracting any increase in the AV interval of the return cycle beat, as compared with the AV interval during SVT). A differential corrected [PPI – SVT CL] of more than 30 milliseconds after transient entrainment (i.e., corrected PPI following pacing from the RV base being consistently ≥ 30 milliseconds longer than that following pacing from the RV apex) is consistent with AVNRT, whereas a differential corrected [PPI – SVT CL] of less than 30 milliseconds is consistent with orthodromic AVRT. Additionally, a differential VA interval (ventricular stimulus-to-atrial interval during entrainment from RV base versus RV septum) of more than 20 milliseconds is consistent with AVNRT, whereas a differential VA interval of less than 20 milliseconds is consistent with orthodromic AVRT.¹⁹

Entrainment with Manifest Ventricular Fusion

Manifest ventricular fusion during entrainment of SVT indicates that the circuit includes ventricular tissue (i.e., AVRT), excluding both AVNRT and AT (see Fig. 18-30).

Length of Pacing Drive Required for Entrainment

As discussed in Chapter 17, assessing the timing and type of response of SVT to RV pacing can help differentiate orthodromic AVRT from AVNRT. Because the RV pacing site is closer to the reentrant circuit in AVRT than to the AVNRT circuit, RV pacing resets the tachycardia in the setting of AVRT once ventricular capture is achieved, whereas the resetting response is delayed in the setting of AVNRT. Consequently, when resetting of the SVT occurs after a single paced QRS complex, orthodromic AVRT is suggested and AVNRT is generally excluded. On the contrary, if resetting occurs only after at least two beats AVNRT is suggested (Fig. 20-9).²⁰

Atrial Resetting during the Transition Zone

In patients with AVNRT or AT, acceleration of the timing of atrial activation cannot occur via the AVN during the transition zone on initiation of RV pacing (during which the pacing train fuses with anterograde ventricular activation), because the HB is expected to be refractory, as indicated by ventricular activation still occurring via anterograde conduction over the HPS. If perturbation (≥ 15 milliseconds) of atrial timing occurs during the transition zone, it indicates the presence of a retrogradely conducting BT, which can be an integral part of the SVT circuit (i.e., orthodromic AVRT) or a bystander (as discussed in Chap. 17).²¹

Atrial and Ventricular Electrogram Sequence Following Cessation of Ventricular Pacing

As discussed in Chapter 11, the sequence of atrial and ventricular electrograms following cessation of overdrive ventricular pacing during SVT (without tachycardia termination) can help distinguish between the different mechanisms of SVT. It is necessary to verify the presence of 1:1 VA conduction during ventricular pacing before analyzing electrogram sequence. In the setting of AVNRT and orthodromic AVRT, the electrogram sequence immediately after the last paced QRS complex is atrial-ventricular (i.e., “A-V response”; see

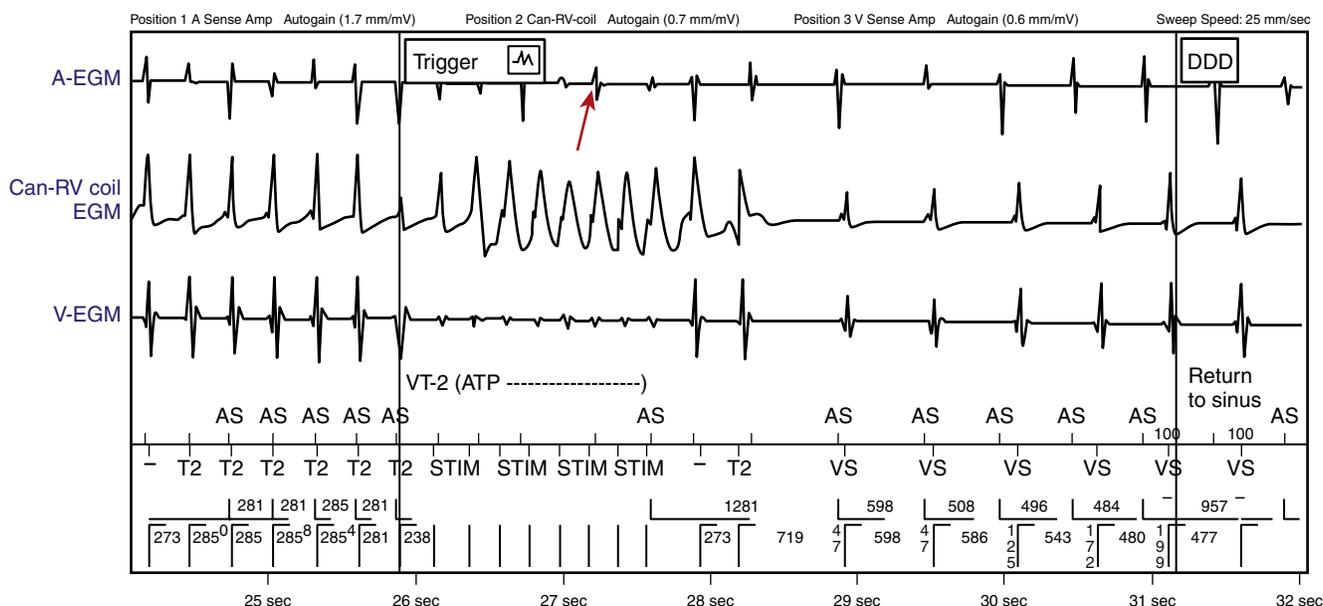

FIGURE 20-9 Intracardiac atrial, shock lead, and ventricular electrograms (A-EGM, Can-RV coil EGM, and V-EGM, respectively) stored by the ICD during an episode of tachycardia at a cycle length (CL) of 275 to 285 milliseconds and a 1:1 AV relationship. The supraventricular tachycardia (SVT) triggered antitachycardia pacing (ATP) therapy by the ICD with a burst of eight ventricular paced beats. ATP terminates the tachycardia, and sinus rhythm is restored. Note that the first three captured complexes during ATP failed to conduct to the atrium, and atrial activity continued unperturbed, which excludes VT as the mechanism of the tachycardia. Furthermore, the first reset (accelerated) atrial complex occurs after the fourth captured paced ventricular complex (red arrow), which is inconsistent with atrioventricular reentrant tachycardia (AVRT) and favors atrioventricular nodal reentrant tachycardia (AVNRT) or atrial tachycardia. The simultaneous atrial and ventricular activation during the tachycardia at baseline line also excludes AVRT and favors AVNRT.

instead of A-A-V or A-V, respectively) can be more accurate and can help eliminate the pseudo-A-A-V response in patients with AVNRT and long HV intervals, short HA intervals, or both (see Fig. 20-8). On the other hand, a pseudo-A-V response can occur with automatic AT when the maneuver is performed during isoproterenol infusion, and can theoretically occur when AT coexists with retrograde dual AVN pathways or bystander BT (see Chap. 11).²²

Termination

Ventricular pacing can easily terminate orthodromic AVRT, and failure to terminate the SVT with ventricular pacing argues against orthodromic AVRT. Termination of AVNRT is also common, but AT is less likely to be terminated by ventricular pacing.

Diagnostic Maneuvers during Normal Sinus Rhythm after Tachycardia Termination

When pacing the atrium or ventricle at the tachycardia CL, it is important that the autonomic tone be similar to its state during the tachycardia, because alterations of autonomic tone can independently influence AV or VA conduction.

ATRIAL PACING AT THE TACHYCARDIA CYCLE LENGTH

Atrial–His Bundle Interval

During AT and orthodromic AVRT, the AH interval during SVT is comparable to that during atrial pacing at a CL similar to the tachycardia CL because the activation wavefront propagates through a similar pathway during both the SVT and atrial pacing. On the other hand, the AH interval during AVNRT is shorter than that during atrial pacing, because the atrium and HB are activated in parallel during AVNRT (because of the presence of an upper common pathway) but in sequence during atrial pacing. Therefore, a ΔAH ($AH_{\text{atrial pacing}} - AH_{\text{SVT}}$) greater than 40 milliseconds is consistent with AVNRT. However, a ΔAH of less than 20 milliseconds favors AT and orthodromic AVRT. This has only been tested with RA pacing during right ATs and should be applied with caution when a left AT is suspected.

Atrioventricular Block

For AT and orthodromic AVRT, the AVN should be able to conduct 1:1 during atrial pacing and during the SVT, given that the pacing CL is equal to the tachycardia CL and that the same degree of autonomic tone is maintained, as would be expected when pacing is performed shortly after termination of SVT. Therefore, if AV block develops during atrial pacing, it suggests the presence of an upper common pathway and is consistent with AVNRT.

VENTRICULAR PACING AT THE TACHYCARDIA CYCLE LENGTH

His Bundle–Atrial Interval

Ventricular pacing during NSR at a CL similar to the tachycardia results in HA and VA intervals that are shorter than those during orthodromic AVRT (see Fig. 18-30). Contrariwise, in the setting of AVNRT, ventricular pacing at the tachycardia CL results in HA and VA intervals that are equal or longer during pacing than those during the SVT (see Fig. 17-20). To help distinguish between orthodromic AVRT and AVNRT, the HA interval is measured from the *end* of the His potential (where the impulse leaves the HB to enter the AVN) to the atrial electrogram in the high RA recording and the ΔHA interval ($HA_{\text{pacing}} - HA_{\text{SVT}}$) is calculated. In the setting of orthodromic AVRT, the ΔHA interval is typically less than -10 milliseconds; whereas, in the setting of AVNRT, the ΔHA interval is more than -10 milliseconds. When the retrograde His potential is not visualized, using the ΔVA interval instead of the ΔHA interval is not as accurate in discriminating orthodromic AVRT from AVNRT (see Chap. 17).²³

Ventriculoatrial Block

In the setting of AT and AVNRT, and under comparable autonomic tone, 1:1 VA conduction over the AVN may or may not be

maintained during ventricular pacing at a CL similar to the tachycardia CL because of possible retrograde block in the AVN or the lower common pathway. Anterograde conduction properties of the AVN or the lower common pathway may allow 1:1 conduction from the AT or AVNRT circuit down to the ventricle, but its retrograde conduction properties may not allow 1:1 retrograde conduction from the ventricle up to the atrium during ventricular pacing at a CL similar to the tachycardia CL. On the contrary, in the setting of orthodromic AVRT, 1:1 VA conduction is expected to be maintained because of the presence of an AV BT that was capable of mediating VA conduction at a similar rate during the AVRT. Therefore, if VA block is observed during ventricular pacing at the tachycardia CL, orthodromic AVRT is excluded (with the exception of orthodromic AVRT using a slowly conducting AV BT), and AT or AVNRT with lower common pathway physiology is more likely.

Atrial Activation Sequence

The retrograde atrial activation sequence during ventricular pacing is usually similar to that during SVT in the setting of AVNRT, but can be similar to or different from that during orthodromic AVRT, depending on whether retrograde VA conduction during ventricular pacing propagates over the AVN, the BT, or both. However, for AT, the retrograde atrial activation sequence during ventricular pacing is usually different from that during AT, except for ATs originating close to the AV junction.

DIFFERENTIAL RIGHT VENTRICULAR PACING

The response to differential-site RV pacing can be evaluated by comparing the VA interval and atrial activation sequence during pacing at the RV base versus the RV apex (see Chap. 18).

Ventriculoatrial Interval

When the VA interval during RV apical pacing is shorter than that during RV basal pacing, a retrogradely conducting septal BT is excluded. However, this maneuver may not exclude the presence of a free wall or a slowly conducting BT. On the other hand, when the VA interval during RV apical pacing is longer than that during RV basal pacing, a retrogradely conducting AV BT is diagnosed (see Fig. 18-33).

Atrial Activation Sequence

A retrograde atrial activation sequence that is different depending on the site of ventricular pacing indicates the presence of a BT. However, a constant atrial activation sequence does not help exclude or prove the presence of an AV BT.

Importantly, this maneuver does not exclude the presence of a distant right or left free wall AV BT, because the site of pacing is far from the AV BT; as a consequence, pacing from the RV apex or RV base may result in preferential VA conduction exclusively over the AVN and a constant atrial activation sequence. Similarly, this maneuver does not exclude the presence of a slowly conducting BT.

PARA-HISIAN PACING

The response to para-Hisian pacing can be determined by comparing the following four variables between HB-RB capture and non-capture while maintaining local ventricular capture and no atrial capture: (1) atrial activation sequence, (2) S-A interval, (3) local VA interval, and (4) HA interval (see Figs. 18-31 and 18-32).²⁴ Seven patterns of response to para-Hisian pacing can be observed (see Table 18-3). Please refer to Chapter 18 for a more detailed discussion of para-Hisian pacing.

Atrial Activation Sequence

An identical retrograde atrial activation sequence, with and without HB capture, indicates that retrograde conduction is occurring over the same system during HB-RB capture and noncapture (either the BT or the AVN) and does not help prove or exclude the presence of

a BT. On the other hand, a retrograde atrial activation sequence that is different depending on whether the HB is captured indicates the presence of a BT.

His Bundle—Atrial and Ventriculoatrial Intervals

The HA and S-A (VA) intervals are recorded at multiple sites, including close to the site of earliest atrial activation during SVT. An S-A (VA) interval that is constant regardless of whether the HB-RB is being captured indicates the presence of a BT, whereas prolongation of the S-A (VA) interval on loss of HB capture, compared with that during HB capture, excludes the presence of a retrogradely conducting BT, except for slowly conducting and far free wall BTs.²⁴

DUAL-CHAMBER SEQUENTIAL EXTRASTIMULATION

Dual-chamber sequential extrastimulation is a useful maneuver for identifying concealed slowly conducting BTs not revealed with standard pacing maneuvers. This maneuver involves the delivery of an eight-beat drive train of simultaneous atrial and RV pacing at a CL of 600 milliseconds, followed by an AES (A_2) delivered at a coupling interval equal to the predetermined AVN ERP, followed by a VES (V_2) delivered at a coupling interval equal to the drive train CL (600 milliseconds). Repeat drives are then performed with decrements of 10 milliseconds for V_2 until VA block is observed.²⁵

The critically timed A_2 prolongs the AVN refractory period via concealed anterograde conduction, causing the V_2 to block retrogradely in the AVN when it would have conducted had the A_2 not been delivered (analogous to delivering a VES during SVT while the HB is refractory). If a BT is present, the V_2 conducts back to the atrium while the AVN remains refractory, resulting in a retrograde atrial activation pattern consistent with exclusive BT conduction. Please refer to [Chapter 18](#) for a more detailed discussion on dual-chamber sequential extrastimulation.

Practical Approach to Electrophysiological Diagnosis of Supraventricular Tachycardia

It is important to understand that there is no single diagnostic maneuver or algorithm that is adequate in distinguishing between the different types of SVTs in all cases. Each maneuver has its own applications and limitations. Although several diagnostic criteria were found to have high specificity, sensitivity is frequently limited. Therefore, the investigator will often need to use a combination of SVT features and pacing maneuvers to establish an accurate diagnosis. Systematic evaluation of all possibilities and adherence to fundamental EP principles will help establish the correct diagnosis. Each step during the EP study in these patients can offer valuable information to the vigilant investigator that, if recognized, can potentially reduce procedure time and improve outcome.

Tables 20-1, 20-2, and 20-3 and Figure 20-11 outline some of the proposed strategies for the EP diagnosis of narrow complex SVTs. Baseline tachycardia features, atrial and ventricular programmed stimulation during the tachycardia and then during sinus rhythm after tachycardia termination, provide a diagnosis of the mechanism of SVT in the vast majority of cases.

When sustained SVT is inducible, overdrive pacing from the RV apex and base is performed at a CL 10 to 30 milliseconds shorter than the tachycardia CL; the pacing CL is then progressively reduced by 10 to 20 milliseconds in a stepwise fashion with discontinuation of ventricular pacing after each pacing CL to verify continuation versus termination of the SVT. When acceleration of the atrial CL to the pacing CL during ventricular pacing (with 1:1 VA conduction) is verified, several diagnostic criteria can be applied (see [Table 20-2](#)). Overdrive ventricular pacing during the SVT represents the single most important diagnostic maneuver that can provide several clues to the diagnosis of most SVTs. Therefore,

TABLE 20-1 Diagnostic Strategy for Narrow QRS Supraventricular Tachycardia: Tachycardia Features

Atrial activation sequence	<ul style="list-style-type: none"> Eccentric atrial activation sequence excludes AVNRT (except for the left variant of AVNRT). An initial atrial activation site away from the AV groove and AV junction is diagnostic of AT and excludes both AVNRT and orthodromic AVRT.
VA interval	<ul style="list-style-type: none"> VA interval of <70 msec or a ventricular-to-high RA interval of <95 msec during SVT excludes orthodromic AVRT, and is consistent with AVNRT, but can occur during AT with a long PR interval.
AV block	<ul style="list-style-type: none"> Spontaneous or induced AV block with continuation of the tachycardia is consistent with AT, excludes AVRT, and is uncommon in AVNRT.
VA block	<ul style="list-style-type: none"> VA block can rarely occur during AVNRT because of block in an upper common pathway. Other potential mechanisms of SVT with VA block include automatic junctional tachycardia with retrograde VA block and orthodromic AVRT using a nodofascicular or nodoventricular BT for retrograde conduction.
Effects of BBB	<ul style="list-style-type: none"> BBB does not affect the tachycardia CL or VA interval in AT, AVNRT, or orthodromic AVRT using a BT contralateral to the BBB. BBB that prolongs the VA interval, with or without affecting the tachycardia CL, is diagnostic of orthodromic AVRT using an AV BT ipsilateral to the BBB and excludes AT and AVNRT.
Tachycardia CL variations	<ul style="list-style-type: none"> Spontaneous changes in PR and RP intervals with a fixed A-A interval is consistent with AT, and excludes orthodromic AVRT. Spontaneous changes in the tachycardia CL accompanied by a constant VA interval favor orthodromic AVRT. Changes in atrial CL preceding similar changes in subsequent ventricular CL strongly favor AT or atypical AVNRT. Changes in ventricular CL preceded by similar changes in the atrial CL favor typical AVNRT or orthodromic AVRT.
Tachycardia termination	<ul style="list-style-type: none"> Spontaneous termination of SVT with a P wave not followed by a QRS practically excludes AT, except in the case of a nonconducted PAC terminating the AT. Reproducible SVT termination in response to adenosine with a QRS not followed by a P wave excludes orthodromic AVRT using a rapidly conducting AV BT as the retrograde limb, is unusual in typical AVNRT, and is consistent with AT, PJRT, or atypical AVNRT.

A-A = atrial-atrial; AT = atrial tachycardia; AV = atrioventricular; AVNRT = atrioventricular nodal reentrant tachycardia; AVRT = atrioventricular reentrant tachycardia; BBB = bundle branch block; BT = bypass tract; CL = cycle length; PAC = premature atrial complex; PJRT = permanent junctional reciprocating tachycardia; RA = right atrium; SVT = supraventricular tachycardia; VA = ventriculoatrial.

it is preferable to employ this maneuver as an initial step in the diagnostic approach.²⁶

Subsequently, a VES is delivered when the HB is refractory and then at progressively shorter VES coupling intervals (approximately 10-millisecond stepwise shortening of the VES coupling interval) so as to scan all of diastole. First, ventricular capture of the VES should be verified, and then the effect of the VES on the following atrial activation (advancement, delay, termination, or no effect) should be evaluated, as well as the timing of the VES in relation to the expected His potential during the SVT. Furthermore, conduction of the VES to the atrium and sequence of atrial activation following the VES should be carefully examined (see [Fig. 20-6](#)).

Atrial pacing is then performed at a CL 10 to 20 milliseconds shorter than the tachycardia CL. The pacing CL is then progressively reduced by 10 to 20 milliseconds in a stepwise fashion, with discontinuation of atrial pacing after each pacing CL to

TABLE 20-2 Diagnostic Strategy for Narrow QRS Supraventricular Tachycardia: Programmed Electrical Stimulation during Tachycardia**Ventricular Extrastimulation**

When the VES advances the next atrial activation	<ul style="list-style-type: none"> • Advancement of the next atrial impulse occurring with a VES delivered when the HB is not refractory usually does not help differentiate among the different types of SVTs. • If the advanced atrial activation occurs with similar prematurity (i.e., same coupling interval) to that of the VES (exact coupling phenomenon) or with more prematurity (i.e., shorter coupling interval) than that of the VES (paradoxical coupling phenomenon), orthodromic AVRT is diagnosed. • If advancement occurs when the HB is refractory, AVNRT is excluded. • If advancement occurs with an atrial activation sequence similar to that during SVT, regardless of the timing of the VES, AT is less likely than AVNRT or orthodromic AVRT. • When advancement occurs when the HB is refractory, with an atrial activation sequence similar to that during SVT, AVNRT is excluded, AT is unlikely, and orthodromic AVRT is the most likely diagnosis. • Resetting with manifest QRS fusion is consistent with orthodromic AVRT and excludes both AVNRT and focal AT.
When the VES delays the next atrial activation	<ul style="list-style-type: none"> • When the VES causes delay in the next atrial activation, regardless of the timing of the VES, AT is excluded, and when such delay occurs with a VES delivered when the HB is refractory, both AVNRT and AT are excluded.
When the VES terminates the SVT	<ul style="list-style-type: none"> • When termination occurs reproducibly with a VES delivered when the HB is refractory, AVNRT is excluded, and the presence of a retrogradely conducting AV BT is diagnosed. • If the atrial activation sequence following the VES is similar to that during the SVT, orthodromic AVRT is indicated and AT is practically excluded, except for the rare case in which AT originates close to the atrial insertion site of an innocent bystander AV BT. • When termination occurs reproducibly with a VES that does not activate the atrium, regardless of the timing of the VES in relation to the HB, AT is excluded; when this phenomenon is observed with a VES delivered when the HB is refractory, both AT and AVNRT are excluded and orthodromic AVRT is diagnosed.
When the VES fails to affect the next atrial activation	<ul style="list-style-type: none"> • If resetting does not occur with a relatively late VES, this usually does not help in the differential diagnosis of SVT. • If resetting does not occur with an early VES, despite advancement of the local ventricular activation at ventricular sites near the site of earliest atrial activation by >30 msec, orthodromic AVRT and the presence of a retrogradely conducting AV BT are excluded.

Ventricular Pacing

VA dissociation	<ul style="list-style-type: none"> • When overdrive ventricular pacing during SVT fails to accelerate atrial CL to the pacing CL (i.e., the ventricles are dissociated from the tachycardia), AVRT is excluded, AT is the most likely diagnosis, but AVNRT is still possible.
VA interval	<ul style="list-style-type: none"> • ΔVA interval ($VA_{\text{pacing}} - VA_{\text{SVT}}$) >85 msec is consistent with AVNRT. • ΔVA of <85 msec is consistent with orthodromic AVRT.
Post-pacing interval	<ul style="list-style-type: none"> • [PPI – SVT CL] difference >115 msec is consistent with AVNRT. • [PPI – SVT CL] difference <115 msec is consistent with orthodromic AVRT.
Entrainment with ventricular fusion	<ul style="list-style-type: none"> • Ventricular fusion during entrainment indicates AVRT and excludes both AVNRT and AT.
Differential right ventricular entrainment	<ul style="list-style-type: none"> • Differential corrected [PPI – SVT CL] of >30 msec after transient entrainment from the RV apex versus the RV base is consistent with AVNRT. • Differential corrected [PPI – SVT CL] of <30 msec is consistent with orthodromic AVRT. • Differential VA interval (ventricular stimulus-to-atrial interval during entrainment from RV base versus RV septum) of >20 msec is consistent with AVNRT. • Differential VA interval of <20 msec is consistent with orthodromic AVRT.
Length of pacing drive required for entrainment	<ul style="list-style-type: none"> • Acceleration of the SVT to the pacing CL occurring after a single captured paced QRS complex is consistent with orthodromic AVRT and essentially excludes AVNRT. • Acceleration of the SVT to the pacing CL occurring only after ≥ 2 captured paced QRS complexes is consistent with AVNRT and excludes orthodromic AVRT.
Atrial activation sequence during ventricular pacing	<ul style="list-style-type: none"> • Atrial activation sequence during pacing different from that during the SVT is consistent with AT and practically excludes both orthodromic AVRT and AVNRT. • Atrial activation sequence during pacing similar to that during the SVT favors orthodromic AVRT or AVNRT over AT.
Atrial and ventricular electrogram sequence following cessation of ventricular pacing	<ul style="list-style-type: none"> • A-A-V response is consistent with AT (as long as pseudo-A-A-V response is excluded). • A-V response is consistent with AVNRT and orthodromic AVRT.

Atrial Pacing

Entrainment during atrial pacing	<ul style="list-style-type: none"> • Demonstration of entrainment excludes automatic and triggered activity ATs.
Entrainment with atrial fusion	<ul style="list-style-type: none"> • Demonstration of entrainment with manifest atrial fusion excludes AVNRT and focal AT.
Overdrive suppression	<ul style="list-style-type: none"> • Overdrive suppression of the SVT favors automatic AT and excludes AVNRT and orthodromic AVRT.
AH interval	<ul style="list-style-type: none"> • ΔAH interval ($AH_{\text{atrial pacing}} - AH_{\text{SVT}}$) of >40 msec favors AVNRT over AT and orthodromic AVRT. • ΔAH interval of <20 msec favors AT and orthodromic AVRT over AVNRT.
VA linking	<ul style="list-style-type: none"> • On cessation of overdrive atrial pacing (with 1:1 AV conduction), if the VA interval following the last entrained QRS is reproducibly constant (<10 msec variation), despite pacing at different CLs or for different durations (VA linking) and similar to that during SVT, AT is unlikely. • If no VA linking is demonstrable, AT is more likely than other types of SVT.
Differential site atrial pacing	<ul style="list-style-type: none"> • On cessation of overdrive atrial pacing (with 1:1 AV conduction) from different atrial sites (high RA and proximal CS) at the same pacing CL, a maximal difference in the post-pacing VA intervals (the interval from last captured ventricular electrogram to the earliest atrial electrogram of the initial tachycardia beat after pacing) among the different atrial pacing sites (ΔVA interval) of >14 msec is consistent with AT. • ΔVA interval of <14 msec favors AVNRT or orthodromic AVRT over AT.

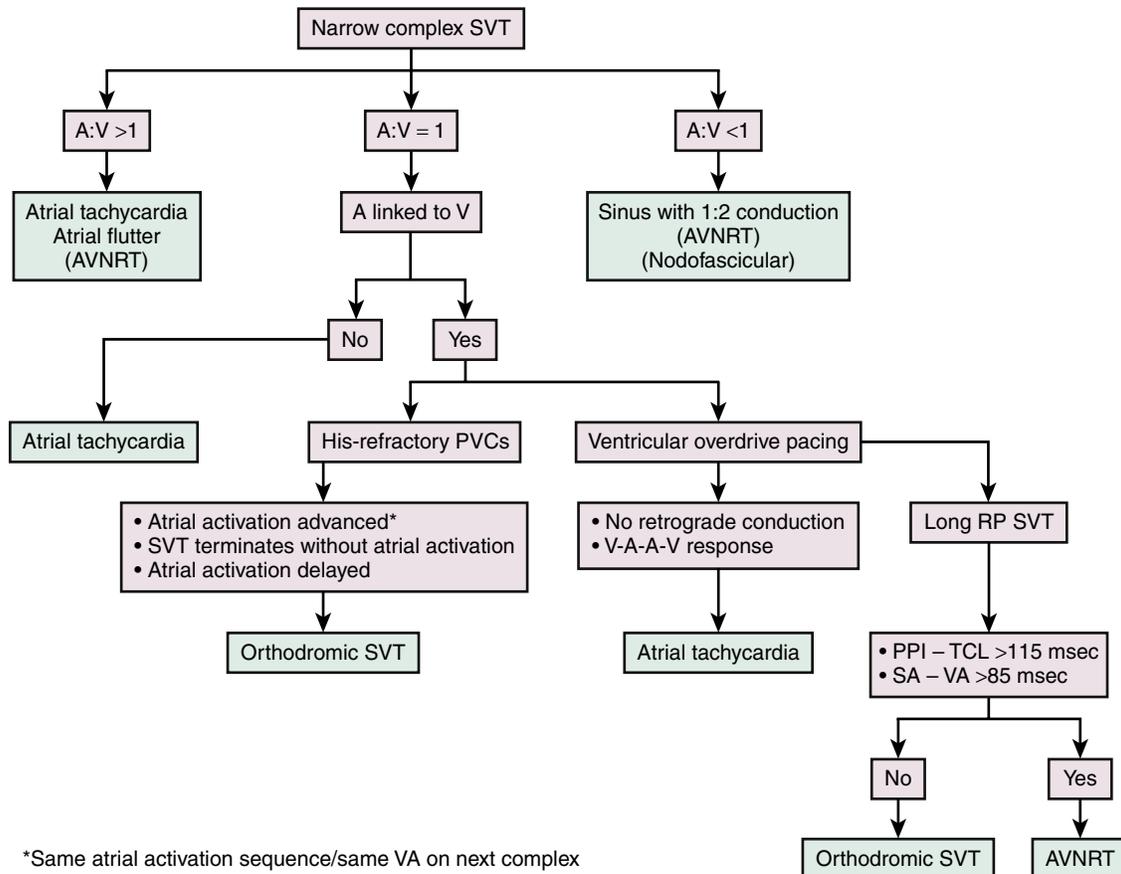

A-A = atrial-atrial; A-A-V = atrial-atrial-ventricular; AH = atrial-His bundle interval; AT = atrial tachycardia; AV = atrioventricular; AVNRT = atrioventricular nodal reentrant tachycardia; AVRT = atrioventricular reentrant tachycardia; BT = bypass tract; CL = cycle length; CS = coronary sinus; HB = His bundle; PPI = post-pacing interval; RA = right atrium; RV = right ventricle; SVT = supraventricular tachycardia; VA = ventriculoatrial; VES = ventricular extrastimulus.

TABLE 20-3 Diagnostic Strategy for Narrow QRS Supraventricular Tachycardia: Programmed Electrical Stimulation during Sinus Rhythm

Ventricular Pacing from Right Ventricular Apex at Tachycardia Cycle Length	
HA interval	<ul style="list-style-type: none"> • ΔHA interval ($HA_{\text{pacing}} - HA_{\text{SVT}}$) of more than -10 msec favors AVNRT. • ΔHA interval of less than -10 msec favors orthodromic AVRT.
Retrograde atrial activation sequence	<ul style="list-style-type: none"> • A retrograde atrial activation sequence during ventricular pacing similar to that during SVT favors orthodromic AVRT and AVNRT over AT.
VA block	<ul style="list-style-type: none"> • The presence of VA block or decremental VA conduction during ventricular pacing at a CL similar to the tachycardia CL and under comparable autonomic tone argues against orthodromic AVRT and favors AT and AVNRT.
Atrial Pacing from High Right Atrium at Tachycardia Cycle Length	
AH interval	<ul style="list-style-type: none"> • ΔAH interval ($AH_{\text{atrial pacing}} - AH_{\text{SVT}}$) of >40 msec favors AVNRT over AT and orthodromic AVRT. • ΔAH interval of <20 msec favors AT and orthodromic AVRT over AVNRT.
AV block	<ul style="list-style-type: none"> • Development of AV block during atrial pacing argues against AT and orthodromic AVRT, and favors AVNRT, given that the same degree of autonomic tone is maintained.
Differential Right Ventricular Pacing	
VA interval	<ul style="list-style-type: none"> • When the VA interval during RV apical pacing is shorter than that during RV basal pacing, a retrogradely conducting septal BT is excluded. • When the VA interval during RV apical pacing is longer than that during RV basal pacing, a retrogradely conducting AV BT is diagnosed.
Atrial activation sequence	<ul style="list-style-type: none"> • A retrograde atrial activation sequence that is different depending on the site of ventricular pacing indicates the presence of a BT. • A constant atrial activation sequence does not help exclude or prove the presence of an AV BT.
Para-Hisian Pacing	
Atrial activation sequence	<ul style="list-style-type: none"> • An identical retrograde atrial activation sequence, with and without HB capture, indicates that retrograde conduction is occurring over the same system during HB-RB capture and noncapture (either the BT or AVN) and does not help prove or exclude the presence of BT. • A retrograde atrial activation sequence that is different depending on whether HB is captured indicates the presence of a BT.
HA and VA intervals	<ul style="list-style-type: none"> • S-A (VA) interval (recorded at multiple sites, including close to the site of earliest atrial activation during SVT) that is constant regardless of whether the HB-RB is being captured indicates the presence of a BT. • Prolongation of the S-A (VA) interval on loss of HB capture, compared with that during HB capture, excludes the presence of a retrogradely conducting BT, except for slowly conducting and far free wall BTs.

AH = atrial-His bundle interval; AT = atrial tachycardia; AV = atrioventricular; AVN = atrioventricular node; AVNRT = atrioventricular nodal reentrant tachycardia; AVRT = atrioventricular reentrant tachycardia; BT = bypass tract; CL = cycle length; HA = His bundle-atrial interval; RB = right bundle branch; RV = right ventricle; S-A = stimulus-atrial interval; SVT = supraventricular tachycardia; VA = ventriculoatrial.

Clinical Considerations

Causes of Wide Complex Tachycardias

A narrow QRS complex requires rapid, highly synchronous electrical activation of the right ventricular (RV) and left ventricular (LV) myocardium, which can only be achieved through the specialized, rapidly conducting His-Purkinje system (HPS). A wide QRS complex implies less synchronous ventricular activation of longer duration, which can be due to intraventricular conduction disturbances (IVCDs), or ventricular activation not mediated by the His bundle (HB) but by a bypass tract (BT; preexcitation) or from a site within a ventricle (ventricular arrhythmias). IVCDs may be fixed and present at all heart rates, or they may be intermittent and related to either tachycardia or bradycardia. IVCDs can be caused by structural abnormalities in the HPS or ventricular myocardium or by functional refractoriness in a portion of the conduction system (i.e., aberrant ventricular conduction).¹

Wide QRS complex tachycardia (WCT) is a rhythm with a rate of more than 100 beats/min and a QRS duration of more than 120 milliseconds. Several arrhythmias can manifest as WCTs (Table 21-1); the most common is ventricular tachycardia (VT), which accounts for 80% of all cases of WCT. Supraventricular tachycardia (SVT) with aberrancy accounts for 15% to 20% of WCTs. SVTs with bystander preexcitation and antidromic atrioventricular reentrant tachycardia (AVRT) account for 1% to 6% of WCTs.

In the stable patient who will undergo a more detailed assessment, the goal of evaluation should include determination of the cause of the WCT (particularly distinguishing between VT and SVT). Accurate diagnosis of the WCT requires information obtained from the history, physical examination, response to certain maneuvers, and careful inspection of the electrocardiogram (ECG), including rhythm strips and 12-lead tracings. Comparison of the ECG during the tachycardia with that recorded during sinus rhythm, if available, can also provide useful information.²

Clinical History

AGE

WCT in a patient older than 35 years is likely to be VT (positive predictive value of up to 85%). SVT is more likely in the younger patient (positive predictive value of 70%).

SYMPTOMS

Some patients with tachycardia can have few or no symptoms (e.g., palpitations, lightheadedness, diaphoresis), whereas others can have severe manifestations, including chest pain, dyspnea, syncope, seizures, and cardiac arrest. The severity of symptoms during a WCT is not useful in determining the tachycardia mechanism because symptoms are primarily related to the fast heart

rate, associated heart disease, and the presence and extent of LV dysfunction, rather than to the mechanism of the tachycardia. It is important to recognize that VT does not necessarily result in hemodynamic compromise or collapse. Misdiagnosis of VT as SVT on the basis of hemodynamic stability is a common error that can lead to inappropriate and potentially dangerous therapy.²

DURATION OF THE ARRHYTHMIA

SVT is more likely if the tachycardia has recurred over a period of more than 3 years. The first occurrence of a WCT after myocardial infarction (MI) strongly implies VT.

PRESENCE OF UNDERLYING HEART DISEASE

The presence of structural heart disease, especially coronary heart disease and a previous MI, strongly suggests VT as the cause of WCT. In one report, over 98% of patients with a previous MI had VT as the cause of WCT, whereas only 7% of those with SVT had had an MI. It should be realized, however, that VT can occur in patients with no apparent heart disease, and SVT can occur in those with structural heart disease.²

PACEMAKER OR IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR IMPLANTATION

A history of pacemaker or implantable cardioverter-defibrillator (ICD) implantation should raise the possibility of a device-associated tachycardia. Ventricular pacing can be associated with a small and almost imperceptible stimulus artifact on the ECG. The presence of an ICD is also of importance because such a device should identify and treat a sustained tachyarrhythmia, depending on device programming, and because the presence of an ICD implies that the patient is known to have an increased risk of ventricular tachyarrhythmias.

MEDICATIONS

Many different medications have proarrhythmic effects. The most common drug-induced tachyarrhythmia is torsades de pointes. Frequently implicated agents include antiarrhythmic drugs such as sotalol and quinidine, and certain antimicrobial drugs such as erythromycin. Diuretics are a common cause of hypokalemia and hypomagnesemia, which can predispose to ventricular tachyarrhythmias, particularly torsades de pointes in patients taking antiarrhythmic drugs. Furthermore, class I antiarrhythmic drugs, especially class IC agents, slow conduction and have a property of use dependency, a progressive decrease in impulse conduction velocity at faster heart rates. As a result, these drugs can cause rate-related aberration and a wide QRS complex during any tachyarrhythmia. Digoxin can cause almost any cardiac arrhythmia, especially with

increasing plasma digoxin concentrations above 2.0 ng/mL (2.6 mmol/L). Digoxin-induced arrhythmias are more frequent at any given plasma concentration if hypokalemia is also present. The most common digoxin-induced arrhythmias include monomorphic VT (often with a relatively narrow QRS complex), bidirectional VT (a regular alternation of two wide QRS morphologies, each with a different axis), and nonparoxysmal junctional tachycardia.²

Physical Examination

Most of the elements of the physical examination, including the blood pressure and heart rate, are of importance primarily in determining how severe the patient's hemodynamic instability is and thus how urgently a therapeutic intervention is required. In patients with significant hemodynamic compromise, a thorough diagnostic evaluation should be postponed until acute management has been addressed. In this setting, emergency cardioversion is the treatment of choice and does not require knowledge of the mechanism of the arrhythmia.

Evidence of underlying cardiovascular disease should be sought, including the sequelae of peripheral vascular disease or stroke. A healed sternal incision is obvious evidence of previous cardiothoracic surgery. A pacemaker or defibrillator, if present, can typically be palpated in the left or, less commonly, right pectoral area below the clavicle, although some older devices are found in the anterior abdominal wall.

An important objective of the physical examination in the stable patient is to attempt to document the presence of atrioventricular

(AV) dissociation. AV dissociation is present, although not always evident, in approximately 20% to 50% of patients with VT, but it is very rarely seen in SVT. Thus, the presence of AV dissociation strongly suggests VT, although its absence is less helpful. AV dissociation, if present, is typically diagnosed on ECG; however, it can produce a number of characteristic findings on physical examination. Intermittent cannon A waves may be observed on examination of the jugular pulsation in the neck, and they reflect simultaneous atrial and ventricular contraction; contraction of the right atrium (RA) against a closed tricuspid valve produces a transient increase in RA and jugular venous pressure. Cannon A waves must be distinguished from the continuous and regular prominent A waves seen during some SVTs. Such prominent waves result from simultaneous atrial and ventricular contraction occurring with every beat. Additionally, highly inconsistent fluctuations in the blood pressure can occur because of the variability in the degree of left atrial (LA) contribution to LV filling, stroke volume, and cardiac output. Moreover, variability in the occurrence and intensity of heart sounds (especially S₁) can also be observed and is heard more frequently when the rate of the tachycardia is slower.²

The response to carotid sinus massage can suggest the cause of the WCT. The heart rate during sinus tachycardia and automatic atrial tachycardia (AT) will gradually slow with carotid sinus massage and then accelerate on release. The ventricular rate during AT and atrial flutter (AFL) can transiently slow with carotid sinus massage because of increased atrioventricular node (AVN) blockade. The arrhythmia itself, however, is unaffected. Atrioventricular reentrant nodal tachycardia (AVRNT) and AVRT will either terminate or remain unaltered with carotid sinus massage. VTs are generally unaffected by carotid sinus massage, although this maneuver may slow the atrial rate and, in some cases, expose AV dissociation. Some VTs, such as idiopathic outflow tract VT, can rarely terminate in response to carotid sinus massage.

Laboratory Tests

The plasma potassium and magnesium concentrations should be measured as part of the laboratory evaluation. Hypokalemia and hypomagnesemia can predispose to the development of ventricular tachyarrhythmias. Hyperkalemia can cause a wide QRS complex rhythm, usually with a slow rate, with loss of a detectable P wave (the so-called sinoventricular rhythm; Fig. 21-1) or abnormalities of AVN conduction. In patients taking digoxin, quinidine, or procainamide, plasma concentrations of these drugs should be measured to assist in evaluating possible drug toxicity.

TABLE 21-1 Causes of Wide QRS Complex Tachycardia	
CAUSE	DESCRIPTION, EXAMPLES
VT	Macroreentrant VT Focal VT
SVT with aberrancy	Functional BBB Preexistent BBB
Preexcited SVT	Antidromic AVRT AT or AVRNT with bystander BT
Antiarrhythmic drugs	Class IA and IC agents, amiodarone
Electrolyte abnormalities	Hyperkalemia
Ventricular pacing	

AT = atrial tachycardia; AVRNT = atrioventricular nodal reentrant tachycardia; AVRT = atrioventricular reentrant tachycardia; BBB = bundle branch block; BT = bypass tract; SVT = supraventricular tachycardia; VT = ventricular tachycardia.

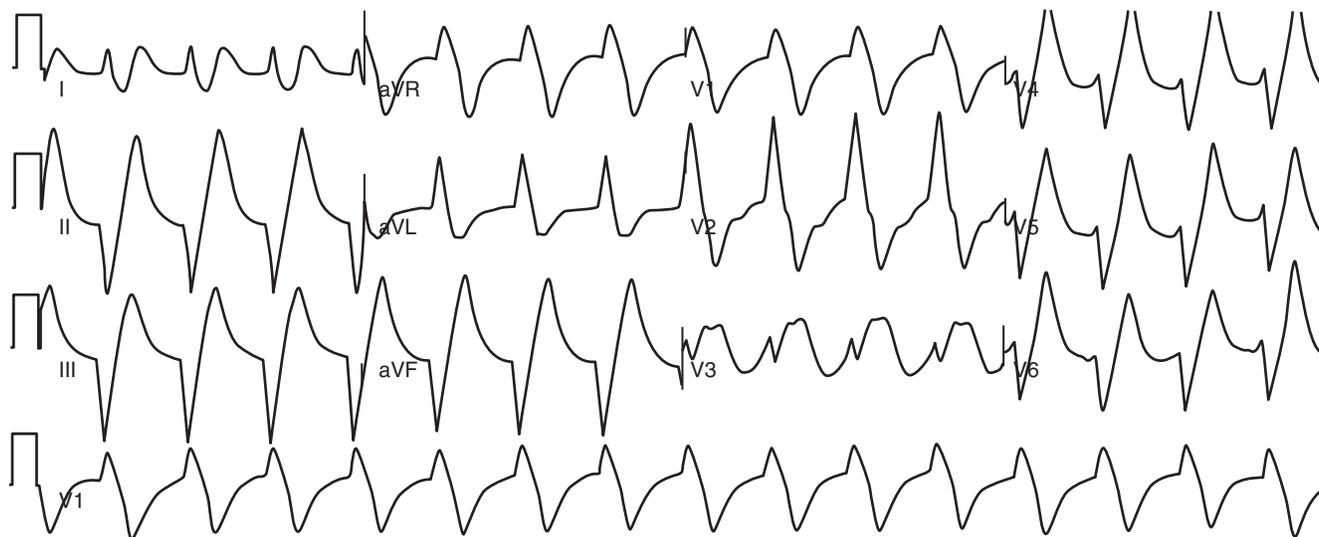

FIGURE 21-1 Wide QRS complex rhythm caused by hyperkalemia. No P waves are visible.

Pharmacological Intervention

The administration of certain drugs can be useful for diagnostic, as opposed to therapeutic, purposes. Termination of the arrhythmia with lidocaine suggests, but does not prove, that VT is the mechanism. Infrequently an SVT, especially AVRT, can terminate with lidocaine. On the other hand, termination of the tachycardia with procainamide or amiodarone does not distinguish between VT and SVT. Termination of the arrhythmia with digoxin, verapamil, diltiazem, or adenosine strongly implies SVT. However, VT can also occasionally terminate after the administration of these drugs.

Unless the cause for the WCT is definitely established, however, verapamil, diltiazem, and probably adenosine should not be administered, because they have been reported to cause severe hemodynamic deterioration in patients with VT and can even provoke ventricular fibrillation (VF) and cardiac arrest. Direct current (DC) cardioversion in unstable patients and intravenous procainamide or amiodarone in hemodynamically stable patients are the appropriate management approach.²

Electrocardiographic Features

Ventricular Tachycardia Versus Aberrantly Conducted Supraventricular Tachycardia

Because the diagnosis of a WCT cannot always be made with complete certainty, the unknown rhythm should be presumed to be VT in the absence of contrary evidence. This conclusion is appropriate both because VT accounts for up to 80% of cases of WCT, and because making this assumption guards against inappropriate and potentially dangerous therapy. As noted, the intravenous administration of drugs used for the treatment of SVT (verapamil, adenosine, or beta blockers) can cause severe hemodynamic deterioration in patients with VT and can even provoke VF and cardiac arrest. Therefore, these drugs should not be used when the diagnosis is uncertain.

In general, most WCTs can be classified as having one of two patterns: a right bundle branch block (RBBB)-like pattern (QRS polarity is predominantly positive in leads V_1 and V_2) or a left bundle branch block (LBBB)-like pattern (QRS polarity is predominantly negative in leads V_1 and V_2). The determination that the WCT has an RBBB-like pattern or an LBBB-like pattern does not, by itself, assist in making a diagnosis; however, this assessment should be made initially because it is useful in evaluating several other features on the ECG, including the QRS axis, the QRS duration, and the QRS morphology (Table 21-2).

RATE

The rate of the WCT is of limited value in distinguishing VT from SVT because there is wide overlap in the distribution of heart rates for SVT and VT. When the rate is around 150 beats/min, AFL with 2:1 AV conduction and aberrancy should be considered.

REGULARITY

Regularity of the WCT is not helpful in distinguishing VT from SVT because both are regular. However, VT is often associated with slight irregularity of the RR intervals, QRS morphology, and ST-T waves. Although marked irregularity strongly suggests atrial fibrillation (AF), VTs can be particularly irregular within the first 30 seconds of onset and in patients treated with antiarrhythmic drugs.

QRS DURATION

In general, a wider QRS duration favors VT. In the setting of RBBB-like WCT, a QRS duration more than 140 milliseconds suggests VT, whereas for LBBB-like WCT, a QRS duration more than 160 milliseconds suggests VT. In an analysis of several studies, a QRS duration more than 160 milliseconds overall was a strong predictor of VT

(likelihood ratio > 20:1). On the other hand, a QRS duration less than 140 milliseconds is not helpful for excluding VT, because VT can sometimes be associated with a relatively narrow QRS complex.

A QRS duration more than 160 milliseconds is not helpful in identifying VT in several settings, including preexisting bundle branch block (BBB), although it is uncommon for the QRS to be wider than 160 milliseconds in this situation, preexcited SVT, and the presence of drugs capable of slowing intraventricular conduction (e.g., class IA and IC drugs). Of note, a QRS complex that is narrower during WCT than during normal sinus rhythm (NSR) suggests VT. However, this is rare, occurring in less than 1% of VTs.²

Rarely (4% in one series), VT can have a relatively narrow QRS duration (<120 to 140 milliseconds). This can be observed in VTs of septal origin or those with early penetration into the His-Purkinje system (HPS), as occurs with fascicular (verapamil-sensitive) VT.

A recent report found that the QRS onset-to-peak time (also termed "R wave peak time" or "intrinsicoid deflection") in lead II (measured from the beginning of the QRS to the first change of the polarity, independent of whether the QRS deflection is positive or negative) was significantly wider in VT compared with SVT with aberrancy, and a cutoff value of 50 milliseconds or greater identified VT with high sensitivity, specificity, and positive predictive values (93%, 99%, and 98%, respectively). However, this criterion has not been tested prospectively or validated in patients with preexisting conduction system disease, antiarrhythmic drug therapy, electrolyte imbalance, prior MI, and preexcited tachycardias. Additionally, certain types of VTs such as fascicular VT, bundle branch reentrant (BBR) VT, and septal myocardial VT, can have a shorter QRS onset-to-peak time because of their origin within or in close proximity to the His-Purkinje network.^{1,3}

TABLE 21-2 Electrocardiographic Criteria Favoring Ventricular Tachycardia

AV Relationship

- Dissociated P waves
- Fusion beats
- Capture beats
- A/V ratio < 1

QRS Duration

- >160 msec with LBBB pattern
- >140 msec with RBBB pattern
- QRS during WCT is narrower than in NSR
- Onset QRS to peak (+ or -) in lead II >50 msec

QRS Axis

- Axis shift of >40 degrees between NSR and WCT
- Right superior (northwest) axis
- Left axis deviation with RBBB morphology
- Right axis deviation with LBBB morphology

Precordial QRS Concordance

- Positive concordance
- Negative concordance

QRS Morphology in RBBB Pattern WCT

- Monophasic R, biphasic qR complex, or broad R (>40 msec) in lead V_1
- Rabbit ear sign: Double-peaked R wave in lead V_1 with the left peak taller than the right peak
- rS complex in lead V_6
- Contralateral BBB in WCT and NSR

QRS Morphology in LBBB Pattern WCT

- Broad initial R wave of ≥ 40 msec in lead V_1 or V_2
- R wave in lead V_1 during WCT taller than the R wave during NSR
- Slow descent to the nadir of the S, notching in the downstroke of the S wave in lead V_1
- RS interval >70 msec in lead V_1 or V_2
- Q or QS wave in lead V_6

AV = atrioventricular; BBB = bundle branch block; LBBB = left bundle branch block; NSR = normal sinus rhythm; RBBB = right bundle branch block; WCT = wide complex tachycardia.

QRS AXIS

Generally, the more leftward the axis, the greater the likelihood of VT. A significant axis shift (>40 degrees) between the baseline NSR and WCT is suggestive of VT (Fig. 21-2A). A right superior ("northwest") axis (axis from -90 degrees to ± 180 degrees) is rare in SVT and strongly suggests VT (see Fig. 21-2B).²

In a patient with an RBBB-like WCT, a QRS axis to the left of -30 degrees suggests VT (see Fig. 21-2A) and, in a patient with an LBBB-like WCT, a QRS axis to the right of $+90$ degrees suggests VT. Additionally, RBBB with a normal axis is uncommon in VT ($<3\%$) and is suggestive of SVT.

PRECORIAL QRS CONCORDANCE

Concordance is present when the QRS complexes in the six precordial leads (V_1 through V_6) are either all positive in polarity (tall R waves) or all negative in polarity (deep QS complexes). Negative concordance is strongly suggestive of VT (see Fig. 21-2D). Rarely, SVT with LBBB aberrancy will demonstrate negative concordance, but there is almost always some evidence of an R wave in the lateral precordial leads. Positive concordance is most often caused by VT (see Fig. 21-2A); however, this pattern may also be caused by preexcited SVT using a left posterior BT. Although the presence of precordial QRS concordance strongly suggests VT ($>90\%$ specificity), its absence is not helpful diagnostically (approximately 20% sensitivity).

ATRIOVENTRICULAR DISSOCIATION

AV dissociation is characterized by atrial activity (P waves) that is completely independent of ventricular activity (QRS complexes). The atrial rate is usually slower than the ventricular rate. Detection of AV dissociation is obviously impossible if AF is the underlying supraventricular rhythm.

AV dissociation is the hallmark of VT (specificity is almost 100%). However, although the presence of AV dissociation establishes VT as the cause, its absence is not as helpful (sensitivity is 20% to 50%). AV dissociation can be present but not obvious on the surface ECG because of a rapid ventricular rate. Additionally, AV dissociation is absent in a large subset of VTs; in fact, approximately 30% of VTs have 1:1 retrograde ventriculoatrial (VA) conduction (see Fig. 21-2D) and an additional 15% to 20% have second-degree (2:1 or Wenckebach) VA block (Fig. 21-3).²

Several ECG findings are helpful in establishing the presence of AV dissociation, including the presence of dissociated P waves, fusion beats, or capture beats.

DISSOCIATED P WAVES. When the P waves can be clearly seen and the atrial rate is unrelated to and slower than the ventricular rate, AV dissociation consistent with VT is present (Fig. 21-4). An atrial rate faster than the ventricular rate is more often seen with SVT having AV conduction block. However, during a WCT, the P waves are often difficult to identify; they can be superimposed on the ST segment or T wave (resulting in altered morphology). Sometimes, the T waves and initial or terminal QRS portions can

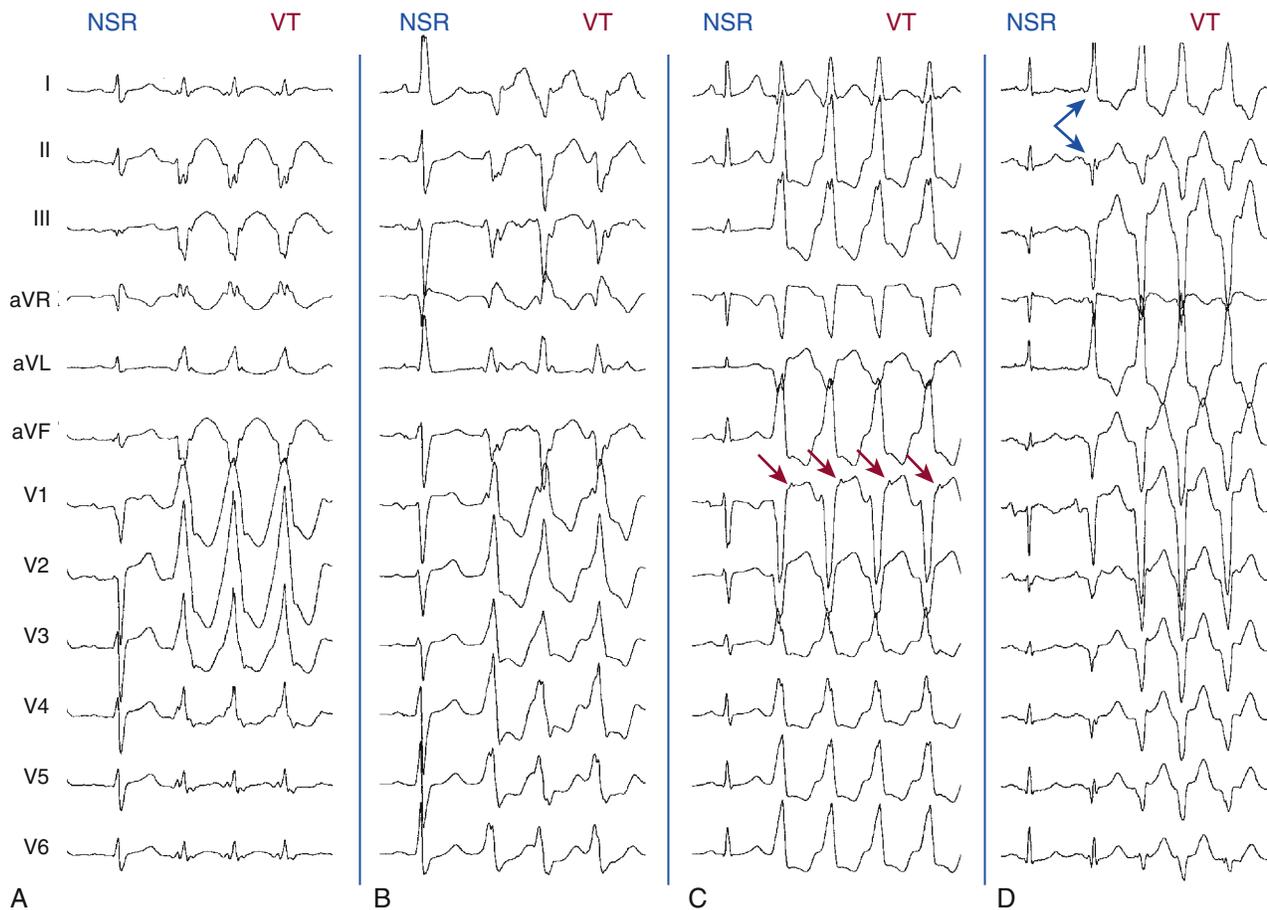

FIGURE 21-2 Surface ECG of four different patients illustrating ECG morphology during normal sinus rhythm (NSR) versus ventricular tachycardia (VT). **A**, VT with right bundle branch block (RBBB) pattern, positive concordance, and long RS interval. Note the monophasic R in lead V_1 during VT and the significant shift in the frontal plane axis in VT versus NSR. **B**, VT with an RBBB pattern and long RS interval. Note the superior ("northwest") frontal plane axis during VT. **C**, VT with a left bundle branch block (LBBB) pattern, long RS interval, and 1:1 ventriculoatrial conduction. Retrograde P waves (red arrows) are visible following the QRSs during VT. **D**, VT with LBBB pattern and negative concordance. Note that the second QRS (blue arrows) is a fusion between the sinus beat and the VT beat.

resemble atrial activity. Furthermore, artifacts can be mistaken for P waves. If the P waves are not obvious or suggested on the ECG, several alternative leads or modalities can help in their identification, including a modified chest lead placement (Lewis leads), an esophageal lead (using an electrode wire or nasogastric tube), a right atrial recording (obtained by an electrode catheter in the RA), carotid sinus pressure (to slow VA conduction and therefore change the atrial rate in the case of VT), or invasive electrophysiological (EP) testing.

FUSION BEATS. Ventricular fusion occurs when a ventricular ectopic beat and a supraventricular beat (conducted via the AVN and HPS) simultaneously activate the ventricular myocardium. The resulting QRS complex has a morphology intermediate between the appearance of a sinus QRS complex and that of a purely ventricular complex. Intermittent fusion beats during a WCT are diagnostic of AV dissociation and therefore of VT (see Fig. 21-4). It is also possible for premature ventricular complexes (PVCs) during SVT with aberration to produce fusion beats, which would erroneously be interpreted as evidence of AV dissociation and VT.

DRESSLER BEATS. A Dressler beat (capture beat) is a normal QRS complex identical to the sinus QRS complex, occurring during the VT at a rate *faster* than the VT. The term *capture beat* indicates that the normal conduction system has momentarily captured control of ventricular activation from the VT focus (see Fig. 21-4). Fusion and capture beats are more commonly seen when the tachycardia rate is slower. These beats do not alter the rate of the VT, although a change in the preceding and subsequent RR intervals may be observed.

QRS MORPHOLOGY

As a rule, if the WCT is caused by SVT with aberration, then the QRS complex during the WCT must be compatible with some form of BBB that could result in that QRS configuration. If there is no combination of bundle branch or fascicular blocks that could result in such a QRS configuration, then the diagnosis by default is VT or preexcited SVT.

As noted, WCTs can be classified as having an RBBB-like pattern or an LBBB-like pattern. Certain features of the QRS complex have been described that favor VT in RBBB-like or LBBB-like WCTs (Fig. 21-5).²

In the patient with a WCT and positive QRS polarity in lead V₁ (RBBB pattern), a monophasic R, biphasic qR complex, or broad R (>40 milliseconds) in lead V₁ favors VT (Fig. 21-6), whereas a triphasic RSR', rSr', rR', or rSR' complex in lead V₁ favors SVT (where the capital letter indicates large-wave amplitude, duration, or both; and the lowercase letter indicates small-wave amplitude, duration, or both; see Fig. 21-5). Additionally, a double-peaked R wave in lead V₁ favors VT if the left peak is taller than the right peak (the so-called rabbit ear sign; likelihood ratio > 50:1). A taller right rabbit ear does not help in distinguishing SVT from VT. On the other hand, an rS complex in lead V₆ is a strong predictor of VT (likelihood ratio > 50:1), whereas an Rs complex in lead V₆ favors SVT (see Fig. 21-6).

In the patient with a WCT and a negative QRS polarity in lead V₁ (LBBB pattern), a broad initial R wave of 40 milliseconds or more in lead V₁ or V₂ favors VT, whereas the absence of an initial R wave (or a small initial R wave of < 40 milliseconds) in lead V₁ or V₂

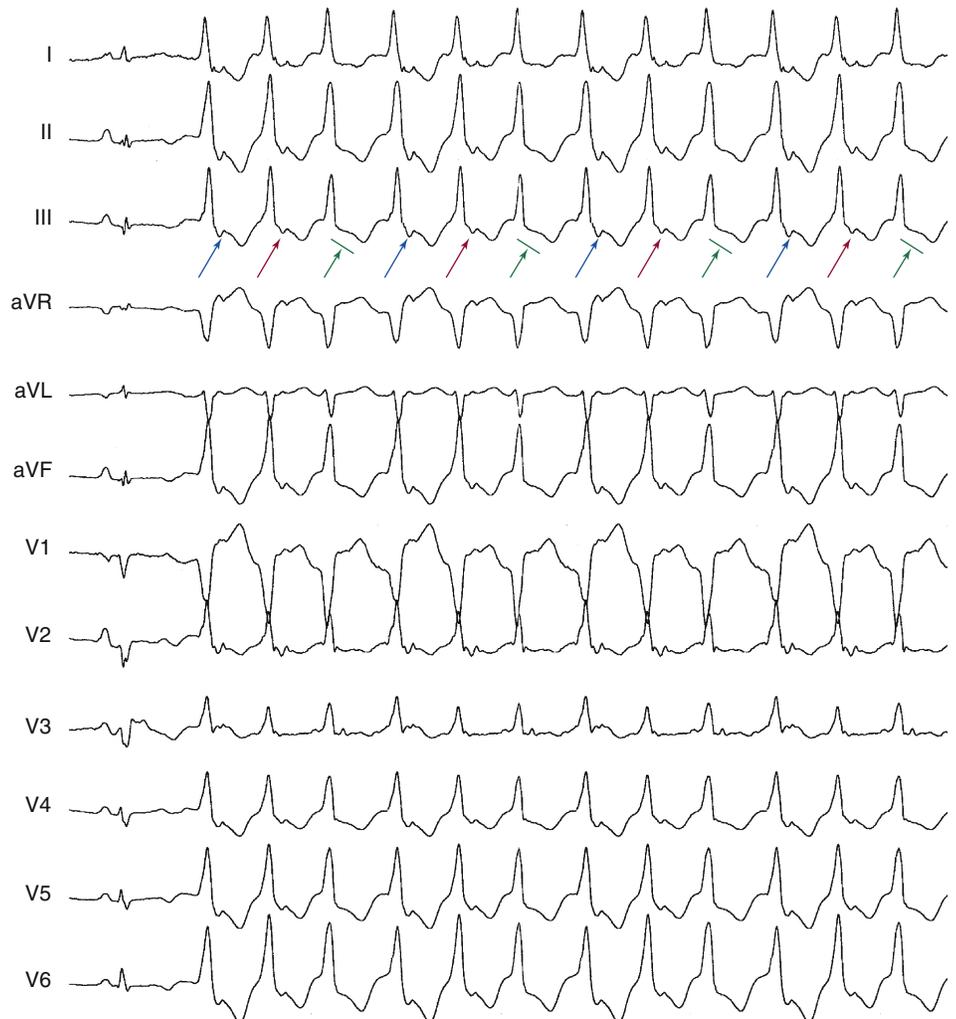

FIGURE 21-3 Ventricular tachycardia (VT) with type 1 second-degree (Wenckebach) ventriculoatrial (VA) block. The first beat is sinus with normal atrioventricular (AV) conduction. VT develops with an initially short VA interval (blue arrows), which then slightly prolongs (red arrows), and then VA block occurs (green arrows). Note that the VT has a right bundle branch block with long RS interval (in lead V₂).

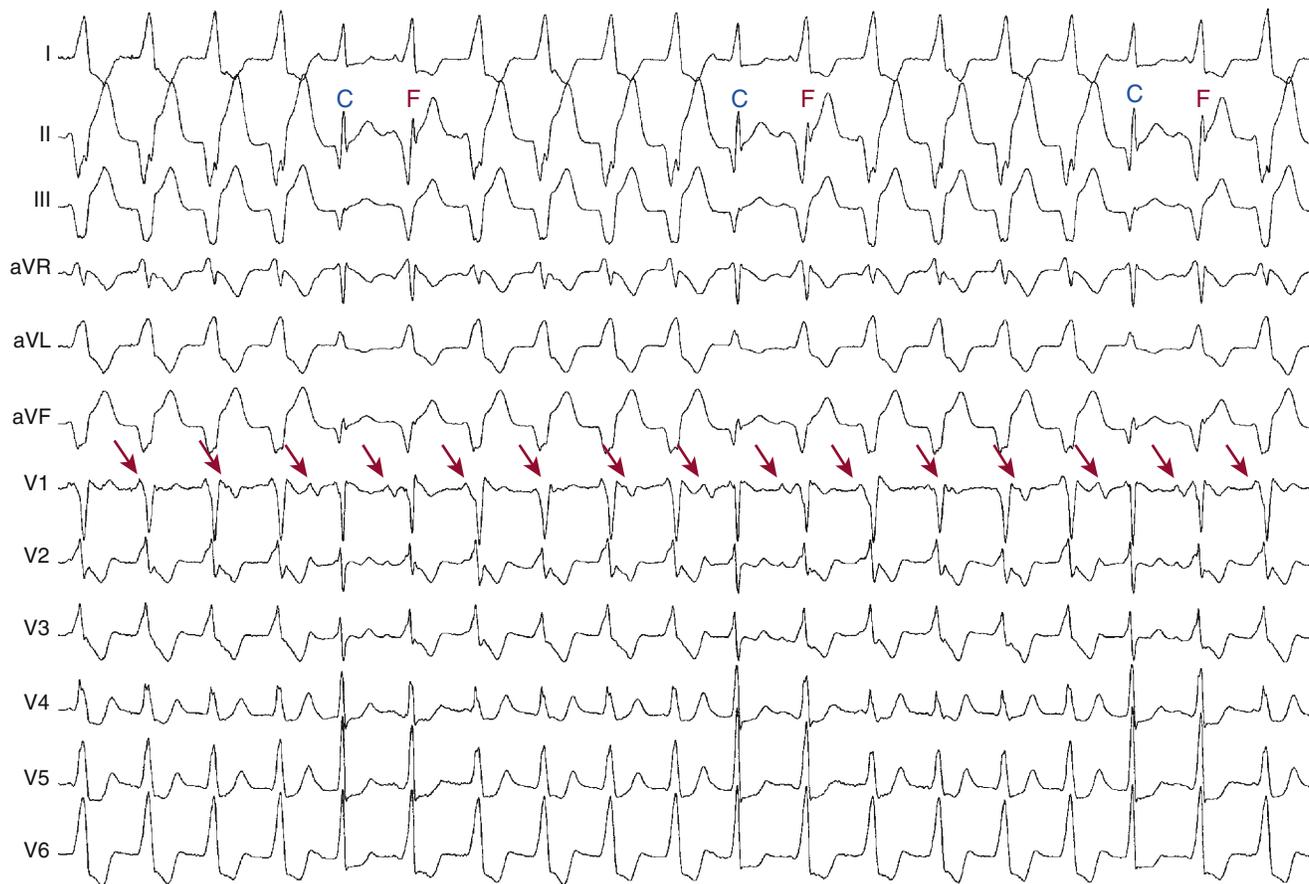

FIGURE 21-4 Ventricular tachycardia (VT) with atrioventricular (AV) dissociation. Sustained monomorphic VT with a cycle length (CL) of 488 milliseconds with AV dissociation coexists with sinus rhythm with a CL of 616 milliseconds. The sinus P waves can be clearly seen (arrows) marching throughout the different phases of the VT QRS complexes, and the atrial rate is unrelated to and slower than the ventricular rate. Because of the relatively slow VT rate, capture (C) and fusion (F) beats are observed frequently.

	V1		V6	
Normal conduction				
	LBBB	RBBB	LBBB	RBBB
SVT with aberration				
VT				

FIGURE 21-5 Diagrammatic representation of common QRS morphologies encountered in ventricular tachycardia (VT) and supraventricular tachycardia (SVT) with aberration in leads V₁ and V₆ for both left bundle branch block (LBBB) and right bundle branch block (RBBB) patterns. Note the initial portions of the QRS complex in normal and aberrant QRS complexes, contrasted with the initial QRS forces in VT complexes. The RS configurations can be designated as an RBBB or LBBB type (grouped with LBBB-type morphologies). (From Miller JM, Das MK, Arora R, Alberte-Lista C. *Differential diagnosis of wide QRS complex tachycardia*. In Zipes DP, Jalife J, editors: *Cardiac electrophysiology: from cell to bedside*, ed 4, Philadelphia, 2004, WB Saunders, pp 747-757.)

favors SVT (see Fig. 21-6). Additionally, an R wave in lead V₁ during a WCT taller than that during NSR favors VT. Furthermore, a slow descent to the nadir of the S wave, notching in the downstroke of the S wave, or an RS interval (from the onset of the QRS complex to the nadir of the S wave) of more than 70 milliseconds in lead V₁ or V₂ favors VT. In contrast, a swift, smooth downstroke of the S wave in lead V₁ or V₂ with an RS interval of less than 70 milliseconds favors SVT. In an analysis of several studies, the presence of any of these

three criteria in lead V₁ (broad R wave, slurred or notched downstroke of the S wave, and delayed nadir of S wave) was a strong predictor of VT (likelihood ratio > 50:1). The QRS morphology in lead V₆ is also of value; the presence of any Q or QS wave in lead V₆ favors VT (likelihood ratio > 50:1; see Fig. 21-2D), whereas the absence of a Q wave in lead V₆ favors SVT.

When an old 12-lead surface ECG is available, comparison of the QRS morphology during NSR and WCT is helpful. Contralateral BBB in WCT and NSR strongly favors VT (see Fig. 21-6C and D). It is important to note that identical QRS morphology during NSR and WCT, although strongly suggestive of SVT, can also occur in bundle branch reentrant (BBR) and interfascicular reentrant VTs.

Unfortunately, the value of QRS morphological criteria in the diagnosis of a WCT is subject to several limitations. Most of the associations between the QRS morphology and tachycardia origin are based on statistical correlations, with substantial overlap. Moreover, most of the morphological criteria favoring VT are also present in a substantial number of patients with intraventricular conduction delay present during sinus rhythm, limiting their applicability in these cases. Additionally, morphological criteria tend to misclassify SVTs with preexcitation as VT. However, preexcitation is an uncommon cause of WCT (1% to 6% in most series), particularly if other factors (e.g., age, history) suggest another diagnosis.

VARIATION IN QRS AND ST-T MORPHOLOGY

Subtle, non-rate-related fluctuations or variations in the QRS and ST-T wave configuration suggest VT and reflect variations in the VT reentrant circuit within the myocardium. In contrast, because most SVTs follow fixed conduction pathways, they are generally characterized by complete uniformity of QRS and ST-T shape, unless the tachycardia rate changes.

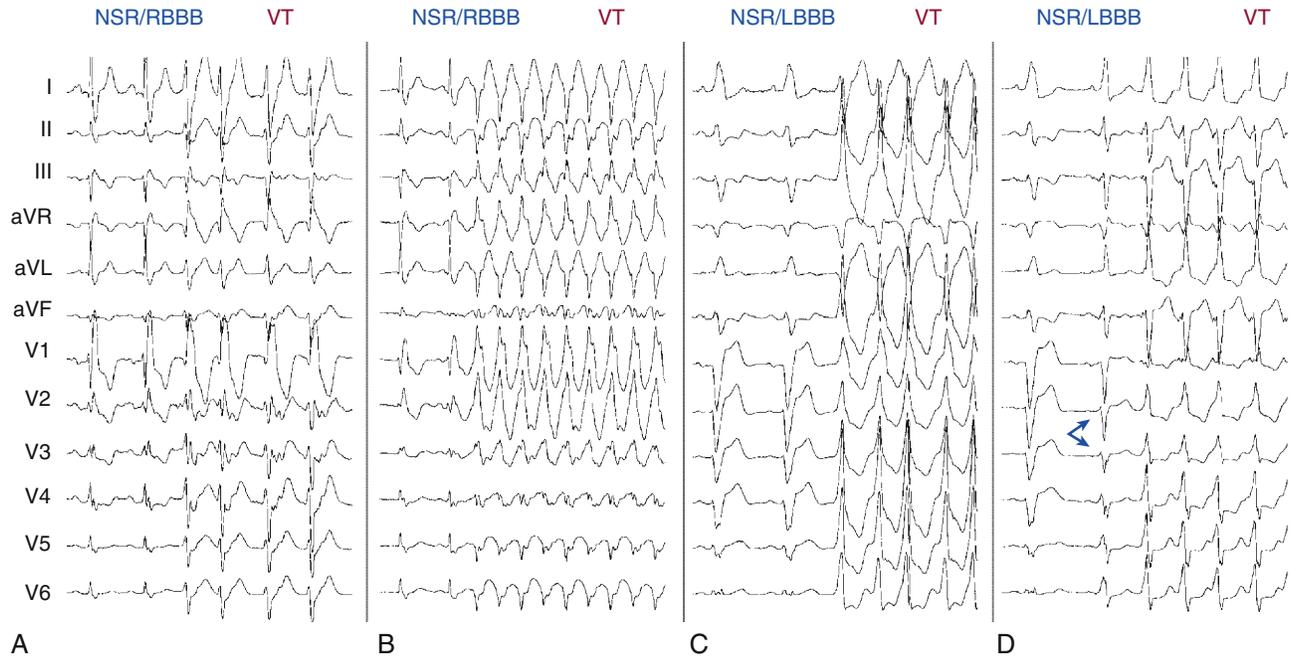

FIGURE 21-6 Surface ECG of four different patients illustrating ECG morphology during normal sinus rhythm (NSR) with bundle branch block (BBB) versus ventricular tachycardia (VT). **A**, NSR with right bundle branch block (RBBB) and VT with RBBB pattern. Note the loss of the initial r wave in V_1 and the larger S wave in V_6 during VT compared with NSR with RBBB. Additionally, note the shift in the frontal plane QRS axis from $+90$ degrees during NSR with RBBB to the northwest quadrant during VT. **B**, NSR with RBBB and VT with RBBB pattern. Note the change in QRS morphology in lead V_1 (from rsR during NSR with RBBB to monophasic R during VT) and lead V_6 (from RS during NSR with RBBB to QS during VT). Additionally, no RS complexes are observed in the precordial leads during VT. **C**, NSR with LBBB and VT with RBBB pattern. Note the positive precordial concordance during VT. **D**, NSR with LBBB and VT with RBBB pattern. Note the positive precordial concordance during VT. The second QRS (blue arrows) is a fusion between the sinus beat and the VT beat, and the fusion QRS is narrower than both the sinus and VT complexes.

Algorithms for the ECG Diagnosis of Wide Complex Tachycardia

The various criteria for the diagnosis of WCT listed are difficult to apply in isolation, because most patients will have some, but not all, of the features described. Several algorithms have been proposed to guide integrating ECG findings into a diagnostic strategy. **Figure 21-7** illustrates an example of one approach. The effect of history of prior MI, preexcited tachycardias, antiarrhythmic medication usage, precordial lead placement, heart transplantation status, and the presence of congenital heart disease on QRS morphology criteria should be taken into account while applying these elements. Preexcited tachycardias may not be differentiated consistently with the proposed criteria, especially those using epicardial left-sided paraseptal or left-sided inferoposterior BTs.

ALGORITHM 1

The most commonly used algorithm is the so-called Brugada algorithm or Brugada criteria. The Brugada algorithm consists of four steps (**Fig. 21-8**). First, all precordial leads are inspected to detect the presence or absence of an RS complex (with R and S waves of any amplitude). If an RS complex cannot be identified in any precordial lead, the diagnosis of VT can be made with 100% specificity. Second, if an RS complex is clearly identified in one or more precordial leads, the interval between the onset of the R wave and the nadir of the S wave (the RS interval) is measured. The longest RS interval is considered if RS complexes are present in multiple precordial leads. If the longest RS interval is more than 100 milliseconds, the diagnosis of VT can be made with a specificity of 98% (see **Fig. 21-8**). Third, if the longest RS interval is less than 100 milliseconds, either VT or SVT still is possible and the presence or absence of AV dissociation must therefore be determined. Evidence of AV dissociation is 100% specific for the diagnosis of VT, but this finding has a low sensitivity. Fourth, if the RS interval is less than 100 milliseconds and AV dissociation cannot clearly be demonstrated, the QRS morphology criteria for V_1 -positive and V_1 -negative WCTs

are considered. The QRS morphology criteria consistent with VT must be present in lead V_1 or V_2 and in lead V_6 to diagnose VT. A supraventricular origin of the tachycardia is assumed if either the V_1 and V_2 or V_6 criteria are not consistent with VT.

The Brugada algorithm was originally prospectively applied to 554 patients with electrophysiologically diagnosed WCTs. The reported sensitivity and specificity were 98.7% and 96.5%, respectively. Other authors also found the Brugada criteria useful, although they reported a lower sensitivity (79% to 92%) and specificity (43% to 70%).

ALGORITHM 2

A newer algorithm for differential diagnosis of WCT was analyzed in 453 monomorphic WCTs recorded from 287 patients, based on the following: (1) the presence of AV dissociation; (2) the presence of an initial R wave in lead aVR; (3) QRS morphology; and (4) estimation of the initial (V_i) and terminal (V_t) ventricular activation velocity ratio (V_i/V_t), determined by measuring the voltage change on the ECG tracing during the initial 40 milliseconds (V_i) and the terminal 40 milliseconds (V_t) of the same biphasic or multiphasic QRS complex (**Fig. 21-9**).^{4,5}

This algorithm had superior overall total accuracy than that of the Brugada algorithm (90.3% versus 84.8%). The total accuracy of the fourth Brugada criterion was significantly lower (68% versus 82.2%) than that of the V_i/V_t criterion in the fourth step, accounting for most of the difference in outcome between the two methods.

The rationale proposed for the V_i/V_t criterion is that during WCT caused by SVT, the initial activation of the septum should be invariably rapid and the intraventricular conduction delay causing the wide QRS complex occurs in the mid to terminal part of the QRS. In contrast, in WCT caused by VT, there is initial slower muscle-to-muscle spread of activation until the impulse reaches the HPS, after which the rest of the ventricular muscle is more rapidly activated.

Antiarrhythmic drugs that impair conduction in the HPS, ventricular myocardium, or both (e.g., class I drugs and amiodarone) would be expected to decrease the V_i and V_t approximately to

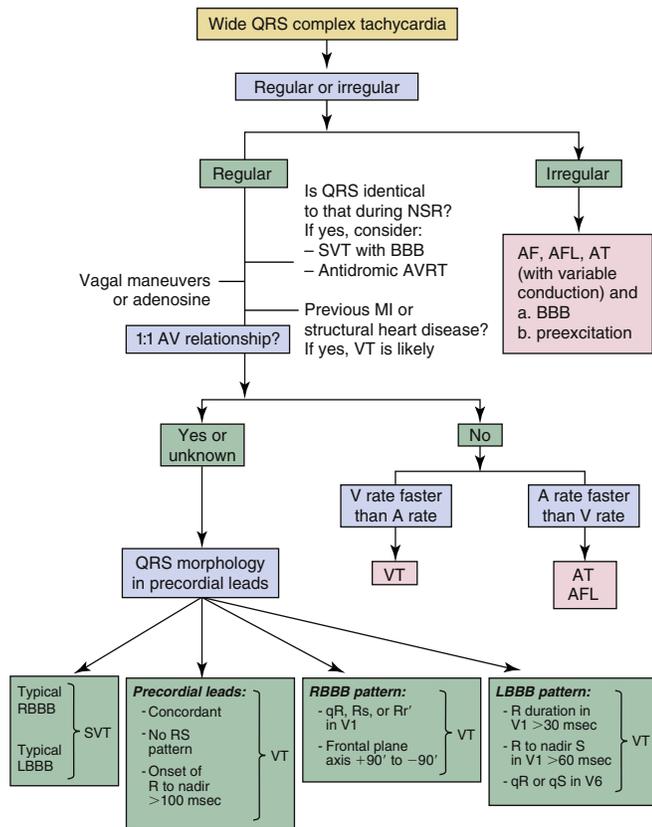

FIGURE 21-7 Differential diagnosis for wide QRS complex tachycardia. A = atrial; AF = atrial fibrillation; AFL = atrial flutter; AT = atrial tachycardia; AV = atrioventricular; AVRT = atrioventricular reentrant tachycardia; BBB = bundle branch block; LBBB = left bundle branch block; MI = myocardial infarction; NSR = normal sinus rhythm; RBBB = right bundle branch block; SVT = supraventricular tachycardia; V = ventricular; VT = ventricular tachycardia. (From Blomström-Lundqvist C, Scheinman MM, Aliot EM, et al: American College of Cardiology; American Heart Association Task Force on Practice Guidelines; European Society of Cardiology Committee for Practice Guidelines [Writing Committee to Develop Guidelines for the Management of Patients with Supraventricular Arrhythmias]: ACC/AHA/ESC guidelines for the management of patients with supraventricular arrhythmias—executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and the European Society of Cardiology Committee for Practice Guidelines [Writing Committee to Develop Guidelines for the Management of Patients with Supraventricular Arrhythmias], *Circulation* 108: 1871, 2003.)

the same degree; therefore, the V_i/V_t ratio should not change significantly. Although the V_i/V_t ratio reflects the electrophysiology of many VTs, there are a number of exceptions to these criteria. First, disorders involving the myocardium locally can alter the V_i or V_t . For example, a decreased V_i with unchanged V_t can be present in the case of an SVT occurring in the presence of an anteroseptal MI, leading to the misdiagnosis of VT. Similarly, a scar situated at a late activated ventricular site can result in a decreased V_i in the presence of VT, leading to the misdiagnosis of SVT. Second, in the case of a fascicular VT, the V_i is not slower than the V_t . Third, if the exit site of the VT reentry circuit is very close to the HPS, it might result in a relatively narrow QRS complex and the slowing of the V_i can last for such a short time that it cannot be detected by the surface ECG.

ALGORITHM 3

The positive aVR criterion in algorithm 2 suggesting VT was further tested in 483 WCTs in 313 patients, and another algorithm based solely on QRS morphology in lead aVR was developed for distinguishing VT from SVT (Fig. 21-10).⁶ The new aVR algorithm is based solely on the principle of differences in the direction and velocity of the initial and terminal ventricular activation during WCT caused by VT and SVT. During SVT with BBB, both the initial rapid

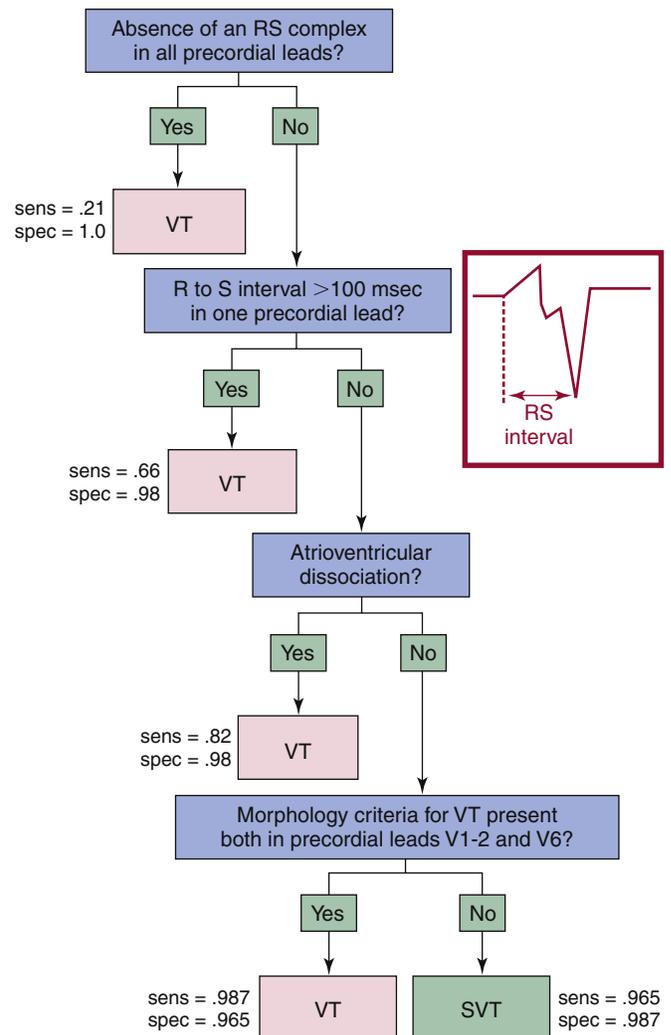

FIGURE 21-8 Brugada algorithm for distinguishing ventricular tachycardia (VT) from supraventricular tachycardia (SVT). As indicated in the inset, the RS interval is between the onset of the R wave and the nadir of the S wave. sens = sensitivity; spec = specificity. (From Brugada P, Brugada J, Mont L, et al: A new approach to the differential diagnosis of a regular tachycardia with a wide QRS complex, *Circulation* 83:1649, 1991.)

septal activation, which can be either left to right or right to left, and the later main ventricular activation wavefront proceed in a direction away from lead aVR, yielding a negative QRS complex in lead aVR. An exception to this generalization occurs in the presence of an inferior MI; an initial r wave (Rs complex) may be seen in lead aVR during NSR or SVT because of the loss of initial inferiorly directed forces. An rS complex also may be present as a normal variant in lead aVR, but with an R/S ratio less than 1. With these considerations, an initial dominant R wave should not be present in SVT with BBB, and its presence suggests VT, typically arising from the inferior or apical region of the ventricles.

Furthermore, VTs originating from sites other than the inferior or apical wall of the ventricles, but not showing an initial R wave in aVR, should yield a slow, initially upward vector component of variable size pointing toward lead aVR (absent in SVT), even if the main vector in these VTs points downward, yielding a totally or predominantly negative QRS in lead aVR. Thus, in VT without an initial R wave in lead aVR, the initial part of the QRS in lead aVR should be less steep because of the slower initial ventricular activation having an initially upward vector component, which may be manifested as an initial r or q wave with a width more than 40 milliseconds, a notch on the downstroke of the QRS, or a slower ventricular activation during the initial 40 milliseconds

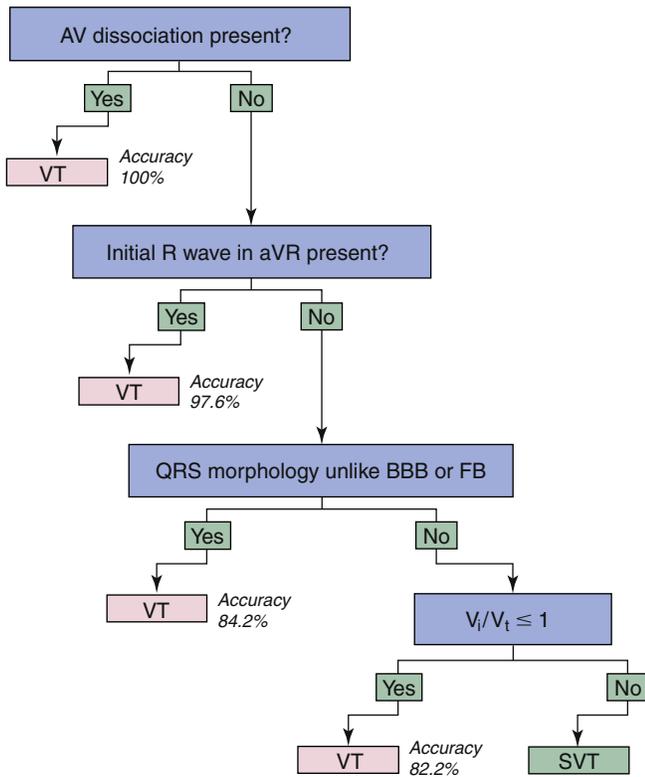

FIGURE 21-9 Stepwise algorithm for distinguishing ventricular tachycardia (VT) from supraventricular tachycardia (SVT). AV = atrioventricular; BBB = bundle branch block; FB = fascicular block; V_i/V_t = ratio of initial (V_i) to terminal (V_t) ventricular activation velocity. (From Vereckei A, Duray G, Szénási G, et al: Application of a new algorithm in the differential diagnosis of wide QRS complex tachycardia, *Eur Heart J* 28:589, 2007.)

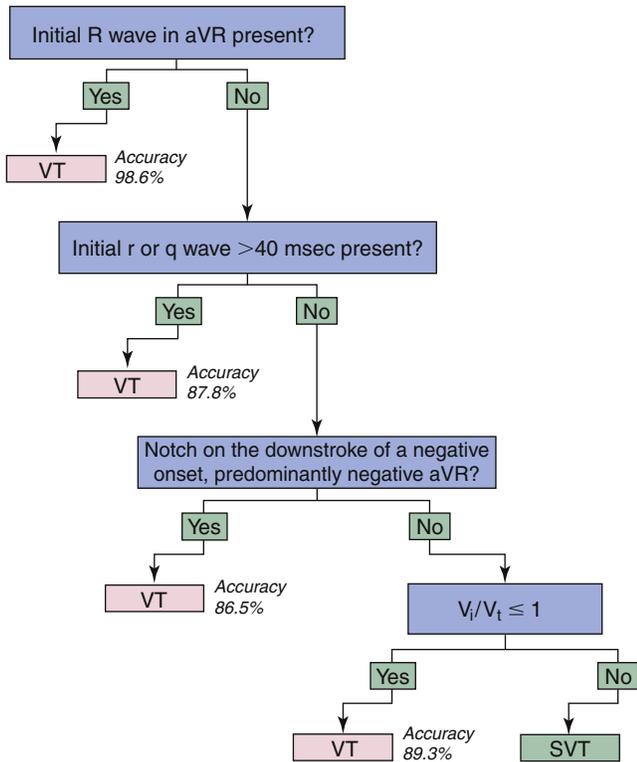

FIGURE 21-10 New algorithm using only lead aVR for differential diagnosis of wide QRS complex tachycardia. SVT = supraventricular tachycardia; V_i/V_t = ratio of initial (V_i) to terminal (V_t) ventricular activation velocity; VT = ventricular tachycardia. (From Vereckei A, Duray G, Szénási G, et al: New algorithm using only lead aVR for differential diagnosis of wide QRS complex tachycardia, *Heart Rhythm* 5:89, 2008.)

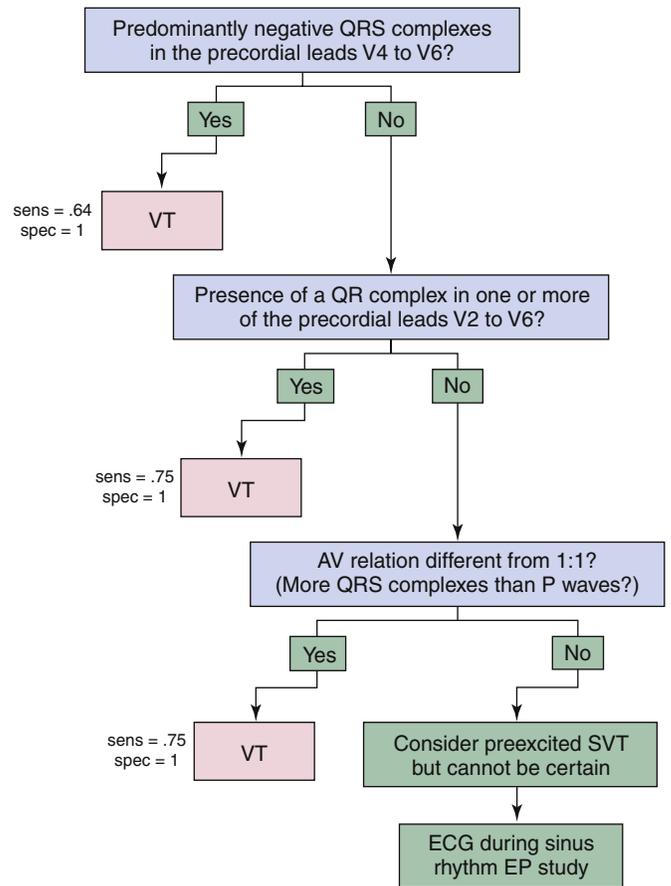

FIGURE 21-11 Brugada algorithm for distinguishing ventricular tachycardia (VT) from preexcited supraventricular tachycardia (SVT). AV = atrioventricular; EP = electrophysiology; sens = sensitivity; spec = specificity. (From Antunes E, Brugada J, Steurer G, et al: The differential diagnosis of a regular tachycardia with a wide QRS complex on the 12-lead ECG, *Pacing Clin Electrophysiol* 17,1515-1524, 1994.)

than during the terminal 40 milliseconds of the QRS ($V_i/V_t \leq 1$) in lead aVR. In contrast, in SVT with BBB, the initial part of the QRS in lead aVR is steeper (fast) because of the invariably rapid septal activation going away from lead aVR, resulting in a narrow (≤ 40 milliseconds) initial r or q wave and V_i/V_t more than 1.⁶

The overall accuracy of the aVR algorithm was 91.5%, which is similar to algorithm 2 and superior to the Brugada algorithm (90.3% and 84.8%, respectively). The inability of the aVR algorithm to differentiate preexcited tachycardias from VTs, with the possible exception of the presence of an initial R wave in lead aVR, is a limitation of the algorithm.⁶

Ventricular Tachycardia Versus Preexcited Supraventricular Tachycardia

Differentiation between VT and preexcited SVT is particularly difficult, because ventricular activation begins outside the normal intraventricular conduction system in both tachycardias (see Fig. 12-6). As a result, algorithms for WCT, like QRS morphology criteria, tend to misclassify SVTs with preexcitation as VT. However, preexcitation is an uncommon cause of WCT, particularly if other factors, such as age and past medical history, suggest another diagnosis. For cases in which preexcitation is thought to be likely, such as a young patient without structural heart disease, or a patient with a known BT, a separate algorithm has been developed by Brugada and colleagues (Fig. 21-11). This algorithm consists of three steps. First, the predominant polarity of the QRS complex in leads V_4 through V_6 is defined as positive or negative. If predominantly negative, the diagnosis of VT can be made with 100% specificity. Second, if the polarity of the QRS complex is predominantly positive in V_4 through V_6 ,

the ECG should be examined for the presence of a qR complex in one or more of precordial leads V_2 through V_6 . If a qR complex can be identified, VT can be diagnosed with a specificity of 100%. Third, if a qR wave in leads V_2 through V_6 is absent, the AV relationship is then evaluated. If a 1:1 AV relationship is not present and there are more QRS complexes present than P waves, VT can be diagnosed with a specificity of 100%.

If the ECG of the WCT does not display any morphological characteristics diagnostic of VT after using this algorithm, the diagnosis of preexcited SVT must be considered. Although this algorithm has a specificity of 100% for VT, it has a sensitivity of only 75% for the diagnosis of preexcited SVT when all three steps are answered negatively (i.e., 25% of such cases are actually VT).

Electrophysiological Testing

Baseline Observations during Normal Sinus Rhythm

The presence of preexcitation during NSR or atrial pacing suggests SVT, and the absence of preexcitation during NSR and atrial pacing excludes preexcited SVT.

Induction of Tachycardia

The mode of induction cannot distinguish between SVT and VT. Both atrial and ventricular stimulation may induce SVT or VT. VTs that can be induced with atrial pacing include verapamil-sensitive VT, adenosine-sensitive VT, and BBR VT.⁷

Tachycardia Features

QRS MORPHOLOGY

As noted, when the QRS configuration of the WCT is not compatible with any known form of aberration, the rhythm is likely to be VT or preexcited SVT. QRS morphology during WCT that is identical to that during NSR may occur in SVT with BBB, preexcited SVT (when NSR is also fully preexcited), BBR VT, and interfascicular VT.

HIS BUNDLE–VENTRICULAR INTERVAL

When the His bundle–ventricular (HV) interval is positive (i.e., the His potential precedes the QRS onset), an HV interval during the WCT shorter than that during NSR ($HV_{WCT} < HV_{NSR}$) indicates VT or preexcited SVT. In contrast, an HV_{WCT} equal to or longer than HV_{NSR} indicates SVT with aberrancy, BBR VT, or (rarely) other VTs (see Figs. 18-24 and 26-3).^{7,8}

When the HV interval is negative (i.e., the His potential follows the QRS onset), BBR VT and SVT with aberrancy are excluded. However, myocardial VTs and preexcited SVT generally have negative HV intervals (see Figs. 18-3 and 22-10).

Prolongation of the VA (and VH) interval and tachycardia cycle length (CL) with transient RBBB (caused by catheter-induced trauma or introduction of a ventricular extrastimulus [VES]) is diagnostic of antidromic AVRT using a right-sided BT and excludes preexcited AVNRT, but can theoretically occur in VT originating in the right ventricle (RV; with LBBB-like morphology). However, continuation of the WCT after development of RBBB excludes BBR VT except for the rare case of intrafascicular reentry.

OSCILLATION IN THE TACHYCARDIA CYCLE LENGTH

Variations in the tachycardia CL (the V-V intervals) that are dictated and preceded by similar variations in the A-A or H-H intervals are suggestive of SVT with aberrancy or BBR VT (Fig. 21-12). In contrast, variations in the V-V intervals that predict the subsequent H-H interval changes are consistent with myocardial VT or preexcited SVT.

HIS BUNDLE–RIGHT BUNDLE BRANCH POTENTIAL SEQUENCE

When both the HB and right bundle branch (RB) potentials are recorded, an HB-RB-V activation sequence occurs in SVT with aberrancy and BBR VT with an LBBB pattern. In either case, the HB-RB interval during WCT is equal to or longer than that in NSR. On the other hand, an RB-HB-V activation sequence occurs in antidromic AVRT using an atriofascicular or right-sided BT, the uncommon type of BBR VT with RBBB pattern, or myocardial VT originating

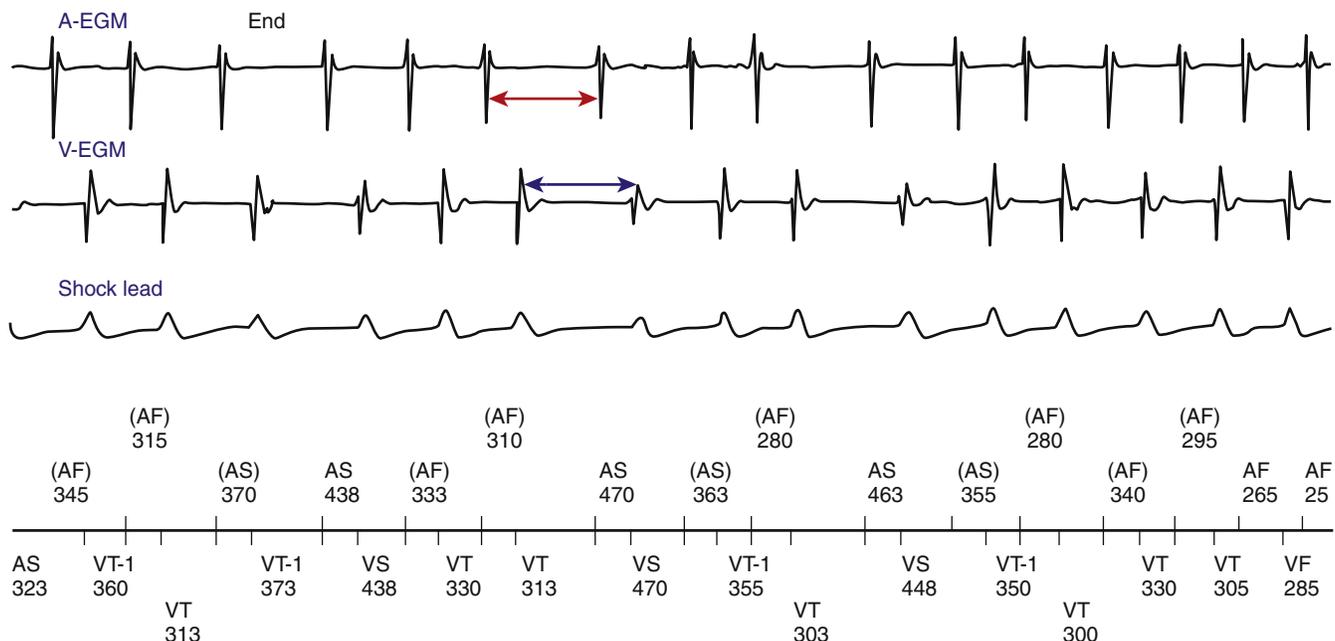

FIGURE 21-12 Intracardiac atrial (A-EGM) and ventricular (V-EGM) and shock lead electrograms stored by the implantable cardioverter-defibrillator during an episode of tachycardia with a 1:1 AV relationship. Note that variations in the tachycardia cycle length (the V-V intervals; blue double-headed arrow) are dictated and preceded by similar variations in the A-A intervals (red double-headed arrow), which is consistent with supraventricular tachycardia rather than ventricular tachycardia.

in the RV. An RB-VHB activation sequence occurs in antidromic AVRT using atriofascicular BT, and a V-RB-HB or a VHB-RB activation sequence can occur in VT.⁷

ATRIOVENTRICULAR RELATIONSHIP

A 1:1 AV relationship can occur in VT and SVT. When the atrial rate is faster than the ventricular rate, VT is unlikely, except in the rare case of coexistent atrial and ventricular tachycardias (Fig. 21-13). In contrast, when the ventricular rate is faster than the atrial rate, VT is more likely, except for the rare case of junctional tachycardia or AVNRT with VA block in an upper common pathway.

ATRIAL ACTIVATION SEQUENCE

A concentric atrial activation sequence can occur in SVT and VT, whereas an eccentric atrial activation sequence practically excludes VT.

EFFECTS OF ADENOSINE

Termination of WCT with adenosine can occur in SVT and adenosine-sensitive VT. AV block with continuation of the WCT can occur in aberrantly conducted AFL, AF, or AT. Adenosine can also have no effect on the WCT, whether it is a VT or SVT.

Diagnostic Maneuvers during Tachycardia

ATRIAL EXTRASTIMULATION

An atrial extrastimulus (AES), regardless of its timing, that advances the next ventricular activation with similar QRS morphology to that of the WCT excludes VT (see Fig. 18-28). Also, an AES (regardless of

its timing) that delays the next ventricular activation excludes VT (see Fig. 19-4).

With a late-coupled AES delivered when the AV junctional portion of the atrium is refractory, if the AES advances the next ventricular activation, it proves the presence of an anterogradely conducting AV BT and excludes any arrhythmia mechanism that involves anterograde conduction over the AVN in the absence of a bystander BT. Moreover, if the AES advances the next ventricular activation with similar QRS morphology as that of the WCT, it proves that the BT is mediating ventricular activation during the WCT (as an integral part of the SVT circuit or as a bystander) and that the WCT is a preexcited SVT, and VT is excluded. Additionally, if the AES advances the timing of both the next ventricular activation and the subsequent atrial activation, it proves that the SVT is an antidromic AVRT using an atrioventricular or atriofascicular BT anterogradely, and excludes preexcited AVNRT and VT (see Fig. 18-28). Also, if the AES delays the next ventricular activation, it proves that the SVT is an antidromic AVRT using an atrioventricular or atriofascicular BT anterogradely, and excludes preexcited AVNRT and VT (see Fig. 19-4).^{7,9,10}

ATRIAL PACING

The ability to entrain the WCT with atrial pacing can occur in VT and SVT. However, the ability to entrain the WCT with similar QRS morphology to that of the WCT (i.e., entrainment with concealed QRS fusion) excludes myocardial VT, but can occur in BBR VT and is typical for SVT. Additionally, atrial entrainment of WCT with manifest QRS fusion can occur in VT in the presence of a bystander BT, or in AVRT with multiple BTs, but not in antidromic AVRT without another BT, nor in SVT with aberrancy.⁹

The ability to dissociate the atrium with rapid atrial pacing without influencing the tachycardia CL (V-V interval) or QRS morphology suggests VT and excludes preexcited SVTs, AT with aberrancy,

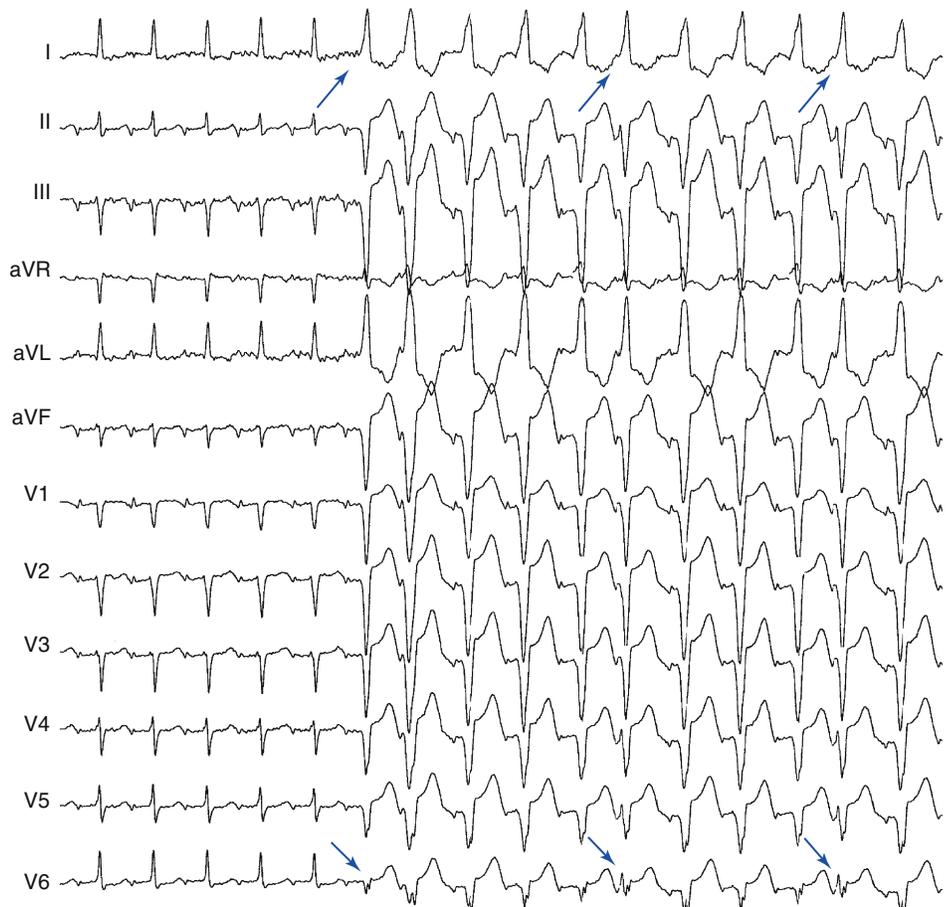

FIGURE 21-13 Surface ECG of atrial tachycardia (AT) with a narrow QRS complex with the development of ventricular tachycardia (VT) with a left bundle branch block (LBBB)-like pattern. Although the atrial rate is faster than the ventricular rate, aberrant conduction during AT as the mechanism of the widening of the QRS can be excluded by observation of QRS morphology in lead V₆ (QS) inconsistent with LBBB aberrancy, a significant shift in the frontal plane QRS axis between AT and VT, and the presence of fusion beats (arrows). Additionally, the atrial rate continues unperturbed, whereas the ventricular rate is slightly irregular.

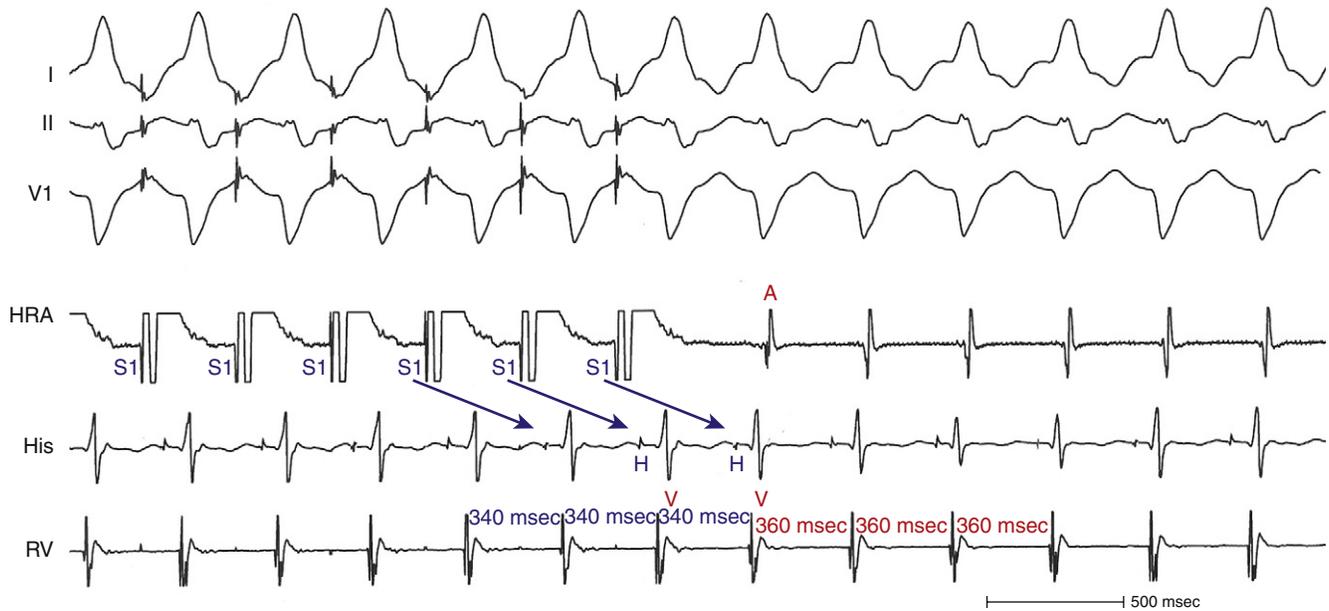

FIGURE 21-14 Pseudo-V-V-A response to atrial overdrive pacing (at a cycle length [CL] of 340 milliseconds) during wide QRS complex tachycardia (WCT) (tachycardia CL, 360 milliseconds). The QRS morphology and His bundle-ventricular (HV) interval (45 milliseconds) during atrial pacing are similar to those during tachycardia. On cessation of pacing, the last atrial-paced beat is followed by a “V-V-A response” suggestive of ventricular tachycardia as the mechanism. However, although the last atrial-paced beat is followed by two QRS complexes, the last captured QRS complex (which characteristically occurs at an R-R interval equal to the atrial pacing CL) is actually the second one (as indicated by blue arrows) due to anterograde conduction over the slow atrioventricular (AV) nodal pathway, resulting in an AV interval longer than the pacing CL. Therefore, the actual response is a “V-A response” consistent with supraventricular tachycardia. This supraventricular tachycardia was atrioventricular nodal tachycardia with left bundle branch block aberrancy.

and orthodromic AVRT with aberrancy. However, it does not exclude the rare case of AVNRT with aberrancy associated with anterograde block in an upper common pathway during rapid atrial pacing.

The response to atrial overdrive pacing during WCTs with a 1:1 AV relationship can help distinguish VT from SVT. The concept is analogous to examination of the response to ventricular overdrive pacing during narrow complex tachycardia. During VT, atrial overdrive pacing at a CL 20 to 60 milliseconds shorter than the tachycardia CL with 1:1 AV conduction results in anterograde capture with changing or narrowing of the tachycardia QRS morphology. When the tachycardia resumes after cessation of pacing, the earliest event (after the last reset ventricular complex) occurs in the ventricle because the atrium is being passively driven by the ventricle during the tachycardia. This results in a “V-V-A response.” On the contrary, during antidromic AVRT or aberrantly conducted SVT, anterograde conduction occurs over a BT or AVN; and on cessation of atrial pacing, the last reset ventricular activation conducts to the atrium over the retrograde limb of the circuit, resulting in a “V-A response” and continuation of the tachycardia. This pacing maneuver is not useful when 1:1 AV conduction during atrial pacing is absent. Thus, when determining the response after atrial pacing during WCT, the presence of 1:1 VA conduction must be confirmed. Isorhythmic AV dissociation can mimic 1:1 AV conduction, especially when the pacing train is not long enough or the pacing CL is too slow. It is also important to ensure that atrial pacing does not terminate the tachycardia.^{9,10}

A “pseudo-V-V-A response” can occur during SVTs associated with a long AV interval during atrial pacing (Fig. 21-14). Because anterograde conduction during atrial pacing occurs through the slow AVN pathway, the AV interval can be longer than the pacing CL (A-A interval), so that the last paced P wave is followed first by the QRS complex resulting from slow AV conduction of the preceding paced atrial beat, and then by the QRS complex resulting from the last paced P wave. Careful examination of

the last QRS complex that resulted from AV conduction during atrial pacing helps avoid this potential pitfall; the last reset QRS complex characteristically occurs at an R-R interval equal to the atrial pacing CL, whereas the first tachycardia QRS complex usually occurs at a different return CL. Furthermore, a “pseudo-A-V response” can theoretically occur in the setting BBR VT or in those with intra- or interfascicular reentrant VT, whereby the return atrial impulse may precede the first non-reset QRS complex.^{9,10}

VENTRICULAR EXTRASTIMULATION

A VES that resets (advances or delays) the next QRS without affecting the A-A interval is consistent with VT and practically excludes SVT. Furthermore, a VES that terminates the WCT without conduction to the atrium excludes AT and AVRT, is consistent with VT, but can also occur in AVNRT. In addition, a VES delivered when the HB is refractory and that terminates the WCT without atrial activation excludes SVT and is consistent with VT, although it can occur in orthodromic AVRT with aberrant conduction or in antidromic AVRT using a second BT as the retrograde limb of the circuit.⁷

VENTRICULAR PACING

When overdrive ventricular pacing during the WCT fails to accelerate the atrial CL to the pacing CL (i.e., the ventricles are dissociated from the tachycardia), VT and AVRT are excluded, AT is the most likely diagnosis, but AVNRT is still possible (Fig. 21-15). Additionally, entrainment with manifest QRS fusion can occur in VT or AVRT but excludes AT and AVNRT, whereas entrainment with concealed fusion excludes SVT with aberrancy. Additionally, entrainment from the RV apex followed by a post-pacing interval (PPI) that is equal (within 30 milliseconds) to the tachycardia CL excludes AVNRT, AT, and myocardial VT, but can occur with BBR VT and AVRT using a right-sided BT.

Pathophysiology

Classification of Ventricular Tachycardia

Ventricular tachycardia (VT) is defined as a tachycardia (rate >100 beats/min) with three or more consecutive beats that originates below the bifurcation of the His bundle (HB), in the specialized conduction system, the ventricular muscle, or in a combination of both tissues, independent of atrial or atrioventricular nodal (AVN) conduction.^{1,2}

CLASSIFICATION ACCORDING TO TACHYCARDIA MORPHOLOGY

Monomorphic VT has a single stable QRS morphology from beat to beat, indicating repetitive ventricular depolarization in the same sequence (Fig. 22-1). *Multiple monomorphic VTs* refers to more than one morphologically distinct monomorphic VT, occurring as different episodes or induced at different times. *Polymorphic VT* has a continuously changing or multiform QRS morphology (i.e., no constant morphology for more than five complexes, no clear isoelectric baseline between QRS complexes, or QRS complexes that have different morphologies in multiple simultaneously recorded leads), indicating a variable sequence of ventricular activation and no single site of origin (see Fig. 22-1).³ *Torsades de pointes* is a polymorphic VT associated with a long QT interval, and is electrocardiographically characterized by twisting of the peaks of the QRS complexes around the isoelectric line during the arrhythmia. *Pleomorphic VT* has more than one morphologically distinct QRS complex occurring during the same episode of VT, but the QRS morphology is not continuously changing. *Bidirectional VT* is associated with a beat-to-beat alternans in the QRS frontal plane axis, often associated with digitalis toxicity or catecholaminergic VT. *Ventricular flutter* is a term that has been applied to a rapid (250 to 350 beats/min) VT that has a sinusoidal QRS configuration that prevents identification of the QRS morphology (see Fig. 22-1). *Ventricular fibrillation (VF)* is a rapid (usually >350 beats/min), grossly irregular ventricular rhythm with marked variability in QRS amplitude and cycle length (CL), and a changing morphology (see Fig. 22-1).^{1,2}

CLASSIFICATION ACCORDING TO TACHYCARDIA DURATION

Sustained VT lasts for more than 30 seconds or requires termination (e.g., cardioversion) in less than 30 seconds because of hemodynamic compromise, whereas *nonsustained VT* is a tachycardia at more than 100 beats/min lasting for three or more complexes but for less than 30 seconds.³ However, during electrophysiological (EP) testing, nonsustained VT is defined as more than five or six complexes of non-bundle branch reentrant (BBR) VT, regardless of morphology. BBR complexes are frequent (50%) in normal individuals in response to a ventricular extrastimulation (VES) and have no relevance to clinical nonsustained VT. Repetitive polymorphic responses are also common (up to 50%), especially in response to multiple (three or more) VESs with very short coupling intervals (less than 180 milliseconds). The clinical significance of induced polymorphic nonsustained VT is questionable.³ *Incessant VT* is a continuous sustained VT that recurs promptly over several hours despite repeated interventions (e.g., electrical cardioversion) for termination.⁴ Less commonly, incessant VT manifests as repeated bursts of VT that spontaneously terminate for a few intervening sinus beats, followed by the next tachycardia burst. The latter form is more common with the idiopathic VTs (see Fig. 23-1).^{1,2}

CLASSIFICATION ACCORDING TO QRS MORPHOLOGY IN V₁

VT with a left bundle branch block (LBBB)-like pattern has a predominantly negative QRS polarity in lead V₁ (QS, rS, qR), whereas VT with a right bundle branch block (RBBB)-like pattern has a predominantly positive QRS polarity in lead V₁ (rsR', qR, RR, R, RS). However, the VT may not show features characteristic of the same bundle branch block (BBB)-like morphology in other leads.^{1,3}

CLASSIFICATION ACCORDING TO TACHYCARDIA MECHANISM

Focal VT has a point source of earliest ventricular activation with a centrifugal spread of activation from that site. The mechanism can be automaticity, triggered activity, or microreentry. *Scar-related*

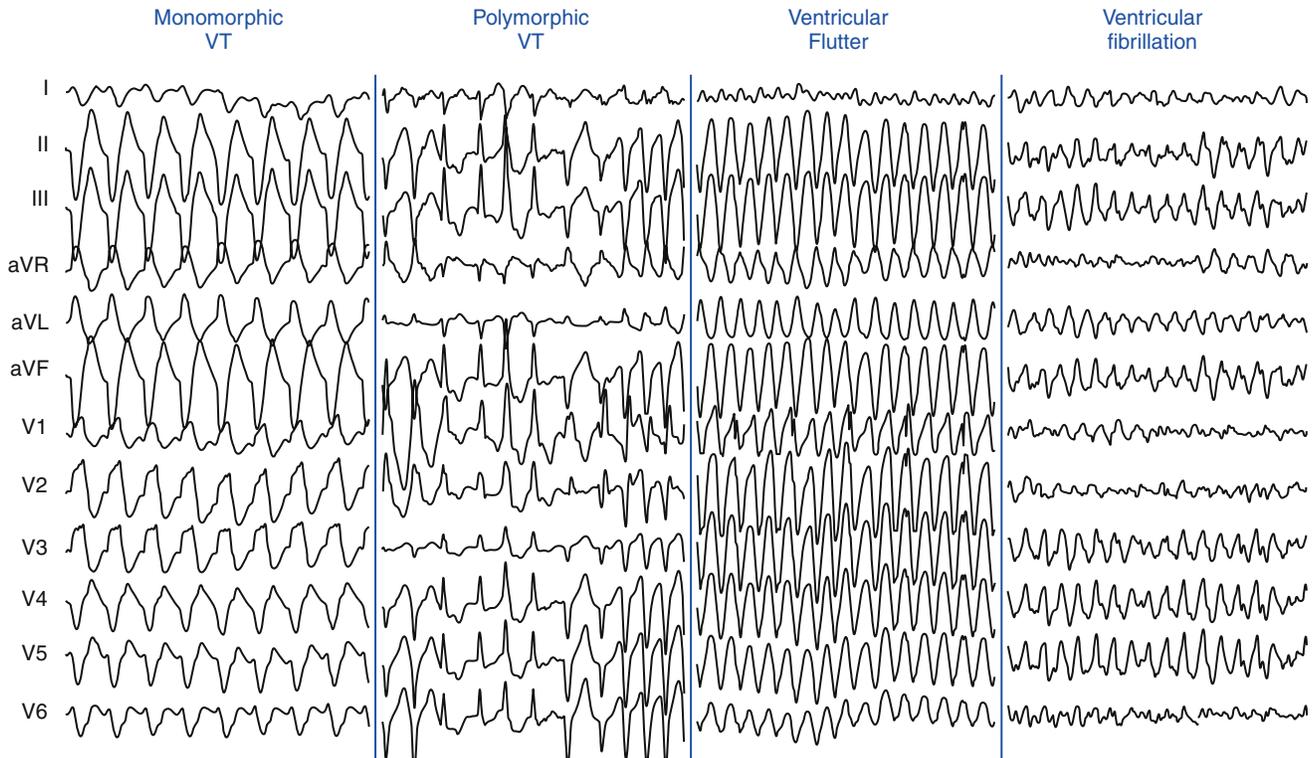

FIGURE 22-1 Surface ECG of different types of ventricular tachycardias. VT = ventricular tachycardia.

reentrant VT describes arrhythmias that have characteristics of reentry and originate from an area of myocardial scar identified from electrogram characteristics or myocardial imaging. Large reentry circuits that can be defined over several centimeters are commonly referred to as “macroreentry” circuits.^{1,2}

Mechanism of Post-Infarction Ventricular Tachycardia

The majority of sustained monomorphic VTs (SMVTs) are caused by reentry involving a region of ventricular scar. The scar is most commonly caused by an old myocardial infarction (MI), but right ventricular (RV) dysplasia, sarcoidosis, Chagas disease, other nonischemic cardiomyopathies, surgical ventricular incisions for repair of tetralogy of Fallot, other congenital heart diseases, or ventricular volume reduction surgery (Batista procedure) can also cause scar-related reentry. Dense fibrotic scar creates areas of anatomical conduction block, and fibrosis between surviving myocyte bundles decreases cell-cell coupling and distorts the path of propagation, causing areas of slow conduction and block, which promotes reentry. In post-MI VT, a variety of different circuit configurations are possible. Generally, the reentrant circuit arises in areas of fibrosis interspersed with bundles of viable myocytes, producing a zigzag course of activation of and transverse conduction along a pathway lengthened by branching and merging bundles of surviving myocytes, leading to inhomogeneous anisotropy (see Fig. 3-18). Heterogeneity in tissue composition and autonomic innervations in these regions may create areas of aberrant conduction that generate the substrate for reentrant arrhythmias. Buried in the arrhythmogenic area is the common central pathway, the critical isthmus, causing slowing of impulse conduction, allowing reentry to occur. The isthmus itself can be surrounded by dead ends or branches that do not participate in the common pathway of the main reentrant circuit (bystander).^{4,5}

Although previous data suggested that most isthmuses are anatomically determined by heterogeneous scar geometry, a recent study found that the diastolic pathway critical to post-MI VT reentrant circuits is typically protected by a boundary of fixed and functional block. In the majority of cases, development of functional

unidirectional block was a prerequisite for initiation of VT, by protecting a region of myocardium that subsequently forms at least one border of the diastolic pathway. Evidence indicates that formation of functional block leading to reentry is associated with large dispersion in refractory periods over short anatomical distances.⁶

The critical isthmus contained in these reentry circuits often is a narrow path of tissue with abnormal conduction properties. Depolarization of the small mass of tissue in the isthmus is usually not detectable on the surface electrocardiogram (ECG) and constitutes the electrical diastole between QRS complexes during VT. The wavefront leaves the isthmus at the exit site and propagates out to depolarize the remainder of the ventricles, producing the QRS complex. After leaving the exit of the isthmus, the reentrant wavefront can return back to the entrance of the isthmus through an outer loop or an inner loop (see Fig. 5-14).⁴ An outer loop is a broad sheet of myocardium along the border of the infarct. Depolarization of the outer loop can be detectable on the surface ECG. Reentrant circuits can have one or more outer loops. An inner loop is contained within the scar. Inner loop pathways can serve as potential components of a new reentrant circuit should the central common pathway be ablated. If multiple loops exist, the loop with the shortest conduction time generally determines the VT CL and is therefore the dominant loop. Any loop with a longer conduction time behaves as a bystander. Those bystander loops can serve as a potential component of a new reentrant circuit if the dominant loop is ablated.

The critical isthmus in post-MI VT is typically bounded by two approximately parallel conduction barriers that consist of a line of double potentials, a scar area, or the mitral annulus. The endocardial reentrant VT rotates around the isthmus boundaries and propagates slowly through the critical isthmus, which harbors diastolic potentials and measures, on average, approximately 30 mm long by 16 mm wide. The axis of a critical isthmus is typically oriented parallel to the mitral annulus plane in perimitral circuits and perpendicular to the mitral annulus plane in other circuits.⁴ Ablation lesions produced with standard radiofrequency (RF) ablation catheters are usually less than 8 mm in diameter, relatively small in relation to the entire reentry circuit, and can be smaller than the

width of the reentry path at different points in the circuit. Successful ablation of a large circuit is achieved by targeting an isthmus where the circuit can be interrupted with one or a small number of RF lesions, or by creating a line of RF lesions through a region containing the reentry circuit.

A recent study using electroanatomical substrate mapping found that patients without clinical SMVT had markedly smaller endocardial low-voltage areas, fewer scar-related electrograms (i.e., fractionated, isolated, and very late potentials, which represent electrically viable sites within the scar), and fewer putative conducting channels compared with similar ischemic cardiomyopathy patients with spontaneous SMVT, despite equally severe left ventricular (LV) dysfunction as well as similar infarct age and distribution. These differences in the endocardial EP substrate can play an important role in VT arrhythmogenesis in the chronic post-MI context. Both the extent of the scar areas (electrogram voltage <0.5 mV) and the presence of numerous channels within this zone seem to be critical to the development of VT. Although the border zone region of the scar (electrogram voltage, 0.5 to 1.5 mV) did not differ in area between the two groups, this zone also had a significantly higher prevalence of putative conducting channels in the SMVT patients. This suggests a fundamentally different scar composition (more “arrhythmogenic”) in the SMVT patients. As noted, inhomogeneous scarring with varying degrees of subendocardial myocardial fiber preservation within dense zones of fibrosis leads to slowed conduction, nonuniform anisotropy, and the potential for channels within the scar zone—conditions necessary for the development of reentry.⁷

It is not uncommon for patients with post-MI VT to have more than one VT morphology. Even in patients presenting with a single SMVT, multiple distinct uniform VTs may be induced in the EP laboratory, especially during antiarrhythmic therapy. The induction of multiple VT morphologies during an ablation procedure suggests that the arrhythmogenic substrate has the capability to support multiple reentrant circuits or different exit sites from a single circuit. Distinct VT morphologies (as defined by the 12-lead ECG and tachycardia CL) often share a common isthmus but differ in propagation direction, location, or both across the isthmus perimeter during reentry, but can also arise from distinct, usually adjacent, circuits.

A focal mechanism of VT (abnormal automaticity or triggered activity) has been implicated in the settings of acute ischemia. Focal VT may also occur in the absence of an acute ischemic event in patients with chronic ischemic heart disease. A recent study found that a focal mechanism was present in up to 9% of VTs that were induced in patients with ischemic heart disease during EP study for RF ablation.⁸

Cardiac arrest and sudden cardiac death (SCD) in post-MI patients are predominantly caused by VT or VF. Bradyarrhythmias, including heart block, as well as electromechanical dissociation contribute to SCD, although they seem to account for a minority of events.

Clinical Considerations

Epidemiology

Coronary heart disease is the most frequent cause of clinically documented VT and VF (76% to 82% of patients). The incidence of SMVT in patients with an acute MI varies with the type of MI. Among almost 41,000 patients with an ST elevation (Q wave) MI treated with thrombolysis in the GUSTO-1 trial, 3.5% developed VT alone and 2.7% developed both VT and VF. A pooled analysis of four major trials of almost 25,000 patients with a non-ST elevation acute coronary syndrome (non-ST elevation MI and unstable angina) noted a lower incidence of VT—0.8% developed VT alone and 0.3% developed both VT and VF.^{1,9}

SMVT within the first 2 days of acute MI is uncommon, occurring in up to 3% of patients as a primary arrhythmia and with VF in up to 2%, and is associated with an increase in in-hospital mortality compared with those without this arrhythmia. However, among 21-

30-day survivors, mortality at 1 year is not increased, suggesting that the arrhythmogenic mechanisms can be transient in early post-MI SMVT. On the other hand, the typical patient with SMVT occurring during the subacute and healing phases, beginning more than 48 hours after an acute MI, has had a large, often complicated infarct with a reduced LV ejection fraction (LVEF), and such VT is a predictor of a worse prognosis.⁹ SMVT within 3 months of an MI is associated with a 2-year mortality rate of 40% to 50%, with most deaths being sudden. Predictors of increased mortality in these patients are anterior wall MI; frequent episodes of sustained VT, nonsustained VT, or both; heart failure; and multivessel coronary disease, particularly in individuals with residual ischemia.

Early reperfusion of infarct-related arteries results in less aneurysm formation, smaller scars, and less extensive EP abnormalities, although a significant risk of late VT (often with rapid CLs) persists.^{2,10} In patients with ST elevation MI treated with primary percutaneous coronary intervention, delayed reperfusion (>5 hours after MI) was associated with a sixfold increase in the odds of inducible SMVT by programmed electrical stimulation (performed 6 to 10 days post-MI) as well as an increased risk of spontaneous ventricular arrhythmias and SCD (after a mean follow-up of 28 ± 13 months) compared with early reperfusion (≤ 3 hours) independent of LVEF. It was estimated that each 1-hour delay in reperfusion conferred a 10.4% increase in the odds of inducible VT.¹¹

Most episodes of SMVT associated with MI occur during the chronic phase. VT occurs in 1% to 2% of patients late after MI. The first episode can be seen within the first year post-MI, but the median time of occurrence is about 3 years and SMVT can occur as late as 10 to 15 years after an MI. Late SMVT often reflects significant LV dysfunction and the presence of a ventricular aneurysm or scarring. Late arrhythmias can also result from new cardiac events. The annual mortality rate for SMVT that occurs after the first 3 months following acute MI is approximately 5% to 15%. Predictors of VF include residual ischemia in the setting of damaged myocardium, LVEF less than 40%, and electrical instability, including inducible or spontaneous VT, particularly in those who present with cardiac arrest.

Recent evidence suggests that coronary revascularization before or shortly after implantable cardioverter-defibrillator (ICD) placement in high-risk post-MI patients with LV dysfunction and wide QRS duration can potentially reduce the risk for life-threatening ventricular arrhythmias and appropriate ICD shocks, and, hence, improve quality of life and reduce mortality.¹²

The relationship between SMVT and VF is uncertain, and it is not clear how often VF is triggered by SMVT rather than occurring de novo. SMVT can simply be the company kept by VF in a number of patients or, in the appropriate setting such as recurrent ischemia, a rapid VT can develop a wavefront that becomes fractionated, leading to VF.

SCD accounts for up to 15% of total mortality in industrialized countries and claims the lives of more than 300,000 people per year in the United States. Approximately 50% of deaths in patients with prior MI occur suddenly and unexpectedly. Ventricular arrhythmias are responsible for most of these deaths in stable ambulatory populations. Most SCD victims have known heart disease—most frequently coronary artery disease or prior MI. Cardiac arrest is the initial manifestation of heart disease in approximately 50% of cases. Such patients are more likely to have single-vessel coronary disease and normal or mildly abnormal LV systolic function than cardiac arrest victims with prior MI. Although heart failure increases risk for both sudden and nonsudden death, a history of heart failure is present in only approximately 10% of arrest victims.¹³

The risk for total and arrhythmic mortality is highest in the first month after an acute MI and stays high during the first 6 months after acute MI. After the first year post-MI, there appears to be a relatively quiescent period of relatively low rates of SCD, followed by a second peak 4 to 10 years after acute MI. The later occurrence of SCD may result from delayed ventricular remodeling resulting in the creation or activation of reentrant VT circuits on the infarct border as well as from heart failure developing late after MI.¹⁴

Several studies in patients with cardiac arrest have shown that VF as the causative rhythm appears to be decreasing, being replaced by pulseless electrical activity and asystole. Although the cause of this change is unknown, it may reflect patients with sicker hearts who are living longer due to better therapy. Hearts with advanced disease may be more likely to develop pulseless electrical activity and asystole than VF.¹⁵

Clinical Presentation

In chronic ischemic heart disease, VT results in a wide spectrum of clinical presentations, ranging from mild symptoms (palpitations) to symptoms of hypoperfusion (lightheadedness, altered mental status, presyncope, and syncope), exacerbation of heart failure and angina, and cardiovascular collapse. Hemodynamic consequences associated with VT are related to ventricular rate, duration of VT, presence and extent of LV dysfunction, ventricular activation sequence (i.e., ventricular dyssynchrony), and loss of atrioventricular (AV) synchrony.

Initial Evaluation

EVALUATION OF TYPE AND BURDEN OF VENTRICULAR ARRHYTHMIAS

Identifying and quantifying the types and burden of sustained and nonsustained VT are necessary. Ideally, a 12-lead ECG should be obtained. In patients with ICDs, stored device data such as electrogram morphology and CL can be used to identify the clinical VT.²

EVALUATION OF THE TRIGGERS OF VENTRICULAR ARRHYTHMIAS

Initial testing in patients with post-MI VT should evaluate for reversible causes of the arrhythmia. These include electrolyte imbalances, acute ischemia, heart failure, hypoxia, hypotension, drug effects, and anemia.

EVALUATION OF MYOCARDIAL ISCHEMIA

Although recurrent SMVT is rarely due to acute myocardial ischemia in patients with known coronary artery disease, diagnostic evaluation for acute or persistent ischemia is warranted to improve patient outcome, especially if the severity of coronary artery disease has not been previously established or prior episodes of VT caused hemodynamic compromise. This may include echocardiographic examination, exercise testing, and cardiac catheterization. In patients with reversible myocardial ischemia, coronary revascularization may be warranted, and can potentially reduce the risk of life-threatening ventricular arrhythmias.¹² However, if the severity of coronary disease has been recently defined and symptoms and hemodynamic tolerance of VT do not suggest significant ischemia, further evaluation may not be required.^{1,2}

PREABLATION EVALUATION

Patients with post-MI VT should be evaluated for comorbidities that can alter the approach to mapping and ablation. Treatment of congestive heart failure and myocardial ischemia should be optimized. Coronary revascularization should be considered in patients with reversible ischemia, because substantial ischemic burden can often be aggravated by the potential induction of prolonged periods of tachycardia or hemodynamically unstable arrhythmias during the ablation procedure. In patients with frequent or incessant VT, however, catheter ablation may be required on an urgent basis before the assessment for coronary artery disease in order to gain prompt control of the ventricular arrhythmia.^{1,2}

Mobile LV thrombus is an absolute contraindication to endocardial catheter ablation. In contrast, LV catheter ablation may be performed despite the presence of laminated thrombus, if the patient

has been therapeutically anticoagulated with warfarin for at least 4 weeks prior to ablation. Similarly, the presence of intraatrial clots should be excluded in patients with inadequately anticoagulated persistent atrial fibrillation (AF) to reduce the risk of thromboembolism in the event of AF termination following electrical shocks for termination of unstable ventricular arrhythmias.

In patients with suspected peripheral vascular disease, evaluation of the presence of severe arterial disease is warranted, as it can affect the approach to LV access (atrial transseptal versus retrograde transaortic versus epicardial).¹⁶ Similarly, an atrial transseptal approach allowing access to the LV through the mitral valve can be considered in the presence of a mechanical aortic valve or severe aortic valve disease.²

Assessment of the risks for sedation and anesthesia must be performed prior to the procedure, because these patients are likely to require deep sedation or general anesthesia.²

ARRHYTHMOGENIC SUBSTRATE IMAGING

In patients with ventricular dysfunction, tissue heterogeneity with inexcitable myocardial fibrous scar and surviving myocardium may provide a potential substrate for reentry circuits. Several non-invasive methodologies have been used to assess the substrate and identify patients at high risk for ventricular arrhythmias.

VENTRICULOGRAPHY. Left ventriculography provides valuable information about LV function and ventricular thrombi, representing a relative contraindication to catheter manipulation. Additionally, regions of wall motion abnormalities and aneurysms can be identified that likely harbor the VT substrate.

ECHOCARDIOGRAPHY. Transthoracic echocardiography is routinely performed to evaluate LV systolic function, LVEF, and wall motion abnormalities that may contain the potential VT substrate. Transthoracic echocardiography also serves as a reliable tool to rule out ventricular thrombi before LV procedures. Additionally, it helps to identify relatively infrequent cardiomyopathies associated with VT, for example, arrhythmogenic right ventricular dysplasia-cardiomyopathy and hypertrophic cardiomyopathy. Although echocardiography can provide anatomical and contractile parameters, it cannot provide relevant clinical information about transmural extent and intramyocardial location of the scar.¹⁷

Transesophageal echocardiography can be used in patients with AF or atrial flutter (AFL) to detect thrombi within the left atrium (LA) and LA appendage to prevent thromboembolic events when a transseptal access to the LV or cardioversion is required. Severe atheroma in the aorta detected on transesophageal echocardiography may encourage the operator to avoid the retrograde approach to the LV.

Intracardiac echocardiography (ICE) applied from the right atrium (RA) and the RV has been used for real-time imaging during VT ablation procedures. ICE provides both an anatomical and a functional assessment of the LV, allowing for real-time identification of wall motion abnormalities. ICE also allows for visualization of scarred tissue and thus may help to identify the VT substrate and facilitate mapping and ablation (see later).

DELAYED CONTRAST-ENHANCED CARDIAC MAGNETIC RESONANCE. Cardiac magnetic resonance (MR) imaging is a valuable tool for assessing cardiac anatomy and function and for identifying structural abnormalities serving as arrhythmia substrate. Delayed contrast-enhanced MR imaging delineates regions of scar tissue potentially forming part of the arrhythmia substrate in patients with ischemic cardiomyopathy (CMP).

Cardiac MR is extremely valuable for assessing viable and nonviable myocardium in infarcted and poorly contracting myocardial areas, and enables the depiction of transmural and nontransmural infarctions with high spatial resolution and better accuracy than scintigraphic techniques. Assessing the characteristics and distribution of myocardial scar by cardiac MR can potentially help identify patients at high risk of VT. In patients with ischemic CMP, the nontransmural hyperenhanced areas, but not the transmural hyperenhanced areas, were found to predict higher risk of sustained VT.¹⁸

Additionally, delayed enhancement cardiac MR imaging can potentially predict the approach required for successful VT ablation (endocardial versus epicardial) by visualizing the location of the scar (endocardial, intramyocardial, or epicardial). In a recent report, the presence of epicardial or intramyocardial scar on pre-procedure MR was associated with a 0% procedural success rate when the operator limited ablation to the endocardium.

Recently, registration of preacquired MR images with real-time electroanatomical mapping has successfully been used to facilitate and guide catheter navigation and ablation in the LV. Visualization of ventricular anatomy and obstacles to procedural success, for example, epicardial fat in the case of epicardial mapping approaches, and the possibility of navigation and ablation in the ventricular chambers have the potential to reduce procedure time, decrease the rate of complications, and increase success rates.

One potential disadvantage concerns the safety of MR imaging in patients with implanted devices. Evolving technologies have improved the MR imaging compatibility of some devices.

POSITRON EMISSION TOMOGRAPHY. Currently, positron emission tomography (PET) is considered the gold standard for tissue viability assessment. In patients with scar-related VT, PET can accurately detect myocardial scar within the LV and provide additional tissue characterization by displaying metabolic and morphological information of the VT substrate. Its spatial resolution of 4 to 6 mm can delineate scar in any wall segment with good correlation between areas of endocardial voltage less than 0.5 mV and PET-defined myocardial scar.

Because PET scans alone do not provide the necessary anatomical information required for integration with electroanatomical maps, a computed tomography (CT) angiography scan is required to provide an anatomical skeleton onto which the biological information acquired from the PET scan would be superimposed on its precise anatomical location. Fusion of multimodality imaging sets derived from PET/CT allows accurate, simultaneous display of LV anatomy and myocardial scar and can facilitate an image-guided approach to substrate-based VT ablations.

CARDIAC CONTRAST-ENHANCED COMPUTED TOMOGRAPHY. Cardiac contrast-enhanced CT scanning enables a detailed and comprehensive evaluation of LV myocardium using multimodality imaging based on anatomical, dynamic, and perfusion parameters to identify abnormal substrate (myocardial scar and border zone) with high spatial (≤ 1 mm) and temporal resolution, which can be derived from a single CT scan. Areas of CT hypoperfusion correlate best with areas of abnormal voltage (< 1.5 mV) rather than scar alone (< 0.5 mV). Perfusion imaging from CT can indicate scar transmural and intramyocardial scar location.¹⁷

The ability of contrast-enhanced CT to characterize the transmural extent and intramyocardial location of scar tissue and to visualize surviving mid- and epicardial myocardium at sites of endocardial scar can potentially help identify areas involved in myocardial reentry representing appropriate ablation targets and help to overcome one of the significant limitations of endocardial voltage mapping. Additionally, the presence of an epicardial VT substrate can facilitate planning of VT ablations, such as for a combined endocardial and epicardial approach.¹⁷ When compared with contrast-enhanced MR, absolute sizes of early hypoperfused and late hyperenhanced regions were similar on contrast-enhanced CT and contrast-enhanced MR.¹⁷

The three-dimensional (3-D) CT-defined image of abnormal myocardium can be accurately extracted and embedded in clinical mapping systems displaying areas of abnormal anatomical, dynamic, and perfusion parameters for substrate-guided VT ablations.¹⁷

ROLE OF ELECTROPHYSIOLOGICAL TESTING

In patients with sustained monomorphic VT, EP testing is not recommended unless catheter ablation is planned. However, EP testing is useful in patients with coronary heart disease for the diagnostic evaluation of wide QRS complex tachycardias of unclear

mechanism and in those with unexplained syncope. Additionally, EP testing can be used for risk stratification late after MI in patients with ischemic CMP and nonsustained VT (see below).¹⁹

Programmed stimulation induces VT in over 90% of patients with a history of VT. Although the rate and QRS morphology of induced VT may differ from that observed during spontaneous tachycardia, the induction of VT signifies the presence of a fixed anatomical substrate associated with an increased likelihood of future spontaneous events.²

Risk Stratification

There are more than 50 million North American adults with coronary artery disease and more than 7 million have had an MI. However, only a fraction of these patients will suffer a cardiac arrest. Therefore, noninvasive risk assessment after MI is required to identify patients at risk of SCD. Various tests assessing the extent of myocardial damage and scarring, myocardial conduction disorders, dispersion of repolarization, and autonomic imbalance have been proposed to identify patients at high risk of SCD who are likely to benefit from prophylactic ICD therapy. Some of these techniques potentially identify the underlying substrate (e.g., myocardial scar, intramyocardial conduction abnormalities) or triggers (e.g., autonomic imbalance, nonsustained VT) of malignant ventricular arrhythmias. However, most of these techniques have not been validated in independent populations and, although they can predict higher risk of total mortality, their ability to predict arrhythmic death is uncertain. Additionally, the majority of conventional risk stratifiers of SCD have a relatively low positive predictive value that would preclude their wide application as guidelines for ICD implantation in patients known to be at risk for SCD.^{14,20}

To date, only two approaches have been proven useful in guiding prophylactic ICD therapy in post-MI patients: the presence of significant LV dysfunction alone or in combination with the inducibility of sustained VT/VF during programmed electrical stimulation beyond the early phase after MI. It should be recognized, however, that the development of SCD in post-MI patients is multifactorial, and multiple events need to coincide for a cardiac arrest to ensue; therefore, no one risk stratification test alone will be sufficient for all patients. Rather, combining multiple tests screening for the different potential mechanisms of SCD may be necessary. Furthermore, because progression of ischemic heart disease can result in the evolution of new mechanisms of SCD in individual patients, repetition of risk stratification tests at certain intervals may be required. It would seem reasonable (in the absence of data) to retest every 2 years in apparently stable patients to detect potential changes in substrate, regardless of which tests appear to have the highest yield.^{14,20}

LEFT VENTRICULAR EJECTION FRACTION

Multiple studies evaluating survival of patients with prior MI established a clear relationship between reduced LVEF and increased mortality. LVEF behaves as a continuous variable, with gradually increasing mortality risk until the LVEF declines to 40% and then markedly increasing risk for values less than 40%. Nevertheless, the exact mechanisms involved in the strong correlation between decreased LV systolic function and increased incidence of SCD are not clearly defined.¹⁴

Although low LVEF identifies one patient population at relatively increased risk for SCD, there are clear limitations to LVEF as the ideal risk-stratification test for deciding whether to implant an ICD for primary prevention of SCD. LV systolic dysfunction lacks specificity. There is no evidence of any direct mechanistic link between low LVEF and mechanisms responsible for ventricular tachyarrhythmias and no study has demonstrated that reduced LVEF is specifically related to SCD. In fact, in studies that enrolled all patients after MI, patients with LVEF less than 30% to 35% account for no more than 50% of sudden cardiac arrest victims. Thus, although LVEF is

a good marker of risk for *total* mortality, it does not provide insight into how patients are likely to die (sudden versus nonsudden).

Another limitation of LVEF is its poor sensitivity. Although most studies have focused on patients with markedly reduced LVEF, this group currently accounts for only 10% to 15% of MI survivors. Furthermore, patients with low LVEF are not uniform with regard to other prognostic markers, and not all are at high risk for SCD. In fact, most contemporary managed post-MI patients who suffer a cardiac arrest have better-preserved LV systolic function (i.e., LVEF $\geq 35\%$).

It is also recognized that methods of LVEF determination lack precision. Different imaging modalities can produce significantly different LVEF values and the accuracy of techniques varies among laboratories and institutions, and there is evidence that prognosis, and hence risk, depends on the method by which the LVEF is measured. It is therefore recommended to use the LVEF determination that clinicians believe is the most clinically accurate and appropriate in their institution.

INVASIVE ELECTROPHYSIOLOGICAL TESTING

Inducibility of VT/VF during invasive EP testing can enhance the predictive accuracy of reduced LVEF for post-MI patients with high mortality risk. The first Multicenter Automatic Defibrillator Implantation Trial (MADIT I) study demonstrated that those patients with inducible VT/VF and LVEF values less than or equal to 35% late after MI are likely to benefit from prophylactic ICD therapy. Moreover, the absolute mortality reduction in MADIT I (26.2% over 27 months) was substantially greater than what was found in either the second MADIT (MADIT II) or SCD Heart Failure Trial (SCD-HeFT). Similar results were found in the Multicenter UnSustained Tachycardia Trial (MUSTT).^{19,21}

However, secondary analysis from MUSTT revealed that despite the significant difference in outcome between inducible patients enrolled in the trial and noninducible patients enrolled in a registry, EP inducibility was of limited value because the 5-year mortality rate in inducible patients was 48% compared with 44% in noninducible patients. Later, data from MADIT II showed that there is no need for additional risk stratifiers (including EP testing) when LVEF is so low. In more than 80% of patients randomized to the ICD arm of MADIT II, invasive EP testing with an attempt to induce tachyarrhythmias was performed at the time of ICD placement. VT inducibility, observed in 40% of studied patients, was not effective in identifying patients with cardiac events defined as VT, VF, or death. These observations from both MUSTT and MADIT II subanalyses suggest that in patients with substantially depressed LV function, EP inducibility should not be considered a useful predictor of outcome. It is possible, however, that inducibility might have much better predictive value in post-MI patients with LVEF greater than 30% or greater than 35%.^{19,21}

Furthermore, using inducible VT/VF to guide prophylactic ICD therapy is limited by low sensitivity. Patients with LVEF values not exceeding 35% after MI and no inducible VT/VF still appear to have a substantial (>25%) risk of serious events over the near term.²¹

There are also no data to support the use of invasive EP testing in post-MI patients with LVEF values more than 40% or in the early post-MI period. In fact, the Beta-blocker Strategy plus Implantable Cardioverter-Defibrillator (BEST-ICD) trial found that inducible VT/VF early after MI does not predict benefit from ICD therapy. In contrast, the Cardiac Arrhythmias and Risk Stratification after Acute Myocardial Infarction (CARISMA) study found that inducible VT identified 6 weeks following an acute MI was a strong predictor of future life-threatening arrhythmias.^{19,21}

Additionally, EP testing is invasive and not practical for broad application as a screening tool. Nonetheless, it can be valuable when used in patients in whom the risk of sustained arrhythmias and SCD is intermediate, and the potential benefit of ICD therapy uncertain. Current guidelines recommend prophylactic ICD therapy in post-MI patients with nonsustained VT and LVEF less than 40% if sustained VT/VF is inducible at EP study.¹⁴

MEASURES OF CARDIAC REPOLARIZATION

Microvolt-level T wave alternans (TWA) has emerged as a promising noninvasive marker of risk for SCD. TWA, measured on the surface ECG, detects subtle beat-to-beat oscillations in cardiac repolarization and has been linked to cellular mechanisms of arrhythmogenesis. Initial clinical studies of TWA demonstrated a high negative predictive value ($\geq 95\%$). Additionally, an abnormal TWA was associated with significantly increased mortality risk as well as risk of arrhythmic events, although the positive predictive values were far more variable, depending on the characteristics of the study populations and pretest probability. Although those studies suggested that TWA could potentially provide prognostically useful information beyond the LVEF and help guide selection of appropriate patients for prophylactic ICD therapy, more recently, several large multicenter studies of TWA failed to support these findings and, in contrast, strongly suggested that a negative TWA result should not be used to withhold ICD therapy among patients who meet other standard criteria. Other noninvasive measures of dispersion of repolarization, including QT dispersion, QT variability, and QT dynamics, have had similar mixed predictive results in studies with limited clinical applicability.

MEASURES OF AUTONOMIC IMBALANCE

Methods to assess the autonomic nervous system, which has been thought to be a modulator between triggers of ventricular tachyarrhythmias and the underlying substrate, including heart rate variability, baroreflex sensitivity, heart rate turbulence, and deceleration capacity, have been evaluated for risk stratification of SCD. Multiple studies have correlated relative excess of sympathetic tone (or deficient parasympathetic tone) with increased mortality in post-MI patients as well as increased propensity for VF during acute ischemia. However, the majority of studies showed no significant difference in relative risk for SCD versus total mortality. Thus, these measures do not appear to provide a reliable measure of SCD risk and there is no evidence to support their use in guiding prophylactic ICD therapy.²²

MEASURES OF MYOCARDIAL CONDUCTION DISORDERS

Increased QRS duration on a surface ECG has been associated with a higher risk of death after MI and appears to reflect greater LV dysfunction, but association with SCD has not been proven. Similarly, the presence of late potentials on signal-averaged ECG failed to identify patients likely to benefit from ICD therapy.²² Recently, fragmentation of the QRS complex on the 12-lead surface ECG (filter range, 0.15 to 100 Hz; AC filter, 60 Hz, 25 mm/sec, 10 mm/mV), which likely signifies inhomogeneous ventricular activation due to myocardial scar, ischemia, or both in patients with coronary artery disease, has been found to potentially predict increased risk of appropriate ICD therapies in patients who received an ICD for primary and secondary prevention. The usefulness of this parameter needs further evaluation.^{23,24}

GENETIC TESTING

There is compelling evidence that a genetic mechanism may increase patient susceptibility to SCD following MI, and genetic assessment may play a role in the future. However, there is presently no evidence for using genetic testing to identify post-MI patients at risk.^{14,20}

CARDIAC MAGNETIC RESONANCE IMAGING

Characteristics of myocardial scar architecture and tissue heterogeneity in the perinfarct zone, as defined by contrast-enhanced cardiac MR, can potentially identify a proarrhythmic substrate and appears to be a strong predictor of ventricular arrhythmias and appropriate ICD therapies. In patients with ischemic CMP, the nontransmural, but not the transmural, hyperenhanced areas were

found to predict higher risk of sustained VT.¹⁸ However, large prospective trials are still required to evaluate the reliability of these techniques for risk stratification.²⁵

RISK STRATIFICATION EARLY POST-INFARCTION

The risk of SCD is greatest in the first month after MI and appears to decline in the first year after MI. Nevertheless, both prospective and retrospective studies of prophylactic ICD therapy have failed to show a reduction in all-cause mortality in early post-MI patients. The reduction in the rate of death due to arrhythmia associated with ICD therapy was offset by an increase in the rate of death from nonarrhythmic cardiac causes in the ICD groups. This discrepancy not only highlights the limitations of current risk stratification techniques, but also reflects relative differences in the risk factors for SCD at different time points after MI and the fact that nonarrhythmic death accounts for an appreciable percentage of deaths during that time. Heart rate and creatinine clearance measured at baseline are strongly associated with SCD during the in-hospital period, whereas recurrent cardiovascular events (including heart failure, MI, and rehospitalization) and a baseline LVEF of 40% or less are more strongly associated with the occurrence of SCD after discharge.^{21,26}

Whereas the cumulative incidence of SCD is greatest in post-MI patients with an LVEF of 30% or less, the incidence of SCD is greater in patients with an LVEF greater than 40% in the first 30 days after MI when compared with patients with an LVEF of 30% or less after 90 days. The strength of the association between LVEF and survival free from SCD appears to be greatest in long-term follow-up (>6 months). Currently, there is no strategy (invasive or noninvasive) that can reliably predict the risk for SCD or guide empiric ICD implantation soon after an MI. Data suggest it is best to wait 2 to 3 months after acute MI before performing risk stratification.^{14,21,26}

Recent data suggest a potential benefit of EP testing in risk stratification in patients with ST elevation MI and LVEF less than 40% treated with primary percutaneous coronary intervention. Inducible SMVT by programmed electrical stimulation performed 6 to 10 days post-MI was associated with an increased risk of spontaneous VT/VF and SCD (after a mean follow-up of 28 ± 13 months). However, further evaluation in randomized clinical trials is required before adoption of this approach.¹¹

Principles of Management

PHARMACOLOGICAL THERAPY

ACUTE THERAPY. The degree of hemodynamic tolerance should dictate the initial therapeutic strategy. VTs causing severe symptoms of angina or hemodynamic collapse almost always respond to synchronized electrical cardioversion. Treatment of pulseless VT is the same as that for VF and should follow the ACLS protocol. In patients with difficult-to-control or recurrent VT, intravenous amiodarone is the drug of choice. Intravenous procainamide and sotalol are alternatives. Lidocaine is less effective in the absence of acute ischemia; however, it can be considered in combination with either procainamide or amiodarone if the latter drugs are ineffective alone. Beta blockers offer additional benefit in patients with ischemic heart disease. Treatment of underlying conditions (e.g., acute ischemia, decompensated heart failure, electrolyte abnormalities) is also necessary.¹⁹ For refractory VT storm, general anesthesia, sympathetic neural blockade, catheter ablation, and intraaortic balloon counterpulsation have been used.

CHRONIC THERAPY. Antiarrhythmic drugs can be considered in two main settings: as adjunctive therapy in patients with an ICD and as preventive therapy in patients who do not want or are not candidates for an ICD (e.g., because of marked comorbidities). Because an ICD does not prevent arrhythmias, patients who have frequent symptoms or device discharges triggered by VT/VF may benefit from adjunctive drug therapy. There are three main indications for antiarrhythmic drug therapy along with an ICD: to

reduce the frequency of ventricular arrhythmias in patients with unacceptably frequent ICD therapies, to reduce the rate of VT so that it is better tolerated hemodynamically and more amenable to pace termination or low-energy cardioversion, and to suppress other arrhythmias (e.g., sinus tachycardia, AF, nonsustained VT) that cause symptoms or interfere with ICD function or cause inappropriate discharges.^{19,27}

When ICD patients need drugs because of frequent shocks, the weight of evidence supports optimizing beta blocker therapy. When long-term antiarrhythmic therapy is required, amiodarone is the drug of choice. Sotalol is less effective than amiodarone and can cause torsades de pointes. Azimilide may be effective with fewer side effects (except torsades de pointes), but is not approved by the U.S. Food and Drug Administration or European authorities, and experience is limited. No comparative data for amiodarone and azimilide are available. For patients who cannot tolerate amiodarone or sotalol, dofetilide has been suggested as an alternative.²⁷

Although some reports suggested the early use of antiarrhythmic drugs (prophylactically or after a single ICD shock), early prophylactic use may overtreat a large group of patients who will never have an ICD intervention but are exposed to drug side effects; or the drug may elicit an ICD intervention due to proarrhythmia. At this point, the decision as to when to start adjuvant antiarrhythmic drug therapy in patients who receive an ICD for secondary prevention should be individualized, with the expectation that well-designed therapy can reduce ICD shocks and improve quality of life. Until more data are available, routine use of prophylactic antiarrhythmic drugs in device patients does not appear to be warranted.²⁷

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

SECONDARY PREVENTION. ICD therapy has a proven mortality benefit among patients with structural heart disease and a history of VT or VF, with an absolute reduction in all-cause mortality of 7% and a significant 25% relative reduction in mortality compared with amiodarone therapy, due entirely to a 50% reduction in SCD. Implantation of an ICD is recommended for secondary prevention in patients with prior cardiac arrest or sustained VT, even in patients undergoing successful catheter ablation of the VT or responding to antiarrhythmic therapy, because the latter two approaches do not sufficiently reduce residual risk of SCD.²⁸

Although one report has questioned the benefit from an ICD compared with pharmacological therapy in patients with VT and LVEF exceeding 40%, the guidelines did not stratify recommendations based on the LVEF.²⁹ This seems appropriate for two reasons: the prognostic importance of the LVEF was based on subset analysis and, given the current ease of ICD implantation, the potential adverse consequences of choosing a possibly less effective therapy are too great.¹⁹

PRIMARY PREVENTION. Current guidelines recommend prophylactic ICD implantation in patients with prior MI and reduced LVEF (<35%) who are on optimal medical management. These recommendations are based on the fundamental relationship that exists between reduced LVEF and cardiovascular mortality and the findings of MADIT II and SCD-HeFT. Both MADIT II and SCD-HeFT clearly demonstrated a mortality benefit from prophylactic ICD therapy in patients with a history of MI and severely reduced LVEF ($\leq 30\%$ and $\leq 35\%$, respectively). However, the absolute mortality reduction in these trials was modest: 5.6% over 27 months in MADIT II and 7.3% over 60 months in SCD-HeFT. Fewer than one in five ICD recipients in MADIT II and SCD-HeFT received appropriate ICD therapies over average follow-up periods of 20 and 60 months, respectively. Therefore, because appropriate ICD therapies overestimate the mortality benefit of ICD therapy by at least twofold, fewer than 1 in 10 patients who receive a prophylactic ICD for an LVEF of 35% or less post-MI are likely to receive a survival benefit in the near term.¹⁹

EP testing appears most useful as an adjunct test in patients having equivocal results after noninvasive testing and in whom the

potential benefit of ICD therapy is uncertain. Examples include patients with remote MI, nonsustained VT, and an LVEF between 30% and 40%, as suggested by the recent American College of Cardiology/American Heart Association/European Society of Cardiology (ACC/AHA/ESC) guidelines, or in combination with other clinical risk factors or symptoms suggestive of ventricular tachyarrhythmias including palpitations, presyncope, and syncope. Patients with coronary artery disease who are found to have inducible monomorphic VT during programmed stimulation should be treated for the prevention of SCD. The mode of stimulation (burst pacing, single, or double VESs versus triple VESs) of sustained VT does not influence prognosis and should not influence treatment decisions.^{19,21}

Although the risk of SCD is highest in the first month after MI, there is currently no reliable risk stratification strategy that can guide prophylactic ICD implantation, and primary prevention trials with ICD have failed to show a reduction in all-cause mortality in early post-MI patients identified on the basis of the current risk stratifiers. Therefore, in the early post-MI period, medical therapy and coronary revascularization, when feasible, should be optimized. The LVEF should then be measured at least 40 days post-MI and, if the LVEF is not more than 35%, the patient should be considered for ICD implantation.^{21,26}

CATHETER ABLATION

Catheter ablation of post-MI VT is generally indicated as a *palliative* and *adjunctive* therapy in post-MI patients with ICD who experience frequent recurrences of VT or ICD therapies. Recurrences of VT/VF causing frequent ICD therapies (including ICD shocks) are relatively common. Approximately 20% to 35% of ICD recipients for primary SCD prevention and up to 45% of those who receive an ICD for secondary SCD prevention will receive an appropriate shock within 3 years of implantation. ICD therapy acting via such appropriate ICD shocks reduces the risk of SCD by approximately 60%, but the occurrence of shocks is associated with progressive heart failure symptoms, a significant decline in psychosocial quality of life, and a two- to fivefold increase in mortality. The incidence of appropriate shocks can be reduced by using antitachycardia pacing in the VT or VF detection zones, or with up-titration of medical therapies. If optimization of pharmacological therapies and device programming fails to suppress appropriate ICD shocks for VT, patients are eligible for catheter ablation. Catheter ablation reduces VT/VF recurrences and thereby ICD interventions by more than 75% in patients after multiple ICD shocks. In this patient population, the incidence of procedure-related death ranges from 0% to 3%, and the incidence of major complications from 3.6% to 10%.^{19,30,31} Nonetheless, most patients with post-MI VT have multiple types of monomorphic VTs, and elimination of all VTs is often not feasible, and because the recurrence of an ablated VT or the onset of a new VT can be fatal, RF ablation is rarely used as the sole therapy for VT. Instead, it is typically used for patients with coronary artery disease as an adjunct to an implantable ICD or, less commonly, to antiarrhythmic drug therapy.²

Additionally, catheter ablation is necessary and can be life-saving in patients with electrical storm and incessant VT without any apparent correctable cause and despite adequate medical treatment. Repeated ICD shocks within a short time interval, known as an ICD "storm," occur in 10% to 25% of patients. Catheter ablation has a high acute success rate in eliminating the dominant type of VT. Accumulated evidence suggests that acute suppression of clinical VT in electrical storm can be achieved in approximately 90% of patients. However, arrhythmic recurrences are frequent during follow-up.

Catheter ablation also should be considered for patients with frequent premature ventricular complexes (PVCs), nonsustained VTs, or VT that is presumed to cause ventricular dysfunction.²

The optimal time of catheter ablation in ICD patients (after multiple ICD interventions or before any ICD intervention) remains unclear. In clinical practice, VT ablation is often not considered

until pharmacological options have been exhausted, often after the patient has suffered substantial morbidity from recurrent episodes of VT and ICD shocks. However, recent studies suggest that catheter ablation for VT should generally be considered early in the treatment of patients with recurrent VT, even before initiating antiarrhythmic drug therapy. In fact, catheter ablation was found to reduce VT/VF recurrences and thereby ICD shocks by 43% to 73% when applied prophylactically, that is, before any ICD shock has been delivered. Interestingly, in this patient population the ablation-related mortality rate was 0%, and major complications occurred in 3.8% to 4.7%. Catheter ablation also significantly reduced the rate of hospitalizations for cardiac reasons, and was associated with a trend to fewer deaths in the ablation group during follow-up. The benefit was more pronounced in patients with LVEF of 30% or less.^{2,19,30,31}

Table 22-1 lists the indications of ablation for ischemic VT, in accordance with the ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of sudden death.¹⁹

TABLE 22-1 Indications for Ablation of Ischemic Ventricular Tachycardia*

Class I	<p>Patients after MI with an ICD who present with repetitive monomorphic VT that leads to multiple shocks or who present with drug-refractory incessant VT or "electrical storms" that cannot be prevented despite adequate reprogramming of the antitachycardia pacing mode, beta blocker and/or antiarrhythmic drug therapy, or when patients are intolerant of these drugs or do not wish to take them (level C)</p> <p>Patients after MI with an ICD who present with repetitive sustained VT, which made mandatory therapy with antiarrhythmic drugs that decreased the rate of VT below an acceptable intervention rate into the range of exercise-induced sinus rhythm despite concomitant beta blocker therapy (level C)</p> <p>Patients with bundle branch reentry after MI (level C)</p>
Class IIa	<p>Patients after MI with an ICD who present with infrequent monomorphic VT that has been terminated successfully by more than one electrical shock and that most probably cannot be avoided in the future despite adequate reprogramming of the antitachycardia pacing mode, and where it is difficult to predict whether future events can be avoided by beta blocker and/or antiarrhythmic drug therapy or when patients are not willing to take long-term drugs (level C)</p>
Class IIb	<p>As the sole procedure, that is, without an ICD, in patients after MI who have relatively well-preserved LV function (above 35% to 40%) and in whom VT is monomorphic, relatively slow, and well tolerated; who are considered to have a good long-term prognosis; and who are drug resistant, do not tolerate an antiarrhythmic drug, or do not accept long-term therapy (level C)</p> <p>Patients after MI who present with frequent self-terminating monomorphic VT that may cause ICD shock intervention that potentially cannot be avoided by changing the intervention rate of the ICD (level C)</p> <p>Patients with markedly reduced longevity and comorbidities (e.g., heart failure, reduced renal function) where VT can either not be prevented by antiarrhythmic drug therapy or drugs have not been tolerated and for whom an ICD would not be indicated because of the overall condition of the patient</p> <p>Patients with more than one ICD shock that is causing severe anxiety and psychological distress</p>

*In accordance with the ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of sudden death.

ICD = implantable cardioverter-defibrillator; LV = left ventricular; MI = myocardial infarction; VT = ventricular tachycardia.

From Zipes DP, Camm AJ, Borggrefe M, et al: ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death: a report of the American College of Cardiology/American Heart Association Task Force and the European Society of Cardiology Committee for Practice Guidelines (Writing Committee to Develop Guidelines for Management of Patients with Ventricular Arrhythmias and the Prevention of Sudden Cardiac Death), *J Am Coll Cardiol* 48:e247-e346, 2006.

Electrocardiographic Features

In general, QRS patterns are less accurate in localizing the site of origin of reentrant VTs in patients with prior MI and wall motion abnormalities than they are for focal VTs in patients with normal hearts.^{3,32} Nonetheless, the ECG is capable of regionalizing the VT to areas smaller than 15 to 20 cm², even in the most abnormal hearts.

The site of origin of VT is the source of electrical activity producing the VT QRS. Although this is a discrete site of impulse formation in automatic and triggered (i.e., focal) rhythms, during reentrant VT it represents the exit site from the diastolic pathway (isthmus) to the myocardium giving rise to the QRS. The pattern of ventricular activation and hence the resultant QRS depends on how the wavefront propagates from the site of origin to the remainder of the heart; this can be totally different during VT than during pacing from the same site in normal sinus rhythm (NSR).

A sophisticated algorithm has been developed using eight different patterns of R wave progression in the precordium in addition to the relationship with prior anterior or inferior MI, axis deviation, and BBB morphology. This algorithm has a predictive accuracy of more than 70% for a specific QRS morphology to identify for a particular endocardial region of 10 cm² or less (Fig. 22-2). A recent report indicated that the 12-lead surface ECG characteristics could reliably predict the LVVT exit site region in 71% of clinical VTs without prior knowledge of infarct location. That report described a new algorithm that was used independently of the sustainability of VT and could be applied over a wide range of tachycardia CLs and to patients with posterior or multiple sites of infarction (Figs. 22-3 and 22-4).³³

ECG Clues to the Underlying Substrate

VTs arising from normal myocardium typically have rapid initial forces, whereas slurring of the initial forces is frequently seen when the VT arises from an area of scar or from the epicardium. Additionally, VTs originating from very diseased hearts usually have lower amplitude complexes than those arising in normal hearts, and the presence of notching of the QRS can be a sign of scar tissue.^{3,32}

Whereas QS complexes can be seen in a variety of disorders, the presence of qR, QR, or Qr complexes in related leads is highly suggestive of the presence of an infarct. Sometimes it is easier to recognize the presence of MI during VT than during NSR.

General Principles in Localizing the Origin of Post-Infarction Ventricular Tachycardias

QRS DURATION. QRS duration is affected by the proximity of the VT origin to the septum. Post-MI VTs almost always arise in the LV or interventricular septum.^{1,3,12} Septal VTs generally have QRS durations that are narrower than free wall VTs. Additionally, QRS width during VT is affected by the amount of myocardial disease, being wider with poor overall ventricular conduction.¹

QRS AXIS. A right superior QRS axis suggests apical septal or apical lateral sites of origin, often demonstrating QS in leads I, II, and III and QS or rS in leads V₅ and V₆. A right inferior axis suggests a high basal origin (high LV septum, or high lateral LV). A left inferior axis is occasionally associated with VTs arising from the top of the LV septum. Sometimes, the QRS axis is inappropriate for the exit site. This almost always occurs with large apical infarcts. Typically, discrepancies occur in VTs with LBBB or RBBB with a right or left superior axis. Such discrepancies can be related to abnormalities of conduction out of the area of the reentrant circuit toward the rest of the myocardium.³²

BUNDLE BRANCH BLOCK PATTERN. VTs with RBBB patterns always arise in the LV, and VTs with LBBB patterns almost always arise in or adjacent to the LV septum. Therefore, LBBB patterns, which all cluster on or adjacent to the septum, have a higher predictive accuracy (regardless of the presence of anterior versus

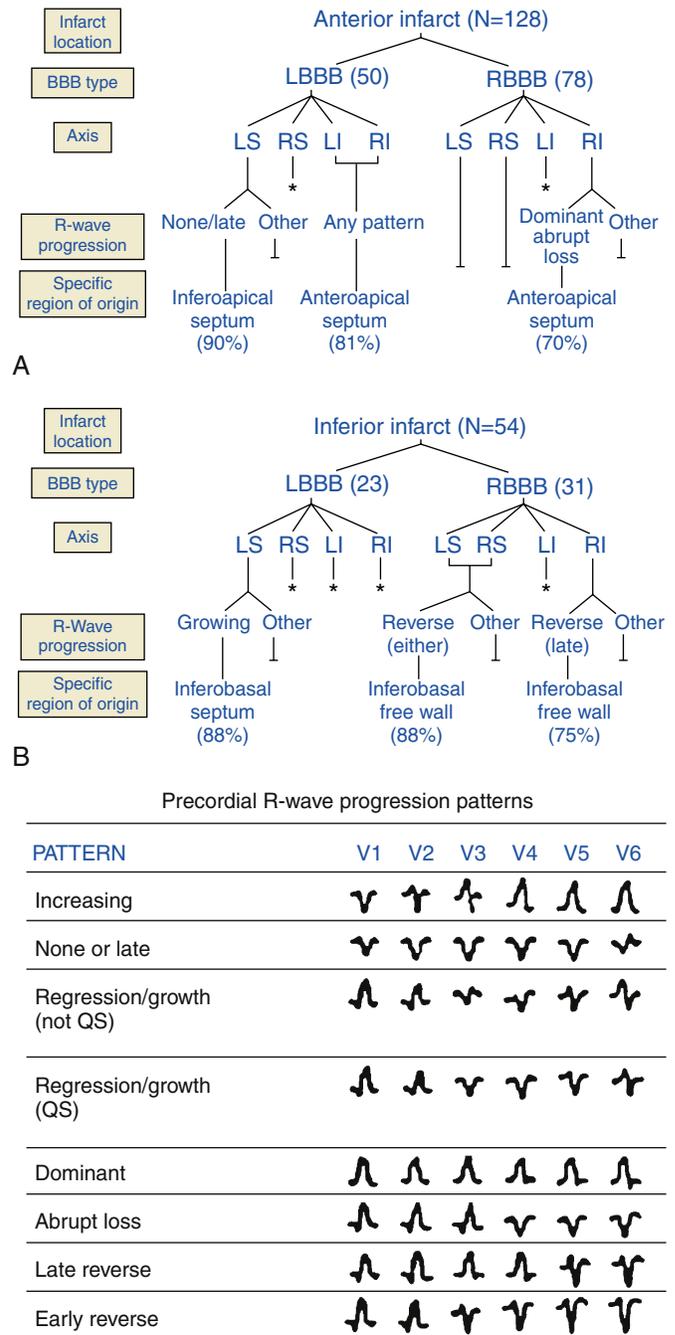

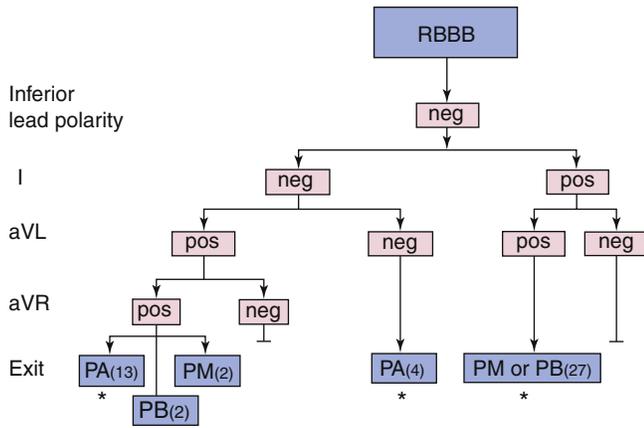

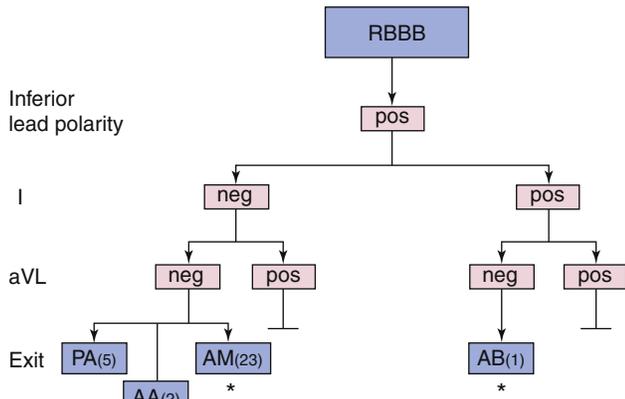

FIGURE 22-2 Algorithm correlating region of origin to 12-lead ECG of ventricular tachycardia (VT), derived from the retrospective analysis. **A**, Anterior infarct-associated VTs. **B**, Inferior infarct-associated VTs. The first branch point is bundle branch block (BBB) configuration, followed by QRS axis and R wave progression. When possible, a specific region of origin is indicated. The number of VTs in each group is indicated in parentheses. A vertical line ending in an asterisk indicates inadequate numbers of VT for analysis; a vertical line terminating in a horizontal bar indicates adequate numbers for analysis, but no specific patterns. **C**, Precordial R wave progression patterns. Eight different patterns are listed, with the number of examples in parentheses. Typical R wave patterns for V₁ through V₆ are shown. I = inferior; L = left; LBBB = left bundle branch block; R = right; RBBB = right bundle branch block; S = superior. (From Miller JM, Marchlinski FE, Buxton AE, Josephson ME: Relationship between the 12-lead electrocardiogram during ventricular tachycardia and endocardial site of origin in patients with coronary artery disease, *Circulation* 77:759, 1988.)

A vertical line ending in a horizontal bar indicates that no VT with this ECG pattern was identified. Exit sites with a positive predictive value (PPV) of at least 70% are marked by asterisks. The numbers of VTs for each ECG pattern and exit site region identified in retrospective analysis are shown in parentheses. AA = anteroapical; AB = anterobasal; AM = midanterior; PA = posteroapical; PB = posterobasal; PM = midposterior. (From Segal OR, Chow AW, Wong T, et al: A novel algorithm for determining endocardial VT exit site from 12-lead surface ECG characteristics in human, infarct-related ventricular tachycardia, *J Cardiovasc Electrophysiol* 18:161, 2007.)

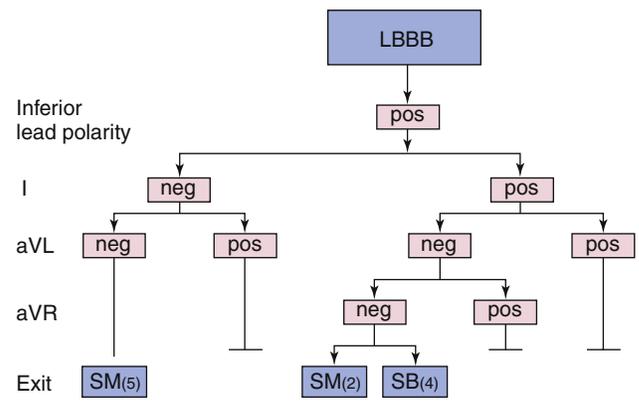

inferior MI) than RBBB patterns, which could be septal or located on the free wall. Most VTs with RBBB patterns associated with inferior MI are clustered in a small region, but are more widely disparate with anterior MI (Figs. 22-5 and 22-6).^{3,32}

CONCORDANCE. VTs with positive concordance in all precordial leads arise only at the base of the heart (LV outflow region [LVOT], along the mitral or aortic valves, or in the basal septum), whereas negative concordance is seen only in VTs originating near the apical septum, most commonly seen with anteroseptal MI.³

PRESENCE OF QS COMPLEXES. The presence of a QS complex in any lead suggests that the wavefront is propagating away from that site. Therefore, QS complexes in the inferior leads suggest that the activation is originating in the inferior wall, whereas QS complexes in the precordial leads suggest activation moving away from the anterior wall. QS complexes in leads V₂ to V₄ suggest anterior wall origin, QS complexes in leads V₃ to V₅ suggest apical location, and QS complexes in leads V₅ and V₆ suggest lateral wall. The presence of Q waves in leads I, V₁, V₂, and V₆ is seen in VTs with an RBBB pattern originating near the apex, but not those originating in the inferobasal parts of the LV. R waves in leads I, V₁, V₂, and V₆ are specific for VTs

A vertical line ending in a horizontal bar indicates that no VTs with this ECG pattern were identified. SA = anteroseptal; SB = basal septum; SM = midseptum. Exit sites with a positive predictive value (PPV) of at least 70% are marked by asterisks. Numbers of VTs for each ECG pattern and exit site region identified in retrospective analysis are shown in parentheses. (From Segal OR, Chow AW, Wong T, et al: A novel algorithm for determining endocardial VT exit site from 12-lead surface ECG characteristics in human, infarct-related ventricular tachycardia, *J Cardiovasc Electrophysiol* 18:161, 2007.)

with an RBBB or LBBB pattern of posterior origin. Additionally, the presence of Q waves in leads I and V₆ in VTs with an LBBB pattern is seen with apical septal locations, whereas the presence of R waves in leads I and V₆ is associated with inferobasal septal locations.^{3,32}

INFERIOR MYOCARDIAL INFARCTION VENTRICULAR TACHYCARDIAS

With inferior MI, most VTs have basal exit sites and thus have relatively preserved precordial R waves (that usually are present in leads V₂ to V₄ with the persistence of an r or R wave through lead V₆), although apical exit sites also occur (Fig. 22-7).¹⁶ In VTs with RBBB, the R waves can persist across the precordium (positive concordance). When the VT originates near the posterior basal septum and when it arises more laterally (or posteriorly), there can be a decrease in the R wave amplitude across the precordium because the infarct can extend to the posterolateral areas (see Fig. 22-5).³⁴

Left axis deviation is seen in inferior MI VTs when the exit site is near the septum. The more the VT moves from the midline toward

the lateral (i.e., posterior) wall, the more right or superior the axis will become. VTs with LBBB (especially when left axis deviation is present) have a characteristic location at the inferobasal septum (see Fig. 22-6). As the VT axis shifts to a more normal axis, the exit site moves higher up along the septum. Rarely, inferior MI VTs can have exit sites as high as the aortic valve along the septum. Very rarely, the VT can only be ablated from the RV.

The mitral isthmus (between the mitral annulus and inferior infarct scar) contains a critical region of slow conduction in some patients with VT following inferior MI, providing a vulnerable and anatomically localized target for catheter ablation. This critical zone of slow conduction is activated parallel to the mitral annulus in either direction, resulting in two distinct QRS configurations not seen in VTs arising from other sites: LBBB pattern (rS in lead V_1 , R

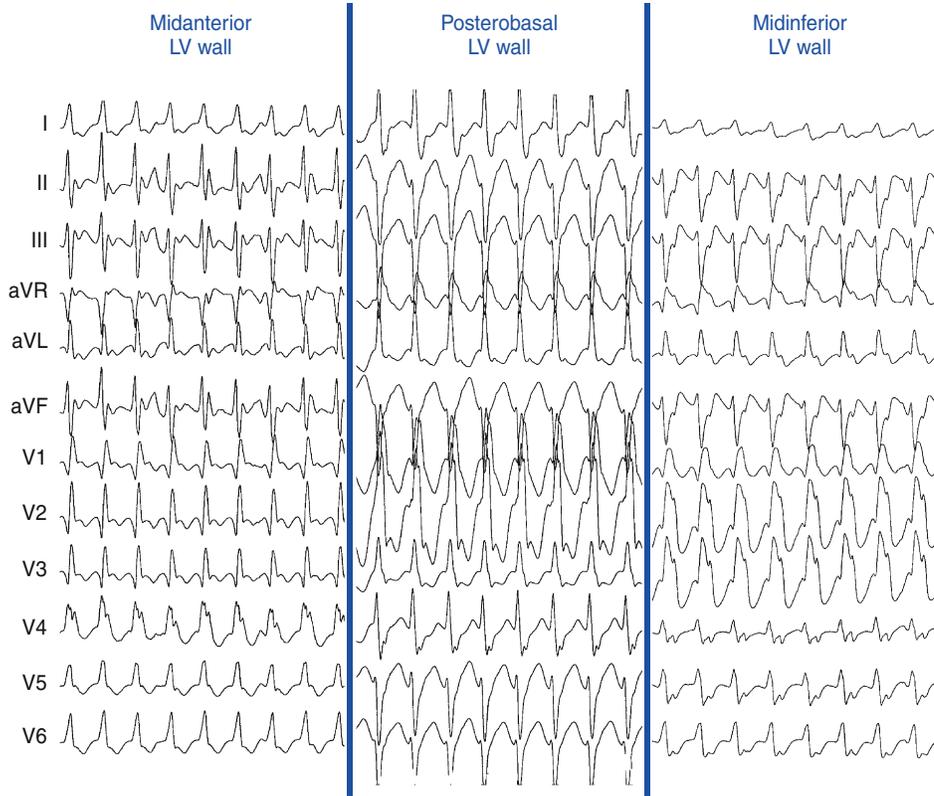

FIGURE 22-5 Surface ECG of sustained monomorphic ventricular tachycardia (SMVT) with right bundle branch block (RBBB) pattern. **Left panel**, Ventricular tachycardia (VT) with RBBB pattern and normal axis in a patient with prior anterior myocardial infarction (MI). The site of origin was mapped to the midanterior left ventricular (LV) wall. Note the qR pattern in leads V_1 to V_3 , consistent with anterior infarct. **Middle panel**, VT with RBBB pattern and left superior axis in a patient with prior inferior MI. The site of origin was mapped to the posterobasal LV free wall. **Right panel**, VT with left bundle branch block (LBBB) pattern and left superior axis in a patient with prior inferior MI. The site of origin was mapped to the midinferior LV wall.

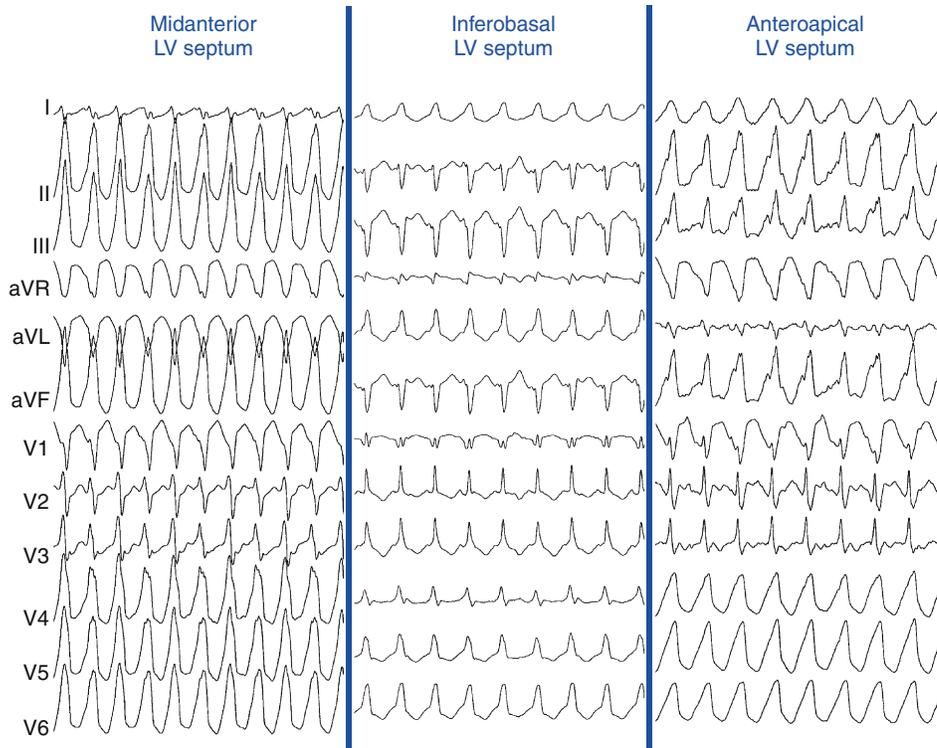

FIGURE 22-6 Surface ECG of sustained monomorphic ventricular tachycardia (SMVT) with left bundle branch block (LBBB) pattern. **Left panel**, Ventricular tachycardia (VT) with LBBB pattern and right inferior axis in a patient with prior anterior myocardial infarction (MI). The site of origin was mapped to the midanterior left ventricular (LV) septum. **Middle panel**, VT with LBBB pattern and left superior axis in a patient with prior inferior MI. The site of origin was mapped to the inferobasal LV septum. **Right panel**, VT with LBBB pattern and left inferior axis in a patient with prior anterior MI. The site of origin was mapped to the anteroapical LV septum.

in lead V₆) with left superior axis, and RBBB pattern (R in lead V₁, QS in lead V₆) and right superior axis.^{3,32}

ANTERIOR MYOCARDIAL INFARCTION VENTRICULAR TACHYCARDIAS

Anterior MIs are usually associated with more extensive myocardial damage. Therefore, the accuracy of the ECG in localizing the origin of VTs associated with anterior MI is less than in those with inferior MI.³⁴

VTs with LBBB and left axis deviation usually originate from the inferoapical septum, but occasionally there is a discrepancy, with the exit site being more superior than expected for the QRS axis. LBBB VTs associated with anteroseptal MI can present with QS complexes across the precordium (i.e., negative concordance), and they are always associated with a Q wave in leads I and aVL. If an R wave is seen in lead V₁ along with the Q wave in lead aVL, the location of the exit site is more posterior on the septum, closer to the middle third (see Fig. 22-6). VTs with LBBB and right inferior axis arise on the upper half of the mid- or apical septum but occasionally can be off the septum (see Fig. 22-7).^{16,32}

RBBB VTs originating from the apex usually have a right and superior axis. Lead V₁ usually has a qR or, occasionally, a monophasic R wave, but there is almost always a QS or QR complex in leads V₂, V₃, and/or V₄. More commonly, when there are QS complexes in leads I, II, and III, there are also QS complexes across the precordium from lead V₂ through V₆. VTs with RBBB and right inferior axis arise on the septum but also can be seen across the apex superiorly on the free wall. In both cases, there is a negative deflection in leads aVR and aVL. VTs with LBBB or RBBB patterns and a marked inferior right axis arise superiorly on what usually is the edge of an anterior aneurysm.³²

The most difficult VTs to localize are VTs with RBBB and right superior axis associated with anterior MI. QS complexes in the lateral leads (V₄ to V₆) reflect an origin near the apex, regardless of whether it is septal or lateral. It is almost impossible to distinguish VTs arising from the apical septum and the apical free wall based on the ECG alone. It is only when the VT location moves more

posterolaterally that a difference can be appreciated as the R wave in lead aVR becomes dominant over the R wave in lead aVF. This is usually associated with a large apical aneurysm, but occasionally can also be seen with a posterolateral MI.³²

HIGH POSTEROLATERAL MYOCARDIAL INFARCTION VENTRICULAR TACHYCARDIAS

VTs associated with high posterior MI (left circumflex artery territory) are characterized by a prominent R wave in leads V₁ to V₄ and right inferior axis.³²

Epicardial Ventricular Tachycardias

With all other factors being equal, the epicardial origin of ventricular activation widens the initial part of the QRS complex (pseudo-delta wave). When the initial activation starts in the endocardium, rapid depolarization of the ventricles occurs along the specialized conducting system, resulting in a relatively narrower QRS on the surface ECG and the absence of a pseudo-delta wave. In contrast, when the initial ventricular activation occurs in the epicardium, the intramyocardial delay of conduction produces a slurred initial part of the QRS complex.

Several ECG findings suggest an epicardial origin of the LV VT with an RBBB pattern, and all generally rely on the late engagement of rapidly conducting His-Purkinje fibers by exits on the epicardium: (1) a pseudo-delta wave (measured from the earliest ventricular activation to the earliest fast deflection in any precordial lead) of 34 milliseconds or more has a sensitivity of 83% and a specificity of 95%; (2) a long R-wave peak time in lead V₂ (i.e., an interval from the beginning of the QRS complex to the time of initial downstroke of the R wave after it has peaked [previously known as the *intrinsicoid deflection*]) of at least 85 milliseconds has a sensitivity of 87% and a specificity of 90%; (3) a shortest RS complex duration (measured from the earliest ventricular activation to the nadir of the first S wave in any precordial lead) of 121 milliseconds or more has a sensitivity of 76% and a specificity of 85%; and (4) a QRS duration of more than

200 milliseconds (Fig. 22-8). These parameters were assessed in patients without MI, however.³⁴

Electrophysiological Testing

Induction of Tachycardia

RECOMMENDED STIMULATION PROTOCOLS

For evaluation of ventricular arrhythmias, multipolar catheters are typically positioned in the high RA, the HB position, and the RV apex. Recording the His potential during VT is important to differential BBR VT from myocardial VT. The most commonly used stimulation protocol applies pacing output at twice the diastolic threshold current and a pulse width of 1 to 2 milliseconds. Single VESs during NSR and at pacing drive CLs of 600 and 400 milliseconds are delivered, first from the RV apex and then from the RV outflow tract (RVOT). The prematurity of extrastimuli is increased until refractoriness or induction of sustained VT is achieved. Long-short cycle sequences may be tested. If these measures fail to induce VT, double and then triple VESs are used in the same manner. Because a VES with a very short coupling interval is more likely to induce VF as opposed to monomorphic VT, it may be reasonable to limit the prematurity of the VESs to a minimum of 180 milliseconds when studying patients for whom only inducible SMVT would be considered a positive endpoint. If VT still cannot be induced, rapid ventricular pacing is started at a CL of 400 milliseconds, gradually decreasing the pacing CL until 1:1 ventricular capture is lost or a pacing CL of 220 milliseconds is reached. Repeating the protocol at other pacing drive CLs, at other RV or LV stimulation sites, and/or after administration of isoproterenol or procainamide is then attempted.^{3,19}

An alternative stimulation protocol uses a shorter pacing drive CL (350 milliseconds) and a reverse order of the pacing drive CL (i.e., starting the stimulation protocol at 350, then 400, and then 600 milliseconds). This *accelerated protocol* has been shown in one report to reduce the number of protocol steps and duration of time required to induce monomorphic VT by an average of more than 50% and improves the specificity of programmed electrical stimulation without impairing the yield of monomorphic VT.

Another proposed stimulation protocol exclusively uses four VESs; at no point are one, two, or three VESs used. At each basic drive train pacing CL, programmed electrical stimulation is initiated with coupling intervals of 290, 280, 270, and 260 milliseconds for the first through fourth VES. The coupling intervals of the VESs are then shortened simultaneously in 10-millisecond steps until S_2 (the first VES) falls during the refractory period or a 200-millisecond coupling interval is reached. If S_2 is refractory at 290 milliseconds, all extrastimuli are lengthened by 30 milliseconds, and programmed electrical stimulation is then initiated. This *six-step protocol* was tested in a single report and was shown to improve the specificity and efficiency of programmed electrical stimulation

without compromising the yield of inducibility of monomorphic VT in patients with coronary artery disease.

NUMBER OF VENTRICULAR EXTRASTIMULI. The sensitivity of programmed electrical stimulation to initiate SMVT increases with increasing the number of VESs used, but at the expense of decreasing specificity. The use of three VESs seems optimal because it offers the highest sensitivity associated with an acceptable specificity. More aggressive stimulation is likely to produce nonspecific responses, usually polymorphic VT or VF.

In the majority of patients with coronary artery disease undergoing EP testing for risk stratification for SCD, triple VESs are typically required for VT induction. Sustained VT induced with triple VESs is usually faster and more likely to result in hemodynamic compromise. Despite these differences, long-term prognosis does not appear to be affected by the mode of induction. In a recent report, there was no difference in the incidence of arrhythmic death or all-cause mortality at 2 years between patients induced with burst pacing, one or two VESs, and those induced with three VESs.²¹

When SMVT is studied, the use of four VESs may be considered. However, when a patient resuscitated from cardiac arrest is studied, four VESs should not be used because the likelihood of inducing a nonspecific response (polymorphic VT/VF) is far higher than that of inducing SMVT (10:1). Triple VESs are required to induce SMVT in 20% to 40% of patients presenting with SMVT and in 40% to 60% of patients presenting with cardiac arrest.³

PACING DRIVE CYCLE LENGTH. The use of at least two pacing drive CLs (typically 600 and 400 milliseconds) is required to enhance the sensitivity of induction of SMVT in patients presenting with sustained VT of any morphology or those with cardiac arrest. VES at shorter or longer CLs or even in NSR may be necessary to initiate VT in some patients. Abrupt changes in CL can also facilitate VT induction. The CL used can also influence the number and prematurity of VESs required to initiate VT. Rapid ventricular pacing has a low yield in VT initiation.³

In 5% of patients with SMVT, and in less than 5% of those with cardiac arrest, VT can be initiated only with VES during NSR. On the other hand, most VTs that can be induced during NSR can also be induced during ventricular pacing or VESs delivered after a pacing drive.

SITE OF VENTRICULAR STIMULATION. In contrast to automatic or triggered activity VT, in which the stimulation site has no effect on VT inducibility, reentrant VT can demonstrate absolute or relative site specificity for initiation. In the majority of cases, development of functional unidirectional block is a prerequisite for initiation of macroreentrant VT; however, during VES, functional block may not always develop despite short coupling intervals, suggesting that formation of functional block is dependent on direction of activation following stimulation.⁶ Therefore, the use of at least two sites of stimulation enhances the ability to induce VT.

If triple VESs are delivered only from the RV apex, 10% to 20% of patients will require the use of a second RV or LV pacing site for initiation of SMVT (less than 5% require an LV site). If double

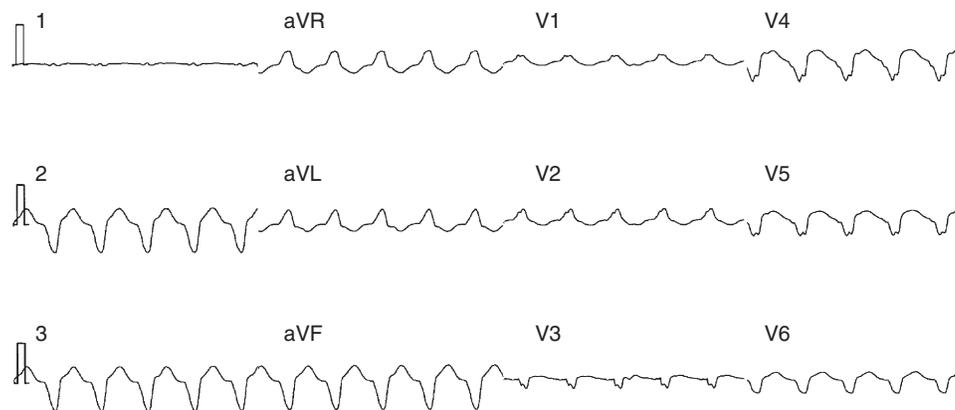

FIGURE 22-8 ECG of post-myocardial infarction ventricular tachycardia that required epicardial ablation. Note delayed QRS upstroke in V_2 and delayed S wave downstroke (pseudo-delta wave) and long RS interval in V_3 and V_4 .

VESs are used, 20% to 30% will require a second pacing site (10% require an LV site). Because the number of VESs required for initiation can differ depending on the site of stimulation, which occurs in approximately 20% of patients with SMVT, the site that allows the use of the fewest number of VESs is preferred to avoid nonspecific responses. Thus, it is preferable to stimulate from both the RV apex and the RVOT at each drive CL and with the number of VESs before proceeding to more aggressive stimulation.³

If stimulation from the RV apex and RVOT fails to initiate VT, stimulation from the LV may be used. However, the yield is low (2% to 5%) for patients with SMVT and somewhat higher in patients with cardiac arrest.

Atrial extrastimulation (AES) can initiate VT in approximately 5% of patients with SMVT. Usually, those VTs can also be initiated by VES, are usually slower, and are reproducibly initiated over a broad zone of VES coupling intervals. Initiation with AES is more common in patients without coronary artery disease.

PACING CURRENT OUTPUT. Increasing the current (more than twice the diastolic threshold current or pulse width more than 2 milliseconds) produces only a small increase in sensitivity of initiating SMVT (more than 5%), but this is outweighed by a significant decrease in specificity and increase in the incidence of VF. The use of currents more than 5 mA is not recommended.³

ISOPROTERENOL. Isoproterenol has a low yield in facilitating induction in patients with coronary artery disease and SMVT and is more useful in initiation of exercise-related VTs or triggered activity outflow tract VTs.

REPRODUCIBILITY OF VENTRICULAR TACHYCARDIA INITIATION

More than 90% of patients with clinical SMVT will have inducible VT, regardless of the underlying pathology, with the exception of exercise-induced VT. Patients with cardiac arrest or nonsustained VT have a lower incidence of inducibility; inducibility is higher in patients with coronary artery disease.

SMVT can be reproducibly initiated from day to day and year to year, especially in patients with coronary artery disease. However, the exact mode of initiation is not necessarily reproducible. Once SMVT is initiated, it is easier to reinitiate by repeating the same stimulation protocol that was initially successful, either longitudinally (by repeating the entire protocol) or horizontally (by repeating each coupling interval).³

While reproducibility of sustained VT can be variable when comparing induction during the initial month post-MI with subsequent months, induction of any sustained VT in the more chronic phase of MI is highly reproducible over both short-term and extended time intervals. However, a change in the number of extrastimuli required for VT reinduction is reported in 30% to 70% of patients, and is more common as the time interval between studies increases. Similar inconsistencies are reported in the exact QRS morphology and CL of induced VTs during repeated testing. These data confirm that the substrate for chronic post-MI inducible VT per se can be highly stable for up to several years in the absence of major changes in clinical status. However, the mode of induction and VT characteristics demonstrate substantial variability; therefore, it is improbable that such features would predict long-term outcome.³⁵

RELATIONSHIP OF VENTRICULAR EXTRASTIMULUS COUPLING INTERVAL AND PACING CYCLE LENGTH TO THE ONSET OF VENTRICULAR TACHYCARDIA

Conduction delay is required for the initiation of reentrant rhythms; thus, an inverse relationship between the coupling interval of the VES initiating the VT or the pacing train CL and the interval from the VES to the first VT complex favors reentry. In contrast, a linear relationship of the pacing CL or VES coupling interval to the interval to the first VT complex and initial CL of the VT favors triggered activity. In reentrant VT, the initial CL reflects conduction through the VT circuit, which in the absence of exit block should

demonstrate the same or longer CL as the remaining VT cycles, depending on whether any conduction delay is produced in the circuit on initiation.³

ENDPOINTS OF PROGRAMMED ELECTRICAL STIMULATION

INDUCTION OF CLINICAL SUSTAINED MONOMORPHIC VENTRICULAR TACHYCARDIA. Induction of SMVT is very specific, especially with a VES coupling interval of more than 240 milliseconds, and only occurs in patients with spontaneous VT, cardiac arrest, or an arrhythmogenic substrate. In patients who had spontaneous VT prior to the EP study, the endpoint of programmed electrical stimulation should be induction of the clinical arrhythmia or the assumed arrhythmia. Clinical VT is defined as an inducible SMVT that matches the 12-lead ECG QRS morphology and approximate CL of the patient's documented, spontaneously occurring SMVT. Nonclinical VTs are defined as inducible SMVTs that were not previously known to have occurred spontaneously.²

INDUCTION OF MULTIPLE SUSTAINED MONOMORPHIC VENTRICULAR TACHYCARDIAS. The majority (85%) of patients with post-MI VT have more than one VT morphology. Even in patients presenting with a single SMVT, multiple distinct uniform VTs may be induced in the EP laboratory, especially during antiarrhythmic therapy. Multiple VT morphologies are defined as two or more inducible VTs having at least one of the following: (1) contralateral BBB patterns; (2) a frontal plane axis of 30 degrees or more divergent; (3) marked differences in individual ECG leads recorded from the same electrode locations; (4) a precordial transition zone in one or more leads or a different dominant deflection in more than one precordial lead; and/or (5) a different tachycardia CL (more than 100 milliseconds for VTs with a similar morphology). A change in VT morphology need not reflect a change in a reentrant circuit or site of impulse formation but may merely reflect a change in the overall pattern of ventricular activation. In some cases, pacing can reverse the direction of wavefront propagation within the same reentrant loop. Approximately 85% of multiple morphologically distinct SMVTs arise from the same region of the heart (i.e., have closely located exit sites or shared components of an isthmus or diastolic pathway).³

Multiple uniform VTs inducible in the EP laboratory are of clinical significance because the distinction between clinical and nonclinical is often uncertain. Clinically, the ECG of spontaneous VTs terminated by an ICD or emergency medical technicians is often not available. Even when available, differences in ECG lead placement, patient position, and antiarrhythmic drugs can influence the similarity between two episodes of VT that arise from the same circuit. Additionally, the presence of multiple VT morphologies might have been overlooked because of the lack of 12-lead ECGs obtained during multiple spontaneous episodes on a variety of different antiarrhythmic agents. The use of single-lead rhythm strips to record VT has been a major misleading factor suggesting that there is only one VT. The minimal number of ECG leads required to discern differences between different VT origins or circuits is not clear. The VT CL alone is influenced by antiarrhythmic drugs and can be similar for different VTs or may be different for VTs originating from the same region, and is therefore unreliable as a sole indicator of clinical VT. Of note, inducible VTs never seen spontaneously in the preablation state can occur spontaneously following ablation of the clinical VT.

Therefore, the term *clinical VT* should be reserved for induced VTs that are known to have the same 12-lead ECG QRS morphology and approximate CL as a spontaneous VT. Other VTs should be designated as *presumptive clinical* or *previously undocumented* VT morphology.²

INDUCTION OF POLYMORPHIC VENTRICULAR TACHYCARDIA OR VENTRICULAR FIBRILLATION. When EP testing is performed in patients presenting with SMVT, polymorphic VT and VF must be considered as nonspecific responses. Both sustained and nonsustained polymorphic VT and VF can be induced, even

in normal subjects. In general, induction of VF requires multiple VESs delivered at shorter coupling intervals (usually less than 180 milliseconds) than induction of SMVT. On the other hand, induction of polymorphic VT or VF in a patient who presents with cardiac arrest can have a different implication. Because cardiac arrest can be initiated by a polymorphic VT, the induction of polymorphic VT in this patient population can be significant. Therefore, although doubt will always exist, reproducible polymorphic VT induction is treated as a possible indicator of the clinical arrhythmia. Features that suggest that a polymorphic VT can be mechanically meaningful are reproducible initiation of the same polymorphic VT template, especially from different stimulation sites; inducibility with relatively mild stimulation (single or double VESs); and transformation of the polymorphic VT to SMVT by procainamide. The induction of any arrhythmia (SMVT, polymorphic VT, or VF) in the setting of a recent MI (less than 1 month) may not have clinical significance.³

INDUCTION OF VERY FAST VENTRICULAR TACHYCARDIA. The induction of VT with a CL longer than 230 milliseconds is predictive of recurrent ventricular arrhythmia in high-risk patients, such as those with prior MI and reduced LVEF ($\leq 40\%$), ischemic cardiomyopathy presenting with syncope, resuscitated cardiac arrest, or asymptomatic nonsustained VT. In up to 20% of patients undergoing EP testing, VT with a CL ranging from 200 to 250 milliseconds may be inducible. Although a limited number of studies have closely and specifically examined long-term outcomes of this group of patients, and although previous large ICD trials, such as MADIT and MUSTT, excluded such patients if this arrhythmia was induced by more than two VESs, there is a growing body of evidence that this induced arrhythmia is of sufficient clinical importance that it should no longer be considered a nonspecific finding of EP testing, as it poses a significant risk of spontaneous ventricular arrhythmia or SCD over long-term follow-up. This risk appears equivalent to that of patients with inducible VT with a CL of 251 to 320 milliseconds, and markedly worse than that of patients who are noninducible, have inducible VF, or ventricular flutter (CL < 200 milliseconds). These findings seem to be consistent regardless of the mode of induction of VT (with two or fewer, three or fewer, or four extrastimuli), or measured LVEF ($\leq 30\%$ or between 31% and 40%).³⁵

Tachycardia Features

HIS BUNDLE ACTIVATION

NO VISIBLE HIS POTENTIAL DURING VENTRICULAR TACHYCARDIA. The His potential cannot be observed during VT in many patients, likely because the retrograde His potential is masked by ventricular activation or because of suboptimal catheter position. A proper HB catheter position can be verified by observation of the immediate appearance of the His potential on termination of the VT, the disappearance of the His potential on initiation of VT, or the sudden appearance of the His potential when spontaneous or induced supraventricular beats capture the HB (with or without ventricular capture) during VT. Additionally, when complete ventricular–His bundle (VH) block is present, dissociated His potentials will be observed.³

VISIBLE HIS POTENTIAL DURING VENTRICULAR TACHYCARDIA. His potentials can be recorded during VT in approximately 80% of patients. When the His potential is visible during VT, it is often difficult to determine whether the recorded His potential is anterograde or retrograde, and whether an apparent His potential is actually a right bundle branch (RB) potential. Recording the RB or left bundle branch (LB) potentials to demonstrate that their activation precedes HB activation during VT, and HB pacing producing a longer HV interval than the one noted during VT, usually helps clarify the situation.³

In patients with coronary artery disease, the relative timing of the retrograde His potential in the QRS depends on how quickly the His–Purkinje system (HPS) is engaged and how slowly the impulse reaches the ventricle to produce the QRS. Thus, depending on the

relative conduction time up the HPS versus through the slowly conducting muscle to give rise to the QRS, the His potential can occur before, during, or after the QRS. The His potential can occasionally occur before ventricular activation (with a His bundle–ventricular [HV] interval during VT shorter than that during NSR; Fig. 22-9) and can also occur just after the onset of ventricular activation (with a VH interval; Fig. 22-10). The occurrence of an HV interval (i.e., with the His potential preceding the QRS onset) shorter than that during NSR (in the absence of preexcitation) or a VH interval (i.e., with the His potential following the QRS onset) implies the presence of retrograde HB activation; it further implies that retrograde conduction from the exit of VT (defined by the onset of the QRS) to the HB is less than the anterograde conduction time over the HPS to activate the ventricle.¹ Engagement of the HPS, when present, can allow for more rapid activation of the myocardium, which in turn results in a narrower QRS. Some have suggested that the site of origin of such VTs is within the HPS (i.e., fascicular VTs), although proof that such VTs originate from the fascicles and differ from other forms of VT is often lacking. The retrograde His potential appears to reflect passive activation of the HPS, rather than involvement of the HPS in the reentrant circuit. This concept is supported by several observations. HB deflections can appear intermittently (typically in a 2:1 or 3:2 fashion, and occasionally in a Wenckebach periodicity), and changes in the VH interval can occur without changes in the tachycardia

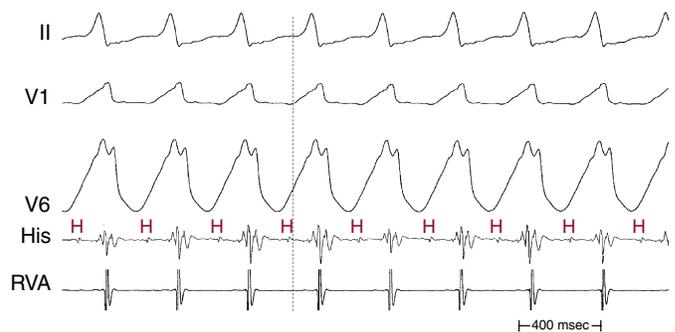

FIGURE 22-9 Ventricular tachycardia with short constant His bundle (HB)–ventricular (HV) interval, consistent with early retrograde activation of the HB.

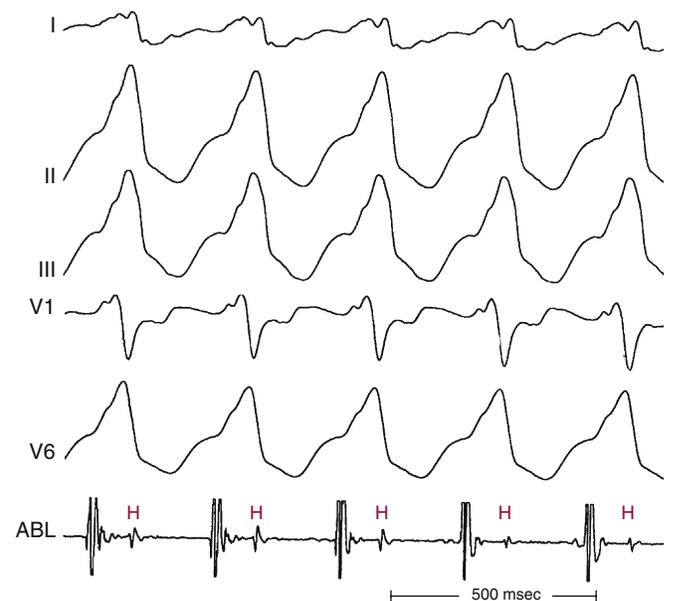

FIGURE 22-10 Ventricular tachycardia with a constant ventricular–His bundle (VH) interval, consistent with retrograde activation of the His bundle (HB). HB activation is recorded by the ablation catheter positioned in the left ventricular outflow tract.

CL (Fig. 22-11). In fact, marked changes in the tachycardia CL can be present with no changes in the VH interval. Furthermore, AES or atrial pacing can result in anterograde capture of the HB in the presence or absence of ventricular capture or fusion beats. Such an event, linking atrial activation to the HB deflection, proves that HB deflections are caused by anterograde activation and are unrelated to maintenance of the VT in the vast majority of cases.³

The mere presence of a His potential before the QRS with a normal HV interval is not absolutely reliable evidence that the tachycardia is a supraventricular tachycardia (SVT). The HV interval during VT is usually less than that during NSR; hence, if infranodal conduction delay is present during NSR, the VT can exist in the presence of an apparently normal HV interval (i.e., 35 to 55 milliseconds), but will be less than that during NSR. In post-MI VT, because ventricular activation is occurring in diastole (albeit slow enough not to be apparent on the surface ECG), the HPS could be activated during this time, giving rise to a short or possibly normal HV interval during the VT. The time to conduct retrogradely to the HB can theoretically be less than the time required to exit from the VT circuit and produce the onset of the QRS, thereby producing an HV interval. Such VTs, which are rare, have a narrow QRS. BBR VT can also give rise to an HV interval that is longer than that during NSR.

For wide complex tachycardias with the His potential preceding the QRS, an HV interval that is shorter during tachycardia than during NSR suggests VT or preexcited SVT (see Fig. 18-3), whereas an HV interval during tachycardia that is equal to or longer than that during NSR suggests SVT with aberrancy (see Fig. 18-24), BBR VT (see Fig. 26-3), or, rarely, other VTs. A changing AH interval, failure to observe anterograde His potential during VT with AV dissociation, or both suggests the presence of retrograde conduction with concealment in the AVN.

RIGHT VENTRICULAR APICAL LOCAL ACTIVATION TIME

In the setting of apical MI, VT with an RBBB pattern and R/S ratio in lead V₁ more than 1 is common, but lateral versus septal surface ECG QRS morphologies significantly overlap, with variable early R wave progression and a similar frontal plane axis. Assessing the activation time to a fixed reference endocardial recording at the RV apex can help regionalize a septal versus lateral origin for such VTs. For RBBB-type VT in the setting of an apical infarct, the QRS-to-RV apical activation time is consistently less than 100 milliseconds for an apical LV septal origin and more than 125 milliseconds for a lateral apical origin. The same values for the QRS-to-RV apical activation time will also help identify a septal versus lateral wall origin in the setting of prior nonapical infarcts.

Diagnostic Maneuvers during Tachycardia

The response of VT to programmed stimulation can be studied only for SMVT. Nonsustained VT is too short and unpredictable in duration to allow reliable evaluation. Polymorphic VT is invariably

associated with rapid hemodynamic collapse. Also, SMVT must be well tolerated (tachycardia CL usually longer than 280 milliseconds) and must have a stable CL to evaluate the response to stimulation. Fast, unstable SMVT usually can be slowed by antiarrhythmic drugs (e.g., procainamide) to permit evaluation by programmed stimulation.

VENTRICULAR EXTRASTIMULATION DURING VENTRICULAR TACHYCARDIA

Initially, a single VES is delivered at a coupling interval 10 to 20 milliseconds shorter than the tachycardia CL. The coupling interval is then gradually decreased by 5- to 10-millisecond decrements, until the local effective refractory period (ERP) is reached. The RV apex is used as the initial site of stimulation. Stimulation from other sites (RVOT and LV) also can be used to gain information regarding the site specificity of a given response. The return CL is analyzed to evaluate whether the VES has influenced the VT in terms of resetting, ability and pattern of termination, and site specificity for stimulation affecting the VT.³

If resetting or termination of VT is not observed with single VESs, stimulation is repeated using double VESs. The first VES is delivered at a coupling interval 20 milliseconds greater than the longest coupling interval at which a single VES resets the VT, or 20 milliseconds above the local ERP if a single VES fails to interact with the VT. The second VES is delivered at a coupling interval equal to the tachycardia CL, and then this coupling interval is progressively decreased in 5- to 10-millisecond decrements until the local ERP is reached. The use of double VESs allows comparable coupling intervals to reach the circuit at a greater relative degree of prematurity and ability to influence the VT than if the same coupling interval were used for a single VES. By this methodology, only a single VES interacts with the circuit; if the two VESs are delivered such that each VES interacts with the site of impulse formation, interpretation of the response would then be difficult. Thus, the first VES is delivered so that it would not interact with the circuit but would help the second VES to do so.³

The response of VT to VES is evaluated for manifest or concealed perpetuation, resetting with or without fusion, and termination.

MANIFEST PERPETUATION. Manifest perpetuation is said to be present when the VES fails to influence the VT, resulting in a full compensatory pause surrounding the VES. Factors influencing the ability of the VES to interact with the VT include tachycardia CL, local ventricular ERP at the stimulation site, and distance between the stimulation site and VT circuit. The tachycardia CL and duration of the excitable gap are the most important factors; the faster the VT (especially with CLs less than 300 milliseconds) and the shorter the duration of the reentrant circuit excitable gap, the more difficult it is for the VES to enter the VT circuit. Local ERP at the stimulation site and at the site of impulse formation also can limit the prematurity with which the VES can be introduced.

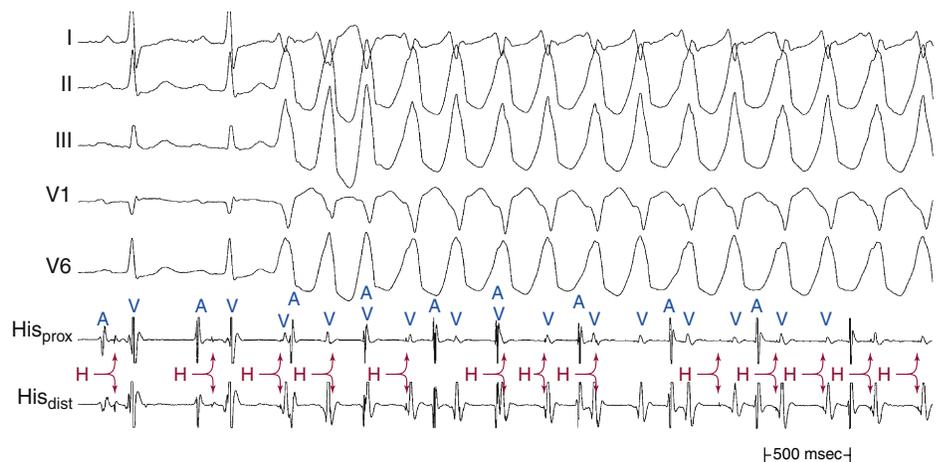

FIGURE 22-11 Ventricular tachycardia (VT) with variable relationship between ventricular and His bundle (HB) activation. HB catheter position is verified by observation of His potentials during normal sinus rhythm (NSR) at left. His potentials are observed intermittently during VT, with variable relationship to the QRS complexes, suggesting that the His-Purkinje system is not an essential part of the VT circuit.

Also, the farther the stimulation site is from the VT circuit, the more difficult it is for the VES to reach the circuit with adequate prematurity.

Failure of a VES to affect the VT circuit helps demonstrate the extent of the ventricular myocardium that is *not* required for the VT. Thus, the ability to capture significant portions of the ventricle by the VES without affecting the VT suggests that those captured areas are not required for the VT circuit. Similarly, intermittent capture of the HPS during VT suggests that it also is not necessary to maintain the VT, regardless of where the His potential is located relative to the QRS during the VT. In an analogous fashion, sinus captures (occurring spontaneously or in response to atrial stimulation) may occur without influencing the VT. The demonstration that neither the proximal HPS nor the majority of the ventricles are required to sustain the VT suggests that the VT circuit must occupy a relatively small and electrocardiographically silent area of the heart.³

CONCEALED PERPETUATION. Concealed perpetuation implies that the VES not only fails to influence the VT circuit, but also is followed by a pause that exceeds the tachycardia CL or that is occasionally interrupted by a sinus capture before the next VT beat. Such pauses are a form of functional exit block, because the VT impulse is unable to exit the circuit and depolarize the ventricles that have just been activated by the VES (Fig. 22-12).³

RESETTING. Resetting is the advancement (acceleration) of VT by a timed VES with a pause that is less than fully compensatory before resumption of the VT (Fig. 22-13). The first return VT complexes should have the same morphology and CL as the VT before the VES, regardless of whether a single or multiple extrastimuli are used.

The introduction of a single VES (S_2) during VT yields a return cycle (S_2-V_3) if the VT is not terminated. If S_2 does not affect the VT circuit, the coupling interval (V_1-S_2) plus the return cycle (S_2-V_3) will be equal to twice the VT cycle ($2 \times V_1-V_1$)—that is, a fully compensatory pause will occur (see Fig. 3-14). Resetting of VT occurs when a less than fully compensatory pause occurs (by at least 20 milliseconds). In this situation, $V_1-S_2 + S_2-V_3$ will be less than $2 \times V_1-V_1$, as measured from the surface ECG. Tachycardia CL oscillation should be taken into account when the return cycle is evaluated. To

account for any tachycardia CL oscillation, at least a 20-millisecond shortening of the return cycle is required to demonstrate resetting. When more than a single VES is used, the relative prematurity should be corrected by subtracting the coupling interval(s) from the spontaneous tachycardia cycles when the VESs are delivered.³

To reset a reentrant VT, the stimulated wavefront must reach the reentrant circuit, encounter excitable tissue within the circuit (i.e., enter the excitable gap of the reentrant circuit), collide in the antidromic (retrograde) direction with the previous tachycardia beat, and continue in the orthodromic (anterograde) direction to exit at an earlier than expected time and perpetuate the tachycardia (see Fig. 3-15). If the VES encounters a fully excitable tissue, which commonly occurs in reentrant tachycardias with large excitable gaps, the tachycardia is advanced (i.e., made to occur earlier) by the extent to which the stimulated wavefront arrives at the entrance site prematurely. If the tissue is partially excitable, which can occur in reentrant tachycardias with small or partially excitable gaps, or even in circuits with large excitable gaps when the VES is very premature, the stimulated wavefront will encounter some conduction delay in the orthodromic direction within the circuit. As a consequence, the degree of advancement of the next tachycardia beat will depend on both the degree of prematurity of the VES and the degree of slowing of its conduction within the circuit. Therefore, the reset tachycardia beat can be early, on time, or later than expected.

EFFECT OF NUMBER OF VENTRICULAR EXTRASTIMULI. Approximately 60% of VTs can be reset with a single VES and 85% with double VESs using RV pacing. All VTs reset by a single VES can also be reset by double VESs. Double VESs produce resetting over a longer range of coupling intervals and should therefore be used to characterize the excitable gap of the VT more fully. The resetting zone is approximately 70 milliseconds for most VTs, but is usually longer in those VTs reset by both single and double VESs than those requiring double VESs. Resetting zones in response to single VESs usually occupy 10% to 20% of the VT cycle. This is increased to approximately 25% in response to double VESs, but occasionally can exceed 30%, even in response to a single VES. VTs with LBBB morphology are less likely to require double VESs for resetting than VTs with RBBB morphology, regardless of the

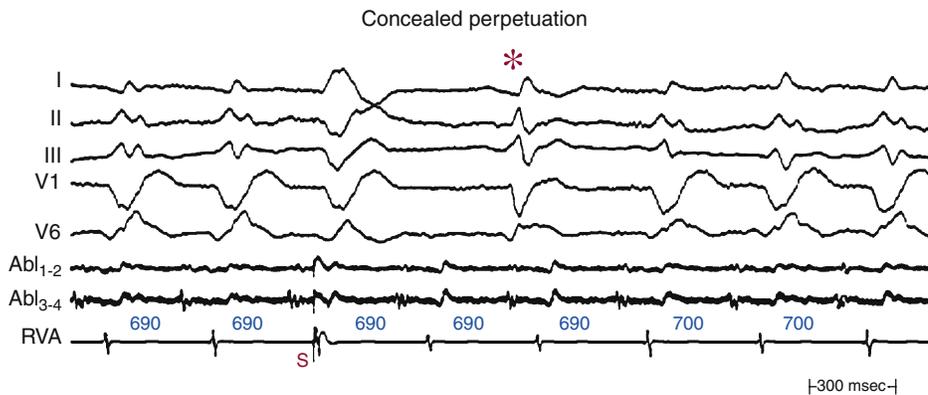

FIGURE 22-12 Concealed perpetuation in ventricular tachycardia (VT). For reentrant slow VT (cycle length = 690 milliseconds), a single ventricular extrastimulus (VES) is introduced (S) that seems to terminate the VT; a conducted sinus complex (*) follows and then VT recurs. However, inspection of the distal ablation (Abl_{1-2}) electrogram shows that VT never actually terminated, because the mid-diastolic electrogram continues unperturbed by the VES.

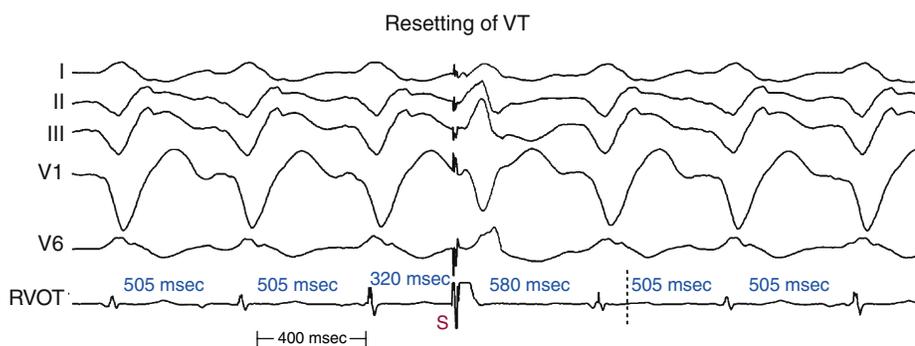

FIGURE 22-13 Resetting of ventricular tachycardia (VT). A single ventricular extrastimulus from the right ventricular outflow tract (RVOT) captures the ventricle during VT and causes the subsequent QRS to occur earlier than anticipated (dashed line), indicating resetting.

frontal plane axis, because VTs with LBBB arise in or adjacent to the septum, closer to the RV stimulation site.³

EFFECT OF SITE OF STIMULATION. Resetting does not require that the pacing site be located in the reentrant circuit. The closer the pacing site to the circuit, however, the less premature a single VES can be and reach the circuit without being extinguished by collision with the tachycardia wavefront emerging from the VT circuit. The longest coupling interval for a VES to be able to reset a reentrant tachycardia will depend on the tachycardia CL, the duration of the excitable gap of the tachycardia, local refractoriness at the pacing site, and conduction time from the stimulation site to the reentrant circuit. Neither local ventricular ERP nor local activation time influences the number of VESs required for resetting. Approximately 10% to 20% of VTs demonstrate site specificity in response to VES. Using double VESs reduces this site specificity. Approximately 70% of VTs can be reset with a single VES delivered to the RV apex or RVOT. Resetting of VT by a single VES can always be achieved from some site in the LV, even when resetting cannot be achieved from RV sites.³

RETURN CYCLE. The return cycle is the time interval from the resetting VES to the next excitation of the pacing site by the new orthodromic VT wavefront. This corresponds to the time required for the stimulated impulse to reach the circuit, conduct through the circuit, and exit. The noncompensatory pause following the VES and the return cycle are typically measured at the pacing site; however, they can also be measured to the onset of the surface ECG complex. Conduction time between the pacing site and the VT circuit may or may not be equal to that from the VT circuit to the pacing site. Differences in the VT circuit entrance and exit can result in differences in conduction time to and from the pacing site. These differences depend on the site of stimulation and VT site of origin. In VTs reset by both single and double VESs, the shortest return cycle seen by both methods is usually the same. If the return cycle is measured from the VES producing resetting to the onset of the first return VT QRS complex on the surface ECG, the shortest return cycle will be less than the tachycardia CL in more than 40% of VTs. Because stimulation is usually performed from the RV, conduction time into the VT circuit is incorporated into that measurement. If one considers conduction time between the pacing site and the circuit to be equal to that from the circuit to the pacing site (i.e., local activation time) and subtracts this value from the return cycle as measured to the surface ECG QRS, the resultant value for the return cycle is less than the tachycardia CL in 80% of VTs.³

RESETTING RESPONSE CURVES. Flat or mixed (flat, and then increasing) response curves characterize reentrant VTs. A flat curve is noted in approximately two-thirds of VTs, suggesting that a fully excitable gap is present. It also signifies anatomically separate entrance and exit sites of the circuit (see Fig. 3-16). In approximately 40% of VTs, the types of resetting curves can vary, depending on the site of ventricular stimulation. VESs from different pacing sites likely engage different sites in the VT circuit that are in different states of excitability or refractoriness and, therefore, result in different conduction velocities and resetting patterns.³

RESETTING WITH FUSION. The ability to reset a tachycardia after it has begun activating the myocardium (i.e., resetting with fusion) excludes automatic and triggered mechanisms and is diagnostic of reentry. Resetting with ECG fusion requires wide separation (in time, distance, or both) of entry and exit sites of the VT circuit, with the stimulus wavefront preferentially engaging the entrance. For resetting with fusion to occur, the premature paced wavefront has to reach the entrance of the reentrant circuit before it reaches the exit, and, at the same time, allow for the VT wavefront to exit the reentrant circuit, while the VT wavefront is unable to reach the entrance of the circuit before the paced wavefront (Fig. 22-14). Fusion of the stimulated impulse can be observed on the surface ECG and/or intracardiac recordings if the stimulated impulse is intermediate in morphology between a fully paced complex and the tachycardia complex. The ability to recognize

surface ECG fusion requires a significant mass of myocardium to be depolarized by both the VES and VT. If presystolic activity in the reentrant circuit is present before delivery of the VES that resets the VT, this must be considered to represent local fusion. Thus, a VES delivered after the onset of the tachycardia QRS on the surface ECG that enters and resets the VT circuit will always demonstrate local fusion. Resetting with local fusion and a totally paced surface QRS complex suggests that the reentrant circuit is physically small. The farther the stimulation site is from the reentrant circuit, the less likely resetting with ECG fusion will occur. In this setting, the VES should be delivered at a shorter coupling interval to enable the paced wavefront to reach the VT circuit with sufficient prematurity; hence, the stimulated impulse will reflect a purely paced QRS without ECG fusion.

Resetting with surface ECG fusion of the QRS during RV stimulation is observed in 60% of VTs, 40% of which are usually reset with a VES delivered after the onset of the VT QRS. VTs reset with fusion have a higher incidence of flat resetting curves, longer resetting zones, and significantly shorter return cycle, measured from the stimulus to the onset of the VT QRS, than VTs not reset with fusion. The return cycle corrected to the tachycardia CL is shorter with VTs reset with fusion (0.89 versus 1.12). In 80% of VTs reset with fusion, the return cycle is shorter than the tachycardia CL measured at the onset of the QRS (versus only 4% of VTs reset without fusion). The return cycle minus local activation time is equal to the time for the wavefront to traverse the distance from the entrance to the exit of the circuit. This interval is less than the tachycardia CL in 100% of VTs reset with fusion. These findings are consistent with widely separate entrance and exit sites of the VT circuit.³

TERMINATION. Termination of VT by a VES occurs when the VES collides with the preceding tachycardia impulse antidromically and blocks in the reentrant circuit orthodromically (see Fig. 3-15). This occurs when the VES enters the reentrant circuit early enough in the relative refractory period, because it fails to propagate in the anterograde direction and encounters absolutely refractory tissue. In the retrograde direction, it confronts increasingly recovered tissue and is able to propagate until it collides with the circulating wavefront and terminates the arrhythmia.

Termination of VT by a single VES is uncommon, occurring in 10% to 46% of VTs. The closer the stimulation site to the circuit, the more prematurely a VES can engage the VT circuit, because the refractoriness and conduction delay in intervening myocardial tissue are avoided. The success of termination, however, is directly related to the number of VESs used. Occasionally, when stimulation is performed at the critical isthmus of the VT circuit, termination can occur with a nonpropagated VES that fails to depolarize the bulk of the myocardium but is adequate to depolarize the isthmus and make it refractory to the incoming VT wavefront, resulting in termination of the VT (Fig. 22-15).³

VENTRICULAR PACING DURING VENTRICULAR TACHYCARDIA

Rapid ventricular pacing is performed during VT at a pacing CL 10 to 20 milliseconds shorter than the tachycardia CL. The pacing CL is then decreased in 10-millisecond decrements in a stepwise fashion until the VT is terminated. Pacing is stopped after each pacing CL and the response of VT to pacing is assessed. It is important to ensure that termination and reinitiation of the VT have not occurred during the pacing train, which would then affect the interpretation of the VT response.

It is critical to synchronize the initiation of pacing to the electrogram at the pacing site, because absence of synchronization will lead to a variable coupling interval of the first paced impulse to the VT. It is also important to perform overdrive ventricular pacing at each pacing CL for sufficiently long duration to allow the pacing drive to penetrate and affect the VT circuit. Pacing for a short period is a common mistake; it results in erroneous evaluation of the VT response. For VTs that are not stable enough to allow completion of an entire stimulation protocol,

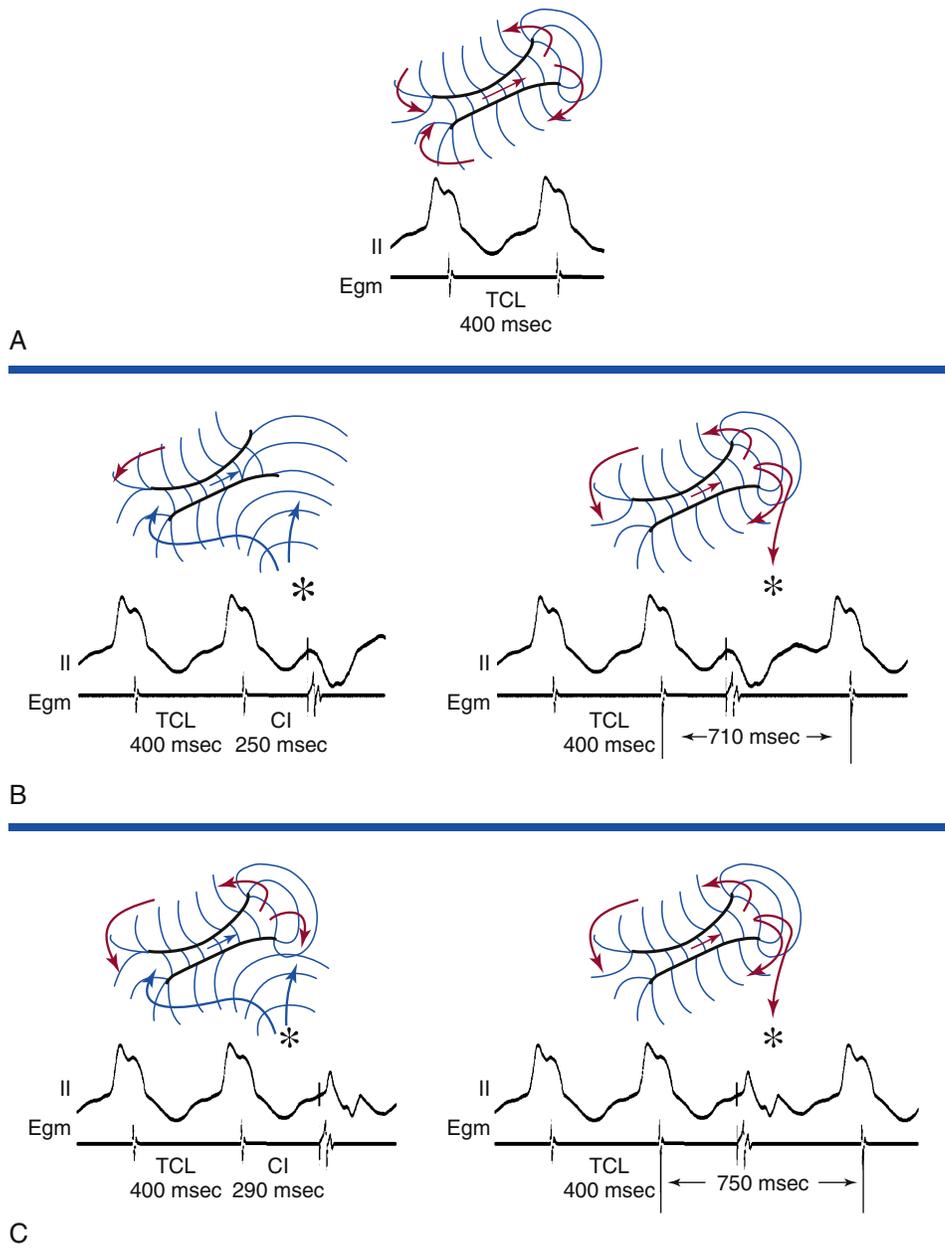

FIGURE 22-14 Schematic representation of the relationship of the return cycle during resetting of ventricular tachycardia (VT) to the absence or presence of surface ECG fusion. **A**, Stylized VT circuit, with direction of propagation as shown; electrogram is from a remote site. **B**, Single ventricular extrastimulus (VES) is introduced during VT at a coupling interval of 250 milliseconds. **Left panel**, The VES occurs early enough that the circuit's exit site is captured; thus, there is no fusion. Meanwhile, the paced wavefront (blue arrows) enters the entrance of the diastolic corridor before the approaching wavefront of the prior VT cycle (red arrow), allowing resetting. **Right panel**, Resetting is demonstrated in that the first VT cycle after the VES occurs at less than twice the tachycardia cycle length (TCL). **C**, A slightly later VES is introduced, with a paced wavefront (blue arrows) approaching the diastolic pathway's exit after the VT wavefront (red arrows) has already left; this results in ECG fusion. Meanwhile, as before, the paced wavefront arrives at the entrance site before the VT wavefront, allowing resetting. The **right panel** again shows resetting, this time with fusion. Asterisks = pacing site; CI = coupling interval; Egm = intracardiac electrogram.

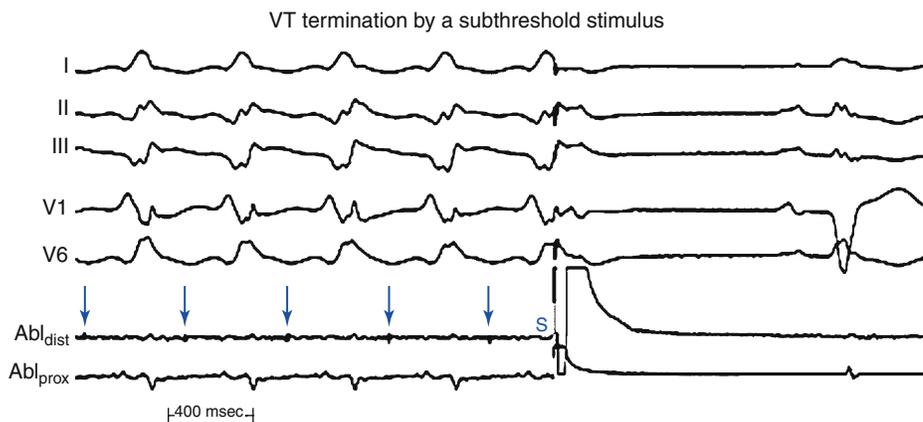

FIGURE 22-15 Ventricular tachycardia (VT) termination by a subthreshold ventricular extrastimulus (VES). VT is shown with the ablation electrode recording a small mid-diastolic potential (arrows). A single VES (S) is delivered during VT that does not appear to capture myocardium, yet terminates the tachycardia.

synchronized bursts of pacing at variable pacing CLs for a specified but variable number of beats, can usually be performed and can provide information about resetting or entrainment, overdrive suppression, and termination.

The response of VT to overdrive pacing is evaluated for overdrive suppression, acceleration, transformation into distinct uniform VT morphologies, entrainment, ability and pattern of termination, and site specificity for stimulation affecting the VT.

OVERDRIVE SUPPRESSION. Overdrive suppression analogous to that seen with automatic rhythms has not been observed in post-MI VTs, although prolonged return cycles can be seen at rapid pacing rates.

ACCELERATION. Acceleration by overdrive pacing refers to sustained shortening of the tachycardia CL following cessation of pacing. Acceleration occurs in 25% of VTs, and is more common with ventricular pacing than with VES (35% versus 5%). However, overdrive acceleration of VT analogous to that seen in triggered rhythms (i.e., linear relation of pacing CL to early acceleration of the tachycardia CL) is uncommon in post-MI VT. Because rapid ventricular pacing is usually required to terminate faster VTs, these VTs have a higher incidence of acceleration (40% of VTs with CL < 300 milliseconds with rapid ventricular pacing). Approximately 50% of the accelerated VTs can be terminated with even faster ventricular pacing; the other 50% (which can be polymorphic VT or ventricular flutter) require electrical cardioversion.

Acceleration is classified according to the morphology of the accelerated tachycardia: VT morphology identical to or different from the original VT, or polymorphic VT. An accelerated VT with a QRS morphology identical to the original VT suggests that the accelerated VT is using the same exit of the original VT circuit. The most likely mechanism underlying this form of VT acceleration is an area of block that determines the size of the reentrant circuit, which is determined to some extent by refractoriness. Rapid pacing can shorten the refractoriness in a proximal region of the arc of block, which would in turn shorten the length of the reentrant pathway. If the distal component of the arc of block remains unchanged, acceleration of the VT will occur with the same exit site and hence the same QRS morphology. Alternatively, rapid pacing can remove block in a shorter potential pathway, creating a smaller circuit.³

On the other hand, a VT morphology different from the original VT can be secondary to a change in the exit site from the same circuit, a reversal of the reentrant circuit, or the termination of the initial VT and initiation of a different VT elsewhere. Polymorphic VT with or without degeneration to VF can occur because of the inability of the myocardium to respond to the pacing CL with the development of changing activation wavefronts, leading to multiple reentrant wavelets that can degenerate into VF. There is no way to predict which type of acceleration will occur. However, in the presence of antiarrhythmic drugs, acceleration to different morphologically distinct VTs is common.

TRANSFORMATION. Transformation of the index VT into multiple distinct uniform VT morphologies can occur in response to overdrive pacing. It is not infrequent for stimulation during one VT to induce another VT of different morphology and CL, only to be changed to a third or fourth one by continued stimulation. The significance of all these multiple morphologically distinct VTs induced during overdrive pacing of the spontaneous VT is uncertain if they were never seen before spontaneously or induced by programmed stimulation. Usually, however, these VTs can also be induced by programmed electrical stimulation. Nevertheless, any VT (even if not seen before) that is uniform and has a CL longer than 250 milliseconds is clinically important. Those VTs may not have been observed previously because the original VT dominates because it is more readily inducible. Induction of rapid unstable VTs (CL < 250 milliseconds) in patients who presented with only stable VT does not have prognostic value.³

The ability to change from one VT to another with a different CL using single or double VESs is infrequent during triggered rhythms

(other than those because of digitalis), and is another observation that is most compatible with a reentrant mechanism.

ENTRAINMENT. Overdrive ventricular pacing at long CLs (i.e., 10 to 30 milliseconds shorter than the tachycardia CL) can almost always entrain reentrant VTs. The slower the pacing rate and the farther the pacing site from the reentrant circuit, the longer the pacing drive required to penetrate and entrain the tachycardia.

Following the first beat of the pacing train that penetrates and resets the reentrant circuit, the subsequent stimuli will interact with the reset circuit, which has an abbreviated excitable gap. Depending on the degree that the excitable gap is preexcited by that first resetting stimulus, subsequent stimuli fall on fully or partially excitable tissue. Entrainment is said to be present when two consecutive extrastimuli conduct orthodromically through the circuit with the same conduction time while colliding antidromically with the preceding paced wavefront. During entrainment, the paced stimuli enter the reentrant circuit, block with the existing tachycardia wavefront in the antidromic direction, and conduct through the circuit in the orthodromic direction to produce the return cycle beat.

ENTRAINMENT CRITERIA. Classic criteria for recognition of entrainment are the following: (1) fixed fusion of the paced complexes at any single pacing CL; (2) progressive fusion as the pacing CL decreases (i.e., the surface ECG progressively looks more like the purely paced QRS complex than a pure tachycardia QRS complex); and (3) resumption of the same VT morphology following pacing with a nonfused tachycardia QRS complex at a return cycle equal to the pacing CL (see Figs. 5-15 and 5-16). The return cycle is defined as the interval from the last paced beat to the first VT beat, and is measured from the surface QRS or RV electrograms.^{36,37}

ENTRAINMENT WITH FUSION. As noted, fusion of the stimulated impulse can be observed on the surface ECG, intracardiac recordings, or both. The stimulated impulse will have hybrid morphology between the fully paced QRS and the tachycardia QRS (Fig. 22-16; and see Figs. 5-15 and 5-16). The ability to demonstrate surface ECG fusion requires a significant mass of myocardium to be depolarized by both the extrastimulus and the tachycardia. The farther the stimulation site from the reentrant circuit, the less likely entrainment with ECG fusion will occur. Overdrive pacing of a tachycardia of any mechanism can result in a certain degree of fusion, especially when the pacing CL is only slightly shorter than the tachycardia CL. Such fusion, however, is unstable during the same pacing drive at the same pacing CL, because pacing stimuli fall on a progressively earlier portion of the tachycardia cycle, producing progressively less fusion and more fully paced morphology. Such phenomena should be distinguished from entrainment, and sometimes this requires pacing for long intervals to demonstrate variable degrees of fusion. Focal tachycardias (automatic, triggered activity, or microreentrant) cannot manifest fixed or progressive fusion during overdrive pacing (Fig. 22-17). Moreover, overdrive pacing frequently results in suppression (automatic) or acceleration (triggered activity) of focal VTs rather than resumption of the original tachycardia with an unchanged tachycardia CL.^{36,37}

ENTRAINMENT WITH MANIFEST FUSION. Entrainment of reentrant tachycardias commonly produces manifest fusion that is stable (fixed) during the pacing drive at a given pacing CL; repeated entrainment at pacing CLs progressively shorter than the tachycardia CL results in different degrees of QRS fusion, with the resultant QRS configuration looking more like a fully paced configuration (see Figs. 5-15 and 5-16).

ENTRAINMENT WITH INAPPARENT FUSION. Entrainment with inapparent fusion (also referred to as local or intracardiac fusion) is said to be present when a fully paced QRS morphology (with no ECG fusion) is observed during entrainment, even when the tachycardia impulse exits the reentrant circuit (orthodromic activation of the presystolic electrogram is present). In this setting, fusion is limited to a small area and does not produce surface ECG fusion, and only intracardiac (local) fusion can be recognized (see Fig. 5-18). Local fusion can only occur when the presystolic electrogram

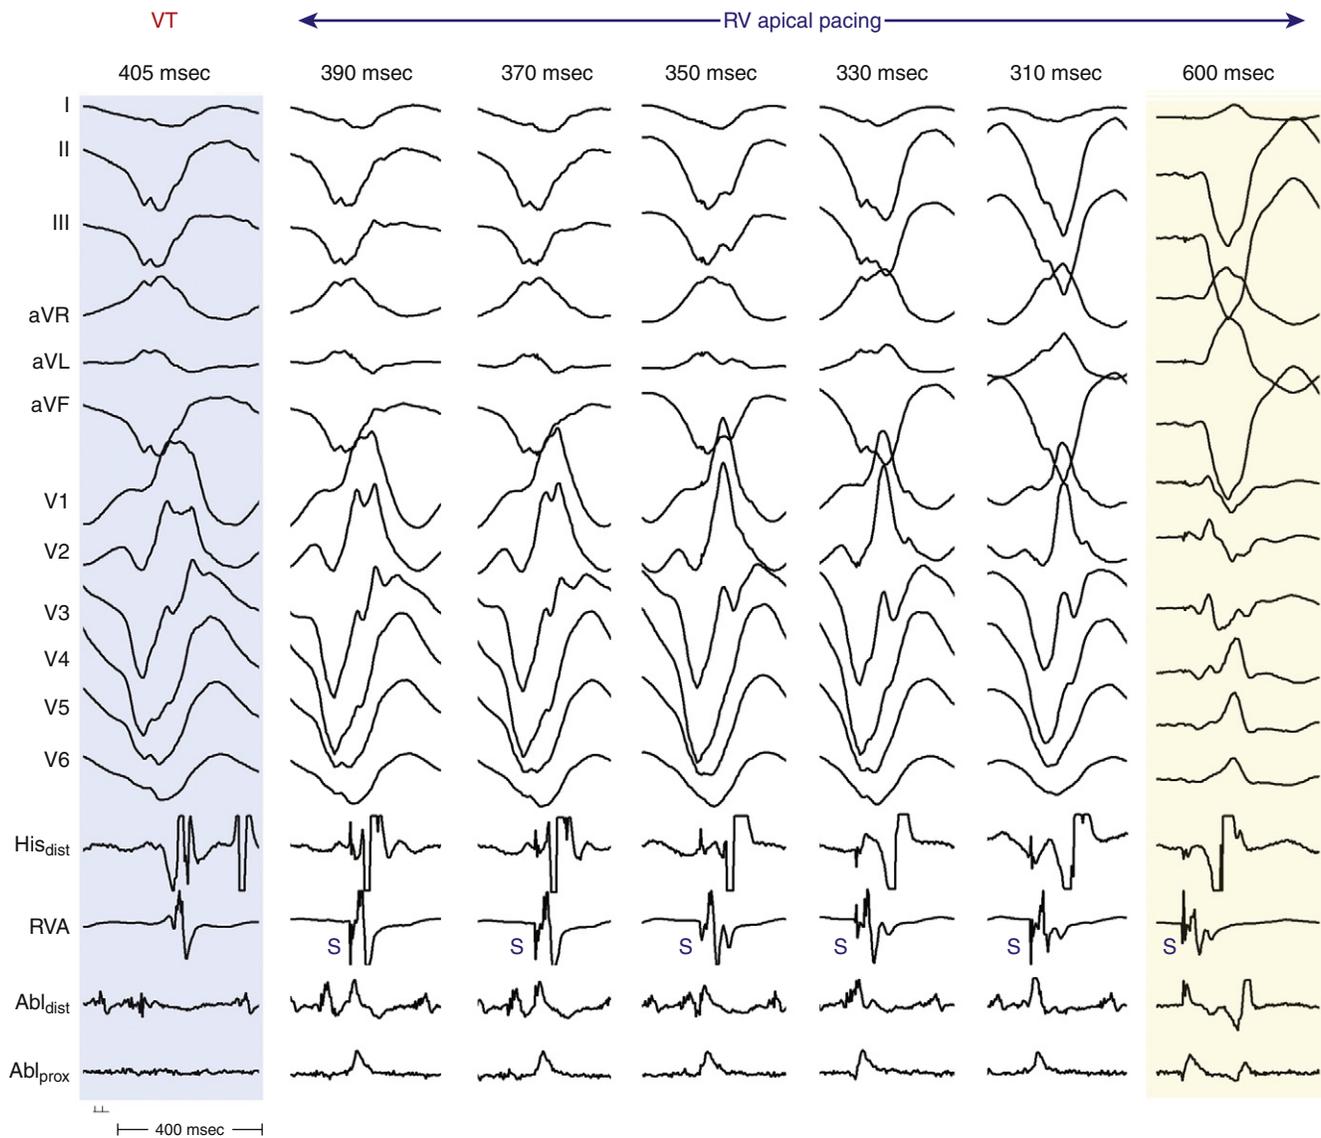

FIGURE 22-16 Fusion with ventricular pacing during macroreentrant post-infarction ventricular tachycardia (VT). VT with a right bundle branch block pattern and right superior axis is shown at left (cycle length [CL], 405 milliseconds, in blue shading). In the panels at right, pacing during VT over a range of CLs from the right ventricular (RV) apex (with a left bundle branch block pattern and left superior axis) is shown. Pure RV pacing during sinus rhythm at CL of 600 milliseconds is shown at far right (yellow shading). It is evident that while pacing during VT, QRS complexes at each paced CL are different from both VT and pure pacing, indicating contribution of both the VT and paced wavefronts to the QRS complexes (fusion, most evident in leads III, aVL, aVF, and V₁ and V₂).

is activated orthodromically. Collision with the last paced impulse must occur distal to the presystolic electrogram, either at the exit from the circuit or outside the circuit. In such cases, the return cycle measured at this local electrogram will equal the pacing CL. Therefore, a stimulus delivered after the onset of the surface ECG QRS during entrainment will always demonstrate local fusion. This is to be distinguished from entrainment with antidromic capture. When pacing is performed at a CL significantly shorter than the tachycardia CL, the paced impulse can penetrate the circuit antidromically and retrogradely (antidromically) capture the presystolic electrogram so that no exit from the tachycardia circuit is possible. Consequently, the surface QRS appears fully paced. When pacing is stopped, the impulse that conducts antidromically also conducts orthodromically to reset the reentrant circuit with orthodromic activation of the presystolic electrogram. When antidromic (retrograde) capture of the local presystolic electrogram occurs, the return cycle, even when measured at the site of the presystolic electrogram, will exceed the pacing CL by the difference in time between when the electrogram is activated retrogradely (i.e., pre-excited antidromically) and when it would have been activated orthodromically (see Fig. 5-15).³⁶

ENTRAINMENT WITH CONCEALED FUSION. Entrainment with concealed fusion (sometimes also referred to as “concealed entrainment”) is defined as entrainment with orthodromic capture and a surface ECG complex identical to that of the tachycardia (Fig. 22-18). Entrainment with concealed fusion suggests that the pacing site is within a protected isthmus inside or outside the reentrant circuit, but attached to the circuit (i.e., the pacing site can be in, attached to, or at the entrance to a protected isthmus that forms the diastolic pathway of the circuit). In this setting, transient entrainment is achieved when the orthodromically directed stimulated wavefront resets the tachycardia, but an antidromically stimulated wavefront collides with the tachycardia wavefront in or near the reentry circuit and fails to exit the slow conduction zone. Only tissue near the pacing site within the critical isthmus is antidromically activated; hence, there is no evidence of fusion. Compared with the intrinsic tachycardia, this antidromic capture may result in earlier intracardiac recordings from bipole sites located adjacent to the pacing region. The morphological appearance of the ECG, however, is the same during entrainment as during the tachycardia. Entrainment with concealed fusion can occur by pacing from bystander pathways, such as a blind alley, alternate

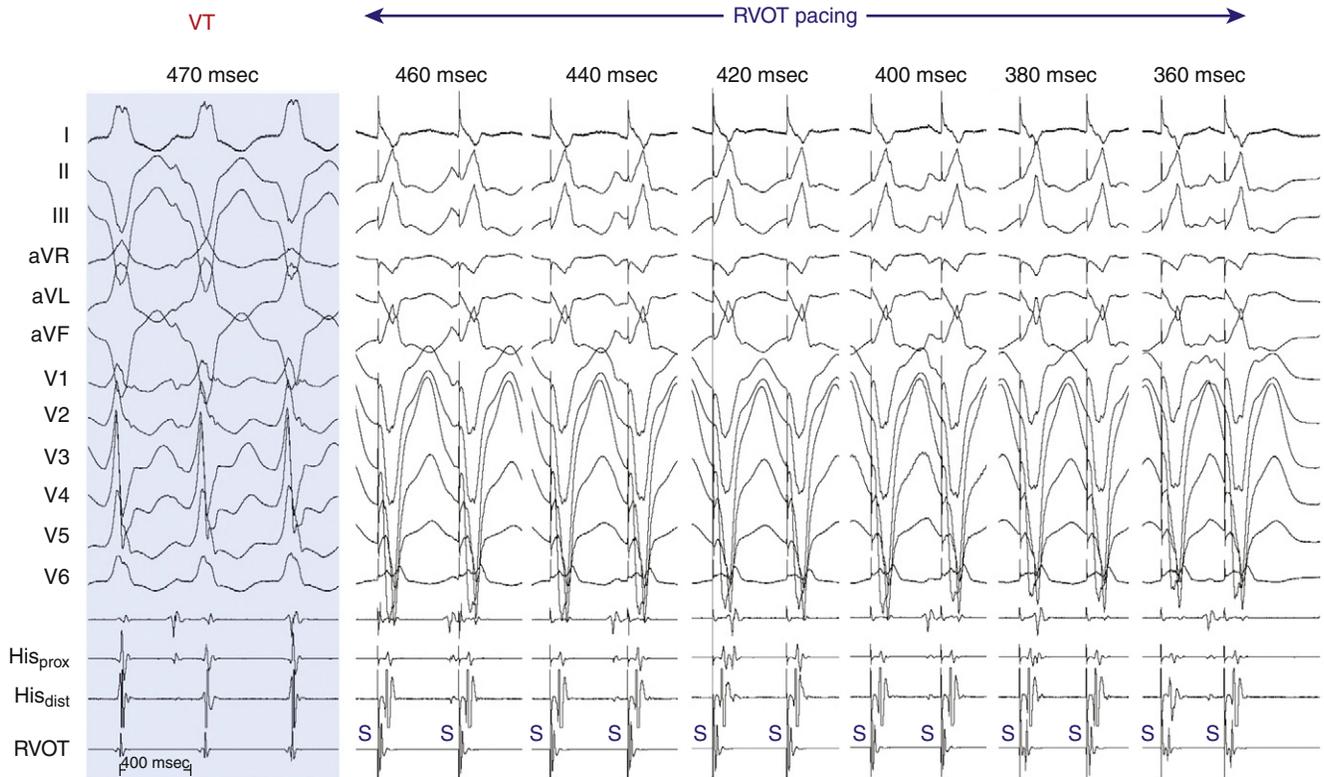

FIGURE 22-17 Lack of fusion with ventricular pacing during focal ventricular tachycardia (VT) in a patient with cardiomyopathy. VT with a right bundle branch block pattern and left superior axis is shown at left in blue shading (cycle length [CL], 470 milliseconds). In the panels at right, pacing during VT over a range of CLs from the right ventricular outflow tract (RVOT, with a left bundle branch block pattern and right inferior axis) is shown. It is clear that while pacing during VT, all QRS complexes are identical, indicating no contribution of the VT to the QRS complexes (thus no fusion).

pathway, or inner loop, that are not critical to the maintenance of reentry. In this situation, activation propagates from the main circuit loop but is constrained by block lines having the shape of a cul-de-sac; ablation at these sites does not terminate reentry.³⁶

Occasionally, one of the first few stimuli of a drive train intended to entrain VT terminates VT without propagation. Subsequent stimuli often result in QRS complexes that do not resemble VT, leading the operator to conclude that the site is far from the isthmus. Review of the first few stimuli of pacing may show that the site actually was very attractive for ablation (Fig. 22-19).

POST-PACING INTERVAL. The post-pacing interval (PPI) is the interval from the last pacing stimulus that entrained the tachycardia to the next recorded electrogram at the pacing site (see Fig. 22-18). The PPI should be measured to the near-field potential that indicates depolarization of tissue at the pacing site. The PPI remains relatively stable when entrainment of VT is performed at the same site, regardless of the length of the pacing drive. This is in contrast to overdrive suppression seen in automatic arrhythmias, which would be associated with progressive delay of the first tachycardia beat return cycle with progressively longer overdrive pacing drives.³⁶⁻³⁸

TERMINATION. The ability to terminate SMVT by rapid ventricular pacing, VES, or both is influenced most importantly by the tachycardia CL (50% of VTs with CLs <300 milliseconds will require electrical cardioversion), but also by the local ERP at the pacing site, conduction time from the stimulation site to the site of origin of the VT, duration of the excitable gap, and presence of antiarrhythmic agents.

Failure of rapid ventricular pacing or VES to terminate VT has several potential explanations: the reentrant circuit being a protected focus; inability of VES to access the reentrant circuit because of local myocardial refractoriness; absence of an accessible excitable gap; termination of VT followed by reinitiation by a subsequent pacing impulse in the same pacing drive; and/or failure of conduction block to occur within the reentrant circuit, despite accelerating the VT to the faster pacing rate.

Factors influencing termination of VT can be modified. Refractoriness at the site of stimulation can be modified by the use of multiple VESs or a higher pacing current. The distance, conduction time, or both from the site of stimulation to the VT site can be modified by changing the site of stimulation. The tachycardia CL can be increased by antiarrhythmic agents, but the response is unpredictable. However, two problems are frequently encountered in attempts to terminate VT—acceleration of the VT by overdrive pacing and the appearance of multiple distinct uniform VT morphologies.³

Regardless of the mode of stimulation used, termination is usually abrupt, which distinguishes reentrant VTs from triggered VTs. In reentrant VTs, termination must occur when an impulse penetrates the circuit and blocks in both directions. Rapid ventricular pacing is the most efficacious way of VT termination, regardless of the tachycardia CL. Approximately 80% of VTs terminated by a single VES have a tachycardia CL longer than 400 milliseconds. All VTs terminated by single or double VESs can also be terminated by ventricular pacing. Termination is less likely to occur when the VT cannot be reset with very premature VES (i.e., the VES coupling interval is more than 75% of the tachycardia CL).³

A single VES delivered during entrainment of VT can facilitate termination of VT by allowing easier access to the excitable gap. Even when a single VES or overdrive pacing alone fails to terminate the VT, the combination of both may be successful. Overdrive pacing ensures stable resetting of the VT circuit, allowing a single VES to interact with the circuit much more prematurely than it could in the absence of entrainment. Overdrive pacing also shortens the excitable gap of tissue in the reset circuit, making it possible for a single VES to terminate the VT. This technique avoids the need for multiple VESs, which can increase the heterogeneity of conduction and refractoriness in the intervening tissue and produce polymorphic VT, and the need for rapid pacing, which might induce acceleration of the VT. This method is especially helpful in VTs that were accelerated by rapid pacing and especially in those VTs for which antiarrhythmic agents have made the tachycardia more difficult to terminate.³

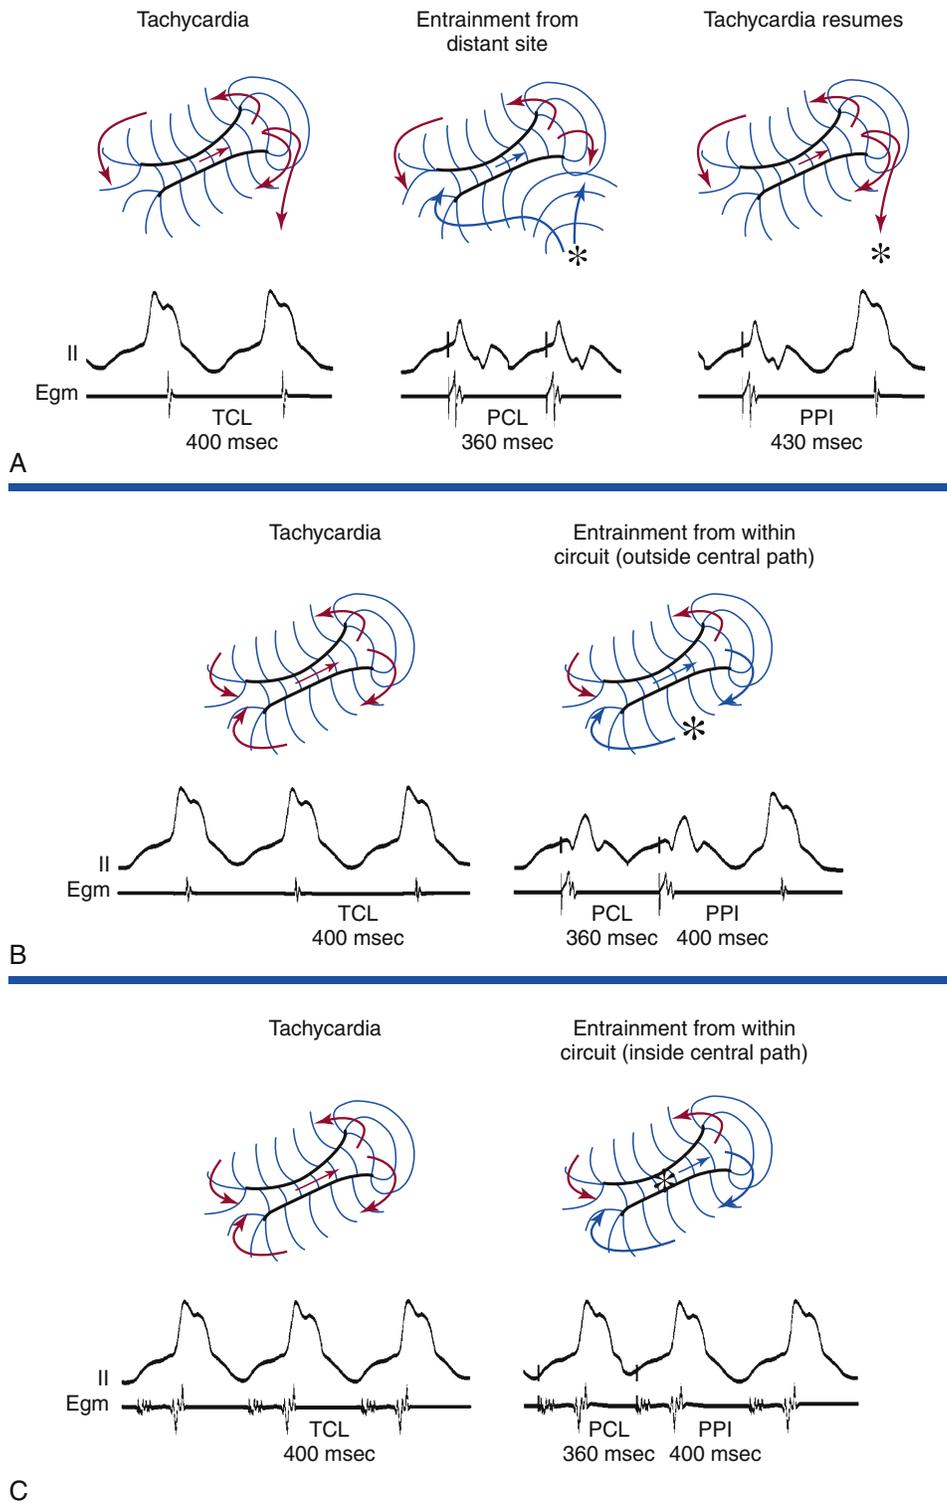

FIGURE 22-18 Entrainment mapping of ventricular tachycardia (VT). **A**, Entrainment of VT from a distant site. Diagrammatic representation of a figure-of-8 VT circuit at left, with an electrogram recorded at a site remote from critical circuit elements. At center, during entrainment pacing, the paced wavefront from this remote site (*) interacts with the circuit by colliding with a VT wavefront that has exited the diastolic corridor while also entering the diastolic corridor at the opposite end. This results in fusion (part of the ventricle depolarized by the VT wavefront, part by the paced wavefront). For as long as pacing continues, this fusion of ventricular activation remains stable. With cessation of pacing (right figure), the last paced wavefront enters the diastolic corridor as on other cycles but there is no subsequent paced wavefront to collide with the wavefront that is exiting the corridor; thus the first return cycle complex is entrained, but not fused. The post-pacing interval (PPI) measured at the site of pacing reflects the time it takes to make one complete revolution around the circuit plus any time required to get from the pacing site to the circuit and back from the circuit to the pacing site. **B**, Entrainment of VT from a site within the circuit. The pacing site (*) is within the circuit but outside the diastolic corridor. As a result, the entrained QRS complex shows fusion and the PPI equals the VT cycle length (CL). **C**, Entrainment of VT from a site within the circuit and inside the diastolic corridor, recording the mid-diastolic electrogram. As a result, the entrained QRS complex shows no fusion and the PPI equals the VT CL. The S-QRS interval equals the electrogram-to-QRS interval during VT. This is the ideal ablation site. Egm = intracardiac electrogram; PCL = pacing cycle length; TCL = tachycardia cycle length.

EFFECTS OF DRUGS ON VENTRICULAR TACHYCARDIA

Class I agents are the most uniformly successful drugs for slowing the rate of or terminating SMVT. These drugs can also facilitate the induction of SMVT in patients in whom SMVT cannot be induced by the standard programmed electrical stimulation protocol and in patients with coronary artery disease and nonsustained VT. These drugs can also occasionally produce incessant SMVT in patients who, before therapy, only had paroxysmal events. This phenomenon, almost always associated with a slower VT and prolongation of conduction by the agent, would not be expected if the mechanism were triggered activity or abnormal automaticity.

Adenosine, beta blockers, and calcium channel blockers are ineffective for termination of post-MI VT.³

Exclusion of Other Arrhythmia Mechanisms

EXCLUSION OF TRIGGERED ACTIVITY VENTRICULAR TACHYCARDIA

STIMULATION SITE SPECIFICITY. The site of ventricular stimulation should have no effect on the initiation of triggered activity VT as long as the impulse reaches the focus of the VT. Reentrant

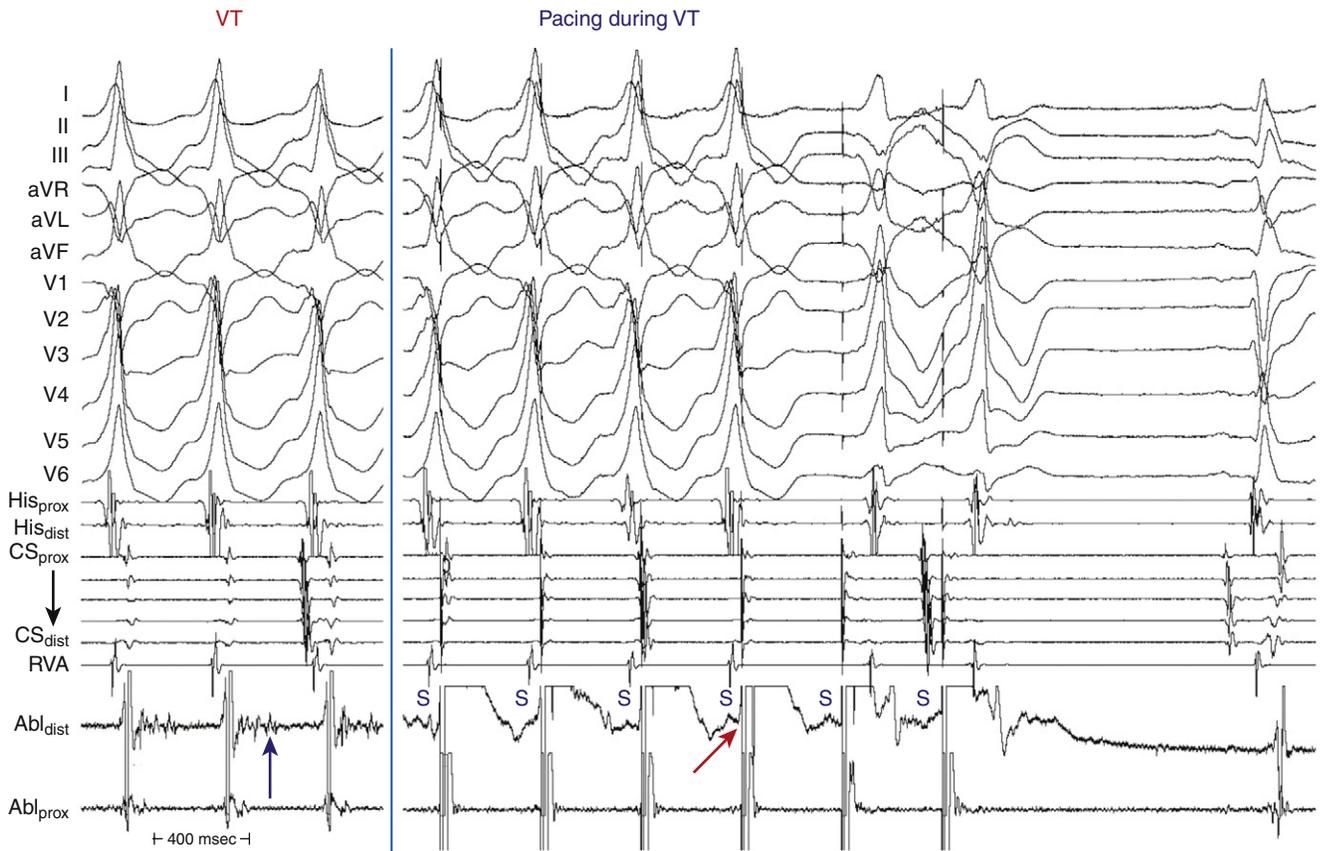

FIGURE 22-19 Nonpropagated ventricular tachycardia (VT) termination during attempted entrainment. VT is shown with a diastolic potential (blue arrow); during attempted stimulation at this site during VT, the first several stimuli (S) have no effect but the fifth stimulus (red arrow) results in VT termination without propagation of the impulse (no subsequent QRS). Subsequent stimuli capture the site but result in a very different QRS configuration.

VT, on the other hand, can demonstrate absolute or relative site specificity for initiation.

INDUCIBILITY WITH PROGRAMMED ELECTRICAL STIMULATION. Ventricular stimulation can initiate triggered activity VT in less than 65% of cases. Rapid ventricular pacing to initiate triggered VT should be more effective than VES, whereas it has a low yield in initiating reentrant VT. Multiple VESs during NSR or following a drive train of fewer than 8 to 10 beats usually fail to initiate triggered activity VT. Most episodes of triggered activity VT induced by ventricular stimulation are usually nonsustained. Induction of triggered activity VT with atrial pacing is not uncommon.³

REPRODUCIBILITY OF INITIATION. Reproducibility of triggered activity VT induction using all methods is less than 50%. Reproducibility of induction with single or double VESs is approximately 25%. Reproducibility is markedly affected by quiescence. Once a triggered rhythm is initiated, a period of quiescence is necessary to reinitiate the rhythm. Thus, the ability to initiate, terminate, and reinitiate sequence is uncommon, in contrast to reentrant VT.³

RELATIONSHIP OF PACING CYCLE LENGTH AND VENTRICULAR EXTRASTIMULUS COUPLING INTERVAL TO VENTRICULAR TACHYCARDIA. Typically, both the initial cycle of the triggered activity VT (the return cycle) and the tachycardia CL following cessation of pacing bear a direct relationship to the pacing CL, and a direct relationship to the coupling interval of the VES, when used. Thus, the shorter the initiating ventricular pacing CL, or the shorter the initiating VES coupling interval, the shorter the interval to the first VT beat and the shorter the initial VT CL. Occasionally, with early VESs, a jump in the interval to the onset of the VT complex occurs, so that it is approximately twice the interval to the onset of the VT initiated by later coupled VESs. This is secondary to failure of the initial delayed

afterdepolarization (DAD) to reach threshold while the second DAD reaches threshold. Thus, in triggered activity VTs caused by DADs, the coupling interval of the initial VT complex shortens or suddenly increases in response to progressively premature VES. It would not be expected to demonstrate an inverse or gradually increasing relationship, in contrast to reentrant VT. Only with the addition of very early VESs or, occasionally, very rapid ventricular pacing (CL <300 milliseconds) can a sudden jump in the interval to the first VT complex be observed. Furthermore, ventricular pacing CLs longer or shorter than the critical CL window fail to induce triggered activity VT. This critical window may shift with changing autonomic tone.³

EFFECTS OF CATECHOLAMINE. Inducibility of triggered activity VT is facilitated by catecholamines, whereas in the setting of reentrant VT, isoproterenol facilitates VT induction in only 5% of cases. However, induction of triggered activity VT can be inconsistent and is exquisitely sensitive to the immediate autonomic status of the patient. Therefore, noninducibility during a single EP study is not enough evidence to attribute the arrhythmia to a nontriggered activity mechanism.

RESPONSE TO ANTIARRHYTHMIC DRUGS. Triggered activity VTs respond favorably to calcium channel blockers and beta blockers. Conversely, those drugs fail to terminate more than 95% of VTs associated with coronary artery disease.

DIASTOLIC ELECTRICAL ACTIVITY. In reentrant VT, electrical activity occurs throughout the VT cycle. Thus, during diastole, conduction is extremely slow and in a small enough area that it is not recorded on the surface ECG. Demonstration that the VT initiation is dependent on a critical degree of slow conduction, manifested by fragmented electrograms spanning diastole, and that maintenance of the VT is associated with repetitive continuous activity is consistent with a reentrant mechanism.

EXCLUSION OF BUNDLE BRANCH REENTRANT VENTRICULAR TACHYCARDIA

HIS BUNDLE–VENTRICULAR INTERVAL. BBR should be suspected when the His potential precedes ventricular activation and the HV interval during VT is longer than that during NSR. In other VTs, the His potential is usually immediately before or after, or obscured within, the local ventricular electrogram. Occasionally, the His potential can precede the onset of the QRS in post-MI VT; however, in contrast to BBR VT, the HV interval in those VTs is shorter than that during NSR.

OSCILLATION OF TACHYCARDIA CYCLE LENGTH. Spontaneous variation in the V-V intervals during BBR VT is dictated and preceded by similar changes in the H-H intervals. These changes can be demonstrated by ventricular stimulation during VT or can occur spontaneously following initiation. In other VTs, in contrast to BBR VT, the V-V interval variation usually dictates the subsequent H-H interval changes.

ACTIVATION SEQUENCE. In the common type of BBR (LBBB pattern), the activation wavefront travels retrogradely up the LB to the HB and then anterogradely down the RB, with subsequent ventricular activation. This sequence is reversed in BBR with an RBBB pattern. Unfortunately, RB and LB potentials are not always recorded, so that the typical activation sequences (LB-HB-RB-V or RB-HB-LB-V) are not available for analysis. Even if either sequence is present, the HPS (usually the LB) could be activated passively in the retrograde fashion to produce an HB-RB-V sequence during a VT with an LBBB pattern without reentry requiring the LB. In these cases, other diagnostic criteria for BBR should be used.

EXCLUSION OF SUPRAVENTRICULAR TACHYCARDIA

SUPRAVENTRICULAR TACHYCARDIA WITH ABERRANCY. If VT exhibits 1:1 VA conduction, it can mimic SVT with aberrancy. Surface QRS morphology usually helps distinguish SVT with typical RBBB or LBBB from VT. In VT, the atrium is not part of the tachycardia circuit and can be dissociated by atrial pacing. The HV interval in aberrantly conducted SVT is always equal to or longer than that during NSR, which is in contrast to intramyocardial VTs. Additionally, tachycardia response to VES and atrial pacing can be useful for distinguishing SVT from VT, as discussed in detail in [Chapter 21](#).^{39,40}

PREEXCITED SUPRAVENTRICULAR TACHYCARDIA. Differentiation between VT and preexcited SVT (i.e., an SVT with anterograde conduction over an AV bypass tract [BT]) is particularly difficult on the surface ECG, because ventricular activation begins outside the normal intraventricular conduction system in both tachycardias. As a result, many of the standard criteria cannot discriminate between preexcited SVT and VT. The HV interval is usually short or negative in both preexcited SVT and VT, and does not help in the differential diagnosis.

As noted, because the atrium is not part of the VT circuit, the ability to dissociate the atrium with rapid atrial pacing without influencing the tachycardia CL (V-V interval) or QRS morphology suggests VT and excludes preexcited SVTs. Other pacing maneuvers used for differential diagnosis are discussed in [Chapter 21](#).^{39,40}

Mapping

The main goal of VT mapping is identification of the site of origin or critical isthmus of the VT. The site of origin of the tachycardia is the source of electrical activity producing the QRS. Although this is a discrete site of impulse formation in automatic and triggered rhythms, during macroreentrant VT it represents the exit site from the diastolic pathway (the critical isthmus) to the myocardium giving rise to the QRS. An isthmus is defined as a conductive myocardial tissue bounded by nonconductive tissue (conduction barriers). This nonconductive tissue can be a scar area surrounding a corridor of surviving myocardium (indicated by double potentials), or an anatomical obstacle, such as the mitral annulus.

The critical isthmus is a narrow segment of muscle cells connecting larger masses of myocardium that the depolarization wavefront must traverse to perpetuate the tachycardia. As a consequence, ablation of the critical isthmus should interrupt the tachycardia and prevent its inducibility.

Mapping of post-MIVT has several prerequisites, including inducibility of VT at the time of EP testing, hemodynamic stability of the VT (which usually requires a relatively slow VT rate), and stability of the VT reentry circuit (i.e., stable VT morphology and CL). If the tachycardia is not stable (morphologically or hemodynamically), mapping can still be performed by starting and stopping the VT after data acquisition at each site. Additionally, poorly tolerated rapid VTs sometimes can be slowed by antiarrhythmic drugs to allow for mapping. Antiarrhythmic drugs do not alter the sequence of activation, despite slowing of the VT and widening of the QRS and, although the electrogram at the site of origin can widen, its relationship to the onset of the QRS remains unchanged. Newer techniques such as basket catheter and noncontact mapping can also provide large amounts of activation mapping data during non-sustained or unstable VT.²

Mapping of VT circuits and identification of critical isthmuses are often challenging. The abnormal area of scarring, where the isthmus is located, is often large and contains false isthmuses (bystanders) that confuse mapping. Although in the majority of cases a portion of the VT isthmus is located in the subendocardium, where it can be ablated, in some cases the isthmuses or even the entire circuits are deep in the endocardium or even in the epicardium and cannot be identified or ablated from the endocardium. Additionally, multiple potential reentry circuits are frequently present, giving rise to multiple different monomorphic VTs in a single patient. Ablation in one area may abolish more than one VT or leave VT circuits in other locations intact.

When multiple VTs are inducible, it is recommended that all mappable VTs be completely mapped and targeted. However, some recommend targeting only the clinical VT, especially in very ill patients in whom the goal is to decrease the frequency of ICD shocks. It is important to have a 12-lead ECG of the clinical VTs available, if possible, for review at the time of the EP procedure. This information can be used to focus on the exit region suggested by the VT morphology to limit the extent of detailed mapping, particularly when the clinical VT is hemodynamically unstable. In patients with ICDs, VT is usually terminated promptly and a 12-lead ECG is often not available. Nonetheless, comparing the VT CL and ICD electrogram morphology during spontaneous and induced VTs can be helpful, particularly when trying to limit ablation targeting presumptive clinical VT.²

Activation Mapping

The main goal of activation mapping of post-MI VT is to seek sites with continuous activity spanning diastole, isolated diastolic potentials, or both. Typically, bipolar electrogram recordings are used for activation mapping, as they provide an improved signal-to-noise ratio and more clearly defined high-frequency components. In contrast, unipolar recordings in scar areas have very low amplitudes with a poor signal-to-noise ratio and distant activity can be difficult to separate from local activity. This is especially true when recording from areas of prior MI, where the QS potentials are ubiquitous and it is often impossible to select a rapid negative dV/dt when the entire QS potential is slowly inscribed. Therefore, unipolar electrograms are typically filtered at comparable settings to those of bipolar electrograms (30 to 300 Hz or more) when scar-related VT is studied. Filtering gives reasonably clean signals; however, the signal is often of very low amplitude. Therefore, bipolar recordings are preferred for activation mapping; filtered unipolar electrograms can be used to help ensure that the tip electrode, which is the ablation electrode, is responsible for the early component of the bipolar electrograms.⁴¹

Endocardial activation time is the timing of the local electrogram measured relative to the earliest onset of the QRS complex

in the 12-lead ECG. Local activation time is best taken from the onset of the high-frequency bipolar electrogram as it leaves the baseline. Using the peak deflection or the point of the most rapid deflection as it crosses the baseline is of less value in multicomponent fractionated electrograms. The distal pole of the mapping catheter should be used for mapping of the earliest activation site, because it is the pole through which RF energy is delivered.

Contact is critical when standard quadripolar catheters are used. The degree of contact can be assessed by pacing threshold or impedance measurements at the recording electrode pair. Recording from multiple bipolar pairs from a multipolar electrode catheter in the LV is helpful in that if the proximal pair has a more attractive electrogram than the distal pair, the catheter can be withdrawn slightly to achieve the same position with the distal electrode. Using standard equipment, mapping a single SMVT requires recording and mapping performed at a number of sites, based on the ability of the investigator to recognize the mapping sites of interest from the morphology of the VT on the surface ECG.

CONTINUOUS ACTIVITY

Theoretically, if reentry is the mechanism of VT, electrical activity should occur throughout the VT cycle. Thus, during diastole, conduction should be extremely slow and in a small enough area such that it is not recorded on surface ECG. The QRS complex is caused by propagation of the wavefront from the exit of that diastolic isthmus to the surrounding myocardium. Demonstration that VT initiation is dependent on a critical degree of slow conduction, manifested by fragmented electrograms spanning diastole, and that maintenance of the VT is associated with repetitive continuous activity, would be compatible with reentry.

In post-MI VT, continuous activity, when observed, invariably occurs at sites that demonstrate markedly abnormal electrograms during NSR (Fig. 22-20). However, continuous diastolic activity can be recorded in only 5% to 10% of post-MI VTs with detailed mapping using standard equipment. The ability to record continuous activity depends on the spatial and geometric arrangement of the involved tissue, the position of the catheter, and the interelectrode distance. Thus, continuous diastolic activity is likely to be recorded only if a bipolar pair records a short isthmus. If a longer isthmus is recorded (i.e., the isthmus is larger than the recording area of the catheter, the catheter is not covering it completely, or both), a nonholodiastolic electrogram will be recorded. In such VTs, when nonholodiastolic electrical activity is recorded at the site of origin, repositioning of the catheter to other sites can allow recording of the bridging of diastole (electrical activity in these adjacent sites spans diastole) (Fig. 22-21). Failure to record continuous activity is then not surprising, because catheter and intraoperative VT

mapping suggest that most post-MI VTs incorporate a diastolic pathway 1 to 3 cm long and a few millimeters to 1 cm wide, with a circuit area probably larger than 4 cm².

All areas from which diastolic activity is recorded are not necessarily part of the reentrant circuit. Such sites may reflect late activation and may not be related to the VT critical isthmus. Analysis of the response of these electrograms to spontaneous or induced changes in tachycardia CL is critical in deciding their relationship to the VT circuit. Electrical signals that come and go throughout diastole should not be considered continuous. For continuous activity to be consistent with reentry, the following must be demonstrated: (1) VT initiation is dependent on continuous activity (i.e., broadening of electrograms that span diastole); (2) VT maintenance is dependent on continuous activity, so that termination of continuous activity, either spontaneously or following stimulation, without affecting the VT would exclude such continuous activity as requisite for sustaining the VT; (3) the recorded continuous diastolic activity is not just a broad electrogram whose duration equals the diastolic interval, which can be verified by analyzing the local electrogram while pacing during sinus rhythm at a CL comparable to VT CL—if pacing produces continuous diastolic activity in the absence of VT, the continuous electrogram has no mechanistic significance; (4) motion artifact should be excluded (this is easiest because such electrograms are recorded only in infarcted areas and never from moving, contractile normal areas); (5) the continuous activity should be recorded from a circumscribed area; and (6) if possible, ablation of the area from which continuous activity is recorded will terminate the VT.

MID-DIASTOLIC ACTIVITY

An isolated mid-diastolic potential is defined as a low-amplitude, high-frequency diastolic potential separated from the preceding and subsequent ventricular electrograms by an isoelectric segment (Fig. 22-22). It is likely that isolated mid-diastolic potentials that cannot be dissociated from the VT are generated in segments of the zone of slow conduction or critical isthmus, which are integral components of the reentry circuit. The earliest presystolic electrogram closest to mid-diastole is the most commonly observed indicator of an isthmus site in a VT circuit; however, continuous diastolic activity and/or bridging of diastole at adjacent sites or mapping a discrete diastolic pathway would be most consistent with a reentrant circuit (see Fig. 22-20).

In post-MI reentrant VT, the earliest presystolic electrogram is invariably abnormal and frequently fractionated, split, or both, regardless of the QRS morphology of the VT or the location of the isthmus. Thus, a normal presystolic bipolar electrogram (amplitude >3 mV, duration <70 milliseconds) should prompt further search for earlier activity. The early activity often appears focal, with propagation from the early site to the remainder of the heart.

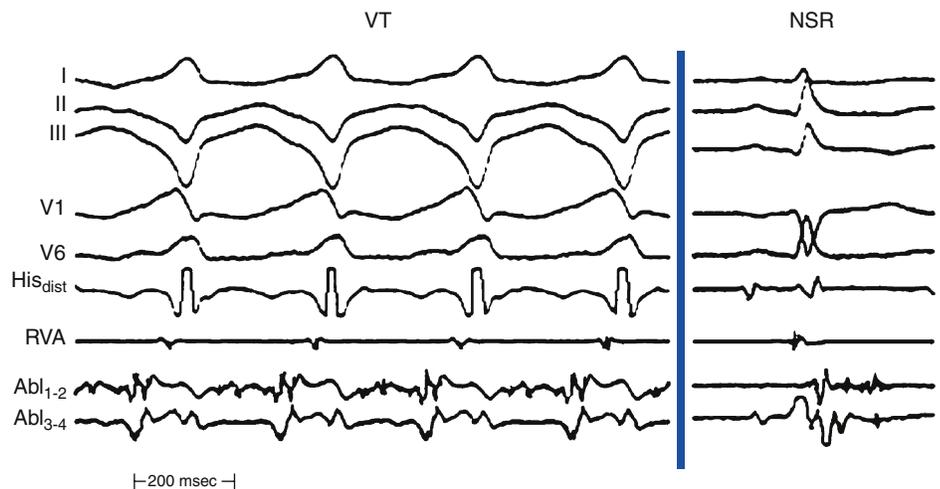

FIGURE 22-20 Continuous diastolic electrical activity during reentrant ventricular tachycardia (VT). VT is shown with almost continuous electrical activity in the distal ablation recording. During sinus rhythm (right), the electrogram is very fragmented and outlasts the surface QRS complex. NSR = normal sinus rhythm.

The earliest electrogram in post-MI VT not infrequently has diastolic and systolic components separated by an isoelectric component (see Fig. 22-22). Detailed mapping will usually reveal more than one site of diastolic activity. It is therefore essential to demonstrate that the diastolic site recorded is in fact the earliest site. This can be done by demonstrating that sites surrounding the assumed earliest site are activated later than that site, even though they may be diastolic in timing. If, after very detailed mapping, the earliest recorded site is not at least 50 milliseconds presystolic, this suggests that either the map is inadequate (most common) or the VT

arises deeper than the subendocardium, in the midmyocardium, or even incorporating the subepicardium.

It is important to recognize that mid-diastolic sites also can be part of a larger area of abnormal slow conduction unrelated to the VT circuit (i.e., a dead-end pathway), and can be recorded from a bystander site attached to the isthmus. Therefore, regardless of where in diastole the presystolic electrogram occurs (early, mid, or late), its appearance on initiation of VT and diastolic timing, although necessary, does not confirm its relevance to the VT mechanism. One must always confirm that the electrogram cannot be

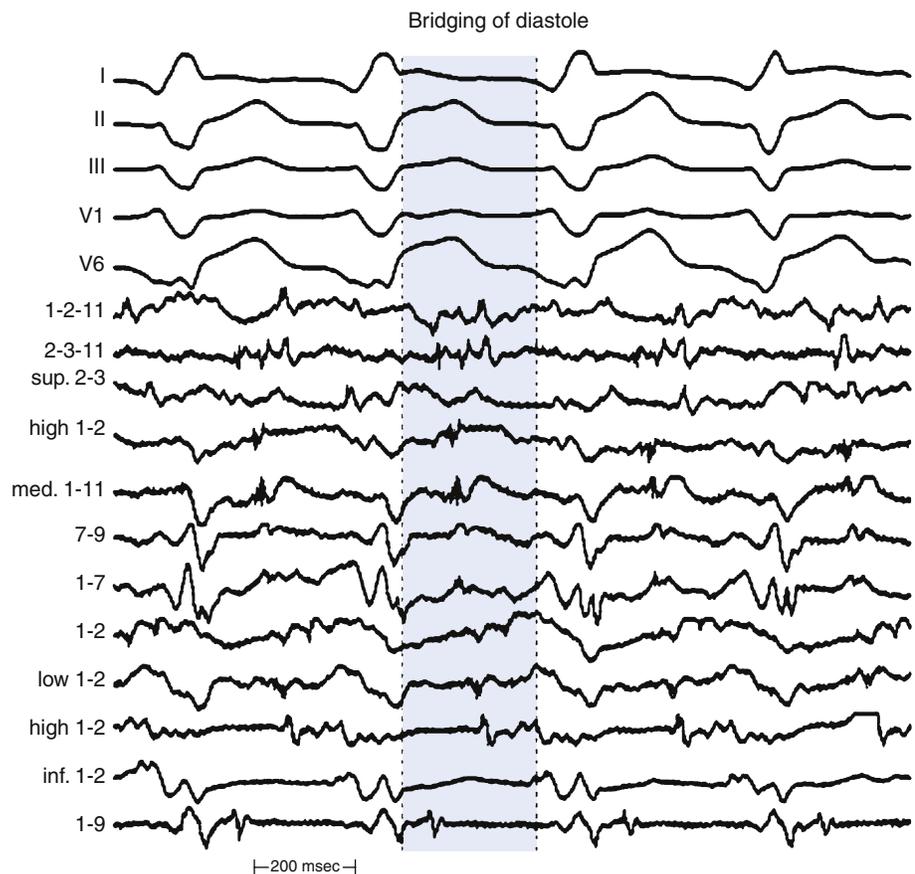

FIGURE 22-21 Bridging of diastole during reentrant ventricular tachycardia (VT). Shown is the compilation of numerous mapping sites around the left ventricular apical region during VT; diastole is shaded, showing progression of activation from early to mid to late diastole.

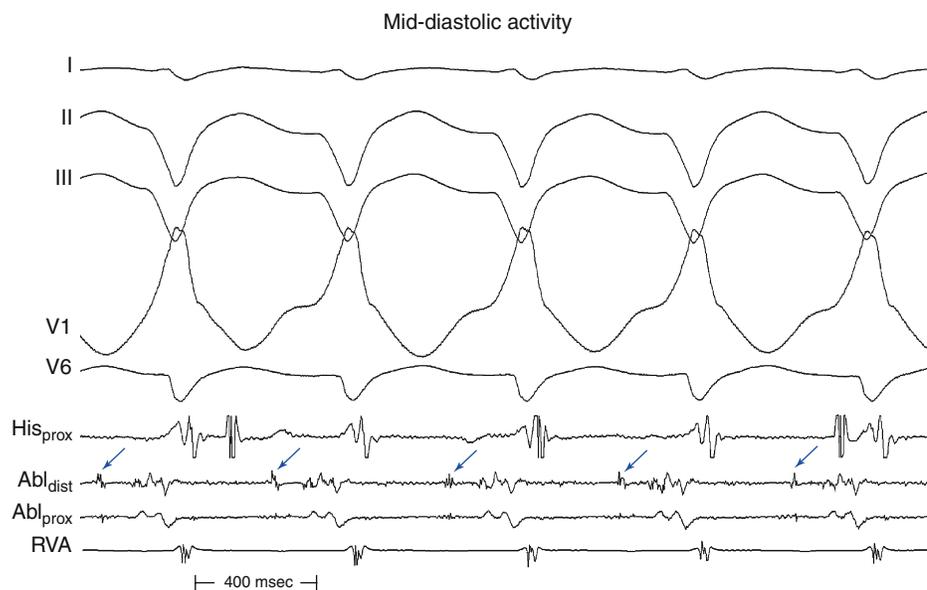

FIGURE 22-22 Mid-diastolic electrical activity during reentrant ventricular tachycardia (VT). VT is shown with small mid-diastolic potentials (arrows) on the ablation recording.

dissociated from the VT and is required for VT maintenance (see Fig. 5-12). Thus, during spontaneous changes in the tachycardia CL or those produced by programmed electrical stimulation, the electrogram, regardless of its position in diastole, should show a fixed relationship to the subsequent QRS and not the preceding QRS. Very early diastolic potentials, in the first half of diastole, can represent an area of slow conduction at the entrance of a protected isthmus. Such potentials will remain fixed to the prior QRS (exit site from the isthmus), and delay between it and the subsequent QRS would reflect delay entering or propagating through the protected diastolic pathway. This phenomenon is an uncommon response of presystolic electrograms occurring in the second half of diastole to pacing at rates slightly faster than the VT rate in post-MI VTs, but has been described in idiopathic and verapamil-sensitive VTs. Theoretically, such electrical activity may also arise from tissue between the site of impulse formation (the reentrant circuit) and the muscle mass that gives rise to the surface ECG. This response is also uncommon.

LIMITATIONS OF ACTIVATION MAPPING

Standard transcatheter endocardial mapping as performed in the EP laboratory is limited by the number, size, and types of electrodes that can be placed within the heart. Because these methods cover only a small portion of the endocardial surface, time-consuming point-by-point maneuvering of the catheter is required to trace the origin of an arrhythmic event and its activation sequence in the neighboring areas.

The success of roving point mapping is predicated on the sequential beat-by-beat stability of the activation sequence being mapped and the ability of the patient to tolerate the sustained arrhythmia. Therefore, it can be difficult to perform activation mapping in the case of poorly inducible VT at the time of EP testing, hemodynamically unstable VT, and unstable VT morphology. Extensive mapping is not possible when the VT repeatedly changes, causing multiple different morphologies. However, as noted, mapping can still be facilitated by starting and stopping the tachycardia after data acquisition at each site, slowing the VT rate by antiarrhythmic agents, or the use of multipolar basket catheters or noncontact mapping arrays.

Although activation mapping is adequate for defining the site of origin of focal tachycardias, it is deficient by itself in defining the critical isthmus of macroreentrant tachycardias. Adjunctive mapping modalities (e.g., entrainment mapping, pace mapping) are required for this.

Finally, using conventional activation mapping techniques, it is difficult to conceive the 3-D orientation of cardiac structures because these use a limited number of recording electrodes guided by fluoroscopy. Although catheters using multiple electrodes to acquire data points are available, the exact location of an acquired unit of EP data is difficult to ascertain because of inaccurate delineation of the location of anatomical structures. The inability to associate the intracardiac electrogram accurately with a specific endocardial site also limits the reliability with which the roving catheter tip can be placed at a site that was previously mapped. This results in limitations when the creation of long linear lesions is required to modify the substrate, and when multiple isthmuses, or channels, are present. This inability to identify, for example, the site of a previous ablation increases the risk of repeated ablation of areas already dealt with and the likelihood that new sites can be missed.

Entrainment Mapping

Focal ablation of multiple sites defined as in the reentrant circuit may not result in elimination of VT; that instead requires ablation of an isthmus bordered by barriers on either side, which is critical to the reentrant circuit. Because the circuit incorporates sites outside this critical isthmus, ablation of these external sites will eliminate VT, although it may slightly alter the tachycardia CL or morphology.

Stimulation at sites recording diastolic activity can provide evidence of its relationship to the VT circuit. Entrainment mapping is used to verify whether a diastolic electrogram (regardless of where in diastole it occurs, its position, and appearance on initiation of VT) is part of the VT circuit, focusing ablation efforts in areas likely to eliminate VT (see Fig. 22-18).⁴²

Pacing is usually started at a CL just shorter than the tachycardia CL. Pacing should be continued for a sufficiently long duration to allow for entrainment; short pacing trains are usually not helpful. Pacing is then repeated at progressively shorter pacing CLs. After cessation of each pacing drive, the presence of entrainment should be verified by the presence of fixed fusion of the paced complexes at a given pacing CL, progressive fusion at faster pacing CLs, and resumption of the same tachycardia morphology following cessation of pacing with a nonfused complex at a return cycle that is equal to the pacing CL (see Figs. 5-15 and 5-16). The mere acceleration of the tachycardia after cessation of pacing does not establish the presence of entrainment, and evaluation of the PPI or other criteria is meaningless when the presence of true entrainment has not been verified. Moreover, it is important to verify the absence of termination and reinitiation of the tachycardia during the same pacing train. Once the presence of entrainment has been verified, several criteria can be used to indicate the relation of the pacing site to the reentrant circuit, as listed in Table 22-2 (Fig. 22-23; and see Fig. 5-14).⁴²

There are several limitations to the entrainment mapping technique. Entrainment requires the presence of sustained, hemodynamically well-tolerated tachycardia of stable morphology and CL. Furthermore, overdrive pacing can result in termination, acceleration, or transformation of the index tachycardia into a different one, making further mapping challenging. Additionally, pacing and recording from the same area is required for entrainment mapping. This is usually satisfied by pacing from electrodes 1 and 3 and recording from electrodes 2 and 4 of the mapping catheter. However, this technique has its own limitations. Differences, albeit slight, exist in the area from which electrodes 2 and 4 record as compared with electrodes 1 and 3, as do differences in the relationship of the site of stimulation from poles 1 and 3 to the recorded electrogram from poles 2 and 4 (i.e., proximal or distal to the recording site). Furthermore, the total area affected by the pacing stimulus can exceed the local area, especially when high currents (more than 10 mA) are required for stimulation, in addition to the fact that the pacing artifact can obscure the early part of the captured local electrogram. In such a case, a comparable component of the electrogram can be used to measure the PPI.

TABLE 22-2 Entrainment Mapping Reentrant Ventricular Tachycardia

Pacing from Sites Outside VT Circuit

- Manifest fusion on surface ECG and/or intracardiac recordings
- PPI – tachycardia CL > 30 msec
- S-QRS interval > local electrogram to QRS interval

Pacing from Sites Inside VT Circuit but Outside Protected Isthmus

- Manifest fusion on surface ECG and/or intracardiac recordings
- PPI – tachycardia CL < 30 msec
- S-QRS interval = local electrogram-to-QRS interval

Pacing from Protected Isthmus Outside VT Circuit

- Concealed fusion
- PPI – tachycardia CL > 30 msec
- S-QRS interval > local electrogram to QRS interval

Pacing from Protected Isthmus Inside VT Circuit

- Concealed fusion
- PPI – tachycardia CL < 30 msec
- S-QRS interval = local electrogram to QRS interval (± 20 msec)

CL = cycle length; PPI = post-pacing interval; VT = ventricular tachycardia.

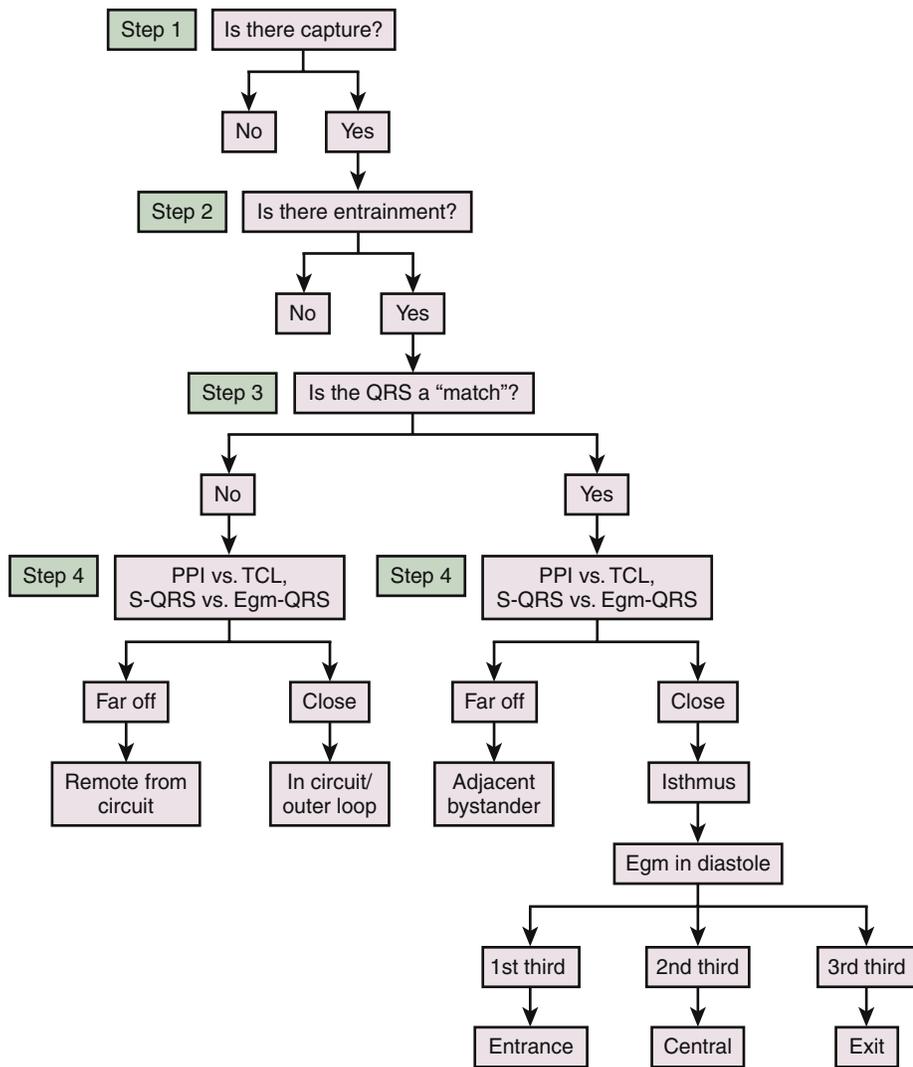

FIGURE 22-23 An algorithmic approach to entrainment in ventricular tachycardia. See text for details. Egm = electrogram; PPI = post-pacing interval; TCL = tachycardia cycle length.

The RV electrogram can also be used because it should have the same relationship to the paced site as it does from the electrogram during VT if the paced site is in the circuit. In both cases, these measurements provide indirect evidence of events in the circuit (i.e., the PPI will approximate the tachycardia CL if the stimulation site is in the circuit).

ENTRAINMENT WITH CONCEALED FUSION

Entrainment with concealed fusion (sometimes also referred to as “concealed entrainment” or “exact entrainment”) is defined as entrainment with orthodromic capture and a QRS complex on the 12-lead surface ECG identical to that of the VT, and it suggests that the pacing site is within, attached to, or at the entrance to a protected isthmus that forms the diastolic pathway of the circuit (Fig. 22-24; and see Fig. 22-18). However, the positive predictive value of entrainment with concealed fusion in identifying effective ablation sites is only 50% to 60%, indicating that entrainment with concealed fusion can often occur at sites that are not critical to the maintenance of reentry (bystander pathway), such as a blind alley, alternate pathway, or inner loop. Even when such sites are believed to reside within the reentrant circuit isthmus, ablation can fail if lesions are too small to interrupt the circuit completely.³⁶

Other mapping criteria can be helpful in increasing the probability of identifying an effective site for ablation of VT in combination with entrainment with concealed fusion (Table 22-3). If the S-QRS interval-to-tachycardia CL ratio is less than 0.7, the positive

predictive value for successful ablation is approximately 70%. Furthermore, if the electrogram-QRS interval is equal to the S-QRS interval at a site at which there is entrainment with concealed fusion, the positive predictive value increases to approximately 80%. Finally, an isolated mid-diastolic potential that cannot be dissociated from VT increases the positive predictive value for identifying an effective ablation site to approximately 90%.^{36,43,44}

POST-PACING INTERVAL

Assessment of the PPI helps differentiate early presystolic electrical activity from late diastolic activity that can be unrelated to the tachycardia circuit (see Fig. 22-24). During entrainment from sites within the reentrant circuit, the orthodromic wavefront from the last stimulus propagates through the reentry circuit and returns to the pacing site following the same path as the circulating reentry wavefront. The conduction time required is the revolution time through the circuit. Thus, the PPI, measured from the pacing site recording, should be equal (within 20 to 30 milliseconds) to the tachycardia CL. At sites distant from the circuit, stimulated wavefronts propagate to the circuit, then through the circuit, and finally back to the pacing site. Thus, the PPI should be equal to the tachycardia CL, plus the time required for the stimulus to propagate from the pacing site to the tachycardia circuit and back (see Fig. 5-14). The greater the difference between the PPI and the tachycardia CL, the longer the conduction time and distance between the pacing site and the reentry circuit.^{36,43}

TABLE 22-3 Sensitivity, Specificity, and Predictive Values of Analyzed Mapping Criteria in Association with Concealed Entrainment for Effective Ablation Sites

MAPPING CRITERION	SENSITIVITY (%)	SPECIFICITY (%)	POSITIVE PREDICTIVE VALUE (%)	NEGATIVE PREDICTIVE VALUE (%)
Concealed entrainment	—	—	54	—
IMDP				
Overall	40	76	67	53
Not dissociable from VT	32	95	89	54
PPI = VT CL	58	19	45	29
S-QRS/VT CL <0.7	96	52	71	92
S-QRS = EGM-QRS				
Excluding IMDP	32	86	73	51
Including IMDP	56	86	82	62

CL = cycle length; EGM = electrogram; IMDP = isolated mid-diastolic potential; PPI = post-pacing interval; S-QRS = stimulus-to-QRS interval; VT = ventricular tachycardia.

From Bogun F, Bahu M, Knight BP, et al: Comparison of effective and ineffective target sites that demonstrate concealed entrainment in patients with coronary artery disease undergoing radiofrequency ablation of ventricular tachycardia, *Circulation* 95:183, 1997.

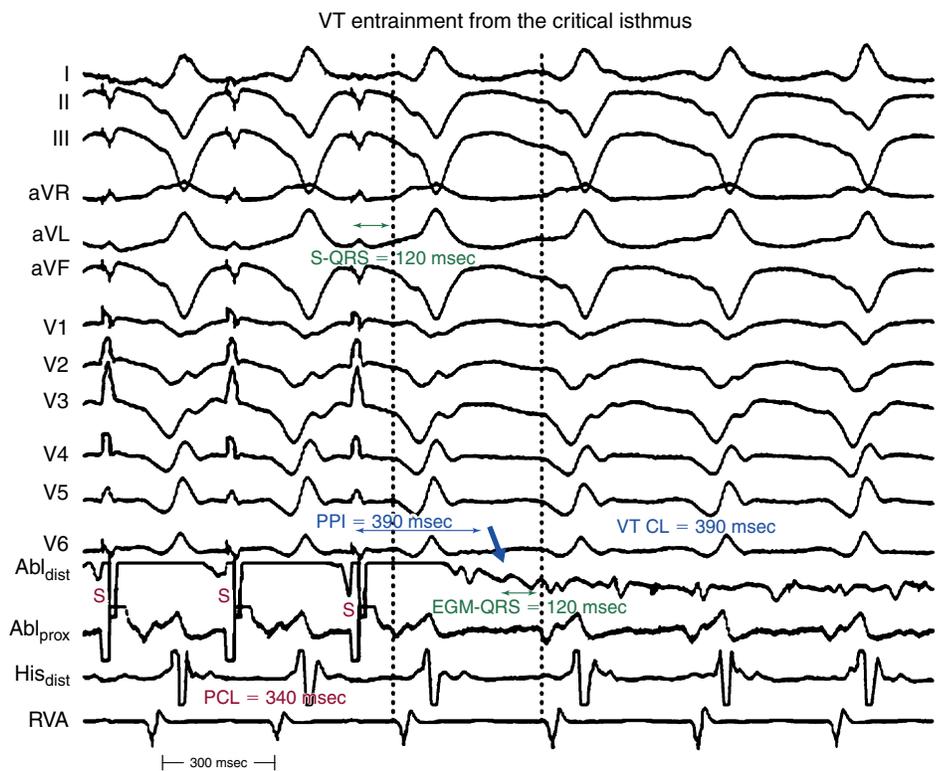

FIGURE 22-24 Entrainment during post-myocardial infarction ventricular tachycardia (VT) from the critical isthmus. The mid-diastolic potential (arrow) is present at the pacing site. Dashed lines denote QRS onset. Each stimulated complex is identical to that of VT at right (entrainment with concealed fusion). This, and findings that the stimulus-QRS (S-QRS) interval with pacing equals the electrogram-QRS (EGM-QRS) interval in VT and that the post-pacing interval (PPI) equals the VT cycle length (CL), indicates that pacing is from the protected diastolic corridor. Radiofrequency delivery at this site terminated VT in 4 seconds. PCL = pacing cycle length.

The PPI should be measured to the near-field potential that indicates depolarization of tissue at the pacing site (see Figs. 22-18 and 22-24). In regions of scar, electrode catheters often record multiple potentials separated in time, some of which are far-field potentials that are caused by depolarization of adjacent myocardium. Far-field potentials are common during catheter mapping of infarct-related VT and can confound interpretation of the PPI. Assignment of an incorrect time of activation will render activation sequence maps misleading. The presence of far-field potentials also reduces the accuracy of entrainment mapping using the PPI. Measurement of the PPI to a far-field potential introduces an error, the magnitude of which is related to the conduction time between the pacing site and the source of the far-field potential (Fig. 22-25). When the PPI appears to be shorter than the tachycardia CL, the potential used for measurement is likely a far-field potential. Analysis of the potentials recorded during entrainment often allows identification of the far-field potential so that it can be excluded from activation

maps and the PPI measurement and, hence, improves the accuracy of mapping scar-related arrhythmias. The stimulus artifact obscures the potential produced in the tissue immediately at the stimulation site (i.e., near-field potentials). Thus, the local potential is not visible during pacing, but reappears after the last entrained QRS complex. On the other hand, far-field potentials usually fall sufficiently late after the pacing stimulus to be visible, and remain undisturbed during entrainment (see Fig. 22-25). These far-field potentials are accelerated to the pacing rate, but are not changed in morphology compared with those observed during tachycardia. The far-field potentials often precede the next stimulus by a short interval so that the tissue generating the far-field potential is probably refractory at the time of the next stimulus. Hence, the stimulus is not directly depolarizing the tissue generating the far-field potential. That these potentials are distant from the distal recording electrode is further supported by the lack of effect of RF ablation on the far-field potential.³⁶

VT entrainment from entrance of the critical isthmus

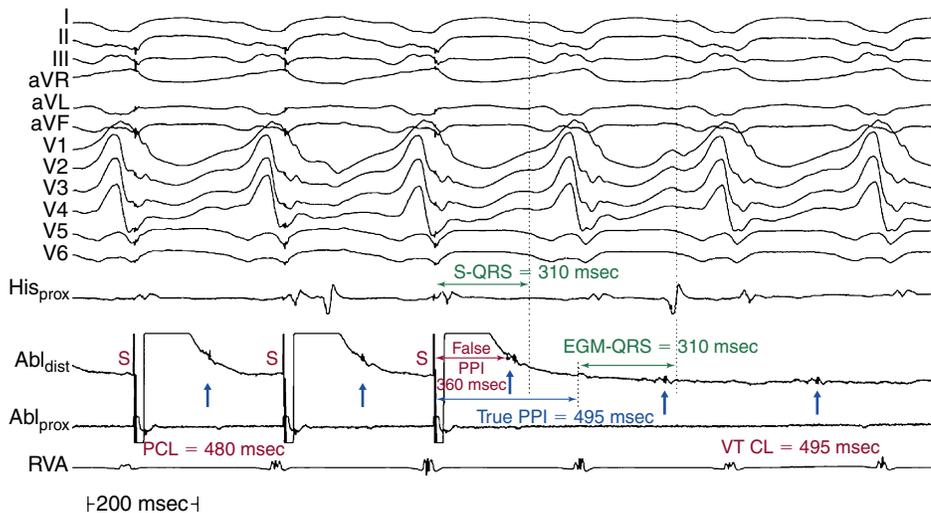

FIGURE 22-25 Entrainment during post-myocardial infarction ventricular tachycardia (VT) at a site with both systolic and late diastolic (arrows) potentials. Stimulation (S) entrains VT with an identical QRS configuration (concealed fusion) and a very long S-QRS interval, suggesting pacing at the entrance of the protected isthmus. The sharp electrogram (arrows) at this site is present and accelerated to the pacing cycle length (PCL), suggesting that the tissue generating this potential is not directly depolarized by the pacing stimulus and is, therefore, a far-field potential. The post-pacing interval (PPI) measured from the last stimulus to this far-field potential is falsely short. The local potential (red arrow) is not discernible during pacing, consistent with direct capture, but reappears after the last stimulus. The true PPI is measured from the last stimulus to this local potential.

The validity of the difference between the PPI and VT CL ($PPI - VT CL$) is based on the assumption that the recorded electrogram represents depolarization at the pacing site. Ideally, electrograms are recorded from the mapping catheter electrodes used for stimulation, but this is sometimes difficult. Electrical noise introduced during pacing can obscure the electrograms at the stimulating electrodes, and some recording systems do not allow recording from the pacing site. When the electrograms from the pacing site are not discernible because of stimulus artifact, relating the timing of the near-field potential to a consistent intracardiac electrogram or surface ECG wave can be used to determine the PPI. A reasonable alternative is to calculate the PPI from electrograms recorded by electrodes adjacent to those used for pacing (i.e., from the proximal electrodes of the mapping catheter), provided such electrograms are also present in the distal electrode recordings (Fig. 22-26). However, this does introduce potential error, particularly if low-amplitude local electrograms present at the pacing site are absent at the proximal recording site. A more accurate alternative is assessment of the $[PPI - VT CL]$ value from the conduction time between the last pacing stimulus that entrains tachycardia and the second beat after the stimulus (the $N + 1$ beat) by comparing this interval with the electrogram timing at the pacing site in any following beat (Fig. 22-27). Additional errors can also be introduced by the decremental conduction properties of the zone of slow conduction that might cause a rate-dependent lengthening of the PPI.^{36,44}

ELECTROGRAM-TO-QRS INTERVAL VERSUS STIMULUS-TO-QR INTERVAL

This criterion is helpful in differentiating a critical component of the zone of slow conduction from a blind alley or noncritical alternate (bystander) pathway, in a manner analogous to that of the $[PPI - VT CL]$ method (see Fig. 5-14). An electrogram-QRS interval equal to the S-QRS interval (± 20 milliseconds) suggests that the pacing site lies within the reentry circuit and not in a dead-end bystander pathway attached to the circuit (see Figs. 22-24 and 22-25). This method requires that the stimulated orthodromic wavefronts exit from the circuit at the same site as the tachycardia wavefronts (i.e., presence of entrainment with concealed fusion). Any degree of QRS fusion indicates that the stimulated wavefronts could be exiting from another route, invalidating this analysis. However, QRS fusion is often difficult to detect when less than 22% of the QRS is fused, which poses a major limitation to the S-QRS method.

To avoid this limitation, a modification of the S-QRS interval method has been proposed whereby the S-QRS interval is measured to the second beat, which unquestionably results from a

wavefront that has emerged from the tachycardia circuit and is not fused. The QRS complex and electrogram inscribed during or immediately after the pacing stimulus are defined as $QRS_{(N)}$ and $electrogram_{(N)}$, respectively; the following QRS and electrogram are defined as $QRS_{(N+1)}$ and $electrogram_{(N+1)}$, respectively. The $S-QRS_{(N+1)}$ interval and $electrogram_{(N+1)}-QRS_{(N+2)}$ interval are then determined; the difference between these two intervals is defined as the $N + 1$ difference. Because the $S-QRS_{(N+1)}$ interval is not influenced by QRS fusion during entrainment, an endocardial electrogram that is remote from the pacing site can potentially be used as the timing reference, instead of the QRS onset. Often, the endocardial recording is more precise and easily used for the fiducial point.⁴⁴

The S-QRS criterion increases the positive predictive value of successful ablation outcome at sites demonstrating entrainment with concealed fusion to 80% (see Table 22-3). However, the electrogram-QRS interval may not be equal to the S-QRS interval at sites within the reentrant circuit. Several factors can explain this. Decremental conduction properties of the zone of slow conduction can potentially lengthen the S-QRS interval during pacing, and stimulus latency in an area of diseased tissue can also account for a delay in the S-QRS interval compared with the electrogram-QRS interval. In addition, failure of the recording electrodes to detect low-amplitude depolarizations at the pacing site can account for a mismatch of the S-QRS and electrogram-QRS intervals (Fig. 22-28).

RATIO OF STIMULUS-TO-QRS INTERVAL TO TACHYCARDIA CYCLE LENGTH

Some investigators have proposed that critical areas of slow conduction within the reentrant circuit could be identified by overdrive pacing from LV sites associated with prolonged conduction times from the pacing site to the exit from the infarct scar, as reflected by the S-QRS interval. Although sites requisite for the reentrant circuit that exhibit slow conduction can behave in this manner, the mere presence of prolonged conduction from the S-QRS interval does not prove that the slow conduction is part of a reentrant circuit pathway. Multiple areas within the infarct zone can exhibit fractionated or abnormal electrograms and reduced excitability, which are associated with increased S-QRS intervals, yet may have nothing to do with the VT circuit itself.

Others have used a prolonged stimulus to local electrogram time during entrainment to identify pathways containing slow conduction. This again does not prove that the electrogram at the recording site has anything to do with the VT, because slow conduction involved in the orthodromic capture of this electrogram can occur inside or outside the circuit. In fact, whenever ECG fusion occurs, some electrograms outside the circuit (i.e., those activated after

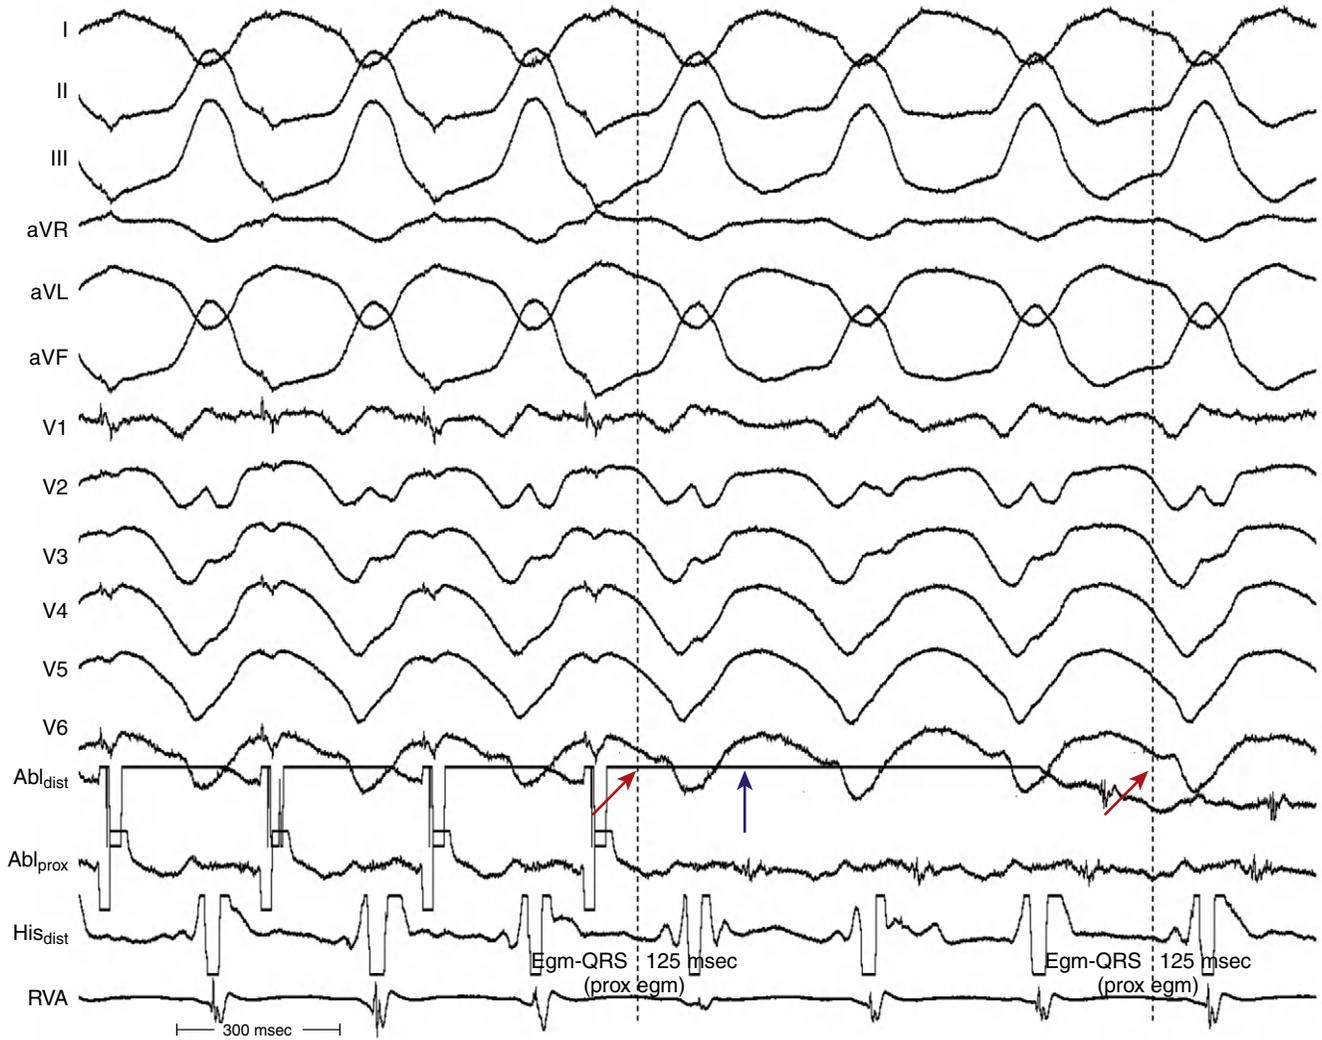

FIGURE 22-26 Using the proximal electrogram recording as a surrogate for the distal electrogram. Entrainment of ventricular tachycardia (VT) is shown. The post-pacing interval cannot be directly assessed owing to saturation of the distal ablation electrode (Abl_{dist}) recording (blue arrow). The interval from the proximal ablation electrode (Abl_{prox}) recording electrogram to QRS can be compared with the same interval during VT (red arrows) to serve as a surrogate for the distal ablation recording electrogram, as long as there is minimal disparity in the timing of these two recordings. Egm = electrogram.

leaving the exit that is part of the VT wavefront) will be orthodromically activated and will fulfill the requirements for entrainment. For the same reason, termination with block before this orthodromically entrained electrogram does not mean that it was a critical component of the circuit.

On the other hand, during entrainment with concealed fusion, the S-QRS interval is an approximate indication of the location of the pacing site relative to the reentry circuit exit. A short S-QRS interval (<30% of the tachycardia CL) suggests a site near the exit. Long S-QRS intervals (>70% of the tachycardia CL) suggest bystander sites rather than a critical isthmus. Therefore, at sites demonstrating entrainment with concealed fusion, an S-QRS interval-to-tachycardia CL ratio not exceeding 0.7 suggests that the sites lie within the common pathway (isthmus) of the reentrant circuit, and sites at which the ratio is equal to or more than 0.7 are considered to lie outside the common pathway (see Fig. 5-14). The S-QRS interval-to-VT CL ratio not greater than 0.7 criterion improves the positive predictive value of entrainment with concealed fusion to approximately 70%. Moreover, the negative predictive value of this criterion is 92%, indicating that ablation at sites with entrainment with concealed fusion at which the S-QRS interval-to-VT CL ratio is more than 0.7 is unlikely to be successful (see Table 22-3).

Pace Mapping

QRS MORPHOLOGY DURING PACING VERSUS VENTRICULAR TACHYCARDIA

When ventricular activation originates from a pointlike source (e.g., during focal VT or during pacing from an electrode catheter), the QRS configuration recorded in the surface ECG is determined by the sequence of ventricular activation, which is largely determined by the initial site of ventricular depolarization. Analysis of specific QRS configurations in multiple leads allows estimation of the pacing site location to within several square centimeters (see Figs. 5-21 and 5-22). Therefore, comparing the paced QRS configuration with that of VT is particularly useful for locating a small arrhythmia focus in a structurally normal heart (e.g., idiopathic RVOTVT), whereas pace mapping has been less useful for guiding the ablation of post-MIVT.⁴⁴

Reentry circuits in healed infarct scars often extend over several square centimeters and can have a variety of configurations. In many circuits, the excitation wavefront circulates through surviving myocytes within the scar, the depolarization of which is not detectable on the standard surface ECG. The QRS complex is then inscribed after the reentry wavefront exits the scar and propagates across the

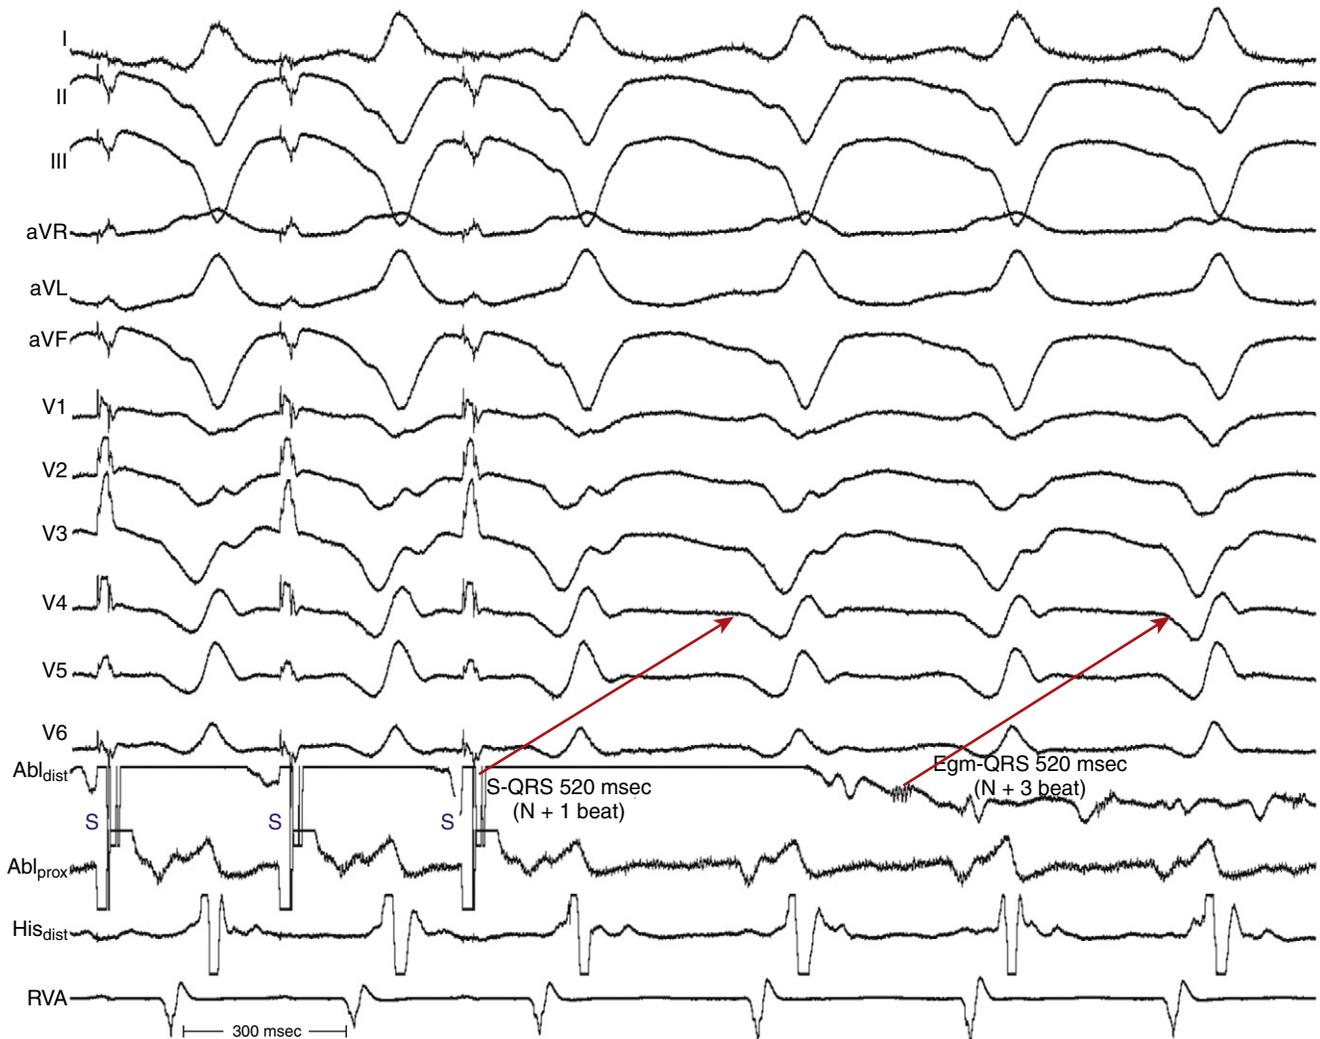

FIGURE 22-27 The “N + 1” rule. Entrainment of ventricular tachycardia (VT) is shown. The post-pacing interval cannot be directly assessed because of saturation of the distal ablation electrode (Abl_{dist}) recording. The interval from stimulus (S) to the next VT complex (“N + 1”) can be compared with the interval from the electrogram after it is again visible, to a subsequent VT complex (“N + 3” in this case). If the difference between these intervals is less than 20 milliseconds, the site of stimulation is likely in the circuit.

ventricles. At sites at which the reentrant wavefront exits the scar, pace mapping is expected to produce a QRS configuration similar to that of the VT (see Fig. 5-23). Pace mapping at sites more proximally located in the isthmus should also produce a similar QRS complex, but with a longer S-QRS interval. The S-QRS interval lengthens progressively as the pacing site is moved along the isthmus, consistent with pacing progressively farther from the exit (see Fig. 5-23).⁴⁴

In infarct-related VT, however, a paced QRS configuration different from that during VT does not reliably indicate that the pacing site is distant from the reentry circuit. At many reentry circuit sites, pacing during NSR can produce a QRS configuration different from that during VT. In fact, it is uncommon to have similar or even almost identical morphology result from pacing from a known isthmus determined by mapping. Several factors can explain this mismatch.⁴⁵ First, the pattern of ventricular activation and hence resultant QRS depends on how the wavefront propagates from the exit of the isthmus to the remainder of the heart, which can be totally different during VT than during pacing from the same site during NSR (see Fig. 5-23). In fact, such pacing would be expected to produce a different QRS than the VT because the paced wavefront spreads centrifugally to the heart while the VT wavefront spreads in one direction (i.e., orthodromically). This observation is one of the important limitations of the use of pace mapping to identify the critical isthmus of post-MI VT. Propagation in the

diseased myocardium is not homogeneous, and small differences in catheter location can cause grossly different propagation wavefronts and resultant QRS complexes. Even small differences in the angle of contact of catheter to the ventricular wall and site of initial ventricular activation can alter the precise QRS configuration. The relationship between conduction time, pacing site location in the isthmus, and conduction block determines whether pace mapping in an isthmus produces a QRS that resembles that of VT. When pace mapping in a defined isthmus is performed, the stimulated wavefront can only follow along its course, which occurs in at least two directions—orthodromic and antidromic (relative to the direction of VT propagation). The wavefront is only detected on the surface ECG when it leaves this protected channel. If the isthmus is long and the catheter is positioned in the distal part, near the exit, the orthodromic wavefront leaves the exit and rapidly depolarizes the region along the infarct, colliding with and preventing emergence of the antidromic wavefront from the infarct region. The resulting QRS complex is then similar to that of VT. If the isthmus is short, or the catheter is positioned more proximally, the stimulated antidromic wavefront leaves the protected isthmus at the entrance, propagating to the surrounding myocardium and producing a different QRS morphology (see Fig. 5-23). If the orthodromic wavefront reaches the exit, a fusion QRS is produced that includes depolarization from both the antidromic and orthodromic wavefronts.

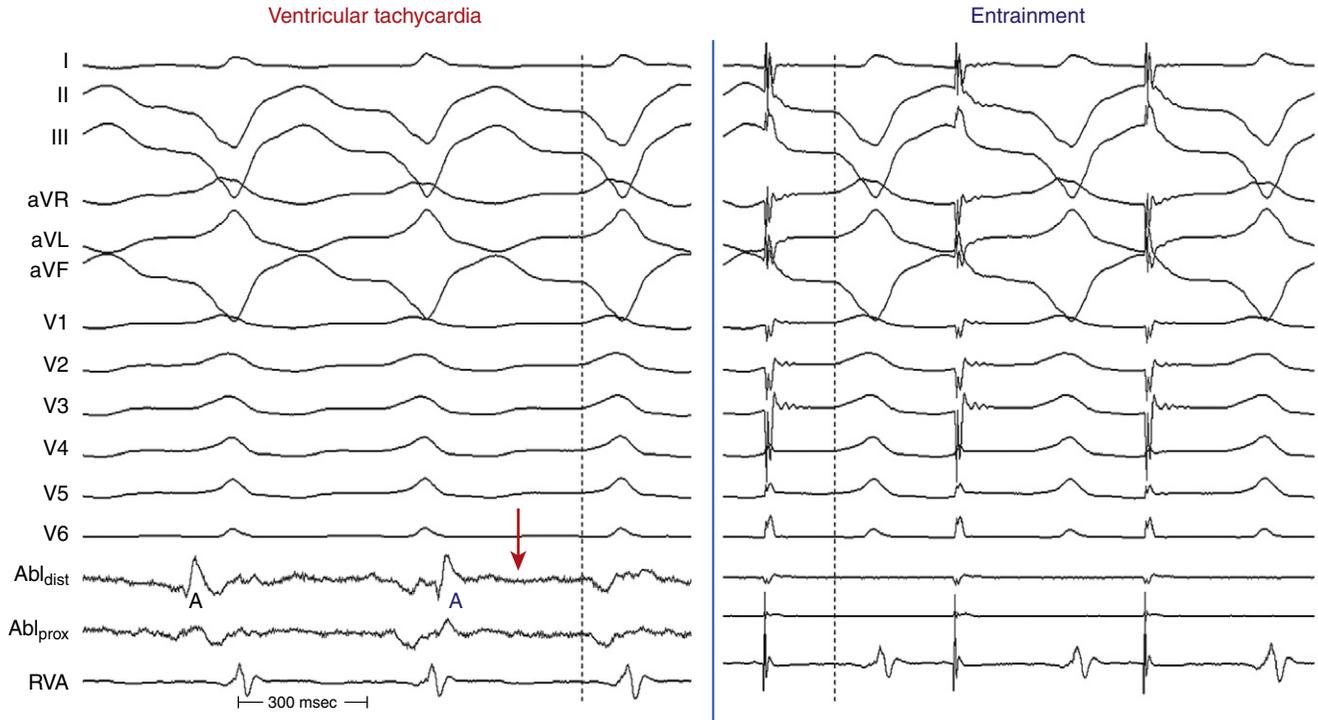

FIGURE 22-28 Capture during inferobasal post-infarct ventricular tachycardia (VT) without recorded electrogram. At left is VT during which the distal ablation electrode (Abl_{dist}) recording shows no clear diastolic activity; however, stimulation at this site readily captures the ventricle. The red arrow shows the timing during VT equal to the stimulus-QRS interval during pacing. A = atrial recording.

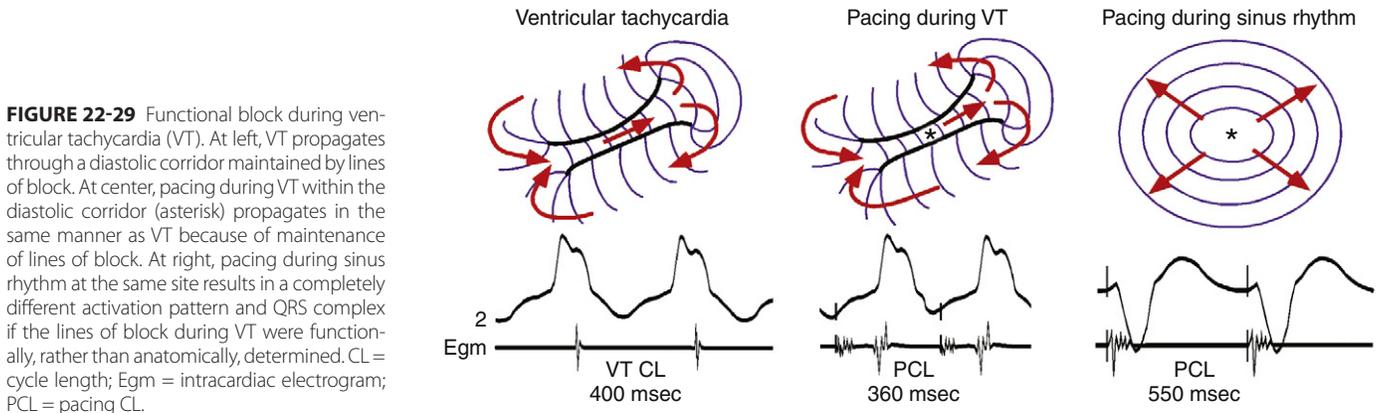

FIGURE 22-29 Functional block during ventricular tachycardia (VT). At left, VT propagates through a diastolic corridor maintained by lines of block. At center, pacing during VT within the diastolic corridor (asterisk) propagates in the same manner as VT because of maintenance of lines of block. At right, pacing during sinus rhythm at the same site results in a completely different activation pattern and QRS complex if the lines of block during VT were functionally, rather than anatomically, determined. CL = cycle length; Egm = intracardiac electrogram; PCL = pacing CL.

A second explanation is that the process whereby VT is generated in patients with structural heart disease usually involves the development of an area of functional block to conduction. Such functional block is not fixed, not anatomical, and variable in its extent. When formed, it combines with an area of fixed conduction block caused by, for example, the infarct scar, to create a protected channel for conduction that allows reentry to occur. Regions of functional block, present during VT, can define propagation paths during tachycardia but not during pace mapping in NSR. Therefore, if block defining an isthmus is present only during VT and is absent during pace mapping in NSR, the stimulated wavefront produced by pacing at the isthmus site would propagate in all directions, resulting in a different QRS morphology (Fig. 22-29). This is further exaggerated by the fact that pace mapping is usually performed at rates slower than the VT to avoid VT induction during the mapping process, which can reduce the likelihood of development of a line of functional block. Additionally, the area over which the current is delivered, especially where high current is required for relatively inexcitable tissue, can influence the pattern of subsequent

ventricular activation, presumably by capturing more distant (i.e., far-field) tissue. When this occurs, it can indicate pacing in a region of a protected isthmus, where pacing at low output would capture only the isthmus, whereas pacing at a higher output can capture both the isthmus and far-field tissue, resulting in different QRS morphologies and S-QRS intervals (Fig. 22-30). Finally, some circuits can have more than one exit, with wavefronts emerging from the scar at multiple locations. Different exits can participate preferentially during VT but not during pace mapping, and vice versa.

On the other hand, pacing during NSR from sites attached to the reentrant circuit but not part of the circuit can occasionally produce QRS morphology identical to that of the VT, because the stimulated wavefront can be physiologically forced to follow the same route of activation as the VT as long as pacing is carried out between the entrance and exit of the protected isthmus. Although this strategy can result in the identification of irrelevant inner loop and adjacent bystander sites as well as the desired isthmus sites, it still can be helpful in gross identification of the region of the VT circuit.²

Conduction away from the pacing site (and the resultant QRS morphology) can potentially be influenced by the pacing output, pacing rate, and antiarrhythmic drugs. To minimize the impact of rate-related changes in conduction, pacing is performed at a relatively slow rate. Pacing slower than the rate of the VT, however, can further reduce the relationship of the paced QRS morphology to that of the VT target area. During bipolar pacing, capture at the proximal electrode rather than the distal electrode can also modify the QRS morphology. The sequence of ventricular activation can vary during pacing at different stimulus strengths. This phenomenon is more pronounced with bipolar than unipolar pacing, likely because of anodal capture at higher stimulus strengths (Fig. 22-31). This potential problem can be avoided by using unipolar pacing and by limiting the current output to 10 mA and 2 milliseconds, which is within the range of routine programmed stimulation.⁴⁶

STIMULUS-TO-QRS INTERVAL DURING PACE MAPPING

Parts of VT reentry circuit isthmuses can be traced during NSR by combining both the QRS morphology and the S-QRS delay during pace mapping in anatomical maps. Pacing in normal myocardium is associated with an S-QRS interval of less than 40 milliseconds. On the other hand, an S-QRS interval more than 40 milliseconds is consistent with slow conduction away from the pacing site, and is typically associated with abnormal fractionated electrograms recorded from that site. Thus, pace mapping can provide a measure of slow conduction, as indicated by the S-QRS interval, which can indicate a greater likelihood that the pacing site is in a reentry

circuit. Creating a latency map using an electroanatomical mapping system to represent the regions of S-QRS latency graphically also can be a useful method for initially screening sites during NSR (see Fig. 5-23). It is likely that pacing sites with long S-QRS delays are in a potential isthmus, adjacent to regions of conduction block. However, this isthmus can be part of the reentrant circuit (i.e., critical isthmus) or a bystander (see Fig. 5-14).

The reentry circuit exit, which is more likely to be at the border of the infarct and close to the normal myocardium, often has no delay during pace mapping during NSR, even though it may be reasonable to target for ablation. Sites with long S-QRS intervals can be more proximal in the isthmuses; therefore, they are more likely to be associated with propagation of the paced wavefront in the antidromic direction away from the reentry circuit, producing a QRS different from that of the VT (see Fig. 5-23). Sites with prolonged S-QRS intervals during pace mapping are frequently associated with other markers of reentry circuit sites; however, this can be a somewhat limited mapping guide. Approximately 25% of likely reentry circuit sites have short S-QRS intervals during pace mapping, and more than 20% of sites with long S-QRS intervals do not appear to be in the reentry circuit.²

VALUE OF PACE MAPPING

At best, a pace map that matches the VT would only identify the exit site to the normal myocardium, which can be distant from the critical sites of the circuit required for ablation. Thus, pace mapping remains only a corroborative method of localizing reentrant

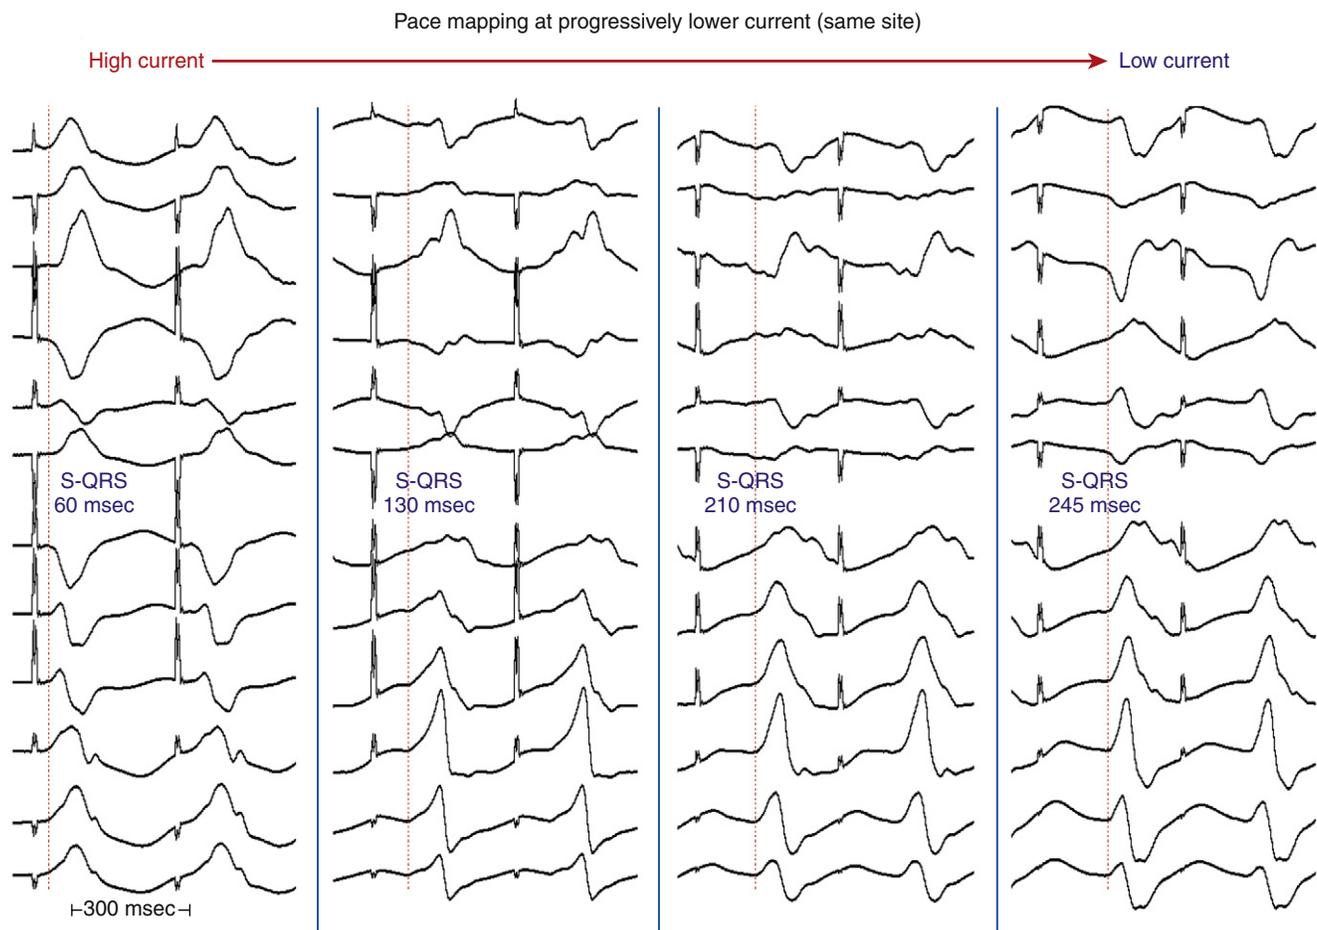

FIGURE 22-30 Effect of stimulus strength on QRS complex and stimulus (S)-QRS during pace mapping. QRS complexes resulting from pacing from the same site, but at different current strength, are shown from higher (left) to lower (right) output. Note the dramatic changes in QRS configuration as well as the progressively longer S-QRS interval. This was easily reproducible; increasing output reversed the ECG and S-QRS interval findings, and lowering output again recapitulated the data shown here.

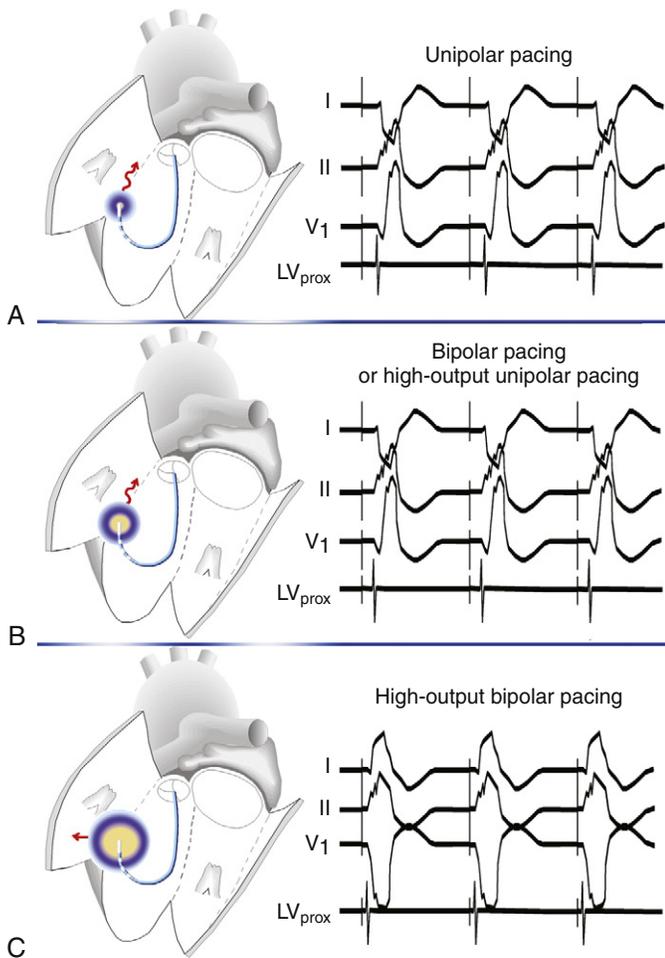

FIGURE 22-31 Effect of bipolar and high-output stimulation on the paced QRS complex morphology in scarred myocardium. The diagram illustrates a catheter stimulating a site within scar tissue on the left ventricular (LV) anterior septum. **A**, With low-output unipolar pacing, a relatively small zone is captured (blue halo) resulting in a long stimulus (S)-QRS interval because the impulse must travel through scar until it encounters enough tissue to generate a QRS complex. **B**, Bipolar or higher output unipolar pacing captures a larger area, resulting in a shorter S-QRS but using the same path, resulting in the same QRS morphology as at lower output unipolar pacing. **C**, High-output bipolar pacing captures a much larger area and can now activate normal myocardium directly, bypassing the slow conduction zone in scar tissue. This results in a very short S-QRS and a very different QRS complex morphology than previously, despite pacing at the same site.

VT. It can be used to focus initial mapping to regions likely to contain the reentrant circuit exit or abnormal conduction but is not sufficiently specific or sensitive to be the sole guide for ablation. Pace mapping can also be used in conjunction with substrate mapping when other mapping techniques are not feasible, so that it can provide information on where ablation can be directed.²

TECHNIQUE OF PACE MAPPING

At isthmus sites, as identified by activation and entrainment mapping during VT, pace mapping in NSR is attempted after VT termination. Either bipolar or unipolar pacing may be used. Pace mapping is preferably performed with unipolar stimuli (10 mA, 2 milliseconds) from the distal electrode of the mapping catheter (cathode) and an electrode in the inferior vena cava (IVC; anode). Bipolar pacing produces a smaller stimulus artifact; however, there is the possibility of capture at the proximal ring electrode as well as at the tip electrode that may reduce accuracy, particularly if larger interelectrode distances (8 to 10 mm) and high-current strength is used. Pacing only slightly above threshold is likely to improve accuracy. The pacing CL is usually the same for each site in an individual patient (500 to 700 milliseconds), faster than the sinus rate and slower than the rate of the induced VTs.²

The resulting 12-lead ECG morphology is compared with that of the VT. ECG recordings should be reviewed at the same gain and filter settings and at a paper-sweep speed of 100 mm/sec. It is often helpful to have a split-screen display of the target VT in one panel, comparing this with all 12 leads of the paced QRS complexes brought into another panel, as well as with print regular 12-lead ECGs for side-by-side comparison on paper. The greater the degree of concordance between the morphology during pacing and tachycardia, the closer the catheter is to the site of origin of the tachycardia (see Fig 5-22).

Evaluation of the S-QRS also is of value. The S-QRS interval is measured to the onset of the earliest QRS on the 12-lead ECG. Sites from which pace mapping produces the same QRS as that of the initial isthmus site with different S-QRS delays are identified in an attempt to trace the course of the VT isthmus (see Figs 5-14 and 5-23).

Substrate Mapping during Baseline Rhythm

Substrate mapping refers to delineation of the infarcted myocardium (VT substrate) based on the identification of abnormal local electrogram configuration (fractionated electrograms, multipotential electrograms, and/or electrograms with isolated delayed components) and abnormal local electrogram amplitude (voltage mapping) during the baseline rhythm (NSR, AF, ventricular pacing; Fig 22-32). Post-MI VTs can be unstable or unsustainable and therefore not approachable by conventional point-by-point activation

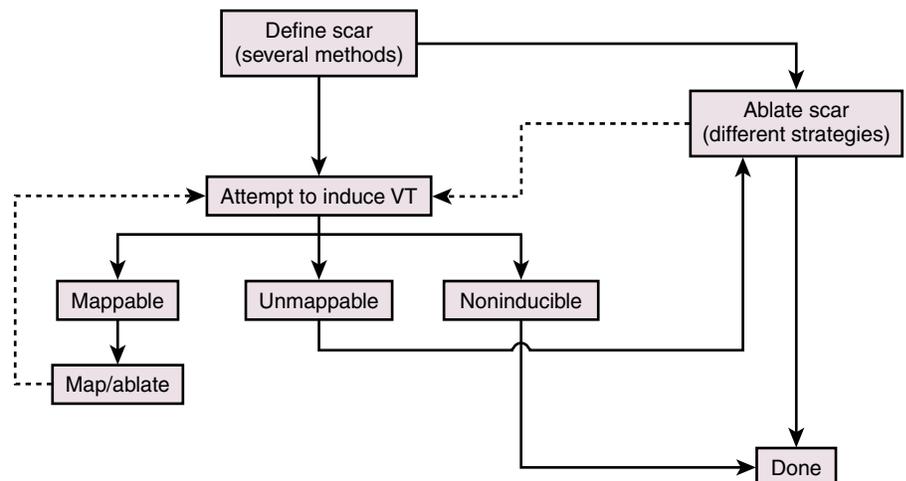

FIGURE 22-32 An algorithmic approach to treatment of scar-based ventricular tachycardia, consisting of an iterative process. See text for details.

mapping and entrainment maneuvers. Therefore, mapping during the baseline rhythm rather than during VT is of significant value. Substrate mapping helps identify the VT substrate and facilitates ablation of multiple VTs, pleomorphic VTs, and VTs that are unmapable because of hemodynamic instability or that are not reliably inducible. Substrate mapping is also of value in ablation of stable VTs, because it can help focus activation and entrainment mapping efforts on a small region harboring the VT substrate, and therefore help minimize how long the patient is actually in VT.²

ABNORMAL ELECTROGRAMS DURING THE BASELINE RHYTHM

The vast majority (approximately 85%) of post-MI VTs occurs at sites that have abnormal and/or late electrograms during NSR (see Fig. 22-20). Infarct regions are well delineated as areas of low-amplitude abnormal electrograms. Therefore, potential arrhythmogenic areas can be identified in the presence of abnormalities, late electrograms, or both, which are associated with arrhythmogenic tissue. However, abnormal sinus rhythm electrograms with multiple potentials are also frequently seen in bystander regions that are not integral parts of the reentrant circuit. Recording of simply abnormal low-voltage electrograms is highly nonspecific because the extensive areas in which they are located are not sufficiently specific to be the sole guide for ablation if the ablation approach seeks to target a small focal region. Therefore, additional electrogram characteristics have been proposed to improve the accuracy of sinus rhythm mapping.

FRACTIONATED ELECTROGRAMS. Reentry circuit isthmuses consist of a proximal part (entrance), a central part, and an exit from which the wavefront leaves the abnormal region and rapidly depolarizes the normal myocardium, resulting in the formation of the QRS complex. Conduction through the isthmus or at its entrance, exit, or both is often slow and nonuniformly anisotropic because of the transverse uncoupling of myocytes by fibrosis; hence electrogram fractionation is a common finding in areas of scar and VT substrate. Additionally, during NSR, a typical local electrogram in the border of an infarct has a low voltage but is adjacent to more normal myocardium in the border, causing a multipotential electrogram that has markedly different amplitudes, with a large rounded potential (reflecting a far-field signal from activation of the large mass of surrounding tissue) and a small sharp potential (reflecting local depolarization of a small mass of fibers in the infarct). These electrograms are common in the infarct region, may be found throughout the scar, and are not specific for the critical isthmus of the reentry circuit. Therefore targeting of fractionated electrograms has never been shown to be an effective ablation strategy.^{4,7}

WIDE ELECTROGRAMS. Critical isthmus sites in the VT reentry circuit are likely to be located at sites with the latest activation during NSR. Most critical isthmus sites display electrograms that have a duration of more than 200 milliseconds, isolated diastolic potentials during NSR, or both (see Fig. 22-20). These findings are consistent with post-infarction remodeling, which results in progressive EP effects in the anatomical substrate for VT. Moreover, there is a significant positive correlation between infarct age and the duration of the broadest endocardial electrograms (>200 milliseconds) during sinus rhythm mapping in the peri-infarct zone. The older the infarct, the broader are the electrograms and the longer is the delay between the electrogram and isolated potentials. Sites with the broadest electrograms or isolated potentials detected during sinus rhythm mapping are typically identical to those at the critical isthmus of the reentrant circuit recorded during induced VT.^{4,7}

ELECTROGRAMS WITH ISOLATED DELAYED COMPONENTS. Electrograms with isolated delayed components are defined as electrograms with double or multiple components separated by a very low-amplitude signal or an isoelectric interval more than 50 milliseconds in duration. These electrograms can reflect local depolarization of surviving fiber bundles that are well insulated

by dense scar, where local activation is recorded late, well after the higher amplitude far-field electrogram and often well after the end of the surface QRS complex or T wave. Late isolated potentials during NSR are relatively uncommon (15% of all multiple potentials) but can be markers of an anatomically constrained, slowly conducting critical diastolic isthmus during VT.^{4,7} However, isolated potential mapping is limited by the imperfect specificity due to bystander cul-de-sacs or nonspecific slowed conduction as well as imperfect sensitivity due to low-amplitude local signals or the direction of wavefront propagation obscuring isolated potentials. Nevertheless, this type of electrogram, although unable to differentiate the central isthmus from a close bystander, can help refine the area of interest. The areas demonstrating such electrograms are relatively small compared with scar areas; therefore, this method permits a focus on the diagnostic techniques and ablation in defined areas. Furthermore, recording of these electrograms before and during VT induction serves to relate them and VT within seconds, provided that the isolated diastolic component of the electrogram precedes the first VT beat and then becomes mid-diastolic. Additionally, pacing at these sites may capture the local potential and conduct slowly out of the scar, resulting in a long S-QRS interval and, if sharing an exit of a targeted VT, a good or excellent pace map.⁴ The ablation of all sites demonstrating electrograms with isolated diastolic components can overcome the lack of specificity of the selection of a single site as an ablation target when entrainment mapping criteria are not fulfilled (Fig. 22-33). Ablation of these electrograms can also eliminate the substrate for different VTs otherwise not ablated by limited, conventional strategies.⁷

CHANGING DIRECTION OF VENTRICULAR ACTIVATION WAVEFRONT

Electrogram amplitude is in part a reflection of the depolarizing muscle mass as well as wavefront direction. Multipotential electrograms are sometimes detectable during NSR, but low-amplitude potentials can be obscured by the signal from the surrounding larger mass of myocardium. In regions of block, changing the direction of depolarization can produce greater separation between activation of adjacent bundles, altering the separation of multipotential electrograms. Regions containing isthmuses and conduction block can be detected by analyzing electrograms recorded during two different ventricular activation sequences, such as sinus rhythm (or atrial pacing) and then RV pacing.

Theoretically, a wavefront propagating parallel to the long axis of adjacent but separate fiber bundles would activate adjacent bundles simultaneously, reducing the time between potentials. Consequently, multiple potentials can become superimposed on each other, preventing their detection. On the other hand, a wavefront traveling perpendicular to a fiber long axis that encounters bundles would be expected to result in greater temporal separation of potentials in these regions (Fig. 22-34). Conversely, multipotential electrograms that persist in both activation sequences are more likely to be associated with the reentry circuit isthmuses. Persistent multipotential electrograms may indicate greater separation from surrounding muscle, with fixed block and disordered conduction, regardless of the direction of activation. Therefore, changing the direction of the activation wavefront can unmask some areas of block and slow conduction. Multipotential electrograms with more than two deflections, highly predictive of a reentry substrate, are more frequently recorded during RV pacing. Theoretically, this can be related to the fact that during NSR several simultaneous activation wavefronts can coexist, making the probability of electrogram overlap higher than during RV pacing, when only one activation wavefront is present.

Electroanatomical Mapping

Electroanatomical mapping can help in the precise description of VT reentrant circuits, sequence of ventricular activation during the

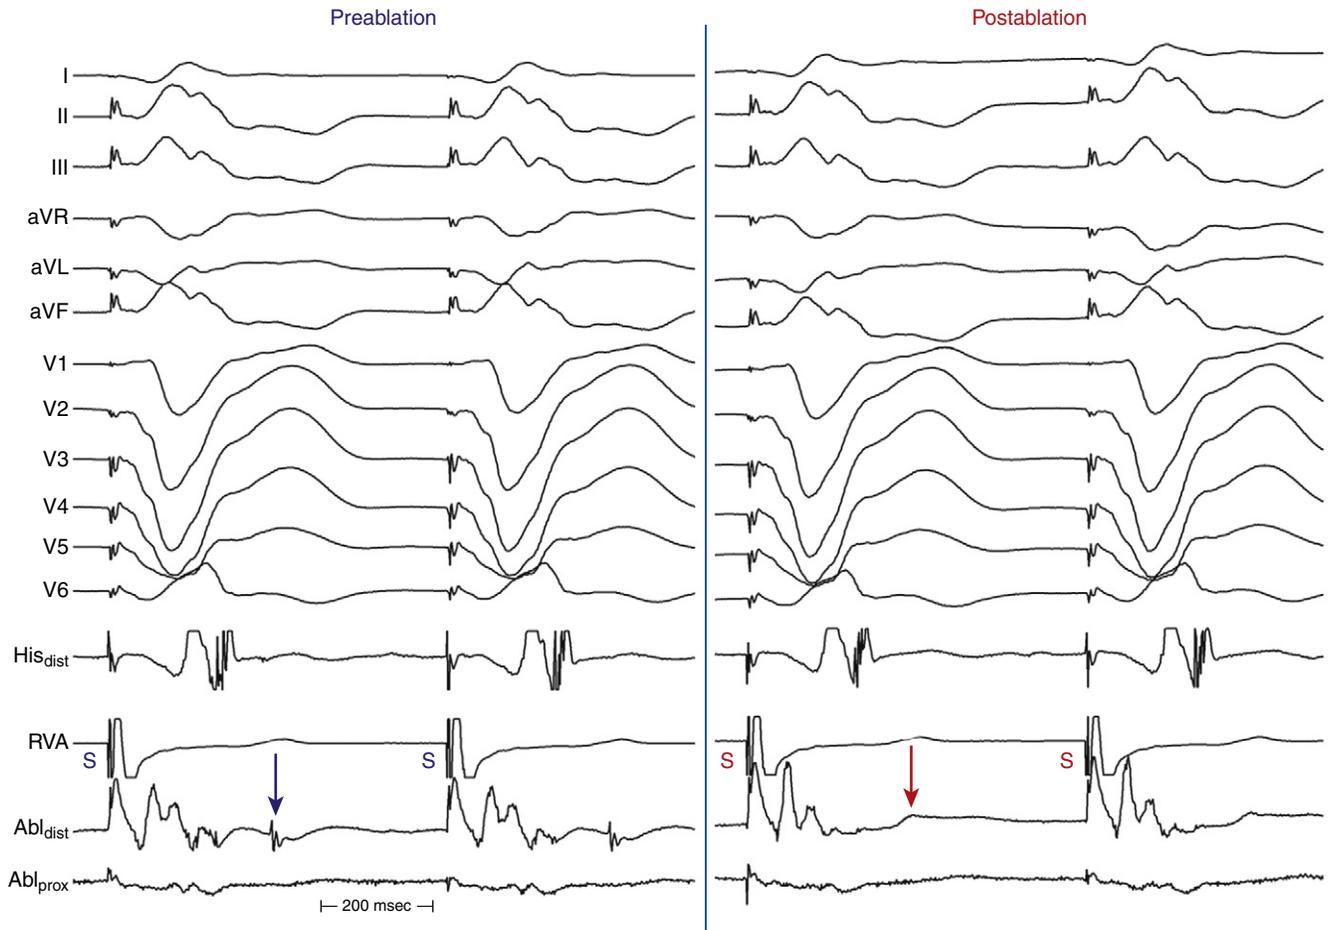

FIGURE 22-33 Elimination of endocardial late potentials with ablation. At left, a very delayed potential is seen during ventricular pacing (blue arrow); after ablation at this site (right panel), the potential has been eliminated (red arrow).

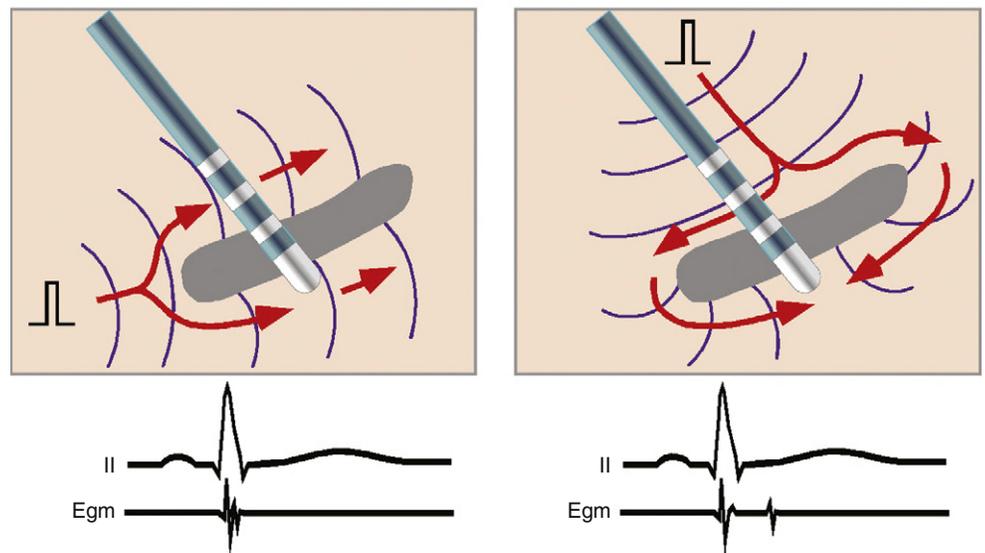

FIGURE 22-34 Effect of direction of wavefront propagation on electrogram (Egm) configuration. A catheter is recording over an island of scar surrounded by normal tissue. At left, a wavefront arriving from the left side is split by the scar, but tissue on each side of the scar is activated at about the same time, resulting in a relatively normal Egm. At right, a wavefront arriving from right angles to the prior one is split by the scar, with tissue on the near side activated early and that on the opposite side activated much later, resulting in a markedly split recording.

VT, rapid visualization of the activation wavefront, and identification of slow-conducting pathways and appropriate sites for entrainment mapping. These systems also help navigation of the ablation catheter, planning of ablation lines, and maintaining a log of sites of interest (e.g., sites with favorable entrainment or pace mapping findings), which can then be revisited with precision. Additionally, voltage

(scar) mapping is a helpful feature of the current electroanatomical mapping systems.²

The CARTO electroanatomical mapping system (Biosense Webster, Diamond Bar, Calif.) has been extensively used in mapping and ablation of post-MI VT, and is described here as a model for 3-D mapping. The ESI-NavX (St. Jude Medical, St. Paul, Minn.)

has also been successfully used for mapping and ablation of scar-related VT.

ELECTROANATOMICAL ACTIVATION MAPPING

The electrical reference is chosen as a morphologically stable and regular electrogram obtained from an endocardial (e.g., RV apical electrogram) or surface lead (e.g., surface ECG lead with a QRS complex during VT demonstrating a sharp apex and a strong positive or negative deflection). The width of the window of interest is adjusted to approximate, usually 20 milliseconds less than, the VT CL. The middle of the window of interest is selected to coincide with the electrical reference.

Activation mapping is performed to define the ventricular activation sequence during VT. A reasonable number of points have to be recorded. The LV is plotted during VT by dragging the mapping catheter over the endocardium. Stability is assessed by monitoring position on biplane fluoroscopy and on the electroanatomical mapping system and by continuous monitoring of electrogram morphology and timing. Points are added to the map only if stability criteria in space and local activation time are met. The local activation time at each site should have a beat-to-beat variability of less than 5 milliseconds. The local activation time for each endocardial position under the mapping catheter is calculated as the interval between the electrical reference and the onset of the high-frequency bipolar electrogram as it leaves the baseline. Infarct regions are sought first and more data points are acquired around these areas, as identified by low-amplitude potentials, with diastolic electrograms, or double potentials. The resulting reentrant circuit is considered to be the spatially shortest route of unidirectional activation encompassing a full range of mapped activation times (>90% of the tachycardia CL) and returning to the site of earliest activation.

The activation map can also be used to catalogue sites at which pacing maneuvers are performed during assessment of the VT. Silent areas are defined as ventricular potential amplitude of less than 0.05 mV, which is the baseline noise in the Biosense Webster system, and the absence of ventricular capture at 20 mA. Such areas are tagged as scar and therefore appear in gray on the 3-D maps.

VOLTAGE (SCAR) MAPPING

VALUE. Voltage mapping is of value when activation mapping cannot be performed during VT because of hemodynamic instability. In these cases, voltage mapping can be used to delineate areas of low-voltage infarct scar that harbor the VT substrate to guide ablation. Even in well-tolerated VTs, the identification of these conducting channels by voltage mapping before induction of VT can facilitate subsequent mapping, ablation, or both and minimize the duration during which the patient is actually in VT.

CONCEPT. Bipolar electrogram amplitude of 0.5 mV has been accepted as the signal amplitude that best defines the anatomical region of dense scar, with signal amplitudes between 0.5 and 1.5 mV representing the infarct border zone. The voltage cutoff of 1.5 mV was based on normal hearts without significant hypertrophy. Therefore, cutoff values of 2.0 mV or even 2.2 mV will better define the substrate in the setting of markedly hypertrophied ventricles, especially given the fact that the distinction between normal and abnormal bipolar signals in most patients with prior MI tends to be very discrete and dramatic and, as a consequence, altering the upper limit of the color range to 2.0 mV will do little to alter the bipolar voltage map. On the other hand, whereas bipolar voltages less than 1.5 mV likely represent underlying myocardial fibrosis, further subdivision of voltage zones below this value is perhaps somewhat arbitrary, with human validation data presently lacking. The border zone at the margins of confluent post-infarct scarring do, however, tend to have relatively more preserved voltages (in the range from 0.5 to 1.5 mV), and some data suggest that the majority of rapid unmappable VTs have critical circuit components located in this zone.⁴ Additionally, pacing provides

complementary information to electrogram amplitude; only 2% of sites with amplitude more than 0.5 mV have a pacing threshold more than 10 mA, whereas a substantial number of very low-amplitude sites have high pacing thresholds, and many sites in reentry circuit isthmuses have very low amplitudes.

In patients with post-MI VT, the low-voltage infarct areas are relatively large (average area, 38.6 ± 34.6 cm²; range, 6.4 to 205.4 cm²), so that complete encirclement with RF ablation lesions is likely to be difficult, although linear ablation to join areas of electrically unexcitable scar to each other or to other conduction barriers can be associated with good ablation outcomes.⁴ On the other hand, identification of the conducting channels within the infarct region, which are relatively small bundles of viable tissue compared with the scar areas, can permit focus on the diagnostic techniques and ablation to defined areas that potentially harbor the VT substrate. In one study, 86% of such channels were related to induced or clinical VT, which implies high arrhythmogenic potential. This procedure can also allow the ablation of some nontolerated or non-inducible VTs not approachable by conventional entrainment and activation mapping methods.⁴

Relative voltage preservation within denser regions of scar is a hallmark of central conducting channels that may form anatomically constrained diastolic isthmuses during VT, and adjusting the voltage representation on the isopotential map can help visualize these zones. Another operational definition of dense scar is based on its electrical inexcitability. Anatomical isthmuses are identified on the basis of voltage mapping as regions where the pacing threshold is less than 10 mA, located between two areas of electrically unexcitable scar or between electrically unexcitable scar and an anatomical obstacle, such as the mitral or aortic valve annulus.⁴

TECHNIQUE. The LV is mapped during NSR to construct a voltage map displaying peak-to-peak electrogram amplitude, with the color range set between 0.5 and 1.5 mV. Thus, purple areas represent normal-amplitude electrograms, and electrogram amplitude progressively diminishes as colors proceed to blue, green, yellow, and red. At low-amplitude (<0.5 mV) sites, pacing is performed with 10-mA, 2-millisecond pulse width stimuli. If pacing does not capture, the contact of the catheter is confirmed by observing the response to gentle manipulation. Sites with a pacing threshold greater than 10 mA are tagged as electrically unexcitable scar, marked as gray regions (see Fig. 6-14). A color-coded voltage map is then created and superimposed on the anatomical model to show the amplitudes of all selected points, with red as the lowest amplitude and orange, yellow, green, blue, and purple indicating progressively higher amplitudes (Fig. 22-35). Careful step-by-step adjustment of voltage scar definition on the isopotential map and analysis of different voltage levels within the 0.5-mV scar (i.e., the voltage limits are reset to 0.3 to 0.5 mV as the upper limit and to 0.1 mV as the lower, representing dense scar) may be required for the identification of viable myocardium and conducting channels within the scar area (Fig. 22-36).⁴⁸ Points of interest (e.g., those with favorable pace maps) can also be marked or tagged as location only, enabling one to return precisely to the region of interest after several points have been investigated.

LIMITATIONS. Voltage mapping relies heavily on the correct interpretation of electrograms. Because voltage is used to define scar, consistent catheter contact is necessary. If catheter contact is not sufficient, the voltage map will suggest an erroneous scar. Although an electrogram amplitude of 0.5 mV has been used to identify electrical scars, a minimal amplitude that distinguishes excitable tissue from unexcitable scar has not been established.⁴ Additionally, although voltage mapping likely identifies large unexcitable areas of scar, small strands of fibrosis, which may still create important conduction block, may escape detection amidst the background of high-amplitude far-field signals. Furthermore, it is likely that large sheets of surviving endocardial myocardium occur in some patients with circuits created by functional block during VT and no endocardial electrically unexcitable scar. When the boundaries of the isthmus are functional lines of block, they cannot be detected during NSR. The dispersion of voltage in some

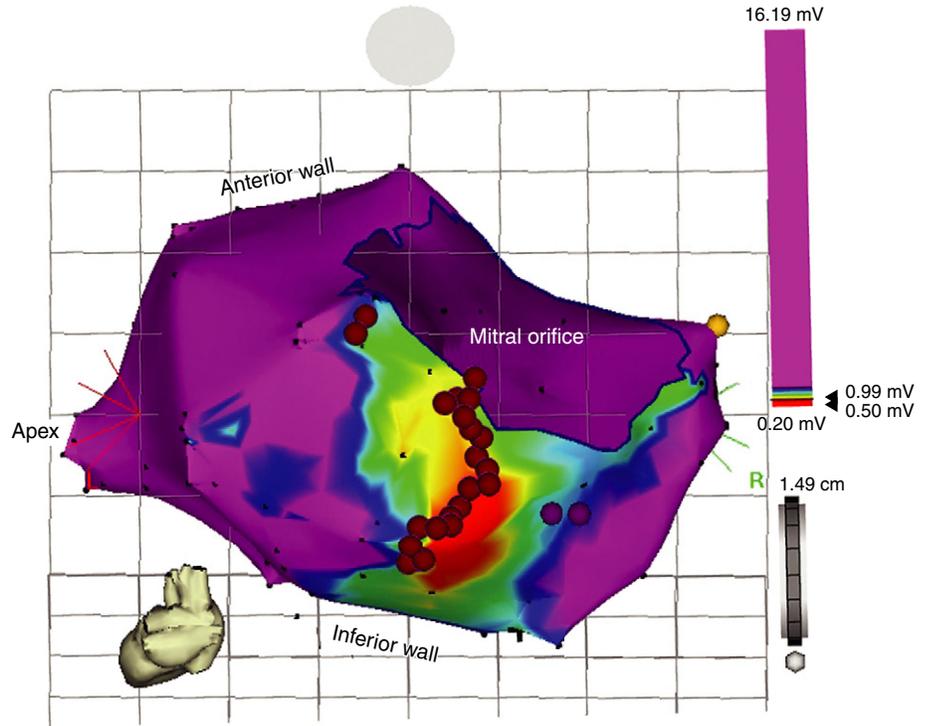

FIGURE 22-35 Electroanatomical voltage map of scar-based ventricular tachycardia (VT) in a patient with a prior inferior wall myocardial infarction (posterior view). The scale at right shows bipolar voltage; the red area denotes a very low-voltage (<0.5 mV) infarct zone with a small isthmus of higher voltage between this area and the mitral annulus. Red dots indicate a line of radiofrequency applications to transect this isthmus (additional red dots denote ablation at other sites that terminated VT).

scar areas can appear only when activated at the VT rate. Even when conducting channels within the scar area can be identified by voltage mapping, their relationship to the VT circuit remains to be assessed by other mapping methods (e.g., entrainment mapping); plots of electrogram amplitude alone do not adequately identify VT circuit isthmuses. In well-tolerated VT, no more than 50% of proven isthmus sites will be revealed by this approach.⁴ Also, differences in wavefront direction, such as seen with RV pacing, may obscure the presence of double potentials or higher voltage local channel signals. Finally, electrogram amplitude is influenced by the particular recording methods, and these values may differ with other electrode spacings and filter settings.

SUBSTRATE IMAGE INTEGRATION

LV scar and its border zone represent the target of “substrate modification” VT ablations; therefore, an exact anatomical delineation is critical. However, the current gold standard of voltage mapping has several limitations—a single endocardial voltage measurement only incompletely describes a complex intramural scar anatomy. Detailed voltage maps prolong the procedure time and falsely low voltage measurements (caused by suboptimal catheter contact) can lead to incorrect scar definition. Additionally, small areas of scar may not be detected, given the spatial resolution of at least 5 mm, covered by the 3.5- or 4-mm catheter tip/proximal ring distance.

Many of these limitations can be overcome by integrating scar imaging into the VT ablation. Multiple imaging modalities detailing the LV substrate in a 3-D format can be visualized and displayed simultaneously with the electroanatomical 3-D LV voltage map. These imaging approaches can be used to correctly predict abnormal voltage locations in advance of the mapping procedure, which may allow the electrophysiologist to concentrate on areas of likely myocardial scar, obviate the need to perform a complete point-by-point voltage mapping, identify falsely low-voltage recordings in areas of normal perfusion due to suboptimal catheter contact, as well as reduce procedure time and fluoroscopic exposure. Additionally, some imaging modalities are able to characterize the transmural extent and intramyocardial location of scar tissue, which can potentially help to identify

intramural and epicardial arrhythmia substrate, overcoming a limitation of endocardial voltage mapping.

IMAGE INTEGRATION USING POSITRON EMISSION TOMOGRAPHY-COMPUTED TOMOGRAPHY. Because PET scans alone do not provide the necessary anatomical information required for integration with electroanatomical maps, a CT angiography scan is required to provide an anatomical skeleton onto which the biological information acquired from the PET scan would be superimposed on its precise anatomical location.

Both PET and CT images can be spatially aligned using an automatic registration algorithm. All regions in the PET image with uptake greater than a threshold (50% of maximal uptake) are overlaid at the corresponding location on the CT image. Thus a fused image can be created having accurate anatomical information at the spatial resolution of the original CT with accurate metabolic information for the LV myocardium from the registered PET. The regions in the fused image showing [18F]fluorodeoxyglucose (FDG) uptake represent non-scarred myocardium, and regions with no uptake indicate scarred myocardium.⁴⁹ Myocardial scar is displayed as an area of absent voxels (“hole in the wall”) within the reconstructed LV wall to indicate scar location and size. The use of PET 3-D reconstructions at multiple metabolic thresholds allows the characterization of the scar border zone and simultaneous 3-D display of myocardial scar and border zone embedded into the LV anatomy as well as the display of detailed scar anatomy which can be targeted during the VT ablation.⁵⁰

The fused “anatomical-metabolic” PET-CT image is imported into the CARTO system using the commercially available CARTOMerge software (Biosense Webster). To merge the PET-CT image, landmark points at the coronary ostia or in the coronary cusps and at the apical septum are usually acquired (guided by ICE; see below). The corresponding points are matched on the fused PET-CT image. Once the 3-D voltage map is created, surface registration is performed. Alternatively, multiple points can be acquired at different planes of the aorta as the catheter is dragged along the descending aorta, arch, and ascending aorta. Using an automated program available in the mapping system, the electroanatomical map and the fused PET-CT image are then aligned.⁴⁹

IMAGE INTEGRATION USING MAGNETIC RESONANCE. The spatial resolution of PET/CT imaging is limited to 4 to 6 mm, which does not allow for determination of complex scar anatomy and

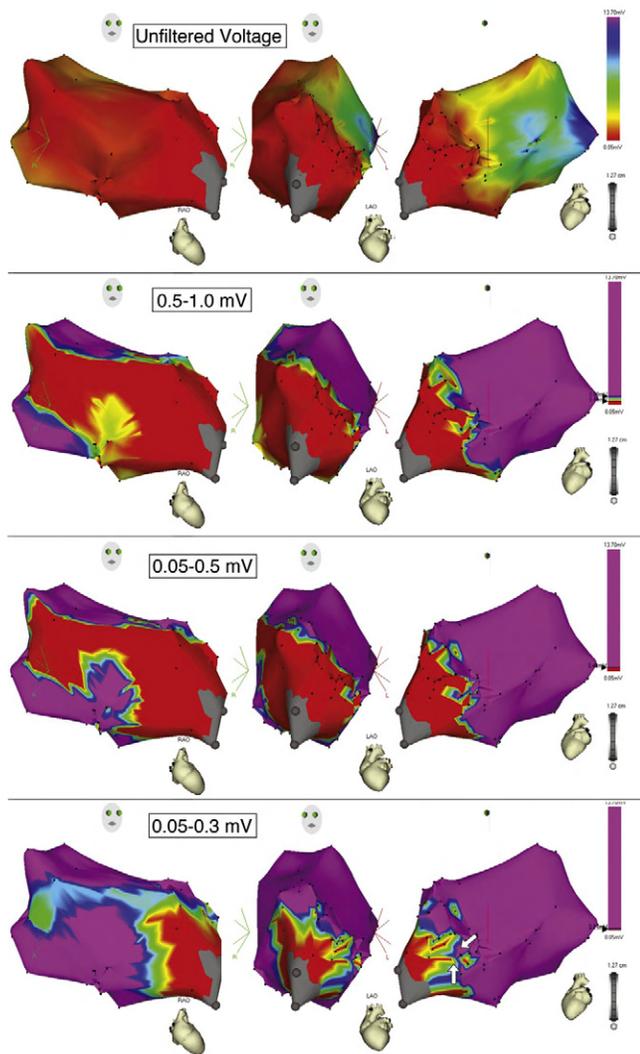

FIGURE 22-36 Filtering voltage maps to expose conduction channels. Right and left anterior oblique (RAO and LAO, respectively) and left lateral views of endocardial left ventricular voltage maps are shown (higher, normal voltages are purple, low voltages red; dense scar is gray). At top is the “raw,” unfiltered voltage. Successive panels beneath show different bandwidths of filtering as indicated at the top of each panel, revealing possible “channels” of viable tissue coursing with scar areas (white arrows in bottom panel). Ablation lines to transect these channels (which would not otherwise be evident) can then be performed.

mural location. Epicardial scar may have low PET signal, but normal endocardial voltage. In contrast, delayed-enhancement MR imaging provides excellent detail and is quickly becoming the gold standard for scar determination and is currently the only modality that can assess the transmuralty of the infarct (i.e., can determine whether the scar is endocardial, intramyocardial, or epicardial).

The MR image can be merged with the 3-D electroanatomical voltage map, using CARTOMerge software, employing landmark and surface registration (as discussed above).¹⁸

IMAGE INTEGRATION USING CONTRAST-ENHANCED CARDIAC TOMOGRAPHY. Cardiac contrast-enhanced CT scanning enables a comprehensive three-modality characterization (anatomical, dynamic, and perfusion) of LV scar from a single contrast-enhanced CT with high spatial (≤ 1 mm) and temporal resolution. Areas of CT hypoperfusion correlate best with areas of abnormal voltage (<1.5 mV) rather than scar alone (<0.5 mV). Perfusion imaging from CT can indicate scar transmuralty and intramyocardial scar location. The 3-D CT scan can be integrated into clinical mapping systems to guide VT ablation. Primary registration is performed with landmark points and visual alignments, as previously discussed.¹⁷

IMAGE INTEGRATION USING INTRACARDIAC ULTRASOUND. Although preacquired MR, PET, and CT imaging have been used to define LV scar and guide mapping and ablation in post-MI VT, registration is often difficult, unfortunately, and may be imprecise. Additionally, images obtained on different days may confound registration if LV geometry changes because of loading conditions.

ICE has been recently used to guide catheter navigation. Real-time ICE images can provide accurate chamber geometries and scar boundaries of the LV. Additionally, ICE provides both an anatomical and a functional assessment of the LV, allowing for real-time identification of wall motion abnormalities. Unlike PET/CT and MR imaging, ICE imaging does not require potentially toxic contrast agents, nor does it expose the patient to ionizing radiation.

The CARTOSound image integration module (Biosense Webster) incorporates the electroanatomical map into a map derived from ICE and allows for 3-D reconstruction of the LV from real-time 2-D ICE images, facilitating interventional navigation within the LV. ICE imaging is performed using a 10 Fr phased-array transducer-catheter incorporating a navigation sensor (SoundStar; Biosense Webster), which records individual 90-degree sector image planes of the cardiac chamber of interest, including their location and orientation, to the CARTO workspace. A 3-D volume rendered image is created by obtaining electrocardiogram-gated ICE images of the endocardial surface of the LV.^{51,52}

To create the CARTOSound volume map of the LV, the ICE catheter is manipulated in the RA, RV, and RVOT to visualize all parts of the LV. The LVOT, the aortic root, and the mitral valve are mapped with the probe positioned in the RA, whereas the body of the LV is mapped with the probe positioned in the RV, against the interventricular septum. The latter position provides a longitudinal view of the LV cavity. Lateral tilt allows base-to-apex scanning through the body of the LV with deeper insertion, withdrawal, or rotation of the probe used as necessary to complete the map. Short-axis cross-sectional views of the LV can be obtained with the ICE probe positioned in the RVOT. Images are acquired in end expiration and gated to the R wave or the pacing spike. Ultrasound imaging in which the wall segment is well visualized can reliably identify scar both by wall thickness and motion, a process that does not require wall contact. Akinetic and thinned wall segments are marked in a separate volume and labeled as scar on the ultrasound volume map. Normal or hypokinetic segments are labeled as nonscar. Separate geometries (scar and nonscar) are made of the LV and each of the papillary muscles. Once the ultrasound map is completed, a distinct CARTO voltage map is created (as described above).⁵¹

The area of scar identified using ICE was found to correspond accurately to that defined using standard bipolar voltage settings during point-by-point mapping. This may help limit catheter manipulation in the LV by focusing effort on the potential substrate regions identified by ICE. Real-time monitoring of the endocardial-catheter interface also helps direct the catheter to the important anatomical structures that can be critical to the VT circuit, such as crypts and trabeculations, which may otherwise be missed.^{51,52} Additionally, the CARTOSound volume map of the LV can also be used as a facilitator of CT/MR image integration.^{49,53}

Noncontact Mapping

When VT is short-lived, hemodynamically unstable, or cannot be reproducibly initiated, simultaneous multisite data acquisition using a noncontact mapping system (EnSite 3000; St. Jude Medical) can help localize the VT site of origin. The system has been shown to reliably identify presystolic endocardial activation sites (potential exits) for reentrant VTs and thus starting points for conventional mapping. It may also help identify VT isthmuses and therefore suitable targets for ablation.

Substrate mapping based on scar or diseased tissue, which has been recently introduced to noncontact mapping technology, can be particularly helpful when the VT is not inducible during the procedure. Dynamic substrate mapping allows the creation of voltage

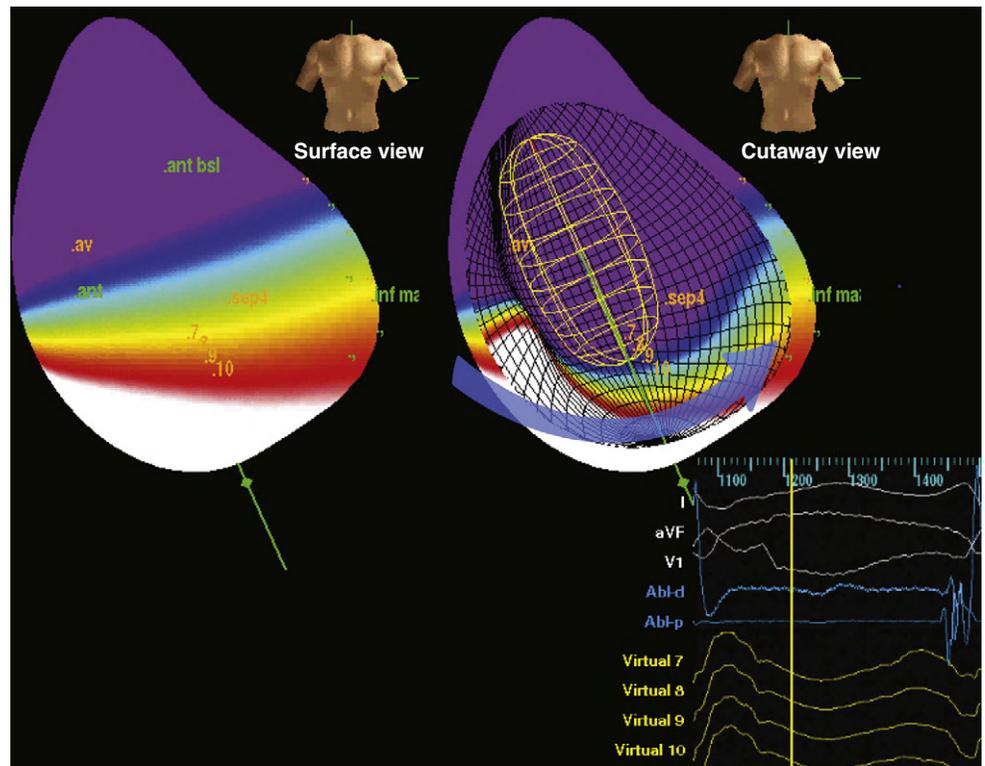

FIGURE 22-37 Use of multipolar electrode array for ventricular tachycardia (VT) mapping. Maps from the EnSite system are shown in a patient with inferior wall infarction. At left is a snapshot of the activation wavefront projected on the endocardial surface (white = activation). At right is the same instant of activation in a cutaway view, showing the wireframe of the endocardial balloon-based electrode array. At bottom right are contact and virtual electrograms from the array during VT; the wavefront propagates from left to right, along the mitral annulus (curved blue arrow).

maps from a single cardiac cycle and provides the ability to identify low-voltage areas, as well as fixed and functional block, on the virtual endocardium through noncontact methodology.⁵⁴

CONCEPT

The noncontact mapping system records electrical potentials from a multielectrode array (MEA) surrounding a 7.5-mL balloon within the LV cavity. Electrical potentials at the LV endocardial surface some distance away are calculated. Sites of mid-diastolic endocardial activity, which are likely adjacent to reentry circuit exits, are usually identifiable; in some cases, isthmuses can be identified (Fig. 22-37).

Voltages are displayed as a colored isopotential map on the virtual endocardium. The color scale is adjusted to create a binary display, with negative unipolar potentials in white on a purple background, producing a unipolar activation map. Diastolic depolarization is defined as activity on the isopotential map that can be continuously tracked back in time from VT exit sites, defined on the map as synchronous with the QRS onset. Diastolic activity and exit sites are then marked on the virtual endocardium, and the mapping catheter is navigated to them by the locator.⁵⁴

The dynamic substrate mapping algorithm allows the creation of unipolar noncontact voltage maps from a single cardiac cycle, defined as the percentages of the maximal voltage recorded in the entire chamber. Until further studies define the correct dynamic substrate mapping percentage that can be compared with the scar and scar border zone defined by contact mapping, areas having values less than 50% may be defined as “abnormal myocardium.” A recent report assessed the relationship between successful ablation sites determined by noncontact mapping and concealed entrainment as well as the region of “abnormal myocardium” defined by the dynamic substrate mapping; 85% of VTs arose from the border defined by the dynamic substrate mapping 30% area.⁵⁴

TECHNIQUE

The EnSite 3000 system requires a 9 Fr MEA and a 7 Fr conventional (roving) deflectable mapping-ablation catheter. A standard ablation catheter is placed in the LV by a retrograde transaortic route.

Using a separate arterial access site, the MEA catheter is advanced to the LV apex over a 0.032-inch J-tipped guidewire. The right anterior oblique (RAO) and left anterior oblique (LAO) views are used to assess the correct position of the balloon catheter, placed parallel to the long axis and with the pigtail end as close as possible to the LV apex. The guidewire is then withdrawn and the balloon inflated with a contrast-saline mixture. The balloon is positioned in the center of the LV and does not come in contact with the LV wall. Care is taken in order to have a distance between the MEA catheter and the region of interest less than 40 mm; if necessary the catheter can be repositioned.

Construction of the virtual endocardium model is preliminarily obtained during sinus rhythm by moving the ablation catheter along the LV endocardial surface to collect a series of geometric points during NSR or VT. Using this geometric information, the computer creates a model of the LV. After the LV geometry is reconstructed, 5 seconds of NSR is recorded by the system, and the substrate map is superimposed on the anatomy. High-pass filters are adjusted at the lowest value that minimizes the shift of the isoelectric baseline to avoid confusing depolarization with repolarization.⁵⁴

Subsequently, VT is induced by programmed stimulation and mapping of the arrhythmia can begin. A 5- to 10-second segment of any induced VT is recorded with the noncontact system and the VT may then be terminated by overdrive pacing or electrical shock. The data acquisition process is performed automatically by the system, and all data for the entire LV are acquired simultaneously.

VT circuit exit points and potential ablation targets can be identified as sites where a QS unipolar electrogram morphology is recorded, which, on the color-coded isopotential map, corresponded to the site of earliest activation followed by a rapid activation wavefront. Projection of the virtual endocardial electrograms over this area is performed at different high-pass filter settings (1, 2, 4, 8, 16, and 32 Hz) to avoid misinterpretation with repolarization waveforms. This region is searched starting from the abnormal myocardium defined by dynamic substrate mapping and is considered a good target site for ablation when confirmed by EP criteria (contact activation mapping, entrainment mapping, and/or pace mapping).⁵⁴

The locator technology is used to guide the ablation catheter to the proper location in the heart. The system allows the operator to create linear ablation lesions that transect critical regions and then return precisely to areas of interest, visualizing lines of ablation as they are being created and performing the ablation during NSR.

LIMITATIONS

The most important shortcoming of the noncontact mapping system is the deterioration in the accuracy of noncontact electrograms for distances greater than 40 mm between the MEA catheter and the recording site, which can occur in dilated ventricles. Very low-amplitude signals may not be detected, particularly if the distance between the center of the balloon catheter and endocardial surface exceeds 40 mm, limiting the accurate identification of diastolic signals.

Because the geometry of the cardiac chamber is contoured at the beginning of the study during NSR, changes in chamber size and in contraction pattern during tachycardia can adversely affect the accuracy of the location of the endocardial electrograms. Additionally, detection and display of activation from two adjacent structures, such as the papillary muscle and subjacent myocardium, is problematic.²

Moreover, because isopotential maps are predominantly used, ventricular repolarization must be distinguished from atrial depolarization and diastolic activity. Early diastole can be especially challenging to map during VT. Care has to be taken to confirm that the virtual electrogram is related to local activation and not baseline drift or repolarization.²

Because of the potential for thrombus formation, the use of this system requires the maintenance of a greater degree of anticoagulation (activated clotting time [ACT] >350 seconds) while the mapping balloon is in place than is generally required for the point-by-point mapping techniques. Additionally, positioning of the MEA catheter in the LV can be difficult in the setting of atherosclerotic aorta or tortuous peripheral arteries, requiring a transseptal approach.⁵⁴ The mapping sheath is 9 Fr in diameter; femoral hematomas and pseudoaneurysms are the most frequently encountered complications.²

Mapping Post-Infarction Premature Ventricular Complexes

A recent study found that in post-MI patients with frequent PVCs, the PVCs originated at sites of low voltage corresponding with the infarct location in approximately 85% of patients, similar to patients with post-MI VT. Additionally, in patients with ischemic CMP and VT that matches the PVC morphology, both types of arrhythmias have critical target sites within areas of low voltage, and the site of origin of PVCs often corresponds with the exit site of the VT reentrant circuit.⁵⁵ Furthermore, as is the case with VT, late potentials can be detected during diastole at the site of origin of most of the PVCs. The late potentials follow the ventricular electrogram during sinus rhythm and precede the ventricular electrogram during PVCs. Slight differences in morphology between PVCs and VT may be observed and may be rate-related.⁵⁶

Possible mechanisms of PVCs in post-MI patients include reentry, triggered activity, and abnormal automaticity. Because of several features in common with post-MI VT, reentry may play a principal role in post-MI PVCs; however, this has not been confirmed by high-resolution mapping. Nevertheless, in a small percentage of patients, PVCs do not originate from scar tissue. In those patients, the PVCs can be due to triggered activity or abnormal automaticity, similar to idiopathic PVCs.⁵⁶

Because post-MI PVCs and VT often share critical areas, mapping of the PVCs can be used as a surrogate for mapping of the VT. Ablation of frequent PVCs can potentially eliminate VT in these patients. However, the sensitivity and specificity of this approach in a nonselected population are not known, nor is the prevalence of PVCs indicating VT exit sites. If this concept is confirmed in

larger series, PVC mapping can be used to identify exit sites of PVCs and to search for diastolic potentials prior to PVCs that may indicate areas of slow conduction relevant for the VT. Targeting the PVCs alone may be sufficient to eliminate the VTs that had an exit site near or at the PVC site of origin, obviating the need for induction of VT, which can be of great value in patients with unstable or unmappable VTs.⁵⁷ Voltage mapping in these patients can be helpful in focusing the mapping procedure to the low-voltage areas, because this area contains the arrhythmogenic substrate in most patients.⁵⁶

Furthermore, in post-MI patients with frequent PVCs, PVC ablation may result in an improvement in the LVEF. It may be appropriate to screen patients with ischemic CMP for frequent PVCs with a 24-hour Holter monitor before implanting an ICD for primary prevention of SCD. Ablation of the frequent PVCs may improve the LVEF such that the patient no longer meets the LVEF criterion for an ICD.⁵⁵

Mapping of Intramural and Epicardial Circuits

A significant proportion of VT circuits have one or more critical components located in the epicardium. This is particularly true in nonischemic substrates. VT originating from the subepicardium is an important cause of failure of endocardial ablation approaches. In tertiary centers, epicardial ablation has been required in approximately 10% to 25% of post-MI VTs, and seems to be more common with inferior rather than anterior wall infarctions.

Various ECG characteristics have been used to predict whether an epicardial approach may be required based on the VT morphology; however, the surface ECG alone is not reliably predictive of the need for epicardial access and mapping for any given VT. QRS morphology is related solely to the VT exit site and this does not imply that some other component of the circuit (such as the critical isthmus or entrance site) cannot be ablated from the endocardium, even when an epicardial exit is implied by the ECG characteristics.^{34,43}

Additionally, contrast-enhanced CT and delayed enhancement cardiac MR can identify areas of myocardial scar that correlate with VT substrate and can determine whether the scar is endocardial, intramyocardial, or epicardial. In a recent report, the presence of epicardial or intramyocardial scar on preprocedure delayed enhancement MR was associated with a 0% procedural success rate when the operator limited ablation to the endocardium. Having this MR imaging information before entering the procedure permits the operator to plan an appropriate mapping and ablation strategy and to better inform the patient about the risks, benefits, and chances of procedural success.

During endocardial mapping of post-MI VT, inability to identify the reentry circuit isthmus on the endocardium can suggest that the isthmus is epicardial or intramural. In these cases, endocardial activation mapping can demonstrate a focal point of earliest endocardial activation where entrainment indicates a potential exit or outer loop site, but ablation fails to interrupt VT, suggesting that there is an epicardial or intramural circuit with a broad endocardial exit.

Mapping arrhythmia foci or circuits that are deep within the myocardium or in the epicardium can be performed via the coronary sinus (CS) or pericardial space, and is discussed in detail in [Chapter 27](#).

Practical Approach to Ventricular Tachycardia Mapping

EVALUATION PRIOR TO MAPPING

Evaluation of potential ischemia, which could contribute to instability during the ablation procedure, is necessary. Echocardiography; ventriculography; or nuclear, PET, and/or MR imaging may be used to identify the size and location of the infarct that potentially contains the arrhythmogenic scars ([Fig. 22-38](#)). These tests also help exclude the presence of LV thrombus, which can increase the risk of embolization during mapping. Organized thrombus

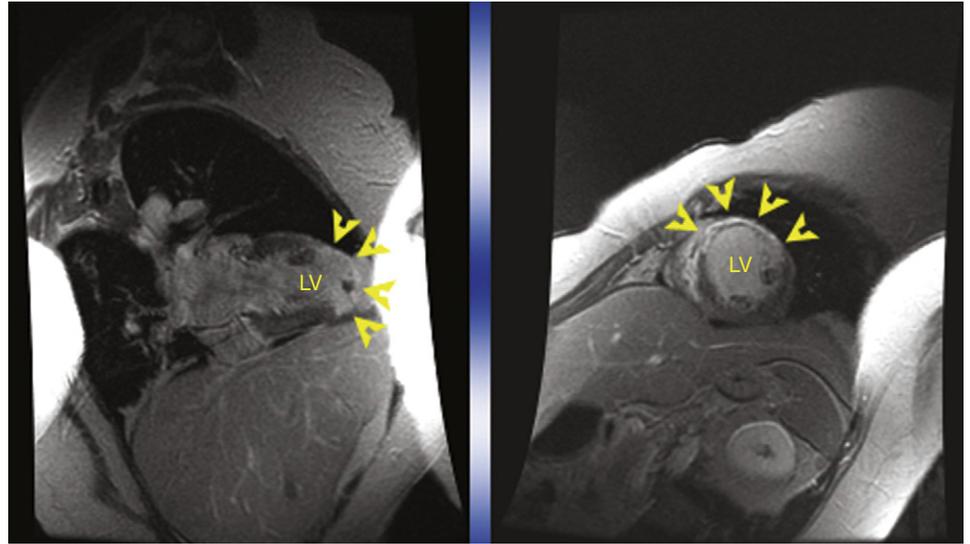

FIGURE 22-38 Magnetic resonance scans of the left ventricle (LV) in a patient with an old anterior myocardial infarction. Long axis (at left) and short axis (at right) views of the LV show a dense anteroapical scar (arrowheads), which can be visualized as a white thin area of the LV wall. (Courtesy of Dr. Nasar Nallamothe, Prairie Cardiovascular Consultants, Springfield, Ill.)

can overlie the area of interest for ablation and prevent effective energy delivery to target sites.

MAPPING HEMODYNAMICALLY STABLE SUSTAINED MONOMORPHIC VENTRICULAR TACHYCARDIA

LEFT VENTRICULAR ACCESS. The LV is accessed through the retrograde transaortic approach, usually via a femoral arterial access. An atrial transseptal approach may also be used, although accessing the entire LV is then more difficult. Both transseptal and retrograde approaches may be used concomitantly, so when a particular region of the LV cannot be mapped using one approach, it may be mapped using the other approach. Anticoagulation (with intravenous heparin) is started once the LV is accessed to maintain the ACT between 250 and 350 seconds. Certain electrode arrays with high thrombogenicity may require an ACT of at least 300 seconds.¹

A standard 4-mm- or 8-mm-tip or, preferably, an irrigated-tip ablation catheter with 2.5–2-mm spacing for proximal electrodes is used. Poles 1 to 3 (distal) and 2 to 4 (proximal) of the ablation catheter are used for recording, and poles 1 to 3 are used for stimulation. Catheter position is identified fluoroscopically in the RAO and LAO views. Three-dimensional electroanatomical mapping is usually used to aid mapping and ablation.

STEP 1: SUBSTRATE MAPPING DURING BASELINE RHYTHM. Infarct regions are sought first and more data points are acquired around these areas. Refining the area under investigation relies on the usual clinical indicators, such as echocardiographic, ventriculographic, PET, or MR imaging findings (e.g., regions of wall motion abnormalities, areas of scars), and 12-lead ECG recordings of spontaneous and induced VT are analyzed to regionalize the site of origin of the VT. Also, ICE can be of value for real-time identification of scar regions as well as for facilitation of atrial septal puncture if required. Additionally, integration of those imaging modalities into the 3-D electroanatomical mapping can help visualize and display the LV substrate in a 3-D format and focus initial mapping efforts to those regions.

Substrate mapping may be attempted initially during NSR or ventricular pacing (unless VT is incessant), targeting the LV scar and its border zone as identified by scar imaging modalities, to help refine the area of interest and identify potential targets for further activation and entrainment mapping. Goals of substrate mapping are the identification of abnormal local electrogram configuration during NSR and/or RV pacing and voltage mapping. Sites with fractionated electrograms, multipotential electrograms, and/or isolated diastolic electrograms are tagged and catalogued on the 3-D mapping system for future revisiting and guidance. Voltage mapping is performed using a 3-D mapping

system to identify areas of abnormal low-amplitude local electrograms during NSR.

STEP 2: ACTIVATION MAPPING DURING VENTRICULAR TACHYCARDIA. Programmed stimulation is used to induce VT and to ascertain the ease of inducibility for subsequent testing, unless the VT is incessant. Activation mapping during VT is then carried out, initially focusing mapping to regions of VT substrate as identified during substrate mapping.

During activation mapping, particular sites of interest are sought, including the following: (1) sites with abnormal local bipolar electrogram (amplitude ≤ 0.5 mV; duration ≥ 60 milliseconds); (2) sites at which the local electrogram precedes the QRS complex by at least 50 milliseconds (activation times are taken from the onset of the bipolar electrogram); and (3) sites with the earliest local activation closest to mid-diastole, isolated mid-diastolic potentials, or continuous activity. Filtered unipolar electrograms can help ensure that the tip electrode, which is the ablation electrode, is responsible for the early component of the bipolar electrograms. In addition, demonstration of a fixed relationship of the diastolic electrograms to the subsequent VT QRS, despite spontaneous or induced oscillations of the tachycardia CL, is important to exclude the possibility that those electrograms do not reflect late activation from unrelated dead-end pathways.

STEP 3: ENTRAINMENT MAPPING DURING VENTRICULAR TACHYCARDIA. Pacing is performed during VT at selected LV sites, as identified during activation and substrate mapping. Pacing trains at CLs 10 to 30 milliseconds shorter than the tachycardia CL are introduced using the least pacing output that captures the ventricle. Pacing should be continued for sufficiently long durations to ensure entrainment of the VT.

The presence of entrainment should be confirmed by the demonstration of fixed fusion of the paced QRS at any single pacing CL, progressive fusion (i.e., the surface ECG progressively looks more like the VT QRS than a purely paced QRS) as the pacing CL decreases, and resumption of the VT following pacing with a non-fused VT QRS at a return cycle equal to the pacing CL. Once the presence of entrainment is confirmed, three parameters should be evaluated—the presence of manifest or concealed fusion, the PPI, and the local electrogram-QRS interval during VT versus the S-QRS interval during entrainment. The 12-lead ECGs during pacing and during VT are compared to evaluate whether manifest or concealed fusion is present. The PPI is measured from the stimulus artifact to the onset of the local electrogram of the first VT (unpaced) beat at the pacing site. Finally, the local electrogram-QRS interval during VT and the S-QRS interval during entrainment are measured on the distal bipolar pair recording of the mapping catheter or with the use of the proximal bipolar pair when the presence of artifacts in the distal pole recording prevents reliable measurement.

The following three criteria are used to define the critical isthmus and predict the success of RF application in elimination of the VT: (1) entrainment with concealed fusion; (2) PPI minus tachycardia CL not exceeding 30 milliseconds; and (3) S-QRS interval minus local electrogram to QRS interval not exceeding 20 milliseconds. Other predictors of successful ablation sites include an S-QRS interval to VT CL ratio not exceeding 0.7, long S-QRS interval, alteration of the tachycardia CL and/or termination by subthreshold or nonpropagated stimuli (see Fig. 22-19), and repeated VT termination occurring with catheter manipulation or pacing at the site.

STEP 4: PACE MAPPING DURING NORMAL SINUS RHYTHM.

Pace mapping can be used to complement activation and entrainment mapping findings, although it may not always be necessary, especially when several criteria localizing the VT isthmus have been identified. At isthmus sites defined during VT, pace mapping during NSR is attempted after VT termination, with the mapping catheter being kept at the isthmus location. Pace mapping is preferably performed with unipolar stimuli (10 mA, 2 milliseconds) from the distal electrode of the mapping catheter (cathode) and an electrode in the IVC (anode). The same pacing CL is usually used for each site in an individual patient (500 to 700 milliseconds), slightly faster than the sinus rate and slower than the rate of the induced VTs. The resulting 12-lead ECG morphology is compared with that of the tachycardia. ECG recordings should be reviewed at the same gain and filter settings. It is often helpful to have the 12-lead ECGs of the VT and paced QRS complexes displayed side-by-side on split screens of the recording system for comparison. The greater the degree of concordance between the morphology during pacing and tachycardia, the closer is the catheter to the exit site of the tachycardia isthmus. It is important to recall that pace mapping at an isthmus may not produce a QRS identical to VT for reasons discussed above.

Evaluation of the S-QRS interval during pace mapping is of interest. The S-QRS interval is measured to the onset of the earliest QRS on the 12-lead ECG. Sites from which pace mapping produces the same QRS as that of the initial isthmus site with different S-QRS delays are identified in an attempt to trace the course of the VT isthmus.

MAPPING HEMODYNAMICALLY UNSTABLE OR UNSUSTAINABLE MONOMORPHIC VENTRICULAR TACHYCARDIA

Only 30% of patients referred for treatment of VT are suitable for ablation guided only by mapping during VT. Most patients have VTs that are too unstable to allow extensive mapping during the arrhythmia because of hemodynamic collapse, frequent changes from one VT to another, or inability to reproducibly induce the VT. In patients in whom the induced VT is only marginally tolerated (hypotension without syncope), circulatory support can be achieved with an intravenous infusion of dopamine, dobutamine, or phenylephrine; intraaortic balloon counterpulsation; partial or complete cardiopulmonary bypass; or LV assist device. Additionally, intravenous procainamide (infused with a maximal loading dose of 15 mg/kg at a rate of 50 mg/min, followed by a continuous infusion at a maximal rate of 0.11 mg/kg/min) can help slow and stabilize the VT rate.⁴³

When the VT is unstable or unsustainable and, therefore, not approachable by conventional entrainment maneuvers and point-by-point activation mapping techniques, substrate mapping during NSR rather than during VT is of significant value, and can help delineate the infarcted myocardium (VT substrate) as well as help focus limited activation-entrainment mapping efforts on small predefined regions harboring the VT substrate and, therefore, help minimize how long the patient is actually in VT, which may be feasible even for poorly tolerated VT.

STEP 1: SUBSTRATE MAPPING DURING BASELINE RHYTHM. Infarct regions that potentially harbor the VT substrate (as identified on preacquired imaging techniques and VT morphology on 12-lead ECG) are sought first and more data points are acquired

around these areas. Sites are identified to represent VT substrate based on their amplitude and configuration. Activation mapping is used to identify sites with abnormal local electrogram configuration (fractionated electrograms, multipotential electrograms, and isolated diastolic electrograms) during NSR, RV pacing, or both. These sites are tagged and catalogued by the 3-D mapping system for future revisiting and guidance. Voltage mapping (using a 3-D mapping system) is used to identify areas of abnormal low-amplitude local electrograms during NSR. These sites are then used to guide designing linear ablation lesions targeting the VT exit sites or slow conducting channels within scar areas, or to guide other mapping maneuvers (activation, entrainment mapping, or both) that then can be performed quickly during short periods of VT.

STEP 2: PACE MAPPING DURING NORMAL SINUS RHYTHM.

Pace mapping during NSR is performed at the border zone between scar and normal tissue to approximate the exit site of each inducible VT. Pacing at each site is evaluated for two criteria: paced QRS morphology matching that of the VT and long S-QRS interval. The resulting 12-lead ECG pace QRS morphology is compared with that of the VT. The greater the degree of concordance between the morphology during pacing and tachycardia, the closer is the catheter to the site of origin of the tachycardia. Sites with S-QRS latency are also sought, which may correlate with slow channels and isthmuses within the infarct area that may be in or close to the VT circuit.

STEP 3: LIMITED ACTIVATION AND ENTRAINMENT MAPPING DURING VENTRICULAR TACHYCARDIA.

When hemodynamic compromise during the VT is the main limitation for conventional activation and entrainment mapping methods, inductions of brief episodes of VT (with the mapping catheter at the optimal site, as identified by substrate and pace mapping approaches) can allow assessment of the relationship of the abnormal electrograms to the VT circuit. This can also allow entrainment maneuvers to be performed at those sites to help distinguish sites critical to the VT circuit from bystander sites. VT is then quickly terminated before significant hemodynamic compromise ensues. This approach can be facilitated by hemodynamic support with the use of intravenous vasopressors, intraaortic balloon pump, or both. However, it requires being able to reproducibly induce the same VT morphology.

STEP 4: MULTISITE DATA ACQUISITION MAPPING. This approach uses a system that simultaneously records electrograms throughout the ventricle during one or a few beats of the unstable VT, following which the VT can be terminated to allow ablation during stable sinus rhythm. Simultaneous multisite data acquisition using the noncontact mapping system (EnSite 3000) may rapidly identify VT exit sites and thus starting points for conventional mapping. It can also help identify VT isthmuses and therefore suitable targets for ablation.

STEP 5: ACTIVATION MAPPING OF PREMATURE VENTRICULAR COMPLEXES. In post-MI patients with frequent PVCs and VT, these arrhythmias can share an anatomically preformed reentrant circuit or at least a common exit site. Therefore, mapping the PVCs (rather than the VT) can be a helpful additional technique for identifying critical areas, especially exit sites, in scar-related VT.

Ablation

Target of Ablation

HEMODYNAMICALLY STABLE VENTRICULAR TACHYCARDIA

As noted, focal ablation of multiple sites defined as in the reentrant circuit may not eliminate VT. Elimination requires ablation of an isthmus bordered by barriers on either side. These isthmuses are usually found at the border zone of the infarct and are defined as conductive myocardial tissue delineated by nonconductive tissue. The nonconductive tissue can be a scar area or an anatomical

obstacle, such as the mitral annulus. The isthmuses are the preferred targets for VT ablation because they are usually narrow and critical parts of the VT reentry circuit, allowing ablation with a small set of RF lesions.

Results of ablation of infarct-related VTs have been improving over the past decade because of better understanding and selection of ablation sites. Initial attempts at ablation targeted early presystolic potentials, followed by the use of mid-diastolic potentials; both approaches yielded unsatisfactory results. Presystolic potentials were found to be nonspecific, because they might be in an area of scar tissue—for example, inner loop, bystander (inner sites attached to the central pathway), or not related to the VT circuit. Mid-diastolic potentials, which cannot be dissociated from the VT during entrainment, are uncommon (30% of patients) and can be related to a bystander site. Demonstration of entrainment of VT with concealed fusion as a guide to VT ablation has increased ablation success rates. However, entrainment with concealed fusion alone to guide VT ablation has only a 50% positive predictive value for terminating VT, because concealed entrainment can be observed during pacing from bystander sites connected to, but not integral parts of, the reentrant circuit. Multiple criteria (e.g., S-QRS latency, mid-diastolic potentials) have been suggested, alone or in combination, to improve identification of the critical zone of the VT. These criteria have a different sensitivity and specificity with variable positive predictive values whenever they are used in different combinations. Recent data have shown that sites where the three entrainment criteria described (concealed fusion, PPI equal to the VT CL, and S-QRS interval <70% of the VT CL) are met have the highest ablation success rates, with a positive predictive value of 100% and negative predictive value of 96% (see Table 22-3).

The inability to find the appropriate target site can be caused by inadequate density of mapping points; the presence of a large amount of scar tissue; intramyocardial or epicardial location of the VT isthmus; technical difficulty in catheter manipulation; and acceleration, termination, or changing of VT to a different arrhythmia during attempts at entrainment limiting mapping of the VT.

STABLE SUSTAINED VENTRICULAR TACHYCARDIA

For stable VTs, reentry circuit isthmuses are defined by activation and entrainment mapping as sites with continuous activity or isolated mid-diastolic potentials, entrainment with concealed fusion, PPI equal to the VT CL, and S-QRS interval less than 70% of the VT CL. Additionally, there are other criteria that can identify the location of the critical isthmus. Reproducible alteration of the tachycardia CL or termination of VT by subthreshold or nonpropagated pacing stimuli is also an indication that the pacing site is in a circuit isthmus (see Fig. 22-19). The stimulus likely captures locally, but the propagated impulse blocks before exiting the scar region and creates bidirectional conduction block in the reentry circuit. Alternatively, the stimulus prolongs refractoriness at the site through an electrotonic effect. This finding is specific for predicting a successful ablation site, but is observed infrequently, with a sensitivity of only 16%.⁴³ Furthermore, mild mechanical trauma caused by the mapping catheter occasionally terminates the VT and may render the tachycardia noninducible for a variable period of time, preventing further mapping. This event suggests that the vulnerable region for the VT is small as well as superficial, and ablation at the site can be successful.^{16,43} Empiric thermal mapping (RF application for 10 seconds to assess VT termination) can also help confirm sites within the VT isthmus. VT termination during short RF applications without induction of PVCs suggests an isthmus location. When RF application fails to terminate the VT at a site that appears to be in the circuit, catheter-tissue contact may be inadequate, the site may be a bystander, or the isthmus may consist of a broad band.⁴³

MULTIPLE INDUCIBLE VENTRICULAR TACHYCARDIAS

In patients referred for post-MI VT ablation, an average of three to four VTs is commonly inducible by programmed electrical stimulation. When multiple VTs are inducible during EP testing, several

investigators have targeted the predominant morphology of VT. Ablation that focused on the clinical VT but did not target other inducible VTs successfully abolished the clinical VT in 71% to 76% of cases. However, during follow-up, approximately one-third of patients with acutely successful ablation of the clinical VT had arrhythmia recurrences, some of which occurred because of a VT different from that initially targeted for ablation. Furthermore, there are several difficulties with selecting a dominant, clinical VT for ablation. Often, it is not possible to determine which VT is the one that has occurred spontaneously. Only a limited recording of one or a few ECG leads may be available. In patients with an ICD, the device typically terminates VT before an ECG is obtained, and VT is documented only on intracardiac recordings. Even if one VT is identified as predominant, other VTs that are inducible can subsequently occur spontaneously.

An alternative approach is to attempt ablation of all inducible VTs that are sufficiently tolerated to allow mapping. The 3-year risk of recurrent VT after such an approach is 33%.

At present, the clinical endpoint for VT ablation remains unclear. Although the targeting of all induced VTs is a prevalent strategy, the level of aggressiveness to achieve this endpoint must be weighed against hemodynamic stability, volume shifts, and prolonged anesthesia in tenuous patients.⁵⁸ The goal(s) of ablation, however, should be individualized. In patients undergoing ablation because of frequent ICD shocks or tachycardia-induced CMP, elimination of problematic VT morphologies is appropriate. On the other hand, elimination of all inducible VTs should be considered especially for patients who cannot undergo or decline ICD implantation.

UNMAPPABLE VENTRICULAR TACHYCARDIA

Over the past three decades, two effective surgical strategies have been developed for treatment of post-MI VT. Subendocardial resection, guided by the presence of the endocardial scar and involving removal of the subendocardial layer containing the arrhythmogenic tissue, is associated with a 70% to 80% arrhythmia cure rate. Such surgical therapy is performed when uniform sustained VT cannot be initiated at the time of surgery. The second technique is encircling endocardial ventriculotomy, whereby circumferential surgical lesions are placed through the border zone, presumably interrupting potential VT circuits. This experience was critical in establishing the concepts on which substrate-based ablation is based; the arrhythmogenic substrate is predominantly located in the subendocardium and resides, at least partly, in the border zone between densely infarcted or fibrotic tissue and normal tissue. This substrate has distinguishing electrogram characteristics, and removal or interruption of this arrhythmogenic tissue can abolish the VT.

Catheter ablation of post-MI VT during stable sinus rhythm, guided by delineation of the infarct region from sinus rhythm electrograms, maintains hemodynamic stability while ablation of unstable VTs and multiple VTs can potentially be achieved. However, how best to guide placement of ablation lesions is unclear. Single-point ablation guided by analysis of individual electrograms during NSR (used to identify surviving myocardial strands in the infarcted area that can be relevant for a VT reentrant circuit) or pace mapping (used to identify potential exit sites of the VT circuit) has proved insufficient to guide VT ablation and carries a risk of unnecessary ablation at ineffective sites (e.g., in dead-end pathways not integral to the tachycardia circuit). Ablation over the entire infarct region or around the entire infarct border zone (as identified by LV scar imaging modalities and voltage mapping) is often not feasible, nor necessarily desirable. The infarct size or area of low-voltage electrograms is usually large (averaging 21 cm in circumference in one study), necessitating extensive and transmural ablation lesions, which is difficult to achieve using the current catheter-based ablative techniques and can result in increased risk of complications, including damage to functioning myocardium.

Currently, ablation strategies are guided by the identification of potential reentry circuit isthmuses and exit sites based on substrate, pace, and entrainment mapping. Given the less precise localization

of the reentry circuit, a more extensive ablation approach involving the delivery of energy over a relatively large area within the scar is commonly employed.² Linear RF lesions are placed using one of several guiding principles:

- Ablation lines extending across the borders of the endocardium that demonstrate abnormal bipolar electrogram voltage.¹
- Focal ablation lesions delivered at sites demonstrating delayed electrograms (“late potentials”) during substrate mapping, to eliminate these electrograms (see Fig. 22-33).
- Ablation lines extending perpendicular to the scar border, from the area of dense scar (i.e., areas demonstrating the lowest amplitude signals [<0.5 mV]) across the border zone and connecting out to normal myocardium (i.e., areas demonstrating a distinctly normal signal [>1.5 to 2.0 mV]) or to anatomical barriers (e.g., mitral annulus) (see Fig. 22-35). This approach represents the closest approximation achieved by endocardial catheter ablation to subendocardial surgical resection of the VT substrate.¹
- Ablation lines extending parallel to the scar edge in the border zone of the scar and intersecting sites where pace mapping approximates the QRS morphology of VT. The ablation lines should be deployed within the border zone defined by voltage mapping (0.5 to 1.0 mV) to avoid damaging normal myocardium.¹
- Ablation lines extending perpendicular to all defined isthmuses (channels of surviving myocardium) within the scar areas or between islands of unexcitable segments within the infarct (identified as a region of relatively larger voltage bordered by low voltage within the scar and abnormal electrograms during NSR).
- Focal ablation lesions delivered at sites demonstrating electrograms with isolated diastolic components, provided that pace mapping at those sites reproduces target VT QRS morphology, with an S-QRS interval of more than 40 milliseconds, the electrogram at those sites becomes mid-diastolic during VT induction, and entrainment maneuvers during brief inductions of VT have confirmed relationship of those sites to the VT circuit.

These different substrate ablation strategies have not been directly compared and differences in outcomes are not apparent in the literature. Variations in anatomy may also influence the effectiveness of the different methods. In many patients, a combination of these techniques is needed for successful identification and ablation of critical sites of the reentrant circuit.

Ablation Technique

Catheter ablation of scar-related VT usually requires relatively extensive tissue injury to abolish the arrhythmia substrate, which can be facilitated by the use of larger electrodes or irrigated electrodes. For ablation of scar-related VT, irrigated RF electrodes are preferred to large (8-mm)-tip electrodes. Cooled RF ablation allows increased power delivery, deeper lesions in myocardial scar, and potentially improved outcomes. In contrast, increasing the size of the electrode both reduces the spatial resolution of mapping and increases the disparity in temperatures across the surface of the electrode such that hot regions can lead to coagulum formation despite relatively low temperatures recorded from the electrode. On the other hand, external irrigation involves administration of potentially large amounts of intravascular saline, which can cause acute heart failure; therefore, careful monitoring of fluid balance is required and a urinary catheter and diuretic administration may be needed during the procedure. Internal irrigation catheters or large-tip catheters should be considered if intravascular volume administration will be difficult to manage, as in patients with renal failure, severe heart failure, or both.²

Once a target is selected, cooled RF ablation may be performed using an external or internal irrigation system. The external irrigation system (ThermoCool; Biosense Webster) uses an 8 Fr catheter that has an electrode 3.5 mm in length with six holes in the tip through which saline flows at 30 mL/min during RF application. In the internal irrigation system (Chilli; Boston Scientific, Natick,

Mass.), saline flows at 36 mL/min through the electrode and returns through a second lumen to be discarded outside the patient. For both cooled RF systems, RF application is initiated at a power output of 20 to 30 W; the power is gradually increased to achieve a fall in impedance of 5 to 10 Ω or a maximal measured electrode tip temperature of 40°C to 45°C. Energy application is continued for 30 to 120 seconds. RF current application is discontinued if measured impedance increases by more than 10 Ω , the catheter changes position, or VT fails to terminate after 30 to 60 seconds.

Alternatively, RF current can be delivered generally during VT from a mapping catheter with a solid 8-mm tip. RF energy is delivered in a temperature-controlled mode for 60 to 120 seconds at each ablation target site, with a maximal temperature target of 60°C to 70°C and 50-70 W of maximal power delivered. Alternatively, RF energy is delivered at an initial power of 10 W and the power is titrated upward, as guided by temperature monitoring, to attain a temperature of 60°C. Once this endpoint is reached, the application of energy is continued for 20 seconds or longer. If VT fails to terminate, the energy application is discontinued and mapping is continued at other sites; if VT does terminate, the RF application is continued for a total of 60 seconds at the final power setting. Ablation can also be performed with a 4-mm-tip electrode with power titrated to a 5- to 10- Ω drop in impedance or a maximal temperature of 60°C to 65°C. Impedance is monitored during RF delivery. In case of an impedance rise, the ablation catheter is removed from the body and the distal electrode is wiped clean of the coagulum before continuing with the procedure.

At isthmus sites identified by entrainment, RF ablation typically terminates VT within 20 seconds. A second RF application is typically given at successful target sites if VT cannot immediately be reinitiated and the catheter has not moved. Successful ablation sites usually result in VT termination within 5 to 15 seconds of the RF application. Therefore, if there is no termination of VT by 30 seconds, it is suggested to discontinue RF energy application to decrease the likelihood of ablation of noninvolved myocardial tissue, with potential impairment of LV function. However, assuring adequate catheter-tissue contact is important before abandoning what appeared to be a good target site. This can be done with monitoring the catheter tip on fluoroscopy or on ICE and observing the rise in temperature or drop in impedance during RF application.

For ablation of unstable VT, RF energy is delivered during NSR. A series of ablation lesions are made to transect the critical isthmus in the most convenient area, targeting the narrowest portion of the isthmus when allowed by catheter positioning and stability. To join the isthmus boundaries, RF lines are usually drawn perpendicular to the mitral annulus plane in perimitral circuits (see Fig. 22-35) and parallel to the mitral annulus plane in all other circuits. RF lesions are applied to the region until pacing with 10-mA, 2-millisecond strength stimuli fails to capture, or reversal of ventricular electrograms in CS recordings occurs (Fig. 22-39). After completion of each set of RF lesions, programmed electrical stimulation is repeated.

Application of RF energy at successful exit, central, or entry VT circuit sites usually results in termination of the VT within a mean time of 10 ± 11 seconds. When RF application at other sites terminates the VT, the average time to termination is 19 ± 16 seconds, which suggests that a larger region must be heated for interruption of reentry. Persistence of inducibility of VT after successful termination with a single RF application, despite further applications of RF energy at the same site, is probably secondary to inadequate lesion size because of a wide isthmus, epicardial location, and/or significant fibrosis, thrombus, or calcification. In some cases, lack of consistent electrode-tissue contact can result from dislodgment of the electrode when a sudden change in rhythm occurs (such as VT termination).

When RF application fails to terminate the VT at a site that appears to be in the circuit, the site may be a bystander. Failure of ablation has been attributed to a number of factors, including inaccurate mapping because of failure to apply appropriate criteria for localizing a protected isthmus and/or inability to find such a site,

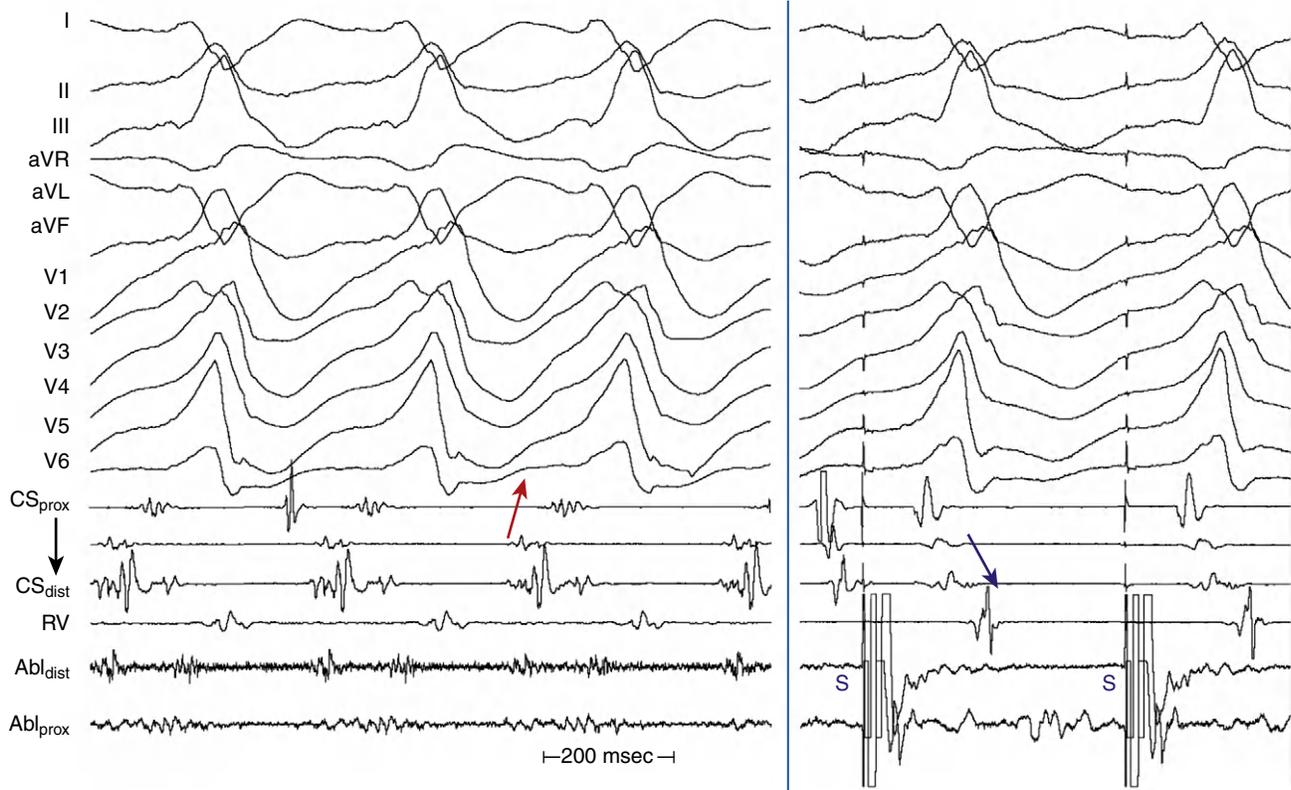

FIGURE 22-39 Mitral isthmus block in inferior wall post-infarction ventricular tachycardia (VT). During VT, shown in the left panel (as well as sinus rhythm and right ventricular pacing [data not shown]), ventricular electrograms in the coronary sinus (CS) recordings propagate from distal to proximal (red arrow). After ablation to the mitral annulus, pacing from a coronary vein branch distal to the ablation line (right panel) shows propagation now from proximal to distal CS (blue arrow), indicating conduction block in the mitral isthmus.

and also to inadequate lesion size produced by the RF application. Occasionally, successful termination of VT is achieved with RF application at a site at which failure is predicted. This may occur if the site is not at the isthmus region but in the nearby vicinity, with good conduction of temperature to the isthmus.

Endpoints of Ablation

At effective target sites, RF energy terminates VT and prevents reinduction of the targeted VT using the entire programmed electrical stimulation protocol. An ablation target site is deemed ineffective when the application of RF energy does not terminate or prevent the reinduction of VT despite an electrode-tissue interface temperature of more than 55°C.

Successful VT ablation is defined as noninducibility of any VT (excluding polymorphic VT, ventricular flutter, and VF). When clinical or presumed clinical VTs have been adequately documented previously and can be induced at the outset of the procedure, the minimal endpoint of ablation should be to eliminate the induction of that VT during postprocedure programmed stimulation. The entire programmed electrical stimulation protocol should be performed and should include up to three VESs delivered from at least two ventricular sites (one of which may be LV), with the shortest coupling intervals of 180 to 200 milliseconds or to refractoriness. If the initial stimulation protocol required additional LV pacing sites or catecholamine infusion to induce VT, then that protocol should be repeated following ablation. The complete protocol of programmed electrical stimulation is again repeated after a 30-minute waiting period, unless such aggressive stimulation places the patient at risk of cardiopulmonary deterioration.²

VT modification is defined as noninducibility of all clinical VTs (i.e., all inducible VTs that are known to have the same 12-lead ECG QRS morphology and approximate CL as spontaneous VTs), but with other monomorphic VTs remaining inducible. Following

ablation of one or more reentry circuits, the remaining inducible VTs are often faster, suggesting that regions of slow conduction have been ablated; the remaining circuits that can form have a shorter revolution time. Thus, the arrhythmia substrate appears to have been modified. Modification of the reentry substrate is a common outcome of ablation, and is usually associated with a favorable outcome and a relatively low risk of arrhythmia recurrence.

On the other hand, the mere change in the “intensity” of stimulation required to induce VT (greater number of extrastimuli and alternative stimulation sites) is not a reliable endpoint.² In one report, induction of any VT post ablation was associated with a significantly greater risk of VT recurrence (nearly twofold), whereas persistent induction of only more rapid “nonclinical” VTs did not predict recurrence.⁵⁹

In patients who present with incessant VT, restoration of stable sinus rhythm may represent a reasonable clinical endpoint, irrespective of the outcome of subsequent programmed stimulation.

Outcome

MANAGEMENT AFTER ABLATION

Following successful catheter ablation, antiarrhythmic drugs may be discontinued. Nonetheless, because of the relatively high risk of VT recurrence and the progressive nature of the VT substrate, antiarrhythmic drug therapy is often continued in most patients following VT ablation. In some cases, cessation of antiarrhythmic drugs that had suppressed some VTs may allow them to occur; therefore, freedom from antiarrhythmic drugs may not be a reasonable goal of ablation; instead, dose reduction may be an important goal, particularly for amiodarone, for which the incidence of side effects is closely related to daily dose. In various trials, dose reduction of amiodarone is reported and doses may be reduced in a progressive manner starting within the first 3 to 6 months post ablation.^{1,2}

Within the first 3 months post ablation in the LV, there may be a risk of systemic thromboembolism, particularly if extensive ablation lesions were applied. Antiplatelet agents (aspirin, clopidogrel, or both) are typically used in all patients with ischemic heart disease. Additionally, warfarin may be used for higher risk patients (documented thrombus, previous stroke or transient ischemic attack, AF, severe LV dysfunction). Short-term (6 to 12 weeks) warfarin therapy may also be considered in patients who received extensive ablation over large areas (e.g., several centimeters).^{1,2}

SUCCESS AND RECURRENCE

Catheter ablation generally results in improved arrhythmia control in the majority (50% to 83%) of patients who have a mappable scar-related VT and can also decrease the frequency of VT episodes triggering ICD therapies. The variable success of post-MI VT ablation has been attributed to a number of factors, including inaccurate mapping because of failure to apply appropriate criteria for localizing a protected isthmus and/or inability to find such a site, and inadequate lesion size produced by RF. Outcome appears to be improved with irrigated ablation techniques.¹ Ablation targeting critical isthmuses for stable VTs is successful, abolishing the inducible “targeted” or “clinical” VT in 71% to 86% of selected patients. During average follow-ups ranging from 9 to 42 months, noninducibility of the clinical VT immediately postprocedure is associated with a lower risk of VT recurrence and nonfatal VT (13% to 46%), compared with persistent inducibility of the clinical VT (up to 80%); the risk of SCD is low (0% to 6%), reflecting common use of ICDs for patients felt to be at risk.⁴³

Also, substrate-guided ablation generally achieves a marked reduction in VT episodes and ICD shocks in patients with scar-related VT, even if occasional recurrences of VT persist during follow-up. It is a reasonable approach for patients with unmappable VT and may be combined with other mapping approaches in patients with mappable VTs.¹ In patients with a single stable spontaneous VT morphology well documented prior to the procedure, the persistent induction of “nonclinical” VTs that are faster than the targeted VT was reported to have little influence on subsequent spontaneous recurrence rates. Although the occasional spontaneous occurrence of these “nonclinical” VTs during follow-up is well documented, ablation of clinical VT (but not necessarily all VTs) can be associated with a lower incidence of electrical storm and cardiac death, despite a high likelihood of sporadic VT recurrence.^{2,59} Nonetheless, lack of inducible ventricular arrhythmias following VT ablation is associated with improved survival.⁶⁰ In patients with failure of ablation or another VT inducible, the 3- to 4-year risk of VT recurrence is much higher (60% to 64%) as compared with patients with no inducible monomorphic VT of any morphology (recurrence, 14% to 20%). Additionally, induction of multiple VT morphologies during the procedure may predict higher risk of arrhythmia recurrence post ablation.⁵⁸ In patients with incessant VT or VT storm, catheter ablation can be life-saving and can acutely control the arrhythmia in over 90% of patients. Although single episodes of VT recur in approximately one-third of patients, 74% to 92% remain free of incessant VT or VT storm.²

Recurrence of the patient’s initial spontaneous VT is usually presumed to occur if either the 12-lead ECG demonstrates the same VT morphology as the initial VT, or the VT CL as recorded from the ICD is within 20 milliseconds of the initial VT CL (if there has been no change in antiarrhythmic drug therapy). When the clinical VT recurs, it generally has a longer CL. This occurs because (1) the RF lesion might have produced slowing of conduction, and not block, in the critical isthmus, possibly because the width of the isthmus exceeds the size of the ablation lesion; (2) the RF lesion might have increased the length of the central common pathway by increasing the barrier around which the impulse circulated, without changing the circuit exit; and/or (3) the RF lesion might actually have been successful in eliminating the critical isthmus of the VT circuit, but an inner loop, which was present and not part of the primary reentry circuit, became an active participant in a new longer circuit that had the same exit site as the original VT.

When a VT with different morphology occurs, it is usually one of the inducible VTs from the same region. This likely reflects different exit sites or different potential reentrant circuits in the same area of the infarct.

COMPLICATIONS

Patients with post-MI VT typically have depressed LV function and concomitant illnesses. Ablation is often a late attempt in controlling refractory arrhythmias, sometimes after significant hemodynamic compromise has developed. Therefore, significant complications (e.g., worsened heart failure, stroke, transient ischemic attack, MI, cardiac perforation, or heart block) occur in approximately 3.6% to 10% of patients. Procedure-related mortality ranges from 0% to 3%. Local hemorrhagic complications (large hematomas or arterial pseudoaneurysms, arteriovenous fistula) occur in more than 2% of patients. Strokes and transient ischemic attacks occur in approximately 1%, and cardiac tamponade in 1%.¹

Exacerbation of heart failure can develop in the acute phase post ablation. Extensive ablation in viable myocardium, injury to the aortic or mitral valves during LV catheter manipulation, repeated hemodynamically unstable VT episodes, and saline administration from externally irrigated ablation catheters are procedural complications that can potentially exacerbate heart failure and myocardial ischemia. Therefore, it is prudent to restrict ablation lesions to areas of infarction, as identified from low-amplitude electrograms in regions observed to have little contractility on echocardiography or ventriculography.^{1,2}

On the other hand, coronary artery injury is not common during endocardial RF application of post-MI VT. Larger coronary vessels are less susceptible to injury than small vessels, likely due to the greater cooling effect of blood flow. Additionally, ablation in infarct-related areas is likely to involve territories of occluded infarct arteries. Of 215 patients in one series, only a single patient suffered MI from occlusion of a marginal artery.

Although ablation guided by substrate mapping avoids the hemodynamic consequences of prolonged mapping during VT, the lack of a precise reentry circuit target is compensated by extensive ablation lesion sets, which increases the potential for complications. In a recent multicenter study, major complications including worsening heart failure were observed in 7.3% of patients, and 3.0% died within 7 days of ablation.¹

During follow-up later after ablation, the largest source of mortality was death from heart failure, accounting for more than one third of mortality and exceeding 10% per year in some studies. Although this risk of death is not unexpected in this population, because the mere occurrence of VT is a marker for increased heart failure and mortality, ablation of VT can potentially contribute to progression of heart failure.

In a recent meta-analysis of five studies including 457 participants with structural heart disease (predominantly ischemic CMP), complications of catheter ablation occurred in 6.3% of patients, including death (1%), stroke (1%), cardiac perforation (1%), and complete heart block (1.6%). There was no statistically significant difference in mortality compared with patients treated with antiarrhythmic medications.⁶¹

Before considering VT ablation, possible aggravating factors should be addressed to reduce the risks of procedural complications. Although myocardial ischemia by itself does not generally cause recurrent monomorphic VT, it can be a trigger in patients with scar-related reentry circuits. Furthermore, severe ischemia during induced VT increases the risk of mapping and ablation procedures. An assessment of the potential for ischemia is generally warranted in these patients. Patients with LV dysfunction should also have an echocardiogram to assess the possible presence of LV thrombus that could be dislodged and embolize during catheter manipulation in the LV. Scar-related VTs are often associated with poor LV function and multiple inducible VTs; most patients will remain candidates for an ICD, with ablation used for control of symptoms caused by frequent arrhythmia recurrences.

Classification

Ventricular tachycardia (VT) is usually associated with structural heart disease, with coronary artery disease and cardiomyopathy (CMP) being the most common causes. However, about 10% of patients who present with VT have no obvious structural heart disease (idiopathic VT).¹ Absence of structural heart disease is usually suggested if the electrocardiogram (ECG) (except in Brugada syndrome and long QT syndrome), echocardiogram, and coronary arteriogram collectively are normal. Nevertheless, magnetic resonance (MR) imaging may demonstrate mild structural abnormalities and subtle areas of diminished wall motion in some patients with idiopathic VT, even if all other test results are normal. In addition, focal dysautonomia in the form of localized sympathetic denervation has been reported in patients with VT and no other obvious structural heart disease. Of note, idiopathic VT occasionally occurs in patients with structural heart disease, in whom the structural heart disease is not related to the VT. Furthermore, frequent or incessant idiopathic VT can be a cause of tachycardia-induced CMP.²

Several distinct types of idiopathic VT have been recognized and classified with respect to the origin of VT (right ventricle [RV] versus left ventricle [LV]), VT morphology (left bundle branch block [LBBB] versus right bundle branch block [RBBB] pattern), response to exercise testing, response to pharmacological agents (adenosine-sensitive versus verapamil-sensitive versus propranolol-sensitive VT), and behavior of VT (repetitive salvos versus sustained).³

Pathophysiology

Mechanism of Adenosine-Sensitive Ventricular Tachycardia

Most forms of outflow tract VTs are adenosine-sensitive and are thought to be caused by catecholamine-induced, cyclic adenosine monophosphate (cAMP)-mediated delayed afterdepolarizations (DADs) and triggered activity, which is supported by several tachycardia features (see Chap. 4).⁴ Heart rate acceleration facilitates VT initiation. This can be achieved by programmed stimulation, rapid pacing from either the ventricle or the atrium, or infusion of

a catecholamine alone or during concurrent rapid pacing. Additionally, termination of the VT is dependent on direct blockade of the dihydropyridine receptor by calcium channel blockers or by agents or maneuvers that lower cAMP levels (e.g., by activation of the M₂ muscarinic receptor with edrophonium or vagal maneuvers, inhibition of the beta-adrenergic receptor with beta blockers, or activation of the A₁ adenosine receptor with adenosine). Furthermore, a direct relationship exists between the coupling interval of the initiating ventricular extrastimulus (VES) or ventricular pacing cycle length (CL) and the coupling interval of the first VT beat. Additionally, VT initiation is CL-dependent; pacing CLs longer or shorter than a critical CL window fail to induce VT. This critical window can shift with changing autonomic tone.^{1,5,6}

Types of Adenosine-Sensitive Ventricular Tachycardia

Approximately 90% of idiopathic VTs are caused by one of two phenotypic forms of adenosine-sensitive VT. Repetitive monomorphic VT is the most common form (60% to 90%) and is characterized by frequent premature ventricular complexes (PVCs), couplets, and salvos of nonsustained VT, interrupted by brief periods of normal sinus rhythm (NSR; Fig. 23-1). This form of VT usually occurs at rest or following a period of exercise, and typically decreases during exercise, but can be incessant.¹ On the other hand, paroxysmal exercise-induced VT is characterized by sustained episodes of VT precipitated by exercise or emotional stress, separated by long intervals of NSR with infrequent PVCs (Fig. 23-2).¹ Evidence has suggested that both types represent polar ends of the spectrum of idiopathic VT caused by cAMP-mediated triggered activity and there is considerable overlap between the two types. Furthermore, this subtype classification, although useful, is not necessarily precise and depends on the means and duration of rhythm recordings. Patients are typically categorized based on their presenting or index arrhythmia. Prolonged telemetry and long-term ambulatory ECG recordings have demonstrated that most patients with one subtype of outflow tract VT show evidence for at least one other subtype with an identical morphology. Almost all patients with nonsustained VT have high-density repetitive runs and frequent PVCs. In patients who present with repetitive PVCs, nonsustained VT can also be observed in approximately 70%; however, only 20% of these patients develop runs of more than five beats.⁷

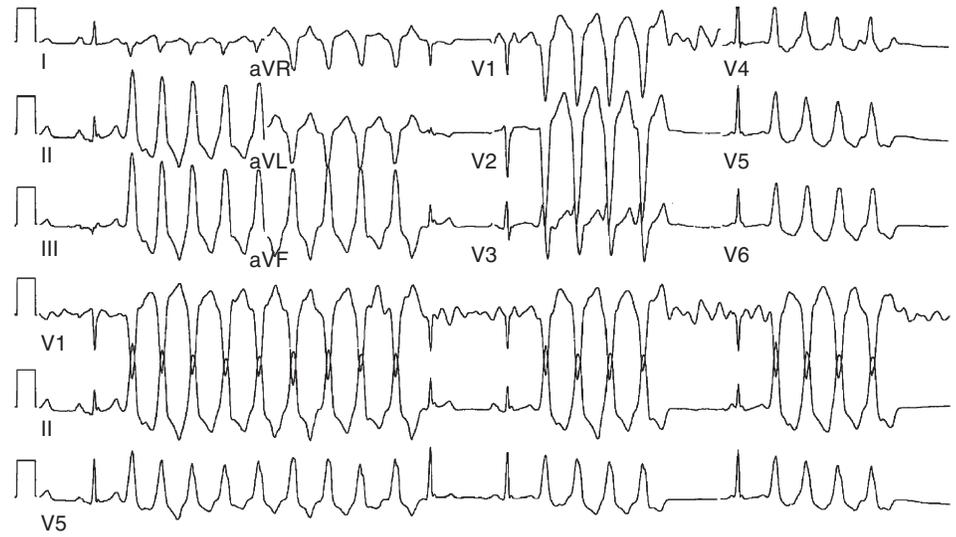

FIGURE 23-1 Surface ECG of repetitive monomorphic right ventricular outflow tract tachycardia. Repetitive bursts of ventricular tachycardia are present, with occasional sinus complexes.

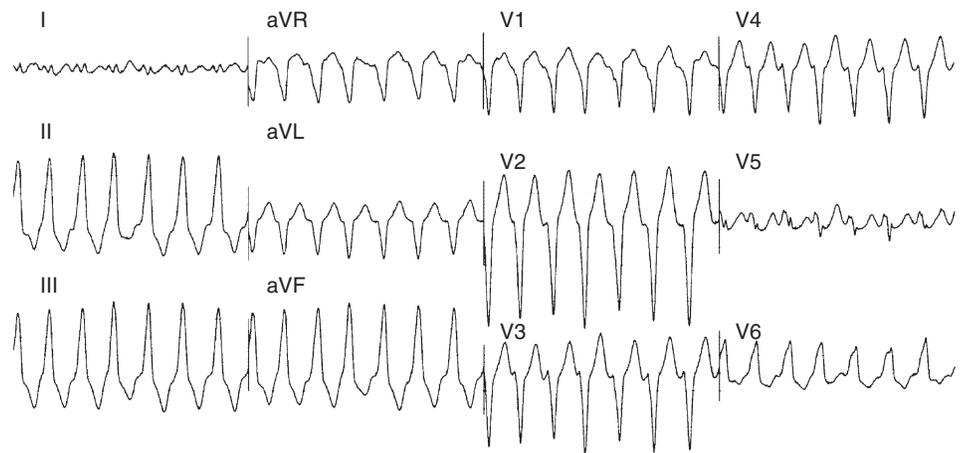

FIGURE 23-2 Surface ECG of sustained right ventricular outflow tract tachycardia.

Anatomical Considerations

Adenosine-sensitive idiopathic VT usually arises from outflow tracts (most frequently from the RV outflow tract [RVOT]). Other variants of outflow tract VT (with similar underlying electrophysiological [EP] mechanism) include ventricular arrhythmias arising from the aortic cusps, pulmonary artery, mitral or tricuspid inflow tracts, papillary muscles, and epicardial foci in close proximity to the coronary venous system.³ Understanding the unique and complex anatomical relationships of the outflow tracts is critical for analyzing the ECG and mapping findings during outflow tract VT as well as for safe catheter maneuvering and ablation.

RIGHT VENTRICULAR OUTFLOW TRACT

The RVOT is the tubelike portion of the RV cavity above the supra-ventricular crest, and is defined superiorly by the pulmonic valve and inferiorly by the RV inflow tract and the top of the tricuspid annulus (the region of the His bundle [HB] and proximal right bundle branch). The lateral aspect of the RVOT region is the RV free wall. The RVOT passes cephalad in a posterior and slightly leftward direction. The medial aspect is formed by the anterior interventricular septum at the base of the RVOT and RV musculature opposite to the anterior LV outflow region (LVOT) (as a cephalad continuation of the interventricular septum) and the root of the aorta (immediately adjacent to the right coronary cusp) at the region just inferior to the pulmonic valve (Fig. 23-3).⁸

Although the medial aspect of the RVOT is frequently referred to as the “septal” wall, it should be noted that the outflow tract per se is not part of the interventricular septum, and the septum is a component only of the most proximal part of the RVOT at the branch point of the septomarginal trabeculation. Above this area, the RVOT curves to pass anterior and cephalad to the LVOT, and, therefore, any perforation in the septal part is more likely to go outside the heart than into the LV (Fig. 23-4).

From the coronal view above the pulmonic valve, the RVOT region is seen wrapping around the LVOT and the root of the aorta and extending leftward (see Fig. 23-3). Whereas the inflow portion of the RV lies to the right and anterior to the inflow portion of the LV, the RVOT courses anterior to the LVOT such that the distal RVOT and pulmonic valve are located to the left side of the body in relationship to the aortic valve and the distal LVOT. The pulmonic valve is typically placed approximately 5 to 10 mm cephalad and to the left of the aortic valve such that the supra-ventricular portion of the aorta lies in immediate proximity to the portions of the pulmonic valve; immediately anterior to the aortic valve is the posterior muscular infundibular portion of the RVOT.^{8,9}

The top of the RVOT can be convex or crescent-shaped, with the posteromedial region directed rightward and the anterolateral region directed leftward. The anteromedial aspect of the RVOT actually is located in close proximity to the LV epicardium, adjacent to the anterior interventricular vein and in proximity to the left anterior descending coronary artery. The aortic valve

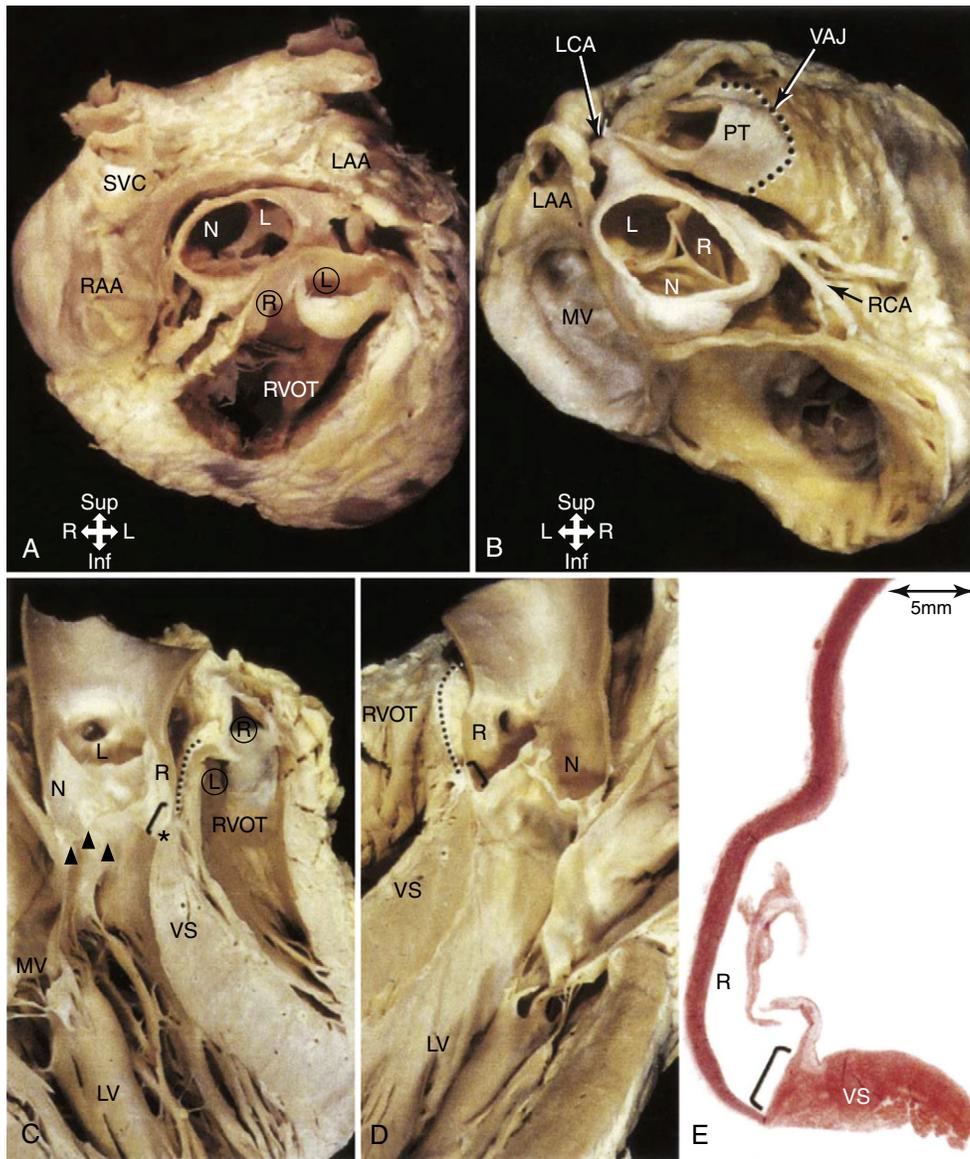

FIGURE 23-3 Anatomy of the outflow tracts and aortic sinuses. These heart specimens illustrate the anatomical arrangement between the right ventricular outflow tract (RVOT) and the aortic sinuses. **A**, Viewed superoanteriorly the RVOT passes leftward and superior to the aortic valve. **B**, The superoposterior view shows the left (L) and right (R) coronary aortic sinuses adjacent to the pulmonary infundibulum. The noncoronary (N) aortic sinus is remote from the RVOT, but is related to the mitral valve (MV) and central fibrous body. The dotted line marks the ventriculoarterial junction (VAJ) between the wall of the pulmonary trunk (PT) and right ventricular muscle. Note the cleavage plane behind the pulmonary infundibulum and in front of the aortic root. **C** and **D**, These simulated parasternal long-axis sections show two halves of the same heart and display the left and right coronary orifices. The right- and left-facing pulmonary sinuses (R and L in circles, respectively) are situated superior to the aortic sinuses. The dotted line marks the epicardial aspect of the subpulmonary infundibulum in the so-called “septal” area (as illustrated in **E**). Inf = inferior; LAA = left atrial appendage; LCA = left coronary artery; LV = left ventricle; RAA = right atrial appendage; RCA = right coronary artery; SVC = superior vena cava; Sup = superior; TV = tricuspid valve; VS = ventricular septum. (From Ouyang F, Fotuhi P, Ho SY, et al: Repetitive monomorphic ventricular tachycardia originating from the aortic sinus cusp: electrocardiographic characterization for guiding catheter ablation. *J Am Coll Cardiol* 39:500, 2002.)

cusps sit squarely within the crescent-shaped posterior region of the RVOT and are inferior to the pulmonic valve (see Fig. 23-3). The most posterior aspect of the RVOT is adjacent to the region of the right coronary cusp, and the posteromedial (leftward) surface is adjacent to the anterior margin of the right coronary cusp or the medial aspect of the left coronary cusp.¹⁰ The thickness of the RVOT wall is variable, ranging from approximately 3 to 6 mm, and is thinnest in the rightward, anterior, and subpulmonic valve portions, and thickest in the posterior infundibular part that is adherent to the anterior LVOT as a cephalad continuation of the interventricular septum.⁸

LEFT VENTRICULAR OUTFLOW REGION

Unlike the RV, the inflow and outflow tracts of the LV are at an acute angle to one another. The central location of the aortic valve places the LVOT between the mitral valve and the ventricular septum. In turn, approximately half of the aortic outlet is muscular and the other half (being the area of valvular continuity between the mitral and aortic valves) is fibrous. The curvature of the ventricular septum continuing into the free wall forms the anterosuperior wall of the LVOT. It is the deep anterior (aortic) leaflet of the mitral valve that forms the aortic-mitral curtain. The extremities of the fibrous continuity are the left and right fibrous trigones, the right trigone forming the central fibrous body. The LVOT passes underneath the

RVOT in a rightward and cephalad direction pointing toward the right shoulder (see Fig. 23-4).¹¹

AORTIC CUSPS

The aortic root is defined as the interface between the LV and the ascending aorta, extending from the sinotubular junction in the aorta to the basal valvular leaflets with their attachment within the LV (see Fig. 23-3). Approximately two-thirds of the circumference of the lower part of the aortic root is connected to the muscular ventricular septum, with the remaining one-third in fibrous continuity with the aortic leaflet of the mitral valve. Its components are the sinuses of Valsalva, the fibrous interleaflet triangles, and the valvular leaflets themselves. The aortic valve is composed of three symmetric, semilunar-shaped cusps. The recess of each cusp is called the “sinus of Valsalva.” The aortic (coronary) cusps are firmly anchored to the fibrous skeleton within the root of the aorta. A circular ridge on the innermost aspect of the aortic wall, at the upper margin of each sinus, is the sinotubular ridge—the junction of the sinuses and the aorta. The aortic cusps are named according to their orientation in the body—left and right (both facing the pulmonic valve anteriorly) and posterior. The left aortic sinus gives rise to the left coronary artery, and the right aortic sinus gives rise to the right coronary artery. Usually, no vessels arise from the posterior aortic sinus, which is therefore known as the noncoronary

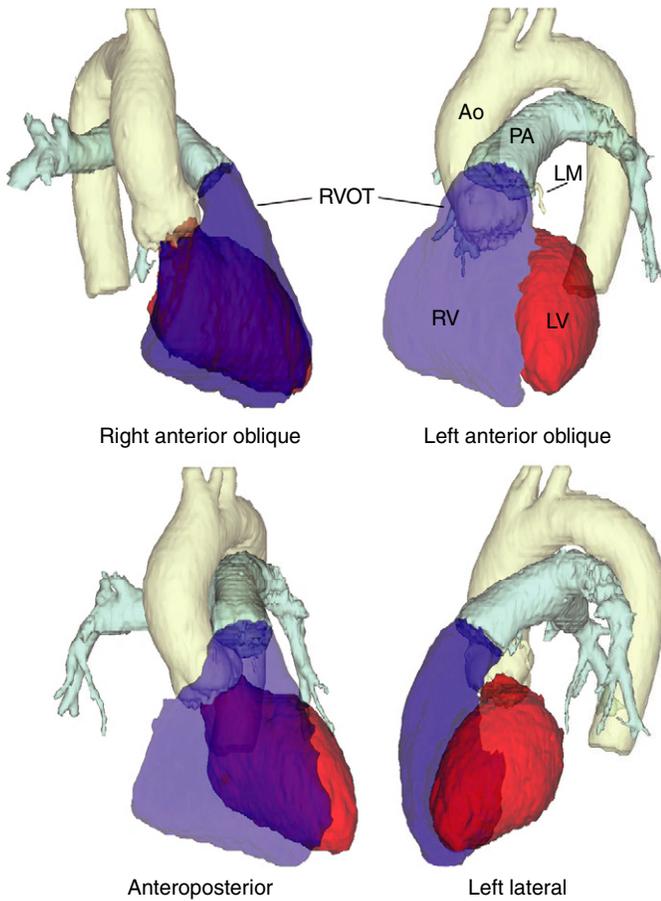

FIGURE 23-4 Anatomical relationships for ablation of outflow tract ventricular tachycardia (VT). Most RVOT VTs arise from just proximal to the pulmonic valve; note that the RVOT in this region is all free wall (not septal wall) and the leftward aspect of the RVOT is very near the LM, making it vulnerable to injury. Note also the close relationships between RVOT, aortic sinuses of Valsalva, and subaortic left ventricle (LV), explaining why VTs from this general region can have similar ECG morphologies. Ao = aorta; LM = left main coronary artery; PA = pulmonary artery; RVOT = right ventricular outflow tract.

sinus. Three equally spaced sites of minimal tethering within the aortic root mark the junctions of the sinuses of Valsalva. Each sinus is associated with a leaflet of the aortic valve, whereas the junctions between the adjacent sinuses are aligned with the commissures between the aortic valve leaflets.¹²⁻¹⁴

The aortic valve is the cardiac centerpiece; it lies in contact or continuity with all four cardiac chambers and shares important proximate relationships with each of the other cardiac valves (Video 20). It comes into contact with the right atrium (RA), left atrium (LA), interatrial septum, RVOT, mitral valve (aortomitral continuity), pulmonic valve, tricuspid valve, and conduction system (see Fig. 23-3).^{8,9}

The aortic root is inferior, posterior, and somewhat rightward compared with the RVOT. As noted, the posterior subpulmonic valve portions of the RVOT are immediately anterior and more proximally continuous with the anterior myocardial subaortic LVOT and more distally to the right coronary cusp. The lateral and more distal portions of the left coronary cusp lie immediately subjacent to the peripulmonic valve portions of the RVOT. In some instances, the supravalvular myocardial fibers of one outflow tract may be continuous with the other outflow tract's intravalvular myocardium, thus forming a functional syncytium.⁸

The left coronary cusp lies to the left of the right coronary cusp and is related to the posterior wall of the RVOT (Fig. 23-5). The commissure between the right and left coronary cusps is just posterior to the distal RVOT and is close but caudal to the posterior pulmonic valve annulus. More leftward and posteriorly, the left coronary cusp lies in continuity with the anterior leaflet of the mitral

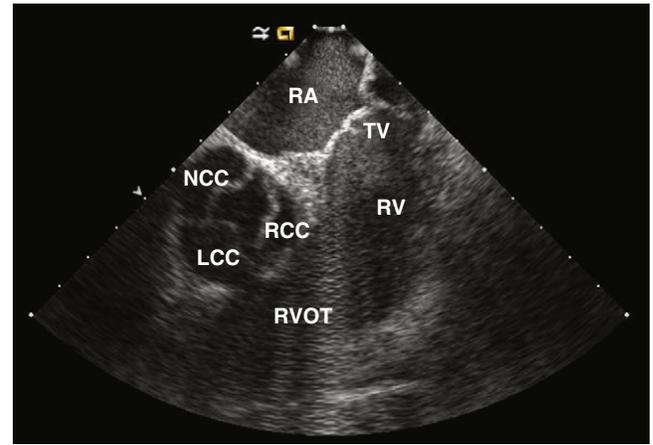

FIGURE 23-5 Intracardiac echocardiography (ICE) cross-sectional image of the aortic valve acquired with the ICE catheter positioned at the His bundle region of the RV septum. LCC = left coronary cusp; NCC = noncoronary cusp; RA = right atrium; RCC = right coronary cusp; RV = right ventricle; RVOT = right ventricular outflow tract; TV = tricuspid valve.

valve (aortomitral continuity). Adjacent to this site lies the peripulmonic valve myocardium and, more laterally, the posterior lobe of the LA appendage (when present).^{8,9}

The right coronary cusp lies immediately posterior to the relatively thick posterior infundibular portion of the RVOT. Caudally, there is continuity with the anterior LVOT, and at the level of valve insertion there is either physical continuity or very close proximity between myocardium that extends above this valve cusp, the LVOT, and the posterior RVOT. The posterior part of the right coronary cusp is adjacent to the central fibrous body, which carries within it the penetrating portion of the HB. Anteriorly, the right coronary cusp is related to the bifurcating atrioventricular (AV) bundle and the origin of the left bundle branch. The right coronary cusp does not have a direct relationship with either atrium, but lateral to the commissure with the noncoronary cusp lies the RA appendage, trunk of the right coronary artery, and a variable amount of fat.^{8,9}

The noncoronary cusp is the most posterior of the aortic cusps, and lies immediately anterior to the interatrial septum and superior to the central fibrous body, and has the RA and LA as the posterior right and left relations, respectively (see Fig. 23-5). In fact, atrial tachycardias have reportedly been ablated from within the noncoronary cusp because of its close relationship to the atria. Caudally, like the other cusps, the noncoronary cusp is in continuity with the LVOT myocardium. Other than this site, however, it has no anatomical relationship with any other ventricular myocardium. The triangle between the noncoronary and the right coronary sinuses incorporates within it the membranous part of the septum (the location of the penetrating HB). This fibrous part of the septum is crossed on its right side by the hinge of the tricuspid valve, which divides the septum into *atrioventricular* and *interventricular* components.^{8,9,12,13}

Because of the semilunar nature of the attachments of the aortic valvular leaflets, there are three triangular extensions of the LVOT that reach to the level of the sinotubular junction. These triangles, however, are formed not of ventricular myocardium but of the thinned fibrous walls of the aorta between the expanded sinuses of Valsalva.¹⁴

For the greater part, the aortic sinuses are made up of the wall of the aorta. However, sleeves of ventricular myocardium extend beyond the aortic valve attachments for variable distances (analogous to atrial myocardial extensions in the pulmonary veins). Whereas the right coronary cusp and the anterior portions of the left coronary cusp frequently exhibit these myocardial sleeves, the posterior portions of the left coronary cusp and the noncoronary cusp, particularly in relation to the fibrous continuity with the anterior leaflet of the mitral valve (the aortomitral continuity), are exclusively fibrous and usually devoid of myocardium.^{8,9,15} The

noncoronary cusp at its junction of the right coronary cusp may have sleeves of ventricular myocardium and, at present, it is not clearly known whether myocardial extensions into the noncoronary cusp represent atrial or ventricular myocardium.⁸

Idiopathic VT can originate from the right or, more commonly, left coronary cusp, as well as from the junction of the left and right coronary cusps. The substrate of this VT likely originates from the strands of ventricular myocardium present at the bases of those cusps. In contrast, the base of the noncoronary cusp is composed of fibrous tissue and, thus, is an extremely rare site of origin of VT.^{16,17} However, the nature of the actual substrate being ablated has not been clearly defined. For example, the ablation electrode placed in the depth of the right coronary cusp may be mapping and ablating a focus arising from the supraventricular extension into the cusp, LVOT myocardium, or a deeper posterior RVOT myocardium.⁹

PULMONARY ARTERY

The pulmonary sinuses are not as prominent as the aortic sinuses. Nevertheless, owing to the semilunar configuration of the valvular leaflets, the hinge line of each leaflet crosses the ventriculoarterial junction at two points. Consequently, there are always small segments of myocardium of the infundibulum at the nadirs of the three sinuses. Between adjacent sinuses, the wall comprises small triangles of fibrous tissue that become incorporated into the RV when the valve closes. On the epicardial aspect, the ventriculoarterial junction is not always a sharply defined line. Extensions of ventricular myocardium into the adventitia occur in approximately 20% of individuals and have been traced to a maximal distance of 6 mm beyond the junction.¹¹

As noted, the pulmonic and aortic valves are not at the same level (see Fig. 23-3). The pulmonic valve, the most superiorly situated of the cardiac valves, lies at the level corresponding to the third left costal cartilage at its junction with the sternum. The transverse plane of the aortic valve slopes inferiorly, away from the plane of the pulmonic valve, such that the orifice of the aortic valve faces rightward at an angle of at least 45 degrees from the median plane.¹¹

Because of its anterior and leftward location, only the posterior and rightward parts of the pulmonary artery have important relations with other cardiac structures. Of the three cusps of the pulmonic valve, the septal (right) pulmonic cusp lies at variable distances from and sometimes adjacent to the distal portions of the RA appendage. The left pulmonic cusp, being the most superficial, lies immediately beneath the pericardium and has no other cardiac structures related to it. The posterior pulmonic cusp externally lies in the proximal portion of the left main coronary artery and the distal portions in the LA appendage. The supraventricular portion of the aorta lies close to and in some cases adjacent to the junction and surrounding parts of the right and posterior pulmonic cusps.^{8,9}

The pulmonic valve and supraventricular portion of the pulmonary artery are well-established locations of origin for ventricular arrhythmias. As noted, ventricular myocardial sleeves extend above the semilunar valves for a variable distance (a few millimeters and up to more than 2 centimeters). Whereas the myocardial sleeves typically extend circumferentially around the pulmonic valve between and above all three cusps just above the annulus, more distally the extension is patchy and generally asymmetrical. Myocardial extensions also occur in the intercuspal clefts in addition to within the cusps.⁸

Clinical Considerations

Epidemiology

Approximately 60% to 80% of idiopathic VTs arise from the RV (most commonly the RVOT). RVOT VT comprises 10% of all VTs referred to an electrophysiologist. Age at presentation is usually 30 to 50 years (range, 6 to 80 years). Women are more commonly affected.^{1,5}

Clinical Presentation

Most patients present with palpitations, 50% develop dizziness, and a minority (10%) present with syncope. Most commonly, symptoms are related to frequent PVCs or nonsustained VT. Less commonly, paroxysmal sustained VT is precipitated by exercise or emotional stress. The clinical course is benign and the prognosis is excellent. Sudden cardiac death (SCD) is rare. Spontaneous remission of the VT occurs in 5% to 20%.

Very frequent idiopathic nonsustained VT, PVCs, or both can precipitate a reversible form of LV systolic dysfunction, similar to tachycardia-induced dilated CMP. The relationship between the LV dysfunction and VT may not be initially recognized, and those patients can present with heart failure symptoms and become diagnosed with nonischemic dilated CMP and may even undergo prophylactic implantation of a defibrillator, which unfortunately often results in delivery of inappropriate shocks triggered by frequent nonsustained episodes of idiopathic VT.² Interpolation of the PVCs appears to predict an increased risk of PVC-induced CMP.¹⁸ Notably, in a recent report, 20% of patients with PVC-induced CMP had the PVC focus in one of the aortic cusps.¹⁹

Initial Evaluation

Diagnostic features include (1) structurally normal heart; (2) origin in the outflow tract (RVOT and, less commonly, LVOT), although the VT can also originate from the RV inflow tract, RV apex, or LV; and (3) QRS with LBBB-like morphology and inferior axis. The echocardiogram is normal in most patients. Slight RV enlargement is observed rarely. Exercise testing can help reproduce patients' clinical VT 25% to 50% of the time, but is not clinically helpful in most cases.

The diagnosis of idiopathic VT is one of exclusion; structural heart disease, CMP, and coronary artery disease have to be excluded, usually by cardiac stress testing and echocardiography. Left heart catheterization, right heart catheterization, or both may be warranted.

Additionally, it is important to differentiate idiopathic VT from other potentially malignant forms of VT that may also arise from the outflow tract region, including VT in arrhythmogenic RV dysplasia-cardiomyopathy (ARVD), catecholaminergic polymorphic VT (CPVT), Brugada syndrome, and idiopathic polymorphic VT and ventricular fibrillation (VF). A Brugada ECG pattern, findings of reduced LV or RV function, polymorphic VT or multiple VT morphologies, a history of recurrent syncope, or a family history of SCD mandates further detailed evaluation.

The diagnosis of ARVD should be carefully considered. Signal-averaged ECG, MR imaging of the RV, RV biopsy, and RV angiography are all unremarkable in idiopathic RVOT VT and help exclude ARVD. An invasive EP study is usually not necessary to establish a diagnosis, although it can occasionally help exclude other forms of tachyarrhythmias (see later).²

It is important to recognize that, in some patients, idiopathic VT can coexist with structural heart disease, including CMP, in which setting the VT is not related to the cardiac disease. On the other hand, very frequent idiopathic nonsustained VT, PVCs, or both can precipitate dilated CMP. The responsible ectopy can arise from any ventricular site, but the RVOT, being the most common type of idiopathic ventricular ectopy, is more commonly associated with ectopy-related CMP. Therefore, in patients who present with a dilated CMP of unclear etiology and who have frequent PVCs or nonsustained VT, it is important to assess the contribution of PVCs or VT to LV systolic dysfunction. A reversible form of dilated nonischemic CMP precipitated by idiopathic VT should be suspected when very frequent PVCs, nonsustained VT, or both are observed on a 24-hour Holter recording, especially when the QRS morphology is monomorphic and is suggestive of origin from the outflow tract. A PVC burden of more than 20% is present in most of those patients with tachycardia-induced CMP, but some patients have as few as 5% PVCs. In a recent report, a cutoff PVC burden of more than 24% was strongly associated with the presence of CMP. However, this cutoff value failed to identify

every patient at risk of CMP, and for individual patients, the critical PVC burden can be lower. A cutoff PVC burden of more than 16% would result in a sensitivity of 90% for CMP, but the specificity would be reduced to 58%.²⁰ Although pharmacological suppression of the PVCs, such as by amiodarone therapy, may help evaluate the relationship between the arrhythmia and CMP, the usefulness of this approach and duration of therapy required have not been defined. Often, elimination of the PVCs by catheter ablation results in improvement and resolution of LV dysfunction within a few months. Therefore, catheter ablation of the PVCs is appropriate prior to implantable cardioverter-defibrillator (ICD) implantation for primary prevention of SCD; successful elimination of the PVCs may result in improvement in LV function such that the patient no longer qualifies for an ICD.^{2,21}

Principles of Management

ACUTE MANAGEMENT

Acute termination of outflow tract VT can be achieved by vagal maneuvers or intravenous administration of adenosine (6 mg, titrated up to 24 mg as needed). Intravenous verapamil (10 mg given over 1 minute) is an alternative, provided the patient has adequate blood pressure and has a previously established diagnosis of a VT that is sensitive to verapamil. Hemodynamic instability warrants emergency cardioversion.

CHRONIC MANAGEMENT

Long-term treatment options for outflow tract VT include medical therapy and catheter ablation. Medical therapy may be indicated in patients with mild to moderate symptoms. For patients with symptomatic, drug-refractory VT or those who are drug intolerant or who do not desire long-term drug therapy, catheter ablation is the treatment of choice. Catheter ablation is also recommended for patients with frequent PVCs or nonsustained VT when they are presumed to cause LV dysfunction, even in otherwise asymptomatic patients.²

Medications, including beta blockers, verapamil, and diltiazem, have a 25% to 50% rate of efficacy. Alternative therapy includes class IA, IC, and III agents. Radiofrequency (RF) ablation now has cure rates of over 90%, which makes it a preferable option, given the young age of most patients with outflow tract VT.

Electrocardiographic Features

Surface Electrocardiogram

ECG DURING NORMAL SINUS RHYTHM

The surface ECG during NSR is usually normal. Up to 10% of patients have complete or incomplete RBBB.

ECG DURING VENTRICULAR TACHYCARDIA

Repetitive monomorphic VT is characterized by frequent PVCs, couplets, and salvos of nonsustained VT, interrupted by brief periods of NSR (see Fig. 23-1). Paroxysmal exercise-induced VT is characterized by sustained episodes of VT precipitated by exercise or emotional stress (see Fig. 23-2). Both types characteristically have an LBBB pattern with a right inferior (more common) or left inferior axis. The tachycardia rate is frequently rapid (CL < 300 milliseconds), but can be highly variable. A single morphology for the VT or PVCs is characteristic.^{1,6}

Exercise Electrocardiogram

Exercise testing reproduces VT in less than 25% to 50% of patients with clinical VT. The VT can manifest as nonsustained or, less commonly, sustained. There are two general positive response patterns: initiation of VT during the exercise test and initiation of VT during the recovery period. Both scenarios likely represent examples

of the dependence of VT on a critical window of heart rates for induction. This window can be narrow and only transiently present during exercise, resulting in induction of VT only during recovery. In patients with repetitive monomorphic VT, the VT is often suppressed during exercise. CPVT, also exercise dependent, can be distinguished by the alternating QRS axis with 180-degree rotation on a beat-to-beat basis (bidirectional VT) or polymorphic VT, which can degenerate into VF.

Ambulatory Monitoring

Several VT characteristics can be observed on ambulatory monitoring recordings. Ventricular ectopy typically occurs at a critical range of heart rates (CL dependence). The coupling interval of the first PVC is relatively long (approximately 60% of the baseline sinus CL). A positive correlation exists between the sinus rate preceding the VT and the VT duration. Additionally, the VT occurs in clusters, and is most prevalent on waking and during the morning and later afternoon hours. The VT is extremely sensitive to autonomic influences, resulting in poor day-to-day reproducibility.^{1,6}

Electrocardiographic Localization of Outflow Tract Ventricular Tachycardia

VTs originating from the RVOT typically display LBBB morphology with a precordial QRS transition (first precordial lead with R/S ratio >1) that begins no earlier than lead V₃ and more typically occurs in lead V₄. The frontal plane axis, precordial R/S transition, QRS width, and complexity of the QRS morphology in the inferior leads can more precisely indicate the origin of VT within the RVOT. Most RVOT VTs originate from the anterosuperior aspect of the leftward ("septal") aspects, just under the pulmonic valve. These tachycardias produce a characteristic 12-lead ECG appearance with tall positive QRS complexes in leads II, III, and aVF and large negative complexes in leads aVR and aVL. The QRS morphology in lead I typically is multiphasic and has a net QRS vector of zero or is only modestly positive (see Fig. 23-2).

However, not all VTs with a QRS morphology of LBBB and inferior or normal axis can be ablated successfully from the RVOT. Some VTs originate in the subaortic LV (LVOT, 10% to 15% of adenosine-sensitive VTs), above the pulmonic valve (i.e., from muscle tracts in the pulmonary artery), and occasionally in the aortic root. Idiopathic RV VTs with a superior QRS axis generally originate in the body of the RV on the anterior free wall, or in the mid- and distal septum (Table 23-1).

It is important to recognize that the prediction of the precise origin of outflow tract VT can still be challenging because of the close anatomical relationship of the different anatomical compartments of the outflow tract area. For example, an R/S transition zone in precordial lead V₃ is common in patients with idiopathic outflow tract VT, with a prevalence of up to 58%. The prevalence of R/S transition in lead V₃ in RVOT VT is not statistically different from VT originating outside the RVOT; therefore, the predictive value for this ECG criterion is low. Approximately 50% of outflow tract tachycardias with an R/S transition in V₃ could be successfully ablated from the RVOT; however, one study has shown that a significant proportion of patients need different anatomical approaches for successful RF catheter ablation using up to six different anatomical accesses, including the LV, the aortic sinus of Valsalva, the coronary sinus (CS), the pulmonary artery, and the epicardium via a percutaneous pericardial puncture.²²

RIGHT VENTRICULAR OUTFLOW TRACT VERSUS LEFT VENTRICULAR OUTFLOW REGION

The absence of an R wave in lead V₁ and precordial transition zone in lead V₄, V₅, or V₆ predicts an RVOT origin. On the other hand, the presence of an R wave in leads V₁ and V₂ and RS transition in leads V₁ or V₂ are characteristic of an LVOT origin (Figs. 23-6 and 23-7). Because of the continuity between the posterior RVOT and the anterior LVOT, a very similar R wave in lead V₃ may be seen with arrhythmia that originates in either structure, and R/S transition in lead V₃ is not specific.

TABLE 23-1 Estimation Indexes of Right Ventricular Outflow Tract Ventricular Tachycardia Origins by 12-Lead ECG*

Anterior Versus Posterior: QRS Duration, Leads II and III R Wave Pattern				
QRS duration	>140 msec	≤140 msec	Rr' or rr' in II and III	R in II and III
Free wall side	7	1	0	8
"Septal"	6	21	5	22
Left Versus Right: Leads aVR and aVL QS Wave Amplitude, Lead I Polarity				
QS amplitude	aVR < aVL	aVR ≥ aVL	Lead I negative	Lead I positive
Left side	18	5	20	3
Right side	2	10	3	9
Superior Versus Inferior: Leads V₁ and V₂ Initial r Wave Amplitude				
V ₁ and V ₂	High r*	Low r†		
Proximal side below pulmonic valve	14	8		
Distal side below pulmonic valve		4	9	
LVOT Versus RVOT: Lead V₃ R/S Ratio				
V ₃	R/S ≥ 1	R/S < 1		
LVOT side	4	1		
RVOT side	6	29		

*High r means initial r wave amplitude greater than 0.2 mV in both leads.

†Low r means r wave amplitude less than 0.2 mV in one or both leads.

LVOT = left ventricular outflow region; RVOT = right ventricular outflow tract.

From Kottkamp H, Chen X, Hindricks G, et al: Idiopathic left ventricular tachycardia: new insights into electrophysiological characteristics and radiofrequency catheter ablation, *Pacing Clin Electrophysiol* 18:1285, 1995.

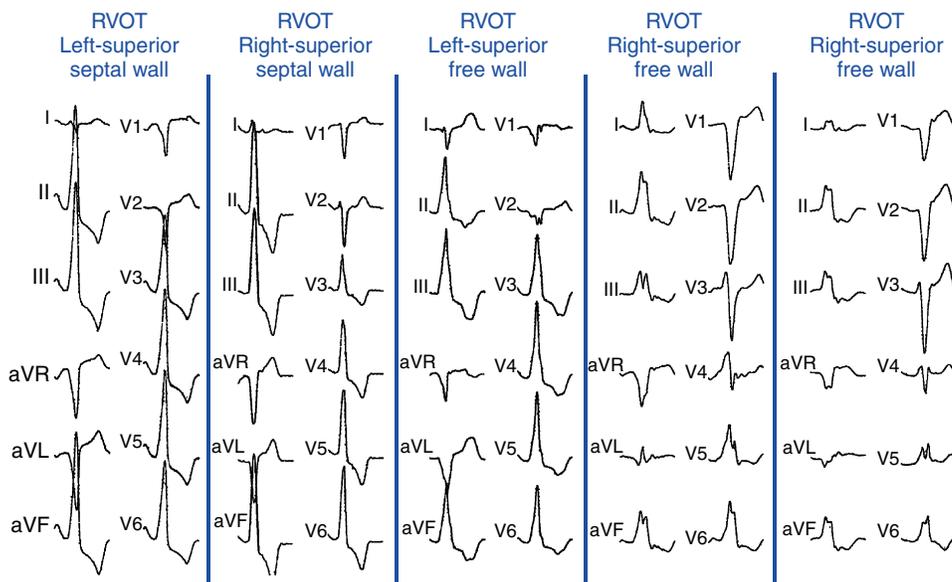

FIGURE 23-6 ECG of premature ventricular complexes from the right ventricular outflow tract (RVOT).

In the latter setting, a precordial R/S transition during VT that is earlier than that during NSR argues against an LVOT origin. Additionally, comparing the R wave amplitude divided by total QRS amplitude (i.e., R/[R + S]) in lead V₂ during VT with that during NSR can help distinguish between LVOT and RVOT origins in patients with lead V₃ precordial transition. A transition ratio (R/[R + S]_{VT} ÷ R/[R + S]_{NSR}) of at least 0.60 is highly suggestive of an LVOT origin.²³ Furthermore, a QS complex in lead I is also suggestive of subaortic LV origin.^{8,22}

"SEPTAL" VERSUS FREE WALL RIGHT VENTRICULAR OUTFLOW TRACT

QRS duration less than 140 milliseconds, monophasic R wave without notching (i.e., no RR' or Rr') in leads II and III, and early precordial transition (by lead V₄) suggest a septal origin. On the other hand, the triphasic RR' or Rr' waves in VT of free wall origin

probably reflect the longer QRS duration and the phased excitation from the RV free wall to the LV (see Fig. 23-6).

LEFT (ANTEROMEDIAL ATTACHMENT) VERSUS RIGHT (POSTEROLATERAL ATTACHMENT) SIDE OF THE RIGHT VENTRICULAR OUTFLOW TRACT

In general, a QS complex in lead I is generated from sites at or near the anterior medial aspect of the RVOT (the most leftward portion of the RVOT in the supine anteroposterior orientation). As the site of origin moves rightward, on either the posterior or the anterior wall, R waves appear in lead I and become progressively dominant and the QRS axis becomes more leftward. Similarly, a QS amplitude in aVL greater than that in aVR suggests an origin in the left side of the RVOT; a QS amplitude in aVR greater than that in aVL suggests an origin in the right side (see Fig. 23-6).

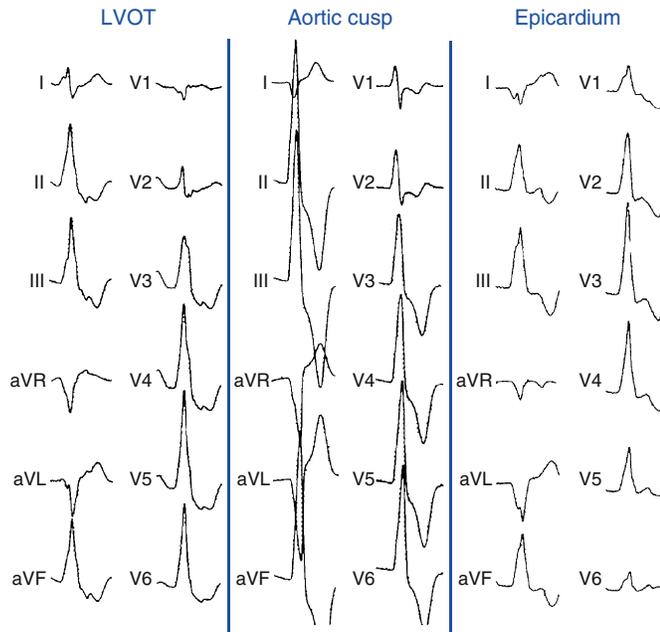

FIGURE 23-7 ECG of premature ventricular complexes from the left ventricular outflow region (LVOT), aortic cusp, and epicardium.

SUPERIOR VERSUS INFERIOR RIGHT VENTRICULAR OUTFLOW TRACT

The R wave amplitude tends to be larger in leads V_1 and V_2 at superior and leftward sites; as the site of origin shifts to the right or inferiorly, there is a trend toward lower right precordial R wave amplitude and a shift in the precordial transition zone to the left. Furthermore, R wave amplitude in lead V_2 or “r” wave amplitude in leads V_1 and V_2 greater than 0.2 mV suggests a superior origin. Additionally, the closer the origin to the pulmonic valve, the more rightward and inferior the axis (i.e., R wave taller in lead III than in lead II) because of the anatomical leftward location of the pulmonic valve and lead III being an inferior *and* rightward lead; the more posterior and inferior the origin, the more leftward the axis (see Fig. 23-6). Also, lead aVL (being a left-sided lead) becomes isoelectric or slightly positive as the site of origin moves inferiorly (close to the HB region), whereas aVR (being a right-sided lead) remains negative.⁸

VENTRICULAR TACHYCARDIAS ARISING ABOVE THE PULMONIC VALVE

Because of the superior and leftward location of these sites, VTs arising above the pulmonic valve are associated with a small but definite vector toward the right, resulting in a small initial R wave in lead V_1 . Additionally, suprapulmonic origins exhibit a strong right inferior frontal plane axis (a QS or rS wave in lead I, large R waves in II, III, aVF, and deep QS complexes in aVR and aVL, with the R wave being taller in lead III than in lead II and the S wave being deeper in aVL than in aVR). Those VTs also tend to display an R/S ratio in lead V_2 and R wave amplitude in inferior leads that are significantly larger than those in RVOT VT.^{8,9,24} However, moderate overlap exists between VTs originating above the pulmonic valve and RVOT VTs, and because the RVOT is the exit site of VT arising from the pulmonary artery, discriminating between the two groups using ECG parameters can be difficult.²⁵

VENTRICULAR TACHYCARDIAS ARISING FROM THE TRICUSPID ANNULUS

VTs arising from the tricuspid annulus demonstrate LBBB morphology and positive QRS polarity in leads I, V_5 , and V_6 . In contrast to VTs arising from the RVOT, no positive QRS polarities in any of the

inferior leads characterize VTs arising from the tricuspid annulus. No negative component of the QRS complex is found in lead I, and the R wave magnitude in lead I is typically greater in VTs arising from the tricuspid annulus than those arising from the RVOT.²⁶ Additionally, VTs arising from the tricuspid annulus have an rS or QS pattern in lead aVR, just as those arising from the RVOT; however, in lead aVL, a QS or rS pattern is rare (8%), and the QRS polarity in lead aVL is positive in almost all VTs arising from the annulus (89%), in contrast to those arising from the RVOT.²⁶

VENTRICULAR TACHYCARDIAS ARISING FROM THE RIGHT VENTRICULAR PAPILLARY MUSCLES

RV papillary muscle VTs display LBBB morphology with a QS or rS pattern in lead V_1 and a wider QRS complex and more prevalent notching than in RVOT VT. VTs arising from the anterior and posterior papillary muscles are frequently associated with a superior axis and a late R wave transition in the precordial leads (later than lead V_4), whereas septal papillary muscle VTs more often display an earlier precordial transition (in lead V_4 or earlier) and an inferior axis (due to the more basal insertion of the septal compared with the anterior and posterior papillary muscles). More than one PVC or VT morphology can be present in a significant proportion of patients with papillary muscle VTs.²⁷ Compared with origins from the septum, VTs from the free wall exhibit longer QRS duration and deeper S waves in leads V_2 and V_3 .²⁸

VENTRICULAR TACHYCARDIAS ARISING FROM THE LEFT VENTRICULAR PAPILLARY MUSCLES

VT can also arise from posterior or anterior papillary muscles. The QRS morphology during VT has an RBBB pattern with either left superior (posterior papillary muscle) or rightward inferior (anterior papillary muscle) axis.^{29,30} The ECG features are very similar in the LV papillary muscle and fascicular VTs; nonetheless, in contrast to fascicular VT, papillary muscle VT has a broader QRS complex (150 ± 15 milliseconds versus 127 ± 11 milliseconds). Additionally, all fascicular VTs, versus none of papillary muscle VTs, had an rsR' pattern in lead V_1 . An R/S ratio not exceeding 1 in lead V_6 for VTs in the LV anterolateral region also suggests papillary muscle VT.³¹ Furthermore, spontaneous variations in QRS morphology occur relatively frequently during VTs originating from the LV papillary muscles, a feature that can help distinguish these VTs from LV fascicular VT, the latter being a reentrant tachycardia with a consistent QRS morphology.³²

OTHER LEFT VENTRICULAR SITES OF ORIGIN

VT can originate from multiple LV sites, including the subaortic LV, the superior basal region of the left interventricular septum, papillary muscle, aortomitral continuity, mitral annulus, aortic cusps, and epicardial sites in the region of the great cardiac and anterior interventricular veins. Most of these sites of origin are associated with an LBBB pattern and inferior axis. A basal LV septal origin is suggested by LBBB morphology associated with an early precordial transition in lead V_1 or V_2 . An origin from the aortomitral continuity is associated with RBBB morphology and broad monophasic R waves across the precordial leads. As the origin moves laterally along the mitral annulus, the R wave in lead I and in the inferior leads decreases in amplitude. LVOT free-wall VTs have an early transition and persistent dominant R wave across the precordium, with a small or absent S wave out to the apex (see Fig. 23-7). The R wave in V_2 is broad and occupies a greater percentage of the QRS width than RVOT VTs. LVOT VT can occasionally have an epicardial site of origin. This form is associated with an R wave in lead V_1 , S wave in lead V_2 , precordial transition in leads V_2 to V_4 , deep QS in lead aVL, and tall R wave in the inferior leads. Contrariwise, an R wave in lead V_2 taller than in leads V_1 or V_3 suggests an origin in the so-called crux of the heart, near the posterior descending artery.^{1,33}

VENTRICULAR TACHYCARDIAS ARISING FROM THE AORTIC CUSPS

For LVOT VT, the absence of an S wave in leads V₅ or V₆ suggests a supraventricular origin, whereas the presence of such waves is consistent with an intraventricular origin (see Fig. 23-7). An R wave in lead aVL may exclude an origin in the left or right aortic cusp.¹⁶

Origin from the aortic cusp is also strongly suggested by a longer duration and greater amplitude of the R wave in leads V₁ and V₂ (R/QRS duration >50% and R/S amplitude >30%) as compared with VT originating from the RVOT, because the aortic valve lies to the right and posterior to the RVOT. Correction of the transitional zone to cardiac rotation (i.e., comparing the R/S transitional zone in precordial leads during VT with that during NSR) can be a useful marker for differentiating an RVOT origin from an aortic cusp origin. When the transitional zone during VT occurs in one or more precordial leads earlier than during NSR, an aortic cusp origin is favored, even when the transitional zone during VT occurs later than lead V₂ (Fig. 23-8).³⁴

Left aortic cusp VTs initially depolarize the LV and typically have a multiphasic QRS complex such as an M or W pattern in lead V₁, suggesting transeptal activation (see Fig. 23-7). A simple qR complex or a monophasic R wave suggests an origin near the aortomitral continuity.¹⁵ The R wave is positive by lead V₂ or V₃ with VT from the right aortic cusp and by lead V₁ or V₂ from the left aortic cusp.¹⁰ Additionally, left aortic cusp VTs tend to have a QS or rS complex in lead I, whereas right aortic cusp VTs have a greater R wave amplitude in lead I based on how posterior and rightward the right aortic cusp is positioned. In young patients with a vertical heart, the QRS complex in lead I can be negative in and around both the left and right aortic cusp regions. In patients with a horizontal heart, the area surrounding the aortic valve will be directed rightward relative to the LV apex–lateral wall, and a positive QRS complex in lead I can be seen.¹⁰

When comparing origins from the right versus the left aortic cusps, RBBB morphology may exclude origins from the right coronary cusp. Additionally, the ratio of the R wave amplitude in leads II and III (III/II ratio) is significantly greater (>0.9) for VTs with a left coronary cusp origin than for those with a right coronary cusp origin.¹⁶

A common site of origin is just between the right and left commissures. This site is often recognized by a notch on the downstroke in V₁ with an intermediate (relative to the right and left cusps) precordial transition. A qrS pattern in leads V₁ to V₃ is very helpful for predicting an origin in the junction between the right and left coronary cusps.³⁵

VTs originating from the aortic cusp often (25%) show preferential conduction to the RVOT, which can render some algorithms using the ECG characteristics less reliable. In fact, 20% of the VTs with an aortic cusp origin in that report showed a late QRS transition after V₃. In some of those cases, an insulated myocardial fiber across the ventricular outflow septum may exist.³⁶

EPICARDIAL VENTRICULAR TACHYCARDIA

Several QRS characteristics suggest an epicardial VT origin of LV VTs, including the presence of a very slurred upstroke (pseudo-delta wave ≥ 34 milliseconds), long R-wave peak time (i.e., the interval from the beginning of the QRS complex to the time of initial downstroke of the R wave after it has peaked [previously known as the *intrinsicoid deflection*] ≥ 85 milliseconds) in lead V₂, and shortest precordial RS complex of at least 121 milliseconds (see Fig. 23-7).

These criteria, however, do not seem to apply uniformly to all LV regions or to VTs originating from the RV. Other site-specific criteria have been suggested for identifying an epicardial origin for LV VTs: the presence of a Q wave in lead I for basal superior and apical superior VTs; the absence of a Q wave in any of the inferior leads for basal superior VTs; and the presence of a Q wave in the inferior leads for basal inferior and apical inferior VTs.³⁷ Also, measurement of the *maximal deflection index* (defined as the product of the time

to maximal deflection in precordial leads divided by the QRS duration) can help identify epicardial LVOT VT. A delayed shortest precordial maximal deflection index (≥ 0.55) identifies epicardial VT remote from the aortic sinus of Valsalva with high sensitivity and specificity. This observation is consistent with slower spread of activation from a focus on the epicardial surface relative to the endocardium and delayed global ventricular activation resulting from later engagement of the His-Purkinje network.^{3,38}

Epicardial VTs originating close to the proximal segment of the great cardiac vein typically display RBBB morphology, whereas VTs originating close to the distal segment have LBBB morphology. This can be explained by a location within the basal-lateral myocardium for the former and a more anterobasal location for the latter arrhythmias. If the site of origin is in the proximal segment of the great cardiac vein, the initial vector is directed toward lead V₁, accounting for the RBBB morphology. As the site of origin moves toward the distal part of the great cardiac vein, closer to the anteroseptal myocardium, the initial vector is directed away from V₁, resulting in LBBB morphology. An R-wave width greater than 75 milliseconds in lead V₁ is useful for differentiating epicardial idiopathic VTs from endocardial arrhythmias. The broader R wave is explained by a more posterior position relative to lead V₁ compared with the RVOT. However, because of a more anterior position relative to lead V₁, the epicardial arrhythmias that are located within the distal part of the great cardiac vein have a narrow R wave in lead V₁, making them impossible to distinguish from RVOT VT.^{38,39} Epicardial VTs that appear to follow the anterior interventricular vein often have a characteristic loss of R wave from leads V₁ and V₂, with broad R waves in leads V₃ through V₆.

For VTs originating from the RV, the presence of an initial Q wave in lead I and QS in lead V₂ for anterior sites in the RV strongly predicts an epicardial origin. Similarly, an initial Q wave in leads II, III, and aV_F is observed with pace mapping from the inferior epicardial locations in the RV.⁴⁰

Electrophysiological Testing

Induction of Tachycardia

Frequently, VT foci can become inactive in the EP laboratory environment, caused by sedative medications or deviation from daily activities (e.g., exercise or caffeine intake) that can affect VT activity. Thus, in preparation for a VT ablation procedure, antiarrhythmic drugs should be withheld for at least five half-lives before the EP study and minimal sedation should be used throughout the procedure if possible. Additionally, it may be appropriate to monitor the patient in the EP laboratory initially without sedation. If no spontaneous tachycardia is observed, isoproterenol is administered. If no VT can be induced, a single quadripolar catheter is placed in the RV, and programmed electrical stimulation is performed. If VT focus remains quiescent, the procedure may be aborted and retried at a future date. If VT is inducible at any step, the full EP catheter arrangement and EP study are undertaken.⁶

The programmed electrical stimulation protocol usually includes incremental ventricular burst pacing from the RV apex and RVOT (until 1:1 capture is lost or a pacing CL of 220 milliseconds is reached) and single, double, and triple VESs at multiple CLs (600 and 400 milliseconds) from the RV apex and RVOT. Additionally, VT inducibility can be facilitated by catecholamines.^{1,6} Isoproterenol infusion (up to 4 $\mu\text{g}/\text{min}$, or 30% increase in heart rate) is frequently used. If VT is not induced with isoproterenol, rapid ventricular pacing and VES should be repeated. If VT is still non-inducible, isoproterenol is discontinued because VT can develop during the washout phase, analogous to VT occurring during the recovery phase post-exercise. If VT is still not inducible, isoproterenol is restarted and atropine (0.04 $\mu\text{g}/\text{kg}$) and aminophylline (2.8 mg/kg) may be sequentially administered (with and without programmed electrical stimulation) to attenuate the potential antiarrhythmic effects of endogenous acetylcholine and adenosine, which inhibit cAMP.⁶

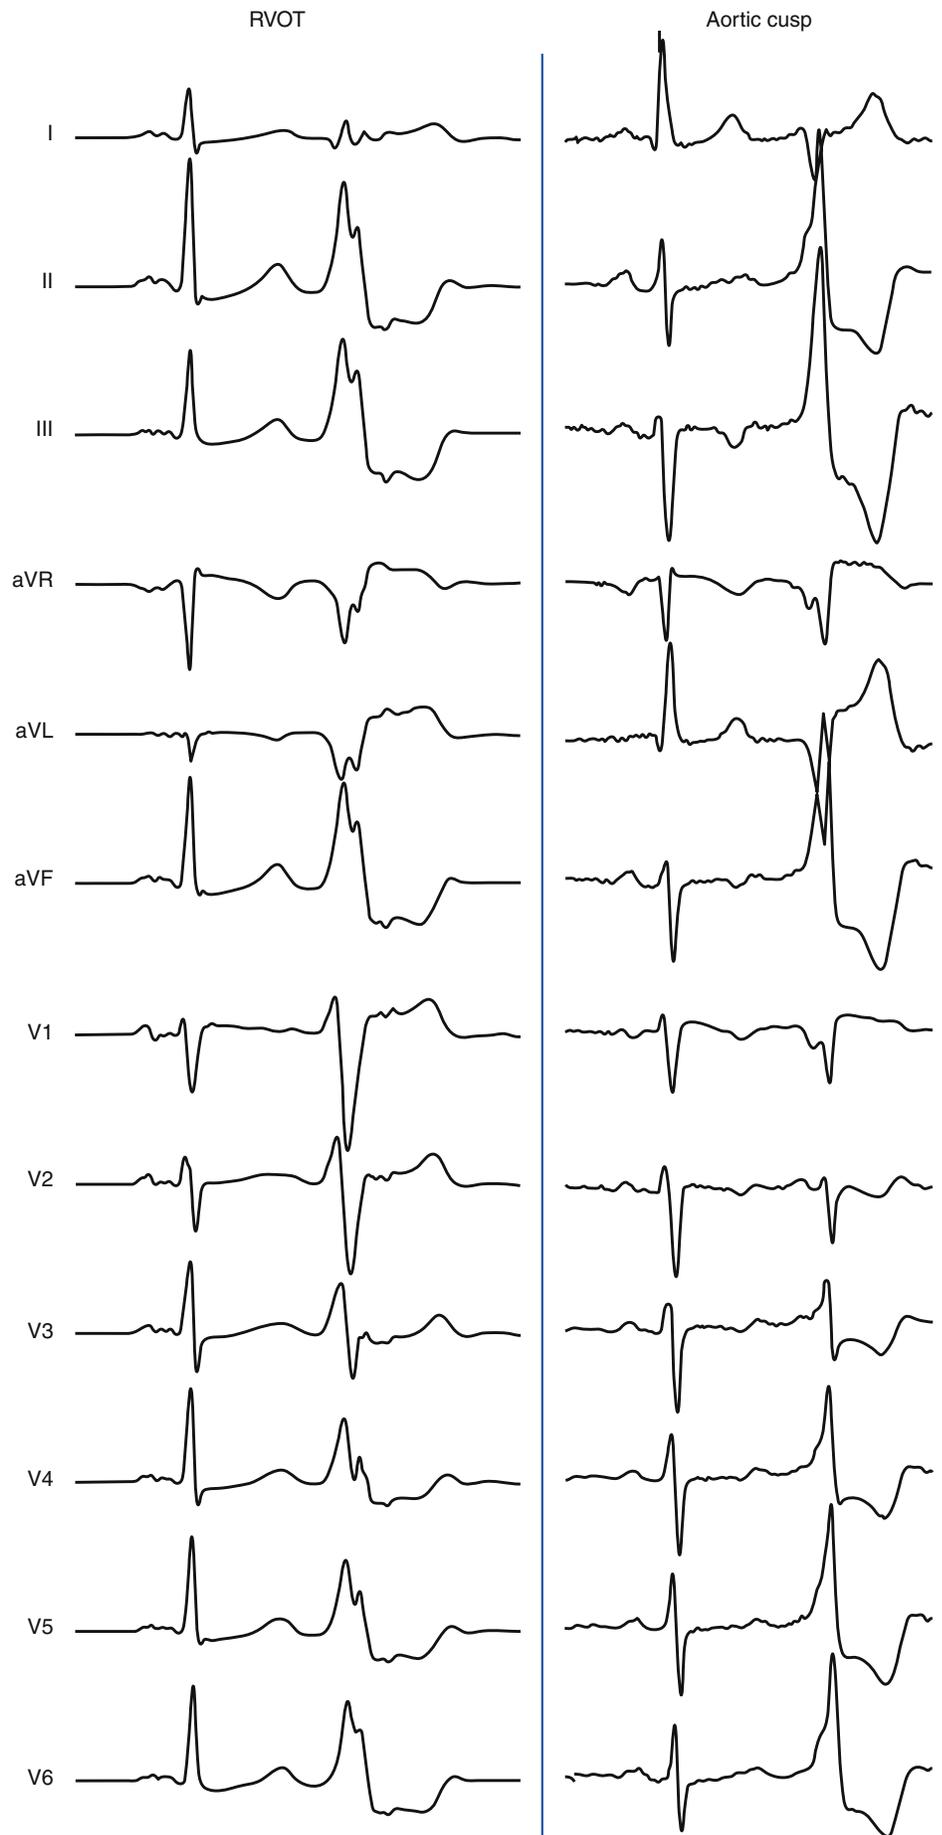

FIGURE 23-8 Correction of the precordial R/S transitional zone to cardiac rotation for differentiation between right ventricular outflow (RVOT) origins and aortic cusp origins of premature ventricular complexes (PVCs). At left, the transitional zone occurs between leads V_2 and V_3 during both normal sinus rhythm (NSR) and PVC, but slightly earlier in NSR, suggestive of RVOT origin of the PVC. At right, the transitional zone during PVC occurs in lead V_3 , earlier than that during NSR (occurring in V_6), which is suggestive of an aortic cusp origin of the PVC. Note that although the transitional zone during the PVC at left occurs earlier than during the PVC at right, correction of the transitional zone to cardiac rotation (i.e., comparing the R/S transitional zone in precordial leads during VT with that during NSR) demonstrates that the transitional zone during the PVC at right occurs much earlier than during NSR, consistent with aortic cusp origin, whereas the transitional zone occurs during the PVC at left slightly later than during NSR, suggesting an RVOT origin.

Ventricular stimulation can initiate the VT in less than 65% of patients and, in contrast to reentrant VT, rapid ventricular pacing is usually more effective than VES. Induction of sustained VT is less common in patients with repetitive monomorphic VT than in those with paroxysmal sustained VT. In one report, sustained VT was inducible during EP testing in 78% of patients who presented clinically with sustained VT, in 48% of patients who presented with nonsustained VT, and in 4% of those with PVCs only.⁷ Most episodes of triggered activity VT induced by ventricular stimulation are usually nonsustained. Reproducibility of VT induction using all methods is less than 50%, whereas reproducibility of induction with single or double VESs is approximately 25%. Induction with atrial pacing is not uncommon. Of note, in contrast to reentrant VT, initiation of outflow tract VT does not require associated ventricular conduction delay or block for initiation.⁶

Typically, the initial cycle of the VT bears a direct relationship to the pacing CL (whether or not VESs are delivered following the pacing drive). Thus, the shorter the initiating pacing CL, the shorter the interval to the first VT beat and the shorter the initial VT CL. Similarly, the initial cycle of the VT bears a direct relationship to the coupling interval of the VES initiating the VT.^{1,6} Occasionally, with the addition of very early VESs or with very rapid ventricular pacing (CL <300 milliseconds), a sudden jump in the interval to the first VT complex may be observed, such that it is approximately twice the interval to the onset of the VT initiated by later coupled VESs. This can be caused by failure of the initial DAD to reach threshold, whereas the second DAD reaches threshold. Thus, in triggered activity VTs caused by DADs, the coupling interval of the initial VT complex either shortens or suddenly increases in response to progressively premature VESs; it usually does not demonstrate an inverse or gradually increasing relationship (in contrast to reentrant VT).⁶

Ventricular pacing CLs longer or shorter than the critical CL window may fail to induce VT. This critical window can shift with changing autonomic tone. The site of ventricular stimulation has no effect on the initiation of triggered activity VT as long as the paced impulse reaches the focus of the VT (in contrast to reentrant VT).⁶

VT induction can be inconsistent. Induction is exquisitely sensitive to the immediate autonomic status of the patient. Therefore, noninducibility during a single EP study is not enough evidence to attribute the arrhythmia to a nontriggered activity mechanism.^{1,6}

Tachycardia Features

As noted, the VT can be sustained or in the form of frequent monomorphic PVCs, couplets, and salvos of nonsustained VT. QRS morphology has an LBBB pattern with a right inferior or left inferior axis. The VT rate is frequently rapid (CL <300 milliseconds) but can be highly variable.^{1,6}

During VT, the His potential follows the onset of the QRS (i.e., negative His bundle–ventricular [HV] interval) and is usually buried inside the local ventricular electrogram. Ventriculoatrial (VA) conduction may or may not be present. The VT is very sensitive to adenosine, Valsalva maneuvers, carotid sinus massage, edrophonium, verapamil, and beta blockers.¹

Diagnostic Maneuvers during Tachycardia

RESPONSE TO VENTRICULAR EXTRASTIMULATION

VES results in a decreasing resetting response curve characteristic of DAD-related triggered activity.⁶

RESPONSE TO OVERDRIVE PACING

The VT cannot be entrained by ventricular pacing (i.e., no fusion demonstrable). Rapid ventricular pacing during the VT can result in acceleration in the VT. There is a direct relationship between the

overdrive pacing CL and the coupling interval and CL of the VT resuming after cessation of pacing.¹

Exclusion of Other Arrhythmia Mechanisms

Idiopathic outflow tract VT should be differentiated from other forms of VT with an LBBB pattern, including VT in ARVD, bundle branch reentrant VT, reentrant VT following surgical repair of congenital heart disease, and post-infarction VT originating from the LV septum. In addition, antidromic atrioventricular reentrant tachycardia using an atriofascicular bypass tract also presents with wide complex tachycardia with an LBBB pattern.

RVOT VT should, in particular, be distinguished from ARVD, a disorder with a more serious clinical outcome. Although RVOT VT is associated with a benign prognosis with no familial basis, it can be extremely difficult to distinguish from the concealed phase of ARVD, in which typical ECG and imaging abnormalities are absent. The VT in ARVD also affects young adults, is commonly catecholamine-facilitated, and can originate from the RVOT.

Although the VT in ARVD can have morphological features similar to RVOT VT (LBBB with inferior axis), several ECG criteria during VT can help distinguish between the two arrhythmias. Longer QRS duration (≥ 120 milliseconds), precordial transition at lead V₆, and the presence of notching in the QRS in one or more leads all favor ARVD over RVOT VT. Additionally, the presence of an LBBB morphology with a superior axis is very unlikely in idiopathic RVOT VT. Also, VTs in ARVD patients generally have lower QRS amplitude and more fragmentation, but these are qualitative differences and not always present.⁴¹

In ARVD, the resting 12-lead ECG in NSR typically shows inverted T waves in the right precordial leads. When present, RV conduction delay with an epsilon wave (best seen in leads V₁ and V₂) is helpful in the diagnosis of ARVD. The resting surface ECG in NSR is typically normal in patients with idiopathic VT, with no epsilon wave, QRS widening or fragmentation, or other markers of delayed activation of the RV. Nevertheless, the ECG can also be normal in up to 40% to 50% of patients with ARVD at presentation, but in almost no patient after 6 years. Furthermore, approximately 10% of patients with idiopathic VT can have complete or incomplete RBBB during NSR.^{2,42}

Although the induction of multiple VT morphologies is very unlikely in idiopathic RVOT VT, patients with several idiopathic VT morphologies have been reported. On the other hand, patients with ARVD may initially present with only one VT morphology consistent with an RVOT origin.

Patients with idiopathic VT have a normal signal-averaged ECG when in NSR and normal imaging studies (echocardiography, MR imaging, contrast ventriculography) of RV size and function. In contrast, the presence of RV dilation, aneurysm, or both is consistent with ARVD.

The response of VT during EP testing is also helpful in distinguishing idiopathic RVOT VT from ARVD. The repetitive initiation of these VTs by programmed ventricular stimulation suggests a reentrant mechanism, and is much more common in ARVD than idiopathic outflow tract VT (93% versus 3%).⁴² Additionally, recording fractionated diastolic electrograms during VT or NSR at the site of origin of VT or other RV sites is inconsistent with idiopathic RVOT VT, but is typical for ARVD. As noted, the induction of VTs with different QRS morphologies is common in ARVD (observed in 73% of patients in one report) and is inconsistent with RVOT VT. Although isoproterenol infusion can induce VT in patients with idiopathic RVOT VT, it has a similar effect in ARVD and therefore does not help distinguish between these disorders. Reentry is the mechanism of VT in the majority of the ARVD patients, whereas RVOT VT almost always displays features of triggered activity. The VT in ARVD does not terminate with adenosine.

Additionally, electroanatomical voltage mapping can help distinguish early or concealed ARVD from idiopathic VT by detecting RV electroanatomical scars that correlate with the histopathological features pathognomonic of ARVD.⁴³

Malignant ventricular arrhythmias (VF or polymorphic VT) are sometimes associated with idiopathic VT or PVCs originating from the outflow tract, even in patients with no established diagnosis of ARVD. It is of particular importance to distinguish the malignant form from the benign form of idiopathic outflow tract VT, because the malignant form of idiopathic VT or PVCs often leads to unexpected SCD. Data suggest that a shorter CL during monomorphic VT, when present, as well as a history of syncope with malignant characteristics, may be a predictor of the coexistence of VF or polymorphic VT in patients with idiopathic VT originating from RVOT. Holter monitoring to record spontaneous episodes of RVOT VT and obtaining detailed previous history of syncope with malignant characteristics are useful to differentiate the malignant form from the benign form of RVOT VT.⁴²

Mapping

VT origins in the RVOT are anatomically classified into three-dimensional (3-D) directions: anterior and posterior, right and left, and superior and inferior. The anterior half of the RVOT by fluoroscopy in the 60-degree left anterior oblique (LAO) projection is defined as the anterior side (or free wall side) and the posterior half is defined as the posterior side (or "septal" side; see Fig. 23-4). When viewed by fluoroscopy in the 30-degree right anterior oblique (RAO) projection, the posterior half of the outflow is defined as the right (or posterolateral) side, and the anterior half is defined as the left (or anterolateral) side. The area within 1 cm just below the pulmonary valve is defined as the superior (or distal) side, and the area more than 1 cm away is defined as the inferior (or proximal) side.

The prediction of the precise origin of outflow tract tachycardias can be challenging because of the close anatomical relationship of the different anatomical compartments of the outflow tract area. Therefore, a stepwise mapping procedure has been proposed, especially when the ECG does not provide clear criteria to guide localization of the VT site of origin.²² Because most VTs originate from the RVOT, mapping is started there and, if that fails to identify the origin of the VT, mapping is extended to involve the pulmonary artery, although this site of origin is rare, because no additional anatomical access is required.²⁴ If activation mapping and pace mapping suggest a focus outside the RVOT and pulmonary artery, mapping of the CS can add useful information as to whether a left-sided epicardial origin is present.²² If a transvenous access is not successful, mapping the LVOT and aortic cusps via a retrograde arterial access is usually the next step.

Finally, if all previous anatomical accesses are unsuccessful, epicardial mapping via a percutaneous pericardial access should be considered. Mapping findings suggestive of epicardial origin include suboptimal pace maps generated from the ventricular endocardial surface, absence of sharp potentials greater than 15 milliseconds prior to QRS onset, low-amplitude far-field potentials at the earliest endocardial sites, the occurrence of a very slurred upstroke and wide QS complex, and a large area of equally (and minimally) presystolic sites on the activation map.

Activation Mapping

Activation mapping is the method of choice for identifying a hemodynamically stable, focal VT. It may be performed by point-by-point mapping with a roving mapping catheter, with the use of multiple catheters, or with multielectrode arrays. Initially, one should seek the general region of the origin of ectopy as indicated by the surface ECG. All 12 leads should be inspected and the lead showing the earliest and most discernible onset of the QRS during VT or PVCs should be selected as the reference point for subsequent mapping. Subsequently, a single mapping catheter is moved under the guidance of fluoroscopy into the RVOT, and the bipolar signals are sampled from several endocardial sites.

Endocardial activation mapping is performed during VT or PVCs to identify the site of earliest activation relative to the onset of the QRS. It is important to record examples of VT or PVCs prior to inserting catheters, because the catheters can cause ectopic complexes

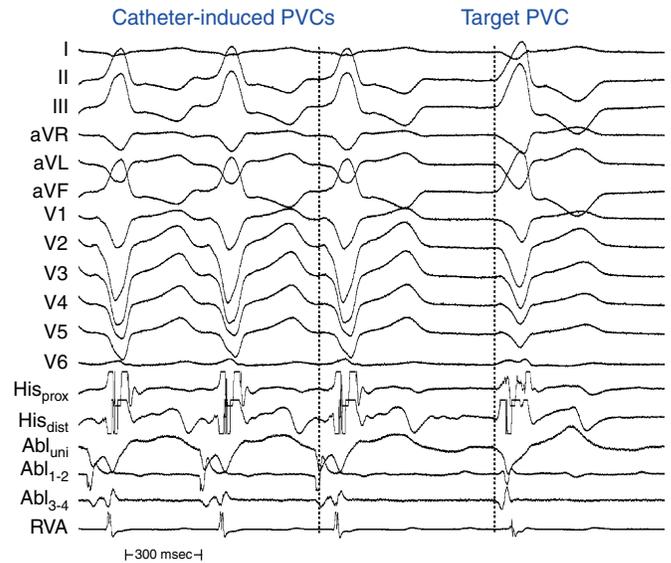

FIGURE 23-9 Catheter-induced premature ventricular complexes (PVCs) versus target spontaneous PVCs. Three complexes of catheter-induced PVCs are seen at left, during which both unipolar and bipolar signals are very early (as would be expected, because catheter tip irritation is causing these complexes). During the actual target PVC, however, this site is not early at all. This illustrates the need to be certain of the characteristics of the target PVC or ventricular tachycardia complex before beginning mapping.

that resemble the target VT or PVCs (Fig. 23-9). The site of origin of the VT is defined as the site with the earliest bipolar recording in which the distal tip shows the earliest intrinsic deflection and QS unipolar electrogram configuration.

Activation times are generally measured from the onset or the first rapid deflection of the bipolar electrogram to the earliest onset of the QRS on the surface ECG during VT or PVCs. The distal pole of the mapping catheter should be used for searching for the earliest activation site, because it is the pole through which RF energy is delivered. Once an area of relatively early local activation is found, small movements of the catheter tip in that region are undertaken until the site is identified with the earliest possible local activation relative to the tachycardia complex.

Bipolar electrograms at the site of origin are modestly early (preceding the surface QRS by 10 to 45 milliseconds) and have high-amplitude and rapid slew rates. Fractionated complex electrograms and mid-diastolic potentials are rarely, if ever, seen and should raise suspicion of underlying heart disease.¹

Once the site with the earliest bipolar signal is identified, the unipolar signal from the distal ablation electrode should be used to supplement conventional bipolar mapping (Fig. 23-10). The unfiltered (0.05 to >300 Hz) unipolar signal morphology should show a monophasic QS complex with a rapid negative deflection. Although this electrogram configuration is very sensitive for successful ablation sites, it is not specific (70% of unsuccessful ablation sites also manifest a QS complex). The size of the area with a QS complex can be larger than the VT site of origin, exceeding 1 cm or more in diameter. Additionally, because the entirety of the heart is directed away from most positions in the RVOT, a QS can be observed with unipolar recordings from most locations in the outflow tract. The timing of the unipolar electrograms recorded at sites distant from the VT focus, however, does not precede the onset of the VT QRS.⁴⁴ Thus, a QS complex should not be the only mapping finding used to guide ablation (see Fig. 23-10). Nonetheless, successful ablation is unusual at sites with an RS complex, because these are generally distant from the VT focus. Concordance of the timing of the onset of the bipolar electrogram with that of the filtered or unfiltered unipolar electrogram, with the rapid downslope of the S wave of the unipolar QS complex coinciding with the initial peak of the bipolar signal, helps ensure that the tip electrode,

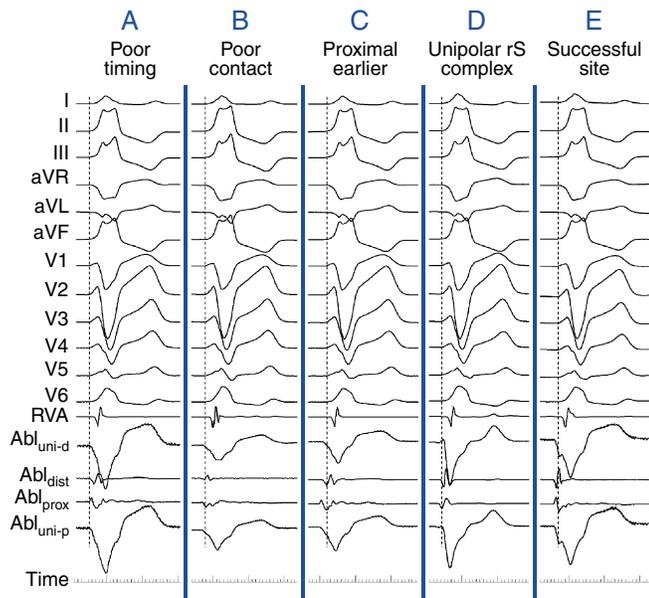

FIGURE 23-10 Activation mapping results from five sites are shown with 12 leads of a single ventricular tachycardia (VT) complex, as well as intracardiac recordings from the right ventricular apex, proximal and distal ablation electrode bipolar recordings, and unipolar recordings from the tip electrode (uni-d) and the second electrode (uni-p). A vertical dashed line denotes QRS onset. Sites A to D are suboptimal ablation sites for the reasons noted. Site E was where ablation terminated VT.

which is the ablation electrode, is responsible for the early component of the bipolar electrogram (see Fig. 23-10).⁶ Additionally, the presence of slight ST elevation on the unipolar recording and the ability to capture the site with unipolar pacing are used to indicate good electrode contact.

It is important to recognize that some myocardial fibers in the RVOT can potentially be in continuity with those in the LVOT. As a consequence, what mapping defines as the earliest site of activation relative to neighboring myocardium can be misleading. For example, if the true origin of an arrhythmia in the supraventricular aortic cusps then exits both to the infravalvular LVOT myocardium and to the posterolateral subpulmonic RVOT, an early site relative to all neighboring RVOT myocardium may be found in the RVOT.⁴⁴

Careful catheter manipulation during mapping should seek to avoid mechanical trauma that can transiently abolish the arrhythmia. On the other hand, catheter manipulation frequently induces PVCs that can closely mimic target PVCs. The findings on the mapping catheter during these catheter-induced complexes are invariably excellent (e.g., substantial presystolic activation time, sharp QS on the unipolar recording). These complexes must be analyzed and carefully compared with prerecorded VT or PVC complexes to avoid delivery of RF energy at sites with no relevance to actual VT.

When mapping above the aortic or pulmonic valve, near- and far-field potentials are typically recorded. The exact nature and cause of these spikes are unknown but are thought to be analogous to PV potentials, that is, they represent electrical activation of myocardial sleeves distal to valve attachment. Because of the overlapping nature of the outflow tract and supraventricular region, when two potentials are seen, only the near-field potential should be used for activation timing. In addition to noting the actual timing of activation, the timing of the near-field electrogram relative to the far-field electrogram should be evaluated.⁹ Typically, in sinus rhythm, the near-field potential (representing local supraventricular myocardial activation) is seen after the far-field ventricular electrogram (likely representing outflow tract activation) separated by an isoelectric period (presumably from conduction delay across the site of valve insertion). If during VT or PVC, the sequence of activation is reversed, that is, the near-field electrogram precedes the

far-field electrogram by a similar or greater isoelectric period duration, an etiological role for the supraventricular myocardium can be inferred. This finding alone, however, does not suggest that ablation at this particular site will be successful because (as with PV phenomena) other supraventricular locations may show earlier activation than the site being mapped. On the other hand, if the near-field electrogram still succeeds the far-field ventricular electrogram during VT or PVC, then the supraventricular tissue, although present, is a bystander being passively activated during arrhythmia originating in the outflow tract myocardium below the valve. In some cases, the near-field electrogram is fused with the far-field electrogram during tachycardia. This suggests an origin of arrhythmia exactly at the cusp or passive activation from a true distant site of origin to both the supraventricular and infravalvular myocardium.⁸

Pace Mapping

Pace mapping is pacing during or in the absence of tachycardia to assess the possible relation of the pacing site to a tachycardia focus or a reentry circuit. Pace mapping is used to confirm the results of activation mapping and can be of great value, especially when the VT is scarcely inducible. Although there are some limitations to this technique, several studies have demonstrated efficacy using pace mapping to choose ablation target sites for idiopathic VT.⁴⁵

TECHNIQUE

Pace mapping during VT (at pacing CL 20 to 40 milliseconds shorter than the tachycardia CL) is preferable whenever possible, because it facilitates rapid comparison of VT and paced QRS complexes at the end of a pacing train in simultaneously displayed 12-lead ECGs. If sustained VT cannot be induced, mapping is performed during spontaneous nonsustained VT or PVCs. In this setting, the pacing CL and coupling intervals of the VES should match those of spontaneous ectopy. Pace mapping is preferably performed with unipolar stimuli (≤ 10 mA, 2 milliseconds) from the distal electrode of the mapping catheter (cathode) and an electrode in the inferior vena cava (IVC) (anode). Unipolar pacing, however, causes a large stimulus artifact in the surface ECG. Bipolar pacing from the closely spaced distal electrodes of the mapping catheter is more commonly used. Although the possibility for capture at either the distal or proximal bipolar electrodes can reduce spatial accuracy, this does not appear to be a major limitation. Use of current strengths near threshold should improve accuracy by limiting the size of the virtual electrode in the tissue and preventing capture of myocardium distant from the pacing site. Pacing thresholds of at least 5 to 10 mA typically indicate insufficient electrode-tissue contact or inexcitable areas.³

INTERPRETATION

Pace maps with identical or near-identical matches of VT morphology in all 12 surface ECG leads can be indicative of the site of origin of VT (see Fig. 5-22). ECG recordings should be reviewed at the same gain and filter settings and at a papersweep speed of 100 mm/sec. It is often helpful to have a split-screen display of the target VT in one panel, comparing this with all 12 leads of the paced QRS complexes brought into another panel, as well as with printed regular 12-lead ECGs for side-by-side comparison on paper. Differences in the QRS morphology between pacing and spontaneous VT in a single lead can be critical. Pacing at a site 5 mm from the index pacing site can result in minor differences in QRS configuration (notching, new small component, change in amplitude of individual component, or overall change in QRS shape) in at least one lead in most patients. In contrast, if only major changes in QRS morphology are considered, pacing sites separated by as much as 15 mm can appear similar.

Although qualitative comparison of the 12-lead ECG morphology between a pace map and VT is frequently performed, there are few objective criteria for quantifying the similarity between two 12-lead ECG waveform morphologies. Such comparisons are

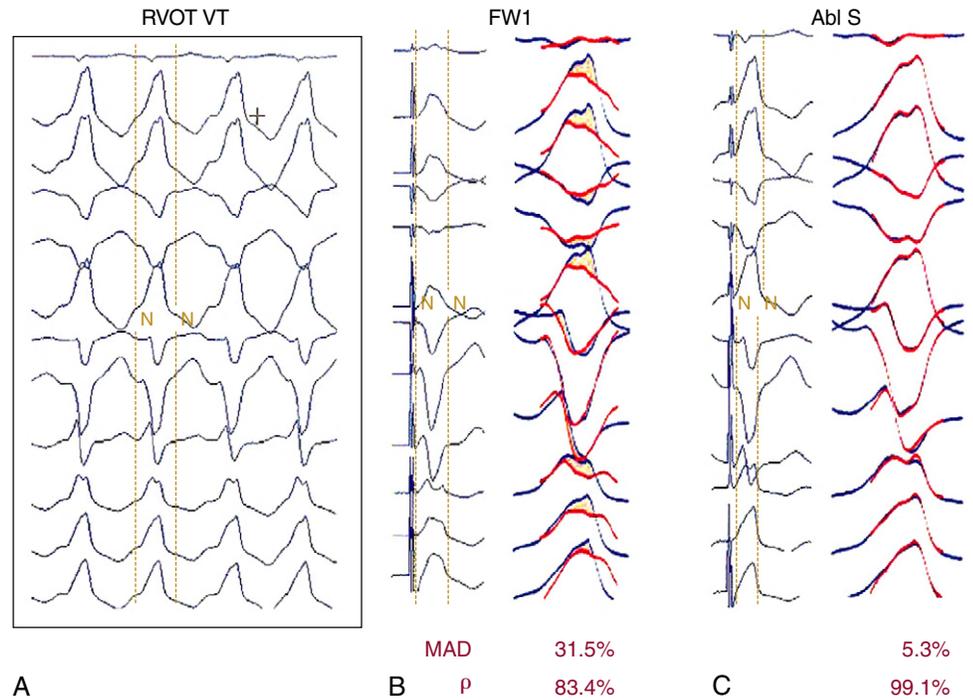

FIGURE 23-11 The mean absolute deviation (MAD) score. **A**, Example of right ventricular outflow tract (RVOT) ventricular tachycardia (VT). The second VT complex has been identified as the target waveform by the annotation markers placed on either side of this complex. **B**, Pace map from a free wall site 1 (FW1) next to the superimposed VT and pace map waveforms after automatic computer alignment. There are substantial differences between these two waveforms (highlighted in gray), resulting in an MAD score of 31.5%. **C**, Pace map from the successful ablation site (Abl S) near the posterior septum and the superimposed pace map and VT waveform. Note in the Abl S panel that when these two waveforms are aligned they are nearly superimposable, and result in a very low MAD score of 5.3%. Correlation coefficients for these comparisons are also shown. (From Gerstenfeld EP, Dixit S, Callans DJ, et al: Quantitative comparison of spontaneous and paced 12-lead electrocardiogram during right ventricular outflow tract ventricular tachycardia, *J Am Coll Cardiol* 41:2046, 2003).

frequently completely subjective or semiquantitative, such as a “10/12 lead match.” Discrepancies in ablation outcome can result, in part, from subjective differences in opinion regarding the closeness of a pace map match to the clinical VT. On the other hand, automated objective interpretation can offer some advantage to human interpretation. Template matching processes digital images to match the target QRS complex (template signal) and the paced QRS complex (test signal), and provides a score according to the similarity between the two QRS morphologies.⁴⁶ The most common human error in analyzing a pace map is not appreciating subtle amplitude or precordial lead transition differences between two ECG patterns, and such subtle differences can be reflected in a single quantitative number calculated by an automated metric.

Two waveform comparison metrics, the correlation coefficient (CORR) and the mean absolute deviation (MAD), have been evaluated to calculate the template-matching score. Although both metrics quantitatively compare the waveforms, MAD tends to be more sensitive to differences in waveform amplitude than CORR. Successful ablation sites were associated with significantly lower MAD score than were unsuccessful sites, but only a trend toward a higher CORR at the successful ablation sites was observed. The MAD score grades 12-lead ECG waveform similarity as a single number, ranging from 0% (identical) to 100% (completely different). An MAD score less than or equal to 12% was found to be 93% sensitive and 75% specific for a successful ablation site (Fig. 23-11). It is not surprising that the MAD score is more sensitive than specific; characteristics other than a 12-lead ECG match are necessary for a successful ablation, including catheter-tissue contact, catheter orientation, and tissue heating. An MAD score greater than 12%, and certainly greater than 15% (100% negative predictive value), suggests sufficient dissimilarity between pace map and clinical tachycardia to dissuade ablation at that site. An MAD score less than or equal to 12% is considered an excellent match, and ablation at these sites is warranted if catheter contact and stability are adequate (see Fig. 23-11). The MAD score is computationally simple and should be easy to incorporate into current EP recording systems, allowing feedback to the physician of pace map comparison before turning on the RF energy. The MAD score can also be used to standardize 12-lead ECG waveform

morphology comparisons among different laboratories, and can be useful for guiding ablation of RVOT VT.⁴⁶

Studies using the CORR have found that the spatial resolution of a good pace map for targeting RVOT VT was 1.8 cm² in diameter and therefore was inferior to the spatial resolution of activation mapping. Of note, in almost 20% of patients in this report, pace maps failed to reproduce adequate correlation coefficients to identify the site of origin of all PVCs/VT. Nonetheless, the effective ablation sites had a high degree of correlation with pace mapping at effective ablation sites. Another metric, root-mean-square error, also was found to be a better discriminator of differences among individual lead waveforms than CORR.⁴⁶

PITFALLS

Current strengths up to 10 mA have little effect on unipolar paced ECG configuration. In contrast, bipolar pacing can introduce some variability in the paced ECG, which can be minimized by low pacing outputs and small interelectrode distance (≤ 5 mm). Additionally, the morphology of single paced QRS complexes can vary depending on coupling interval, and the QRS morphology during overdrive pacing is affected by the pacing CL. Therefore, the coupling interval or CL of the template arrhythmia should be matched during pace mapping; otherwise, rate-dependent changes in QRS morphology independent of the pacing site can confound mapping results. Similarly, spontaneous couplets from the same focus may have slight variations in QRS morphology that must be considered when seeking a pace match. Of note, isoproterenol infusion has no significant effect on the QRS configuration.

Pace mapping can be difficult to perform above the semilunar valves (in the aortic cusps or pulmonary artery) and can require high pacing current strengths. Because of the close anatomical proximity of the various structures in the supraventricular outflow tract region, high-output pacing may reproduce the ECG or clinical arrhythmia even when the origin is in a different cardiac chamber. For example, high-output pace mapping from the right coronary cusp may reproduce the ECG even when the origin is in the posterior RVOT or subvalvular anterior LVOT.⁹ Additionally, supraventricular arrhythmia origin may exit to the ventricular

myocardium below the valve. Thus, pace mapping above the valve and at the exit site may be similar. For example, if pace mapping is performed during aortic cusp VT at a breakthrough site on the posterior RVOT, a perfect result (despite supraaortic origin) will be obtained. Yet, ablation energy delivered there typically fails in terminating the arrhythmia and may result in a change in VT morphology resulting now from a different exit of the cuspal arrhythmogenic focus.⁸

Electroanatomical Mapping

Propagation of activation during RVOT VT is so rapid that minor differences between adjacent sites become difficult to detect, leading to a large number of sites with clinically indistinguishable activation times when examined on a site-by-site basis. However, when displayed simultaneously on a spatially precise electroanatomical reconstruction, the centers of the early activation area and the presumed site of VT origin become easy to identify (Fig. 23-12).⁴⁵ Electroanatomical 3-D mapping (CARTO mapping system [Biosense Webster, Diamond Bar, Calif.] or EnSite NavX system [St. Jude Medical, St. Paul, Minn.]) uses a single mapping catheter attached to a system that can precisely localize the catheter tip in 3-D space and store activation time on a 3-D anatomical reconstruction.^{1,45} Electroanatomical mapping permits spatial discrimination between sites separated by less than 1 mm.

Initially, a stable reference electrogram is selected. This is the fiducial marker on which the entire mapping procedure is based. Preferably, a QRS on the surface ECG is selected as the reference signal. Alternatively, an intracardiac electrogram (e.g., RV apex) can be selected as the reference point, in which case care must be taken to avoid dislodging this catheter because, if it moves, timing of mapping catheter activations will not be comparable to previously mapped sites. Following selection of the reference electrogram, positioning of the anatomical reference, and determination of the window of interest, the mapping catheter is positioned in the RVOT under fluoroscopic guidance.

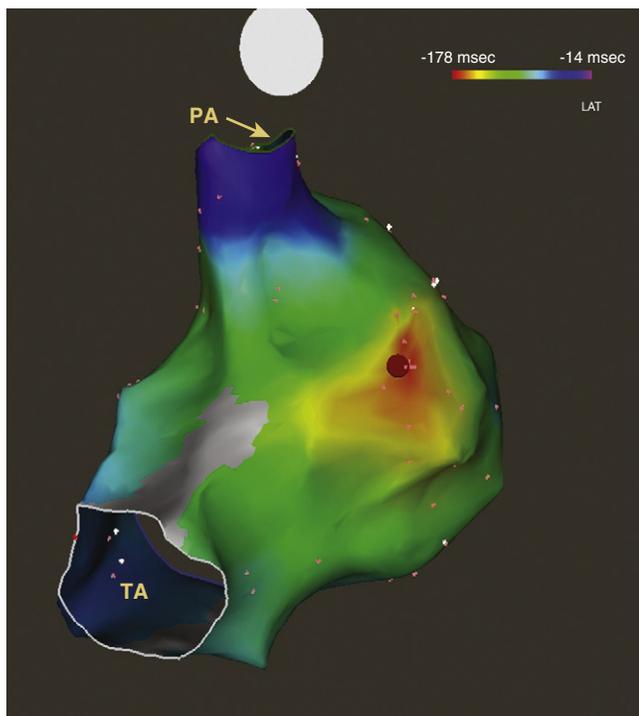

FIGURE 23-12 Electroanatomical (CARTO 3) activation map (posterior view) of ventricular ectopy originating from the right ventricular outflow tract (RVOT). The site of impulse origin during ectopy was in the posterolateral aspect of the RVOT (red area), at which point ablation eliminated the ventricular tachycardia (red dot). PA = pulmonic valve annulus; TA = tricuspid annulus.

At the outset, the plane of the HB location and pulmonic valve are defined and tagged to outline the superior and inferior limits of the RVOT. The mapping catheter is advanced superiorly in the RVOT until no discrete bipolar electrograms are seen in the distal electrode pair. The catheter then is retracted until electrograms in the distal electrode pair reappear and pacing results in capture of the RVOT endocardium. This marks the level of the pulmonic valve. At least three points are acquired and tagged to construct the pulmonic valve.²² Next, a detailed electroanatomical activation map of the RVOT is constructed by acquiring multiple points during PVCs or VT. The local activation time at each site is determined from the intracardiac bipolar electrogram and is measured in relation to the fixed reference electrogram (surface QRS or intracardiac electrogram). Points are added to the map only if stability criteria in space and local activation time are met. The end-diastolic location stability criterion is less than 2 mm and the local activation time stability criterion is less than 2 milliseconds. Activation maps display the local activation time by a color-coded overlay on the reconstructed 3-D geometry (see Fig. 23-12). The electroanatomical maps of focal VT demonstrate radial spreading of activation, from the earliest local activation site (red in CARTO, white in NavX) in all directions (a well-defined early activation site surrounded by later activation sites).

The principles used for conventional activation mapping discussed above are also used here to define the site of origin of VT. Although the traditional single-catheter mapping of the region of interest is still required, the ability to use the catheter localization system to steer precisely back to previously obtained sites of earliest activation greatly facilitates the ablation process. Display of activation times facilitates comparison of data from nearby sites, overcoming the imprecision of assigned activation times at single points, and permits rapid identification of a putative site of origin. The activation map can also be used to catalogue sites at which pacing maneuvers are performed during assessment of the tachycardia (e.g., sites with a good pace map).

When using a 3-D electroanatomical mapping system, it is important to understand that a change in rhythm during the mapping procedure can alter cardiac geometry to the extent that anatomical points acquired during one rhythm cannot be relied on after a change in rhythm. This is relevant during mapping of isolated PVCs or nonsustained VT, because locations assigned to early activation sites during the arrhythmia can potentially be removed from the same locations when assigned during normal rhythm (e.g., at the time of RF delivery after tachycardia termination). Therefore, after termination of the arrhythmia, “revisiting” the site of early activation tagged during PVCs or tachycardia may be unfeasible or even misleading as a target for ablation.

Noncontact Mapping

The spatial and temporal resolution of point-by-point activation mapping is limited by the number of contact electrodes and the time required. When VT is hard to induce or of short duration, simultaneous multisite data acquisition can help map the VT focus. The biggest advantage of noncontact endocardial mapping is its ability to recreate the endocardial activation sequence from simultaneously acquired multiple data points over a few (theoretically one) tachycardia beats, without requiring sequential point-to-point acquisitions. More detailed mapping, however, is necessary to find the precise site to ablate.^{3,47}

The EnSite 3000 noncontact mapping system (St. Jude Medical, St. Paul, Minn.) consists of a noncontact catheter (9 Fr) with a multielectrode array (MEA) surrounding a 7.5-mL balloon mounted at the distal end. To create a map, the balloon catheter is advanced over a 0.035-inch guidewire under fluoroscopic guidance and positioned in the RVOT. The balloon is then deployed; it may be filled with contrast dye, permitting it to be visualized fluoroscopically (Fig. 23-13). The balloon is positioned in the center of the RVOT and does not come in contact with the endocardial walls being mapped. Systemic anticoagulation is critical to prevent

thromboembolic complications; intravenous heparin is usually administered to maintain the activated clotting time (ACT) at 250 to 300 seconds.³

A conventional (roving) deflectable mapping catheter is also positioned in the RVOT and used to collect geometry information. The tricuspid annulus, HB, and pulmonic valve are initially tagged and a detailed 3-D geometry of the RVOT (“virtual” endocardium) is reconstructed by moving the mapping catheter around the RVOT.

The MEA simultaneously acquires multiple data points over a few tachycardia beats or PVCs. The system then reconstructs over 3360 unipolar electrograms simultaneously and superimposes them onto the computer-generated model of the RVOT, producing isopotential maps with a color range representing voltage amplitude. The highest chamber voltage is at the site of origin of the electrical impulse (see Video 8). Color settings are adjusted so that the color range matches 1 to 1 with the millivolt range of the electrogram deflection of interest. The color scale for each isopotential map is set so that white indicates the most negative potential and blue indicates the least negative potential. Activation can be tracked on the isopotential map throughout the cycle to the onset of the tachycardia beat. Wavefront propagation can be displayed as a user-controlled 3-D movie (Fig. 23-14).^{3,47}

Additionally, the system can simultaneously display as many as 32 electrograms as waveforms. Unipolar or bipolar electrograms (virtual electrograms) are then reconstructed at sites of earliest activation on the isopotential maps to look for a unipolar QS pattern. The

origin of VT is defined as the earliest site showing a single spot of isopotential mapping and a QS pattern of the noncontact unipolar electrogram. Isochronal maps can also be created, which represent progression of activation throughout the chamber relative to a user-defined electrical reference timing point.

Contact mapping using the conventional ablation catheter may also be performed at sites of interest to supplement noncontact mapping findings, and color-coded contact activation maps can be displayed on the same 3-D geometry. Once the earliest activation is identified, the site is labeled on the 3-D map and the locator signal is used to navigate the ablation catheter to it in real time during tachycardia or during normal rhythm when sustained tachycardia is not inducible.

Although noncontact mapping can rapidly identify VT foci, a second catheter is still required for precise localization of the target site and delivery of RF energy. Thus, noncontact mapping helps identify starting points for conventional activation mapping. Additionally, manipulation of the array into the RVOT can be difficult and contact of some portions of the area with myocardium may induce PVCs that appear similar to clinical PVCs or VT.

Basket Catheter Mapping

Basket catheters have been used successfully to guide ablation of idiopathic VT arising from the RVOT, and are of particular interest in patients with infrequent arrhythmia that limits mapping. This

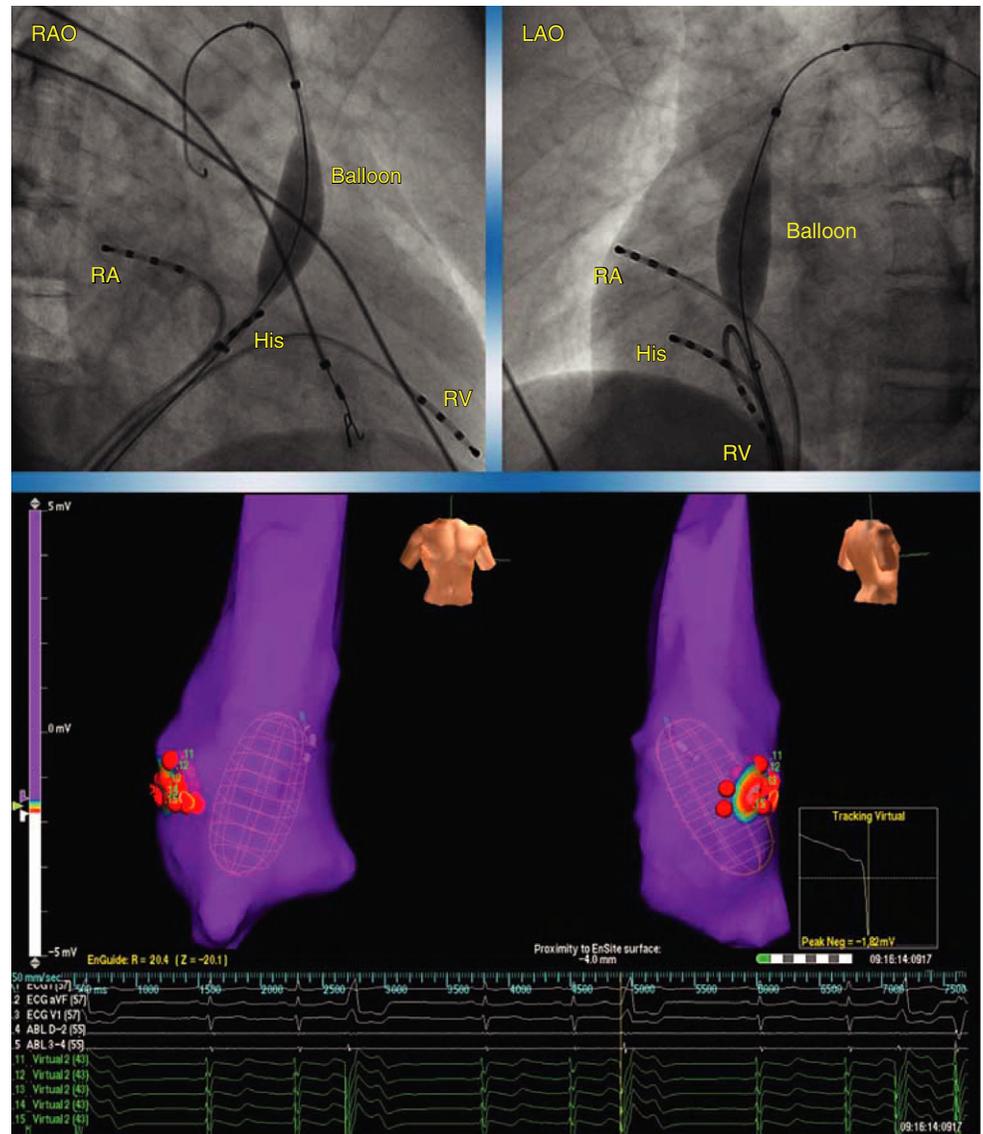

FIGURE 23-13 Noncontact mapping of idiopathic right ventricular outflow tract (RVOT) ventricular tachycardia. **Upper panel,** Fluoroscopic (right anterior oblique [RAO] and left anterior oblique [LAO]) views of the EnSite balloon catheter positioned in the RVOT. **Middle panel,** Color-coded isopotential map of RVOT activation during a single premature ventricular complex (PVC). The inset shows a virtual electrogram at the site of earliest activation (note the QS pattern). Red dots indicate radiofrequency applications. Further detailed mapping using a standard mapping catheter localized the PVC focus to a site adjacent to the site, with the earliest local activation identified by the balloon catheter. **Lower panel,** Surface ECG and intracardiac contact (ABL) and virtual noncontact (green) electrograms are shown during mapping of PVCs. (Courtesy of Dr. James Mullin, Prairie Cardiovascular Consultants, Springfield, Ill.)

mapping catheter consists of an open-lumen catheter shaft with a collapsible, basket-shaped distal end, which is composed of 64 electrodes mounted on eight flexible, self-expanding, equidistant metallic splines (each spline carrying eight ring electrodes; see Fig. 4-4). The electrodes are equally spaced 4 or 5 mm apart, depending on the size of the basket catheter used (with diameters of 48 or 60 mm, respectively). Each spline is identified by a letter (from A to H) and each electrode by a number (from 1 to 8), with electrode 1 having the distal position on the splines.³

The size of the RV is initially evaluated (usually with echocardiography) to help select the appropriate size of the basket catheter. The collapsed basket catheter is advanced under fluoroscopic guidance through an 11 Fr long sheath into the RV; the basket is then expanded. After basket catheter deployment, the conventional catheters are introduced and positioned in standard positions (Fig. 23-15). Several observations can help determine electrical-anatomical relations of the basket catheter electrodes, including fluoroscopically identifiable markers (spline A has one marker and spline B has two markers located near the shaft of the basket catheter) and electrical signals recorded from certain electrodes (e.g., ventricular, atrial, or HB electrograms), which can help identify the location of those particular splines.

From the 64 electrodes, 64 unipolar signals and 32 to 56 bipolar signals can be recorded, by combining 1-2, 3-4, 5-6, 7-8, or by combining 1-2, 2-3, until 7-8 electrodes are on each spline. The color-coded animation images simplify the analysis of multielectrode recordings and help in establishing the relation between activation patterns and anatomical structures. The degree of resolution is lower than that in 3-D mapping systems but appears satisfactory for clinical purposes.

The concepts of conventional activation mapping discussed above are then used to determine the site of origin of the tachycardia. The ablation catheter is placed in the region of earliest activity and is used for more detailed mapping of the site of origin of the VT. The Astronomer navigation system (Boston Scientific, Natick, Mass.) permits precise and reproducible guidance of the ablation catheter tip electrode to targets identified by the basket catheter. Without the use of this navigation system, it can be difficult to identify the alphabetical order of the splines by fluoroscopic guidance. The capacity of pacing from most basket electrodes allows the evaluation of activation patterns and pace mapping.

Basket catheter mapping is not commonly used because of several limitations. Most basket catheters are difficult, if not impossible, to steer; thus, positioning in the RVOT can be challenging. In addition, firm contact with the tip of the basket and RVOT myocardium can induce ectopic complexes that mimic spontaneous VT or PVCs. Spatial sampling is limited by the interspline and interelectrode distances, and endocardial contact is often limited because of the complex geometry of the ventricles. A second catheter is still required to be manipulated to the site identified for more precise localization of the target for ablation as well as RF energy delivery.³

Ablation

Target of Ablation

The ablation target site is defined as the site where the earliest endocardial activation time during VT or PVCs and exact or best pace map matches can be obtained. Activation mapping and pace mapping are highly correlated techniques and both methods are

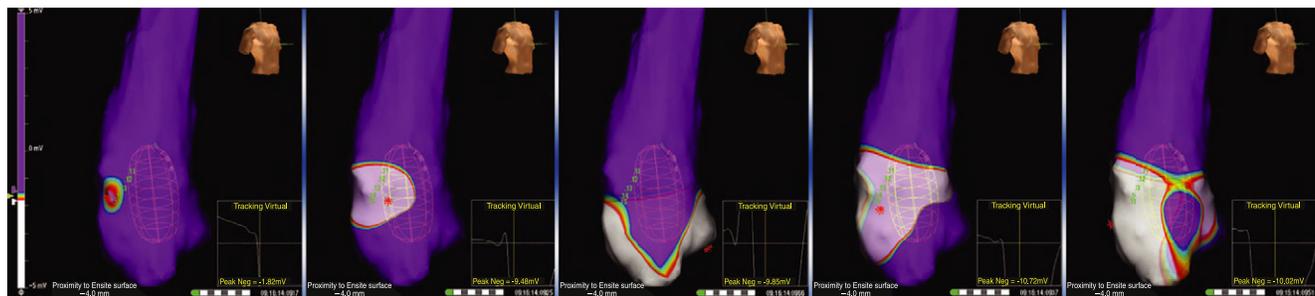

FIGURE 23-14 Noncontact color-coded propagation maps during a premature ventricular complex (PVC) originating from the right ventricular outflow tract. Wavefront propagation spreads radially from a small focus (from left to right). The insets show a virtual electrogram with the bar indicating the timing of activation during the PVC.

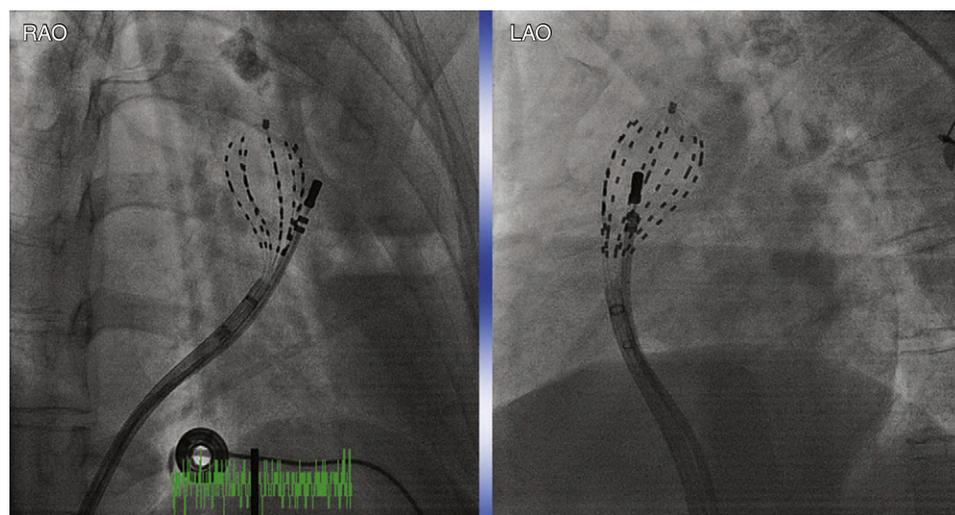

FIGURE 23-15 Fluoroscopic (right anterior oblique [RAO] and left anterior oblique [LAO]) views of a basket catheter positioned in the right ventricular outflow tract for mapping of idiopathic outflow tract ventricular tachycardia. A second catheter is used for further mapping and ablation.

typically used to select ablation sites—the more confirmatory information, the more likely the site of origin will fall within the range of the RF lesion produced (see Fig. 23-10). There is little objective evidence to support the widely held notion that pace mapping provides superior spatial resolution for localizing idiopathic outflow tract VT, compared with activation mapping.^{3,45}

Ventricular Tachycardias Originating in the Right Ventricular Outflow Tract

To map the RVOT via the femoral vein, the mapping catheter is advanced into the mid-RV. From there, a sharp clockwise torque directs the catheter toward the anterior portion of the RVOT. The mapping catheter is then advanced into the proximal pulmonary artery and slowly withdrawn into the RVOT until the first local endocardial electrogram is recorded. This site is just below the pulmonic valve, and is at the level where most RVOT VTs originate.^{1,6} It is important to avoid trying to advance the catheter when its tip is perpendicular to the RVOT, because this can result in perforation and cardiac tamponade. Torque is applied to the catheter for circumferential mapping of the RVOT within 1 cm of the pulmonic valve. The plane of the septum in the LAO view is nearly perpendicular to the imaging plane. Delineating the boundaries within which mapping will be carried out is useful, rather than discovering after several minutes of mapping that more tissue lies in one direction or another from where efforts had previously been concentrated. A second catheter positioned at the proximal HB, midanterior septum, or both helps in accurate localization, because “septal” sites are almost always within the same vertical plane or further rightward relative to these catheter positions in the LAO view.

For mapping of the posterior portion of the RVOT, the catheter needs to be flexed posteriorly and counterclockwise torque applied. Such application of counterclockwise torque, however, will tend to pull the electrodes back into the RV inflow portion. Using a long guiding sheath in the RV may offer adequate catheter stability. Additionally, mapping of the posterior RVOT wall can be facilitated by advancing the mapping catheter retrogradely into the right aortic sinus (see below), which lies immediately anterior to the RVOT (see Fig. 23-3).^{8,9} Also, it is important to carefully analyze the electrogram at the site of early activation on the RVOT to see if a far-field pattern is seen. Mapping the supra-ventricular aortic cusp can be necessary if the earliest signal is far field in character near the posterior portion of the pulmonic valve.⁸

Based on the results of activation and pace mapping at these initial sites, and guided by surface QRS morphology, attention is then directed to sites of early activation and best pace map matches. If very thorough mapping in the RVOT fails to localize the VT site of origin, mapping is extended into the pulmonary artery. It is important to resist the temptation to ablate the earliest site in a given

chamber unless all of the different chambers have been mapped or unless the unipolar electrogram displays a QS morphology concordant with the earliest bipolar electrogram and the pace map at the site of earliest activation matches perfectly.⁴⁴

Ventricular Tachycardias Originating in the Left Ventricular Outflow Region

If very thorough mapping and ablation in the RVOT and pulmonary artery fail to localize or terminate the tachycardia, and recordings from distal CS or great cardiac or anterior interventricular veins suggest LV origin, the femoral artery is cannulated. The catheter is advanced to the descending aorta and, in this position, a tight J curve is formed with the catheter tip before passage to the aortic root to minimize catheter manipulation in the arch. In a 30-degree RAO view, the curved catheter is advanced through the aortic valve with the J curve opening to the right, so the catheter passes into the LV oriented anterolaterally (see Fig. 4-9). The straight catheter tip must never be used to cross the aortic valve because of the risk of leaflet damage or perforation, and also because the catheter tip can slip into the left or right coronary artery or a coronary bypass graft, mimicking entry to the LV and causing damage to these structures. A long vascular sheath can provide added catheter stability. Anticoagulation should be started once the LV is accessed (intravenous heparin, 5000-unit bolus followed by a 1000-unit infusion is usually used), to maintain the ACT between 250 and 300 seconds.³

The catheter is carefully manipulated in the LVOT until an early ventricular electrogram is recorded and pace mapping shows a QRS identical to the clinical VT morphology. Pace mapping at these sites often requires high output pacing. Other parts of the LV can occasionally harbor the focus of the VT (Fig. 23-16).

Ventricular Tachycardias Originating in the Aortic Cusps

When mapping the sinuses of Valsalva, it is important to consider the entire surface of each of the cusps as well as the corresponding area just beneath the valve, as distinct activation times and pace maps are obtained from each point. Additionally, myocardial extensions can exist between the right and left cusps, and mapping and ablation of these sites usually require the catheter prolapsed below the valve and flexed onto the great arterial wall for contact and then gently pulled up into this intercuspular region.^{8,44}

Fluoroscopy alone or in combination with a 3-D electroanatomical mapping system may not be sufficient to facilitate comprehensive mapping of the supra-ventricular region, and intracardiac echocardiographic (ICE) imaging or contrast aortography is typically used. ICE imaging can be particularly useful in identifying mapping-ablation catheter location (see Video 20). Longitudinal

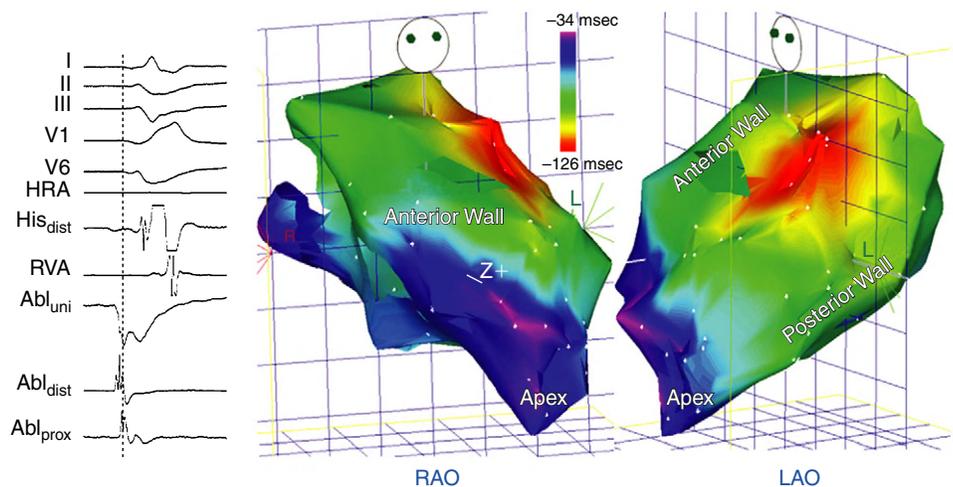

FIGURE 23-16 Focal left ventricle ventricular tachycardia (LV VT)—intracardiac recordings during VT and electroanatomical map of focal anterior wall LV VT. Note electrogram features of focality (QS on unipolar and slight presystolic timing of unipolar and bipolar electrograms during VT) as well as centrifugal spread of activation on the color map. LAO = left anterior oblique; RAO = right anterior oblique.

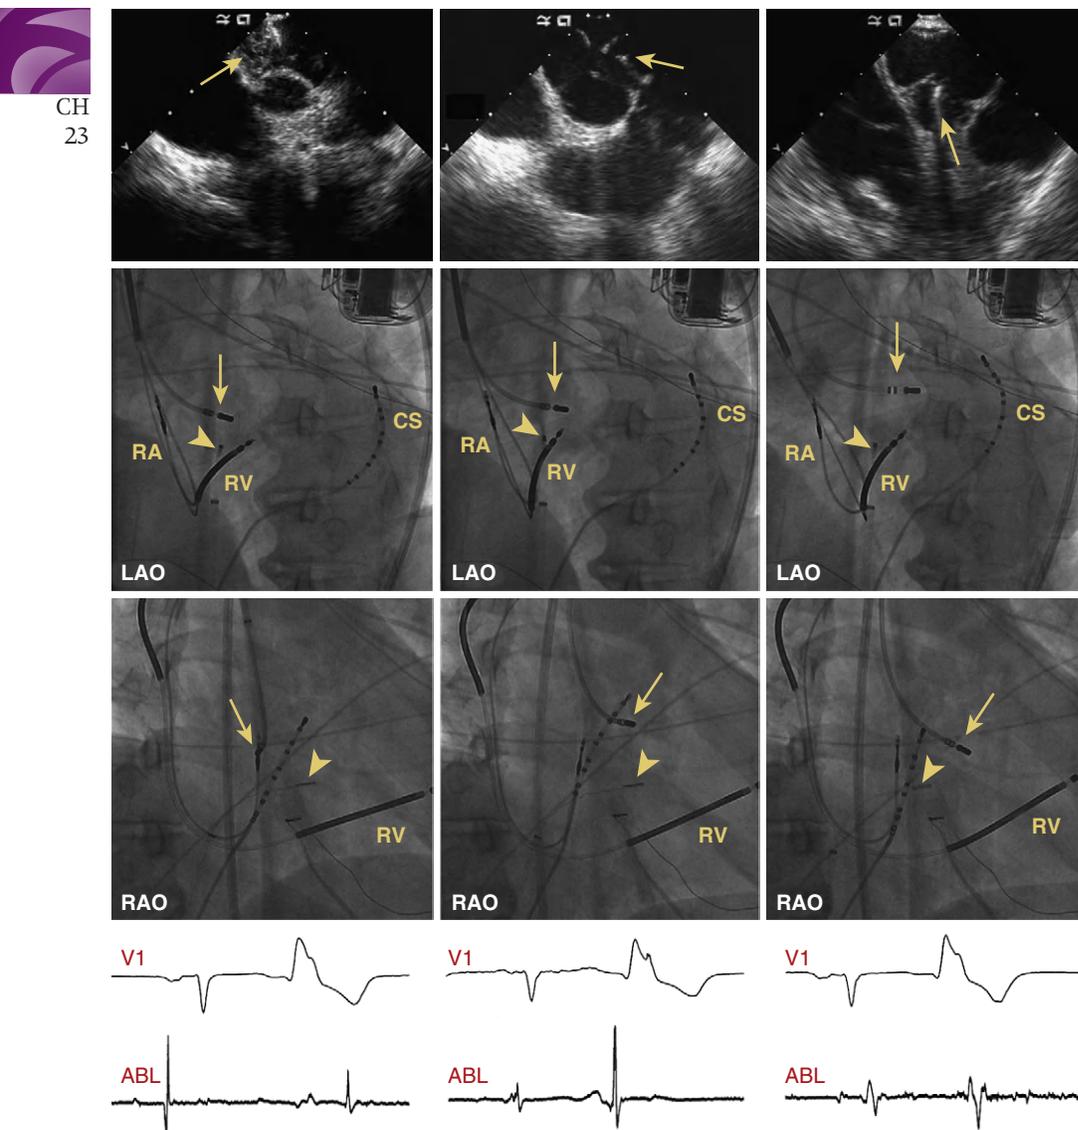

FIGURE 23-17 Top, Intracardiac echocardiography (ICE) images (top row) and left anterior oblique (LAO) and right anterior oblique (RAO) fluoroscopic views (middle and bottom rows, respectively). Bottom, Intracardiac recordings. Images and recordings were obtained during mapping in the noncoronary cusp (NCC, left panels), right coronary cusp (RCC, middle panels), and left coronary cusp (LCC, left panels). The ablation catheter tip on ICE and fluoroscopic images is marked by yellow arrows. Cross-sectional ICE images of the aortic valve were obtained with the ICE catheter (arrowheads) positioned at the His bundle region of the right ventricular (RV) septum. Right atrial (RA) and RV leads of an implantable cardioverter-defibrillator and a decapolar catheter positioned in the coronary sinus (CS) are marked. In the NCC, large near-field atrial and small far-field ventricular electrograms are recorded. The recorded electrograms from the RCC show a large ventricular electrogram and far-field atrial electrogram. In the LCC, large ventricular and small, far-field atrial electrograms are recorded. See text for discussion.

views are best to appreciate the relationship of the RVOT and LVOT and for identifying the ostia of the coronary arteries. A cross-sectional view is of most value in identifying the cusps themselves (Fig. 23-17). Once the three cusps are visualized, the interatrial septum will be seen in immediate relationship to the noncoronary cusp. Rightward and anterior to the noncoronary cusp and immediately behind the RVOT lies the right coronary cusp. Another landmark for the right coronary cusp is that the septal and anterior leaflets of the tricuspid valve will meet at the junction between the right and noncoronary cusps. The left coronary cusp is identified as being leftward and anterior to the noncoronary cusp and in close relation to the anterior leaflet of the mitral valve.^{8,44}

In some VTs originating from the aortic cusps, a preferential conduction to the RVOT may render pace mapping less reliable. Therefore, when the local ventricular activation does not precede the QRS onset of the VT or PVCs adequately or RF ablation is not effective in the RVOT, despite obtaining a good pace map, mapping of the aortic cusp should be considered. On the other hand, in one report, 27% of patients with VTs with an aortic cusp origin had the local ventricular activation in the RVOT preceding the QRS onset of the VT or PVCs. Therefore, when a good pace map is not obtained or RF ablation is not effective in the RVOT, despite the fact that local ventricular activation adequately precedes the QRS onset of the VT or PVCs, mapping of the aortic cusp should be considered.³⁶

A catheter positioned at the RV HB region can be very useful in catheter ablation of aortic cusp VTs. It can be used as a landmark for mapping within the noncoronary and right coronary cusps, where the proximity of the to the HB should be kept in mind to avoid inadvertent damage to the AV conduction system. Additionally, the local ventricular activation time relative to the QRS onset at the HB region in the RV can be an electrophysiological clue for differentiating VT origins in the aortic root. The activation time in the HB region is usually significantly earlier during PVCs originating from the right versus the left coronary cusp, suggesting that the activation from the right coronary cusp may propagate to the ventricular septum and RV before the LV free wall, whereas that from the left coronary cusp may do so after part of the LV free wall activates (Fig. 23-18). The local ventricular activation time relative to the QRS onset at the RV HB region is typically significantly greater for the VTs with origins from left coronary cusp and the junction of the right and left coronary cusps than for those from the noncoronary and right coronary cusps.¹⁶

When the left coronary cusp site appears early but ablation is unsuccessful, the posterior supraventricular pulmonary artery region and the anterior interventricular ring and branches should be mapped. Sometimes the LA appendage, which lies close to the posterior pulmonary artery laterally, can be mapped and in rare instances ablated for supraventricular tachycardia. Similarly, the

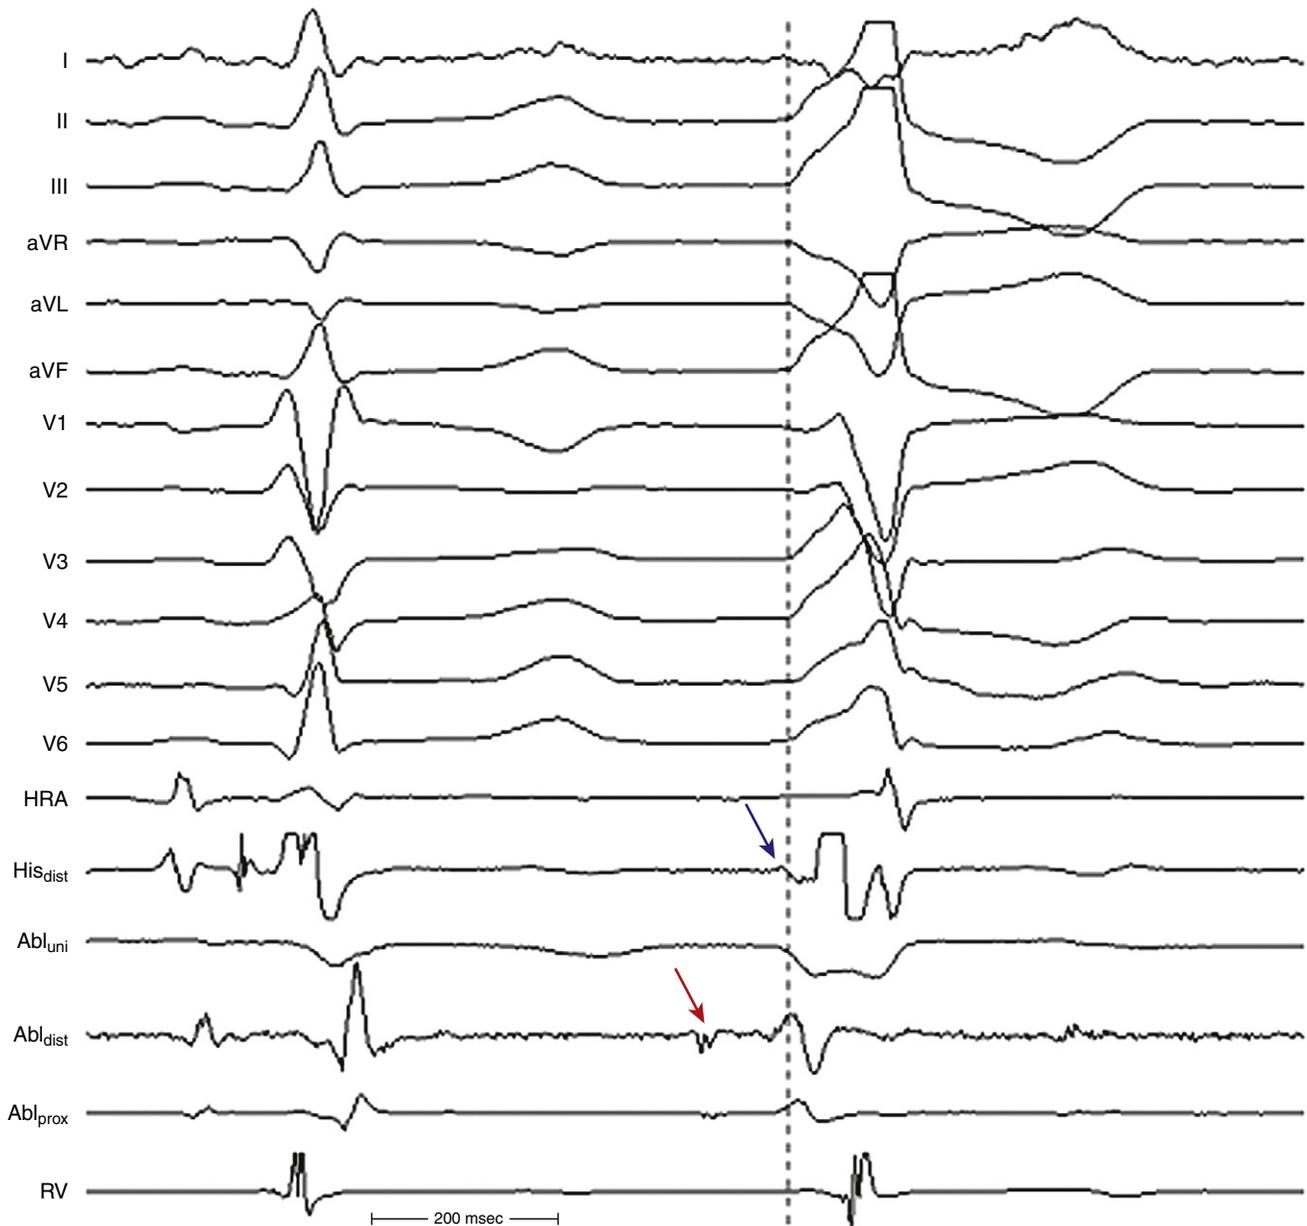

FIGURE 23-18 Recordings from a patient with premature ventricular complexes (PVCs) originating from the right aortic cusp. A sinus rhythm complex as well as the PVC is shown; the vertical line denotes the onset of the PVC QRS. The blue arrow shows that the His bundle ventricular electrogram is slightly presystolic, whereas the red arrow shows the electrogram at the site of origin of the PVC in the sinus of Valsalva, occurring about 100 milliseconds prior to the QRS onset.

superior vena cava medially lies close to the supra-avalvular portions of the ascending aorta above the right coronary cusp.⁹

When the earliest ventricular activation is identified in an aortic cusp, it is preferable to insert a 5 Fr pigtail catheter into the aortic root through the left femoral artery. The aortic root and the ostia of the right coronary artery and left main coronary artery are visualized by aortic root angiography.^{9,22} Selective angiography of the coronary arteries may also be performed with the ablation catheter positioned at the desired location so as to assess the anatomical relationships between these structures and the location of the ablation catheter. If the origin of VT is in the left coronary cusp, it is preferable to cannulate the left main coronary artery with a 5 Fr left Judkin catheter, which serves as a marker and for protection of the left main coronary artery in case of ablation catheter dislodgment during RF application.⁴⁸ Alternatively, a combination of electroanatomical mapping and ICE imaging (usually appreciated

in the longitudinal view of the LVOT) may be used to confirm anatomical location, catheter tip position and contact, and distance to coronary vasculature and to monitor RF delivery.^{35,44}

RIGHT CORONARY CUSP

The recorded electrogram from the right coronary cusp typically shows a large ventricular electrogram, which represents activation of the overlying relatively thick posterior wall of the RVOT infundibulum (see Fig. 23-17). Because this tissue is immediately adjacent to the anterior portion of the right coronary cusp, the electrogram may appear near field, and the site of early activation can be difficult to distinguish between arrhythmic origination from the myocardium extending above this cusp.⁸ Nonetheless, during PVCs originating from the right coronary cusp itself, a smaller and relatively fragmented but near-field electrogram will be observed

to precede the large ventricular electrogram and results from activation of the small myocardial sleeve extending into the cusp.

A far-field atrial electrogram may also be recorded in the right coronary cusp, particularly at more posterior locations (closer to the noncoronary cusp), and represents atrial activation of the anteroseptal tricuspid annulus, the RA appendage, or both.^{8,49}

On fluoroscopy, a catheter positioned in the right coronary cusp (using the retrograde approach) will point rightward in the LAO projection and anterior in the RAO projection. When the fluoroscopic view appears to suggest right cusp position but a large atrial electrogram is noted, the catheter should be manipulated with clockwise torque to see whether the atrial electrogram becomes larger. If so, the catheter is likely to be in the noncoronary cusp and the fluoroscopic images are misleading, perhaps because of atrial enlargement or counterclockwise rotation of the heart. In this setting, withdrawal of the catheter followed by application of counterclockwise torque and then advancing the catheter again will move the catheter from the noncoronary cusp to the right coronary cusp.⁸

LEFT CORONARY CUSP

Electrograms obtained in the left coronary cusp are the most variable of the aortic cusps, but typically the ventricular electrogram amplitude is larger than that of the atrial electrogram. More anteriorly close to the commissure with the right coronary cusp, a large ventricular electrogram, again originating in the posterior RVOT, can be recorded (see Fig. 23-17). More leftward and posteriorly, however, because of the aortomitral continuity, recorded ventricular electrograms are small and far field in nature. In the RAO fluoroscopic view, as the catheter is rotated counterclockwise in the left coronary cusp, a relatively larger but usually far-field atrial electrogram is located representing LA activation close to the anteroseptal mitral annulus.⁴⁹

NONCORONARY CUSP

A large near-field atrial electrogram is typically recorded in the noncoronary cusp, which represents activation of the thick myocardium of the interatrial septum located immediately posterior to the midportion of the noncoronary cusp (see Fig. 23-17).⁴⁹ When the catheter is rotated leftward and rightward from the interatrial septum, electrograms from the LA and RA, respectively, are recorded. A far-field ventricular electrogram may also be recorded from the noncoronary cusp and, depending on the exact catheter location, this smaller electrogram may reflect ventricular activation of the posterior LVOT, anteroseptal tricuspid annulus, or supraaortic myocardial activation.⁸

On fluoroscopy, a catheter positioned in the noncoronary cusp will point posteriorly in the RAO projection. In the LAO projection, however, the noncoronary cusp can be difficult to distinguish from the left coronary cusp because both appear to be somewhat leftward. When counterclockwise torque is applied and a large near-field atrial electrogram is seen, catheter location in the noncoronary cusp is verified. As discussed previously, ICE imaging can also help to clarify catheter location. The probe should be placed close to the tricuspid annulus and directed leftward. If the catheter tip is located in a cusp and the interatrial septum can be visualized in the same plane, noncoronary cusp location can be determined. If the tricuspid valve anterior leaflet is visualized along with the RVOT, then the catheter tip is probably in the right coronary cusp and simply directed posteriorly. Again, a simple maneuver of counterclockwise torque on the catheter while visualizing fluoroscopically and with ICE will result in a large ventricular electrogram being recorded and thus identifying catheter location in the right coronary cusp.⁹

Ventricular Tachycardias Originating from the Left Ventricular Papillary Muscles

The anterolateral (or anterior) and posteromedial (or posterior) LV papillary muscles are thick, finger-like processes attached to the ventricular wall at one end and to the mitral leaflets by multiple

tendons (chordae tendineae) on the other end. The anterior papillary muscle originates from the middle to apical site of the LV ventral wall, whereas the posterior papillary muscle arises from the inferior wall of the LV. VTs generally originate from the base of the papillary muscle.

RF catheter ablation of these VTs is particularly challenging, likely secondary to the complex structure of the papillary muscles as well as the relatively deep VT origins within the thick muscle.³²

Generally, large-tip (8-mm) or irrigated-tip ablation catheters and RF lesions in a relatively wide area and, not infrequently, on both sides of the papillary muscle are required to completely eliminate the VT. This is likely related to either poor catheter contact with the tissue or a relatively deep focus of the VT. ICE can be helpful in these cases and can facilitate catheter navigation and positioning.³²

Sites with the earliest endocardial activation and matching pace maps are targeted by ablation. Purkinje potentials often (in 40% of patients) can be observed at successful ablation sites. However, pace mapping alone is usually insufficient to guide successful ablation. The site of origin of VT can be located deep within the papillary muscle and away from the breakout site; although the latter site can be recognized as the site with the best pace map, ablation there may not eliminate the VT.^{31,32,50}

In up to 50% of patients, LV papillary muscle VTs exhibit variable QRS morphologies spontaneously, after the initial RF ablation lesions, or both, likely related to different directions of propagation of the wavefront exiting the papillary muscle.³²

Epicardial Idiopathic Ventricular Tachycardias

The anterior and lateral portions of the RVOT are fairly thin. Thus, ablation from the endocardium is usually effective, even when VT foci occur on the epicardial surface. The posterior RVOT (infundibulum) is much thicker, but the epicardial surface of the posterior infundibulum is the LVOT, and thus ablation may be effective from either the LVOT or the RVOT for arrhythmias arising deep in the myocardium of the posterior RVOT.¹⁵

For the supraaortic aortic region there is no true epicardial location because the RVOT lies anterior to the right and left coronary cusps and the atria lie posterior to the noncoronary cusp.¹⁵

On the other hand, idiopathic VTs can originate from the LV epicardium in up to 14% of patients with idiopathic VT. Epicardial idiopathic VTs typically arise in close proximity to the coronary venous system, including the anterior interventricular vein (which runs in the anterior interventricular sulcus parallel to the left anterior descending coronary artery), the great cardiac vein (which runs in the left AV groove parallel to the left circumflex coronary artery and forms the CS once it is joined by the left atrial oblique vein of Marshall and the posterolateral vein of the LV), the junction of the anterior interventricular and great cardiac veins (near the bifurcation of the left coronary artery), and less commonly the middle cardiac vein (which runs with the posterior descending coronary artery in the posterior interventricular groove).^{3,39}

The region of the epicardial surface of the LV near the bifurcation of the left main coronary artery that is bounded by an arc from the left anterior descending coronary artery (superior to the first septal perforating branch) and the left circumflex coronary artery occupies the most superior portion of the LV and has been termed the LV summit (Fig. 23-19). This region is the most common site of idiopathic epicardial LV VT origins. The LV summit is bisected by the great cardiac vein into an inferior portion, lateral to this structure (which is accessible to epicardial catheter ablation) and a superior region that is inaccessible to catheter ablation because of the close proximity of the coronary arteries and the thick layer of epicardial fat that overlies the proximal portion of these vessels.⁵¹

LV summit VTs are most commonly ablated within the great cardiac or anterior interventricular veins.⁸ Epicardial mapping via the coronary venous system can be achieved with small (2.5 Fr), flexible, multipolar electrode catheters introduced through a guiding catheter positioned at the CS ostium. CS venography is typically required to help delineate its anatomy and to visualize the great

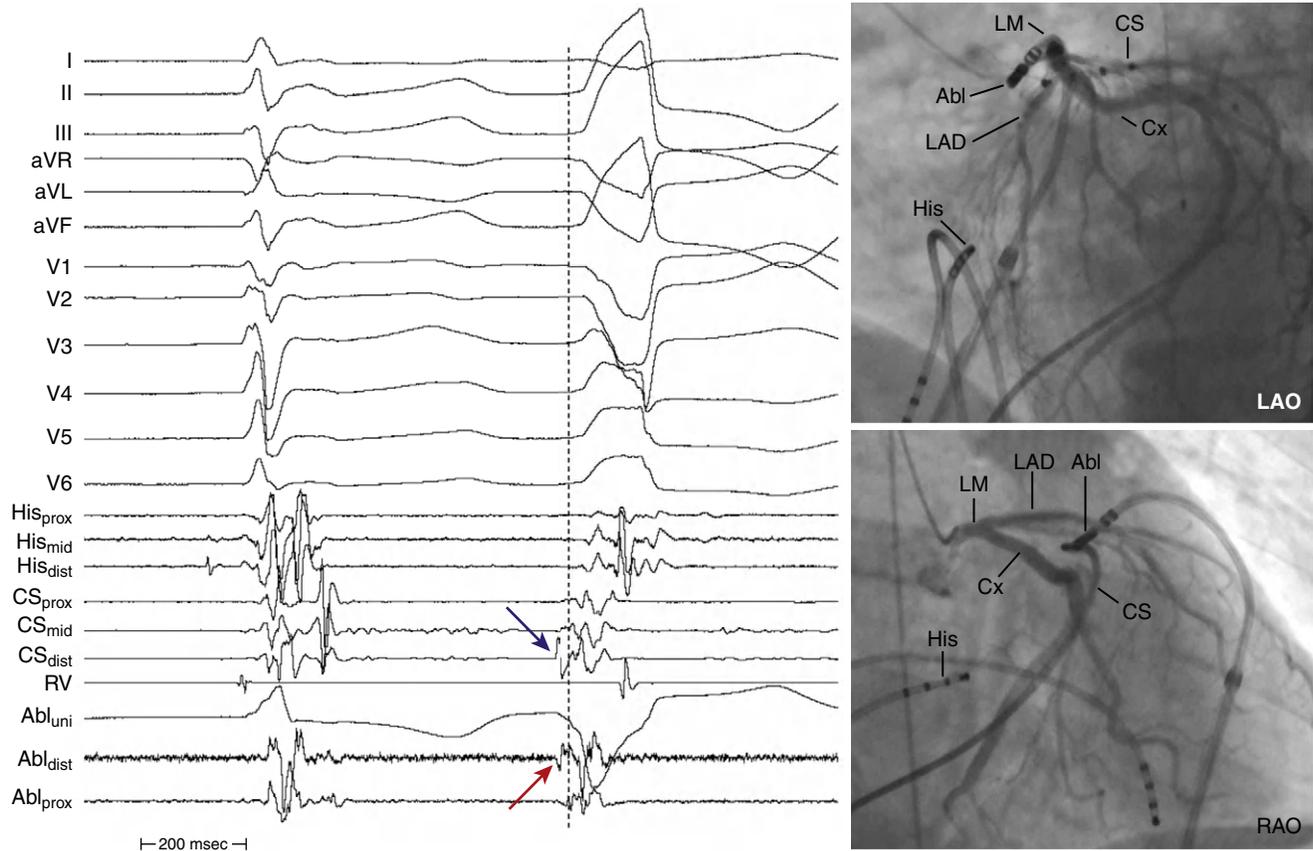

FIGURE 23-19 Recordings from a patient with premature ventricular complexes (PVCs) originating on the left ventricular (LV) summit. The dashed line denotes the onset of the PVC QRS complex. Note that the distal coronary sinus electrogram (CS_{dist}) occurs well before the onset of the QRS, similar to the ablation catheter recording in the pericardial space; the location is shown in the fluoroscopic views at right (Abl). Cx = circumflex coronary artery; LAD = left anterior descending artery; LAO = left anterior oblique; LM = left main coronary artery; RAO = right anterior oblique.

cardiac and anterior interventricular veins. Once the catheter is positioned at the target site, and before RF energy delivery, coronary arteriography should be performed to outline the spatial relationship between the target vein and the adjacent coronary artery (see Fig. 23-19). After ablation, coronary arteriography should be performed to rule out damage to coronary arteries. Additionally, pacing from the distal ablation electrode should be performed at an output of 20 mA. If diaphragmatic capture can be demonstrated, then ablation should not be attempted to avoid phrenic nerve injury.^{38,39}

However, epicardial mapping and ablation via the coronary venous system can be challenging. Currently available ablation catheters often are difficult to advance beyond the distal great cardiac vein or the proximal portions of the middle cardiac vein because of the tortuosity, sharp angulation, and small caliber of the distal veins. Additionally, with conventional 4-mm electrodes, delivery of more than 10 to 15 W seldom is possible because of limited electrode cooling, leading to a rapid rise in electrode temperature, although even low power often is sufficient. Given those difficulties, the percutaneous epicardial approach may offer potential advantages for mapping and ablation of those VTs. The latter approach provides access to the entire epicardial surface and the deployment of a greater range of ablation catheters and energy sources, although technical challenges related to access and the insulating effects of epicardial fat remain.^{38,39} Nonetheless, despite these technical challenges, ablation of idiopathic VT via the coronary venous system appears to be at least as effective as with a percutaneous transthoracic approach, which has a reported success rate of approximately 70%. Using the coronary venous system for mapping and ablation may result in a lower complication rate because damage to the RV or extracardiac structures is less likely

to occur. Percutaneous epicardial mapping and ablation may be considered in patients with epicardial VTs when ablation from within the coronary venous system is not feasible (see Chap. 27 for detailed discussion).

Radiofrequency Energy Delivery

Because outflow tract VTs are focal in nature and the target tissue consists of structurally nondiseased myocardium, extensive tissue injury is usually not necessary for successful ablation. Steerable catheters with 4- or 5-mm-tip electrodes and conventional nonirrigated energy application are generally used. RF applications at moderate temperatures (target temperature, 55°C) and a maximal power output of 30 to 40 W seem to be safe and effective. Duration of energy application should not exceed 30 to 60 seconds.¹³ Rarely, if ever, does one need more than 50 W or use of irrigated or large-tip electrodes to ablate outflow tract VTs successfully, and it is preferable to avoid those ablation approaches to prevent cardiac perforation. Some investigators recommend the use of lower target temperatures and irrigated electrodes for left-sided idiopathic focal VT, assuming a higher risk of coagulum formation and thromboembolic complications compared with ablation in the RV.^{3,44}

Several measures must be taken to avoid injuring the coronary arteries during ablation of VTs arising from the coronary cusps. RF energy delivery in the aortic sinuses is preferably started at a low power output (15 W) and then increased to no more than 30 W to achieve a target temperature of approximately 50°C. Ablation should also be performed during continuous fluoroscopy to observe for catheter dislodgment, and energy delivery should be discontinued in case of even minimal dislodgment from the site showing the best mapping findings. RF application should also be

Ablation of RVOT VT

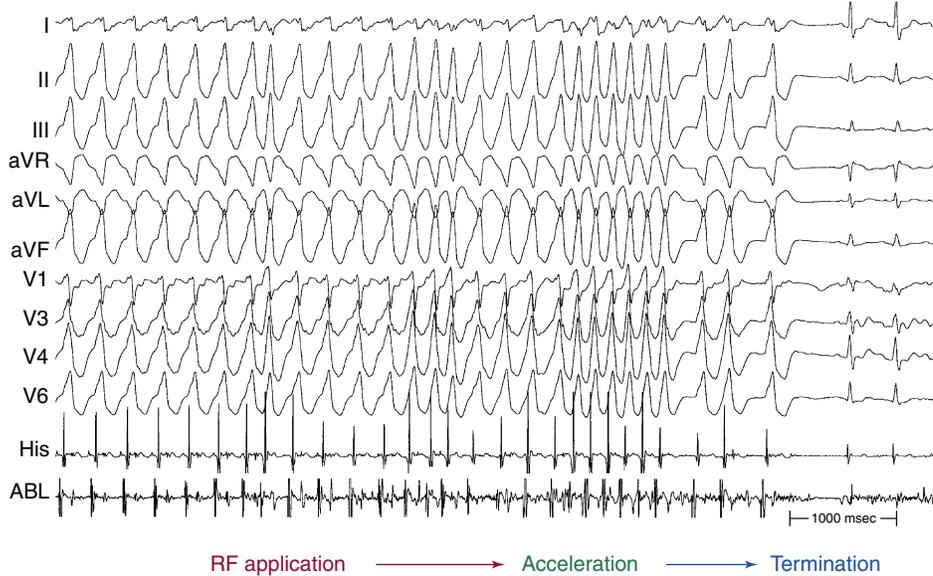

FIGURE 23-20 Ablation of right ventricular outflow tract (RVOT) ventricular tachycardia (VT). Radiofrequency energy delivery is started during sustained VT. Acceleration of the VT is observed within a few seconds, followed by slowing and termination of the VT.

stopped if the repetitive or sustained VT cannot be terminated after 10 seconds. Coronary angiography is often performed immediately after the ablative procedure to exclude coronary artery spasm, dissection, or thrombus.

RF delivery at successful ablation sites often can result in a rapid ventricular response (identical QRS morphology to that of VT), followed by gradual slowing and complete resolution (Fig. 23-20). This finding has a high specificity, but low sensitivity, for successful ablation sites.¹ When RF is delivered during VT, termination of VT at successful sites usually occurs within 10 seconds.

Typically, a few (range, 2 to 11; mean, 5) RF applications are required. Occasionally, following several RF applications, the first VT morphology is no longer seen but a second, similar one is now observed. This can be caused by an actual second focus near the first or modification of the exit site from the first focus (Fig. 23-21). In this situation, ablation within 1 to 2 cm of the first site eliminates the second VT morphology.

Endpoints of Ablation

Successful ablation is defined as the lack of spontaneous or inducible PVCs and VT, with and without isoproterenol administration (using the best method for induction documented before ablation), at least 30 minutes after ablation.

Outcome

The acute success rate is greater than 90%. The recurrence rate is approximately 7% to 10%. Of these, 40% recur during the first 24 to 48 hours after the ablation procedure. Recurrence of VT beyond the first year post ablation is rare. The success of ablation depends on the presence of spontaneous or inducible VT or PVCs at the time of the procedure. Predictors of recurrences include poor pace map, late activation at target sites, reliance on pace mapping alone, and termination of VT inducibility with mechanical trauma by the mapping-ablation catheter before RF delivery.

Complications are rare. RBBB develops in 2% and cardiac tamponade is rare. Systemic thromboembolism and damage to the aortic valve can occur during ablation of LVOT or aortic cusp VTs.³

The potential for acute coronary artery occlusion is a major risk consideration with catheter manipulation within the aortic cusps. Damage to the coronary arteries can result from catheter manipulation and ablation in the aortic root, secondary to RF energy delivery in close proximity to the ostia of the right or left coronary arteries as well as inadvertent catheter engagement of the left main

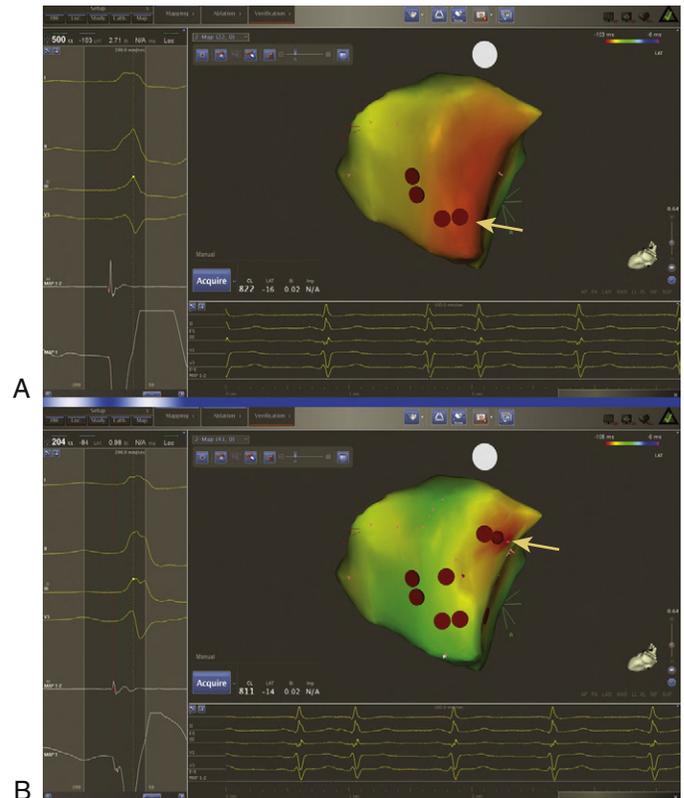

FIGURE 23-21 Electroanatomical (CARTO) activation map (posterior views) of premature ventricular complexes (PVCs) originating from the right ventricular outflow tract (RVOT). Left panels show (in order from top to bottom) surface ECG leads (I, II, III, V₁) and bipolar and unipolar recording of the distal ablation electrodes during the PVCs. **A**, The site of impulse origin during ectopy is in the posterolateral aspect of the RVOT (red area, arrow) at which intracardiac recordings show early bipolar electrogram concordant with a QS-unipolar electrogram; ablation (red dots) at this site eliminated VT. **B**, PVCs with slightly different QRS morphology (note the notching in the QRS in ECG leads II and III) emerged after initial ablation. Mapping revealed the focus of the latter PVCs (note intracardiac recordings) at a close but different location from the site targeted by initial ablation, at which ablation (red area, arrow) eliminated all PVCs.

coronary artery when ablating in the left coronary cusp. It is also important to recognize the potential risk of coronary artery damage when ablating in the RVOT and pulmonary artery. The right coronary artery is typically 4 to 5 mm away from the proximal part of the RVOT near the free wall, and is separated by a variable amount of fat. Additionally, the cephalocaudal separation of the pulmonary and aortic valve results in close proximity of the pulmonary valve to the origin of the right coronary artery, and the left main coronary artery lies in immediate posterior proximity to the subvalvular RVOT near the pulmonary valve as well as the supra-ventricular pulmonary artery. Thus, when concern exists about possibly damaging the artery, the ablation catheter should be kept where energy delivery is to be given, and either a root aortogram, coronary angiography, or careful ICE imaging should be performed.⁹

The penetrating HB lies at the membranous septum formed in part by the commissure between the right coronary and noncoronary cusps. Ablation at this site could potentially damage the HB. The HB electrogram can be obtained at several supra-ventricular locations including the right coronary cusp posteriorly, the noncoronary cusp anteriorly, and when the electrode has been prolapsed below the plane of the semilunar valve in between these two cusps. During VT, however, the His potential can be inscribed within the ventricular electrogram as a result of retrograde activation to the HB.⁹ Therefore, when ablating in the depths of the noncoronary cusp, particularly toward the junction with the right coronary cusp, monitoring for fast pathway damage (AH interval prolongation, junctional beats) is advisable.

Cryoablation

Initial experience suggests cryocatheter techniques to be a potent tool in treating idiopathic RVOT VT.⁵² A major advantage of cryoablation is the virtual absence of pain, which makes the use of analgesia unnecessary. Moreover, reasonable fluoroscopy and procedure times can be achieved by an experienced investigator. Stability of the catheter during cryoablation can be advantageous because monitoring of catheter position by fluoroscopy is not necessary. Adhesion of the catheter, however, requires precise positioning before the start of cryoablation. Slight dislocations, as may easily occur with breathing, can delay ablation success. Furthermore, brushing of the catheter within a small, defined area, as often observed with RF ablations, cannot occur; therefore, repositioning of the catheter to adjust for a dislocation is not possible during cryoablation. The cryocatheter differs substantially in size and rigidity from standard RF catheters and requires some experience in handling.

Complete disappearance of the arrhythmia is typically observed within 20 seconds of cryoablation. Therefore, cryoablation is stopped after 60 seconds if no positive effect is observed.

Given the high success rate and low risk of RF ablation of outflow tract VT, it may be difficult to demonstrate a clinical advantage of cryoablation over RF ablation. Cryoablation can be useful in difficult or atypical sites when a maximal stability of the catheter is necessary—for example, to avoid dislodgment of the catheter into the coronary arteries during ablation of idiopathic VT originating from the aortic cusps. Additionally, cryoablation may be considered for elimination of epicardial VTs from within the coronary venous system, when RF energy delivery is limited. Also, the absence of pain during ablation may render the procedure more comfortable for the patient, especially when the use of sedative medications suppresses inducibility of the VT.^{38,39}

Pathophysiology

Verapamil-sensitive left ventricular tachycardia (LV VT) is a reentrant tachycardia. The diagnosis of reentry as the mechanism of fascicular VT is supported by several observations. The VT can reproducibly be initiated and terminated by programmed electrical stimulation, entrainment and resetting with fusion can be demonstrated, and an inverse relationship between the coupling interval of the initiating ventricular extrastimulus (VES) or ventricular pacing cycle length (CL) and the first VT beat can be observed.

The exact nature of the reentry circuit in verapamil-sensitive VT has provoked considerable interest. Some investigators have suggested that it is a microreentry circuit in the territory of the left posterior fascicle (LPF). Others have suggested that the circuit is confined to the Purkinje system, which is insulated from the underlying ventricular myocardium. False tendons or fibromuscular bands that extend from the posteroinferior LV to the basal septum have also been implicated in the anatomical substrate of this tachycardia. Less often, the reentry circuit is located in fibers distal to the left anterior fascicle (LAF) or may arise from fascicular locations high in the septum.¹

Currently, overwhelming evidence suggests that the VT is caused by a reentrant circuit incorporating the posterior Purkinje system with an excitable gap and a slow conduction area.^{2,4} The VT substrate can be a small macroreentrant circuit consisting of the LPF serving as one limb and abnormal Purkinje tissue with slow, decremental conduction serving as the other limb. The anterograde limb may be associated with longitudinal dissociation of the LPF or contiguous tissue that is directly coupled to the LPF (such as a false tendon) or, alternatively, has ventricular myocardium interposed. The zone of slow conduction appears to depend on the slow inward calcium current, because the degree of slowing of tachycardia CL in response to verapamil is entirely attributed to its negative dromotropic effects on the area of slow conduction.

The entrance site to the slow conduction zone is thought to be located closer to the base of the LV septum. From there, activation propagates anterogradely (from basal to apical along the LV septum) over the abnormal Purkinje tissue with decremental conduction properties and verapamil sensitivity, which serves as the anterograde limb of the circuit and appears to be insulated from the nearby ventricular myocardium. The lower turnaround point of the reentrant circuit is located in the lower third of the septum, where the wavefront captures the fast conduction Purkinje tissue from or contiguous to the LPF, and retrograde activation occurs over the LPF from the apical to basal septum forming the retrograde limb of the reentrant circuit. Also, at the lower turnaround point anterograde activation occurs down the septum to break through (at the exit of the tachycardia circuit) in the posterior septal myocardium

below. The upper turnaround point of the reentrant circuit occurs over a zone of slow conduction located close to the main trunk of the left bundle branch (LB) in the basal interventricular septum (Fig. 24-1). The estimated distance between the entrance and exit of the circuit is approximately 2 cm.^{3,5}

Clinical Considerations

Epidemiology

Age at presentation is typically 15 to 40 years (unusual after 55 years). Males are more commonly affected (60% to 80%). Verapamil-sensitive VT is the most common form of idiopathic LV VT, and it accounts for 10% to 15% of all idiopathic VTs.^{2,6}

Clinical Presentation

Most patients present with mild to moderate symptoms of palpitations and lightheadedness. Occasionally, symptoms are debilitating, and include fatigue, dyspnea, and presyncope. Syncope and sudden cardiac death are very rare. The VT is typically paroxysmal and can last for minutes to hours. Although idiopathic LV VT can occur at rest, it is sensitive to catecholamines and often occurs during exercise, after exercise, or emotional distress. Occasionally, the VT can be incessant, may be sustained for a long period (days), and does not revert spontaneously to normal sinus rhythm (NSR). Patients with incessant tachycardia can develop cardiomyopathy.⁷ The clinical course is benign and the prognosis is excellent. Spontaneous remission of the VT may occur with time.

Initial Evaluation

Diagnostic features of fascicular VT include induction with atrial pacing, right bundle branch block (RBBB) with left (or, less commonly, right) axis deviation, structurally normal heart, and verapamil sensitivity. Evaluation to exclude structural heart disease is necessary and typically includes echocardiographic examination, stress testing, and/or cardiac catheterization, depending on patient age and risk factors.

Principles of Management

ACUTE MANAGEMENT

Intravenous verapamil is typically successful in acutely terminating the VT. Termination with adenosine is rare, except for patients in whom isoproterenol is used for induction of the tachycardia in the EP laboratory.

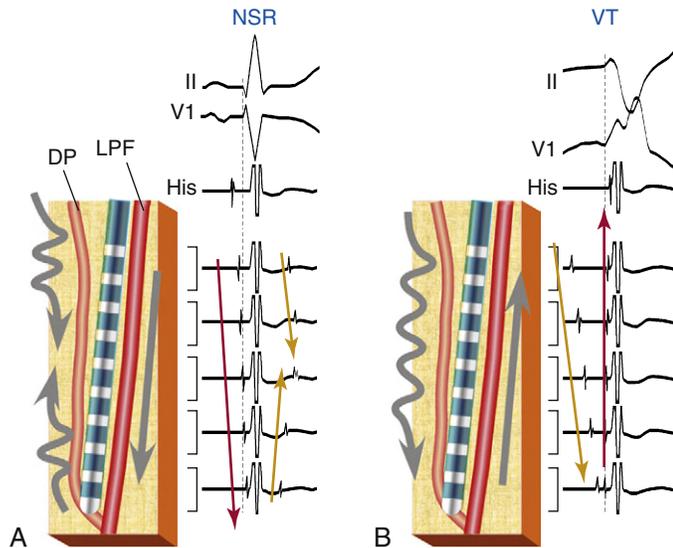

FIGURE 24-1 Schematic illustration of the reentrant circuit in verapamil-sensitive left ventricular tachycardia (LV VT). A block of the LV septum is depicted with the left posterior fascicle (LPF) and diastolic pathway (DP) running in parallel until they intersect at the bottom. A 10-pole catheter is shown recording between pathways; electrograms from each pair are shown along with surface ECG leads and His bundle recordings. **A**, A sinus rhythm complex is shown; the dashed line denotes QRS onset. Note the direction and speed of propagation over the LPF while the DP is activated after the QRS and in both directions (arrows). **B**, During a VT complex, the DP is activated anterogradely and the LPF retrogradely (arrows). NSR = normal sinus rhythm. See text for discussion.

CHRONIC MANAGEMENT

Long-term therapy with verapamil is useful in mild cases; however, it has little effect in patients with severe symptoms and the efficacy of oral verapamil in preventing tachycardia relapse is variable. Radiofrequency (RF) ablation is highly effective (success rate of 85% to 90%) and is recommended for patients with severe symptoms.²

Electrocardiographic Features

ECG during Normal Sinus Rhythm

The resting ECG is usually normal. Symmetrical, inferolateral T wave inversion can be present after termination of the VT.

ECG during Ventricular Tachycardia

The QRS during VT typically has RBBB with LAF block configuration. The R/S ratio is less than 1 in leads V₁ and V₂ (Fig. 24-2).³ VTs arising more toward the middle at the region of the posterior papillary muscle have a left superior axis and RS in leads V₅ and V₆, whereas those arising closer to the apex have a right superior axis with a small “r” and deep S (or even QS) in leads V₅ and V₆. In contrast to VT associated with structural heart disease, the QRS duration during fascicular VT is relatively narrow (<140 to 150 milliseconds), and the RS interval (the duration from the beginning of the QRS to the nadir of the S wave) in the precordial leads is relatively short (60 to 80 milliseconds); thus, the VT is frequently called “fascicular” VT. The VT rate is approximately 150 to 200 beats/min (range, 120 to 250 beats/min). Alternans in the CL is frequently noted during the VT; otherwise, the VT rate is stable.

Fascicular VT can be classified into three subtypes: (1) left posterior fascicular VT with an RBBB and superior axis configuration (common form); (2) left anterior fascicular VT with RBBB and right-axis deviation configuration (uncommon form); and (3) upper septal fascicular VT with a narrow QRS and normal axis configuration (rare form).¹

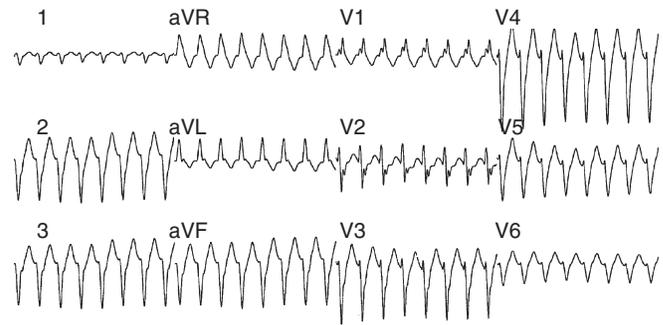

FIGURE 24-2 Surface ECGs of verapamil-sensitive left ventricular tachycardia (LV VT). Note the right bundle branch block and left anterior fascicle block pattern characteristic of these VTs.

Electrophysiological Testing

Induction of Tachycardia

Fascicular VT can usually be initiated with atrial extrastimulation (AES), VES, atrial pacing, or ventricular pacing. Often, isoproterenol alone, or during concurrent programmed stimulation, facilitates induction. An inverse relationship is observed between the coupling interval of the initiating VES or ventricular pacing CL and the first VT beat.

Tachycardia Features

SITE OF EARLIEST VENTRICULAR ACTIVATION

The site of earliest ventricular activation during VT (which represents the exit of the reentrant circuit) is in the region of the LPF (inferoposterior LV septum) in 90% to 95% of LV VTs (explaining the RBBB–superior axis configuration of the QRS), and in the region of the LAF (anterosuperior LV septum) in 5% to 10% of LV VTs (explaining the RBBB–right axis configuration of the QRS). In most cases, ventricular electrograms are discrete during both NSR and VT. The His bundle (HB) is not a component of the reentrant circuit, because a retrograde His potential is often recorded 20 to 40 milliseconds after the earliest ventricular activation (Fig. 24-3).

PURKINJE POTENTIAL

The Purkinje potential (PP or P2) is a discrete, high-frequency potential that precedes the site of earliest ventricular activation by 15 to 42 milliseconds and is recorded in the posterior third of the LV septum during VT and NSR (Fig. 24-4; see also Fig. 24-3).^{3,4} Because this potential also precedes ventricular activation during NSR, it is believed to originate from activation of a segment of the LPF and to represent the lower turnaround point in the reentrant circuit. The earliest ventricular activation site (exit) during VT is identified more apically in the septum than the region with the earliest recorded PP.

LATE DIASTOLIC POTENTIAL

The late diastolic potential (LDP, P1, or pre-PP) is a discrete potential that precedes the PP during VT, and is recorded at the basal, middle, or apical LV septum. The LDP is thought to originate from activation at the entrance to the abnormal Purkinje tissue (the specialized, verapamil-sensitive zone), which is thought to serve as the anterograde limb of the reentrant circuit. The LDP differs in morphology from the PP and has a relatively small amplitude and low-frequency component. The area with LDP recording is confined to a small region (0.5 to 1.0 cm²) and is included in the larger area where the PP is recorded (2 to 3 cm²); hence, the LDP often is recorded simultaneously with the PP by the same electrode. The LDP is recorded within an area proximal to the earliest PP recording

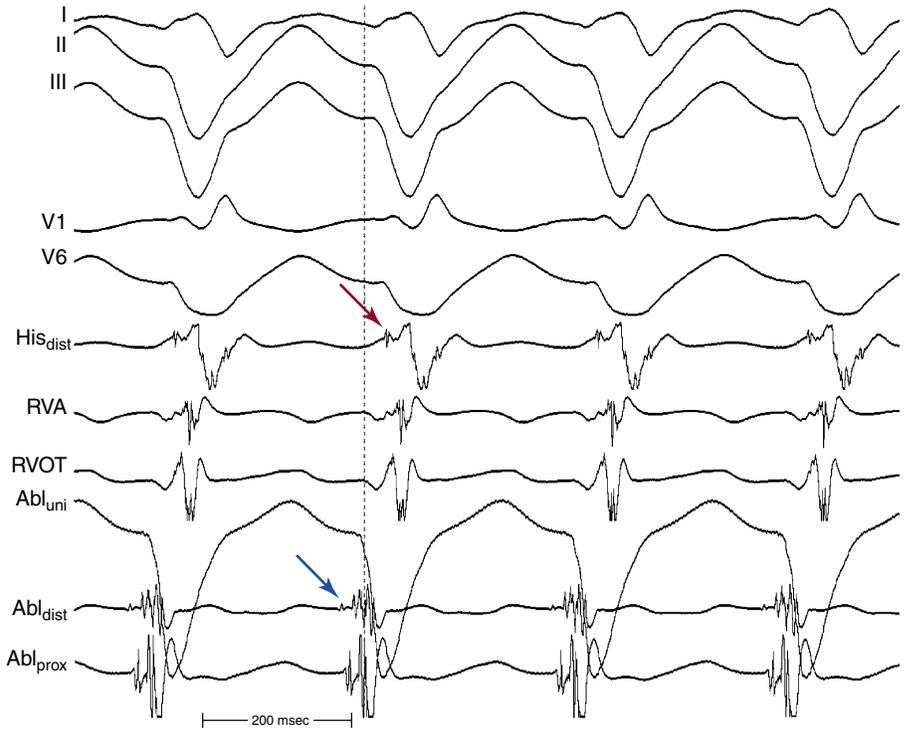

FIGURE 24-3 Idiopathic (fascicular) left ventricular tachycardia. The blue arrow shows late diastolic small potential, 45 milliseconds prior to QRS onset. Distinct Purkinje-like potentials (blue arrow) are evident before the dotted line denoting QRS onset, as well as in the proximal ablation electrogram. The red arrow indicates retrograde His potential. Note the unipolar QS configuration just coinciding with QRS onset.

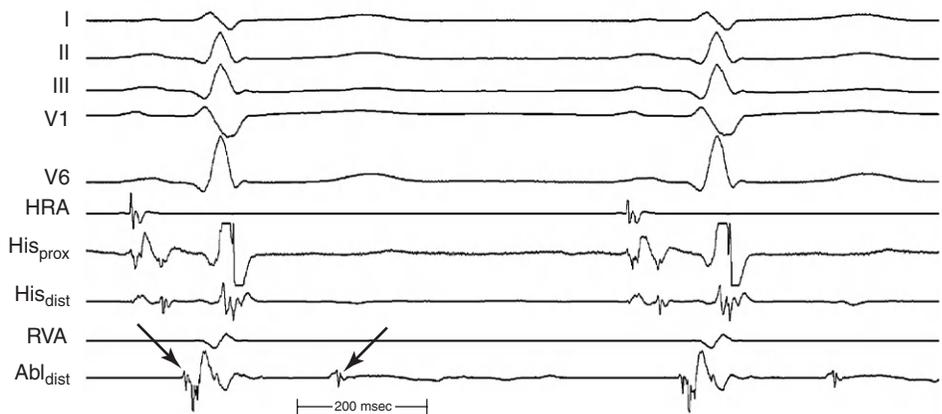

FIGURE 24-4 Sinus rhythm recordings at a successful ablation site for idiopathic (fascicular) left ventricular tachycardia. The left arrow points to a Purkinje-like potential just prior to the local electrogram (also slightly preceding the onset of the QRS); the right arrow shows a sharp, delayed diastolic potential, purportedly from the slow-conducting limb of the circuit.

site, and is activated from the basal to apical septum toward the earliest PP site. The relative activation times of the LDP, PP, and local ventricular potential at the LDP recording site to the onset of QRS complex are -50.4 ± 18.9 , -15.2 ± 9.6 , and 3.0 ± 13.3 milliseconds, respectively (see Fig. 24-3). The earliest ventricular activation site (exit) during VT is identified at the posteroapical septum and is more apical in the septum than the region with LDP.^{3,4}

VENTRICULAR ACTIVATION SEQUENCE

During NSR, conduction propagates anterogradely (proximal to distal or basal to apical) and rapidly down the LPF, generating an anterograde PP followed by ventricular activation (see Fig. 24-1). In parallel, the impulse slowly conducts anterogradely over the abnormal Purkinje tissue, and such slow conduction, block in the proximal segment, or both allow the anterograde wavefront traveling rapidly over the LPF to conduct retrogradely up the slow pathway, resulting in fusion of delayed (late) ascending and descending potentials that follow or are buried in local ventricular depolarization, which likely represent the LDPs recorded during VT (see Fig. 24-4). Those late potentials have been found only

in patients with idiopathic LV VT and not in control subjects, and have been recorded in the midinferior septum within or contiguous to the LPF.³

During ventricular pacing, the LPF is activated retrogradely, generating a retrograde PP. In parallel, the impulse produces bidirectional activation of the abnormal Purkinje pathway in a manner similar, but in reverse direction, to that during NSR.²

During VT, activation propagates anterogradely (from the basal to the apical site of the LV septum) over the abnormal Purkinje tissue, giving rise to an anterograde LDP; hence, the earliest LDP is seen in the basal septum and the latest LDP is seen in the apical septum. The reentrant wavefront then turns around in the lower third of the septum and activates the fast conduction Purkinje fibers along the LPF, generating a retrograde PP. Subsequently, the wavefront propagates anterogradely down the septum to exit the reentrant circuit and activate the posterior septal myocardium, and retrogradely over the LPF from apical to basal septum, forming the retrograde limb of the tachycardia, with an upper turnaround point of the reentrant wavefront occurring over a zone of slow conduction (between LDP and PP areas) located close to the main trunk of the LB (see Fig. 24-1).^{3,5}

For a VES to initiate VT, retrograde block has to occur in the abnormal Purkinje tissue with retrograde conduction of the paced wavefront up the LPF (generating a retrograde PP) with some delay, and then down the abnormal Purkinje tissue (generating an anterograde LDP) to initiate reentry. Thus, during VT, the LDP precedes PP, which in turn precedes ventricular activation.

RESPONSE TO PHARMACOLOGICAL AND PHYSIOLOGICAL MANEUVERS

Intravenous verapamil slows the rate of VT progressively and then terminates it. Diltiazem is equally effective. Nonsustained VT may continue to occur for a while after termination. VT is usually rendered noninducible after verapamil. Verapamil significantly prolongs the VT CL, LDP-PP interval, and PP-LDP interval during VT. However, the interval from PP to the onset of the QRS complex remains unchanged.^{3,7}

Response of VT to lidocaine, procainamide, amiodarone, sotalol, and propranolol is less consistent, and these drugs are usually ineffective. Carotid sinus massage and Valsalva maneuvers have no effect on the VT. Fascicular VT is generally unresponsive to adenosine; however, when catecholamine stimulation (isoproterenol infusion) is required for the initiation of VT, the VT can become adenosine-sensitive.

Diagnostic Maneuvers during Tachycardia

ENTRAINMENT

Ventricular pacing can entrain the VT with antidromic or orthodromic capture.³ Manifest entrainment is more frequently achieved when pacing is performed from the right ventricular outflow tract (RVOT), because the RVOT is closer to the entrance site of the area of slow conduction in the reentrant circuit, located near the base of the LV septum. On the other hand, pacing from the RV apex is less likely to demonstrate entrainment and, when it does, it is unlikely to demonstrate manifest fusion because of the distance from the entrance site of the circuit and because of the narrow excitable gap of the reentrant circuit. During entrainment, the LDP (representing the entrance of the circuit) is orthodromically captured and, as the pacing rate is increased, the LDP-PP interval (representing an area of decremental Purkinje tissue) prolongs, whereas the stimulus-to-LDP and PP-QRS intervals typically remain constant. Entrainment can usually be demonstrated with ventricular pacing at a CL approximately 10 to 30 milliseconds shorter than the tachycardia CL.^{2,3} Analysis of entrainment from different ventricular sites helps identify the relationship of those sites to the VT circuit (Table 24-1).

RESETTING

VT can be reset by VES, with an increasing or mixed resetting response (characteristic of reentrant circuit with an excitable gap).³

TERMINATION

VT can be reproducibly terminated with programmed electrical stimulation.³

Exclusion of Other Arrhythmia Mechanisms

The differential diagnosis of idiopathic LV VT should include interfascicular VT, which has several characteristic features: (1) bifascicular block QRS morphology during VT, which is identical to that during NSR; (2) reversal of activation sequence of the HB and LB during VT; and (3) spontaneous oscillations in the VT CL caused by changes in the LB-LB interval that precede and drive the VT CL. Interfascicular VT terminates with VES or RF ablation that produces block in LAF or LPF.

TABLE 24-1 Entrainment Mapping of Verapamil-Sensitive Left Ventricle Ventricular Tachycardia

Pacing from Sites Outside VT Circuit (RV Apex or RVOT)

- Manifest ventricular fusion on the surface ECG (fixed fusion at a single pacing CL and progressive fusion on progressively shorter pacing CLs) or fully paced QRS morphology
- PPI – tachycardia CL >30 msec
- Interval between stimulus artifact to onset of QRS on surface ECG is greater than the interval between local ventricular electrogram on pacing lead to onset of QRS on surface ECG

Pacing from Sites Inside VT Circuit (Posteroinferior LV Septum)

- Manifest ventricular fusion on the surface ECG (fixed fusion at a single pacing CL and progressive fusion on progressively shorter pacing CLs)
- PPI – tachycardia CL <30 msec
- Interval between stimulus artifact to onset of QRS on surface ECG equals the interval between local ventricular electrogram on pacing lead to onset of QRS on surface ECG (± 20 msec)

Pacing from Protected Isthmus Inside VT Circuit (Site Where Both PP and LDP Are Recorded)

- Concealed ventricular fusion (i.e., paced QRS is identical to the VT QRS)
- PPI – tachycardia CL <30 msec
- Interval between stimulus artifact to onset of QRS on surface ECG equals the interval between PP to onset of QRS on surface ECG (± 20 msec)
- Stimulus-to-LDP interval is long and LDP is orthodromically captured from proximal to distal sites during activation

CL = cycle length; LDP = late diastolic potential; LV = left ventricle; PP = Purkinje potential; PPI = post-pacing interval; RV = right ventricle; RVOT = right ventricular outflow tract; VT = ventricular tachycardia.

When fascicular VT is associated with 1:1 ventriculoatrial (VA) conduction, and because of its responsiveness to verapamil and inducibility by atrial pacing, it can be misdiagnosed as supraventricular tachycardia (SVT) with bifascicular block aberrancy. The His bundle–ventricular (HV) interval during SVT with aberrancy is equal to or slightly longer than that during NSR. In contrast, the HV interval during fascicular VT is negative or shorter than that during NSR. Furthermore, the HB is activated in an anterograde direction during SVT but in a retrograde direction during fascicular VT.

Recently, VT originating from the LV papillary muscles in patients with or without prior myocardial infarction has been described. In contrast to fascicular VT, papillary muscle VT has a broader QRS complex (150 ± 15 milliseconds versus 127 ± 11 milliseconds). Additionally, all fascicular VTs, versus none of papillary muscle VTs, had an rsR' pattern in lead V₁. An R/S ratio less than or equal to 1 in lead V₆ for VTs in the LV anterolateral region also suggests papillary muscle VT.⁸ Furthermore, spontaneous variations in QRS morphology occur relatively frequently during VTs originating from the LV papillary muscles, a feature that can help distinguish these VTs from LV fascicular VT; the latter being a reentrant tachycardia with a consistent QRS morphology.⁹⁻¹¹

Ablation

Target of Ablation

Definition of the appropriate ablation target has evolved with better understanding of the anatomical substrate of the VT. Initially, the ablation target site was defined as the site where the best pace map and the earliest endocardial ventricular activation time could be obtained during VT. Subsequently, in combination with pace mapping, the earliest PP potential preceding QRS onset during VT (considered to be the lower turnaround point of the reentrant circuit) in the posterior third of the LV septum was reported to be a marker for successful ablation. Successful ablation is achieved at sites where PP is recorded 30 to 40 milliseconds before QRS onset (Fig. 24-5). Entrainment mapping at this location helps confirm the relationship to the reentrant circuit. Of note, this area is located

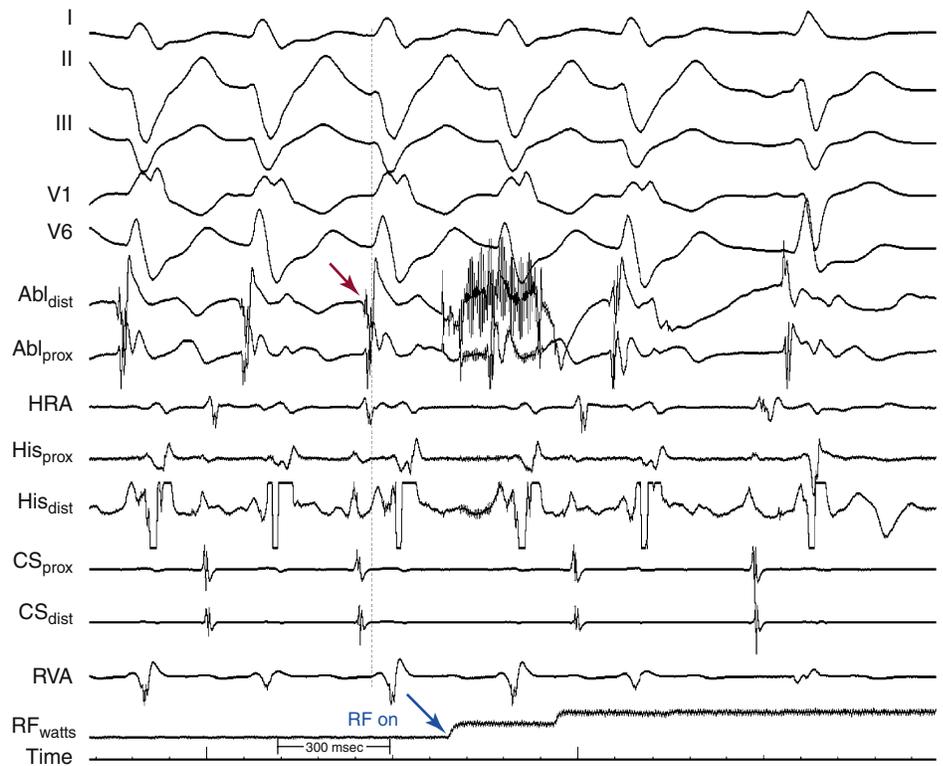

FIGURE 24-5 Ablation of idiopathic (fascicular) left ventricular tachycardia (LVVT). Radiofrequency (RF) delivery is begun (blue arrow) at the site of the diastolic Purkinje potential during idiopathic LVVT. Within less than 1 second, VT terminates. The red arrow indicates probable Purkinje potentials.

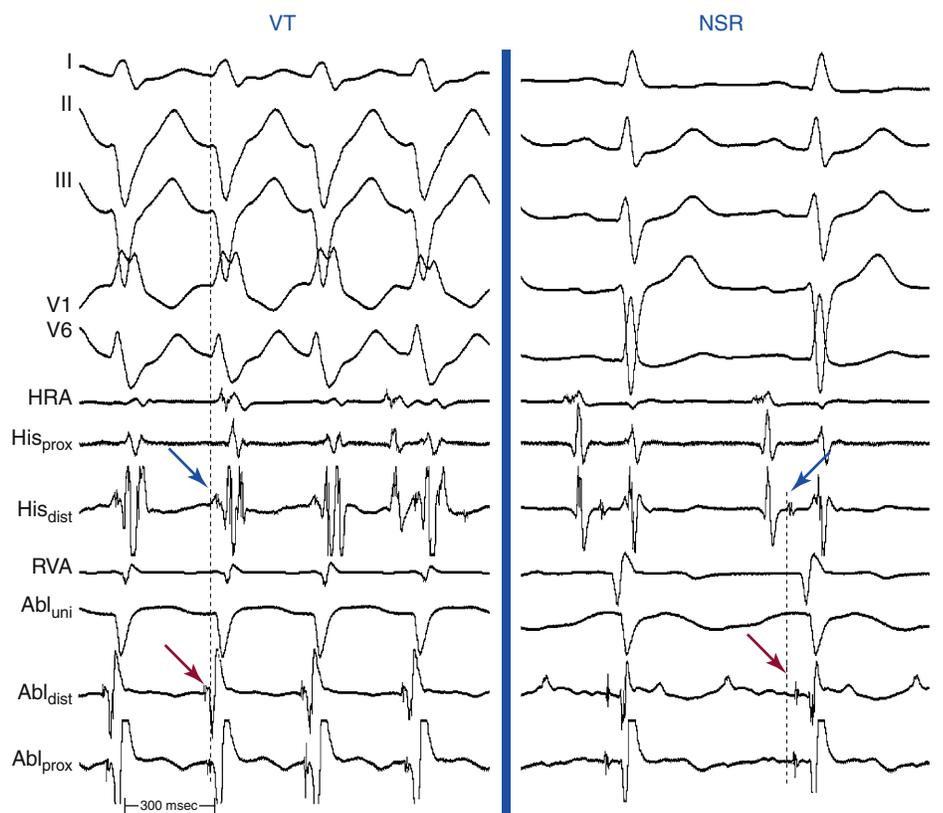

FIGURE 24-6 Ablation of idiopathic (fascicular) left ventricular tachycardia (LV VT). Shown are recordings during VT (left) and normal sinus rhythm (NSR; right) from a successful ablation site for idiopathic LV VT. Red arrows indicate probable Purkinje potentials, activated distal-to-proximal during VT and proximal-to-distal during sinus. Blue arrows show His potentials, occurring after QRS onset during VT.

more basally than the LV area that shows the earliest ventricular activation during VT (the exit point of the circuit into the ventricular septum), suggesting that the location of the earliest ventricular activation during tachycardia is not an ideal site for ablation of this arrhythmia.

Later on, the LDP recorded during VT, which likely reflects the excitation within the critical slow conduction area participating in

the reentry circuit, was reported to be a useful marker in guiding successful ablation.^{3,4}

Currently, ablation is targeted to a site over the middle or inferoapical portion of the LV septum where the earliest PP and LDP are recorded (Fig. 24-6). Verification of these sites can be achieved with entrainment mapping demonstrating concealed fusion and progressive prolongation of the LDP-PP interval with increasing

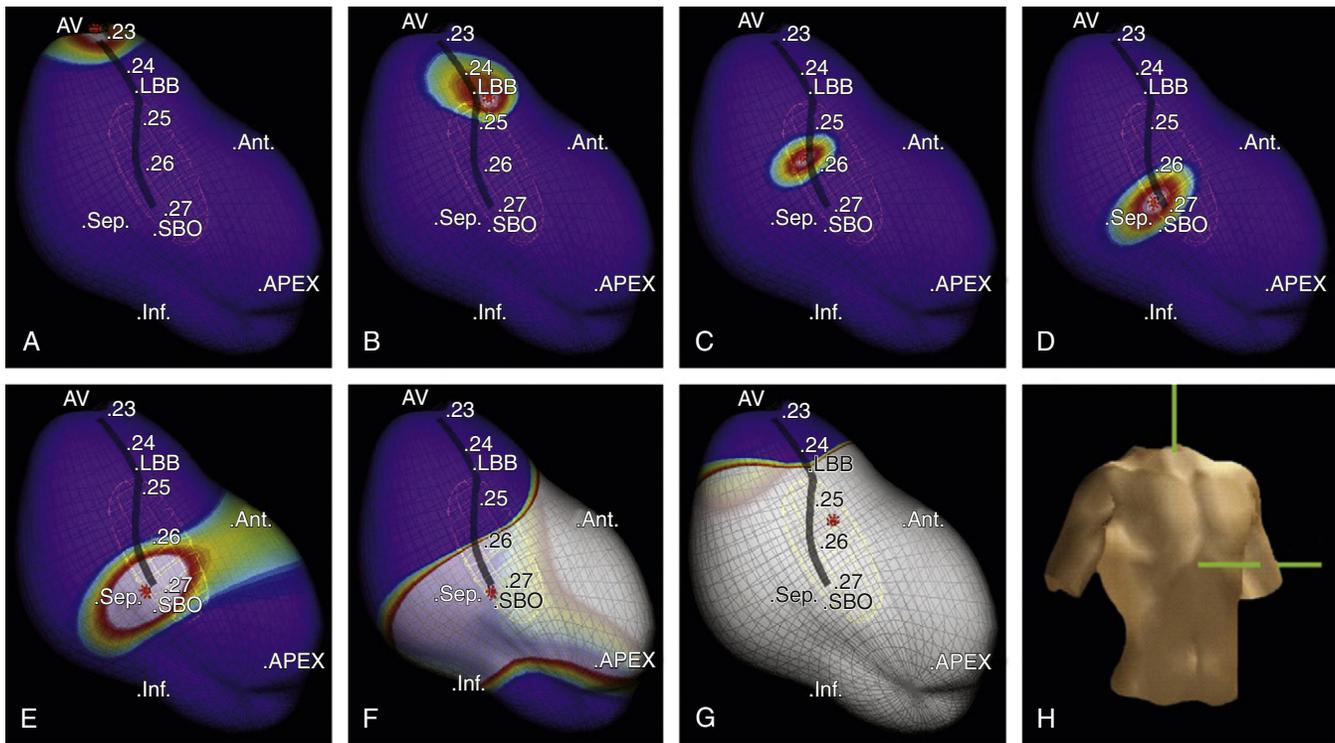

FIGURE 24-7 Noncontact mapping during normal sinus rhythm (NSR). Shown is an animated propagation map of the left ventricle (LV) from frames A to G in the right anterior oblique view during NSR. Note that the sinus activation propagates down from the His bundle (AV) to the left bundle branch (LBB), and then bifurcates into left anterior and left posterior fascicles before the entire LV is finally activated. The activation breakout point is at the midposterior septum and marked sinus breakout point (SBO) on the map. The thick black line indicates the propagation direction of the wavefronts from AV down to SBO. Ant = anterior; Inf = inferior; Sep = septal. (From Chen M, Yang B, Zou J, et al: Non-contact mapping and linear ablation of the left posterior fascicle during sinus rhythm in the treatment of idiopathic left ventricular tachycardia, *Europace* 7:138, 2005.)

pace rate. In addition, pressure applied to the catheter tip at the LDP region occasionally results in VT termination with conduction block between LDP and PP. Pace mapping can also be used as an adjunct to verify this site, but because of poor sensitivity, is less helpful than in focal VTs.

It is important to recognize that successful ablation is not necessarily predicted by targeting the earliest (most proximal) LDP. Success can actually be achieved by ablating an LDP distal to the earliest potential. This approach helps reduce the risk of damaging the trunk of the LB. If such an LDP cannot be detected, the site with the earliest ventricular activation with a fused PP may then be targeted.³

Ablation Technique

It is helpful to initiate the VT reproducibly prior to entering the LV; if VT is not inducible, LV mapping may not be warranted. If VT can be readily initiated before but not after entering the LV, a portion of the circuit has probably been traumatized and one should wait several minutes and try to reinitiate before mapping any further.

Ablation is performed through the retrograde transaortic approach using a deflectable 4-mm-tip catheter. The catheter is advanced by prolapsing into the LV and directed to the LV septum. Mapping is initially concentrated at the inferoapical septum. If an ideal site is not found in this area, the ablation catheter is moved upward to the midseptal area. It is important to move the catheter slowly and carefully to avoid mechanical trauma to the circuit. Endocardial activation mapping and entrainment mapping are performed to define the target site of ablation.

Once the target site is identified, a test RF current is applied for 20 seconds with an initial power of 20 to 35 W, targeting a temperature of 60°C.^{3,12} If the VT is terminated or slowed within 15 seconds, additional current is applied for another 60 to 120 seconds and power is increased up to 40 W to reach the target temperature

if necessary. If the test RF current is ineffective despite adequate catheter contact, ablation should be directed to another site after additional mapping. This approach helps limit RF damage to the area of LPF and LB.

Successful ablation sites are often associated with progressive prolongation of the LDP-PP interval, with termination of VT coincident with conduction block between the two potentials.³ Rarely, if ever, does one need more than 50 W or the use of irrigated or large-tip electrodes to ablate these VTs successfully. After successful ablation, the LDP appears after the QRS complex during sinus rhythm.

Endpoints of Ablation

Successful ablation is defined as the lack of inducibility of VT, with and without isoproterenol administration (using the best method for induction documented before ablation), at least 30 minutes after ablation.

Outcome

The acute success rate is more than 90%, even when different mapping methods are used. The recurrence rate is approximately 7% to 10%, with most recurrences occurring in the first 24 to 48 hours after the ablation procedure. Complications are rare and include different degrees of fascicular block, LBBB, cardiac tamponade, aortic regurgitation, and mitral regurgitation caused by torn chordae that may result from entrapment of the ablation catheter in a chorda of the mitral leaflet.¹²

Ablation of Noninducible Ventricular Tachycardia

Conventional activation mapping, guided by either the earliest PP or the LDP, although effective, depends on the inducibility and

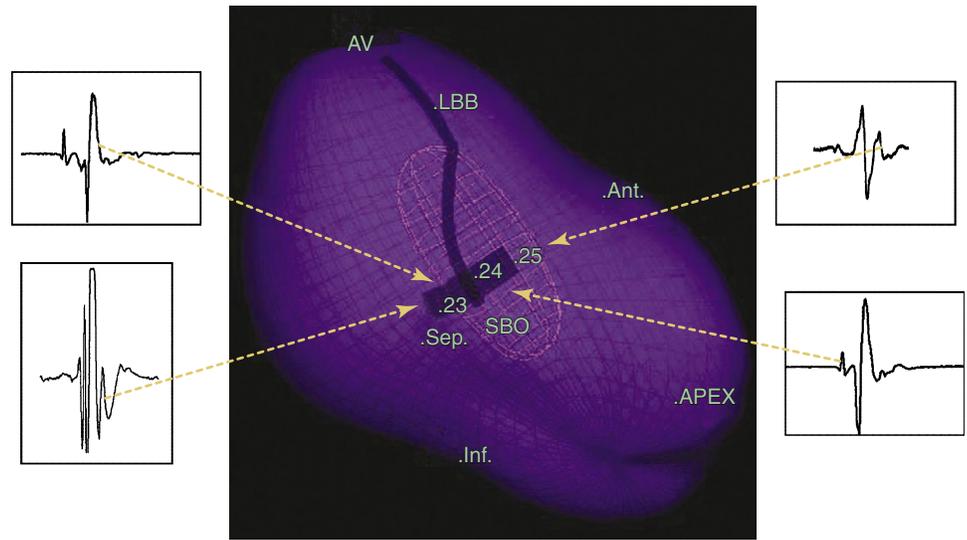

FIGURE 24-8 Noncontact mapping during normal sinus rhythm (NSR). A linear ablation lesion was created perpendicular to the wavefront propagation direction and 1 cm above the sinus breakout point (SBO). Both the starting and ending lesion points have a small Purkinje potential preceding the ventricular activation. Ant = anterior; AV = His recording area; Inf = inferior; LBB = left bundle branch; Sep = septal. (From Chen M, Yang B, Zou J, et al: Non-contact mapping and linear ablation of the left posterior fascicle during sinus rhythm in the treatment of idiopathic left ventricular tachycardia, *Europace* 7:138, 2005.)

endurance of fascicular VT. However, the VT may not be inducible in the EP laboratory. Additionally, the critical substrate of LV VT is amenable to mechanical injury because of catheter manipulation, which will render the tachycardia noninducible. In these cases, substrate mapping and ablation during NSR have been suggested to eradicate LV VT.

Two approaches have been used for substrate mapping during sinus rhythm: (1) ablation of the site where the earliest LDP is recorded during sinus rhythm (occurring 15 to 45 milliseconds after the PP). The PP-QRS interval at the successful ablation site with LDP is relatively short (mean, 13 ± 8 milliseconds); and (2) anatomical linear ablation to transect the involved middle to distal LPF and destroy the substrate of LV VT.^{3,13}

The EnSite 3000 noncontact mapping system (St. Jude Medical, St. Paul, Minn.) has been used to identify the sinus breakout point (i.e., the LV site with the earliest local activation during NSR), and that point has been used to guide linear ablation perpendicular to the conduction direction of LPF.^{13,14} Particular attention is paid to the geometric detail in the areas of the HB, septum, and apex of the LV. Once the ventricular geometry has been generated, the system can then calculate electrograms from more than 3000 endocardial points simultaneously by reconstructing far-field signals to create the isopotential map of sinus rhythm using a single cardiac cycle. The HB, LB, fascicles, and sinus breakout point are tagged as special landmarks in the geometry. The sinus breakout point is located in the midposterior septum and the local virtual electrogram presents with QS morphology (Fig. 24-7). Virtual electrograms at points from the HB down to the sinus breakout point show a sharp, low-amplitude potential preceding the ventricular potential. The interval between these two potentials becomes progressively shorter as the activation propagates from the HB to the sinus breakout point, until the two potentials finally fuse together at the sinus breakout point. Virtual electrograms recorded from the points placed in the pattern of block above the sinus breakout point show the whole Purkinje network in the LPF area. An ablation line is created perpendicular to the activation direction of LPF and 1 cm above the sinus breakout point (Fig. 24-8). A small Purkinje potential preceding the ventricular activation is observed at its starting and ending

points (see Fig. 24-8). The mean length of the deployed line is usually 2.0 ± 0.4 cm, requiring a mean of 5.5 ± 1.6 RF applications. A significant rightward shift of the QRS axis in the surface limb leads can be observed after the ablation procedure.^{13,14}

Pathophysiology

Cardiomyopathies are traditionally defined on the basis of structural and functional phenotypes, notably dilated, hypertrophic, and restrictive. The dilated cardiomyopathy (CMP) phenotype is the most common and is often viewed as a “final common pathway” of numerous types of cardiac injuries.

The diagnosis of nonischemic dilated CMP is established by the absence of significant (>75% stenosis) coronary artery disease and prior myocardial infarction (MI). Nonischemic dilated CMP is not a single disease entity. Valvular heart disease, hypertension, sarcoidosis, amyloidosis, Chagas disease, alcohol abuse, infections, and pregnancy, among others, need to be considered as possible etiologies. An underlying etiology for adult dilated CMP is found in only 50% of patients. The remaining 50% are considered idiopathic. Idiopathic dilated CMP is characterized by an increase in myocardial mass and a reduction in ventricular wall thickness. The heart assumes a globular shape, and there is a pronounced ventricular chamber dilation and atrial enlargement.¹

There is increasing evidence that a significant portion (35%) of idiopathic dilated CMP is secondary to familial forms of dilated CMP. Familial dilated CMP is clinically and genetically heterogeneous and it exhibits various patterns of hereditary transmission, including autosomal dominant with variable penetrance (most common, accounting for about 90% of cases), X-linked (5% to 10%), autosomal recessive (rare), and maternal transmission through mitochondrial DNA (rare).

To date, 33 genes have been linked to nonsyndromic familial dilated CMP. Notably, the frequencies of dilated CMP mutations in any one gene are low (<1% to 8%), and a genetic cause is identified in only 30% to 35% of familial dilated CMP cases. Although usually nonsyndromic, dilated CMP can be included in syndromic disease involving various organ systems, most commonly skeletal muscle disease (muscular dystrophy).²

Mutations in the genes responsible for sarcomere and cytoskeletal protein synthesis have been identified as the cause of familial dilated CMP, and several hypotheses have been put forward to explain the etiology and pathology of the disease. Several gene mutations have been identified in the autosomal form of familial dilated CMP, including those encoding Z-disc proteins (alpha-actin-2, muscle LIM protein, titin-cap), costameres, adherens junctions, desmosomes, intermediate filaments, sarcomere proteins (cardiac alpha-actin, beta-myosin heavy chain, cardiac troponin T, alpha-tropomyosin, titin), sarcoplasmic reticulum proteins (phospho-lamban), and ion channel (SUR2A). Of note, different mutations in the sarcomere genes can cause hypertrophic CMP. Mutations in lamin A/C also cause Emery-Dreifuss muscular

dystrophy. Autosomal dominant dilated CMP can exhibit either a pure CMP phenotype or dilated CMP with cardiac conduction system disease. X-linked familial CMP is usually caused by defects in the dystrophin gene and is typically associated with skeletal muscle involvement (Duchenne and Becker muscular dystrophy). The infantile form of X-linked dilated CMP or Barth syndrome typically affects male infants (characterized by neutropenia and growth retardation).

As compared with sporadic cases of idiopathic dilated CMP, familial CMP patients are younger and tend to have higher left ventricular ejection fraction (LVEF) and more significant myocardial fibrosis. In patients with idiopathic dilated CMP, the proposed diagnostic criteria for the familial form of the disease are the existence of two or more affected family members, or of one first-degree relative with a documented history of unexplained sudden death before 35 years of age. In most cases, proof of a genetic cause of a CMP has a limited impact on the treatment of the index patient, but can have important implications in regard to family screening and genetic counseling. Dilated CMP in patients who do not have a known family history may also have a genetic basis.³

In contrast to ischemic heart disease, the electrophysiological (EP) substrate for sustained monomorphic ventricular tachycardia (VT) in patients with nonischemic dilated CMP is not clearly defined. Although bundle branch reentry (BBR) VT is identified as the VT mechanism in a significant percentage of patients with monomorphic VT in the setting of nonischemic CMP, the majority (80%) of VTs appear to originate from the myocardium and are due to scar-related reentry rather than BBR.⁴ BBR VT is discussed separately in [Chapter 26](#).

On the other hand, premature ventricular complexes (PVCs) and nonsustained VTs induced by programmed electrical stimulation or occurring spontaneously in patients with end-stage idiopathic dilated CMP initiate primarily in the subendocardium by a focal mechanism without evidence of macroreentry. The nature of the focal mechanism remains unknown; triggered activity arising from early or delayed afterdepolarizations seems to be more likely than microreentry.

Myocardial fibrosis, myocyte disarray, and membrane abnormalities are important factors in the substrate causing VT in patients with dilated CMP. Sustained VT is associated with more extensive myocardial fibrosis and nonuniform anisotropy involving both the endocardium and epicardium, compared with patients without sustained reentry. The reentry circuits are typically associated with regions of low-voltage electrograms, consistent with scar. Catheter mapping studies of patients with nonischemic CMP point to reentry around scar deep in the myocardium, near the ventricular base and in the perivalvular region, as the underlying mechanism for VT.

Studies of explanted hearts with dilated nonischemic CMP have found inexcitable fibrosis creating regions of conduction block and surviving myocardium providing the substrate for potential reentry circuits. Slow conduction through muscle bundles separated by interstitial fibrosis can cause a zigzag path and promote reentry. Furthermore, patients with nonischemic CMP and predominance of scar distribution involving 26% to 75% of wall thickness (as quantified by magnetic resonance [MR] imaging) are more likely to have inducible VT. Delayed-enhancement MR imaging typically reveals nontransmural scar areas often distributed in the basal portion of the ventricular free wall or basal to midportion of the septum. Sustained VTs are observed more frequently in patients having a greater volume of hyperenhanced areas and greater number of hyperenhanced segments, and nontransmural scar tissue was present at the VT circuit exit site in the majority of patients.^{5,6}

The cause of fibrosis in CMP is not well defined. Scattered regions of replacement fibrosis are commonly seen at autopsy, but confluent regions of scar are not common. The unique propensity for abnormal basal endocardial voltage and VT site of origin in patients with nonischemic CMP remains unexplained. Low-voltage areas have also been observed during electroanatomical mapping in patients with focal VT and BBR VT, although the scar areas appeared to be smaller.

The scar and fibrosis resulting from nonischemic etiologies are distinctly different from post-MI scar; hence, the reentrant circuit may have different anatomical and functional properties that affect propagation. Compared with post-MI VT, the scar tends to be smaller and less confluent, the total number of the transmural scar segments is significantly smaller, and with less endocardial involvement in nonischemic CMP.⁴ Whereas ischemia produces a predictable wavefront of necrosis progressing from subendocardium to epicardium (and scar areas larger endocardially than epicardially), usually confined to a specific coronary vascular territory, scars in nonischemic CMP have been shown to have a predilection for the midmyocardium and epicardium. In contrast to the dense scar with isolated surviving myocardial bundles, scar in nonischemic CMP is patchy and may have fewer fixed boundaries and protected channels or isthmuses, which can alter the extent of local conduction slowing.⁷

Nonetheless, several similarities of the arrhythmia substrate exist in myocardial reentry VT in patients with dilated nonischemic CMP compared with that in patients with previous MI. Low-voltage areas are observed in all patients, and the regions of scar are frequently adjacent to a valve annulus, as is often the case in VT after inferior wall MI. The annulus often seems to form a border for an isthmus in the reentry path, which suggests the formation of a long channel, or isthmus, along an annulus contributing to the formation of reentry circuits that can support VT.

Clinical Considerations

Epidemiology

The incidence of nonischemic dilated CMP in adults in Western countries varies from 5 to 8 per 100,000 person-years, with a prevalence of 36 to 40 per 100,000 individuals. The 5-year mortality for dilated CMP has been estimated at 20%, with sudden cardiac death (SCD) accounting for approximately 30% (8% to 51%) of deaths. Nonetheless, nonischemic dilated CMP patients may represent a low arrhythmic death risk subgroup among all CMP patients.

Ventricular arrhythmias, both symptomatic and asymptomatic, are common in patients with nonischemic dilated CMP. Nonsustained VT can be observed in 30% to 50% of patients, but its incidence decreases significantly after optimization of medical treatment.⁸ However, syncope and SCD are infrequent initial manifestations of the disease. The incidence of SCD is highest among patients with indicators of more advanced cardiac disease who are also at highest risk of all-cause mortality. Although VT, ventricular fibrillation (VF), or both are considered the most common mechanism of SCD, bradycardia, pulmonary embolism,

electromechanical dissociation, and other causes account for up to 50% of SCDs in patients with advanced heart failure.

Initial Evaluation

Transthoracic echocardiography is the usual modality for diagnosis of dilated CMP. Cardiac stress testing, coronary angiography, or both are typically performed in patients with coronary risk factors. Ambulatory cardiac monitoring is required for patients with symptoms suggestive of arrhythmias, but not for screening purposes. Cardiac MR is a useful tool for detecting and assessing the characteristics and heterogeneous distribution of scar tissue in its composition of the wall layer, as well as its precise location within the ventricle. The location of scar tissue often corresponds to areas critical for VT circuits in these patients. Unfortunately, most patients presenting with appropriate implantable cardioverter-defibrillator (ICD) shocks currently cannot undergo MR imaging because of the device. New ICD technology will eliminate that restriction in the future.

Risk Stratification

Risk stratification is difficult in dilated CMP. Although SCD occurs less frequently in patients with less advanced cardiac disease, the proportion of SCD to all-cause death is higher in this group.

Predictors of overall outcome (such as LVEF, end-diastolic LV volume, older age, hyponatremia, pulmonary capillary wedge pressure, systemic hypotension, atrial fibrillation) also predict SCD and generally reflect severity of disease. Unfortunately, they do not specifically predict arrhythmic death and are not useful in the patient with less severe disease.

LVEF has remained the most studied and the most powerful predictor and is the primary method currently used in clinical decisions for the prevention of SCD in patients with heart failure. Depressed LVEF is also a powerful predictor of cardiac mortality. On the basis of the results of large clinical trials, in clinical practice an LVEF of 35% or less has become the primary criterion used for prophylactic ICD placement. The use of LVEF as the predominant risk stratifier has serious limitations, however, because LVEF lacks sensitivity for prediction of SCD. Even a low LVEF (<20%) may not have high positive predictive value for SCD. Clinical factors such as functional class, history of heart failure, nonsustained VT, age, LV conduction abnormalities, inducible sustained VT, and atrial fibrillation influence arrhythmic death and total mortality risk and, consequently, potentially influence the prognostic value of a depressed LVEF. Therefore, patients with an LVEF greater than 30% and other risk factors may have a higher mortality and a higher risk of SCD than those with an LVEF less than 30% but no other risk factors.⁹

Syncope has been associated with a higher risk of SCD regardless of the proven etiology of the syncope, and ICD recipients with syncope receive appropriate shocks at a rate comparable to a secondary prevention cohort.

PVCs and nonsustained VT correlate with the severity of cardiac disease and occur in the majority of patients with severe LV dysfunction. This limits the usefulness of ventricular arrhythmias as risk stratifiers as they would be expected to be sensitive but not specific. Additionally, the presence and characteristics (frequency, length, and rate) of nonsustained VT do not appear to predict increased risk of subsequent life-threatening ventricular arrhythmias in patients with severe LV impairment receiving optimal medical treatment. Nevertheless, it has been suggested that the presence of nonsustained VT may be more specific in the individual with better LV systolic function. Nonsustained VT significantly increases the risk of malignant ventricular arrhythmias in the subgroup with an LVEF greater than 35%. In these patients, even without worsening LV systolic function and symptoms, survival free from malignant ventricular arrhythmias is similar to that of patients with an LVEF less than 35% with or without nonsustained VT.⁸

Cardiac MR can be used to evaluate the presence and magnitude of nontransmural scar tissue. Patients with nonischemic CMP and sustained VT typically have a greater volume and number of hyperenhanced (scar) areas compared with those without sustained VT.⁵

CH
25

Patients typically have wide QRS complexes during the baseline rhythm, often with left bundle branch block or a nonspecific intraventricular conduction defect. Prolonged QRS duration has been associated with increased mortality in heart failure patients, but association with SCD has not been proven. Recently, fragmentation of the QRS complex on the 12-lead surface electrocardiogram (ECG) (filter range, 0.15 to 100 Hz; AC filter, 60 Hz, 25 mm/sec, 10 mm/mV) has been found to potentially predict increased risk of appropriate ICD therapies as well as a higher combined endpoint of ICD therapy and mortality in nonischemic CMP patients who received an ICD for primary and secondary prevention. The usefulness of this parameter needs further evaluation.¹⁰ During VT, QRS complexes are typically very wide and fragmented; most patients have multiple QRS morphologies of VT (Fig. 25-1).¹¹

Prolongation of the QT interval, QT dispersion, and QT variability have had mixed predictive results with limited clinical applicability at present. Furthermore, studies evaluating the association of abnormal heart rate turbulence and reduced heart rate variability and SCD in heart failure patients have had conflicting results.⁹

Microvolt T-wave alternans has relatively modest (0.22) positive predictive value for SCD in patients with dilated CMP. Previous studies suggested a high negative predictive value for primary prevention of SCD, and T-wave alternans was hypothesized to be a useful tool to differentiate between patients who would benefit from ICD implantation and those who would not. However, results from recent studies failed to support this hypothesis and strongly suggested that a negative microvolt T-wave alternans result should not be used to withhold ICD therapy among patients who meet standard criteria.⁹

EP testing plays a minor role in risk stratification because of low VT inducibility, low reproducibility, and poor predictive value of induced VT. Although induction of VT by EP testing has been shown to predict SCD, unfortunately failure to induce VT misses most individuals destined to die suddenly.¹

Principles of Management

PHARMACOLOGICAL THERAPY

Drug therapy, such as beta blockers and angiotensin-converting enzyme inhibitors, improves overall mortality in patients with heart failure and reduces the risk of SCD. In contrast, the use of antiarrhythmic drugs for primary prevention in patients with nonischemic CMP does not improve survival and is not recommended.¹

In patients with symptomatic ventricular arrhythmias, amiodarone is generally the preferred antiarrhythmic agent because of the absence of significant negative hemodynamic effects and low proarrhythmic potential, although controlled comparative trials of drugs are not available. Antiarrhythmic drug therapy can help improve quality of life in ICD patients receiving frequent appropriate shocks. Although amiodarone can potentially improve mortality and reduce the incidence of SCD in patients with nonischemic dilated CMP, it is inferior to ICD therapy for secondary prevention of VT and VF.^{1,12}

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

The benefit of ICD therapy in secondary prevention of SCD in nonischemic dilated CMP has been well established and is superior to amiodarone or any other drug therapy. ICD implantation is recommended in patients with prior cardiac arrest or sustained VT, even in those undergoing catheter ablation of the VT or responding to antiarrhythmic therapy.

On the other hand, the benefit of ICD treatment for primary prevention of nonischemic CMP is still uncertain. Whereas prophylactic ICD implantation is of significant benefit in ischemic CMP patients, the magnitude of absolute benefit in nonischemic CMP patients is relatively small (1.4% per year; cumulative, 7% over 5 years), but there is a relative risk reduction of 23%, as nonischemic CMP patients have a better prognosis and a lower mortality rate than patients with ischemic CMP.

Vigorous efforts have been made in developing noninvasive stratification methods to identify the subgroup of nonischemic CMP patients at high risk for SCD. However, the best approach to

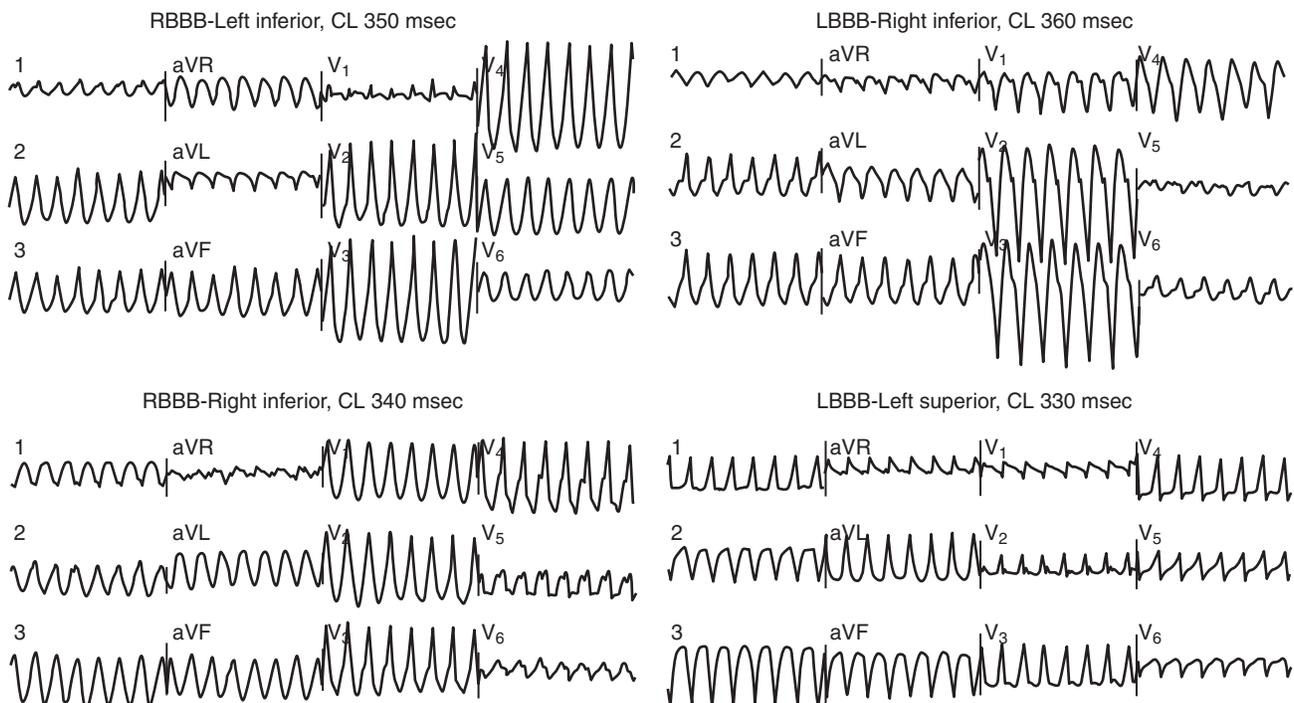

FIGURE 25-1 Surface 12-lead ECGs of different ventricular tachycardia (VT) configurations in a patient with dilated cardiomyopathy. VTs were mapped to sites on the anteroapical, anterobasal, and inferobasal septum. CL = cycle length; LBBB = left bundle branch block; RBBB = right bundle branch block.

identifying patients and the value of various risk stratification tools are not entirely clear. Currently, there is no coherent strategy for intervention based on data integrating the results of these techniques. Many of the identified risk factors are also associated with increased risk for nonsudden death. At the present time, LVEF remains the single most important risk stratification tool to identify individuals with a high risk of SCD, again emphasizing that it predicts all-cause mortality and not necessarily arrhythmic risk. Despite some uncertainty regarding ICD benefit for nonischemic CMP patients without heart failure, regardless of LVEF, the cumulative information available from clinical trials and observational data, in conjunction with opinions of experts in the field, supports prophylactic ICD therapy among the subgroup of patients with nonischemic CMP and LVEF less than 35% who remain in NYHA functional class II or III heart failure on optimal medical therapy.¹²

The appropriate timing to perform ICD implantation in dilated CMP is still controversial. It is important to understand that medical management with angiotensin-converting enzyme inhibitors and beta blockers with or without aldosterone antagonists has proven mortality benefit in these patients and should be optimized as much as possible before ICD placement. Many patients significantly improve their clinical status, and may be excluded as candidates for an ICD after optimization of medical treatment. The most recent European Society of Cardiology (ESC)/American College of Cardiology (ACC)/American Heart Association (AHA) guidelines suggest ICD implantation for primary prevention only in patients with dilated CMP receiving chronic optimal medical therapy. How long it takes to reach optimal medical treatment can be debatable.⁸

CATHETER ABLATION

The most common indication for catheter ablation of VT in patients with nonischemic CMP is frequent ICD discharges (or electrical storm) that are refractory to antiarrhythmic drug therapy. However, because of the future risk of life-threatening VT due to progression of the myopathic process, catheter ablation is not a substitute for an ICD, even when excellent short-term results are achieved.

Additionally, some investigators have suggested consideration of catheter ablation as a therapeutic option in conjunction with ICD implantation in patients with nonischemic CMP who present with a first documented episode of sustained monomorphic VT, with the goal of avoiding future ICD shocks.

Mapping

After exclusion of BBR, mapping of sustained VT in nonischemic CMP employs the approaches for scar-related VT (see Chap. 22). QRS morphology during VT can be used to regionalize the site of origin of the VT. Endocardial activation mapping is performed in patients with stable VTs. Most VTs are localized to the area around the mitral annulus. Entrainment and pace mapping are used to define the relationship of different endocardial sites to the circuit of the VT. Furthermore, the relationship of reentry circuits to regions of scar supports the feasibility of a substrate mapping approach, targeting the abnormal area based on voltage mapping during sinus rhythm, to guide ablation of unstable VT, similar to that described for patients with post-MI VT.

Substrate Mapping

Patients with nonischemic CMP frequently have VTs that are unstable or unsustainable and therefore not approachable by conventional entrainment maneuvers and point-by-point activation mapping. Therefore, mapping during the baseline rhythm (substrate mapping) rather than during VT is of significant value. *Substrate mapping* refers to delineation of the VT substrate based on the identification of abnormal local electrogram configuration (fractionated electrograms, multipotential electrograms, and/or electrograms with isolated delayed components) and the identification of

abnormal local electrogram amplitude during sinus rhythm (voltage mapping). Substrate mapping is also of value in ablation of stable VTs, because it can help focus activation-entrainment mapping efforts on a small region harboring the VT substrate, and therefore help minimize how long the patient is actually in VT.⁴

Isolated potentials during sinus rhythm likely reflect fixed scar tissue. Although large areas of scar are uncommon in patients with nonischemic CMP, extensive interstitial fibrosis is frequently seen histologically. Strands of fibrous tissue may serve as electrical barriers and result in electrogram fragmentation. Isolated potentials can be identified in many, but not all, patients with nonischemic CMP. Additionally, isolated potentials are not present to the same extent in all forms of nonischemic CMP. They could be identified in all patients with ARVD and most patients with cardiac sarcoidosis but not in all patients with idiopathic dilated CMP. Patients in whom isolated potentials can be identified at critical ablation sites appear to have a better short- and mid-term prognosis after catheter ablation than patients in whom the arrhythmogenic substrate is not characterized by isolated potentials.⁸

Electroanatomical Voltage Mapping

Voltage mapping during sinus rhythm (or ventricular pacing) in patients with nonischemic CMP typically demonstrates a modest-sized area of endocardial electrogram abnormalities (ranging from 6% to 48% of the LV endocardial surface, but uncommonly involving more than 25% of the total endocardial surface area) located near the ventricular base, frequently surrounding the aortic and mitral valve region and then extending apically. The amount of dense scar (<0.5 mV) accounts for approximately $27\% \pm 20\%$ (range, 0% to 64%) of the overall abnormal low-voltage endocardial substrate. The exit site of a VT circuit corresponds to these basal electrogram abnormalities. Therefore, voltage mapping during sinus rhythm can be used to guide further mapping techniques (entrainment and pace mapping) and also to guide ablation lesions (especially in patients with unmappable VTs).

Frequently, the VT substrate may be solely or predominantly intramural or epicardial. Because of the frequent presence of an epicardial substrate, some experienced operators use a simultaneous endocardial and epicardial mapping approach.¹³

Activation Mapping

After construction of an endocardial voltage map during the baseline rhythm, VT is induced by programmed ventricular stimulation. The average number of induced VT morphologies is 3 ± 1 per patient, with a range of one to six VTs. Because surface ECG documentation of the presenting arrhythmia is often not available, clinical versus nonclinical VT is difficult to define with certainty. Mapping is therefore directed at all sustained monomorphic VTs induced by programmed stimulation. For hemodynamically tolerated sustained VT, activation mapping is performed to identify sites with early presystolic or mid-diastolic activity (Fig. 25-2).¹⁴

Entrainment Mapping

Entrainment can be demonstrated in most patients with sustained monomorphic VT. The critical isthmus for hemodynamically tolerated VT is defined as the site of entrainment with concealed fusion and a return cycle length equal to the VT cycle length (see Fig. 25-2). For unstable VT, limited entrainment mapping can be feasible with brief induction and termination of the tachycardia.¹⁴

Pace Mapping

Pace mapping has been shown to be an effective corroborative method to regionalize the VT circuit and define potential exit sites along the border zone of any low-voltage region. Pace mapping with the paced QRS morphology mimicking that of VT on the 12-lead ECG can help identify the exit site of the VT circuit.

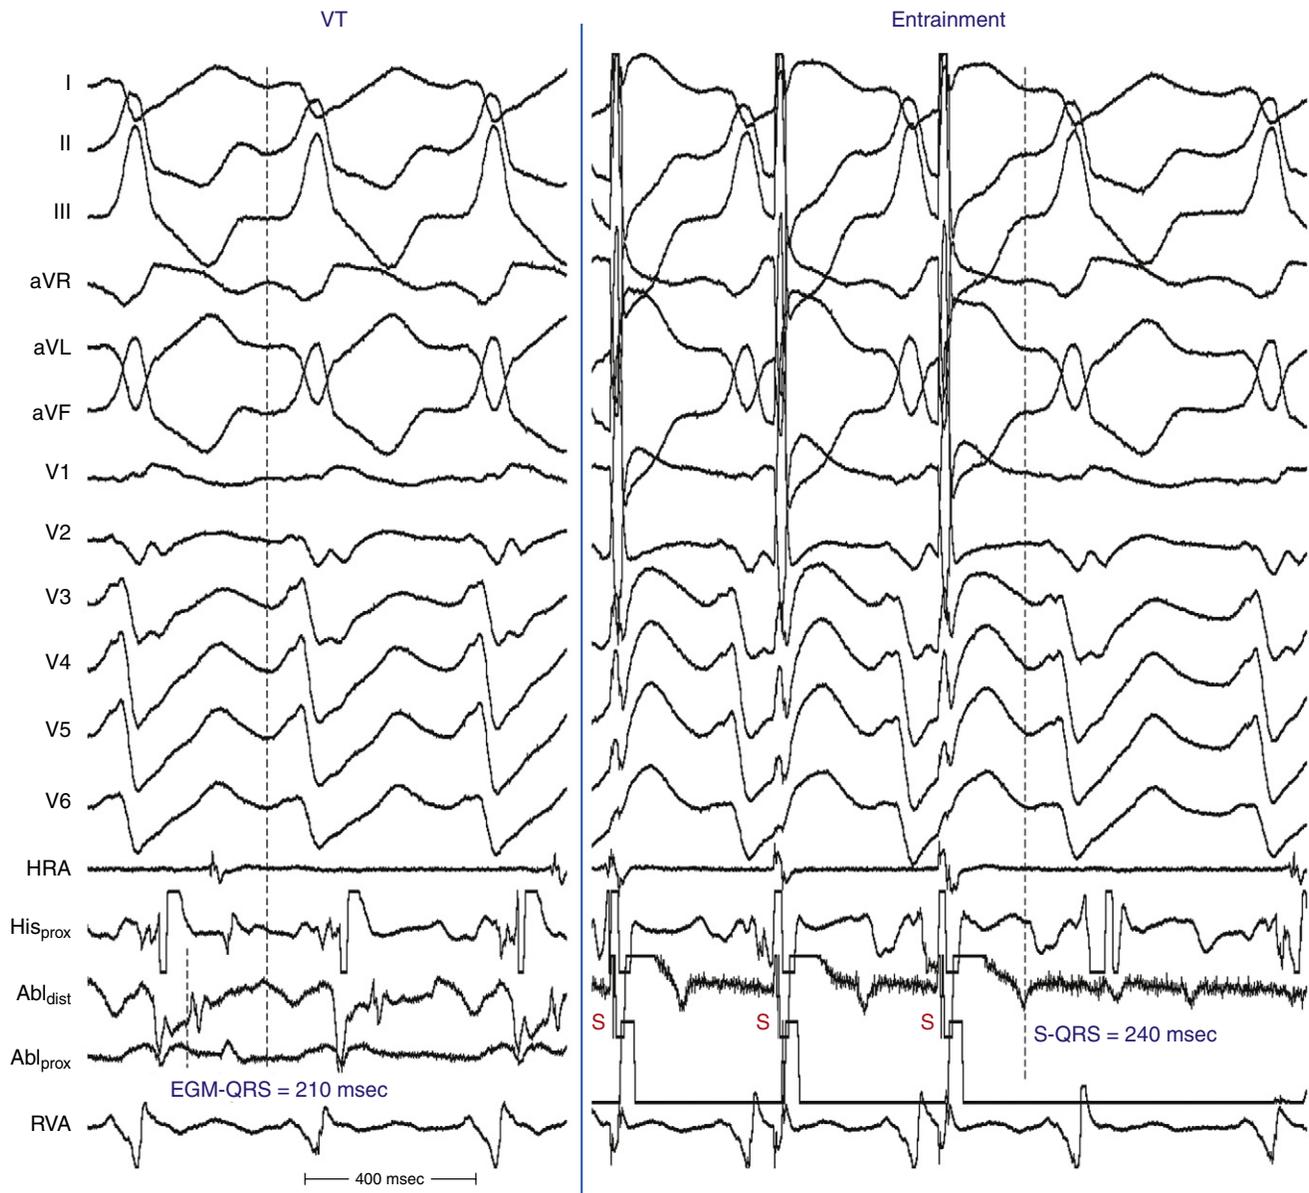

FIGURE 25-2 Entrainment mapping of ventricular tachycardia (VT) in dilated nonischemic cardiomyopathy. VT is shown at left, with the ablation catheter at a site with an early diastolic recording; entrainment at this site has a stimulus-QRS interval similar to that of the electrogram-QRS during VT, with a perfect pace match. Ablation at this site eliminated VT.

Additionally, pace mapping can identify regions of slow conduction with a stimulus-QRS interval (S-QRS) greater than 40 milliseconds and a pace map match consistent with the exit region from an isthmus. For the unmappable VT (because of hemodynamic intolerance, inconsistent induction, altering QRS morphology, and/or nonsustained duration), pace mapping is the predominant mapping technique and is directed to the scar border zone as defined by voltage mapping.¹⁴

Epicardial Mapping

When endocardial mapping and ablation fail, the epicardial approach should be considered. Mapping is initially attempted within the coronary venous system, and if no suitable ablation sites are identified, mapping within the pericardial space is then performed. However, if there are clues on the ECG that suggest an epicardial VT or if there is documentation by MR imaging of largely epicardial scar, performing percutaneous epicardial mapping as the first step (before the administration of heparin) may be considered.¹⁵

The importance of epicardial reentry circuits in CMP has been demonstrated for patients with Chagas disease and, more recently, for patients with dilated CMP unrelated to Chagas disease (see Fig. 27-1). In fact, the epicardial approach may be required in about 30% of patients with nonischemic CMP and VT.¹⁵ Percutaneous epicardial ablation of VT can be guided by activation, entrainment, and pace mapping (see Chap. 27).

Ablation

For patients with mappable VTs, focal ablation targets the critical isthmus of the reentrant circuit as defined by activation, entrainment, and pace mapping techniques. For unmappable VTs, linear ablation lesions are guided by substrate mapping and pace mapping in the scar border zone. Linear lesions are created in regions that cross the border zone and intersect the best pace map site, which approximates the exit site of the VT circuit, similar to strategies described for unmappable post-MI VT (see Chap. 22).

An irrigated-tip ablation catheter is preferred for ablation because it can create larger lesions and also can be used for

radiofrequency (RF) energy delivery within the coronary venous system if needed. The power setting is adjusted to an impedance drop of 10 Ω starting with 30 to 35 W. If RF energy is applied during VT, it is applied for 30 seconds and, if VT does not terminate, the catheter is moved to an alternate site. If VT terminates during the energy application, the application is continued for a total of 120 milliseconds. In the setting of nontolerated VTs, RF energy is delivered for 60 to 120 milliseconds at each site to create ablation lines as guided by substrate mapping.¹⁵

The endpoint of the procedure is noninducibility of all the VTs for which an appropriate target site can be identified. Induction of multiple VTs is not uncommon in patients with dilated CMP. Whether targeting all inducible VTs is superior to targeting only the VTs that have been clinically documented is still unclear.¹⁵

There are only a few single-center reports on acute outcome of VT ablation in the setting of nonischemic CMP, with short- to intermediate-term follow-up in relatively small numbers of patients. Acute success in eliminating inducible VT has varied from 56% to 74% with VT recurrence of 42% to 75% with endocardial ablation. Satisfactory control of VTs previously refractory to medical treatment can be achieved in a majority of patients (60% to 70%) with continuing antiarrhythmic medications, if tolerated. Outcome appears to be somewhat improved with epicardial ablation, but long-term follow-up in a large cohort of patients is lacking.^{13,15}

The success of endocardial ablation of VTs associated with nonischemic CMP is lower than that observed for post-MI VTs. Reentry circuits deep to the endocardium and in the epicardium appear to be a likely explanation. Combined endocardial and epicardial mapping approaches are likely to improve the success of ablation.⁷

Less than 5% of patients have major complications, such as cardiac tamponade, thromboembolic events, or death. Electromechanical dissociation after multiple VT inductions can occur in patients with very low ejection fractions. Limiting the number of inductions of VT may help to prevent this life-threatening complication.¹⁵

Sarcoid Cardiomyopathy

Pathophysiology

Sarcoidosis is an inflammatory noncaseating (necrotizing) granulomatous disease characterized histologically by epithelioid cells and multinucleated giant cells. It is thought to represent a T cell-mediated immune process, but the etiology remains unknown. The main organ systems involved by sarcoidosis are the lungs and thoracic lymph nodes, although virtually no organ systems are spared, including the central nervous system and the skin. Clinical cardiac involvement occurs in approximately 4% to 5% of patients, whereas at autopsy 20% to 25% are found to have some cardiac involvement. Importantly, pulmonary involvement may be minimal or even clinically absent; extensive cardiac sarcoid may be present as the only disease manifestation.

Cardiac sarcoidosis is an infiltrative disease and has a predilection for involving the base of the interventricular septum and cardiac conduction system. Patients can develop various degrees of heart block and tachyarrhythmias. A dilated CMP can occur, with the LV and the interventricular septum primarily involved. Two patterns of regional wall motion abnormalities are frequently observed, involving the basal free wall and the anteroapical septum. Mitral valve abnormalities, papillary muscle dysfunction, LV aneurysm formation, and pericardial effusions are also seen. Cor pulmonale can develop due to chronic pulmonary fibrotic disease.

The inflammatory process in cardiac sarcoidosis often is initiated in the myocardium, creating lesions (granulomas) that then extend to the epicardium, endocardium, or both. Inflammation and fibrosis participate in ventricular arrhythmogenesis, one of the hallmarks of cardiac sarcoidosis. Surviving muscle bundles within scar tissue most likely form the substrate for reentry.¹⁶

Multiple, monomorphic VTs, which are common in cardiac sarcoidosis, are predominantly due to a scar-related, reentrant mechanism.

Low-amplitude and fragmented potentials are recorded both in the endocardial and epicardial regions of both ventricles. The presence of isolated potentials during sinus rhythm at most effective ablation sites suggests that a process similar to post-MI VT is responsible for VTs in patients with cardiac sarcoidosis. The most common site of VT circuit is the peritricuspid area, which is consistent with the predominance of basal involvement of the right ventricular septum in cardiac sarcoidosis. The disease process can be located intramurally and may be reachable by neither the endocardial nor the epicardial approach.^{13,16}

Clinical Considerations

Determining cardiac involvement in patients with sarcoidosis is difficult because granulomas may be present without clinical dysfunction. Patients with cardiac sarcoidosis can present with congestive heart failure, atrioventricular block, supraventricular arrhythmia, and/or ventricular tachyarrhythmia. Importantly, cardiac involvement of sarcoidosis is associated with a mortality rate greater than 40% at 5 years, and many of the deaths are caused by ventricular tachyarrhythmias. Approximately 50% of patients with cardiac sarcoidosis require treatment for ventricular arrhythmias. These patients usually have multiple monomorphic VTs, with either left or right bundle branch block morphology. Arrhythmias can be refractory to a combination of steroids and antiarrhythmic drugs in almost half of the patients. ICD implantation is the mainstay therapy in these patients. Nonetheless, RF catheter ablation as an adjunct therapy to ICD can be effective in eliminating VT or in markedly reducing the VT burden, with success rates in a recently reported registry ranging from 25% to 70%, depending on the location of the reentrant circuit.^{13,16}

EP testing can potentially provide prognostic information in asymptomatic patients with cardiac sarcoidosis. VT inducibility may help to identify those at risk for ventricular arrhythmia. A negative EP study appears to predict a benign course within the first several years after diagnosis. More studies are needed to guide prophylactic ICD therapy in this population.¹⁷

For cardiac sarcoidosis, cardiac biopsy is one of the few ways to confirm the diagnosis, although cardiac MR imaging with delayed enhancement can sometimes detect the granular cells, which resemble clumps of sand or salt grains, and help to regionalize the disease process and indicate whether scarring is located intramurally, epicardially, endocardially, or transmurally.¹⁸ About one-third of the patients with cardiac sarcoidosis have detectable abnormalities visible in an echocardiogram.¹⁶

Chagas Cardiomyopathy

Pathophysiology

Chagas disease is an endemic disease in Latin America caused by a unicellular parasite, *Trypanosoma cruzi*. Almost 18 million people are infected and almost 25% of them will develop chronic myocardial disease in the following years or decades.¹⁹

Chronic Chagas heart disease, the most serious manifestation of Chagas disease, is an inflammatory form of dilated CMP. The panmyocarditis of Chagas heart disease progressively involves the various cardiac tissues and results in extensive cardiac fibrosis. When the extent of myocardial damage is severe, the disease manifests as myocardial dysfunction that may be segmental, typically a ventricular aneurysm, or global, resembling a dilated CMP.^{19,20}

Myocardial damage can occur in various areas of both ventricles, but the inferolateral segment of the LV is the most commonly involved site, with frequently observed wall motion abnormalities. Apical, septal, and apical inferior aneurysms have also been described. The classic lesion of Chagas disease is a localized aneurysm of the LV apex, with relatively normal surrounding wall motion. This results in a narrow neck when visualized by echocardiography or ventriculography; when present, this can usually distinguish an aneurysm of Chagas heart disease from one due to coronary artery

disease. The aneurysms and segmental abnormalities are thought to result from localized destruction of extracellular matrix collagen along with myocyte loss, which leads to focal weakening of the ventricular wall. The apical location is particularly vulnerable because of the nature of the collagen structure at this location, normal apical thinning, and a relatively increased wall stress, which would promote the gradual development of aneurysmal dilation of the weakened segment. Regional dyssynergy caused by segmental conduction abnormalities could also contribute to aneurysm formation.^{19,21}

Histological examination reveals focal and diffuse myocardial fibrosis, predominantly in the subepicardium, interspersed with viable but often damaged myocardial fibers. VT can arise from various regions in both ventricles, but LV inferolateral scar is the main source of sustained VT reentrant circuits. In these areas, endocardial mapping frequently shows fragmented and late potentials during sinus rhythm as well as continuous or diastolic activity during VT. Histological analysis of those segments has shown focal and diffuse fibrosis that is predominantly subepicardial with nonuniform anisotropy of the surviving fibers. Epicardial VT reentrant circuits occur frequently in Chagas CMP; approximately 70% of VTs are epicardial in origin.^{19,20}

Clinical Considerations

Cardiac abnormalities can be detected in all phases or forms of Chagas disease. The natural history and the type of cardiac involvement can vary widely in patients with Chagas disease. Patients can present with a wide variety of clinical manifestations; the most important of these are ventricular arrhythmias, sudden death, congestive heart failure, thromboembolism, stroke, and heart block.^{20,21}

VT in Chagas disease can have heterogeneous presentations. SCD, usually due to VF and VT, is the most common cause of death, occurring more often than in other types of dilated CMP, with an incidence ranging from 51% to 65%. Frequently, the arrhythmic episodes are clustered in short periods, causing electrical storms ("chagasic storm"). Ventricular ectopy is remarkably frequent in all stages of the disease, even when there is no other evidence of cardiac involvement. Ectopy is dense and temporally unvarying, with patients often having tens of thousands of ectopic beats per day. In one report, 14% of patients presented with aborted sudden death, and sustained VT or sudden death occurred subsequently in 39% of patients with LV aneurysm or dysfunction. Nonsustained VT has been found by ambulatory monitoring in 10% of patients with mild wall motion abnormalities, in 56% of those with severe wall motion abnormalities or aneurysms without heart failure, and in 87% of those with advanced congestive heart failure.^{19,20}

The presence of nonsustained VT detected during ambulatory Holter monitoring and particularly during stress testing is a strong predictor of SCD. LV dysfunction is also a predictor of poor outcome, particularly if associated with ventricular arrhythmias.

Sustained VT is inducible with programmed ventricular stimulation in most patients who present with sustained ventricular arrhythmias and in half of those who have symptomatic nonsustained VT. EP testing in asymptomatic patients with cardiac involvement has shown that sinus node dysfunction is present in 18%, pacing-induced atrioventricular block in 41%, and multiple sites of conducting system dysfunction often coexist.

Ventricular tachyarrhythmias in the setting of Chagas disease are very difficult to treat. Antiarrhythmic drug therapy is frequently

ineffective. Limited data exist on the catheter ablation of VTs associated with Chagas CMP. Success rates are limited when only endocardial mapping and ablation techniques are used. Epicardial ablation has been shown to improve outcome and should be considered in these cases, perhaps as the initial ablation strategy. ICDs are generally the treatment of choice.

Because of the high incidence of thromboembolic phenomena, oral anticoagulants are recommended for patients with atrial fibrillation, previous embolism, and apical aneurysm with thrombus, even in the absence of controlled clinical trials demonstrating their efficacy.^{20,21}

Pathophysiology

Bundle branch reentrant (BBR) ventricular tachycardia (VT) is a reentrant VT with a well-defined reentry circuit, incorporating the right bundle branch (RB) and left bundle branch (LB) as obligatory limbs of the circuit, connected proximally by the His bundle (HB) and distally by the ventricular septal myocardium (Fig. 26-1).

Single BBR beats can be induced in up to 50% of patients with normal intraventricular conduction undergoing electrophysiological (EP) study. The QRS during BBR can display either left bundle branch block (LBBB) or right bundle branch block (RBBB) when anterograde ventricular activation occurs over the RB or LB, respectively. The vast majority have LBBB configuration. BBR with an LBBB pattern can also occur occasionally during right ventricular (RV) pacing. This requires that the effective refractory period of the LB be longer than that of the RB, or that retrograde conduction over the RB be resumed after an initial bilateral block in the His-Purkinje system (HPS) (i.e., gap phenomenon). Left ventricular (LV) pacing does not seem to increase the yield of induction of BBR with RBBB morphology.¹

In patients with normal intraventricular conduction, BBR is a self-limited phenomenon. The rapid conduction and long refractory period of the HPS prevent sustained BBR in normal hearts. Spontaneous termination of BBR most commonly occurs in the retrograde limb between the ventricular muscle and the HB.¹ Sometimes, anterograde block can also occur, making refractoriness in the RB-Purkinje system the limiting factor. Continuation of BBR as a tachycardia is critically dependent on the interplay between conduction velocity and recovery of the tissue ahead of the reentrant wavefront. Two changes from normal physiology must occur for BBR to become sustained: (1) an anatomically longer reentrant pathway caused by a dilated heart, providing sufficiently longer conduction time around the HPS; and (2) slow conduction in the HPS caused by HPS disease.¹ These two factors are responsible for sufficient prolongation of conduction time to permit expiration of the refractory period of the HPS ahead of the propagating reentrant wavefront.

Rarely, self-terminating BBR can occur with a narrow QRS during ventricular extrastimulation (VES) in the setting of normal intraventricular conduction. After retrograde conduction via the left anterior fascicle (LAF) or left posterior fascicle (LPF), anterograde propagation occurs over the RB and the remaining LB fascicle, resulting in a narrow QRS with either LAF or LPF block.

Clinical Considerations

Epidemiology

Sustained BBR VT usually occurs in patients with structural heart disease, especially dilated cardiomyopathy. Idiopathic dilated

cardiomyopathy is the anatomical substrate for BBR VT in 45% of cases, and BBR VT accounts for up to 41% of all inducible sustained VTs in this population. BBR VT can also be associated with cardiomyopathy secondary to valvular or ischemic heart disease, and has been reported with Ebstein anomaly, hypertrophic cardiomyopathy, and even in patients without structural heart disease other than intraventricular conduction abnormalities.²

In patients with spontaneous sustained monomorphic VT, the incidence of inducible BBR VT ranges from 4.5% to 6% in patients with ischemic heart disease to 16.7% to 41% in patients with nonischemic cardiomyopathy. BBR VT accounts for up to 6% of all forms of induced sustained monomorphic VT. Importantly, in patients with BBR VT, additional myocardial VTs occur in 25%.³ Of note, BBR VT is more frequently found in patients with VT clusters (up to 12.5%) than in patients with less frequent episodes of VT.⁴

Clinical Presentation

Sustained BBR VT is typically unstable secondary to very rapid ventricular rates (often 200 to 300 beats/min) and poor underlying ventricular function; 75% of patients present with syncope or cardiac arrest.

Initial Evaluation

BBR VT should be suspected in the presence of typical electrocardiogram (ECG) QRS morphology during normal sinus rhythm (NSR) and VT (see later), especially in a patient with dilated cardiomyopathy. Echocardiographic examination and coronary arteriography are required in most patients to evaluate for structural heart disease.

Principles of Management

Pharmacological antiarrhythmic therapy is usually ineffective. Radiofrequency (RF) catheter ablation of a bundle branch (typically the RB) can cure BBR VT and is currently regarded as first-line therapy.

Associated myocardial VT occurs in approximately 25% of patients post ablation, and these patients continue to be at a high risk of sudden cardiac death. Therefore, implantable cardioverter-defibrillator (ICD) therapy is indicated for secondary prevention, and additional antiarrhythmic therapy is required for some patients. ICD implantation will also provide back-up pacing, which is frequently required post ablation secondary to the development of atrioventricular (AV) block or an excessively prolonged His bundle-ventricular (HV) interval. Implantation of a dual-chamber or biventricular ICD should be considered in these patients.

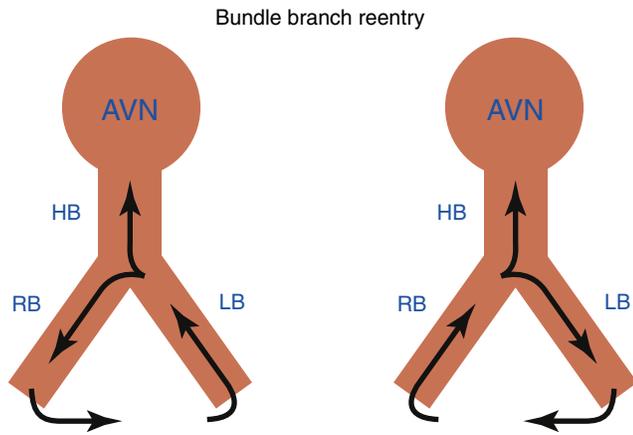

FIGURE 26-1 Schematic illustration of the two types of bundle branch reentry (BBR) circuits. At left is the most commonly seen type of BBR ventricular tachycardia (VT). Retrograde conduction occurs via the left bundle branch (LB) and anterograde conduction occurs via the right bundle branch (RB). This yields a VT in which the QRS has a left bundle branch block (LBBB) pattern. At right is the uncommon type of BBR VT. Retrograde conduction occurs via the RB and anterograde conduction occurs via the LB, which yields a VT in which the QRS has an RBBB pattern. AVN = atrioventricular node; HB = His bundle.

Because BBR VT has a limited response to antiarrhythmic drugs and can be an important cause of repetitive ICD therapies, catheter ablation of the arrhythmia should always be considered as an important adjunct to the device therapy.

EP testing should be considered in patients with repetitive episodes of VT and dilated cardiomyopathy, history of cardiac valve repair or replacement, or QRS morphology during VT similar to sinus rhythm QRS. If sustained BBR VT is inducible during programmed stimulation, catheter ablation is recommended.⁴

Electrocardiographic Features

Baseline ECG

The baseline rhythm is usually NSR or atrial fibrillation (AF). Almost all patients with BBR VT demonstrate intraventricular conduction abnormalities. The most common ECG abnormality is nonspecific intraventricular conduction delay (IVCD) with an LBBB pattern and PR interval prolongation (Fig. 26-2). Complete RBBB is rare but does not preclude BBR as the mechanism of VT. Although total interruption of conduction in one of the bundle branches would theoretically prevent occurrence of BBR, an ECG pattern of complete BBB may not be an accurate marker of *complete* conduction block; a similar QRS configuration can be caused by conduction delay, rather than block, in the bundle branch. Occasionally, complete AV block may be observed.²

ECG during Ventricular Tachycardia

Twelve-lead ECG documentation of BBR VT is usually unavailable because the VT is rapid and hemodynamically unstable. The VT rate is usually 180 to 300 beats/min. QRS morphology during VT is a typical BBB pattern and can be identical to that in NSR. BBR VT with an LBBB pattern is the most common VT morphology, and it usually has normal or left axis deviation (see Fig. 26-2). In contrast to VT of myocardial origin, BBR with an LBBB pattern characteristically shows a rapid intrinsicoid deflection in the right precordial leads, suggesting that initial ventricular activation occurs through the HPS and not ventricular muscle. BBR VT with an RBBB pattern usually has a leftward axis, but it can have a normal or rightward axis, depending on which fascicle is used for anterograde propagation.¹

Electrophysiological Testing

Baseline Observations during Normal Sinus Rhythm

Conduction abnormalities in the HPS are almost invariably present and are a critical prerequisite for the development of sustained BBR, regardless of the underlying anatomical substrate (Fig. 26-3).⁵ The average HV interval is about 80 milliseconds (range, 60 to 110 milliseconds). Although some patients can have the HV interval in NSR within normal limits, functional HPS impairment in these patients manifests as HV interval prolongation or split HB potentials, commonly becoming evident during atrial programmed stimulation or burst pacing. Nonspecific IVCD with an LBBB pattern and PR interval prolongation are the most common abnormalities.²

Induction of Tachycardia

VES from the RV apex is the usual method used to induce BBR with an LBBB pattern. Induction is consistently dependent on the achievement of a critical conduction delay in the HPS (i.e., critical ventricular–His bundle [VH] interval) following the VES.

During RV pacing at a constant cycle length (CL) and during introduction of VES at relatively long coupling intervals, retrograde conduction to the HB occurs via the RB. At shorter VES coupling intervals, retrograde delay and block occur in the RB when its relative and effective refractory periods are encountered, respectively. When retrograde block occurs in the RB, the impulse propagates across the septum and retrogradely up the LB to the HB, producing a long V_2 - H_2 interval. The LB would still be capable of retrograde conduction because of its shorter refractoriness and because of the delay associated with transeptal propagation. Further shortening of the coupling intervals is associated with increasing delay in LB conduction (i.e., increasing V_2 - H_2 interval). Within a certain range of coupling intervals, increasing retrograde LB delay allows for the recovery of anterograde conduction via the RB, and another ventricular activation ensues, displaying a wide QRS with an LBBB pattern. This beat is called the “BBR beat” or “ V_3 phenomenon.”²

An inverse relationship exists between retrograde conduction delay in the LB (V_2 - H_2 interval) and the time of anterograde conduction in the RB (H_2 - V_3 interval). This is because the faster the impulse propagates transeptally and up the LB, the more likely it will reach the RB while it is still refractory from the previous retrograde activation (concealment) by the VES, resulting in slower anterograde conduction down the RB.

BBR is more likely to occur when the VES is delivered following pacing drives incorporating long to short CL changes as compared with constant CL drives, because of CL dependency of the HPS refractoriness. An abrupt change in CL (i.e., long to short) can result in a more distal site of retrograde block, and less concealment, along the myocardium-Purkinje-RB axis, which can allow sufficient recovery of excitability in the anterograde limb of the circuit (i.e., the RB-Purkinje-myocardium axis) for reentry to develop. In addition, earlier recovery of excitability along this axis, because of the more distal site of block and less concealment, is associated with a shorter H_2 - V_3 interval in this reentrant beat.¹

Procainamide, which increases conduction time within the HPS, especially in the diseased HPS, and, potentially, isoproterenol can facilitate induction of sustained BBR. In some patients, the arrhythmia can be inducible only with atrial pacing.²

Tachycardia Features

BBR VT can only be diagnosed using intracardiac recording (Table 26-1). AV dissociation is typically present, during the tachycardia, but 1:1 ventriculoatrial (VA) conduction can occur. BBR VT is characterized by inscription of the His potential before the QRS complex, with the HV interval during BBR with an LBBB pattern generally being similar to or longer than that during baseline

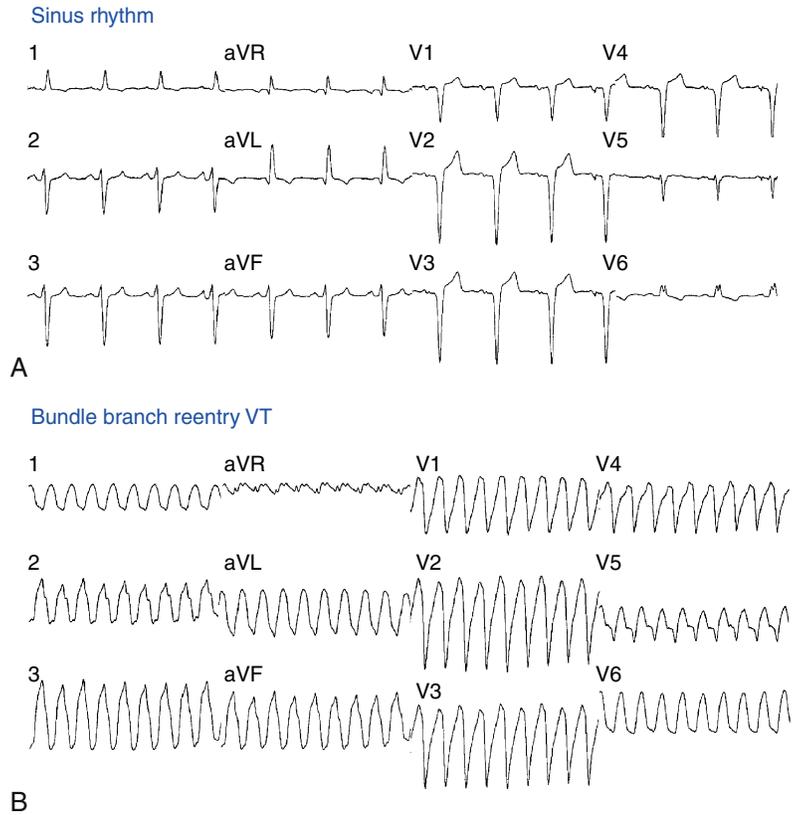

FIGURE 26-2 ECG of bundle branch reentrant (BBR) ventricular tachycardia (VT). **A**, Normal sinus rhythm baseline with intraventricular conduction delay resembling left bundle branch block. **B**, BBR VT. Note typical-appearing complete LBBB in this rapid VT.

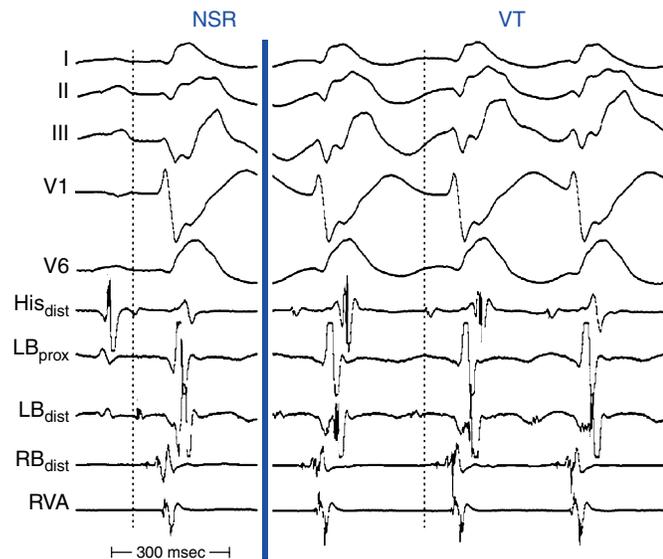

FIGURE 26-3 Bundle branch reentrant (BBR) ventricular tachycardia (VT) versus normal sinus rhythm (NSR). Sinus and BBR VT with His, left bundle branch (LB), and right bundle branch (RB) recordings in a patient with a prior septal myocardial infarction. Dashed lines mark the onset of His deflection. During NSR, the His potential is followed first by the LB potential; RB activation is further delayed. The fact that left bundle branch block (LBBB) is present on the ECG suggests that, although the LB is activated prior to the RB, delay is encountered more distally in the left ventricular His-Purkinje system such that LBBB is evident on the ECG. During BBR VT, activation propagates in an LB-His-RB sequence. Retrograde LB activation is very delayed, most likely because of the same factors responsible for the ECG in NSR.

rhythm (the HV interval is usually 55 to 160 milliseconds; see Fig. 26-3). However, in rare cases, the HV interval during BBR VT can be slightly shorter (by less than 15 milliseconds) than the HV interval in NSR, because during BBR the HB is activated in the retrograde direction simultaneously (in parallel) with the proximal part of the

TABLE 26-1 Diagnostic Criteria of Bundle Branch Reentrant Ventricular Tachycardia

- The QRS morphology of the tachycardia shows a typical RBBB or LBBB pattern.
- The onset of ventricular depolarization is preceded by HB, RB, or LB potentials with an appropriate sequence of H-RB-LB activation and relatively stable HV, RB-V, or LB-V intervals.
- Spontaneous variations in V-V intervals are preceded by similar changes in H-H/RB-RB/LB-LB intervals.
- The induction of tachycardia during programmed stimulation is consistently dependent on achieving a critical conduction delay in the HPS.
- Tachycardia termination is preceded by a spontaneous or pacing-induced block in the HPS.
- The HV during tachycardia is longer than HV during sinus rhythm.
- BBR is noninducible after successful ablation of the RB.

BBR = bundle branch reentry; HB = His bundle; HPS = His-Purkinje system; HV = His bundle-ventricular; LB = left bundle branch; LBBB = left bundle branch block; LB-V = left bundle-ventricular; RB = right bundle branch; RBBB = right bundle branch block; RB-V = right bundle-ventricular.

bundle branch serving as the anterograde limb of the reentry circuit, whereas during NSR, activation of the HB and activation of the bundle branch occur in sequence.¹

The relative duration of the HV interval recorded during VT as compared with NSR would depend on two factors: the balance between anterograde and retrograde conduction times from the upper turnaround point of the reentry circuit, and the site of HB recording relative to the upper turnaround point (i.e., the HB catheter electrode positioned at the proximal versus distal HB). Conduction delay in the bundle branch used as the anterograde limb of the circuit tends to prolong the HV interval during VT, whereas retrograde conduction delay to the HB recording site, as well as the use of a relatively proximal HB recording site (far from the turnaround point), tend to shorten the HV interval. The right bundle-ventricular (RB-V) interval during VT with LBBB morphology must always be longer than that recorded in sinus rhythm, emphasizing the importance of recording the RB potential during VT.¹

The HV interval during BBR with an RBBB pattern can be significantly different from that during NSR (HV interval, 65 to 250 milliseconds). During NSR, the HV interval is usually determined by conduction over whichever bundle branch conducts most rapidly, whereas during BBR it is determined by conduction over the typically diseased LB.

In the common type of BBR VT (LBBB pattern), the activation wavefront propagates retrogradely up the LB to the HB and then anterogradely down the RB, with subsequent ventricular activation. This sequence is reversed in BBR with an RBBB pattern. The HV and RB-V (during VT with LBBB morphology) or left bundle-ventricular (LB-V) intervals (during VT with RBBB morphology) are relatively stable.

During BBR VT, spontaneous variations in the V-V intervals are preceded and dictated by similar changes in the H-H (and RB-RB or LB-LB) intervals. In other words, the VT CL is affected by variation in the V-H (V-RB or V-LB) intervals. These changes can occur spontaneously, most commonly immediately after induction of the VT, or be demonstrated by ventricular stimulation during VT. However, oscillations in the V-V intervals can occasionally precede those of the H-H intervals during BBR VT because of conduction variations in the anterograde, rather than the retrograde, conducting bundle branch.³

Recording from both sides of the septum can help to identify the BBR mechanism. Documentation of a typical H-RB-V-LB activation sequence (during VT with LBBB morphology), or of an H-LB-V-RB activation sequence (during VT with RBBB morphology), supports the diagnosis of BBR (see Fig. 26-3).¹ Unfortunately, the RB potentials, LB potentials, or both are not always recorded, so that the typical activation sequences (LB-H-RB-V or RB-H-LB-V) are not available for analysis. Even if either activation sequence is present, the HPS (usually the LB) could be activated passively in a retrograde fashion to produce an H-RB-V sequence during a VT with LBBB pattern without reentry requiring the LB. In these cases, other diagnostic criteria for BBR should be used. In addition, during VT with LBBB morphology, RV activation must precede the LV activation. The opposite is true for the VT with RBBB morphology.

BBR can be terminated by block in the HPS—spontaneous, pacing-induced, secondary to catheter trauma, or caused by ablation.

Diagnostic Maneuvers during Tachycardia

Pacing maneuvers can be extremely helpful to establish the diagnosis of BBR; however, application of the pacing maneuvers during BBR is often not feasible because of the hemodynamic compromise commonly associated with these VTs.

ENTRAINMENT

BBR VT can be entrained by ventricular pacing. Entrainment with manifest QRS fusion during ventricular pacing is classic for BBR VT. Entrainment with concealed fusion can be demonstrated by pacing at the LB or RB (i.e., within the reentrant circuit). During entrainment from the RV apex, a post-pacing interval (PPI) – VT CL difference of greater than 30 milliseconds excludes a BBR mechanism, provided that the RV apex catheter is correctly positioned. The greater this value is, the more reliable is the certainty of exclusion. Conversely, a $p[PPI - VT CL]$ difference of less than 30 milliseconds is consistent with, but not diagnostic of, a BBR mechanism.³

Entrainment of BBR VT with concealed QRS fusion can also occur during atrial pacing. This approach, however, demands that the patient not be in AF and usually requires the infusion of atropine, isoproterenol, or both to avoid AV block during rapid atrial pacing. The combination of entrainment with concealed QRS fusion during atrial pacing and entrainment with manifest QRS fusion during ventricular pacing has been recently proposed as a useful diagnostic criterion for BBR VT with LBBB QRS morphology.

RESETTING

VES can reset the VT by advancing the HB or bundle branch potential. In addition, VES can reverse the direction of impulse propagation during BBR. Theoretically this requires double VESs, with the first VES producing block and the second initiating the reentry in the opposite direction.

OTHER PACING MANEUVERS

The ability to dissociate the HB or, particularly, a bundle branch (RB or LB) potential strongly argues against a BBR mechanism. An atrial extrastimulus (AES) that blocks below the HB deflection should terminate BBR. Additionally, simultaneous LV and RV pacing should prevent BBR.²

Exclusion of Other Arrhythmia Mechanisms

MYOCARDIAL VENTRICULAR TACHYCARDIAS

Myocardial VTs are rarely associated with classic LBBB (or RBBB) QRS morphology, as is expected with BBR VT. Additionally, in myocardial VTs, the His potential is often obscured within the local ventricular electrogram. Occasionally, the His potential may precede the onset of the QRS, thus resembling BBR VT; however, the HV interval in myocardial VTs is usually shorter than that during NSR. In contrast to BBR VT, spontaneous or induced tachycardia CL variations during myocardial VTs usually precede and dictate H-H interval changes.³

Entrainment with concealed QRS fusion during atrial pacing excludes myocardial VT and should be expected in BBR VT. When entrainment with concealed fusion can be demonstrated by pacing at the LB or RB, BBR VT is very likely. In addition, a $[PPI - VT CL]$ difference of less than 30 milliseconds after entrainment of the VT from the RV apex is suggestive of BBR VT; in contrast, in myocardial VTs, the $[PPI - VT CL]$ difference is greater than 30 milliseconds, unless the VT originates in the apex.

IDIOPATHIC (FASCICULAR) LEFT VENTRICULAR TACHYCARDIA

The QRS and HV interval are normal during NSR in idiopathic VT. In contrast, BBR VT is rare in the absence of baseline HPS conduction abnormalities. Additionally, the His potential falls within or before the QRS in idiopathic LV VT, producing a negative or short HV interval, and HB activation follows activation of the left fascicles, which is inconsistent with RBBB-type BBR VT.

SUPRAVENTRICULAR TACHYCARDIA WITH ABERRANCY

BBR VT typically exhibits AV dissociation, which excludes atrial tachycardia (AT) and atrioventricular reentrant tachycardia (AVRT). Occasionally, BBR VT can be associated with 1:1 VA conduction, and it can then mimic supraventricular tachycardia (SVT) with aberrancy.

Multiple HB recordings, using a hexapolar or octapolar catheter, can help demonstrate the direction of HB depolarization—anterograde during SVT and retrograde during BBR VT. Also, recording of LB and RB potentials in addition to the HB potential can be helpful; activation of the HB occurs anterogradely via the atrioventricular node (AVN) during SVT and precedes the RB potential by an interval equal to or longer than that during NSR.

The atrium is not part of the circuit in the BBR VT and can be dissociated by atrial pacing, which excludes AT and AVRT as the mechanism of wide complex tachycardia. Moreover, during entrainment from the RV apex, a $[PPI - tachycardia CL]$ difference of greater than 30 milliseconds excludes a BBR mechanism. Conversely, a $[PPI - tachycardia CL]$ difference of less than 30 milliseconds excludes atrioventricular nodal reentrant tachycardia (AVNRT). Additionally, entrainment with manifest fusion during ventricular pacing excludes AVNRT and AT and should be expected in BBR VT.

Furthermore, the ability to terminate or reset the tachycardia with a VES introduced when HB is refractory excludes AT and AVNRT.

ANTIDROMIC ATRIOVENTRICULAR REENTRANT TACHYCARDIA USING AN ATRIOFASCICULAR BYPASS TRACT

During antidromic AVRT, the impulse propagates retrogradely over the RB to the HB, a sequence inconsistent with BBR with an LBBB pattern. The AV relationship is always 1:1 during AVRT and rarely so during BBR VT. Because the atrium is not part of the circuit in BBR VT, it can be dissociated by atrial pacing, which excludes AVRT. Moreover, resetting the tachycardia with an AES from the right atrial (RA) free wall, timed when the AV junctional atrium is refractory, excludes VT. Similarly, the ability of an AES to terminate the tachycardia without conduction to the ventricle or to retard (delay) the following ventricular activation excludes VT (see Figs. 18-28 and 19-4).

Ablation

Target of Ablation

The ablation target is either the RB or the LB; however, RB ablation is easier and usually is the method of choice. In most patients with BBR VT, although diffuse conduction system disease is present, the conduction abnormality in the LB is more severe than that in the RB. Nonetheless, preserved slow conduction over the LB can be demonstrated in the majority of patients, and the LB can still maintain 1:1 AV conduction during NSR.⁶ For the occasional patients in whom anterograde conduction down the LB is known to be inadequate for maintaining AV conduction, ablation of the RB will commit the patient to a permanent pacemaker. Therefore, ablation of the LB in these patients is preferable because it can prevent BBR and still preserve anterograde conduction.

The mere presence of LBBB on the surface ECG does not mean complete block in the LB. Signs that can indicate that conduction down the LB may be inadequate in maintaining 1:1 AV conduction and favor ablation of the LB over the RB include (1) development of high-grade AV block below the HB on transient RBBB that can occur secondary to RV catheter manipulation, and (2) observation of an LB potential following the ventricular electrogram either intermittently or during every sinus beat.

Ablation Technique

ABLATION OF THE RIGHT BUNDLE BRANCH

The HB divides at the junction of the fibrous and muscular boundaries of the intraventricular septum into the RB and LB. The RB is an

anatomically compact unit that travels as the extension of the HB after the origin of the LB. The RB courses down the right side of interventricular septum near the endocardium in its upper third, deeper in the muscular portion of the septum in the middle third, and then again near the endocardium in its lower third. The RB is a long, thin, discrete structure; it does not divide throughout most of its course, and begins to ramify as it approaches the base of the right anterior papillary muscle, with fascicles going to the septal and free walls of the RV.

A quadripolar catheter is positioned at the HB region and maintained as a reference. The ablation catheter is initially positioned in the HB region and the area of the septum at which the largest His potential is recorded. The catheter is then advanced gradually (in the right anterior oblique [RAO] view) superiorly and to the patient's left side, with clockwise torque to ensure adequate catheter tip contact with the septum and RB and continuous adjustment of the catheter's curvature until the RB potential is recorded. Attempts should be made to obtain the distal RB recording to ensure that the catheter tip is away from the HB and LB.

The RB potential can be distinguished from the HB potential by the absence of or minimal atrial electrogram on the recording and presence of a sharp deflection inscribed at least 15 to 20 milliseconds later than the His potential (Fig. 26-4). An RB-V interval value of less than 30 milliseconds may not be a reliable marker of the RB potential in these patients because disease of the HPS can cause prolongation of the RB-V conduction time.

When there is RB conduction delay at baseline, the RB potential can become hidden within the ventricular electrogram, and it may be impossible to map during NSR, especially when the surface ECG shows complete or incomplete RBBB. However, the RB potential should be readily observed during BBR beats induced by RV stimulation or during BBR VT. In this setting, anatomically guided lesions or a linear ablation perpendicular to the axis of the RB distal to the HB recording may be effective.

A 4-mm-tip ablation catheter is typically used for RB ablation. RF application is usually started at low levels (5 W) and gradually increased every 10 seconds, targeting a temperature of 60°C. In general, RBBB develops at 15 to 20 W. Successful ablation will result in clear development of RBBB in lead V₁ (Fig. 26-5; and see Fig. 26-4). Occasionally, an accelerated rhythm from the RB is observed during ablation (analogous to accelerated junctional rhythm with HB ablation; see Fig. 26-5).

ABLATION OF THE LEFT BUNDLE BRANCH

Whereas the RB is anatomically a continuation of the HB, the LB arises as a broad band of fibers from the HB in a perpendicular direction toward the inferior septum. The main LB penetrates the membranous portion of the interventricular septum under the

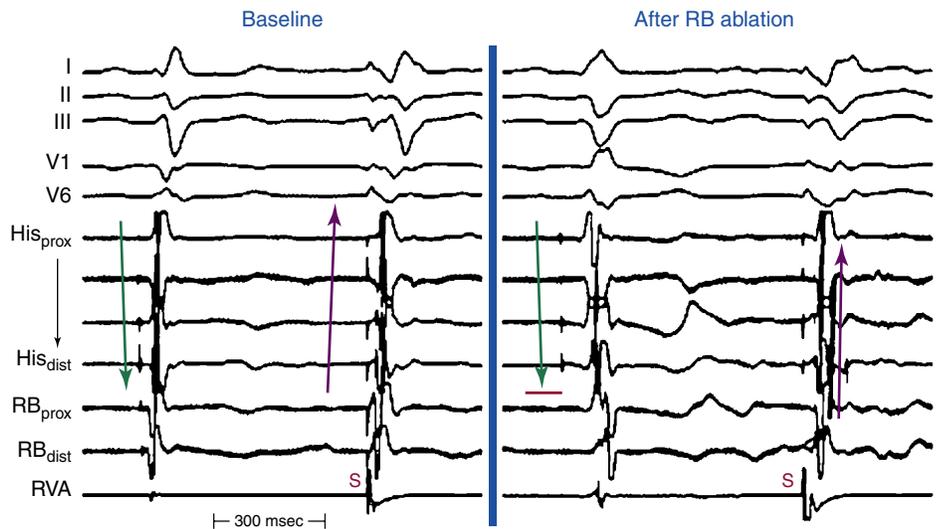

FIGURE 26-4 Ablation of bundle branch reentry (BBR). Sinus and right ventricular apical paced complexes from before (left) and after (right) catheter ablation of the right bundle branch (RB) in a patient with BBR VT. Four bipolar recordings from a catheter at the His position and RB are shown. Prior to RB ablation, propagation along the His-RB axis is linear, anterograde during sinus rhythm (green arrow), and retrograde during RV pacing (purple arrow). After RB ablation, anterograde propagation is interrupted (green arrow, red line) and retrograde activation of the His electrograms occurs after the local ventricular electrogram (purple arrow), indicating block in the RB with transseptal propagation, then up the left bundle.

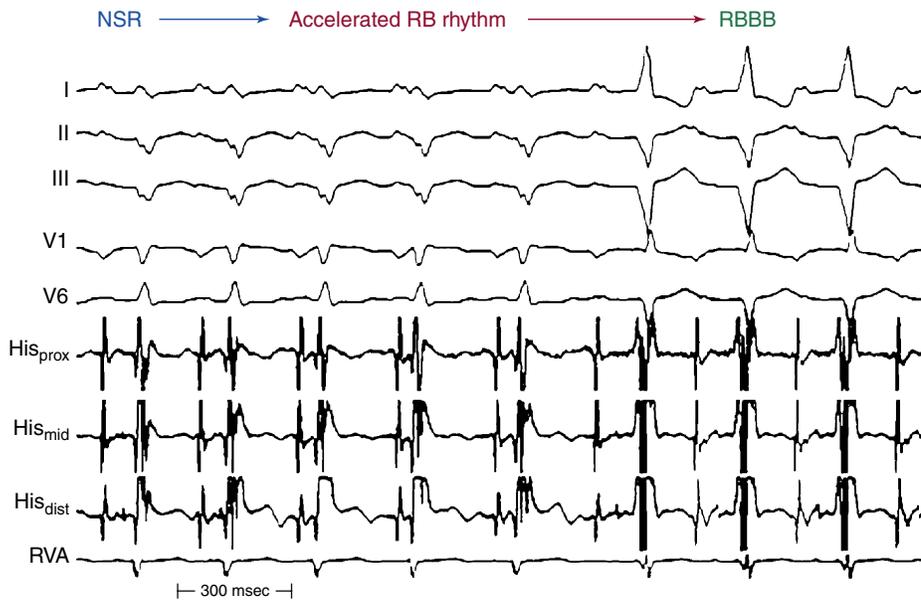

FIGURE 26-5 Right bundle branch (RB) ablation. During RB ablation, delivery of radiofrequency current causes accelerated rhythm from the RB until complete block occurs (note lead V₁). The His bundle–ventricular interval after ablation is 145 milliseconds (baseline, 80 milliseconds). NSR = normal sinus rhythm; RBBB = right bundle branch block.

aortic ring and then divides into several fairly discrete branches. The LPF arises more proximally than the LAF, appears as an extension of the main LB, and is large in its initial course. It then fans out extensively posteriorly toward the papillary muscle and inferoposteriorly to the free wall of the LV. The LAF crosses the LV outflow region and terminates in the Purkinje system of the anterolateral wall of the LV. In the RAO view, the LPF extends from the HB region toward the inferior diaphragmatic wall and the LAF extends toward the apex of the heart. However, considerable variability exists.

The mapping catheter is placed via a transaortic approach into the LV. The inferoapical septum is a starting point. The catheter is then gradually withdrawn toward the HB until a discrete LB potential is recorded. The LB–V interval should be less than or equal to 20 milliseconds, and the AV electrogram amplitude ratio should be less than or equal to 1:10. At this position, the tip of the catheter typically is 1 to 1.5 cm inferior to the optimal HB recording site near the distal portion of the common LB. On the other hand, the disease process that results in LBBB in patients with BBR probably leaves only a remnant of conducting tissue that may be more readily ablated than a normal LB would be.

Because the LB is a broad band of fibers (typically 1 to 3 cm long and 1 cm wide), it can be difficult to ablate with a single RF application. Furthermore, the fascicles can diverge proximally; thus, ablation of the LB can be difficult without harming the HB. In these situations, it may be necessary to deliver several lesions along the left side of the septum in an arc distal to the HB, extending from the anterior superior septum (a point near the RB in the RAO view) to the inferior basal septum to transect both fascicles.

It is more difficult to monitor the progress of LB ablation during RF delivery. Most patients will already have some IVCD localized to the LB system. As opposed to the usually clear development of RBBB in lead V₁ during RB ablation, LB ablation can produce relatively subtle ECG changes, primarily manifesting as widening of the QRS and changes in the QRS axis. One can also monitor the presence of retrograde conduction during VES after each RF application. Elimination of the retrograde V₂–H₂ conduction that was present before ablation is a good indication that sufficient ablation of the LB has been achieved to eliminate BBR.

Endpoints of Ablation

Endpoints of RB ablation include the development of an RBBB pattern (see Fig. 26-5), noninducibility of BBR, and reversal of the direction of HB and RB activation during RV pacing. Prior to ablation, HB electrodes are depolarized during RV pacing from distal to

proximal (RB–HB); after RB ablation, HB activation is delayed and reversed (HB–RB; see Fig. 26-4).

Endpoints of LB ablation include elimination of retrograde conduction of VESs over the LB and noninducibility of BBR.

After ablation, aggressive ventricular stimulation should be performed to evaluate the inducibility of VT. Also, decremental atrial pacing should be performed to evaluate the conduction properties of the HPS and the propensity for infra-Hisian AV block. It is advisable to stress the HPS with intravenous procainamide and ensure that anterograde conduction is preserved.³

Outcome

Recurrence of BBR VT after successful ablation is extremely rare. The reported incidence of clinically significant conduction system impairment requiring implantation of a permanent pacemaker varies from 10% to 30%.²

Pacemaker implantation is indicated when infra-Hisian AV block is demonstrated with atrial pacing, or when the post-ablation HV interval is 100 milliseconds or greater. As noted, associated myocardial VT is observed in approximately 25% of patients post ablation, and these patients continue to be at a high risk of sudden cardiac death. Therefore, ICD implantation is indicated for secondary prevention, and additional antiarrhythmic therapy is required for some patients.

Interfascicular Reentrant Ventricular Tachycardia

Of the two types of macroreentry in the HPS (i.e., BBR and interfascicular reentry), BBR is by far, the most common mechanism of VT.⁷ VT secondary to interfascicular reentry is extremely rare; when it does occur, it is most commonly seen in patients with coronary artery disease, specifically those with anterior myocardial infarction (MI) with LAF or LPF block. In these patients, RBBB is complete and bidirectional, so true BBR cannot occur. Additionally, there is slow conduction in the apparently blocked fascicle.² Of note, interfascicular reentrant VT can develop in patients following ablation of the RB for the treatment of BBR VT.⁷

Interfascicular reentry incorporates the LAF and LPF as obligatory limbs of the circuit, connected proximally by the main trunk of the LB and distally by the ventricular myocardium (Fig. 26-6). The tachycardia usually has an RBBB morphology. The orientation of the frontal plane axis is variable and depends on the direction

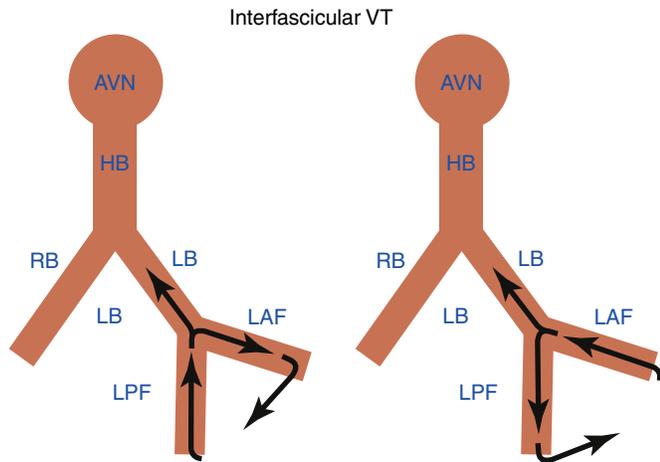

FIGURE 26-6 Schematic illustration of the two types of interfascicular ventricular tachycardia (VT) circuits. **Left:** The interfascicular reentrant VT uses the left posterior fascicle (LPF) as the retrograde limb of the reentrant circuit and the left anterior fascicle (LAF) as the anterograde limb. **Right:** The interfascicular reentrant VT uses the LAF as the retrograde limb of the reentrant circuit and the LPF as the anterograde limb. In both types, because the ventricle is activated via the left bundle branch (LB), the QRS has right bundle branch block morphology. The QRS axis will depend on which fascicle serves as the anterograde route of ventricular activation. The right bundle branch (RB) is activated in a bystander fashion and is not necessary for sustaining the tachycardia. AVN = atrioventricular node; HB = His bundle.

of propagation in the reentrant circuit. Anterograde activation over the LAF and retrograde through the LPF would be associated with right axis deviation, whereas the reversed activation sequence shows left axis deviation (see Fig. 26-6).^{1,2}

In contrast to BBR VT, the HV interval during interfascicular VT is usually shorter by more than 40 milliseconds than that recorded in NSR.¹ This is because the upper turnaround point of the circuit, the distal end of the LB bifurcation point, is relatively far from the retrogradely activated HB. During interfascicular VT, the LB potential should be inscribed before the His potential. In contrast, during BBR VT with RBBB morphology, the His potential usually precedes the LB potential, although the reverse is theoretically possible if the retrograde conduction time to the HB recording point is significantly prolonged. Interfascicular reentry also demonstrates

variations in the V-V interval preceded by similar changes in the H-H interval.

Atrial pacing, AES, VES, and ventricular pacing can initiate interfascicular reentry by producing transient anterograde block in the slowly conducting fascicle (LAF or LPF), with subsequent impulse anterograde conduction over the healthy fascicle, giving rise to a QRS morphology identical to that during NSR, and then retrogradely in the initially blocked fascicle to initiate reentry. Compared with BBR VT, interfascicular VT can be more difficult to induce by ventricular pacing, because of the inability to create the necessary EP conditions for this type of reentry during ventricular stimulation (i.e., retrograde block in the distal LAF and slow conduction via the LPF, or vice versa), although this may occur during anterograde penetration of the HPS by supraventricular impulses (i.e., anterograde block in the LPF and slow conduction in the LAF or vice versa).⁷

Successful ablation of the arrhythmia can be performed by targeting the diseased fascicle (LAF or LPF), guided by fascicular potentials.² When interfascicular reentry occurs in the setting of an anterior MI, complete cure by ablation is usually not possible because other myocardial VTs are almost always present, and the LV ejection fraction is usually poor, thereby mandating ICD implantation for improved survival. When interfascicular reentry occurs without coronary artery disease, in association with degenerative disease of the conduction system, LV systolic function is usually normal and cure of the VT is possible by ablation of the diseased fascicle, although implantation of a permanent pacemaker will likely be required.

Electrophysiological Substrate

Mapping and ablation of arrhythmogenic substrates have traditionally been performed via the endocardial approach. Not infrequently, however, the site of origin of a focal tachycardia or a portion of the critical isthmus or even the entire circuit of a macroreentrant tachycardia is located deep in the endocardium or even in the subepicardium and cannot be identified or ablated from the endocardium. In these settings, the epicardial approach to mapping and ablation can be a valuable strategy for elimination of the arrhythmia.

The importance of epicardial ventricular tachycardia (VT) circuits was first highlighted in Chagas disease, which classically results in an epicardial involvement in approximately 70% of patients. Epicardial substrates also have recently been increasingly recognized in the setting of scar-related VT in patients with nonischemic cardiomyopathy (CMP), arrhythmogenic right ventricular cardiomyopathy-dysplasia (ARVD), and prior myocardial infarction (MI, "ischemic CMP"), as well as in patients with idiopathic VT.

Patients with ischemic heart disease tend to have larger endocardial than epicardial scars, usually confined to a specific coronary vascular territory. Although there is a predilection for a subendocardial location of the VT substrate, epicardial circuits can be observed in a significant portion of patients. In tertiary centers, epicardial ablation has been required in up to 10% of post-MI VTs, and appears to be more frequently required for inferior wall infarct VTs than for those with anterior wall infarcts.

In patients with nonischemic CMP, detailed epicardial electroanatomical substrate mapping has identified large confluent low-voltage areas consistent with myocardial scar. The epicardial scar areas are typically larger than the endocardial left ventricular (LV) scar areas and have a typical distribution similar to that for endocardial LV scars, usually located in basal lateral areas of the LV adjacent to the mitral valve annulus. Epicardial ablation is needed more often in patients with sustained monomorphic VT associated with dilated, nonischemic CMP than in patients with prior MI.¹

In patients with ARVD, sizable low-voltage areas often involve the infundibulum, free wall, and basal perivalvular regions, constituting the endocardial substrate. More recently, extensive epicardial low-voltage areas, often with fractionated and late electrographic recordings, have been identified. The epicardial scar is consistently larger than that on the endocardial surface. In patients with ARVD and VT refractory to endocardial ablation, the origin of VT defined on the epicardium is frequently noted beyond the endocardial-defined scar.² In a recent report, the highest prevalence of epicardial VTs was observed in patients with ARVD (41%) and nonischemic CMP (35%), followed by patients with ischemic heart disease (16%).³

Small series have also reported successful ablation of epicardial VTs following a failed endocardial ablation in patients with idiopathic outflow tract VTs. Often underrecognized, the incidence of

an epicardial origin in idiopathic VT may be as high as 14%. Idiopathic outflow tract VTs with epicardial origins can originate close to the anterior interventricular vein, great cardiac vein, and middle cardiac vein; and successful ablation from within these structures has been reported. When this approach fails, percutaneous epicardial mapping and ablation have been reported to be feasible and successful.⁴

Electrocardiographic Features

Several ECG findings can suggest an epicardial origin of the VT with right bundle branch block (RBBB)-like configuration, all of which generally rely on the late engagement of His-Purkinje fibers by exits on the epicardium, resulting in intramyocardial delay of conduction and a slurred initial part of the QRS complex: (1) pseudo-delta wave (so called because of its similarity to the slurred upstroke delta wave observed during ventricular preexcitation) greater than 34 milliseconds (measured from the earliest ventricular activation to the earliest fast deflection in any precordial lead) has a sensitivity of 83% and a specificity of 95%; (2) long R-wave peak time in lead V₂ (i.e., interval from the beginning of the QRS complex to the time of initial downstroke of the R wave after it has peaked [previously known as the *intrinsicoid deflection*]) greater than 85 milliseconds has a sensitivity of 87% and a specificity of 90%; (3) shortest RS complex duration (measured from the earliest ventricular activation to the nadir of the first S wave in any precordial lead) equal to or greater than 121 milliseconds has a sensitivity of 76% and a specificity of 85%; and (4) QRS duration greater than 200 milliseconds (see Fig. 22-8).^{4,5}

These criteria, however, do not seem to apply uniformly to all LV regions or to VTs originating from the right ventricle (RV). Other site-specific criteria have been suggested for identifying an epicardial origin for LV VTs: (1) the presence of a Q wave in lead I for basal superior and apical superior VTs; (2) the absence of a Q wave in any of the inferior leads for basal superior VTs; and (3) the presence of a Q wave in the inferior leads for basal inferior and apical inferior VTs. Also, measurement of the *maximal deflection index* (defined as the time from QRS onset to maximal deflection in precordial leads divided by the QRS duration) can help identify epicardial VT originating in the LV outflow region. A delayed shortest precordial maximal deflection index (≥ 0.55) identifies epicardial VT remote from the aortic sinus of Valsalva with high sensitivity and specificity. This observation is consistent with slower spread of activation from a focus on the epicardial surface relative to the endocardium and delayed global ventricular activation resulting from later engagement of the His-Purkinje network.^{6,7}

Epicardial VTs originating close to the proximal segment of the great cardiac vein typically display RBBB morphology, whereas VTs originating close to the distal segment have left bundle branch block (LBBB) morphology. This may be explained by a location within the basal-lateral myocardium for the former and a more antero-basal location for the latter arrhythmias. If the site of origin is in

the proximal segment of the great cardiac vein, the initial vector is directed toward lead V_1 , accounting for the RBBB morphology. As the site of origin moves toward the distal part of the great cardiac vein, closer to the anteroseptal myocardium, the initial vector is directed away from V_1 , resulting in LBBB morphology. An R-wave width greater than 75 milliseconds in lead V_1 is useful for differentiating epicardial idiopathic VTs from endocardial arrhythmias. The broader R wave is explained by a more posterior position relative to lead V_1 compared with the RV outflow tract (RVOT). However, because of a more anterior position relative to lead V_1 , the epicardial arrhythmias that are located within the distal part of the great cardiac vein have a narrow R wave in lead V_1 , making them impossible to distinguish from RVOT VT.^{7,8} Epicardial VTs that appear to follow the anterior interventricular vein often have a characteristic loss of R wave from leads V_1 and V_2 with broad R waves in leads V_3 through V_6 .

For VTs originating from the RV, the presence of an initial Q wave in lead I and QS in lead V_2 for anterior sites in the RV strongly predicts an epicardial origin. Similarly, an initial Q wave in leads II, III, and aVF is observed with pace mapping from the inferior epicardial locations in the RV.

Although various ECG characteristics have been used to predict whether an epicardial approach may be required based on the VT morphology, it is important to understand that the QRS morphology is related solely to the VT exit site and this does not imply that some other component of the circuit (such as the critical isthmus or entrance site) cannot be ablated from the endocardium, even when an epicardial exit is implied by the ECG characteristics. Therefore, it is unlikely that the surface ECG by itself will ever be entirely predictive of the need for epicardial access for mapping and ablation for any given VT.⁵ Additionally, large areas of conduction delay often present in patients with myocardial scar can produce misleading activation sequences and confound ECG prediction.⁹

Percutaneous Epicardial Approach

Clinical Considerations

VT originating from the subepicardium is an important cause of failure of endocardial ablation approaches. Mapping arrhythmia foci or circuits that are deep within the myocardium or in the epicardium can be attempted via the coronary sinus (CS) or pericardial space. The CS approach, however, has important limitations. Catheter manipulation is limited by the anatomical distribution of the cardiac veins, and epicardial circuits may be identified only when the vessel cannulated happens to be in the region of the

circuit. An alternative epicardial approach involves inserting an introducer sheath percutaneously into the pericardial space in the manner used for pericardiocentesis. The subxiphoid approach to the epicardial space allows extensive and unrestricted mapping of the epicardial surface of both ventricles, and has been used most commonly for VT mapping and ablation (far less so for supraventricular arrhythmias). Nonetheless, mapping of the CS and accessible coronary venous branches can be performed prior to the percutaneous epicardial approach to look for clues of an epicardial origin of the VT circuit, and has been particularly useful in idiopathic outflow tract VTs.^{4,9}

Catheter ablation from the epicardium is often required for elimination of VTs due to nonischemic CMP and is occasionally useful for VTs in a variety of other diseases, as well as some idiopathic VTs. Nonetheless, despite the increasing recognition that ventricular arrhythmias may originate from epicardial foci, epicardial VT ablation remains a specialized procedure and is performed at relatively few centers. In the majority of reported cases, percutaneous epicardial VT ablation has been performed only after failure of a thorough endocardial mapping and ablation session, at a separate setting or during the same setting after exhausting endocardial mapping efforts. Simultaneous endocardial and epicardial mapping can have several advantages (Fig. 27-1), such as a better chance to map and ablate all inducible VTs, reduce the number of procedures required for patients with suspected epicardial VTs, and an opportunity to acquire more expertise with the technique.⁴ Also, epicardial mapping and ablation may be useful as a first procedure when endocardial mapping is not an option because of intraventricular thrombi or in patients with metallic prostheses in the aortic and mitral valves.⁴

There are several conditions that can significantly limit the feasibility of percutaneous epicardial mapping and ablation. Previous cardiac surgery usually results in significant pericardial fibrosis, and the pericardial space is often, but not always, virtually replaced by fibrotic adhesions. In this setting, percutaneous cannulation of the pericardial sac is very difficult; even when percutaneous cannulation is successful, manipulation of the instruments is extremely limited and difficult. Additionally, pericardial venous varices have been reported in patients with SVC and azygous venous occlusion. Thus, catheter manipulation and ablation inside the pericardial space of a patient with pericardial varices can result in severe bleeding complications. When pericardial varices are suspected, the diagnosis can be made by three-dimensional (3-D) computed tomography (CT) angiography. Also, the presence of a large hiatal hernia can predispose to inadvertent perforation (and subsequent mediastinal infections) during cannulation attempts. Congenital

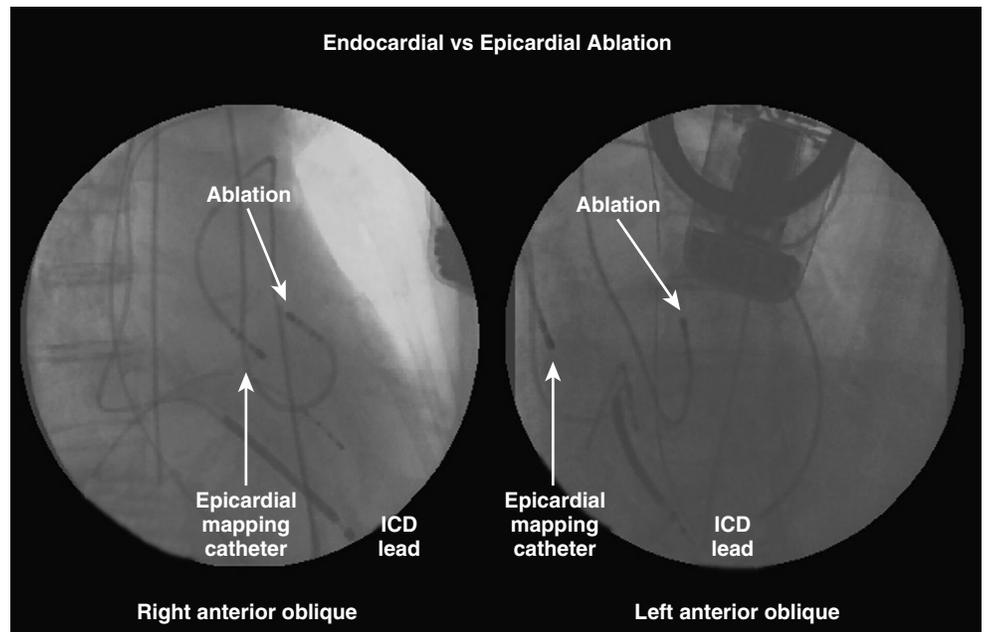

FIGURE 27-1 Combined endocardial and epicardial mapping of ventricular tachycardia (VT) in dilated nonischemic cardiomyopathy. Shown are fluoroscopic views of endocardial and epicardial catheter positions. VT was eventually eliminated with endocardial ablation at the site shown (basal left ventricle). ICD = implantable cardioverter-defibrillator.

absence of the pericardium is a rare congenital anomaly (approximately 1 in every 10,000 autopsies) that is most often asymptomatic and can be an incidental finding after the patient is referred for a pericardial procedure. In the preprocedural evaluation, this rare anomaly may be suspected by an abnormal cardiac rotation or silhouette on the chest x-ray film. Definitive diagnosis can be made by CT or magnetic resonance (MR) imaging.¹⁰

Preablation Evaluation

Epicardial access should be obtained only when an epicardial origin of the VT circuit is strongly suspected based on a thorough preprocedural assessment. In a recent study employing simultaneous endocardial and epicardial mapping, the endocardium was ultimately thought to be a better target than the epicardium in up to 21% of patients. This highlights the importance of preoperative evaluations and procedure planning.

Careful analysis of the ECG during VT or premature ventricle complexes (PVCs) is essential. As noted, different ECG criteria for recognizing an epicardial origin of arrhythmia have been proposed. Additionally, MR imaging can help identify epicardial substrate in cardiomyopathies.³ Furthermore, evaluation should include comprehensive clinical assessment and imaging studies to recognize any preexisting contraindications, and to minimize complications. Chest radiograph, echocardiography, and cardiac CT or MR imaging have proven to be useful for screening these patients.

CONTRAST-ENHANCED MAGNETIC RESONANCE IMAGING

Delayed contrast-enhanced MR imaging delineates regions of scar tissue potentially forming part of the arrhythmia substrate in patients with ischemic and nonischemic CMP and enables the depiction of transmural and nontransmural scars with high spatial resolution, allowing determination of whether the scar is endocardial, intramyocardial, or epicardial (Fig. 27-2).

The suspicion of an epicardial VT substrate can facilitate planning of VT ablations, such as for a combined endocardial and epicardial approach, especially given the fact that visualization of epicardial or intramyocardial scar on preprocedure delayed enhancement MR imaging was found to be predictive of failure of the endocardial approach and of the need for the epicardial approach for VT ablation.¹¹

Cardiac MR imaging can also help determine the underlying etiology of nonischemic CMP in some patients, such as myocarditis, sarcoidosis, and ARVD, which can be associated with a higher susceptibility for VT. Furthermore, in patients undergoing epicardial mapping and ablation procedures, registration of preacquired MR images with real-time electroanatomical mapping allows visualization of

ventricular anatomy and obstacles to procedural success, such as epicardial fat, which can be helpful during the mapping procedure in differentiating the cause of low epicardial voltages (fat versus scar).¹¹

One potential disadvantage concerns the safety of MR imaging in patients with implantable cardioverter-defibrillators (ICDs). In these patients, cardiac CT may be used for scar and fat imaging.

CONTRAST-ENHANCED COMPUTED TOMOGRAPHY

A contrast-enhanced CT scan enables detailed and comprehensive evaluation of LV myocardium using triple, multimodality imaging based on anatomical, dynamic, and perfusion parameters to identify abnormal substrate (myocardial scar and border zone) with high spatial (≤ 1 mm) and temporal resolution, which can be derived from a single CT scan. Areas of CT hypoperfusion correlate best with areas of abnormal voltage (< 1.5 mV) rather than scar alone (< 0.5 mV). Perfusion imaging from CT enables characterization of the transmural extent and intramyocardial location of scar tissue and visualization of surviving mid- and epicardial myocardium in the regions of scar, which can help identify areas potentially involved in the VT substrate. Such preprocedural information can help the operator plan an appropriate mapping and ablation strategy and better inform the patient about the risks, benefits, and chances of procedural success.¹²

The 3-D CT-defined abnormal myocardium can be accurately extracted and embedded in clinical mapping systems displaying areas of abnormal anatomical, dynamic, and perfusion parameters for substrate-guided VT ablations.¹² Additionally, CT epicardial fat imaging can be used to characterize the extent of fat tissue by extracting and integrating epicardial fat information into the 3-D electroanatomical voltage map, thereby helping to distinguish epicardial fat from scar tissue.¹³

Anatomical Considerations

The pericardium is a double-walled, flask-shaped sac that contains the heart and the roots of the great vessels, superior vena cava (SVC), and pulmonary veins (PVs). By separating the heart from its surroundings—the descending aorta, lungs, diaphragm, esophagus, trachea, and tracheobronchial lymph nodes—the pericardial space allows complete freedom of cardiac motion within this sac.¹⁰

The pericardium consists of two sacs intimately connected with one another: an outer fibrous envelope (the fibrous pericardium) and an inner serous sac (the serous pericardium). The fibrous pericardium consists of fibrous tissue and forms a flask-shaped bag, the neck of which is closed by its fusion with the external coats of the great vessels, while its base is attached by loose fibroareolar tissue to the central tendon and to the muscular fibers of the left side of the diaphragm. The fibrous pericardium is also attached to the

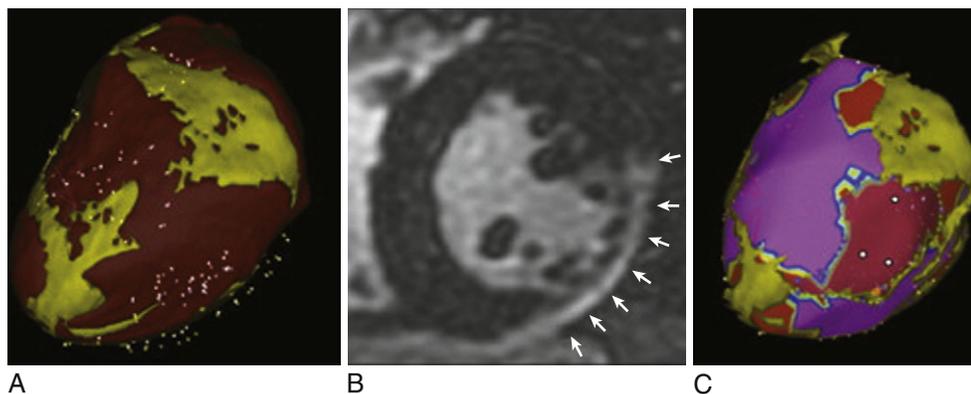

FIGURE 27-2 Epicardial fat and scar. **A**, Extracted epicardial fat (yellow) together with the epicardium (dark red) in a patient with nonischemic cardiomyopathy. **B**, Short-axis magnetic resonance imaging indicates an epicardial scar in the inferolateral left ventricular area (white arrows). **C**, Voltage map in the same patient, indicating an area of low voltage extending from the basolateral free wall of the left ventricle to the left ventricular apex. The epicardial fat (yellow) is merged with the electroanatomical voltage map. The low-voltage area projects on the left ventricular epicardium that is devoid of fat. (From Desjardins B, Morady F, Bogun F: Effect of epicardial fat on electroanatomical mapping and epicardial catheter ablation, *J Am Coll Cardiol* 56:1320-1327, 2010.)

posterior sternal surface by superior and inferior sternopericardial ligaments.¹⁰ These attachments are essential to maintain the normal cardiac position in relation to the surrounding structures, to restrict the volume of the thin-walled cardiac chambers (right atrium and ventricle), and also to serve as direct protection against injuries.

The vessels receiving fibrous prolongations from the fibrous pericardium are the aorta, the SVC, the right and left pulmonary arteries, and the four PVs. The inferior vena cava (IVC) enters the pericardium through the central tendon of the diaphragm, and receives no covering from the fibrous layer.

The serous pericardium is a delicate membrane that lies within the fibrous pericardium and lines its walls; it is composed of two layers: the parietal pericardium and the visceral pericardium. The parietal pericardium is fused to and inseparable from the fibrous pericardium. On the other hand, the visceral pericardium, which is composed of a single layer of mesothelial cells, is part of the epicardium (i.e., the layer immediately outside of the myocardium) and covers the heart and the great vessels except for a small area on the posterior wall of the atria. The visceral layer extends to the beginning of the great vessels, and is reflected from the heart onto the parietal layer of the serous pericardium along the great vessels in tubelike extensions. This happens at two areas: where the aorta and pulmonary trunk leave the heart and where the SVC, IVC, and PVs enter the heart.¹⁰ The serous pericardium is also metabolically active.

At the pericardial reflections and at the posterior wall between the great vessels, the pericardial space is divided up into a contiguous network of recesses and sinuses. There are three sinuses in the pericardial space: the superior sinus, the transverse sinus, and the oblique sinus. The superior sinus (superior aortic recess) lies anterior to the upper ascending aorta and main pulmonary artery. The transverse sinus is limited by a pericardial reflection between the superior PVs and contains the right pulmonary artery. The oblique sinus is confined by the pericardial reflections around the PVs and the IVC. The postcaval recess lies behind the SVC, the right pulmonary artery, and the right superior PV. The right and left PV recesses extend between their respective superior and inferior PVs.¹⁰

The pericardial cavity or sac is a continuous virtual space that lies between the parietal and visceral layers of serous pericardium. The heart invaginates the wall of the serous sac from above and behind, and practically obliterates its cavity, the space being merely a potential one. The sac normally contains 20 to 40 mL of clear fluid that occupies the virtual space between the two layers. Because all pericardial reflections are located basally in relation to the great vessels, the entire epicardial surface is accessible from the pericardial space, except for the atrial and ventricular septa, which are not in direct contact with the pericardium. Unlike the endovascular approach, the pericardial space is notable for the absence of obstacles and the relative ease with which catheter manipulation can be performed.¹⁰ By the same token, achieving firm, stable contact with the catheter tip at the target site may be difficult.

Technical Considerations

Although the procedure is usually performed in the electrophysiological (EP) laboratory, it is more ideal to perform percutaneous pericardial procedures in a hybrid laboratory where cardiac surgery can be performed promptly.

The subxiphoid approach procedure may be performed under conscious sedation, deep sedation with the support of an anesthesiologist, or general anesthesia. Deep sedation or general anesthesia allows better control of respiratory motion, which can potentially reduce the chance of unintentional RV puncture, as well as better pain control, given the fact that epicardial radiofrequency (RF) ablation is usually associated with significant pain and patient discomfort. On the other hand, if patients are paralyzed under general anesthesia, diaphragmatic motion with phrenic nerve stimulation during pacing may not occur to warn of proximity of RF applications.⁴ Intravenous antibiotics should be routinely administered within an hour prior to the procedure. Previous heparin administration should be reversed before pericardial access;

this is accomplished by protamine infusion to decrease the activated clotting time to less than 150 seconds.

Initially, catheters are positioned in the CS and RV apex through the femoral approach. The pericardial space is accessed using a 17- or 19-gauge Tuohy needle (Codman Inc., Raynham, Mass.), which is also used to enter the epidural space when administering epidural anesthesia (typically approximately 100 mm in overall length and a 1.5-mm outer diameter). The puncture is performed at the angle between the left border of the subxiphoid process and the lower left rib, with the needle pointing to the left shoulder. The puncture needle approaches the site with a shallow angle in order to penetrate the skin and slide under the rib cage. After crossing the subcutaneous tissue, the stylet is removed, and a 10-mL syringe containing 1% lidocaine or a nonionic contrast agent is attached to the proximal port of the needle. The needle is then advanced under fluoroscopic guidance (40-degree left anterior oblique [LAO] view or, preferably, biplane right anterior oblique [RAO] and LAO projections) until close to the cardiac silhouette. The needle angle is adjusted according to the region that the operator wishes to access. Directing the needle superiorly at a relatively shallow angle, aiming for the RV apex in the RAO projection, generally allows entry into the pericardial space anteriorly over the RV and facilitates access to the anterior aspect of the RV and LV. Directing the needle more posteriorly and toward the left shoulder allows it to enter the pericardium over the diaphragmatic portion of the heart, such that the sheath typically tracks along the posterior aspect of the LV, as observed in the LAO projection. The medial third of the RV is the preferred entry region because of the absence of major coronary vessels in this region.^{9,14}

In the 40-degree LAO view, injection of a small amount of contrast (approximately 1 mL) can help assess the relation of the needle to the parietal pericardium (Video 21). If the diaphragm has not been reached, the contrast will be seen in the subdiaphragmatic area. Once tenting of the pericardium is seen, a slight advance achieves entry into the space, and often one can feel the “pop” as the needle penetrates the fibrotic parietal pericardial wall. Contact of needle with the myocardium can be suggested by tactile feedback, occurrence of ventricular ectopy, or observation of a current of injury from a crocodile clip attached to the shaft of the needle. In this setting, further advancement of the needle can result in ventricular puncture and should be avoided.¹⁵

When the needle reaches the pericardial sac, aspiration without blood indicates that the needle has not entered the RV, and injected contrast will spread around the heart, restricted to its silhouette. In some cases, the needle will get close enough to the heart, but the contrast will not be clearly identified in the pericardial sac. In this situation, despite the needle being out of the pericardial sac, it is likely that a defect has been created in the membrane, through which it is possible to advance a soft-tipped guidewire and enter the pericardial sac. If the needle is not close enough to the pericardial membrane, the guidewire will move toward the subdiaphragmatic area. In these cases, the wire must be pulled back and small movements with the needle and the wire must be performed until the pericardial space is reached.⁹

Confirmation that the wire is intrapericardial and has not been inadvertently inserted into a cardiac chamber is obtained by observing the course of the wire in multiple fluoroscopic projections confirming that it crosses multiple cardiac chambers, hugging the edge of the cardiac silhouette in the 40-degree LAO view, circumferential to both the right and left heart, and without induction of PVCs. Observation in the RAO or anterior-posterior projection alone can be misleading, as a wire that enters the RV and passes into the right atrium (RA) or pulmonary artery can be misinterpreted as intrapericardial.^{9,15}

Inadvertent RV puncture is not rare, but is usually benign if only the needle or wire has entered the chamber in a patient who is not anticoagulated. When the RV is inadvertently entered with the needle (indicated by aspiration of blood or contrast injection passing to the pulmonary artery), the needle can be withdrawn slightly (reentering the pericardial space after exiting the ventricle); contrast injection can then show silhouetting of the heart, and at that point the

guidewire is advanced into the pericardial space. The small hole in the RV generally seals without incident. If the dilator and sheath have been passed into the RV, the larger hole may require surgical repair.⁴

Attempted epicardial access fails in approximately 10% of patients. The percutaneous approach to the pericardial space can be difficult in patients with pericardial adhesions (e.g., following cardiac surgery or pericarditis). In postsurgical patients, the adhesions are mostly concentrated in the anterior portion of the heart; therefore, the puncture must be directed toward the diaphragmatic area. In contrast, adhesion can be more diffuse in postpericarditis patients. Surgical creation of a subxiphoid pericardial window and manual dissection and lysis of the lesions to allow catheter mapping and ablation in the EP laboratory have been shown to be feasible in a small series.⁴

After reaching the pericardial space, a long soft “J” tip guidewire is advanced far enough to silhouette the pericardial space. The puncture needle is then withdrawn and an 8 Fr dilator is advanced over the guidewire under fluoroscopic guidance for predilation, followed by insertion of a standard 8 Fr sheath (see Video 21). If it is necessary to insert another catheter, a second guidewire can be advanced through the sheath, which should be removed, leaving two wires inside the pericardial space. Subsequently, a separate sheath is introduced over each of the guidewires. Alternatively, a second puncture of the pericardial sac may be performed, using the same steps described for the first puncture. Before removing the dilator out of the sheath, the sheath must be pushed against the chest to ensure that the tip of the sheath is placed inside the pericardial sac. Although using a standard 15 cm, 8 Fr sheath may suffice for inferior wall VT circuits, the use of longer sheaths (e.g., Agilis; St. Jude Medical, St. Paul, Minn.) should be considered, especially in patients with a larger thoracic anteroposterior dimension.

There is concern that abrasion or laceration of pericardial structures can occur by the edges of a stiff sheath if the sheath is left in the pericardium without a catheter protruding from the lumen. Therefore, it is recommended not to leave a large sheath in the pericardial space without a catheter in place. Also, it is important to lead with a wire or ablation catheter before advancing or moving the curl of the sheath to avoid damaging epicardial structures.⁹

Before introducing the mapping-ablation catheter, the sheath must be aspirated to check for bleeding. Approximately 10% to 20% of patients experience pericardial bleeding, particularly if inadvertent RV puncture has occurred. Bleeding is managed by frequent aspiration from the pericardial access sheath. It is not uncommon to aspirate 10 to 30 mL of bloody drainage from the pericardial sheath early in the procedure. At this point, anticoagulation should not have been administered; therefore, any bleeding should be self-limited and is generally considered a minor complication because it is not necessary to interrupt the procedure. Major bleeding is rare, and it can be related to the learning curve. Systemic anticoagulation with intravenous heparin is started when subsequent LV endocardial mapping, coronary angiography, or both are desired only after verifying the absence of continued pericardial bleeding.⁹

When bleeding is under control, the mapping-ablation catheter can be introduced. Once it is inside the pericardial sac, the catheter can be easily moved, allowing exploration of the entire epicardial surface. In patients with pericardial adhesions, the catheter can be used to perform blunt dissection of the adhesions; however, care must be taken to avoid cardiac perforation with the catheter tip in these cases. If the area of interest is too close to the tip of the sheath, a simple pull-back in the catheter can lead to the loss of pericardial access. Therefore, it is preferable to advance the catheter inside the pericardial space and return to the point of interest by deflecting the tip of the catheter back toward it.

Percutaneous Epicardial Mapping

Once an introducer sheath and catheter are in place, the catheter can be moved freely in the pericardial sac, constrained only by the reflections of the pericardial membrane located around the PVs and great vessels. Catheter mapping of the epicardium can be performed using fluoroscopy, an electroanatomical mapping system,

or both. Atrial surface mapping can be limited by the normal pericardial reflections and by the atrial irregular anatomy (right and left atrial appendages). Ventricular surface mapping, however, can be performed more easily. During manipulation of the sheath, small amounts of air can reach the pericardial space, which can easily be detected by fluoroscopy. The presence of air can induce instability to the catheter secondary to the lack of contact between the parietal and visceral membranes of the pericardial sac. Aspiration of air will restore contact characteristic of the pericardial space.

The approach to epicardial mapping is essentially the same as for endocardial ablation, including activation mapping, entrainment mapping, substrate mapping, and pace mapping, discussed in detail in [Chapter 22](#). The following discussion highlights certain peculiarities pertaining to the percutaneous epicardial approach to mapping.

ACTIVATION MAPPING

In scar-related VTs, inability to identify the reentry circuit isthmus on the endocardium can suggest that the isthmus is epicardial or intramural. In these cases, endocardial activation mapping can demonstrate a focal point of earliest endocardial activation where entrainment mapping indicates a potential exit or outer loop site, but ablation fails to interrupt VT, suggesting that there is an epicardial or intramural circuit with a broad endocardial exit. Some idiopathic VTs that have a focal origin also have a point of earliest endocardial breakthrough, but typically activation is not presystolic.⁹

If an appropriate target site for VT ablation cannot be identified despite extensive endocardial and epicardial mapping, an epicardial VT circuit sheltered by epicardial fat or an intramural circuit should be suspected. Cardiac MR imaging can potentially help delineate the extent of epicardial fat as well as intramural scarring suggestive of an intramural circuit.¹³

ENTRAINMENT AND PACE MAPPING

Entrainment and pace mapping maneuvers are usually difficult to perform using bipolar pacing because of a very high epicardial stimulation threshold (>15 mA) in approximately 70% of cases, likely related to the presence of epicardial fat and/or poor catheter contact due to freedom of catheter movement in the pericardial space.⁴ With unipolar pacing, the pacing threshold generally is less than 10 mA at 2 milliseconds in normal tissue.⁹ Epicardial fat less than 5 mm in thickness interposed between the ablating catheter and the epicardium usually does not modify the epicardial ventricular stimulation threshold.¹⁴ Of note, ablation with irrigated RF generally renders the pacing threshold at the target area greater than 10 mA secondary, in part, to introduction of the irrigant fluid into the pericardial space.⁹ This fluid can potentially result in decreased physical contact between the electrode and epicardial surface.

ELECTROANATOMICAL SUBSTRATE MAPPING

Substrate and VT mapping approaches are similar to those described for the endocardium. Areas of infarction or scar have low-amplitude electrograms similar to findings during endocardial mapping. However, epicardial fat, which is concentrated along the coronary sulcus and the interventricular grooves, can cause low-amplitude electrograms, falsely suggesting scar in voltage maps. Normal epicardial electrograms demonstrate bipolar signal amplitude typically above 0.94 to 1.5 mV; whereas signal amplitude associated with fat, large vessel coronary anatomy, or both might demonstrate significantly lower amplitude.^{4,9,13,16}

As noted, epicardial fat less than 0.8 to 5 mm in thickness interposed between the ablating catheter and the epicardium usually does not modify the amplitude or duration of the bipolar epicardial electrogram. However, in areas with a layer of epicardial fat greater than 5 mm in thickness the amplitude of the bipolar epicardial electrogram can decrease, resulting in ventricular noncapture, which may confound the ability to discriminate between fat and scar. Importantly, despite the lower electrogram amplitude, epicardial fat

will not produce “abnormal” (fractionated and split) electrograms. Therefore, to avoid a misclassification of low-voltage areas due to epicardial fat or major coronary vasculature as abnormal, it is important to analyze the location and extent of the confluent voltage abnormality as well as the electrogram signal characteristics. The presence of abnormal electrograms (fractionated, split, or late potentials) is usually a more reliable indicator of scar.^{1,13,14}

Registration of preacquired CT or MR images detailing the LV substrate with the real-time 3-D electroanatomical voltage map allows visualization of regions of scar tissue and can potentially facilitate mapping and ablation (see Fig. 27-2). CT and MR imaging can also be used to characterize the extent of fat tissue by extracting and integrating epicardial fat information into the electroanatomical voltage maps, thereby helping to distinguish epicardial fat from scar tissue and identify areas that are difficult to penetrate because of extensive epicardial fat (Fig. 27-3).¹³

Percutaneous Epicardial Ablation

RADIOFREQUENCY ABLATION

The target for ablation is selected exactly like the endocardial target is selected. RF energy remains the primary ablative energy source for epicardial ablation. During standard RF energy application in the pericardial space, heating to the point of thrombus formation and charring is of less concern, because there is no potential for arterial embolization from the epicardial space; therefore, higher temperatures ($>60^{\circ}\text{C}$) can be tolerated. However, standard RF ablation may not be as effective when delivered to the epicardium compared with lesions delivered to the endocardium because of the lack of convective cooling of the ablation electrode by the circulating blood. This results in high electrode temperatures at low-power settings ($\leq 10\text{ W}$), limiting power delivery in the pericardial space and impairing lesion formation. Additionally, the presence of epicardial fat (≥ 3.5 to 10 mm in thickness) between the ablation catheter and the targeted area can also represent an important obstacle to the effectiveness of VT ablation.^{4,9,13,14}

On the other hand, open and closed loop irrigated catheters allow the delivery of energy at power settings capable of creating larger and deeper (up to 5 mm) epicardial lesions than standard RF ablation, even in the absence of circulating blood in the pericardial space. Additionally, the presence of epicardial fat interposed between the catheter tip and the myocardial tissue only moderately attenuates the efficacy of cooled-tip ablation.⁴

Optimal parameters for RF power titration and irrigation are not completely defined. With external irrigation, it is desirable to use lower flow rates, as compared with those used during endocardial

mapping and ablation, to limit infusion of fluid into the pericardial space, because thrombus formation in the epicardium does not pose a risk of embolization. Commonly, the flow rate is set at 0 to 2 mL/min during mapping and at 10 to 20 mL/min during ablation, and is titrated as required to maintain electrode temperature at less than 50°C . RF energy is commonly delivered at a power output of 30 to 50 W for 60 to 120 seconds. Monitoring for an impedance fall is commonly used to assess likely adequate power delivery.⁹

With open irrigation, an obligatory fluid volume will enter the pericardial sac and, unless intermittently or continuously evacuated, it gradually results in cardiac tamponade. Therefore, intrapericardial fluid must be periodically drained after every few RF applications or every 15 to 20 minutes. This can be accomplished by intermittently removing the ablation catheter to allow aspiration from the pericardial sheath or placing a second pericardial catheter for drainage purposes. Alternatively, using a single sheath that is larger than the ablation catheter allows aspiration of fluid around the catheter from the side port, either intermittently or continuously (via attaching the side port to a suction bottle or gravity drain) without withdrawing the ablation catheter.^{4,9,17}

Internally cooled RF ablation is an attractive choice for pericardial ablation as no fluid is infused and one need not worry about monitoring pericardial fluid throughout the ablation procedure.¹⁸

At the completion of the mapping-ablation procedure, the ablation catheter is replaced by a pigtail catheter, which is gently aspirated to remove excess intrapericardial fluid, and to confirm the absence of bleeding. Evaluation of the pericardial space can be performed by transthoracic echocardiography and by injecting 2 to 3 mL of contrast under fluoroscopy, to confirm complete drainage before removing the sheath. Methylprednisolone at 0.5 to 1.0 mg can be injected into the pericardial space prior to removal of the pigtail catheter to decrease the likelihood of postprocedure pericarditis. Generally, no major reaccumulation of pericardial fluid is observed following postprocedure draining of the pericardial fluid. The pigtail catheter may be kept inside the pericardial sac for as long as it is considered necessary. After controlling the bleeding, monitoring the patient with serial transthoracic echocardiography 24 hours later is recommended. Intravenous antibiotic therapy is administered postprocedure and follow-up echocardiogram should be performed.

PREVENTION OF CORONARY ARTERY INJURY

Coronary artery injury, severe spasm, or both can occur during epicardial mapping and RF ablation. The base and the anterior and posterior septal areas are the more dangerous zones. Prior to ablation, direct visualization of the relation between the ablation site and

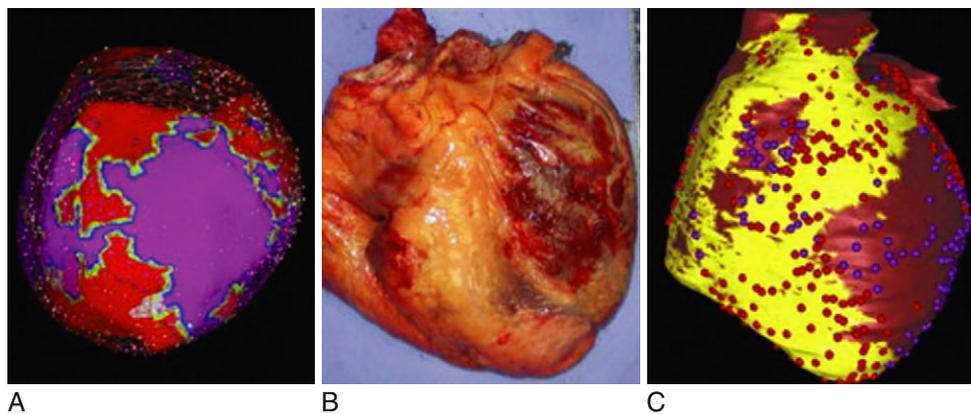

FIGURE 27-3 Distribution of epicardial fat and electroanatomical mapping. **A**, Epicardial voltage map of a patient with nonischemic cardiomyopathy. The voltage map shows surface reconstruction of the anterior surface of the heart. There is a low-voltage area (red) extending from the right ventricular outflow tract to the apex and following the lateral inferior margin to the base of the right ventricle. **B**, Gross pathology of the same heart after cardiac transplantation illustrating that the area of low voltage on the left largely corresponds to an area of epicardial fat. **C**, The extracted epicardial fat from the computed tomography data in this patient is shown in yellow. The remaining epicardial surface (dark red) is devoid of fat. The three-dimensional epicardial fat map was integrated with the voltage map. Low-voltage points are bright red and normal voltage points are purple. (From Desjardins B, Morady F, Bogun F: Effect of epicardial fat on electroanatomical mapping and epicardial catheter ablation, *J Am Coll Cardiol* 56:1320-1327, 2010.)

adjacent coronary arteries must be obtained, usually by coronary angiography performed with the ablation catheter on the target site. An absolute safe distance between the ablation site and epicardial artery has not been defined, and likely varies depending on the RF energy applied, coronary artery diameter and flow, and the presence of overlying fat. Based on available data and experience, a distance of at least 5 mm between the ablation electrode and an epicardial artery is commonly accepted. It is also important to ensure that the catheter is not touching the vessel at any point of the cardiac cycle during angiography. Coronary artery spasm has been reported during mapping in the pericardial space and could occur as a result of ablation close to the artery; extrinsic compression of a coronary artery can also result from edema caused by nearby ablation. Cryoablation appears to have less risk of coronary injury in animal models, but can still create occlusion and intimal damage when in close proximity, particularly to small vessels. Further confirmatory studies are warranted.⁴

PREVENTION OF PHRENIC NERVE INJURY

The left phrenic nerve is potentially susceptible to injury along its epicardial course adjacent to the lateral LV wall. The left phrenic nerve descends behind the left brachiocephalic vein and passes over the aortic arch, pulmonary trunk, and then with the pericardium over the left atrial (LA) appendage. From there it descends along the pericardium over the LV and frequently passes laterally over the obtuse margin of the LV, close to the lateral vein and the left marginal artery and, in only a small percentage of cases, close to the left main coronary artery and great cardiac vein. Not infrequently, the phrenic nerve courses through sites that might be considered appropriate target ablation sites, potentially limiting the safety and efficacy of ablation.¹⁹

Proximity to the nerve can be detected by high-output pacing (typically at more than 10 mA) to detect diaphragmatic stimulation on fluoroscopy, allowing its course to be marked on a 3-D map. The nerve can branch over the LV, so simply noting sites at which phrenic capture occurred does not necessarily delineate the course of all branches. It is important to recognize that detection by phrenic nerve capture is prevented by the use of paralytic agents during general anesthesia. However, these drugs are typically used during induction of anesthesia and their effects have dissipated by the time ablation is being performed.

Catheter ablation should be avoided at sites adjacent to the phrenic nerve. Alternatively moving the nerve away from the myocardium by injection of air into the pericardium or placement of a balloon catheter between the ablation target site and nerve can allow safe RF ablation. Alternative energy sources such as cryoenergy have been used to prevent phrenic nerve injury. Cryomapping uses temporary phrenic nerve injury to determine when to avoid full cryoablation. However, data on the success of cryoablation in the pericardial space are limited.^{4,19,20}

Mechanical separation of the phrenic nerve from adjacent structures, using a large balloon, involves insertion of a wire through one of the existing pericardial sheaths to the vicinity of the ablation catheter positioned at the target epicardial site. A 25 mm × 40 mm peripheral angioplasty balloon is advanced over the wire to these locations. The balloon is inflated using an insufflator and contrast until complete inflation is seen on fluoroscopy. This technique can be limited by the inability to steer the balloon catheter and position it in the desired epicardial location. Occasionally, a deflectable sheath can be required to direct the balloon to the appropriate location and provide additional support and stability.¹⁹

Another method is to introduce a combination of saline and air into the pericardium to achieve a “controlled” hydropneumopericardium to increase the distance between the phrenic nerve and the ablation target area. This involves using a 20-mL syringe to introduce saline and air alternately in 20-mL increments under careful monitoring of arterial pressure and fluoroscopy. At each step, epicardial pacing is performed to assess phrenic nerve capture and diaphragmatic stimulation. Instillation of air and/or saline is performed slowly until phrenic nerve capture is lost or systolic arterial pressure drops to 60 mm Hg. Although cardiac tamponade

can develop secondary to sudden accumulation of fluid or air in the pericardial space, controlled and progressive introduction of fluid and air with careful hemodynamic monitoring usually allows separation of the phrenic nerve from the epicardial surface without causing clinically significant tamponade.¹⁹

The combination of air and fluid appears to be more successful in preventing phrenic nerve injury during epicardial ablation than injecting air alone or fluid alone. In contrast to injection of fluid alone, the combination of air and fluid allows injection of a higher volume in the pericardial space with a lower impact on blood pressure than use of fluid alone. With air only, a significant resistance can be felt in most patients after injections of more than 300 mL despite stable blood pressure. Of note, air in the pericardial space can increase the defibrillation threshold, requiring emergency evacuation if defibrillation is required.¹⁹

CRYOABLATION

Cryoablation is an alternative to RF ablation that is not limited by absence of cooling blood flow in the pericardial space and is less prone to cause coronary artery injury in animal models. In fact, the absence of circulating blood in the pericardial space theoretically should favor creation of cryolesion. However, human experience is limited, and more studies are needed to assess safety and efficacy. Cryoablation did not produce significantly larger lesions than irrigated RF in an animal model.⁴ Cryoablation is commonly used in the operating room. Surgical cryoablation with hand held surgical probes achieves much lower temperatures (less than -150°C) and generates larger lesions than small EP catheters.⁹

Outcome

Percutaneous epicardial catheter techniques have expanded the options for investigating and treating arrhythmias. Percutaneous pericardial access can be obtained in more than 90% of patients who have not had prior cardiac surgery or clinical pericarditis, even in those who required repeated epicardial procedures. However, pericardial adhesions after cardiac surgery often prevent percutaneous access, although limited access is possible in some patients. A direct surgical approach to the pericardial space via a subxiphoid pericardial window or thoracotomy can achieve access in most patients.^{9,21}

Percutaneous access to the pericardial space has improved the outcome of catheter ablation in patients with scar-related VT. In several reports, arrhythmia control with epicardial ablation was achieved in 63% to 78% of patients.^{3,9} However, it is important to note that these findings reflect practices at centers that specialize in arrhythmia management and may not be applicable to less experienced operators or centers. Careful patient selection is important, and the procedure should be performed by experienced operators with surgical backup.³

The transthoracic epicardial mapping and ablation technique is a relatively safe procedure. Severe complications have been relatively infrequent (approximately 5%), but several potential risks require attention. RV perforation and hemopericardium can be observed in up to 30% of cases. The amount of blood drained from the pericardial space usually ranges from 20 to 300 mL. Thus, most of the time, the occurrence of hemopericardium does not preclude the continuation of the procedure, although repeated aspiration of the pericardial space may be required throughout the procedure. However, major pericardial bleeding remains the most common complication (4.5%), occasionally requiring surgical intervention. Therefore, precautions must be in place for managing severe bleeding, including availability of appropriate surgical expertise.³

Several precautions are important to avoid injury to adjacent structures. RF injury to coronary arteries can cause acute thrombosis or damage to the arterial wall. Coronary angiography must be performed immediately before ablation to select a safe area for RF applications.⁴

Left phrenic nerve injury and diaphragmatic paralysis can result from RF ablation over the lateral LV wall. As noted, different strategies have been proposed with the aim of localizing the

nerve, defining the nerve course, and then increasing the distance between the ablation site and the nerve itself.²⁰

Infrequently, hemoperitoneum can result after injuring a sub-diaphragmatic vessel during the puncture, and these patients may require surgery to control the intraabdominal bleeding. Hepatic laceration and bleeding are also potential risks.^{4,14}

Symptomatic pericarditis is common after the procedure, occurring in approximately 30% of patients. In the majority of cases, pericardial inflammation is mild and resolves within a few days with nonsteroidal antiinflammatory medications. Administration of methylprednisolone at 0.5 to 1 mg/kg into the epicardial space at the end of the procedure can potentially help reduce the pericardial inflammatory reaction. It is important to note that inflammatory pericarditis can render the epicardial space percutaneously inaccessible for repeat procedures because of the development of adhesions.^{4,9,14}

Transvenous Epicardial Mapping and Ablation

Clinical Considerations

Coronary veins provide endovascular access to the epicardial regions of the ventricles, and have been used for mapping and ablation of arrhythmia foci or circuits that are deep within the myocardium or in the epicardium without having to access the epicardium percutaneously. Access through the great cardiac and anterior interventricular veins allows mapping over a wide area of the anterolateral LV wall, whereas access through the middle cardiac vein allows mapping over the inferior wall of the ventricles and posterior aspect of the interventricular septum.

Up to 14% of patients with idiopathic PVCs can have an epicardial site of origin identified within the coronary venous system, most often in the great cardiac vein. Successful long-term ablation of these arrhythmias was achieved from within the coronary venous system in approximately 70% of patients.⁸

However, epicardial mapping and ablation via the coronary venous system has important limitations. Epicardial circuits may be identified only when the cannulated vessel happens to be in the region of the circuit. Additionally, catheter manipulation is limited by the anatomical distribution and size of these vessels. Currently available ablation catheters often are difficult to advance beyond the distal great cardiac vein or the proximal portions of the middle cardiac vein because of the tortuosity, sharp angulation, and small caliber of the distal veins. Furthermore, a conventional ablation catheter may completely occlude a branch of the CS, preventing cooling of the ablation electrode and resulting in high impedance when RF energy is delivered. This markedly reduces the amount of power that can be delivered and may result in adherence of the ablation electrode to the wall of the vein. In fact, delivery of more than 10 to 15 W seldom is possible. An external saline-cooled ablation catheter allows more consistent delivery of RF energy, with less heating at the electrode-tissue interface.⁷

Anatomical Considerations

The myocardium drains mainly by three groups of veins: (1) the CS and its tributaries, which return blood from almost the whole heart; (2) the anterior cardiac veins, which primarily drain the anterior regions of the RV and the right cardiac border, ending principally in the RA; and (3) the Thebesian venous network (*venae cordis minimae*), which is the smaller cardiac venous system and is composed of small venous branches made primarily of endothelial cells, which are continuous with the lining of the cardiac chambers, and drains the subendocardium. The Thebesian veins open directly into any of the four chambers but are more prominent on the right and, to a lesser extent, the LA and sometimes the LV.²²⁻²⁴

Normally, the CS has five first-order tributaries: the great cardiac vein, the middle cardiac vein, the small cardiac vein, the posterior cardiac vein of the LV, and the oblique vein of the LA (oblique

vein of Marshall). These tributaries then branch into second- and third-order tributaries. The CS returns the blood to the RA from the whole heart (including its septa) except the anterior region of the RV and small, variable parts of both atria and the LV.

The CS begins as a continuation of the great cardiac vein, extending from the valve of Vieussens (which often marks the junction of the CS with the great cardiac vein) to the ostium of the CS as it terminates in the RA. The length of the CS varies from 30 to 55 mm and its diameter varies from 6 to 16 mm in its middle portion (depending on the loading conditions and the presence of underlying cardiac disease or prior cardiac surgery).^{22,23}

The CS invariably lies in the posterior aspect of the atrioventricular (AV) groove in the sulcus between the LA and LV and opens into the RA. The CS ostium (CS os) is 5 to 15 mm in diameter and is located on the posterior interatrial septum anterior to the Eustachian ridge and valve and posterior to the tricuspid annulus. The CS os is guarded by the highly variable, crescent-shaped Thebesian valve. This valve usually covers the superior and posterior surfaces of the CS os, but may nearly completely cover the os with formation of fenestrations and can hinder cannulation of the CS.²²⁻²⁴

The anterior interventricular vein is the largest and most consistent of the cardiac veins. It drains a significant portion of the LV anterior wall and the interventricular septum, begins at the cardiac apex, and ascends toward the base of the heart in the anterior interventricular sulcus, parallel to the left anterior descending coronary artery. The phrenic nerve may lie close to lateral branches of this vein. The anterior interventricular vein is the most anterior vein seen in the RAO projection. At the base of the heart, near the bifurcation of the left coronary artery, the anterior interventricular vein turns laterally and becomes the "great cardiac vein," which courses along the left AV groove (parallel to the left circumflex coronary artery) and wraps around the left side of the heart.²²⁻²⁴

The great cardiac vein is joined by the LA oblique vein of Marshall and the posterolateral vein of the LV to form the CS. In addition to several smaller tributaries from the LA and ventricles, the great cardiac vein receives two main branches, namely, the large left marginal vein (along the lateral border of the heart) and the posterior cardiac vein of the LV (also known as the posterolateral vein).²²⁻²⁴

The middle (or "posterior interventricular") cardiac vein is the largest proximal tributary of the CS and is present in nearly all hearts. This vein drains the inferior walls of both ventricles and interventricular septum and courses with the posterior descending coronary artery in the posterior interventricular groove, joining the CS close to the RA orifice or, rarely, entering the RA directly.

The small cardiac vein is an inconstant vessel that receives blood from the back of the RA and RV, runs in the coronary sulcus between the RA and RV parallel to the right coronary artery, and empties into either the CS, the middle cardiac vein, or the RA.

Of all of the branches of the coronary venous system, the great cardiac and middle cardiac veins are the two most consistently present branches. Unlike the middle cardiac vein, the great cardiac vein varies considerably in its course. Lateral and posterior venous branches together are seen in approximately 50% of human hearts, unlike the anterior interventricular and middle cardiac veins, which are seen in more than 90%.

The venous valves can hinder catheter access within the coronary venous system, especially the Thebesian valve, which may completely cover the CS os in a variety of forms or be imperforate. Other venous valves, like the valve of Vieussens, are often present at the entrances of the ventricular veins into the great cardiac vein, or at the entrance of a smaller vein into a larger vein. These tend to be flimsy endothelial ridges but can present some resistance on probing or when trying to pass a catheter.²²⁻²⁴

Technical Considerations

CS venography is typically required to help delineate its anatomy and guide ablation. The great cardiac and the anterior interventricular veins allow epicardial access to the anterior basal ventricular

surface. The middle cardiac vein allows epicardial access to the inferior ventricular surface.

Small electrode catheters (e.g., the 2.5 Fr multipolar catheter Pathfinder; Cardima, Inc., Fremont, Calif.) can be introduced into the CS and advanced out into the cardiac veins. The catheter can be positioned in different coronary venous branches to map different regions of the epicardial surface of the ventricles.⁸

Once the ablation catheter is positioned at the target site, and before energy delivery, coronary angiography should be performed to assess the distance of the catheter tip to a major epicardial

coronary artery (see Fig. 23-19). If this distance is less than 4 mm ablation should not be attempted. In this situation, cryoablation can be performed with little or no risk of coronary artery injury. Additionally, pacing from the distal ablation electrode should be performed at an output of 20 mA. If diaphragmatic capture can be demonstrated, then ablation should not be attempted to avoid phrenic nerve injury.

RF ablation within the coronary venous system is usually performed with a 3.5-mm open-irrigated-tip catheter at a power output of 15 to 25 W for up to 60 seconds (Fig. 27-4). If this catheter cannot

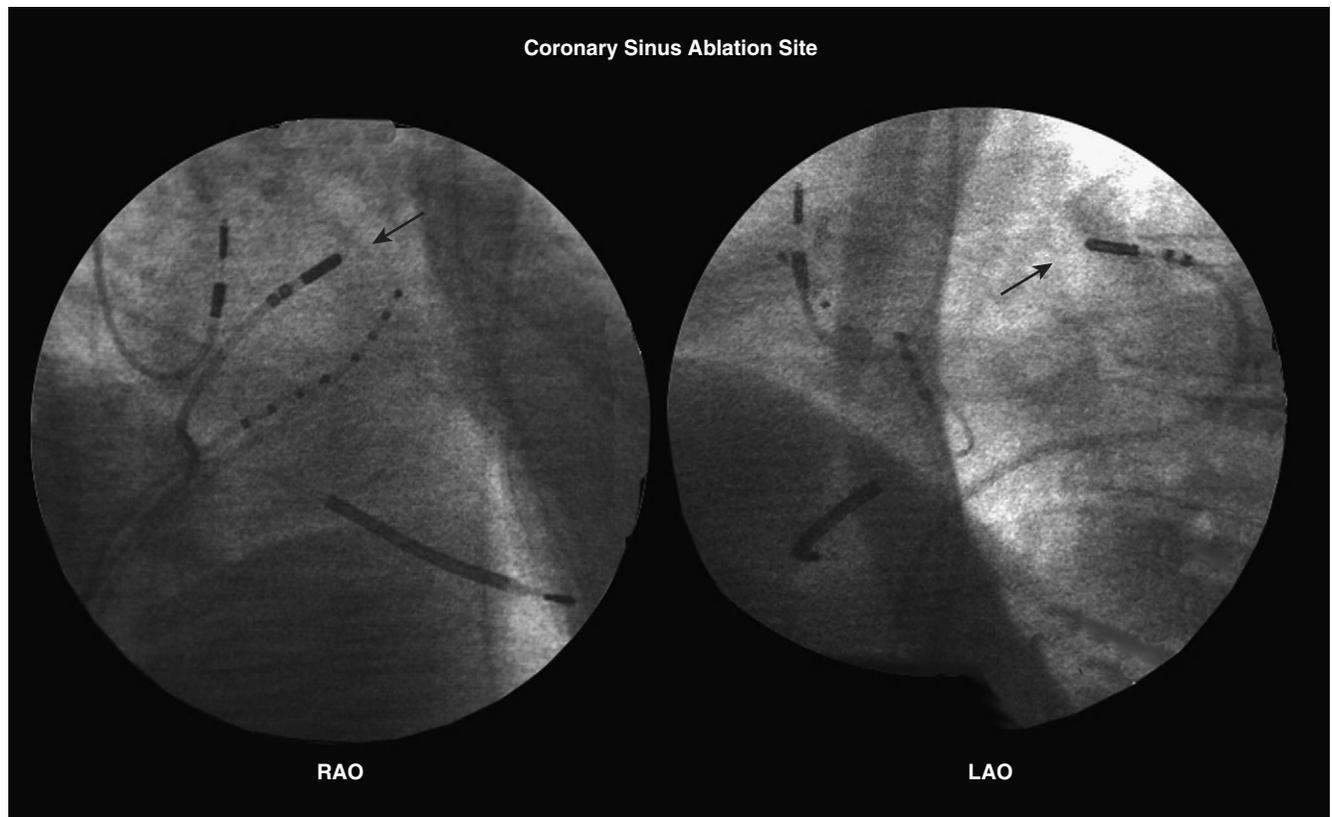

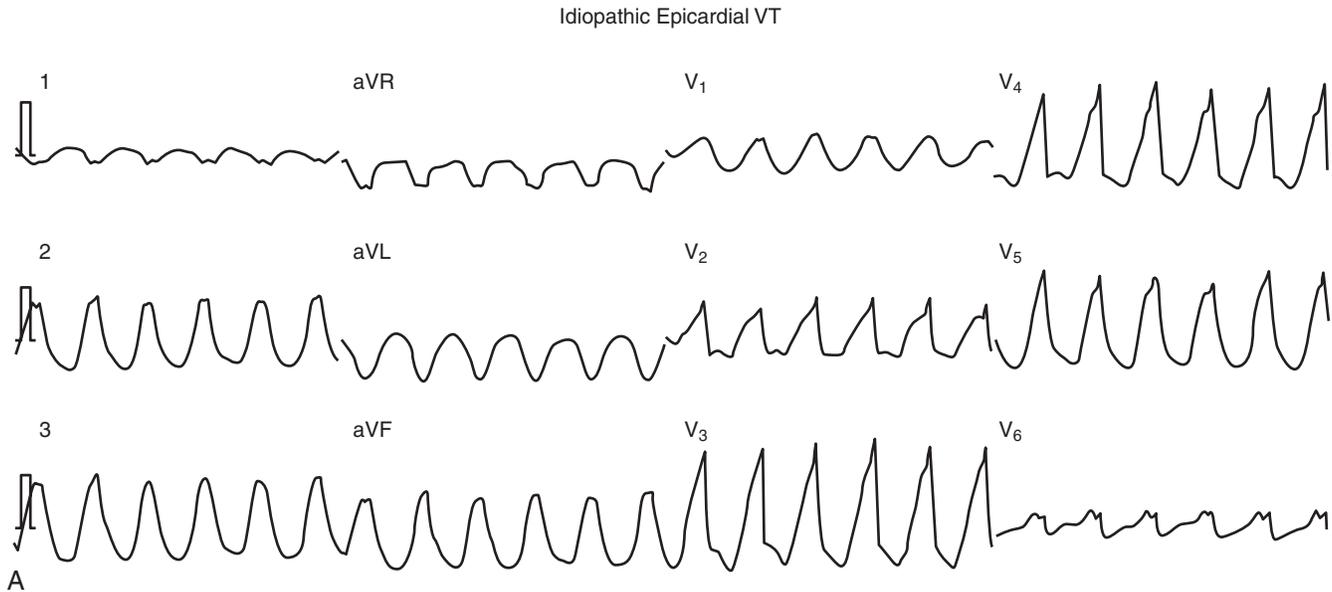

FIGURE 27-4 Idiopathic epicardial ventricular tachycardia (VT). **A**, Surface ECG of a slow VT that was ablated from the coronary sinus (CS) after both endocardial and epicardial mapping failed to eliminate the VT. **B**, Right anterior oblique (RAO) and left anterior oblique (LAO) fluoroscopic views of catheter location for VT ablation from the CS.

be maneuvered to the ablation target site, a 5 Fr, 6 Fr, or 7 Fr ablation catheter may be used. For nonirrigated-tip catheters, the target temperature is usually set to 55°C to 60°C with a power output of 15 to 30 W. Impedance should be monitored during RF applications, and RF energy delivery should be stopped if impedance rises significantly. If RF energy delivery is limited, cryoablation using a 6-mm CryoAblation catheter (Medtronic, Minneapolis, Minn.) may be considered, although this catheter is less maneuverable than an RF catheter.⁸

Outcome

The outcome of the ablation procedure is a function of the proximity of the ideal target site to accessible portions of the coronary venous system as well as the ability to deliver an effective amount of ablative energy to the target site. Despite the anatomical constraints, ablation via the coronary venous system has yielded success rates of approximately 70%. Using the coronary venous system for mapping and ablation can potentially result in a lower complication rate than the percutaneous pericardial approach because damage to the RV or extracardiac structures is less likely to occur.⁷

Coronary artery injury is an ever-present risk, especially near the proximal part of the anterior interventricular vein. Arterial injury, including thrombosis, medial necrosis, and hyperplasia, is inversely proportional to vessel diameter; there is little evidence of injury when vessel diameter exceeds 0.5 to 1.0 mm. Similar findings were reported for cryoablation. As noted, coronary angiography should be performed before delivering RF energy near or within a branch of the CS to determine whether there are any branches of the right or left coronary artery in proximity to the ablation site.⁷

Pathophysiology

Hypertrophic cardiomyopathy (CMP) is characterized by an otherwise unexplained thickened but nondilated left ventricle (LV) in the absence of any other cardiac or systemic condition capable of producing the magnitude of hypertrophy evident (e.g., aortic valve stenosis, systemic hypertension, some expressions of athlete's heart, infiltrative or storage disorders), independent of whether obstruction to LV outflow is present.

Hypertrophic CMP is characterized by myocyte disarray. Cardiomyocytes in hypertrophic CMP become hypertrophied, enlarged, and distorted, which leads to disorientation of adjacent cells and arrangement in chaotic disorganized patterns (instead of the normal parallel cellular arrangement), forming circles or whorls around foci of connective tissue. Although the disorganized architecture is evident in the majority (95%) of patients dying of hypertrophic CMP, it is not specific to hypertrophic CMP, and it occurs in other syndromic causes of LV hypertrophy such as Noonan syndrome and Friedreich ataxia, congenital heart disease, hypertension, and aortic stenosis. Nevertheless, myocyte disarray in hypertrophic CMP is typically more extensive, occupying more than 5% of the total myocardium, including substantial portions of hypertrophied as well as nonhypertrophied LV myocardium, 33% of the ventricular septum, and 25% of the free wall.

Changes in myocyte architecture lead to ventricular hypertrophy (Fig. 28-1). The degree and distribution of LV hypertrophy vary markedly. LV hypertrophy can be asymmetrical or symmetrical. The symmetrical form of hypertrophic CMP accounts for more than one-third of cases and is characterized by concentric thickening of the LV with a small ventricular cavity dimension. Asymmetrical septal hypertrophy is the most common variant, which is associated with thickening of the basal anterior septum, which bulges beneath the aortic valve and causes narrowing of the LV outflow region. However, isolated segmental hypertrophy may affect the LV apex (apical hypertrophic CMP) or any portion of the LV. The morphological pattern of LV hypertrophy is not closely predictive of the severity of symptoms or prognosis. Although LV apical aneurysms are observed only rarely (2%), they are associated with a higher rate of adverse disease consequences (10.5% per year) as compared with the general hypertrophic CMP population.¹

Hypertrophic CMP is a complex and clinically heterogeneous disease that demonstrates remarkable diversity in disease course, age of onset, severity of symptoms, LV outflow obstruction, and risk for sudden cardiac death (SCD). The characteristic diversity of the hypertrophic CMP phenotype is attributable to the intergenetic heterogeneity (with a variety of mutations encoding protein components of the cardiac sarcomere), the intragenetic heterogeneity (with multiple different mutations identified in each gene), as well as the potential influence of modifier genes and environmental factors.

The arrhythmogenic substrate responsible for ventricular tachycardia (VT) occurrence in hypertrophic CMP has not been completely defined. Myofibrillar disarray as well as diffuse interstitial myocardial fibrosis or extensive scarring (likely caused by abnormalities of intramural coronary arteries and focal ischemia), which potentially predispose to disordered conduction patterns and increased dispersion of electrical depolarization and repolarization, have been suggested as factors contributing to ventricular arrhythmogenesis.²

Molecular Genetics

Hypertrophic CMP is familial in approximately half the cases and sporadic in the other half. The disease is transmitted as a Mendelian trait with an autosomal dominant pattern of inheritance and variable clinical penetrance. There is substantial diversity in the genetic causes of hypertrophic CMP. To date, nearly 900 different mutations have been reported in at least 24 genes encoding eight sarcomere proteins, including cardiac alpha- and beta-myosin heavy chains; cardiac troponins T, I, and C; cardiac myosin-binding protein C; alpha-tropomyosin; actin; titin; and essential and regulatory myosin light chains. Among these genes, mutations in *MYH7*, encoding beta-myosin heavy chain, and *MYBPC3*, encoding cardiac myosin binding protein-C, are the most common, each accounting for one-quarter to one-third of all cases.^{3,4} For each gene, several different mutations have been identified, and specific mutations are associated with different disease severity and prognosis.⁵

In addition, nonsarcomeric protein mutations in genes involved in cardiac metabolism (e.g., the gamma subunit of adenosine monophosphate [AMP]-activated protein kinase, PRKAG2, and lysosome-associated membrane protein 2 [LAMP-2], as in Danon disease), which are responsible for primary cardiac glycogen storage cardiomyopathies in older children and young adults, can be associated with a clinical presentation mimicking or indistinguishable from sarcomeric hypertrophic CMP. A high prevalence of conduction system dysfunction (with the requirement of permanent pacing in 30% of patients) characterizes PRKAG2 mutations. These diseases are often associated with ventricular preexcitation (Wolff-Parkinson-White syndrome). LAMP2 mutations are associated with early-onset LV hypertrophy (often in childhood) with rapid progression of heart failure and poor prognosis. These clinical entities are distinct from hypertrophic CMP caused by sarcomere protein mutations, despite the shared feature of LV hypertrophy. In addition, there can be genetic overlap between hypertrophic CMP and LV noncompaction.⁴

In infants and children, LV hypertrophy mimicking typical hypertrophic CMP caused by sarcomere protein mutations is often associated with congenital malformations and syndromes, inherited disorders of metabolism, and neuromuscular diseases, such as Fabry disease, Pompe disease, amyloidosis, carnitine deficiency, mitochondrial diseases, Friedreich ataxia, Noonan syndrome, and

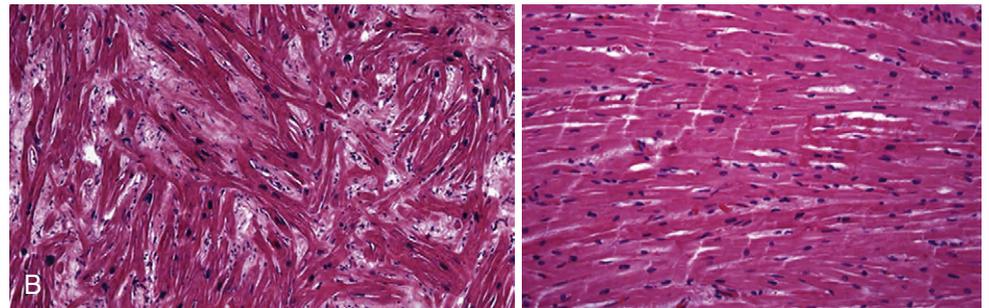

FIGURE 28-1 Pathological features of hypertrophic cardiomyopathy (CMP). **A**, Gross pathology showing markedly increased LV wall thickness associated with hypertrophic CMP (left) as compared with normal cardiac morphology (right). **B**, Histological sections stained with hematoxylin and eosin demonstrate myocyte disarray, where myocytes are oriented at bizarre and variable angles to each other, and increased myocardial fibrosis (left), the pathognomonic features of hypertrophic CMP. In contrast, normal myocardium demonstrates a very orderly arrangement of myocytes (right). Images are shown at $\times 10$ magnification. (From Ho CY: Hypertrophic cardiomyopathy, *Heart Fail Clin* 6:141-159, 2010.)

LEOPARD syndrome. Hypertrophic CMP can be distinguished from these disorders by dysmorphological examination, neuromuscular examination, metabolic screening, family information, and genetic testing.^{3,6}

Clinical Considerations

Epidemiology

Hypertrophic CMP is the most common genetic cardiovascular disease, with a prevalence of approximately 0.2% of the general population for the disease phenotype recognized by echocardiography.

Approximately 10% to 20% of individuals with hypertrophic CMP have a lifetime-increased risk for SCD, most likely resulting from VT and ventricular fibrillation (VF). Hypertrophic CMP is the leading single cause of SCD in competitive athletes in the United States, accounting for approximately one-third of such deaths. Although SCD occurs most often in adolescents or young adults, it can occur at any age. However, SCD is uncommon in young children.

SCD can be the first manifestation of disease. Individuals with hypertrophic CMP who are at the highest risk for SCD can have an at least 3% to 5% annual risk for SCD, whereas individuals in the general hypertrophic CMP population have a 1% annual risk for SCD.

Early studies based on tertiary referral-based populations with hypertrophic CMP suggested a poor prognosis with estimated annual mortality rates of 4% to 6%; however, subsequent studies on broader-based populations suggest that prognosis is typically more favorable with estimated annual mortality rates of 1% to 3% and a normal life expectancy of 75 years or more in about 25% of individuals, the majority of whom have little functional disability.

Clinical Presentation

The clinical presentation of hypertrophic CMP is characterized by extreme variability in disease course, age of onset, severity of symptoms, and risk for SCD. Many patients are either asymptomatic or mildly symptomatic. The majority of patients present during

adolescence or young adulthood, but symptoms can develop at any age. Symptomatic patients typically present with dyspnea, chest pain, palpitations, fatigue, orthostatic lightheadedness, presyncope, and syncope. Other complications include atrial and ventricular arrhythmias, infective endocarditis, and congestive heart failure. As noted, SCD can be the first manifestation of the disease.⁷

Shortness of breath, particularly exertional, is the most common symptom of hypertrophic CMP, occurring in up to 90% of patients, typically secondary to diastolic LV dysfunction. Syncope occurs in approximately 15% to 25% of patients, typically secondary to abnormal hemodynamic function (i.e., dynamic LV outflow obstruction) or, infrequently, secondary to cardiac arrhythmias.^{7,8} Atrial fibrillation (AF) is the most common arrhythmia observed in hypertrophic CMP, occurring in approximately 20% to 25% of patients, and is associated with an increased risk of stroke and thromboembolic complications.

LV outflow obstruction, when present, can produce a characteristic dynamic systolic ejection murmur and bifid pulse. About 25% of individuals with hypertrophic CMP demonstrate LV outflow obstruction at rest, but in many patients the obstruction is variable, occurring in response to exercise or maneuvers that decrease LV preload or afterload or increase contractility or heart rate (dynamic outflow obstruction).

Although LV ejection fraction (LVEF) is typically preserved or even hyperdynamic, up to 5% to 10% of patients may progress to the “burned-out” or end-stage phase of hypertrophic CMP, marked by LV systolic dysfunction, and occasionally progressive LV dilatation and wall thinning. These patients may develop refractory symptoms or end-stage heart failure requiring cardiac transplantation.

Ventricular Arrhythmias

The predominant arrhythmia syndrome associated with hypertrophic CMP is sudden cardiac arrest, presumably due to polymorphic VT or VF. SCD occurs with an annual mortality rate of approximately 6% in referral-based populations and 1% in community-based studies. However, certain patient subgroups can have much

higher rates, surpassing the American College of Cardiology/American Heart Association (ACC/AHA) guideline document definition of high risk for SCD ($\geq 2\%$ annual risk).⁹

Hypertrophic CMP is the most common cause of SCD in young people, including competitive athletes, in the United States. SCD occurs throughout life, with a peak in adolescence and young adulthood (<30 to 35 years of age), and can be the initial disease presentation. SCD occurs most commonly during mild exertion or sedentary activities; nonetheless, an important proportion of such events is associated with vigorous exertion.

Ambulatory electrocardiogram (ECG) monitoring frequently reveals premature ventricular complexes (in 88% of patients), nonsustained VT (25% to 30%), and supraventricular tachyarrhythmias such as AF and atrial flutter (30% to 40%). The frequency of all arrhythmias during 48-hour ambulatory ECG monitoring is age related. Nonsustained VT is associated with severity of hypertrophy and symptom class; supraventricular arrhythmias are more common in patients with LV outflow obstruction.

Stable sustained monomorphic VT (SMVT) is rare, but can occur in patients with midventricular obstruction or apical LV aneurysms. The recurrence rate of VT is relatively high (56%) in hypertrophic CMP patients, and electrical storm can occur. During electrophysiological (EP) testing, induction of SMVT has a low reproducibility, and polymorphic VT and VF are often induced. The VT is commonly associated with a superior axis on the frontal plane, suggesting LV apical origins. An arrhythmic substrate, such as an aneurysm, can be important for the occurrence of stable SMVT.^{1,10}

Appropriate implantable cardioverter-defibrillator (ICD) discharges in hypertrophic CMP patients occur annually in 10.6% of ICD recipients for secondary prevention after cardiac arrest (5-year cumulative probability, 39%), and in 3.6% of ICD recipients for primary prevention (5-year probability, 17%).¹¹ Of note, arrhythmogenic events do not necessarily portend other adverse clinical outcomes. Specifically, appropriate ICD discharges do not appear to predict the occurrence of heart failure or the need for other invasive therapies (e.g., surgical myectomy, septal ablation).¹²

Initial Evaluation

Clinical diagnosis is generally made with transthoracic echocardiography, demonstrating LV hypertrophy in a nondilated ventricle (Fig. 28-2). Cardiac magnetic resonance (MR) imaging also can provide very valuable additional information in the diagnosis of

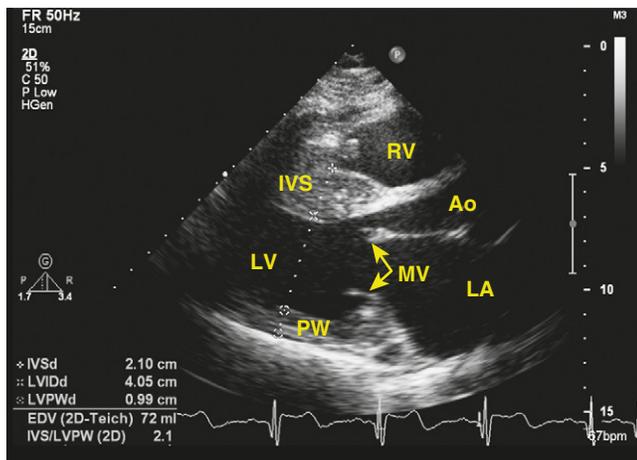

FIGURE 28-2 Echocardiographic appearance of hypertrophic cardiomyopathy. Parasternal long-axis view from a patient with hypertrophic cardiomyopathy demonstrating asymmetrical septal hypertrophy. The interventricular septum (marked by arrow) measures 2.1 cm, the posterior wall measures 0.99 cm. Ao = aorta; IVS = interventricular septum; LA = left atrium; LV = left ventricle; MV = mitral valve; PW = posterior wall; RV = right ventricle.

hypertrophic CMP and in differentiating it from other disorders. Marked ECG abnormalities are typically present in the majority of patients.

In addition to clinical history, risk stratification for SCD in hypertrophic CMP patients requires family pedigree analysis (premature sudden death), echocardiogram (hypertrophy, LV outflow gradient), 48-hour ambulatory ECG (nonsustained VT), and a symptom-limited exercise test with careful measurement of blood pressure (abnormal blood pressure response).

Clinical genetic testing for hypertrophic CMP comprising the eight most common disease-causing genes is now commercially available. Overall, the yield of genetic testing in probands with hypertrophic CMP is approximately 60%, but it depends on patient selection, falling to approximately 30% in sporadic disease.^{13,14} Although the knowledge of the underlying gene and mutation has a limited role in risk stratification and management of the individual patient, genetic testing is recommended for patients with an established clinical diagnosis of hypertrophic CMP in whom mutation-specific confirmatory testing would benefit, confirm, or exclude the diagnosis in at-risk family members. Once a pathogenic mutation has been detected, cascade screening of the relatives is indicated. On the other hand, genetic testing is not recommended for diagnosis of hypertrophic CMP in patients with nondiagnostic clinical features because the absence of a sarcomere mutation cannot rule out familial hypertrophic CMP. Furthermore, variants of uncertain significance can pose a problem in subjects with lower clinical pretest probability of a pathogenic sarcomere mutation.⁴

Risk Stratification

The traditionally acknowledged noninvasive risk stratification strategy for primary prevention uses five clinical markers that have been defined in several retrospective and observational studies. These primary prevention risk factors (applicable to hypertrophic CMP patients without prior cardiac arrest) are: (1) premature hypertrophic CMP-related sudden death in one or more relatives; (2) unexplained syncope (especially in the young and related to exertion); (3) multiple, repetitive (or prolonged) nonsustained VT on ambulatory (Holter) monitoring; (4) severe LV hypertrophy (maximal wall thickness of ≥ 30 mm); and (5) an abnormal blood pressure response during upright exercise (i.e., failure of blood pressure to rise appropriately by more than 20 to 30 mm Hg from baseline).^{8,15,16}

The risk associated with each of these factors is greatest in younger patients; hence, this risk stratification approach is generally employed in patients younger than 50 years. However, it is important to understand that even achieving this measure of longevity does not confer immunity to SCD.

The relative weight that can be assigned to each of the traditional risk markers has not been defined. A consensus document on hypertrophic CMP from the ACC and European Society of Cardiology (ESC) categorized known risk factors for SCD as “major” and “possible in individual patients” (Table 28-1). Although the absence of risk factors identifies a low-risk group, the positive predictive value of any single risk factor is limited. Risk stratification based on incorporation of multiple risk factors would likely improve positive predictive accuracy.⁹

It is also important to note that the traditional risk stratification strategy in hypertrophic CMP remains imprecise and a few SCDs have been reported in young hypertrophic CMP patients judged to be at low risk without any of the acknowledged risk markers.¹⁷

In addition to the five traditional risk factors, other features of hypertrophic CMP may increase SCD risk for patients in selected subgroups. LV apical aneurysm (which is observed only in 2% of hypertrophic CMP patients) has been associated with a substantial (10%) annual event rate, largely because of the arrhythmogenic substrate created by the fibrotic thin-walled aneurysm.^{1,18} Similarly, patients in the end-stage phase of the disease (characterized by LV systolic dysfunction, wall thinning, and chamber enlargement)

awaiting heart transplantation have a substantial arrhythmia-related event rate of 10% per year.¹⁷

Although LV outflow obstruction (subaortic gradient ≥ 30 mm Hg at rest) is a determinant of progressive heart failure and cardiovascular death (particularly from stroke), the specific relationship to SCD is weak and insufficient to regard LV outflow obstruction as a primary SCD risk marker.¹⁹ Reduction of obstruction by myotomy/myectomy (or alcohol ablation) is not considered a primary strategy for mitigating SCD risk. Similarly, the severity of clinical symptoms such as dyspnea, chest pain, and effort intolerance has not been correlated with increased risk of SCD.⁹

Currently, genetic testing appears to have little clinical application to the assessment of prognosis. Although certain mutations (e.g., some beta-myosin heavy chain and troponin T mutations) responsible for hypertrophic CMP can be associated with a higher risk for SCD compared with other mutations, there is substantial overlap between different disease gene groups, and exceptions are common.⁴ Hence, the prognostic value of disease-causing mutations in hypertrophic CMP for risk stratification is questionable, and the clinical course of individual patients cannot be reliably predicted based solely on particular genetic substrates and disease-causing mutations.¹⁷

Percutaneous alcohol septal ablation appears to augment the risk of SCD in patients with hypertrophic CMP. Alcohol septal ablation typically creates a sizable transmural scar occupying on average 30% of the ventricular septum and 10% of the overall LV chamber. Alcohol-induced infarcts can potentially compound pre-existing and underlying myocardial electrical instability resulting in increased arrhythmogenicity and higher risk of malignant ventricular arrhythmias. Several studies have documented the occurrence of sustained ventricular arrhythmias and SCD following

septal ablation in approximately 10% to 20% of patients with or without SCD risk factors. Long-term outcome and survival following alcohol ablation is fourfold less favorable compared with myotomy/myectomy (which leaves no intramyocardial septal scar), and the rate of appropriate ICD therapy among alcohol ablation patients with primary prevention ICDs is threefold more frequent than in other patients (10.3% per year versus 3.6% per year).

Invasive EP testing has little predictive value for SCD in hypertrophic CMP, and has proved an impractical and nonspecific prognostic strategy, and without advantage over the traditional noninvasive risk stratification. In addition, it may be difficult to defibrillate hypertrophic CMP patients if rapid VT or VF is initiated.

Similarly, there is insufficient evidence to regard specific 12-lead ECG patterns, T wave alternans, heart rate variability, QT interval prolongation and dispersion, or coronary arterial bridging as risk markers in hypertrophic CMP patients.^{17,20}

The role of cardiac MR imaging in risk stratification in patients with hypertrophic CMP is being evaluated. Cardiac MR imaging can help determine the severity and distribution of LV hypertrophy. Detection of myocardial fibrosis by gadolinium cardiac MR imaging (i.e., delayed enhancement) may have a role as a clinical predictor for increased risk of SCD. Up to 80% of patients with hypertrophic CMP have some degree of myocardial gadolinium hyperenhancement (the presumptive imaging correlate of increased myocardial fibrosis or scar) on cardiac MR (Fig. 28-3). However, the extent of hyperenhancement is greater in patients with progressive disease (28.5% versus 8.7%) and in patients with two or more risk factors for SCD (15.7% versus 8.6%).²¹ Additionally, patients with diffuse rather than confluent enhancement had two or more risk factors for SCD (87% versus 33%).¹⁷

Electrocardiographic Features

The ECG is abnormal in more than 90% of patients with hypertrophic CMP and in 75% of asymptomatic relatives. An abnormal ECG in the young is a sensitive marker of early disease expression. ECGs show a wide variety of abnormal patterns; however, no particular ECG pattern is characteristic or predictive of future events. Left atrial enlargement, repolarization abnormalities (ST-T changes including marked T wave inversion), and deep and narrow Q waves (most commonly in the inferolateral leads) are the most frequent ECG findings (Fig. 28-4). Voltage criteria for LV hypertrophy alone are nonspecific and are often seen in normal young adults. Giant negative T waves in the midprecordial leads are characteristic of hypertrophy confined to the LV apex.

Principles of Management

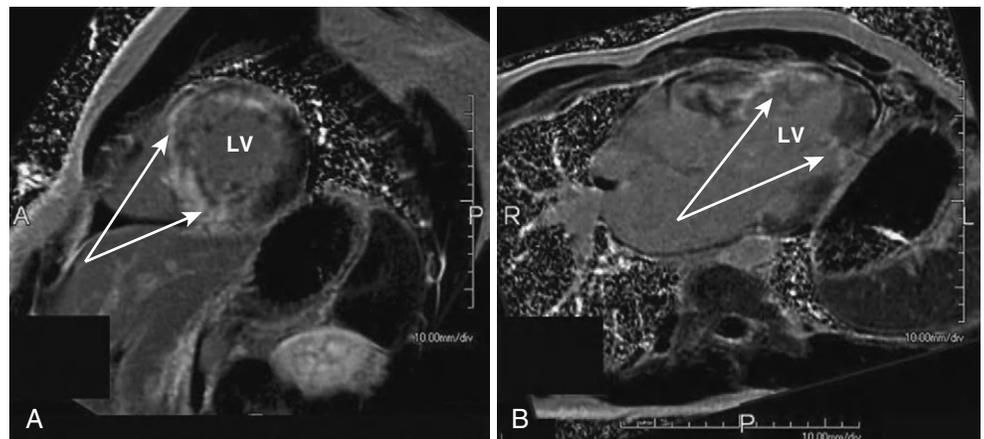

No treatments to prevent or modify disease progression currently exist. Therefore current treatment focuses on symptom management, assessment for risk of SCD, and family screening. Patients

TABLE 28-1 Risk Factors for Sudden Cardiac Death in Hypertrophic Cardiomyopathy

MAJOR RISK FACTORS	POSSIBLE IN INDIVIDUAL PATIENTS
<ul style="list-style-type: none"> • Cardiac arrest (ventricular fibrillation) • Spontaneous sustained ventricular tachycardia • Family history of premature sudden death • Unexplained syncope • Left ventricular thickness ≥ 30 mm • Abnormal exercise blood pressure • Nonsustained spontaneous ventricular tachycardia 	<ul style="list-style-type: none"> • Atrial fibrillation • Myocardial ischemia • Left ventricular outflow obstruction • High-risk mutation • Intense (competitive) physical exertion

From Zipes DP, Camm AJ, Borggrefe M, et al: ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death: a report of the American College of Cardiology/American Heart Association Task Force and the European Society of Cardiology Committee for Practice Guidelines, *J Am Coll Cardiol* 48:e247-e346, 2006.

FIGURE 28-3 Delayed hyperenhancement magnetic resonance images from a patient with symptomatic hypertrophic obstructive cardiomyopathy, demonstrating areas of extensive scarring in the basal interventricular septum (A, arrow). Notice also the areas of patchy scarring in the posterior wall (B, arrow). The image on the left is a short-axis view, and the image on the right is a three-chamber view. LV = left ventricle. (From Kwon DH, Smedira NG, Rodriguez ER, et al: Cardiac magnetic resonance detection of myocardial scarring in hypertrophic cardiomyopathy: correlation with histopathology and prevalence of ventricular tachycardia, *J Am Coll Cardiol* 54:242-249, 2009.)

with LV outflow obstructive symptoms or heart failure are treated with beta blockers, verapamil, and disopyramide. Reduced heart rate and decreased contractility resulting from their action can potentially alleviate symptoms related to LV outflow obstruction. In cases that are unresponsive to drugs, septal surgical myotomy/myectomy or percutaneous alcohol septal ablation (Fig. 28-5) should be considered.

For AF the goal is to restore and maintain sinus rhythm. Anticoagulation is also required because of the high risk for thromboembolic complications.

Dual-chamber pacing modifies the LV excitation pattern by changing the depolarization synchrony of the LV contraction, and can potentially be useful in a subset of symptomatic patients who have substantial LV outflow gradients (>30 mm Hg at rest or >50 mm Hg provoked) refractory to medical therapy and are not candidates for surgical myotomy/myectomy or alcohol septal ablation (Fig. 28-6). Although the initial observational studies in patients with hypertrophic CMP showed promising results, subsequent randomized clinical studies failed to show a significant benefit of dual-chamber pacing, and there are currently no data available to support the contention that pacing alters the clinical course of the disease or improves survival or long-term quality of life in hypertrophic CMP. Hence, routine implantation of dual-chamber pacemakers is no longer used, except in rare situations.²²

Implantable Cardioverter-Defibrillator

ICD therapy is the most effective and reliable approach for reduction of the risk of SCD in patients with hypertrophic CMP, both for secondary prevention and altering the natural history of this disease. Of note, the interval from ICD implantation to first appropriate device intervention is quite variable, and often considerable in length. Even ICD recipients for secondary prevention after a cardiac arrest can survive for many years with or without the aid of ICD discharge.¹⁷ On the other hand, prophylactic pharmacological treatment alone (amiodarone, beta blockers, or verapamil) does not offer hypertrophic CMP patients reliable protection against SCD and is generally not indicated.

ICD implantation is recommended for secondary prevention in patients with prior cardiac arrest or sustained VT, because of the relatively high recurrence rates in this subgroup. ICD implantation is also recommended for primary prevention in patients with multiple risk factors (two or more) for SCD. However, ICD implantation

for primary prevention in patients with only one risk factor is controversial. In this subgroup, management decisions should be individualized, taking into consideration other markers of disease severity, other less established risk factors (e.g., prior alcohol septal ablation, LV aneurysm), as well as the desires of the fully informed patient and family.

It is important to note that the number of risk factors in ICD recipients for primary prevention is unrelated to the likelihood of an appropriate therapy; about 35% of patients with appropriate ICD interventions for VT/VF had undergone implantation for only a single risk factor; and the likelihood of appropriate discharge was similar in patients with one, two, or three or more risk markers.¹¹ Therefore, a single marker of high risk may represent sufficient evidence to justify the recommendation for a prophylactic ICD in selected patients with hypertrophic CMP. Indeed, the most recent ACC/AHA/ESC practice guidelines make primary prevention with the ICD a class IIa indication, based on the presence of one or more risk factors.^{9,22} Whether hypertrophic CMP patients should have ICDs implanted routinely following alcohol septal ablation is presently unresolved.

The absence of risk factors for SCD accurately identifies a cohort of patients with a low risk of SCD. Nevertheless, regular periodic reassessment of low-risk adults with Holter monitoring, exercise testing, and echocardiography is recommended. Changes in symptoms, particularly sustained palpitations or syncope, warrant urgent reevaluation at any age.

Catheter Ablation

In patients with apical aneurysms and SMVT, recurrence is quite high and antiarrhythmic drug therapy or catheter ablation should be considered. Antiarrhythmic medications have limited efficacy. When catheter ablation is undertaken, it should be appreciated that an epicardial approach may be warranted in a significant number of patients; in a recent report, an electrophysiologically identifiable epicardial scar was present in 80% of patients compared with 60% with an endocardial scar.^{1,2,18,23,24}

Participation in Sports

Participation in intense competitive sports can represent a potential risk factor in athletes with hypertrophic CMP, even when conventional markers are absent, and exclusion from most participation in contact and most organized competitive sports is recommended

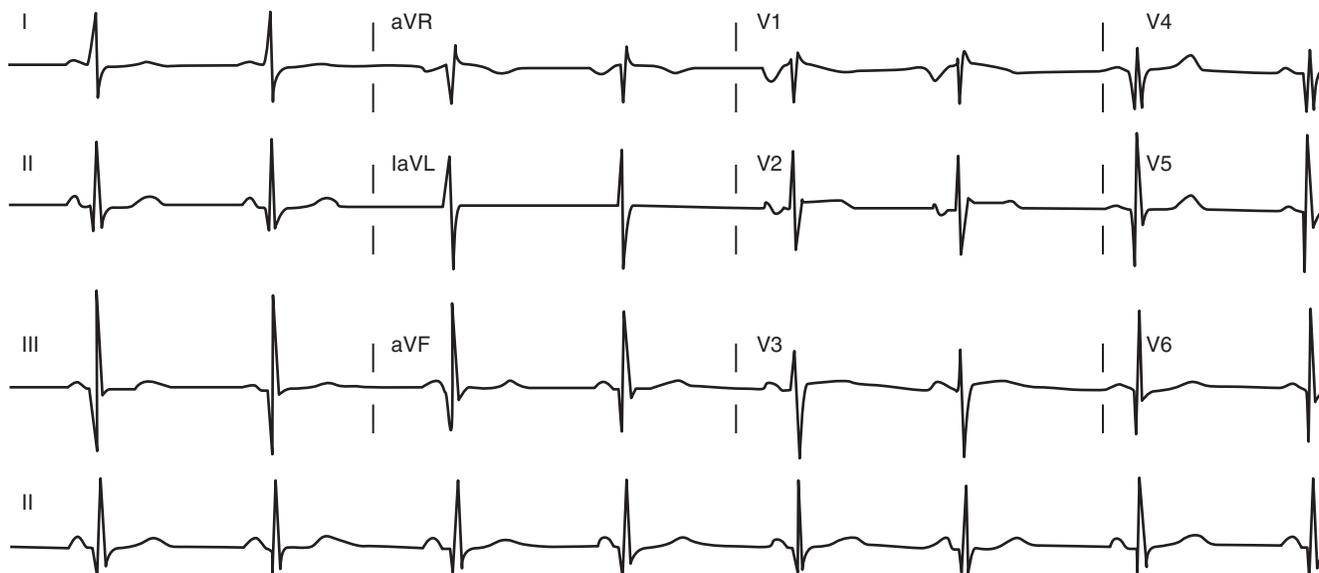

FIGURE 28-4 Surface ECG in a patient with hypertrophic cardiomyopathy. Note the deep narrow Q waves in the inferolateral leads.

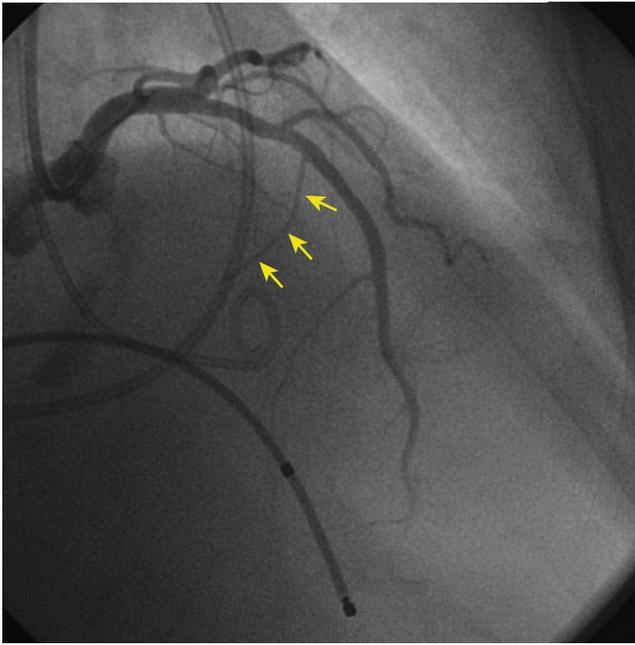

FIGURE 28-5 Left coronary angiography in a patient with asymmetrical septal hypertrophic cardiomyopathy. A right lateral oblique view is shown. The septal perforator branch (marked by arrows) of the left anterior descending artery is the target for alcohol septal ablation. A temporary pacing wire is positioned in the right ventricle and a pigtail catheter is positioned in the left ventricle.

(even in patients with ICDs), with the exception of low-intensity, class 1A sports (e.g., golf, bowling, billiards).

Family Screening

As expected in an autosomal dominant disease, every offspring has a 50% chance of inheriting the mutation and therefore of developing hypertrophic CMP. However, because of age dependence of penetrance, many mutation carriers may not exhibit phenotypic expression early in life, and many others may express the phenotype, but remain asymptomatic and, hence, remain undiagnosed unless screened. Therefore, it is generally considered that all first- and second-degree genetically related family members of patients with hypertrophic CMP should undergo screening with detailed history and physical examination, 12-lead ECG, and echocardiogram.

Because penetrance is age dependent, many family members may not express the phenotype at the time of examination and may be falsely considered “unaffected.” Thus, periodic evaluation of the “unaffected” family members is necessary, as some may develop hypertrophic CMP later in life. Annual screening should be considered in adolescents and young adults (ages 12 to 25 years), in athletes, and in those with a family history of early-onset disease. Screening every 3 to 5 years in other individuals may be adequate (Table 28-2).¹³

When the causative mutation in the index patient is identified, genetic testing is recommended for all first-degree relatives and can have particular advantages over clinical screening, as ECG or echocardiographic abnormalities may be absent or subtle, or develop late in life. Furthermore, genetic testing affords permanent reassurance to those family members who test gene-negative,

FIGURE 28-6 Reduction of left ventricular (LV) outflow obstruction by ventricular pacing. The four panels show ECG and hemodynamics (femoral arterial [FA] and LV) under different conditions in a patient with hypertrophic cardiomyopathy and dynamic LV outflow obstruction. Panels from left to right: Baseline sinus rhythm showing a peak LV-FA gradient of almost 40 mm Hg. During atrial pacing at 100/min, the gradient increases to 50 mm Hg. With addition of right ventricular pacing at 100/min and an atrioventricular (AV) interval of 110 milliseconds, the gradient is almost eliminated; finally, when the AV interval is shortened, the gradient increases again to about 30 mm Hg.

TABLE 28-2
Clinical Screening Strategies with Echocardiography and 12-Lead ECG for Detection of Hypertrophic Cardiomyopathy in Families

AGE OF FAMILY MEMBER	SCREENING STRATEGY
<12 yr old	Optional unless: <ul style="list-style-type: none"> Family history of premature hypertrophic CMP death or other adverse complications Competitive athlete in an intense training program Onset of symptoms Other clinical suspicion of early left ventricular hypertrophy
12 to ~18–21 yr old	Every 12–18 mo
>18–21 yr old	Probably about every 5 yr, or more frequent intervals with a family history of late-onset hypertrophic CMP and/or malignant clinical course

CMP = cardiomyopathy.

obviating the need for clinical investigations or long-term follow-up and screening of their offspring.^{4,14}

Athletes with a family history of hypertrophic CMP should probably undergo annual ECG, echocardiography, 24-hour Holter monitoring, exercise testing, and genetic testing before being allowed to participate in competitive sports.

Asymptomatic individuals found to carry a hypertrophic CMP mutation on genetic screening should undergo a comprehensive cardiac evaluation and risk stratification similar to patients with known hypertrophic CMP. Additionally, genotype-positive athletes should be excluded from most competitive sports, even when they are asymptomatic and have no abnormalities on echocardiogram and ECG.

Prophylactic pharmacological therapy in asymptomatic carriers of hypertrophic CMP genes is ineffective and not recommended.

Pathophysiology

Arrhythmogenic right ventricular cardiomyopathy-dysplasia (ARVD) is an inherited primary disease of the myocardium characterized by ventricular arrhythmias and structural abnormalities of the right ventricle (RV). The hallmark pathological findings are progressive myocyte loss and fibrofatty (fibrous and adipose) tissue replacement, with a predilection for the RV, but the left ventricle (LV) and septum also can be affected. Fibrofatty replacement of the myocardium produces “islands” of scar that can lead to reentrant VTs, and these patients have an increased risk of sudden cardiac death (SCD), mostly secondary to ventricular tachycardia (VT).¹

The exact cause of ARVD is not fully understood. Several theories for the pathogenesis of ARVD have been proposed, some of which reflect acquired rather than familial disease: dysontogenic, degenerative, inflammatory, and apoptotic. Progressive myocyte replacement can be secondary to a metabolic disorder affecting the RV. This process would be analogous to the situation involving skeletal muscle in patients with muscular dystrophy, in whom progressive degeneration of muscle occurs with time. The loss of myocardial tissue also can reflect increased apoptosis (programmed cell death) of myocardial cells. A possible infectious or immunological cause resulting in post-inflammatory RV fibrofatty cardiomyopathy has also been suggested—up to 80% of hearts at autopsy documenting inflammatory infiltrates. In recent years, research has focused on identifying the genetic basis for ARVD.

Molecular Genetics

Familial disease occurs in approximately 30% to 50% of cases of ARVD, and two patterns of inheritance have been described: autosomal dominant disease with incomplete penetrance (most common) and autosomal recessive disease (rare). Autosomal recessive forms of ARVD include Naxos disease (also known as familial palmoplantar keratosis and “mal de Meleda” disease) and Carvajal syndrome (a disorder of LV cardiomyopathy), both of which are associated with skin and hair abnormalities.

The autosomal dominant nonsyndromic ARVD-1 to ARVD-12 as well as the two rare recessive forms (Naxos disease and Carvajal syndrome) have been mapped to 12 genetic loci, with mutations in eight gene loci identified (Table 29-1). Although some identified gene mutations such as RYR2 may be phenocopies of ARVD, a common theme of desmosomal protein mutations has been emerging. In fact, five of the eight gene loci encode desmosomal proteins (desmoplakin [DSP], plakophilin-2 [PKP2], desmoglein-2 [DSG2], desmocollin-2 [DSC2], junctional plakoglobin

[JUP]) and have been found in association with the ARVD phenotype in up to 50% of cases. Among the known genes, mutations in PKP2 appear to be the most common causes of ARVD, accounting for approximately 20% of cases. Mutations in DSG2 and DSP each account for approximately 10% to 15% of cases. Therefore, ARVD is currently considered, at least in a subset, a disease of the cardiac desmosome.^{2,3} The majority of these mutations are insertion/deletion or nonsense mutations, which are expected to cause premature termination of the encoded proteins.¹

Mutations in genes encoding nondesmosomal proteins also can potentially cause ARVD. Alterations of the 5' and 3' regulatory elements of *TGFB3*, encoding transforming growth factor- β_3 , have each been reported. More recently, a mutation in *TMEM43*, encoding a transmembrane protein with ties to an adipogenic transcription factor, was reported as the cause for ARVD-5, a subtype of ARVD with prominent LV involvement. Mutations in *RYR2*, encoding the

TABLE 29-1 Known Genetic Loci for Arrhythmogenic Right Ventricular Cardiomyopathy-Dysplasia

LOCUS NAME	CAUSATIVE GENE	MODE OF INHERITANCE
ARVD-1	Transforming growth factor- β_3	Autosomal dominant
ARVD-2	Cardiac ryanodine receptor (RYR2)	Autosomal dominant
ARVD-3	Unknown	Autosomal dominant
ARVD-4	Unknown	Autosomal dominant
ARVD-5	Transmembrane protein-43	Autosomal dominant
ARVD-6	Unknown	Autosomal dominant
ARVD-7	Unknown	Autosomal dominant
ARVD-8	Desmoplakin (DSP)	Autosomal dominant
ARVD-9	Plakophilin-2 (PKP2)	Autosomal dominant
ARVD-10	Desmoglein-2	Autosomal dominant
ARVD-11	Desmocollin-2	Autosomal dominant
ARVD-12	Plakoglobin (JUP)	Autosomal dominant
Naxos disease	Plakoglobin (JUP)	Autosomal recessive
Carvajal syndrome	Desmoplakin (DSP)	Autosomal recessive

cardiac ryanodine receptor (the major calcium release channel of the sarcoplasmic reticulum in cardiomyocytes, also implicated in familial catecholaminergic polymorphic VT), result in a form of arrhythmogenic cardiomyopathy (ARVD-2) characterized by exercise-induced polymorphic VT that does not appear to have a reentrant mechanism, occurring in the absence of significant structural abnormalities. Patients do not develop characteristic features of ARVD on the 12-lead electrocardiogram (ECG) or signal-averaged ECG, and global RV function remains unaffected. ARVD-2 shows a closer resemblance to familial catecholaminergic polymorphic VT in both etiology and phenotype; its inclusion under the umbrella term of ARVD remains controversial.^{2,4}

Pathogenesis

Cardiac desmosomes are specialized, multiprotein complexes in the intercalated disks that anchor intermediate filaments to the cytoplasmic membrane in adjacent cardiomyocytes, thereby forming a three-dimensional (3-D) scaffolding and providing mechanical strength and cohesion of cardiomyocytes in the beating heart (Fig. 29-1). Cardiac desmosomes are also responsible for regulating

transcription of genes involved in adipogenesis and apoptosis as well as maintaining proper electrical conductivity through regulation of gap junctions and calcium homeostasis. Cardiac desmosomes are composed of three groups of proteins: the cadherin family, the Armadillo family, and the plakin family. The cadherin family is composed of three desmocollins and three desmogleins, which are primarily responsible for anchoring the structure to the membrane. The Armadillo family is composed of plakoglobin and three plakophilins, which form the core structure and possess signaling capabilities. The plakin family is composed of DSP, envoplakin, periplakin, plectin, and pinin, which are responsible for the attachment of the desmosomes to intermediary filaments.^{1,5}

The mechanisms by which the affected desmosomes cause myocyte apoptosis, fibrogenesis, adipogenesis, and slow ventricular conduction, thus leading to impaired RV function and increased arrhythmogenicity, remain to be determined. Mutations in desmosomal genes alter the number or integrity of desmosomes and thereby lead to impaired mechanical coupling and failure of cell-to-cell adhesion structures during exposure to physical strain, resulting in cardiomyocyte detachment and degeneration, with subsequent inflammation and replacement by fibrofatty

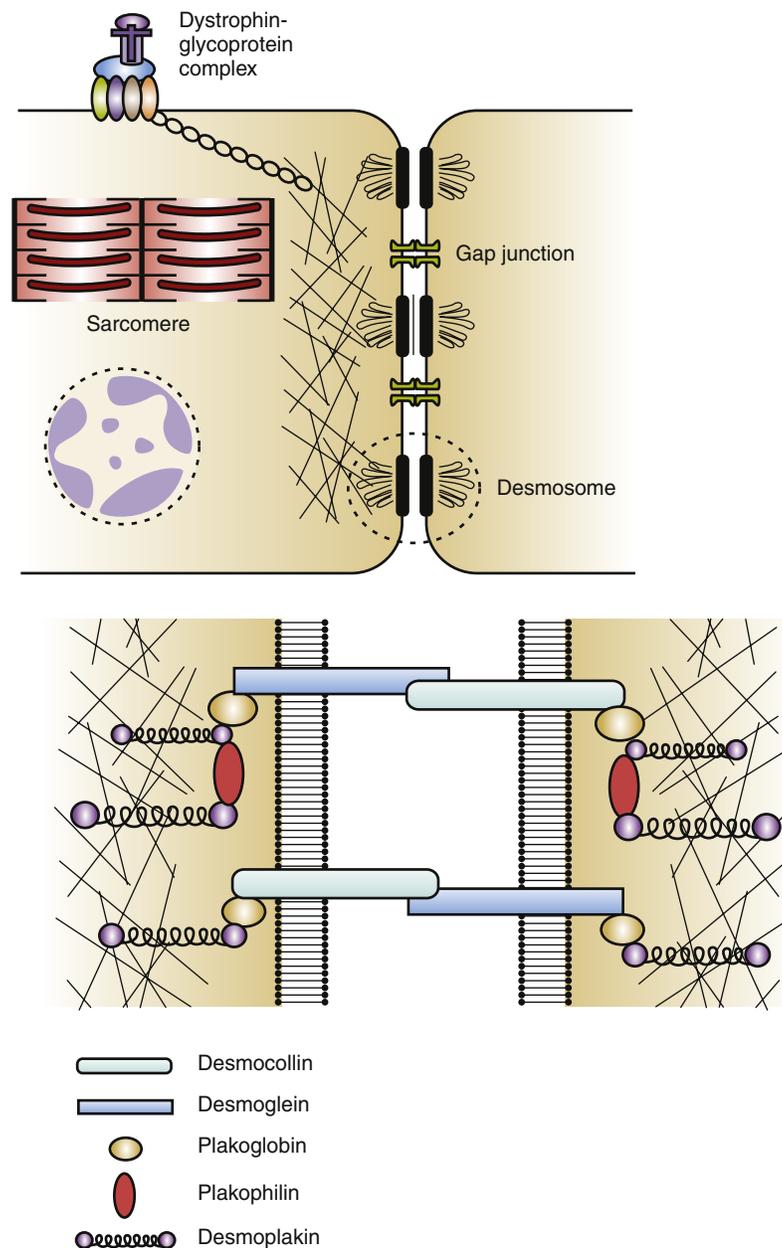

FIGURE 29-1 Molecular structure of the cardiac desmosome. The desmosomal cadherins desmocollin and desmoglein form classic homotypic and heterotypic interactions between cells. These membrane-bound proteins are linked through the Armadillo family members, plakoglobin, and plakophilin to the intermediate filament-binding protein desmoplakin. This complex anchors the desmosome to the cytoskeleton of the cell, and thus indirectly to the sarcomere, nuclear membrane, and the dystrophin-associated glycoproteins. (From Ellinor PT, MacRae CA, Thierfelder L: Arrhythmogenic right ventricular cardiomyopathy, *Heart Fail Clin* 6:161-177, 2010.)

tissue. Fibrofatty replacement is a nonspecific repair process also observed in the muscular dystrophies. The architecture of thin surviving myocardial bundles within the fibrofatty tissue creates lengthened conduction pathways, conduction slowing at pivotal points, and conduction block. All factors contribute to activation delay and can create an electrophysiological (EP) substrate for reentry and VT. Ventricular dysfunction can ensue in the later stages owing to progressive myocyte detachment and death.⁶

Additionally, mutations in desmosomal proteins can impair expression of interacting proteins at the intercalated disk (e.g., gap junction or ion channel proteins), giving rise to impairment of intercellular conductance and promoting ventricular arrhythmogenesis, even in the absence of fibrofatty tissue replacement. Impaired desmosomal structure and function also can affect other cell-to-cell contact structures in the myocardium. In particular, connexin-43 remodeling in the gap junctions, which contributes to delayed conduction and ventricular arrhythmogenesis, is often observed in ARVD patients, and these potential electrical conduction abnormalities may favor arrhythmic events that characterize the disease and predispose patients to high risk of SCD.^{2,4}

Pathology

Regardless of the mechanism, the patchy replacement of the RV myocardium by fibrofatty tissue provides a substrate for reentrant ventricular arrhythmias. The most striking morphological feature of the disease is the diffuse or segmental loss of RV myocytes, with replacement by fibrofatty tissue and thinning of the RV wall. Patchy inflammatory infiltrates can be present in areas of myocardial damage. Fibrofatty replacement usually begins in the subepicardium or midmural layers and progresses to the subendocardium. Only the endocardium and myocardium of the trabeculae may be spared. The sites of involvement can be localized and in early disease are often confined to the so-called “triangle of dysplasia”—namely, the RV outflow tract (RVOT), RV apex, and inferolateral wall near the tricuspid valve. RV aneurysms (Fig. 29-2), and segmental RV hypokinesia are typical. Diffuse myocardial involvement leads to global RV dilation. However, the fibrofatty pattern of ARVD is limited not only to the RV; the disease also can migrate to the LV free wall (commonly observed in advanced disease), with a predilection for the posteroseptal and posterolateral areas, with relative sparing of the septum.^{2,4}

In ARVD, the regions of abnormal myocardium do not always follow the pattern of dense scar surrounded by a ring of abnormal myocardium, often referred to as the scar border zone. Sometimes, abnormal voltages are found alone, without dense scar defining the regions. This is because ARVD is a different process from scarring caused by myocardial infarction (MI). Infarction causes dense scar surrounded by a border zone because of the ischemic

penumbra that surrounds the infarcted territory. In ARVD, however, the process is patchy and can cause inhomogeneous scarring in anatomically disparate areas. Nonetheless, previous data have shown that it is still possible to identify well-demarcated borders around these abnormal regions.

Despite the widespread impression that ARVD is universally a progressive disease process, a recent report found that the extent of the endocardial scar as measured by bipolar voltage mapping in patients with ARVD and VT remained relatively stable, despite progressive RV dilation.⁷

A monomorphic VT in the setting of ARVD is associated with a predominantly perivalvular distribution of endocardial electrogram abnormalities and arrhythmia origin. Reentry in areas of abnormal myocardium is the most likely mechanism of VT in ARVD. Most reentrant circuits cluster around the tricuspid annulus and the RVOT. The critical isthmus contained in these reentry circuits often is a narrow path of tissue with abnormal conduction properties, typically bounded by two approximately parallel conduction barriers that consist of scar areas, the tricuspid annulus, or both. Depolarization of the small mass of tissue in the isthmus is usually not detectable on the surface ECG and constitutes the electrical diastole between QRS complexes.

Clinical Considerations

Epidemiology

ARVD occurs in young adults (80% are younger than 40 years) and is more common in men. The mean age at diagnosis of familial ARVD is approximately 31 years. The disease is almost never diagnosed in infancy and rarely before the age of 10.

The incidence and prevalence of ARVD are uncertain and may vary regionally. The prevalence of the disease in the general population is estimated at 0.02% to 0.1% but is dependent on geographic circumstances. In certain regions of Italy (Padua, Venice) and Greece (island of Naxos), an increased prevalence of 0.4% to 0.8% for ARVD has been reported. Others estimate the prevalence in Europe and North America to be 1 per 5000 individuals.

Clinical Presentation

The clinical presentation varies widely because ARVD includes a spectrum of different conditions rather than a single entity. Different pathological processes can manifest a diversity of symptoms. Additionally, ARVD can have a temporal progression and can present differently according to the time of presentation.

Four clinicopathological stages of ARVD can be considered: the early “concealed” phase, followed by the “overt electrical disorder,” the “phase of RV failure,” and finally, the phase of

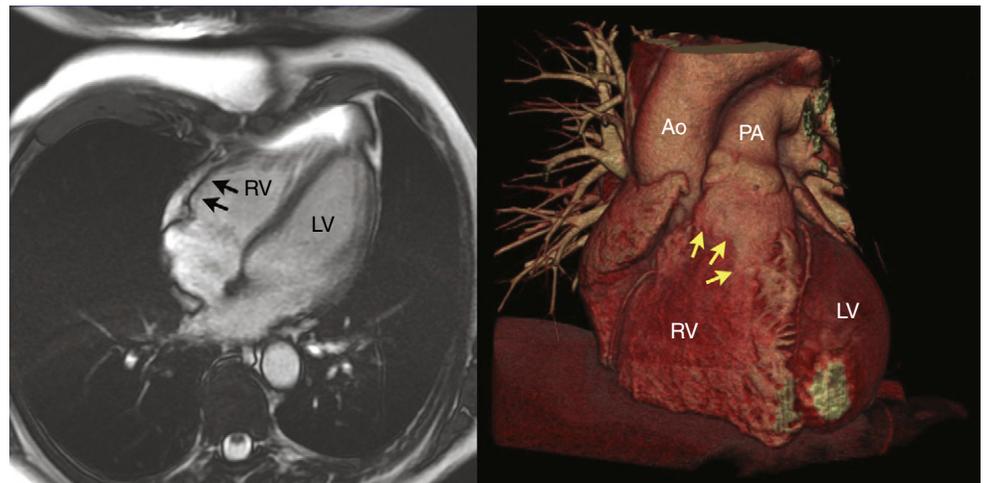

FIGURE 29-2 Right ventricular (RV) aneurysm. This cardiac computed tomography angiogram shows thinning and aneurysmal dilation of the RV anterior wall and outflow tract (arrows) in a patient with arrhythmogenic right ventricular dysplasia-cardiomyopathy and ventricular tachycardia. Ao = aorta; LV = left ventricle; PA = pulmonary artery. (Courtesy of Dr. Nasar Nallamothu, Prairie Cardiovascular Consultants, Springfield, Ill.)

“biventricular failure.” Although ARVD is a genetically transmitted disease, it is associated with a long asymptomatic lead time and individuals in their teens may not have any characteristics of ARVD clinically or on screening tests. Early ARVD is often asymptomatic (the “concealed” phase), occasionally associated with minor ventricular arrhythmias and subtle structural changes. Nonetheless, these patients are still at risk of SCD, especially during intense physical exertion. With disease progression, the “overt electrical disorder” typically causes symptomatic ventricular arrhythmia and more obvious morphological abnormalities detectable by imaging. Further disease extension results in RV dilation and dysfunction (the “phase of RV failure”), precipitating symptoms and signs of right heart failure. Unless SCD occurs, progressive impairment of cardiac function can result in biventricular heart failure late in the evolution of ARVD, usually within 4 to 8 years after typical development of complete right bundle branch block (RBBB). End-stage disease is often indistinguishable from dilated cardiomyopathy and manifests with congestive heart failure, atrial fibrillation, and an increased incidence of thromboembolic events. Overall, judging the accurate position of the patient on the time scale of the spectrum can be difficult, and some patients may remain stable in the same phase of the disease for several decades.⁸

ARVD is one of the most arrhythmogenic human heart diseases known. Electrical instability is present at the very early stages of ARVD. Ventricular arrhythmias range from isolated ectopy to sustained VT or ventricular fibrillation (VF).⁸ Approximately 50% of patients with ARVD present with symptomatic ventricular arrhythmias, most commonly sustained and nonsustained VT, manifested by palpitations, dizziness, and/or syncope. The frequency of ventricular arrhythmias in ARVD varies with the severity of the disease, ranging from 23% in patients with mild disease to almost 100% in patients with severe disease. Ventricular arrhythmias characteristically occur during exercise; up to 50% to 60% of patients with ARVD show monomorphic VT during exercise testing.

One of the unfortunate features of ARVD is SCD, which is the first clinical manifestation of ARVD in 50% of afflicted individuals. In fact, up to 5% of SCDs in young adults in the United States are attributed to ARVD. In northeast Italy, ARVD was found to be responsible for 22.4% of SCDs in young athletes and in 8.2% of SCDs in nonathletes. In most patients, the mechanism of SCD in ARVD is acceleration of VT, with ultimate degeneration into VF. Generally, RV failure and LV dysfunction are independently associated with cardiovascular mortality.

Supraventricular tachycardias are observed in approximately 25% of patients with ARVD referred for treatment of ventricular arrhythmias; less often, they are the only arrhythmia present. In decreasing order of frequency, supraventricular tachycardias in these patients include atrial fibrillation, atrial tachycardia, and atrial flutter.

Some patients are asymptomatic and ARVD is only suspected by the finding of ventricular ectopy and other abnormalities on routine ECG or other testing because of a positive family history. In a review of 37 families, only 17 of 168 patients with ARVD (10%) were healthy carriers. In one report, 9.6% of those initially unaffected subjects developed structural signs of disease on echocardiography during a mean follow-up of 8.5 years; almost 50% had symptomatic ventricular arrhythmias. Progression from mild to moderate disease occurred in 5% of patients, and progression from moderate to severe disease occurred in 8%.

Initial Evaluation

The noninvasive diagnosis of ARVD can be exceedingly difficult. Several factors, including marked phenotypic variation, incomplete and low (30%) penetrance, and age-related disease development and progression contribute to the complexity of the clinical diagnosis. Particularly problematic is recognition of the early stages of ARVD, when overall RV function may be normal, with local or regional wall-motion abnormalities that are difficult to quantify; nonetheless, the absence of clinical features does not necessarily confer low risk.

Definitive diagnosis of ARVD requires histological confirmation. A myocardial biopsy showing myocyte loss (<45% residual myocytes) with fibrosis and fatty infiltration (>40% fibrous tissue and >3% fat) confirms the diagnosis. However, myocardial biopsy lacks sufficient sensitivity (67% in one report) owing to the patchy nature of the disease. For safety reasons, the biopsy is performed mostly in the interventricular septum, which is histopathologically rarely involved in the disease process. Biopsy sampling performed on the RV free wall may improve the ability to diagnose ARVD. Nevertheless, because of the frequently observed wall thinning with aneurysms or diverticula, free wall sampling is associated with risk of perforation, particularly when performed at random sites. Therefore, the role of endomyocardial biopsy in the diagnosis of ARVD remains controversial.

Electroanatomical voltage mapping, which seems to be an effective technique to detect RV low-voltage regions reflecting fibrofatty myocardial atrophy in patients with ARVD, has been shown to improve the diagnostic accuracy of myocardial biopsy by reducing the sampling errors. Endomyocardial biopsies are obtained from low-voltage areas, preferably from the border zone, in order to minimize the risk of perforation.⁹

Additionally, immunohistochemical analysis of conventional biopsy samples to detect a change in the distribution of desmosomal proteins can also improve the sensitivity and specificity of this diagnostic tool. Reduced immunoreactive signal levels of plakoglobin at intercalated disks were found to be a consistent feature in patients with ARVD but not seen in other forms of myocardial disease.¹⁰

Recognition of the problems in diagnosing ARVD and the fact that there is no “gold standard” or single test that is diagnostic of ARVD led to the formation of a task force in 1994 that proposed major and minor criteria to aid in the diagnosis, based on family history as well as structural, histological, functional, arrhythmic, and ECG abnormalities (Table 29-2).¹¹ The diagnosis of ARVD is based on the presence of two major criteria, one major plus two minor criteria, or four minor criteria. It is important to recognize, however, that these criteria were defined retrospectively from aggregated series of referrals to tertiary care institutions dominated by the overt or severe end of the disease spectrum (i.e., symptomatic index cases and SCD victims) and have never been prospectively validated; therefore, their applicability is limited in situations where the prior probability of ARVD is different from the initial derivation set of patients. Consequently, the original task force criteria are highly specific but lacked sensitivity for early and familial disease. Furthermore, this diagnostic approach does not specify the preferred order of imaging techniques to examine and score RV morphology and function.^{5,11}

A recent study of a large number (108) of newly diagnosed patients suspected of having ARVD found that a combination of diagnostic imaging tests is needed to evaluate the presence of RV structural, functional, and electrical abnormalities. ECG, echocardiography, RV angiography, signal-averaged ECG (SAECG), and Holter monitoring provide optimal clinical evaluation of patients suspected of having ARVD. The diagnostic performance of MR imaging and RV biopsy seemed to be inferior in comparison with the five tests recommended.¹² Based on these findings, the original task force criteria have been recently modified to incorporate the emerging diagnostic modalities and advances in the genetics of ARVD to improve diagnostic sensitivity while maintaining diagnostic specificity. In this modification of the task force criteria, quantitative criteria were proposed and abnormalities were defined on the basis of comparison with normal subject data.¹¹ Scoring by major and minor criteria was maintained, structural abnormalities were quantified, and task force criteria highly specific for ARVD were upgraded to major. Furthermore, new criteria were added: terminal activation duration of QRS equal to or greater than 55 milliseconds, VT with left bundle branch block (LBBB) morphology and superior axis, and genetic criteria.¹³

A recent study found that the new task force criteria are increasing the diagnostic yield of ARVD when applied to patients with suspected disease.¹³ When performing and analyzing imaging studies,

**TABLE 29-2 Original and Revised Task Force Diagnostic Criteria for Arrhythmogenic Right Ventricular Cardiomyopathy-Dysplasia**

ORIGINAL TASK FORCE CRITERIA		REVISED TASK FORCE CRITERIA

TABLE 29-2 Original and Revised Task Force Diagnostic Criteria for Arrhythmogenic Right Ventricular Cardiomyopathy-Dysplasia—cont'd

ORIGINAL TASK FORCE CRITERIA		REVISED TASK FORCE CRITERIA
VI. Family History		
Major	<ul style="list-style-type: none"> • Familial disease confirmed at necropsy or surgery 	<ul style="list-style-type: none"> • ARVC/D confirmed in a first-degree relative who meets current task force criteria • ARVC/D confirmed pathologically at autopsy or surgery in a first-degree relative • Identification of a pathogenic mutation[†] categorized as associated or probably associated with ARVC/D in the patient under evaluation
Minor	<ul style="list-style-type: none"> • Family history of premature sudden death (<35 yr of age) due to suspected ARVC/D • Familial history (clinical diagnosis based on present criteria) 	<ul style="list-style-type: none"> • History of ARVC/D in a first-degree relative in whom it is not possible or practical to determine whether the family member meets current task force criteria • Premature sudden death (<35 yr of age) due to suspected ARVC/D in a first-degree relative • ARVC/D confirmed pathologically or by current task force criteria in second-degree relative

*Hypokinesis is not included in this or subsequent definitions of RV regional wall motion abnormalities for the proposed modified criteria.

[†]A pathogenic mutation is a DNA alteration associated with ARVC/D that alters or is expected to alter the encoded protein, is unobserved or rare in a large non-ARVC/D control population, and either alters or is predicted to alter the structure or function of the protein or has demonstrated linkage to the disease phenotype in a conclusive pedigree.

Diagnostic terminology for original criteria: This diagnosis is fulfilled by the presence of two major, or one major plus two minor, criteria or by four minor criteria from different groups. Diagnostic terminology for revised criteria: definite diagnosis: two major or one major and two minor criteria, or four minor from different categories; borderline: one major and one minor or three minor criteria from different categories; possible: one major or two minor criteria from different categories.

2-D = two-dimensional; ARVC/D = arrhythmogenic right ventricular cardiomyopathy/dysplasia; aVF = augmented voltage unipolar left foot lead; aVL = augmented voltage unipolar left arm lead; BSA = body surface area; LV = left ventricle; MRI = magnetic resonance imaging; PLAX = parasternal long-axis view; PSAX = parasternal short-axis view; RVOT = right ventricular outflow tract; RV = right ventricle; SAECG = signal-averaged ECG.

it is important to recognize, because ARVD is a rare disease, the importance of expert interpretation of the complex-shaped RV and the need for quantitation of RV structure and function as well as specific protocols for optimal evaluation. Referral to centers with expertise in this field should be considered.

Molecular genetic analysis can potentially facilitate timely diagnosis, guiding interpretation of borderline investigations, and enabling cascade screening of relatives. Unfortunately, sequence analysis of the known desmosomal ARVD-related genes only identifies a responsible mutation in approximately 50% of ARVD probands. Nevertheless, recent studies support the use of genetic testing as a new diagnostic tool in ARVD and also suggest a prognostic impact, as the severity of the disease appears different according to the underlying gene or the presence of multiple mutations.^{8,14} In a substantial number of probands, more than one disease-causing mutation can be found (mostly in different genes).¹⁵ Therefore, it is recommended that all desmosome genes be tested simultaneously in the proband. Whenever a pathogenic mutation is identified, it becomes possible to establish a presymptomatic diagnosis of the disease among family members and to provide them with genetic counseling to monitor the development of the disease and to assess the risk of transmitting the disease to offspring.¹⁶ Importantly, genetic testing is not recommended for patients with only a single minor criterion according to the 2010 task force criteria.¹⁷

ARVD is distinguished from dilated cardiomyopathy by the greater degree of arrhythmogenicity. Although ventricular arrhythmia is a relatively common finding in dilated cardiomyopathy, it is rare in the absence of significant ventricular dysfunction, and SCD is seldom the mode of presentation. In contrast, ARVD is associated with a propensity toward ventricular arrhythmia even in the absence of significant ventricular dysfunction. SCD is the first clinical manifestation of the disease in more than 50% of probands with ARVD. Additionally, regional involvement and aneurysm formation, characteristic of ARVD, argue against the diagnosis of dilated cardiomyopathy.

Risk Stratification

Factors identifying patients with ARVD who are at risk for SCD have not yet been defined in large prospective studies focusing on survival. Nonetheless, several markers of increased risk for life-threatening ventricular arrhythmias have been described, including (1) previous history of cardiac arrest or a history of VT with

hemodynamic compromise; (2) history of unexplained syncope (when VT or VF has not been excluded as the cause of syncope); (3) extensive RV disease; (4) LV involvement; (5) family history of cardiac arrest in first-degree relatives; (6) genotypes of ARVD associated with a high risk for SCD (e.g., patients with ARVD2, who can develop polymorphic VT and juvenile SCD associated with sympathetic stimulation); (7) increased QRS dispersion (maximal measured QRS duration minus minimal measured QRS duration is 40 milliseconds or more); (8) S wave upstroke equal to or greater than 0 milliseconds on the 12-lead ECG; (9) patients with Naxos disease; (10) induction of VT during EP testing; (11) detection of nonsustained VT on noninvasive monitoring; (12) male gender; and (13) young age at presentation (<5 years).¹⁸

Principles of Management

PHARMACOLOGICAL THERAPY

Beta blockers, sotalol, and amiodarone have been used to reduce the risk of recurrence of ventricular arrhythmias in ARVD patients. The usefulness of antiarrhythmic drugs for primary prevention, however, is less well established.

Previous studies, which determined selection of antiarrhythmic therapy based on suppression of VT in the EP laboratory, found that sotalol was more effective than beta blockers and amiodarone in patients with inducible VT and in those with noninducible VT. Thus, sotalol was considered as a first-line antiarrhythmic agent in ARVD both for primary and secondary prevention. However, this was questioned in a recent study of a cohort of rigorously characterized ARVD population treated with empirically prescribed antiarrhythmic agents. In this study, beta blockers were neither protective nor harmful, sotalol was not effective, and amiodarone, although only received by a relatively small number of patients, showed superior efficacy in preventing sustained VT and implantable cardioverter-defibrillator (ICD) therapies.¹⁹

Therefore, among asymptomatic patients and those with mild disease, beta blockers may still be a reasonable recommendation to reduce the possibility of adrenergically induced arrhythmia. Patients with well-tolerated and non-life-threatening ventricular arrhythmias are at relatively low risk for SCD and can be treated with antiarrhythmic drugs, guided either noninvasively with ambulatory monitoring or with EP testing.²⁰ Recent data argue against the empirical use of sotalol therapy, especially when permitting additional episodes of VT/VF is highly undesirable. It appears that,

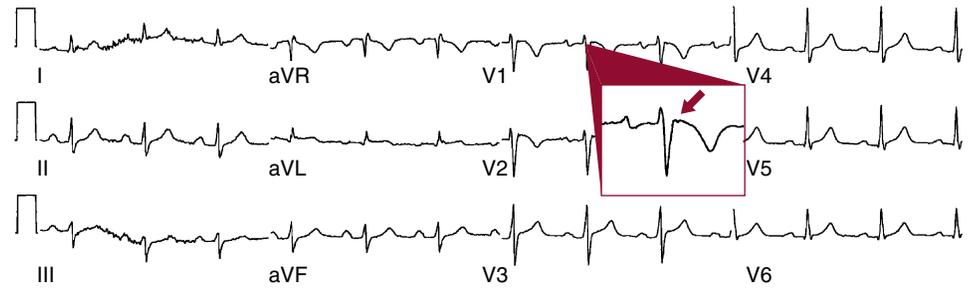

FIGURE 29-3 Surface ECG of sinus rhythm in a patient with arrhythmogenic right ventricular dysplasia-cardiomyopathy. Inset, Magnified view of a single complex in V_1 showing epsilon waves (arrow).

as in other settings, amiodarone is the most effective empirical antiarrhythmic drug therapy in patients with ARVD.¹⁹

Antiarrhythmic drugs can also be given to reduce the frequency of ventricular arrhythmia in patients with unacceptably frequent ICD therapies.

When the disease has progressed to right or biventricular failure, treatment consists of the current therapy for heart failure, including diuretics, beta blockers, and angiotensin-converting enzyme inhibitors. Although angiotensin-converting enzyme inhibitors are well known for slowing progression in other cardiomyopathies, they have not been proven to be helpful in ARVD. Individuals with reduced RV ejection fraction with dyskinetic portions of the RV may benefit from long-term anticoagulation with warfarin to prevent thrombus formation and subsequent pulmonary embolism. For intractable RV failure, cardiac transplantation can be the only remaining alternative.²⁰

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

An ICD is the most effective prevention against SCD. For secondary prevention, ICD implantation is recommended in patients with prior cardiac arrest and those with poorly tolerated arrhythmias that are not completely suppressed by antiarrhythmic drug therapy. During a mean follow-up of 39 months, nearly one-half of these patients had an appropriate ICD therapy, 16% had an inappropriate therapy, and 14% had a device-related complication.^{5,21}

ICD implantation is also recommended for primary prevention in patients who are considered to be at high risk for SCD (see above). It is important to recognize, however, that there is not yet clear consensus on the specific risk factors that identify those patients with ARVD in whom the probability of SCD is sufficiently high to warrant an ICD for primary prevention.¹⁸

Importantly, ICD implantation in ARVD patients is associated with several risks. Areas of the RV myocardium in patients with ARVD may be thin and noncontractile and can be penetrated during placement of the RV leads, with subsequent cardiac tamponade. Also, the fibrofatty nature of the RV can lead to difficulty in attaining a location with acceptable R wave amplitude and pacing threshold. Marginal parameters may prevent adequate sensing of arrhythmias, resulting in improper ICD function or failure. A separate pace-sense lead may be necessary, positioned in the RV septum or outflow tract.²⁰

CATHETER ABLATION

Catheter ablation of monomorphic VT has a 60% to 90% success rate in patients with ARVD. However, given the chance of long-term recurrence, ablation is not considered curative. Therefore, catheter ablation of VT has been considered mainly in patients with recurrent VT causing frequent ICD shocks and refractory to antiarrhythmic medications and those with VT storm or incessant VT refractory to antiarrhythmic medications. Nonetheless, with the recent advances in mapping and ablation techniques and the improved safety and success of the ablation procedures, as well as the lack of highly effective antiarrhythmic drug therapy, some investigators recommend catheter ablation as a first-line approach in patients presenting with recurrent monomorphic VT.^{8,22} ICD

implantation is recommended as well, because of the unpredictability of recurrences.

Patients with limited endocardial substrate, those with late VT termination with RF delivery, and certainly those with persistent VT despite aggressive endocardial ablation should be considered for an epicardial approach.²³

PARTICIPATION IN SPORTS

Because of the association between exercise and the induction of ventricular tachyarrhythmias, a diagnosis of ARVD is generally considered incompatible with competitive sports and moderate- to high-intensity-level recreational activities. Furthermore, any activity, competitive or not, that causes symptoms of palpitations, presyncope, or syncope should be avoided.²⁰

FAMILY SCREENING

First-degree relatives should be screened clinically with 12-lead ECG, echocardiography, and cardiac MR imaging. Given the low penetrance observed in most families, screening should be extended throughout the kindred to at least one generation beyond the last affected individual. Asymptomatic family members with a normal comprehensive evaluation are less likely to have inherited the gene defect, but should undergo follow-up at regular intervals (every 2 to 3 years) until definitive diagnostic tools are available.⁵ When the causative mutation in the index patient is identified, genetic testing is recommended in family members. A negative genetic test result for the familial mutation would obviate the need for repeated follow-up examinations.

Electrocardiographic Features

ECG during Sinus Rhythm

Approximately 40% to 50% of patients with ARVD have a normal ECG at presentation. However, by 6 years, almost all patients have one or more of several findings on ECG during normal sinus rhythm (NSR), including epsilon wave, T wave inversion, QRS duration equal to or greater than 110 milliseconds in leads V_1 through V_3 , and RBBB. Significant differences exist in most ECG features among ARVD patients according to the degree of RV involvement, and they are more prevalent in diffuse ARVD than in the localized form of the disease.^{6,8}

The hallmark feature of ARVD, the epsilon wave, is a marker of delayed activation of the RV free wall and outflow tract and is considered a major diagnostic criterion for ARVD. The epsilon wave has the appearance of a distinct wave just beyond the QRS, in the ST segment, in the right precordial leads, particularly in lead V_1 , and represents low-amplitude potentials caused by delayed activation of some portion of the RV (Fig. 29-3). Although the epsilon wave has been considered highly specific for ARVD, ECG markers that reflect ventricular conduction delay in ARVD (including the epsilon wave) are frequently observed in subjects with a spontaneous or drug-induced type 1 ECG pattern of Brugada syndrome.²⁴ Additionally, this criterion is of limited sensitivity, observed in only 10% to 37% of ARVD patients when evaluated by standard ECG. The use

of highly amplified (20 mV) precordial leads and modified limb leads can increase the detection of epsilon potentials to 75% but is rarely utilized.^{6,8}

Other markers of delayed activation of the RV include prolongation of the QRS duration to at least 110 milliseconds in leads V_1 through V_3 , and a ratio of the sum of the QRS duration in leads $(V_1 + V_2 + V_3)/(V_4 + V_5 + V_6) \geq 1.2$ (sensitivity of 35% to 98%). In fact, a QRS duration greater than 110 milliseconds in lead V_1 has a sensitivity of 26% to 75% and a specificity of 100% in patients suspected of having ARVD based on historical features. Additionally, incomplete or complete RBBB can be observed in 18% and 15% of patients, respectively. Epicardial mapping suggests that these patterns are usually caused by parietal block, rather than by disease of the bundle branch itself. In the presence of an RBBB pattern, selective prolongation of the QRS duration in leads V_1 to V_3 compared with lead V_6 (>25 milliseconds, parietal block) is an important hallmark of ARVD (sensitivity of 52% to 64%).^{6,8,11,12} Furthermore, T wave inversion in leads V_1 through V_3 in the absence of RBBB is considered a minor diagnostic criterion for ARVD and its prevalence in ARVD has been reported as 55% to 94% in different series. The extent of right precordial T wave inversion relates to the degree of RV involvement. Increased QT dispersion (i.e., inter-lead variability of the QT interval) has been observed in ARVD.

Prolongation of the upstroke of the S wave (≥ 55 milliseconds from the nadir of the S wave to the isoelectric line) in leads V_1 through V_3 in the absence of RBBB, which presumably represents altered depolarization, was found in the original report to be a very sensitive ECG criterion for ARVD (present in all cases with diffuse ARVD and in 90% in the localized form of the disease). However, the sensitivity of this criterion was less than 60% in several other reports. This measurement has the highest diagnostic usefulness for differentiating the localized form of ARVD from idiopathic RVOT VT, correlates with the degree of RV involvement, and is an independent predictor of VT induction. It is recognized that a prolonged S wave upstroke directly relates to QRS width in the right precordial leads; nonetheless, it is superior to localized QRS prolongation in distinguishing the mild form of ARVD from idiopathic RVOT VT.^{6,11,12}

Another ECG marker of ARVD described recently is the "terminal activation delay." This parameter is measured from the nadir of the S wave to the end of all depolarization deflections, thereby including not only the S wave upstroke but also both late fractionated signals and epsilon waves, to the completion of the QRS complex. A prolonged terminal activation delay (≥ 55 milliseconds) was observed in 71% of ARVD patients and only 4% of controls.^{6,25}

QRS fragmentation in standard ECG leads, defined as deflections at the beginning of the QRS complex, on top of the R wave or in the nadir of the S wave, has a sensitivity of 85% for the diagnosis of ARVD.²⁶

The SAECG is a highly amplified and signal-processed ECG that can detect microvolt-level electrical potentials in the terminal QRS complex, known as late potentials. Late potentials, which reflect the slow conduction in the ventricular myocardium and electrical potentials that extend beyond the activation time of normal myocardium, typically arise from scarred myocardium, an anatomical substrate potentially responsible for reentrant ventricular arrhythmias. The SAECG and its three components (filtered QRS duration, low-amplitude signal duration, and root-mean-square voltage of the last 40 milliseconds of the QRS) are highly associated with the diagnosis of ARVD. Late potentials and fragmented electrical activity can be detected by signal-averaged ECG in 50% to 80% of patients with ARVD. Although there are no guidelines for abnormal SAECG in patients with ARVD, it is common practice to categorize the SAECG as abnormal if two or more of these parameters are abnormal. In a recent report, the sensitivity of using SAECG for diagnosis of ARVD was increased from 47% using two of the three criteria to 69% by using any one of the three criteria, while maintaining a high specificity of 90% to 95%. Abnormal SAECG was strongly associated with dilated RV volumes and decreased RV ejection fraction detected by cardiac

MR imaging. SAECG abnormalities did not vary with clinical presentation or reliably predict spontaneous or inducible VT, and had limited correlation with ECG findings.^{11,24,27} Additionally, SAECG abnormalities appear to correlate with the presence of low-voltage areas selectively in the RVOT as observed during electroanatomical voltage mapping, whereas surface ECG abnormalities are associated with a more diffuse RV involvement.²⁸ The usefulness of SAECG for predicting inducible VT in ARVD remains uncertain.²⁴

ECG during Ventricular Tachycardia

Ventricular ectopy in ARVD usually arises from the RV and therefore has an LBBB pattern similar to that seen in idiopathic RVOT VT. The ECG morphology of the VT is predominantly LBBB, but RBBB can be observed and does not exclude an RV origin (Fig. 29-4). The QRS axis during VT is typically between -90 and $+110$ degrees; an extreme rightward direction of the QRS axis is uncommon.²⁹ No correlation has been observed between any specific ECG morphology and a particular activation pattern, although all RBBB morphology VTs exhibit a peritricuspid circuit.

Additionally, patients with ARVD frequently demonstrate the presence of more than one VT morphology, either spontaneously (64%) or during an EP study (88%).⁶

Electrophysiological Features

Tachycardia Features

Tachycardia is inducible with programmed electrical stimulation in the majority of ARVD patients with clinical VT. Isoproterenol infusion facilitates VT induction in many patients.

Reentry in areas of abnormal myocardium is the most likely mechanism of VT in ARVD. Most reentrant circuits cluster around the tricuspid annulus and the RVOT. Multiple morphologies of inducible VT are common. A variety of different reentry circuit sites can be identified with entrainment mapping. A single region can give rise to multiple VT morphologies. Previous studies showed mean numbers of different VT morphologies per patient ranging from 1.8 to 3.8.⁶

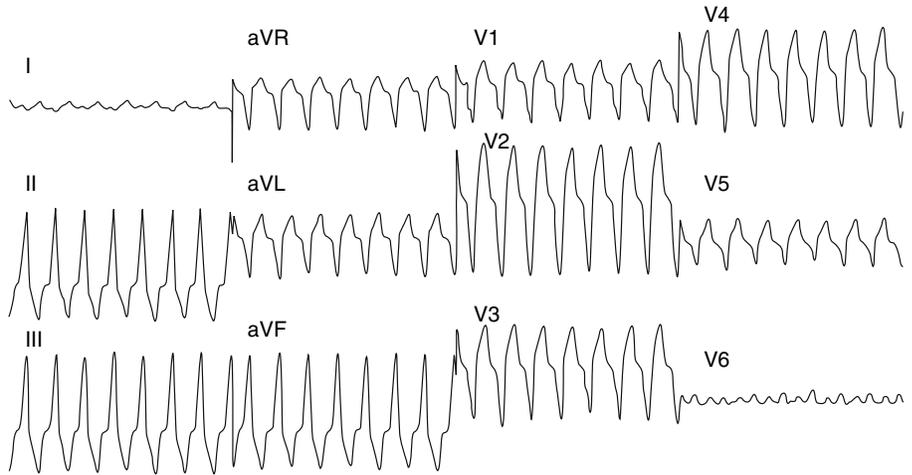

Overdrive pacing during VT at cycle lengths (CLs) 20 to 50 milliseconds shorter than the tachycardia CL typically results in entrainment of the tachycardia. The presence of entrainment should be confirmed by the demonstration of fixed fusion of the paced QRS at any single pacing CL, progressive fusion as the pacing CL decreases (i.e., the surface ECG progressively looks more like the VT QRS than a purely paced QRS), and resumption of the VT following pacing with a nonfused VT QRS at a return cycle equal to the pacing CL. Once the presence of entrainment is confirmed, three parameters should be evaluated—the presence of manifest or concealed fusion, the post-pacing interval (PPI), and the local electrogram-to-QRS interval during VT versus the stimulus-to-QRS (S-QRS) interval during entrainment. The 12-lead ECGs during pacing and during VT are compared to evaluate whether manifest or concealed fusion is present. The PPI is measured from the stimulus artifact to the onset of the local electrogram of the first VT (unpaced) beat in the pacing lead recording. Finally, the local electrogram-to-QRS interval during VT and the S-QRS interval during entrainment are measured on the distal bipolar pair recording of the mapping catheter or with the use of the proximal bipolar pair when the presence of artifacts in the distal pole recording prevents reliable measurement.

Exclusion of Other Arrhythmia Mechanisms

In clinical practice, the disease that most frequently mimics ARVD is idiopathic RVOT VT. Although RVOT VT is associated with a benign prognosis with no familial basis, it can be extremely difficult to distinguish from the concealed phase of ARVD, in which typical ECG and imaging abnormalities are absent.

VT-1

VT-2

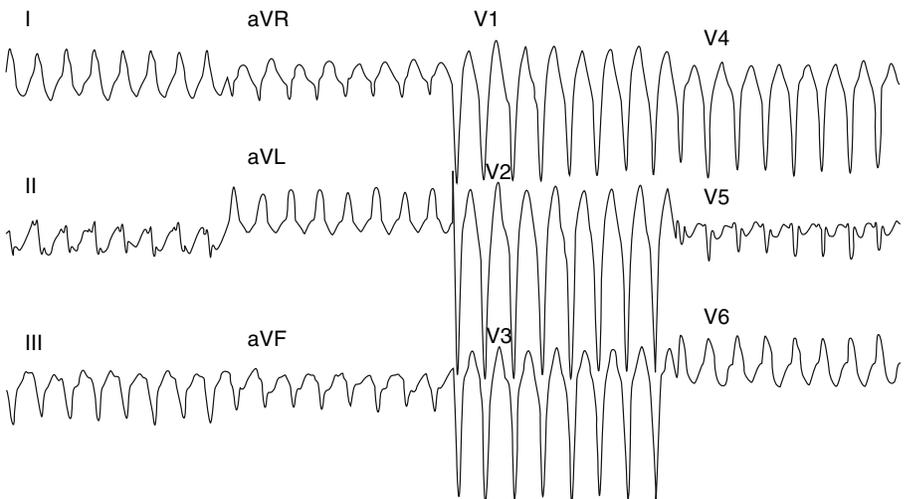

FIGURE 29-4 Surface lead ECGs of ventricular tachycardia (VT) in a patient with arrhythmogenic right ventricular dysplasia-cardiomyopathy. Both have left bundle branch block-type morphology but with very different frontal axes.

The resting surface ECG in NSR is typically normal in patients with idiopathic VT, with no epsilon wave, QRS widening or fragmentation, or other markers of delayed activation of the RV typically observed in ARVD patients. However, the ECG is also normal in 40% to 50% of patients with ARVD at presentation, but in almost no patient after 6 years.³⁰

Both idiopathic RVOTVT and VT caused by ARVD generally have LBBB morphology. However, the presence of an LBBB morphology VT with a superior axis is very unlikely in idiopathic RVOTVT. Additionally, VTs in ARVD patients generally have lower QRS amplitude and more fragmentation, but these qualitative differences are not always present.

Patients with idiopathic VT have a normal SAECG when in NSR and normal imaging studies (echocardiography, MR imaging, contrast ventriculography) of RV size and function. Other clues suggesting the presence of an RV cardiomyopathy include the presence of RV dilation, multiple VT morphologies, and a well-defined anatomical substrate.

The response during EP testing is also helpful in distinguishing idiopathic RVOT VT from ARVD. The repetitive initiation of VT by programmed stimulation suggests a reentrant mechanism. In one report, programmed electrical stimulation induced VT in all but 1 of 15 patients with ARVD compared with only 2 patients with idiopathic RVOT VT (93% versus 3%). Additionally, fractionated diastolic electrograms recorded during VT or NSR at the VT site of origin or other RV sites were present in all but one patient with

ARVD, but were not seen in any patient with idiopathic RVOT VT. Furthermore, the induction of VTs with different QRS morphologies was seen only in ARVD (73% versus 0%). Although isoproterenol infusion can induce VT in patients with idiopathic RVOT VT, it has a similar effect in ARVD and therefore does not help distinguish between these disorders. Reentry was the mechanism of tachycardia in 80% of the ARVD group, whereas 97% of RVOT VT had features of triggered activity.

Electroanatomical voltage mapping appears to be an effective way of distinguishing early or concealed ARVD from idiopathic VT by detecting RV electroanatomical scars that correlate with the histopathological features pathognomonic of the disease.³¹

Mapping

VTs in ARVD share many features observed in post-MI VTs. First, the tachycardias typically are monomorphic and have a macroreentrant mechanism. Second, the circuits are composed of zones of abnormal conduction, characterized by low-amplitude abnormal electrograms, with identifiable exit regions to the surrounding myocardium. Third, outer loops, which can be broad portions of the reentry circuit in communication with the surrounding myocardium, have also been observed. Fourth, the same types of targets for ablation previously identified in post-MI VT (critical isthmus) can also be useful for targeting VT in ARVD. Therefore, mapping techniques for ARVD-related VT are similar to those used for post-MI VT (see Chap. 22).⁸

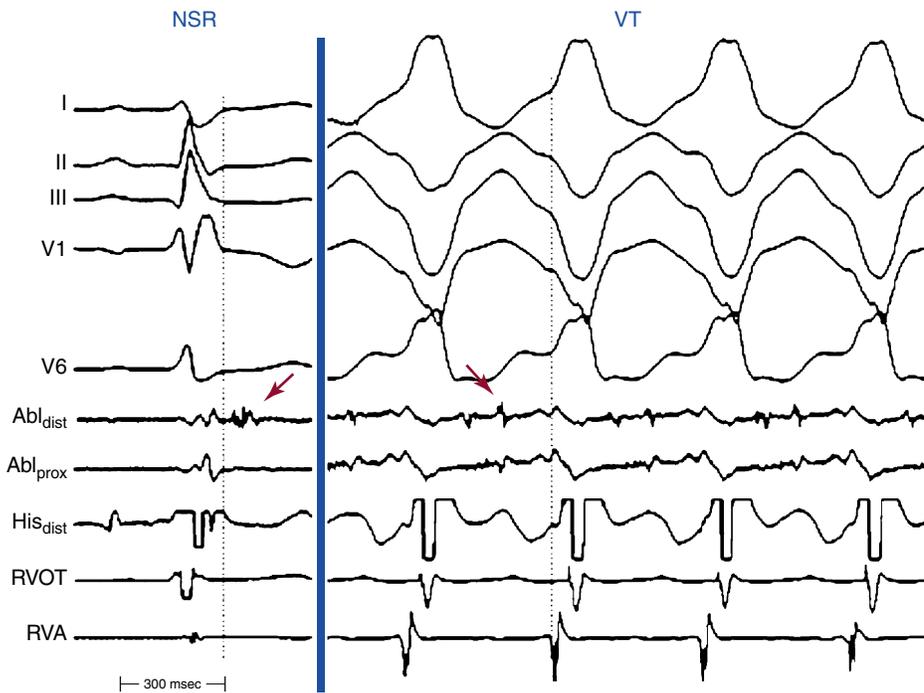

FIGURE 29-5 ECG and intracardiac recordings during normal sinus rhythm (NSR; left) and ventricular tachycardia (VT; right) in a patient with arrhythmogenic right ventricular dysplasia-cardiomyopathy. During NSR, a late potential is present (arrow); the same potential occurs during mid-diastole during VT. RVOT = right ventricular outflow tract.

Activation Mapping

Most reentrant circuits cluster around the inferolateral tricuspid annulus, the RVOT, and the RV apex, which are the typical areas of fibrous and fatty infiltration in ARVD. Hence, these areas are targeted first by activation mapping. Because the VT circuit is composed of zones of abnormal conduction, characterized by low-amplitude abnormal electrograms, with identifiable exit regions to the surrounding myocardium, endocardial activation mapping during VT typically detects abnormal fragmented or split low-voltage electrograms, with diastolic potentials (Fig. 29-5).⁸

During activation mapping, particular sites of interest include: (1) sites with abnormal local bipolar electrogram (amplitude, ≤ 0.5 mV; duration, ≥ 60 milliseconds); (2) sites at which the local electrogram precedes the QRS complex by at least 50 milliseconds (activation times are taken from the onset of the bipolar electrogram); and (3) sites with the earliest local activation closest to mid-diastole, isolated mid-diastolic potentials, or continuous activity. Once identified, these sites are targeted by entrainment mapping (see later) to establish their relationship to the tachycardia circuit.

Detailed mapping will usually reveal more than one site of presystolic activity. It is therefore essential to demonstrate that the presystolic site recorded is in fact the earliest site. A normal presystolic bipolar electrogram (amplitude, >3 mV; duration, <70 milliseconds) should prompt further search for earlier activity. If, after very detailed mapping, the earliest recorded site is not at least 50 milliseconds presystolic, this suggests that either the map is inadequate (most common) or the VT arises deeper than the subendocardium, in the midmyocardium, or even incorporating the subepicardium. VTs in patients with ARVD exhibiting a focal activation pattern have also been described; however, an epicardial reentrant circuit with a defined endocardial exit may explain the focal activation pattern of the RV endocardium.^{8,29}

An isolated mid-diastolic potential is defined as a low-amplitude, high-frequency diastolic potential separated from the preceding and subsequent ventricular electrograms by an isoelectric segment. It is likely that isolated mid-diastolic potentials that cannot be dissociated from the VT are generated in segments of the zone of slow conduction or common pathway (isthmus), which are integral components of the reentry circuit. It is important to recognize

that not all presystolic activity recorded during VT is related to the mechanism; it could represent delayed activity not related to the tachycardia mechanism, dead-end pathways, or even an artifact. Therefore, it is important to confirm that presystolic activity is related to the reentrant circuit. Demonstration of a fixed relationship of the diastolic electrograms to the subsequent VT QRS, despite spontaneous or induced oscillations of the tachycardia CL, helps exclude the possibility that those electrograms reflect late activation from unrelated dead-end pathways.⁸

Additionally, 3-D electroanatomical mapping can help in the precise description of VT reentrant circuits, sequence of ventricular activation during the VT and rapid visualization of the activation wavefront, and identification of slow-conducting pathways and appropriate sites for entrainment mapping. Local activation times are assigned according to the onset of the bipolar electrogram registered at the tip of the mapping catheter and are color-coded. These systems also help in navigation of the ablation catheter, planning of ablation lines, and maintaining a log of sites of interest (e.g., sites with favorable entrainment or pace mapping findings), which can then be revisited with precision. Additionally, voltage (scar) mapping is a helpful feature of some of the electroanatomical mapping systems (see later).⁸

Entrainment Mapping

Entrainment mapping is used to characterize reentry circuits in ARVD, identify critical isthmuses, and guide ablation. Pacing is performed during VT at a CL 10 to 30 milliseconds shorter than the VT CL, at RV sites identified during activation mapping, demonstrating continuous activity or isolated mid-diastolic potentials. For stable VTs, the following three criteria are used to define the critical isthmus and predict the success of RF application in termination of the VT: (1) entrainment with concealed fusion; (2) PPI equal to the tachycardia CL (within 20 to 30 milliseconds); (3) and S-QRS interval equal to the local electrogram-to-QRS interval (± 20 milliseconds). Other predictors of successful ablation sites include S-QRS interval-to-VT CL ratio less than 0.7, long S-QRS interval, and alteration of the tachycardia CL and/or termination by subthreshold or nonpropagated stimuli. However, because of the diffuse nature of the disease in ARVD, isthmuses may sometimes be wide and good entrainment maps can be obtained from a rather large area. In this case, linear lesions across the diastolic pathway may be necessary.⁸

Pace Mapping

Pace mapping can be used to complement activation and entrainment mapping findings and to confirm ablation target sites, although it may not be always necessary, especially when several criteria localizing the VT isthmus have been identified. At isthmus sites defined during VT, pace mapping during NSR is attempted after VT termination, with the mapping catheter being kept at the same location. Pace mapping is preferably performed with unipolar stimuli (10 mA, 2 milliseconds) from the distal electrode of the mapping catheter (cathode) and an electrode in the inferior vena cava (anode).

The resulting 12-lead ECG morphology is compared with that of the tachycardia. ECG recordings should be reviewed at the same gain and filter settings. The greater the degree of concordance between the morphology during pacing and tachycardia, the closer is the catheter to the site of origin of the tachycardia.

At best, a pace map that matches the VT would only identify the exit site to the normal myocardium, and can be distant from the critical sites of the circuit required for ablation. Thus, pace mapping remains only a corroborative method of localizing VT. It can be used to focus initial mapping to regions likely to contain the reentrant circuit exit or abnormal conduction but is not sufficiently specific or sensitive to be the sole guide for ablation.

Pace mapping can also be used in conjunction with substrate mapping when other mapping techniques are not feasible, so that it can provide information on where ablation can be directed. The VT circuit's exit site is approximated by the site of pace mapping that generates QRS complexes similar to those of VT. From that point, evaluation of the S-QRS interval (measured to the onset of the earliest QRS on the 12-lead ECG) can help trace the course of the VT isthmus. Sites along the VT isthmus are associated with good pace maps but with progressively longer S-QRS intervals.⁸

Electroanatomical Substrate Mapping

Electroanatomical substrate mapping provides a helpful tool in reconstructing the VT circuit in patients with ARVD and hemodynamically stable VTs, in conjunction with activation and entrainment mapping techniques.²⁹ Additionally, in a subset of ARVD patients, conventional mapping during VT can be limited by changing multiple morphologies, nonsustainability, or hemodynamic instability. Substrate-based voltage mapping during sinus rhythm can be used in these cases to identify regions of scar and abnormal myocardium and guide, in conjunction with pace mapping, ablation of linear lesions to connect or encircle the abnormal regions.²²

The dysplastic regions can be identified, quantified, and differentiated from healthy myocardium by the presence of electrograms with low amplitudes and longer durations, reflecting replaced myocardial tissue. Voltage mapping is performed during sinus rhythm, atrial pacing, or ventricular pacing. The peak-to-peak signal amplitude of the bipolar electrogram is measured automatically. Endocardial regions with a bipolar electrogram amplitude greater than 1.5 mV are defined as normal, and dense scar areas are defined as those with an amplitude less than 0.5 mV. Abnormal myocardium is defined as an area of contiguous recordings with a bipolar electrogram amplitude between 0.5 and 1.5 mV.

As noted, in ARVD, the normal myocardium is replaced by fatty and then fibrous tissue, causing thinning and scarring, predominantly in the RV. Studies have found that regions of abnormal voltage suggestive of scar were observed in all ARVD patients. The endocardial bipolar voltage abnormalities tend to be perivalvular and, although affecting predominantly the RV free wall, involve some aspect of the septum in most (76%) patients. This pattern is consistent with pathological studies demonstrating a predilection for scar to occur in these particular areas in ARVD. Whether an extensive perivalvular fibrotic process is specific for patients who present with sustained monomorphic VT in the setting of ARVD is yet to be determined.^{22,29} In contrast to the post-MI pattern of

dense scar surrounded by a border zone, the regions of abnormal myocardium in ARVD are commonly patchy and inhomogeneous, occurring in anatomically disparate areas. As a consequence, low-voltage identification in ARVD is less useful as a marker for ablation because it is very widespread. Nonetheless, evaluating the existence of different voltage areas within the 0.5-mV scar (i.e., the voltage limits are reset to 0.3 to 0.5 mV as the upper limit and to 0.1 mV as the lower, representing dense scar) can potentially help visualize channels of slow conduction within scar tissue.⁸ The critical isthmus of each of the reentrant circuit typically is bounded by an area of low-voltage scar on one side and an anatomical barrier (tricuspid annulus) on the other side, or by two parallel lines of double potentials.²⁹

A recent report found that identifying ventricular electrograms with an isolated delayed component during sinus rhythm (defined as a distinct electrogram after the QRS separated [by ≥ 40 milliseconds] by an isoelectric interval or very low-amplitude signal of < 0.1 mV) can be used to define the substrate for the VT circuit and, when combined with other mapping maneuvers, can help guide catheter ablation in ARVD patients with noninducible or unmappable VTs.³²

Importantly, the disease in ARVD has been reported to begin epicardially and progress to the endocardium; therefore, endocardial fibrosis, as reflected by the voltage map findings, can be a manifestation of more extensive disease involvement and can be anticipated to be the more common substrate for uniform sustained VT (Fig. 29-6).²³

Endocardial *unipolar* voltage mapping (with a cutoff of 5.5 mV) can potentially provide a more global assessment of myocardial voltage and more closely approximate the degree and location of epicardial bipolar voltage abnormalities that serve as a substrate for VT in ARVD patients with no or limited endocardial bipolar voltage abnormalities. Therefore, endocardial *unipolar* voltage mapping may help in decision making related to proceeding to epicardial substrate mapping and ablation (Fig. 29-7).³³

Noncontact Mapping

When VT is short-lived, hemodynamically unstable, or cannot be reproducibly initiated, simultaneous multisite data acquisition using a noncontact mapping system (EnSite 3000; St. Jude Medical, St. Paul, Minn.) can help localize the VT site of origin. The system can help identify presystolic endocardial activation sites (potential exits) for reentrant VTs and thus starting points for conventional mapping. It may also help identify VT isthmuses and therefore suitable targets for ablation.

The EnSite 3000 noncontact mapping system consists of a non-contact catheter (9 Fr) with a multielectrode array surrounding a 7.5-mL balloon mounted at the distal end. To create a map, the balloon catheter is positioned in the RV through the left subclavian vein approach with a 260-cm-long 0.035-inch guidewire. The distal tip is placed at the RV apex. The balloon is then deployed, and it can be filled with a mixture of contrast and saline to be visualized fluoroscopically. The balloon is positioned in the center of the RV cavity and does not come into physical contact with the atrial walls being mapped. Systemic anticoagulation is critical to avoid thromboembolic complications. Intravenous heparin is usually given to maintain the activated clotting time (ACT) at 250 to 300 seconds.

A conventional deflectable mapping-ablation catheter is also positioned in the RV and used to collect geometry information. The tricuspid annulus, His bundle, and pulmonic valve are initially tagged and a detailed geometry of the RV and RVOT is reconstructed by moving the mapping catheter around the RV. Subsequently, a detailed geometry of the RV is reconstructed by moving the mapping catheter around the endocardium. Using this information, the computer creates a model, called a convex hull, of the chamber during diastole. The patient may be in NSR or tachycardia during creation of the geometry.

Once chamber geometry has been delineated, VT is induced and mapping can begin. The data acquisition process is performed

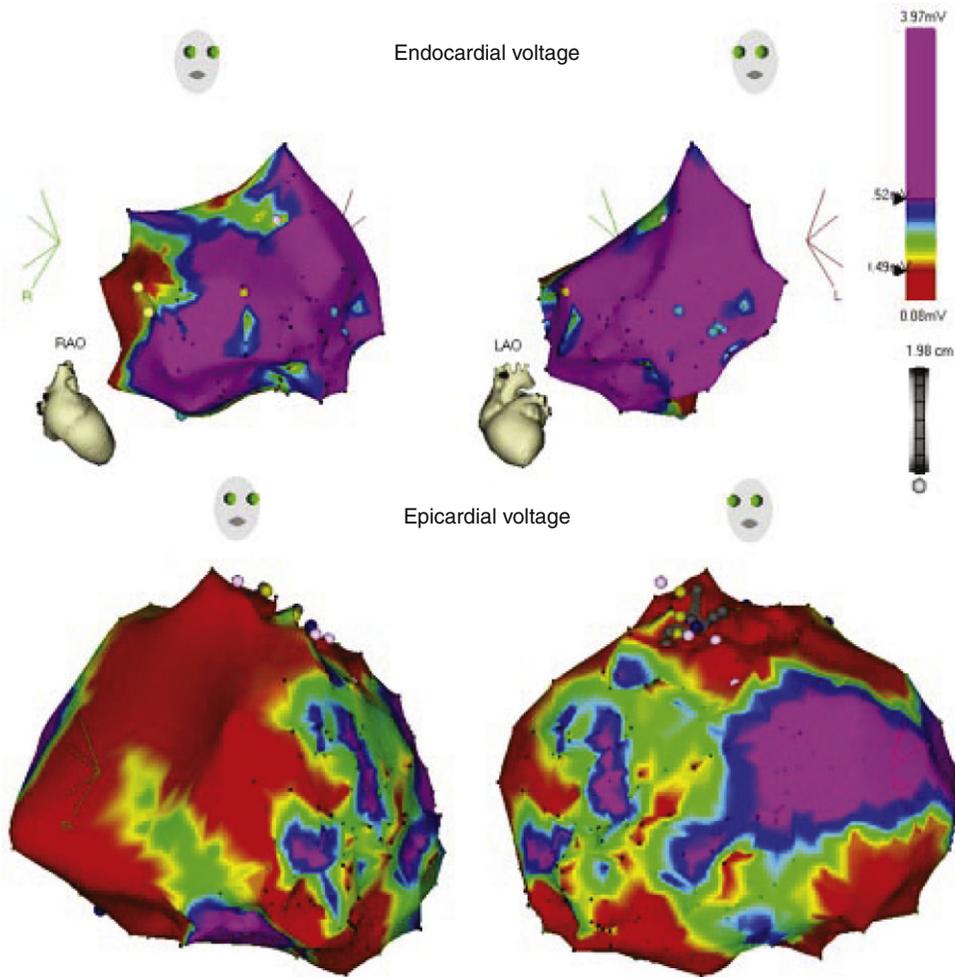

FIGURE 29-6 Right and left anterior oblique electroanatomical endocardial (top) and epicardial (bottom) voltage maps in a patient with ARVD. Red areas denote low voltage/scar. On the endocardial map, only a small area shows abnormal voltage (near lateral tricuspid valve, red area); however, on the epicardial map, substantially larger areas show abnormal low voltage. LAO = left anterior oblique; RAO = right anterior oblique.

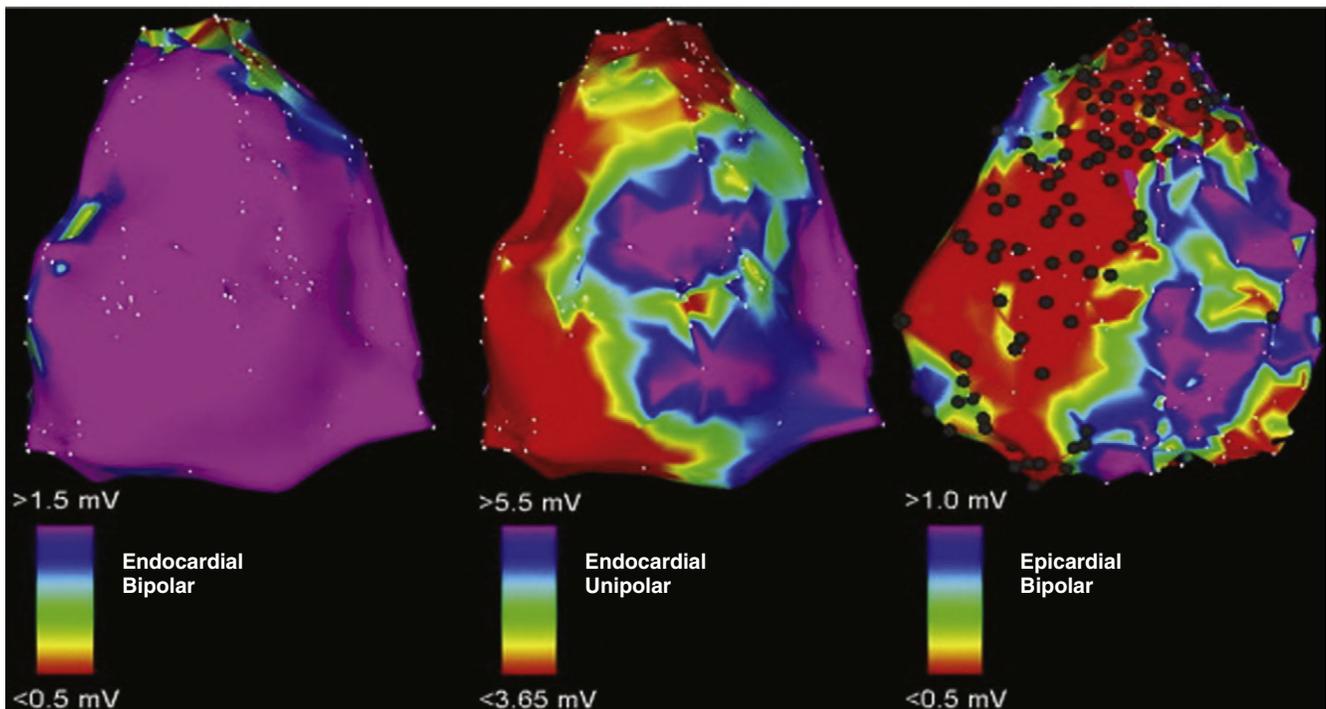

FIGURE 29-7 Unipolar endocardial electrograms defining the location and greater extent of epicardial bipolar electrogram abnormalities in a patient with arrhythmogenic right ventricular cardiomyopathy-dysplasia. **Left:** Endocardial bipolar voltage map demonstrates a paucity of low-voltage regions. **Center:** Endocardial unipolar voltage mapping reveals a much greater burden of abnormal myocardium (<5.5 mV) extending from the lateral tricuspid valve up to the pulmonic valve region and inferiorly across the right ventricular free wall. **Right:** Epicardial bipolar voltage map confirms the extensive area of abnormal epicardium. Black dots represent wide, split, and/or late epicardial electrograms and help to identify low-voltage areas consistent with scar versus fat. (From Polin GM, Haqqani H, Tzou W, et al: Endocardial unipolar voltage mapping to identify epicardial substrate in arrhythmogenic right ventricular cardiomyopathy/dysplasia, *Heart Rhythm* 8:76-83, 2011.)

automatically by the system, and all data for the entire chamber are acquired simultaneously. The system then reconstructs more than 3000 unipolar electrograms simultaneously and superimposes them onto the virtual endocardium, producing color-coded isopotential maps to depict graphically regions that are depolarized. Activation can be tracked on the isopotential map throughout the tachycardia cycle and wavefront propagation can be displayed as a user-controlled 3-D “movie.” The color range represents voltage or timing of onset. Sites of early (presystolic) endocardial activity, which are likely adjacent to reentry circuit exits, are usually identifiable; in some cases, isthmuses can be identified. Diastolic depolarization is defined as activity on the isopotential map that can be continuously tracked back in time from VT exit sites, defined on the map as synchronous with the QRS onset. Diastolic activity and exit sites are then marked on the virtual endocardium, and a mapping catheter is navigated to them by the locator technology. Ablation lesions can be tagged, facilitating performing linear ablation devoid of gaps across the tachycardia critical isthmus.

Unless the multielectrode array position is significantly changed, the accepted geometry can be applicable during the entire procedure, and the same geometry can be used for mapping different VT morphologies as well as for substrate mapping.

Substrate mapping based on scar or diseased tissue, which has been recently introduced to the noncontact mapping technology, can be particularly helpful when the VT is not inducible during the procedure. Dynamic substrate mapping allows the creation of voltage maps from a single cardiac cycle and provides the ability to identify low-voltage areas, as well as fixed and functional block, on the virtual endocardium through noncontact methodology.³⁴

Percutaneous Epicardial Mapping

A recent report found that, in patients with ARVD and VT who failed endocardial ablation, low-voltage areas consistent with scar were more extensive on the epicardium than the endocardium and uniformly included wide, split, and late electrograms consistent with abnormal conduction. The origin of VT defined by activation/entrainment mapping and suggested by the detailed substrate mapping observations and targeted for ablation was also frequently noted beyond the endocardially defined scar. Successful

epicardial ablation sites were often opposite endocardial sites with normal voltage or where ablation had been ineffective.²³

Therefore, patients with limited endocardial substrate, those with late VT termination with endocardial RF delivery, and certainly those with persistent VT despite aggressive endocardial ablation should be considered for an epicardial approach. Additionally, surface ECG criteria identifying a QS complex in lead V₂ or leads III and aVF during VT can be helpful in identifying patients who should be considered for an epicardial approach with the initial procedure.²³

The approach to epicardial mapping is essentially the same as for endocardial ablation, including activation mapping, entrainment mapping, substrate mapping, and pace mapping, and is discussed in detail in [Chapter 27](#).

Ablation

Target of Ablation

For stable VTs, reentry circuit isthmuses are the target of ablation and are defined by activation and entrainment mapping as sites with continuous activity or isolated mid-diastolic potentials, entrainment with concealed fusion, PPI equal to the VT CL, and S-QRS interval less than 70% of the VT CL. Alteration of the tachycardia CL or termination of VT by subthreshold or nonpropagated stimuli, and repeated VT termination occurring with catheter manipulation or pacing at the site, also suggest an isthmus location ([Fig. 29-8](#)).²⁹

For hemodynamically unstable VTs, substrate mapping during sinus rhythm followed by brief inductions of VT (with the mapping catheter at the optimal site, as identified by substrate and pace mapping) can allow assessment of the relationship of the abnormal electrograms to the VT circuit. This can also allow entrainment maneuvers to be performed at those sites to help distinguish sites critical to the VT circuit from bystander sites. VT is then quickly terminated before significant hemodynamic compromise ensues. This approach can be facilitated by hemodynamic support with the use of intravenous vasopressors, intraaortic balloon pump, or both. This approach, however, requires being able to induce the same VT reproducibly. The use of noncontact mapping can be of value in these cases.

FIGURE 29-8 Ablation of arrhythmogenic right ventricular dysplasia-cardiomyopathy (ARVD) ventricular tachycardia. Shown is radiofrequency (RF) energy delivery in the basal lateral right ventricle in a patient with ARVD. Note the mid-diastolic potential (red arrow) 130 milliseconds prior to QRS onset and almost immediate cessation of ventricular tachycardia on RF delivery. Blue arrow marks initiation of RF energy delivery.

When the critical isthmuses of the reentrant circuit(s) can be identified, linear ablation lesions are delivered to sever those isthmuses. For unmappable VTs (due to poor inducibility or changing VT morphology), RF ablation can be performed as linear lesions targeting potential exit sites and isthmuses of VT circuits based on the location of the best pace map, location of valvular anatomical boundaries, and the substrate defined by the voltage mapping. Typically, linear lesions are created over target regions by sequential point lesions designed to: (1) connect scar or abnormal myocardium to a valve continuity; (2) connect scar or abnormal myocardium to another scar; (3) extend from the most abnormal endocardium (<0.5 mV) to normal myocardium (>1.5 mV); or (4) encircle the scar or abnormal region, depending on the scar location and size.^{22,32}

Ablation Technique

Ablation may be performed with a 4-mm-tip (maximal target temperature of 60°C and maximal power of 50 W), an 8-mm-tip (maximal temperature of 65°C and maximal power of 75 W), or an irrigated-tip catheter (maximal temperature of 40–45°C and maximal power of 50 W). Irrigated RF ablation catheters are preferred, because power delivery can be limited in the trabeculated and annular regions where cooling from circulating blood flow is low. However, careful attention to power titration and monitoring impedance is necessary to reduce the risk of perforation when ablating in the free wall of the RV.³⁵ Ablation is usually maintained for 60 to 120 seconds at the site where the tachycardia is terminated (in ablation during stable VT) or at each point along the linear ablation.⁸

Endpoints of Ablation

Lack of inducibility of VT is the endpoint of the ablation procedure. When the VT is scarcely inducible at baseline, the disappearance of all the isolated delayed components of the VT-related area can be used as an endpoint for the substrate-based ablation approach.

Outcome

Ablation of VT in ARVD remains a clinical challenge and should be viewed as a potential palliative procedure in selected patients. Although VT ablation has been reported to successfully eliminate inducible VT acutely in 41% to 88% of patients, long-term success is low, and during average follow-ups of 11 to 24 months, VT recurs in 11% to 83% of patients, even following extensive or repeated ablation attempts.^{22,29,36} Recurrences usually manifest as nonsustained VT, a slower monomorphic sustained VT, or a new monomorphic VT.^{8,35}

Multiple morphologies, hemodynamic instability, or noninducibility can limit the success of VT ablation. Additionally, ARVD can create a large number of potential circuits; an empirical approach may not eliminate all the possible pathways. Achieving adequate energy delivery can also be a problem, especially in regions difficult to access by catheter—in particular, abnormal regions along the tricuspid annulus, which can require the use of 8-mm-tip or irrigation-tip ablation catheters to achieve effective lesions underneath the tricuspid valve. It must be emphasized that caution must be taken when using irrigated-tip ablation in patients with very thin ventricular walls, although thick fibrous tissue is present in many areas. The risk of creating deeper lesions in thin walls of the RV body or apex potentially increases the risk of perforation. Although the magnitude of this risk is not well known, it seems to be infrequent.⁸

Furthermore, recent studies have shown a high prevalence of epicardial isthmuses in ARVD. Epicardial mapping and ablation have yielded a significant improvement in ablation efficacy; thus, it is reasonable to begin mapping endocardially, but be prepared to move to epicardial mapping following pericardial puncture if endocardial mapping and ablation do not quickly yield good

results. In a recent report, percutaneous epicardial mapping and ablation were performed in 13 consecutive patients with ARVD after failed endocardial VT ablation. Twenty-seven distinct VTs were targeted for ablation from the epicardium; during 18 ± 13 months of follow-up, 77% of patients were free of VT.²³

The discrepancy between the good acute results and the unfavorable long-term outcome may be explained by the progressive nature of ARVD, which predisposes to the occurrence of new and malignant arrhythmogenic substrates over time. This hypothesis, however, has been questioned by a recent study that demonstrated the absence of progression of the area of the endocardial scar as measured by voltage mapping in patients with ARVD and VT, despite demonstrating progressive RV dilation in these patients.⁷

Pathophysiology

Most information concerning patients with ventricular tachycardia (VT) and congenital heart disease pertains to tetralogy of Fallot, as compared with other forms of congenital heart disease. Tetralogy of Fallot is the most common cyanotic congenital cardiac malformation. The core lesion is an underdeveloped subpulmonary infundibulum, which is superiorly and anteriorly displaced, resulting in the well-known tetrad of pulmonary stenosis, ventricular septal defect, aortic override, and right ventricular (RV) hypertrophy. Correction of the defect involves patch closure of the ventricular septal defect and relief of RV outflow tract (RVOT) obstruction, which typically requires resection of a large amount of RV muscle. When the procedure was first performed, it was not done through the tricuspid valve but required a ventriculotomy. The pulmonic valve annulus is usually small, and repair with a transannular patch leads to chronic pulmonic insufficiency, which can be severe if associated with downstream obstruction caused by significant pulmonary arterial stenosis. It has been hypothesized that ventricular arrhythmias in these patients are of the result of years of chronic cyanosis, followed by the placement of a ventriculotomy, increased RV pressures caused by inadequate relief of obstruction, and severe pulmonic regurgitation with RV dysfunction. Such factors can lead to myocardial fibrosis and result in the substrate for reentrant ventricular arrhythmias.¹

Using intraoperative mapping, VT after surgical correction of tetralogy of Fallot has been classified into two types: VT originating from the RVOT, which is considered to be related to prior right ventriculotomy or reconstruction of the RVOT (Fig. 30-1); and VT originating from the RV inflow tract septum, which is thought to be related to closure of the ventricular septal defect.

The electrophysiological (EP) mechanism responsible for VT after surgical correction of congenital heart disease is typically a macroreentrant circuit within the RV around a scar or prosthetic materials used during surgical repair. Reentry circuit isthmuses are located within anatomically defined pathways bordered by unexcitable tissue. Four discrete anatomical isthmuses that often support VT have been identified. The most common isthmus is between the superior aspect of the tricuspid annulus and unexcitable scar/patch in the free wall of the RVOT. The other isthmuses exist between the pulmonic valve and RV free wall scar (in the absence of a transannular patch), between the septal patch and tricuspid annulus through the region of the ventriculo-infundibular fold, and between the septal patch and pulmonic valve.^{2,3}

The sites of the diastolic activation and delayed conduction along the reentrant circuit have been shown to have significant abnormalities such as fibrosis, adiposis, and degeneration of the myocardium. The scattered surviving myocyte islets embedded in the extensive adiposis and/or fibrosis can form an electrical maze around the surgical suture area, resembling the histological findings in the border zone of infarcted myocardium. Furthermore, RV remodeling induced by pressure or volume load promotes hypertrophy and fibrosis, which can potentially result in slow conduction, providing the link between impaired hemodynamics and VT.³

Clinical Considerations

Epidemiology

Congenital heart disease is the most common form of birth defect, with an estimated 1% to 2% of live newborns afflicted by moderate or severe types. Ventricular arrhythmias late after repair of congenital heart disease are a common finding, predominantly in those with tetralogy of Fallot, and potentially contribute to sudden cardiac death (SCD) in this population. The incidence of late SCD has been debated but ranges from 1% to 5% during a follow-up period of 7 to 20 years after surgery. The incidence of arrhythmias generally increases as the patient with congenital heart disease ages. Patients with surgical correction of ventricular septal defect or pulmonary stenosis also have a higher than normal risk of serious ventricular arrhythmias and SCD.¹ SCD is the most common cause of death in patients after repair of congenital heart disease, with a 25- to 100-fold increased risk compared with the general population.⁴

In patients with tetralogy of Fallot, serious ventricular arrhythmias are rare during the first 10 to 15 years following corrective surgery. This is followed by a steady increase in the incidence of ventricular arrhythmias, primarily VT, which are prevalent in 15% of adult patients late after surgery. The incidence of VT in this population is 11.9%, with an 8.3% risk of SCD by 35 years of follow-up.^{3,7}

Although tetralogy of Fallot is typically cited as the archetypal lesion when VT in the adult congenital heart disease patient population is discussed, serious ventricular arrhythmias can also develop in other types of congenital heart malformations, even in the absence of direct surgical scarring to ventricular muscle, including congenital aortic stenosis, transposition of the great arteries when the RV supports the systemic circulation, severe Ebstein anomaly, certain forms of single ventricle, and ventricular septal defect with pulmonary arterial hypertension. The appearance of ventricular arrhythmias in these cases commonly coincides with deterioration in overall hemodynamic status.⁸ In the past 20 years, many patients with tetralogy of Fallot have undergone transatrial repair, operating on the RV through the tricuspid valve after right atriotomy. In these cases, there is no incision in the RV free wall around which reentry can occur, although reentry around the ventricular septal defect patch can still take place.

Risk Stratification

NONINVASIVE RISK STRATIFICATION

Although controversy still exists, considerable progress has been made toward identifying noninvasive risk factors for VT and SCD in congenital heart disease patients. Tetralogy of Fallot is perhaps the one condition for which such data are fairly extensive. Independent predictors of clinical VT include QRS duration equal to or greater than 180 milliseconds, late and rapid increase in QRS

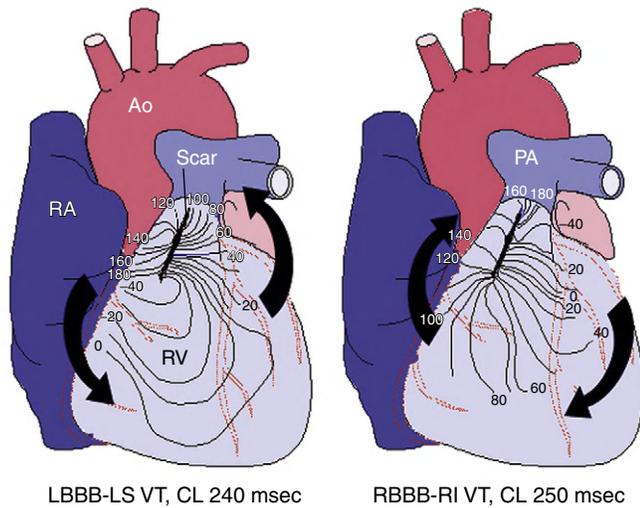

FIGURE 30-1 Ventricular tachycardia (VT) postsurgical repair of tetralogy of Fallot. Illustrated is scar-based reentry in surgically repaired tetralogy of Fallot with a right ventriculotomy. The incision heals as a nonconductive scar, leaving a small rim of muscle between the pulmonic valve annulus and scar. This is the diastolic corridor for rotation in either direction as shown, giving rise to VT with left bundle branch block–like QRS morphology and left superior axis or, in the opposite direction of rotation, right bundle branch block–like QRS morphology and right inferior axis. Ao = aorta; CL = cycle length; LBBB = left bundle branch block; LS = left superior; PA = pulmonary artery; RA = right atrium; RI = right inferior; RV = right ventricle.

duration after surgery, dispersion of QRS duration on the surface electrocardiogram (ECG), increased QT interval dispersion, high-grade ventricular ectopy on Holter monitoring, complete heart block, older age at surgery (especially older than 10 years), presence of a transannular RVOT patch, increased RV systolic pressures, RVOT aneurysm, pulmonic and tricuspid regurgitation, and left ventricular diastolic dysfunction.^{1,6,7}

ELECTROPHYSIOLOGICAL TESTING

Despite advances in noninvasive risk stratification, identification of high-risk subgroups has not been sufficiently accurate to guide management decisions reliably. More recently, in patients with repaired tetralogy of Fallot, inducible monomorphic or polymorphic sustained VT by programmed ventricular stimulation was found to be a significant independent predictor of subsequent clinical sustained VT or SCD in patients with and without antiarrhythmic drug therapy, VT ablation, or implantable cardioverter-defibrillator (ICD). In this patient population, the rate of inducible sustained VT is approximately 35%, which is similar to that reported in patients with prior myocardial infarction (MI) and left ventricular ejection fractions less than 40% and spontaneous nonsustained VT. Additionally, the diagnostic value of EP testing (sensitivity, 77%; specificity, 80%; diagnostic accuracy, 79%) and prognostic significance (relative ratio, 4.7 for subsequent clinical VT or SCD) compares favorably with programmed ventricular stimulation in post-MI patients. Independent risk factors for inducible sustained VT were age greater than 18 years at the time of testing, palpitations, prior palliative surgery, frequent or complex ventricular ectopy, or nonsustained VT, and a cardiothoracic ratio of 0.6 or more on chest radiograph.⁷

Nonetheless, EP testing yield remains too imperfect and too impractical to be recommended as a general screening tool and is usually reserved for selected patients with concerning symptoms (e.g., palpitations, dizziness, or unexplained syncope) or Holter findings, when VT is suspected but not yet proven. Additionally, the subpopulation of patients deemed at intermediate risk of SCD based on a combination of other parameters may benefit most from risk stratification with an EP study.^{7,8}

TABLE 30-1 Risk Score for Appropriate Defibrillator Shocks in Primary Prevention in Patients with Tetralogy of Fallot

VARIABLE	EXPONENTIAL VALUES OF BETA COEFFICIENTS	POINTS ATTRIBUTED
Prior palliative shunt	3.2	2
Inducible sustained ventricular tachycardia	2.6	2
QRS duration ≥ 180 msec	1.4	1
Ventriculotomy incision	3.4	2
Nonsustained ventricular tachycardia	3.7	2

Principles of Management

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

ICDs play an important role in the primary and secondary prevention of SCD in this patient population. In a recent prevalence study, ICDs were implanted in 10% of the adult population with tetralogy of Fallot repair for either primary (59%) or secondary (41%) prevention indications. Both groups experienced high rates of appropriate therapies.

SECONDARY PREVENTION. ICD implantation is recommended in patients who have survived cardiac arrest or an episode of sustained VT with hemodynamic compromise.⁹ The most common anatomical diagnosis among device recipients is tetralogy of Fallot, followed by transposition of the great arteries and aortic stenosis. The rate of appropriate therapies for VT or ventricular fibrillation (VF) events in this patient population averages 9.8% per year and about 35% over a follow-up period of 5 years, with the median time to first shock less than 1 year.^{5,6,9,10}

PRIMARY PREVENTION. Some subgroups of patients with congenital heart disease are recognized as being at risk for life-threatening ventricular arrhythmias and SCD, including those with large scars from a prior ventriculotomy (e.g., tetralogy of Fallot repair), and those who develop advanced degrees of ventricular dysfunction from long-standing hemodynamic burdens (e.g., congenital aortic stenosis, single ventricle). Recent data support the benefit of ICD implantation for primary prevention in patients deemed to be at high risk for SCD. Up to 44% of patients with tetralogy of Fallot repair who received prophylactic ICDs experience sustained ventricular tachyarrhythmias, and appropriate therapies occur in 7.7% of patients per year. These annual rates are comparable to those of other high-risk populations, including patients with primary prevention ICDs for ischemic, dilated, or hypertrophic cardiomyopathy. A combination of surgical, hemodynamic, ECG, and EP factors modulates the risk of appropriate shocks.^{5,6}

As noted, multiple risk factors for VT and SCD in congenital heart disease patients have been identified in an effort to better define which are most likely to benefit from a primary prevention ICD. Recently, a risk score to predict appropriate ICD shocks in tetralogy patients with ICDs for primary prevention indications was derived from six clinical variables (surgical, hemodynamic, electrocardiographic, and EP factors) identified by multivariate analyses (Table 30-1). Patients with fewer than 3 points (low risk) experienced no appropriate shocks. In patients with 3 to 5 points (intermediate risk) and more than 5 points (high risk), appropriate shocks were received by 3.8% and 17.5% of patients per year, respectively.⁵ Although these risk-stratification schemes can provide reasonable sensitivity, they have suboptimal specificity for patients at highest risk because of

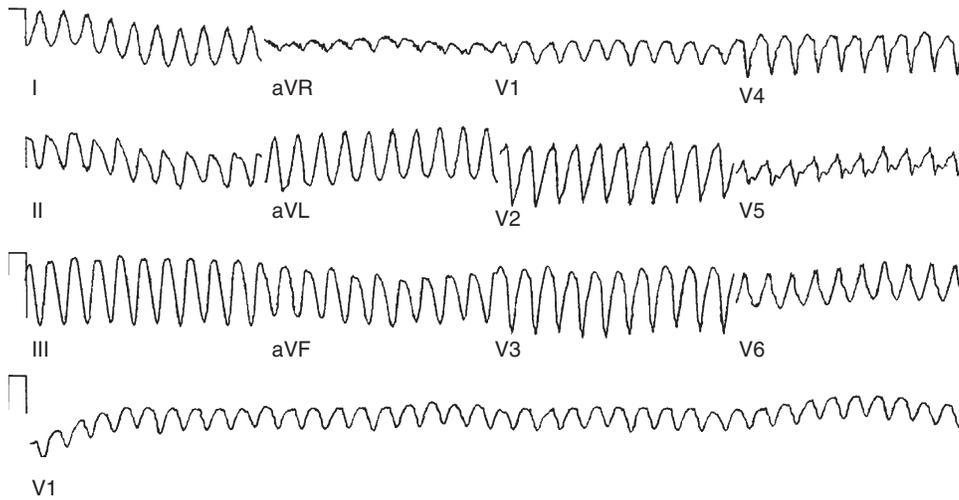

FIGURE 30-2 Surface ECG of ventricular tachycardia postsurgical repair of tetralogy of Fallot. Note the left bundle branch block pattern and left superior axis morphology characteristic of clockwise macroreentry around the right ventriculotomy scar.

the small population size and the relatively low incidence of SCD in congenital heart disease patients (approximately 2% per decade of follow-up in patients with tetralogy of Fallot repair).⁹ EP testing can potentially help to identify patients at risk for malignant ventricular arrhythmias; however, patient selection for screening with EP testing and the timing and frequency of testing remain to be elucidated. At present, there is no generally accepted scheme for rhythm surveillance in asymptomatic tetralogy patients.^{5,7,8}

Even in patients considered at risk for malignant ventricular arrhythmias, the benefit of ICD implantation should be carefully weighed against the risks of such a procedure in this unique group of patients. Transvenous implantation of the ICD may not be feasible in patients with the more complex varieties of congenital heart disease, necessitating epicardial insertion of the ICD leads with the added morbidity of a sternotomy or thoracotomy for epicardial electrodes. Even when transvenous implantation procedures are feasible, they can be very challenging in patients with distorted anatomy, requiring that the implanting physician be well acquainted with the details of congenital heart lesions and the types of surgical repairs. Because of the considerable variation in surgical techniques and individual anatomy, careful review of detailed operative reports is essential in these cases. Additionally, the ICD lead failure rate from both insulation breaches and conductor breaks is high in this patient population, exceeding 20% over 5 years (likely due to the young age and high activity level of this patient group), which results in added morbidity of corrective procedures. Moreover, the negative psychological impact of an implanted device and inappropriate shocks (occurring in up to 47%, predominantly caused by supraventricular tachycardias and lead failures) in a relatively young patient should not be underestimated.^{5,9,10}

For all these reasons, ICD decisions in congenital heart disease patients should be individualized, taking into account the various risk factors, all of which must then be viewed in the context of the individual patient's history and general hemodynamic status to refine the selection process.^{8,10}

ANTIARRHYTHMIC DRUG THERAPY

Similar to patients with post-MI VT, antiarrhythmic agents are generally not considered a stand-alone therapy in congenital heart disease patients with sustained ventricular arrhythmias or cardiac arrest, but can be considered in two main settings: as adjunctive therapy in patients with an ICD and as preventive therapy in patients who do not want or are not candidates for an ICD. ICD patients who experience frequent symptoms or device discharges triggered by ventricular arrhythmias may benefit from adjunctive drug therapy. When antiarrhythmic drug therapy is required, beta blockers and sotalol are commonly used. Amiodarone can carry significant long-term risk of adverse events given the young age of the patient population. The efficacy of dofetilide and dronedarone has not been adequately evaluated.^{7,8}

SURGICAL REPAIR

Surgical interventions to improve cardiac status and alleviate residual hemodynamic problems (such as septal defect or valvular regurgitation) may play a role in reducing arrhythmia risk in certain carefully selected congenital heart disease patients, especially those with new-onset or worsening arrhythmias. Furthermore, VT mapping and ablation can be performed intraoperatively at the time of cardiac surgery. Nonetheless, the impact of surgery on modifying the risk for SCD remains controversial.^{5,7,8}

CATHETER ABLATION

Catheter ablation for VT in tetralogy of Fallot generally is not considered as a stand-alone therapy, given the potential risk of recurrences of the same or new ventricular arrhythmias, and is primarily performed in patients with recurrent sustained monomorphic VT that is causing frequent ICD shocks or significant symptoms. Catheter ablation can also be considered in patients with symptomatic spontaneous sustained VT in whom ICD implantation is not recommended or not feasible.

Additionally, catheter ablation can be considered as isolated VT therapy for those patients with hemodynamically stable monomorphic and slow VT, and even then, follow-up EP studies are necessary to ensure that the same or different circuits cannot be induced before dismissing the need for an ICD.⁸

Furthermore, patients after tetralogy repair with a history of syncope and induced monomorphic VT during EP testing may be considered for either ICD placement or an attempt at catheter ablation of the VT with or without backup ICD implantation.^{2,7}

Electrocardiographic Features

During normal sinus rhythm (NSR), QRS widening after tetralogy of Fallot repair is probably the result of a combined effect of the surgical injury to the myocardium and the right bundle branch, and from the RV enlargement. Therefore, a prolonged QRS duration cannot be considered the specific expression of delayed intraventricular conduction from an arrhythmogenic substrate, but a non-specific marker of electrical instability.¹¹

The VT is most commonly monomorphic and macroreentrant, rotating clockwise or counterclockwise around myotomy scars or surgical patches. QRS morphology during VT is determined by the pattern of ventricular activation around the scar. Most commonly, left or right bundle branch block with right inferior axis morphology is seen during clockwise rotation around the scar. Less commonly, left bundle branch block with left axis morphology is observed (Fig. 30-2).¹² Right bundle branch block–like morphology can be present if the tachycardia exits on the septal aspect of the RV free wall.

Mapping

Detailed knowledge of the congenital and surgical anatomy, including all available operative reports, is essential before ablation. Transthoracic and transesophageal echocardiography, right heart catheterization, computed tomography, and/or magnetic resonance imaging should be considered to clarify the anatomical landmarks for mapping.

As noted, in patients with repaired tetralogy of Fallot, the mechanism of VT is macroreentry involving the RV, either at the site of anterior right ventriculotomy or at the site of a ventricular septal defect patch. Once sustained and stable monomorphic VT is induced, endocardial activation mapping and entrainment mapping are performed to detect an adequate site for ablation. Activation mapping during VT is used to identify sites with mid-diastolic activity. Entrainment mapping is performed in a manner analogous to that used for post-MI VT, and is used to characterize the relationship of ventricular sites to the reentrant circuit and to verify that a diastolic electrogram, regardless of where in diastole it occurs and its position and appearance on initiation of VT, is part of the VT circuit. Entrainment with concealed fusion and a difference between the post-pacing interval and the VT cycle length not exceeding 30 milliseconds and a stimulus-to-QRS (S-QRS) interval not exceeding 70% of the VT cycle length helps identify the critical isthmus of the reentrant circuit to be targeted by catheter ablation.

For VTs that are not mappable because of hemodynamic instability or termination during catheter manipulation or entrainment mapping, pace mapping during sinus rhythm is used to identify exit sites of the reentrant circuit. Reentry circuit isthmuses can be approximated by pace mapping at sites where the QRS morphology matches that of the VT with an S-QRS interval of at least 40 milliseconds. If the VT can be briefly tolerated, the catheter is moved to the presumed isthmus site during NSR, and the VT is reinduced to confirm the position within the circuit either by entrainment mapping or by termination during radiofrequency (RF) energy application.³

Electroanatomical mapping can be of value because the presence of multiple circuits and the complexity of anatomical alteration, particularly in the vicinity of surgical scar, can pose significant challenges to mapping and ablation procedures. Additionally, voltage mapping of the area of interest can help identify the area of scar and border zone and guide conventional mapping techniques. Furthermore, most reentrant circuit isthmuses are located within anatomically defined isthmuses bordered by unexcitable tissue. These boundaries can be identified by three-dimensional mapping during normal NSR. Transecting anatomical isthmuses by linear RF lesions during NSR can potentially eliminate the tachycardia, even when conventional mapping is not feasible because of poorly tolerated or noninducible tachycardia.^{1,3,11}

When VT is short-lived, hemodynamically unstable, or cannot be reproducibly initiated, simultaneous multisite data acquisition using a noncontact mapping system (EnSite 3000; St. Jude Medical, St. Paul, Minn.) can help localize the VT site of origin. Propagation of activation within the RV can be traced throughout the whole tachycardia cycle by analyzing color-coded isopotential maps to identify the protected zone of the reentrant circuit between surgical barriers, anatomical barriers, or both. Additionally, dynamic substrate mapping allows the creation of voltage maps from a single cardiac cycle and provides the ability to identify low-voltage areas, as well as fixed and functional block, on the virtual endocardium through noncontact methodology.¹³

Ablation

The critical isthmus of the VT circuit is the usual target of ablation. A good pace map and entrainment with concealed QRS fusion and a prolonged S-QRS interval indicate more precisely an adequate site for ablation. Linear ablation lesions can also be performed using data obtained from substrate mapping to target anatomical isthmuses between surgical and structural lines of

block. In tetralogy of Fallot patients, most VT circuits use the anatomical isthmus between the RVOT free wall scar or patch and the tricuspid annulus or pulmonic valve, and/or the septal scar or patch and either the tricuspid annulus or the pulmonic valve. Ablation lines transecting these anatomical isthmuses eliminate the VT in most patients. In one report, all of the ablation lines that needed to be created extended from 10 to 40 mm.^{3,14}

RF ablation is usually performed with an open saline-irrigated catheter (power limit, 50 W), a closed irrigation catheter, or an 8-mm-tip catheter (power limit, 70 W). Ablation is performed during VT when possible. If VT is terminated or slowed during RF application, additional lesions are placed to connect the adjoining anatomical boundaries across the VT circuit isthmus, as defined by voltage mapping and pace mapping techniques, and RF lesions are placed during NSR until unipolar pacing fails to capture. After completion of the lesions, programmed stimulation is repeated to reassess tachycardia inducibility.³

Ablation success for any particular VT is defined by lack of reinducibility. Completeness of linear RF lesion lines can be validated by demonstrating absence of capture during pacing along the line, double potentials, and activation mapping during pacing from above or below the line.¹⁴

The experience with catheter ablation of VT in congenital heart disease is limited. Several reports have described single-center experiences spanning several eras of technological advances. In a report of 20 patients with VT and congenital heart disease, 50% of patients were unable to undergo ablation because of VT noninducibility, hemodynamic instability, access or anatomical problems, or proximity of the ablation target to the His bundle. The acute success rate for mappable VTs was 83%, with a long-term recurrence rate of 40%. In another report, immediate noninducibility of sustained or nonsustained VT was achieved in 15 of 16 patients (94%) after the ablation procedure. Repeat ventricular stimulation 5 to 7 days later revealed noninducibility in 14 patients (88%). At successful ablation sites, a good pace map during sinus rhythm could be found in 15 of the 16 patients (94%). However, an area of slow conduction, defined as mid-diastolic low-amplitude endocardial potential, could be found in only 3 patients (19%). The mean activation time of the endocardial electrogram preceding the QRS complex on the surface ECG at the ablation site was -69 ± 16 milliseconds. In 9 of 11 patients with inducible sustained VT (82%), entrainment with concealed fusion and a prolonged S-QRS interval (10 to 120 milliseconds) could be demonstrated. A recent report of 11 patients with VT after repair of congenital heart disease used electroanatomical substrate mapping during NSR in addition to conventional mapping, when feasible. RF ablation eliminated VT in all patients, with 91% remaining free of VT at a follow-up time of 30 ± 29 months. In another report, noncontact mapping facilitated successful ablation in 8 of 10 patients (80%).^{1,3,14}

Sudden cardiac death (SCD) is a major contributor to population mortality, with an overall incidence in the United States estimated to be between 0.1% and 0.2%, resulting in approximately 300,000 to 350,000 deaths annually.

Ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT) is the initial rhythm recorded in 25% to 36% of witnessed cardiac arrests occurring at home, but in a much higher proportion (38% to 79%) of witnessed cardiac arrests occurring in a public setting.¹ The majority of SCD events are associated with structural heart disease, with coronary artery disease and its complications being involved in up to 60% to 80% of cases, followed by other cardiomyopathies. However, in 10% to 20% of SCDs, no cardiac structural abnormalities are detectable. The lack of an apparent cause in many of those cases initially led to the classification as “sudden unexplained death syndrome” (SUDS) or “sudden infant death syndrome” (SIDS). Many of these are caused by primary electrical disorders, including long QT syndrome (LQTS), catecholaminergic polymorphic VT (CPVT), Brugada syndrome, and short QT syndrome (SQTS), as well as cases identified as “idiopathic VF” when the underlying cause often remains unknown.²

SCD may originate from a variety of arrhythmias, as a wide spectrum of pathogenic mechanisms has been identified over the years. VT degenerating first to VF and later to asystole appears to be the most common pathophysiological cascade involved in fatal arrhythmias recorded as the primary electrical event at the time of SCD, particularly in patients with advanced heart disease. In patients without structural heart disease, polymorphic VT and torsades de pointes caused by various genetic or acquired cardiac abnormalities, such as ion channel abnormalities, or acquired LQTS commonly contribute to the initiation of life-threatening arrhythmias.

Long QT Syndrome

The LQTS is a rare inherited cardiac channelopathy with variable penetrance that is associated with an abnormally prolonged QT interval and an increased propensity to life-threatening ventricular arrhythmias in the presence of a structurally normal heart.³⁻⁵

In 1957, Anton Jervell and Fred Lange-Nielsen published the first report on a familial (autosomal recessive) disorder characterized by the presence of a striking prolongation of the QT interval, congenital deafness, and a high incidence of SCD at a young age. Subsequently, Romano and Ward independently identified an almost identical, but autosomal dominant, disorder that is not associated with deafness. A genetic relationship between the two was then proposed and the two syndromes were considered variants of one disease under the unifying name of “LQTS.”

The progressive unraveling of the molecular basis of LQTS has disclosed that whereas the autosomal dominant Romano-Ward syndrome depends on mutations affecting at least five genes encoding sodium (Na^+) and potassium (K^+) channels, the autosomal recessive Jervell and Lange-Nielsen syndrome depends on homozygous or compound heterozygous mutations of either one of the two genes encoding the subunits forming the channel conducting the slowly activating delayed rectifier K^+ current (I_{Kr}). Being a recessive disease, the Jervell and Lange-Nielsen syndrome is far less common than the Romano-Ward syndrome.^{3,6,7}

The initial molecular studies suggested that all genes linked to the LQTS phenotype encode for various subunits of cardiac ion channels. Subsequent findings, however, revealed that LQTS could also be caused by mutations of genes coding for channel-associated cellular structural proteins as well. Nonetheless, the concept that LQTS genes ultimately affect cardiac ion currents, either directly (ion channel mutations) or indirectly (modulators), still holds true.³

In the contemporary literature, Romano-Ward syndrome is used interchangeably with LQTS, but is now less commonly used in favor of the LQT1 to LQT13 scheme according to the underlying genetic mutation (see below).

Epidemiology

There are no systematic studies on LQTS prevalence in the general population. A recent estimate of the prevalence of LQTS is 1:2000 based on the results of genetic screening in families and the incidence of compound heterozygotes (i.e., persons with two

TABLE 31-1 Common Types of the Long QT Syndrome

	LQT1	LQT2	LQT3
Pathophysiology			
Gene	<i>KCNQ1 (K_vLQT1)</i>	<i>KCNH2 (HERG)</i>	<i>SCN5A</i>
Protein	K _v 7.1	K _v 11.1	Na _v 1.5
Ionic current	Decreased I _{Ks}	Decreased I _{Kr}	Increased late I _{Na}
Clinical Presentation			
Incidence of cardiac events	63%	46%	18%
Incidence of SCD	4%	4%	4%
Arrhythmia triggers	Emotional/physical stress (swimming, diving)	Emotional stress, arousal (alarm clock, telephone), rest	Sleep/rest
ECG	Broad-based T wave	Low-amplitude, bifid T wave	Long isoelectric ST segment
QT response to exercise	Attenuated QTc shortening and an exaggerated QTc prolongation during early and peak exercise	Normal QT during exercise but with exaggerated QT hysteresis	Supernormal QT shortening
Management

Left cervicothoracic sympathectomy	++	++	++
Response to mexiletine	+	+	++

I_{Kr} = rapidly activating delayed rectifier K⁺ current; I_{Ks} = slowly activating delayed rectifier potassium current; I_{Na} = sodium current; QTc = corrected QT interval; SCD = sudden cardiac death.

mutations). However, the clinical disease is less common (approximately 1 in 5000) because most mutation carriers remain asymptomatic.⁸ The usual mode of inheritance is autosomal dominant, with the exception of the autosomal recessive Jervell and Lange-Nielsen type.⁶

The most frequent clinical types of LQTS are LQT1 to LQT3. The remaining 10 types (LQT4 to LQT13) make up less than 5% of the genotype-identified LQTS.

Clinical Presentation and Natural Course

ROMANO-WARD SYNDROME

Most information regarding the clinical features of LQTS have been derived from analysis of data from large series of LQTS patients, the largest of which is the International LQTS Registry. LQTS probands are diagnosed at an average age of 21 years. The clinical course of patients with LQTS is variable, owing to incomplete penetrance. It is influenced by age, genotype, gender, environmental factors, therapy, and possibly other modifier genes. At least 37% of individuals with the LQT1 phenotype, 54% with the LQT2 phenotype, and 82% with the LQT3 phenotype remain asymptomatic and many are referred for evaluation because of the diagnosis of LQTS of a family member or the identification of long QT interval on surface electrocardiogram (ECG) obtained for unrelated reasons.⁵

Symptomatic patients can present with palpitations, presyncope, syncope, or cardiac arrest. Recurrent syncope can mimic primary seizure disorders. Syncope in patients with LQTS is generally attributed to polymorphic VT (torsades de pointes), but can also be precipitated by severe bradycardia in some patients with LQT3. Death is usually due to VF.

Syncope is the most frequent symptom, occurring in 50% of symptomatic probands by the age of 12 years, and in 90% by the age of 40 years. The incidence of syncope in LQTS patients is approximately 5% per year, but can vary depending on the LQTS genotype. On the other hand, the incidence of SCD is much lower, approximately 1.9% per year. Nonfatal events (syncope and aborted cardiac arrest) in LQTS patients remain the strongest predictors of subsequent LQTS-related fatal events. The overall risk of

subsequent SCD in an LQTS patient who has experienced a previous episode of syncope is approximately 5% per year.⁹

LQT1, LQT2, and LQT3 comprise more than 90% of all genotyped LQTS cases. LQT1 is the most frequent genetic form of LQTS, accounting for 42% to 45% of genotyped LQTS cases. LQT2 is the second most prevalent form of the disease and accounts for 35% to 45% of genotyped LQTS cases (Table 31-1).^{5,10}

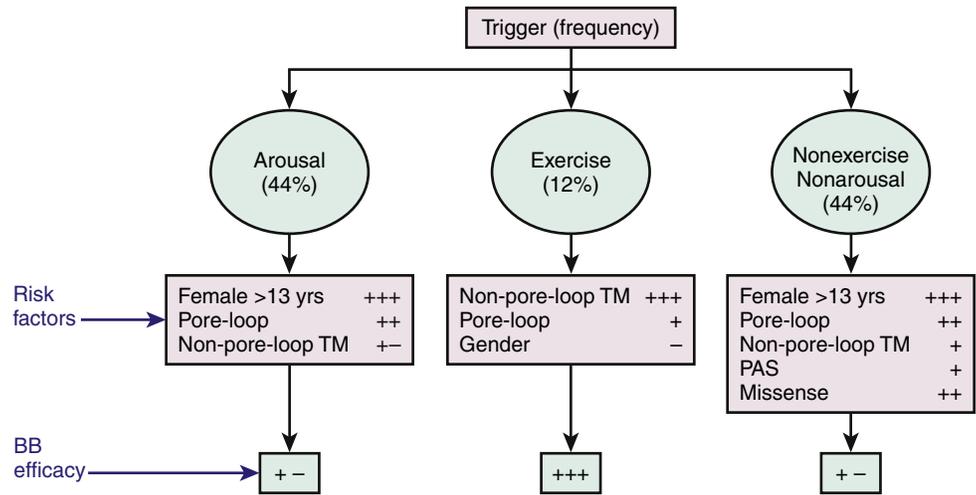

Of individuals who die of complications of Romano-Ward syndrome, SCD is the first sign of the disorder in an estimated 10% to 15%. The risk for SCD from birth to age 40 years has been reported as approximately 4% in each of the phenotypes.

Risk and lethality of cardiac events among untreated individuals are strongly influenced by the genotype. The frequency of cardiac events is significantly higher among LQT1 (63%) and LQT2 (46%) patients than among patients with the LQT3 genotype (18%). However, the likelihood of dying during a cardiac event is significantly higher among LQT3 patients (20%) than among those with the LQT1 (4%) or the LQT2 (4%) genotype.¹⁰⁻¹²

Cardiac events (syncope, cardiac arrest, SCD) in LQTS patients do not occur at random; the factors precipitating cardiac events seem to be specific for each genetic variant. LQT1 patients present an increased risk during physical or emotional stress (90%), and only 3% of the arrhythmic episodes occur during rest/sleep. Swimming and diving appear as highly specific triggers in LQT1 patients. LQT2 patients are at higher risk for lethal events during arousal (44%), but are also at risk during sleep and at rest (43%). Only 13% of cardiac events occur during exercise. Cardiac events in LQT2 patients are typically associated with arousal and auditory stimulation. In fact, the triggering of events by startling, sudden awakening, or sudden loud noises (such as a telephone or alarm clock ring) is virtually diagnostic of LQT2. Notably, individual factors such as gender, location and type of mutation, and QTc prolongation appear to be associated with triggerspecific events; female adolescents with LQT2 appear to experience a greater than ninefold increase in the risk for arousal-triggered cardiac events compared with male adolescents in the same age group. In contrast, gender does not seem to be a significant risk factor for exercise-triggered events among carriers of the same genotype (Fig. 31-1).¹³

On the other hand, LQT3 patients experience cardiac events largely while asleep or at rest (65%) without emotional arousal,

FIGURE 31-1 Trigger-specific risk factors and response to therapy in long QT syndrome type 2 (LQT2). Plus and minus signs are approximate representations of the risk/response based on the hazard ratios and associated *p* values from the multivariate models. and only occasionally during exercise (4%). Notably, the majority of patients continue to experience their cardiac events under conditions similar to their first classified event.^{10,11}

The effect of gender on outcome is age-dependent, with boys being at higher risk than girls during childhood and early adolescence, but no significant difference in gender-related risk being observed between 13 and 20 years. The gender-related risk reverses afterward, and female patients maintain higher risk than male patients throughout adulthood.¹⁴

The genotype can potentially affect the clinical course of the LQTS and modulate the effects of age and gender on clinical manifestations.¹⁵ Although the three major LQTS genotypes (LQT1, LQT2, or LQT3) are associated with similar risks for life-threatening cardiac events in children and adolescents after adjustment for clinical risk factors (including gender, QTc duration, and time-dependent syncope), the risk for cardiac events is augmented in LQT2 women aged 21 to 40 years and in LQT3 patients greater than 40 years of age. The risk of syncope and SCD decreases during pregnancy but increases in the postpartum period, especially among LQT2 women.¹⁰⁻¹²

JERVELL AND LANGE-NIELSEN SYNDROME

The Jervell and Lange-Nielsen syndrome is the recessive variant of the LQTS, characterized by congenital deafness and cardiac phenotype (QT prolongation, ventricular arrhythmias, and SCD). The Jervell and Lange-Nielsen syndrome is caused by two homozygous or compound heterozygous mutations of either one of the two genes (*KCNQ1* and *KCNE1*) that encode components of the I_{Ks} channel.

Patients with Jervell and Lange-Nielsen syndrome have a more severe cardiac phenotype than those with Romano-Ward syndrome. Complete loss of I_{Ks} in hair cells and endolymph of the inner ear results in congenital bilateral sensorineural deafness. Patients begin to experience cardiac events very early in life; 15% suffer a cardiac event during the first year of life, 50% by age 3 years, and 90% by age 18 years. In untreated patients, approximately 50% die of ventricular arrhythmias by the age of 15 years. Furthermore, SCD occurs in more than 25% of patients despite medical therapy.⁶

The conditions that trigger the cardiac events are, overall, very similar to those described for LQT1. Up to 95% of events occur during sympathetic activation (exercise and emotions), and only 5% of the events occur at rest or during sleep.⁶

ANDERSEN-TAWIL SYNDROME

Andersen-Tawil syndrome (LQT7) is a rare autosomal dominant disorder caused by mutations of the gene *KCNJ2*, which encodes the inward rectifier potassium channel, Kir2.1. This syndrome is

characterized by a triad of a skeletal muscle phenotype (periodic paralysis caused by abnormal muscle relaxation), a cardiac phenotype (borderline or mildly prolonged QT interval, prominent U waves, and adrenergically mediated ventricular arrhythmias), and distinctive skeletal dysmorphic features (low-set ears, ocular hypertelorism, small mandible, fifth-digit clinodactyly, syndactyly, short stature, scoliosis, and a broad forehead).¹⁶⁻¹⁸

Affected individuals present initially with either periodic paralysis or cardiac symptoms (palpitations, syncope, or both) in the first or second decade. The arrhythmias displayed by affected patients are generally more benign compared with other types of LQTS and rarely degenerate into hemodynamically compromising rhythms like torsades de pointes, as ultimately evidenced by the lack of SCD cases so far.¹⁷ Intermittent weakness occurs spontaneously, or may be triggered by prolonged rest or rest following exertion; however, the frequency, duration, and severity of symptoms are variable between and within affected individuals, and are often linked to fluctuations in plasma potassium levels. Mild permanent weakness is common.

There is a high degree of variability in penetrance and phenotypic expression. Approximately 60% of affected individuals manifest the complete triad and up to 80% express two of the three cardinal features.

TIMOTHY SYNDROME

Timothy syndrome (LQT8) is a rare multisystem disorder caused by mutations of the *CACNA1C* gene, which encodes the L-type Ca^{2+} channel, $Ca_v1.2$, and is characterized by syndactyly, QT prolongation, congenital heart disease, cognitive and behavioral problems, musculoskeletal diseases, immune dysfunction, and more sporadically autism.

Timothy syndrome is characterized by a remarkable prolongation of the QTc interval, functional 2:1 atrioventricular (AV) block (observed in up to 85% of patients, and likely caused by the extremely prolonged ventricular repolarization and refractory periods), and macroscopic T wave alternans (positive and negative T waves alternating on a beat-to-beat basis). Additionally, congenital heart defects are observed in approximately 60% of patients and include patent ductus arteriosus, patent foramen ovale, ventricular septal defect, tetralogy of Fallot, and hypertrophic cardiomyopathy. Timothy syndrome is highly malignant; the majority of patients seldom survive beyond 3 years of age. Polymorphic VT and VF occur in 80% of patients (commonly triggered by an increase in sympathetic tone) and are the leading cause of death, followed by infection and complications of intractable hypoglycemia.

Extracardiac features include cutaneous syndactyly (variably involving the fingers and toes), which is observed in almost all patients. Facial findings (observed in approximately 85% of individuals)

include low-set ears, flat nasal bridge, thin upper lip, small upper jaw, small, misplaced teeth, and round face. Neuropsychiatric involvement occurs in approximately 80% of individuals and includes global developmental delays and autism spectrum disorders.

In general, the diagnosis of Timothy syndrome is made within the first few days of life based on the markedly prolonged QT interval and 2:1 AV block. Occasionally, the diagnosis is suspected prenatally because of fetal distress secondary to AV block or bradycardia.

Electrocardiographic Features

Abnormal prolongation of the QT interval on the surface ECG, reflecting delayed ventricular repolarization, is the hallmark of LQTS. In addition, T wave abnormalities are also encountered in the majority of patients.

QT INTERVAL MEASUREMENT

QT interval is the body surface representation of the duration of ventricular depolarization and subsequent repolarization. Any deviation or dispersion of either depolarization (e.g., bundle branch block) or repolarization (e.g., prolongation or dispersion of the action potential duration) prolongs the QT interval.¹⁹

An accurate measurement of the QT interval is important for the diagnosis of LQTS. A 12-lead ECG tracing at a paper speed of 25 mm/sec at 10 mm/mV is usually adequate to make accurate measurements of the QT interval. The QT interval is measured as the interval from the onset of the QRS complex, that is, the earliest indication of ventricular depolarization, to the end of the T wave, that is, the latest indication of ventricular repolarization. The QT interval is measured in all ECG leads where the end of the T wave can be clearly defined (preferably leads II and V₅ or V₆), with the longest value being used. The end of the T wave is the point at which the descending limb of the T wave intersects the isoelectric line. Three to five consecutive cardiac cycles are taken to derive average values for R-R, QRS, and QT intervals.^{5,20-23}

When the end of the T wave is indistinct, or if a U wave is superimposed or inseparable from the T wave, it is recommended that the QT be measured in the leads not showing U waves (often aVR and aVL) or that the downslope of the T wave be extended by drawing a tangent to the steepest proportion of the downward limb of the T wave until it crosses the baseline (i.e., the T-P segment). Nonetheless, it should be recognized that defining the end of the T wave in these ways might underestimate the QT interval.²² Some investigators advocate measurement of both the QT interval and the QTU interval (with the latter measurement taken to the end of the U wave as it intersects the isoelectric line) because the QTU interval probably reflects the total duration of ventricular depolarization.²⁰

The highest diagnostic and prognostic value in LQTS families has been observed for QTc in leads II and V₅ of the 12-lead ECG. Thus, QTc should be obtained in one of these leads if measured in only one ECG lead. However, other leads presented with similar diagnostic (aVR) or prognostic (V₂/V₃) value alone, and, in general, the lead with the longest QT interval is used for measurement.²³

QT INTERVAL CORRECTION FOR GENDER

The QT interval shortens after puberty in men but not women, resulting in a longer QT in women than in men. The reported gender difference in various studies varies from 6 to 10 milliseconds in older age groups and from 12 to 15 milliseconds in younger adults. Overall, the gender difference in the rate-corrected QT interval becomes small after 40 years of age and practically disappears in older men and women. Separate gender- and age-specific QT adjustment formulas have been proposed to accommodate these differences.²²

QT INTERVAL CORRECTION FOR HEART RATE

Because the heart rate (R-R cycle length) is the primary modifier of ventricular action potential, QT interval measurements must be

TABLE 31-2 Formulas for Heart Rate Correction of the QT Interval

Bazett	$QTcB = QT / (R-R \text{ interval})^{1/2}$ (all intervals in seconds)
Framingham-Sagie	$QTcFa = QT + 154(1 - 60/\text{heart rate})$
Fridericia	$QTcFi = QT / (R-R \text{ interval})^{1/3}$
Hodges	$QTcH = QT + 1.75(\text{heart rate} - 60)$
Nomogram-Karjalainen	$QTcN = QT + \text{nomogram correction factor}$

corrected for the individual's R-R interval (QTc) to allow for comparisons. Various correction formulas have been developed (Table 31-2), the most widely used being the formula derived by Bazett in 1920 from a graphic plot of measured QT intervals in 39 young subjects. The Bazett correction, however, performs less well at high and low heart rates (undercorrects at fast heart rates and overcorrects at slow heart rates).²⁰ Therefore, it was recommended by the American Heart Association/American College of Cardiology Foundation/Heart Rhythm Society (AHA/ACC/HRS) in 2009 that linear regression functions rather than the Bazett formula be used for QT rate correction. In addition to the Bazett formula, many other correction formulas, such as the Framingham-Sagie, Fridericia, Hodges, and Nomogram-Karjalainen formulas, have been proposed.^{5,21,22}

In a recent report, the accuracy of five different QT correction formulas was evaluated for determining drug-induced QT interval prolongation. The Bazett correction formula provided the most marked QTc variations at heart rates distant from 60 beats/min. The Fridericia formula was found to overestimate QTc at faster heart rates, being more reliable at slower heart rates. Conversely, the Hodges, Nomogram, and Framingham formulas demonstrated less QTc variability over the whole range of the investigated heart rates and seemed to be similarly satisfactory at heart rates of up to 100 beats/min. Among them, the Hodges method, followed by the Nomogram-Karjalainen method, appeared to be the most accurate in determining the correct QTc and subsequently in guiding clinical decisions.²¹

Importantly, there exists a substantial interindividual variability of the QT/R-R relationship, which represents the relationship between QT duration and heart rate. In contrast, a high intraindividual stability of the QT/R-R pattern has been shown, suggesting that a genetic component might partly determine individual QT length. Therefore, population-based and averaged QT correction cannot accurately predict a normal QT interval at a given R-R interval in a *given* patient. Individual-specific QT/R-R hysteresis correction in combination with individualized heart rate correction can potentially reduce intrasubject QTc variability.^{19,24}

QT INTERVAL CORRECTION TO QRS DURATION

The QT interval prolongs in ventricular conduction defects, and an adjustment for QRS duration becomes necessary. This can be accomplished best by incorporating QRS duration and R-R interval as covariates into the QT adjustment formula or by using the JT interval (QT duration minus QRS duration). If the JT interval is chosen, normal standards established specifically for the JT interval should be used. QT and JT adjustment formulas have recently been introduced for use in the setting of prolonged ventricular conduction. With confirmation, they may be incorporated into automated algorithms to provide appropriate correction factors.²²

QT INTERVAL PROLONGATION

The diagnosis of QT interval prolongation can be challenging because of the difficulty in defining the "end" of the T wave and the need for correction for heart rate, age, and gender. This is further complicated by the lack of linear behavior of the Bazett formula at slower and faster heart rates as well as the arbitrary definition

TABLE 31-3 Suggested Bazett-Corrected QT Interval Values for Diagnosis of QT Prolongation

RATING	1-15 YEARS	ADULT MAN	ADULT WOMAN
Normal	<440	<430	<450
Borderline	440-460	430-450	450-470
Prolonged	>460	>450	>470

Values given in milliseconds.

From Goldenberg I, Moss AJ: Long QT syndrome, *J Am Coll Cardiol* 51:2291-2300, 2008.

of the gender-based diagnostic cut-off values that define an abnormally prolonged QTc (QTc of 450 milliseconds for men and QTc of 460 milliseconds for women; Table 31-3).

Furthermore, no single QTc value separates all LQTS patients from healthy controls. The QT interval is subject to large variations even in healthy individuals, and substantial overlap exists with QTc values obtained from LQTS mutation carriers in the range between 410 and 470 milliseconds. In up to 40% of LQTS patients QTc intervals fall in the normal range. Nevertheless, QTc values greater than 470 milliseconds in men and greater than 480 milliseconds in women are practically never seen among healthy individuals (especially when their heart rate is 60 to 70 beats/min), but LQTS cannot be excluded merely by the presence of a normal QTc interval.²⁵ Therefore, unless excessive QTc prolongation (>500 milliseconds, corresponding to the upper quartile among affected genotyped individuals) is present, the QTc interval should always be evaluated in conjunction with the other diagnostic criteria. In the case of borderline QTc prolongation, serial ECG and 24-hour Holter recordings can potentially assist in establishing QT prolongation, as can various challenge tests.⁷

Of note, a considerable variability in QTc interval duration can be observed in patients with LQTS when serial ECGs are recorded during follow-up. This time-dependent change in QTc duration is an important determinant of the phenotypic expression of the disease. Up to 40% of patients with LQTS will have QTc greater than 500 milliseconds at least once during long-term follow-up, but only 25% will have that degree of QT prolongation during their initial evaluation. The maximal QTc duration measured at any time before age 10 years was shown to be the most powerful predictor of cardiac events during adolescence, regardless of baseline, mean, or most recent QTc values. In addition, the QT interval normally may exhibit individual variations during the day.^{25,26}

T WAVE MORPHOLOGY

ST-T wave abnormalities are common among LQTS patients, and some of the ST-T anomalies are characteristic for a specific genotype. Patients with LQT1 commonly exhibit a smooth, broad-based T wave that is present in most leads, particularly evident in the precordial leads. The T wave generally has a normal to relatively high amplitude and often no distinct onset. LQT2 patients generally present with low-amplitude T waves, which are notched or bifid in approximately 60% of carriers. The bifid T wave can be confused with a TU complex; however, unlike the U waves, the bifid T waves are usually present in most of the 12 ECG leads. LQT3 patients often show late-onset, narrow, peaked, and/or biphasic T waves with a prolonged isoelectric ST segment. Occasionally, the T wave is peaked and asymmetrical with a steep downslope. These ST-T wave patterns can be seen in 88% of LQT1 and LQT2 carriers and in 65% of LQT3 carriers. However, exceptions are present in all three genotypes, and the T wave pattern can vary with time, even in the same patient with a specific mutation.^{27,28}

No specific T wave pattern has been suggested in the LQT5 and LQT6 syndromes. TU wave abnormalities such as biphasic T waves following long pauses like those found in the LQT2 syndrome are commonly observed in the LQT4 syndrome. Enlarged U waves separated from the T wave are reported to be characteristic ECG

features in the LQT7 syndrome. Severe QT interval prolongation and macroscopic T wave alternans can be observed in LQT8.²⁷

Despite the initial enthusiasm in achieving a genotype-phenotype correlation for specific LQT-associated genes, this approach failed to provide a high diagnostic yield because of the frequent exceptions in T wave morphology presentation. Therefore, other T wave parameters, such as duration, amplitude, asymmetry, and flatness, as well as the T wave peak-to-T wave end interval, have been used as highly specific quantitative descriptors (see below).²⁸

TORSADES DE POINTES

Torsades de pointes is a polymorphic VT occurring in the setting of QT interval prolongation (acquired or congenital LQTS) and is characterized by a progressive change of the electrical axis, typically rotating 180 degrees in approximately 10 to 12 cycles. This results in the characteristic sinusoidal twisting of the peaks of the QRS complexes around the isoelectric line of the recording; hence, the name *torsades de points* or “twisting of the points.”

The tachycardia rate typically is in the range of 150 to 300 beats/min. In many cases, torsades de pointes is a self-limiting arrhythmia that spontaneously dies out after a few tens of cycles; however, most patients experience multiple episodes of the VT occurring in rapid succession. Only in a minority of cases does torsades de pointes degenerate into VF which almost without exception leads to SCD if immediate rescue intervention is unavailable.⁷

DISPERSION OF REPOLARIZATION

In experimental models of the LQTS, prolonged repolarization, transmural dispersion of repolarization, and early afterdepolarizations (EADs) are the three EP components linked to the genesis of torsades de pointes. Prolongation of the action potential duration (and QT interval) per se is not pathogenic, as demonstrated by the fact that a homogeneous action potential duration prolongation (such as occurs following amiodarone therapy) fails to generate reentry. Several ECG indices have been proposed in recent years as noninvasive surrogates for transmural dispersion of repolarization. Transmural dispersion of repolarization arises from repolarization heterogeneity that exists between the epicardial and putative midmyocardial (M) cells that lie toward the endocardium of the left ventricular (LV) wall. These midmyocardial cells are especially sensitive to a repolarization challenge and exhibit significant prolongation of the action potential duration compared with other transmural cell types.^{7,29,30}

Although some controversy exists, some experimental models suggest that the peak of the T wave coincides with the end of epicardial repolarization (the shortest action potentials), whereas the end of the T wave coincides with the end of repolarization of the M cells (the longest action potentials). Hence, the interval from the peak of the T wave to the end of the T wave ($T_{\text{peak-to-end}}$) in each surface ECG lead has been proposed as an index of transmural repolarization, which can potentially be a more sensitive predictor of arrhythmogenic risk than the QT interval, because the latter represents the total duration of electrical ventricular activation) and not necessarily the dispersion of transmural repolarization.^{7,29,30}

Although changes in the $T_{\text{peak-to-end}}$ interval can potentially show the dynamicity of the transmural dispersion of repolarization in clinical settings in LQTS patients, the role of measuring the $T_{\text{peak-to-end}}$ interval in these patients is not clearly defined yet. In fact, the normal value of the $T_{\text{peak-to-end}}$ interval on the ECG has not been established. Nonetheless, an interval of more than 100 milliseconds is uncommon in normal subjects compared with that in subjects with LQTS (9% versus 55%).³⁰

LQT2 exhibits a larger-degree transmural dispersion of repolarization, as measured by the $T_{\text{peak-to-end}}$ interval, compared with LQT1 and normal hearts. In fact, the $T_{\text{peak-to-end}}$ interval has been proposed as a diagnostic criterion in differentiation between LQT2 and LQT1 patients. Additionally, whereas LQT1 patients and normal subjects demonstrate stable $T_{\text{peak-to-end}}$ intervals independent

of heart rates, LQT2 patients exhibit a trend to decreased $T_{\text{peak-to-end}}$ intervals at fast heart rates and to increased $T_{\text{peak-to-end}}$ durations at slow heart rates. In both LQT1 and LQT2 patients, the longest $T_{\text{peak-to-end}}$ intervals are associated with sudden changes in the heart rate trend. Importantly, the magnitude of transmural dispersion of the repolarization interval does not seem to differ between asymptomatic and symptomatic patients in either LQT1 or LQT2. Conversely, symptomatic LQT2 patients exhibit a trend toward longer QT intervals than do asymptomatic patients.²⁹

On ambulatory monitoring, transmural dispersion of repolarization, measured as $T_{\text{peak-to-end}}$ intervals during normal daily activities, appears to be greater in LQT2 than in LQT1 patients. LQT1 patients exhibit abrupt increases in $T_{\text{peak-to-end}}$ intervals at elevated heart rates, whereas LQT2 patients exhibit increases in transmural dispersion of repolarization at a much wider range of rates. In addition, beta-adrenergic stimulation (exercise or epinephrine infusion) increases transmural dispersion of repolarization in both LQTS models, transiently in LQT2 and persistently in LQT1.²⁹

An alternate approach to determine repolarization heterogeneity is provided by the QT interval dispersion. The QT dispersion index is obtained by the difference between the maximal and minimal QT intervals ($QT_{\text{max}} - QT_{\text{min}}$) measured on a 12-lead ECG. It reflects the spatial heterogeneity of myocardial refractoriness more accurately than single QT values. Visualization of the differences in QT interval in the different ECG leads is facilitated by the display of a suitable subset of temporally aligned simultaneous leads with a slight separation on the amplitude scale.²² However, QT interval dispersion measurements are subject to similar shortcomings encountered with the QT interval assessment, as a large overlap between affected and healthy individuals is observed.⁷ Further, accurate measurement on the scalar ECG at a paper speed of 25 mm/sec is difficult. The same caveat applies to measuring $T_{\text{peak-to-end}}$.

The ratio of the amplitudes of the U and T waves has been suggested as the clinical counterpart of EADs, and a progressive increase in this ratio was found to precede the onset of torsades de pointes in an experimental model of LQTS. In addition, the increment in U wave amplitude after a premature ventricular complex (PVC) has been suggested as a marker for arrhythmia risk in “pause-dependent” LQTS. In patients with bifid T waves, some investigators used the late component of the T wave, rather than the U wave. The diurnal maximal ratio between late and early T wave peak amplitude correlates with a history of LQTS-related symptoms better than the baseline QTc interval in both LQT1 and LQT2 patients. In LQT1 and LQT2 patients, diurnal distributions of maximal T2-to-T1 wave amplitude ratios are similar to reported corresponding distributions of cardiac events, and can potentially be used as a predictor of the arrhythmia risk for asymptomatic patients with known type 1 or 2 LQT genotype.³¹

Diagnosis of the Long QT Syndrome

The LQTS is a clinical diagnosis, primarily based on the clinical presentation, personal and family history, and ECG findings. A detailed family history of syncope and SCD is essential, not only in first-degree relatives (mother, father, siblings, children), but also in more distant relatives. Importantly, family history should also be investigated for other potential manifestations of malignant arrhythmias that might not have been classified as cardiac in origin, such as drowning, death while driving, epileptic seizures, as well as SIDS. Data on comorbidities in evaluated individuals or family members (such as congenital deafness) should also be acquired. Clinical features such as triggers of syncope and specific QT morphological attributes in patients in whom the clinical diagnosis has been made can suggest the affected gene in 70% to 90% of patients.^{5,32}

The QTc interval is the most common standardized parameter used for diagnosing LQTS and quantifying ventricular repolarization. As noted, QTc values greater than 470 milliseconds in men and greater than 480 milliseconds in women are practically never seen among healthy individuals (especially at heart rates of 60 to

70 beats/min) and are considered diagnostic of LQTS (as long as acquired forms of LQTS are excluded) even in asymptomatic subjects and those having a negative family history. When a prolonged QTc is observed during faster heart rates (>90 beats/min), it is important to repeat the ECG once the heart rate slows down, to minimize the error that can potentially be introduced by heart rate correction formulas.²⁵

Additionally, LQTS can be suspected in individuals with QTc values exceeding 450 milliseconds for men and exceeding 460 milliseconds for women; these subjects are considered to have “high probability for LQTS” if they have a history of syncope and familial SCD. On the other hand, LQTS is very unlikely among men with QTc less than 390 milliseconds and among women with QTc less than 400 milliseconds.²⁵

Importantly, a significant proportion (20% to 40%) of patients with genetically proven LQTS have normal or borderline QTc measurements at rest (“concealed” LQTS). Therefore, the diagnosis of LQTS should not be excluded based solely on a QTc interval in the normal range (400 to 450 milliseconds), and additional testing is indicated whenever the clinical history requires exclusion of LQTS. In this setting, obtaining a resting ECG periodically sometimes can uncover an abnormal prolongation of the QTc interval, given the considerable day-to-day variability in QTc of patients with LQTS. Additionally, reviewing the ECGs of all family members can be valuable, because some family members can have obvious QT prolongation. Several additional clinical tests and tools have been used in the clinical evaluation of LQTS, including ambulatory ECG recordings, exercise stress testing, epinephrine QT stress testing, and genetic testing. Although these diagnostic tools can all contribute to identifying patients with LQTS, a “gold standard” diagnostic tool is still lacking. Invasive EP testing is generally not useful in the diagnosis of LQTS.^{33,34}

CLINICAL SCORING SYSTEMS

When the diagnosis is not clear, two clinical scoring systems have been developed to enhance the diagnostic reliability of clinical parameters and to estimate the probability of LQTS: the Keating criteria and the Schwartz score. The Keating criteria are a binary combination of QTc values with LQTS-related symptoms. According to these criteria, individuals are affected if they have a QTc interval greater than 470 milliseconds even in the absence of symptoms, or if they have typical symptoms with a QTc interval greater than or equal to 450 milliseconds. The Schwartz score incorporates ECG features in combination with personal clinical history and family history. Scores were arbitrarily divided into three probability categories, providing a quantitative estimate of the risk for LQTS (Table 31-4).^{35,36}

When applied to family members of positively genotyped patients, these systems demonstrated excellent high specificity (99%) but very low sensitivity (19% for the Schwartz “high probability” score and 36% for the Keating criteria), and severely underdiagnosed disease carriers (false negatives). Significant underdiagnosis was also found among probands, despite the fact that probands are generally more seriously affected than their relatives. A high probability of LQTS (Schwartz criteria) was found only in 57% of probands with a confirmed molecular diagnosis. The performance of QTc interval measurement alone (with a cut-off value of 430 milliseconds) is superior to the Schwartz and Keating criteria when DNA testing is available for the confirmation of disease carriership, as it has far better sensitivity (72%) while retaining reasonable specificity (86%). Thus, in families with known causal gene mutations, genetic analysis is the method of choice to identify the relatively high proportion of silent carriers of disease-causing mutations.^{35,36}

AMBULATORY CARDIAC MONITORING

Holter monitoring is not sufficiently well standardized to serve in the primary assessment for ventricular repolarization analysis, and only rarely will show spontaneous arrhythmias in LQTS patients.

TABLE 31-4 Diagnostic Criteria for the Long QT Syndrome

FINDING	SCORE
ECG*	
QTc [†] ≥ 480 msec	3
QTc [†] = 460-470 msec	2
QTc [†] = 450 msec (in men)	1
Torsades de pointes [‡]	2
T wave alternans	1
Notched T wave in three leads	1
Low heart rate for age [§]	0.5
Clinical History	
Syncope with stress [‡]	2
Syncope without stress [‡]	1
Congenital deafness	0.5
Family History[¶]	
Family members with definite LQTS	1
Unexplained SCD in immediate family members <30 yr of age	0.5

*Findings in the absence of medications or disorders known to affect these ECG findings.

[†]The corrected QT interval (QTc) is calculated by the Bazett formula.

[‡]Torsades de pointes and syncope are mutually exclusive.

[§]Resting heart rate below the second percentile for age.

[¶]The same family member cannot be counted in both categories.

Scoring: 1 point, low probability of LQTS; 2 or 3 points, intermediate probability of LQTS; 4 or more points, high probability of LQTS.

LQTS = long QT syndrome; SCD = sudden cardiac death.

Modified from Goldenberg I, Moss AJ: Long QT syndrome, *J Am Coll Cardiol* 51:2291-2300, 2008.

However, this method can sometimes be used for the detection of extreme QT interval events that occur infrequently during the day. Characteristic T wave changes may be revealed during sleep or following post-extrasystolic pauses.^{25,32}

EXERCISE STRESS TESTING

Exercise testing can be useful to assess QT adaptation to heart rate, a measure of the integrity of the I_{Ks} channels. Postural changes in QTc and prolonged QT hysteresis during exercise testing can be helpful in identifying patients with LQTS and even in predicting the genotype and can potentially help direct genetic testing. Gradual supine bicycle testing can help minimize signal artifact from upper body motion observed during treadmill exercise.

Attenuated QTc shortening and an exaggerated QTc prolongation during early and peak exercise are characteristic of LQT1. As will be discussed later, genetic mutations in LQT1 result in reduction of the amplitude of I_{Ks}, one of the dominant K⁺ currents responsible for repolarization especially at rapid heart rates (during sympathetic stimulation). Attenuation of I_{Ks} results in failure of the QT to adapt (i.e., shorten) in response to increasing heart rate. Unlike LQT1 patients, normal subjects, LQT2 patients, and LQT3 patients decrease their respective QTc intervals from rest at peak exercise. A maladaptive paradoxical QTc prolongation during the recovery phase (QTc >460 milliseconds or a ΔQTc [QTc at 3 minutes of recovery minus the baseline supine QTc] >30 milliseconds) was found to distinguish patients with either manifest or concealed LQT1 from normal subjects and those with LQT2 and LQT3 genotypes.³⁷

In contrast, patients with LQT2 mutations have normal QT shortening and minimal QTc prolongation during exercise, but they characteristically demonstrate an exaggerated QT hysteresis compared with LQT1 patients and normal subjects. QT hysteresis is normally measured by comparing the QT intervals during exercise versus the recovery period at comparable heart rates (e.g., when the heart rate accelerates to approximately 100 beats/min during

early exercise and 1 to 2 minutes into the recovery phase, when the heart rate typically decelerates to approximately 100 beats/min). In LQT2 patients, the QT fails to shorten at these intermediate heart rates in early exercise because of attenuated I_{Kr} (rapidly activating delayed rectifier potassium current; a so-called I_{Kr} zone). This is followed by recruitment of the unimpaired, sympathetically responsive I_{Ks}, resulting in appropriate QT shortening at faster heart rates through to peak exercise, which persists into the recovery phase. This consequently leads to an exaggerated QT difference between exercise and recovery at comparable heart rates, which is manifested as increased QT hysteresis.^{34,38}

The LQT3 phenotype is characterized by a constant shortening of the action potential duration (and QT interval) with exercise because of stimulation of the intact I_{Ks} channel and augmentation of a late inward Na⁺ current.³⁸

QTc prolongation when comparing lying with standing positions at the beginning of exercise testing also can be useful in identifying LQTS patients and predicting genotype. In a recent report, postural QTc increase was more than 30 milliseconds in 68% of “concealed” LQTS patients, and QT hysteresis was more than 25 milliseconds in 67% of concealed LQT2 patients.

Postural and exercise-induced QTc prolongation and QT hysteresis can be attenuated with beta blockade; therefore, beta blocker therapy should be discontinued before exercise testing. Additionally, exercise treadmill testing can also reveal the characteristic T wave morphology in patients with LQT1 and LQT2 syndromes.⁷

Importantly, induction of arrhythmias during exercise is very rare in LQTS patients. Exercise-induced ventricular ectopy exceeding isolated PVCs is observed in less than 10% of patients.^{7,32} The presence of exercise-induced ventricular ectopy beyond single, isolated PVCs must prompt intense evaluation because it was found to have a positive predictive value exceeding 90% for the presence of significant cardiac pathology. However, CPVT, rather than LQTS, is the far more likely diagnosis.³⁹

EPINEPHRINE QT STRESS TEST

Catecholamine provocation testing can help diagnose patients with concealed LQT1, with a positive predictive value approaching 75% and a negative predictive value of 96%. Furthermore, epinephrine provocation testing was found to be a powerful test to predict the genotype of LQT1, LQT2, and LQT3 syndromes.^{32,38,40}

Two major protocols have been developed for epinephrine infusion. Using the “escalating-dose infusion protocol,” epinephrine infusion is initiated at 0.025 μg/kg/min and then increased sequentially every 10 minutes to 0.05, 0.1, and 0.2 μg/kg/min. The 12-lead ECG is continuously recorded during sinus rhythm under baseline conditions and during epinephrine infusion. The QT interval is measured 5 minutes after each dose increase. Epinephrine infusion should be stopped for systolic blood pressure greater than 200 mm Hg, nonsustained VT or polymorphic VT, frequent PVCs (>10 per minute), T wave alternans, or patient intolerance. A paradoxical QT interval response (prolongation of the absolute QT interval of ≥30 milliseconds) during low-dose epinephrine infusion provides a presumptive clinical diagnosis of LQT1, with a positive predictive value of 75%. The diagnostic accuracy can be reduced in patients receiving beta blockers.³⁸

Using the “bolus and infusion protocol,” an epinephrine bolus (0.1 μg/kg) is administered and immediately followed by continuous infusion (0.1 μg/kg/min) for 5 minutes. The QT interval is measured 1 to 2 minutes after the start of epinephrine infusion when the R-R interval is the shortest (which represents the peak epinephrine effect) and 3 to 5 minutes after the start of epinephrine infusion (which represents the steady-state epinephrine effect).⁴⁰

During the epinephrine test, patients with LQT1 manifest prolongation of the QTc at the peak of the epinephrine effect, which is maintained under steady-state conditions of epinephrine. In contrast, epinephrine prolongs the QTc more dramatically at the peak of epinephrine infusion in LQT2 patients, but the QTc returns to baseline levels under steady-state conditions. A much

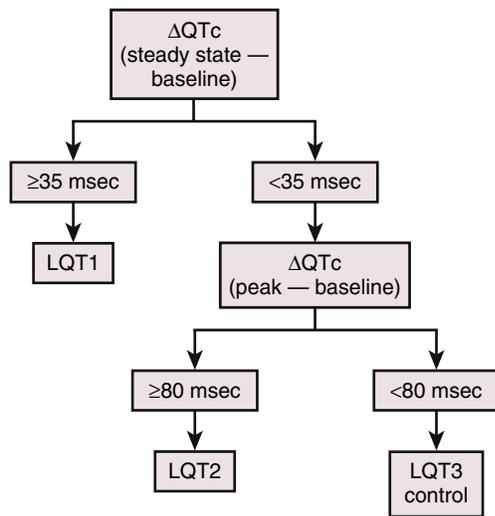

FIGURE 31-2 Epinephrine provocative testing for the diagnosis of LQTS. Control = normal subjects; LQT = long QT syndrome genotype; QTc = corrected QT interval.

milder prolongation of QTc at the peak of epinephrine has been described in LQT3 patients and in healthy subjects, and it returns to the baseline levels under steady-state conditions. A subject is considered to have an LQT1 response if the QTc increase in the peak phase is greater than 35 milliseconds and is maintained throughout the steady-state phase (Fig. 31-2). LQT2 response is likely if the peak QTc increase of greater than 80 milliseconds is not maintained in the steady-state phase. In one report, the sensitivity and specificity of the epinephrine test to differentiate LQT1 from LQT2 were 97% and 96%, those from LQT3 were 97% and 100%, and those from healthy subjects were 97% and 100%, respectively, when Δ QTc greater than 35 milliseconds at steady state was used. The sensitivity and specificity to differentiate LQT2 from LQT3 or healthy subjects were 100% and 100%, respectively, when Δ QTc greater than 80 milliseconds at peak was used.⁴⁰

The escalating-dose infusion protocol is generally better tolerated by the patient and carries a lower incidence of false-positive responses. On the other hand, the bolus and infusion protocol offers the ability to monitor the temporal course of the epinephrine response at peak dose (during the bolus) and during steady state (during the infusion), which is particularly important in individuals with LQT2 in whom transient prolongation of the uncorrected QT interval can occur, followed by subsequent shortening.³⁸

GENETIC TESTING

Although the diagnosis of LQTS frequently can be certain based on clinical diagnostic measures, in which setting molecular screening may not be necessary, genetic testing can still be of value; identification of the specific gene affected (or the site of the mutation within the gene) can potentially guide therapeutic choice and enhance risk stratification. Importantly, identification of the disease-causing mutation in the proband provides the ability to easily identify affected family members and implement lifestyle adjustment and presymptomatic treatment, and is thereby potentially lifesaving. Furthermore, genetic testing may be important in the identification of concealed LQTS, because a significant minority (25% to 50%) of individuals with genetically proven LQTS have a nondiagnostic QTc.^{3,5,7,32}

Genetic testing is a powerful tool to identify patients with LQTS. Yet, it remains expensive and unavailable to many centers. Depending on the stringency of clinical phenotype assessment, the yield for positive genetic results in LQTS ranges from 50% to 78%, and

is highest among tested individuals with the highest clinical probability (i.e., those with longer QTc intervals and more severe symptoms). The remaining probands with a strong clinical probability of LQTS will have a negative genetic test result, probably because of technical difficulties with genotyping, noncoding variants, or as yet unidentified disease-associated genes. Therefore, a negative genetic test in a subject with clinical LQTS (i.e., genotype-negative/phenotype-positive LQTS) does not provide a basis to exclude the diagnosis.^{3,32-34}

There is also the potential for false-positive results; genetic testing may identify novel mutations of unclear significance, which could represent normal variants, and require validation and further analysis (e.g., linkage within a family or in vitro studies).³²⁻³⁴

Currently, comprehensive or LQT1 to LQT3 (*KCNQ1*, *KCNH2*, and *SCN5A*)-targeted LQTS genetic testing is recommended for symptomatic patients with a strong clinical index of suspicion for LQTS as well as for asymptomatic patients with QT prolongation (QTc \geq 480 milliseconds [prepuberty] or \geq 500 milliseconds [adults]) in the absence of other clinical conditions that might prolong the QT interval.⁴¹

Genetics of the Long QT Syndrome

To date, more than 500 mutations of 13 different genes responsible for a hereditary form of LQTS have been identified (Table 31-5), with the majority of the known mutations located in the first three: LQT1 (*KCNQ1*) mutations account for 42% to 45% of genetically positive LQTS, LQT2 (*KCNH2*) for 35% to 45%, and LQT3 (*SCN5A*) for 8% to 10%.

Overall, nine of these genes encode ion channel subunits that are specifically involved in cardiac action potential generation. LQT4 (*ANK2*), LQT9 (*CAV3*), LQT11 (*AKAP9*), and LQT12 (*SNTA1*) are caused by mutations in a family of versatile membrane adaptors other than ion channel subunits. Nonetheless, the concept that LQTS genes ultimately affect ionic currents, either directly (ion channel mutations) or indirectly (modulators), still holds true.

Two modes of inheritance are involved in the LQTS: an autosomal dominant pattern and an autosomal recessive pattern. The majority of LQTS cases are inherited in an autosomal dominant fashion. Conversely, Jervell and Lange-Nielsen syndrome, which is inherited in an autosomal recessive fashion, is very rare, affecting less than 1% of LQTS cases.

Genetic analysis reveals two or more mutations in 5% to 10% of LQTS patients with clinical phenotypes of Romano-Ward syndrome. These compound mutations (so-called double hits) appear to be associated with a more severe phenotype than that associated with a single hit.⁴²

Most reported mutations are in coding regions, although noncoding mutations (resulting in the loss of allele expression) have also been described. Most LQTS families have their own mutations, which are often termed “private” mutations.³²

Several genetic mechanisms have been implicated in the development of LQTS including abnormalities in protein synthesis (transcription, translation), posttranslational protein processing resulting in abnormal transport to the cell surface membrane (protein trafficking, folding, assembly of subunits, glycosylation), ion channel gating (biophysical and kinetic properties), or permeation (ion selectivity, unitary conductance).

The majority of LQTS cases are caused by heterozygous disease; thus, mutations causing abnormalities in channel coassembly or trafficking result in up to 50% maximal reduction in the number of functional channels (haplotype insufficiency), because the gene product from the healthy allele remains intact. On the other hand, mutations that abolish channel function while preserving subunit assembly can result in dominant-negative suppression of the healthy allele as well, causing a more severe reduction (up to 94%) of the total amount of functional protein (dominant-negative effect) and favoring a more severe clinical course and a higher frequency of arrhythmia-related cardiac events.^{7,12}

TABLE 31-5 Molecular Basis of the Congenital Long QT Syndrome

DISEASE	GENE	PROTEIN	IONIC CURRENT	FUNCTION	FREQUENCY	INHERITANCE
LQT1	<i>KCNQ1</i> (<i>K_vLQT1</i>)	K _v 7.1	Subunit alpha I _{Ks}	Loss	42%-45%	Autosomal dominant
LQT2	<i>KCNH2</i> (<i>HERG</i>)	K _v 11.1	Subunit alpha I _{Kr}	Loss	35%-45%	Autosomal dominant
LQT3	<i>SCN5A</i>	Na _v 1.5	Subunit alpha I _{Na}	Gain	8%-10%	Autosomal dominant
LQT4 (ankyrin-B syndrome)	<i>ANKB</i>	ANK2	Adaptor I _{Na}	Loss	<1%	Autosomal dominant
LQT5	<i>KCNE1</i>	MinK	Subunit beta I _{Ks}	Loss	<1%	Autosomal dominant
LQT6	<i>KCNE2</i>	MiRP1	Subunit alpha I _{Kr}	Loss	<1%	Autosomal dominant
LQT7 (Andersen-Tawil syndrome)	<i>KCNJ2</i>	Kir2.1	Subunit alpha I _{K1}	Loss	<1%	Autosomal dominant
LQT8 (Timothy syndrome)	<i>CACNA1C</i>	Ca _v 1.2	Subunit alpha I _{CaL}	Gain	<1%	Autosomal dominant
LQT9	<i>CAV3</i>	Caveolin-3	Adaptor I _{Na}	Gain	<1%	Autosomal dominant
LQT10	<i>SCN4B</i>	Na _v β ₄	Subunit beta I _{Na}	Gain	<1%	Autosomal dominant
LQT11	<i>AKAP9</i>	Yotiao	Regulatory adaptor I _{Ks}	Loss	<1%	Autosomal dominant
LQT12	<i>SNTA1</i>	Alpha ₁ -syn trophin	Scaffolding protein I _{Na}	Gain	<1%	Autosomal dominant
LQT13	<i>KCNJ5</i>	Kir3.4 (GIRK4)	Subunit alpha I _{KACH}	Loss	<1%	Autosomal dominant
JLN1	<i>KCNQ1</i> (<i>K_vLQT1</i>)	K _v 7.1	Subunit alpha I _{Ks}	Loss	99.5%	Autosomal recessive
JLN2	<i>KCNE1</i>	MinK	Subunit beta I _{Ks}	Loss	0.5%	Autosomal recessive

I_{CaL} = L-type Ca²⁺ current; I_{K1} = inward rectifier K⁺ current; I_{KACH} = acetylcholine-activated inward rectifier K⁺ current; I_{Kr} = rapidly activating delayed rectifier K⁺ current; I_{Ks} = slowly activating delayed rectifier K⁺ current; I_{Na} = Na⁺ current; JLN1 and JLN 2 = Jervell and Lange-Nielsen syndrome types 1 and 2, respectively; LQT1 to LQT13 = long QT syndrome types 1 to 13, respectively.

MUTATIONS RELATED TO THE SLOWLY ACTIVATING DELAYED RECTIFIER POTASSIUM CURRENT (I_{Ks})

I_{Ks} contributes to human atrial and ventricular repolarization, particularly during action potentials of long duration, and plays an important role in determining the rate-dependent shortening of the cardiac action potential. As heart rate increases, I_{Ks} increases because channel deactivation is slow and incomplete during the shortened diastole. This allows I_{Ks} channels to accumulate in the open state during rapid heart rates and contribute to the faster rate of repolarization.^{43,44} Importantly, I_{Ks} is functionally upregulated when other repolarizing currents (such as I_{Kr}) are reduced, potentially serving as a “repolarization reserve” and a safeguard against loss of repolarizing power (see Chap. 2). Mutations in LQT1, LQT5, and LQT11 result in attenuation of I_{Ks} and, as a consequence, prolongation of repolarization, action potential duration, and QT interval.^{7,43} LQT1 is caused by loss-of-function mutations of the *KCNQ1* (*K_vLQT1*) gene, which encodes the alpha subunit (K_v7.1) of the inward I_{Ks}. More than 170 mutations of this gene have been reported, comprising many Romano-Ward (autosomal dominant) syndromes and accounting for approximately 45% of all genotyped LQT families.¹² Of note, mutations involving the transmembrane domain of *KCNQ1* result in more severe disease compared with C-terminal mutations.

LQT5 is caused by loss-of-function mutations of the *KCNE1* gene, which encodes the beta subunit (MinK) that modulates I_{Ks}.⁷

Homozygous or compound heterozygous loss-of-function mutations of either the *KCNQ1* or *KCNE1* gene cause the autosomal recessive form of LQTS (the Jervell and Lange-Nielsen syndrome). Patients with *KCNQ1* mutations (type 1 Jervell and Lange-Nielsen syndrome) have an almost sixfold greater risk of arrhythmic events, whereas patients with *KCNE1* mutations (type 2 Jervell and Lange-Nielsen syndrome) appear to be at lower risk. Although the Jervell and Lange-Nielsen syndrome is the most severe among the major variants of LQTS, the parents of Jervell and Lange-Nielsen syndrome patients are generally less symptomatic than other

LQT1 patients, despite the fact that they all are heterozygous for the same gene. This is likely related to the observation that most of the LQT1 genetic variants are missense mutations exerting a dominant-negative effect, whereas most (74%) Jervell and Lange-Nielsen mutations of *KCNQ1* are frame-shift/truncating mutations that are unable to cause dominant-negative suppression but are likely to interfere with subunit assembly. Jervell and Lange-Nielsen syndrome accompanies complete loss of I_{Ks} in hair cells and endolymph of the inner ear, which results in congenital deafness.⁶

LQT11 is caused by loss-of-function mutations of the *AKAP9* gene, which encodes an A-kinase anchoring protein (Yotiao), shown to be an integral part of the I_{Ks} macromolecular complex. The presence of Yotiao is necessary for the physiological response of the I_{Ks} to beta-adrenergic stimulation. LQT11 mutations reduce the interaction between Yotiao and the I_{Ks} channel (K_v7.1), preventing the functional response of I_{Ks} to cyclic adenosine monophosphate (cAMP) and adrenergic stimulation and causing an attenuation of I_{Ks}.³

MUTATIONS RELATED TO THE RAPIDLY ACTIVATING DELAYED RECTIFIER POTASSIUM CURRENT (I_{Kr})

I_{Kr} is largely responsible for repolarization of most cardiac cells and plays an important role in governing the cardiac action potential duration and refractoriness. Mutations in LQT2 and LQT6 result in attenuation of I_{Kr} and cause a decrease in the K⁺ outward current and prolongation of repolarization, action potential duration, and QT interval.⁴⁴

LQT2 is caused by loss-of-function mutations of the *KCNH2* (*HERG*) gene, which encodes the alpha subunit (K_v11.1) of the inward I_{Kr}. LQT2 syndrome accounts for almost 45% of all genotyped congenital LQTS cases. Approximately 200 mutations in this gene have been identified, which result in rapid closure of the HERG channels and decrease the normal rise in I_{Kr}, leading to delayed ventricular repolarization and QT prolongation. Mutations

involving the pore region of the HERG channel are associated with a significantly more severe clinical course than nonpore mutations; most pore mutations are missense mutations with a dominant-negative effect.¹²

LQT6 is caused by loss-of-function mutations of the *KCNE2* gene, which encodes the accessory beta subunit (MiRP1) of the HERG channel. LQT6 displays clinical resemblance to LQT2.⁷

MUTATIONS RELATED TO THE INWARD RECTIFIER POTASSIUM CURRENT (I_{K1})

Andersen-Tawil syndrome (LQT7) is caused by loss-of-function mutations of the *KCNJ2* gene, which encodes the voltage-dependent K^+ channel (Kir2.1) that contributes to the inward I_{K1} . Kir2.1 channels are expressed primarily in skeletal muscle, heart, and brain. The majority of mutations exerts a dominant-negative effect on channel current.^{7,16,17}

Disruption of the I_{K1} function can potentially lead to prolongation of the terminal repolarization phase and QT interval, which can predispose to the generation of EADs and diastolic membrane depolarizations (DADs) causing ventricular arrhythmias. However, unlike other types of LQTS, where the afterdepolarizations arise from reactivation of L-type Ca^{2+} channels, the EADs/DADs generated in LQT7 are likely secondary to Na^+ - Ca^{2+} exchanger-driven depolarization. It is believed that the differential origin of the triggering beat is responsible for the observed discrepancy in arrhythmogenesis and the clinical features compared with other types of LQTS. Additionally, it is likely that prolongation of the action potential duration in LQT7 is somewhat homogeneous across the ventricular wall (i.e., transmural dispersion of repolarization is less prominent than in other types of LQTSs), which can potentially explain the low frequency of torsades de pointes. Flaccid paralysis results from failure to propagate action potentials in the muscle membrane as a result of sustained membrane depolarization.^{7,16,17}

MUTATIONS RELATED TO THE ACETYLCHOLINE-ACTIVATED POTASSIUM CURRENT (I_{KACH})

LQT13 is caused by loss-of-function mutations of the *KCNJ5* gene, which encodes the alpha subunit (Kir3.4, GIRK4) of the inward I_{KACH} . The Kir3.4 mutation is the most recently identified LQT-associated gene, and it exerts dominant-negative effects on Kir3.1/Kir3.4 channel complexes by disrupting membrane targeting and stability of Kir3.4.⁴⁵

MUTATIONS RELATED TO THE SODIUM CURRENT (I_{Na})

LQT3 is caused by gain-of-function mutations of the *SCN5A* gene, which encodes the alpha subunit ($Na_v1.5$) of the cardiac voltage-gated Na^+ channel that is responsible for the I_{Na} . LQT3 accounts for approximately 8% of the congenital LQTS cases. More than 80 mutations have been identified in the *SCN5A* gene, with the majority being missense mutations mainly clustered in $Na_v1.5$ regions that are involved in fast inactivation (i.e., S4 segment of DIV, the DIII-DIV linker, and the cytoplasmic loops between the S4 and S5 segments of DIII and DIV), or in regions that stabilize fast inactivation (e.g., the C-terminus).^{12,46,47}

Several mechanisms have been identified to underlie ionic effects of *SCN5A* mutations in LQT3. Most of the *SCN5A* mutations cause a gain of function through disruption of fast inactivation, allowing repeated reopening during sustained depolarization and resulting in an abnormal, small but functionally important sustained (or persistent) noninactivating Na^+ current (I_{sus}) during the action potential plateau. Other, less common mechanisms include increased window current, which results from delayed inactivation of mutant Na^+ channels, occurring at more positive potentials and widening the voltage range during which the Na^+ channel may reactivate without inactivation. Additionally, some mutations cause slower inactivation, which allows longer channel openings, and causes a slowly inactivating Na^+ current (the late Na^+ current,

I_{NaL}). Because the general membrane conductance is small during the action potential plateau, the presence of a persistent inward Na^+ current, even of small amplitude, can potentially have a major impact on the plateau duration and can be sufficient to prolong repolarization and QT interval. QT prolongation and the risk of developing arrhythmia is more pronounced at slow heart rates, when the action potential duration is longer, allowing more Na^+ current to enter the cell.^{12,46}

Regardless of the mechanism, increased Na^+ current (I_{sus} , window current, I_{NaL} , or peak I_{Na}) upsets the balance between depolarizing and repolarizing currents in favor of depolarization. The resulting delay in the repolarization process triggers EADs (i.e., reactivation of the L-type Ca^{2+} channel during phase 2 or 3 of the action potential), especially in Purkinje fiber myocytes where action potential durations are intrinsically longer.⁴⁷

LQT9 is caused by gain-of-function mutations of the *CAV3* gene, which encodes caveolin-3, a plasma membrane scaffolding protein that interacts with $Na_v1.5$ and plays a role in compartmentalization and regulation of channel function. Mutations in caveolin-3 induce kinetic alterations of the Na^+ channel that result in persistent late Na^+ current (I_{sus}) and have been reported in cases of SIDS.^{7,47}

LQT10 is caused by gain-of-function mutations of the *SCN4B* gene, which encodes the beta subunit ($Na_v\beta_4$) of the $Na_v1.5$ ion channel. To date, only a single mutation in one patient has been described, which resulted in a shift in the inactivation of the Na^+ current toward more positive potentials, but did not change the activation. This resulted in increased window currents at membrane potentials corresponding to phase 3 of the action potential.^{7,47}

LQT12 is caused by mutations of the *SNTA1* gene, which encodes alpha₁-synthrophin, a cytoplasmic adaptor protein that enables the interaction between $Na_v1.5$, nitric oxide synthase, and sarcolemmal Ca^{2+} ATPase complex that appears to regulate ion channel function. By disrupting the interaction between $Na_v1.5$ and sarcolemmal calcium ATPase complex, *SNTA1* mutations cause increased $Na_v1.5$ nitrosylation with consequent reduction of channel inactivation and increased I_{sus} densities.^{3,47}

MUTATIONS RELATED TO THE L-TYPE CALCIUM CURRENT (I_{CaL})

Timothy syndrome (LQT8) is caused by gain-of-function mutations of the *CACNA1C* gene, which encodes the alpha subunit ($Ca_v1.2$) of the voltage-dependent L-type Ca^{2+} channel that contributes to I_{CaL} .

The inward I_{CaL} sustains depolarization and gives rise to the plateau phase essential for excitation-contraction coupling. Gain-of-function mutations of *CACNA1C* result in near complete elimination of voltage-dependent inactivation of $Ca_v1.2$ channels, leading to inappropriate continuation of the depolarizing I_{CaL} and lengthening of the plateau phase.

MUTATIONS IN THE ANKYRIN-B GENE

LQT4 is caused by loss-of-function mutations of the *ANK2* gene, which encodes ankyrin-B, a structural membrane adapter protein that anchors ion channels to specific domains in the plasma membrane. Functionally, ankyrins bind to several ion channel proteins, targeting these proteins to specialized membrane domains, such as the anion exchanger (chloride-bicarbonate exchanger), Na^+ - K^+ adenosine triphosphatase (ATPase), I_{Na} , the Na^+ - Ca^{2+} exchanger (I_{Na-Ca}), and Ca^{2+} release channels (including those mediated by the receptors for inositol triphosphate [IP_3] or ryanodine [$RyR2$]). Hence, *ANK2* mutations can potentially result in improper localization and activity of ion-conducting proteins. Five mutations of this gene have been reported, resulting in increased intracellular concentration of Ca^{2+} and, sometimes, fatal arrhythmia. However, QT interval prolongation is not a consistent feature in patients with ankyrin-B dysfunction; instead, varying degrees of cardiac dysfunction are observed including bradycardia, sinus arrhythmia, idiopathic VF, CPVT, and SCD. Therefore, ankyrin-B dysfunction is now

regarded as a clinical entity distinct from classic LQTS (referred to as the “ankyryn-B syndrome”).

Pathophysiology of the Long QT Syndrome

MECHANISM OF QT INTERVAL PROLONGATION

Any factor that evokes lengthening of the action potential duration holds the potential of causing an LQTS phenotype, especially if it does it heterogeneously. Electrophysiologically, prolongation of the action potential duration and QT interval can arise from either a decrease in the outward repolarizing current (K^+ currents: I_{Kr} , I_{Ks} , I_{K1} , I_{KACh}) or an increase in inward depolarizing membrane current (Na^+ current, Ca^{2+} current, or both) during phases 2 and 3 of the action potentials (Fig. 31-3).

Most commonly, QTc prolongation is produced by delayed repolarization due to attenuation of I_{Ks} (LQT1, LQT5, LQT11), I_{Kr} (LQT2, LQT6), I_{K1} (LQT7), or I_{KACh} (LQT13). Less commonly, QT prolongation results from prolonged depolarization due to an increase in I_{Na} (LQT3, LQT4, LQT9, LQT10, LQT12) or I_{CaL} (LQT8).⁷

MECHANISM OF DISPERSION OF REPOLARIZATION

The LQTS is caused by an excessive and heterogeneous prolongation of the repolarization phase of the ventricular action potential. In the normal ventricle, there are heterogeneous cell types with different action potential morphologies and durations, mainly attributed to cell-specific and regional variability in the functional expression of different populations of ion channels (transient outward K^+ channels [I_{to}], I_{Ks}), and the Na^+ window current (I_{Na}) and/or their accessory proteins. Some experimental studies proposed the presence of three irregular cell layers in the ventricle with distinct electrical properties: endocardial, midmyocardial (M cells), and epicardial cells. Overall, the putative midmyocardial cells (which have a smaller I_{Ks} , a larger late I_{Na} , and a larger Na^+Ca^{2+} exchange current [I_{Na-Ca}]) appear to generate longer action potential durations that are more susceptible to modification compared with the endocardium and epicardium. The epicardial cells have the shortest action potential durations

because of a prominent I_{to} . Repolarization of endocardial cells usually occurs between repolarization of the epicardial and midmyocardial cells. Notably, factors that prolong the action potential appear to elicit a disproportionate prolongation of the action potential duration in midmyocardial cells. As a result, dispersion of the action potential duration becomes irregularly exaggerated across the ventricular wall, yielding an increase in the action potential duration heterogeneity.⁷

Conditions leading to a reduction in I_{Kr} (e.g., LQT2) or augmentation of late I_{Na} (e.g., LQT3) produce a preferential prolongation of the M cell action potential. Consequently, QT interval prolongation is accompanied by a dramatic increase in transmural dispersion of repolarization. In contrast, conditions leading to a reduction in I_{Ks} alone (e.g., LQT1) result in a homogeneous prolongation of action potential duration across the ventricular wall with little increase in transmural dispersion of repolarization. However, concurrent beta-adrenergic stimulation (e.g., exercise, isoproterenol) results in abbreviation of epicardial and endocardial action potential duration with little or no change in the M cell action potential, resulting in marked augmentation of transmural dispersion of repolarization and arrhythmogenesis (see Fig. 31-3).²⁷

On the surface ECG, the peak of the normal T wave coincides with repolarization of the epicardial action potential (the shortest action potential) whereas repolarization of the longest action potential in the midmyocardial cells coincides with the end of the T wave. Hence, the increased dispersion of transmural repolarization results in prolongation of the interval from the peak of the T wave to the end of the T wave ($T_{peak-to-end}$) on the surface ECG.^{7,29,30}

MECHANISM OF TORSADES DE POINTES

The excessive increase in the spatial and/or temporal action potential duration heterogeneity favors the generation of EADs because of reactivation of L-type Ca^{2+} channels, and on some occasions the late I_{Na} or Na^+Ca^{2+} exchanger. The EADs can cause PVCs that can potentially trigger the initiation of ventricular arrhythmias. Furthermore, excessive transmural heterogeneity of the action potential duration provides the substrate for unidirectional block and functional reentry circuits to propagate torsades de pointes.⁷

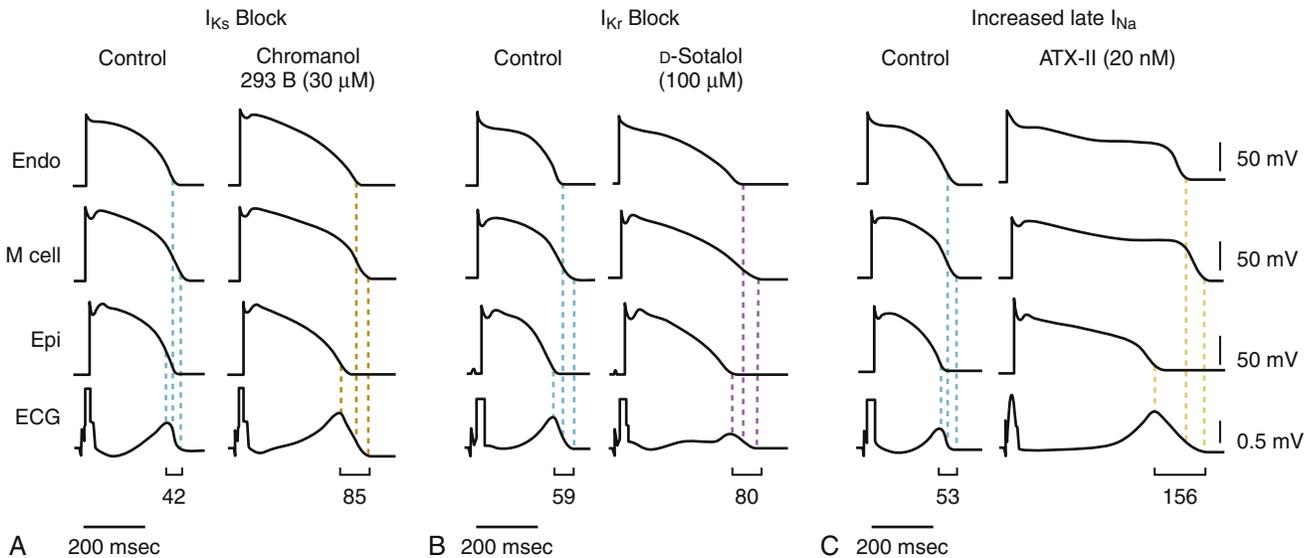

FIGURE 31-3 Pathophysiology of long QT syndrome. Transmembrane action potentials and transmurals ECG traces in control and after I_{Ks} block (A), I_{Kr} block (B), and increase in late I_{Na} (C), in arterially perfused canine left ventricular wedge preparations. A to C depict action potentials simultaneously recorded from endocardial (Endo), M cell, and epicardial (Epi) sites, together with a transmurals ECG trace. Basic cycle length, 2000 milliseconds. In all cases, the peak of the T wave in the ECG is coincident with the repolarization of the epicardial action potential, whereas the end of the T wave is coincident with the repolarization of the M cell action potential. Repolarization of the endocardial cell is intermediate between that of the M cell and epicardial cell. Transmural dispersion of repolarization across the ventricular wall, defined as the difference in the repolarization time between M and epicardial cells, is denoted below the ECG traces. From ATX-II = sea anemone toxin; I_{Na} = sodium current; I_{Kr} = rapidly activating delayed rectifier K^+ current; I_{Ks} = slowly activating delayed rectifier potassium current. (From Antzelevitch C: Drug-induced channelopathies. In Zipes DP, Jalife J, editors: *Cardiac electrophysiology: from cell to bedside*, ed 5, Philadelphia, 2009, WB Saunders, pp 195-203.)

Although torsades de pointes is presumably often initiated by EAD-triggered PVCs, its propagation likely is due to intramural reentrant mechanisms, giving rise to one or more intramural rotors that impose a rapid ectopic ventricular rhythm (typically 150 to 300 beats/min) while migrating inside the ventricular wall. Hence, with each new cycle the principal depolarization focus migrates accordingly, resulting in a progressive change of the electrical axis, typically rotating 180 degrees in approximately 10 to 12 cycles. This results in a polymorphic VT with the characteristic sinusoidal “twisting of the points” pattern on the 12-lead ECG.⁷

Notably, although the atrium seems to be resistant to generating EADs in response to agents that prolong repolarization, atrial EADs and “atrial torsades de pointes” have been reported in some LQTS patients as well as cesium-treated dogs.⁴⁸

MECHANISM OF EXERCISE-INDUCED CHANGES

Patients with LQT1 and LQT2 genotypes have differing patterns of QT adaptation during beta-adrenergic stimulation (e.g., during stress, exercise, epinephrine infusion). Patients with LQT1 appear to have less repolarization reserve during exercise as evidenced by a progressive or persistent pattern of QTc prolongation at faster heart rates, compared with patients with LQT2, in whom maximal QTc prolongation occurs at submaximal heart rates in the early phase of sympathetic stimulation with subsequent fall toward baseline values at faster heart rates.¹⁰

I_{Ks} is markedly enhanced by beta-adrenergic stimulation through G-protein/cAMP-mediated channel phosphorylation by protein kinase A (PKA) (requiring AKAP9 [Yotiao]) and PKC (requiring MinK). This produces a rate-dependent shortening of the action potential duration in normal hearts. Importantly, I_{Ks} is functionally upregulated when other repolarizing currents (such as I_{Kr}) are reduced, potentially serving as a “repolarization reserve” and a safeguard against loss of repolarizing power, especially when beta-adrenergic stimulation is present.^{44,49}

LQT1 subjects have compromised I_{Ks} channels that are not as responsive to sympathetic stimulation, and phase 3 repolarization in these individuals is retarded. Consequently, during beta-adrenergic stimulation, there are relatively more unopposed depolarizing forces via the L-type Ca^{2+} channel and the Na^+Ca^{2+} exchanger that prolong the action potential duration and hence the QT interval.

In contrast, subjects with LQT2 have dysfunctional I_{Kr} channels, which represent a smaller fraction of the K^+ channels responsible for phase 3 repolarization and are not as sympathetically responsive as I_{Ks} channels. Therefore, in LQT2 patients, the QT fails to shorten at the intermediate heart rates in the early phase of exercise or epinephrine infusion because of attenuation of I_{Kr} . This is followed by recruitment of I_{Ks} (“repolarization reserve”) at faster heart rates during continuing exercise or epinephrine infusion, with concomitant appropriate abbreviation of the action potential duration and QT shortening, which persists into the recovery phase. This consequently leads to an exaggerated QT difference between the exercise and recovery QT/R-R curves that is manifested as increased QT hysteresis, which appears to be a characteristic feature of the LQT2 phenotype.³⁴

The LQT3 phenotype is characterized by a constant reduction of the action potential duration with epinephrine because of stimulation of the intact I_{Ks} channel and augmentation of the late inward Na^+ current. In fact, LQT3 patients may have supranormal QT adaptation in response to exercise compared with control subjects. *SCN5A* mutations in LQT3 cause a gain of function through disruption of fast channel inactivation, allowing repeated reopening during sustained depolarization and resulting in a small but functionally important enhancement of the I_{Na} during action potential plateau. As a consequence, the risk of developing arrhythmia will be expected to be particularly high at slow heart rates, when the action potential duration is longer, allowing more Na^+ current to enter the cell.³⁸

The differences in the dynamic response of ventricular repolarization to sympathetic stimulation may explain the epidemiological

observation that patients with LQT1 are more likely to have life-threatening events during sympathetic activation compared with patients with other genotypes and also may underlie the responsiveness of LQT1 patients to beta blocker therapy.¹⁰

MECHANISM OF GENOTYPE-PHENOTYPE VARIABILITY

The LQTS is a complex and multifactorial disorder characterized by a broad phenotypic heterogeneity. The clinical phenotype (QTc values, arrhythmia-related symptoms, and outcomes) is highly variable, not only between families carrying different causal mutations, but also among family members carrying an identical mutation, with a broad continuous spectrum of clinical or subclinical phenotypes. One end of this spectrum is concealed LQTS (silent carriers of disease-causing mutations), whereby no QT prolongation or related symptoms are observed. At the other end of the spectrum are the severe symptomatic LQTS cases, these often representing the index cases easily identified in families. In between are patients with different degrees of QT prolongation and different levels of severity of arrhythmias.⁷

A multitude of genetic and acquired interacting factors (some defined but many still unknown) influence the pathophysiology and clinical course of each person and ultimately determine a spectrum of phenotypes. Among these factors is the fact that action potential generation is a polygenic process; different LQTS genes affect different ion current mechanisms. Even mutations in the same gene can affect gene expression levels and ionic current activity to different extents and via different mechanisms. As noted above, mutations located in the transmembrane segment (for LQT1) or pore region (for LQT2) generally result in more malignant disease compared with mutations in other locations. Similarly, mutations causing a dominant-negative effect (e.g., missense mutations involving the pore region of the channel) result in more profound channel dysfunction and more severe clinical disease that those associated with haplotype insufficiency (e.g., mutations causing coassembly or trafficking abnormalities).^{7,12}

The “repolarization reserve” hypothesis, whereby multiple hits to repolarization are required to compromise repolarization and surpass the threshold for developing clinical QT prolongation and torsades de pointes, can underlie, at least in part, the phenotypic heterogeneity in LQTS. In this setting, a mutation in one of the LQT-linked genes causing an attenuation of a cardiac ionic current may result in only a limited disruption of the repolarization process, which can be clinically concealed and become unmasked (manifesting as QT prolongation and arrhythmias) only when accompanied by another insult to the same or a different ionic current (e.g., drugs or electrolyte abnormalities). In fact, it has been suggested that some cases of acquired LQTS represent inadvertent “unmasking” of subclinical congenital LQTS.^{7,30}

Adding to the complexity is the “double-hit” phenomenon, secondary to either two mutations in the same gene (compound heterozygosity) or mutations in two different LQT genes (digenic heterozygosity). Double hits occur in 5% to 10% of LQTS patients and the resulting phenotype is more severe than with a single hit.⁷

Genetic factors are also involved in the control of cardiac repolarization at the population level. The heritability of the QTc interval has been estimated as between 25% and 52%. Ventricular action potential is under the joint control of multiple ionic currents, and the activity and expression levels of the channels underlying each of these currents establish a subtle equilibrium between depolarizing and repolarizing currents determining the action potential duration in each individual. Common genetic variants differing from the ancestor sequence by one nucleotide (i.e., single nucleotide polymorphism) in genes coding for proteins that are known or suggested to affect ion channel function appear to influence this equilibrium even via weak effects on activity and/or expression level of channel subunits and can potentially play a role in determining cardiac repolarization duration and QTc length in healthy individuals.⁵⁰ Therefore, apart from the known LQT-linked genetic mutations, allelic variation elsewhere in the genome,

most often single nucleotide polymorphisms, in the same disease-causing gene or in other genes can amplify otherwise subclinical disturbances of the repolarization into overt LQTS and potentially contribute to the variable penetrance and clinical phenotype heterogeneity.^{50,51}

Furthermore, the genetic constitution is dynamic over time; the resultant intrinsic risk for arrhythmias can change according to age, LV hypertrophy, and heart failure resulting in structural and electrical remodeling of the heart.⁷

In summary, the cardiac repolarization process is strongly dependent on various parameters, among them heart rate, age, gender, sympathetic tone, electrolyte balance, and medications, as well as inherited and acquired pathological conditions. The interaction of the underlying LQTS genetic mutation with other genetic factors in the same gene or elsewhere in the host genome, as well as with multiple superimposed acquired risk determinants (“disease modifiers”), has a substantial impact on the expressivity of the phenotype of the LQT genotype.

Differential Diagnosis

Typical cases of LQTS are so characteristic that differential diagnosis is not even considered. When dealing with borderline cases, several conditions should be considered including vasovagal syncope, orthostatic hypotension, arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVD), CPVT, hypertrophic cardiomyopathy, and epilepsy.

It is especially important to distinguish acquired factors that result in QT prolongation from the inherited form of LQTS. The acquired form of LQTS is far more prevalent than the congenital form. Causes of abnormal prolongation of the QT interval include myocardial ischemia, cardiomyopathies, hypokalemia, hypocalcemia, hypomagnesemia, autonomic influences, drugs, and hypothermia.⁵ Hypokalemia causes prolongation of the action potential duration because of reduced K^+ conductance. Low extracellular K^+ levels accelerate fast inactivation of the HERG channel and further decrease I_{Kr} .

By far, the most common environmental stressor resulting in acquired LQTS is drug therapy, including antiarrhythmic drugs, some antihistaminics, antipsychotics, and antibiotics. Noncardiovascular drugs that can potentially precipitate QT interval prolongation and arrhythmias comprise approximately 2% to 3% of total prescribed medications. Indeed, the risk of acquired LQTS is the most common cause of withdrawal or restriction of drugs that have already been marketed. The vast majority of drugs associated with the acquired form of LQTS are known to interact with the HERG channel (which mediates I_{Kr}), likely because of unique structural properties rendering this channel unusually susceptible to blockade by a wide range of different drugs. Compared with other cardiac K^+ channels, the HERG channel has a large, funnel-like vestibule that allows many small-sized molecules to enter and block the channel (see Chap. 2). The more spacious inner cavity is due to the lack of the Pro-X-Pro sequence motif in the S6 segment (which is present in most other voltage-gated K^+ channels and is believed to induce a sharp bend in the inner S6 helices of voltage-gated K^+ channels, reducing the inner vestibule), which presumably facilitates access of drugs to the pore region from the intracellular side of the channel to block the channel current. Additionally, the HERG channel contains two aromatic sites inside its pore (not present in most other K^+ channels), which provide high-affinity binding sites for aromatic moieties of a wide range of structurally diverse compounds. Interaction of these compounds with the channel's pore causes functional alteration of its biophysical properties, occlusion of the permeation pathway, or both.^{7,44,52}

Other mechanisms underlying drug-induced LQTS have been recently described, including disruption of HERG channel protein trafficking, with consequent reduction of surface membrane expression of otherwise functional channels (e.g., pentamidine), or folding and assembly of channel subunits. The accessory beta subunit (MiRP1, *KCNE2*) also determines the drug sensitivity.⁷

Several factors can potentially increase the risk of susceptibility of acquired LQTS as a complication of drug therapy, including female gender (70% of patients with drug-induced torsades de pointes are women), hypokalemia, hypomagnesemia, hypocalcemia, bradycardia, congestive heart failure, LV hypertrophy, recent conversion from atrial fibrillation (AF), and the degree of QT interval prolongation on baseline ECG. Other risk factors include high drug doses, rapid intravenous infusion, and concurrent use of drugs that prolong the QT interval or that slow drug metabolism. Additionally, genetically determined variability in pharmacodynamics (e.g., polymorphisms and mutations of the cytochrome system) can be responsible for significant variations in drug response. Most patients with drug-induced torsades de pointes have one or more risk factors.^{44,49,53}

Furthermore, mutations of ion channel genes responsible for LQTS have been implicated as a risk factor. In fact, previously unrecognized congenital LQTS, of any subtype, can be identified in 5% to 20% of patients with drug-induced torsades de pointes. Therefore, it might be useful to screen for genetic variations in patients with overt drug-induced LQTS.⁴¹ In addition, polymorphisms (i.e., common genetic variations present in >1% of the population) in cardiac ion channels can potentially increase the risk for the development of drug-induced torsades de pointes. In these patients, drug-induced LQTS appears to represent a “forme fruste” of congenital LQTS. This is likely related to a redundancy in repolarizing currents; normal repolarization is accomplished by multiple ion channels, providing a safety reserve for repolarization. As a result, a mutation or polymorphism in one of the LQTS genes can be clinically inapparent until another insult to repolarization, such as a drug, hypokalemia, or hypomagnesemia, is superimposed.^{7,32}

In contrast to the most common types of congenital LQTS (LQT1 and LQT2), a short-long-short cycle length sequence constitutes the typical pattern of initiation of torsades de pointes in acquired LQTS. The short-long R-R intervals are usually caused by a PVC followed by a compensatory pause. Torsades de pointes also can occur in association with bradycardia or frequent pauses (sometimes referred to as “pause-dependent LQTS”).

Risk Stratification

The clinical course in LQTS patients is not uniform and is influenced by many factors, including age, gender, genotype, environmental factors, therapy, and possibly other modifier genes.

GENETIC MARKERS OF RISK

The genotype has been shown to be an important predictor of LQTS-related cardiac events. The risk of cardiac events has been shown to be significantly higher in LQT1 and LQT2 when compared with LQT3, with events occurring at a younger age. The cumulative mortality, however, appears to be similar regardless of the genotype, as patients with LQT3 exhibit a higher percentage of potentially lethal events.

LQT1 patients exhibit a 49% increase in the risk of cardiac events as compared with LQT2 patients. However, in the 15- through 40-year age group, the risk of a first cardiac event is significantly higher among LQT2 patients (67% increase in the risk as compared with LQT1 patients).¹⁵ Among LQTS patients receiving beta blocker therapy, the LQT2 and LQT3 genotypes are associated with increased risk of arrhythmic events as compared with LQT1.¹⁰

In addition to identifying the LQT genotype, knowing the specific mutation and its biophysical function can help improve risk stratification. For LQT1, patients with mutations in the transmembrane domain of the *KCNQ1* ion channel had more frequent cardiac events (syncope, aborted cardiac arrest, or SCD) and a greater risk of the first cardiac event occurring at a younger age than did patients with C-terminal mutations. For LQT2, pore mutations have a more severe clinical course and a higher frequency of arrhythmic events occurring at a younger age when compared with nonpore mutations. In particular, missense mutations in the transmembrane

pore (S5-loop-S6) region appear to be associated with the highest risk of clinical arrhythmia. Preliminary data for LQT3 patients also suggest that the location of the mutation can play a role in determining the severity of the clinical phenotype. Furthermore, the biophysical function of the mutation is also important in determining the phenotype. Mutations with a dominant-negative effect on ion channel function (>50% reduction in function) have a more severe phenotype compared with mutations exhibiting haploinsufficiency ($\leq 50\%$ reduction in function). These genetic risks were independent of traditional clinical risk factors such as the manifest QTc interval on the ECG, suggesting that variability in the electrophysiological effects of the different mutations contributes to the variability in the risk of life-threatening cardiac events.^{10,15}

Patients with the Jervell and Lange-Nielsen and Timothy syndromes have poor prognosis and are less likely to respond to beta blocker therapy alone. In contrast, the Andersen-Tawil syndrome has a generally more benign clinical course in terms of arrhythmic death.

ELECTROCARDIOGRAPHIC MARKERS OF RISK

QT INTERVAL PROLONGATION. The QTc interval is the best prognostic ECG parameter in LQTS families. A QTc interval of at least 470 milliseconds is a predictor for increased risk for symptoms, whereas a QTc of at least 500 milliseconds predicts an increased risk of life-threatening cardiac events. The risk for cardiac events demonstrates a nearly exponential increase for the QTc interval decile. The maximal QTc duration measured at any time before age 10 was shown to be the most powerful predictor of cardiac events during adolescence, regardless of baseline, mean, or most recent QTc values.^{23,26}

T-U WAVE MORPHOLOGY. The ratio of amplitude of the U wave to that of the T wave has been suggested as the clinical counterpart of EADs; a progressive increase in the ratio of the U wave to the T wave preceded the onset of torsades de pointes in an experimental model of LQT. In addition, the increment in U wave amplitude after a PVC has been suggested as a marker for arrhythmia risk in “pause-dependent” LQT.

Furthermore, in patients with bifid T waves, the diurnal maximal ratio between late and early T wave peak amplitude was found to correlate with a history of LQTS-related symptoms better than the baseline QTc interval in both LQT1 and LQT2 patients, and can potentially be used to assess the risk of symptoms in asymptomatic patients with known type 1 or 2 LQTS genotype. In LQT1 patients, a ratio of at least 3 suggests a high probability of being symptomatic whereas a ratio not exceeding 2 suggests a low probability. Among LQT2 patients, ratios suggestive of being symptomatic or asymptomatic are, respectively, at least 2.4 and not more than 1.5.³¹

CLINICAL MARKERS OF RISK

SYNCOPE. Nonfatal events (syncope and aborted cardiac arrest) in LQTS patients remain the strongest predictor of subsequent LQTS-related fatal events, and the overall risk of subsequent SCD in an LQTS patient who has experienced a previous episode of syncope is approximately 5% per year.⁹

The risk of subsequent syncopal episodes can be reduced with beta blocker therapy; however, patients experiencing syncope while receiving beta blockers are at high risk of subsequent cardiac events, a risk similar to that observed in patients who are not treated with beta blockers.⁹

Both the timing and frequency of syncopal events are related to the subsequent risk of cardiac events. Patients with recent (within the past 2 years) syncope and a higher number of syncopal events during this period carry a higher risk of cardiac events.⁵⁴

FAMILY HISTORY. The incomplete penetrance and variable expressivity in LQTS preclude predicting severity of symptoms in relatives of a symptomatic LQTS patient. In fact, SCD of a sibling (at any age) does not seem to contribute to increased personal risk of LQTS-related life-threatening cardiac events. Instead, the

risk of adverse events in relatives appears to be determined more by the individual's own risk factors (QTc duration, personal history of syncope, and gender).⁵⁵

GENDER. The effect of gender on outcome is age-dependent, with boys exhibiting a significant (71% to 85%) increase in risk for syncope, aborted cardiac arrest, or SCD as compared with girls during childhood and early adolescence. However, a gender risk reversal occurs after age 14 years, in which girls exhibit an 87% increase in the risk of cardiac events compared with boys among probands and a 3.3-fold increase in the risk among affected family members. When only life-threatening cardiac events (aborted cardiac arrest or SCD) are considered, the onset of gender risk reversal occurs at a later age. The cumulative probability of a first life-threatening cardiac event from age 1 to 12 years is 5% in boys compared with only 1% among girls, whereas in the age range of 12 to 20 years, there is no significant gender difference in risk. Risk reversal for the endpoint of aborted cardiac arrest or SCD occurs after the age of 20 years, and female patients maintain higher risk than male patients throughout adulthood.¹⁴

Importantly, the effect of gender on outcome appears to be genotype-dependent. Among those not more than 14 years of age, male LQT1 patients exhibit the highest risk of cardiac events; female LQT1 patients had intermediate risk; and both male and female LQT2 patients had the lowest risk. No significant gender-related difference in risk was shown among LQT2 and LQT3 children. In contrast, in the 15- through 40-year age group, risk is highest among LQT2 women, intermediate among LQT1 women, and lowest among LQT1 and LQT2 men.¹⁵

The mechanisms behind these age-dependent differences in gender-related risk are unknown. Environmental (increased physical activity), hormonal (opposing effects of estrogens and androgens on ventricular repolarization), and/or genetic (modifier genes not shared by boys and girls) factors can potentially play a role.¹⁴

AGE. Risk factors in LQTS are time-dependent and age-specific (Table 31-6). LQTS patients who experience an aborted cardiac arrest during the first year of life are at a very high risk for subsequent life-threatening cardiac events during the first decade of life. The risk factors for a cardiac event in LQTS infants also include a QTc of at least 500 milliseconds, a heart rate not exceeding 100 beats/min, and female gender.⁵⁶ In LQTS children, risk factors for life-threatening cardiac events include male gender, a history of syncope at any time during childhood, and a QTc duration greater than 500 milliseconds.¹⁴ Among adolescent patients with suspected LQTS, recent episodes of syncope (in particular within the past 2 years) and QTc greater than 530 milliseconds predict increased risk of LQTS-related cardiac events.⁵⁴ Although LQT1 genotype predicts higher risk in patients not more than 14 years of age (especially boys), the risk is higher for LQT2 in patients 15 years of age or older (especially women). In adult patients, predictors of worse outcome include a QTc greater than 500 milliseconds, female gender, and history of syncope before age 18 years. Additionally, patients with LQT2 mutations appear to be at a greater risk for a cardiac event than patients with LQT1 or LQT3 genotypes.⁴

Beyond 40 years of age, recent syncope (within the past 2 years) appears to be the predominant risk factor in affected subjects, and those with a positive mutation had a significantly higher mortality, particularly those with an LQT3 mutation. Furthermore, women with a QTc greater than 470 milliseconds are at a higher risk of LQTS-related cardiac events, whereas in men event rates are similar in the various QTc categories. After the age of 60 years, the risk of death due to LQTS competes with other disease entities that may lead to death.

Principles of Management

The main therapeutic modalities for the prevention of life-threatening cardiac events include beta blockers, left cervicothoracic sympathetic denervation, and ICD implantation. In nongenotyped patients, beta blockers comprise the mainstay therapy, whereas

TABLE 31-6 Age-Specific Risk Factors for Life-Threatening Cardiac Events in Long QT Syndrome Patients*

AGE GROUP	RISK FACTOR	HAZARD RATIO (P VALUE)	BETA BLOCKER EFFICACY, % REDUCTION (P VALUE)
Childhood (1-12 yr)	Male gender	3.96 (<0.001)	73% (0.002)
	QTc > 500 msec	2.12 (0.02)	
	Prior syncope		
	Recent (<2 yr)	14.34 (<0.001)	
Adolescence (10-20 yr)	Remote (≥2 yr)	6.45 (<0.001)	64% (0.01)
	QTc > 530 msec	2.3 (<0.001)	
	Syncope		
	≥2 syncopal events in past 2 yr	18.1 (<0.001)	
	1 syncopal event in past 2 yr	11.7 (<0.001)	
Adulthood (18-40 yr)	≥2 syncopal events in past 2-10 yr	5.8 (<0.001)	60% (<0.01)
	1 syncopal events in past 2-10 yr	2.7 (<0.001)	
	Female gender	2.68 (<0.05)	
	QTc duration		
	QTc ≥ 500 msec	6.35 (<0.01)	
	QTc = 500-549 msec	3.34 (<0.01)	
	Prior syncope	5.10 (<0.01)	
Adulthood (41-60 yr) [†]	Recent syncope (<2 yr)	9.92 (<0.001)	42% (0.40) [‡]
	QTc > 530 msec	1.68 (0.06)	
	LQT3 genotype	4.76 (0.02)	

*Findings are from separate multivariable Cox models in each age group for the endpoint of aborted cardiac arrest or sudden cardiac death.

[†]Because long QT syndrome (LQTS)-related events are more difficult to delineate in the older age group, the endpoint in the 41- to 60-year age group comprised aborted cardiac arrest or death from any cause.

[‡]Lack of a statistically significant beta blocker effect in this age group may relate to the broad endpoint of death from any cause.

QTc = corrected QT interval.

From Goldenberg I, Moss AJ: Long QT syndrome, *J Am Coll Cardiol* 51:2291-2300, 2008.

cervicothoracic sympathetic denervation and implantation of an ICD are therapeutic options in high-risk LQTS patients who experience recurrent cardiac events despite beta blocker therapy.¹²

PHARMACOLOGICAL THERAPY

Treatment with beta blockers is associated with a significant (53% to 64%) reduction in risk of LQTS-related life-threatening events (syncope, cardiac arrest, and SCD), regardless of age (see Table 31-6). The benefit appears to be most substantial in patients at highest risk for cardiac events. On the other hand, very low-risk patients (no history of syncope, QTc <500 milliseconds, girls <age 14, LQT2 men of any age, and LQT1 women >age 14) have such a small frequency of events that beta blockers may not provide a significant benefit.¹⁵

Genetic data can be used to guide the therapeutic management plan. Given the critical role of catecholamines in precipitating arrhythmias in LQT1, beta blocker therapy is particularly effective for this group of patients; approximately 90% of LQT1 patients treated with beta blockers remained free from syncope and cardiac arrest after a mean follow-up time of 5.4 years and showed a total mortality rate of 1%. Although beta blockers were generally considered to have lower efficacy in LQT2 patients as compared with LQT1 patients, recent data argue for a similar magnitude of risk reduction in LQT2 patients (beta blocker therapy decreased cardiac events from 58% to 23% after an average follow-up of 4.9 years on therapy). The higher residual event rate in LQT2 patients while receiving beta blocker therapy is likely due to a higher overall event rate in patients with this genotype, rather than to an attenuated efficacy of medical therapy in this high-risk population.^{10,15} A recent report found that a trigger-specific response to beta blocker therapy exists within the LQT2 population. Beta blockers appear to

be more protective against exercise-triggered cardiac events than arousal- or non-exercise-related events (see Fig. 31-1).¹³

On the other hand, LQT3 patients were not shown to have a significant benefit from beta blockers; in these patients, prolongation of the QT intervals is aggravated at slow heart rates. Thus, a reduction in heart rate with beta blockers can potentially pose a therapeutic problem in these patients. Among LQT3 patients receiving beta blocker therapy, the adjusted risk for a cardiac event is fourfold higher than among LQT1 patients.¹²

In summary, beta blockers comprise the mainstay therapy for the prevention of life-threatening cardiac events and, given the approximately 12% risk of SCD as the first manifestation of LQTS, they should be considered the first-line measure in all nongenotyped patients and in patients with LQT1 or LQT2 genotypes, regardless of their symptomatic or risk status. Recent data have argued against the routine empirical administration of beta blockers to all patients and advocated limiting therapy to high-risk patients (including LQT1 boys in the ≤14-year group, LQT2 women in the 15- to 40-year age group, patients with a history of syncope and/or documented torsades de pointes, and patients with a QTc ≥500 milliseconds), whereas low-risk LQT1 and LQT2 patients (including female LQT1 patients and LQT2 patients in the 0- to 14-year age group and LQT1 patients and LQT2 men in the 15- to 50-year age group, without prior syncope and with a QTc <500 milliseconds) are treated with beta blocker therapy on an individual basis, and routine initiation of medical therapy if they become symptomatic or if follow-up ECGs show an increase in QTc duration. That said, it is important to understand that all these recommendations are based on observational studies and not randomized clinical trials.¹⁵

Propranolol and nadolol are the beta blockers most frequently used, although different beta blockers (including atenolol and metoprolol) demonstrate similar effectiveness in preventing

cardiac events in patients with LQTS. The protective effect of beta blockers is related to their adrenergic blockade that diminishes the risk of cardiac arrhythmias; hence, the goal of beta blocker therapy is to blunt the maximal heart rate during exercise, and the adequacy of beta blockade can be assessed by exercise testing or ambulatory monitoring. Beta blockers do not substantially shorten the QT interval.³²

Despite the beneficial effects of beta blockers, a high rate of residual cardiac events has been reported in patients receiving beta blocker therapy, occurring in 10%, 23%, and 32% of LQT1, LQT2, and LQT3 patients, respectively, after a mean follow-up time of 5.4 years. Therefore, patients who remain symptomatic despite treatment with beta blockers should be considered for other therapeutic modalities.⁵⁷ Interestingly, it has been reported that lack of compliance can be an important cause of events occurring during beta blocker treatment in LQT1 patients.¹⁰

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

ICD therapy is highly effective to prevent SCD in high-risk LQTS patients (mortality of 1.3% in high-risk ICD patients compared with 16% in non-ICD patients during a mean follow-up time of 8 years) and should be considered for secondary prevention in patients with prior cardiac arrest and for primary prevention in those who experience syncope and/or ventricular tachyarrhythmias while receiving beta blocker therapy.^{4,14,54}

Although prophylactic ICD therapy can be considered for LQTS patients with risk factors for SCD (see Table 31-6) regardless of medical therapy, recent data suggest that high-risk LQT1 and LQT2 patients should be considered for prophylactic ICD implantation only if they develop recurrent cardiac events (e.g., syncope or torsades de pointes) despite beta blocker therapy or when compliance with or intolerance to medical therapy is a concern. Clear understanding by the patient and/or family of the relative merits of each strategy is essential. Although beta blocker therapy significantly reduces the risk of SCD in this population, it is not completely protective, and residual cardiac events still occur. On the other hand, data suggest that syncopal episodes almost always precede cardiac arrest in patients receiving beta blockers, allowing for institution of other therapeutic modalities, such as ICD implantation. Additionally, ICD therapy is not without complications. Infection, lead malfunction, inappropriate shocks, psychiatric sequelae, as well as device and lead longevity, especially in the young patient, have to be taken into consideration.^{9,15,32,58}

Early ICD therapy should be considered in patients with the LQT3 genotype, Jervell and Lange-Nielsen syndrome, or Timothy syndrome because the lethality among these patients is high and the efficacy of beta blockers appears to be more limited.

It is important to recognize that a strong family history of SCD is not an independent risk factor for LQTS patients. Although prophylactic ICD implantation is a class IIb indication in these patients, personal risk factors should be considered before recommending prophylactic ICD implantation.

Importantly, because ICD therapy does not prevent the occurrence of arrhythmias, the concurrent administration of beta blockers is recommended for symptomatic and high-risk patients.

LEFT CERVICOTHORACIC SYMPATHECTOMY

Left cervicothoracic sympathectomy, which involves resection of the left stellate ganglion and the first two to four thoracic ganglia, is another antiadrenergic therapeutic measure used in high-risk patients with LQTS, especially in those with recurrent cardiac events despite beta blocker therapy. In addition to beta-adrenergic inhibition, cervicothoracic sympathetic denervation provides alpha-adrenergic inhibition, which may be important for some patients.

Although left cardiac sympathetic denervation is associated with a significant long-term reduction in the frequency of aborted cardiac arrest and syncope, it is not completely protective against SCD, with a residual mortality rate of 5% at 5 years. Therefore, ICD is

superior therapy to cervicothoracic sympathectomy. Left cardiac sympathetic denervation is more effective in patients with LQT1 than in those with other types of LQTS.¹²

Cervicothoracic sympathectomy may be indicated in some high-risk patients with recurrent symptoms while receiving a full dose of beta blocker or those intolerant to beta blocker therapy, especially those in whom ICD implantation is not feasible (e.g., small infants). Additionally, cervicothoracic sympathectomy can be of value in ICD patients experiencing frequent shocks despite receiving adequate doses of beta blockers.¹²

PERMANENT PACEMAKER

Cardiac pacing, in conjunction with beta blocker therapy, can potentially reduce the risk of bradycardia-dependent QT prolongation, decrease heart-rate irregularities (eliminating short-long-short sequences), and reduce repolarization heterogeneity. Permanent pacemakers can be of value especially in patients who continue to be symptomatic despite beta blocker therapy or those in whom bradycardia or AV block limits the use of such therapy. In particular, patients with documented pause- or bradycardia-induced torsades de pointes and those with LQT3 genotype may derive significant benefit from cardiac pacing.¹²

Nevertheless, the high mortality in patients with recurrent symptoms (syncope or torsades de pointes) while receiving beta blocker therapy is not adequately attenuated by the addition of cardiac pacing. Therefore, if cardiac pacing is being considered, the use of an ICD is more logical, because it provides protection from SCD as well as the benefit of cardiac pacing.

When cardiac pacing is employed, atrial pacing is preferred, at a rate that shortens the QTc to less than 440 milliseconds. It is recommended to minimize ventricular pacing as much as possible, because it can potentially increase the heterogeneity of ventricular repolarization. However, in patients with AV block, ventricular pacing is important to maintain AV synchrony and elimination of ventricular pauses and long-short cycles.

CATHETER ABLATION

In LQTS patients, frequent episodes of torsades de pointes are occasionally triggered by focal, monomorphic PVCs. In this setting, focal radiofrequency (RF) ablation of the PVCs can be valuable in reducing the burden of arrhythmias and the frequency of ICD therapies.

LIFESTYLE MODIFICATIONS

Physical activity and stress-related emotions frequently trigger cardiac events in patients with LQTS, especially patients with LQT1 or LQT2. Therefore, all competitive sports (except those in the class IA category, such as billiards, bowling, cricket, and golf) should be restricted in symptomatic LQTS patients (regardless of the QTc duration or underlying genotype) as well as asymptomatic patients with baseline QT prolongation (QTc \geq 470 milliseconds in men, \geq 480 milliseconds in women). Swimming is particularly hazardous in LQT1 patients and should therefore be limited or performed under appropriate supervision, even in subjects with genotype-positive/phenotype-negative LQT1.⁵⁹

Because many first cardiac events occur before the age of 15 years in male patients, particularly those with the LQT1 genotype, whereas female patients may experience first cardiac events after the age of 20 years, LQT1 men require stricter exercise restriction before the age of 15, but less restriction after age 15 years.⁵⁹

The restriction limiting participation to class IA activities may be liberalized for the asymptomatic patient with genetically proven LQT3 genotype and those with genotype-positive/phenotype-negative LQTS (i.e., identification of an LQTS-associated mutation in an asymptomatic individual with a nondiagnostic QTc).⁵⁹

Preventive measures in LQTS patients in general and LQT2 patients in particular include avoidance of unexpected auditory

stimuli (such as alarm clocks and telephones), especially during rest or sleep.

All patients with LQTS should avoid drugs that prolong the QT interval or reduce their serum potassium or magnesium levels. Patients should consult with their physician before taking any medications or over-the-counter supplements. Families with LQTS may also consider basic life support training and operation of an automated external defibrillator.

GENE-SPECIFIC THERAPY

The standard therapeutic options for LQTS (including beta blockers, cardiac sympathetic denervation, ICD) rely on genotype to only a minor degree, yet are quite effective. Nevertheless, beta blockers and left cervicothoracic sympathectomy have some degree of genotype specificity, being quite effective in LQT1 and LQT2 and less effective in LQT3 (see Table 31-1). Similarly, behavior modification is most helpful in LQT1 and LQT2. For practical purposes, however, this apparent genotype specificity influences therapy decisions in only a very small number of patients.^{12,27}

Gene-specific LQTS therapy is an area under investigation and appears to be promising, including Na⁺ channel blockers, K⁺ channel activators, alpha-adrenergic receptor blockers, protein-kinase inhibitors, and atropine. However, current experience with these drugs is limited.¹²

Intravenous nicorandil, an agent that promotes ATP-dependent K⁺ channel (I_{KATP}) opening, has been shown to improve repolarization abnormalities and can potentially be of therapeutic value in suppressing repetitive episodes of torsades de pointes in the LQT1 and LQT2 patients and less efficiently in LQT3 patients. Unfortunately, oral administration of nicorandil reaches much lower plasma concentrations than those used in the experimental setting, thus limiting the potential for its clinical use.²⁷

Mexiletine, a class IB Na⁺ channel blocker, was shown to shorten the QT interval and was suggested as gene-specific therapy for patients with the LQT3 genotype, in whom enhanced late Na⁺ inward current underlies prolongation of the QT interval. However, the response to mexiletine was not consistent and was shown to be mutation-specific. Furthermore, there is no conclusive evidence that shortening of the QT interval in these patients translates into a clinical benefit. Until prospective clinical trials confirm the effectiveness of mexiletine, it should be used in LQT3 patients only in conjunction with beta blockers or with the backup of an ICD. In addition, some investigators recommend testing the effectiveness of mexiletine by the administration of half the daily dose during continuous ECG monitoring. Only if the QTc is shortened by more than 40 milliseconds within 90 minutes of drug administration (when the peak plasma concentration is reached) should mexiletine be added to beta blocker therapy.^{12,27}

Similarly, the antianginal agent ranolazine reduces late Na⁺ current, shortens the action potential duration, and suppresses EAD-triggered arrhythmias in animal models of LQT3, and can potentially offer a therapeutic benefit in LQT3 patients.¹²

Additionally, flecainide, a class IC Na⁺ channel blocker, was shown to shorten the QT interval in LQT3 patients with a specific mutation (D1790G) in the *SCN5A* gene. However, flecainide is reported to elicit a Brugada phenotype in some LQT3 patients; therefore, this drug should not be used in LQT3 patients except for those with this specific *SCN5A* mutation.¹²

Potassium supplements can be of value especially in LQT2 patients, who are particularly sensitive to low K⁺ levels because the conductance of KCNH2 channels is directly related to extracellular K⁺ concentrations. Therefore, efforts should be made to maintain a serum K⁺ level greater than or equal to 4 mEq/L in patients with this genotype. Acute intravenous treatment with K⁺ can be effective in suppressing torsades de pointes. Furthermore, long-term oral potassium supplements, even in patients with normal K⁺ levels at baseline, can potentially reduce repolarization abnormalities in LQT2. Increasing extracellular K⁺ concentrations enhances I_{Kr} and at least partially compensates for the loss of I_{Kr} in LQT2

and can potentially limit the development of an arrhythmogenic substrate under long QT conditions. Whether these effects translate into clinical benefit in reduction of the risk of cardiac events is still unclear.^{12,15}

FAMILY SCREENING

Timely (often presymptomatic) identification of disease carriers is important because preventive measures and therapies can effectively avert SCD.²⁷ Therefore, when a patient is diagnosed with LQTS, ECGs should be obtained on all first-degree family members (i.e., parents, siblings, offspring) to determine whether others are affected. Unexplained sudden death in a young individual should trigger a similar evaluation to determine if LQTS is present in the family.⁵

When the causal mutation has been identified in the proband, first-degree relatives should be offered genetic screening, even those with a negative clinical and ECG phenotype.^{36,41} Genotyping of family members can help exclude the diagnosis in some persons as well as identify silent mutation carriers and allow prophylactic treatment.⁷ However, detailed genetic counseling is warranted before proceeding to this testing, particularly for asymptomatic persons for whom the option of not testing must also be recognized.³²

Brugada Syndrome

The Brugada syndrome is an autosomal dominant inherited channelopathy characterized by ST segment elevation or J wave in the right precordial leads. First described in 1992, the syndrome is associated with a high incidence of SCD secondary to a rapid polymorphic VT or VF in patients with structurally normal hearts.

Epidemiology

The prevalence of the Brugada ECG pattern in an apparently healthy population is varied, ranging from 0.14% in the Japanese population to 0.61% in Europeans, and may reach as high as 3% in endemic areas of Southeast Asia. In the United States, the prevalence ranges from 0.012% to 0.43%, depending on the demographics of the patient population studied. However, because the aberrant ECG pattern can be intermittently present or concealed, it is difficult to estimate the true prevalence of the disease in the general population.^{60,61} For unclear reasons, the Brugada syndrome is either more prevalent or more penetrant in Eastern countries (mainly in Southeast Asia), where the disease occurs endemically.⁶²

The Brugada syndrome exhibits an autosomal dominant pattern of transmission and variable penetrance. In up to 60% of patients the disease can be sporadic, that is, absent in parents and other relatives. A family history of unexplained SCD is present in approximately 20% to 40% of Brugada probands in Western countries and in a lower percentage of probands (15% to 20%) in Japan.

Although the disease is inherited as an autosomal dominant trait, there is a striking male predominance in its phenotype (ratio of men to women, 8:1). It remains unknown why men have a more penetrant form of the disease. Although gene mutations provide a proarrhythmic substrate, the adult male dominance of clinical manifestation suggests that gender- and age-related factors (e.g., sex hormones) may play a role in triggering the arrhythmia in Brugada syndrome.^{61,63,64}

The age of onset of clinical manifestations (syncope or cardiac arrest) is the third to fourth decade of life (mean age of SCD occurrence, 41 ± 15 years), but cases have been diagnosed in infancy and in patients in their 80s.^{61,65}

Clinical Presentation

Patients with Brugada syndrome are at high risk of rapid polymorphic VT, VF, and SCD. Syncope, agonal respirations, nocturnal labored respiration with agitation, and “seizures” are the only symptoms the patient may have before SCD occurs.

The Brugada syndrome is the leading cause of death in men not more than 40 years of age, particularly in countries in which the syndrome is endemic. The Brugada syndrome is believed to be responsible for 4% to 12% of all SCDs, and at least 20% of those occurring in patients with structurally normal hearts. The Brugada syndrome has even been described as responsible for SIDS as well as the sudden unexplained nocturnal death syndrome (SUNDS; also known as SUDS).^{62,65} Nevertheless, the majority of Brugada syndrome patients do not manifest life-threatening events; approximately 10% to 15% of clinically affected patients experience one or more cardiac arrests before age 60.⁶¹ In a meta-analysis of prognostic studies, patients with Brugada ECG pattern have an approximately 10% risk of SCD, syncope, or ICD shock at an average follow-up time of 2.5 years, or approximately 3.8% per year.⁶⁶

Cardiac arrhythmia and death in the Brugada syndrome seem to occur largely in the early morning hours during sleep and in the setting of bradycardia. Circadian variation of sympathovagal balance, hormones, and other metabolic factors are likely to contribute to this circadian pattern. Bradycardia resulting from altered autonomic balance or other factors likely contributes to the initiation of arrhythmia.⁶⁵

Some episodes of syncope or SCD can be triggered by fever, large meals (gastric distention), alcohol and cocaine toxicity, and drugs.⁶² In fact, it now appears that many previously described episodes of “febrile seizures” may in fact represent bouts of polymorphic VT in patients with temperature-sensitive mutations.^{67,68} Some patients with the Brugada syndrome experience an electrical storm of VF, but with no obvious precipitating factors.

Approximately 20% of patients with Brugada syndrome develop supraventricular arrhythmias. AF is observed in 10% to 20% of patients. Atrioventricular nodal reentrant tachycardia and Wolff-Parkinson-White syndrome also have been reported. A recent study reported that inducibility of ventricular arrhythmias is positively correlated with a history of atrial arrhythmias. In patients with an

indication for an ICD, the incidence of atrial arrhythmias was 27% versus 13% in patients without an indication for an ICD, which suggests a more advanced disease process in patients with Brugada syndrome and spontaneous atrial arrhythmias.⁶⁵

The identification of concomitant conduction defects (PR interval ≥ 210 milliseconds and His bundle–ventricular [HV] interval ≥ 60 milliseconds) has been shown to correlate with the presence of *SCN5A* mutations. Therefore, all *SCN5A*-positive patients should be closely monitored for the onset of conduction block.

Electrocardiographic Features

BRUGADA ST SEGMENT ELEVATION

Three ECG repolarization patterns in the right precordial leads are recognized (Fig. 31-4). Type 1 is characterized by ST segment elevation of at least 2 mm (0.2 mV) with a coved (downward convex) morphology, associated with an incomplete or complete right bundle branch block (RBBB) pattern and followed by a descending negative T wave, with little or no isoelectric separation. The type 2 pattern has a “saddleback” appearance with a high take-off ST segment elevation of at least 2 mm, a trough displaying an ST elevation greater than or equal to 1 mm, and then either a positive or biphasic T wave. The type 3 pattern has either a saddleback or coved appearance with an ST segment elevation of less than 1 mm. These three patterns can be observed spontaneously in serial ECG tracings from the same patient or after the introduction of specific drugs. Only the type 1 ECG pattern is diagnostic of the Brugada syndrome, with type 2 and type 3 ECG patterns being suggestive but not specific.^{62,65}

The use of more cephalad placement of the right precordial leads in a superior position (up to the second intercostal space above normal) can increase the sensitivity for detecting the Brugada ECG pattern in some patients, both in the presence or absence of a drug

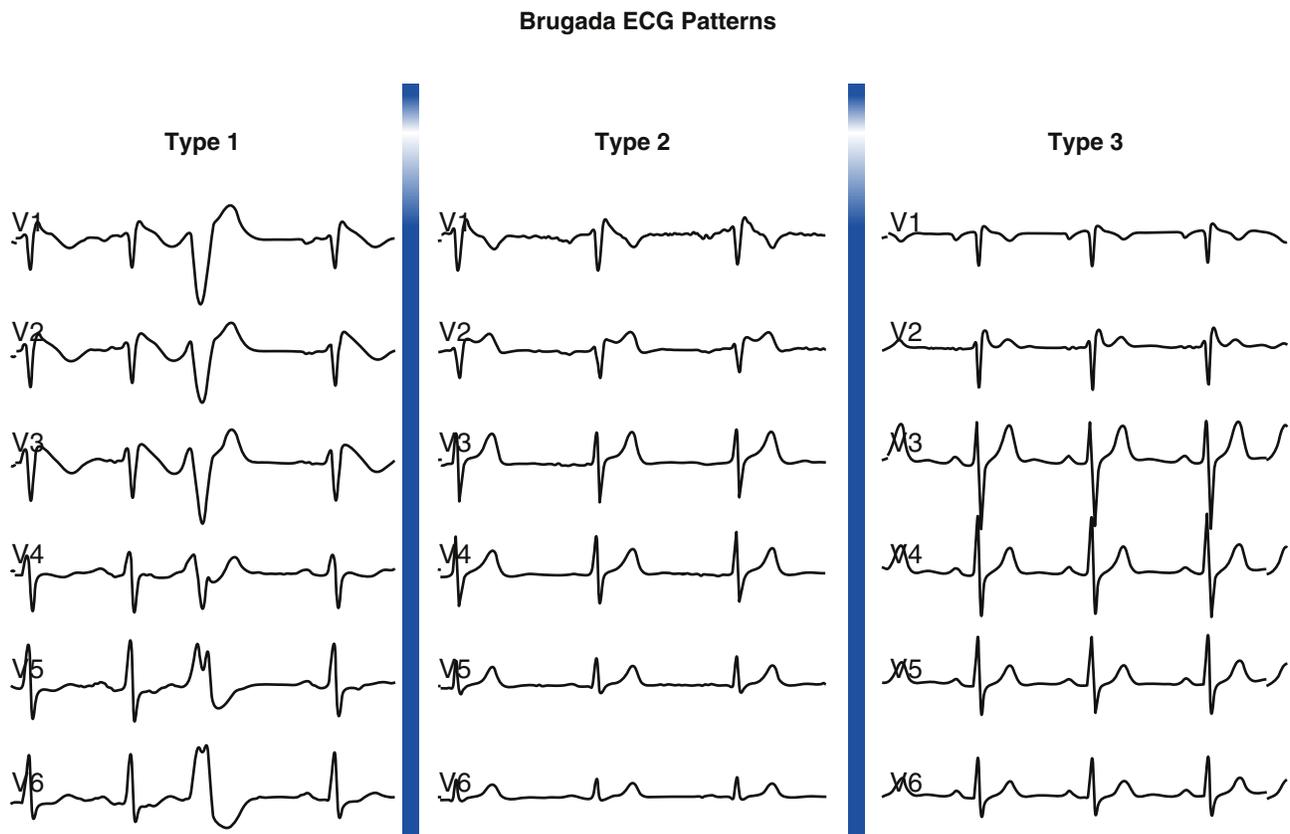

FIGURE 31-4 Brugada ECG patterns. Note the ventricular ectopic beat in the left panel with a QRS morphology consistent with origin from the right ventricular outflow tract. See text for discussion.

challenge. Recent data suggest that patients with a diagnostic ECG with the leads positioned at a higher position have a prognosis similar to that of individuals with a type 1 ECG recorded using the standard position.^{65,69}

The presence of the type 1 pattern is dynamic, and it is rare for patients to present with uniformly diagnostic tracings. Therefore, serial ECGs can be necessary for diagnostic evaluation in high-risk patients. Continuous Holter monitoring also can help assess ST segment elevation at nighttime, because such changes can be modified by autonomic tone.⁶¹

The ECG manifestations of the Brugada syndrome, when concealed, can be unmasked by stress, fever, various vagal stimuli (including gastric distention), vagotonic agents, a combination of glucose and insulin, hyperkalemia, hypokalemia, hypercalcemia, alcohol and cocaine toxicity, class I antiarrhythmic medications, as well as a number of other noncardiac medications.⁶⁵

Furthermore, the ECG phenotype in the Brugada syndrome can be modified by autonomic changes. Adrenergic stimulation attenuates whereas acetylcholine accentuates the ECG abnormalities in affected individuals. Clinically, this correlates well with the propensity for cardiac events to occur at rest or during sleep.⁶¹

QT INTERVAL PROLONGATION

A slight prolongation of the QT interval is sometimes observed in association with ST segment elevation in patients with the Brugada syndrome. The QT interval is prolonged more in the right precordial leads than it is in the left precordial leads, presumably because of a preferential prolongation of action potential duration in right ventricular (RV) epicardium secondary to accentuation of the action potential notch.

QRS FRAGMENTATION

In addition to the repolarization abnormality, the Brugada syndrome is associated with depolarization abnormalities and conduction disturbances. Fragmentation of the QRS complex (manifesting as multiple small spikes within the QRS complex) has been recently observed in 40% of patients with the Brugada syndrome and in the majority (85%) of those who had VF episodes. It has been proposed that the multiple spikes within the fragmented QRS complex suggest the presence of an arrhythmogenic substrate that has multiple areas of conduction slowing, and can potentially predict a high risk of life-threatening ventricular arrhythmias. Notably, fragmentation of the QRS occurs preferentially in the right precordial leads, especially in the higher intercostal spaces, suggesting a localized conduction abnormality within the RV outflow tract (RVOT) region. The use of a low-pass filter with a low cutoff frequency (>25 Hz), as commonly employed to remove the electromyogram signal, can eliminate the QRS fragmentation. Thus, low-noise amplifier and a relatively high cutoff low-pass filter frequency (150 Hz) need to be used.⁷⁰

Epsilon-like waves and localized prolongation of the QRS complex in the right precordial leads have been observed in some patients with a spontaneous or drug-induced type 1 Brugada ECG pattern, likely reflecting RV activation delay.⁷¹

CONDUCTION ABNORMALITIES

Depolarization abnormalities, including prolongation of P wave duration, PR interval, and QRS duration, are frequently observed, particularly in patients linked to *SCN5A* mutations. PR interval prolongation likely reflects HV conduction delay. Of note, loss-of-function *SCN5A* mutations can lead to isolated cardiac conduction defects or Lev-Lenègre disease, characterized by disturbances in any part of the conduction system without QT interval prolongation or Brugada ST segment elevation. Additionally, prolonged sinus node recovery time and sinoatrial conduction time, slowed atrial conduction, and atrial standstill have been reported in association with the syndrome.^{61,65}

SIGNAL-AVERAGED ELECTROCARDIOGRAPHY

Signal-averaged ECG demonstrates late potentials in approximately 60% to 70% of clinically affected Brugada syndrome patients. In this setting, late potentials can be a clinical marker of the disease, representing the delayed second upstroke of the epicardial action potential, a local phase 2 reentry (failing to trigger transmural reentry), or an intraventricular conduction delay.^{61,65}

EXERCISE TESTING

Treadmill exercise testing can potentially aggravate the ECG abnormalities in the Brugada syndrome, including widening of the QRS, prolongation of the QTc duration, and augmentation of precordial peak ST segment elevation (which reaches its maximal amplitude during the early phase of recovery from exercise). Nonetheless, exercise was not found to induce ventricular arrhythmia in Brugada patients.⁷²

Diagnosis of the Brugada Syndrome

DIAGNOSTIC CRITERIA

The diagnosis of Brugada syndrome is based on clinical diagnostic criteria. The Brugada syndrome is definitively diagnosed when type 1 ST segment elevation is observed in more than one right precordial lead (V₁ to V₃), in conjunction with one of the following: (1) documented VF; (2) polymorphic VT; (3) a family history of SCD at age less than 45 years; (4) coved-type ECGs in family members; (5) inducibility of VT with programmed electrical stimulation; (6) syncope; or (7) nocturnal agonal respiration.⁶⁵

The diagnosis of Brugada syndrome is also considered positive when type 2 (saddleback pattern) or type 3 ST segment elevation is observed in more than one right precordial lead under baseline conditions and conversion to the diagnostic type 1 pattern occurs after administration of a Na⁺ channel blocker. One or more of the clinical criteria described above also should be present. Drug-induced conversion of type 3 to type 2 ST segment elevation is considered inconclusive for a diagnosis of Brugada syndrome.^{65,73}

PROVOCATIVE DRUG TESTING

When concealed, the ECG characteristics of the Brugada syndrome can be unmasked by potent Na⁺ channel blockers (class IA or IC agents). Provocative drug testing is generally not performed if a patient displays an intermittently spontaneous type 1 ECG, because the test does not offer additional diagnostic or prognostic value in these patients, and it is not devoid of risk for provoking arrhythmic events.

The drug challenge test involves administration of ajmaline, flecainide, procainamide, or pilsicainide (Table 31-7) under close cardiac monitoring and in a setting that is fully equipped for resuscitation. Procainamide remains the only choice for intravenous pharmacological induction protocols in the United States, despite consensus that both ajmaline and flecainide are more efficacious and are likely safer because of shorter half-life.⁷⁴

TABLE 31-7 Drugs Used to Unmask Brugada ECG Pattern

DRUG	DOSE
Ajmaline	1-mg/kg IV infusion over 5 min
Flecainide	2-mg/kg IV infusion over 10 min, maximum 150 mg; or 400 mg oral
Procainamide	10-mg/kg IV infusion over 10 min
Pilsicainide	1-mg/kg IV infusion over 10 min

IV = intravenous.

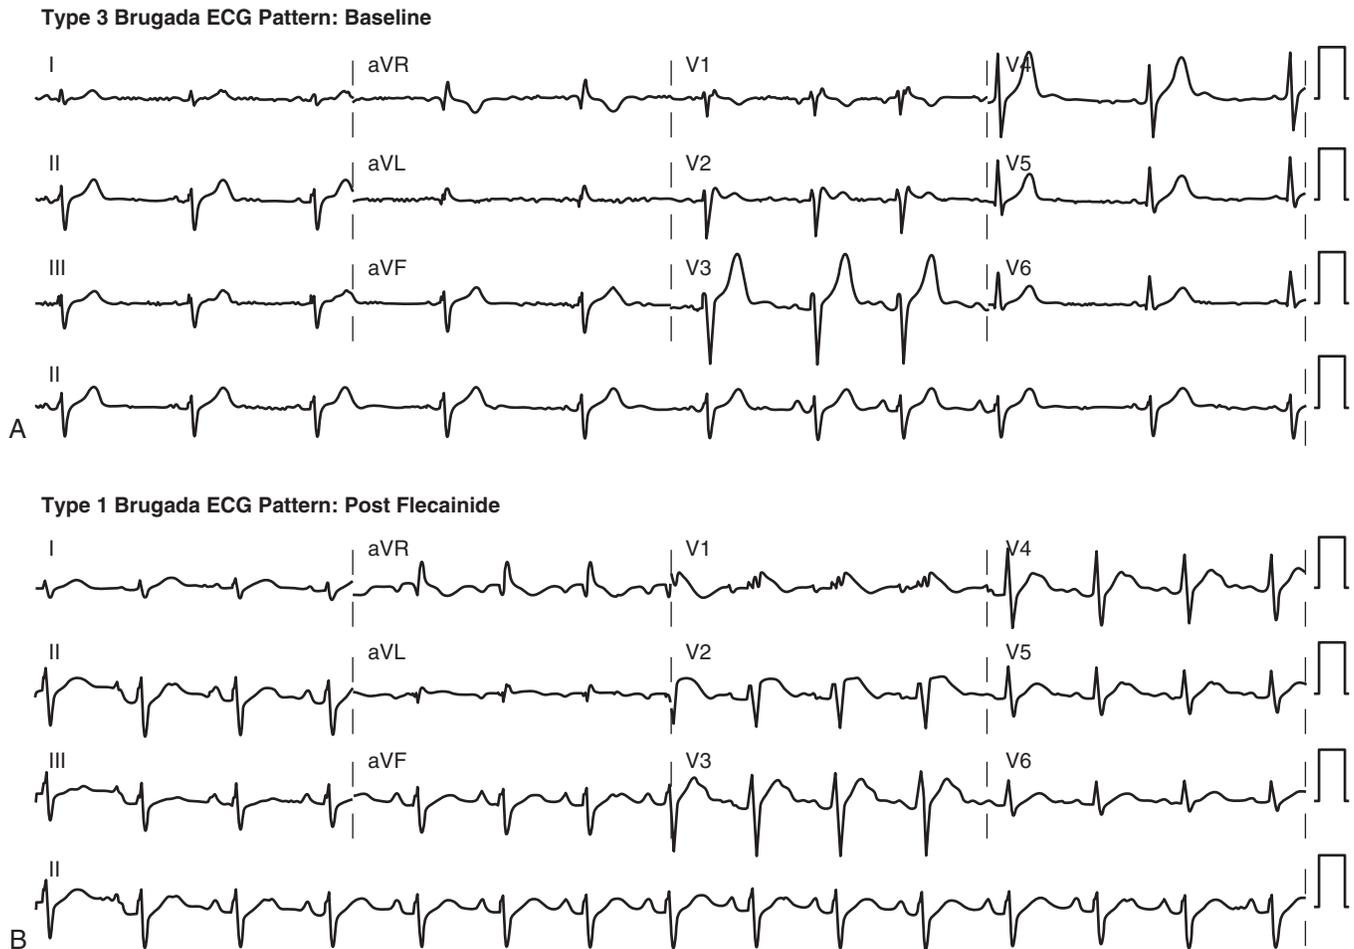

FIGURE 31-5 Brugada ECG patterns. A, ECG showing type 3 Brugada ECG pattern at baseline. B, Type 1 Brugada ECG pattern developed post administration of flecainide.

The drug challenge test is terminated when (1) the diagnostic type 1 ST segment elevation develops (Fig. 31-5), (2) the ST segment elevation in type 2 ECG pattern increases by at least 2 mm, (3) PVCs or other arrhythmias develop, or (4) the QRS widens by 30% or more. Although the drug challenge test is generally safe, it can potentially precipitate malignant cardiac arrhythmias or advanced AV block, particularly in patients with preexisting intraventricular conduction disturbances (wide QRS complex) or infranodal AV conduction delay. Isoproterenol and sodium lactate can be effective antidotes in this setting. The sensitivity and specificity of flecainide testing have recently been estimated at 77% and 80%, respectively. Of note, quinidine, a class IA antiarrhythmic and a Na⁺ channel blocker, generally normalizes ST elevation in Brugada syndrome patients owing to its potent I_{to}-blocking effect.^{61,65,69,73}

GENETIC TESTING

Diagnostic genetic testing may be considered for patients who clinically manifest with symptoms of the Brugada syndrome. Although the knowledge of a specific mutation may not provide guidance for determining prognosis or treatment, identification of a disease-causing mutation in the family can lead to genetic identification of at-risk family members who are clinically asymptomatic and who may have normal ECG. However, it is important to remember that a negative result of genetic testing does not exclude the presence of the disease and, therefore, only a positive genetic diagnosis is informative.^{65,75} Genetic screening of *SCN5A* in unselected patients with diagnosis of Brugada syndrome has low yield and may not be cost-effective. Only 13% of patients with spontaneous or drug-induced type 1 Brugada ECG pattern, 4% of those with type

2 or 3 Brugada ECG pattern, and 2% of individuals with idiopathic VF or family history of SCD are genotyped on *SCN5A*. The yield of genotyping increases substantially in patients with type 1 Brugada ECG pattern and prolonged PR interval, suggesting that this subset of patients with Brugada syndrome should be screened.⁷⁵ Genetic testing is not indicated in the setting of an isolated type 2 or type 3 Brugada ECG pattern.⁴¹

Genetics of the Brugada Syndrome

The Brugada syndrome is a channelopathy that causes current dysfunction in those channels participating in the generation of the cardiac action potential. *SCN5A*, the gene that encodes the alpha subunit (Na_v1.5) of the cardiac Na⁺ channel, was the first gene linked to Brugada syndrome. Although most mutations occur in *SCN5A*, mutations in other genes related to the Na⁺ current as well as genes that affect L-type Ca²⁺ channels (I_{CaL}) or transient outward K⁺ channels (I_{to}) have been identified in patients with the Brugada syndrome (Table 31-8). These channelopathies cause Brugada syndrome phenotype by attenuating I_{Na}, attenuating I_{CaL}, and/or enhancing I_{to}. However, the relationships between genotype and phenotype are not always predictive. Mutations in different genes can express similar Brugada syndrome phenotypes. Conversely, mutations in the same gene can lead to different syndromes.^{62,63,65}

On the other hand, the failure to identify gene mutations in most patients with the Brugada syndrome suggests that unknown mutations or pathophysiological cellular regulations (such as post-translational modulations, phosphorylation, glycosylation) may also cause similar ion current defects and clinical manifestations.⁶³

TABLE 31-8 Molecular Basis of the Brugada Syndrome

DISEASE	GENE	PROTEIN	IONIC CURRENT	FUNCTION	INHERITANCE
BrS type 1	<i>SCN5A</i>	Na _v 1.5	Subunit alpha I _{Na}	Loss	Autosomal dominant
BrS type 2	<i>GPD1L</i>	G3PD1L	Interaction subunit alpha I _{Na}	Loss	Autosomal dominant
BrS type 3	<i>CACNA1C</i>	Ca _v 1.2	Subunit alpha I _{CaL}	Loss	Autosomal dominant
BrS type 4	<i>CACNB2B</i>	Ca _v β ₂	Subunit beta I _{CaL}	Loss	Autosomal dominant
BrS type 5	<i>SCN1B</i>	Na _v β ₁ /β _{1b}	Subunit beta I _{Na}	Loss	Autosomal dominant
BrS type 6	<i>KCNE3</i>	MiRP2	Subunit beta I _{Ks} /I _{to}	Gain	Autosomal dominant
BrS type 7	<i>SCN3B</i>	Na _v β ₃	Subunit beta I _{Na}	Loss	Autosomal dominant

BrS = Brugada syndrome; I_{CaL} = L-type Ca²⁺ current; I_{Ks} = slowly activating delayed rectifier K⁺ current; I_{Na} = Na⁺ current; I_{to} = transient outward K⁺ current.

MUTATIONS RELATED TO THE SODIUM CURRENT

On average 18% to 30% of cases of the Brugada syndrome can be attributed to loss-of-function mutations in the *SCN5A* gene, which encodes the alpha subunit (Na_v1.5) of the cardiac voltage-gated Na⁺ channel, resulting in a reduction of the depolarizing inward sodium current (I_{Na}). A higher incidence of *SCN5A* mutations has been reported in familial than in sporadic cases. I_{Na} initiates the ventricular action potential, thereby controlling cardiac excitability and electric conduction velocity.⁶²

So far, more than 200 Brugada syndrome-associated mutations have been described in the *SCN5A* gene. Some of these mutations result in loss of function due to impaired channel trafficking to the cell membrane, disrupted ion conductance, or altered gating function. Most of the mutations are missense mutations, whereby a single amino acid is replaced by a different amino acid. Missense mutations commonly alter the gating properties of mutant channels. Because virtually all reported *SCN5A* mutation carriers are heterozygous, mutant channels with altered gating can result in an up to 50% reduction of I_{Na}. Different *SCN5A* mutations can cause different degrees of I_{Na} reduction and, hence, different levels of severity of the clinical phenotype of the Brugada syndrome.^{62,65,66}

SCN5A loss-of-function mutations have also been linked to patients with progressive cardiac conduction system disease (Lev-Lenègre disease). Mutated *SCN5A* can also impede the closure (gain of function) of the Na⁺ channel, leading to type 3 LQTS (LQT3). It was reported that all three syndromes (Brugada syndrome, LQT3, and Lev-Lenègre disease) occurred within a single family because of a single mutated *SCN5A* gene. Approximately 65% of mutations identified in the *SCN5A* gene are associated with the Brugada syndrome phenotype.⁶³

Compared with Brugada patients without an *SCN5A* mutation, those with *SCN5A* mutations generally exhibit longer and progressive conduction delays (PQ, QRS, and HV intervals), frequent occurrences of fragmented QRS complex, and ventricular arrhythmias of extra-RVOT origin.⁶³

In addition to *SCN5A* mutations, reduction in I_{Na} can be caused by mutations in the *SCN1B* gene (encoding the beta₁ and beta_{1b} subunits of the Na⁺ channel) and the *SCN3B* gene (encoding the beta₃ subunit of the Na⁺ channel), resulting in Brugada syndrome type 5 and type 7, respectively.^{62,63}

Furthermore, mutations in the *GPD1L* (glycerol-3-phosphate dehydrogenase 1-like) gene, which encodes the protein glycerol-3-phosphate dehydrogenase 1-like (G3PD1L), affect the trafficking of the cardiac Na⁺ channel to the cell surface, resulting in reduction of I_{Na} and “type 2” Brugada syndrome.⁶² Brugada syndrome associated with *GPD1L* gene mutations is characterized by progressive conduction disease, low sensitivity to procainamide, and a relatively good prognosis.⁶³

MUTATIONS RELATED TO THE CALCIUM CURRENT

Approximately 11% to 12% of cases of the Brugada syndrome are attributable to loss-of-function mutations in the cardiac Ca²⁺

channel resulting in a reduction of the depolarizing I_{CaL}. Brugada syndrome type 3 is caused by mutations in the *CACNA1C* gene, which encodes the pore-forming alpha₁ subunit (Ca_v1.2) of the L-type voltage-gated Ca²⁺ channel. Brugada syndrome type 4 is caused by mutations in the *CACNB2* gene, which encodes for the regulatory beta₂ subunit (Ca_vβ₂) of Ca_v1.2, which modifies gating of I_{CaL}. The mechanism of Brugada syndrome type 3 and type 4 involves a reduction of the depolarizing I_{CaL}. Mutations in the alpha and beta subunits of the Ca²⁺ channel can also lead to a shorter than normal QT interval, creating a new clinical entity consisting of combined Brugada/SQTS.⁶²

MUTATIONS RELATED TO THE POTASSIUM CURRENT

Gain-of-function mutations in the *KCNE3* gene, which encodes the auxiliary beta subunit (MiRP2) of the transient outward K⁺ channel (K_v4.3), results in an increase in I_{to} density and causes Brugada syndrome type 6.^{53,62,63}

Pathophysiology of the Brugada Syndrome

MECHANISM OF BRUGADA ECG PATTERN

The STT wave changes in Brugada syndrome likely reflect a profound change in the process of ventricular repolarization, particularly in the relationship between the endocardial and epicardial repolarization processes. The cellular basis for this phenomenon is thought to be the result of loss of function of Na⁺ channels (reduced I_{Na}) that differentially alters the action potential morphology in epicardial versus endocardial cells.^{47,63}

I_{to} is a prominent repolarizing current; it partially repolarizes the membrane, shaping rapid (phase 1) repolarization of the action potential, setting the height of the initial plateau (phase 2), and resulting in a pronounced action potential notch and, in combination with depolarizing Ca²⁺ currents, in a “spike-and-dome” morphology. I_{to} channel densities are heterogeneously distributed across the myocardial wall and in different regions of the heart, being much higher in the RV than in the LV, in the epicardium than in the endocardium, and nearer the base than the apex of the ventricles. These regional differences are responsible for the shorter duration, the prominent phase 1 notch, and the “spike and dome” morphology of RV epicardial and midmyocardial action potentials compared with endocardium and LV. A prominent I_{to}-mediated action potential notch in ventricular epicardium but not endocardium produces a transmural voltage gradient during early ventricular repolarization that registers as a J wave or J point elevation on the ECG (Fig. 31-6).^{76,77}

Na⁺ channel malfunction and reduction of I_{Na} associated with the Brugada syndrome accentuate the notch produced by I_{to}, leading to partial or complete loss of the action potential dome, premature repolarization, and significant action potential shortening, presumably by deactivation or voltage modulation that reduces I_{CaL}. These changes occur predominantly in regions where I_{to} is abundant (such as RVOT epicardium). In contrast, endocardial

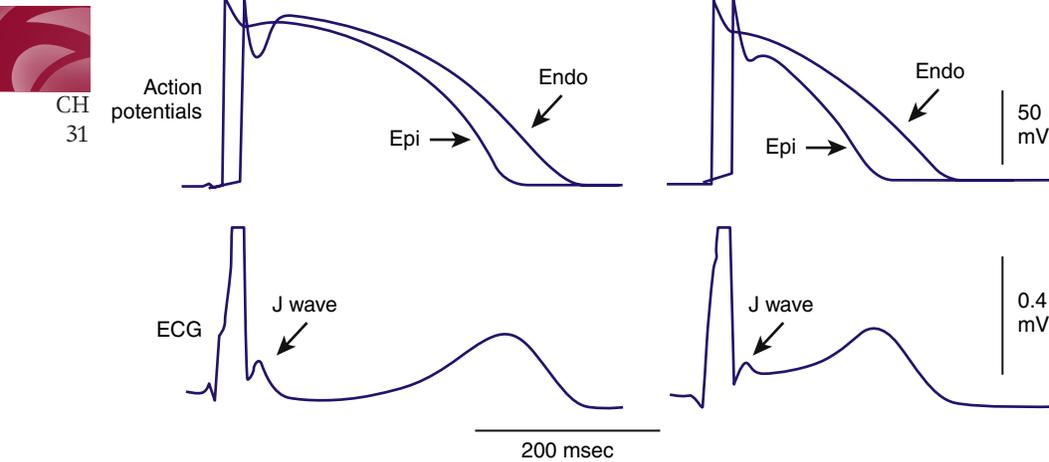

FIGURE 31-6 Cellular basis for the early repolarization syndrome. Shown are a simultaneous recording of transmembrane action potentials from epicardial (Epi) and endocardial (Endo) regions and a transmural ECG in an isolated arterially perfused canine left ventricular wedge. The J wave on the transmural ECG is manifest because of the presence of an action potential notch in epicardium but not endocardium. Pinacidil, an ATP-sensitive K^+ channel opener, causes depression of the action potential dome in epicardium, resulting in ST segment elevation on the ECG resembling the early repolarization syndrome. (Reproduced with permission from Yan GX, Lankipalli RS, Burke JF, et al: Ventricular repolarization components on the electrocardiogram: cellular basis and clinical significance, *J Am Coll Cardiol* 42:401-409, 2003.)

cells display a much smaller I_{to} and, consequently, I_{Na} reduction would not significantly affect action potential morphology and duration.⁶² This is likely to manifest on the ECG as an early repolarization pattern consisting of a J point elevation, slurring of the terminal part of the QRS, and mild ST segment elevation. A further increase in net repolarizing current can result in complete loss of the action potential dome in the RVOT epicardium, leading to more pronounced dispersion of repolarization (epicardial repolarization precedes repolarization in endocardial regions) and a transmural voltage gradient that manifests as greater ST segment elevation.^{62,76}

Additionally, the reduction in I_{Na} observed in Brugada syndrome linked to an *SCN5A* mutation leads to a reduction in the upstroke velocity of action potential phase 0, and, as a result, slowing in atrial and ventricular electrical conduction. Conduction slowing preferentially involves the RVOT. This often is reflected by prolongation in atrioventricular and intraventricular conduction intervals (PR and HV intervals and QRS duration) on the ECGs of Brugada syndrome patients with an *SCN5A* mutation. Slowed transmural conduction (which preferentially involves the RVOT) likely contributes to ST elevation by delaying epicardial activation, thus increasing the transmural gradient of the membrane potential.^{47,63}

MECHANISM OF VENTRICULAR ARRHYTHMIAS

The excessive increase in intramural dispersion of repolarization (between epicardium and endocardium) facilitates reentrant excitation waves between depolarized endocardium and prematurely repolarized epicardium. A significant outward shift in current can cause a prominent action potential notch causing more negative potentials during phase 1 of the action potential and loss of activation of I_{CaL} . As a consequence, loss of the action potential dome and marked abbreviation of the action potential develop in regions where I_{to} is prominent (epicardium) but not in other locations. The dome then can propagate from regions where it is maintained to regions where it is lost, giving rise to a very closely coupled extrasystole (phase 2 reentry) that in turn can initiate polymorphic VT or VF (Fig 31-7).

Although the repolarization abnormalities facilitate the onset of polymorphic VT, it is the depolarization disturbance (conduction slowing leading to wave break of the reentrant wave) that allows the VT to become sustained and to degenerate to VF. Because the RVOT is the critical area associated with depolarization and repolarization abnormalities, it is a frequent origin of VT and VF in the setting of Brugada syndrome (see Fig 31-4).^{47,62,78}

MECHANISM OF AGE AND GENDER EFFECTS

The effects of gender on the Brugada syndrome phenotype (being more prevalent in men) may be due to intrinsic differences in Na^+ channel expression between men and women (e.g., higher I_{to}

densities in men) or due to differences in hormone levels (e.g., higher testosterone levels in men). The phase 1 notch potentially mediates the effects of sex hormones on the phenotypic expressions of Na^+ channel dysfunction, thus contributing to the male predominance of Brugada syndrome. Estrogen suppresses the expression of the $K_v4.3$ channel, resulting in reduced I_{to} and a shallow phase 1 notch, whereas testosterone enhances the outward currents (I_{Kr} , I_{Ks} , I_{K1}) and reduces the inward current (I_{CaL}), thus deepening the phase 1 notch.^{47,63,64}

MECHANISM OF TEMPERATURE SENSITIVITY

The exact mechanism by which fever triggers arrhythmias in Brugada syndrome remains unknown. Mutations responsible for Brugada syndrome can potentially alter the temperature sensitivity of fast inactivation of the Na^+ channel (e.g., more slow inactivation at higher temperatures). Alternatively, temperature elevation can potentially result in a positive shift of steady-state activation, acceleration of inactivation, and slow recovery from inactivation in both wild and mutant Na^+ channels, resulting in I_{Na} reduction, deepening of the phase 1 notch of the action potential, and aggravation of the Brugada syndrome.^{47,63,68,79}

MECHANISM OF EXERCISE-INDUCED CHANGES

Mechanisms that underlie ECG responses in the Brugada syndrome to exercise are complex, which may be related to different molecular-genetic mutations underlying the Brugada syndrome phenotype. Exercise testing can potentially aggravate the ECG abnormalities in the Brugada syndrome. However, other factors (e.g., autonomic nervous system, ion current imbalances) also play a role. Nonetheless, exercise was not found to induce ventricular arrhythmia in Brugada patients.^{47,72}

Brugada syndrome-linked loss-of-function mutations in *SCN5A* reduce I_{Na} more during tachycardia, likely secondary to accumulation of mutant Na^+ channels in the slow inactivated state. Na^+ channels activate on depolarization and inactivate within milliseconds thereafter. Before reopening, channels must recover from inactivation during diastole. At fast heart rates, the diastolic interval becomes too short for mutant channels to completely recover from the slow inactivated state, resulting in decreased availability of open channels and, as a consequence, accentuation of Na^+ channel loss of function produced by *SCN5A* mutations.^{47,72}

MECHANISM OF DRUG EFFECTS

Pharmacological agents that primarily block I_{Na} but not I_{to} (flecainide, ajmaline, and procainamide) can further diminish I_{Na} that is already reduced by the Brugada mutations. This may explain the

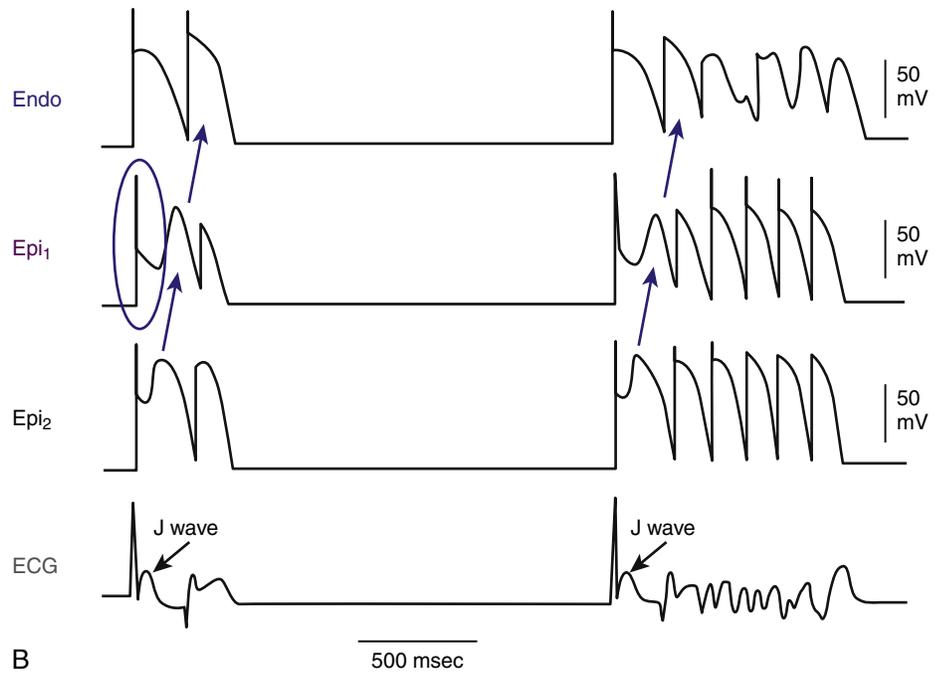

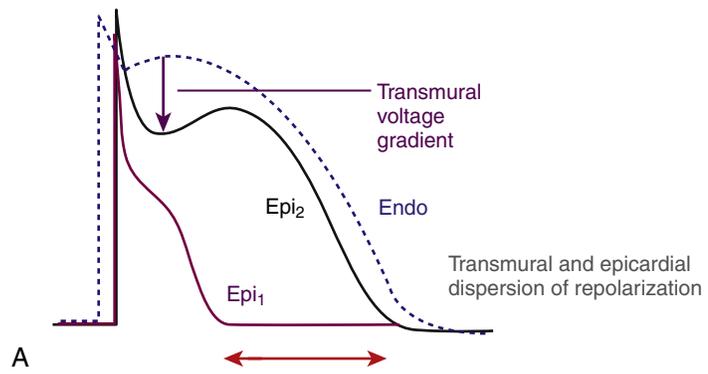

FIGURE 31-7 Potential mechanism for arrhythmogenesis in the Brugada and early repolarization syndromes. **A**, With enhanced repolarization in regions with prominent transient outward current (I_{to}), all-or-none repolarization can occur, creating a substrate for arrhythmias. **B**, Simultaneous action potentials from two epicardial sites (Epi_1 and Epi_2) and one endocardial site (Endo), and surface ECG. A loss of the action potential dome in Epi_1 , but not in Epi_2 , leads to apparent propagation of the dome from Epi_2 to Epi_1 , inducing reentry. (Reproduced with permission from Benito B, Guasch E, Rivard L, Nattel S: Clinical and mechanistic issues in early repolarization of normal variants and lethal arrhythmia syndromes, *J Am Coll Cardiol* 56:1177-1186, 2010.)

use of Na^+ channel blockers to unmask concealed forms of the Brugada syndrome and the potential proarrhythmic adverse effects of these and other pharmacological agents. In contrast, quinidine, in addition to blocking I_{Na} , has a relatively strong effect in blocking I_{to} . Hence, quinidine can effectively suppress ST elevation and ventricular arrhythmias in patients with the Brugada syndrome.⁶⁴

Beta-adrenergic stimulation induces increased inward I_{CaL} and attenuates the excess of outward current, resulting in reduction of ST segment elevation in right precordial leads and potentially underlying the therapeutic benefit observed for isoproterenol infusion for prevention of ventricular arrhythmias in Brugada syndrome patients with electrical storm. In contrast, acetylcholine facilitates the loss of the action potential dome by suppressing I_{CaL} and/or augmenting K^+ current.⁸⁰

Differential Diagnosis

A variety of pharmacological agents and conditions have been reported to produce a Brugada-like ST segment elevation, although the likelihood of arrhythmias is unclear. In general, factors that increase outward currents (e.g., I_{to} , I_{KATP} , I_{Kr} , I_{Ks}) or decrease inward currents (e.g., I_{Na} , I_{CaL}) at the end of phase 1 of the action potential can potentially accentuate or unmask ST segment elevation similar to the ECG pattern observed in patients with the Brugada syndrome.

Among antiarrhythmic drugs, class IC agents (flecainide, propafenone, pilsicainide) most effectively amplify or unmask ST segment elevation, owing to their strong use-dependent blocking effect

of the fast I_{Na} . Pilsicainide, a pure class IC drug, is likely to more strongly induce ST segment elevation than flecainide, because the latter also mildly blocks I_{to} .

On the other hand, class IA drugs (ajmaline, procainamide, disopyramide) exhibit less use-dependent block of fast I_{Na} and, consequently, induce a weaker ST segment elevation than class IC drugs. Additionally, the degree of I_{to} blockade inflicted by class IA agents can ameliorate their I_{Na} -blocking effect and, as a consequence, influence the degree of ST elevation. Ajmaline exhibits less inhibition of I_{to} and induces more pronounced ST segment elevation than flecainide. In contrast, quinidine generally normalizes ST segment elevation, despite its I_{Na} -blocking effect, owing to its relatively strong I_{to} -blocking effect.

Class IB antiarrhythmic drugs (lidocaine, mexiletine) block fast I_{Na} primarily at fast heart rates (because of the rapid dissociation of these drugs from Na^+ channels). Therefore, these drugs have little or no effect on fast I_{Na} at moderate or slow heart rates.

Several psychotropic drugs have been reported to unmask Brugada-like ST segment elevation, secondary to block of fast I_{Na} usually with drug overdose. Other drugs that can potentially unmask a Brugada-like ECG pattern include verapamil, lithium, H_1 antihistamines, propofol, alcohol intoxication, cocaine intoxication, and potentially nitrates, vagomimetic agents, and beta blockers (Table 31-9).⁶⁴

Whether this “acquired” form of Brugada syndrome unmasks clinically inapparent Brugada syndrome (“forme fruste”) or merely represents one end of a broad spectrum of responses to Na^+ channel blockers is not known. The prognosis of asymptomatic patients

TABLE 31-9 Drug-Induced Brugada Syndrome

DRUG GROUP	EXAMPLE(S)
Class IC antiarrhythmic drugs	Flecainide, propafenone, pilsicainide
Class IA antiarrhythmic drugs	Ajmaline, procainamide, disopyramide
Calcium channel blockers	Verapamil, diltiazem, nifedipine
Beta blockers	Propranolol
H ₁ -Antihistamines	Dimenhydrinate
Tricyclic antidepressants	Amitriptyline, nortriptyline, desipramine
Tetracyclic antidepressants	Maprotiline
Selective serotonin reuptake inhibitors	Fluoxetine
Phenothiazines	Perphenazine, trifluoperazine
Local anesthetics	Bupivacaine
Other drugs	Lithium, nitrates, propofol

with drug-induced Brugada ECG pattern, but without a family history of SCD, appears to be benign once the offending agent is discontinued, provided the full-blown Brugada syndrome is not uncovered.⁶⁴

In addition to drug-induced Brugada syndrome, it is also important to exclude a variety of pathological and physiological conditions that can potentially mimic the Brugada ECG pattern. These include atypical RBBB, LV hypertrophy, pulmonary embolism, acute pericarditis, various central and autonomic nervous system abnormalities, hyperkalemia, hypercalcemia, ARVD, mechanical compression of the RVOT (e.g., by tumor), pectus excavatum, hyperthermia, and hypothermia. Acute myocardial infarction or ischemia involving the RVOT can produce Brugada-like ST elevation, likely because of the attenuation of I_{CaL} and enhancement of I_{KATP} during ischemia. Additionally, a Brugada-like ST elevation can occasionally appear for a brief period after direct-current cardioversion; it is not known whether these patients are gene carriers for the Brugada syndrome.^{61,65}

Early repolarization syndromes (J wave syndromes) can mimic Brugada ECG pattern (see later discussion). ST segment elevation encountered in healthy well-trained athletes is usually distinguished from Brugada ECG pattern by an upslope rather than a downslope of the ST segment and by remaining largely unaffected by challenge with a Na⁺ channel blocker.^{61,65}

Risk Stratification

Brugada syndrome patients initially presenting with aborted SCD are at the highest risk for a recurrence (69% at 54 ± 54 months of follow-up), whereas patients presenting with syncope and a spontaneously appearing type 1 ECG have a recurrence rate of 19% at 26 ± 36 months of follow-up.^{65,69}

On the other hand, risk stratification in asymptomatic patients with Brugada syndrome has been a matter of continuous controversy in recent years. Multiple reports suggested that male gender and spontaneous occurrence of type 1 ST elevation predict higher risk for cardiac events (syncope, aborted cardiac arrest, SCD; odds ratios, 3.47 and 4.65, respectively), whereas asymptomatic patients in whom ST segment elevation appeared only after provocation with Na⁺ channel blockers appear to be at minimal risk for arrhythmic events.

Importantly, familial forms of the Brugada syndrome do not appear to be associated with a worse prognosis than are sporadic cases; in other words, a positive family history of Brugada syndrome does not predict outcome. Similarly, a positive family history for SCD and the identification of an *SCN5A* genotype are not reliable predictors for poor outcome in asymptomatic patients.^{66,69,81}

The usefulness of inducibility of ventricular arrhythmias by programmed stimulation as a predictor for poor outcome has been

debated and is unresolved. VF or sustained polymorphic VT can be induced in approximately 50% to 70% of Brugada patients during EP testing. Whereas some investigators found programmed stimulation to be a useful discriminator of risk, others have not found it to be predictive. These discrepancies are likely the result of differences in patient characteristics, subtle differences in the diagnostic criteria, and the use of nonstandardized or noncomparable stimulation protocols. It is important to recognize that VF can be induced by programmed electrical stimulation in 6% to 9% of apparently healthy individuals and can represent a false-positive and nonspecific response, particularly when aggressive stimulation protocols are used.^{65,66,69}

Patients with a type 2 or 3 ECG pattern that did not convert to type 1 during drug challenge testing were found to have a good prognosis and noninducible ventricular arrhythmias during programmed electrical stimulation. However, in a recent report, the prognosis of probands with non-type 1 Brugada-pattern ECG (even after challenge with a Na⁺ channel blocker) was similar to that of patients with spontaneous or drug-induced type 1 ST elevation. Patients presenting with aborted cardiac arrest had a grim prognosis (annual rate of arrhythmic events of 10.6%), whereas those presenting with syncope or no symptoms had an excellent prognosis (annual rate of arrhythmic events ≤1.2%) irrespective of their ECG pattern (that is, type 1 versus non-type 1). Also, a family history of SCD at age less than 45 years and coexistence of early repolarization in the inferolateral leads (observed in 8% to 11% of Brugada patients) were predictors of poor outcome. In contrast, VT/VF inducibility during programmed stimulation was not a predictor of outcome. Furthermore, men with a spontaneous type 1 ECG recorded only at the higher leads V₁ and V₂ showed a prognosis similar to that of men with a type 1 ECG when using standard leads.^{73,81}

Principles of Management

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

Currently, an ICD is the only proven effective treatment for the Brugada syndrome. There is general consensus that ICD implantation is recommended in patients with type 1 Brugada ECG (either spontaneously or after Na⁺ channel blockade) and a history of aborted SCD or related symptoms such as syncope, seizure, or nocturnal agonal respiration, given that noncardiac causes of these symptoms have been carefully excluded. The cumulative efficacy of ICD therapy (at least one appropriate defibrillation) in these patients is 18%, 24%, 32%, 36%, and 38% at 1, 2, 3, 4, and 5 years of follow-up, respectively. ICD devices need to be carefully programmed in Brugada syndrome patients in order to avoid inappropriate shocks, given the high incidence of supraventricular arrhythmias (especially AF) in this population. Programming a single VF zone of more than 210 beats/min with or without a monitoring zone of more than 180 beats/min is preferable.^{65,82}

On the other hand, there is no similar consensus regarding the management of asymptomatic patients with the Brugada syndrome. Whereas some experts advocate close follow-up, others propose the evaluation of VT/VF inducibility by programmed stimulation for risk stratification and to decide on ICD implantation in patients with spontaneous type 1 Brugada ECG. It is important to recognize that ICD therapy is not without complications. A recent study of ICD use in 220 patients with the Brugada syndrome, of whom nearly 50% were symptomatic, showed that during a 3-year follow-up inappropriate shocks occurred 2.5 times more frequently (20%) than appropriate shocks (8%), and other procedure-related complications occurred in 8% of patients. Therefore, more studies are needed to define further the risk stratification strategy in these patients.⁸²

For asymptomatic patients with normal baseline ECG and those with spontaneous type 1 Brugada ECG but noninducible VT/VF during programmed stimulation, reassurance is adequate management.^{65,69}

CATHETER ABLATION

In Brugada syndrome patients with frequent episodes of VT/VF, monomorphic PVCs originating predominantly in the RVOT or RV Purkinje network are often the trigger for VT, and focal RF ablation of the PVCs can be valuable in reducing the burden of arrhythmias and ICD therapies. Furthermore, recent work suggests that extensive ablation over the RVOT epicardium can revert the ECG pattern to normal and eliminate episodes of VT/VF.

PHARMACOLOGICAL THERAPY

At present, there is no specific pharmacological treatment to prevent SCD in patients with Brugada syndrome. Because of the critical role of I_{to} in the arrhythmogenesis in the Brugada syndrome, I_{to} blockade may be protective. Additionally, agents that augment I_{CaL} have been shown to have a therapeutic value. Both groups of drugs can potentially restore the RV epicardial action potential dome, thus normalizing the ST segment and preventing phase 2 reentry and polymorphic VT in the Brugada syndrome. Although clinical evidence of the long-term efficacy in the prevention of SCD is limited, the use of I_{to} blockers and agents that augment I_{CaL} may be considered in high-risk patients who are not candidates for ICD implantation, as adjunctive chronic treatment in ICD patients with frequent appropriate ICD therapies, as well as in patients with VF storm.^{65,67} Additionally, these agents may be considered as an alternative therapeutic strategy to early ICD implant if an acceptable therapeutic response (i.e., ECG normalization and noninducibility of ventricular arrhythmia on programmed stimulation) can be achieved. Further systematic evaluation of the usefulness of these oral agents in larger numbers of Brugada patients is required to make a definitive conclusion.^{67,69}

Quinidine, a class IA Na^+ channel blocker, has a relatively strong effect in blocking I_{to} and has been found effective in suppressing arrhythmia inducibility on EP testing in up to 76% of Brugada syndrome patients as well as in preventing the occurrence of spontaneous arrhythmias. Relatively high doses (1200 to 1500 mg/day) of quinidine are recommended.

Denopamine, an alpha/beta-adrenergic stimulant, also can potentially be effective as a chronic treatment, probably by increasing I_{CaL} . Also, cilostazol, a phosphodiesterase III inhibitor that increases I_{CaL} , has been reported to be effective in suppressing VF in Brugada syndrome. More recently, bepridil was shown to suppress the incidence of VF episodes, probably by blocking I_{to} . Tedisamil, an experimental potent I_{to} blocker without the relatively strong inward current-blocking actions of quinidine, may become a therapeutic option.

In patients with Brugada syndrome and electrical storm of VF, isoproterenol, a beta-adrenergic agonist, is reported to decrease ST elevation and suppress repetitive episodes of VF, likely via augmentation of I_{CaL} . In one report, five of seven patients with VF storm were successfully treated with isoproterenol infusion (dose titrated to achieve a 20% increase in heart rate). However, discontinuation or decrease in the infusion rate often resulted in recurrence of arrhythmias, and the total duration of intravenous therapy was quite long (average, 20 days). Eventually, all patients were successfully switched to oral medications (denopamine, quinidine, cilostazol, bepridil, or a combination thereof). Before consideration of isoproterenol therapy, however, it is critical that the diagnosis of Brugada syndrome be clearly established as the underlying etiology of VF storm. Isoproterenol infusion can be devastating in patients with VF due to other mechanisms, especially CPVT. This is especially important to recognize because a Brugada-like ST segment elevation can occasionally appear for a brief period in a patient successfully defibrillated from VF.⁶⁷

Interestingly, in some *SCN5A* mutations that impair protein trafficking to the cell membrane, mexiletine (a class IB Na^+ channel blocker) has the potential to serve as a mutation-specific therapy. Mexiletine binds to mutant proteins and acts as a molecular chaperone to rescue their trafficking to the sarcolemma and restore I_{Na} . However, it is questionable whether such drugs can be used as

therapy because (once expressed on the sarcolemma) the mutant proteins can potentially display arrhythmia-causing gating defects. Moreover, Na^+ channel-blocking effects of the drug reduce I_{Na} and, hence, can potentially aggravate the ECG changes or trigger arrhythmias in the Brugada syndrome.⁴⁷

Finally, several drugs have been reported to exacerbate the ECG pattern of ST segment elevation in the Brugada syndrome and to trigger arrhythmias, and should be avoided. These drugs include antiarrhythmics (class IA, IC), beta blockers, tricyclic antidepressants, local anesthetics (bupivacaine), opioid analgesics (propoxyphene), propofol, K^+ channel activators (pinacidil), lithium, cocaine, alpha-adrenergic agonists (methoxamine), and vagomimetic agents. Furthermore, fever, which can potentially trigger fatal events, should be treated promptly.⁶⁵ It should be stressed that ventricular arrhythmias in Brugada syndrome respond differently from most other VTs in that they are suppressed by sympathomimetic agents and enhanced by vagomimetic agents.

PARTICIPATION IN SPORTS

Although a clear association between exercise and SCD has not been established, restriction to participation in class IA sports seems advisable, especially given the potential impact of hyperthermia on triggering cardiac events in patients with the Brugada syndrome. The presence of an ICD device warrants the same restrictions to class IA sports.^{59,83}

FAMILY SCREENING

Most individuals diagnosed with the Brugada syndrome have inherited the disease-causing mutation from a parent. Although a proband with the Brugada syndrome may have the disorder as the result of a de novo gene mutation, this is very rare (approximately 1%). Because the disease is inherited as autosomal dominant, each child of an individual with Brugada syndrome has a 50% chance of inheriting the mutation. Nonetheless, the family history may appear to be negative because of failure to recognize the disorder in family members, decreased penetrance, early death of the parent before the onset of warning symptoms, or late onset of symptoms in the affected parent. Therefore, the lack of a family history does not rule out a heritable disease.

It is recommended that at-risk individuals with a family history of Brugada syndrome should undergo ECG monitoring every 1 to 2 years. The presence of type 1 ST elevation should be further investigated.

Given the insensitivity of ECG changes in establishing the diagnosis, molecular genetic testing of at-risk asymptomatic family members of a patient with Brugada syndrome should be considered if the disease-causing mutation has been identified in the proband. Family members who test positive for the familial mutation should receive baseline ECG and annual ECG screening examinations, and should be instructed to avoid medications that can induce ventricular arrhythmias and to seek medical attention immediately on occurrence of symptoms.⁴¹ On the other hand, a negative genetic test result for the familial mutation would obviate the need for repeated follow-up examinations. Genetic testing also can be used for prenatal diagnosis. All patients who undergo genetic testing should receive pretest and post-test genetic counseling to understand the implications of testing.

Short QT Syndrome

The SQTS is a recently recognized inherited channelopathy, first described in 2000, occurring in young individuals with structurally normal hearts. Affected patients are characterized by constantly short QT intervals ($QTc < 360$ milliseconds) associated with AF, syncope, and/or SCD.⁸⁴

Epidemiology

SQTS has been described in very few families worldwide; therefore, all the information available is based on small numbers of cases.

The majority (75.4%) of affected subjects have been men. The age of presentation is quite variable, ranging from infancy to the eighth decade of life, with a mean age of 20 to 30 years. Up to 72% of patients with SQTs have a family history of SQTs or SCD.^{84,85}

Clinical Presentation

More than 60% of the subjects have symptoms at presentation, with cardiac arrest being the most frequent symptom, representing the first clinical manifestation in one-third of patients. Syncope is observed as a first clinical presentation less frequently (14%). AF has been documented in approximately 30% of patients with SQTs. No information is available on whether specific triggers may precipitate cardiac events, as cardiac arrest has occurred both at rest and under stress.^{84,85}

Electrocardiographic Features

In the reported cases of SQTs, the QTc interval (using the Bazett formula) was always less than 320 milliseconds, except for the three cases with loss-of-function mutations of the cardiac L-type Ca²⁺ channel associated with familial SCD and a Brugada syndrome phenotype, in whom the QTc interval was less than 360 milliseconds.

In addition to constantly short QTc intervals, affected patients have in common a short or even absent ST segment, with the T wave initiating immediately from the S wave. Extreme abbreviation of the J_{point}-T_{peak} interval (<120 milliseconds) can help distinguish patients with SQTs from healthy subjects with an apparent abbreviation of the ST segment and shortened QT intervals (mean J_{point}-T_{peak} interval of 188 ± 11 milliseconds). Additionally, high-amplitude, narrow, and symmetrical T waves in the precordial leads are frequently observed in SQTs patients.⁸⁴

Furthermore, the physiological shortening of the QT interval during exercise-induced tachycardia can be blunted in patients with SQTs.⁸⁴

Diagnosis of the Short QT Syndrome

At present, there is still no clear consensus concerning the definition of the lower limit of a “normal” QT interval or the diagnostic criteria sufficient to establish the diagnosis of SQTs. Based on ECG analysis of 14,379 healthy individuals, some investigators proposed that a QTc interval less than 350 milliseconds, which is less than 88% of the mean predicted value (i.e., >2 standard deviations below the mean), be considered short, and a QTc interval less than 320 milliseconds, which is less than 80% of the mean predicted value, be considered abnormally short. The prevalence of a QTc interval less than 88% was 2.5% and that of a QTc interval less than 80% was 0.03%.

Importantly, the presence of a short QT interval on the surface ECG is not sufficient to make a diagnosis of SQTs and does not imply a significant risk of SCD. In fact, in a recent study in a middle-aged Finnish population (n = 10,822) followed up for 29 ± 10 years, the prevalence of QTc less than 320 milliseconds (using the Bazett formula) was 0.1% and that of QTc less than 340 milliseconds was 0.4%. There was no difference in the all-cause or cardiovascular mortality between subjects with a very short QTc (≤320 milliseconds) or short QTc (≤340 milliseconds) and those subjects with a normal QTc interval (360 to 450 milliseconds).⁸⁶ Nevertheless, the rare finding of a short QT interval should initiate exclusion of a familial occurrence. When the occurrence of a short QT interval is associated with episodes of AF, sustained palpitation, unexplained syncope, VF, and/or a positive family history for premature SCD, SQTs should be suspected. Additionally, the morphology of the T wave, the J_{point}-T_{peak} interval, and QT adaptation to heart rate acceleration can potentially help distinguish patients with SQTs from healthy patients with shortened QT intervals.

Furthermore, other potential underlying etiologies for shortening of the QT interval should be excluded, including hyperkalemia,

TABLE 31-10 Diagnostic Criteria of the Short QT Syndrome

QTc	
<370 msec	1
<350 msec	2
<330 msec	3
J _{point} -T _{peak} Interval < 120 msec	1
Clinical History*	
History of sudden cardiac arrest	2
Documented polymorphic VT or VF	2
Unexplained syncope	1
Atrial fibrillation	1
Family History*	
First- or second-degree relative with high-probability SQTs	2
First- or second-degree relative with autopsy-negative sudden cardiac death	1
Sudden infant death syndrome	1
Genotype*	
Genotype positive	2
Mutation of undetermined significance in a culprit gene	1

Notes:

- High-probability SQTs, ≥4 points; intermediate-probability SQTs, 3 points; low-probability SQTs, ≤2 points.
- ECG: Must be recorded in the absence of modifiers known to shorten the QT.
- J_{point}-T_{peak} interval must be measured in the precordial lead with the greatest amplitude T wave.
- Clinical history: Events must occur in the absence of an identifiable etiology, including structural heart disease.
- Points cannot be combined for the following three markers: cardiac arrest, documented polymorphic VT, and unexplained syncope.
- Family history: Points can only be received once in this section.
- A minimum of 1 point must be obtained in the electrocardiographic section in order to obtain additional points.

QTc = corrected QT interval; SQTs = short QT syndrome; VF = ventricular fibrillation; VT = ventricular tachycardia.

hypercalcemia, hyperthermia, acidosis, digitalis overdose, and/or administration of acetylcholine and catecholamines.⁸⁴

The role of EP study in diagnosis and risk stratification is not yet fully defined. During EP testing, atrial and ventricular effective refractory periods are significantly shortened, and VT/VF is inducible in 60% to 91% of patients. However, whether inducibility of ventricular arrhythmias is predictive of adverse clinical outcome remains unclear.⁸⁴

Genetic analysis may be considered for patients with a strong clinical index of suspicion for SQTs based on the personal and family history, and ECG phenotype.⁴¹ A mutation in genes related to SQTs is observed in 23% of probands.⁸⁵ Genetic testing can help identify silent carriers of SQTs-related mutations; however, the risk of cardiac events in genetically affected individuals with a normal ECG is currently not known. Similarly, given the limited number of patients with SQTs so far identified, genetic analysis at present does not contribute to risk stratification.

A diagnostic scoring system to facilitate diagnosis of SQTs has been proposed recently, based on a comprehensive review of 61 reported cases of the SQTs. The diagnostic criteria incorporate the ECG findings, clinical history, family history, as well as genotype findings (Table 31-10). In this system, all patients should have a QTc interval (using the Bazett formula) of no more than 370 milliseconds. Clinical events (cardiac arrest, nonsustained polymorphic VT or VF, syncope, AF) must occur in the absence of other identified clinical pathologies. Although these diagnostic criteria can potentially facilitate evaluation in suspected cases of SQTs, their value for evaluation of family members can potentially be

TABLE 31-11 Molecular Basis of the Short QT Syndrome

DISEASE	GENE	PROTEIN	IONIC CURRENT	FUNCTION	INHERITANCE
SQT1	<i>KCNH2 (HERG)</i>	K _v 11.1	Subunit alpha I _{Kr}	Gain	Autosomal dominant

I_{CaL} = L-type Ca²⁺ current; I_{K1} = inward rectifier K⁺ current; I_{Kr} = rapidly activating delayed rectifier K⁺ current; I_{Ks} = slowly activating delayed rectifier K⁺ current; SQT1 to SQT5 = short QT syndrome types 1 to 5, respectively.

limited because of incomplete disease penetrance. Importantly, treatment considerations should be reserved for subjects receiving a high-probability score, whereas medical surveillance or expert opinion should be considered for intermediate- or low-probability cases.⁸⁷

Genetics of the Short QT Syndrome

To date, mutation analysis has implicated five distinct genes in the etiology of a proportion of patients diagnosed with SQTS, although the majority of diagnosed cases do not have reported genetic associations. It is expected that further genes will be identified. Genetic studies reveal a genetically heterogeneous disease with gain-of-function mutations of voltage-gated K⁺ channel genes and loss-of-function mutation in the L-type Ca²⁺ channel genes (Table 31-11). These mutations cause either an increase in the outward repolarizing K⁺ currents or a decrease in the inward depolarizing currents, leading to shortening of the action potential duration, the QT interval, and the effective refractory period. Shortening of refractoriness is a key mechanism predisposing to increased atrial and ventricular susceptibility to premature stimulation, leading to AF and VF.⁸⁴

SQT1, the most common genotype, is caused by mutations of the *KCNH2* gene (*HERG*, encoding the alpha subunit K_v11.1 of the I_{Kr}). A gain-of-function mutation on *KCNH2* causes a shift of voltage dependence of inactivation of I_{Kr} by +90 mV out of the range of the action potential, which results in a significant increase in I_{Kr} during the action potential plateau. The resulting I_{Kr} increase achieved by altered gating hastens repolarization, thereby shortening action potential duration and facilitating reentrant excitation waves to induce atrial and/or ventricular arrhythmia. Additionally, gain-of-function mutations in *KCNE2* (MiRP1) have been found in two families with AF. In contrast, loss-of-function mutations in the *KCNH2* gene are responsible for LQT2.^{11,49,53,85}

SQT2 is caused by mutations of the *KCNQ1* gene (*K_vLQT1*, encoding the alpha subunit K_v7.1 of the I_{Ks}). A gain-of-function mutation of *KCNQ1* causes a shift in the voltage dependence of I_{Ks} activation by -20 mV and acceleration of activation kinetics, leading to enhancement of I_{Ks} and of the action potential duration and shortening of the QT interval. Loss-of-function mutations in the *KCNQ1* gene are responsible for LQT1.

SQT3 is caused by a mutation in the *KCNJ2* gene (encoding for the strong inwardly rectifying channel protein Kir2.1 of the I_{K1}). A gain-of-function mutation causes a significant increase in the outward I_{K1} at potentials between -75 and -45 mV, leading to shortening of the QT interval and asymmetrical T waves with a rapid terminal phase. On the other hand, loss-of-function mutations in the *KCNJ2* gene, identified in patients with the Andersen syndrome, generate prolongation of the QT intervals (LQT7).⁸⁴

SQT4 is caused by mutations of the *CACNA1C* gene (encoding the alpha₁ subunit Ca_v1.2 of the cardiac L-type Ca²⁺ channel) and SQT5 is caused by mutations of the *CACNB2* gene (encoding the beta_{2b} subunit of the cardiac L-type Ca²⁺ channel). Loss-of-function mutations of those genes result in major attenuation in I_{CaL} amplitude, leading to shortening of the action potential duration, and are associated with asymmetrical T waves, attenuated

QT-heart rate relationship, and AF. The three patients reported to harbor these mutations had a Brugada type 1 phenotype. Additionally, loss-of-function mutations of the *CACNA1C* and *CACNB2* genes have recently been linked to a sudden death syndrome that combines the features of Brugada syndrome, including the characteristic ECG pattern, and a short QT interval. It was speculated that these mutations cause Brugada syndrome by aggravating transmural voltage gradients. Conversely, a gain-of-function mutation of the Ca²⁺ channel is known to generate the LQT8 (Timothy syndrome).^{88,89}

Principles of Management

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

At present, ICD implantation is the therapy of choice for the prevention of SCD in symptomatic patients with SQTS. Importantly, patients with SQTS are potentially susceptible to inappropriate shocks because of the tall, narrow T waves and the high prevalence of AF.^{84,90}

PHARMACOLOGICAL THERAPY

Quinidine was shown to prolong the QT interval, normalize atrial and ventricular effective refractory periods, and prevent inducibility of ventricular arrhythmias during EP testing in patients with SQT1. In a recent report, the incidence of arrhythmic events during the follow-up was 4.9% per year in the patients without pharmacological prophylaxis, whereas no arrhythmic events occurred in those receiving hydroquinidine (even if previously symptomatic).⁸⁵

Hence, quinidine can potentially serve as an adjunct to ICD therapy in the treatment of paroxysmal AF or recurrent ventricular tachyarrhythmias in this subgroup of patients or as an alternative option to ICD in patients who cannot receive it (children) or who decline the implant.^{84,85}

PARTICIPATION IN SPORTS

Until the phenotype of SQTS is better understood, a universal restriction from competitive sports with the possible exception of class IA activities seems to represent the most prudent recommendation.⁵⁹

Catecholaminergic Polymorphic Ventricular Tachycardia

CPVT, also known as familial polymorphic VT, is a rare but highly malignant inherited arrhythmia disorder characterized by exercise- and stress-induced polymorphic or bidirectional VT, which is an important cause of syncope and SCD in individuals with a structurally normal heart.^{91,92}

Epidemiology

The prevalence of CPVT has been estimated to be 1:10,000. The mean age of onset is between 7 and 9 years, although later onset

has been reported. Approximately 30% of probands have a family history of stress-related syncope, seizure, or SCD before age 40 years. There is a high level of penetrance of the disease (75% to 80%).⁹³

Clinical Presentation

CPVT patients typically present with syncope triggered by exercise or emotion, and a distinctive pattern of reproducible, stress-related, bidirectional VT in the absence of structural heart disease or QT interval prolongation.

CPVT is one of the most malignant forms of ventricular arrhythmia. Approximately 80% of untreated CPVT patients develop symptoms (syncope, VT or VF) by age 40 and overall mortality is 30% to 50%.⁹¹ SCD can be the first manifestation of the disease in a significant proportion of cases.⁹⁴

Electrocardiographic Features

The resting ECG of patients with CPVT is often normal, without prolongation or shortening of the QT interval, atrioventricular and intraventricular conduction defects, or Brugada-like ST elevation. Sinus bradycardia and prominent U waves can be observed in some patients.

The distinguishing ventricular arrhythmia of CPVT ("bidirectional VT") is characterized by alternating QRS axis with 180-degree rotation on a beat-to-beat basis. However, the typical bidirectional VT is not observed in all patients. In one report, bidirectional VT was documented in only 35% of probands, whereas the remaining patients showed polymorphic VT or VF. Importantly, the morphology of VT, which is polymorphic or bidirectional, is strongly dependent on the ECG recording lead. When the maximal QRS vector changes in one lead during bidirectional VT, the axis perpendicular to the former lead shows polymorphic VT. However, unlike other polymorphic VTs, such as torsades de pointes, the QRS morphology is not chaotic but has some regularity.^{94,95}

A characteristic feature of CPVT is the progressive worsening of arrhythmias with increasing exercise workload. Ventricular arrhythmias during exercise stress testing appear quite consistently at a heart rate of 110 to 130 beats/min; initially, polymorphic PVCs appear. The complexity and frequency of arrhythmias progressively worsen as workload increases: ventricular bigeminy, salvos of polymorphic PVCs, and polymorphic or bidirectional VT, often appearing in this order. If exercise is not promptly discontinued, bidirectional VT may degenerate into polymorphic VT and VF. On termination of exercise, arrhythmias progressively diminish in term of VT rate and VT duration until they disappear. Isolated premature atrial complexes, nonsustained supraventricular tachycardia, and short runs of AF usually are observed during exercise, with an onset at a range of heart rates similar to or slower than that of ventricular arrhythmias.^{94,95}

Diagnosis of Catecholaminergic Polymorphic Ventricular Tachycardia

Diagnosing CPVT patients may be challenging because the resting ECG, echocardiography, signal-averaging ECG, and EP testing frequently are completely normal. Clinical diagnosis is made based on symptoms (syncope or aborted SCD), family history, and response to exercise or isoproterenol infusion. Ventricular arrhythmias can be observed with a combination of Holter monitoring, exercise, and drug provocation in more than 80% of patients.

CPVT diagnosis is frequently missed or delayed, unless exercise stress testing or ambulatory cardiac monitoring is performed to document ventricular arrhythmias. Not infrequently, syncopal episodes are considered as vasovagal in origin, and no further workup is performed. If the loss of consciousness is associated with convulsions, it may be misdiagnosed as epileptic seizures if a prolonged circulatory arrest resulted in brain ischemia. Unexplained cardiac arrest also is frequently misdiagnosed as idiopathic VF.⁹³ CPVT should be

suspected when a syncopal episode induced by exercise or emotion occurs in a child or in a young patient with a normal resting ECG and no structural heart disease. Additionally, CPVT should be considered in all cases of idiopathic VF and unexplained cardiac arrest (normal coronary arteries, normal ventricular function, and normal ECG), especially if an adrenergic trigger is present.^{93,94}

A standardized exercise stress test is the most important step for diagnosis of CPVT. In at least 80% of CPVT patients, exercise stress testing induces ventricular arrhythmias, which typically appear when the sinus rate exceeds an individual threshold rate (usually at 110 to 130 beats/min). As noted, the progressive worsening of arrhythmias during exercise is highly reproducible and is a diagnostic marker of CPVT. Progressive ventricular arrhythmias can also be provoked by intravenous infusion of catecholamines (e.g., isoproterenol or epinephrine).^{91,95}

Sometimes, the exercise-provoked arrhythmias can be demonstrated only after a delay of months or more after the first syncopal episode has occurred, emphasizing the necessity of repeated exercise stress tests when there is a high suspicion of CPVT.⁹⁵

Additionally, continuous ambulatory monitoring may reveal arrhythmias typical for CPVT if the sinus rate of the patient exceeds the individual arrhythmia-inducing threshold during monitoring, and can be very useful in young children, whenever performing a maximal exercise stress test is difficult. Implantation of a loop recorder can also be valuable in some cases.^{93,95}

Invasive EP testing is of no value in the diagnosis or risk stratification in patients with CPVT. Arrhythmias are seldom inducible by programmed electrical stimulation.^{93,95}

Genetic testing should be performed in all definitive CPVT probands and also considered in subjects with idiopathic VF when an adrenergic trigger is identified.⁴¹ Using a comprehensive screening approach, the percentage of successfully genotyped CPVT patients is approximately 55% to 60%. However, because the cardiac ryanodine receptor gene (*RyR2*, which underlies the most common form of CPVT) is one of the largest genes in the human genome, genetic testing is usually time-consuming and costly. Genetic screening for disease-causing mutations in the calsequestrin gene (*CASQ2*, which underlies the autosomal recessive form of CPVT) is advisable in all pedigrees compatible with a recessive pattern of inheritance but also in all apparently sporadic CPVT cases with negative *RyR2* screening even in the absence of parental consanguinity.^{93,94}

Genetics of Catecholaminergic Polymorphic Ventricular Tachycardia

CPVT is caused by mutations in genes that encode for key Ca²⁺ regulatory proteins. Two genetic variants of CPVT have been described: an autosomal dominant trait (CPVT1; most common) caused by mutations in the *RyR2* gene, and a recessive form (CPVT2; rare) associated with homozygous mutations in the *CASQ2* gene. Heterozygous carriers of one *CASQ2* mutation are usually healthy.⁹³

RyR2 is the major calcium release channel of the sarcoplasmic reticulum, mediating excitation-contraction coupling. Approximately 50% to 70% of patients with CPVT harbor *RyR2* mutations. To date, more than 70 *RyR2* mutations linked to CPVT have been identified. CPVT mutant *RyR2*s typically show gain-of-function defects following channel activation by PKA phosphorylation (in response to beta-adrenergic stimulation or caffeine), resulting in uncontrolled Ca²⁺ release from the sarcoplasmic reticulum during electrical diastole, which facilitates the development of DADs and triggered arrhythmias.^{91,96,97}

CASQ2 is a sarcoplasmic reticulum Ca²⁺ buffering protein associated with *RyR2*. *CASQ2* plays an active role in the control of Ca²⁺ release from the sarcoplasmic reticulum to the cytosol. So far, seven *CASQ2* mutations linked to CPVT have been reported. Whereas some of these mutations are thought to compromise *CASQ2* synthesis and result in reduced expression or complete absence of *CASQ2* in the heart, other mutations seem to cause expression of defective *CASQ2* proteins with abnormal regulation of cellular Ca²⁺ homeostasis.^{91,94,96}

Missense mutations in *RyR2* also have been linked to a form of arrhythmogenic cardiomyopathy (ARVD-2) characterized by exercise-induced polymorphic VT that does not appear to have a reentrant mechanism, occurring in the absence of significant structural abnormalities. Patients do not develop characteristic features of ARVD on the 12-lead ECG or signal-averaged ECG, and global RV function remains unaffected. ARVD-2 shows a closer resemblance to familial CPVT in both etiology and phenotype; its inclusion under the umbrella term of ARVD remains controversial.⁹⁸⁻¹⁰⁰

Recently, three novel loss-of-function mutations of the *KCNJ2* gene (encoding for the strong inwardly rectifying channel protein Kir2.1 of the I_{K1}) have been found in patients with CPVT. These patients had prominent U waves, ventricular ectopy, and polymorphic VT, but no dysmorphic features or skeletal muscle abnormalities.¹⁰¹ I_{K1} reduction may trigger arrhythmia by allowing inward currents, which are no longer counterbalanced by the strong outward I_{K1} , to gradually depolarize the membrane potential during phase 4. Membrane depolarization during phase 4 induces arrhythmia by facilitating spontaneous excitability.⁵³

Pathophysiology of Catecholaminergic Polymorphic Ventricular Tachycardia

MECHANISM OF VENTRICULAR ARRHYTHMIAS

Abnormalities in the control of sarcoplasmic reticulum Ca^{2+} release constitute the central pathogenic abnormality in CPVT, although considerable controversy exists about the molecular mechanisms causing these defects. RyR2 and CASQ2 are both critically involved in the regulation of cardiac excitation-contraction coupling. Ca^{2+} influx via the L-type Ca^{2+} channels in the cell membrane during the action potential plateau triggers more massive Ca^{2+} release (Ca^{2+} transients) from the sarcoplasmic reticulum into the cytosol via activation of Ca^{2+} release channels (RyR2). This amplifying process, termed Ca^{2+} -induced Ca^{2+} release (CICR), causes a rapid increase in cytosolic Ca^{2+} concentration to a level required for optimal binding of Ca^{2+} to troponin C and induction of contraction.^{89,97,102} During diastole, most of the surplus Ca^{2+} in the cytosol is resequenced into the sarcoplasmic reticulum by the sarcoplasmic/endoplasmic reticulum calcium adenosine triphosphatase (SERCA), the activity of which is controlled by the phosphoprotein phospholamban. Additionally, some of the Ca^{2+} is extruded from the cell by the Na^+ - Ca^{2+} exchanger to balance the Ca^{2+} that enters with the Ca^{2+} current. Recurring Ca^{2+} release-uptake cycles provide the basis for periodic elevations of the cytosolic Ca^{2+} concentration and contractions of myocytes, and hence for the orderly beating of the heart (see Fig. 3-6).^{96,103,104}

The molecular mechanisms by which *RyR2* mutations alter the physiological properties and function of RyR2 are not completely defined. It has been suggested that CPVT mutations in *RyR2* reduce the binding affinity of RyR2 for the regulatory protein FKBP12.6 (calstabin-2) that stabilizes the closed conformational state of the RyR2 channel, thus enabling the channel to close completely during diastole (at low intracellular Ca^{2+} concentrations) and preventing aberrant Ca^{2+} leakage from the sarcoplasmic reticulum, ensuring muscle relaxation. PKA phosphorylation (induced by beta-adrenergic stimulation) of the mutant channels results in further worsening of the binding affinity of FKBP12.6 for the mutant RyR2, thus increasing the probability of an open state at diastolic Ca^{2+} concentrations. As a consequence, the mutant RyR2 channel fails to completely close during diastole, resulting in diastolic Ca^{2+} leak from the sarcoplasmic reticulum during stress or exercise.^{91,96,105}

An alternative hypothesis is that CPVT mutations in *RyR2* sensitize the channel to luminal (sarcoplasmic reticulum) Ca^{2+} such that under baseline conditions, where sarcoplasmic reticulum load is normal, there is no Ca^{2+} leak. Under beta-adrenergic (sympathetic) stimulation, sarcoplasmic reticulum Ca^{2+} concentration becomes elevated above the reduced threshold, causing Ca^{2+} to leak out of the sarcoplasmic reticulum. A third hypothesis for *RyR2*-related CPVT is that mutations in *RyR2* impair the intermolecular

interactions between discrete *RyR2* domains necessary for proper folding of the channel and self-regulation of channel gating.^{96,105}

Calsequestrin is the most important Ca^{2+} storage protein in the sarcoplasmic reticulum and it forms a part of a large quaternary complex with RyR2, triadin, and junctin; all together, these proteins play a major role in regulating intracellular Ca^{2+} . Calsequestrin represents a high-capacity, low-affinity Ca^{2+} -binding protein that is able to bind luminal Ca^{2+} (40 to 50 Ca^{2+} ions per molecule) during diastole, buffering Ca^{2+} within the sarcoplasmic reticulum and preventing diastolic Ca^{2+} release via RyR2 to the cytosol. CASQ2 mutations result in disruption of the control of RyR2s by luminal Ca^{2+} required for effective termination of sarcoplasmic reticulum Ca^{2+} release and prevention of spontaneous Ca^{2+} release during diastole, leading to diminished Ca^{2+} signaling refractoriness and generation of arrhythmogenic spontaneous Ca^{2+} releases (Fig. 31-8).⁹⁶

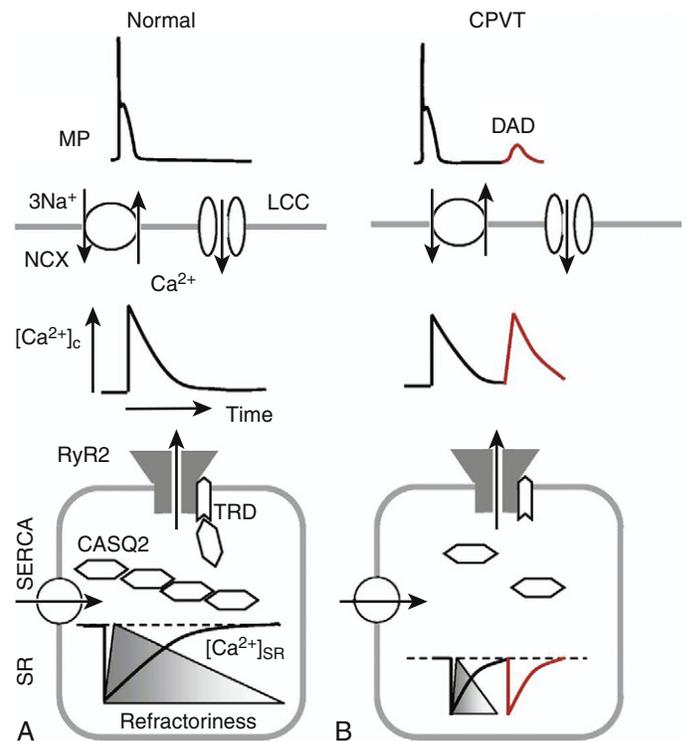

FIGURE 31-8 Calcium cycling in normal myocytes and myocytes harboring catecholaminergic polymorphic ventricular tachycardia (CPVT) *CASQ2* mutations. **A**, In normal myocytes, Ca^{2+} influx through L-type Ca^{2+} channels during the action potential activates RyR2s and initiates the release of Ca^{2+} stored in the sarcoplasmic reticulum (SR) on CASQ2 polymers. SR Ca^{2+} release terminates when the drop in intra-SR $[Ca^{2+}]_{SR}$ causes RyR2s to close because of inhibition by CASQ2 monomers at reduced $[Ca^{2+}]_{SR}$. The RyR2s stay refractory until $[Ca^{2+}]_{SR}$ is restored by SERCA. The rate of $[Ca^{2+}]_{SR}$ recovery and thus the rate of restitution from luminal Ca^{2+} -dependent refractoriness depends on both SERCA activity and the Ca^{2+} -binding capacity of CASQ2. Ca^{2+} signaling refractoriness prevents spontaneous Ca^{2+} release during diastole. **B**, Arrhythmogenic *CASQ2* mutations disrupt Ca^{2+} handling through either one or a combination of decreased CASQ2 expression, reduced CASQ2 Ca^{2+} binding capacity (via disruption of CASQ2 polymerization), and impaired CASQ2 interaction with the RyR2 complex (via TRD). Alterations in CASQ2 abundance and/or behavior result in diminished and shortened Ca^{2+} signaling refractoriness after each release through accelerating recovery of $[Ca^{2+}]_{SR}$, altering RyR2 gating dependency on $[Ca^{2+}]_{SR}$, or both. PKA-mediated stimulation of SERCA (via PLB) further accelerates SR refilling, accounting for the dependency of CPVT on adrenergic stimulation. Compromised RyR2 refractoriness results in spontaneous SR Ca^{2+} release, which in turn elicits DADs through stimulation of NCX. CASQ2 = calsequestrin; DAD = delayed afterdepolarization; LCC = L-type Ca^{2+} channel; NCX = Na^+ - Ca^{2+} exchange; PKA = protein kinase A; PLB = phospholamban; RyR2 = ryanodine receptor type 2; SERCA = sarcoplasmic/endoplasmic reticulum calcium ATPase; TRD = triadin. (Reproduced with permission from Györke S. Molecular basis of catecholaminergic polymorphic ventricular tachycardia, *Heart Rhythm* 6:123-129, 2009.)

DADs and triggered activity have been proposed as the arrhythmogenic mechanism in CPVT because the bidirectional ECG pattern of this VT closely resembles the arrhythmias associated with intracellular Ca^{2+} overload and the DADs observed during digitalis toxicity. Mutations in *RyR2* or *CASQ2* lead to cytosolic Ca^{2+} overload that results in activation of the $\text{Na}^+\text{-Ca}^{2+}$ exchanger, which in turn generates a net inward current (the so-called transient inward current [I_{Ti}]). I_{Ti} underlies diastolic membrane depolarizations (DADs), which may reach the threshold for Na^+ channel activation and trigger abnormal beats.^{91,93}

When the DADs are of low amplitude, they usually are not apparent or clinically significant. Probably the most important influence that causes subthreshold DADs to reach threshold is a decrease in the initiating cycle length; fast heart rates increase both the amplitude and rate of the DADs. Additionally, catecholamines can facilitate the development of DADs by several mechanisms, including (1) increasing the L-type Ca^{2+} current through stimulation of beta-adrenergic receptors and increasing cAMP, which results in an increase in transsarcolemmal Ca^{2+} influx and intracellular Ca^{2+} overload (see Fig. 3-6); (2) enhancing the activity of the $\text{Na}^+\text{-Ca}^{2+}$ exchanger, thus increasing the likelihood of DAD-mediated triggered activity; (3) enhancing the uptake of Ca^{2+} by the sarcoplasmic reticulum, leading to increased Ca^{2+} stored in the sarcoplasmic reticulum and the subsequent release of an increased amount of Ca^{2+} from the sarcoplasmic reticulum during contraction; and (4) increasing the heart rate. These effects underlie the increased susceptibility to ventricular arrhythmias in CPVT patients during exercise and emotional stress associated with increased sympathetic stimulation and increased heart rates.

Importantly, in the setting of digitalis poisoning, the abnormal RyR2 behavior leading to spontaneous Ca^{2+} release and DADs is secondary to the elevation of the sarcoplasmic reticulum Ca^{2+} content (store overload-induced Ca^{2+} release, SOICR). In CPVT, on the other hand, spontaneous Ca^{2+} release and DADs can occur without Ca^{2+} overload. Mutations in *RyR2* or *CASQ2* lead to defective Ca^{2+} signaling lowering of the sarcoplasmic reticulum Ca^{2+} threshold for spontaneous Ca^{2+} release below the normal baseline level (“perceived” Ca^{2+} overload). A similar mechanism may underlie triggered arrhythmias in other disease conditions, including heart failure and ischemic heart disease, in which sarcoplasmic reticulum Ca^{2+} release regulation is compromised because of acquired defects in components of the RyR2 channel complex.⁹⁶

As expected with DAD-mediated triggered activity, a positive direct correlation has been observed between the coupling interval of ventricular arrhythmias and the preceding R-R interval. This observation may also suggest that supraventricular arrhythmias commonly observed prior to the onset of ventricular arrhythmias during exercise in CPVT patients may act as a trigger for the development of DADs and triggered activity in the ventricle.⁹³

MECHANISM OF THE BIDIRECTIONAL MORPHOLOGY OF VENTRICULAR TACHYCARDIA

The EP mechanisms leading to the characteristic bidirectional morphology of the VT are not clear. Changes in conduction direction from a single ventricular focus with every other beat, VT originating from one focus that triggers another focus, and double ventricular foci (from the right and left apical portions of the heart) are some of the proposed mechanisms. The QRS morphology of bidirectional VT is inconsistent in the same recording lead, suggesting that the focus of the arrhythmia can vary to some extent.^{93,96} Some investigators suggested that CPVT starts from a single focus or double foci, usually originating from the RVOT, whereas the ensuing beats tend to originate from the LV. Others found that a left posterior inferior origin accounts for the majority of cases. Additionally, the Purkinje network has been suggested as the site of origin of bidirectional VT, with alternating firing from the right and left branches of the Purkinje fibers.⁹⁴

A recent experimental model suggested a “ping-pong” mechanism may underlie ventricular arrhythmias in CPVT, whereby

DAD-induced triggered activity develops at different heart rate thresholds in different regions of the His-Purkinje system (HPS) or ventricles. First, once the heart rate exceeds a certain threshold, ventricular bigeminy develops from a single site in the HPS or ventricular myocardium. The shortened R-R cycle length due to ventricular bigeminy induces DAD-triggered beats from a second focus within the HPS, with the latter reciprocally activating PVCs from the first focus; a process that is repeated back and forth, in a ping-pong pattern. “Reciprocating bigeminy” from the two sites produces the bidirectional VT characteristic of CPVT. Polymorphic VT results when three or more sites concurrently develop bigeminy, whereas monomorphic VT develops when repetitive DADs generate a run of triggered activity from a single site.¹⁰⁶

MECHANISM OF DRUG EFFECTS

The demonstration that DADs are the initiating mechanism for arrhythmogenesis in CPVT provides a twofold rationale for the use of beta blockers for the treatment of CPVT. Antiadrenergic therapy is a logical therapy to attenuate the effect of adrenergic stimulation induced by exercise or emotion. In addition to this effect, the bradycardia induced by beta blockers is likely to exert an additional antiarrhythmic action by reducing the probability that a DAD would reach the threshold for triggering premature beats. Accordingly, the lower the heart rate achieved with beta blocker therapy, the higher the probability of preventing malignant arrhythmias.⁹¹

Flecainide (a Na^+ channel blocker) has recently been demonstrated to prevent lethal ventricular arrhythmias in CPVT, an effect likely mediated by inducing brief closures of open RyR2 to subconductance states and, thus, reducing Ca^{2+} spark amplitude.¹⁰⁵

Differential Diagnosis

Other inherited arrhythmogenic cardiac disorders that can cause malignant ventricular tachyarrhythmias should also be excluded. A QTc interval less than 320 milliseconds should raise a suspicion of SQTS. On the other hand, a prolonged QTc suggests LQTS. Whereas the onset of clinical symptoms of LQTS is often around puberty, the first syncopal events in CPVT patients tend to occur during childhood. Importantly, induction of arrhythmias during exercise is very rare in LQTS patients. Furthermore, LQTS patients develop torsades de pointes (characterized by the twisting of the points of the QRS complexes), in contrast to CPVT patients, who manifest with the typical bidirectional VT with a beat-to-beat 180-degree rotation of the QRS complex.^{91,93,94}

Bidirectional VT can also occur in patients with type 7 LQTS (LQT7, Andersen-Tawil syndrome) linked to mutations in the *KCNJ2* gene, which may be considered a CPVT phenocopy, particularly in patients with Andersen-Tawil syndrome having borderline QT interval prolongation. SCD is exceptional among Andersen-Tawil syndrome and *KCNJ2* mutation carriers.^{16,17} Furthermore, unlike CPVT, Andersen-Tawil syndrome is characterized by extracardiac features such as periodic paralysis and facial dysmorphism.^{91,93,94}

Ankyrin-B syndrome can also manifest with catecholamine-mediated ventricular arrhythmias. Loss-of-function mutations in the *ANK2* gene (encoding cardiac ankyrin-B, a structural membrane adapter protein) result in increased intracellular concentration of Ca^{2+} and, sometimes, fatal arrhythmia. Although this syndrome has been categorized under LQTS (LQT4), the inconsistent QT interval prolongation and the varying degrees of cardiac dysfunction and arrhythmias observed (including bradycardia, sinus arrhythmia, idiopathic VF, adrenergically mediated VT, and SCD) distinguishes ankyrin-B syndrome as a clinical entity distinct from classic LQTS.

Exercise-provoked arrhythmias also can develop in ARVD, but the typical ECG pattern of ARVD and the structural abnormalities of the RV separate ARVD from CPVT. The typical arrhythmia in ARVD, monomorphic VT with a left bundle branch block (LBBB) pattern, is clearly different from the polymorphic PVCs or VT in CPVT.⁹⁵

In contrast to CPVT, patients with Brugada syndrome do not manifest polymorphic PVCs on physical effort; rather, arrhythmias

in Brugada syndrome appear usually at rest or during sleep. Furthermore, the absence of ST segment elevation in the precordial ECG leads at baseline and after provocation testing with Na⁺ channel blockers helps distinguish CPVT from Brugada syndrome.⁹⁵

Risk Stratification

Risk stratification for SCD in CPVT is not possible because of the relatively small number of patients reported. As noted, CPVT is one of the most malignant forms of ventricular arrhythmias, with a high mortality rate. CPVT patients with prior cardiac arrest and those in whom symptoms are not completely suppressed by pharmacological therapy are considered at high risk for SCD. Programmed electrical stimulation typically fails in inducing ventricular arrhythmias, and is of no value for risk stratification. Furthermore, the predictive value of inducibility of ventricular arrhythmias by catecholamine infusion or exercise for risk stratification has not been demonstrated.

Principles of Management

PHARMACOLOGICAL THERAPY

Beta blockers are the first line of treatment for CPVT and should be promptly initiated to prevent occurrence of ventricular tachyarrhythmias. Because of the poor prognosis of untreated CPVT, drug therapy is indicated for all clinically diagnosed patients and usually also for all silent carriers of a CPVT mutation. The most widely used beta blockers are nadolol (1 to 2.5 mg/kg per day) and propranolol (2.5 to 3.5 mg/kg per day). Intravenous propranolol is the treatment of choice for acute management of CPVT.

Whereas some studies have reported an almost complete prevention of cardiac events during beta blocker therapy, other studies found a high recurrence rate (up to 30% to 50%) of symptoms and even SCD despite the drug therapy, and the efficacy of beta blockers in CPVT appears to be lower than that seen in the LQT1 variant of LQTS.^{93,95}

Exercise stress testing and Holter monitoring can help determine the adequate beta blocker dosage for arrhythmia control. It should be noted, however, that the absence of exercise-provoked arrhythmias does not completely exclude the risk of arrhythmia recurrence, and the maximal tolerated dose of beta blockers should be prescribed to maximize control of arrhythmias with a goal to avoid the heart rate exceeding the threshold rate for CPVT. Furthermore, compliance with regular therapy is extremely important, because missing even a single dose can potentially lead to arrhythmias and increase the risk of SCD.^{93,95}

Recent studies show that the addition of flecainide to beta blocker therapy can effectively reduce exercise-induced ventricular arrhythmias in CPVT patients not controlled by beta blocker therapy alone.¹⁰⁷ As noted, flecainide effects are mediated by direct blockade of RyR2 channels and reduction of Ca²⁺ spark amplitude rather than Na⁺ channel blockade.¹⁰⁸⁻¹¹⁰

Limited data suggest that verapamil (an inhibitor of RyR2) can be an alternative option for treatment of CPVT. Also, verapamil can potentially provide additional protection when used in combination with beta blockers. However, because of the small number of patients and the limited follow-up, there is no conclusive evidence for recommending verapamil alone or in combination with beta blockers, and its impact on prognosis is not known.⁹⁵

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

Given that no drugs can be effective in providing complete protection from SCD, ICD therapy is recommended for CPVT patients who have survived a cardiac arrest, as well as those who continue to have symptoms (syncope or sustained or hemodynamically unstable VT) despite adequate beta blocker therapy.⁵⁸

Approximately half of ICD recipients experience an appropriate shock to terminate VT during 2 years of follow-up. It is important

to maintain the maximal tolerated dose of beta blockers in ICD patients to help reduce the risk of arrhythmic storms and ICD shocks.^{91,93}

CATHETER ABLATION

When ventricular arrhythmias are triggered by monomorphic PVCs, catheter ablation of the focus of PVCs may be attempted to help reduce the frequency and burden of arrhythmias and ICD shocks. Not infrequently, the initiating beat of VT exhibits an LBBB–inferior axis pattern, suggestive of a ventricular outflow tract origin.¹¹¹

SYMPATHETIC DENERVATION

Small case series suggest the effectiveness of left cardiac sympathetic denervation in patients with recurrent symptoms despite beta blocker therapy or those experiencing frequent ICD shocks or intractable arrhythmic storms.⁹³

PARTICIPATION IN SPORTS

Symptomatic CPVT patients as well as asymptomatic patients (detected as part of familial screening) with documented exercise- or isoproterenol-induced VT should refrain from all competitive sports with the possible exception of minimal contact, class IA activities. A less restrictive approach may be possible for the genotype-positive/phenotype-negative (asymptomatic, no inducible VT) athlete.⁵⁹

FAMILY SCREENING

Given the severe clinical manifestations and poor prognosis of CPVT, once CPVT diagnosis is made in a proband, it is essential to expand the evaluation to both first- and second-degree relatives to find other potential CPVT patients.⁴¹ Exercise testing, Holter monitoring, or both are used for screening family members. Importantly, some CPVT patients may not have arrhythmias in the exercise stress test during early childhood, but a change in the phenotype occurs later in life. Therefore, regular follow-up with repeated exercise stress tests is indicated, for example, for younger siblings of a CPVT patient.

Screening of family members by genetic testing is recommended when a gene mutation has been identified in the proband.⁹⁴ Considering the early age of manifestation of CPVT and its association with SIDS, confirmatory genetic testing should be performed at birth. Genetic evaluation facilitates diagnosis in silent carriers and allows implementation of preventive pharmacological therapy and reproductive risk assessment.^{41,75,112}

Early Repolarization Syndromes

Early repolarization ECG patterns, consisting of a distinct J wave or J point elevation, a notch or slur of the terminal part of the QRS, and an ST segment elevation, are predominantly found in healthy young men and have traditionally been viewed as totally benign, “normal variants.” However, this concept has been challenged by several recent studies, which suggested that early repolarization patterns in apparently healthy subjects could represent a marker of increased dispersion of repolarization and arrhythmogenesis, and of the presence of a relationship between certain repolarization patterns and some cases of idiopathic VF and SCD.^{113,114}

Epidemiology

The prevalence of early repolarization in the general population varies from 1% to 9%, depending on age (predominant in young adults), race (highest among black populations), gender (predominant in men), and the criterion for J point elevation (0.05 mV versus 0.1 mV).^{2,115} In a study of a community-based general population of 10,864 middle-aged subjects, the prevalence of early repolarization

(J point elevation >0.1 mV) was 5.8%, including 3.5% in the inferior leads, 2.4% in the lateral leads, and 0.1% in both. With J point elevation greater than 0.2 mV, the prevalence dropped to 0.33%.¹¹⁶ The ST segment after the J point was horizontal or descending in approximately 71.5% and rapidly ascending in 28.5%. In young athletes, early repolarization in the inferior and/or lateral leads was observed in up to 44%, with the majority of subjects having ascending ST segment patterns after J point elevation.¹¹⁷

Early repolarization is more frequent in patients with idiopathic VF than in control subjects (31% versus 5% in one report, 42% versus 13% in a second report). Moreover, among patients with idiopathic VF, those with early repolarization are more likely to have a history of syncope or SCD than those without early repolarization.^{115,118}

The presence of an early repolarization pattern, especially in the inferior or lateral leads, has recently been recognized in some studies as associated with vulnerability to VF and a 4- to 10-fold increase in the risk for SCD.¹¹⁵ In the 35- to 45-year age range of maximal early repolarization-related SCD incidence, a J wave is estimated to increase idiopathic VF risk from 3.4 per 100,000 to 11 per 100,000.¹¹⁸ The prevalence of inferolateral J-point elevation is higher in the family members of sudden arrhythmic death syndrome probands compared with the general population (23% versus 11%).¹¹⁹ Furthermore, J point elevation of more than 0.2 mV in inferior leads appears to be a stronger predictor of death from cardiac causes than other well-known ECG risk markers, such as the QTc interval and signs of LV hypertrophy.¹¹⁶

It is important to recognize, however, that the interrelations between epidemiological factors predisposing to early repolarization per se and SCD-associated early repolarization are still unclear.²

Electrocardiographic Features

The early repolarization pattern is a common ECG variant characterized by an elevation of the J point, ST segment elevation with upper concavity, and tall/symmetric T waves in at least two contiguous leads. The J point marks the junction between the end of the QRS complex and the beginning of the ST segment on the surface ECG. Elevation of the J point, the so-called J wave, is defined as a positive “humplike” deflection at the onset of the ST segment immediately after a positive QRS complex. In most studies, elevation of the J point and/or ST segment from the baseline by at least 0.1 mV was considered definitive of early repolarization.^{115,116} The pattern of ST segment elevation after the J point can be classified as horizontal/descending (≤ 0.1 -mV elevation of the ST segment within 100 milliseconds after the J point), or concave/rapidly ascending (>0.1 -mV elevation of ST segment within 100 milliseconds after the J point or a persistently elevated ST segment of >0.1 mV throughout the ST segment).¹¹⁷

The early repolarization pattern can vary in response to autonomic tone and heart rate. Bradycardia and increased vagal tone (e.g., during sleep) accentuate ST segment elevation. Contrariwise, tachycardia and adrenergic stimulation (e.g., exercise testing or the infusion of isoproterenol) suppress J wave amplitude and ST segment elevation. Additionally, hypothermia can induce prominent J waves (“Osborn waves”).^{2,115}

Pathophysiology of Early Repolarization Syndromes

MECHANISM OF EARLY REPOLARIZATION AND J WAVES

The exact ionic and cellular mechanisms for the J wave and early repolarization pattern are still unknown. Heterogeneity in the distribution of I_{to} channels across the myocardial wall, being more prominent in ventricular epicardium than endocardium, results in the shorter duration, prominent phase 1 notch, and “spike and dome” morphology of the epicardial action potential as compared with the endocardium. The resultant transmural voltage gradient during the early phases (phases 1 and 2) of the action potential is

thought to be responsible for the inscription of the J wave on the surface ECG (see Fig. 31-6).^{76,77}

An outward shift of currents, secondary to a decrease in the inward currents (I_{Na} and I_{CaL}), an increase in the outward K^+ currents (I_{to} , I_{Kr} , I_{Ks} , I_{KACH} , I_{KATP}), or both, can cause accentuation of the action potential notch, leading to augmentation of the J wave or the appearance of ST segment elevation on the surface ECG. An outward shift of currents that extends beyond the action potential notch not only can accentuate the J wave but also can lead to partial or complete loss of the dome of the action potential, leading to a protracted transmural voltage gradient that manifests as greater ST segment elevation and gives rise to J wave syndromes. The type of ion current affected and its regional distribution in the ventricles determines the particular phenotype (including the Brugada syndrome, early repolarization syndrome, hypothermia-induced ST segment elevation, and infarction-induced ST segment elevation).^{2,76,77}

In this context, factors that influence the kinetics of I_{to} or the other repolarization currents can modify the manifestation of the J wave on the ECG. Na^+ channel blockers (procainamide, pilsicainide, propafenone, flecainide, and disopyramide), which reduce the inward I_{Na} , can accentuate the J wave and ST segment elevation in patients with concealed J wave syndromes. Quinidine, which inhibits both I_{to} and I_{Na} , reduces the magnitude of the J wave and normalizes ST segment elevation. Additionally, acceleration of the heart rate, which is associated with reduction of I_{to} (because of the slow recovery of I_{to} from inactivation), results in a decrease in the magnitude of the J wave. Male predominance can potentially result from larger epicardial I_{to} density versus that in women.^{2,76}

MECHANISM OF ARRHYTHMOGENESIS

The exact relationship of an early repolarization pattern and malignant ventricular arrhythmias remains unclear. It is likely that the increased transmural heterogeneity of ventricular repolarization (i.e., dispersion of repolarization between epicardium and endocardium), which is responsible for J point elevation and the early repolarization pattern on the surface ECG, is also responsible for the increased vulnerability to ventricular tachyarrhythmias. A significant outward shift in current can cause partial or complete loss of the dome of the action potential in regions where I_{to} is prominent (epicardium), with the consequent loss of activation of I_{CaL} . The dome of the action potential then can propagate from regions where it is preserved (midmyocardium and endocardium) to regions where it is lost (epicardium), giving rise to phase 2 reentry, which can generate PVCs that in turn can initiate polymorphic VT or VF (see Fig. 31-7).^{2,76,116}

Differential Diagnosis

Based on the localization of the early repolarization pattern on the 12-lead surface ECG and its potential association with risk for life-threatening arrhythmias, some investigators classified early repolarization patterns into three types. In type 1, the early repolarization pattern manifests predominantly in the lateral precordial leads; this form is very prevalent among healthy male athletes and is thought to be associated with a relatively low level of risk for arrhythmic events. In type 2, the early repolarization pattern is localized to the inferior or inferolateral leads; this form is associated with a moderate level of risk. In type 3, early repolarization is more global, involving the inferior, lateral, and right precordial leads. Type 3 is associated with the highest level of risk (Table 31-12).⁷⁶

Early repolarization ECG patterns can also be observed during hypothermia, with cocaine abuse, in patients with Brugada syndrome, and with hypertrophic cardiomyopathy. In the Brugada syndrome, ST segment elevation is limited to the right precordial leads (see Table 31-12). In hypothermia, J waves (Osborne waves) can manifest diffusely in all leads or be confined to selected leads. Rarely, hypothermia can induce ECG changes that mimic those of Brugada syndrome. Although Brugada and early repolarization syndromes

TABLE 31-12 J Wave Syndromes

	Inherited				Acquired	
	EARLY REPOLARIZATION IN LATERAL LEADS (ERS TYPE 1)	EARLY REPOLARIZATION IN INFERIOR OR INFEROLATERAL LEADS (ERS TYPE 2)	GLOBAL EARLY REPOLARIZATION (ERS TYPE 3)	BRUGADA SYNDROME	ISCHEMIA-MEDIATED VT/VF	HYPOTHERMIA-MEDIATED VT/VF
Anatomical location responsible for chief electrophysiological manifestations	Anterolateral left ventricle	Inferior left ventricle	Left and right ventricles	Right ventricle	Left and right ventricles	Left and right ventricles
Leads displaying J point/J wave abnormalities	I, V ₄ -V ₆	II, III, aVF	Global	V ₁ -V ₃	Any of the 12 leads	Any of the 12 leads
Response of J wave amplitude/ST elevation to:						
Bradycardia or pause	Increase	Increase	Increase	Increase	N/A	N/A
Sodium channel blockers	Little or no change	Little or no change	Little or no change	Increase	N/A	N/A
Gender dominance	Male	Male	Male	Male	Male	Either gender
VF	Rare; commonly seen in healthy men and athletes	Yes	Yes; electrical storms	Yes	Yes	Yes

ERS = early repolarization syndrome; N/A = data not available; VF = ventricular fibrillation; VT = ventricular tachycardia.
From Antzelevitch C, Yan GX: J wave syndromes, *Heart Rhythm* 7:549-558, 2010.

differ with respect to the magnitude and lead location of abnormal J wave manifestation, they are thought to represent a continuous spectrum of phenotypic expression termed *J wave syndromes*.¹¹⁴

Risk Stratification

Although early repolarization is a common entity, unexplained SCD in young adults is very rare. Even in the 35- to 45-year age range of maximal early repolarization-related SCD incidence, a J wave is estimated to increase idiopathic VF risk from 3.4 per 100,000 to 11 per 100,000, which is still relatively low. Therefore, the incidental discovery of a J wave on routine screening should not be interpreted as a marker of "high risk" for SCD because the odds for this fatal disease would still be roughly 1:10,000. Nonetheless, the presence of early repolarization should attract careful attention in certain groups of patients. Additionally, several properties of the early repolarization pattern (location, magnitude of the J wave, and degree of ST elevation) can potentially have significant prognostic implications.^{2,118}

J WAVE AMPLITUDE

Evidence suggests that the height of J point elevation, rather than its mere presence, can potentially provide important risk stratification information. J point elevation greater than 0.2 mV in the inferior leads predicts a 2.9-fold increase in SCD risk, whereas an elevation of

at least 0.1 mV predicts a more modest (1.4-fold) increase in risk of arrhythmic death. A similar phenomenon was also observed in survivors of primary VF. It is worth noting that a J point elevation greater than 0.2 mV seems to be rare (0.3% to 0.7%) in the normal population, but was observed in 16% of patients with idiopathic VF.^{2,115,116,120}

J WAVE DISTRIBUTION

A recent study found that 46.9% of patients with VF and early repolarization exhibited the early repolarization pattern in both inferior and lateral leads.¹¹⁵ The early repolarization pattern in the inferior leads is a stronger predictor of death from cardiac causes or from arrhythmia than that localized to the lateral leads. Conversely, in asymptomatic individuals, early repolarization is most prominent in midprecordial leads (V₂ to V₄), a pattern that is especially predominant among athletes and is thought to entail a more benign prognosis.^{2,120}

J WAVE FLUCTUATION

Although the pattern of J point elevation on baseline measurement remains constant during long-term follow-up in the majority of subjects, the magnitude of J point elevation can fluctuate even without drug provocation or exercise. Marked spontaneous accentuation of J wave amplitude as well as spontaneous beat-to-beat fluctuation in the morphological pattern of early repolarization can frequently

be observed during periods of electrical storm (including frequent PVCs and episodes of VF). Therefore, transient and marked augmentation of J wave amplitude can potentially portend a high risk for VF in patients with early repolarization.^{120,121}

ST SEGMENT PATTERN

For early repolarization patterns in the inferior or lateral leads, the presence of horizontal or descending ST segments after the J point predicts an increased risk for arrhythmic death, especially if accompanied by a high-amplitude (>0.2 mV) J point elevation. In contrast, the presence of rapidly upsloping ST segments after the J point (which is the most common pattern observed in young athletes) predicts a benign prognosis.¹¹⁷

OTHER REPOLARIZATION ABNORMALITIES

The presence of only ST segment elevation or R wave slurring, without J point elevation, does not appear to predict high risk of arrhythmic events. Moreover, the presence of QRS slurring does not add diagnostic value to the presence of J point elevation, regardless of its magnitude or the leads where it is observed.¹¹⁸ Additionally, T wave alternans and QT dispersion do not appear to be useful for SCD risk stratification in early repolarization, although evidence is scarce.

EXERCISE TESTING

Exercise suppresses the early repolarization pattern both in symptomatic and asymptomatic subjects, irrespective of the location of early repolarization. Therefore, exercise testing does not seem to provide prognostic information.

INVASIVE ELECTROPHYSIOLOGICAL TESTING

Invasive EP testing is not helpful for risk stratification. Patients with early repolarization do not exhibit significantly higher inducibility with programmed ventricular stimulation than those without early repolarization. Furthermore, EP testing has limited sensitivity for risk stratification of symptomatic patients; VF is inducible by programmed stimulation in only 34% of the patients with a clinical history of VF.

GENETIC SCREENING

Genetic contributions to SCD-associated early repolarization are suggested by common familial SCD histories in symptomatic early repolarization patients. Early repolarization appears to be a heritable phenotype; offspring of early repolarization-positive parents have a 2.5-fold increased risk of presenting with early repolarization in their ECG.¹²² Additionally, in a recent report, 16% of cases with VF and early repolarization had a family history of SCD. Geographic differences in distribution have also been described, with early repolarization-related SCD being particularly prevalent among Southeast Asians.² However, because early repolarization was not associated with an increased risk of SCD until recently, the genetic markers to differentiate benign and arrhythmic forms of early repolarization have not been identified. Recently, mutations of the *DPP6* gene, identified in a subset of patients with idiopathic VF, may prove valuable in the identification of asymptomatic subjects. However, at this time, the role of genetic screening for risk stratification has not been well characterized.¹¹³

Principles of Management

Management of VF associated with early repolarization is similar to that of idiopathic VF discussed below. There is not yet a clear consensus on the specific risk factors that identify asymptomatic early repolarization subjects in whom the probability of SCD is sufficiently high to warrant an ICD for primary prevention. Even the presence of unexplained syncope or family history of SCD in the context of

early repolarization is not sufficient to recommend prophylactic ICD implantation, because those parameters have not been shown to reliably identify patients at risk for life-threatening arrhythmias. The latter group of patients, however, should be offered close follow-up and general guidelines for the management of syncope.^{2,58}

On the other hand, the presence of an early repolarization pattern in the right precordial leads or the presence of a rapidly upsloping ST segment after the J point in patients with early repolarization in the inferior or lateral leads predicts a benign prognosis, at least in middle-aged subjects. These individuals should probably not be profiled as high risk if they are asymptomatic and have no family history of life-threatening arrhythmias or SCD.¹¹⁷

PARTICIPATION IN SPORTS

Restriction from competitive sports is appropriate in patients with idiopathic VF. However, no information is available about lifestyle modification in patients with early repolarization. Given the high prevalence of early repolarization patterns (especially in leads V₂ to V₆) in athletes, occurring in 20% of noncompetitive athletes and in up to 90% of high-performance athletes, and because the midprecordial early repolarization location is generally believed to be benign, and in the absence of reliable risk-stratifying parameters, a universal restriction from competitive sports in asymptomatic athletes with early repolarization, even at competitive levels, does not seem warranted. Nonetheless, certain restrictions may be considered in highly active patients with resting bradycardia and prominent early repolarization patterns localized to the inferior or inferolateral leads, although definitive guidelines are still lacking.²

Idiopathic Ventricular Fibrillation

Idiopathic VF is defined as spontaneous VF without any known structural or electrical heart disease.¹¹³

Epidemiology

Idiopathic VF accounts for up to 10% of victims of SCD, mainly in the young. The mean age at presentation is approximately 35 to 45 years, and two-thirds of patients are men. A family history of SCD or idiopathic VF is present in up to 20% of patients, suggesting that at least a subset of idiopathic VF is hereditary.¹¹³

Clinical Presentation

Idiopathic VF manifests as either syncope or cardiac arrest that is typically not related to physical or emotional stress. VF often occurs at night, when heart rate is slower and vagal tone is augmented. The recurrence of VF in patients with idiopathic VF is approximately 30%, and the proportion of patients presenting with cardiac arrest as opposed to syncope appears to be much higher in idiopathic VF than in other channelopathies, suggesting that ventricular arrhythmias in other channelopathies are more likely to terminate spontaneously whereas idiopathic VF tends to be sustained. Electrical storm occurs in approximately 10% of patients.^{113,123}

Diagnosis of Idiopathic Ventricular Fibrillation

The diagnosis of idiopathic VF is based on exclusion of an underlying structural or primary electrical heart disease. Hence, a thorough cardiac evaluation is warranted. Echocardiography, stress testing, coronary angiography, and cardiac magnetic resonance imaging need to be considered to exclude structural cardiac disease, such as coronary artery disease, congenital coronary anomalies, dilated cardiomyopathy, hypertrophic cardiomyopathy, ARVD, cardiac sarcoidosis, myocarditis, and left apical ballooning. Metabolic disorders, electrolyte abnormalities, and drug intoxication also need to be excluded.¹²³

Careful analysis of the surface 12-lead ECG is mandatory to exclude primary electrical heart disease. Abnormal shortening or

prolongation of the QT interval can suggest SQTS or LQTS, respectively. Repolarization abnormalities in the right precordial leads can suggest the Brugada syndrome. The presence of ventricular preexcitation can suggest preexcited supraventricular tachyarrhythmias as the underlying cause of VF. It is important to understand that all these disorders can manifest with minor or borderline ECG abnormalities, and recording serial ECGs, recording of modified precordial leads (such as in the Brugada ECG pattern), ECG recording during exercise or after drug challenge, and/or continuous ambulatory cardiac monitoring can be necessary to unmask diagnostic ECG abnormalities.¹²³ Pharmacological drug challenge to exclude the Brugada syndrome, and exercise stress testing or catecholamine infusion to exclude CPVT, should be considered. Invasive EP testing may be considered, especially when sinus node dysfunction, AV conduction abnormalities, or the presence of a bypass tract is suspected.¹²³

Genetics of Idiopathic Ventricular Fibrillation

A recent report provided evidence for a familial component in idiopathic VF and suggested a role for *DPP6* as the causal gene. Overexpression of *DPP6*, which encodes dipeptidyl-peptidase 6, a putative component of the transient outward current (I_{to}) channel complex in the heart, was proposed as the likely pathogenetic mechanism. *DPP6* significantly alters the inactivation kinetics of both $K_{v4.2}$ and $K_{v4.3}$ and promotes expression of these alpha subunits in the cell membrane. Clinical evaluation of 84 risk-haplotype carriers and 71 noncarriers revealed no ECG or structural parameters indicative of cardiac disease. Penetrance of idiopathic VF was high; 50% of risk-haplotype carriers experienced (aborted) SCD before the age of 58 years.¹¹³

The I_{to} current, which mediates phase 1 of the action potential, is distributed heterogeneously across the ventricular wall, being more prominent in epicardium compared with endocardium. An increase in I_{to} amplitude resulting from increased *DPP6* can potentially cause a deeper phase 1 in the epicardium with the appearance of a J wave on the surface ECG. An additional increase in I_{to} potentially leads to ST segment elevation. However, no EP abnormalities were observed on the baseline ECG in carriers of the risk haplotype and no differences in prevalence of early repolarization were observed between haplotype carriers and noncarriers.

Importantly, arrhythmic episodes appeared not to be preceded by any discernable ECG abnormality. Any morphological action potential changes that might be present were apparently not sufficient to inscribe on the ECG and, therefore, are as yet obscuring the nature of the arrhythmogenic substrate, which in fact might be very local, in the lower part of the RV free wall.¹¹³

Principles of Management

PHARMACOLOGICAL THERAPY

Data from controlled trials or experimental studies are largely lacking. Preliminary clinical experience with quinidine is promising. Beta-adrenergic agonists are beneficial in idiopathic VF, particularly for arrhythmic storm. Amiodarone has limited efficacy. Beta blockers, lidocaine, mexiletine, and verapamil are usually not beneficial.

Acceleration of the heart rate (up to 120 beats/min) by isoproterenol infusion or by atrial or ventricular pacing can be very effective for the acute control of ventricular arrhythmias. Deep sedation may also be considered in refractory cases.^{2,124}

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

SECONDARY PREVENTION. For secondary prevention, ICD implantation is recommended in patients with prior cardiac arrest due to VF. In patients with ICDs and frequent nonsustained ventricular arrhythmias, recurrent sustained arrhythmias precipitating frequent ICD shocks, or both, adjuvant antiarrhythmic therapy with quinidine can be helpful.⁵⁸ Of note, patients with VF and early repolarization have shown a higher incidence of VF recurrence than VF patients without early repolarization (43% versus 23% during 5 years of follow-up).

PRIMARY PREVENTION. In view of the lack of specific risk factors or of ECG or imaging abnormalities in patients with idiopathic VF (apart from the early repolarization patterns discussed earlier), identification of at-risk subjects is currently not possible. The presence of unexplained syncope or family history of idiopathic VF or SCD is not sufficient to recommend prophylactic ICD implantation, because those parameters have not been shown to reliably identify patients at risk for life-threatening arrhythmias. Nevertheless, careful work-up of the cause of syncope and close follow-up should be undertaken.^{2,58}

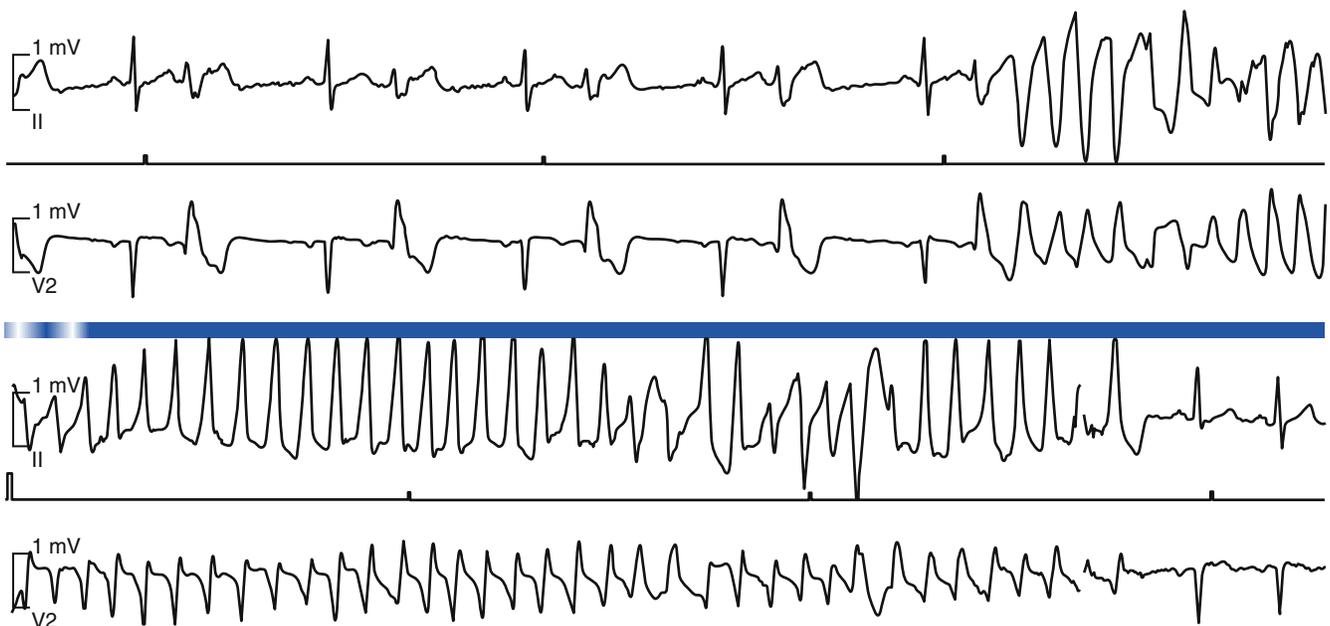

FIGURE 31-9 Polymorphic ventricular tachycardia (VT) triggered by premature ventricular complexes (PVCs). The telemetry rhythm strips show normal sinus rhythm with PVCs that trigger an episode of polymorphic VT. Note that the morphology of the triggering PVCs is similar to that of the isolated PVC.

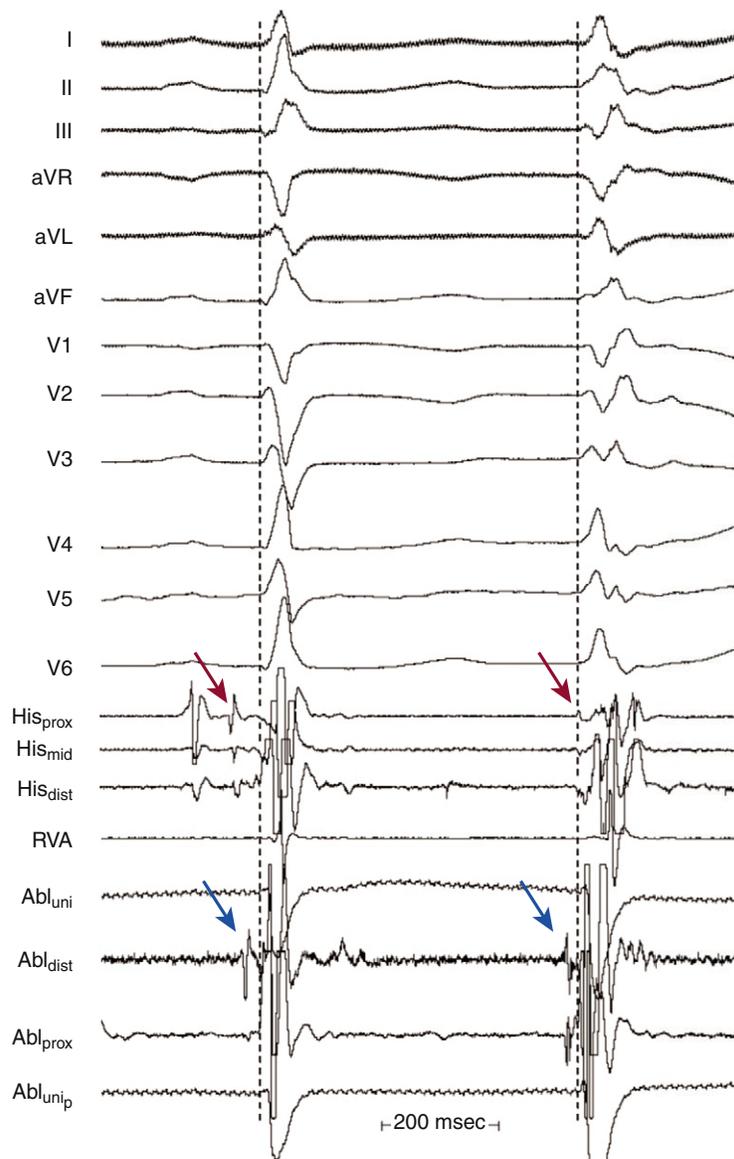

FIGURE 31-10 Sinus rhythm (left) and premature ventricular complexes (PVCs, right) in a patient with idiopathic ventricular fibrillation. Dashed lines denote the onset of QRS complexes. Blue arrows indicate Purkinje potentials, and red arrows indicate His potentials. During sinus rhythm, His potentials precede Purkinje potentials, the sequence of which is reversed in the PVCs.

CATHETER ABLATION

Recent evidence suggests an important role of specific triggers in the RVOT or in the Purkinje system for initiation of idiopathic VF (Fig. 31-9). VF-triggering PVCs originate from various locations within the Purkinje system in the majority of patients. PVCs originating in the right Purkinje system display relatively uniform ECG morphologies and typically have an LBBB pattern with a left superior axis and a relatively short QRS duration. On the other hand, PVCs arising in the left Purkinje system produce more variable 12-lead ECG patterns.

PVCs originating from the RVOT, although generally considered “benign,” can also initiate polymorphic VT and VF in some patients with idiopathic VF. Distinguishing between the “malignant” forms and the benign form of RVOT PVCs is often challenging. Data suggest that shorter CLs during monomorphic VT, short coupling intervals of the PVCs, as well as a history of syncope with malignant characteristics, can potentially predict the coexistence of VF or polymorphic VT in patients with idiopathic RVOT VT/PVCs. However, significant overlap exists.¹²⁵

When ventricular arrhythmias are triggered by monomorphic PVCs, catheter ablation of the PVC focus can potentially prevent further episodes of VF or reduce the burden of arrhythmias. In the setting of PVCs arising from the Purkinje network, a presystolic low-amplitude and high-frequency signal (Purkinje potential) is typically recorded at the successful ablation site, whereby the Purkinje potential precedes and is closely coupled to the ventricular signal of the culprit PVC (Fig. 31-10). Abolition of the local Purkinje potentials and suppression of the targeted PVCs have been shown in a small series to significantly reduce the frequency of VF.¹²⁶

The presence of frequent PVCs during the ablation procedure can significantly improve the success of ablation. Not infrequently, the optimal time for ablation is at the time of an arrhythmic storm when the PVCs tend to be frequent. When the PVCs are absent at the time of the procedure, provocative maneuvers including the use of isoproterenol or programmed electrical stimulation are not usually helpful. Pace mapping can be used in cases of monomorphic ventricular ectopy when a clear 12-lead recording of the clinical PVCs initiating VF has been obtained (Figs. 31-11 and 31-12).^{126,127}

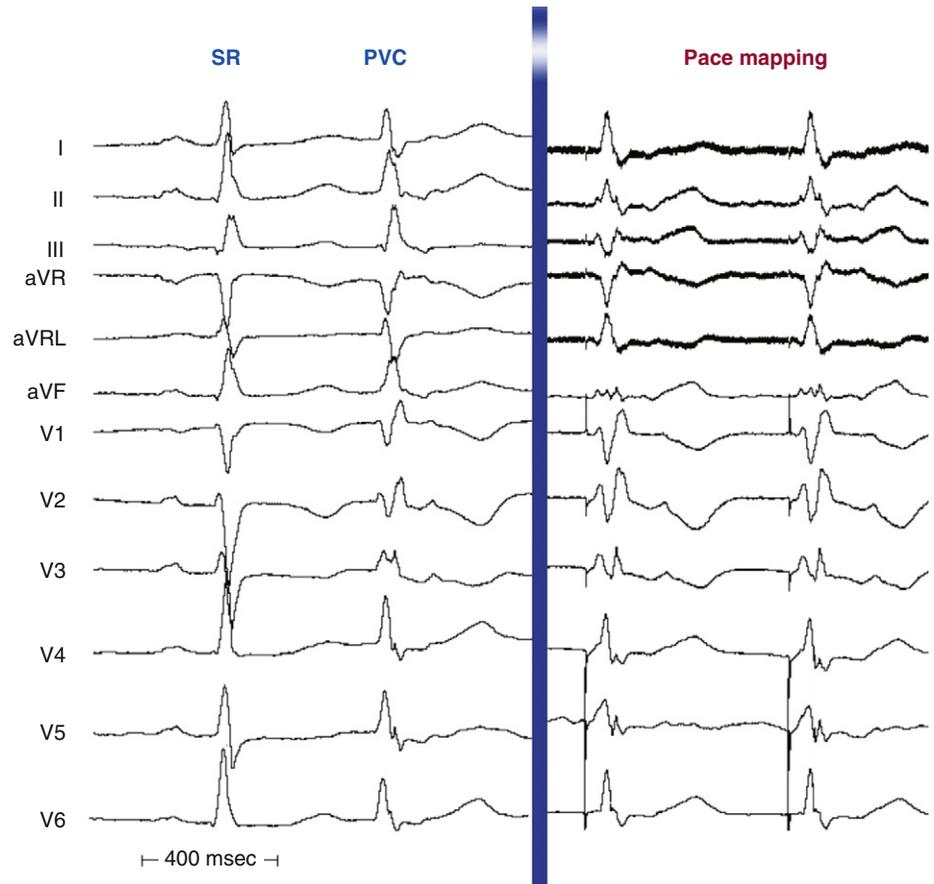

FIGURE 31-11 At left, sinus rhythm (SR) and a premature ventricular complex (PVC) in a patient with idiopathic VF are shown. At right, pacing at the PVC site of origin closely mimics the PVC.

Catheter ablation of focal PVCs may be considered especially in patients with frequent episodes of syncope or repeated ICD shocks refractory to drug therapy. Nonetheless, ablation therapy is not a substitute for ICD therapy because of the risk of recurrence of VF (in 18% of patients) triggered by PVCs either from the original focus or from new foci.^{126,127}

It is worth noting that recent studies found a concordance between the site of origin of VF-triggering PVCs and the location of the early repolarization pattern on the surface ECG. Patients with early repolarization recorded in inferior leads alone had PVCs originating from the inferior LV wall, whereas those with early repolarization recorded in both inferior and lateral leads had PVCs originated from multiple regions.¹¹⁵

PARTICIPATION IN SPORTS

Restriction from competitive sports is appropriate in patients with idiopathic VF.

FAMILY SCREENING

Unlike other arrhythmia syndromes, such as Brugada syndrome or LQTS, no cardiac abnormalities are observed in idiopathic VF patients, apart from the early repolarization ECG pattern, which is also not infrequently observed in the general population. Hence, family members who may be at risk cannot be identified and the penetrance of idiopathic VF cannot be assessed on the basis of an ECG phenotype.

Elucidation of underlying genetic defects will provide more insight into the pathogenesis of the disorder and, crucially, will allow presymptomatic identification of individuals at risk. The recent identification of mutations of the *DPP6* gene as a potential familial component in idiopathic VF may prove valuable in the identification of presymptomatic subjects. However, at this time, the role of genetic screening has not been well characterized.¹¹³

FIGURE 31-12 Three seconds after the onset of radiofrequency energy delivery at the site of premature ventricular complex (PVC) origin in a patient with idiopathic VF, a burst of ectopy occurs having the same QRS configuration as the spontaneously occurring PVC (see Figs. 31-10 and 31-11).

REFERENCES, 698

Reported rates of major complications following contemporary catheter ablation procedures vary by as much as five- to eight-fold between various types of ablation procedures, ranging from 0.8% for supraventricular tachycardia (SVT), 3.4% for idiopathic ventricular tachycardia (VT), 5.2% for atrial fibrillation (AF), and 6.0% for VT associated with structural heart disease. Death is a rare complication of catheter ablation, occurring in 0.11% to 0.30% of patients with regular SVT, and in 0.31% of those with VT. Transseptal catheterization appears to be the cause of death in 0.2% of procedures.¹

Local Vascular Complications

Complications at the catheter insertion sites are among the most common problems observed following catheter ablation procedures, estimated to occur in about 2% to 6% of procedures, and can cause significant morbidity. Local vascular complications are higher among females, older adults, obese patients, and those with preexisting peripheral vascular disease. Additionally, the risk is related to the type of procedure performed (right or left heart catheterization), the size and number of sheaths and catheters used during the procedure, as well as the associated periprocedural use of anticoagulant or antiplatelet agents.² The rates of complications related to the site of vascular access are higher following catheter ablation of AF (1.8%) and VT in patients with structural heart disease (0.7% to 4.7%) compared with ablation of SVT (0.4%).¹

Bleeding is the most common vascular complication. This can simply result in a local hematoma of little clinical significance. Vascular laceration can cause large hematomas in the groin and thigh. Acute bleeding generally can be controlled with prolonged manual compression. Groin hematomas usually resolve in 1 to 2 weeks if ongoing bleeding is stopped. Large hematomas can require blood transfusion, but surgical repair is rarely required. Arteriovenous fistulas and pseudoaneurysms need to be excluded in the setting of large or continually expanding hematomas. Retroperitoneal hematomas are often the result of arterial puncture above the inguinal ligament, allowing bleeding and hematoma to extend to the retroperitoneal space. Retroperitoneal hematomas should be suspected in the setting of a marked drop in hematocrit or unexplained hypotension or flank pain. Abdominal computed tomography (CT) scanning or ultrasound is required to confirm

the diagnosis. Retroperitoneal bleeds are generally managed conservatively (bed rest, blood transfusion). Catheter or surgical interventions, however, can occasionally be required.³

Femoral artery pseudoaneurysms form when a tear through all the layers of the artery at the puncture site fails to seal, allowing persistent blood flow outside the vessel into a space contained by the surrounding tissue. This is in contrast to a hematoma, which has clotted blood outside the vessel with absence of flow. Pseudoaneurysms lack a fibrous wall and are contained by a surrounding shell of hematoma and the overlying soft tissues. Risk factors for pseudoaneurysm development include the use of large vascular sheaths, potent post-procedure anticoagulation, inadequacy of initial effort at hemostasis after removal of sheaths, and punctures of the femoral artery that are too distal, that is, at the level of bifurcation of the femoral artery or below. Also, multiple attempts at vascular access (arterial or venous) with inadvertent arterial puncture appear to increase the risk for pseudoaneurysm formation. Repeated damage to the arterial wall may result in weakening that leads to pseudoaneurysm development.

A pseudoaneurysm typically manifests a painful pulsatile mass with a systolic bruit or thrill, and the diagnosis is confirmed by duplex ultrasonography. Pseudoaneurysms can be complicated by rupture or distal embolization. Pseudoaneurysms that are less than 2 cm in size and not enlarging may resolve without intervention, with serial imaging to confirm spontaneous resolution; those that are enlarging or are greater than 2 cm in size can be treated by ultrasound-guided compression of the “neck” connecting the pseudoaneurysm with the vessel or by percutaneous thrombin injection. Occasionally, surgical repair is required, especially for large pseudoaneurysms with a wide connection to the parent artery. Once diagnosed, a pseudoaneurysm should be treated rather than allowing the opportunity for spontaneous resolution.

Femoral arteriovenous fistulas commonly result when bleeding from the arterial puncture tracks into the adjacent venous puncture. Arteriovenous fistulas are more likely to arise when arterial and venous punctures are performed on the same side or when arterial puncture is performed below the common femoral artery, where several superficial branches of the femoral vein overlie the femoral artery. Diagnosis is made on examination with the finding of a pulsatile mass with a continuous “to and fro” bruit and confirmed by ultrasound. Many of the iatrogenic arteriovenous fistulas are small and close spontaneously within 1 year,

but ultrasound-guided compression or surgical repair can be necessary. Because cardiac volume overload and limb damage are highly unlikely with persistent arteriovenous fistulas, conservative management for at least 1 year is reasonable.²

Deep venous thrombosis and pulmonary embolism are rare and can result from venous injury, especially during prolonged procedures requiring multiple venous lines, or in the setting of venous compression by a large arterial hematoma. Femoral arterial thrombosis is rare and occurs more commonly in the setting of a small vessel lumen, the use of a large-diameter sheath, preexisting peripheral vascular disease, diabetes mellitus, and female gender.

Accurate vascular puncture and effective initial control of bleeding after sheath removal are the best measures to prevent local vascular complications. Early diagnosis and management of local access-site complications are important to reduce morbidity and improve outcome.

Cardiac Perforation

Incidence

Previous studies reported the incidence of cardiac perforation with catheter-based interventions as follows: 0.8% for all procedures, 1.5% to 4.7% for valvuloplasty, 0.5% to 0.8% for angioplasty-atherectomy, 0.01% for diagnostic catheterization, 0.1% to 0.2% for electrophysiological (EP) studies, 0.2% for SVT ablation, 0.4% to 2.7% for VT ablation, and 0.5% to 4.0% for left atrial (LA) ablation.^{1,4,5}

The incidence of procedure-related cardiac tamponade increases with the increasing number of catheter ablation procedures for the treatment of AF, which typically involves one or more atrial septal punctures, extensive intracardiac catheter manipulation and ablation within the thin-walled LA, and the need for high levels of systemic anticoagulation during the procedure.^{2,6}

Mechanism

Cardiac perforation can be caused by mechanical trauma secondary to catheter manipulation, myocardial tissue rupture due to radiofrequency (RF) ablation, or inadvertent injury during atrial septal puncture. Extensive catheter manipulation, especially in areas with thin walls such as the LA roof, right ventricular (RV) free wall, RV outflow tract (RVOT), RV apex, and atrial appendages, can cause mechanical tear of the chamber wall. Cardiac perforation can also occur away from the area of mapping and ablation, usually caused by penetration of an unattended RV catheter in the setting of rapid and vigorous heart action because of high-dose isoproterenol infusion. Inadvertent puncture of the right atrial (RA) free wall or lateral LA wall can occur during transeptal catheterization. High RF power output, especially when using large- or irrigated-tip ablation catheters, can increase the risk of cardiac perforation. An audible pop associated with an abrupt rise in impedance is heard in many patients who develop tamponade. Popping occurs because of tissue boiling causing myocardial rupture, and is increased by irrigated-tip ablation, high tissue-catheter interface flow, poor or unstable tissue contact, and high catheter tip temperature.^{2,6}

Detection

Prompt recognition and management of cardiac perforation are critical to prevent the development of cardiac tamponade and potentially life-threatening hemodynamic collapse. Although the presentation often is dramatic with abrupt hypotension, it can be insidious with a more gradual fall in blood pressure. The use of an arterial line that provides continuous blood pressure monitoring can help detect early hemodynamic compromise. Sinus tachycardia is common in the setting of cardiac tamponade that gradually develops. Nonetheless, the absence of tachycardia does not exclude cardiac tamponade; in fact sinus bradycardia can develop secondary to a vagal reflex in the setting of a rapidly developing

cardiac tamponade. Any chest pain that persists beyond the completion of an ablation lesion, especially if associated with hypotension and diaphoresis, should alert the operator to the possible development of pericardial effusion.^{2,6-8}

Assessment of the cardiac silhouette fluoroscopically can provide the first clue, especially if a similar assessment was made at baseline. Decreased excursion of the lateral heart border on fluoroscopy in the left anterior oblique (LAO) projection, indicating accumulating pericardial effusion, usually can be seen well before a drop in blood pressure and prior to progression to cardiac tamponade. Some operators obtain a baseline LAO cine image at the onset of a procedure to serve as a reference for comparison during the procedure, followed by intermittent evaluation of the same fluoroscopic projection during the procedure.^{2,6-8}

Transthoracic echocardiography is the most definitive method for confirming the development of pericardial effusion. Intracardiac echocardiography (ICE), commonly used to guide transeptal puncture for LA procedures, also can facilitate the early detection of pericardial effusions before the emergence of tamponade physiology. Most of the pericardial space is not visualized from the RA imaging venue used to visualize the interatrial septum, and limited catheter rotation is usually required. Advancing the ICE catheter into the RV and rotating the transducer against the interventricular septum can readily identify pericardial effusions (Fig. 32-1).

Perforation without tamponade may occur during placement of diagnostic catheters or while accessing the LA by transeptal catheterization; detection at this time can prevent progression to tamponade but requires a high index of suspicion. Several clues should alert the operator to the possibility of cardiac perforation, including a ventricular catheter that reaches the edge of the cardiac silhouette, high pacing thresholds at sites despite normal electrograms and apparent good tissue contact on fluoroscopy, a right bundle branch block (RBBB) complex during "RV" pacing, and a catheter tip position discordant from where it should be (i.e., an RV catheter too far leftward with intended RV apical location; Fig. 32-2). With atrial septal puncture for accessing the left heart chambers, the aorta can be inadvertently entered; if only the needle enters the aorta and this is recognized before advancing the dilator and sheath, the needle can be withdrawn and the patient monitored for stability of vital signs and with echocardiography. The procedure can be continued if there is no accumulation of pericardial fluid after 15 to 30 minutes of monitoring. If the dilator and sheath have been advanced into the aortic root before the error is recognized, it is imperative that the sheath not be removed immediately, as this can result in immediate and perhaps irretrievable hemodynamic collapse due to intractable bleeding into the pericardial space.

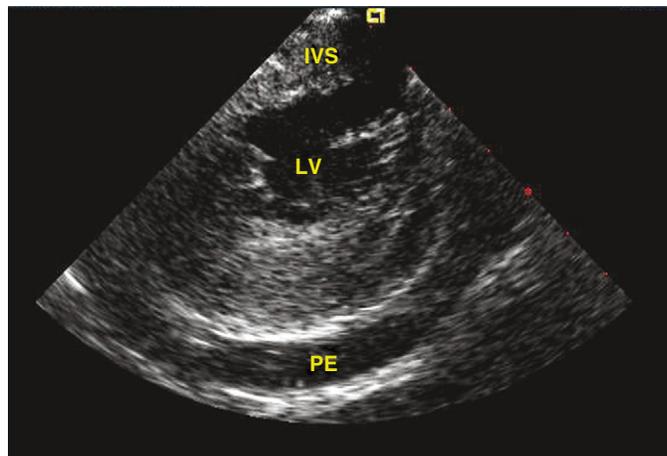

FIGURE 32-1 Intracardiac echocardiography (ICE) imaging of pericardial effusion. The phased-array ICE transducer is positioned in the right ventricle, showing a short-axis view of the left ventricle (LV) and a moderate pericardial effusion (PE). IVS = interventricular septum.

Management

The management of pericardial effusion is largely determined by its relative size and hemodynamic effect. Trivial pericardial effusions, if recognized early during the procedure, should be monitored continuously but do not warrant termination of the procedure. For larger effusions, the procedure should be terminated and anticoagulation, if administered, should be reversed. Protamine is used to reverse the effects of heparin, and activated factor VII, fresh frozen plasma, and vitamin K can be used in patients with therapeutic anticoagulation with warfarin. Intravenous fluids, vasopressors, and transfusion of blood products can be required, depending on the extent of the effusion and the severity of hemodynamic decompensation. Intravenous atropine can be of value in patients with increased vagal tone.^{3,9}

If perforation without tamponade is recognized, an echocardiogram should be obtained as a baseline. If the offending catheter is a standard 5 or 6 Fr shaft, it can often be withdrawn back into the heart while monitoring the echocardiogram for accumulation of pericardial fluid. Most often, there will be no bleeding into the pericardial space and the procedure can be continued. If systemic anticoagulation is planned for left-sided catheterization, the operator must decide how important it is to continue the procedure with the risk of bleeding into the pericardium. If a larger catheter or large vascular sheath has been inadvertently placed in the pericardial space, echocardiography should be obtained along with cardiothoracic surgical consultation. In many if not most cases, the sheath may be safely withdrawn into the heart without adverse consequences, but the team must be ready to transport the patient to an operating room for repair of a hole or tear in the wall of the affected heart chamber. In some cases, especially when the patient is fully anticoagulated, it may be prudent to transport the patient to the operating room and prepare for urgent sternotomy before removing the catheter/sheath so as to be able to rapidly enter the chest if hemodynamic collapse occurs.

Although pericardiocentesis typically is required for large pericardial effusions, smaller effusions manifesting signs of cardiac tamponade, or both, and can effectively restore hemodynamic function, it carries the potential risk of cardiac chamber laceration, inadvertent puncture of the RV, pneumothorax, and infection. In a subset of patients (especially older female patients with a small to moderate amount of pericardial effusion who are not anticoagulated), a conservative approach incorporating administration of

intravenous fluids and vasopressors to address the hemodynamic consequences of cardiac tamponade was found in a recent report a reasonable initial strategy and could obviate the need for emergency pericardiocentesis.^{2,7}

Pericardiocentesis should be performed promptly when indicated, because there is usually a narrow therapeutic time window for intervention before critical hemodynamic compromise ensues. The procedure can be performed under fluoroscopic guidance (Video 22). Echocardiography can also be used to guide pericardiocentesis (Video 23). When echocardiography is not readily available, fluoroscopy is usually adequate to guide a safe procedure, and reliance on transthoracic echocardiography should not lead to unnecessary delay in diagnosis or therapy. The technique of percutaneous pericardiocentesis is discussed in [Chapter 27](#). In most patients, an indwelling catheter is required for a short interval after initial drainage to confirm that the bleeding has stopped and that no effusion is reaccumulating. In the event of persistence or rapid reaccumulation of the effusion, exploration by thoracic surgery can be required. Up to 13.3% of LA perforations during AF ablation require surgical closure. Autotransfusion of blood removed from the pericardial space can be of value in patients with persistent bleeding, and is best done using an autologous blood recovery system, because direct autotransfusion can result in a systemic inflammatory response.^{3,6,9}

Early pericarditis after cardiac perforation is common. In one report, 53.3% of such patients had persistent chest pain after effusion evacuation and removal of the pericardial catheter suggestive of pericardial inflammation. Nonsteroidal antiinflammatory agents are adequate in most patients. Additionally, intrapericardial steroids (triamcinolone, 20 mg) can help reduce pericardial inflammation. Subacute reaccumulation of pericardial fluid suggestive of postcardiac injury syndrome or inflammatory pericarditis can also occur, requiring repeat pericardiocentesis.^{3,9}

Thromboembolism

Systemic thromboembolism can complicate EP procedures in the left side of the heart. The rate of thromboembolic events is 0.4% to 2.1% for AF ablation and up to 2.8% for ablation of VT originating in the left ventricle (LV).^{1,4,10} In patients undergoing AF ablation, history of a prior cerebrovascular event is the most potent individual risk factor for post-ablation cerebrovascular events and is associated with a ninefold increased risk of periprocedural stroke. Additionally, the incidence of periprocedural stroke increases in

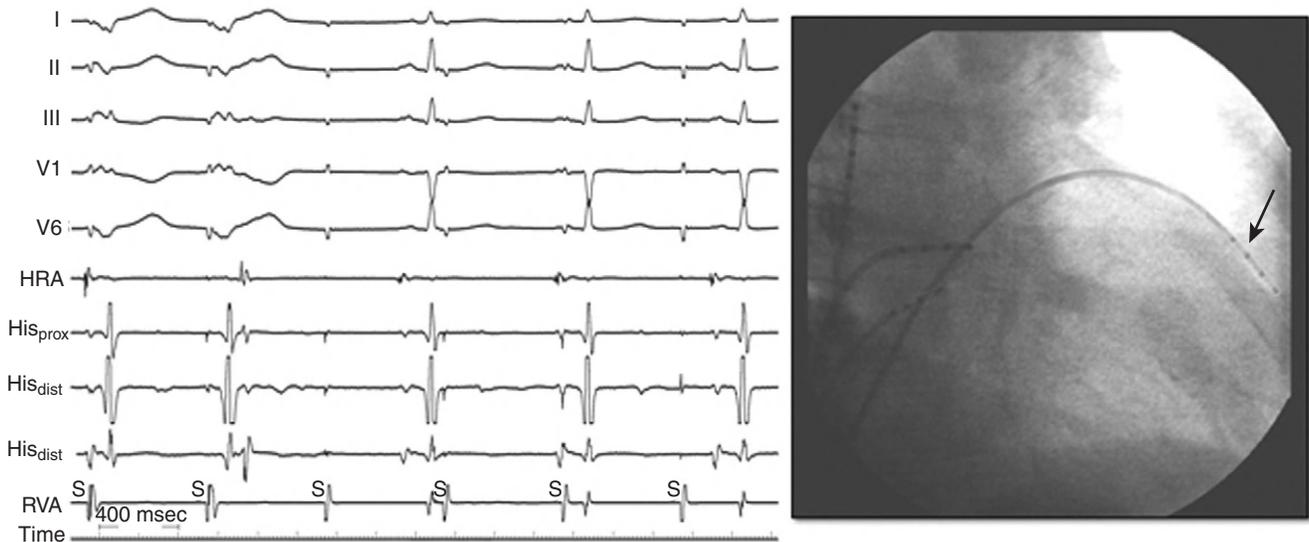

FIGURE 32-2 Cardiac perforation during electrophysiological study. Surface ECG and intracardiac recordings from a patient who was undergoing electrophysiological study. Recordings show poor capture from a catheter intended for the right ventricular apex (RVA); captured complexes have a right bundle branch block pattern. These features are explained by the accompanying right anterior oblique fluoroscopic image showing that the RVA catheter (arrow) has perforated the RV anterior wall and is pacing the anterolateral left ventricular epicardium.

a step-wise fashion with an increasing CHADS₂ score (congestive heart failure, hypertension, age >75 years, diabetes, and previous stroke/transient ischemic attack).¹⁰

Mechanism

Potential sources of emboli include thrombus formation on high-profile wires, catheters, and sheaths inserted in the LA or LV, char formation at the tip of the ablation catheter or at the site of ablation, thrombi or air passing through a patent foramen ovale or transseptal puncture, and dislodgment of a preexistent LA or LV thrombus by catheter manipulation. Additionally, new LA appendage thrombi may develop in patients with persistent AF after planned or inadvertent conversion to sinus rhythm, especially in the setting of insufficient levels of anticoagulation before, during, or after ablation. Furthermore, endocardial disruption from the ablation lesions can potentially become a nidus for thrombus formation. Also, aortic atheroembolism can occur during retrograde transaortic LV access for ablation of VTs or atrioventricular (AV) bypass tracts (BTs), and it tends to be associated with difficulty in manipulation of catheters within a severely diseased aorta.¹⁰

Thromboembolic events typically occur within 24 hours of the ablation procedure, with the high-risk period extending for the first 2 weeks following ablation. Cerebral thromboembolism is most common, but emboli can also involve the coronary, abdominal, or peripheral vascular circulations. Although silent cerebral thromboembolism has been reported, its incidence and clinical significance are unknown.¹¹

Prevention

Prevention remains the best strategy in minimizing cerebrovascular events during left heart mapping and ablation, and this may be achieved by the following: (1) preprocedural transthoracic or transesophageal echocardiography (TEE) in patients with AF as well as those with ischemic VT with LV dysfunction; (2) aggressive intraprocedural anticoagulation, including early heparin administration (once vascular access is obtained), followed by continuous infusion to maintain the activated clotting time at greater than 300 seconds; (3) meticulous attention to sheath management, including constant infusion of heparinized saline and air filters; (4) minimizing char formation during lesion creation by regulating power delivery to prevent abrupt impedance rise; and (5) using ICE during AF ablation for early detection of intracardiac thrombi and accelerated bubble formation consistent with endocardial tissue disruption with RF application. Open-irrigation RF ablation or cryoablation, compared with standard 4- or 8-mm solid tip or closed irrigation electrodes, can potentially decrease the formation of char and thrombus at the tip of the ablation catheter.¹⁰ Administration of large doses of protamine on completion of the ablation procedure to reverse heparin abruptly can potentially promote thrombogenesis and warrants further evaluation to confirm its safety. Continuation of warfarin at a therapeutic level at the time of AF ablation can potentially be a better alternative to strategies that use bridging with heparin or enoxaparin, as it eliminates a period of inadequate anticoagulation immediately following the ablation procedure, a critical period for thromboembolic risk because of the inflammation and irritation inherently associated with ablation.^{12,13}

In patients with severe disease of the aorta, using a long vascular sheath to advance the ablation catheter directly into the LV can potentially reduce the risk of aortic atheroembolism.

Air Embolism

Vascular air embolism is a potentially life-threatening event that can occur during left and right heart procedures. Because many cases of venous air embolism go unnoticed, the true incidence of this complication is unknown. Air embolism has been reported in the interventional radiology literature at an incidence of 0.13%.^{2,3,9}

Mechanism

Small amounts of air embolized in the venous circulation are generally broken up in the capillary bed and absorbed from the circulation without significant sequelae. Embolization of large volumes of air (>5 mL/kg) can cause severe complications (shock or cardiac arrest). However, complications have been reported with as little as 20 mL of air. On the other hand, embolization of as little as 2 or 3 mL of air into the arterial circulation can be fatal.

Paradoxical air embolization into the arterial circulation can occur through direct passage of air into the arterial system via anomalous structures such as an atrial or ventricular septal defect, a patent foramen ovale, or pulmonary arterial-venous malformations. Direct arterial air embolism is caused by the introduction of air into the LA via the transseptal sheath as well as via long vascular sheaths occasionally used for catheter stabilization during transaortic mapping and ablation in the LV.^{3,9}

With the patient in the supine position, large volumes of air rapidly entering the venous circulation typically lodge in the RVOT or pulmonary artery, and can cause RVOT obstruction, marked reduction of cardiac output, and potentially hemodynamic collapse. Also, air embolization can lead to serious inflammatory changes in the pulmonary vessels including direct endothelial damage and accumulation of platelets and fibrin. Air in the systemic circulation can induce ischemia by various mechanisms, such as obstruction of the blood flow, vasospasm, and thrombus formation because of platelet activation.

Clinical Presentation

Most cases of venous air embolism are subclinical and do not result in untoward outcomes, and even when symptomatic, they go unrecognized because of the nonspecific nature of clinical presentation that can mimic other cardiac, pulmonary, and neurological dysfunctions. Therefore, a high index of suspicion is necessary to establish the diagnosis.³

The outcome of venous air embolism is directly related to the amount of air and the rate at which it enters the vein. Spontaneously breathing patients can experience more serious consequences than those under controlled positive-pressure ventilation because they generate negative intrathoracic pressure during the respiratory cycle, facilitating air entrainment. Awake patients typically manifest shortness of breath, continuous coughing, chest pain, and a sense of "impending doom." Jugular venous distention, hypotension, tachycardia, and electrocardiographic (ECG) signs of right heart strain (ST-T wave abnormalities) can be observed. Severe cases are characterized by cardiovascular collapse.^{3,9}

Arterial air emboli can distribute to almost any organ and can have devastating clinical sequelae. Direct cerebral air embolism can be associated with altered mental status, seizures, and focal neurological signs. A common presentation of air embolism during LA mapping and ablation is acute inferior ischemia, heart block, or both (Fig. 32-3). This reflects preferential downstream migration of air emboli into the right coronary artery.

Detection

Routine diagnostic modalities to identify air embolism in the terminal arterial circulations lack sensitivity, and diagnosis is typically based on the appropriate clinical scenario, with possible air identified in cardiac chambers. Air in the RV or pulmonary artery can be visualized on fluoroscopy as well as transthoracic echocardiography. TEE is currently the most sensitive monitoring device for venous air embolism. Prompt CT or magnetic resonance (MR) imaging obtained before the intravascular air is absorbed may show multiple serpiginous hypodensities representing air in the cerebral vasculature, with or without acute infarction, but imaging later in the course of the disease shows diffuse acute infarcts (Fig. 32-4).^{3,9}

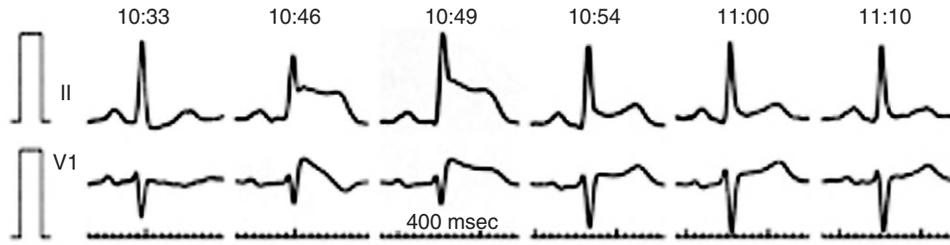

FIGURE 32-3 Coronary air embolism. Leads II and V₁ are shown from a patient with a left-sided bypass tract who suffered air embolism during transeptal catheterization and catheter advancement into the left atrium. Snapshots of ECGs taken at the designated times show the baseline (10:33) normal findings, dramatic ST elevation immediately following transeptal catheterization (10:46), and progressive resolution over the next 25 minutes. Time scale and 10-mV calibration marks are shown.

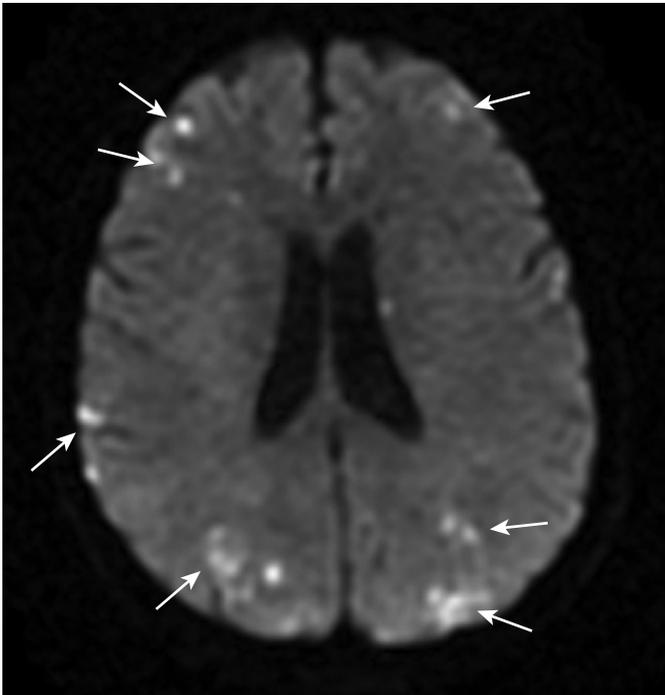

FIGURE 32-4 Cerebral air embolism. A transverse section of a magnetic resonance image of the brain in a patient who sustained cerebral air embolism during ablation of atrial fibrillation, showing many areas of diffusion restriction scattered throughout both hemispheres, representing acute infarcts.

Prevention

The optimal management of air embolism is prevention. Careful sheath management, including constant infusion of heparinized saline and air filters, should be observed. Although air can be introduced through the infusion line, it can also occur with suction when catheters are removed. Therefore, whenever catheters are removed, they need to be withdrawn slowly to minimize suction effects and the fluid column within the sheath should be aspirated simultaneously. The sheath should then be aspirated and irrigated to ascertain that neither air nor blood has collected in the sheath.³ Importantly, the entire volume of the sheath should be aspirated after initial deployment as well as after each time a catheter is removed and reinserted, in order to ensure that a continuous column of fluid is present in the sheath and disallowing the possibility of trapped air that could otherwise be introduced when a catheter is advanced through the sheath. Testing to ascertain the sheath's capacity prior to insertion is a good practice.

Management

Initially, it is essential to take all measures necessary to prevent further air embolization. For venous air embolism, placing the patient in the left lateral decubitus and Trendelenburg position helps air

remain in the RA, where it will not contribute to an "air lock" in the RVOT. Additionally, direct extraction of air from the venous circulation if localized in the RA or RV can be attempted by aspiration from a central venous or pulmonary artery catheter. Air aspiration should be performed with the patient supine or in a Trendelenburg position while holding his or her breath at the end of inspiration or during a Valsalva maneuver.¹⁴

Administration of intravenous fluids and vasopressors can be necessary for hemodynamic support. Supplemental 100% oxygen therapy can reduce the size of the air embolus by increasing the rate of nitrogen absorption from air bubbles. Because gas bubbles are not buoyant enough to counteract arterial blood flow, these measures are more suitable for treating venous and RV air emboli.¹⁴

When cerebral air embolism is suspected, it is important to maximize cerebral perfusion by administration of fluids and supplemental oxygen. Hyperbaric oxygen therapy is regarded as the treatment of choice in patients with cerebral air embolism and prompt transfer to a hyperbaric oxygen therapy center should be considered. When started within a few hours, hyperbaric oxygen therapy can potentially compress the existing bubbles, speed resolution of bubbles by establishing a high diffusion gradient, improve oxygenation of ischemic tissues, and reduce endothelial thromboinflammatory injury.^{3,11,14}

Coronary Artery Injuries

The incidence of coronary artery injuries during ablation procedures is extremely low despite the close proximity of coronary arteries to common sites of ablation. The low incidence is likely due, at least in part, to the high-velocity blood flow within the epicardial coronary arteries, allowing these vessels to act as a heat sink; substantive heating of vascular endothelium is prevented by heat dissipation in the coronary blood flow (convective cooling), even when the catheter is positioned close to the vessel. However, high RF power delivery in small hearts, such as in pediatric patients, or in direct contact with the vessel can potentially cause coronary arterial injury.^{15,16} Additionally, the rarity of coronary artery injury can be due to underrecognition, because its clinical presentation (e.g., chest discomfort and elevation in cardiac troponin levels) can easily be misdiagnosed as pericardial irritation, myocardial injury secondary to RF ablation, or both.

Mechanism

The potential for acute coronary artery occlusion is a significant risk consideration with catheter ablation within the aortic cusps. Damage to the coronary arteries can result from catheter manipulation and ablation in the aortic root, secondary to RF energy delivery in close proximity to the ostium of the right or left coronary artery, as well as inadvertent catheter engagement of the left main coronary artery when ablating in the left coronary cusp.^{17,18}

It is also important to recognize the potential risk of coronary artery damage when ablating in the RVOT and pulmonary artery. The right coronary artery is typically 4 to 5 mm away from the proximal part of the RVOT near the free wall, and is separated by a variable amount of

fat. Additionally, the cephalocaudal separation of the pulmonic and aortic valves results in close proximity of the pulmonic valve to the origin of the right coronary artery, and the left main coronary artery lies in immediate posterior proximity to the subvalvular RVOT near the pulmonic valve as well as the supraventricular pulmonary artery.^{17,18}

Because of the proximity of the right coronary artery to the cavotricuspid isthmus and the left circumflex artery to the lateral mitral annulus, coronary artery injury can potentially occur during ablation at mitral or tricuspid annuli.¹⁵ Transient inferior ST segment elevation and acute occlusion of the right coronary artery have been reported following ablation of the cavotricuspid isthmus, and left circumflex artery injury has been reported following ablation of left-sided AV BTs. Also, late stenosis of the right coronary artery has been observed in children with Ebstein anomaly of the tricuspid valve who undergo ablation of a right-sided AV BT.¹⁹

Percutaneous epicardial ablation probably poses a greater risk of coronary artery injury, severe spasm, or both, whereby the large epicardial coronary arteries can be in direct contact with the ablation catheter and movement of the ablation catheter in the pericardial space can occur during ablation endangering adjacent coronary arteries. The coronary sinus (CS) and its branches are also in close relation to the distal circumflex and the posterolateral branches of the right coronary artery, and ablation within the coronary venous system (for AV BTs, lateral mitral isthmus, and VT) can cause coronary injuries.^{5,15}

RF injury to coronary arteries can cause acute thrombosis or damage to the arterial wall. Arterial injury is inversely proportional to vessel diameter; there is little evidence of injury when vessel diameter exceeds 0.5 to 1.0 mm.¹⁵

Coronary artery spasm has been reported during mapping in the pericardial space and can occur as a result of ablation close to the artery. Extrinsic compression of a coronary artery can also result from edema caused by nearby ablation.

Clinical Presentation

Coronary arterial injury generally presents with acute coronary occlusion or spasm at the time of ablation associated with chest pain and ST elevation; nonetheless, delayed presentations can also occur.¹⁵

Importantly, RF ablation frequently (in 25% to 100% of cases) causes significant elevations in cardiac troponin levels that are not related to coronary arterial injury, with mean peak levels of 0.13 to 6 ng/mL for troponin I, and 0.20 to 2.41 ng/mL for troponin T. In contrast to acute coronary syndromes, troponin elevations observed following RF ablation typically peak early (2 to 8 hours versus 18 to 24 hours) and normalize early.²⁰ The levels of troponin elevation correlate with the number of RF lesions applied, the site of lesions (ventricular more than atrial more than annular), and the approach to the left side (transaortic more than transeptal). Ablation of focal lesions (atrioventricular nodal reentrant tachycardia [AVNRT], atrioventricular reentrant tachycardia [AVRT]) causes less frequent (in 25% to 88% of cases) elevation of troponin levels as compared with linear lesion ablation (typical and atypical atrial flutter [AFL], AF and VT) where all patients are expected to have an increase in troponin levels. The prognostic significance of asymptomatic elevations of troponin I remains unclear.²⁰

Prevention

Several precautions are important to avoid injury to coronary arteries during percutaneous epicardial ablation, ablation via the coronary venous system, and ablation in the coronary cusps. Prior to ablation near or within a branch of the CS or in the pericardial space, direct visualization of the relation between the ablation site and adjacent coronary arteries must be obtained, usually by coronary angiography performed with the ablation catheter on the target site. An absolute safe distance between the ablation site and epicardial artery has not been defined; nonetheless, a distance of at least 5 mm between the ablation catheter and an epicardial artery is commonly accepted. It is also important to ensure that the

catheter is not touching the vessel at any point of the cardiac cycle during angiography. Cryoablation appears to have less risk of coronary injury in animal models, but can still create occlusion and intimal damage when in close proximity, particularly to small vessels.⁵

When ablation in the aortic cusp is planned, it is preferable to insert a 5 Fr pigtail catheter into the aortic root and obtain aortic root angiography to visualize the aortic root and the ostia of the right and left coronary arteries.¹⁸ Selective angiography of the coronary arteries also can be performed with the ablation catheter positioned at the desired location so as to assess the anatomical relationships between these structures and the location of the ablation catheter. If the origin of VT is in the left coronary cusp, it is preferable to cannulate the left main coronary artery with a 5 Fr left Judkins catheter, which serves as a marker and for protection of the left main coronary artery in case of ablation catheter dislodgment during RF application. Alternatively, a combination of electroanatomical mapping and ICE imaging can be used to confirm anatomical location, catheter tip position and contact, and distance to coronary vasculature and to monitor RF delivery.¹⁷

To avoid injuring the coronary arteries during ablation of arrhythmias arising from the coronary cusps, it is preferable to start RF energy delivery at a low power output (15 W) and then increase to no more than 30 W to achieve a target temperature of approximately 50°C. Additionally, ablation should also be performed during continuous fluoroscopy to observe for catheter dislodgment, and energy delivery should be discontinued in case of even minimal dislodgment from the site showing the best mapping findings. RF application should also be stopped if the repetitive or sustained VT cannot be terminated after 10 seconds. Coronary angiography is often performed immediately after the ablation procedure to exclude coronary artery spasm, dissection, or thrombus.¹⁸

Iatrogenic Cardiac Arrhythmias

Atrioventricular Block

AV block is the most important complication of AVNRT ablation. AV block occurs in about 0.2% to 0.8% of slow pathway ablation using the posterior approach, generally occurs during RF delivery or within the first 24 hours postablation, and is almost always preceded by junctional ectopy with VA block. The level of block is usually in the atrioventricular node (AVN). Predictors of AV block include proximity of the anatomical ablation site to the compact AVN, occurrence of fast junctional tachycardia (cycle length <350 milliseconds) during RF application, occurrence of junctional rhythm with VA block, the number of RF applications (related to the amount of tissue damage), and significant worsening of anterograde AV conduction during the ablation procedure. The anterior approach for AVNRT ablation is associated with a higher risk of inadvertent complete AV block (approximately 10%, but ranging from 2% to 20%).²¹ During ablation of AVNRT, careful monitoring of AV conduction during RF application and prompt discontinuation of energy delivery on evidence of AV block are the keys to minimize the incidence of AV block. RF delivery should be immediately discontinued when the following occur: (1) the impedance rises suddenly (>10 Ω); (2) the PR interval (during normal sinus rhythm [NSR] or atrial pacing) prolongs; (3) AV block develops; (4) retrograde conduction block is observed during junctional ectopy; or (5) fast junctional tachycardia (tachycardia cycle length <350 milliseconds) occurs, which can herald imminent heart block.

AV block can also occur when ablating along the interventricular septum in the close vicinity of the compact AVN or His bundle (HB), including ablation of superoparaseptal and midseptal AV BTs or ATs as well as para-Hisian VTs. Additionally, because the penetrating HB lies at the membranous septum formed in part by the commissure between the right coronary and noncoronary cusps, ablation of VTs originating in this region can potentially damage the HB (Fig. 32-5).

When a His potential is detectable at the ablation catheter location, titrated RF energy output and RF application for a short

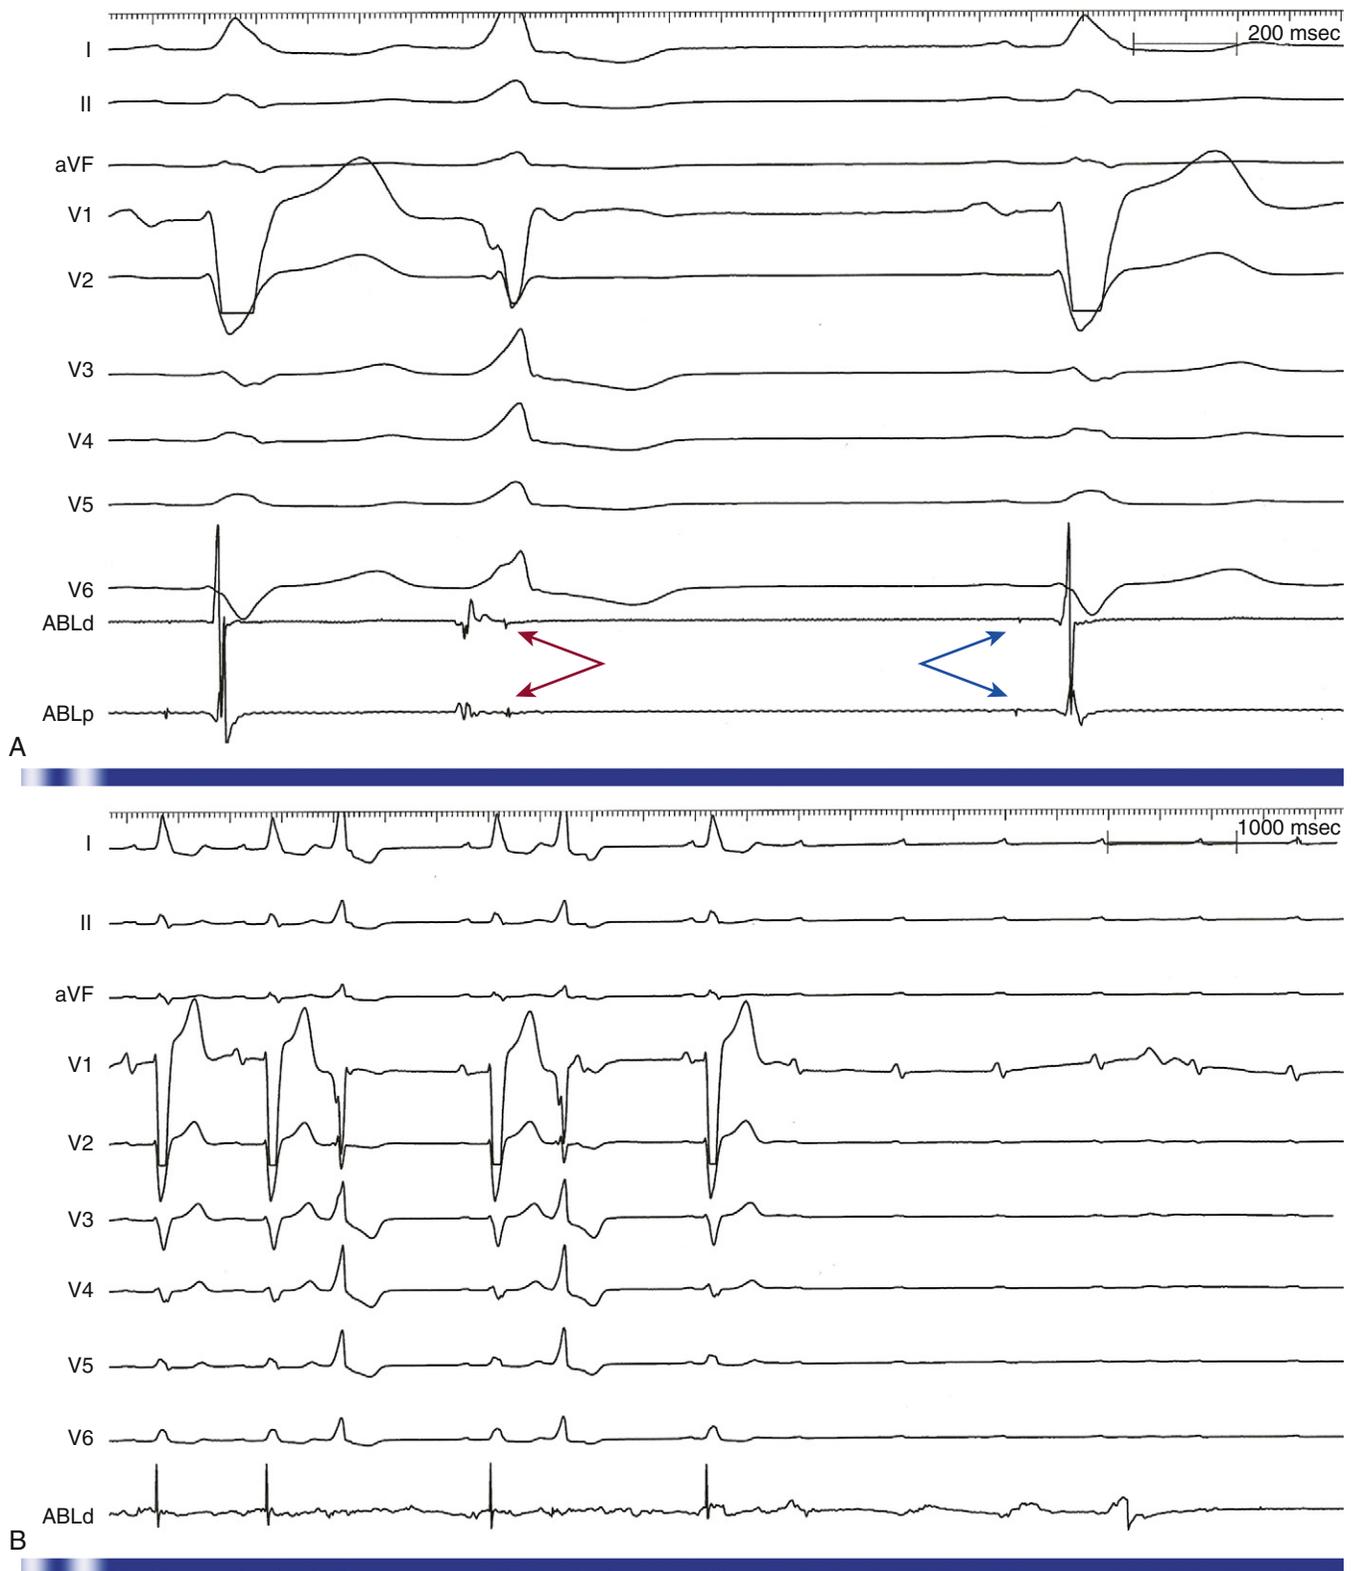

FIGURE 32-5 Atrioventricular (AV) block complicating catheter ablation of premature ventricular complexes (PVCs) originating from the para-Hisian region. In **A**, note the presence of anterograde His potentials on the proximal and distal ablation electrodes (ABLp and ABLd, respectively) during sinus rhythm (blue arrows) and retrograde His potentials during PVCs (red arrows) at the site of earliest ventricular activation during PVCs. In **B**, radiofrequency energy delivery results in complete AV block secondary to injury to the His bundle.

duration should be used, coupled with overdrive atrial pacing to monitor AV conduction in case accelerated junctional rhythm occurs. Alternatively, cryoablation can be used in this region with its slightly better safety margin for AV conduction.^{22,23}

In some patients, mechanical trauma from the catheter induces temporary AV block. Also, catheter manipulation in the RV or LV can cause mechanical bundle branch block (often transient), which can potentially cause complete AV block in patients with preexisting block in the contralateral bundle branch. Furthermore, ablation of the right bundle branch in patients with bundle branch reentrant VT is commonly followed by complete AV block (in up to 30%) because of preexisting severe disease in the left bundle branch.

Macroreentrant Atrial Tachycardias

Whereas the occurrence of new arrhythmias following focal RF ablation has not been a clinical problem, linear ablation lesions, if incomplete, can promote reentry propagating through the gaps in the ablation lines. Even when conduction block across the ablation lines is verified, the ablation lines commonly performed in the LA for ablation of AF can still facilitate reentry by providing conduction obstacles and protected isthmuses with adjacent anatomical structures in the atrium.^{24,25} In fact, LA macroreentry is a relatively common complication of catheter ablation of AF, occurring in up to 50% of cases. The incidence of ATs seems to be lower following segmental ostial pulmonary vein (PV) isolation (<5%) compared with circumferential PV isolation, and much higher following circumferential or linear LA ablation (>30%). Targeting complex fractionated atrial electrograms without linear lesions or PV isolation is associated with a moderate risk (8.3%) for post-ablation ATs. Following stepwise approaches of catheter ablation incorporating extensive lesions in the LA and RA to terminate persistent AF, ATs can be observed in more than 50% of patients.²⁶⁻²⁸ Although ATs can occur at variable time intervals after AF ablation procedures, the most common timing appears to be 1 to 2 months postablation.^{29,30}

Ventricular Arrhythmias

Ventricular fibrillation has been reported in up to 6% of patients with chronic AF after AVN ablation when the ventricular pacing rate is lower than 70 beats/min. This complication can be minimized by postablation pacing for 3 months at a higher rate—that is, 90 beats/min. A possible mechanism for postablation ventricular arrhythmia is activation of the sympathetic nervous system and a prolongation of action potential duration.

Inappropriate Sinus Tachycardia

Inappropriate sinus tachycardia can occur in some patients after posteroseptal BT or AVN ablation, suggesting disruption of the parasympathetic input and/or sympathetic input into the sinus node and AVN.

Valvular Damage

The aortic valve can be damaged during retrograde crossing of the ablation catheter for retrograde ablation of LV VTs and left-sided BTs. To prevent leaflet damage or perforation, the straight catheter tip must never be used to cross the aortic valve; instead, a tight J curve is formed with the catheter tip before passage to the aortic root. Ablation of arrhythmias originating from the aortic cusp can also result in valvular damage, and limiting RF power output and duration is necessary.

Damage to the mitral valve can result from entanglement of the ablation catheter within the mitral valve apparatus during transaortic or transseptal ablation procedures, but serious damage is unlikely. The risk of valvular damage (occasionally requiring thoracic surgery and valve replacement) is higher following entrapment of catheters with multiple splines or circular mapping catheters in the valvular apparatus (e.g., during AF ablation), which can be potentially difficult to free. Forcible traction of the

catheter should be avoided as it can potentially damage the valve and ultimately lead to mitral valve replacement. To prevent injury to the papillary muscles or chordae tendineae, prior to pulling on the catheter, one may consider instead advancing the catheter toward the LV apex. Advancing the sheath over the catheter and withdrawing the catheter into the sheath followed by withdrawal of the whole assembly can facilitate the effort further. When gentle manipulation and moderate traction are unsuccessful, removing the catheter by thoracic surgery may be preferable; in this way the valve can potentially be spared significant damage.^{3,31}

Phrenic Nerve Injury

Phrenic nerve damage and consequent diaphragmatic paralysis have been a long-recognized complication during endocardial ablation in the RA or LA as well as during percutaneous epicardial ablation procedures.

The intrathoracic course of the right phrenic nerve, especially as it approximates the superior vena cava (SVC) and RA (and not infrequently the right superior PV), is the principal reason for susceptibility to nerve damage from endocardial ablation. Injury to the right phrenic nerve has typically been reported during sinus node modification or ablation of ATs in the RA free wall, SVC, or right superior PV. Right phrenic nerve injury has become more frequent with the increasing number of AF ablation procedures that involve electrical isolation of the SVC as well as ablation around the right superior PV, especially when balloon ablation catheters are used. The reported incidence of phrenic nerve injury secondary to AF ablation varies from 0% to 0.48%.^{32,33}

The left phrenic nerve descends behind the left brachiocephalic vein and passes over the aortic arch, pulmonary trunk, and then with the pericardium over the LA appendage. From there it descends along the pericardium over the LV and frequently passes laterally over the obtuse margin of the LV, close to the lateral vein and the left marginal artery and, in only a small percentage of cases, close to the left main coronary artery and great cardiac vein. Left phrenic nerve injury can occur during AF or AT ablation in the region of the proximal LA appendage roof, during ablation of left posterolateral BTs, as well as during percutaneous epicardial ablation adjacent to the lateral LV wall.^{34,35}

Clinical Presentation

Phrenic nerve injury can be asymptomatic in about one-third of cases. The most frequent symptom is dyspnea. Other symptoms or clinical findings are cough or hiccup during ablation and the development of postablation pneumonia or pleural effusion. In asymptomatic patients, the diagnosis is made on the routine chest x-ray (Fig. 32-6) with hemidiaphragm paresis or paralysis (hemidiaphragm elevation with paradoxical movement). There is no active treatment known to aid phrenic nerve healing. Complete or partial recovery of diaphragmatic function can be observed in 66% and 17% of patients, respectively, sometimes not realized until several weeks or even months later.³⁶

Prevention

In areas at high risk of phrenic nerve injury (RA free wall, posteroseptal part of the SVC, inferoanterior aspect of the right PV ostium, and proximal LA appendage roof) that require ablation, high-output (10 mA) pacing should be performed before energy delivery. The ability to pace the phrenic nerve should prompt attempting to find a slightly different site or, if this is not possible, applying RF energy at low power and/or for short duration. This technique can be combined with electroanatomical mapping of the RA, SVC, LA, and right PVs to reconstruct the anatomical course of the right phrenic nerve. Even when the phrenic nerve cannot be paced, intermittent fluoroscopic visualization of the ipsilateral diaphragm movement should be performed during RF application at high-risk sites, and RF delivery should be terminated if diaphragmatic excursion decreases.

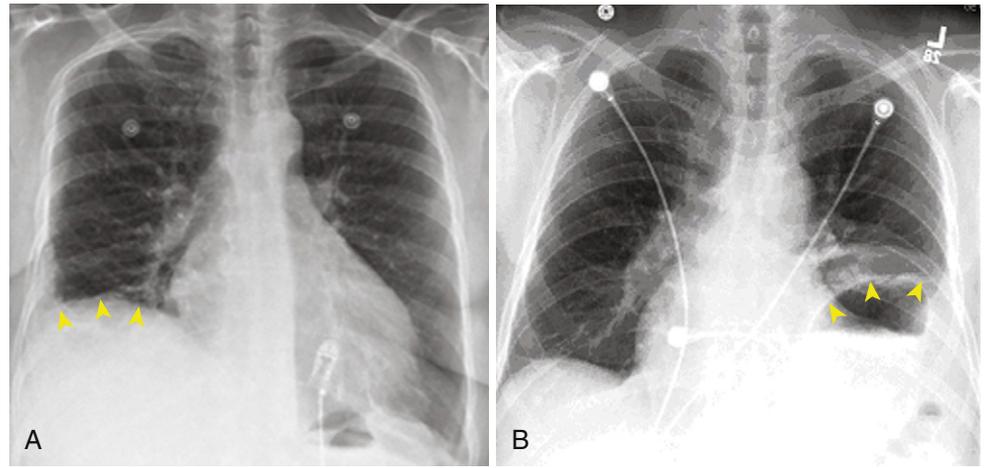

FIGURE 32-6 Chest x-rays (posteroanterior views) showing right hemidiaphragmatic paralysis (arrowheads) caused by right phrenic nerve injury (A), and left hemidiaphragmatic paralysis caused by left phrenic nerve injury (B) during catheter ablation of atrial fibrillation.

An alternative technique is to position a catheter in the SVC at a site where the phrenic nerve can be consistently captured, and pace the phrenic nerve during ablation. RF energy delivery should be stopped immediately if diaphragmatic contraction becomes less vigorous or ceases.

Early recognition of phrenic nerve injury during RF delivery (which can be indicated by the development of hiccup, cough, or decrease in diaphragmatic excursion during energy delivery) allows immediate interruption of the application prior to the onset of permanent injury, which is associated with the rapid recovery of phrenic nerve function. This is not feasible in patients undergoing general anesthesia.

Recently, diaphragmatic electromyography has been used to monitor phrenic nerve integrity during ablation. A progressive decline in compound motor action potential amplitude heralded phrenic nerve palsy, with a 30% decrease yielding the best predictive value, preceding hemidiaphragmatic paralysis by about 30 seconds. To record right diaphragmatic compound motor action potentials, two standard surface electrodes are connected to a central computerized electrophysiology workstation. The recording electrode is placed on the thorax 5 cm superior to the tip of the xiphoid process and the reference electrode is positioned along the right costal margin with a 16-cm interelectrode distance. Diaphragmatic bipolar electromyographic signals are recorded during continuous pacing of the right phrenic nerve, using a catheter in the SVC. The clinical application of this approach to prevent phrenic nerve palsy induced by cryoballoon ablation of the right superior PV is still in its preliminary stages, and further evaluation is required to validate and optimize this approach.^{37,38}

The use of a non-RF source of energy is unlikely to prevent this complication because phrenic nerve injury has been reported with ultrasound, laser, and cryotherapy. Furthermore, phrenic nerve injury occurs independently of the strategy of AF ablation used (PV isolation versus wide circumferential LA ablation).

During percutaneous epicardial ablation, proximity to the phrenic nerve can be detected by high-output pacing (typically at >10 mA) to detect diaphragmatic stimulation on fluoroscopy, allowing its course to be marked on a three-dimensional (3-D) map.³⁹ The nerve can branch over the LV, so simply noting sites at which phrenic nerve capture occurs does not necessarily delineate the course of all branches. It is important to recognize that detection by phrenic nerve capture is prevented by the use of paralytic agents during general anesthesia. However, these drugs are typically used during induction of anesthesia and their effects have dissipated by the time ablation is being performed. Catheter ablation should be avoided at sites adjacent to the phrenic nerve. Alternatively, moving the nerve away from the myocardium by injection of air into the pericardium or placement of a balloon catheter between the ablation target site and nerve can allow safe RF ablation. Alternative energy sources such as cryoenergy have been used to prevent phrenic nerve injury. Cryomapping uses temporary phrenic nerve injury to determine when to avoid full

cryoablation. However, data on the success of cryoablation in the pericardial space are limited.^{34,35}

Pulmonary Vein Stenosis

Incidence

PV stenosis is one of the most serious complications of AF ablation and has been reported with a wide range of incidence (0% to 42%), mainly because of different ablation strategies and differing methodology for estimating postablation PV ostia. The severity of PV stenosis is generally categorized as mild (<50%), moderate (50% to 70%), or severe (>70%). When moderate and mild lesions are included, the overall rate is as high as 15.5% (Fig. 32-7). However, the rate of severe PV stenosis has fallen to as low as 1.0% to 1.4% with increasing experience and improvements in technique, such as performing ablation outside the PVs and the use of ICE. Late progression of PV stenosis to severe stenosis or even complete occlusion can occur in up to 27% of patients (Fig. 32-8), particularly in the smaller PVs. Of note, stenosis seems to be more common in the left-sided PVs.¹¹

Circumferential LA ablation, with ablation limited to atrial tissue outside the PV orifice, seems to have lower rates of PV stenosis, whereas focal ablation inside the PV has a higher risk. Moreover, with PV isolation techniques, the use of an individual encircling lesion set that requires RF ablation between the ipsilateral PVs carries a higher risk of PV stenosis. With the focal ablation approach, PV stenosis can occur at a rate up to 33% to 42%. Although this represents an overestimation of the problem because increased TEE flow velocity was used to establish the diagnosis, it remains a major concern. With PV isolation techniques, the incidence of severe PV stenosis is approximately 1% to 5%. MR and spiral CT scanning have shown that although current PV isolation techniques are associated with minimal reduction of the PV ostial diameter, stenosis exceeding 50% can occur in up to 18% of cases, whereas very severe stenosis (>90%) is found in up to 2% of cases. Following circumferential LA ablation, the prevalence of PV stenosis likely ranges between 2% and 7%. In one report, a detectable reduction in PV diameter was present in 38% of PVs; however, moderate and severe PV stenosis was observed in 3.2% and 0.6% of PVs, respectively.^{3,9}

Mechanism

The mechanism of the development of PV stenosis remains unclear. Acute reduction of PV diameter (by approximately 30%) has been demonstrated during ablation. It was initially speculated that these changes are caused by edema and spasm. Thermal injury, induced by RF, has recently been shown to produce Ca²⁺-mediated irreversible tissue contracture occurring with the production of most if not all RF lesions, and therefore almost certainly contributes to

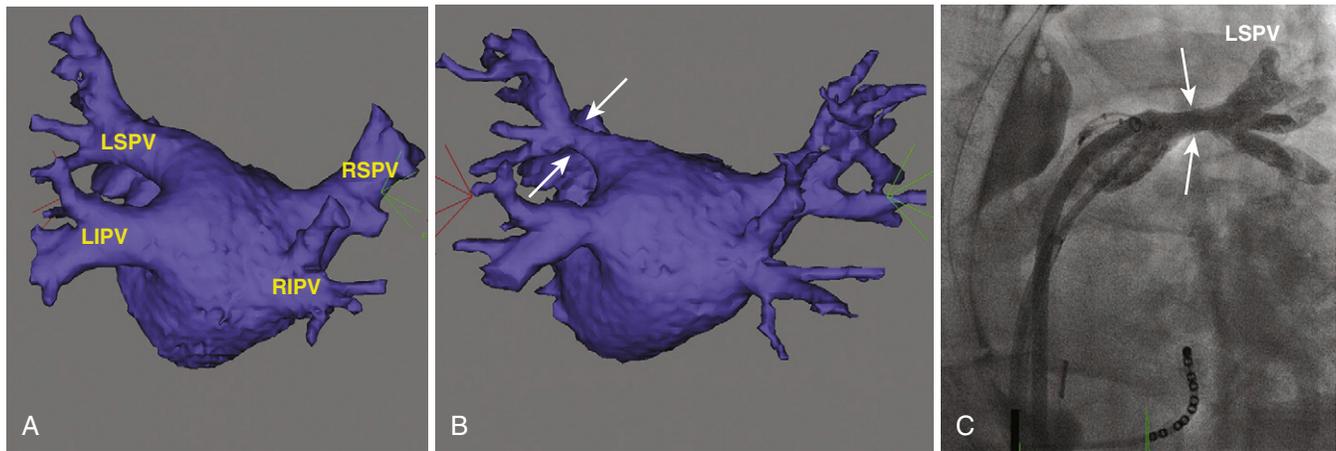

FIGURE 32-7 Pulmonary vein (PV) stenosis. **A**, CT image of the left atrium and PVs at baseline before segmental ostial PV isolation. **B**, CT image 3 months after the ablation procedure, showing moderate stenosis of the left superior pulmonary vein (LSPV; arrows) and mild stenosis of the left inferior pulmonary vein (LIPV). **C**, Angiogram (left anterior oblique view) of the LSPV, showing a moderate degree of stenosis (arrows). RIPV = right inferior pulmonary vein; RSPV = right superior pulmonary vein.

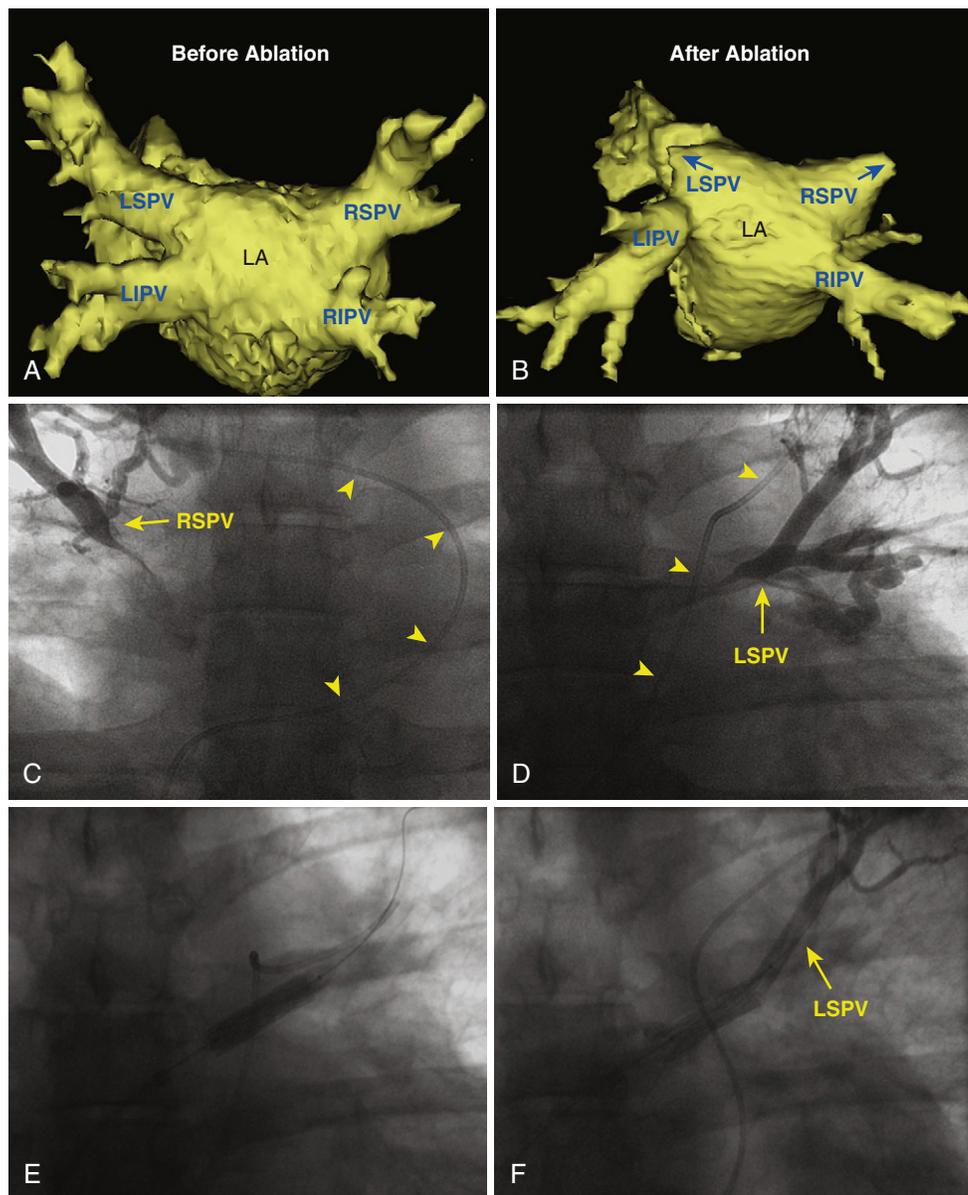

FIGURE 32-8 Pulmonary vein (PV) occlusion. **Upper panels**, CT image of the left atrium (LA) and PVs at baseline before segmental ostial PV isolation (**A**) and 5 months after ablation (**B**). Following ablation complete occlusion of both superior PVs is observed. **Middle panels**, Fluoroscopic (anteroposterior) views during angiography of the right superior pulmonary vein (RSPV) (**C**) and left superior pulmonary vein (LSPV) (**D**), showing severe stenosis-occlusion of both PVs at the ostia. PV angiography was performed with contrast injection via a catheter positioned in the pulmonary artery (arrowheads). **Lower panels**, Fluoroscopic (anteroposterior) views during stenting of the LSPV: **E**, Angioplasty balloon is inflated for stent deployment in the LSPV; **F**, angiogram of the left superior PV following stenting. LIPV = left inferior pulmonary vein; RIPV = right inferior pulmonary vein.

stenosis. It is well known that thermal injury produces denaturation of extracellular proteins, especially collagen. Thermally induced collagen shrinkage has been well documented in animal and human studies. When near-circumferential lesions are produced within the tubular confines of the PVs, the consequences can be easily demonstrated as PV contracture. Thus, PV stenosis likely results from a combination of endothelial disruption with platelet activation and later neointimal proliferation, reversible edema, collagen denaturation, and shrinkage and thermal contracture. The occurrence and degree of PV stenosis correlate with the amount of energy delivered and lesion extension. The high incidence of mild PV stenosis likely reflects PV reverse remodeling rather than pathological PV stenosis. This hypothesis is based on the observation that all the mild PV stenoses were concentric rather than eccentric.^{3,9}

When severe stenosis or occlusion of a PV develops suddenly, gradual decline and then cessation of the arterial flow to the affected lung segment are observed. This is caused by a decline in the arteriovenous gradient as well as compression by the developing tissue edema. As a consequence, the involved alveoli are affected by the resulting ischemia and surrounding edema, leading to atelectasis, infarction, or susceptibility to infections. With the resulting alterations in pulmonary hemodynamics, redistribution of blood flow occurs with the opening of vascular channels or neovascularization in which tissue hypoxia is known to play a role. Hence, the venous drainage of the affected segment becomes mainly dependent on the ipsilateral veins draining the healthy lobes. If the ipsilateral vein(s) is also stenosed, the impedance to the pulmonary flow increases, adding to the hemodynamic burden. Symptoms attributable to PV stenosis are typically not seen unless the perfusion of the affected lobe falls below 20% or the perfusion of the entire lung on the affected side falls below 25%.⁴⁰

Clinical Presentation

PV stenosis after ablation is frequently asymptomatic, especially when a mild or moderate degree of PV stenosis is present or a single vein is involved. Severe PV stenosis can be associated with various respiratory symptoms that frequently mimic more common lung diseases, such as asthma, pneumonia, lung cancer, and pulmonary embolism. A high degree of suspicion is necessary to avoid performing misleading diagnostic procedures and to allow proper and prompt management. The onset of symptoms is usually several months after ablation. The initial manifestation is generally dyspnea on exertion, which typically evolves over the course of 1 to 3 months. Persistent cough is a common symptom. Pleuritic chest pain is a late symptom, and hemoptysis is uncommon. Both pleuritic chest pain and hemoptysis are likely related to complete vessel or branch occlusion.^{3,9}

It seems that symptom severity is related not only to the degree of stenosis but also to the number of PVs with stenosis. Symptoms may improve spontaneously over time in a significant percentage of patients. In one report, this improvement occurred in 50% of patients and was always related to improvement in the radiological abnormalities previously detected, although other hemodynamic compensatory mechanisms (e.g., development of collaterals) can also play a role.

Detection

To date, it remains unclear which is the best and most cost-effective noninvasive modality for detecting PV stenosis after ablation. TEE and CT scanning are most commonly used (Videos 24 and 25); however, no single imaging modality has been able to assess all relevant aspects of PV stenosis. Therefore, complementary methods are used (see Fig. 32-7). Although many investigators recommend routine follow-up CT or MR imaging for detection of asymptomatic PV stenosis 3 to 4 months after ablation of AF, it is unknown whether early diagnosis and treatment of asymptomatic PV stenosis provide any long-term advantage to the patient.⁴⁰ Nevertheless, it is recommended that follow-up PV imaging be performed to screen for PV

stenosis during the initial experience of an AF ablation technique for quality control purposes.^{3,9}

Spiral CT and MR imaging of the PVs are readily available and can reveal the correct diagnosis; they are probably the most helpful in identifying the location and extent of the stenosis (see Fig. 32-7). However, the sensitivity and specificity of these imaging modalities need to be studied further. Of note, the diagnosis of PV occlusion cannot be made reliably using CT or MR imaging, and pulmonary artery wedge angiography is the only method for confirming the diagnosis.⁴¹

TEE provides adequate visualization of the superior PVs, but imaging of the right and left inferior PVs is inconsistent. Hence, TEE is not typically used as a first-line imaging study for routine screening. Nonetheless, TEE provides additional functional data regarding the significance of PV stenosis.⁴⁰ On TEE, PV stenosis is usually indicated by an increased maximal PV Doppler flow velocity or by the presence of turbulence and deformity of the flow signal, as defined by a minimal flow between systolic and diastolic peak flow of 60% of the mean of both peaks. ICE allows straightforward imaging of all PVs and provides a good view into the first 1 to 3 cm of the vein. Color flow contrast imaging is also useful for identifying the location of the orifice of the most tightly stenotic vessels.

Blood gas assessment and pulmonary function testing do not seem to be useful as screening measures for early PV stenosis. Radiographic findings in PV stenosis are nonspecific. Chest radiography often reveals parenchymal consolidation, pleural effusion, or both. Ventilation/perfusion scanning can be done to characterize the functional significance of the stenosis. In the presence of significant PV stenosis, perfusion abnormalities are usually marked and appear similar to the changes seen in pulmonary embolism.

Prevention

The best way to manage PV stenosis is to avoid it. PV stenosis is independently related to RF lesion location, size, and distribution and to baseline PV diameter. The prevalence of this complication has decreased because of various factors, including abandonment of in-vein ablation at the site of the AF focus, limiting ablation to the extraostial portion of the PV or PV antrum, use of advanced imaging techniques to guide catheter placement and RF application, reduction in target ablation temperature and energy output, and increased operator experience.¹¹

Cryothermal ablation has unique characteristics that may prove to be desirable when lesions are required within the PV. Specifically, there is less endothelial disruption, maintenance of extracellular collagen matrix without collagen denaturation, and no collagen contracture related to thermal effects. These characteristics may translate into a reduction in PV stenosis as compared with RF ablation.

Management

PV intervention is recommended in symptomatic patients. PV stenting appears to be associated with a lower restenosis rate compared with angioplasty (Video 26).⁴² For asymptomatic patients with severe PV stenosis, some investigators have also suggested interventional therapy because lesions can progress and eventually lead to total occlusion, precluding dilation and potentially resulting in hemodynamic compromise (see Fig. 32-8).¹¹ Others have proposed regular clinical follow-up and intervention considered only when symptoms develop. However, it is important to understand that patients can become symptomatic only after the long-term sequelae of PV occlusion become manifest, at which time intervention may not be technically feasible or, even when successful, may not be associated with significant improvement in perfusion of the affected lung segments. It is also important to consider the age, functional capacity, and associated comorbidities as well as anatomical and technical factors pertaining to the stenotic vein when making a decision regarding interventional treatment in asymptomatic patients.¹¹

TEE or ICE can facilitate accurate stent placement by reliably identifying the orifice of the tightly stenotic vein. Unfortunately, both in-stent and in-segment restenosis can recur in up to 61% of patients, and repeat intervention is warranted in symptomatic patients. Stenosis within the body of the stent is likely caused by neointimal hyperplasia and fibrosis. Out-of-stent restenosis is usually observed at bifurcation points beyond the stent into the vessel, also suggesting the progression of PV pathology, despite stent placement. There is no experience to date with the use of drug-eluting stents in this setting, but such a high restenosis rate makes a strong case for the investigation of those devices and larger diameter stents.¹¹

Atrioesophageal Fistula

Incidence

The true incidence of atrioesophageal fistula after catheter ablation is unknown, but has been estimated to be between 0.03% and 0.2%, although underreporting is likely.^{43,44} Despite its rarity, atrioesophageal fistula remains a devastating complication associated with high mortality, accounting for 15.6% of cases with fatal outcome (the second leading cause of death post AF ablation, following cardiac tamponade).⁴⁵

On the other hand, esophageal mucosal changes consistent with thermal injury have been reported in up to 47% of the patients following AF ablation, and esophageal ulcerations confirmed by esophagogastrosomy or capsule endoscopy can be observed in 14% to 18%.^{46,47}

Mechanism

The precise mechanism of atrioesophageal fistula formation has not yet been determined. Proposed potential mechanisms include direct thermal injury of the esophageal wall in immediate proximity to the posterior LA wall, thermal injury of the arterial blood supply to the esophagus, and mechanical injury to the esophagus during periprocedural TEE as a contributing or predisposing factor.³

The esophagus is located at the center of the posterior mediastinum and runs in close proximity to the posterior LA wall for about 5 cm of its course. In that region, the esophagus is separated from the LA only by the pericardial sac (the oblique sinus), which insinuates itself between the openings of the right and left PVs. The LA posterior wall thickness is 2 to 4 mm and the thickness of the esophageal wall is 2 to 3 mm in cross section at the LA-esophageal area of contact. During RF catheter ablation, lesion depth, extension, and volume are related to the design of the ablation electrode and RF power delivered. Theoretically, esophageal damage can occur, even during LA ablation using a standard 4-mm-tip ablation catheter. However, cooled and large-tip ablation catheters induce extended lesions. Thus, delivering high-power RF applications on the LA posterior wall between the left and right PVs can potentially deeply damage the esophagus, resulting in atrioesophageal fistula formation.^{48,49}

The esophagus does not have a serosal layer and is fixed primarily in the pharynx and gastroesophageal junction. In the mediastinum, the esophageal position is dynamic because of peristalsis. In fact, the esophagus often shifts sideways by 2 cm or more in most patients undergoing catheter ablation for AF under conscious sedation. Additionally, the position of the esophagus in relation to the LA and PV demonstrates high variability. In many cases, the esophagus is very close to the ostia of the PVs and lies only a short distance from the LA wall. In most subjects (90%), the esophagus courses down beside the ostia of the left PVs with a mean distance of 10.1 mm to the left superior PV and 2.8 mm to the left inferior PV. Therefore, anatomical localization of the esophagus can be critical before or during AF ablation to prevent atrioesophageal fistula, especially as there is a need for transmural atrial lesions.

The risk of esophageal injury likely is enhanced by increasing the magnitude and duration of local tissue heating (i.e., the total ablation energy delivered to cardiac tissue near the esophagus), which is

related to catheter tip size, contact pressure, catheter orientation, and power output and duration. In fact, all reported cases of atrioesophageal fistulas have in common attempts to perform deep RF lesions on the LA posterior wall. Additionally, ablation strategies incorporating extensive ablation in the LA posterior wall and the type of AF (persistent more than paroxysmal AF, possibly due to the additional linear ablation lesions) have been associated with an increased rate of esophageal ulcerations. A short LA-to-esophagus distance, the use of nasogastric tubes, and general anesthesia are other potential risk factors for esophageal injury during RF ablation.^{49,50}

Cryoballoon ablation commonly causes significant decreases in esophageal temperature, especially during cryoablation of the inferior PVs, resulting in esophageal ulcerations. Although no instances of atrioesophageal fistula formation after cryoballoon PV isolation have yet been reported, the total number of cryoballoon ablation cases performed is relatively small to reliably detect this rare complication. Furthermore, esophageal ulcerations have been observed following cryoballoon ablation at rates (17% of patients) similar to those seen with RF ablation. Although there is no definitive proof that esophageal ulcer formation is predictive of fistulas, it is reasonable to assume that esophageal ulcerations may represent the first step on the way to atrioesophageal fistula. Therefore, until further experience indicates otherwise, cryoballoon ablation should not be considered completely safe in regard to atrioesophageal fistula formation.⁵¹

Excessive esophageal heating, esophageal ulcerations, and atrioesophageal fistula formation have been observed post PV isolation using high-intensity focused ultrasound (HIFU). In a recent study, elevated esophageal temperature prompting cessation of HIFU energy delivery occurred in 9% of PVs. Despite use of the safety algorithm, the occurrence of esophageal thermal damage and lethal atrioesophageal fistula could not be prevented, occurring in 1 of 28 patients. This safety concern argues against the clinical use of HIFU in its current iteration for PV isolation.⁵²

Clinical Presentation

The clinical course of atrioesophageal fistula formation varies in abruptness of presentation and timing (ranging from 2 days to 4 weeks), and mostly is manifest after patient discharge from the hospital. The presenting symptoms can include hematemesis, sepsis, or air embolization and stroke. The leading symptom of esophageal perforation is high fever or severe chest or epigastric pain.

Leukocytosis is the earliest and most sensitive laboratory marker. Thoracic CT or MR imaging is the most valuable diagnostic examination (Fig. 32-9, Video 27). The dramatic neurological complications occur with a delay of at least a few hours after the first symptoms. Endoscopy is a diagnostic modality that should be avoided because insufflation of the esophagus with air can result in a devastating cerebrovascular accident and death secondary to a large air embolus. Immediate surgery (within a few hours after the first symptoms) can potentially prevent neurological complications and possibly result in a high survival rate, without residue. Delay of treatment seems to have devastating results.³

Prevention

Various strategies may be used to avoid the development of an atrioesophageal fistula, including the following: (1) assessment of esophageal position before and during ablation; (2) avoiding ablation in the vicinity of the esophagus; (3) mechanical displacement of the esophagus; (4) monitoring of the esophageal temperature during energy delivery; and (5) reduction of ablation energy power output and duration at sites close to the esophagus. However, because of the rarity of this complication, it remains unproven whether the use of these approaches lowers or eliminates the risk of esophageal perforation or fistula formation, and the optimal technique has not yet been determined. Therefore, it appears prudent to apply a combination of these preventive techniques during AF ablation. These strategies are discussed in detail in [Chapter 11](#).^{48-50,53-55}

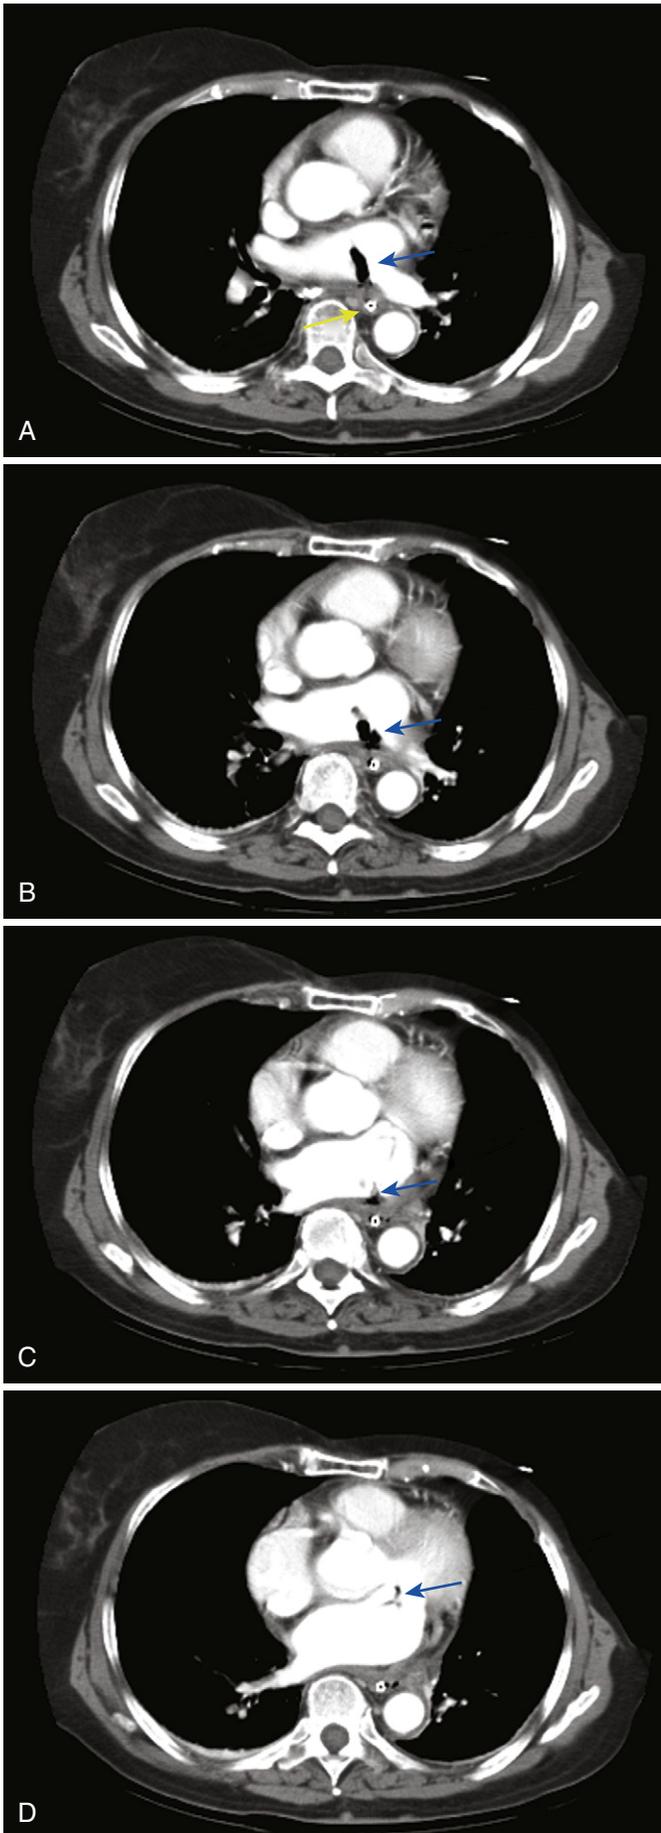

FIGURE 32-9 Atrioesophageal fistula postablation of atrial fibrillation. Multiple transverse sections of a chest computed tomography scan, revealing air bubbles (blue arrows) in the superior aspect of the left atrium (A-C) and at the level of the mitral valve (D). Note that air appears to originate from the anterior esophageal wall (B and C). Nasogastric tube is visualized in the esophagus (yellow arrow).

Radiation Exposure

Catheter ablation of complex cardiac arrhythmias, including AF macroreentrant ATs, and reentrant VTs, can be associated with markedly prolonged fluoroscopy durations. The use of CT scanning before and after AF ablation procedures further increases patient exposure to radiation. Direct monitoring of patient skin doses during procedures is highly desirable.

Radiation exposures during the different interventional procedures are highly variable. Cardiac catheterizations generally expose patients to an average dose of 250 rad (2.5 Gy). Percutaneous coronary interventions are particularly dangerous (average dose, 640 rad [6.4 Gy]) because radiation is focused only on those vessels with stenosis. Although these represent standard exposure estimates, interventional procedures are highly variable.⁵⁶ In one report, only 1 of 15 patients undergoing AF ablation reached a peak skin dose of 2 Gy, despite prolonged fluoroscopy durations (up to 99 minutes). This finding is striking and speaks to the effectiveness of the systems that use several technologies to reduce radiation exposure, such as last image hold, pulsed fluoroscopy, and additional filters.⁵⁷

With similar fluoroscopy durations in both projections, the radiation dose is higher in the LAO than in the right anterior oblique (RAO) projection, primarily because of a longer attenuation path for the x-ray beam entering in the LAO projection.

Clinical Presentation

In EP procedures, the patient tissue receiving the greatest radiation dose is the skin area of the back at the entrance point of the x-ray beam, and skin injuries are well-recognized complications for catheter ablation procedures. The threshold for transient erythema and epilation is 2 to 3 Gy, for acute skin injury is 2 to 8 Gy, and for chronic radiation injury is 10 Gy.⁵⁶ Obese patients, those with pre-existing health conditions such as collagen vascular disease, diabetes mellitus, or ataxia telangiectasia, and those who received a high radiation dose from a previous procedure, can be at a greater risk for radiation skin damage.

Acute radiation injury (characterized by erythema with vesiculation, erosion, and pain) usually starts within days after exposure and persists up to several weeks (Fig. 32-10). Chronic radiation injury manifests months to years after exposure and presents clinically as permanent erythema, dermal atrophy, and ulceration.

Acute radiation-induced skin injury can be misdiagnosed as contact dermatitis, viral or bacterial infection, or a spider bite, and a high index of suspicion is required. Fluoroscopy-induced injuries affect an area congruent to the entrance of the x-ray beam that typically has well-defined borders (see Fig. 32-10), which occur when the beam is not moved or resized during prolonged fluoroscopy over one site. It is important to alert patients who had undergone prolonged procedures or known to have received a high skin radiation dose to examine him- or herself about 2 to 3 weeks after the procedure to look for skin changes and to contact the interventionalist if any are observed.

Skin biopsy is usually not necessary and not recommended, especially given the potential risk of a nonhealing ulcer at the site of biopsy in the radiation-damaged skin area. Furthermore, the findings on skin biopsy generally are not pathognomonic for radiation change.

The estimated lifetime risk of a fatal malignancy after AF ablation using a modern low-frame pulsed fluoroscopy system is relatively low (0.15% for women and 0.21% for men in one report) and is higher than, although within the range of, previously reported risk to result from the ablation of standard types of supraventricular

FIGURE 32-10 Acute radiation-induced skin injury (erythema) 2 to 3 weeks following radiofrequency ablation of atrial fibrillation using biplane fluoroscopy. The affected areas have well-defined borders congruent with the entrance of the x-ray beam.

arrhythmias (0.03% to 0.26%). It has been estimated that for every 60 minutes of fluoroscopy, the mean total lifetime excess risk of a fatal malignancy is 0.03% to 0.065%.

Prevention

Increasing availability and familiarity with 3-D mapping systems should significantly reduce fluoroscopy time and the need for biplane fluoroscopy. The use of remote navigation systems also is likely to reduce fluoroscopy exposure of the patient and operator.⁵⁷ Additionally, judicious and intermittent use of fluoroscopy, that is, keeping the x-rays on for only a few seconds at a time, long enough to view the current catheter position, can reduce total fluoroscopic times considerably. The presence of grids in x-ray systems primarily increases the contrast and hence the image quality; however, they increase the dose to the patient and staff by a factor of two or more, and removal of the grid can help reduce the dose of radiation. Additionally, periodically rotating the fluoroscope at different angles helps spread the total radiation dose over a broader area of the patient's skin so that no single region receives the entire dose. Other methods include adjustment of beam quality, using pulsed fluoroscopy, inserting appropriate metal filters (aluminum, copper, or other materials) into the beam at the collimator, and minimizing geometric magnification by keeping the image receptor close to the patient and the source away.

 - site of earliest activation in, 588, 589f
 - tachycardia features in, 588–590
 - termination of, 590
 - verapamil for
 - intravenous, 587
 - oral, 588
 - Vitamin K antagonists, for atrial fibrillation, 301
 - Voltage mapping. *See* Electroanatomical mapping, voltage.
 - VT. *See* Ventricular tachycardia.
 - V-V-A response, in wide QRS complex tachycardia, 510
- ## W
- Warfarin, for atrial fibrillation, 301
 - Wavelength, in reentry, 51
 - Wenckebach block, 80, 179–181
 - atypical, 80, 180, 180f–181f
 - focal atrial tachycardia and, 215, 219f
 - macroreentrant atrial tachycardia and, 265
 - management of, 191–193, 192t–193t
 - site of, 181, 187–188
 - typical, 180, 180f
 - in ventricular pacing, 84
 - vs. echo beats, 190
 - Wide QRS complex tachycardia, 499–511
 - adenosine effects on, 509
 - atrial activation sequence in, 509
 - atrial extrastimulation/pacing in, 509–510, 510f
 - atrioventricular dissociation in, 500, 502–503
 - atrioventricular relationship in, 509, 509f
 - Brugada criteria for, 505, 506f
 - causes of, 499–500, 500t
 - clinical considerations in, 499–501
 - clinical history in, 499–500
 - cycle length in, 508, 508f
 - device-associated, 499
 - diagnostic algorithms for, 505–507, 506f–507f
 - diagnostic maneuvers during, 509–510
 - differential diagnosis of, 505–507
 - Dressler beats in, 503, 504f
 - drug therapy for, in diagnosis, 501
 - drug-induced, 499–500
 - duration of, 499
 - electrocardiography of, 501–508, 501t
 - electrophysiological testing of, 508–510
 - fusion beats in, 503, 504f
 - HB-RB-V activation sequence in, 508–509
 - HV interval in, 508
 - laboratory tests for, 500

Wide QRS complex tachycardia (*Continued*)
 left bundle branch–like pattern in, 501–503,
 501t, 502f, 504f–505f
 pacemaker/defibrillator–related, 499
 paroxysmal supraventricular tachycardia and,
 481–482
 physical examination in, 499
 potassium imbalance and, 500, 500f
 QRS complex in
 duration of, 501, 501t
 morphology of, 501t, 503–504, 504f–505f, 508
 precordial concordance of, 501t, 502, 502f
 variation in, 504
 rate and regularity of, 501
 right bundle branch–like pattern in, 501–503,
 501t, 502f, 504f–505f
 ST-T morphology in, 504
 supraventricular tachycardia as, 499, 507–508,
 507f
 symptoms of, 499
 tachycardia features in, 508–509
 underlying heart disease and, 499
 ventricular extrastimulation/pacing in, 510,
 511f
 ventricular tachycardia as, 499
 VVA response in, 510

Wolff-Parkinson-White pattern, 411, 414–415,
 418–419, 418f
 management of, 416–417. *See also* Bypass
 tract(s), ablation of.
 mimics of, 418–419, 419f–420f, 448t
 Wolff-Parkinson-White syndrome, 411
 activation mapping in, 93f
 associated supraventricular tachycardias and,
 421–424, 422f–423f
 atrial fibrillation and, 414
 atrial flutter and, 414
 atrial tachycardia and, 413
 atrioventricular nodal reentrant tachycardia
 and, 413
 atrioventricular reentrant tachycardia and. *See*
 Atrioventricular reentrant tachycardia.
 clinical presentation of, 415–416
 electrocardiography of, 416
 electrophysiological testing in, 416,
 425–447. *See also* Atrioventricular
 reentrant tachycardia, antidromic,
 electrophysiological testing in.
 in asymptomatic patients, 416–417
 epidemiology of, 414–415
 familial, 415
 initial evaluation of, 416

Wolff-Parkinson-White syndrome (*Continued*)
 management of
 in asymptomatic patients, 416–417
 in symptomatic patients, 417–418
 pathophysiology of, 411
 reentry in, 48f
 sudden cardiac death in, 414
 ventricular defibrillation in, 414
 ventricular tachycardia and, 414
