N.4.2.2.3 Anti-androgenic activity in female rats

PURPOSE AND RATIONALE

This is another historical bioassay. Neumann and Elger (1966) described a method for testing the anti-androgenic activity of compounds in immature female rats. The inhibition by the anti-androgen cyproterone of the trophic effect of testosterone on uterine and preputial growth was studied in intact as well as in castrated female rats.

PROCEDURE

Female Sprague-Dawley rats weighing 40–45 g are ovariectomized. One week later, the treatment is started for 12 days with daily subcutaneous injections of 0.3 mg testosterone propionate and several doses of the antagonist. Controls receive testosterone propionate only. On the 13th day, the animals are sacrificed and the uteri and preputial glands weighed. Weight increase of female accessory sexual organs due to testosterone is dose-dependently reduced by an anti-androgen. Similar results are found using intact immature female rats.

EVALUATION

Dose-response curves are established for increasing doses of the anti-androgen at a given dose of testosterone propionate or for increasing doses of testosterone propionate at a given dose of the anti-androgen.

N.4.2.2.4 Intra-uterine feminizing/virilizing effect

PURPOSE AND RATIONALE

From clinical observations as well as from experimental data (Neumann and Junkmann 1963), it is well known that the external genitalia of female fetuses can be masculinized by tumors secreting endogenous androgens or by steroids with androgenic activity. This effect can be antagonized by an anti-androgen.

PROCEDURE

Adult female Sprague-Dawley rats are mated and the beginning of pregnancy is determined by vaginal smears. From day 16 to day 19 of pregnancy, the antiandrogens are administered in various doses subcutaneously in sesame oil. Testosterone propionate is used in doses between 1.0 and 10.0 mg as androgenic stimulus. The dams are sacrificed on the 20th day of pregnancy and the external genitalia of the female embryos examined. The sex of the embryos is recognized by the presence of ovaries und uterus. A dose of 10 mg testosterone propionate leads to total masculinization of female embryos with loss of female and appearance of male sex characteristics. The anogenital distance in female rat fetuses measured macroscopically and microscopically is dose-dependent increased by testosterone propionate. This characteristic androgen effect is diminished by an anti-androgen.

EVALUATION

The androgen-dependent decrease of the anogenital distance in female fetuses by various doses of the anti-androgen is expressed as percentage inhibition of the testosterone-induced virilization.

MODIFICATIONS OF THE METHOD

Feminization of male rats was induced by treatment of pregnant rats during the second half of gestation and of the newborn fetuses during week 1–3 post partum with an anti-androgen, e.g., cyproterone acetate (Neumann and Elger 1966; Nishino et al. 1988; review by Neumann 1994). Decrease of the anogenital distance of male fetuses of anti-androgen-treated rats is expressed as percentage inhibition relative to fetuses from untreated mothers.

In feminized male rats, nipples and associated glandular tissues develop after birth as in normal female rats (Neumann and Elger 1967).

Feminization of male rats treated *in utero* was also observed with nonsteroidal anti-androgens and a 5α-reductase inhibitor (Imperato-McGinley et al. 1992).

N.4.2.2.5 Anti-androgenic activity on sebaceous glands

PURPOSE AND RATIONALE

Bioassays for topical antiandrogens are based on inhibition of sebum secretion. Sebum production is increased by endogenous or exogenous androgens in many species including humans. In the mouse (Lapière and Chèvremont 1953; Neumann and Elger 1966), the Mongolian gerbil (Mitchell 1965), and the golden hamster (Hamilton and Montagna 1950), the male sex hormone stimulates sebum production and sebaceous gland growth. Morphometric evaluation by light microscopy in the rat has shown that castration causes a large reduction in the volume of the glands (Sauter and Loud 1975). The administration of testosterone over several days produces an enlargement of the sebaceous glands. This effect is used for morphometric evaluation of topical anti-androgens.

The method is described in detail in Sect. P.9.1.

N.4.2.2.6 Anti-androgenic activity in the hamster flank organ

PURPOSE AND RATIONALE

This is another bioassay preferably for topical antiandrogens. The flank organs of Syrian golden hamsters are located on each flank of the animal consisting mainly of sebaceous tissue. Like sebaceous glands in other species, these pigmented spots respond to androgens by an increase in size. This proliferation is inhibited by systemic or topical anti-androgens.

The method is described in detail in Sect. P.9.5.

N.4.2.2.7 Effect of 5α-reductase inhibitors on plasma and tissue steroid levels

PURPOSE AND RATIONALE

5α-reductase inhibitors change the ratio of plasma testosterone and dihydrotestosterone as well as the tissue concentrations particularly in the prostate tissue.

PROCEDURE

Treatment of animals

Male Sprague-Dawley rats are treated s.c. with the 5α-reductase inhibitor or vehicle beginning on postnatal day 3 until the age of 4 or 7 weeks. After sacrifice, blood is withdrawn for testosterone and DHT determinations (George et al. 1989). Moreover, intraprostatic concentrations of testosterone and DHT are determined as an index of antiproliferative activity (di Salle et al. 1993).

Radioimmunoassay for testosterone and dihydrotestosterone

Serum testosterone and dihydrotestosterone are measured by radioimmunoassay in serum or serum extracts using specific antisera without prior chromatography. Serum samples of 0.5 ml may beextracted with 2 ml of freshly purified, peroxide-free diethylether by shaking for 60 s on a Vortex mixer. The aqueous phase is frozen at –70 °C, the ether phase containing steroids is transferred to conical test tubes, and evaporated under a stream of dry nitrogen. The dry residue is redissolved in BSA/phosphate buffer (1% BSA = bovine serum albumin) for RIA. (1,2,6,7-^{3}H)-Testosterone or (1,2,6,7-^{3}H)-dihydrotestosterone and specific antisera are added and tubes incubated over a period of 24 h at + 4 °C under non-equilibrium conditions. Bound hormone and free hormone are separated by adsorption on dextran-coated charcoal. The activity of each sample is determined by beta-spectrometry

Commercially available RIA-kitscan be used with suitable validation.

EVALUATION

The hormone concentrations in the sample are calculated from a standard curve by a computer program (e.g. RIA-Calc, LKB), using appropriate control sera. The ratios of testosterone to DHT in rats treated with different doses of 5α-reductase inhibitors are compared with vehicle-treated intact control rats.

MODIFICATIONS OF THE METHOD

di Salle et al. (1998) measured prostatic concentrations of testosterone and 5α-dihydrotestosterone in rats by specific radioimmunoassays after treatment with a dual type I and II 5α-reductase inhibitor. Similar measurements of tissue T/DHT ratios have been performed in dogs, in the context of pituitary down-regulation of androgen secretion by LHRH agonists.

N.5 Thyroid hormones

N.5.0.1 General considerations

The thyroid gland secretes two types of hormones: the **thyroid hormones**, i.e., **thyroxin** (T4), **triiodothyronine** (T3) subserving metabolic functions and neuronal development, and the **calcitropic hormone, calcitonin**.

The main biological effects of **T3** and **T4** are on growth and development (e.g., maturation of tadpoles), the calorigenic effect (increase of basic metabolic rate), cardiovascular function (increased sensitivity of the heart to catecholamines), and metabolic functions (lipid, carbohydrate and collagen metabolism). The primary feedback effect is inhibition of TSH-secretion. These effects can be used for testing thyroid hormone analogues and metabolites. The iodine uptake and utilization in the thyroid can be inhibited by antithyroid drugs.

Historical bioassays rely on morphogenesis and neuronal development in **amphibia**. Thyroid hormones induce premature metamorphosis in amphibian tadpoles. Since the first observation by Gudernatsch (1913a,b) this phenomenon has been studied by numerous workers with the purpose to adapt this response for the assay of thyroidal substances (Bomskov 1937). Within a short period of time, the treatment with thyroid hormones induces the transformation of the **tadpole** into a small frog with growth of limbs, lungs, and other terrestrial accoutrements and stimulates the synthesis of enzymes mediating morphogenesis and transformation.

The **axolotl** (*Amblystoma mexicanum* or *tigrinum*) has been used as test object to study metamorphosis induced by thyroid hormones. This animal looses the gills and forms lungs, changing the shape of the tail at the same time (Huxley and Hogben 1922; Zavadovsky and Zavadovsky 1926; Haffner 1927).

Another principle was metabolic activation and increased energy expenditure. Kreitmair (1928) standardized thyroid preparations using the **weight loss of guinea pigs** after one week treatment as parameter. A guinea pig unit was defined as the dose which reduces the body weight of guinea pigs with an initial weight of 250–300 g within 7 days by at least 10%.

A different functional role is subserved by calcitonin. The **hypocalcemic hormone calcitonin**, was discovered by Copp (1962, 1964). Its effects are generally opposite to those of the parathyroid hormone. Calcitonin originates from parafollicular C-cells of the thyroid. The bioassay of calcitonin preparations is performed by assessing their ability to **lower the plasma calcium** in the rat. Assay of serum calcitonin has a significant diagnostic role for thyroid carcinoma.

Thyroid hormone receptors

Nuclear triiodothyronine binding proteins were purified and characterized by Torresanai and Anselmet (1978). Ichikawa and DeGroot (1987a,b) described purification and characterization of rat liver nuclear thyroid hormone receptors and thyroid hormone receptors in a human hepatoma cell line. Apriletti et al. (1988) reported large scale purification of the nuclear thyroid hormone receptor from rat liver and sequence-specific binding of the receptor to DNA. Ichikawa et al. (1988), Ichikawa and Hashizume (1991) published methods of an aqueous two-phase (dextran and poly-ethylene glycol) partitioning study of nuclear thyroid hormone receptors. Glucocorticoids, other steroid hormones, thyroid hormones and vitamin-derived hormones (including retinoids) all exert their effects by the regulation of hormone-responsive target genes within the cell nucleus. William and Franklyn (1994) reviewed the physiology of the steroid-thyroid hormone nuclear receptor superfamily. A nuclear hormone receptor-associated protein that inhibits transactivation by the thyroid hormone and retinoic acid receptors was described by Burris et al. (1995). Two different genes encode two different thyroid hormone receptors, thyroid hormone receptor-α and thyroid hormone receptor-β, and these two thyroid hormone receptors are often co-expressed

at different levels in different tissues. Chiellini et al. (1998) designed a high-affinity subtype-selective agonist ligand for the thyroid hormone receptor-β. The expression of thyroid hormone receptor isoforms in rat growth plate cartilage *in viv*o was described by Ballock et al. (1999). Yuan et al. (1998) described a component of a thyroid hormone receptor-associated protein (TRAP) coactivator complex which interacts directly with nuclear receptors in a ligand-dependent fashion. The sequence of the thyroid hormone response element and the recruitment of retinoid X receptors for thyroid hormone responsiveness was investigated by Wu et al. (2001).

N.5.0.2 Thyroidectomy

PURPOSE AND RATIONALE

Endocrinological experiments for pharmacological evaluation of thyroid hormones and analogues may be performed in thyroidectomized rats. Bomskov (1937) described the method of thyroidectomy in various animal species, such as tadpoles, frogs, birds, goats, dogs, cats, rabbits, guinea pigs, rats and mice, based on the clinical experience with thyroid resection in humans.

PROCEDURE

The thyroid in rats consists of three lobes (left, median and right). The rat is anesthetized with Nembutal and the legs fixed on an surgical table. The fur of the neck is removed with electric clippers and the area disinfected. A median skin incision of 2.0 cm length is made. On both sides large salivary glands and maxillary lymph nodes are found. They are pushed aside, making visible the musculus hyoideus covering the trachea. This muscle is split in the midline. The isthmus of the thyroid connecting both lobes is located

below the thyroid cartilage. The lobes and the isthmus are separated with blunt forceps from the trachea and the blood vessels ligated. Alternatively, the thyroid can be removed by electrocauterization. In most cases, also the parathyroid glands are severed and postoperative substitution with calcium lactate 1% in drinking water is advised.

N.5.1
In vivo tests for thyroid hormones

N.5.1.1
Oxygen consumption

PURPOSE AND RATIONALE

Basal metabolic rate, oxygen consumption and CO_2 production are increased by thyroid hormones. This has been used for diagnostic procedures in man as well as for evaluation of thyroid hormones and their derivatives in animals (indirect calorimetry). The very early method based on survival time of mice placed individually into tightly closed glass jars (Smith et al. 1947; Basil et al. 1950; Gemmill 1953) has been modified by methods which allow survival of the animals, measuring time until occurrence of convulsions. The assays are no longer applied.

PROCEDURE

Mice are placed individually into 200 ml wide-necked bottles. Groups of 10 mice are used for each dose of test preparation or standard. The bottom of the bottles is covered with filter paper to soak up the urine. The bottles are tilted to an angle of 60° and rotated 5 times per min in a special apparatus. The time until asphyctic seizures occur is noted. Immediately after observation of seizures, the mouse is released for recovery. Due to the defined muscle work, the time to seizures is shortened in controls to 20–30 min.

EVALUATION

Average time to seizures is calculated for each dosage and dose-response curves are established.

MODIFICATIONS OF THE METHOD

Several apparatuses have been designed to measure oxygen consumption in animals, e.g., by Holtkamp et al. (1955).

Stock (1975) described an automatic, **closed-circuit oxygen consumption apparatus** for small animals. A Perspex animal chamber is surrounded by a water jacket except for one end, which has a removable cover plate. This cover, as well as allowing access to the chamber interior, also holds the connections for the oxygen delivery line and the pressure line. Forexperiment involving injections, infusions and blood sampling, catheters are passed through, and sealed into rubber bungs which are then forced into holes in the cover plate. A rubber gasket forms an airtight seal between the cover and the chamber. Within the chamber, the animal is supported on a wire grid over a layer of self-indicating soda lime and silica gel. A major determinant of sensitivity in this system is the dead space of the chamber. Chambers with internal dimensions of $20 \times 10 \times 10$ cm are suitable for animals such as mice and rats up to about 250 g body weight. Fixed volumes of oxygen are introduced into the chamber by an automatic syringe dispenser (Fisons Scientific) which draws pure oxygen from a spirometer through a drying tube filled with silica gel. When chamber pressure exceeds atmospheric by about 3 mm H_2O, the microdifferential pressure switch (KDG Instruments) inactivates the dispenser. The dispenser is reactivated when the pressure differential drops below this threshold value. The volume of oxygen dispensed is adjusted to the smallest volume that, with a single action of the syringe, will return chamber pressure to above the threshold value. The particular dispenser used in this system has the advantages of being (a) gas tight and (b) when activated will complete its pump cycle even if the chamber pressure exceeds the threshold value in midcycle. In this way, a discrete fixed volume of oxygen is delivered each

time it is activated. To obtain the rate of oxygen consumption it is merely necessary to record the pump rate. This is done using the travel of the syringe piston to close a microswitch connected to an event recorder.

N.5.1.2 Inhibition of iodine release

PURPOSE AND RATIONALE

The release of ^{131}I from the thyroid in rats is inhibited by treatment with thyroxine (Wolff 1951), and the degree of inhibition is related to the dose administered (Perry 1951). This phenomenon was used to compare thyroid hormone derivatives with the standard thyroxine. It is superseded by direct quantitation of thyroid hormones by analytical methods e.g. radioimmunoassay and HPLC chromatography, and by measuring feedback inhibition directly via the decrease in serum TSH.

PROCEDURE

Male Sprague-Dawley rats weighing 180–240 g are fed a commercial laboratory chow without or with addition of 0.03% propylthiouracil (reference compound for thyroid peroxidase inhibition). Food is withheld 8 h before and for 24 h after ^{131}I or ^{125}I is injected intraperitoneally at a dose of 25 μC. Under light ether anesthesia, radioactivity over the thyroid region of the neck is determined 40 h later. This value is taken as zero time and all further counts made at 24-h intervals are expressed as percent of zero time-counts after correction for physical decay of the isotope. After the reading at zero time, the diet is changed to a diet containing 0.03% propylthiouracil and various doses of the test preparation or the standard are injected subcutaneously at 24-h intervals for a total of four doses. The daily loss of ^{131}I is inversely proportional to the dose of thyroid hormone.

EVALUATION

Percent of zero time counts after 96 h of ^{131}I remaining in the thyroid after the last of 4 doses is plotted against logarithm of dose. From these dose-response curves, potency ratios are calculated.

This approach may be modified for short term uptake of ^{131}I or ^{125}I as a parameter of thyroid peroxidase inhibition by antithyroid drugs.

N.5.1.3 Anti-goitrogenic activity

PURPOSE AND RATIONALE

Increased secretion of TSH induces thyroid enlargement and weight increase within a few days. In normal animals the secretion of TSH by the pituitary is regulated by feedback of thyroid hormones. The administration of goitrogenic compounds which block thyroid hormone synthesis and/or secretion reduces the concentrations of circulating thyroT4/T3 and their pituitary effect, thus releasing TSH from its feedback inhibition. The TSH rise

induces a hyperplasia of the thyroid follicles as indicated by an increase of thyroid weight. Hyperplasia is prevented by injection of thyroxine or thyroid hormone analogs.

PROCEDURE

Male Sprague-Dawley rats weighing 150–180 g are used in groups of 8–10 animals. During the period of treatment, 0.1% propylthiouracil (PTU) is added to the food or to the drinking water, or equivalent doses are given by gavage. Over a period of 2 weeks, the rats are treated (subcutaneously or by gavage) with various doses of the test compound or the thyroxine standard (10–40 µg/kg). PTU controls receive PTU and saline injections only. The rats are sacrificed after 14 days, their thyroid glands are dissected out cleanly and weighed rapidly to avoid evaporation loss. Thyroids may also be lyophilized first to weigh dry matter. The two to three-fold increase of thyroid weight by PTU is reversed dose-dependently to normal values by thyroid active substances.

EVALUATION

Dose-response curves are plotted for test compounds and the standard and activity ratios calculated.

MODIFICATIONS OF THE METHOD

The effect of PTU is monitored by measuring TSH, T4 and T3 and the inhibition of the TSH rise by thyroid substances is used as the parameter of goiter prevention.

N.5.1.4 Tensile strength of connective tissue in rats, modified for thyroid hormones

PURPOSE AND RATIONALE

The decrease of tensile strength after a single injection of thyroid hormones is dose-dependent and can be used for evaluation of thyroid hormone derivatives. Short term treatment with corticosteroids increases the strength of connective tissue (Vogel 1969). This effect is antagonized by thyroid hormones (Ther et al. 1963; Vogel and Ther 1994). Thyroid hormones per se have a biphasic effect: short term treatment decreases the dose-dependent tensile strength of epiphyseal cartilage, tail tendons and skin strips, whereas treatment over 10 days increases these values, probably due to activation of endogenous adrenal secretion.

PROCEDURE

Male Sprague-Dawley rats weighing 110 ±10 g are injected subcutaneously with various doses of thyroid hormones (dose range of the standard L-triiodothyronine 0.1 to 1.0 mg/kg). After 24 h the animals are sacrificed and tensile strength of distal femoral epiphyseal plates, tail tendons, or skin strips are tested as described in Sect. N.2.1.3.2, N.2.1.3.3, N.2.1.3.4, and P.11.2.1.1.

EVALUATION

Doses-response curves of test compounds and standard are established and potency ratios calculated. T3 (L-triiodothyronine) is about 3 times more active than T4 (levothyroxine), in accordance with its metabolic activity.

N.5.2 Antithyroid drugs

N.5.2.1 General considerations

Antithyroid drugs are characterized by their ability to interfere with synthesis, release, and/or peripheral action of the thyroid hormone, lowering the basal metabolic rate. Decrease of T4/T3 reduces thyroidal inhibition of the pituitary gland, TSH secretion increases and induces a goitrogenic response. This response was used for detecting antithyroid drugs and has been widely used for screening procedures. It is, however, non-specific and may be caused by several different mechanisms, including enzyme induction of glucuronyltransferases.

N.5.2.2 Inhibition of iodine uptake into the thyroid of rats

PURPOSE AND RATIONALE

Propyl-thiouracil (PTU) and a wide spectrum of drugs may inhibit thyroid hormone synthesis. Some of these drugs can be used for treatment of thyrotoxicosis. As a consequence of thyroid peroxidase inhibition, the iodine uptake and content of the thyroid is decreased. This phenomenon is dose-dependent and may occur at lower doses than those increasing thyroid weight in rats (McGinty and Bywater (1945). The historical parameter of iodine content was replaced by measuring uptake and release of ^{131}I.

PROCEDURE

Groups of male Wistar rats age 26–28 days, weighing 40–45 g, are placed into metabolism cages. They are fed normal diet, and potassium iodide is added to the drinking water. The test compounds or the reference standard are added in various concentrations to the diet over a period of ten days. The amount of compound which each rat receives is calculated from the total food consumption over 10 days and expressed as milligram daily per kilogram of body weight. After 10 days of treatment, the rats are sacrificed and the thyroids dissected free from adjacent tissue and capsule. The thyroid is weighed and iodine content determined. In daily doses between 0.1 and 10.0 mg/kg, thiouracil decreases the iodine content of the thyroid dose-dependent. Definitely higher doses are necessary to increase thyroid weight.

EVALUATION

Dose-response curves of test compounds are compared with those of the reference standard for calculation of potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

Walker and Levy (1989) used implantable pellets of propylthiouracil to induce thyroid dysfunction in rats. Uptake of labelled iodine is measured instead of iodine content. Release of labelled iodine may be stimulated by protirelin (TRH) injection.

N.5.2.3 Antithyroidal effect on oxygen consumption in iodine treated mice

PURPOSE AND RATIONALE

This is a historical bioassay based on oxygen consumption increased in acutely potassium iodide treated mice resulting in a decrease of asphyxiation time (thyroid activation). The effect is antagonized by antithyroidal compounds. The methods for increased oxygen consumption after thyroid hormones (N.5.1.1) can be applied.

MODIFICATIONS OF THE METHOD

Rabbits treated with goitrogenic compounds or fed exclusively with cabbage (Chesney et al. 1928; Marine et al. 1929) show an up to tenfold increase of thyroid weight, histologically manifested as hyperplasia without colloid formation. These phenomena can be reversed by iodine treatment (Bomskov 1937).

Goiter formation as side effect of non-steroidal anti-inflammatory drugs was studied by Müller et al. (1985).

N.5.3 Calcitonin

N.5.3.1 General considerations

The calcitropic hormone calcitonin, was discovered by Copp (1962, 1964, 1994). The hypocalcemic hypophosphatemic principle of the thyroid gland was termed thyrocalcitonin by Hirsch et al. (1964), Munson and Hirsch (1966), Raisz et al. (1967). Its effects are generally opposite to those of the parathyroid hormone. Calcitonin originates from parafollicular C-cells of the thyroid. Calcitonin secretion can be evaluated using the isolated perfused porcine thyroid (Pento 1985). Radioimmunoassays for calcitonin are available (Tashjian and Voelkel 1979), species specific methods for calcitonin determination need to be considered. Assays for calcitonin receptors have been described (Nissenson et al. 1985). A survey on the effects of exogenous calcitonin was given by Deftos (1989). The biology and clinical relevance of calcitonin gene peptides has been reviewed by Zaidi et al. (1990).

N.5.3.2 Decrease of serum calcium in rats

PURPOSE AND RATIONALE

The bioassay of calcitonin preparations is performed by assessing their ability to lower the plasma calcium in the rat. This procedure has also been adopted by pharmacopoeias, using the International Reference Preparation for Calcitonin (porcine), consisting of freeze-dried purified pork calcitonin, or the International Reference Preparation for Calcitonin (salmon) consisting of freeze-dried purified synthetic salmon calcitonin. These assays, however, are replaced for calcitonin quantitation by physicochemical method for pharmaceutical quality control. Either intravenous or subcutaneous administration can be chosen. International standards for salmon calcitonin, eel calcitonin, and the Asu^{1-7} analogue of eel calcitonin have been elaborated (Zanelli et al. 1990). A second international standard for porcine and human calcitonins has been established by an international collaborative study group based on the *in vivo* rat hypocalcemia bioassay (Zanelli et al. 1993).

PROCEDURE

Groups of at least 5 female Wistar rats, weighing 100 to 120 g, are used. Three doses of standard preparation (usually 1, 3 and 9 milliU per rat) and 3 doses of test preparation are injected intravenously. Exactly 1 h after injection, blood is withdrawn under light anesthesia. Plasma calcium is determined by flame photometry or by atomic absorption photometry.

EVALUATION

Dose-response curves of decreases in plasma calcium are established and potency ratios with confidence limit are calculated.

MODIFICATIONS OF THE METHOD

Yates et al. (1990) assessed the acute hypocalcemic responses to single subcutaneous injections of calcitonin preparations in intact young male ICR Swiss mice weighing 12–20 g.

Calcitonin of the stingray and of the goldfish were characterized by Sasayama et al. (1992, 1993).

Kapurniotu and Taylor (1995) performed *in vitro* hypocalcemic assays in mice by analysis of serum calcium 1 h after sc. injection of lactam-bridged analogues of human calcitonin.

N.5.3.3
Effect of calcitonin on osteoclasts *in vitro*

PURPOSE AND RATIONALE

Calcitonin acts primarily by inhibition of osteoclastic bone resorption (Friedman and Raisz 1965; Aliapoulios et al. 1966). Zaidi et al. (1990) reported the development and validation of three microbioassays for calcitonin based on calcitonin-induced inhibition of the activity of isolated osteoclasts.

PROCEDURE

Femora and tibiae are removed from newborn Wistar rats. The bones are freed from adherent soft tissues and cut across their epiphyses in HEPES-buffered Medium 199 supplemented with heat-inactivated fetal calf serum, benzyl penicillin (100 μU/ml) and streptomycin (100 μg/ml). The osteoclasts are mechanically disaggregated by curetting the bones of each rat with a scalpel blade into 1 ml medium and agitating the suspension with a pipette. Larger fragments are allowed to settle for 10 s, before the supernatant is dropped onto appropriate substrate (bone slices, plastic Petri dishes or glass coverslips).

Motility-based system

The morphological appearance of stained osteoclasts is used as an index to assess the state of cytoplasmic activity. Osteoclasts are settled on coverslips in microtiter wells and are incubated for 20 min at 37 °C. The coverslips are removed, washed with Medium 199 and placed in separate wells, each containing 100 μl medium.

Following a further incubation for 30 min (37 °C), serial dilutions (10-fold) of salmon or human calcitonin or test preparations or appropriate dilutions of plasma samples are added. The cells are finally incubated for 2 h, fixed in 10% glutaraldehyde and stained with toluidine blue. The state of motility of each osteoclast on each coverslip is scored by observing the characteristic shape change these cells undergo when motility is inhibited; a motile cell is characterized by a smooth outline with increased staining intensity over all or part of its periphery, whereas a immotile cell typically shows an irregular pale outline without ruffled edges. The number of immotile cells is counted on each coverslip and expressed as a percentage of the total number of cells counted.

Cytoplasmatic spreading system

Osteoclasts are settled in tissue culture dishes (35 mm) and are incubated at 37 °C for 20 min to allow sedimentation and attachment. The cells are then washed with Medium 199 and 2 ml of the same medium is placed in each well. The dishes are placed in the incubation chamber of an inverted phase-contrast microscope. Images of the osteoclasts are recorded on a time-lapse video recorder. A tracing of their outlines is transferred through a digitizing system into a computer, programmed to measure area within each tracing.

The outlines of each osteoclast are recorded before or after the addition of calcitonin or vehicle to the cultures. For each variable, the outline of 6 osteoclasts is traced after 60 min incubation in the chamber and again 40 min following the addition of the hormone. The mean surface area covered by 6 osteoclasts after incubation is expressed as a percentage of the mean surface area of the osteoclasts before the addition of hormone or vehicle.

Bone resorption system

Specimens of human femoral cortical bone are obtained from patients who died without evidence of bone disease. The adherent soft tissue is removed and the bone cortex cut longitudinally into slices (0.1 mm thick). The slices are then cut into pieces (approximately 3 mm^2). They are cleaned by ultrasonication (15 min, in sterile distilled water), dehydrated by immersion in 80% aqueous ethanol for 2 h and stored to dry at room temperature. Osteoclasts isolated in Medium 199 are dropped onto 12–16 bone slices placed in a well of an 18-mm multiwell dish. Following incubation (37 °C, 15 min), slices are removed, washed gently in Minimal Essential Medium supplemented with 10% FCS and antibiotics as described above. They are placed in separate wells, each well containing 5–6 slices in 900 µl medium. After further incubation (37 °C, 10% humidified CO_2, 10 min), 100 µl of medium containing the test concentration of the hormone or the test solution is added. Human $PTH_{(1-34)}$ (0.1 U/ml) is used to assess functional effects of contaminating osteoblasts.

The calcitonin analogs are tested at various concentrations (10-fold dilutions). Finally, bone slices are incubated overnight (37 °C, 10% humidified CO_2, 18 h). The cells are fixed in glutaraldehyde, stained with toluidine blue and examined by transmitted light microscopy. Osteoclasts and mononuclear cells are counted. The slices are then bleached by immersion in sodium hypochlorite solution for 30 min and dehydrated in 80% aqueous ethanol. Finally, they are sputter coated with gold, randomized and examined in a scanning electronic microscope. The numbers of osteoclastic excavations, each defined by a continuous border, are counted. The area of bone surface resorbed is calculated by tracing the outline of the concavities into a digitizing tablet, linked to a microcomputer. Resorption surface areas may be expressed as a percentage of the mean of the control response.

EVALUATION

Data of each assay are analyzed using classical methods for analysis of parallel line assays. Estimates of relative potencies are calculated from parallel log dose-response lines of test preparations and reference preparation.

Osteoclasts were mechanically disaggregated from neonatal rat long bones and dispersed at low densities on slices of devitalized bovine cartilage bone. The resulting areas of bone excavation were quantified with micrometric precision by scanning electron microscopy together with computer-assisted image analysis. These findings were used to develop a formal bioassay for calcitonin.

N.5.3.4 Receptor binding and cAMP accumulation in isolated cells

PURPOSE AND RATIONALE

The human breast cancer cell line T47D responds to calcitonin and its analogs by receptor binding and accumulation of cAMP. This can be used as biological assay (Findlay et al. 1980, 1983, 1985; Grauer et al. 1992; Sexton and Hilton 1992; Blind et al. 1993).

PROCEDURE

The human breast cancer cell line T47D was originally established from a pleural effusion from an infiltrating ductal breast cancer (Horwitz et al. 1978). For binding experiments, cell monolayers are washed with 0.02% EDTA before treatment with 0.125% trypsin in 0.02% EDTA for 2 min at 37 °C, addition of complete medium before centrifugation at 200 *g*, and resuspension in complete medium.

Iodination of calcitonin is performed with ^{125}I using the chloramine-T method.

For binding experiments T47D cells suspended in isotonic buffer are added to ^{125}I-labeled salmon calcitonin mixed with varying concentrations of unlabeled calcitonin or analogs and incubated at 20 °C for 1 h. Nonspecific binding is assessed as the binding of ^{125}I-labeled salmon calcitonin in the presence of excess (2 µg/ml) unlabeled salmon calcitonin.

Stimulation of adenylate cyclase in intact T47D cells by calcitonin analogs is assessed by measuring

[^{3}H]cAMP production in cells prelabeled with [^{3}H]adenine. Cellular ATP-pools are labeled by incubation with 2,8-[^{3}H]adenine (0.5–2 µCi/ml) for 2 h at 37 °C in 12-well culture dishes in RPMI 1 640 medium containing 0.1% BSA. Cells are then washed twice with serum-free medium and incubated for a further 20 min in medium containing 0.1% BSA and 1 mM isobutylmethylxanthine IBMX before treatment with calcitonin and its analogs for 10 min at 37 °C in the same buffer. Incubations are terminated by removing medium and adding 100 µl 20% trichloroacetic acid at 4 °C. This is followed by 800 µl 5 mM solution of ATP, ADP, AMP, cAMP, and adenine. The [^{3}H]cAMP is isolated by chromatography on Dowex and alumina. Radioactivity is counted in a scintillation counter.

EVALUATION

For both parameters full dose-response curves are generated and the concentrations required for half-maximal responses are calculated.

MODIFICATIONS OF THE METHOD

Yates et al. (1990) measured stimulation of adenylate cyclase activity by calcitonin analogs in primary cultures of mouse renal cortex which were prepared according to the methods of Fukase et al. (1982) from 4-week-old ICR Swiss mice and used at confluence after 4 days of culture.

A radioreceptor assay for potency determinations of formulations of salmon calcitonin was described by Sjödin et al. (1990).

Albrandt et al. (1993) cloned two receptors with high affinity for salmon calcitonin from the nucleus accumbens region of rat brain.

Likewise, Sexton et al. (1993) identified in rats two isoforms of the calcitonin receptor, designated C1a and C1b.

Functional aspects of the isoforms C1a and C1b were discussed by Martin et al. (1995).

The calcitonin receptor isoforms C1a and C1b were localized in rat brain using *in vitro* autoradiography by Hilton et al. (1995).

Keustner et al. (1994) cloned and characterized a second form of the human calcitonin receptor from T47D cells.

Sexton et al. (1994) assayed the cloned renal porcine calcitonin receptor cDNA expressed by transient transfection in COS-1 cells or stable transfection in HEK-293 cells for interaction with calcitonin, amylin and calcitonin gene-related peptide. The results suggested that amylin may act as a natural ligand for the renal porcine calcitonin receptor.

The various pathways in signal transduction by calcitonin were discussed by Horne et al. (1994).

Houssami et al. (1994) found that different structural requirements exist for calcitonin receptor binding specificity and adenylate cyclase activation.

Suva et al. (1997) synthesized benzophenone-containing calcitonin analogs and tested them for receptor binding and stimulation of cAMP accumulation.

Povzek et al. (1997) investigated the structure/function relationship of salmon calcitonin analogues as agonists, antagonists, or inverse agonists in heterologous calcitonin receptor expression systems using 2 calcitonin receptor cell clones, B8-H10 and G12-E12, which express about 5 million and 25 000 C1b receptors/cell, respectively.

The location of the phosphorylation of the human calcitonin receptor by multiple kinases was studied by Nygaard et al. (1997).

N.6 Parathyroid hormone

N.6.0.1 General considerations

The primary function of the parathyroid hormone (PTH) is to maintain a constant concentration of Ca^{2+} in the extracellular fluid. Processes that are regulated include the absorption of Ca^{2+} from the gastrointestinal tract, the deposition and mobilization of bone Ca^{2+}, and the excretion of Ca^{2+} in urine, feces, sweat, and milk. PTH is the functional antagonist of calcitonin. The most prominent effect is to promote the mobilization of Ca^{2+} from bone. In the kidney, tubular re-absorption of Ca^{2+} is increased and tubular re-absorption of phosphate is inhibited. Clinically, idiopathic or postoperative hypoparathyroidism results in hypocalcemia followed by tetany.

PTH can be used for treatment of hypoparathyroidism, but the symptoms of the disease can also be effectively antagonized by administration of dihydrotachysterol. A survey on the structure and function of the parathyroid gland in animals has been published by Capen and Rosol (1989). The biologically active synthetic human parathyroid hormone 1–34 fragment (active sequence of PTH) is used for diagnostic testing (Mallette 1988).

An experimental model for secondary hyperparathyroidism with elevated levels of parathyroid hormone in rats has been described by Sancho et al. (1989).

Assays for parathyroid hormone receptors have been described (Habener and Potts 1976; Nissenson et al. 1985; Schneider et al. 1993).

Immunoassays for PTH are those measuring intact hormone (N-terminal, intact) and those measuring inactive fragments and partial sequences of the intact hormone (mid-region, C-terminal, polyvalent) (Enders et al. 1989). An immunochemiluminometric assay has been described by Klee et al. (1992).

Parathyroid hormone-related protein (PTHrP) has been first identified and cloned from malignant tumor cells and tissues from patients with the syndrome of humoral hypercalcemia of malignancy (Moseley et al. 1987; Strewler et al. 1987; Suva et al. 1987). PTHrP-(1-34) and PTH-(1-34), act via a single species of cloned receptor (Abou-Samra et al. 1992; Schipani et al. 1993) although other studies have shown that specific receptors for each of these peptides exist (Usdin et al. 1995; Behar et al. 1996; Bergwitz et al. 1997; Yamamoto et al. 1997; Fukayama et al. 1998). PTHrP is an example for the widening array of sequences identified by molecular endocrinology, functional characterization of their endocrine role often following with a considerable delay.

N.6.0.2
Receptor binding assay for PTH

PURPOSE AND RATIONALE

In many instances, the presence of receptors is now explored as the counterpart of the presence of hormonally active substances in tissues and organs. Three receptors that are activated by PTH have been cloned. PTH and PTHrP bind to the PTH_1 receptor, for which many studies are published, e.g., (Abou-Samra et al. 1992; Uneno et al. 1992; Schipani et al. 1993; Ureña et al. 1993; Kaufmann et al. 1994; Schermer et al. 1994; Orloff et al. 1995; Usdin et al. 1995; Bergwitz et al. 1996; Gardella et al. 1996; Yasuka et al. 1996; Bergwitz et al. 1997; Bisello et al. 1997; Guo et al. 1997; Yamamoto et al. 1997; Fukayama et al. 1998; Yaghoobian and Drueke 1998).

Behar et al. (1996b) reported ligand binding in stably transfected human embryonic kidney cells, HEK-293/C-21 cells that express the hPTH/PTRrP receptor and HEK/BP16 cells that express the hPTH2 receptor.

The PTH_2 receptor has about 50% amino acid sequence identity with the PTH_1 receptor and is not activated by PTHrP, but by a peptide isolated from bovine hypothalamus, TIP39, which is only distantly related to PTH and PTHrP (Usdin 2000).

The PTH_3 receptor has been isolated from zebrafish (Rubin and Juppner 1999).

PROCEDURE

Stably transfected human embryonic kidney cells, HEK-293/C-21 cells that express the hPTH/PTRrP receptor (Pines et al. 1994) and HEK/BP16 cells that express the hPTH2 receptor (Behar et al. 1996a) are maintained in DMEM supplemented with 10%FBS.

The cells are incubated with [^{131}I]PTH-(1-34) (100 000 cpm/well) with or without competing unlabeled PTH-(1-34) or other ligands in binding buffer for 2 h at room temperature. Cells are washed twice with PBS, then solubilized in 0.5 ml 0.1 M NaOH. Aliquots are taken for determination of bound radioactivity by γ-counting.

EVALUATION

Specific binding is expressed as counts per min bound/well and as the percent specific binding of radioligand. Affinity constants and binding capacity of these receptors in tissue may be calculated, and dose-response curves of ligands may be compared.

MODIFICATIONS OF THE METHOD

McCuiag et al. (1994) reported the molecular cloning of the gene encoding the receptor for the parathyroid hormone/parathyroid hormone-related peptide in the mouse.

Inomata et al. (1995) characterized a parathyroid hormone (PTH) receptor with specificity for the carboxy-terminal region of PTH-(1-84).

N.6.0.3
PTH assay by serum calcium increase

PURPOSE AND RATIONALE

The classical method by Collip and Clark (1925) involved the measurement of the rise in serum calcium after administration of parathyroid extracts to dogs. Hamilton and Schwartz (1932) used rabbits treated

with oral loads of calcium chloride. The intact rat is very insensitive to injected parathyroid hormone; however, parathyroidectomy produces an increase in sensitivity (Davies and Gordon 1953; Davies et al. 1954).

PROCEDURE

Male Wistar rats weighing 200–250 g are anesthetized with pentobarbital sodium i.p. Parathyroidectomy is performed by cauterization. After a recovery period of one week, blood is withdrawn by retroorbital puncture (baseline). Various doses of the test preparation or standard are injected subcutaneously to groups of 6–10 animals. Blood samples are obtained again 21 h later. Serum calcium is determined by flame photometry. The increase of calcium 21 h after PTH injection is calculated for each animal.

EVALUATION

Mean values of the increase in serum calcium are plotted versus logarithm of dose for the test preparation and for the standard calculation of dose-response and potency ratios.

MODIFICATIONS OF THE METHOD

An increase of whole body calcium and skeletal mass after treatment with parathyroid hormone in normal rats and in rats with osteoporosis induced by pregnancy and lactation under a low calcium diet was found by Hefti et al. (1981).

Parathyroid hormone prevented bone loss and augmented bone formation in ovarectomized rats (Kalu et al. 1990; Liu and Kalu 1990).

The active sequence of PTH has been used instead of the full secreted sequence.

N.6.0.4 Serum phosphate decrease after PTH

PURPOSE AND RATIONALE

Tepperman et al. (1947) developed a method using the fall in serum inorganic phosphorus in the rat after injection of parathyroid hormone.

PROCEDURE

Male Wistar rats weighing 150–200 g are fed Purina dog chow for at least 2 weeks prior to the experiment. During the experiment only water is allowed. Blood samples (baseline and PTH stimulated) are taken from the tail and 0.6 ml is collected from each rat into tubes, centrifuged for 10 min and 0.2 ml samples of the serum are pipetted into 6 ml of 10% trichloroacetic acid; this is centrifuged and 5 ml aliquots of the protein-free solution are used for the estimation of inorganic phosphorus, e.g., by the method of Fiske and Subbarow (1925). Serum phosphorus is measured before and 3 h after subcutaneous administration of various doses of test preparation or standard.

EVALUATION

Dose-response curves showing a linear relationship of log dose and response are suitable for the calculation of potency ratios.

N.6.0.5 cAMP release in isolated perfused rat femur

PURPOSE AND RATIONALE

This is an *in vitro* assay. The effect of parathyroid hormone and analogs on release of cAMP from adult bone can be measured in a perfusion system of isolated rat femora (Sugimoto et al. 1985; Lopez-Hilker et al. 1992).

PROCEDURE

Five-week-old Wistar rats anesthetized with pentobarbital (45 mg/kg) are heparinized, and the femora are removed. Adhering muscles are stripped from the bone. A hole with about half of the depth of the cortex is made with a fine drill at the nutrient foramen below the femoral neck. Then a 21-gauge needle is inserted into this hole and fixed by dental cement to avoid leakage of the perfusate. The bone is then placed in an apparatus for liver perfusion and perfused at a flow rate of 1 ml/5 min by a pump with Krebs-Ringer-bicarbonate, continuously gassed with 95% O_2 and 5% CO_2 and containing 1 mg/ml glucose. Once the perfused bone is assembled, the bone is allowed to equilibrate for 45 min. Samples are collected into a chilled tube for the last 5 min for determination of basal cAMP levels. Then various doses of the test preparations or the standard are infused for 5 min and serial samples are collected every 5 min. In the perfusate, cAMP is measured by radioimmunoassay.

EVALUATION

Time-response curves and dose-response curves are established allowing the calculation of potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

Nissenson et al. (1981) measured the activation of canine renal cortical plasma membrane adenylate cyclase activity, produced by parathyroid hormone standard and test sera from parathyroid venous effluent of patients with primary hyperparathyroidism, in the presence of the hydrolysis-resistant GTP analog, 5'-guanylimidodiphosphate.

Gundberg et al. (1995) compared the effects of parathyroid hormone and parathyroid hormone-related protein on osteocalcin release in the isolated rat hindlimb and in intact and thyroparathyreoidectomized rats.

Saito et al. (1987) established a new biological assay system for simultaneous measurement of bone resorption and bone mineralization in **organ cultures of chick embryonic femur**. Eleven-day-old chick embryonic femur was labeled with ^{45}Ca *in vitro*. $T_{1/2}$ of calcium efflux was calculated from the sequential release of the label into the medium. Parathyroid hormone increased calcium mobilization indicating enhanced bone resorption, whereas hydrocortisone and sodium fluoride inhibited bone resorption. Calcitonin was ineffective.

Barling et al. (1989) measured the adenylate cyclase response to parathyroid hormone in cultured rabbit marrow fibroblast cells.

Docherty and Heath (1989) used osteosarcoma cells for an *in vitro* bioassay determining cAMP formation.

N.6.0.6
Renal and metatarsal cytochemical bioassay

PURPOSE AND RATIONALE

Cytochemical bioassays using renal and metatarsal tissue are sensitive enough to detect plasma levels of parathyroid hormone and useful to determine the agonist and antagonist activities of fragments and analogues (Chambers et al. 1978; Goltzman et al. 1980; Bradbeer et al. 1988; Loveridge et al. 1991; Zaman et al. 1991).

PROCEDURE

For the **renal cytochemical assay**, kidney segments from vitamin D-depleted guinea pigs are maintained in non-proliferative organ culture for 5 h using Trowell's T8 medium (GIBCO). The medium is then changed for 8 min before exposure to various doses of the parathyroid hormone standard, the parathyroid hormone fragment or the analog for an additional 8 min. In the experiments for antagonistic activities, each segment is exposed to a single concentration of hPTH-(1-84) (106 fmol/liter) or to hPTH-(1-34) (255 fmol/liter) in the presence or absence of the antagonist to be tested. The segments are then shock-frozen to –70 °C in N-hexane before being sectioned at 16 µm on a cryostat. The sections are examined for glucose 6-phosphate dehydrogenase activity using a

specific staining. The precipitated formazane is quantified in the cells of the distal convoluted tubules by means of a microdensitometer (wavelength 585 nm). Ten readings with each of two duplicate sections are made and the results presented as the mean integrated absorbance × 100 ±SEM.

For the **metatarsal cytochemical assay**, the metatarsals of young female Wistar rats weighing 50–100 g are removed and the growth plates are isolated. Only the four longest metatarsals have growth plates large enough to be of use. The metatarsals are maintained individually in nonproliferative organ culture in 5–10 ml Trowell's T8 medium buffered to pH 7.6 in an atmosphere of 95% O_2, 5% CO_2 at 37 °C for 5 h. After the culture period, the medium is removed and each metatarsal exposed to fresh medium (buffered to pH 7.6 by bubbling with a 95% O_2, 5% CO_2 mixture) containing a low priming dose of PTH (0.5 fg/ml) for 8 min, followed by exposure to known concentrations of a standard PTH preparation or various concentrations of the analog or to dilutions of plasma for 8 min. The metatarsals are then briefly dipped in a 5% solution of polyvinyl alcohol and chilled immediately in N-hexane to –70 °C.

Each bone is sectioned at 10 µm in a cryostat. The sections are reacted for glucose 6-phosphate dehydrogenase activity in a similar way as described for the renal cytochemical assay. The activity in hypertrophic chondrocytes is linear with respect to time from 10 min, at which time there is enough formazan to be measured, up to 40 min when the density of the formazan formed is too great for a reliable linear response. The enzyme activity in each section is measured in 10 individual hypertrophic chondrocytes or osteoblasts lining the metaphyseal trabeculae by scanning and integrating microdensometry at a wave length of 585 nm. The results are presented as the mean integrated extinction × 100 ±SE of 10 measurements from each of two sections of each metatarsal.

EVALUATION

Dose-response curves are tested for linearity and parallelism and potency ratios are calculated.

N.6.0.7 cAMP accumulation in cultured cells

PURPOSE AND RATIONALE

Parathyroid hormone and parathyroid hormone-related protein (PTHrP) stimulate dose-dependent intracellular cAMP accumulation in various cell types, such as in PTHrP-overexpressing ROS cells, a osteoblast-like cell line Motumura et al. (1996); in UMR106 cells, a rat osteosarcoma cell line (Oldenburg et al. 1996); in SaOS cells, a human osteosarcoma cell line (Rodan et al. 1987; Fukayama and Tashjian 1994); in COS-7 cells transfected with the human PTH-1 (PTH/PTHrP) receptor and the human PTH-2 receptor (Bergwitz et al. 1997); or in stably transfected human embryonic kidney cells (HEK-293/C-21 cells that express the hPTH/PTRrP receptor and HEK/BP16 cells that express the hPTH2 receptor) (Behar et al. 1996b).

PROCEDURE

Stably transfected human embryonic kidney cells, HEK-293/C-21 cells that express the hPTH/PTRrP receptor (Pines et al. 1994) and HEK/BP16 cells that express the hPTH2 receptor (Behar et al. 1996a) are maintained in DMEM supplemented with 10%FBS. For cAMP determination, C-21 or BP-16 cells are incubated in 24-well tissue plates with various peptides for 10 min in DMEM in the presence of 1 mM 3-isobutyl-1-methylxanthine. The incubation is terminated by removal of the cell culture medium and addition of perchloric acid (final concentration 30%, vol/vol). Samples are neutralized with potassium bicarbonate and acetylated with acetic anhydrate. Total cAMP values (medium plus cells) are determined by RIA. Data are presented as the percent stimulation, from the ratio of maximal accumulated cAMP levels obtained in the presence of the highest concentration of the agonist PTH-(1-34) compared to the basal cAMP level. The accumulated cAMP levels

(picomoles) are calculated per 100 000 cells. Cell number is determined in a Coulter counter.

EVALUATION

Data are presented as the triplicate mean of ($[cAMP]_c$/$[cAMP]_{PTHmax}$ ±SEM) × 100 or sample stimulation vs. maximal PTH induced stimulation. $[cAMP]_c$ is the concentration of cAMP accumulated in response to a given concentration of a ligand, and $[cAMP]_{PTHmax}$ is the concentration of cAMP accumulated at the maximal dose (10^{-6} M) of PTH-(1-34).

N.6.0.8 Anabolic activity in ovariectomized, osteopenic rats

PURPOSE AND RATIONALE

This is an *in vivo* bioassay. Vickery et al. (1996) tested an analogue of human parathyroid hormone-related protein (1–43) in ovariectomized, osteopenic rats.

PROCEDURE

Groups of 3-month old virgin female rats are subjected to bilateral ovariectomy or sham surgery. The ovariectomized animals are treated by daily subcutaneous injections of 0, 9, 29 or 80 µg/kg of test compound or human parathyroid hormone-related protein (1–43), starting on day 17 after surgery and continuing for 21 days. On day 12 and 19 following the first day of treatment, animals are dosed intraperitoneally with 6 mg/kg of a 3.75 mg/ml solution of calcein (Sigma Chemical Co.) in 2% sodium bicarbonate-saline. Body weights are recorded, following an 18-h fast, on the last day of treatment. The animals are sacrificed immediately following the last injection and the femurs, tibiae, and L2 vertebrae are excised.

The distal part of the right femur is cut in half longitudinally after removal of the epiphysis. The bone marrow is flushed out using a stream of water. The trabecular and cortical bone are separated using a dental drill. Calcium is extracted by immersion of the trabecular bone for 3 days and the cortical bone for 5 days in 5% trichloroacetic acid. The calcium content of the extracts is determined. Measurement are expressed as mean ±SEM in units of milligrams of Ca^{2+}/distal half femur/100 g of body weight.

For histomorphometry, the left tibiae from sham, ovariectomized and high dose-treated rats are removed and fixed in formalin. The tibiae are cut with a diamond disc into three pieces: the proximal 1 cm, 2 cm of the diaphysis, and the distal end. The proximal and diaphyseal portions are transferred to Villanueva stain for 72 h (Villanueva and Lundin 1989). The proximal specimen is then dehydrated through increasing concentrations of ethanol (70–100%), defatted in acetone, and embedded in modified methyl methacrylate. Pairs of 5-µm thick frontal sections are prepared from the anterior aspect with a microtome. The first section is stained with a modified Masson trichrome technique (Goldner 1938) and the second left unstained.

The diaphyseal portion is also dehydrated, defatted and embedded in methyl methacrylate. Five 150-µm-thick sections are prepared, ground to 100 µm thickness and mounted unstained.

Growth cartilage thickness is measured by finding the distance between the proximal border of the epiphyseal growth cartilage and metaphyseal junction at 12 places spaced 0.2 mm apart.

On each slide, a rectangular window is defined as the field for evaluation. The top line is drawn under the primary spongiosa, and the second line is drawn parallel to it and 3.5 mm distally. The side lines are drawn near to, but not touching, the endocortical surface.

Histomorphometric variables are calculated for mean trabecular volume and structure (trabecular thickness, number, spacing, mineralizing surface, individual osteoblast activity, and osteoclast surface). Surface-based, bone-volume based, and total tissue volume-based bone formation rates are also calculated.

In the cortical bone of the tibial diaphysis, the periostal and endocortical surfaces are measured separately. Using transmitted light at 25× magnification, the periosteal and endoosteal perimeters are measured. The periosteal single-labeled and double-labeled surface and endoosteal single-labeled and double-labeled surface are measured using 160× magnification.

Vertebral processing and electron microscopy is performed in sham, ovariectomized and compound treated groups. The second lumbar vertebra is removed, dissected from soft tissue, and split sagitally with a diamond saw. The 2 halves are fixed in a mixture of glutaraldehyde and formaldehyde for 24–48 h at 4 °C. The tissue is decalcified in 10% EDTA in 0.1 M cacodylate, pH 7.2, postfixed for 1.5 h in OsO_4, stained in block with uranyl acetate, dehydrated and fixed in Epon. Fifty nm sections are cut and examined in an electron microscope. Microphotographs are printed at a final magnification of 1 300×. Each microphotograph is overlaid with a grid with a total test line length of 2.22×10^3 µm. Each intercept of the line with the trabecular surface is scored into one of four categories, depending on the cell type adjacent to the intercept: osteoblasts, osteoclasts, lining cells, no cells. The proportion of the trabecular bone surface area covered by each cell type is estimated by pooling the pictures from each rat and summing the grid points that intersect each cell type, then dividing by the total number of intersection, excluding the "no cell" counts.

EVALUATION

The treatment groups are compared by one-way analysis of variance (ANOVA) followed by Fisher's least significance difference to compare each treatment group to ovariectomized vehicle control group. For the histomorphometric determinations, the Kruskal-Wallis test is applied for group differences. For relative surface area cell coverage estimation, the treatments are compared overall as to the proportions of osteoblasts, osteoclasts, lining cells; and no cells using one way ANOVA.

MODIFICATIONS OF THE METHOD

Anderson et al. (1990) proposed the ovariectomized, lactating Sprague-Dawley rat as an experimental model for the rapid development of osteopenia which may be used to test the effectiveness of bone-retentive drugs, potentially useful in treating osteoporotic women. Rats were ovariectomized on day 2 postpartum and were kept on a low calcium diet. Measurements of serum total calcium, ionic calcium, albumin and parathyroid hormone were conducted between days 4 and 21 of lactation.

N.7
Anterior pituitary hormones

N.7.0.1
Hypophysectomy in rats

PURPOSE AND RATIONALE

This is a classical technique for the description of biological effects of pituitary hormones by substitution. Its usefulness is however limited by the fact that all pituitary hormones are eliminated at once. Various techniques of hypophysectomy have been described by Biedl (1916), Thompson (1932), Collip et al. (1933), Anselmino and Pecharz, (1935), Bomskov (1939) in several animal species, including dog, cat, rabbit, ferret, guinea pig, rat, mouse, chicken, and frog. At present, the technique of hypophysectomy in the rat remains of limited interest for biological standardization of anterior pituitary hormones. The parapharyngeal approach is less destructive than the transauricular approach, and is preferred for bioassay.

PROCEDURE

Male Wistar or Sprague-Dawley rats weighing 110–150 g are anesthetized with ether or modern anesthetics. Their legs are fixed to a surgical table. The head is stretched by a thread around the upper incisor teeth. The fur on the neck is removed with electric clippers. The field of surgery is cleaned with alcohol. A median skin incision is made 2.5 cm forward from the sternum. The large salivary glands and the maxillary lymph nodes

are pushed to the side, the muscles over the trachea are divided at the midline, and slightly below the thyroid a hole is made in the trachea with a needle ("tracheotomy"). Tracheal mucus is removed by vacuum aspiration. The insertion of a tracheal cannula is not necessary.

A deep blunt dissection is made directly medial to the tendon of the left or right digastric muscle. The ipsilateral glossopharyngeal nerve and the blood vessels are drawn to the side with a small blunt hook. The pharynx and the trachea are drawn to the other side by a second hook allowing the approach to the midline of the base of the skull.

The base of the skull is cleaned using small pellets of cotton-wool. The spheno-occipital suture running between both mastoid processes is prepared. From behind, the crista occipitalis runs longitudinally up to the middle of this suture. Just at this point, a burr hole is made through the basis of the scull with a dental drill. Care has to be taken to leave the surrounding sinus blood vessels intact. The hole is dried from blood with a cotton pellet. The pituitary can be seen as a small, lens-shaped organ. With a fine glass tube, attached to a vacuum pump over a Woulff bottle, the pituitary is carefully sucked out severing the hypophyseal stalk. Occasional bleeding is stopped with a cotton-wool pellet. The trachea is freed from mucus with the suction pump and the wound closed.

MODIFICATIONS OF THE METHOD

Instead of the parapharyngeal approach, the **transauricular approach** can be used (Jung and Vogel 1963). Male Wistar or Sprague-Dawley rats weighing 120–150 g are anesthetized with ether. The animal is placed with the right side on a glass plate. The head is fixed between the thumb and the index finger of the left hand. In perpendicular direction, a dental drill with a diameter of 2.2 mm is introduced into the meatus acusticus externus osseus. First, the fine lamellae of the middle ear are passed. Then, the drill is directed from the external ear to the contralateral orbita. On this way, the thin inner wall of the bulla tympani is perforated. At this place, the junction of bulla tympanica, os occipitale and os sphenoidale is located. A small, straight forceps is introduced to free the pituitary. Then, a needle with a diameter of 1.6 mm and with a blunted tip being attached to a glass cannula is introduced and the pituitary is removed by suction.

The procedure is less time-consuming than the parapharyngeal approach, but needs much more technical skill.

N.7.1 Gonadotropins

N.7.1.0.1 General considerations

Follicle-stimulating hormone (FSH) and luteinizing-hormone (LH) are glycoproteins which exists in multiple molecular isoforms (microheterogeneity) with different molecular weights and with different degrees of glycosylation (Ulloa-Aguirre et al. 1988; Dahl and Stone 1991). This is however not reflected by the bioassay The immunological methods provide only limited information on biological activity and may measure intact hormone or inactive subunits depending on the assay. *In vivo* animal bioassays, e.g., the classical Steelman-Pohley assay, *in vitro* cell bioassays with a high degree of sensitivity and specific radioreceptors assays have been developed (Simoni and Nieschlag 1991). Striking differences between *in vivo* bioassays, *in vitro* bioassays, receptor bioassays, and immunoassays were found when the International

Standard for Pituitary FSH was assayed in terms of the Second International Reference Preparation of Human Pituitary FSH and LH (Storring and Gaines Das (1989).

Receptors for gonadotropins in various species have been cloned (Poyner and Hanley 1992).

Time-resolved fluoroimmunoassay for gonadotropins has been proposed by Iwasawa et al. (1994).

N.7.1.1 Follicle-stimulating hormone (FSH)

Some of the methods described here are used for quantal assay of biological FSH activity (in animals and *in vitro*), others are used for the assay of FSH containing samples from experimental and clinical studies.

N.7.1.1.1 Ovarian weight in HCG-primed rats

PURPOSE AND RATIONALE

Follicle-stimulating hormone (FSH) increases the weight of ovaries in immature rats by inducing follicular maturation. This effect is greatly enhanced by simultaneous administration of a constant dose of human chorionic gonadotropin (HCG) for additional luteinization allowing the detection of low amounts of FSH (Steelman and Pohley 1953).

PROCEDURE

Immature female Sprague-Dawley rats weighing 40–45 g receive twice daily for 3 days subcutaneous injections of 3 different doses of the standard (e.g., ovine NIH-FSH-S-9, National Institute of Health, Bethesda, USA) or the test preparation both of them together with a total of 25 IU HCG (Primogonyl®, Schering AG, Berlin) dissolved in 2% gelatin solution in saline. Six to 8 animals are used per group. Eighteen hours after the last injection, the animals are sacrificed, the ovaries extirpated, freed from adherent fat and connective tissue, and weighed to the nearest 0.1 mg.

EVALUATION

Dose-response curves for standard and test compound are plotted and potency ratios with confidence limits calculated.

CRITICAL ASSESSMENT OF THE METHOD

The Steelman-Pohley test is rather specific for FSH. The addition of LH, TSH, ACTH, HGH, or prolactin did not influence the dose-response curves of FSH (Christiansen 1972b). The method has been adopted by pharmacopoeias, e.g., British Pharmacopoeia 1988.

MODIFICATIONS OF THE METHOD

Igarashi and McCann (1964) reported a bioassay for follicle stimulating hormone in mice using the synergism with HCG and uterine weight as endpoint.

Brown and Wells (1966) described an assay of human urinary follicle-stimulating hormone using HCG induced augmentation of ovarian weight in mice. The method has been used by Wide and Hobson (1986) studying the influence of the assay method used on the selection of the most active forms of FSH from the human pituitary.

Lamond and Bindon (1966) recommended the use of immature hypophysectomized mice on the basis of augmentation of FSH by HCG and uterus weight as endpoint as an assay for FSH.

Gans and van Rees (1966) studied a testicular augmentation assay method for follicle stimulating hormone. Immature male rats were hypophysectomized and on the same day the right testis was removed and weighed. Treatment with various doses of FSH together with a constant dose of 20 IU HCG was started on the next day and continued for six days. On the seventh day, the animals were sacrificed and the left testis was removed and weighed. The difference between the weights of the right and left testis in each animal served as endpoint of the assay.

Uberoi and Meyer (1967) used uterine weight of the immature rat as a measure of augmentation of pituitary gonadotropins by human chorionic gonado-tropin.

Results obtained with the *in vivo* bioassay according to Steelman and Pohley have been compared with an *in vitro* bioassay based on the estimation of estradiol produced by cultured Sertoli cells and an immunoassay by Storring et al. (1981).

N.7.1.1.2 [^{3}H]thymidine uptake in cultured mouse ovaries

PURPOSE AND RATIONALE

Follicle-stimulating hormone increases dose-dependent the amount of [^{3}H]thymidine uptake by cultured mouse ovaries. This *in vitro* bioassay for FSH uses a tissue specific proliferation response (Ryle 1971; Boggins and Ryle 1972).

PROCEDURE

Intact ovaries are obtained from 15 day old mice. They are dissected carefully with the aid of a stereomicroscope and transferred to culture dishes. Each ovary is placed on a strip of lens tissue supported on a stainless steel mesh grid 4 mm above the floor of a plastic Petri dish and incubated in Eagle's medium supplemented with glucose and glutamine. The dishes are gassed with 5% CO_2 in air at 37 °C. Three replicate dishes are used for each concentration of the standard (0.1 and 0.4 IU/ml) and of the test preparation. [^{3}H]Thymidine (0.02 μC) is added to each dish the day after the cultures are set up. Three days later the tissue is prepared for counting. Each grid is irrigated with about 5 ml saline solution. The ovary is then transferred to a counting vial and dissolved in Soluene (Packard Instruments Comp, Inc.). Scintillation solution is added for counting in a liquid scintillation counter.

EVALUATION

Dose-response curves of uptake of [^{3}H]thymidine are established for the standard and the test preparation and potency ratios with confidence limits are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The [^{3}H]thymidine uptake by cultured mouse ovaries has found less acceptance than other *in vitro* methods described below.

MODIFICATIONS OF THE METHOD

Follicle cultures from mouse ovaries for the study of follicular metabolism have been described by Boland et al. (1993).

N.7.1.1.3 Granulosa cell aromatase assay *in vitro*

PURPOSE AND RATIONALE

The granulosa cell aromatase assay *in vitro* is based on the principle of the *in vivo* bioassay of Steelman and Pohley, where the increase in ovarian weight is the result of FSH-induced follicular maturation and estradiol production, which further stimulates ovarian growth. The concomitant administration of HCG increases androgen production by the theca cells, thus providing androgen substrate for FSH-dependent aromatase activity in granulosa cells. Hsueh et al. (1983), Jia and Hsueh (1985) developed a sensitive *in vitro* bioassay for FSH based on the stimulation of estrogen production by cultured granulosa cells in serum free medium containing androstenedione.

PROCEDURE

Intact Sprague-Dawley rats (21–22 days old) are implanted with Silastic capsules containing diethylstilbestrol to stimulate granulosa cell proliferation. Four days after implantation, the animals are sacrificed and ovaries are dissected for granulosa cell collection. The ovaries are decapsulated, follicles are punctured with 27-gauge hypodermic needles, and granulosa cells are carefully expressed into McCoy's 5a medium. An aliquot is diluted with trypan blue stain, and viable cells are counted with a hemocytometer. Cells are cultured in 16-mm 24-well culture plates for 2–3 days at 37 °C in a humidified, 95% air-5% CO_2 incubator. Each well contains 5×10^4 viable cells in 0.5 ml McCoy's 5a medium supplemented with 2 mM L-glutamine, 100 U/ml penicillin, 100 µg/ml streptomycin sulfate, 10^{-7} M diethylstilbestrol (DES), 10^{-6} M androstenedione (as aromatase substrate), 0.125 mM 1-methy-3-isobutylxanthine (MIX), 1 µg/ml insulin, and 30 ng/ml HCG.

For the measurement of FSH bioactivity in serum samples, each test is performed in triplicate at three dose levels (5, 10, and 20 µl). To ensure a constant volume of 20 µl serum in the total incubation volume of 500 µl, all samples are balanced with the addition of gonadotropin-free serum. For the FSH standard curve, 4% gonadotropin-free serum is added to the culture medium. In order to increase the sensitivity, the serum has to be pretreated with 12% polyethylene-glycol (PEG, mol wt 8 000). At the end of the culture period of 3 days, estradiol content in the medium is measured by radioimmunoassay.

EVALUATION

RIA data are analyzed using weighted logit-log regression analysis. Calculation of FSH bioactivity in serum samples or test preparations is performed using a standard curve fitted with a second order polynomial.

MODIFICATIONS OF THE METHOD

Beers and Strickland (1978), Wang and Leung (1983), Combarnous et al. (1984), Thakur et al. (1990) found that FSH produced a dose-dependent increase of plasminogen activator production in cultures of rat granulosa cells. This assay has been found to be extremely sensitive: as little as 10^{-15} mol of FSH could be detected.

Ax and Ryan (1979) found that FSH stimulates dose-dependently the ^{3}H-glucosamine incorporation into proteoglycans by porcine granulosa cells *in vitro*.

Bhargava et al. (1989) used normal human ovarian cells for long-term cultures. These cells produced progesterone from cholesterol or pregnenolone and estrone from androstenedione when stimulated by FSH.

N.7.1.1.4 Sertoli cell aromatase assay *in vitro*

PURPOSE AND RATIONALE

The Sertoli cell aromatase assay was first described by Van Damme et al. (1979). This *in vitro* bioassay was developed following the observation by Dorrington et al. (1975) that FSH, but not LH, stimulates estradiol production by cultured Sertoli cells from immature rats. The assay has been further improved by Ritzén et al. (1982), Shah and Ritzén (1984), Padmanabhan et al. (1987). Generally, these assays are used to determine bioactive FSH in serum for diagnostic use, they are however also applicable to the activity of FSH preparations intended for therapy.

PROCEDURE

Seven to 10 day-old male Sprague-Dawley rats are used as a source of Sertoli cells. Testes are decapsulated, the testicular tissue is chopped twice, at right angles, with a mechanical tissue slicer and incubated in culture medium containing 0.03% collagenase and 0.003% trypsin inhibitor for 5–10 min at 34 °C. After the initial dispersal, seminiferous tubules settle to the bottom of the incubation flask, and the medium is decanted to remove interstitial cells. The tubules are washed several times; resuspended in medium that contains collagenase, trypsin inhibitor and 0.03% DNase (to prevent clumping of cells); and then incubated for 30 min at 34 °C. During incubation, dispersion of Sertoli cells is hastened by repeated aspiration with a Pasteur pipette. The resulting cell suspension is washed three times; cell number and viability are determined by counting in trypan blue dye-containing medium. Cells are suspended in a density of 5×10^5 viable cells/ml. One milliliter of cell suspension is transferred to each well of Falcon multiwell culture dishes (16 mm diameter, Falcon Plastics, Oxnard, CA).

Sertoli cells are cultured in medium comprised of the following constituents: 1 : 1 (vol/vol) mixture of Ham's F-10 nutrient mixture and Dulbecco's Modified Eagle's Medium that contains 1.2 g/liter sodium bicarbonate, 20 mg/liter gentamycine, and 1 mg/l amphotericin. Also included in the medium are: 1 µg/ml insulin, 5 µg/ml transferrin, 10 ng/ml epidermal growth factor, 20 pg/ml T_4, 10^{-8} M hydrocortisone, and 10^{-6} M retinoic acid. The cell cultures are incubated in this medium in a water-saturated atmosphere that consists of 95% air and 5% CO_2 at 37 °C.

After an initial incubation of the cell monolayers for 72 h, the medium is removed; the cells are washed once with the medium and re-incubated in the medium described above, which contains 2.5×10^{-6} M 19-hydroxyandrostenedione, FSH standard or unknown samples at various concentrations, and 0.1 mM methylisobutylxanthine (MIX). After a 24-h incubation, the medium is aspirated and centrifuged. The resultant supernatants are stored frozen until estradiol measurement by radioimmunoassay (England et al. 1974).

EVALUATION

The results are expressed as picograms of estradiol formed per ml culture medium. To evaluate changes in estradiol secretion with changes in FSH concentration, regression analyses are performed. From these data, activity ratios with confidence limits are calculated.

MODIFICATIONS OF THE METHOD

Rao and Ramachandran (1975) used isolated rat seminiferous tubule cell preparations free of Leydig cells for determination of cyclic AMP production as an *in vitro* assay for follicle stimulating hormone.

Sairam and Manjunath (1982) used seminiferous tubular suspensions of rats containing Sertoli cells, incubated them with FSH-preparations and measured cyclic AMP formation as endpoint.

N.7.1.1.5 Receptor binding assay for FSH

PURPOSE AND RATIONALE

Significant differences between biological activity and receptor binding activity of FSH preparations have been found by Marana et al. (1979), Zaid et al. (1981), Foulds and Robertson (1983), Burgon et al. (1993). This is attributed to the assay principle of measuring binding activity, but not subsequent intracellular signaling. Several receptor binding assay procedures have been described, e.g. Cheng (1975), Andersen (1983) using bovine testes; Reichert (1976) using rat testes tubule tissue.

PROCEDURE

Membrane preparations from bovine testes are used according to the methods of Cheng (1975) and Andersen (1983). Fresh bovine testes or testes from rats weighing 220–280 g are decapsulated and rinsed with cold 0.025 M Tris-HCl buffer at pH 7.2, containing 0.3M sucrose, and then minced and homogenized with a Polytron homogenizer at maximum speed for 30 s at a concentration of 5 ml buffer per g of tissue. The homogenate is first filtered through 4 layers, and the filtrate is again filtered through 8 layers of cheesecloth. The filtrate is then centrifuged at 12 000 *g* for 30 min at 4 °C. The pellet is discarded and the supernatant is further centrifuged at 100 000 *g* for 1 h at 4 °C. The supernatant is discarded and the pellet resuspended in cold 0.025 M Tris-HCl buffer at pH 7.2, containing 10 mM $MgCl_2$, at a concentration of 1 ml buffer per g of the original weight of the testis. The isolated membranes are stored at –70 °C in aliquots of 10 ml per vial until use.

For assays, 12/75 mm glass disposable tubes are used. To each tube, 0.2 ml of 0.025 M Tris-HCl buffer at pH 7.2, containing 10 mM $MgCl_2$ and 0.1% BSA, 0.1 ml of standard FSH or unknown samples in the same buffer, 0.1 ml of ^{125}I-hFSH tracer labeled by the lactoperoxidase method (50 000 cpm, approximately 2 ng), and finally 0.1 ml of plasma membrane receptors of appropriate dilution (approximately 1–2 mg/ml) are added to reach a final volume of 500 µl per tube. All the above solutions are kept at 4 °C before use. The tubes are then shaken vigorously and incubated at room temperature for 20 h. Following incubation, the reaction is stopped by adding 3.0 ml of cold 0.025 M Tris-HCl buffer containing 0.1% BSA. After centrifugation at 4 000 rpm for 30 min, the supernatant is drained and the tip of each tube is dried. The pellet remaining at the bottom of the tube is counted in an automatic gamma counter.

EVALUATION

Specific binding (%) is defined as $(C_B - C_N) \times 100 / C_T$, where C_B is the cpm bound to the testicular receptor (pellet), C_N is the nonspecific bound cpm (nondisplacable by 1 000-fold excess of unlabeled hFSH), and C_T is the total cpm put into the tube. For standard curves, the specific binding of tracer ^{125}I-hFSH in the absence of cold hormone (6–8% by 150–200 µg of receptor protein) is taken as 100% bound ^{125}I-hFSH, and the non-specific bound ^{125}I-hFSH (1–2% of the total cpm added) as the baseline. The specific binding of ^{125}I-hFSH in the presence of a range of standard hFSH concentrations is used for calculating a standard curve for the calculation of sample concentrations.

MODIFICATIONS OF THE METHOD

Simoni, Jockenhovel and Nieschlag (1993) analyzed the biological and immunological properties of the international standard for FSH 83/575 by isoelectrofocusing and compared with other FSH preparations. The results suggested that the international standard 83/575 is not fully representative of pituitary and serum FSH, and its use for calibration of immunometric methods based on monoclonal antibodies is unlikely to resolve problems of inaccuracy in measurement of serum FSH.

Grasso et al. (1993) studied the effects of a testicular toxicant on follicle-stimulating hormone binding to membranes of cultured rat Sertoli cells.

Wakabayashi et al. (1997) reported the cDNA cloning and transient expression of a chicken gene encoding a follicle-stimulating hormone receptor.

Simoni, Weinbauer and Nieschlag (1993) analyzed the molecular heterogeneity of two batches of commercially available urofollitropin by immunofluorometric assay, radioligand receptor assay and *in vitro* bioassay.

N.7.1.2 Luteinizing hormone (LH) = Interstitial cell stimulating hormone (ICSH)

Some of the methods described here are classical animal bioassays for LH/ICSH preparations, others are *in vitro* bioassays used in research and for clinical samples.

N.7.1.2.1 Prostate weight in hypophysectomized rats

PURPOSE AND RATIONALE

The assay is based on a biological response. Injection of ICSH into hypophysectomized male rats causes enlargement of the testes and the secondary sexual organs. The interstitial cells of the testes (Leydig cells) are stimulated by LH/ICSH and secrete androgens which in turn stimulate the accessory organs, such as the ventral prostate of the rat.

PROCEDURE

Immature male Sprague-Dawley rats at an age of 21 days are hypophysectomized. From the second to the fifth day, they receive daily subcutaneous injections of 2 or more doses of the test preparation and the LH/ICSH standard. They are sacrificed on the sixth day. Both testes and the ventral prostate are prepared and weighed. LH/ICSH – but not FSH – induces a specific dose-dependent increase of prostate weight, whereas FSH also induces an increase of testis weight. Thus, a predominant LH activity in the test material would mainly stimulate prostate weight.

EVALUATION

Dose-response curves are plotted for the of the ventral prostate in each group versus logarithm of dose of test preparation or standard allowing the calculation of activities and potency ratios with confidence limits.

N.7.1.2.2 Superovulation in immature rats

PURPOSE AND RATIONALE

An assay for evaluation of LH and the luteinizing component of HCG was described by Zarrow et al. (1958) increasing the sensitivity of the test by priming with pregnant mare serum gonadotropin (PMSG – mainly FSH activity) and by intravenous injection of the LH test preparation.

PROCEDURE

Groups of 5 immature female rats (Charles River strain) are treated at an age of 21 days with a priming dose of 30 IU of PMS to induce follicular development followed by an intravenous injection of various doses of LH reference or test preparations 56 h later, to induce ovulation. Twenty-four hours after the final injection, the animals are sacrificed. At autopsy, the Fallopian tubes are removed and examined under a dissecting microscope at a magnification of 40×. Ovulation is easily noted by the presence of an enlarged translucent segment of the tube, through which the ova can be seen. The segment is then punctured with a dissecting needle and the entire cumulus clot containing the ova is expelled in a single mass. Due to the large number of eggs released at ovulation, the egg mass has to be treated with hyaluronidase. The number of ova is counted.

EVALUATION

Doses-response curves are obtained using three doses of standard/reference and test preparation for calculation of potency ratios with confidence limits.

N.7.1.2.3 Ascorbic acid depletion of ovaries in PMSG/HCG primed rats

PURPOSE AND RATIONALE

Luteinizing hormone (LH = ICSH) induces dose-dependent depletion of ascorbic acid in the ovaries of rats primed with pregnant mare serum gonadotropin (PMSG) and human chorionic gonadotropin (HCG).

PROCEDURE

Female Sprague Dawley rats weighing 40 ±5 g are injected with 50 IU PMSG (e.g., Anteron®, Schering AG, Berlin) in 0.2 ml saline subcutaneously on day 1 at 3:00 P.M. On day 3, the rats receive 25 IU HCG (e.g., Primogonyl®, Schering AG, Berlin) subcutaneously at 9:00 A.M. On day 7, three different doses of the standard (e.g., NIH LH-S-1, National Institute of Health, Bethesda, ML) and the test substance are injected subcutaneously. Eight animals are used per group. Three hours later, the animals are sacrificed, both ovaries removed, weighed and homogenized for determination of ascorbic acid content.

EVALUATION

Dose-response curves for standard and test compound are plotted and activity ratios with confidence limits calculated.

N.7.1.2.4 Testosterone production by Leydig cells *in vitro* induced by LH

PURPOSE AND RATIONALE

LH increases the biosynthesis and secretion of androgens in the Leydig cells of the testes. This can be used for an *in vitro* assay using isolated Leydig cells.

PROCEDURE

For Leydig cell isolation, male Wistar or Sprague-Dawley rats weighing 250–300 g are sacrificed, the testes removed and immediately decapsulated. Two testes are then digested with 7 ml of collagenase solution (1 mg collagenase/1 ml Gibco medium 199) at 37 °C for 18 min. Plastic tubes of 40 ml capacity with tight-fitting caps are used, being placed longitudinally in the water bath with constant shaking (75 cycles/min). After incubation, 15 ml of cold saline is added to each tube. The tubes are inverted a few times and then left at 4 °C for 10 min. The supernatants are then carefully siphoned off from the top. The clear supernatant is mixed with an equal volume of 26% Ficoll/0.4% BSA/medium 199 at pH 6.5, and then centrifuged at 1 500 *g* for 10 min at 4 °C. The cell pellet obtained from the centrifugation is suspended in a known volume of incubation medium (Medium 199 containing 1% BSA and 0.01% lima bean trypsin inhibitor). An aliquot of the cell suspension is taken for counting in a Coulter counter, and the balance is diluted with the incubation medium giving a density of 4×10^6 cells/ml.

For each assay, 0.25 ml of the cell suspension is used. The assay is carried out in 12×75 mm plastic tubes incubated with graded doses of test compound at 37 °C. Constant shaking (100 cycles/min) under a 95% O_2/5% CO_2 atmosphere for 3 h is required. At the end of the incubation, each tube is centrifuged, and the supernatant is assayed for testosterone by a radioimmunoassay (Dufau et al. 1972). The assay is carried out in triplicate and needs to be repeated at least once with different batches of donor animals.

EVALUATION

Dose-response curves are obtained with various doses of standard and test preparation to allow calculation of activities and potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

The effect of chemically deglycosylated human chorionic gonadotropin on cyclic AMP and testosterone production in rat Leydig cells has been used by Chen et al. (1982) for characterization.

Cultures of mouse Leydig cell tumor cells (MA10) have been used by Ascoli (1981), Whitcomb and Schneyer (1990), Dahl and Sarkissian (1993).

N.7.1.2.5 Receptor binding assay for LH

PURPOSE AND RATIONALE

LH receptors are membrane receptors mediating the initial hormone binding step, they are suitable for structure activity studies and *ex vivo* analysis of receptor concentration changes. Luteinizing hormone is a glycoprotein composed of an α- and β-subunit. Carbohydrate moieties are attached to both. Removal of the carbohydrate chains reduces bioactivity but enhances receptor binding.

PROCEDURE

For the preparation of Leydig cell receptors, the partially purified Leydig cells obtained from Ficoll gradient centrifugation as described above for the testosterone formation test are used. The cell pellet obtained from the Ficoll gradient centrifugation is first washed twice with unlabeled radioligand buffer (0.1 M Tris-HCl, pH 7.4, containing 5 mM $MgCl_2$, 0.1 M sucrose, and 0.1% BSA). The pellet is resuspended in a known volume of the same buffer. An aliquot of this suspension is taken for cell counting in a Coulter counter, and the balance is homogenized in a Polytron homogenizer for 10 s to break up the cells. This prevents internalization of the hormone molecule during the binding assay. The iodination of LH is carried out according to the chloramine-T method (Liu et al. 1977). After addition of 2.5 ng of ^{125}I labeled LH-tracer, the binding assay is carried out at 37 °C for 2 h with constant shaking. The hormone-receptor complex is then separated by centrifugation and bound radioactivity is counted in a Packard gamma-counter.

EVALUATION

Competitive inhibition curves for specific binding are established and binding capacity is calculated.

MODIFICATIONS OF THE METHOD

Lee and Ryan (1972) described specific binding of human luteinizing hormone to homogenates of luteinized rat ovaries.

Storring and Gaines-Das (1993) described the second International Standard for Human Pituitary LH. Two new batches (coded as 80/552 and 81/535) were compared with the International Reference Preparation of Human Pituitary LH for Immunoassay (IRP 68/40) by 19 laboratories in 11 countries, using in-vivo and in-vitro bioassays, a receptor assay and immunoassays. An activity of 35 International Units of Human Pituitary LH was assigned to the contents of each ampoule coded 80/552.

Selvaraj and Moudgal (1993) used sheep luteal membranes for an LH receptor assay capable of measuring serum LH/CG in a wide variety of species.

Chen and Bahl (1993) reported a high expression of the hormone binding active extracellular domain (1-294) of rat lutropin receptor in *Escherichia coli*.

Jia et al. (1993) developed a luteinizing hormone/choriogonadotropin bioassay using 293 cells permanently transfected with the human LH receptor cDNA and a luciferase reporter gene driven by a cAMP-dependent promotor.

Selvaraj et al. (1996) established a radioreceptor assay for LH/CG in human sera using immortalized granulosa cells transfected with LH/CG receptor.

N.7.1.3 Other gonadotropins

GENERAL CONSIDERATIONS

The pituitary gonadotropins are species specific and exist in various isoforms containing different carbohydrate moieties. For this reason, human FSH and LH are not available for therapy. For therapy of infertility, they were substituted by gonadotropins excreted in human urine and purified by extraction, hCG and hMG. Pituitary gonadotropins are now prepared by recombinant DNA synthesis for treatment of infertility.

Human chorionic gonadotropin (hCG) is excreted in the urine of pregnant women. However, hCG is also excreted by tumors, such as hydatiform mole and chorionepithelioma. The primary significance of hCG assays was for diagnosis, mainly for early diagnosis of pregnancy. HCG has predominantly a LH-like activity being useful for therapy. Purified preparations of hCG and hMG are tested by bioassays.

Human menopausal gonadotropin (hMG) is excreted in the urine from postmenopausal women and after castration. HMG has predominantly FSH-like activity and is used to induce follicular maturation.

Another gonadotropin previously used in therapy, is *pregnant mares' serum gonadotropin (PMSG).* Pregnant female horses secrete from their pituitaries high amounts of gonadotropin which is not excreted in the urine and accumulates in serum. PMSG has predominantly FSH-like activity. Purified preparations are tested by bioassays.

N.7.1.4 Human chorionic gonadotropin (hCG)

The assays described here are mostly of historical interest. For therapy, hCG is gradually replaced by recombinant human LH. It is measured as a tumor marker and widely used as a research reagent.

N.7.1.4.1 Corpus luteum formation in immature mice (Aschheim-Zondek test)

PURPOSE AND RATIONALE

Aschheim and Zodeck (1927) injected urine of pregnant women (containing FSH and LH-activity) into immature female mice and observed ovulation and formation of corpora lutea. This procedure was widely used as a biological pregnancy test and is replaced by modern *in vitro* methods. Further studies were performed by Hamburger and Pedersen-Bjergaard (1937).

PROCEDURE

Groups of 10–20 mice, 21 days of age, are treated with 5 equal subcutaneous injections of urinary extracts in the course of 48 h. The animals are sacrificed 96 h after the first injection. The ovaries are dissected and the formation of corpora lutea is observed by examination with a lens or a stereomicroscope. Rupture of follicles is indicated by blood spots.

EVALUATION

For testing hCG preparations, various doses were applied and the number of ovaries showing formation of corpora lutea were expressed as percentage dose-response curves.

The biological pregnancy test has been replaced by immunological methods available as commercial kits.

N.7.1.4.2 Biological assay of hCG in immature male rats

PURPOSE AND RATIONALE

The LH-like activity of hCG can be determined by measuring weight increase of prostate and seminal vesicles in immature male rats.

PROCEDURE
Immature male Sprague-Dawley rats at an age between 21 and 24 days are assigned at random to six groups of at least five animals. Three doses of standard (e.g., 4, 8, and 16 IU) and corresponding doses of the test preparation are dissolved in albumin-phosphate buffer, pH 7.2, and injected subcutaneously daily over a period of 4 days. On the fifth day, the animals are sacrificed and the seminal vesicles and prostate glands are prepared and weighed.

EVALUATION
Dose-response curves of weights of seminal vesicles and ventral prostate glands are established for standard and test preparations allowing calculation of potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD
The United States Pharmacopoeia USP 23 (1995) requests standardization of hCG in immature female rats at an age of 20 to 23 days. The animals are injected subcutaneously with three different doses of test preparation or standard daily on three consecutive days. They are sacrificed on the fifth day and the uteri are prepared and weighed.

N.7.1.4.3 Receptor binding assay for hCG

PURPOSE AND RATIONALE
The hCG receptors are obtained from superovulated rat ovaries.

PROCEDURE
Ovaries from pseudopregnant rats primed with PMSG and hCG are homogenized. The homogenates are centrifuged at 2 000 *g* for 15 min and the pellets are washed 3 times with 40 mM Tris buffer and resuspended in the same buffer. The suspension is filtered through 4 layers of cheesecloth prior to use. Fresh 2 000 *g* fraction is prepared for each experiment. Purified hCG is labeled by the chloramine-T method resulting in a specific activity of approximately 60–70 μCi/μg.

For assessment of binding to receptors a mixture consisting of the 2 000 *g* fraction (equivalent to 2.5 or 5 mg of wet ovary or 45–90 μg of protein) and $0.1–30 \times 10^{-10}$ M labeled gonadotropin or other test substances are incubated in a final volume of 1 ml of 40 mM Tris buffer (pH 7.4) containing 0.1% BSA at 25 °C for 16 h. Then 1 ml ice-cold Tris buffer is added to the medium. This is immediately filtered, with suction, through Millipore EHWP filters (pore size 0.5 μm) previously wetted with 4% BSA to reduce nonspecific binding. The adsorbed material is washed with another 10 ml of ice-cold Tris buffer. The radioactivity on the filter is measured. Binding in the presence of a large excess of unlabeled hCG (200 IU/ml) is used to assess nonspecific binding.

EVALUATION
Specific binding is obtained by subtraction of the nonspecific component from total binding.

MODIFICATIONS OF THE METHOD
Selvaraj et al. (1996)described an *in vitro* bioassay and radioreceptor assay for LH/CG in human sera using immortalized granulosa cells transfected with LH/CG receptor

N.7.1.5 Human menopausal gonadotropin (hMG)

N.7.1.5.1 Biological assay of hMG in immature rats

PURPOSE AND RATIONALE
The predominant FSH-like activity can be measured by the increase of ovarian weight in immature female rats. The partial LH-like activity of hMG can be determined by the increase of prostate and seminal vesicle weights of immature male rats as described above.

PROCEDURE

Female Sprague-Dawley rats at an age between 21 and 24 days are assigned at random to six groups of at least five animals. Three doses of standard (e.g., a total dose of 1.5, 3, and 6 IU) and corresponding doses of the test preparation are dissolved in albumin-phosphate buffer, pH 7.2, and injected subcutaneously daily over a period of 3 days. On the fourth day, the animals are sacrificed and the ovaries are removed and weighed.

EVALUATION

Dose-response curves for FSH activity are established by mean weights of ovaries for standard and test preparation, allowing calculation of potency ratios with confidence limits.

N.7.1.7 Immunoassays of gonadotropins

Immunoassays of gonadotropins are important in clinical diagnosis (RIA, ELISA and similar methods). For pharmacological and biological experiments, they are measured in blood, urine and pituitary tissue, e.g. for evaluation of gonadotropin releasing hormones (as described in Sect. N.9.2.5 and N.9.2.6). Many comparisons for results of *in vivo* and *in vitro* bioassays versus immunoassays showed significant discrepancies, when expressed as the ratios of bioactive to immunoreactive LH (B/I ratio). However, there are numerous validated species-specific methods which are used for experimental endocrinology and clinical diagnosis. A few references of immunoassay methods for gonadotropins are presented.

N.7.1.8 Gonadotropin inhibition

N.7.1.8.1 General considerations

Gonadotropin inhibition is suspected when in early testing of compounds or in toxicology studies weight reduction of gonads and the endocrine dependent organs is found. Early tests used the physiological feedback effects of endogenous steroids in rats, e.g., the parabiosis experiment . This technique in rats was applied to the relationship between central and peripheral endocrine organs, the pituitary-gonadal axis. Basically, the defi-

cit in gonadal steroid hormones after castration of one parabiotic partner induces increased secretion of gonadotropin which in turn stimulates hypertrophy of the gonads of the non-castrated partner. The procedure is described in detail by Shipley (1962). The parabiosis technique is now obsolete but has been applied again a few years ago with remarkable success to the identification of the adipose tissue hormone, leptin (see L.4.1).

N.7.1.8.2 Inhibition of gonadotropin secretion in intact animals

PURPOSE AND RATIONALE

In principle, suppression of gonadotropin secretion can be detected in the endocrine survey test, described in Sect. N.1. Young rats, e.g. 80–100 g initial body weight, are treated with gonadal steroids or their derivatives to exert feedback inhibition. Suppression of gonadal weight increase indicates gonadotropin inhibition, whereas weight increase of the sexual hormone dependent organs in castrate control groups (females or males, respectively) indicates the estrogenic or androgenic property of the test compound.

PROCEDURE

Immature male and female Sprague-Dawley rats weighing 55–65 g or young rats 80–100 g are used. Groups of 10 animals per sex and dosage group are treated daily over a period of 21 days with doses of the test compound usually by the oral or subcutaneous route. Controls receive the vehicle only. Testosterone may be used as standard in males and estradiol in females. Twenty-four hours after the last treatment, the animals are sacrificed and body weights recorded. In males, testes, seminal vesicles, ventral prostate and musculus levator ani; and in females, ovaries and uterus are dissected out and weighed.

EVALUATION

Average organ weights are calculated for each treatment group and compared with controls. The reference steroids, testosterone and estradiol, suppress gonadal weight by pituitary gonadotropin inhibition (negative feedback) and increase the weight of the sex hormone dependent organs by direct action on the tissues. Dose-response curves either pituitary inhibition or steroid action can be established for the test compounds and the standard. The relative potency of gonadotropin inhibition can be calculated.

MODIFICATIONS OF THE METHOD

As an example of a classical bioassay, gonadotropin inhibition can be tested in semicastrated male rats (Vogel 1964). Male Sprague-Dawley rats weighing 50–60 g are orchidectomized on the left side. The testis pad is weighed (without epididymis and epididymal fat). Test compounds in various doses or the standard are administered subcutaneously once daily for a period of 10 days. Controls receive the vehicle only. Standards compounds may be medroxyprogesterone acetate 0.4, 2.0, and 10.0 mg per animal and day, or 17-ethinyl-19-nor-testosterone acetate 0.1, 0.5, and 2.0 mg per animal and day subcutaneously.

On day 11, the animals are sacrificed and the testis, the adrenals, the seminal vesicles, the ventral prostate and the musculus levator ani are dissected out and weighed. Gonadotropin suppression results in atrophy of the remaining (contralateral) testis as compared with the weight of the remaining testis of the untreated control. Decrease in adrenal weight indicates feedback inhibition of the pituitary-adrenal axis. Weight of seminal vesicles, the ventral prostate and the musculus levator ani indicates androgenic activity of the test compound. Dose-response curves for the test compound and the standard and potency ratios calculated.

N.7.1.8.3 Inhibition of ovulation and luteinization

PURPOSE AND RATIONALE

This is an assay for progestanional steroids. Progestagens exert feedback inhibition of gonadotropin secretion. Repeated administration of progestional compounds e.g. cyproterone acetate inhibit ovulation and corpus lutea formation in young female rats by reducing luteinizing hormone secretion.

PROCEDURE

Thirty-five days old female rats are treated once daily over a period of 7 days with various doses of gestagens, e.g., 0.125 to 2.0 mg progesterone or 0.025 to 0.40 mg 6α-methyl-17α-acetoxy-progesterone subcutaneously. Controls receive the vehicle only. On the 8th day, the animals are sacrificed and body weight, ovary weight and number of corpora lutea registered. Gestagens depress ovarian weight (by inhibiting follicular maturation) and inhibit corpus luteum formation.

EVALUATION

Number of rats with corpora lutea, average number of corpora lutea per animal and ovarian weight are determined. Dose-response curves can be established for these parameters.

MODIFICATION OF THE METHOD

Ovum count can be performed in the oviduct of immature mice or rats after treatment with estradiol (Austin and Bruce 1956; May 1971). Immature rats or mice are injected with various doses of estradiol or stilbestrol to initiate estrus and ovulation. Seventy-two hours later the animals are sacrificed and the oviducts are removed and examined in saline under a stereomicroscope for the presence of ova. They can be seen through the swollen translucent walls of the oviduct. The swollen part of the oviduct is then punctured with dissecting needles to release the ova, which are then counted. The results are expressed as the mean number of ova per animal. This number is dependent on the dose of estrogen. The inhibition of the estradiol response by the test compounds is determined.

Hahn et al. (1977) treated rats in diestrus with test compounds administered orally in 0.5 ml sesame oil, and again on the following day when the animals were in proestrus. The animals were sacrificed on the next day, at which they would normally have ova in the proximal segment of the Fallopian tubes. Oviducts were separately flushed with saline onto a glass microscope slide. The tubal flushings were examined with a binocular microscope, and condition and number of ova was noted.

Inhibition of ovulation by gestagens can be studied in rabbits (Shipley 1965). Progesterone is known to have a time-dependent biphasic effect on ovulation (stimulatory or inhibitory effects on secretion of pituitary gonadotropins). The timing of injection of progesterone relative to the anticipated time of ovulation is important. Thus, progesterone injected less than 4 h before the ovulation in rabbits facilitates ovulation. In contrast, ovulation is inhibited by progesterone injected four hours or longer prior to the anticipated time of ovulation (Sawyer 1952). The rabbit ovulates within a few hours after mating, after mechanical stimulation of the vagina or after an i.v. injection of copper acetate (0.3 mg/kg). Progesterone injected 24 h before induction of ovulation will prevent ovulation.

Sexually mature female rabbits weighing 3–4 kg are treated with various doses of a standard progestogen or the test compound and, 24 h later, an ovulation inducing stimulus is given. The rabbits are sacrificed and the ovaries are examined 18–24 h later. The total number of ovulation points on both of the ovaries is recorded for each animal. Dose response curves for standard and test preparations are calculated.

N.7.1.8.4 Ovary-spleen-transplantation

PURPOSE AND RATIONALE

This is again a historical assay for gonadal steroids. Venous outflow from the spleen is exclusively to the liver. The steroids secreted by an autografted ovary in the spleen do not reach the peripheral circulation but are degraded to inactive metabolites in the liver. Therefore, they can not exert their systemic feed-back regulation of the pituitary, the increasing gonadotropin secretion stimulates the growth of the transplanted ovary. This effect can be antagonized by systemic application of gonadal hormones. The method has been de-

scribed by Mardones et al. (1951) for the guinea pig and by Desclin (1959) for the rat and was modified by Vogel and Jung (1962).

PROCEDURE

Female Sprague-Dawley rats weighing 100 to 120 g are anesthetized with ether. The abdominal skin is shaved and disinfected. Through a vertical incision in the skin, the abdominal wall is opened lateral to the linea alba. Both ovaries are removed. One ovary is freed from the capsule and connective tissue and weighed to the nearest 0.1 mg. With a scalpel an incision is made into the cranial end of the spleen forming a deep pocket. With a pair of forceps, the ovary is pushed into this pocket being finally placed in the middle of the spleen. The incision is closed with silk suture. The abdominal wall is closed by sutures and the skin by wound clips. The animals are treated with daily subcutaneous injection of an estrogen (e.g., 0.01, 0.1, 1.0, and 10 μg estradiol in 0.1 ml sesame oil) or a gestagen (e.g., 0.001, 0.01, 0.1, and 1.0 mg 6α-methyl-17α-acetoxyprogesterone) for a period of 5 weeks. Controls receive the vehicle only. In controls, the weight of the ovary is increased about 8-fold, i.e., from an average weight at implantation of about 10,0 mg to values around 80.0 mg. Estradiol at doses starting from 0.1 μg and 6α-methyl-17α-acetoxyprogesterone at a dose of 1.0 mg suppress ovarian growth completely. Uterus weight is increased by estradiol only.

EVALUATION

Dose-response curves or minimal effective doses of test compounds and reference standards are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The ovary-spleen-transplantation method is suitable to measure the same effects on pituitary and gonads as the parabiosis experiment, with much less stress to the animals.

N.7.1.8.5 Inhibition of fertility

PURPOSE AND RATIONALE

Fertility in rats can be inhibited by treatment of females with steroids inhibiting pituitary gonadotropin secretion or competing at the progesterone receptor. The test is used for contraceptive steroids.

PROCEDURE

A colony of about 100 adult female Sprague Dawley rats weighing between 200 and 250 g is established. Daily vaginal smears are taken at noon for 5 days. Fifteen regularly cycling females in proesterus are selected and caged separately. The first drug dose is administered at 3:00 P.M. (day 1). At 5:00 P.M. two vigorous males are placed with each female. On day 2, vaginal smears are taken for sperm count at 8:00 A.M. The second drug dose is administered at 4:30 P.M. On day 3, vaginal smears are taken for sperm count at 8:00 A.M. again. The 3rd drug dose is administered and sperm counts are taken at 4:30 P.M. The males are then removed. From the 4th to the 7th day the test drugs are administered in the morning. Controls receive the vehicle only. On day 9, the animals are sacrificed and the uterus examined for implantation sites.

EVALUATION

Compounds which prevent conception as evidenced by the absence of implantation sites at autopsy are given further consideration. Minimal effective doses preventing ovulation in all animals of a test group are determined.

N.7.2 Prolactin

N.7.2.1 General considerations

The classical procedure for bioassay of prolactin is based on the work of Riddle and Bates (1939), namely, the increase of weight of the crop sacs of doves and pigeons. Other methods are based on the induction of secretory changes in the mammary glands of rodents. Most of these methods can now be replaced by cell-based assays using suitable cell les responding to prolactin.

The clinical measurements rely on immunoassays (Shiu and Friesen 1976; Jacobs 1979; Jeffcoate et al. 1986). Due to the species specificity of prolactin, a special radioimmunoassay for rats was developed.

Leroy-Martin et al. (1995) reported an immunocytochemical study of human prolactin receptors using antiidiotypic antibodies in human breast cancer.

N.7.2.2 Radioimmunoassay of rat prolactin

PURPOSE AND RATIONALE

Prolactin is a glycoprotein hormone exhibiting species specificity. For pharmacological experiments in rats, such as evaluation of gonadotropin releasing hormone activity or prolactin inhibiting factor activity, a homologous assay is necessary. The reagents for rat-prolactin and guidance for the method are provided by National Pituitary Agency, USA.

PROCEDURE

Reagents

Standard:	NIAMDD-rat-prolactin-RP-1
Antiserum:	rabbit-anti-rat-prolactin (NIAMDD-S-6)
Tracer:	^{125}I-rat-prolactin (NIAMDD-I-3)
Second antibody:	Goat-anti-rabbit-gammaglobulin (Cat. No. OTP 14/15)
Buffer:	0.01 M-phosphate-saline/0.1% bovine serum albumin, pH 7.4

Assay procedure

Standards:	0.03–1 ng/tube, 200 µl/tube
Antiserum:	1 : 4 000 100 µl/tube,
Tracer:	specific activity 250 µCi/µg, 10 000 cpm in 100 µl/tube

Standards (or sample) are incubated with antiserum for 24 h at +4 °C, the tracer is added and incubated for another 48 h. Then the second antibody (1 : 50), 200 µl/tube, is added, and incubated for 48 h at +4 °C. Separation is performed with 1.0 ml ice-cold phosphate buffered saline, pH 7.4, the vials spun at 1 300 *g* for 15 min, the supernatant decanted, and the residue counted for 1 min in a gamma-counter.

Counting equipment: gamma spectrometer.

EVALUATION

Data processing: standard curves and sample data are calculated by any suitable computer program e.g. using a spline function.

N.7.2.3 Pigeon crop method

PURPOSE AND RATIONALE

This is again a historical bioassay no longer applied. Riddle and Bates (1939) showed that the secretion of "crop milk" by pigeons and doves is initiated and maintained by a factor from the anterior pituitary of these birds being identical with the lactogenic hormone from mammals. Suitable assay methods (Cowie and Folley 1955) have been developed on this basis. Pigeons are exquisitely sensitive to lactogenic hormone, and the assay can be done with considerably less material than

the mammalian assays. The most sensitive assay is the so-called micromethod of local intracutaneous injections of the crop sac.

PROCEDURE
Two to 3 months old pigeons of either sex, but of uniform strain, e.g., White Carneaux, are injected intramuscularly (intrapectorally) with various doses of the test preparation or the standard once daily for 4 days. On the fifth day, the birds are sacrificed. A midventral incision is made through the skin and crop wall from keel to head. The contents of the crop and the adhering crop-milk are removed. The two lateral pouches are removed, the fat cleaned from the back of the glands and the wet weight of the glands determined. Thus, the unstimulated tissue in the dorsal midline and that around the proximal and distal opening of the crop are not weighed.

EVALUATION
Mean values of at least two doses of test preparation and standard are plotted versus logarithms of doses and potency ratios with confidence limits calculated.

MODIFICATIONS OF THE METHOD
The micromethod is based on the observation that only a small area directly over the site of injection is stimulated when lactogenic hormone is injected intradermally over the crop sac forming a "bleb" at the site of injection. A direct comparison of the potency of two different preparations can be made by a similar injection over the other crop sac. The birds are sacrificed on the fifth day and the entire crop sacs removed and examined by transmitted light (Lyons et al. 1935).

N.7.2.4 Lactation in rabbits

PURPOSE AND RATIONALE
Only the rabbit and guinea pig have proven satisfactory for mammalian assays of lactogenic hormones. The assays are based on the prolactin induced mammary growth and milk secretion of pseudopregnant animals.

PROCEDURE
Pseudopregnancy is induced in mature estrus rabbits by intravenous injection of 50 IU of human chorionic gonadotropin. On the fourteenth day, the rabbits are examined for the presence of well-developed mammary glands characteristic of pregnancy. Various doses of the test preparation or the standard of lactogenic hormone are injected subcutaneously once daily for 6 days. On the seventh day the animals are sacrificed and the abdominal skin is incised in the midline and separated from the mammary gland underneath. The degree of enlargement of the glands with secretion is rated as follows:

–	absence of response
+	all ducts are filled with milk
++	all ducts and most of lobules are filled with milk though not greatly thickened
+++	entire gland is filled with milk
++++	mammary glands are greatly extended with milk throughout.

EVALUATION
The mean values of groups of 6 rabbits are compared with the values of the standard groups.

MODIFICATIONS OF THE METHOD
A more sensitive rabbit assay method is based on the ability of lactogenic hormone to act directly on mammary tissue (Lyons 1942). Small amounts of test compound are injected directly into one or more of the six milk ducts of a castrated, estrone-progesterone-pretreated rabbit. A localized lactation appears in the gland sector stimulated. A dose-dependent reaction was found. The assay is suitable for prolactin, placental lactogen and growth hormone.

N.7.3 Growth hormone (GH)

N.7.3.1 General considerations

Growth hormone (GH) has been isolated from the pituitary glands of several species including man and is species specific, and for therapy has been replaced by rDNA preparations. Several methods have been described for detection and assay of growth hormone activity (Russell 1955).

Human GH consists of 190 amino acids with two disulfide bridges between cysteine residues. Human GH synthesis is controlled by two genes hGH-N and hGH-V.

GH secretion is stimulated by the growth hormone-releasing hormone (see N.9.5). GH is released in a pulsatile fashion and has a half live of about 10 min.

Receptors for GH are found in several organs, mainly in liver and muscle.

Receptor binding assays (Ilondo et al. 1991) and radioimmunoassays for growth hormone of several animal species (Greenwood et al. 1963; Peake et al. 1978) and for somatomedins (Chochinov and Daughaday 1978) have been developed.

Amit et al. (1992) measured serum growth hormone by radioimmunoassay and growth-hormone-binding protein by a binding assay with dextran-coated charcoal separation.

An immunoradiometric assay for growth hormone was described by Hofland et al. (1989).

Mertani et al. (1995) studied the cellular localization of the growth hormone receptor/binding protein in the human anterior pituitary gland.

A high performance receptor binding chromatography assay for growth hormone was described by Roswell et al. (1996).

Strasburger et al. (1996) developed an immunofunctional assay for human growth hormone. An anti-hGH monoclonal antibody recognizing binding site 2 of hGH is immobilized and used to capture hGH from the serum sample. Biotin-labeled recombinant GH-binding protein in a second incubation step forms a complex with those hGH molecular isoforms that have both binding sites for the receptor. The signal is detected after a short third incubation step with labeled streptavidin.

Functional characterization of monoclonal antibodies specific to growth hormone receptor were described by Wang et al. (1996).

N.7.3.2 Weight gain in female rats ("growth plateaued rats")

PURPOSE AND RATIONALE

Female rats six months of age, having reached maturity, gain weight at a very slow pace; the slowing down

of the growth rate is described as "plateauing". Such rats can readily be induced to accelerate grow and weight gain by of growth hormone.

PROCEDURE

Groups of 10 adult female rats (Long-Evans or Wistar strain), 6 months old and weighing between 220 and 280 g are used. Only animals which fail to gain more than 10 g in a 20-day period are used. At least two doses of the hormone preparation and the standard dissolved in saline are injected subcutaneously daily over a period of up to 20 days. During this time, weight gains between 10 and 40 grams can be achieved. A straight line relationship exists between the logarithm of the daily dose and the growth response by body weight increase (Marx et al. 1942).

EVALUATION

The weight gain after administration of two doses of the test preparation and of the standard each are used for 2 + 2-point assays and potency ratios are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The test is needs relatively large amounts of test material. In spite of species specificity of growth hormone, rats respond to growth hormone from many other species over a limited time period, before developing neutralizing antibodies.

MODIFICATIONS OF THE TEST

Inmmature female rats hypophysectomized at 26–28 days of age can be used (Li et al. 1945; Groesbeck et al. 1987). Smaller amounts of test substance are necessary for weight gain than in adult rats.

A cell proliferation assay using a stable clone of the myeloid cell line, FDC-P1, transfected with the full length growth hormone receptor (FDC-P1-hGRH) was described by Roswell et al. (1996) as alternative to the classical hypophysectomized rat weight gain bioassay.

N.7.3.3 Tibia test in hypophysectomized rats

PURPOSE AND RATIONALE

Hypophysectomy is followed by cessation of epiphyseal growth due to growth hormone deficiency. The width of the epiphyseal cartilage is markedly reduced after hypophysectomy. Administration of growth hormone to hypophysectomized rats induces a remarkable increase in the width of the epiphyseal cartilage plate.

PROCEDURE

Female rats of the Long-Evans or Sprague-Dawley strains are hypophysectomized at an age of 26–28 days. They are used for the bioassay 12–14 days after the operation. The increase of body weight during this period of time has to be less than 0.5 g per day indicating complete hypophysectomy. Six to 10 animals are used for each group of two doses of test preparation and standard. The solutions are administered intraperitoneally twice daily for 4 days.

On the fifth day, the animals are sacrificed, both tibiae are dissected free of soft tissue, and the bones split in half with a sharp razor at the proximal end in the mid-sagittal plane. The halves are washed in water for 10 min, immersed in acetone for 6 min, and washed again in water for 3 min. They are then placed in 2% silver nitrate solution for 2 min and rinsed with water. During the water rinse, they are exposed to a strong light which turns the calcified portions of the bone dark brown. The stained tibiae are the transferred to a microscopic stage and the width of the uncalcified cartilage plate, which does not stain and remains white, is measured under low power with a calibrated micrometer eyepiece. Ten individual readings are made across the epiphysis.

EVALUATION

Mean values are obtained from a total of 20 readings of each bone specimen. They are averaged for each dose group. With a 2 + 2-point assay, the potency ratio with confidence limits versus the standard is calculated.

CRITICAL ASSESSMENT OF THE METHOD
The test has been firmly established as a standard method for growth-promoting activity. For epiphyseal measurement, morphometry may be applied.

MODIFICATIONS OF THE METHOD
Bentham et al. (1993) described a double-staining technique for detection of growth hormone and insulin-like growth factor-1 binding to rat tibial epiphyseal chondrocytes which were incubated with biotinylated ligands with or without an excess of unlabelled ligands, followed by incubation with Vectastain ABC complex, which was then reacted with diaminobenzidine. Double staining was accomplished by carrying out the first reaction with diaminobenzidine in the presence of nickel ammonium sulphate to give a black precipitate, followed by incubation with the second ligand, then ABC complex and finally diaminobenzidine in the absence of nickel ammonium sulphate to give a brown stain.

N.7.3.4
^{35}S uptake

PURPOSE AND RATIONALE
Cartilage contains glucosaminoglycans, e.g., chondroitinsulfate. The uptake of labeled sulfate into cartilage is greatly reduced after hypophysectomy and restored after growth hormone application. This phenomenon can be used as the basis of a bioassay of growth hormone activity (Collins and Baker 1960).

PROCEDURE
Female Sprague-Dawley rats are hypophysectomized at 21 days of age and used for experimentation three weeks later. The animals are given intraperitoneal injections of growth hormone together with radioactive labeled sulfate once daily for 4 days. Eight to 10 animals are used for at least two doses of test preparations (growth hormone derivatives) and standard. The rats are sacrificed 24 h after the last injection and the amount of radiosulfate present in the seventh rib cartilage is determined. A linear relationship exists between the uptake of radiosulfate and the hormone given over a range of 3 to 20 μg per day for 4 days.

EVALUATION
Mean values of each group and the potency of the test preparation versus standard calculated with confidence limits are calculated in a 2 + 2-point assay.

N.7.3.5
Inhibition of glucose uptake in adipocytes *in vitro*

PURPOSE AND RATIONALE
The conversion of glucose to lipid in murine adipocytes is dose-dependently inhibited by human growth hormone (hGH). A sensitive *in vitro* bioassay was developed by Foster et al. (1993).

PROCEDURE
3T3-F442A embryonic murine fibroblasts (preadipocytes) are grown in Dulbecco's modified Eagle's medium (DMEM) containing 2 mM L-glutamine, 100 μg/ml streptomycin, 100 U/ml penicillin, and 0.1 μg/ml fungizone. The cells are plated in 60 or 100-mm plastic culture dishes at a density of 200 cells/cm^2 and grown to confluence at 37 °C under a humidified atmosphere of 90% air/10% CO_2 in medium supplemented with 25 mM glucose and 10% calf serum. Medium is replaced every 2–3 days. Once confluent, the fibroblasts are converted to cells with the characteristics of adipocytes by incubation for 48 h in medium supplemented with 25 mM glucose, 10% fetal bovine serum, 0.5 mM methylisobutylxanthine, 2 μg/ml insulin, and 250 nM dexamethasone. This medium is then replaced with medium containing 10% fetal bovine serum and 2 μg/ml insulin with changes made every 2 days for 5–8 days until at least 70% of the cells have the characteristics of adipocytes as assessed by phase contrast microscopy.

For bioassays, the medium consists of DMEM containing 5.5 mM glucose, 2% BSA, 25 nM dexamethasone, 37 nM estradiol, 10 µg/liter insulin, and 0.1 µCi/ml uniformly labeled [^{14}C]D-glucose. Cultures are co-incubated with increasing concentrations of 22 kDa human growth hormone (0.313 to 40 µg/liter) as standard or test substance or medium (controls) for 24 h. For determination of hGH in patients, 100 µl or 200 µl serum are added. After incubation, the medium is removed and discarded. The cells are treated with Doles reagent (one part heptane, four parts isopropanol, 0.1 part 1 N H_2SO_4), the plates scraped, and the contents transferred to a glass tube. Lipids are extracted by the method of Dole and Meinertz (1969), and radioactivity of the lipid is determined by scintillation counting in a liquid scintillation spectrophotometer. Results are expressed as ^{14}C counts per min/dish. Lipid accumulation in controls without hGH is taken as 100%. Logarithmic doses of 0.313 to 40 µg/l hGH result in a linear decrease of lipid accumulation. The assay is rather specific for 22 kDa hGH.

EVALUATION

From dose-response curves, activity ratios can be calculated.

MODIFICATIONS OF THE METHOD

Xu et al. (1995) studied the effects of growth hormone antagonists on 3T3-F422A preadipocyte differentiation. The antagonists not only failed to induce adipose differentiation, including late marker gene expression (adipocyte protein 2), immediate early gene expression (c-fos), and tyrosine phosphorylation of intracellular proteins, but also antagonized GH induction of c-fos expression and phosphorylation of proteins of apparent molecular mass of 95 kDa.

N.7.3.6 Eluted stain bioassay for human growth hormone

PURPOSE AND RATIONALE

Ealey et al. (1988, 1995), Dattani et al. (1993, 1995) developed an eluted stain bioassay (ESTA for human growth hormone. This assay is based on the MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium)-formazan production by quiescent Nb2 cells under influence of the hormone.

PROCEDURE

Rat Nb2 lymphoma cells are grown in suspension culture which consists of RPMI medium (Gibco) containing 50 U penicillin/ml, 50 µg streptomycin/ml, 2×10^{-3} M L-glutamine, 10% fetal calf serum and 10% horse serum. The cells are incubated in a humidified atmosphere of 5% CO_2/95% air at 37 °C.

Prior to the bioassay of hGH, the cells are transferred to a quiescent medium, which is identical in composition to the growth medium described above except that the FCS is reduced from 10% to 1%. This slows down the rate of cell division and reduces the optical density of the unstimulated control in the subsequent ESTA bioassays by about 50%. Incubation is continued in a humidified atmosphere of 5% CO_2/95% air at 37 °C for 24 h.

For the bioassay, the cells are transferred to the bioassay medium, which is the same as the growth medium but without FCS. The cells are plated out into 96-well microtiter plates, such that a final density of 2×10^5 cells/ml is obtained. Usually 50 µl of cell suspension at 4×10^4 cells/ml are added to each well. This is followed by the addition of 50 µl various concentrations of test compound or standard (0.1 to 10 mU GH/l). The cells are incubated in a humidified atmosphere of 5% CO_2/95% air at 37 °C for 96 h.

At the end of the bioassay incubation, the colorimetric endpoint is determined by the addition of 10 µl of MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide) solution (5 mg/ml in phosphate buffered saline containing 0.1 mg/ml of $CaCl_2$ and $MgCl_2 \cdot 6\,H_2O$, pH 7.3) to each well: incubation is continued for 40 min at 37 °C in a dry incubator. During this time, activated cells reduce the yellow MTT salt to its purple formazan. After the 40 min incubation, 50 µl of 10% Triton X-100 in 0.1 M HCl is added to each well and the plate gently shaken for 30 min at room temperature. Bioassay responses of the 96 wells are quantified with a Biorad microtitre plate reader at optical densities at a test wavelength of 595 nm and a reference wavelength of 655 nm to correct for differential scattering.

EVALUATION

The determinations for all experiments are made on triplicate or quadruplicate microcultures and the results expressed as means and standard deviations. Dose-response curves for standard and test compounds are established.

MODIFICATIONS OR THE METHOD

The sensitivity of the assay can be increased by addition of ionic zinc (Dattani et al. 1993, 1995).

N.7.3.7 Reverse hemolytic plaque assay for growth hormone

PURPOSE AND RATIONALE

The reverse hemolytic plaque assay as described by Neill et al. (1983), Luque et al. (1986), Smith et al. (1986) can be used for determination of growth hormone secretion by dispersed rat pituitary cells (Niimi 1994a,b).

PROCEDURE

Anterior pituitary lobes of male Sprague-Dawley rats weighing 200–250 g are collected and minced into approximately 1-mm^3 fragments. The pituitary cells are dispersed and transferred to a siliconized flask containing 3 mg/ml trypsin in Dulbecco's phosphate buffered saline containing 0.1% BSA and antibiotics, and incubated in a water bath for 5 min at 37 °C. After gentle trituration by a siliconized pipette, the cells are separated by centrifugation and rinsed with phosphate buffered saline containing 2 mg/ml DNase (type I; Sigma, St. Louis, USA). The dispersed cells are separated by centrifugation and rinsed once in phosphate buffered saline with 1.5 mg/ml trypsin inhibitor (type II-L, Sigma). The cells are washed 5 times with Dulbecco's modified Eagle's medium (DMEM) containing 0.1% BSA and resuspended. Ovine erythrocytes are coupled with staphylococcal protein A (Sigma) in the presence of 0.9% chromium chloride in normal saline. Pituitary cells (10^6 cells/ml) are combined with an equal volume of a 30% solution of protein A-coupled erythrocytes in DMEM containing 0.1% BSA and antibiotics. The cell mixture is infused into a poly-L-lysine coated Cunningham slide chamber and pre-incubated at 37 °C, 95% air/5% CO_2, for 50 min. After preincubation, the chamber is rinsed in DMEM-BSA and placed in Petri dishes containing DMEM and 10% horse serum containing 1% nonessential amino acids before performing the reverse hemolytic plaque assay.

After 24 h co-incubation, the chambers are rinsed with DMEM-BSA. Monkey anti-rat GH serum diluted 1 : 150 in assay medium is then infused into the chambers alone or with different secretagogues and incubated for 2 h. Plaque development is initiated by infusion of guinea pig complement (Gibco) at a final dilution of 1 : 40. The reaction is terminated after 0.5 h by the infusion of B-5 fixative (6 g $HgCl_2$ and 1.25 g sodium acetate in 90 ml distilled water, add 10 ml 37% formaldehyde immediately before use). The pituitary cells are stained with 0.5% toluidine blue to facilitate observation of the hemolytic plaques.

EVALUATION

In each experiment, each concentration of secretagogue or vehicle is run in duplicate, and 150–200 cells/slide are counted. Two separate experiments have to be performed. The plaque area is measured by using a calibrated ocular reticule. The area of 50 plaques/slide is measured. Statistical analysis is performed by Student's *t*-test and one-way analysis of variance.

N.7.3.8 Determination of growth hormone isoforms by 22-kD GH exclusion assay

PURPOSE AND RATIONALE

Human growth hormone exists in variety of isoforms. In the pituitary, the most abundant isoform is 22-kD GH, while other isoforms (non-22-KD GH) are present in variable amounts. Boguszewski et al. (1966) described an analytical approach that focuses on the isoforms differing from monomeric and oligomeric 22-kD GH.

PROCEDURE

Reagents

- Recombinant 22-kD human GH (Genotropin, Pharmacia, Uppsala, Sweden),
- 22-kD GH-specific monoclonal antibody (MCB), (Genentech Inc., San Francisco, USA),
- magnetic polystyrene beads coated with rat anti-mouse IgG 1 (Dynabeads M-450), (Dynal, Oslo, Norway),
- polyclonal antibody-based IRMA (Pharmacia, Uppsala, Schweden),
- assay buffer containing phosphate-buffered saline, 5°g/l BSA, 5 ml/l Tween-20, 0.1 g/l thiomerosal.

Assay procedure

A 100-µl aliquot of serum or test solution is mixed with either 10 µl of assay buffer containing MCB (final concentration 0.3 µmol/l) or 10 µl of assay buffer without MCB. The samples are incubated for 24 h at room temperature. A 160-µl aliquot of magnetic beads coated with rat anti-mouse IgG (concentration 4×10^5 beads/µl) is added to the samples. After further incubation for 2 h at room temperature with gentle agitation in a rotator, the tubes are put in contact with a magnetic device, Dynal MPC-E (Dynal, Oslo, Norway), for 1 min. The magnetic beads with the 22-kD GH-MCB complexes ate attracted by the magnet. While the tubes are in the magnetic device, 50-µl aliquots of the supernatant are transferred to new tubes for measurement of non-22-kD GH levels in duplicate by the polyclonal antibody-based IRMA. The same procedure is performed in samples incubated with assay buffer (without addition of MCB) to determine total GH concentration.

EVALUATION

The amount of non-22-kD GH isoforms is expressed as a percentage of total GH concentration. The Mann-Whitney U test (two-tailed) is used to compare the percentage of non-22-kD GH isoforms between the groups. The method is an example for the increasing use of physicochemical methods to characterize the heterogeneity of hormone preparations obtained by rDNA methods.

N.7.3.9 Steroid regulation of growth hormone receptor and GH-binding protein

PURPOSE AND RATIONALE

Gabrielsson et al. (1995) studied steroid regulation of growth hormone receptor (GHR) and GH-binding protein (GHPB) messenger ribonucleic acids in the rat. GHR and GHBP, arising from alternative splicing of the same gene, show a sexually dimorphic and GH-dependent expression pattern. Multiple alternative 5'-untranslated regions are present in GHR and GHBP transcripts in the rat, one of which, GHR_1, has been shown to be liver specific and found at higher levels in females.

PROCEDURE

Animal treatment

For human GH treatment, groups of Wistar rats are implanted sc with osmotic minipumps delivering recombinant hGH at 200 µg/day for 7, 12, or 14 days. Steroid-treated animals are implanted sc with slow-release pellets delivering E_2 (25 ng/day), testosterone propionate (12.5 µg/day) or corticosterone (3.5 µg/day) for up to 2 weeks. At the end of each study, animals are sacrificed and samples of blood and liver rapidly removed.

Protein binding (GHBP) assay

Plasma GHBP levels are measured by RIA. Recombinant rat GHBP is used for iodination and reference preparation (Carmignac et al. 1992).

GH-receptor based assays

Liver samples are homogenized in 0.3 M sucrose containing 3 mM imidazole HCl, pH 7.4 (Carmignac et al. 1993). Samples of 100 µl (~2 mg protein) are incu-

bated in duplicate at 22 °C with radio-iodinated bGH (100 µl, 20 000 cpm) and 100 µl buffer (25 mM Tris-HCl, pH 7.4, containing 10 mM $CaCl_2$ and 0.1% BSA). After 2 h, 3 ml cold (4 °C) buffer are added, the tubes centrifuged at 2 700 *g* for 30 min, and the radioactivity in the pellets determined. Nonspecific binding is estimated in the presence of 1 µg unlabeled bovine GH and is subtracted from total binding to derive percent specific bGH binding per mg protein.

Generation of RNA probes

Using an *in vitro* transcription kit, probes are labeled with [^{35}S]uridine triphosphate for solution hybridization assay and [^{32}P]uridine triphosphate for Northern blots and RNase protection assays. Total GHR coding region transcripts are measured using an antisense probe corresponding to a 423-nucleotide (nt) NcoI-Kpn1 fragment (nt 989-1 411) of the λ1 clone of the rGHR inserted into the pT7T318U vector. This sequence spans the transmembrane domain and part of the intracellular domain of the GHR and is not present in GHBP mRNA. Total GHBP transcripts are determined using a 46-nt oligonucleotide probe complementary to the alternate splice sequence encoding the GHBP hydrophilic tail. This probe does not detect GHR transcripts. GHR_1-containing transcripts are measured using a probe complementary to this 5'UTR alternative exon sequence.

Northern blots

Total RNA is prepared using the method of Chomczynski and Saachi (1987). RNA is run overnight on a 2.2 M formaldehyde/3-N-morpholine propane-sulfonic acid agarose gel, transferred to a Nylon membrane and cross-linked using a Stratalinker (Strategene, La Jolla, USA). Membranes are prehybridized for 2–4 h at 60–65 °C in 50% formamide, 5 × SSC (1 × SSC = 0.15 M NaCl, 0.015 M Na citrate, pH 7.0), 5 × Denhardt's solution, 50 mM Na_2HPO_4, 0.2% sodium dodecyl sulfate(SDS), 250 µg/ml salmon sperm DNA, and 100 µg transfer RNA/ml, and incubated with ^{32}P-labeled probe ($1–3 \times 10^6$ cpm/ml) at the same temperature in 50% formaldehyde, 5 × SSC, 1 × Denhardt's solution, 20 mM Na_2HPO_4, 0.2% SDS, 10% dextran, 100 µg/ml salmon sperm DNA, and 100 µg tRNA/ml. After washing (60 °C and 20 min/wash, starting at 3 × SSC/0.1% SDS and reducing to 0.3 × SSC/0.1% SDS) membranes are exposed to X-ray film with intensifying screens at –80 °C or detected by phosphorimaging.

Solution hybridization assays

Hepatic mRNAs are quantified by solution hybridization after the method of Möller et al. (1991). Liver is homogenized in 10 mM Tris-HCl, pH 7.5, containing 1% SDS and 5 mM EDTA; after proteinase K digestion. Total nucleic acids (TNAs) are extracted with phenol/chloroform, precipitated with ethanol, and the pellets dissolved in 0.2 × 10 mM Tris-HCl, pH 7.5; containing 1% SDS and 5 mM EDTA. For each assay, 10–100 µg TNAs are hybridized in duplicate with ^{35}S-labeled RNA probes (20 000–30 000 cpm) at 50 °C overnight in 40 µl, 21 mM Tris-HCl buffer, pH 7.5, containing 600 mM NaCl, 4.5 mM EDTA, 7.5 mM dithiothreitol, 0.1% SDS, and 25% formamide. Standard tubes contain known quantities of target RNA, transcribed from the sense strand of the ap-propriate plasmid and quantified by absorption at 260 nm.

After digestion with RNase A (40 µg) and RNase T_1 (2 µg) protected fragments are precipitated with 10% trichloro-acetic acid, collected by filtration (GF/C paper, Whatman), detected by scintillation counting, and expressed as specific mRNA levels (attomoles per µg TNA).

RNase protection assay

Total RNA (20 µg) is hybridized under the same conditions as above, except that a ^{32}P-labeled probe (500 000 cpm) is used. After overnight incubation at 50 °C, the samples are treated with 300 µl of a solution of 10 mM Tris, pH 7.5, 5 MM EDTA, and 300 mM NaCl, containing RNase A (40 µg/ml) and RNase T_1 (2 µg/ml), for 30 min at room temperature. After incubation with 50 µg proteinase K and 20 µl 10% SDS for 15 min at 37 °C, samples are extracted with phenol/chloroform and ethanol precipitated with 10 µg tRNA as carrier. The pellets are dissolved in gel-loading buffer (10 mM EDTA and 1 mg/ml bromophenol blue in 80% formamide), denatured at 85 °C for 4 min, and run on an 8 M urea/6% polyacrylamide gel. Detection is by autoradiography or phosphorimaging.

EVALUATION

Data are calculated as mean ±SEM. Differences between treatment groups are assessed using Student's *t*-test, or analysis of variance followed by Student-Newman-Keul's or Dunnett's tests. A difference of $p < 0.05$ is considered as significant.

MODIFICATIONS OF THE METHOD

Nilsson et al. (1995) described the expression of functional growth hormone receptors in cultured human osteoblast-like cells.

To measure the absolute number of mRNA molecules encoding the growth hormone receptor in human tissue, Martini et al. (1995) developed a quantitative polymerase chain reaction assay.

N.7.4 Adrenocorticotropin (ACTH)

N.7.4.1 Adrenal ascorbic acid depletion

PURPOSE AND RATIONALE

The administration of pituitary adrenocorticotropic hormone (ACTH) is followed by a decrease in the amount of ascorbic acid present in the adrenals. The depletion of adrenal ascorbic acid is a function of the dose of ACTH administered. This relationship has been used for a quantitative assay of ACTH by Sayers et al. (1948). The method has been selected for standardization of ACTH by several Pharmacopoeias, e.g. The United States Pharmacopeia USP 23 (1995), Deutsches Arzneibuch 1986 and British Pharmacopoeia 1988. Furthermore, the test has been used for evaluation of synthetic corticotropin analogues (Geiger et al. 1964; Vogel 1965, 1969a and b). A similar test is used for luteinizing hormone action on the rat ovary.

PROCEDURE

Male Wistar rats weighing between 100 and 200 g are hypophysectomized one day prior to the test. The range of weights in any one test should not exceed 15 g. For one test with 3 doses of test preparation and standard each, at least 36, preferably 60, hypophysectomized rats are necessary.

Solutions

Five units of the International Standard for corticotropin (Bangham 1962) or an amount of test preparation supposed to contain about 5 units are dissolved in 0.25 ml 0.5% phenol solution and diluted with 8.1 ml 15% gelatin solution. In this way, 0.5 ml contain 300 mU ACTH. Three ml of this solution are diluted with 6.0 ml gelatin solution (to prevent adsorption to glassware), resulting in a content of 100 mU ACTH per 0.5 ml. Three ml of this solution are again diluted with 6.0 ml gelatin solution, resulting in a content of 33 mU ACTH per 0.5 ml.

The hypophysectomized rats are randomly distributed to 6 groups. Each rat receives subcutaneously 0.5 ml of one of the various concentrations of test preparation or standard. Three hours after injection, the animals are anesthetized, both adrenals removed, freed from extraneous tissue and weighed. The rats are sacrificed and the scull opened to verify completeness of hypophysectomy.

The adrenals are homogenized in 4% trichloroacetic acid and the ascorbic acid determined according to the method of Roe and Kuether (1943). Other methods have been described.

ASCORBIC ACID DETERMINATION

Reagents

One hundred mg L-ascorbic acid are dissolved in 100 ml 4% trichloroacetic acid. Twenty ml of this solution are diluted with 4% trichloroacetic acid to achieve a 0.2% ascorbic acid solution and 2 ml of this solution are diluted with 4% trichloroacetic acid to achieve a 0.02% ascorbic acid solution.

Sulfuric acid (85%) is obtained by adding 900 ml concentrated sulfuric acid to 100 ml distilled water.

Two g dinitrophenylhydrazine are dissolved in 100 ml 9 N H_2SO_4 (75 ml distilled water and 25 ml concentrated sulfuric acid).

Six g thiourea are dissolved in 100 ml distilled water.

Calibration

Trichloroacetic acid (4%) is added to 0.0, 0.5, 1.0, 2.0, 3.0, 4.0, 6.0, 8.0 ml of the 0.02% ascorbic acid solution and 1.0, 1,5 and 2.0 ml of the 0.2% ascorbic acid solution to reach a final volume of 8.0 ml. Hundred mg charcoal is added to each sample and thoroughly mixed by shaking for 1 min. After 5 min the solutions are filtered. An aliquot of 0.1 ml of the 6% thiourea solution is added to 2.0 ml of the filtrate followed by 0.5 ml dinitrophenylhydrazine solution. The mixture is shaken and heated for 45 min at 57 °C in a water bath. The solutions are placed in an ice-cold water bath

and with further cooling 2.5 ml of the 85% sulfuric acid are added. The calibration curve is established at a wave length of 540 µm using the solutions without ascorbic acid as blank.

Preparation of the adrenals

Both adrenals are homogenized in glass tubes containing 200 mg purified sand and 8.0 ml 4% trichloroacetic acid. The reagents are added as described for the calibration curve.

EVALUATION

The potency ratio including confidence limits is calculated with the 3 + 3 point assay.

MODIFICATIONS OF THE METHOD

The original method, as described by Sayers et al. (1948), uses intravenous administration of ACTH and the difference of ascorbic acid in the left adrenal before injection and the right adrenal one hour after injection as endpoint. Different values of activity of synthetic peptides versus the international standard resulted from different ways of administration (Vogel 1965).

The ascorbic acid depletion test can also be performed in dexamethasone-blocked rats. However, different potency ratios of synthetic corticotropin analogues have been found than in hypophysectomized rats (Vogel 1969a). The difference most likely depends on the dexamethasone blocking dose.

Other authors, including British Pharmacopoeia and Deutsches Arzneibuch, use the 2,6-dichloro-phenol-indophenol method for determination of ascorbic acid.

The glands are homogenized in 2.5% metaphosphoric acid with the addition of a small quantity of washed sand. With additional 2.5% metaphosphoric acid a final volume of 10 ml is reached. Five ml of the filtrate are added to 5 ml indophenol acetate solution, and the absorbance of the mixture is read immediately in a photometer with a 520 mµ filter. The indophenol acetate solution is prepared by dissolving 15 mg 2,6-dichlorophenol-indophenol in 500 ml distilled water and dissolving 22.65 g sodium acetate $\cdot 3\,H_2O$ in 500 ml distilled water and mixing equal volumes.

A cytochemical bioassay of corticotropin was described by Chayen et al. (1976).

N.7.4.2 Corticosterone blood levels in dexamethasone blocked rats

PURPOSE AND RATIONALE

Corticotropin activity can be measured by the increase of corticosterone in venous blood of hypophysectomized or dexamethasone-blocked rats. The test can be used to measure time-response curves of corticotropin analogues or depot-preparations (Vogel 1969a,b). The sensitivity can be increased by determining corticosterone in adrenal venous blood after cannulation of the adrenal vein (Retienne et al. 1962).

PROCEDURE

Male Sprague-Dawley rats weighing 150–200 are injected subcutaneously 24 h and 1 h prior to subcutaneous injection of the ACTH-preparation or the standard with 5 mg/kg dexamethasone in oily solution. Eight rats are used for each dose of test preparation or standard.

Various time intervals after ACTH injection, the rats are anesthetized with 60 mg/kg pentobarbital i.p. and blood is withdrawn by cardiac puncture. One ml plasma is diluted with 2 ml distilled water and extracted (washed) with 5 ml petrolether to remove the lipids. The petrol ether is discarded. Two ml of the water layer are extracted twice with 5 ml methylene chloride by vigorous shaking for 15 min. The methylene chloride phase is separated by centrifugation. Both methylene chloride extracts are unified and shaken with 1 ml ice-cold 0.1 N NaOH. The water phase is immediately removed and the methylene chloride extracts dried by addition of dry sodium sulfate. An aliquot of 5 ml of the methylene chloride extract is mixed with 5 ml of the fluorescence reagent (7 parts concentrated sulfuric acid, 3 parts 96% ethanol, v/v). After vigorous shaking, the methylene chloride phase is removed and fluorescence is measured with primary filters of 436 mμ and secondary filters of 530–545 mμ. For calibration, concentrations of 0, 20, 50, 100, and 250 μg/ml corticosterone are treated identically and measured in each assay.

EVALUATION

Using 3 doses of test compound and standard, activity ratios with confidence limits can be determined after each time interval with the 3 + 3 point assay giving evidence for the duration of action (Vogel 1969a,b).

MODIFICATIONS OF THE METHOD

Pekkarinen (1965) used fluorometric corticosteroid determinations in guinea pigs resulting in highly deviating activity ratios of synthetic and commercial corticotropins as compared with the international working standard of ACTH.

N.7.4.3 *In vitro* corticosteroid release

PURPOSE AND RATIONALE

An *in vitro* assay of corticotropin was described by Saffran and Schally (1955). This test has been modified by Van der Vies (1957) and used by several authors (Staehelin et al. 1965; Vogel 1969).

PROCEDURE

Solutions

"Double Ringer" solution is prepared as follows:

4.50%	(w/v) sodium chloride	200.0 ml
5.75%	potassium chloride	8.0 ml
6.10%	calcium chloride	6.0 ml
10.55%	monopotassium phosphate	2.0 ml
19.10%	magnesium sulphate	2.0 ml
	double distilled water up to	545.0 ml

Final solution:

54.0	ml	double Ringer
26.0	ml	1% glucose solution (freshly prepared)
29.0	ml	double distilled water
21.0	ml	1.3% $NaHCO_3$ solution which has been gassed with carbon dioxide at room temperature for 1 h.

The final solution is gassed with a mixture of 95% O_2 and 5% CO_2 for 10 min.

Preparation of adrenals

Twenty male Sprague-Dawley rats weighing 150–200 g are anesthetized with 50 mg/kg pentobarbital sodium i.p. applying as little handling stress as possible. The adrenals are removed and freed of connective tissue taking care that the adrenals are not damaged. Each adrenal is carefully cut into 4 quarters with fine scissors. The 8 quarters of each rat are randomly distributed to 20 preweighed incubation vessels filled with 1.5 ml of final solution. The flasks are mounted on

Warburg manometers or placed into a suitable shaking water bath and are gassed under continuous shaking for 1 h with a mixture of 95% O_2 and 5% CO_2 at 38 °C (= preincubation period).

The flasks are removed from the bath at the end of the preincubation period. The medium is aspirated as much as possible by means of a small tube attached via a collection bottle to the vacuum line. An aliquot of 1.4 ml fresh medium is added to each flask.

To 5 vessels each of the following solutions are added:

10.0 mU/0.1 ml ACTH standard
50.0 mU/0.1 ml ACTH standard
10.0 mU/0.1 ml test preparation
50.0 mU/0.1 ml test preparation
50.0 mU/0.1 ml medium (control)

The vessels are again incubated and gassed with a mixture of 95% O_2 and 5% CO_2 at 38 °C under continuous shaking for 2 h.

One ml aliquots of the medium of each vessel are transferred to carefully cleaned glass-stoppered tubes containing 2 ml methylene chloride. The tubes are vigorously shaken for 1 min and centrifuged for 5 min. The methylene chloride phase is transferred with a long needle and a syringe to a quartz micro-cuvette and readings are taken at 225, 240, and 255 mμ.

Dry weight of the adrenals is determined by heating the incubations vessels to 150 °C for 2 h.

EVALUATION

Extinction values are calculated for the maximum of absorption (Allen 1950) according to the formula:

$$E = E_{240} - \frac{E_{225} + E_{255}}{2}$$

The potency ratios are calculated with the 2 + 2-point assay.

MODIFICATIONS OF THE METHOD

Saffran et al. (1971) described a flow-through system for the study of adrenocortical function by rat tissue *in vitro*, in which the fluorometric measure of corticosterone is completely automated.

Corticosterone is now conveniently determined by RIA or HPLC.

N.7.4.4 Thymus involution

PURPOSE AND RATIONALE

This is a classical indirect bioassay based on the steroid response of the target organ and its effect. Administration of corticotropin decreases thymus weight (due to corticosterone secretion) and induces an increase of adrenal weight (Hayashida and Li 1952; Thompson and Fisher 1953). Young rats respond with an involution of the thymus gland to graded doses of corticotropin (Rerup 1958). A similar assay is used for adrenal steroids.

PROCEDURE

Sprague-Dawley or Wistar rats of either sex, 7–10 days of age, weighing 10–15 g are used. Littermates are preferred. The animals are distributed at random to three groups of the standard and 3–5 groups of the unknown sample. The ACTH standard or test com-

pounds are injected at different doses once daily subcutaneously for 3 days. Twenty-four hours after the last injection, the animals are sacrificed, the thymus dissected out and weighed to the nearest 0.1 mg. The response is expressed as the average of the individual values for each dose level.

EVALUATION

Dose-response curves are established and potency ratios calculated using a 3 + 3 point assay.

MODIFICATIONS OF THE METHOD

The sensitivity of the assay can be increased using the quotient between increase of the weight of the adrenals and decrease of the weight of the thymus gland (Hohlweg et al. 1960). Male Wistar rats at an age of about 3 weeks weighing 18–22 g are injected three times daily in intervals of 4 h during three days with the test preparation or the standard dissolved in 10% gelatine solution. The animals are sacrificed 18 h after the last injection and the adrenals and the thymus gland removed and weighed. The ratio of adrenal weight to thymus weight provides a steep dose-response curve.

N.7.4.5 Receptor binding assay for ACTH

PURPOSE AND RATIONALE

As for other hormones, receptors have been used as the test preparations for comparison of the binding affinities of adrenocorticotropin peptides using a cloned mouse adrenocorticotropin receptor expressed in a stably transfected HeLa cell line (Kapas et al. 1996). Such assays measure the initial membrane binding but not strictly the biological activation e.g. of adrenal cells or melanocytes.

PROCEDURE

Hela cells are seeded into 12-well culture plates at a density of 10^6 cells/well. On the second day of culture, the cells are washed as follows: 2× in 1 ml of ice-cold 0.9% NaCl, 1× in 1 ml of ice-cold glycine (50 mM glycine, 100 mM NaCl, pH 3.0) for 5 min, 2× in 0.5 ml of ice-cold 0.9% NaCl. Cells are then incubated for 60 min at 20 °C with increasing concentrations of nonradioactive ACTH or various ACTH analogues and the reactions initiated on the addition of [^{125}I-iodotyrosyl^{23}]ACTH[1-39] (2 000 Ci/mmol; final concentration 0.1 pmol/liter) in DMEM. At the end of the incubation, the medium is removed and the cells washed three times with 0.9% NaCl and then dissolved in 0.5 M NaOH/0.4% sodium deoxycholate. Each point is determined in triplicate, and the radioactivity is measured using a gamma-counter. Specific binding is determined by subtracting from the total binding the radioactivity associated with cells in the presence of 10^{-5} M nonradioactive ACTH.

EVALUATION

Binding parameters are determined using a computer assisted calculation, e.g. the LIGAND program (Munson and Rodbard 1980).

MODIFICATIONS OF THE METHOD

Penhoat et al. (1993) reported the identification and characterization of corticotropin receptors in bovine and human adrenals by covalent cross-linking of radiolabeled ACTH with the bifunctional cross-linking agent disuccinimidyl suberate to cultured bovine adrenal fasciculata reticular cells and to crude plasma membrane fractions prepared from both human and bovine adrenals.

Lebrethon et al. (1994), Penhoat et al. (1995) studied the regulation of ACTH receptor mRNA and binding sites by ACTH and angiotensin II in cultured human and bovine adrenal fasciculata cells.

Picard-Hagen et al. (1997) found, that glucocorticoids enhance corticotropin receptor mRNA levels in ovine adrenocortical cells.

Zavyalov et al. (1995) described receptor binding properties of peptides corresponding to the ACTH-like sequence of human pro-Interleukin-1_α.

Naville et al. (1996, 1997) developed a stable expression model in order to characterize the human ACTH receptor by binding studies and functional coupling to adenylate cyclase.

Schioth et al. (1996) described the pharmacological distinction of the ACTH receptor from other melanocortin receptors in the mouse adrenocortical cell line Y1.

Moreover, melanocortin receptors do not have a binding epitope for ACTH beyond the sequence of alpha-MSH (Schioth et al. 1997).

N.7.5 Thyrotropin (TSH)

N.7.5.1 General considerations

The thyroid stimulating hormone TSH can be determined by bioassays and immunoassays, as with other polypeptide hormones (Utiger 1979; Spencer 1994; Meinhold et al. 1994).

Large scale synthesis of recombinant human thyrotropin has been reported (Cole et al. 1993; Hussain et al. 1996). The role of the thyrotropin receptor has been reviewed by Vassart and Dumont (1992). Castagiola et al. (1992) described a binding assay for thyrotropin receptor autoantibodies using the recombinant receptor protein. A brain-derived TSH receptor has been cloned and expressed (Bockmann et al. 1997), on accordance with the developmental effects of TSH in the fetus and newborn. Binding characteristics of antibodies to the TSH receptor were described by Oda et al. (1998).

N.7.5.2 Thyroid histology

PURPOSE AND RATIONALE

Hypophysectomy results in atrophy of the thyroid gland which is reversed by administration of thyrotropin. In the thyroid of normal young guinea pigs (Junkmann and Schoeller 1932; McGinty and McCullough 1936) or chicks (Jones 1939) characteristic histological changes are observed after administration of thyrotropin, associated with an increase of thyroid weight (goitrogenic response). In classical bioassays, these findings were the basis for standardizing by biological units.

PROCEDURE

Male guinea pigs weighing 180–200 g are injected once daily on 4 successive days. Thyroids are removed on the sixth day, weighed, and embedded for histological examination. Administration of thyrotropic hormone is followed by colloid resorption, increased vascularity, and increased epithelial cell height. Several regions of the thyroid are examined histologically. Alternatively, computer-assisted morphometry may be used. Rating scores are defined between +1 and +4.

EVALUATION

The rating scores are averaged and compared between test preparation and standard.

N.7.5.3 Iodine uptake

PURPOSE AND RATIONALE

This is a bioassay for thyroid activation related to the initial step of TSH action. The uptake of iodine (trapping) as well as the release of the newly formed iodinated thyroid hormones is under control of thyrotropin (and in animal assays, under control of hypothalamic TRH). As a consequence, the uptake of ^{131}I and the release of ^{131}I-labeled thyroxin are increased after administration of TSH. A method using ^{131}I-release in mice has been described by McKenzie (1958) and modified by Sakiz and Guillemin (1964).

PROCEDURE

Female mice weighing 10–15 g are kept in a temperature-controlled room and fed a low iodine diet for 10 days. They are then injected intraperitoneally with 1.5 μC ^{131}I, followed 5 h later by 10 μg L-T_4 subcutaneously. Twenty-four hours later they receive a second injection of 5 μg L-T_4 and are used 48 h after the last injection. Under ether anesthesia 0.25 ml blood is withdrawn from the jugular vein in a heparinized syringe. Various doses of the test preparation or standard TSH are injected by the same route in 0.3-ml volume. Two hours later, again under ether anesthesia, a second 0.25-ml sample is taken, and the radioactivity measured. The increase of radioactivity in the blood samples is dependent on the dose of TSH.

EVALUATION

A 4-point assay technique is used with 6 observations for each of 2 doses of the standard and of the unknown preparation.

MODIFICATIONS OF THE METHOD

Depletion of ^{131}I from the thyroids of chicken was used as endpoint for a TSH assay by Bates and Cornfield (1957).

N.7.5.4 TSH bioassay based on cAMP accumulation in CHO cells

PURPOSE AND RATIONALE

Indirect cell assays measure the activation of protein kinase A (PKA) through adenylcyclase. Several cell assays for thyrotropin using cultured FRTL-5 cells were described (Vitti et al. 1986; Nissim et al. 1987; Horimoto et al. 1989). Persani et al. (1993) reported a cell assay for human thyrotropin using measurement of cAMP accumulation on Chinese hamster ovary cells transfected with the recombinant TSH receptor.

PROCEDURE

Cells of the CHO-R strain JP-09 are cultured in Petri dishes in RPMI-1 640 medium supplemented with

1 mM glutamine and 10% fetal calf serum. In these cells TSH biological activity is evaluated by measuring cAMP production. Cells are harvested from Petri dishes using a Trypsin-EGTA mixture and seeded in 96-well plates (10 000 cells/well). Cells are fed with fresh RPMI-1 640 medium 24 h after seeding. The assay is run after 48 h. After washing, 100 µl of TSH standard or samples diluted in hypotonic or isotonic medium containing 0.4% BSA, 10 mM HEPES and 0.5 mM isobutylmethylxanthine, are incubated for 2 h at 37 °C. Three different dilutions of immunoconcentrated TSH are bioassayed in triplicate, as are TSH preparations. CAMP is measured in non-acetylated samples by an RIA method using a commercial polyclonal anti-cAMP antibody (Vitti et al. 1986).

EVALUATION

Dose response curves or single point comparisons are used for potency or activity estimates.

N.7.6 Hormones related to TSH

N.7.6.1 General considerations

These hormonal factors are now characterized by molecular cloning. One of the characteristic symptoms of thyroid activation (Graves or Basedow disease) is exophthalmus. A dissociation of the exophthalmus producing activity from the TSH activity has been found (Dobyns and Steelman 1953). Moreover, time-response curves for TSH activity from serum of patients with hyperthyroidism differed from those of the standard TSH, giving evidence for an abnormal factor, the long acting thyroid stimulating factor (LATS). Bioassays for these factors have been developed. TSH receptor stimulating antibodies have also been identified.

N.7.6.2 Assay of exophthalmus-producing substance (EPS) in fishes

PURPOSE AND RATIONALE

Some TSH fractions were reported to produce more exophthalmus than others (Dobyns and Steelman 1953). A second fraction containing exophthalmus producing substance (EPS) could be separated (Brunish et al. 1962). The activity of this substance was demonstrated in fishes.

PROCEDURE

Fundus heteroclitus Linn., the common Atlantic minnow, has been found to be the suitable animal model (Albert 1945; Sobonya and Dobyns 1967). Other fish species, such as Carassius auratus, the common gold fish (Haynie et al. 1962) and Cyprinus carpio (der Kinderen et al. 1960) were also used but gave less reliable results (Sobonya and Dobyns 1967). *Fundus heteroclitus* Linn., the common Atlantic minnows, 8–10 cm in length, are kept in a tank of running tap water at 10 °C in winter and 18 °C in summer. Before treatment the intercorneal distance is measured with Vernier calipers to the nearest of 0.1 mm. The test compound and the standard are injected intraperitoneally at various, but at least two, doses. To avoid loss of fluids by the intraperitoneal injection route, the needle is inserted into the cloaca, through the rectum, over the pelvic girdle, and into the peritoneal cavity for a distance of about 1.2 cm. The volume of fluid injected should be 0.1–0.5 ml. The effect of the hormone is to cause protrusion of the eyeballs. The intercorneal distance is measured again after 24, 48, and 72 h. The increase in proptosis is expressed as percentage of the intercorneal distance found at the beginning of the test.

EVALUATION

The increases of intercorneal distance after each dose are averaged and activity ratios with confidence limits calculated from the 2 + 2-points assay.

N.7.6.3 Assay of long acting thyroid stimulating factor (LATS) in mice

PURPOSE AND RATIONALE

This is a modified TSH assay. In the assay of McKenzie (1958) (see N.7.5.3) mice previously injected with ^{131}I show a maximum increase in serum ^{131}I after an interval of 2–3 h when TSH is administered. In the assay of serum from thyrotoxic patients, Adams (1958) noted that the maximum response in guinea pigs did not occur until after 16 h. The abnormal responses to thyrotoxicosis sera suggested the presence of an additional factor different from TSH.

PROCEDURE

Mice maintained on a low iodine diet for 10 days are injected with 15 µC ^{125}I and 10 µg Na L-T_4. Four days later, 0.1 ml of blood is obtained by retroorbital puncture immediately before the injection of the test substance and 2 and 9 h later. Radioactivity in the blood is then measured. By definition, radioactivity which is maximal after 2 h is indicative of TSH; whereas long acting thyroid stimulator LATS causes a maximal increase at 9 h.

EVALUATION

The increases of radioactivity after 2 and 9 h are compared and evaluated by statistical methods.

MODIFICATIONS OF THE ASSAY

Ikeda and Nagataki (1983), Ikeda et al. (1984) used male DDY mice weighing 15 g. They were fed a low iodine diet for 14 days and then injected daily with 1 µg of 3,5,3'-triiodothyronine (T_3) s.c. and given T_3 (5 µg/ml) ad libitum in drinking water until sacrifice. From the fifth day of T_3 treatment they were injected i.p. with 0.25 ml of LATS-positive serum for 9 days. Groups of 5 mice were sacrificed before, 1, 3, 5, 7 and 9 days after the first injection of LATS. One µCi (0.5 ml) of Na [^{131}I] was administered i.p. 1 h before sacrifice. Thyroid lobes were excised, weighed and radioactivity was measured by a gamma counter. Immediately before injection of Na [^{131}I], approximately 60 µl of blood were collected from the orbital plexus with heparinized capillary tubes and centrifuged at 12 000 r.p.m. for 3 min. T_4 concentrations in serum were determined by radioimmunoassay.

Ealey et al. (1984, 1985) developed a sensitive cytochemical bioassay for thyroid stimulators, using reference preparations of thyrotropin and long acting thyroid stimulator. Thyroid stimulators cause changes in lysosomal membrane permeability within the thyroid follicular cells of guinea pigs, which can be monitored by measuring increased intralysosomal enzyme activity (in the case of this assay, naphthylamidase), with a chromogenic substrate, leucine-2-naphthylamide, which itself does not readily permeate the lysosomal membrane in unstimulated cells.

N.8
Posterior pituitary hormones

N.8.0.1
General considerations

Oxytocin and vasopressin were the first hormones isolated from the pituitary (Dale and Laidlaw 1912; Hogben et al. 1924; Fromherz 1926; Schaumann 1937). Vasopressin has hypertensive and antidiuretic activity, as well as endocrine functions (Hedge and Huffman 1987) and effects on the central nervous system (Gash et al. 1987). In terms of bioassays however, the antidiuretic activity is the main parameter. Many analogues of vasopressin have been synthesized resulting in selective agonists and antagonists (Vogel and Hergott 1963; Manning et al. 1987; Mah and Hofbauer 1987; Allison et al. 1987). Different types of vasopressin receptors have been identified: V_1 (V_{1a}, V_{1b}) and V_2-receptors (Jard et al. 1976; Jard et al. 1986; Fahrenholz et al. 1988; Walker et al. 1988; Burnatowska-Hledin and Spielman 1989).

Oxytocin receptors have been described in several organs, such as uterus, mammary gland and CNS (Soloff 1976; Hruby et al. 1990).

Synthesis and development of several orally active, nonpeptide oxytocin antagonists were reported (Bell et al. 1998; Kuo et al. 1998).

Radioimmunoassays are available for both oxytocin (Kagan and Glick 1978) and vasopressin (Glick and Kagan 1978).

N.8.1 Oxytocin

N.8.1.1 Isolated uterus

PURPOSE AND RATIONALE

Several authors, such as Dale and Laidlaw (1912), Fromherz (1926), Glaubach and Molitor (1932), Lipschitz and Klar (1933), Simon (1933) used the isolated uterus of virgin guinea pigs as a sensitive test for determination of oxytocin activity. The isolated uterus of the rat (Holton 1948) is less sensitive but in contrast to the guinea pig, the rat uterus shows no spontaneous contractions in solutions with low calcium and glucose concentrations. Historically, the method has been adopted by several pharmacopoeias, e.g., by the British Pharmacopoeia (1988). The United States Pharmacopeia 23 (1995) uses the isolated guinea pig uterus for determination of oxytocin activity in vasopressin preparations. Physicochemical assays are now used for standardising drug content, instead of the biological responses.

PROCEDURE

Female Sprague-Dawley or Wistar rats weighing 120–200 g are used. Eighteen to 20 h prior to the assay, the rat is injected i.m. with 100 µg of estradiol benzoate for priming (receptor induction). Immediately before the assay the rat is tested for estrogen induced epithelial proliferation by vaginal smear. One horn of the uterus is suspended in an organ bath containing a solution of the following composition:

Sodium chloride	6.62 g/l
Potassium chloride	0.45 g/l
Calcium chloride	0.07 g/l
Sodium hydrogen carbonate	2.56 g/l
Disodium hydrogen orthophosphate	0.29 g/l
Sodium dihydrogen orthophosphate	0.03 g/l
Magnesium chloride	0.10 g/l
D-glucose	0.50 g/l

The bath temperature is maintained at 32 °C, a temperature at which spontaneous contractions of the uterus are abolished and the preparation maintains its sensitivity. The solution is bubbled with a mixture of 95% O_2 and 5% CO_2. The preparation is loaded with 1–2 g and the contractions recorded using a Statham transducer and a polygraph. Two doses of the standard preparation are added ranging usually between 10 and 50 microunits per ml organ bath. The preparation examined is diluted in such a way to obtain responses on the addition of two doses similar to those obtained with the standard preparation. The ratio between the two doses of the preparation being examined should be the same as that between the two doses of the standard preparation. The two doses of the standard preparation and the two doses of the preparation being examined are given according to a randomized block or a Latin square design and at least six to eight responses to each are recorded. The doses should be recorded at regular intervals of 3 to 5 min depending on the rate of recovery of the muscle.

EVALUATION

The activity and potency ratios with confidence limits are calculated from the 2 + 2-points assay.

MODIFICATIONS OF THE METHOD

The isolated rat uterus is also used to test spasmolytic activity of various drugs against oxytocin as spasmogen. Liebmann et al. (1993) used the rat uterus to test the pharmacological and molecular actions of the bradykinin B_2 receptor antagonist, Hoe 140.

The method described by Schübel and Gehlen (1933) using the **uterus of cats** two to 4 days after partum is of historical interest only.

In addition to the isolated rat uterus, Berde et al. (1957) used the **rat uterus *in situ***, the **cat uterus *in vitro***, and the **cat uterus *in situ*** for evaluation of synthetic analogues of oxytocin.

Murray and Miller (1960) observed characteristic postural changes in rats following administration of oxytocin to unanesthetized rats described as "cramping" which was dose-dependent in estrogen-pretreated animals.

An *in vitro* **hen oxytocic assay** was designed by Munsick et al. (1966). Muscle strips of the uterine portion of the oviduct of laying hens are dissected and suspended in a van Dyke-Hastings solution containing 0.15 mM/l calcium, 0.5 mM/l magnesium and 100 mg% glucose. The strips are 2–3 cm long and 2–3 mm wide. The solution is gassed with oxygen containing 5% carbon dioxide and maintained at a temperature of 43 °C. These conditions are necessary to prevent spontaneous contractions.

The **isolated uterus from immature guinea pigs** was used for evaluation of oxytocin activity by Fromherz (1926) and by Vogel and Hergott (1963).

Guissani et al. (1995), Pettibone et al. (1996) reported the effect of oxytocin antagonists in **pregnant rhesus monkeys** *in vivo*.

N.8.1.2 Chicken blood pressure

PURPOSE AND RATIONALE

Oxytocin induces a transient fall in blood pressure in chicken and other birds. This effect can be used as assay for oxytocin (Coon 1939). The method has been modified by Munsick et al. (1960) and accepted by pharmacopoeias, e.g., the United States Pharmacopeia 23 (1995) uses the chicken blood pressure method for determination of oxytocin activity with three doses of standard and test preparation and calculation of the activity ratio with confidence limits.

PROCEDURE

White Leghorn chickens weighing 1.2 to 2.0 kg are anesthetized by intravenous injection with 200 mg/kg sodium phenobarbital via the brachial vein. The ischiadic artery is exposed by removing the feathers from the outer surface of the left thigh, an incision 7–8 cm long is made in the skin, parallel to and about 1.5 cm below the femur, exposing the gluteus primus muscle. The lower edge of this incision is retracted to expose the edge of the gluteus primus muscle overlying the semitendinosus muscle. The edge is then freed for the length of the incision, and when the free edge is lifted, the ischiadic artery, the ischiadic vein, and the crural vein can bee seen lying along the edge of semitendinosus muscle. The gluteus primus muscle is cut at right angles near the proximal end of the incision and the resulting flap deflected and secured to the upper thigh. Length of the ischiadic artery and crural vein are dissected free and the artery is cannulated. The cannula is connected to a Statham pressure transducer. Blood pressure should be between 100 and 120 mm Hg. The

crural vein is cannulated for injections of the test preparations. Intravenous injection of oxytocin induces in chickens an immediate, transient fall in blood pressure. Doses of the standard are chosen which are followed by a decrease of blood pressure between 20 and 40 mm Hg. The required doses normally lie between 20 and 100 mU.

Two doses of the standard and two doses of the test preparations are injected according to a randomized block or to a Latin square design and at least six to eight responses to each should be recorded. The interval between injections should be constant and lie between 3 and 10 min, depending on the rate at which the blood pressure returns to normal.

EVALUATION

The responses of each dose are averaged and potency ratios with confidence limits calculated from the 2 + 2-points assay.

N.8.1.3 Milk ejection in the lactating rabbit or rat

PURPOSE AND RATIONALE

A sensitive bioassay for the estimation of oxytocin was described by van Dyke et al. (1955). This test makes use of the milk-ejecting properties of oxytocin.

PROCEDURE

A rabbit in the first or second week of lactation is anesthetized with urethane and pentobarbital. Usually, artificial respiration is not necessary. One jugular vein is cannulated for injections. One of the six ducts in a nipple of the rabbit is cannulated with a hypodermic needle and connected with a Statham strain gauge transducer. Two doses of the standard and the test preparation are injected according to a randomized block or to a Latin square design and at least six to eight responses to each should be recorded. The interval between injections should be constant at 3 min.

EVALUATION

The responses of each dose are averaged and potency ratios with confidence limits calculated from the 2 + 2-points assay.

MODIFICATIONS OF THE METHOD

The British Pharmacopoeia (1988) recommends the measurement of milk-ejection pressure in the lactating rat. A lactating rat weighing about 300 g in the third to twenty-first day after parturition is anesthetized by pentobarbitone sodium. The trachea is cannulated. One jugular or femoral vein is cannulated for injections of the test preparations. The tip of one lower inguinal teat is excised and a polyethylene tube with an external diameter of 0.6 mm is inserted to a depth sufficient to obtain appropriate measurement of pressure into the primary teat duct which opens onto the cut surface and tied firmly in place with a ligature. The cannula is connected with a suitable strain-gauge pressure transducer for recording on a polygraph.

Tindal and Yokoyama (1962) recommended the use of guinea pigs using essentially a similar procedure, but the injection is made into the internal saphenous artery after ligation of the main branches supplying the limb. In the guinea pig the mammary glands are supplied with blood from the external pudendal arteries which branch from the internal saphenous artery just as they enter the legs.

N.8.1.4 Oxytocin receptor determination

PURPOSE AND RATIONALE

Premature labour and pre-term delivery is an important cause of death among infants and a major cause of newborn and child morbidity. Strong evidence exists that oxytocin and catecholamines are involved in the spontaneous uterine contractions which bring about premature delivery. Development of oxytocin antagonists is believed to be of therapeutic value for the prevention of pre-term labor (Manning et al. 1995; Chan et al. 1996).

In vitro binding to the oxytocin receptor is used as the first step of characterization of potential oxytocin antagonists (Pettibone et al. 1990, 1991, 1993a,b, 1996; Evans et al. 1993; Manning et al. 1995; Freidinger and Pettibone 1997; Pettibone and Freidinger 1997).

PROCEDURE

Uterine tissue is taken from nonpregnant adult Sprague Dawley rats pretreated (18–24 h) with diethylstilbestrol (300 µg/kg, i.p.) and mammary tissue from lactating rats (4–14 days lactation). The tissues are homogenized in 10 mM Tris containing 1 mM EDTA and 0.5 mM dithiothreitol, pH 7.4 and centrifuged at 48 000 *g* for 30 min at 4 °C. The resulting pellets from mammary/uterine tissue are resuspended in 50 mM Tris/5 mM $MgCl_2$/0.1% BSA (pH 7.4) and centrifuged again to produce the final pellet. Competition studies are conducted at equilibrium for 60 min at 22 °C using 1 nM [^{3}H]OT (30–60 Ci/mmol, New England Nuclear, Boston, USA) in the following buffer: 50 mM Tris/5 mM $MgCl_2$/0.1% BSA (pH 7.4). Nonspecific binding (5–10% of total binding) is determined using 1 µM unlabeled oxytocin. IC_{50} values are calculated from the linear regression analysis of log concentration of inhibitor versus percent inhibition of specific binding. Saturation binding studies are conducted at equilibrium using a 100-fold range of radioligand concentrations (i.e., 0.1 nM to 10 nM) and analyzed by a non-linear regression program (McPherson 1985a,b). The binding reactions are initiated by the addition of the tissue preparation (final protein concentrations, 100–200 µg protein/ml) and terminated by rapid filtration through Skatron glass fiber filters using a Skatron cell harvester system (Model 7019, Skatron Inc., Sterling, USA).

EVALUATION

Inhibition constants (K_i) are calculated for each compound from 3–6 separate IC_{50} determinations ($K_i = IC_{50} / [1 + c / K_d]$) using mean dissociation constants (K_d) obtained from saturation binding assays.

MODIFICATIONS OF THE METHOD

Maggi et al. (1994) used cultured Hs 805.Ut (corpus uteri, normal, human) cells or cells obtained from women in the early follicular or late luteal phase to study binding of antagonists at the human oxytocin receptor.

Pak et al. (1994) compared the binding affinity of oxytocin antagonists to human and rat oxytocin receptors and correlated the results with the rat oxytocic bioassay.

Species differences in central oxytocin receptor gene expression were investigated by Young et al. (1996).

Cloning and expression of the rhesus monkey oxytocin receptor was reported by Salvatore et al. (1998).

Molecular cloning and functional characterization of the oxytocin receptor from a rat pancreatic cell line (RINm5F) was reported by Jeng et al. (1996).

Elands et al. (1987), Klein et al. (1995) recommended selective radioligands for the oxytocin receptor.

N.8.2
Vasopressin

N.8.2.1
Hereditary vasopressin deficiency in rats (Brattleboro strain)

This bioassay is based on an animal strain with genetic deficiency of vasopressin synthesis. Patients with diabetes insipidus excrete large amounts of very diluted urine and need a high fluid intake. This disorder is due to a lack of vasopressin. A similar syndrome has been found in Brattleboro rats. In the rare nephrogenic form, the vasopressin receptors are defective. Vasopressin is also considered to be a modulator in the central nervous system in particular learning and memory processes. Therefore, many studies on learning and memory have been performed with this strain of rats. Valtin et al. (1965) found very little vasopressin in hypothalami and pituitaries of homozygous Brattleboro rats.

Schmale and Richter (1984), Schmale et al. (1984) found a single base deletion in the vasopressin gene as the cause of diabetes insipidus in Brattleboro rats. The mutant vasopressin gene is transcribed but the message is not efficiently translated. Spontaneous hypertensive rats crossbred with Brattleboro rats inherit the mutated vasopressin gene (McCabe et al. 1988). The abnormal quinine drinking aversion in the Brattleboro rat with diabetes insipidus can be reversed by an vasopressin agonist (Laycock et al. 1994)

For testing aquaretic effects in Brattleboro rats see C.1.2.1.

N.8.2.2 Vasopressor activity

PURPOSE AND RATIONALE

Vasopressin activity can be determined by the increase of blood pressure after surgical or pharmacological elimination of the central and peripheral nervous regulation of the cardiovascular system. Dekanski (1952) described a quantitative assay of vasopressin in anesthetized rats after blockade of other pressor substances by dibenamine (pithed rat).

PROCEDURE

A male Wistar rat weighing about 300 g is anesthetized by subcutaneous injection of 1.75 g/kg urethane. After 45–60 min, the trachea is cannulated with a polyethylene tube of 2.5 mm diameter. One femoral vein is cannulated for injections and the carotid artery for measuring blood pressure with a Statham transducer. The central and peripheral nervous systems, including both vagi and associated sympathetics, are left intact. No artificial respiration is necessary. Heparin (2 000 U/kg) is injected through the venous cannula and washed through with saline. Dibenamine = *N*-(2-chloroethyl)dibenzylamine hydrochloride is injected twice intravenously at an interval of 10 min in a dose of 1 mg/kg. The blood pressure stabilizes at a basal level of about 50 mm Hg. Small doses of vasopressin induce an increase in blood pressure which is dependent on the dose. Two doses of vasopressin standard (approximately 3–5 milliunits) and two doses of test preparation are injected repeatedly (usually 6 times) using a Latin square design. The doses are injected at intervals of 10–15 min.

EVALUATION

The responses of each dose are averaged and potency ratios calculated from the 2 + 2-points assay.

MODIFICATIONS OF THE METHOD

One of the first recommendations to standardize posterior pituitary extract was measuring blood pressure in anesthetized dogs (Hamilton 1912).

Vogel and Hergott (1963) studying the properties of a synthetic vasopressin analogue described a method in decerebrated rabbits previously used in this laboratory for standardization of posterior pituitary extracts. Rabbits weighing 2–3 kg are anesthetized by slow intravenous injection of butallylonal. The trachea is cannulated and the cannula connected with a respiration pump. One femoral vein is cannulated for injection of the test compounds. One carotid artery is cannulated for measurement of blood pressure with a Statham transducer. For chemical decapitation, the head of the anesthetized rabbit is bent forwards and a needle introduced into the foramen occipitale magnum. 0.5 ml of 30% trichloroacetic acid are injected. Artificial respiration is started immediately. Blood pressure is stabilized at a level of 30–40 mm Hg. Two doses of standard and of test preparation are injected according to a Latin square design. The method has been proven to be very sensitive.

The British Pharmacopoeia 1988 recommends the intravenous injection of 10 mg/kg of the α-adrenoreceptor blocking agent phenoxybenzamine hydrochloride 18 h prior to the experiment to stabilize the blood pressure on a low level. USP 23 (1995) uses two doses of standard and test preparation in the phenoxybenzamine blocked rat for calculation of vasopressin activity with confidence intervals in vasopressin and oxytocin preparations.

Knape and van Zwieten (1988) used the pithed rat to study vasoconstrictor activity of vasopressin after pretreatment with various drugs.

N.8.2.3 Antidiuretic activity in the conscious rat

PURPOSE AND RATIONALE

For some period of time, it was uncertain whether or not vasopressin and adiuretin are the same or separate hormones. Special tests for antidiuretic activity in water loaded rats were developed (Burn 1931) and adopted by pharmacopoeias. Vasopressin analogues show considerable dissociation of vasopressive and antidiuretic activity (Vogel and Hergott 1963).

PROCEDURE

Wistar or Sprague-Dawley rats weighing between 140 and 250 g of either sex are used. The range of weights in any one test should not exceed 50 g. Not less than 2 days before testing the preparation, the rats have to be accustomed to the metabolism cage by carrying out a preliminary test. All animals are injected with 0.1 ml saline solution per 100 g body weight instead of the test preparations given in the main test. Any rat that shows signs of stress or undue excitement or that has abnormally low or high rate of urine excretion should not be used in the main test. Food and water is withheld during each test but access allowed between the tests. The rats are assigned at random to four groups each of them not less than four animals, weighed and marked for identification purposes. By stomach tube each rat receives a volume of water warmed to approximately 37 °C and equivalent to 5% of the animal's body weight. Each rat is placed in a separate cage for collection of urine. Thirty min later, the volume excreted by each rat is recorded and a second volume of tap water equal to the volume of urine together with a further volume equivalent to 3% of the animal's body weight is administered. This provides a total water load equivalent to 8% of the animal's body weight.

Using a different group of rats two dilutions of the preparation to be examined and of the standard preparation, immediately after administration of the second dose of water, each rat is injected subcutaneously with a volume of the appropriate dilution equivalent to 0.1 ml per 100 g body weight. The urine passed during the first 5 min after injection is discarded and the volumes collected at intervals of 15 min are noted until a volume greater than 30% of the total water load is excreted.

EVALUATION

The responses of each dose are averaged and activity ratios with confidence limits calculated from the 2 + 2-points assay.

MODIFICATIONS OF THE METHOD

Hydrated **conscious dogs** have been used to test the antidiuretic activity of vasopressin by van Dyke et al. (1955).

N.8.2.4 Antidiuretic activity in the rat in ethanol anesthesia

PURPOSE AND RATIONALE

This is a sensitive bioassay often reported for vasopressin analogues. Ethanol suppresses the excretion of endogenous antidiuretic hormone (van Dyke and Ames 1951). Sensitive methods measuring urine output in ethanol anesthesia were described (Dicker 1953; Dettelbach 1958; Berde and Cerletti 1961), whereby the water load is automatically kept constant.

PROCEDURE

Female Sprague-Dawley rats weighing 200–250 g are spayed 7 to 10 days prior to use in order to eliminate the effect of gonadal steroids on the response to a water load. Each animal is given a 5 ml gavage of tepid tap water. At 3-days intervals thereafter, the water load is increased by 1 ml increments until a 10-ml level is reached. The day before an assay is to be performed, two or three animals are selected and given a 10 ml gavage of 2% ethanol. The animals are fasted overnight but are allowed free access to water. On the test day, they are placed into individual metabolism cages for water loading and anesthetizing. Each rat receives 5% of its body weight of warm 12–15% ethanol by stomach tube. This is anesthetic within a few minutes. After 45 min the same volume of 2% ethanol is again given by gavage. After 1 h the bladder is emptied by suprapubic pressure and the total urine output is measured.

The animal with the largest volume is selected and the water load calculated as the total volume administered less the volume excreted. The load on this animal is now

increased to between 6 and 8% of its body weight with warm 2% ethanol. Then the urinary bladder is catheterized. A polyethylene tubing is inserted into the rat's stomach. A femoral vein is cannulated for injections. The hind legs are secured to the operation table, while the front legs are left free. Assays are started when urine flow reaches a steady level of at least 50 µl/min. The catheter from the bladder is connected to an apparatus consisting of two Woulff bottles. Urine is directed through the catheter into the first Woulff bottle, displacing fluid into the second Woulff bottle. The second bottle is filled with 0.5% NaCl solution in 50% ethanol to reduce the size of the drops. Each drop activates an impulse counter. The drops are collected in a small glass reservoir and led by means of a polyethylene tubing to the urine metering pipette. When the fluid level in this tube rises and makes contact with an adjustable needle electrode near the top, another pipette which is calibrated to the same volume empties a solution of 5% glucose in 2% ethanol through the gavage tube into the rat's stomach. By these means a constant water load is maintained.

The animals produce urine at a relatively steady rate for 3–5 h. Intravenous injections of vasopressin produce characteristic changes in rate of urine flow which begin usually within 2 min and subside in most instances within 15 min. The range in which the assay of antidiuretic activities is useful is between 2 and 64 µU/injection.

EVALUATION

Antidiuretic potency is calculated as the log ratio of the volume excreted in 5 min preceding injection to the volume excreted in the 5 min beginning 1 min after injection. Dose-responses are established for the standard and the test preparation and activity ratios calculated.

MODIFICATIONS OF THE METHOD

Berde and Cerletti (1961) placed the rat anesthetized with ethanol on a balance. The water loss due to urine excretion and perspiratio insensibilis is replaced automatically using a solution of 5% glucose in 2% ethanol.

N.8.2.5 Spasmogenic activity of vasopressin in the isolated guinea pig ileum

PURPOSE AND RATIONALE

The ileum of the guinea pig has been found to be quite sensitive to vasopressin (Simon 1933). This is a direct effect on smooth muscle similar to the pressor effect. This test is not specific for vasopressin.

PROCEDURE

Pieces of guinea pig ileum are suspended in an organ bath according to the Magnus' technique (see J.4.3.1). Two different doses of the test preparation and of the standard are applied according to a Latin square design and the contractions measured using a strain gauge transducer. Four–six doses of each solution are measured.

EVALUATION

The responses of each dose are averaged and activity ratios with confidence limits calculated from the 2 + 2-points assay.

N.8.2.6 Vasopressin receptor determination

PURPOSE AND RATIONALE

As in other areas of drug research, identification of new vaopressin-like compounds has been achieved not by bioassays, but using receptor preparations. Such assays are also used in "receptor screens" for the general pharmacology of new drug candidates, to predict their spectrum of activities.

Arginine vasopressin exerts its action through three membrane bound G-protein-coupled receptor subtypes (V_{1a}, renal V_2 and V_3). The vasopressin-induced antidiuresis (via V_2 receptors coupled to aquaporins) helps maintain plasma osmolality and salt (NaCl) balances. The human V_1, V_2 and V_3 (V_{1b}) receptors and water selective membrane proteins (aquaporins) in the kidney have been cloned.

Pharmacological characterization of the human vasopressin receptor subtypes stably expressed in Chines hamster ovary cells was reported by Tahara et al. (1998).

Selective non-peptide vasopressin antagonists (without agonistic activity) have been shown to be aquaretic agents in animals and humans. Development and therapeutic indications of orally-active vasopressin receptor antagonists were reviewed by Thibonnier (1998).

Serradeil-Le Gal et al. (1993, 1994a) studied the biochemical and pharmacological properties of a non-peptide antagonist on rat and human vasopressin V_{1a} receptors.

PROCEDURE

Tissue samples from human uterus, adrenals, kidneys and pituitaries are collected in conformity with national ethical rules. Uterus, adrenal and kidney samples are immediately chilled in cold saline. Membranes are prepared within 3 h after collection. Pituitaries are collected within 6 h after death and immediately frozen in liquid nitrogen. Bovine kidneys can be obtained from a local slaughterhouse. Rat mammary tissue is taken from 19-day Sprague Dawley pregnant rats.

For human adrenal membrane preparations, pieces of adrenal glomerulosa zone are suspended in a cold buffer (10 mM Tris-HCl, pH 7.4, 3 mM $MgCl_2$, 1 mM EDTA, 250 mM sucrose, 1 mM PMSF) and fragmented using a glass/glass Dounce homogenizer. The homogenate is filtered through glass wool and centrifuged for 15 min at 1 500 *g* at 4 °C. The pellet is incubated for 15 min in ice-cold hypotonic buffer (10 mM Tris-HCl, pH 7.4, 3 mM $MgCl_2$, 1 mM EDTA, and 1 mM PMSF) and kept on ice to allow cell lysis. Lysed cells are recovered by centrifugation at 1 500 *g* for 15 min at 4 °C, homogenized using a loose-fitting Dounce homogenizer in hypotonic buffer supplemented with 40% glycerol, and stored at –20 °C. Before experiments, glycerol is eliminated by washing the membranes in glycerol-free hypotonic buffer.

For preparation of hypophyseal membranes, frozen entire pituitary glands are rapidly thawed at 37 °C in isotonic buffer supplemented with 0.1 mM PMSF, and the adenohypophyses are separated. Adenohypophyseal membranes are prepared as described above for adrenal membranes.

For rat mammary gland membrane preparations, tissues are minced and homogenized in 50 mM 10% (wt/vol) buffer A Tris-HCl, pH 7.4, 320 mM sucrose, and 0.5 mM dithiothreitol and centrifuged at 900 *g* for 15 min; the pellet is resuspended in buffer A and centrifuged as above. The two 900-g supernatants are filtered through cheesecloth and centrifuged at 70 000 *g* for 20 min. The pellet is washed with buffer B containing 50 mM Tris-HCl, pH 7.4, and 10 mM $MgCl_2$. Finally, the 70 000 *g* washed pellet is suspended in buffer B at a final concentration of ~8 mg protein/ml and stored in aliquots in liquid nitrogen.

V_{1a} binding assays using ^{125}I linear AVP antagonist on human adrenal membranes, myometrial membranes from nonpregnant uterus, or platelet membranes are performed in an incubation medium (200 µl) containing 10 mM Tris-HCl, pH 7.4, 3 mM $MgCl_2$, 1 mg/ml BSA, 0.05 mg/ml soy bean trypsin inhibitor, 0.5 mg/ml bacitracin, 0.1 mM PMSF, 0.5 mM EDTA, 10–60 pM ^{125}I-AVP linear antagonist, and increasing amounts of test compound. The reaction is started by addition of membranes (10–40 µg/assay) that are incubated at 30 °C for 45 min. The reaction is stopped by adding 3 ml of ice-cold filtration buffer (10 mM Tris HCl, pH 7.4, and 3 mM $MgCl_2$ followed by filtration through GF/C Whatman glass microfiber filters that have been soaked for at least 5 h in a solution containing 10 mg/ml BSA. Filters are washed five times with 3 ml of filtration buffer and counted for radioactivity by gamma spectroscopy. Nonspecific binding is determined in the presence of 0.3 µM unlabeled iodinated AVP linear antagonist or 1 µM AVP.

EVALUATION

The IC_{50} value is defined as the concentration of inhibitor required to obtain 50% inhibition of the specific binding. Inhibition constant (K_i) values are calculated from the IC_{50} values using the Cheng and Prusoff equation. Data for equilibrium binding (K_d, B_{max}), competition experiments (IC_{50} nHill), and kinetic constants (k_{obs}, k_1) are analyzed using an iterative nonlinear regression program (Munson and Rodbard 1980).

MODIFICATIONS OF THE METHOD

A receptor assay for arginine-vasopressin has been described by Gopalakrishnan et al. (1986).

Pávó et al. (1993) reported synthesis and binding characteristics of two sulfhydryl-reactive probes for vasopressin receptors.

Serradeil-Le Gal et al. (1994b) tested the effect of a non-peptide vasopressin V_{1a} vasopressin antagonist on the binding and the mitogenic activity of vasopressin on Swiss 3T3 cells.

Yatsu et al. (1997) tested the vasopressin antagonistic activities of a non-peptide on V_{1a} receptors in dog platelets and on V_2 receptors in dog kidney homogenates.

Ogawa et al. (1996), Tahara et al. (1997a) tested V_{1a} receptor binding in homogenates of rat liver and V_2 receptor binding in rat kidney.

Barberis et al. (1995) characterized a linear radioiodinated vasopressin antagonist as an excellent radioligand for vasopressin V_{1a} receptors.

Radioligands for vasopressin V_1 receptors were described by Elands et al. (1988) and by Kelly et al. (1989).

Ala et al. (1997) reported the properties of a radioiodinated antagonist for human vasopressin V_2 and V_{1a} receptors and recommended this ligand for further studies on human vasopressin V_2 receptor localization and characterization, when used with a selective vasopressin V_{1a} ligand.

Howl and Wheatley (1995) found a species heterogeneity in the characteristics of V_{1a} receptors and in the expression of hepatic V_{1a} receptors.

Carnazzi et al. (1997) described photoaffinity labeling of the rat V_{1a} vasopressin receptor using a linear azidopeptidic antagonist.

Phalipou et al. (1997) studied the peptide-binding domains of the human V_{1a} vasopressin receptor with a photoactivatable linear peptide antagonist.

DDAVP (1-desamino-8-d-arginine vasopressin) which is considered as a standard V_2 vasopressin receptor selective agonist was found to act also as agonist on the V_{1b} vasopressin receptor (Saito et al. 1997).

Tahara et al. (1997b)investigated the effects of a nonpeptide V_{1a} and V_2 vasopressin receptor antagonist in binding and functional studies on rat vascular smooth muscle cells.

N.9
Hypothalamic hormones

N.9.1
Thyrotropin releasing hormone (TRH)

N.9.1.1
General considerations

Hypothalamic regulatory hormones are used in diagnostic procedures and for therapy, usually modified by chemical synthesis to enhance activities. The existence of regulators of anterior pituitary function, already postulated many years ago (Bargmann 1949; Scharrer and Scharrer 1954), has been experimentally demonstrated for the first time by Saffran and Schally (1955) in experiments utilizing hypothalamic and neurohypophyseal extracts. TRH was the first hypothalamic hormone whose chemical structure was elucidated (Bøler et al. 1969; Schally et al. 1970). Its main use is as a diagnostic in thyroid disorders, pituitary tumors and infertility.

Cloning, characterization, and transcriptional regulation of the thyrotropin-releasing hormone gene was reviewed by Wilber and Ai-Hua-Xu (1998).

Pekary (1998) discussed the physiological role of thyrotropin-releasing hormone-enhancing peptide (Ps4) which results from proteolytic processing of prepro-TRH.

Effects of TRH and its analogues in the CNS not related to the release of TSH (extrapituitary effects) have been found indicating perhaps other therapeutic indications (Metcalf 1983; Flohe et al. 1983; Nemeroff et al. 1984; Horita et al. 1986; Horita 1998).

Radioimmunoassays for TRH are available (Bassiri et al. 1978).

Furukawa et al. (1980) reported the local effects of TRH on the isolated small intestine and taenia coli of the guinea pig. This effect could be related to the local release of catecholamines.

N.9.1.2
TRH receptor binding assays

PURPOSE AND RATIONALE

Thyrotropin hormone releasing hormone receptors from mouse (Straub et al. 1990; Jones et al. 1996), from rat (Sellar et al. 1993) and from men (Duthie et al. 1993; Matre et al. 1993; Yamada et al. 1993; Hinuma et al. 1994) have been expressed and characterized. Two isoforms have been identified (de la Peña et al. 1992; Lee et al. 1995). Constitutive activity of native thyrotropin-releasing hormone receptors has been shown by Jinsi-Parimoo and Gershengorn (1997). Molecular and cellular biology of thyrotropin-releasing hormone receptors has been reviewed by Gershengorn and Osman (1996).

TRH receptors have been localized not only in the pituitary but also in other brain regions (Burt and Taylor (1983). TRH receptors can be determined by binding of [^{3}H]MeTRH (Taylor and Burt 1981; Sharif and Burt 1983; Jarowska-Feil et al. 1995; Yamada et al. 1995) or [^{3}H](3-Me-His^2)TRH (Simasko and Horita 1982).

PROCEDURE

Pooled tissue samples are homogenized in a sodium phosphate buffer (20 mM, pH 7.4) and centrifuged at 30 000 *g* for 30 min. The resultant pellets are washed twice by means of resuspension and centrifugation. The washed membranes are dispersed in fresh buffer and are used for the TRH receptor binding assay.

The membranes are incubated in 250 µl of the total volume with 0.5–8 nM of [^{3}H]MeTRH (NEN, sp. act. 62.8 Ci/mmol), in the presence or absence of 10 µM of TRH for 5–6 h at 0 °C (in a water-ice bath). The receptor bound and free [^{3}H]MeTRH is separated by a rapid filtration through a glass fiber filter GF/B (Whatman) under reduced pressure (Harvester-Brandel). The trapped receptor bound radioactivity is determined by liquid scintillation spectrometry (Beckman). The amount of specifically bound [^{3}H]MeTRH is expressed as fmoles per mg of protein.

EVALUATION

The data are subjected to the 6-point Scatchard analysis. The receptor density (B_{max}) and apparent dissociation constant (K_d) are determined.

MODIFICATIONS OF THE METHOD

Sun et al. (1998) described cloning and characterization of the chicken thyrotropin-releasing hormone receptor.

N.9.1.3 Release of ^{131}I from thyroid glands of mice

PURPOSE AND RATIONALE

An animal bioassay method for TRH utilizes iodine-deficient mice, treated with ^{131}I, codeine, and 1 µg thyroxin (Redding et al. 1966; Bowers et al. 1967; Redding and Schally 1969). This is a historical test based on the effect of thyroid hormone release by TRH (indirect

bioassay). Provided the extract being tested is free of TSH, the rise in radioactivity in blood 2 h after injection of the TRH preparations is proportional to the effect of TSH released by TRH.

PROCEDURE

Weanling mice of the Swiss-Webster strain weighing 15 g are fed a low iodine diet and given distilled water for 10 days. At zero time, 4 μC $Na^{131}I$, 1 μg thyroxin and 1 mg codeine phosphate are injected subcutaneously. Codeine is given again s.c. at 24, 30, and 48 h after 0 time. Two h after the fourth injection of codeine, blood is taken from the orbital venous sinus. The test preparation or TRH standard is injected intravenously at increasing doses (0.01, 0.03, 0.09 μg/mouse). Two hours later, a second blood sample is taken from the orbital venous sinus. The response is obtained by the increase of radioactivity from the first to the second blood sample (Δcpm).

EVALUATION

Dose-response curves are established for test preparation and standard for calculation of potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

TRH also stimulates release of TSH and subsequently of ^{131}I in rats pretreated with $Na^{131}I$ and 5 μg thyroxin (Yamakazi et al. 1963).

TRH increases plasma TSH levels in thyroidectomized rats pretreated with 1 μg of T_3 (Bowers et al. 1965). This assay is based on enhanced TSH secretion after eliminating then feedback of thyroid hormones. The baseline is then lowered by T3 pretreatment to provide a wider range for stimulation by TSH. Rats weighing 350–400 g are surgically thyroidectomized. One to 3 months later, 1 μg of L-triiodothyronine Na is given i.p.; 2 h later urethane is given s.c.; approximately 1 h later 1.5 ml blood is removed from the jugular vein and the TRH preparation is administered i.v. Fifteen min later, another 1.5 ml blood is removed. Heparin is added to the blood and TSH levels in plasma are assayed by release of ^{131}I from the mouse thyroid (Mc Kenzie 1958) (see N.7.5.3). Results are recorded as mean change in blood ^{131}I levels of 5 mice.

TRH produces a significant depletion of pituitary TSH content in mice (Bowers et al. 1967). Swiss-Webster strain mice are treated as described for determination of blood ^{131}I radioactivity. Two hours after administration of TRF, the animals are decapitated and the pituitaries immediately removed. Pituitaries of each group of 5 mice are combined and homogenized in 5 ml of 0.01 M acetic acid which contains 0.9% NaCl. TSH is determined according to McKenzie (1958) (see N.7.5.3). Today, this would be replaced by RIA determination of pituitary TSH content.

N.9.1.4 Release of TSH from rat anterior pituitary glands *in vitro*

PURPOSE AND RATIONALE

The *in vitro* bioassay method of Saffran and Schally (1955a,b), developed for detecting CRF activity, has been modified to measure TRH activity *in vitro* (Guillemin et al. 1963; Bowers et al. 1965; Schally and Redding 1967).

PROCEDURE

Male Sprague-Dawley rats weighing 150–200 g serve as donors. After removal each pituitary is cut in half, transferred to a 15 ml beaker containing 1.5 ml Krebs-Ringer bicarbonate medium with 200 mg% glucose

and incubated for three 60-min periods. The media used in the first 2 incubations are discarded. At the beginning of the third incubation period, various amounts of test preparation or TRH standard are added to individual beakers. At the end of the third incubation period the media from both control and experimental beakers are carefully freed of pituitary tissue. The media are then assayed by RIA for content of TSH.

EVALUATION

Dose-response curves are established for test preparation and standard allowing calculation of potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

For the assay of TRH analogues, cultures of enzymatically dispersed anterior pituitary cells from rats can be used instead of pituitary halves (Vale et al. 1972).

Barros et al. (1986) studied the effect of TRH on cultured GH3 rat anterior pituitary cells using the whole-cell voltage clamp technique.

N.9.2
Luteinizing hormone releasing hormone (LH-RH)

N.9.2.1
General considerations

Gonadotropin secretion is controlled by the hypothalamic peptide LHRH, which stimulates the release of FSH and LH. The discovery of the structure of luteinizing hormone releasing hormone (LH-RH) then led to the synonym of gonadotropin releasing hormone (Gn-RH) and identification of its receptors followed (Conn et al. 1986). Nevertheless, the search for a specific FSH-releasing factor has continued (McCann et al. 1993). LH-RH is secreted in a pulsatile fashion (Levine et al. 1991). This however not of relevance for the bioassays which use injections as well as infusion for several hours. Radiolabeling and photoaffinity labeling of gonadotropin releasing-hormone receptors have been described (Perrin et al. 1982; Hazum and Keinan 1983). LH-RH bioactivity is determined *in vitro* on pituitary cells and *in vivo* by its effects on ovulation, spermatogenesis and other gonadal parameters (McCann 1970; Steelman 1970). Radioimmunoassays and radioreceptorassays are available (Nett and Niswender 1979). Many studies in rats and primates showed that prolonged administration of LH-RH agonists results in a decrease of LH and gonadal hormones to castrate levels (Sandow et al. 1978, 1980; Akhtar et al. 1983; Weinbauer et al. 1987, 1990).

Short- and long-term effects on pituitary-gonadal function in neonatal and adult female rats treated with gonadotropin-releasing hormones were analyzed by Trimino et al. (1993).

FDA recommendations for preclinical testing of gonadotropin releasing hormone (GnRH) analogues including pharmacology, pharmacokinetics and toxicology were published by Raheja and Jordan (1994).

N.9.2.2 LH-RH receptor assays

PURPOSE AND RATIONALE

LH-RH (GnRH) interacts with a membrane receptor which belongs to the G-protein-coupled receptor family. The LH-RH-R is encoded by a single-copy gene consisting of three exons and two introns. Consisting with the site of its action, LH-RH-R mRNA has been found in the brain, pituitary, gonads, placenta, as well as in tumor tissue and tumor cell lines (Jennes and Conn 1994). Binding to LH-RH receptors in rat pituitary membranes has been studied for LR-RH agonists and antagonists. Furthermore, the time course of down-regulation of LH-RH receptors was followed (Halmos et al. 1996).

PROCEDURE

Receptor binding of LH-RH is determined using a sensitive *in vitro* ligand competition assay based on binding of radiolabeled buserelin or [D-Trp^6]LH-RH to rat anterior pituitary membrane homogenates (Halmos et al. 1993; Szöke et al. 1994; Halmos et al. 1996). Membrane homogenates containing 40–80 µg of protein are incubated in triplicate with 60 000–75 000 cpm (≈0.15 nM) [^{125}I] [D-Trp^6]LH-RH as radioligand and with increasing concentrations (10^{-12}–10^{-6} M) of non-radioactive peptides in a total volume of 150 µl of binding buffer. At the end of the incubations, 125-µl aliquots of suspension are transferred onto the top of 1 ml of ice-cold binding buffer containing 1.5% bovine serum albumin in siliconized polypropylene microcentrifuge tubes (Sigma). The tubes are centrifuged at 12 000 *g* for 3 min at 4 °C. Supernatants are aspirated, and the bottoms of the tubes containing the pellet are cut off and assayed in a γ-counter. Protein concentration is determined by the method of Bradford (1976) using a BioRad protein assay kit.

EVALUATION

Specific ligand binding capacities and affinities are calculated by the computerized curve-fitting program of Munson and Rodbard (1980) as modified by McPherson (1985). To determine the types of receptor binding, dissociation constants (K_d values), and the maximal binding capacity (B_{max}), LH-RH binding data are also analyzed by the Scatchard method. Statistical significance is assessed by Duncan's new multiple range test.

MODIFICATIONS OF THE METHOD

Flanagan et al. (1998) recommended ^{125}I-[His^5,Tyr^6]-GnRH as radioligand for analysis of mutant GnRH receptors.

Perrin et al. (1982) compared binding of radiolabeled antagonists and antagonists of gonadotropin-releasing hormone to rats anterior pituitary membrane homogenates.

Fekete et al. (1989) reviewed the role of receptors for luteinizing hormone-releasing hormone, somatostatin, prolactin, and epidermal growth factor in rat and human prostate cancers and in benign prostate hyperplasia.

Cloning, sequencing, and expression of human gonadotropin releasing hormone receptor was published by Kakar et al. (1992).

Marheineke et al. (1998) characterized the human gonadotropin-releasing hormone receptor heterologously produced using the baculovirus/insect cell and the semliki forest virus systems.

The binding kinetics of a long-acting gonadotropin-releasing hormone antagonist to rat LH-RH receptors were studied by Li et al. (1994).

Lovejoy et al. (1995) determined the receptor binding of gonadotropin-releasing hormone analogues in bovine pituitary membrane preparations.

The cDNA encoding the receptor for LH-RH was isolated from a human pituitary cDNA library and heterologously expressed in the murine fibroblast cell line LTK^- by Beckers et al. (1995).

Tsutsumi et al. (1995) investigated the role of altered receptor biosynthesis in agonist-induced receptor down-regulation in αT_3-1 cells, a mouse gonadotrope cell line.

Beckers et al. (1997) characterized gonadotropin-releasing hormone analogs by a cellular luciferase reporter gene assay. The assay is based on a fusion of the c-fos immediate-early gene promotor to Photinus pyralis luciferase (LUC) as reporter gene, stably transfected in murine LTK^- cells expressing the human GnRH receptor. Transcription of endogenous c-fos and fos-Luc fusion gene are transiently induced quite similar by fetal calf serum or a superagonistic GnRH analog. The reporter gene was used to monitor agonist induced signaling via the human GnRH receptor. Whereas Luc activity was induced in a dose-dependent manner by GnRH or an agonistic analog, different antagonistic peptides completely inhibited this stimulation.

N.9.2.3 LH release in the ovarectomized estrogen-progesterone-blocked rat

PURPOSE AND RATIONALE

Ramirez and McCann (1963) recommended the ovarectomized, estrogen progesterone-blocked rat (OEP-rat) as a highly sensitive test model for LH-releasing activity. The gonadotropin content of the pituitary is increased after ovarectomy, due to reduced feedback inhibition by absence of gonadal steroids. Basal secretion is then acutely lowered by estrogen/progesterone blockade, whereas the amplitude for stimulation of LH secretion is augmented. The increase in plasma LH levels of donor rats after injection of LH-RH previously determined by bioassay in recipient rats is now conveniently measured by RIA. Since natural and synthetic LH-RH releases both gonadotropins(Schally et al. 1971b), merely stimulation of LH is necessary for routine LH-RH assay.

PROCEDURE

Female Sprague-Dawley rats weighing 150–200 are ovarectomized. They are kept in a light and temperature controlled animal room at 24 °C and are fed commercial rat chow and tap water ad libitum. Tests are performed 1–3 months after ovarectomy. Three days prior to the assay, the rats receive 50 µg estradiolbenzoate and 25 mg progesterone in sesame oil by the transmuscular-subcutaneous route. For the assay, the rats are anesthetized by subcutaneous injection of 0.6 ml/100 *g* of 25% urethane solution. Various doses of the test compound or the standard are injected intravenously in the jugular vein. Ten min later, 4–6 ml blood are withdrawn by cardiac puncture from each donor allowing the separation of 2 ml plasma.

In the original method, bioassayable LH was measured by the ovarian ascorbic acid depletion (OAAD) method according to Parlow (1963) (see also N.7.1.2.3). Immature female Sprague Dawley rats are injected on day 1 at 3:00 P.M. with 50 IU PMSG in 0.2 ml saline subcutaneously. On day 3, the rats receive at 9:00 A.M. 25 IU HCG subcutaneously. On day 7, three different doses of the standard (e.g., NIH LH-S-1, National Institute of Health, Bethesda, ML) or the 2 ml of plasma from OEP-rats are injected intravenously. Eight animals are used per group. Three hours later, the animals are sacrificed, both ovaries prepared, weighed and homogenized for determination of ascorbic acid content. The LH-activity in OEP-plasma as measure by OAAD, is expressed in terms of NIH-LH-S16 standard.

Furthermore, LH activity in the plasma of OEP-rats is measured by radioimmunoassay. OEP rats are anesthetized with 25% urethane i.p. Blood is withdrawn by retroorbital puncture. Then various doses of the test preparation or the standard are injected intravenously. After 10 min blood is withdrawn by cardiac puncture. Radioimmunoassays of LH are carried out by the double-antibody-method of Niswender et al. (1968).

EVALUATION

Dose-response curves are established of the standard and the test preparation of LH-RH measured by bioassayable LH in OEP plasma as well as for plasma-RIA-LH level allowing the calculation of potency ratios with confidence limits. Furthermore, time-response curves can be established by determination of plasma-RIA-LH levels in OEP rats.

MODIFICATIONS OF THE METHOD

Instead of OEP rats, normal Male Sprague-Dawley rats can be used for measurement of the time course of release of LH after injection of LH-RH or LH-RH derivatives (Arimura et al. 1972). Male Sprague-Dawley rats weighing 120–150 g are anesthetized with 0.6 ml/100 g body weight of 25% urethane solution subcutaneously. After 30 min 0.8 ml blood is withdrawn from the jugular vein being immediately substituted by the same volume of Haemaccel® solution. The LH-RH preparation is injected subcutaneously in 1% gelatine-saline. Blood is withdrawn at hourly intervals up to six hours each time being substituted with Haemaccel® solution. LH in plasma is determined by the double-antibody-method of Niswender et al. (1968) and FSH according to the method of Daane and Parlow (1971).

N.9.2.4 Gonadotropin release from anterior pituitary cells

PURPOSE AND RATIONALE

Anterior pituitaries can be used directly, kept in culture or used for cell lines (Mittler and Meites 1964, 1966; Mittler et al. 1970; Sandow et al. 1972) in order to study the synthesis and release of gonadotropins in response to LH-RH.

PROCEDURE

Female Sprague-Dawley rats weighing 100–150 g are used as donors. Each anterior pituitary is removed and cut into 4–6 pieces of approximately equal size. The cultures are performed in 3.5–1-cm sterile disposable plastic Petri dishes each containing 3 ml medium consisting of 9 parts Difco medium 199 and 1 part of newborn calf serum. Twenty-five U/ml penicillin and 25 µg/ml streptomycin are added. In each dish, the explants are supported at the gas interface. An atmosphere of 95% oxygen and 5% carbon dioxide and a temperature of 36 °C are maintained. Opposite sides of the same pituitaries provide matched control and experimental preparations. The pituitaries are incubated for a total time of 5 days. After the first two days, the medium is removed and discarded. Fresh medium is then added with the LH-RH solutions. Approximately 12 h after the first change of medium and addition of LH-RH, media are removed and frozen. Fresh medium with LH-RH is again added; this procedure is repeated until 6 samples of medium representing the last 3 days of culture are obtained. Media are assayed for LH content by radioimmunoassay according to Niswender et al. (1968) and for FSH content according to Parlow et al. (1963).

EVALUATION

Using various concentrations of test preparation and LH-RH standard dose-response curves are obtained allowing calculation of potency ratios with confidence limits.

CRITICAL ASSESSEMNT OF THE METHOD

These methods do not reflect the time course of release found *in vivo* but are useful for potency estimates.

MODIFICATIONS OF THE METHOD

Instead of pituitary halves for the assay of LH-RH as well as for the assay of TRF and its analogues, cultures of enzymatically dispersed anterior pituitary cells from rats can be used (Vale et al. 1972; Martin and Sattler 1979).

Loughlin et al. (1981) used perifused pituitary cultures as model for LH-RH regulation of LH secretion.

O'Connor and Lapp (1984) studied the effect of pulse frequency and duration of luteinizing hormone releasing hormone in anterior pituitary cells attached to Cytodex I beads.

Functional integrity of anterior pituitary cells separated by a density gradient has been studied (Scheikl-Lenz et al. 1985).

Receptor binding ability to rat pituitary and human breast cancer membranes of different agonists and antagonists of luteinizing hormone-releasing hormone was studied by Fekete et al. (1989).

Vigh and Schally (1984), Csernus and Schally (1991) described in detail a cell superfusion system consisting of a Sephadex column with dispersed pituitary cells. LH response of anterior pituitary cells to 3 min exposure to various concentrations of LHRH at 30 min intervals as well as growth hormone response to human growth hormone releasing hormone resulted in an excellent dose-response curves. The effect of growth hormone releasing hormone was inhibited by somatostatin. Likewise, the effect of LHRH was inhibited by pretreatment with LHRH antagonists.

N.9.2.5 Radioimmunoassay of rat-LH

PURPOSE AND RATIONALE

Luteinizing hormone is a glycoprotein hormone exhibiting species specificity. For pharmacological experiments in rats, such as evaluation of gonadotropin releasing hormone activity, a homologous assay is necessary. The reagents are provided by the National Pituitary Agency, Bethesda, Md. The assay procedure is similar to the standard operating procedure proposed by the National Pituitary Agency, USA.

PROCEDURE

Reagents

Standard:	NIH-rat-LH-RP 1
Antiserum:	rabbit-anti-rat-S 9
Tracer:	^{125}I-rat-LH-I 6
Second antibody:	Behring goat-anti-rabbit-gamma-globulin, (Behring, Cat. No. OTOP 14/15)
Buffer:	0.01 M-phosphate-saline pH 7.4

Standard and samples are dissolved in 1% bovine serum albumin, tracer in 0.1% bovine serum albumin, and antiserum in EDTA-PBS (1 : 350 normal rabbit serum as carrier).

Assay

Standards:	0.25–62.5 ng/tube, 200 µl/tube
Antiserum:	1 : 20 000 100 µl/tube,
Tracer:	specific activity 120 µCi/µg, 8 000 cpm in 100 µl/tube

Standards (or sample) are incubated with antiserum and tracer for 48 h at +4 °C, the second antibody 1 : 50, 200 µl/tube is added, and incubated for 24 h at +4 °C. Separation is performed with 1.0 ml ice-cold phosphate buffered saline pH 7.4, the vial spun at 1 300 *g* for 15 min, the supernatant decanted, and the residue counted for 1 min in a gamma-counter.

EVALUATION

Data processing: standard curves and sample data are calculated on a computer program using a spline function.

Quality control parameters

Limit of detection:	0.36 ng per tube
Standard curve (ED_{80}-ED_{50}-ED_{20}):	1.31-4.56-15.74 ng per tube
Inter-assay CV (15 assays):	20.9%
Intra-assay CV:	<15 %

PURPOSE AND RATIONALE

Follicle-stimulating hormone is a glycoprotein hormone exhibiting species specificity. For pharmacological experiments in rats, such as evaluation of gonadotropin releasing hormone activity, a homologous assay is necessary. The reagents and the procedure are provided by the National Pituitary Agency, Bethesda, Md. The assay procedure is similar to the standard operating procedure proposed by the National Pituitary Agency, USA.

PROCEDURE

Reagents

Standard:	NIAMDD-rat-FSH-RP-1
Antiserum:	rabbit-anti-rat-FSH (NIAMDD-S-9)
Tracer:	^{125}I-rat-FSH (e.g. NIAMDD-I-4)
Second antibody:	Behring goat-anti-rabbit-gamma-globulin, (Behring, Cat. No. OTOP 14/15)
Buffer:	0.01 M-phosphate-saline/0.1% bovine serum albumin, pH 7.4

Assay

Standards:	6.25–1 600 ng/tube, 200 µl/tube
Antiserum:	1 : 2 000 100 µl/tube,
Tracer:	specific activity 200 µCi/µg, 10 000 cpm in 100 µl/tube

Standards (or sample) are incubated with antiserum and tracer for 72 h at +4 °C, the second antibody 1 : 50, 200 µl/tube is added, and incubated for 48 h at +4 °C. Separation is performed with 1.0 ml ice-cold phosphate buffered saline pH 7.4, the vial spun at 1 300 *g* for 15 min, the supernatant decanted, and the residue counted for 1 min in a gamma-counter.

EVALUATION

Data processing: standard curves and sample data are calculated on a computer program using a spline function.

N.9.2.7 Measurement of ascorbic acid depletion in ovaries of pseudo-pregnant rats

PURPOSE AND RATIONALE

The assay for LH-RH and LH-RH analogues can be performed in one step in pseudopregnant immature female rats using the biological response of the luteinized ovaries to gonadotropins released by the test compounds. Pseudopregnancy is induced in immature female Sprague-Dawley rats by treatment with gonadotropins. Numerous corpora lutea are formed after ovulation. On day 7–8 after start of the treatment the corpora lutea are very sensitive to endogenous or exogenous gonadotropins. Stimulation of steroid synthesis, mainly progesterone, is seen associated with dose dependent ascorbic acid depletion in the ovaries. The activity of LH-RH and LH-RH analogues can be determined by the decrease of ovarian ascorbic acid concentration, or increase in progesterone secretion. Ascorbic acid depletion is a sensitive parameter for the endogenous gonadotropin release in the animals.

PROCEDURE

Immature female Sprague-Dawley rats weighing 35–45 g are pretreated with 50 IU PMSG followed by an injection of 25 IU HCG on the third day. On day 7 or 8, they are injected i.m. or s.c. with the test preparation or the LH-RH standard in 0.1 ml 1% gelatine-saline. Eight animals are used for each of three doses of test preparation and standard. One hour later, the ovaries are dissected out, homogenized, and ascorbic acid is determined according to the method of Mindlin and Butler (1938) by photometry.

EVALUATION

Dose-response curves of ascorbic acid depletion are obtained for test preparation and standard allowing the calculation of potency ratios with confidence limits.

MODIFICATION OF THE METHOD

The method has been adopted as biological assay of gonadorelin with some modifications by pharmacopoeias, e.g. the British Pharmacopoeia 1988.

N.9.2.8 Progesterone production in pseudopregnant rats

PURPOSE AND RATIONALE

Pseudopregnancy is induced in immature rats by pretreatment with gonadotropins. Numerous corpora lutea are formed after ovulation which are sensitive to endogenous gonadotropins released by LH-RH or LH-RH analogues on day 6–8 after treatment. By measurement of plasma progesterone, the steroidogenic activity of LH-RH analogues can be determined.

PROCEDURE

Immature female Sprague-Dawley rats weighing 35–45 g are pretreated with 50 IU PMSG (Pregnant mare serum gonadotropin) followed by an injection of 25 IU HCG (human chorionic gonadotropin) on the third day. They are injected intramuscularly with LH-RH or the LH-RH analogue on days 6,7, or 9 between 8 and 10 A.M. Eight animals are used for each of three doses of test preparation and standard. Blood samples are collected 1 h after treatment. Plasma samples of equal volume are extracted with peroxide free diethylether. The ether phase containing progesterone is evaporated and the sample re-dissolved in BSA-phosphate buffer. Tritium labeled progesterone and a specific antiserum against progesterone are added and incubated over a period of 24 h at 4 °C. Bound hormone and free hormone are separated by absorption on dextran coated charcoal. The activity of the sample is determined in a scintillation cocktail containing Triton X.

EVALUATION

Dose-response curves of progesterone concentrations are established for test preparation and standard allowing the calculation of potency ratios with confidence limits.

N.9.2.9 Induction of ovulation in rabbits

PURPOSE AND RATIONALE

Ovulation can be induced in mature rabbits by injection of LH-RH after initial priming. This is a modified assay for LH release.

PROCEDURE

Six unmated, mature female rabbits (Himalayan strain) weighing 1,0 to 1,2 kg are used for each dose of standard or test preparation. Follicular maturation is induced by 8 subsequent daily subcutaneous injections of LH-RH or the LH-RH analogue to be tested in 0.2 ml 1% gelatine-saline. Forty-eight hours after the last injection, ovulation is induced by administering a four- to tenfold higher dose of the peptide in 0.2 ml subcutaneously. Twenty-four hours later, the animals are sacrificed, the ovaries weighed and ovulation is determined by counting the numbers of follicles ovulated in the ovaries, as defined by local bleeding.

EVALUATION

At least two doses of test preparation and standard are used in order to establish dose-response curves allowing calculation of potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

Schröder et al. (1972), Sandow and Hahn (1973) described changes in the ovary transplanted to the anterior eye chamber in the rabbit enabling the direct observation of ovulation. This method is also applicable to steroids and prostaglandins.

REFERENCES

N.9.2.10 Induction of superovulation in immature rats

PURPOSE AND RATIONALE

Immature female rats (24–26 days of age) do not show vaginal cycles before the onset of puberty. Treatment with PMSG induces follicular maturation, followed by spontaneous ovulation 2 days later. Spontaneous ovulation can be blocked by barbiturates (e.g., phenobarbital) acting on the hypothalamus, and is overcome by exogenous LHRH. The rats ovulate due to the release of endogenous gonadotropins. After hypophysectomy, no ovulatory activity is observed in the absence of the pituitary.

PROCEDURE

Immature female Sprague-Dawley rats weighing 55–65 g are injected on day 1 with 10 IU PMSG subcutaneously. Following this pretreatment, the animals will ovulate spontaneously on day 3 between 2:00 and 4:00 P.M. Spontaneous ovulation is blocked by phenobarbital 4 mg/kg at 1:00 P.M. One hour later, the ovulatory peptide, dissolved in 1% gelatine/saline, is injected intravenously. Controls are treated with 1 or 2 IU HCG, negative controls with gelatine-saline only. Eight rats are used for control groups and various doses of LH-RH or the LH-RH analogue. On the next day, the rats are sacrificed at 11:00 A.M. and the oviducts are dissected and stained with Patent blue. The number of ova is counted under a microscope.

EVALUATION

A dose-dependent increase of ova per rat is observed after LHRH due to LH release and after HCG by direct action on the ovary. The effect of LH-RH analogues is compared with the effects of HCG. Minimal effective doses for LH release can be calculated.

REFERENCES

N.9.2.11 Inhibition of experimentally induced endometriosis

PURPOSE AND RATIONALE

This is an example of a disease model in animals designed to mimic treatment of an experimentally induced pathological condition. Endometriosis-like lesions can be induced in female rats by autotransplantation of endometrium under the renal capsule (Sakata et al. 1990; Mizutani et al. 1995). This method was used to compare the effect of steroid-suppression by LHRH analogue after chronic administration (pituitary inhibition).

PROCEDURE

Under anesthesia laparatomy is performed in 9-week old female Sprague Dawley rats. The left uterine horn is resected and opened by a longitudinal incision. The endometrium is dissected from the myometrium. Then a 5×5 mm section of the endometrium is grafted under the capsule of the left kidney of the same animal. Two weeks later, the attachment and the viability of the endometrial explant are examined by a second laparatomy, length, width, and height of the explant are measured and the volume is then calculated. The criterion for a viable graft is fluid accumulation around the lesion. The rate of induction of endometriosis is more than 80%. Animals with endometriosis (with body weights of approximately 250 g) are randomly divided into treatment groups of 10 animals each. Gonadotropin-releasing hormone agonists are injected at doses of 15 or 30 µg/kg subcutaneously daily for 3 weeks. A third laparatomy is performed 3 weeks after the beginning of the experiment. The presence of fluid accumulation and the size of the endometrial explant are examined. The explant is excised and fixed in 10% formalin for histological evaluation.

EVALUATION

The evaluation of treatment on the regression of lesions in experimental endometriosis is analyzed statistically with the χ^2 test.

N.9.3
LH-RH antagonistic activity

N.9.3.1
Testosterone suppression in rats

PURPOSE AND RATIONALE

LH-RH antagonists suppress endogenous secretion of LH and testosterone in adult male rats after single subcutaneous injection, and after repeated dosing (Loy 1994).

PROCEDURE

Groups of 8 adult male Wistar rats weighing 200–250 g are injected subcutaneously with various doses of the test compound or a reference LHRH antagonist dissolved in 5% mannitol solution. Four hours later, rats are decapitated and blood is collected from the trunk. Serum is separated in a refrigerated centrifuge (10 min at 3 000 *g*), and stored frozen at –20 °C until assay.

Radioimmunoassay for testosterone

Serum testosterone is measured by radioimmunoassay in serum extracts using a specific antiserum without prior chromatography, or by direct assay in serum depending on the method. Serum samples of 0.5 ml are extracted with 2 ml of freshly purified, peroxide-free diethylether by shaking for 60 s on a Vortex type mixer. The aqueous phase is frozen at –70 °C, the ether phase containing testosterone is transferred to conical test tubes, and evaporated under a stream of dry nitrogen. The dry residue is re-dissolved in BSA/phosphate buffer (1% BSA = bovine serum albumin) for RIA. (1,2,6,7-3H)-Testosterone (New England Nuclear NET 367) and a specific antiserum (AS-781, Behringwerke, Marburg/ Germany) are added and incubated over a period of 24 h at +4 °C under nonequilibrium conditions. Bound hormone and free hormone are separated by adsorption on dextran-coated charcoal by incubation for 30 min at +4 °C and centrifugation at 3 000 *g* for 15 min. 500 µl of supernatant are transferred into minivials and scintillation cocktail is added. Radioactivity is determined in a beta-counter.

EVALUATION

The hormone levels in the sample are calculated from a standard curve by means of a computer program, using appropriate control sera. Using various doses of standard and test preparation dose-response curves can be established allowing calculation of potency ratios with confidence limits. Alternatively, minimum effective doses can be calculated from comparisons with controls. Using different time intervals, e.g., 4, 8, and 24 h, the duration of the effect can be evaluated.

MODIFICATIONS OF THE METHOD

Testosterone suppression can be measured in several animal species, e.g., dogs and marmoset monkeys, or cynomolgus monkeys (Habenicht et al. 1990).

Ayalon et al. (1993) tested the potency of the LH-RH antagonist on the pituitary-gonadal system of female castrated and intact ovulating rats.

Reissmann et al. (1996) investigated the antitumor and hormone-suppressive effect of the LH-RH antagonist Cetrorelix in the model of DMBA-induced mammary carcinoma in female rats and by testosterone determination in normal male rats.

Danzo (1995) studied the effect of a gonadotropin-releasing hormone antagonist on androgen-binding protein production and its distribution among the epididymis, seminiferous tubule fluid, testicular interstitial fluid, and blood in rats.

Fallest et al. (1995) studied the transcriptional regulation of the rat luteinizing hormone β (rLHβ) gene through the use of **transgenic mice** bearing a region of the rLHβ gene linked to a luciferase (LUC) reporter gene. The postgonadectomy rise in pituitary rLHβLUC activity in females and males was blocked by daily administration of the GnRH antagonist Antide.

Rivier et al. (1996) synthesized and evaluated many GnRH analogs and established a dose relationship between GnRH antagonists and pituitary suppression.

Such assays are suitable for initial compounds screening and need to be checked for relevance of the results in intact animals.

N.9.3.2 Antiovulatory activity in rats

PURPOSE AND RATIONALE

The rat antiovulatory assay (AOA) was widely used for LHRH antagonists. Immature female rats (24–26 days of age) are primed with pregnant mare serum gonadotropin (PMSG) to induce follicular maturation, followed by spontaneous ovulation 2 days later. The endogenous hypothalamic LH-RH discharge can be blocked by barbiturates (e.g., phenobarbital) to prevent spontaneous ovulation (see N.9.2.10). For anti-ovulatory activity, a test dose of 800 ng exogenous LH-RH is administered together with increasing doses of the LH-RH antagonist. The antagonist will then inhibit the LHRH-induced gonadotropin release. The test measures the dose of LH-RH antagonist required to inhibit the effect of a standard dose of LH-RH.

PROCEDURE

Immature female Wistar rats weighing 55–65 g are injected on day 1 at 9:00 A.M. with 10 IU PMSG subcutaneously. This priming induces follicular maturation and estradiol secretion. A spontaneous, endogenous LH discharge is observed on day 3 between 2:00 and 4:00 P.M. The release of LH and spontaneous ovulation is blocked by i.p. injection of phenobarbital 4 mg/kg on day 3 at 1:00 P.M. The LH-RH antagonist is administered in various doses s.c. or i.p. or i.v. 30 min before phenobarbital injection. Two hours later, a standard dose of 800 ng LH-RH is injected subcutaneously to induce ovulation. Control groups receive phenobarbital only (negative control) or phenobarbital and 800 ng LH-RH (positive control). Six to 8 rats are used for control groups and various doses of the LH-RH antagonist. On the next day, the rats are sacrificed at 9:00 A.M. Both ovaries are prepared and weighed. The oviducts are dissected and stained with Patent blue. The number of ova is counted under a microscope. An effective dose of antagonist prevents LH-RH-induced ovulation.

EVALUATION

A dose-dependent suppression of induced ovulation is observed after the LH-RH antagonist. ID_{50} values can be calculated for various LH-RH antagonists according to the procedure of Litchfield-Wilcoxon. Minimal effective doses which fully suppress ovulation in each animal are calculated.

MODIFICATIONS OF THE METHOD

De la Cruz et al. (1975) described the blockade of the pre-ovulatory LH surge in **hamsters** by an inhibitory analog of LH-RH.

Kovács et al. (1993) found that in ovarectomized and normally cycling rats antiovulatory doses of antagonists of LH-RH inhibit LH and progesterone but not FSH and estradiol release.

Evaluation of biological activities of new LH-RH antagonists in male and female rats was reported by Pinski et al. (1993).

Rivier et al. (1995) tested a series of gonadotropin-releasing hormone antagonists in the rat antiovulatory assay.

Pinski et al. (1995) evaluated the optical isomers of the LH-RH antagonist Cetrorelix in ovulation inhibition in rats and in suppression of LH levels.

N.9.3.3 Effect of repeated administration of LH-RH antagonists in rats

PURPOSE AND RATIONALE

Repeated administration of LH-RH antagonists reduces the testosterone secretion in serum and tissue content in the testes, and also decreases weight of testosterone dependent organs, such as prostate and seminal vesicles. Moreover, pituitary LH content is decreased and the secretory capacity of testes for testosterone is diminished. The effects are similar to those after supraphysiological doses of LHRH agonists (paradoxical antifertility effects).

PROCEDURE

Male Wistar rats with an initial weight between 150 and 200 g are housed under standard conditions. They are treated with daily injections of the LH-RH antagonist for a period of 7 days up to 4 weeks. Alternatively, the LH-RH antagonist can be administered subcutaneously by infusion via minipumps or other routes of administration. Animals, receiving the vehicle serve as controls, and rats castrated at the beginning of the experiment may be included for maximum inhibition. At the end of the treatment period, the animals are sacrificed 4 h after the last administration. Blood is collected for testosterone determination by radioimmunoassay. The androgen-dependent organs, testes, epididymides, ventral prostate, and seminal vesicles are dissected and weighed to the nearest 0.1 mg. The testes are decapsulated and incubated with 250 mU HCG in order to determine secretory capacity for testosterone. The testosterone tissue content is determined in the supernatant fraction of a testicular homogenate in the absence of HCG (unstimulated testis), and after 3 h of incubation of the contralateral testis with HCG (stimulated testis). Pituitary glands are dissected and the anterior lobe is frozen at –20 °C for determination of LH by rat-specific radioimmunoassay (N.9.2.5). LH receptors in anterior pituitary homogenate are measured by binding of ^{125}I-buserelin *in vitro*.

EVALUATION

The effects of various doses of the LH-RH antagonist after various time intervals on the different parameters mentioned above are compared with values of intact controls and castrated animals. Significant differences vs. controls at 95% level are calculated by Dunnett's test.

MODIFICATIONS OF THE METHOD

These are mainly models for contraceptive applications and tumor suppression using LHRH antagonists.

Kangasniemi et al. (1996) used a combined treatment with a GnRH antagonist and an antiandrogen (flutamide) to suppress spermatogenesis in mice. Despite this effect, the treatment did not enhance recovery from spermatogenesis produced by a 10-Gray dose of radiation.

Hikim and Swerdloff (1993, 1994) examined the time course of suppression and recovery of spermatogenesis and its relationship to the temporal changes in circulating levels of gonadotropin and testosterone and intratesticular testosterone levels after cessation of treatment with a potent GnRH antagonist.

N.9.3.4 Inhibition of gonadotropin release from anterior pituitary cultures

PURPOSE AND RATIONALE

The same methods as being used for studying the stimulation of gonadotropin release by LH-RH agonists (N.9.2.3, N.9.2.4) can be used for assessment of LH-RH antagonists.

PROCEDURE

Anterior pituitaries of young adult Sprague-Dawley rats are digested with collagenase for 1 h followed by a mechanical dispersion. The resulting cell suspension from 1.5 pituitaries, containing mostly small clusters of cells, is then sedimented together with a suspension of Sephadex G-10 (Sigma) and packed into 6.6-mm columns. Tissue culture medium 199 (Sigma) with supplements, equilibrated with 95% air/5% carbon dioxide, is perfused through the columns at a flow rate of 0.33 ml/min. After an overnight recovery period, during which the baseline stabilizes and the cells regain their full responsiveness, the samples to be tested are introduced through a four-way valve. During a 9 h experimental period, 180 one ml fractions are collected. The system is standardized with 3-min exposures to 100 mM potassium chloride or 3 nM LH-RH. The compounds are introduced in various concentrations, generally for 3–9 min (time of 1–3 fractions), at 30 min intervals. Rat LH levels are measured from aliquots (50 µl) of the collected medium effluent by radioimmunoassay. As a standard, rat LH-RP2 reference standard is used. Repeated stimulation with 3 nM LH-RH for 3 min at 30 min intervals results in a pulsatile LH release.

EVALUATION

The suppression of pulsatile LH release due to repeated administration of LH-RH by antagonists is evaluated.

MODIFICATIONS OF THE METHOD

Krummen et al. (1991) assessed the direct effects of testosterone in primary cultures of pituitary cells.

A special long term superfusion system was developed by Rékási et al. (1993) in order to evaluate the effects of cytotoxic compounds linked to LHRH analogs on different types of rat pituitary cells. LH, GH and PRL were determined simultaneously in the effluent.

N.9.3.5 Anti-tumor affect of LH-RH antagonists

PURPOSE AND RATIONALE

LR-RH antagonists were found to inhibit experimental tumors in rats and mice.

PROCEDURE

To induce mammary carcinomas, female rats are given a single dose of DMBA (dimethylbenzanthracene)/animal at the age of 50 days. The first mammary tumors can be detected 20–30 days later. The tumor weight is determined by palpation, comparing the volume of each tumor to that of preformed plasticine models. The

tumor weight is calculated by multiplication of the model weight by a factor which takes account the specific weights of plasticine and tumor tissue. After the total tumor mass per animal has reached about 1 g, the animals are randomly divided into treatment groups. At least 8 animals are used per group. The rats are treated for 3 weeks with different subcutaneous doses of LH-RH antagonists or vehicle. The experiment is terminated at the end of the 3rd week from the initiation of the experiment. Histological examination of the tumors is performed.

EVALUATION

The change in tumor volume is calculated on the basis of individual responses. For determination of the mitotic index, 4 000 cells are considered in each tumor.

MODIFICATIONS OF THE METHOD

Reduction of tumor weight in female BDF_1 mice bearing MXT mammary adenocarcinomas after treatment for 3 weeks with a LH-RH antagonist was reported by Szende et al. (1990).

Inhibition of MIA PaCa-2 human pancreatic xenografts in nude mice by a LH-RH antagonist was reported by Radulovic et al. (1993).

The involvement of insulin-like growth factors in growth regulation of the Ishikawa endometrial tumor cell line and the possible interference of LH-RH analogues was evaluated by Kleinman et al. (1993).

Pinski et al. (1994) investigated the effects of treatment with a LH-RH antagonist and a LH-RH agonist in Copenhagen rats bearing the anaplastic androgen-independent Dunning R-3 327-AT-1 prostatic adenocarcinoma implanted orthotopically into the ventral lobes of prostate glands.

Vincze at al (1994) tested the anti-tumor effect of the gonadotropin-releasing hormone antagonist MI-1 544 *in vitro* on human breast cancer lines and *in vivo* on xenografts in immunosuppressed mice.

Manetta et al. (1995) reported the *in vitro* and *in vivo* inhibitory effects of a LH-RH antagonist against a panel of human ovarian carcinomas.

The effects of LH-RH and a LH-RH antagonist on cell growth and production of hCG and cAMP in JAR human chorioncarcinoma cells were examined *in vitro* by Horváth et al. (1995).

N.9.4 Corticotropin releasing hormone (CRH)

N.9.4.1 General considerations

A hypothalamic factor inducing release of corticotropin (ACTH) from pituitaries was the first of the hypothalamic releasing hormones identified by using *in vitro* bioassays (Saffran and Schally 1955; Guillemin and Rosenberg 1955). A common pre-pro-hormone, opiomelanocortin was identified as the source of corticotropins and endorphins. Much later, the structure of a 41-residue ovine hypothalamic peptide stimulating the secretion of corticotropin and β-endorphin could be identified (Vale et al. 1981), followed by the elucidation of the structure of human CRH (Shibahara et al. 1983) and of other species, such as porcine CRF (Patthy et al. 1985) and equine CRF (Livesey et al. 1991). Reviews are given by Brodish (1979), Rivier and Plotsky (1986), Taylor and Fishman (1988). Conformational differences of ovine and human corticotropin releasing hormone using circular dichroism, Fourier transform infrared spectroscopy, NMR and dynamic light scattering were reported (Dahte et al. 1996).

The binding sites of immunoreactive corticotropin-releasing hormone in the rat ovary and its potential

physiological role were studied by Mastorakos et al. (1993).

Studies on CRF receptors in the pituitary have been performed (Wynn et al. 1983; Millan et al. 1987). Investigations on general pharmacological properties of human corticotropin-releasing hormone did not reveal any considerable side effects (Andoh et al. 1994).

Derivatives with agonistic and antagonistic properties have been synthesized and tested (Rivier et al. 1984; Kornreich et al. 1992; Chen et al. 1996; Schulz et al. 1996; Webster et al. 1996; Arai et al. 1998).

Studies with **CRF antagonists** indicate a role of CRF in certain psychiatric diseases (Schulz et al. 1996) and drug addiction (Koob 1999). This is in line with the known clinical psychotropic effects of corticotropin and glucocorticoids at elevated doses.

The role of corticotropin-releasing hormone in inflammatory processes was investigated by Webster et al. (1998).

Non-mammalian peptides, sauvagine (from frog) and **urotensin** 1 (from fish) have approximately 50% sequence homology with CRF and share *in vitro* and physiological actions characteristic of CRF (Rivier et al. 1983). A mammalian urotensin-like peptide (named **urocortin**) with partial sequence identity with urotensin 1 and CRF has been identified in rat (Vaughn et al. 1995) and human (Donaldson et al. 1996) tissues. The mouse and human urocortin genes have been isolated and characterized (Zhao et al. 1998).

A **corticotropin releasing factor binding protein (CRFBP)** was isolated which is thought to an important modulator of CRF both in the CNS and in the periphery (Behan et al. 1995; Petraglia et al. 1996; Cortright et al. 1997; Hobel et al. 1999). A rise in CRF-BP levels at 30–35 weeks of pregnancy with a dramatic decrease at 38–40 weeks have been shown. *In vitro*, CRF-BP inhibits the ACTH releasing properties of CRF.

Cortright et al. (1995) described a mouse brain corticotropin-releasing hormone-binding protein (CRH-BP) highly homologous to human and rat CRH-BPs, but distinct from the corticotropin-releasing hormone receptor.

Stenzel-Poore et al. (1996) described **transgenic mice** with CRH overproduction inducing behavioral changes that parallel the stress syndrome.

N.9.4.2 *In vitro* assay for CRH activity

PURPOSE AND RATIONALE

The first *in vitro* assay procedures to detect CRF activity (Saffran and Schally 1955; Saffran et al. 1955) were based on incubation of rat anterior pituitary halves with the test substances in bicarbonate-buffered, oxygenated medium at 38 °C for 1 h in the presence of 0.0004 M DL-arterenol and 0.004 M ascorbate followed by measurement of ACTH release into the medium by incubation with adrenal tissue and determination of corticosterone (a two stage bioassay where a biological product of CRH action is determined by a quantitative biological response). Guillemin and Rosenberg (1955) used pituitary tissue culture from rat and dog and determined the ACTH activity in the medium by the *in vivo* ascorbic acid depletion method in the rat according to Sayers (1954) (see N.7.4.1). The assay was later considerably simplified by using ACTH RIA. Several modifications of these procedures have been used (Schally et al. 1968; Yasuda et al. 1982). Most investigators used rat pituitary cell cultures (Giguère and Labrie 1982; Giguère et al. 1982; Bilezikjan and Vale 1983; Aguilera et al. 1983; Vale et al. 1983a,b; Patthy et al. 1985), while pituitary segments have been used by Antoni et al. (1983) and by Widmaier and Dallman (1984).

PROCEDURE

Anterior pituitaries are obtained from adult Sprague-Dawley rats, cut into small pieces and incubated in a Dubnoff incubator for 45 min at 37 °C in 10 ml of oxygenated Medium 199 (GIBCO) containing 0.5% collagenase, 0.25% BSA, and 50 µg/ml gentamycin. The fragments can be easily dispersed mechanically into single cells by repeated suction and expulsion from a pipette. The cell suspension is centrifuged at room temperature for 10 min at 100 *g*. The cell pellet is then resuspended in 1.0 ml of medium and divided into 4 equal volumes. Each volume (containing about 5×10^6 cells) is mixed with 0.5 ml Sephadex G-15 which has been equilibrated previously with oxygenated medium. The mixture of pituitary cells and Sephadex is transferred into 4 chambers of a superfusion apparatus (Vigh and Schally 1984; Czernus and Schally 1991) consisting of a number of 1 ml plastic syringe barrels (modified by cutting off their distal end) mounted vertically in a Plexiglas holder which is kept at 37 °C by circulating water. Each barrel is fitted with plungers at both ends. Holes are drilled in the plungers to accommodate plastic tubing. The lower plunger is covered with a small piece of 30 µm-pore nylon net

to keep the Sephadex beads from escaping. The "pores" between the beads are small enough to prevent the pituitary cells from escaping and large enough to allow unrestricted flow of medium through the column. The upper plunger tubing is used for directing the flow through the chamber from the medium reservoir. The flow through the system is controlled by a multichannel peristaltic pump which is placed after the superfusion chamber. Thus, the system is operated by suction with negative pressure.

The cells are perfused overnight with medium 199 (Sigma) at a flow rate of 20 ml/h. The samples are administered every half h for 3 min and 1-ml fractions are collected at 3-min intervals. Synthetic CRF at 0.2 and 2 mM is used as standard. The corticotropin released into the medium is measured by a specific RIA for corticotropin.

EVALUATION

Dose-response curves are established for test preparation and standard allowing calculation of potency ratios with confidence limits.

N.9.4.3 *In vivo* bioassay of CRH activity

PURPOSE AND RATIONALE

Munson and Briggs (1955) described an assay using morphine and pentobarbital pretreated rats. Many modifications for a reliable *in vivo* bioassay of CRH activity have been tested including rats with hypothalamic lesions (Schally 1968; Yasuda et al. 1982). Arimura et al. (1967) described an assay for corticotropin-releasing factor (CRF) using rats treated with morphine, chlorpromazine, dexamethasone and nembutal. This assay has been further improved by Graf et al. (1985).

PROCEDURE

Male Sprague-Dawley rats weighing about 200 g are maintained on a 12:12 h light:dark cycle at constant temperature for at least 5 days before use. On the day of the experiment, the rats are prepared with an initial single subcutaneous injection of a mixture of chlorpromazine (10 mg/kg) and morphine sulfate (20 mg/kg) followed after 75 min by pentobarbital (25 mg/kg) i.p. Sixty min after the injection of pentobarbital, various doses of test substances or standard or vehicle (0.9% NaCl, 1% BSA, 0.1% ascorbic acid) are injected into an exposed jugular vein. Blood samples (0.5 ml) are collected in heparinized syringes immediately before and 30 min after injection of test substances. The

blood is transferred to chilled polypropylene tubes containing EDTA (1.0 mg) and aprotinin (Trasylol®, 50 µl) and centrifuged (2 000 *g*, 15 min 4 °C). Plasma samples are stored at –20 °C for corticosterone assay using a crossreacting cortisol RIA that also measures corticosterone, the main corticoid secreted by rats, or a corticosterone RIA.

EVALUATION

Data for CRH activity of experimental groups are evaluated by analysis of variance or covariance followed by Duncan's multiple range test.

N.9.4.4 Collection of hypophyseal portal blood in rats

PURPOSE AND RATIONALE

Worthington (1966), Porter and Smith (1967), Gibbs (1984), Sarkar and Minami (1991) described methods to collect hypophyseal portal blood in rats. These methods can be used to measure the changes in secretion of several hypothalamic hormones under the influence of various factors.

Gibbs and Vale (1982), Gibbs (1985a), Plotsky and Sawchenko (1987) studied the effect of various conditions on hypophyseal portal plasma levels of CRF and arginine vasopressin.

Luteinizing hormone-releasing hormone (LHRH) was determined by Ching (1982), Sarkar (1987), Petraglia et al. (1987),

thyrotropin releasing hormone (TRH) by Fink et al. (1982),

growth hormone-releasing hormone (GHRH) by Plotsky and Vale (1985),

β-endorphin by Sarkar and Yen (1985),

neuropeptide Y by Sutton et al. (1988),

vasoactive intestinal peptide by Sarkar (1989),

vasopressin and oxytocin by Gibbs (1984),

dopamine and epinephrine by Ben-Jonathan et al. (1977), Gibbs (1985).

PROCEDURE

Pentobarbital anesthetized rats are placed on an isothermal heating pad in a stereotactic instrument. After cannulation of the trachea, the animals are mechanically ventilated. The base of the skull is exposed by a transpharyngeal approach, and the basosphenoid bone is drilled away. The dura is cut and deflected, the rat is heparinized, and after the stalk is cut, a polyethylene cannula filled with saline is placed over the hypophyseal stalk for collection of blood. The cannula leads to an ice bath, and the distal end of the tubing ends in a fraction collector where portal blood is collected by gravity flow at a rate of about 10 µl/min.

EVALUATION

Portal plasma concentrations of CRH, LHRH, TRH, GHRH, β-endorphin, neuropeptide Y, vasoactive intestinal peptide, vasopressin and oxytocin and catecholamines were determined after various treatments and compared with control periods of spontaneous secretion.

MODIFICATIONS OF THE METHOD

Cowell et al. (1991) described *in vitro* models for the examination of the mechanisms controlling the secretion of hypothalamic hormones.

N.9.4.5 CRH receptor determination

PURPOSE AND RATIONALE

CRH mediates its effects through high-affinity receptors identified and characterized by radioreceptor studies, cellular signaling was measured by stimulation of adenyl cyclase in membrane fractions of rat brain, pituitary and spleen (Grigoriadis et al. 1993). Cloning studies indicate the existence of at least two types of mammalian receptor (De Souza et al. 1998). The CRF_1 receptor has been cloned from several species including human (Chen et al. 1993; Castro et al. 1996; Di Blasio et al. 1997; Grammatopoulos and Hillhouse 1998), mouse (Vita et al. 1993), and rat (Perrin et al. 1993). Species homologies are 98% identical over the full length of 415 amino acids.

There are three isoforms of the CRF_2 receptor: The $CRF_{2(a)}$ receptor which has been cloned from both rat (Lovenberg et al. 1995) and human (Liaw et al. 1996), is a 411 amino acid protein which shares approximately 70% identity with the CRF_1 receptor. The $CRF_{2(b)}$ receptor isoform has been cloned from rat (Lovenberg et al. 1995), mouse (Stenzel et al. 1995) and human (Kostich et al. 1996) and is 431 amino acids in length, differing from the $CRF_{2(a)}$ receptor in that the first 34 amino acids in the N-terminus are replaced by 54 different amino acids. The $CRF_{2(c)}$ receptor has been identified in human brain (Sperle et al. (1996).

The [^{125}I]sauvagine binding to CRH_2 receptors has been characterized by Rominger et al. (1998).

CRH in plasma is mostly bound to the corticotropin-releasing hormone-binding protein (CRH-BP) and is therefore inactive except for the free fraction. CRH-BP is predominantly produced by the liver and distributed and expressed differently from the CRH receptors (Cortright et al. 1995; Zhao et al. 1997).

Rhode et al. (1996) used whole brains of Wistar rats for the CRH receptor assay.

PROCEDURE

Whole brains of male Wistar rats weighing 220–250 *g* are homogenized with a Teflon-glass homogenizer (10 strokes at 800 rpm) in 0.32 M sucrose, 50 mM Tris/HCl (pH 7.2), 10 mM $MgCl_2$, 2 mM EGTA, and 0.15 mM bacitracin at 50 mg wet weight per ml. After centrifugation at 1 000 *g* for 5 min, the supernatant is centrifuged at 26 000 *g* for 20 min. The pellet is resuspended in 50 mM Tris/HCl (pH 7.2), 10 mM $MgCl_2$, 2 mM EGTA, adding 0.15 mM bacitracin and 0.0015% aprotinin (assay buffer) and again centrifuged. The pellet is suspended in assay buffer containing 0.32 M sucrose and stored at –20 °C. All steps are carried out at 4 °C. Protein concentrations are determined by the method of Bradford (1976) using BSA as standard.

One hundred µg of membrane preparation in 300 µl assay buffer are incubated in quadruplicate with 0.1 nM [^{125}I]Tyr-oCRH in the absence and presence of 12 different concentrations (0.2 nM up to 1 µM) of unlabeled peptides at 25 °C for 2 h. Nonspecific tracer binding is determined in the presence of 1 µM oCRH. At the end of incubation, 3 ml of ice-cold (assay buffer with-

out inhibitors containing 0.01% Triton X-100) is added to the assay tube and the samples are immediately filtered through GF/C filter discs (Whatman), presoaked for 2 h in 0.1% polyethylenimine using a Brandel-Harvester. The incubation tubes and filters are then washed with 3 ml cold washing buffer. Triton X-100 in this buffer strongly reduces nonspecific tracer binding. Radioactivity retained on the filter is measured by γ-counting.

EVALUATION

Receptor affinities (Kass, $K_d = 1 / \text{Kass}$) and capacities (B_{max}) are estimated using the nonlinear least-squares curve fitting program RADLIG (BIOSOFT, Cambridge, UK) and a K_d of 0.48 nM for the binding of the tracer peptide as determined from tracer saturation curves.

MODIFICATIONS OF THE METHOD

Schulz et al. (1996) used P2 membranes from human neuroblastoma IMR32 cells to test receptor binding of a selective nonpeptide antagonist of corticotropin releasing factor.

Webster et al. (1996) used rat frontal cortex, pituitary, cerebellum, and heart tissue for *in vitro* characterization of antalarmin, a nonpeptide CRH receptor antagonist.

Differences between normal and adenomatous pituitary corticotrophs in labeling characteristics of corticotropin-releasing hormone receptors were reported by Abs et al. (1997).

Rabadan-Diehl et al. (1997) studied the role of glucocorticoids and hypothalamic factors in regulation of pituitary corticotropin releasing hormone receptor mRNA and CRH during adrenalectomy in rats.

The differential regulation of hypothalamic pituitary corticotropin releasing hormone receptors during development of adjuvant-induced arthritis in rats was reported by Aguilera et al. (1997).

Grammatopoulos and Hillhouse (1998) reported the solubilization and biochemical characterization of the human myometrial corticotrophin-releasing hormone receptor.

The interaction between glucocorticoids and corticotropin releasing hormone in the regulation of the pituitary CRH receptor has been studied in rats by Ochedalski et al. (1998).

The multiple actions of corticotropin-releasing factor on neuroendocrine and behavioral functions were examined using high affinity, non-peptide antagonists (Lundkvist et al. 1996).

Wei et al. (1998) described analogs of CRH and urocortin with selective activity at CRH_1 and $CRH_{2\beta}$ receptors.

N.9.5
Growth hormone releasing hormone (GH-RH)

N.9.5.1
Radioreceptor assay of growth hormone-releasing hormone

PURPOSE AND RATIONALE

As for other polypeptide hormones, GHRH receptors may be used for quantification and potency estimates of relative binding affinities. Several agonistic and antagonistic analogs of human growth hormone-releasing hormone (hGH-RH) have been synthesized by various groups of investigators. The clinical and basic aspects of growth hormone-releasing peptides have been reviewed by Argente et al. (1996).

In vitro assays with pituitary cells have been used for screening biological activity of hGH-RH analogs prior to their evaluation *in vivo* (Campbell et al. 1991; Heiman et al. 1985; Kovacs et al. 1988). A careful determination of binding activities of the peptides to specific GH-RH receptors provides important data for the design of more active analogs. Several studies demonstrated that the radioligand, [His^1-,^{125}I-Tyr^{10},Nle^{27}]-hGH-RH(1-32)NH_2 binds specifically to a single class of receptors in rat pituitary cells and homogenates, and can be used for radioreceptor assay (Campbell et al. 1991; Seifert et al. 1985a,b; Struthers et al. 1989). The use of a radioreceptor assay for *in vitro* screening of analogs of growth hormone-releasing hormone was described by Halmos et al. (1993).

PROCEDURE

Pituitaries from male Sprague Dawley rats (250–300 g) are used to prepare crude membranes. Immediately after decapitation, anterior pituitaries are removed, rinsed with cold saline, and homogenized in 5 times their volume of homogenization buffer (50 mM Tris-HCl, 5 mM EDTA, 5 mM $MgCl_2$, 30 µg/ml bacitracin, pH 7.4) on ice using an Ultra-Turrax homogenizer at maximal speed. The homogenate is centrifuged at 500 *g* for 10 min at 4 °C. The supernatant containing the crude membrane fraction is again centrifuged at 70 000 *g* for 50 min at 4 °C. The pellet is washed twice by resuspending in ice-cold homogenization buffer and spinning. The final pellet is resuspended in homogenization buffer and stored at –70 °C until used for the receptor binding studies. Protein concentration is determined by the method of Bradford (1976) using a commercially available protein assay kit.

[His^1,^{125}I-Tyr^{10},Nle^{27}]hGH-RH(1-32)NH_2 is iodinated by the chloramine-T method (Greenwood et al. 1963). The receptor binding assay is carried out for

60 min in GH-RH binding buffer (50 mM Tris-HCl, 5 mM EDTA, 5 mM $MgCl_2$, 1% BSA, 30 µg/ml bacitracin, pH 7.4) at 24 °C. For saturation binding analyses, 50–150 µg membrane homogenates are incubated in duplicate with a least 6 concentrations of radio-ligand, ranging from 0.005 to 0.35 nM in the presence or absence of excess unlabeled peptide (1 µM) in a final volume of 300 µl. Incubation is terminated by immersing siliconized borosilicate tubes in ice water, transferring 270 µl of the suspension into cold siliconized polypropylene microfuge tubes, and centrifuging at 12 000 *g* for 2 min at 4 °C, and aspirating the supernatants. To reduce the nonspecific binding, 500 µl/tube of GH-RH binding buffer is added and the tubes recentrifuged. The washing step is repeated and the supernatant again aspirated. Finally, the bottoms of the tubes, containing the pellet, are cut off and counted for radioactivity in a gamma-counter.

In the competition experiments, which also include the specificity experiments, 50–100 µg of membrane homogenates are incubated in duplicate with 0.10–0.15 nM radioligand plus various concentrations of nonradioactive analogs and other peptides (10^{-12}–10^{-6} M).

EVALUATION

Percent specific binding is plotted against the log concentration of competitors. The curves are compared at the 50% specific binding levels (IC_{50}). The ligand-PC and McPherson computerized curve fitting programs of Munson and Rodbard (1980) are used to analyze competition and saturation data. To determine the types of receptor binding, dissociation constants (K_d) and the maximal binding capacity of receptors (B_{max}), the saturation binding data are also analyzed by the Scatchard method.

MODIFICATIONS OF THE METHOD

Carrick et al. (1995) described a rapid and sensitive binding assay for growth hormone releasing factor. Human embryonic kidney (HEK293) cells and rat pituitary tumor (GH_4C_1) cells were transfected with the porcine GRF receptor cDNA. Stably expressing cell lines are referred as 293-P2 and GH_4-P1, respectively. GH_4C_1 cells transfected with somatostatin receptor subtype 2 are called GH_4-R2.20 and HEK293 cells transfected with somatostatin receptor subtype 5 are called 293-R5.2. GH_4-P1 and 293-R5.2 were derived by the calcium phosphate method of transfection and 293-P2 and GH_4-R2.20 using lipofectamine. For binding assays, cells were removed from culture dishes by the addition of phosphate buffered saline containing 1 mM EDTA and cell membrane fractions prepared. Membrane pellets were suspended in 25 mM Tris, pH 7.4, plus protease inhibitors, aliquoted and stored at –80 °C. The binding assay consisted of approximately 25 pM radiolabeled ligand in the presence or absence of unlabeled ligand in assay buffer (50 mM HEPES, pH 7.4, 5 mM $MgCl_2$, 2 mM EGTA) and cell membranes (2–10 µg). The total assay volume of 200 µl included wheat germ agglutinin coated SPA beads at a concentration of 1 mg/assay, and for GRF binding, 0.05 mg/ml alamethicin (Sigma St. Luis, USA). Ninety-six well plates were used for most assays. Assays were agitated on a plate shaker for 3 h. Samples were counted on a Wallac Microbeta Counter for 1 min per sample. The conventional binding assay was performed (Mayo 1992), except that following binding and centrifugation the membranes were washed in 0.5 ml binding buffer, centrifuged and counted.

Abribat et al. (1990), Gaudreau et al. (1992) developed a binding assay for GH-RH in rat pituitaries. Using this technique, Lefrancois and Gaudreau (1994) tried to identify the receptor-binding pharmacophores of GHRH in rat pituitaries.

Hassan et al. (1995) developed a competitive binding assay using cloned porcine growth hormone-releasing hormone receptors in order to study structure-activity relationships.

Kaijkowsi et al. (1997) investigated growth hormone releasing hormone receptor structure and activity using yeast expression technologies.

Muccioli et al. (1998) characterized specific binding sites for synthetic GH secretagogues (sGHS) on membranes from pituitary gland and different human brain regions using a peptidyl sGHS (Tyr-Ala-hexarelin) which has been radio-iodinated to high specific activity at the Tyr residue.

N.9.5.2 Growth hormone release from rat pituitaries *in vitro*

PURPOSE AND RATIONALE

For testing of pituitary cell stimulation, isolated pituitary glands or cell cultures may be used. Antagonism by adding e.g. somatostatin is tested in the presence of a standard concentration of GHRH. Human GHRH has the structure of a 44-amino acid amide, which was isolated from human endocrine tumors and later confirmed as a hypothalamic hormone. The effect of GHRH analogues can be tested on isolated rat pituitaries measuring GH release. This test systems avoids the interference of counterregulatory somatostatin secretion which limits the duration of GH release *in vivo*.

PROCEDURE

The pituitaries of male Sprague-Dawley rats weighing about 100 g are quickly removed after decapitation. The posterior lobe is discarded and the anterior lobe is divided into two halves by a midsagittal cut. Five bisected hemipituitaries are incubated in plastic vials containing 4 ml TCM 199 with 0.1% BSA, 15 µg/ml penicillin and 25 µg/ml streptomycin. The vials are gassed with 95% O_2 and 5% CO_2. After 30 min of control incubation, the medium is changed and various doses of standard and test substances are added for an incubation of 90 min. GH content in the medium and in the pituitaries are determined by a specific radioimmunoassay (Schalch and Reichlin 1966).

EVALUATION

Dose-response curves are established for standard and test compounds measuring GH release into the medium and GH depletion from the pituitaries allowing calculation of potencies ratios with confidence limits.

MODIFICATIONS OF THE METHOD

Superfused pituitary cells may be used measuring activity and duration of effect, as well as interaction of stimulatory and inhibitory factors. Growth hormone releasing factor from tumors in human pancreas and from rat hypothalami as well as analogs of growth hormone-releasing hormone were evaluated in a superfused pituitary cell system (Vigh and Schally 1984; Czernus and Schally 1991; Halmos et al. 1993), see also Sect. N.9.4.2, *in vitro* assay for CRH activity. Anterior pituitaries of two young adult male Sprague Dawley rats were digested with 0.5% collagenase CLS2 (Worthington) for 50 min. After incubation, the fragments were digested into cell clusters (5–40 cells) by mechanical dispersion, and then transferred onto two columns and allowed to sediment simultaneously with 0.8 ml Sephadex G-10. The dead volume of the system was set to 1 ml. Medium 199 containing BSA (2.5 g/l), $NaHCO_3$ (2.2 g/l) and gentamycin sulfate (85 µg/ml) was equilibrated with a mixture of 95% air and 5% CO_2 and used as the culture medium. The medium was pumped at a flow rate of 0.33 ml/min. During an overnight recovery period, the baseline stabilized and the cells regained their full responsiveness. The samples were then infused through a four-way valve at 5×10^{-10} M concentration for 3 min (1 fraction) at 45-min intervals. Rat GH was determined by double-antibody radio-immunoassay.

The same system was used by Rekasi and Schally (1993) and Kovács et al. (1996a) to evaluate the activity of growth hormone-releasing hormone antagonists. For determination of the antagonistic activity, the cells were exposed to 10^{-8}, 10^{-7}, and 10^{-6} M GHRH antagonist simultaneously with 10^{-9} M GHRH or to 10^{-6} M

GHRH antagonist combined with 100 mM KCl (controls for potassium stimulated GH secretion) for 3 min. After 30 min, the duration of the inhibitory effect of GHRH antagonist was also tested by repeated 3-min infusions of 10^{-9} M GHRH.

Using this system with pituitaries of **transgenic mice** overexpressing the human GHRH gene, Kovacs et al. (1997) evaluated the effects of growth hormone-releasing hormone antagonists.

In addition to growth hormone release, Horváth et al. (1995) determined cAMP release from superfused rat pituitary cells stimulated by growth hormone-releasing hormone.

GH release was determined using cultured rat pituitary cells (Brazeau et al. 1982; Perkins et al. 1983; Scheikl-Lenz et al. 1985). Pituitary cells were prepared by enzyme dispersion with collagenase, DNAase and pancreatin. The cells were cultured for 3 days in microbiological Petri dishes in Dulbecco's modified essential medium with 20 mM HEPES, 15% fetal calf serum, 100 mU/ml penicillin-G and 100 µg/ml streptomycin at 37 °C and 10% CO_2.

Cheng et al. (1993) tested time- and dose-dependent growth hormone release by a non-peptidyl growth hormone secretagogue in rat pituitary cells.

Sanchez-Hormigo et al. (1998) tested growth hormone-releasing hexapeptide, one of several synthetic GH secretagogues, on growth hormone secretion from cultured porcine somatotropes.

Kovács et al. (1996b) measured the effects of chronic administration of a growth hormone-releasing hormone agonist on body weight, tibia length and tail length in growth hormone-deficient (monosodium glutamate-lesioned) rats.

Jacks et al. (1996) evaluated an orally active growth hormone secretagogue in dogs. Serum growth hormone levels were dose-dependently increased after oral and intravenous administration. Moreover, an increase of insulin-like growth factor and serum cortisol was found.

N.9.5.3
GH-RH bioassay by growth hormone release in rats

PURPOSE AND RATIONALE

Releasing activity can be determined by plasma GH stimulation after intravenous or subcutaneous injection of GH-RH in rats.

PROCEDURE

Male Sprague-Dawley rats weighing about 100 g are anesthetized by fractionated subcutaneous injections of 0.7 ml/kg of 25% urethane solution. The jugular vein is cannulated. Various doses of GH-RH test preparations or standard are injected intravenously in 0.2 ml 1% gelatine/saline. Fifteen min later blood samples are collected for determination of GH by a specific radioimmunoassay (Schalch and Reichlin 1966). The plasma concentration is expressed in terms of NIAMD-rat-GH-RP-1.

As a modification also suitable for other releasing hormones tested e.g. by subcutaneous application, a double-barreled polyethylene catheter is implanted into the jugular vein, one lumen being used for blood sampling, the second small lumen being used to keep the catheter open by heparin infused into the tip of the collection catheter. Blood is continuously withdrawn by a peristaltic pump and fractions of 500 µl heparinized blood are collected at intervals of 10 min. To compensate for blood losses, the erythrocyte fraction of 4–8 consecutive plasma samples is re-infused in a plasma expander (Haemaccel® 3.5%) via a femoral vein. Before treatment, two 2 min samples are collected, and after injection, two 2 min samples are collected again, followed by sampling intervals of 10 min for up to 3 h. GH is determined by a specific radioimmunoassay (Schalch and Reichlin 1966).

EVALUATION

Using several doses of standard and test preparation dose-response curves are established allowing calculation of potency ratio with confidence limits. Time concentration curves after subcutaneous or e.g. intranasal application allow to evaluate the duration of action.

MODIFICATIONS OF THE METHOD

Wehrenberg and Ling (1983), Wehrenberg et al. (1985) determined *in vivo* biological potency of rat and human growth hormone-releasing factor and fragments of human growth hormone-releasing factor in swivel-cannulated conscious freely moving rats and in cannulated anesthetized rats.

N.10
Other peptide hormones

N.10.1
Melanophore stimulating hormone

N.10.1.1
Skin darkening in whole amphibia

PURPOSE AND RATIONALE

MSH (Melanocyte stimulating hormone or melanotropin) is also called melanophore expanding hormone based on the microscopical observation of expansion of melanocytes in amphibia. Several amphibia species can be used, such as *Xenopus laevis*, *Rana temporaria* or *esculenta*, or *Hyla arborea*. Hypophysectomized animals are more sensitive than intact ones. Numerous corticotropin analogs have MSH activity based on a common peptide core shared with MSH. The structure of two melanocyte-stimulating hormones has been elucidated: α-MSH containing 13 amino acids, and β-MSH containing 18 amino acids.

Hunt (1995) reviewed the role of melanocyte-stimulating hormone as a regulator of human melanocyte physiology.

PROCEDURE

The pretest conditions require adaptation for blanching of the skin, e.g., by keeping the animals on a white background prior to the assay. *Xenopus laevis* or *Rana temporaria* are kept in single cages at 16 °C at humid conditions. Injections of various doses of the test preparation or the standard are given into the dorsal lymph sac. One hour later, the webs between the digits of the hind limbs are investigated under a stereomicroscope, the eyepiece of which is fitted with a photoelectric cell, the other being available for microscopic examination. The state of melanophore expansion can be assessed by direct visual examination and recorded in terms of an arbitrary melanophore index, or by modern methods of morphometry.

EVALUATION
For test preparation and standard, dose-response curves can be established and potency ratios calculated.

N.10.1.2 Assay in isolated amphibian skin

PURPOSE AND RATIONALE
Melanophores in isolated pieces of pale amphibian skin (from background adapted animals or maintained in MSH free medium) expand within a short period of time after immersion in a MSH-containing buffer. Subsequent immersion of the skin in fresh saline results in contraction of the melanophores (Trendelenburg 1926; Jores 1933). Several methods using isolated amphibian skin have been described using either light absorption or light reflection (Landgrebe and Waring 1962). These methods are historical and have been replaced by using cell cultures of melanocytes.

PROCEDURE
For studies on light absorption the skin of *Rana temporaria* or *Rana esculenta* is used. Before sacrificing the donor animal and dissecting the isolated skin, it is important to submit the living animal to varying white and black backgrounds under overhead illumination of a light source of 100 W, so that the melanophores can expand and contract before operation. The areas most suitable for using in this technique are from the thighs. Before using the skin for an actual assay, each piece should be immersed in a sufficiently concentrated MSH-solution to expand the melanophores almost but not quite fully. The skin is then washed with saline until the melanophores are fully contracted again and in a suitable condition for the test. This usually takes about 45 min. A piece of skin is mounted in a cell which holds the skin stretched and enables it to be immersed in saline or test solution. It is placed in position on the stage of a binocular microscope. An eyepiece is used for visual observation and a photoelectric cell is attached to the other connected directly to a sensitive galvanometer. Various concentrations of the test preparation or the standard are added. At least 6 skin pieces are used for each concentration of test preparation or standard. Galvanometer readings and readings of the melanophore index are taken simultaneously every 10–15 min until the maximum response is elicited, usually in 30 to 45 min.

EVALUATION
Assessment of potency is made from the readings of the melanophore index and from the light absorbed which is recorded as a percentage of the light originally passing through the skin and is plotted against the log concentration.

CRITICAL ASSESSMENT OF THE METHOD
The methods were originally developed to standardize extracts with MSH-activity by the use of a bioassay. They are still necessary to evaluate compounds for biological MSH-activity since not only natural ACTH but also synthetic peptides, such as β^{1-24}-corticotropin (Schuler et al. 1963) or β^{1-23}-corticotropin-23-amide (Vogel 1965, 1969), possess MSH-activity.

MODIFICATIONS OF THE METHOD
Measurement of light reflection of skin pieces instead of light absorption has been used by Shizume et al. (1954).

In **cell-based assays**, Siegrist and Eberle (1986), Bagutti and Eberle (1993, Sahm et al. 1993, 1966) used cultured mouse B16 melanoma cells in a sensitive *in situ* melanoma assay to study structure-activity of melanocyte-stimulating hormone peptides. B16 Cells were seeded at a density of 2 500 cells per well in 96-well microtest culture plates. After 24 h the cells were incubated in the presence of serial dilutions of MSH peptides for 3 to 5 days. The melanin released into the medium of each well was then determined spectrophotometrically at a wavelength of 405 nm using an automatic microplate reader calibrated against synthetic melanin.

Sahm et al. (1994, 1996) measured release of ^3H_2O into the medium from [3',5'-^{3}H]L-tyrosine by tyrosinase in B16 mouse melanoma cells after incubation with α-MSH analogues.

MSH assay have also been used to study the factors regulating the release of MSH (**MRF**) or inhibiting the release of MSH (**MIF**) (Kastin et al. 1969; Celis et al. 1971).

N.10.1.3 Binding to the melanocortin receptor

PURPOSE AND RATIONALE

Much of the initial work on biological effects of hormones has been expanded by using cloned subclasses of receptors for identification of more specific ligand compounds. A family of five MSH receptor subclasses for the melanocortic peptides has been identified (Chhajlani and Wikberg 1992; Chhajlani et al. 1993; Gantz et al. 1993b; Schiöth et al. 1988a; Strand 1999). The melanocortin MC_1 receptor is expressed in melanocytes and melanoma cells and binds α-MSH with high affinity. The MC_1 receptor plays an important role in skin and fur pigmentation in a variety of vertebrates (Cone et al. 1996). The melanocortin MC_2 receptor (i.e., the ACTH receptor) has a well-defined function of the steroid production in the adrenal gland (Schiöth et al. 1996a). The melanocortin MC_3 receptor is found in the hypothalamus, the brain and in the placenta, gut tissues and the heart (Gantz et al. 1993a; Sahm et al. 1994; Desarnaud et al. 1994). The melanocortin MC_4 receptor (Schiöth et al. 1996b, 1998b) has been found to affect feeding in rodents and may be important for weight homeostasis (Fan et al. 1997; Huszar et al. 1997). The melanocortin MC_5 receptor is primarily located in various peripheral tissues but has also been found in the brain (Labbé et al. 1994; Fathi et al. 1995).

Schiöth et al. (1998a) described binding of synthetic MSH analogues to the human melanocortin receptor subtypes.

Melanocortin-4 receptor antagonists increase food uptake in rats (Kask et al. 1998a,b; Skuladottir et al. 1999).

PROCEDURE

Expression of receptor clones

The human melanocortin MC_1 and human melanocortin MC_5 receptors are cloned into the expression vector pRc/CMV (In vitrogen). The human melanocortin MC_3 and human melanocortin MC_4 receptors were cloned into the expression vector pCMV/neo. For receptor expression COS-1 cells are grown in Dulbecco's modified Eagle's medium with 10% fetal calf serum. Eighty-percent confluent cultures are transfected with the DNA mixed with liposomes in serum-free medium. After transfection, the serum-free medium is replaced by serum-containing medium and the cells are cultivated for 48 h. Cells are then scraped off, centrifuged and used for radioligand binding.

Binding studies

The transfected cells are washed with binding buffer (Schiöth et al. 1995) and distributed into 96-well non-culture-coated plates, which are centrifuged and the binding buffer is removed. The cells are then immediately incubated in the well plates for 2 h at 37 °C with 0.05 ml binding buffer in each well containing a constant concentration of [125I]NDP (= [Nle^4-D-Phe^7]α-MSH) and appropriate concentrations of the competing unlabeled ligand. After incubation the cells are

washed with 0.2 ml of ice-cold binding buffer and detached from the plates with 0.2 ml of 0.1 M NaOH. Radioactivity is counted by a gamma-counter.

EVALUATION

Data are analyzed by fitting to formulas derived from the law of mass action. The method is generally referred to as computer modelling. K_d values for [125I]NDP are calculated (Schiöth et al. 1995, 1996a). The binding assays are performed in duplicate and repeated three times.

MODIFICATIONS OF THE METHOD

Alan et al. (1994) compared the behavioral effects of melanocortins with binding data on MC_3 and MC_4 receptors.

Sahm et al. (1996) studied receptor binding affinities and biological activities of linear and cyclic melanocortins in B16 murine melanoma cells expressing the native MC_1 receptor.

Quillan and Sadée (1996) searched for peptide ligands that cross-react with melanocortin receptors and found several peptides with previously unrecognized agonistic or antagonistic activity on amphibian and human melanocortin receptors.

Peng et al. (1997) compared the actions of C-terminally modified melanocortin peptides at rodent MC_1 and MC_3 receptors.

Bagutti et al. (1993) recommended [^{111}In]DTPA (diethylenetriaminopentaacetic acid)-labeled analogues of α-MSH as ligands for the detection of MSH receptors *in vitro* and *in vivo*.

Erskine-Grout et al. (1996) described functional photoaffinity-labeled, biotinylated and fluorescent probes for the melanoma MC_1 receptor.

N.10.2 Relaxin

N.10.2.1 General considerations

Relaxin is a peptide hormone originally prepared from sow ovaries. The hormone acts on collagen and induces increased flexibility of the pelvic girdle of guinea pigs. In mice, the length of interpubic ligament is increased. Moreover, relaxin inhibits spontaneous uterine motility. In addition to its effects on the reproductive tract, relaxin exerts hemodynamic effects (Coukson et al. 1996). The actions of relaxin as a pleiotropic hormone were reviewed by Bani (1997).

The therapeutic relevance of relaxin in man is still open to debate (Schwabe and Büllesbach 1994; Goldsmith et al. 1995).

The primary structure of relaxin is highly homologous to insulin. Unlike insulin, the structure of which is remarkably well conserved among the vertebrates, relaxin sequences can vary by more than 50% between different species. Despite these large variations, most relaxins have very similar biological activities in animal test systems, probably, because the receptor binding region of the B chain, in contrast to the rest of the molecule, is highly conserved between species.

Relaxin of various species has been synthesized (Büllesbach and Schwabe 1993; Wade et al. (1994).

Synthetic human relaxin has been characterized by high-performance liquid chromatography (Canova-Davis et al. 1990).

Klonisch et al. (1999) determined the nucleic acid sequence of canine **preprorelaxin** using reverse transcription- and rapid amplification of cDNA ends-polymerase chain reaction. Canine preprorelaxin consists of 534 base pairs encoding a protein of 177 amino acids with a signal peptide of 25 amino acids, a B domain of 35 amino acids, a C domain of 93 amino acids, and an A domain of 24 amino acids.

The **relaxin-like factor (RLF)** is described as a member of the insulin/relaxin/insulin-like growth factor family that is expressed predominantly in the reproductive system, with highest expression in the Leydig cells of the testis (Pusch et al. 1996; Zarreh-Hoshyari-Khah et al. 1999).

Several **bioassays** have been used for relaxin, such as the pubic symphysis method in guinea pigs and mice, inhibition of uterine motility in rats, stimulation of interstitial collagenase activity in cultured uterine cervical cells from guinea pigs (see below).

Taylor and Clark (1989, 1992a,b) developed a **reverse hemolytic plaque assay** which allows the quantitative analysis of relaxin secreted by single porcine luteal cells.

Radioimmunoassays for relaxin were described by Sherwood (1979), Jockenhövel et al. (1991, Steinetz et al. 1996). Lucas et al. (1989) developed an enzyme-linked immunoassay to study human relaxin in human pregnancy and in pregnant rhesus monkeys.

N.10.2.2 Relaxin bioassay by pubic symphysis method in guinea pigs

PURPOSE AND RATIONALE

Experimental relaxation of the pubic symphysis of the spayed guinea pig was described as early as 1929 by Hisaw. The relaxation of the symphysis after relaxin administration is determined by manual palpation.

PROCEDURE

Virgin female guinea pigs of mixed strains weighing 300–400 g are used. Prior to the assay, the animals have to be primed with estrogen and relaxin. Estrogen priming consists of one subcutaneous injection per week of 5 µg of estradiol cyclopentylpropionate in 0.1 ml of sesame oil. Relaxin priming is accomplished by administering 20 µg of relaxin standard in 1 ml saline subcutaneously once a week on day 5 after the estrogen injection.

Six hours after relaxin administration the symphysis of the animal is palpated. The animal is held head down, ventral side away, between the thighs of the seated observer. The sciatic crests and symphysis pubis are firmly grasped between the thumbs and forefingers so that the two halves of the pelvis may be moved back and forth alternately. If the pubic symphysis is rigid at this time, the estrogen and relaxin priming are continued weekly until marked mobility of the symphysis is observed. The increased flexibility is transient, the peak response occurs at 6 h and subsides 12–24 h after injection. Mobility responses are estimated subjectively and scored on an arbitrary scale of 0–6. "Zero" indicates no detectable flexibility of the pubic symphysis, whereas "6" represents extreme softening. Scoring should be performed by the same investigator throughout a study.

One week after an animal has responded positively to 20 µg of relaxin standard, it is added to the assay colony. Before assay time, all eligible animals are mixed and divided into groups of 10–20 each. On the day of the experiment, all animals are palpated before injection. Only those with no symphyseal movement are used. Two doses of test preparation and two doses of standard are injected subcutaneously to different groups. Six hours later, two operators palpate and score each animal.

EVALUATION

The scores are averaged and a median score calculated. The activity of an unknown preparation is determined by comparison with the dose-response curve of concomitantly administered relaxin standard.

MODIFICATIONS OF THE METHOD

Steinetz and Lust (1994) reported that the relaxin-induced pubic symphyseal relaxation in guinea pigs is inhibited by treatment with glycosaminoglycan polysulfates or pentosan polysulfate. The authors recommended the guinea pig symphysis assay for relaxin as a novel rapid screening test for compounds with potential chrondroprotective activity.

N.10.2.3 Relaxin bioassay in mice

PURPOSE AND RATIONALE

Increase in length of the interpubic ligament in mice can be used as bioassay for relaxin. X-ray measurement of pubic separation (Hall 1948; Dorfman et al. 1953) as well as direct measurement of interpubic ligament (Kroc et al. 1959; Steinetz et al. 1960) have been used.

PROCEDURE

Virgin female mice (e.g., NMRI strain) weighing 18–20 g are used for assay. Twenty mice are employed for each of three dose levels of standard and test preparation. On day zero each mouse is primed with a single subcutaneous injection of 5 µg estradiol cyclopentylpropionate in 0.1 ml sesame oil. On day 7, the test preparation and the standard are injected subcutaneously. At 18 to 24 h later, the mice are sacrificed, the abdominal cavities are opened, and uteri are examined for evidence of estrogen priming. Mice exhibiting threadlike uteri are discarded. The anal and vulval areas are then cut away with scissors, and the upper half of the body is cut off to prevent subsequent bleeding at the pubic symphysis. The bony birth canal is freed of skin, vagina, rectum, and fascia are cleaned off the symphysis pubis. The pelvis is placed on a binocular microscope fitted with a calibrated ocular micrometer. A transilluminating device consisting of a U-shaped lucite rod is affixed to the microscope. The tip of the rod is beveled to direct light vertically through the exposed pubic ligament. The feet of the carcass are grasped between the thumb and index finger, applying a slight lateral traction.

The shortest distance between the edges of the pubes is measured, using the ocular micrometer. Micrometer readings are then converted to millimeters.

EVALUATION

Mean values of length of interpubic ligament, expressed in millimeter, are plotted versus logarithm of dose. From dose-response curves activity ratios with confidence limits versus the standard are calculated.

MODIFICATIONS OF THE METHOD

Bullesbach and Schwabe (1996) tested rat relaxin and synthetic analogs in the mouse symphysis pubis assay for structure-activity relationships.

Samuel et al. (1998) studied the effects of relaxin, pregnancy and parturition on collagen metabolism in the **rat** pubic symphysis. During pregnancy and particularly during birth, there was a significant reduction of tissue wet and dry weight, which coincided with an increase in water content and a significant reduction of overall collagen content.

N.10.2.4 Inhibition of uterine motility

PURPOSE AND RATIONALE

This is one of the historical assays based on a nonspecific biological response. Its application and reliability depends on the state of purification of relaxin preparations. Relaxin specifically inhibits the spontaneous motility of estrogen-dominated uterus *in vivo* and *in vitro* (Downing and Hollingsworth 1993). Wiqvist and Paul (1958) proposed a relaxin assay based on inhibition of motility of the rat uterus *in vitro*.

PROCEDURE

The donors (female Sprague-Dawley or Wistar rats weighing 150–180 g) are ovarectomized and primed with 2 µg estradiol daily for 3 days. On day 4, uterine horns are removed, bisected, and suspended in Locke's solution gassed with 1% CO_2 in O_2 at a temperature of 37.5 ±0.5 °C. The contractions are recorded using a Statham transducer and a polygraph. A symmetrical 4-point assay is adopted with 2-fold dose-increments of standard and test preparation. Responses consisting of slowing down the contraction frequency up to

total suppression of the contractions are classified visually and assigned score values of 1–3. All four test doses (2 doses each of standard and test preparation) are run simultaneously on the 4 uterine segments obtained from each rat.

EVALUATION

Mean values of scores are calculated for each dose. Potency ratio with confidence limits are calculated from the 2 + 2-point assay.

MODIFICATIONS OF THE METHOD

Felton et al. (1953) described a test for relaxin activity using the inhibition of uterine contraction in anesthetized guinea pigs *in vivo*.

Inhibition of spontaneous and prostaglandin-driven myometrial activity by relaxin in anesthetized rats was reported by Porter et al. (1979).

Downing and Sherwood (1985) studied the influence of relaxin on uterus contractility and on cervical distensibility in different stages of pregnancy in the rat.

Del Angel Meza et al. (1991) measured the effect of relaxin on uterine and ileum tissue of rats *in vivo* and *in vitro*.

Vu et al. (1993) tested the activity of a recombinant prorelaxin in an *in vitro* bioassay in CHO cells. Human uterine endometrial cells were treated with various dilutions of conditioned medium and the amounts of intracellular cAMP produced were determined by radioimmunoassay.

N.10.2.5
Relaxin assay by interstitial collagenase activity in cultured uterine cervical cells

PURPOSE AND RATIONALE

As an example for the changing approach in assay methods, Mushayandebvu and Rajabi (1995) provided evidence for a biological response suitable for *in vitro* assay. Relaxin is involved in cervical dilatation by stimulating interstitial collagenase, a key enzyme involved in this process. Human recombinant relaxin induces a dose-dependent increase of collagenase activity in cultured guinea pig cervical cells.

PROCEDURE

Abdominal hysterectomy is performed in anesthetized female Hartley guinea pigs under aseptic conditions. The cervix is excised and washed three times in Hank's balanced salt solution (HBSS) containing penicillin G sodium (100 U/ml), streptomycin sulfate 100 µg/ml) and amphotericin B (1.25 µg/ml). The cervix is cut into 2–4 mm pieces and digested in Dulbecco's modified Eagle's medium (DMEM) containing bacterial collagenase type A1 (0.5 mg/ml) and DNase type 1 (0.05 mg/ml) at 37 °C. The digested mixture is filtered once every 15–30 min through a nylon monofilament with a pore size of 400 µm. Following each filtration, separated cells are collected by centrifugation at 365 *g* for 10 min at room temperature followed by a resuspension in DMEM containing 10% heat-inactivated fetal calf serum. Cells are washed twice with HBSS; this is followed by resuspension in DMEM containing 10% penicillin G sodium (100 U/ml), streptomycin sulfate 100 µg/ml) and amphotericin B (1.25 µg/ml). The unfiltered material is redigested and the process is repeated until the cervical tissue is completely digested.

Cells are plated in 24-well plates at 1×10^5 cells per well in 500 µl of medium containing 10% FCS and antibiotics and then are incubated in a humidified atmosphere of 5% CO_2 in air at 37 °C. After 4 days all viable cells are adhered. Culture medium and unattached cells are removed and fresh medium is added. At confluency (5–7 days), culture medium is removed, cells are washed once with HBSS, and serum-free DMEM containing antibiotics is added. The cells are treated with recombinant human relaxin (1–1 000 ng/ml) at 0, 24, and 48 h. Culture media are collected at 96 h from initial treatment with the appropriate controls and frozen immediately at –20 °C until assayed for collagenase activity (Dean and Woessner 1985; Rajabi et al. 1988, 1991).

Enzyme samples (up to 100 µl in assay buffer [50 mM Tris HCl (pH 7.5), 0.2 M NaCl, 10 mM $CaCl_2$, 0.02% sodium azide, 0.035% Brij-35]) are incubated with 10 µl of [^{3}H]telopeptide-free collagen substrate (specific ac-

tivity 3.1×10^6 cpm/mg collagen at 2.24 mg/ml, in 50 mM Tris HCl [pH 7.6], 0.3 M NaCl) in 1.5 ml microfuge tubes. Aminophenylmercuric acetate (0.5 mM) is used was used to activate procollagenase; 1,10-phenanthroline (1 mM) is added to inhibit collagenase and served as blank control for nonspecific collagenolysis. After 18–48 h incubation at 29 °C, the reaction is terminated by addition of EDTA to a final concentration of 40 mM. Collagenase cleavage products are further digested by trypsin and chymotrypsin in the presence of BSA (10 mg/ml assay buffer) for 2 h at 29 °C. The undigested [^{3}H]telopeptide-free substrate is precipitated in 10% trichloroacetic acid at 0 °C for 30 min followed by centrifugation at 18 000 *g* at 4 °C for 30 min. A 100-µl aliquot of the supernatant is mixed in 5 ml Aquasol scintillation fluid and counted in a liquid scintillation counter.

EVALUATION

The percentage digestion is calculated as the total cpm in the supernatant minus cpm in the 1,10-phenanthroline blanks divided by original counts in the [^{3}H]telopeptide-free substrate (in 100 µl of 10% trichloroacetic acid in assay buffer) × 100. One milliunit of collagenase is defined as the amount of collagenase that digests 1 nanogram of collagen in 1 min at 29 °C.

All results are presented as the mean ±SEM of three separate experiments. Statistical analysis is performed by Student's *t*-test for paired observations and by one-way ANOVA for multiple observations.

N.10.2.6 Relaxin receptor binding

PURPOSE AND RATIONALE

Using a monocomponent, high specific activity, carrier-free porcine relaxin tracer [^{125}I], Yang et al. (1992) demonstrated relaxin receptors in the symphysis pubis, uterus and ovary of mice. A linear Scatchard plot suggested the presence of only one kind of receptor and a dissociation constant of 5×10^{-10} M.

PROCEDURE

Crude membranes are prepared from uterine horns of estrogen-primed mice. The tissues are homogenized three times for 10 s with a Polytron homogenizer. The homogenate is centrifuged at 700 *g* for 10 min, and the supernatants are recovered and recentrifuged twice at the same speed. Thereafter, the supernatants are centrifuged at 10 000 *g* for 30 min. The crude membrane pellets are washed with HEPES buffer, centrifuged again, the resuspended in 200–500 µl water, and aliquots are removed for Lowry protein estimates.

The crude membrane suspension is diluted to 3 mg/ml protein with binding buffer (25 mM HEPES, 0.14 M NaCl, 5.7 mM KCl, 1.6 mM $CaCl_2$, 0.025 mM $MgCl_2$, 1.5 mM $MnCl_2$, 1%BSA, 2.8 mM glucose, 0.2 mM phenylmethylsulfonylfluoride, 80 mg/l soybean trypsin inhibitor, pH 7.5). The assay is initiated by adding to 120 µl crude membranes (300 µg protein)with and without 0.2 µg unlabeled relaxin. At the end of the incubation period, 1 ml HEPES buffer, containing 1% of BSA, is added, and bound and free relaxin are separated by three successive washings and centrifugations.

EVALUATION

The tubes are analyzed for radioactivity in a Minigamma 400 (LKB, Rockville, MD). Duplicates are run for each experimental point, and experiments are repeated several times.

MODIFICATIONS OF THE METHOD

The control of relaxin secretion and relaxin receptors by relaxin was studied by Bryant-Greenwood et al. (1982).

Relaxin receptors in the myometrium of rats and pigs were studied by Mercado-Simmen et al. (1982a,b).

Fluoresceinylthiocarbamyl relaxin was prepared by Segaloff and Gabbard (1982) for the demonstration of relaxin receptors.

Experiments by Büllesbach and Schwabe (1988) suggested a unique site for the interaction of relaxin with its uterine and symphyseal receptors.

Using a ^{32}P-labeled human relaxin, Osheroff and Phillips (1991) localized relaxin binding sites in rat uterus, cervix and brain.

The receptor binding site of human relaxin II was studied by Büllesbach et al. (1992).

Min and Sherwood (1996) identified specific cell types that contain relaxin receptors in various organs of pregnant pigs.

N.10.3 Calcitonin gene-related peptide

N.10.3.1 General considerations

In relation to the established traditional hormone definition, many new polypeptides have been identified by molecular biology and characterized by receptor binding and *in vitro* systems, while their definitive function is not yet assigned. Calcitonin-gene-related peptide (CGRP) is an example of this rapid development and change in approach by applying new methods. Calcitonin-gene-related peptide (CGRP) is a 37-amino acid neuropeptide which has been first identified as a product of the calcitonin gene by alternative splicing (Amara et al. 1982). This original peptide is referred to as α-CGRP; a second gene, unrelated to calcitonin, produces β-CGRP (Amara et al. 1985). These two forms are closely related in both rat and man, and are widely distributed throughout most parts of the nervous system. CGRP shares about 50% identity with another 37-amino acid peptide, amylin (Rink et al. 1993). CGRP shows weak but significant homology with adrenomedullin, a 52-amino acid peptide (Kitamura et al. 1993). Several forms of CGRP have been sequenced: α- and β-CGRP from rat and human, and single variants from sheep, pig, chick, salmon, and the laughing frog, *Rana ranri* (Poyer 1997). The calcitonin/CGRP gene is expressed in specific cell types of both the endocrine and nervous systems. The gene is alternatively spliced to yield mRNA encoding calcitonin in thyroid C-cells or the neuropeptide CGRP in a subset of central and peripheral neurons (Amara et al. 1982; Morris et al. 1984; Born and Fischer 1993). The rat as well as the human calcitonin/CGRP gene consists of 6 exons. The calcitonin mRNA contains exons 1 to 4 with a poly(A) tail at exon 4 whereas CGRPα includes exons 1,2,3,5 and 6 with a poly(A) tail at exon 6 (van Rossum et al. 1997).

α- and β-CGRP display several biological activities, including peripheral and cerebral vasodilatation, blood pressure lowering effect, cardiac acceleration, regulation of calcium metabolism, reduction of intestinal motility, regulation of glucose metabolism, stimulation of pancreatic enzyme secretion, diminution of appetite, reduction of growth hormone release, influence on inflammation and nociception, inhibition of interleukin 2 production (Poyner 1992, 1997; Wang et al. 1992; Wimalawansa 1996).

Nuki et al. (1994) compared the vasodilating activity of chicken calcitonin gene-related peptide with human α-CGRP and rat CGRP in the precontracted mesenteric vascular bed of rats (see A.8.2.5).

Wisskirchen et al. (1998) tested agonists of calcitonin gene-related peptide, homologues and antagonists in rat isolated pulmonary artery (see A.1.2.1) and rat deferens (see A.1.2.3).

Tomobe et al. (1998) found that the vasodilation in isolated superior mesenteric arteries by calcitonin gene-related peptide was significantly larger in spontaneously hypertensive rats than in normal Wistar-Kyoto rats.

In order to elucidate the mechanism of endogenous CGRP release in peripheral vasodilation, Brain et al. (1993), used a multiple site ^{133}Xe clearance technique.

Raddino et al. (1997) studied the mechanism of action of human calcitonin gene-related peptide in rabbit heart and human mammary arteries.

Champion et al. (1997) analyzed the responses of human synthetic adrenomedullin and calcitonin gene-related peptides in the hindlimb vascular bed of the cat (see A.8.2.1).

Castellucci et al. (1993) investigated the vasodilator activity of CGRP in the rat isolated and perfused kidney.

McMurdo et al. (1997) investigated the effect of the calcitonin gene-related peptide receptor antagonist $CGRP^{8-37}$ on blood flow in the knee joint of anesthetized rats. Synovial blood flow was measured in both exposed and intact, skin-covered knees by Laser Doppler perfusion imaging.

Sakai et al. (1998) found a synergism of calcitonin gene-related peptide with the blood pressure lowering effect of adenosine.

Preibisz (1993) reported a beneficial effects of CGRP infusions in patients with congestive heart failure and in subjects with neurological deficits after surgical treatment of subarachnoid hemorrhage.

Cadieux et al. (1999) described bronchoprotector properties of calcitonin gene-related peptide in guinea pig and human airways. Calcitonin gene-related peptide inhibited substance P-induced bronchoconstriction *in vivo* and *in vitro*.

Smith et al. (1993) tested the ability of C-terminally truncated fragments of human α-calcitonin gene-related peptide to stimulate amylase secretion from guinea pig pancreatic acini and to relax precontracted mesenteric arteries (see A.1.2.9).

Meini et al. (1995) investigated the propagation of impulses in the guinea-pig ureter and its blockade by calcitonin gene-related peptide. Furthermore, Maggi et al. (1995) studied the mechanisms of the inhibitory effect exerted by calcitonin gene-related peptide on the spontaneous activity of the guinea pig isolated renal pelvis.

Protective effects of calcitonin gene-related peptide in different experimental models of gastric ulcers (reserpine-induced gastric lesions, ethanol-induced gastric lesions, gastric damage and acid secretion in pylorus-ligated rats) were reported by Clementi et al. (1993).

The role of nitric oxide in the anti-ulcer activity of calcitonin gene-related peptide was investigated by Clementi et al. (1994).

Evangelista and Renzi (1997) investigated the protective role of endogenous and exogenous calcitonin gene-related peptide in water immersion stress-induced gastric ulcers in rats.

Li et al. (1997) determined the ability of analogues of human α-calcitonin gene-related peptide to stimulate amylase secretion from guinea pig pancreatic acini (see J.7.0.10) and to relax isolated porcine coronary arteries precontracted with 20 mM KCl (see A.3.1.3).

Calcitonin gene-related peptide acutely augments the contractile response of skeletal muscle to both direct and indirect stimulation as studied in the isolated rat diaphragm by Fleming et al. (1993).

Dumont et al. (1997) used the isolated guinea pig heart (see A.3.1.2) and the isolated rat vas deferens (see A.1.2.3) for *in vitro* bioassays of CGRP agonists and antagonists.

Poyner et al. (1999) found a concentration dependent inhibition of the electrically stimulated twitch response of guinea pig vas deferens by calcitonin gene-rated peptide, amylin and adrenomedullin. (see A.1.2.3).

The role of calcitonin gene-related peptide in protection of capsaicin-induced gastric mucosal hyperemia in rats was studied by Merchant et al. (1994).

Clementi et al. (1994) studied the anti-inflammatory activity of calcitonin gene-related peptide in cutaneous inflammation induced by Croton oil, arachidonic acid, tetradecanolphorbol acetate or cantharidin.

Schaible (1996) investigated the role of tachykinins and calcitonin gene-related peptide in the spinal mechanisms of nociception and in the induction and maintenance of inflammation-evoked hyperexcitability in spinal cord neurons.

The development of tolerance to spinal morphine analgesia in rats was prevented by a calcitonin gene-related peptide receptor antagonist (Menard et al. 1996).

Lutz et al. (1997) investigated the anorectic effects of CGRP and amylin in rats chronically cannulated in the lateral brain ventricle.

Specific calcitonin gene-related peptide receptors were characterized in hamster pancreatic cells (Barakat et al. 1993).

In doses of 25–200 μg/kg i.p., CGRP decreased food intake in mice, suggesting a role for CGRP as a satiety factor (Morley et al. 1996).

CGRP inhibits insulin-stimulated glycogen synthesis in rat skeletal muscle (Leighton and Cooper 1988).

Chatzipantelli et al. (1996) described the lipolytic actions of calcitonin gene-related peptide.

Howitt and Poyner (1997) determined the effects of a series of agonists and antagonists on the calcitonin gene-related peptide receptor of cultured rat L6 skeletal myocytes.

Kurz et al. (1995) studied the receptors of calcitonin gene-related peptide in the rat thymus and suggested that CGRP is a paracrine thymic mediator that may influence the differentiation, maturation and proliferation of thymocytes.

N.10.3.2 Receptor binding of CGRP

PURPOSE AND RATIONALE

Calcitonin gene-related peptide receptors are localized in many tissues, such as brain, heart, spleen, blood vessels, liver, lung, and kidney (Born and Fischer 1993; Muff et al. 1995). They are abundant in the brain, and the pattern is similar in the rat, pig, cow, sheep and man (Wimalawansa and El-Kholy 1993).

Multiple CGRP receptors (subclasses) have been observed: based on pharmacological properties they are divided into at least two subtypes and denoted as $CGRP_1$ and $CGRP_2$ (Dennis et al. 1989, 1991; Quirion 1992). CGRP-(8-37), which lacks 7 terminal amino acid residues, is a selective antagonist of $CGRP_1$ receptors, whereas the linear analog of CGRP, diacetoamidomethyl cysteine CGRP (Cys[ACM2,7]CGRP), is a selective agonist of $CGRP_2$ receptors.

An atypical CGRP subtype has been reported (Dennis et al. 1991; van Rossum 1997).

A sensitive and specific radioreceptor assay for calcitonin gene-related peptide was described by Wimalawansa (1989).

PROCEDURE

For membrane preparation, tissue samples, e.g., dissected brain areas from rats, are placed in 10 vol of ice-cold 50 mM Tris-HCl buffer (pH 7.4) containing 0.32 M sucrose, 0.5 mM dithiothreitol and 5 mM EDTA. After centrifugation of the homogenate at 100 *g* for 10 min, the resultant pellet is rehomogenized with 5 vol of fresh buffer and recentrifuged. The pellet is discarded and the supernatants are pooled and recentrifuged at 30 000 *g* for 45 min at 4 °C. The resulting crude membrane pellet is resuspended in 5 vol of assay buffer (50 mM Tris-HCl, 10 mM KCl, 3 mM sodium azide and 200 IU/ml aprotinin) and recentrifuged at 30 000 *g* for a further 45 min. This procedure is repeated twice with fresh assay buffer. Protein concentrations are determined and adjusted to 1–2 mg/ml. The samples are frozen on dry ice and stored at –70 °C until radioligand binding studies.

For radioligand binding studies, [^{125}I]CGRP (25 pM, ~5 fmol containing ~20 000 cpm/tube) is incubated with various membrane preparations (150–200 µg/ml membrane protein in an incubation medium of 200 µl) in the presence of 200 IU/ml aprotinin and 0.2% heat-inactivated BSA at 4 °C for 120 min in polypropylene microcentrifuge tubes in a shaking water bath. At the end of the incubation period, 700 µl of chilled assay buffer are added and immediately centrifuged at 11 000 *g* for 2 min a refrigerated microcentrifuge. The supernatant is discarded and the resulting membrane pellet is rewashed and the radioactivity remaining in the pellet is counted.

EVALUATION

Specific binding is calculated by subtracting the [^{125}I]CGRP binding in the presence of unlabeled CGRP. Results are expressed as fmol of [^{125}I]CGRP bound/mg membrane protein.

MODIFICATIONS OF THE METHOD

Van Rossum et al. (1994) described the binding profile of a selective calcitonin gene-related peptide receptor antagonist ligand, [^{125}I-Tyr]h$CGRP_{8-37}$, in rat brain and peripheral tissues.

Aiyar et al. (1996) described a cDNA encoding the calcitonin gene-related peptide type 1 receptor. Stable expression in human embryonic kidney 293 (HEK 293) cells produced specific, high affinity binding sites for CGRP that displayed pharmacological and functional properties very similar to native human $CGRP_1$ re-ceptor.

Juaneda et al. (2000) reviewed the molecular pharmacology of CGRP and related peptide receptor subtypes.

N.10.4 Inhibin

N.10.4.1 General considerations

Inhibin is a gonadal dimeric glycoprotein which has an inhibitory effect on the secretion of follicle stimulating hormone by the pituitary gland. The existence of a non-steroidal gonadal hormone was described already by McGullagh in 1932. The hormone was isolated and purified from human seminal plasma, ram rete testis fluid, and from bovine follicular fluid (Franchimont et al. 1979, 1989; Robertson et al. 1986; Vale et al. 1986; de Kretser and Robertson 1989). After the determination of the full structure of bovine (Forage et al. 1986) and human (Mason et al. 1986; Stewart et al. 1986; Tierney et al. 1990) inhibin, it was found that inhibin shares structural homology with a family of glycoproteins which includes Mullarian inhibiting substance, transforming growth factor-β, follistatin, activin and bone morphogenic proteins (Robertson 1991; Moore et al. 1994). Inhibin is a disulfide-linked dimer of an α-subunit and a structurally related β-subunit, either β_A or β_B (Robertson et al. 1992). Inhibin A and inhibin B are related dimeric protein hormones and endocrine regulators of the reproductive axis which show differing pattern during the period of follicular development (Woodruff et al. 1996).

Clinically, inhibin determinations may have uses in the diagnosis of some forms of cancer including granulosa cell tumors, cystadenocarcinoma of the ovary and hydatiform mole and in physiology and pathology of pregnancy including placental function (Halvorson and DeCherney 1996).

An International Standard for porcine inhibin was described by Gaines Das et al. 1992). An International Standard for human recombinant inhibin was established by Rose and Gaines Das (1996).

Tio et al. (1994) purified gonadotropin surge-inhibiting factor (GnSIF), a monomeric polypeptide that shares some biological activities with inhibin, from Sertoli cell-enriched medium.

N.10.4.2 *In vitro* bioassay for inhibin

PURPOSE AND RATIONALE

Several modifications of *in vitro* bioassays for inhibin were used for establishment of the International Standard for porcine inhibin (Gaines Das et al. 1992) and for human recombinant inhibin (Rose and Gaines Das 1996). Mason et al. (1996) used rat anterior pituitary cells for characterization and determination of the biological activities of noncleavable high molecular weight forms of inhibin A and activin A.

PROCEDURE

Anterior pituitary cells are prepared from adult male rats and added to 48-well cluster plates at an initial density of 75 000 cell per 0.4 ml of medium per well. Cultures are preincubated in DMEM-Ham's F12 (1 : 1) medium with bicarbonate supplemented with nonessential amino acids, antibiotics (100 U/ml penicillin, 100 pg/ml streptomycin, and 250 ng/ml fungizone), and 10% charcoal-stripped FBS. Two days later, the cells are washed, and the medium is replaced with serum-free medium supplemented with antibiotics and recombinant human inhibin A (20 pM–100 pM) as standard. Cultures are incubated with test samples for 65–72 h, after which the samples of medium are collected and stored at –20 °C until assayed for FSH by RIA using goat second antibody precipitation with the following reagents (NIDDK): rat FSH-RP-2, rat FSH-I-8 iodinated using iodogen, and anti-rat FSH-S-11 primary antiserum. Each sample for bioassay is tested at least twice in independent cell cultures to confirm the observations.

EVALUATION

Characteristics of the concentration-response curve, including the maximum effect and medium inhibitory concentration (IC_{50}) are computed using the Allfit program (Munson and Rodbard 1980).

MODIFICATIONS OF THE METHOD

Robertson et al. (1991) studied *in vivo* the FSH-suppressing activity of human recombinant inhibin A in the serum of male and female rats.

Wreford et al. (1994) studied the age-dependence of gonadotropin-suppressing activity of human recombinant inhibin in the serum of male rats.

Simpson et al. (1992) induced bilateral cryptorchism in adult male Sprague Dawley rats under ether anesthesia by cutting the gubernaculum of both testes, translocating the testes to the abdominal cavity and ligating the inguinal canal to prevent redescent of the testes into the scrotum. After 28 days, Sertoli cell cultures from these rats were prepared and inhibin secretion in response to follicle-stimulating hormone was measured.

Brown et al. (1991) investigated the effects of inhibin-rich porcine follicular fluid administration on serum bioactive and immunoreactive FSH concentrations and compensatory testosterone secretion in hemicastrated adult rats

Hertan et al. (1999) used primary cultures of ovine anterior pituitary cells for bioassays of inhibin and identified high affinity binding sites for inhibin using iodinated recombinant human 31-kDa inhibin.

Jakobowiak et al. (1989) found similar effects of inhibin and cycloheximide on gonadotropin release in superfused rat pituitary cell cultures.

Demura et al. (1996) studied the levels of inhibin α, β_A and β_B subunit mRNAs by a quantitative reverse transcription-polymerase chain reaction and the changes in their levels by adding inhibin α, β_A and β_B subunit mRNA antisense oligonucleotides and inhibin A, activin A or GnRH to cultured rat anterior pituitary cells.

Robertson et al. (1996) investigated the specificity of several immunoassay methods in terms of their ability to detect the range of inhibin forms found in plasma and their relationship to bioactivity.

A commercially available enzyme-linked immunosorbent assay (ELISA) for inhibin A (Serotec, Oxford) was used by several authors (Wenstrom et al. 1997; Blumenfeld et al. 1998; Wallace et al. 1998). Magoffin and Jakimiuk (1998) used specific and sensitive two-site enzyme-linked immunosorbent assays for determination of inhibin A, inhibin B and activin A.

An *in vitro* method has been developed by Allenby et al. (1991) for culturing isolated seminiferous tubules from adult rats for 1–3 days and optimized on the basis of the secretion of immunoactive inhibin under basal conditions and after maximal stimulation with rat FSH or dibutyryl cAMP. Inhibin was measured using a double-antibody radioimmunoassay based on an antibody generated in a sheep to the 1–26 sequence (plus gycine^{27}tyrosine^{28}) of the N-terminus of the

α-subunit of porcine 32-kDa inhibin. The effect of three known testicular toxicants (meta-dinitrobenzene, nitrobenzene, and methoxy acetic acid) on these cultures was assessed

Knight et al. (1991) described the development of a two-site immunoradiometric assay for dimeric inhibin using antibodies against chemically synthesized fragments of the α and β subunit, Knight and Muttukrishna (1994) the measurement of dimeric inhibin using a modified two-site immunoradiometric assay specific for oxidized (Met O) inhibin.

N.10.5 Activin

N.10.5.1 General considerations

Activin is a pluripotent growth factor that was originally isolated based on its ability to stimulate follicle-stimulating hormone, but is now known to have other important roles during development, erythropoesis, inflammation and wound healing (DePaolo 1997). Three types of activin, formed by dimerization of two inhibin-β subunits, β_A and β_B, are termed activin A ($\beta_A\beta_A$), activin AB ($\beta_A\beta_B$) and activin B ($\beta_B\beta_B$) (Ling et al. 1986; Vale et al. 1986; Mason et al. 1989; Nakamura et al. 1992). In addition, a third β-subunit (β_C) has been identified (Hötten et al. 1995; Loveland et al. 1996). Lee et al. (1989) suggested that in the testis, the Leydig cells secrete activin and the Sertoli cells produce inhibin, or a combination of both. As members of the transforming growth factor beta (TGF-β) family, the activins are involved in a diverse range of physiological processes, including the regulation of FSH biosynthesis and secretion (Mason 1988; MacConnel et al. 1999), steps in embryonic development (Thomsen et al. 1990), spermatogonial mitosis (Mather et al. 1990) and erythroid differentiation (Eto et al. 1986). Activin acts via a family of activin receptor subunits that includes one type I (Act RI or ALK-2) and two homologous type II (IIA and IIB) subunits (Dalkin et al. 1996; Hashimoto et al. 1998).

N.10.5.2 *In vitro* bioassay for activin

PURPOSE AND RATIONALE

In vitro bioassays for activin have been developed using the production of FSH from cultured pituitary cells (Robertson et al. 1992), the accumulation of hemoglobin in K562 erythroleukaemia cells (Schwall and Lai 1991), and the ability to induce mesoderm tissue in animal cap explants of *Xenopus* (de Winter et al. 1992). One of the sites of production of activin A is the bone marrow (Shao et al. 1992; Yamashita et al. 1992; Uchimaru et al. 1995). Brosh et al. (1995) found that the mouse plasmacytoma cell line, MPC-11 (Laskov and Scharff 1970) was exquisitely sensitive to inhibition by activin A without being influenced by a variety of other cytokines and growth factors. On this basis, Phillips et al. (1999) evaluated the MPC-11 cell line as the basis for an *in vitro* bioassay for activin.

PROCEDURE

MPC-11 plasmacytoma cells are cultured in Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum, 24 mM bicarbonate, L-glutamine, non-essential amino acids and Pen-strep in a 95% air/5% CO_2 atmosphere at 37 °C, and passaged at 1×10^6 cells/25 cm^2 flask every second day. For experiments, 100 µl cell suspension are added to 96-well plates at a density of 1 000 viable cells/well in culture medium containing 25 µM β-mercaptoethanol. Activin, other test reagents and sera (100 µl/well) are added to the cultures diluted in phosphate buffer (pH 7.4) containing 6.5 mM Na_2HPO_4, 1.5 mM KH_2PO_4, 0.14 M NaCl, 0.01% BSA and Pen-strep. Cells are cultured in the presence of test reagents for two days; on the third day 25 µl [^{3}H]thymidine (0.25 µCi/25 µl, 6.7 Ci/mmol) are added to each well and 24 h later the cells harvested and thymidine incorporation assessed. Proliferation of MCP-11 cells, as measured by thymidine incorporation, is inhibited by increasing doses of activin A or activin B, whereas follistatin, inhibin A, LH, or interleukin-1β are ineffective.

EVALUATION

All test preparations, including activin standards and sera, are assayed in quadruplicate, and experiments are repeated at least twice. Relative bioactivity and parallelism are assessed using parallel-line bioassay statistics.

MODIFICATIONS OF THE METHOD

Mesoderm induction assays in *Xenopus* were used by Wuytens et al. (1999). *Xenopus* embryos were obtained by *in vitro* fertilization. They were maintained

in 10% Normal Amphibian Medium and staged according to Nieuwkoop and Faber (1967). Animal pole regions were dissected from mid-blastula (stage 8) embryos and cultured in 75% Normal Amphibian Medium containing 0.1% bovine serum albumin and wild type or mutant activin (2.5 ng/ml). A preliminary assessment of mesoderm induction was based on the elongation of the animal caps. Animal pole regions were then frozen on dry ice, and expression of the mesoderm-specific gene Brachyury (Xbra) was assessed by RNAse protection analysis.

LaPolt et al. (1989) examined the effects of purified porcine activin on inhibin secretion and messenger RNA levels in cultured granulosa cells obtained from immature, estrogen-treated rats. Western blot analyses performed with affinity-purified antisera to inhibin α- and β_A-subunits revealed that treatment with either FSH or activin increased the secretion of inhibin $\alpha\beta$ dimer, with a further increase after co-treatment.

Attardi and Miklos (1990) examined the effect of purified recombinant human activin A on steady state levels of mRNAs for the gonadotropin subunits in pituitary cell cultures prepared from adult male rats.

Carroll et al. (1991) used rat anterior pituitary cells *in vitro* and determined the apparent half-life of FSHb mRNA in the presence and absence of recombinant human activin A after addition of actinomycin D.

Demura et al. (1993) measured follistatin-free activin and inhibin in the culture medium of porcine granulosa cells by a competitive protein binding assay and N-fragment RIA, respectively. Both activin and inhibin were secreted under the control of FSH and LH.

Miyamoto et al. (1999) investigated the effect of activin A on secretion of LH, FSH and prolactin by female cultured rat pituitary cells at the single-cell level by means of the cell immunoblot assay. Anterior pituitary cells were preincubated with or without activin A for 24 h, after which they were monodispersed and immediately used for cell immunoblot assay.

Peng et al. (1999) examined the expression of activin receptor mRNAs in human ovary and placenta. Primers specific for two type I and two type II receptors (ActR-I, Act-RI_B, ActR-II, and Act-RII_B) were used in polymerase chain reaction to amplify cDNAs prepared from granulosa-luteal cells, placental tissues and trophoblast cells.

Liu et al. (1996) measured release of immunoreactive activin A from cultured rat anterior pituitary cells by a specific radioimmunoassay.

Shinati et al. (1991) developed a radioimmunoassay for the measurement of activin A, which is identical to erythroid differentiation factor.

For measurement of activin in biological fluids by radioimmunoassay, McFarlane et al. (1996) added sodium deoxycholate, Tween 20 and sodium dodecyl sulphate as dissociating agents in order to remove the interference of follistatin.

Knight et al. (1996) developed a two-site enzyme immunoassay for the determination of total activin A concentrations in serum and follicular fluid.

Saito et al. (1991) developed an assay method for activin-binding protein, which exploits its high affinity for sulfated polysaccharides, and used this method to investigate the production of activin-binding protein by rat ovarian granulosa cells *in vitro*.

N.10.6 Follistatin

N.10.6.1 General considerations

Follistatin is a monomeric glycosylated polypeptide chain which was identified from bovine and porcine follicular fluids on the basis of its inhibition of pituitary follicle-stimulating hormone secretion (Robertson et al. 1987; Ueno et al. 1987; Ying et al. 1987; Bohnsack et al. 2000). Follistatin exerts its inhibitory effect on FSH secretion by neutralizing activin activity (Namakura et al. 1990; Shimonaka et al. 1991; de Winter 1996). Follistatin is able to bind and neutralize the actions of many members or the transforming growth factor-β family of proteins and plays a significant role during organogenesis (Patel 1998). There are two main forms of mature mammalian follistatin which occur as a result of alternative modes of precursor mRNA splicing, giving core proteins of 315 amino acids and the carboxy-truncated variant of 288 amino acids. Further variants in the molecular weight of mature follistatin occur as a result of varying degrees of glycosylation Inouye et al. 1991; Sugino et al. 1993).

N.10.6.2 Immunoassay for follistatin

PURPOSE AND RATIONALE

Evans et al. (1998) developed an ultra-sensitive two-site enzyme immunoassay for human follistatin.

PROCEDURE

Female Balb/c mice are immunized subcutaneously with 20 µg recombinant human follistatin rh-FS288 in an emulsion with complete Freund's adjuvant. The immunization is repeated on two further occasions at monthly intervals in complete Freund's adjuvant, before finally boosting intravenously with rh-FS288 (total 100 µg in saline). The spleen is removed and the splenocytes are fused to Sp2/0 myeloma cells using polyethylene glycol following a standard fusion protocol (Galfre and Milstein 1981). Hybridoma supernatants are screened on a 96-well plate coated with rh-FS288 (0.2 µg/ml in sodium bicarbonate buffer, pH 9.4). Positive clones are expanded and recloned in methyl cellulose. The supernatants from these clones are titrated against rh-FS288 (0.2 µg/ml) under a standard ELISA protocol (Groome et al. 1995). On the basis of these experiments, clones are selected (29/9 and 17/2) and isotoped with a commercial kit. The clones are grown to produce ascitic fluid in pristane-primed BALB/c mice. Purification of IgG is carried out using protein-G affinity chromatography.

Antibody to a selected clone (29/9) diluted in 0.2 M sodium bicarbonate buffer, pH 9.4, is coated by simple absorption onto 96-well ELISA plates overnight at room temperature (10 µg/ml). The following day, the plates ara banged to dryness on paper towelling, then 100 µl dry coat reagent/well are added to the plates. After 1 h incubation at room temperature the plates are banged to dryness and stored in a sealed box.

Both standard (rh-FS288) and samples are diluted in dissociation solution (84 mmol sodium deoxycholate, 3.4% Tween 20, 1% BSA, 5% mouse serum in PBS). Standards are prepared by serially diluting the stock rh-FS288 to give a high standard of 2 500 pg/ml and a low standard of 19.53 pg/ml.

Duplicate 50 µl amounts of standard or test samples are added to wells on the plate, which is then sealed and incubated overnight stationary at room temperature in a sealed moist box. The following day, the plate is washed and to each well is added 50 µl of approximately 1 µg/ml of Fab fragment of clone 17/2, which has previously been coupled to alkaline phosphatase by heterobifunctional chemistry (Ishikawa et al. 1983). This is diluted in Tris conjugate buffer: 1% BSA in 25 mM Tris-HCl, pH 7.5, containing 0.15 M NaCl and 0.5% Tween 20. After 2 h incubation in a moist chamber at room temperature, the plate is washed thoroughly, and banged to dryness on paper towelling. Alkaline phosphate substrate (50 µl) is added to each well and the plate incubated for 2 h stationary at room temperature. Amplifier solution (50 µl) is then added to each well and the ensuing chromogenic reaction is stopped by adding 0.4 M HCl (50 µl/well) once color begins to develop in the zero analyte wells and the top standard has an absorbance of approximately 1.8. The well absorbencies are read at 490 nm with a reference wavelength set at 620 nm using a microplate reader.

EVALUATION

To determine whether dose-response relationships of serially diluted standard and test samples are identical (parallel), the slope values (±95% confidence intervals) of log-transformed data for each response curve are compared by linear regression. The curves are deemed to be parallel if the slopes (±95% confidence intervals) are found to overlap.

MODIFICATIONS OF THE METHOD

Nakamura et al. (1992) investigated the effect of follistatin on activin-induced granulosa cell differentiation in freshly harvested granulosa cells from diethylstilbestrol-treated rats. Activin induced a remarkable change in granulosa cellular morphology from elongated fibroblast-like to round cells, which was prevented by follistatin.

Xiao et al. (1992) studied the effects of activin and follistatin on FSH receptors and differentiation of cultured rat granulosa cells *in vitro*.

DePaolo et al. (1991) determined FSH and LH levels by RIA in the serum of ovarectomized rats and compared *in vivo* the follicle-stimulating hormone-suppressing activity of follistatin and inhibin.

N.10.7 Further peptide hormones discussed in chapters related to the respective indications

Further peptide hormones are discussed in chapters related to the respective indications such as:

Chapter O
Ophthalmologic activity[1]

O.1 Introduction

Ocular pharmacology shares many methods with other indications and treatment of other organs. Therefore, in many instances, the reader has to be referred to other sections, such as:

- neovasculrization of the cornea to Sect. A.8.3.4,
- topical anesthesia of the cornea to Sect. G.1.3.1,
- influence on α- and β-adrenoreceptors in the mouse iris to Sect. A.1.3.24,
- *in vitro* determination of carbonic anhydrase inhibition to Sect. C.1.1.1,
- electroretinogram in diabetic hyperglycemia and galactosemia to Sect. K.8.1.5,
- effect of streptomycin induced cataract to Sect. K.8.1.6,
- effect on galactose feeding-induced cataract to Sect. K.8.1.7,
- effect on naphthalene induced cataract to Sect. K.8.1.8,
- immunological methods to Sect. I.2.2.16.

Nevertheless, ocular pharmacology is a special issue, which justifies a special chapter in this book.

O.2 Intraocular pressure

O.2.1 Acute measurement of intraocular pressure

PURPOSE AND RATIONALE

For evaluation of drugs, intraocular pressure is measured in normal animals or in animals with experimental glaucoma.

PROCEDURE

New Zealand white rabbits, weighing 2.0–2.5 kg, are acclimated to the laboratory environment at least one day prior to experimentation. Intraocular pressure (IOP) measurements consist of topically administering one drop (approximately 50 µl) of a short-acting local anesthetic (Ophthaine 0.5%) directly on the eyes of an unrestrained rabbit. Approximately 40–45 s following local anesthetic administration, an IOP reading for each eye is taken for 10 s and recorded as mm Hg. IOP is determined by applanation pneumotonometry using an Alcon pneumotonograph modified for the rabbit eye (Vareilles et al. 1977).

On the day of the experiment, two baseline IOP measurements are determined and designated as P_1 and P_2, respectively. The P_1 measurement is recorded 30 min prior to drug administration while the P_2 measurement occurs just prior drug or placebo administration. The P_2 measurement is designated as IOP at zero time and is used as the baseline control value for determination of percent reduction in pressure. Thus, a baseline is determined for each rabbit studied.

[1] Review and contributions by W. H. Vogel.

Immediately following the P_2 measurement, the appropriate concentration of drug or vehicle is administered topically to the right eye of 5 rabbits. This is done by placing three successive 20 µl additions directly onto the eye at two- or three-minute intervals. In addition, during drug application, the lower eyelid is held so that excess fluid is collected in the exposed conjunctival sac. Simultaneously, the left eye receives vehicle with the same regimen as the drug-treated right eye. The vehicle (control) treatment is to monitor potential contralateral ocular effects. Following drug or vehicle treatment, IOP measurement are taken at the following time periods: 0.5; 1.0; 1.5; 2.0; 3.0; 4.0; 5.0 and 6.0 h.

EVALUATION

The *IOP* of each rabbit eye for each time period is initially recorded in mm Hg. However, to account for initial *IOP* differences among rabbits, the changes in mm Hg are normalized by converting to percent reduction in outflow pressure (*ROP*).The *ROP* is calculated according to an equation proposed by Mishima (1981):

$$\% \; ROP = (Po - Pe \,/\, Po - Ep) \times 100$$

where *Po* is the *IOP* reading in mm Hg at zero time, *Pe* is the experimental *IOP* reading at the appropriate time following drug or vehicle administration and *Ep* is the episcleral venous pressure taken as a constant of 10 mm Hg. The percent *ROP* for each rabbit at each time period is recorded and grouped to determine a mean percent *ROP* for each time period as well as the duration of action. The overall activity of the drug based on the mean percent *ROP* for five rabbits is categorized as follows:

% reduction in outflow pressure	activity
0 – 10.0	none
10.1 – 20.0	slight
20.1 – 40.0	moderate
>40	marked

MODIFICATIONS OF THE METHOD

Rowland et al. (1981) studied circadian rhythm in intraocular pressure using repeated tonometry in **rabbits**.

Santafé et al. (1997) studied the hypotensive effects of topically applied calcium-antagonists on intraocular pressure in conscious rabbits using a manual applanation tonometer calibrated by direct manometry.

Okada et al. (1995) studied the *IOP* response to different doses of intravitreally injected endothelin-1 in rabbits using a pneumatotonometer.

Drago et al. (1997) studied the effect of repeated administration of combinations of beta-blockers with pilocarpine on *IOP* and heart rate in conscious rabbits.

Chidlow et al. (1999) investigated the effect of topical application of a HT_{1A} receptor agonist on *IOP* in normotensive rabbits using an applanation tonometer.

Goldblum et al. (2000) studied the effect of an acetylcholinesterase inhibitor on *IOP* in normotensive rabbits using a TonoPen XL.

The effect of various carbonic anhydrase inhibitors on *IOP* pressure was measured by several authors, such as Supuran et al. 1999; Briganti et al. (2000).

Burke and Potter (1986) studied the ocular effects of a relatively selective α2 agonist in cats, rabbits and monkeys. Intraocular pressure was measured using an Alcon pneumatonometer, and pupil diameter under constant illumination using a pupillometer. Furthermore, cat nictitating membrane responses were recorded after injections via the lingual artery into the right external artery supplying the nictitating membrane.

Moore et al. (1995) described long-term non-invasive measurement of *IOP* in the **rat** eye. Rats were anesthetized with short-acting isoflurane inhalant and *IOP* was determined by averaging 15 valid individual readings with a TonoPen 2 tonometer.

Krishna et al. (1995) studied the circadian rhythm of *IOP* in Lewis rats using a TonoPen 1 tonometer.

Diurnal variations of *IOP* in the eyes of awake male brown Norway rats were measured by Moore et al. (1996) using a TonoPen XL tonometer.

Cabrera et al. (1999) found no significant difference of *IOP* in four strains of rats using conscious, unsedated animals.

Jia et al. (2000) determined the diurnal *IOP* response of Brown Norway rat eyes after sclerosis of the aqueous humor outflow pathways and its relationship to optic nerve damage. Hypertonic saline was injected into a single episcleral vein and *IOP* measured in both the light and dark phases of the circadian cycle in awake animals.

John et al. (1997) developed a method to measure *IOP* in living **mice** of genetically different mouse strains. Eyes of anesthetized mice were cannulated with a very fine fluid-filled glass micro-needle. The microneedle was connected to a pressure transducer and the pressure signal was analyzed with a computer system.

Miller and Rhaesa (1996) evaluated the effect of a topical α_2-agonist on *IOP*, pupil size and heart rate in normal **cats**.

Bhattacherjee et al. (1999) trained domestic adult cats to accept topical ocular drug administration and pneumotonometry. Cats received either various corticosteroids or vehicle topically to both eyes three times a day for approximately 28 days. The increase of *IOP* was found to depend on the concentration and structure of the corticosteroid.

Gelatt et al. (1997) evaluated the effects of locally applied pilocarpine preparations on *IOP* and pupil size in glaucomatous Beagle **dogs**.

Peterson et al. (1996) compared readings with the Tono-Pen, a handheld applanation tonometer based on the Mackay-Mark principle, with *IOP* measured manometrically after anterior chamber cannulation through the peripheral cornea with a 26-gauge needle connected to a vertically adjustable reservoir and a pressure transducer in cynomolgus **monkeys**.

For *in vitro* determination of carbonic anhydrase inhibition see C.1.1.1.

O.2.2 Measurement of intraocular pressure by telemetry

PURPOSE AND RATIONALE

McLaren et al. (1996), Pericot et al. (1996), Schnell et al. (1996) published methods to measure intraocular pressure by telemetry in conscious, unrestrained rabbits.

PROCEDURE

Telemetric pressure transducers

The implantable pressure monitors (Model TA11PA-C40; Data Sciences International, St. Paul, MN) are cylindrical, measure 25 mm in length and 15 mm in diameter, and weigh approximately 9 g. They contain a pressure transducer, a short-range amplitude modulation radiotransmitter, and a battery in a biocompatible case. Pressure is conducted to the transducer through a fluid-filled polyurethane catheter that is 15 cm long and 0.7 mm in diameter. The 3-mm distal tip of the catheter couples the transducer to the surrounding fluid; it is modified with a thin flexible wall, and the end is filled with a biocompatible gel. The thin wall conducts transient pressure changes, whereas the gel prevents mixing of the fluid in the catheter with the surrounding biological fluid and conducts slow pressure changes.

The transmitter broadcasts an amplitude modulation signal to two antenna and receiver assemblies mounted inside the animal's cage.

Implant surgery

The transducers are implanted in rabbits weighing 2 to 3.5 kg by using aseptic conditions under anesthesia with intramuscular injections of 50 mg/kg ketamine and 5 mg/kg xylazine. A 4-cm midline incision is made on the dorsal neck and connective tissue and muscle layer over the vertebral column and between the scapulae are blunt dissected to form a pocket to contain the transducer capsule. This area is covered with moist gaze while the eye is prepared to receive the catheter.

The right eye is used in all experiments. Eyelids are retracted with an infant lid speculum, and a 7-0 silk suture is placed through the mid-corneal stroma approximately 3 mm from the superior limbus. The two ends are weighted to maintain downward rotation of the globe. The conjunctiva is opened 2 to 3 mm temporal to the superior rectus muscle and gently dissected free of the sclera back to the supertemporal orbital rim.

A 10-cm, 17-gauge catheter needle is inserted through the conjunctival opening, advanced to the orbital rim, and pushed through the orbital fascia into the subcutaneous space just behind the orbital rim. It is advanced carefully under the skin to the top of the skull and back between the ears until the tip emerges from the opening at the back of the neck. The needle is flushed with sterile saline to remove any tissue or blood it has collected.

The transducer is dipped in an antibiotic solution (1 000 U/ml bacitracin and 10 mg/ml neomycin in Ringer's solution) and is placed in the pocket formed earlier in the neck. The tip of the cannula is then inserted into the bore of the 17-gauge needle and advanced carefully as far as possible. The needle is withdrawn and removed from the conjunctival opening, leaving the transducer catheter along its path. Approximately 2 cm of the catheter is left extending through the conjunctival opening.

The anterior edge of the conjunctival flap is reflected forward, and the sclera over the trabecular meshwork is scraped with a sharp, rounded blade until the trabecular meshwork is visible as a dark streak. A 21-gauge needle is inserted through this thinned tissue into the anterior chamber and withdrawn, and the anterior chamber is refilled through the same opening with Healon. The catheter is grasped with a tube forceps and is inserted through the opening into the anterior chamber. The tip is advanced to approximately mid pupil. Care is taken not to touch the corneal endothelium.

The catheter is secured to the sclera with three 9-0 or 10-0 nylon sutures. Each is tied securely around the catheter three times and its ends passed through the sclera before they are tied together. One 8-0 silk suture is also tied tightly three times around the catheter to promote formation of granulation tissue. The catheter is pulled gently back toward the transducer to remove the excess loop in the orbit.

The capsule is anchored in the pocket on the neck. Again, care is taken, not to nick or make any sharp bends in the catheter. The muscle layer and the skin are closed so that the entire transducer and the catheter assembly are located internally.

For measurement of intraocular pressure lowering drugs, ocular hypertension caused by injection of 5% glucose is used. The rabbits are left undisturbed for 30 min before the beginning of telemetric intraocular pressure measurements. One measurement is recorded every 15 s for 5 s with a sampling rate of 250 Hz. Fifty µl of test solution or saline are instilled into the conjunctival sac of the implanted eye and intraocular pressure is recorded for the next 60 min. A sterile 5% glucose solution (20 ml/kg) is then injected into the marginal vein of the ear. Intraocular pressure is recorded for the next 40 min. All studies are performed using a cross-over protocol. A wash-out period of 5 days is allowed between experiments.

EVALUATION

For statistical analysis, the average values of data collected over the time period of interest are calculated for individual animals. For comparisons within groups, statistical analysis is performed on averaged date using two-tailed Student's *t*-test for paired data or unpaired test for unpaired data.

MODIFICATIONS OF THE METHOD

Pericot et al. (1996) induced chronic ocular hypertension by a single injection of α-chymotrypsin into the posterior ocular chamber of rabbits anesthetized by an intramuscular injection of 35 mg/kg ketamine and 4 mg/kg xylazine. Continuous intraocular pressure was measured by telemetry and the effects of timolol, dorzolamide, and epinephrine. The transmitter of a miniaturized radiotelemetry system was implanted into rabbits, and its catheter was tunneled subcutaneously to the superior conjunctival sac and inserted into the midvitreous.

Dinslage et al. (1998) recorded the effects of tonometry, handling, water drinking, and instillation of topical ophthalmic medications on *IOP* by telemetry in rabbits for several months during each 24-h day/night cycle.

McLaren et al. (1999) measured the effects of topical ibopramine and epinephrine on the circadian rhythm of *IOP* in undisturbed rabbits by telemetry.

O.3
Aqueous humor flow rate

PURPOSE AND RATIONALE

Aqueous humor flow rate can be determined by ocular fluorophotometry (Ogidigben et al. 1993, 1994).

PROCEDURE

New Zealand White rabbits weighing 2.5–4 kg of either sex are used. For unilateral sympathectomy, the animals are anesthetized with a dose of ketamine/xylazine (44/8 mg/kg i.v.). Through a midline incision in the neck, the cervical sympathetic nerve trunk is isolated from both the vagus and the common carotid artery by blunt dissection. To be sure that the isolated nerve is the sympathetic trunk, it is electrically stimulated with a square-wave pulse of 4 Hz (0.7-ms duration, 5-s train) at 4 V with a bipolar electrode connected to a Grass SD9 stimulator; dilatation of the rabbit's pupil is satisfactory confirmation of nerve isolation. The preganglionic sympathetic trunk and superior cervical ganglion are severed and removed. During 1–2 weeks post surgery, sympathetically denervated eyes of rabbits are examined for persistent miosis and ptosis.

The corneas of adult rabbits are treated bilaterally by instilling 2% fluorescein topically, 1 drop every 5 min for a period of 30 min (Brubaker 1989). Subsequently, fluorescein concentrations in the cornea and anterior chamber are measured using a Fluorotron Master (Coherent Medical Inc., Palo Alto, CA). Basal aqueous humor flow rates are established both in sympathetically denervated and normal eyes. In the following week, groups of rabbits are treated bilaterally with the test drug or with vehicle. Fluorometry recordings are started 30 min after drug or vehicle administration, and subsequent recordings are made every hour for a total of 5 h.

EVALUATION

Student's *t*-tests for paired data are used to evaluate drug-induced changes.

CRITICAL ASSESSMENT OF THE METHOD

The study in hemi-sympathectomized animals allows the separation of direct drug effects from effects exerted via the sympathetic nervous system

MODIFICATIONS OF THE METHOD

According to Yablonski et al. (1978), the acute decrease in intraocular pressure caused by timolol can be explained entirely by its effect on the aqueous humor flow.

The effect of various compounds on aqueous humor inflow into the posterior chamber of the **rabbit** eye can be used to determine the mechanism of action and to compare the potency of *IOP* lowering compounds. Aqueous humor production is indirectly quantified in the New Zealand white rabbit by means of the *IOP* recovery rate assay of Vareilles and Lotti (1981). After a control pneumotonographic *IOP* measurement, a 20% NaCl solution is infused i.v. into the marginal ear vein of a rabbit at a rate of 1 ml/min for 10 min using an infusion pump. The hypertonic saline infusion causes a rapid and marked fall in *IOP* with a peak reduction occurring 15 min after the start of infusion. Thereafter, the pressure gradually returns to normal over the ensuing 120 min in normal rabbits. Compounds under study are solubilized in a suitable vehicle. Sixty min prior to NaCl infusion, the drugs are instilled directly onto both eyes as three successive 20 µl drops with each drop separated by two or three min. Following the NaCl infusion, the intraocular pressures of both eyes are measured at 5, 10, 15, 30, 60, 90 and 120 min and then every 30 min until *IOP* recovers to preperfusion values. The mean of the *IOP* for the 2 eyes is recorded and plotted against time. The *IOP* recovery rate is then expressed as the slope of the *IOP* recovery line calculated from the points 15 min from the start of NaCl infusion to the ensuing 120 min by means of the least squares method. The difference in slope and percentage change between control and that produced by experimental compounds are analyzed using an unpaired Student's *t*-test. A compound which lowers *IOP* by reducing aqueous humor flow will exhibit a prolonged *IOP* recovery rate as evidenced by a shallow slope compared to that produced by vehicle.

Taarnhøj et al. (1990) reported calibration of measurements *in vivo* of fluorescein in the rabbit cornea. The quenching was measured by four different techniques: (1) by elution of fluorescein, (2) by elution of albumin, (3) by polarization of fluorescence, and (4) by

spectrofluorometry. Quenching of fluorescence of fluorescein in the rabbit cornea can be explained by the interaction of fluorescein and albumin in the cornea.

Burke and Schwartz (1996) surveyed the preclinical data on aqueous humor flow and intraocular pressure of brimonidine.

Beilin et al. (2000) characterized the *IOP* lowering activity and possible mechanism of action of a synthetic, non-psychotropic cannabinoid after i.v. administration in rabbits measuring *IOP* by pneumatonometry, aqueous humor inflow rate by fluorophotometry, blood pressure and heart rate by a computerized physiograph system connected to the central ear artery.

Mermoud et al. (1996) established methods to determine normal outflow facility using anterior chamber infusion with constant pressure and aqueous humor production by a technique of dilution with FITC-albumin in Lewis **rats**.

Tian et al. (1997) determined the effects of adenosine agonists on intraocular pressure with an minified Goldmann applanation tonometer and aqueous humor dynamics by fluorophotometry in cynomolgus **monkeys**.

O.4 Experimental glaucoma

O.4.1 Alpha-chymotrypsin induced glaucoma

PURPOSE AND RATIONALE

Sears and Sears (1974) induced glaucoma in rabbits by intraocular injection of alpha-chymotrypsin. Besides this, relatively few animal models resembling glaucoma in human beings have been described (Gelatt 1977).

PROCEDURE

Male New Zealand rabbits weighing about 2 kg are pretreated with 10 mg/kg i.p. indomethacin to prevent the otherwise immediate onset of inflammation and then slightly anesthetized with pentobarbital to eliminate any nystagmus. The right eye is anesthetized topically with 2% lidocaine. The anterior chamber is cannulated with a 30-gauge needle attached to a reservoir set at a pressure of 25 mm Hg. Then a second cannula, 32-gauge, is introduced into the anterior chamber near the limbus and directed to the posterior chamber through the pupil. A sterile isotonic saline solution (0.5 ml) containing 150 units of alpha-chymotrypsin is irrigated through the cannula into the posterior chamber. Care is taken to avoid the injection of any enzyme into the corneal stroma. Both cannulae are then removed without significant loss of aqueous humor. The eyes are examined at daily intervals for the first week, then on alternate days for the second week, and then weekly for the duration of the experiments. Intraocular pressure is measured with a tonometer adapted for rabbit eyes.

Treatment with drugs is performed before and after surgery.

EVALUATION

Intraocular pressure of animals treated with alpha-chymotrypsin and those treated additionally with drugs is expressed as mean ±SEM and compared statistically with untreated controls using ANOVA followed by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Melena et al. (1998a) measured the effect of topical dihydroergocristine on *IOP* in alpha-chymotrypsin-induced ocular hypertensive **rabbits** with a pneumatonometer.

Drago et al. (1997) measured the effects of beta-blockers combined with pilocarpine on rabbit intraocular pressure. Experimental increase of intraocular pressure was induced by a subconjunctival injection of betamethasone-21-phosphate (4 mg/ml) in both eyes

every week for 4 weeks. The intraocular pressure was measured in conscious rabbits using an electronic pneumotonometer after surface anesthesia with one drop of 0.4% benoxinate solution.

Melena et al. (1997) induced ocular hypertension in rabbits by weekly subconjunctival injection of a betamethasone suspension into the left eye and measured *IOP* with a manometrically calibrated pneumatonograph.

With the same method, Melena et al. (1998b) measured the effect of topical diltiazem on the rise of *IOP* and the effect on established ocular hypertension.

Santafe et al. (1999) induced ocular hypertension in rabbits by oral administration of 60 ml/kg tap water and measured the effect of topical diltiazem on *IOP*.

Balaban et al. (1997) studied the mechanisms of vasopressin effects on intraocular pressure in anesthetized **rats** after cannulation of the anterior chamber of the eye and infusions of artificial cerebrospinal fluid or arginine vasopressin solutions.

Mermoud et al. (1994) described an animal model of uveitic glaucoma. Uveitis was induced in Lewis rats by injection of S-antigen.

Morrison et al. (1998) produced scarring of the aqueous humor outflow pathways by unilateral episcleral vein injections of hypertonic saline in Brown Norway rats and measured *IOP* and optical nerve damage after topical treatment with artificial tears, 0.5% betaxolol, or 0.5% apraclonidine.

Ueda et al. (1998) described an experimental glaucoma model in the rat induced by laser trabecular photocoagulation after an intracameral injection of India ink.

Gu et al. (2000) induced experimental glaucoma in the right eyes of Wistar albino rats by intracameral injection of India ink followed by laser trabecular photocoagulation 4 days later. The left eye served as control. Drugs were injected intraperitoneally just before trabecular photocoagulation. Five days later, 3% fast blue was injected into both superior colliculi. The eyes were enucleated another 3 days later and flat mounts of the retinas were prepared. Labeled ganglion cells were counted in the area 1 mm away from the optical disc.

Wang et al. (1997) induced glaucoma in one eye of cynomolgus **monkeys** by repeated argon laser photocoagulation or diode photocoagulation of the midtrabecular meshwork to study the effects of 5-methylurapidil.

Schmidt et al. (1998) induced glaucoma in rhesus monkeys by 2–3 laser treatments of one eye and measured *IOP*, ocular pulse amplitude and peak pulse blood volume after treatment with anti-glaucoma drugs.

Serle et al. (1998) studied the effect of prostanoid derivates on *IOP* and aqueous humor flow rates in cynomolgus monkeys with unilateral laser-induced glaucoma.

O.5 Local anesthesia of the cornea

PURPOSE AND RATIONALE

Surface anesthesia of the cornea is a prerequisite for ophthalmic surgery. Sigmund Freund studied the pharmacological actions of cocaine and Carl Koller introduced cocaine in 1884 into clinical practice as a topical anesthetic. In pharmacology, following the pioneering work of Sollmann (1918), block of the rabbit corneal reflex as described by Régnier (1923) has become a standard test method for evaluating local anesthetics (Quevauviller 1971; Muschaweck et al. 1986). A detailed description of methods to evaluate the activity of compounds for surface anesthesia is given in Sect. G.1.3.1.

O.6 Experimental cataract formation

PURPOSE AND RATIONALE

Cataract formation can be induced experimentally by various procedures, such as

- **streptomycin** treatment (see Sect. K.8.1.6),
- **galactose feeding** (see Sect. K.8.1.7),
- **naphthalene** treatment (see Sect. K.8.1.8).

Another procedure to induce experimental cataract is treatment of young rats with **selenite**. A review of this model was given by Shearer et al. (1997). Oštádalová et al. (1978) induced cataract by administration of a single dose of sodium selenite to suckling rats.

PROCEDURE

Male Wistar rats are used. On the 2nd day of life, the sucklings are divided in such a way that 8 males were kept with one mother. On the 10th day of life (i.e., when they are in absolute nutritive dependence of the mother) a single dose of 0.02 M solution of Na_2SeO_3 is administered s.c. to 5 experimental groups receiving 5, 10, 20, 40 and 60 µmoles/kg, respectively. The first control group receives s.c. a 0.02 M solution of a sulphur compound (Na_2SO_3), i.e., an element homologous with selenium, at a dose of 60 µmoles/kg. As reference group, 2-months-old male rats are used to which a 0.02 M solution of Na_2SeO_3 is administered s.c. in an amount of 20 µmoles/kg. Mothers of the sucklings as well as the group of adult males, are fed on a standard laboratory diet with water ad libitum. All animals are checked daily and the experiment is terminated 20 days after the treatment.

Cataracts in the sucklings are visible by the naked eye after the opening of their eyes, i.e., on the 14–16th day of life. The opacity is yellowish-white, localized in the center of the lens (nuclear cataract). Two forms are observed: permanent cataracts, persisting through the whole experimental period, and intermittent cataracts, which disappear after some time and reappear after a certain delay. Doses of 40 and 20 µmoles/kg are mostly associated with permanent cataract, the dose of 10 µM/kg causes an uneven distribution of both types of cataracts. The cataractogenic effect is not found in adult animals.

EVALUATION

Dose-dependence of the incidence of cataracts is evaluated using the χ^2-test.

MODIFICATIONS OF THE METHOD

Anderson et al. (1988) observed massive cortical cataract 15–30 days after a single injection of an overdose of sodium selenite into 14-day-old rats.

Watanabe and Shearer (1989) studied the release of crystallins from the lens into aqueous an vitreous humor in rats with a selenite overdose cataract.

Huang et al. (1991) studied DNA damage, repair, and replication in selenite-induced cataract in rat lens.

Huang et al. (1992) observed cataract formation in lenses from rat receiving multiple, low doses of sodium selenite.

Kelley et al. (1993) demonstrated a marked reduction in alpha-crystallin chaperone activity by calpain II in selenite cataract induced in young rats.

Zhao and Shichi (1998) tested the prevention of cataract and other ocular tissue damage induced by injection of 350 mg/kg **acetaminophen** and induction of cytochrome P450 in C57BL/6 mice.

Kojima et al. (1996), Shui et al. (1997) studied cataract formation in Brown Norway rats treated with X-ray irradiation and **corticosteroids** using slit lamp microscopy, photography with a Scheimpflug camera and scanning electron microscopy.

Hatano and Kojima (1996) induced cataract in Brown Norway rats by **UV-B irradiation** and pre-treatment with **l-buthionine sulfoximine**.

Ishida et al. (1997) treated adult rats with oral doses of 0.2, 1 or 5 mg/kf **FK506 (tacrolimus)** over 13 weeks. In the highest dose, cataract development was observed.

Cataract formation in **transgenic mice** was studied by Mitton et al. (1996) and by Cammarata et al. (1999).

O.7
Models of eye inflammation

O.7.1
Allergic conjunctivitis

PURPOSE AND RATIONALE

Allergic conjunctivitis is a common clinical condition that resembles immediate hypersensitivity reactions in the nose, airways, and skin in many aspects. Allergic conjunctivitis is regarded as a mast cell-mediated disease: a similar array of inflammatory mediators, mostly histamine, is released, and the conjunctiva is responsive to many of these inflammatory mediators.

Trocme et al. (1986), Fukushima et al. (1997), Iwamoto et al. (1999) induced allergic blepharoconjunctivitis in rats by immunization with ovalbumin. Keane-Myers et al. (1999) sensitized and challenged mice by local application of a cat dander extract. Ragweed pollen was used for sensitization of mice by Merayo-Lloves et al. (1996), Hu et al. (1998), Magone et al. 1998, 2000).

PROCEDURE

An extract of ragweed pollen is prepared. Ragweed is defatted with acetone and extracted with 50 mM Tris buffer overnight. The extract is then dialyzed against PBS for 48 h, filtered, and stored at 4 °C until use. Protein concentration is determined with Coomassie plus protein assay. The ragweed extract is biotinylated. An $Al(OH)_3$ gel (alum) is prepared, centrifuged for 15 min at 1 000 rpm and stored at 4 °C. Ragweed and alum are mixed at a concentration of 50 µg ragweed in 5 mg of alum 40 min before immunization. On day 0 mice are anesthetized with methoxyflurane during the injection of ragweed and alum in one hind footpad. On day 10, conjunctivitis is induced by topical application of 1.5 mg ragweed suspended in 10 ml phosphate buffered saline, pH 7.2, into each eye. Two groups of control mice are either not immunized or immunized with alum alone; both groups are challenged with the same dose of ragweed on day 10. The animals are sacrificed 20 min and 3, 6, 12, 24, 48, and 72 h after topical ragweed administration.

Animals are examined clinically for signs of immediate hypersensitivity response 20 min after the topical application of ragweed. Chemosis, conjunctival redness, lid edema, and tearing were each graded on a 0–3+ scale. The total score consists of the sum of scores in each of these four categories.

For histology, the eyes are enucleated with the attached lids and intact conjunctiva and immediately fixed in 4% glutaraldehyde for 30 min and then trans-

ferred to 4% formaldehyde for at least 24 h before processing. The tissue is embedded in methyl acrylate, serially sectioned and stained. The numbers of infiltrating neutrophils, eosinophils, goblet cells, and mast cells in one section are counted. Immunohistochemical staining is performed with rat primary antibodies using an avidin-biotin-peroxidase complex technique. Macrophages and lymphocytes in one section of the conjunctiva are assessed.

EVALUATION

All results are presented as mean ±SE. Comparisons between immunized mice, drug treated mice and controls are made with the two-sided Student's *t*-test.

MODIFICATIONS OF THE METHOD

Hu S et al. (1998) compared effectiveness and molecular pharmacological mechanisms of antiallergic agents on experimental conjunctivitis induced by ragweed in SWR/J mice. Allergic conjunctivitis was evaluated by scoring of the clinical signs and histopathology. mRNA expression of interleukin 1β, IL-6 and tumor necrosis factor α was analyzed by reverse transcription polymerase chain reaction techniques.

Woodward et al. (1995) studied the pruritogenic and inflammatory effects of prostanoids in the conjunctiva in **guinea pigs** and counted the scratching episodes by the hind limb.

Reichel et al. (1998) established a simple model of **conjunctival wound healing** in the mouse eye. Four week old BABL/c mouse eyes were studied over a 14 day period. Surgical procedure under general anesthesia involved a blunt dissection of the conjunctiva performed by injection of 25 µl of phosphate buffered saline via a 27 gauge needle into one eye, while the was used as control.

O.7.2 Corneal inflammation

PURPOSE AND RATIONALE

Unlike the conjunctiva, the cornea is an avascular tissue. The cornea serves three major functions: protection, refraction and light transmission. Corneal inflammatory diseases usually result from injury and infection rather than from allergic disorders. Models involving chemical or mechanical injury, therefore, directly mimic clinically encountered situations.

Leibowitz and Kupferman (1974) induced inflammatory response by the injection of clove oil directly into the corneal stroma, resulting in the chemotactic attraction of large numbers of polymorphonuclear leukocytes.

PROCEDURE

New Zealand albino rabbits of either sex are anesthetized with 15 mg/kg i.v. sodium thiamylal. A corneal

inflammatory response is produced in both eyes by the interlaminar inoculation 0.03 ml of laboratory grade clove oil centrally with a 30-gauge needle attached to a tuberculin syringe. All animals receive two intravenous injections of 0.05 mCi/kg of tritiated thymidine (0.7 Ci/mM) 24 h apart. The second thymidine injection is given 24 h prior to the induction of the corneal inflammatory response. Therapy is initiated immediately after the intracorneal injection of clove oil consisting of one drop (0.05 ml) of test compound or standard every hour for a total of 6 doses. One h later, the animals are sacrificed under anesthesia and a 10 mm penetrating corneal button is removed by trephination. The tissue samples are solubilized with a commercially available solubilizing agent (Soluene, Packard Instruments Corp.). The samples are counted in a scintillation counter for 10 min and the amount of radioactivity in each cornea documented.

EVALUATION

The data from individually treated eyes are expressed as percent change in radioactivity relative to their own untreated control eyes. These differences are averaged to determine a mean value for each treatment group. Statistical comparisons are performed by standard methods including random block analysis.

MODIFICATIONS OF THE METHOD

Neovascularization of the rabbit cornea has been used by several authors to study inhibition of angiogenesis (see Sect. A.8.3.4).

Alio et al. (1994, 1995) studied the relative effectiveness of nonsteroidal anti-inflammatory drugs versus corticosteroids and of antioxidants in the topical treatment of experimental acute corneal inflammation induced by corneal alkali burn in rabbits. The corneal inflammatory response was evaluated by Luminol-enhanced chemiluminescence, ultrasonic pachymetry, and computer-assisted analysis of the area of corneal ulceration.

Laria et al. (1997) evaluated combined non-steroidal therapy in experimental corneal injury. A cornmeal alkali burn was induced in New Zealand white rabbits by applying 1-N NaOH filter paper on the central axis of the right cornea for 30 s. The inflammatory index, area and perimeter of the wounded corneal zone, and corneal transparency were evaluated after 5 days treatment.

A similar method was used by Ozturk et al. (2000).

Sonoda et al. (1998) studied inhibition of corneal inflammation by the topical use of Ras farnesyltransferase inhibitors. The central corneas of BALB/c **mice** were cauterized with silver nitrate. Clinical signs and neovascularization were evaluated.

O.7.3 Auto-immune uveitis in rats

PURPOSE AND RATIONALE

The mechanisms of certain types of uveitis have been studied in animals involving autoimmunity. Uveitis has been produced in guinea pigs following injections with homologous uveal tissue.

PROCEDURE

Hartley strain guinea pigs, weighing 400–500 g, are injected at 0, 1, 2, 5, and 8 weeks with a 10% suspension of homologous retina emulsified in Freund's complete adjuvant. The retinas are obtained by dissection of freshly removed eyes of either normal albino or pigmented guinea pigs and stored frozen at –50 °C. Each animal receives 0.2 ml of this emulsion at a time, the first injection being administered intradermally into both hind foot-paws, and the remainder of the series given intramuscularly. Groups of 6 animals receive the test drug or the vehicle orally. Control animals receive similar injections of saline. The severity of the uveal inflammation can be clinically evaluated by slit lamp examination. The animals are sacrificed and the eyes are examined histologically.

EVALUATION

The incidence of uveitis is recorded by histological means as percentage of treated animals.

MODIFICATIONS OF THE METHOD

Highly purified bovine retinal S antigen in complete Freund's adjuvant was injected subcutaneously in **guinea pigs** to induce experimental autoimmune uveitis (Liversidge et al. 1987; Mahlberg et al. 1987).

Cultured retinal pigment epithelial cells from guinea pigs were used by Liversidge et al. (1988).

Experimental autoimmune uveitis has been induced in **rats** (Nussenblatt et al. 1981; Chan et al. 1984, 1987; Mochizuki et al. 1985; Fujino et al. 1988).

Experimental autoimmune uveoretinitis was induced in Lewis rats by injection of very high doses of bovine opsin (Brockhuyse et al. 1987).

Melanin-associated antigen from the iris and ciliar body was used to induce experimental autoimmune anterior uveitis in male Lewis rats by Bora et al. (1995).

Ramanathan et al. (1996) found that recombinant IL-4 aggravates experimental autoimmune uveoretinitis in Lewis rats.

Hanashiro et al. (1997) injected various doses of either lipopolysaccharide or the lipid A region of the lipopolysaccharide into the foot pad of an inbred strain of Lewis rats and compared the inflammation patterns by assessing the protein concentrations and the inflammatory cell content in the aqueous humor.

Merino et al. (1998) reported that lipoteichoic acid from *Staphylococcus aureus* injected into the foot pad of Lewis rats induced a strong ocular inflammation between 24 and 30 h after injection.

Hikita et al. (1995) evaluated the effects of topical FK506 on endotoxin-induced uveitis in the Lewis rat.

Tsuji et al. (1997) investigated the effects of systemically and topically applied betamethasone derivatives on endotoxin-induced uveitis in female Lewis rats.

McMenamin and Crewe (1995) studied kinetics and phenotype of the inflammatory cell infiltrate and the response of the resident tissue macrophages and dendritic cells in the iris and ciliary body in endotoxin-induced uveitis in Lewis rats.

Uchio et al. (1997) achieved suppression of actively induced experimental autoimmune uveoretinitis in rats by $CD4^+$ T cells.

Egwuagu et al. (1999) found in transgenic Lewis rats that expression of interferon-gamma in the lens exacerbates anterior uveitis and induces degenerative changes in the retina.

Immunogenic uveitis in **rabbits** was studied by Kaswan and Kaplan (1988).

Jamieson et al. (1989) sensitized rabbits to bovine serum proteins and then challenged intravitreally to induce an uveitis. They recommended this procedure as a model for anti-inflammatory drug screening.

Whitcup et al. (1996) produced endotoxin-induced uveitis in **mice** by injecting 200 µg *Salmonella typhimurium* endotoxin diluted in 0.1 ml sterile saline into one hindpad.

Geiger et al. (1994) reported that transgenic mice expressing IFN-gamma in the retina develop inflammation in the eye and photoreceptor loss.

O.7.4 Ocular inflammation induced by paracentesis

PURPOSE AND RATIONALE

Paracentesis stimulates prostaglandin PGE_2 and $PGF_{2\alpha}$ release into the anterior chamber of the eye which can be inhibited by antiinflammatory agents (Miller et al. 1973; Kulkarni and Srinivasan 1985).

PROCEDURE

New Zealand white rabbits (2.0 to 2.5 kg) are anesthetized with a 50 : 50 mixture of xylazine (20 mg/kg) and ketamine (100 mg/kg) i.m. Test compounds are topically administered by placing three drops (about 60 µl) on each eye. The eyes are then taped shut to prevent drying. One hour after compound or vehicle administration, inflammation is induced by paracentesis. For each rabbit, the aqueous humor from both eyes is combined to form the "Pre" sample. Three more drops of compound or vehicle are again administered to each eye and the eyes taped shut. Another one-hour period is allowed to elapse, enough time for the aqueous humor to build back up in the eye. Paracentesis is performed a second time and the aqueous humor from both eyes is combined to form the "Post" sample. Prior to this second paracentesis, the general appearance of the eye is rated on a scale of 1 to 3, based on the following criteria: 1 = clear, relatively normal appearance; 2 = opaque, some protein accumulation in the anterior chamber; 3 = very cloudy, protein accumulates in clumps in the anterior chamber, hyperemia, swelling. This rating gives some indication of the extent of inflammation and correlates with the amount of prostaglandin accumulation. Prostaglandins are measured in 10 µl of aqueous humor from the "Pre" and "Post" samples by RIA.

EVALUATION

The amount of prostaglandin present is determined according to the standard curve supplied with each RIA kit. The extent of inflammation is determined by the magnitude of increase in prostaglandin levels in the "Post" versus the "Pre" sample. Dose-response curves for inhibition by test drug and standard are established.

MODIFICATIONS OF THE METHOD

Struck et al. (1995) studied the effects of non-steroidal anti-inflammatory drugs on inflammatory reactions. The right eye of rabbits was burned with alkali (0.25 M sodium hydroxide). The animal were treated with eye drops containing a cyclooxygenase inhibitor and a leukotriene antagonist. Hyperemia of the limbal vessels, corneal vascularization, the number of PMNLs in the cornea and the prostacyclin level in the anterior chamber of the eye served as criteria.

O.7.5 Ocular inflammation by lens proteins

PURPOSE AND RATIONALE

Ocular inflammation can be induced by lens proteins which can be prevented by lipoxygenase inhibitors (Miyano and Chiou 1984; Chiou and Chiou 1985; Chang and Chiou 1989).

PROCEDURE

New Zealand albino rabbits are anesthetized by i.m. injection of 25 mg/kg ketamine hydrochloride and 5 mg/kg xylazine. The anesthesia is maintained by injection of 12.25 mg/kg ketamine and 2.5 mg/kg xylazine every hour throughout the experiment. After the animals are deeply anesthetized, 50 µl of the drug is topically applied to one eye and the other eye receives 50 µl of the solvent. One hour after the application of the drug, 25 µl of lens protein (30 mg/ml, prepared according to Miyano and Chiou 1984) is injected intracamerally with a 27 1/2 gauge needle; extreme care is taken to avoid contact with the iris. Fifteen min after injection of lens proteins, 14 mg/kg of fluorescein is infused through the marginal ear vein at a rate of 1 ml/min. The inflammation which occurs in the eyes of the rabbits is measured by quantifying the amount of fluorescein leakage into the anterior chamber using a fluorophotometer. Measurements are taken at various intervals after injection of lens proteins. At the end of experiments, the animals are sacrificed by an overdose of pentobarbital sodium. Fluorescence measurements are done at 30, 60, 90, 120, 180, 240 and 300 min intervals.

EVALUATION

The concentration of fluorescein in the anterior chamber is determined by taking the average of three values in each of the fluorometric measurements. The results are analyzed by using a paired *t*-test with *P*-values af less than 0.05 as statistically significant.

MODIFICATIONS OF THE METHOD

Augustin et al. (1996) evaluated the effects of allopurinol in lens induced uveitis by morphological methods and compared these effects with those of steroids and a combination of both drugs biochemically and morphologically.

REFERENCES

O.7.6 Proliferative vitreoretinopathy in rabbits

PURPOSE AND RATIONALE

Injection of cultured fibroblast cells into the rabbit vitreous results in a condition that mimics the features of proliferative vitreoretinopathy in man (Algvere and Kock 1976; Sugita et al. 1980; Ophir 1982). Proliferative vitreoretinopathy is a complication of severe eye injury or retinal detachment and is a major cause of failure in retinal reattachment surgery. Because of its simplicity and reproducibility, Wiedemann et al. (1984) proposed this model in rabbits as screening model for antiproliferative drugs.

PROCEDURE

Dermal fibroblasts are obtained from skin explants of young rabbits which are prepared by excising a 1×1 cm area of dorsal skin and scraping it thoroughly with a scalpel blade to remove hair and subcutaneous fat. The explants are rinsed in sterile PBS, minced finely, and placed in 35-mm Petri dishes containing 200 µl of Dulbecco's medium supplemented with 20% heat-inactivated fetal calf serum, 50 µg/ml garamycin, and 5 µg/ml fungizone. When cells begin to grow, tissue pieces and medium are removed and 2 ml of fresh medium is added. When cells have grown to confluence, they are passaged into 75-cc flasks by rinsing with 1 ml of PBS and incubating with 1 ml of 0.25% trypsin/0.02% EDTA for 5–10 min at room temperature. Subsequent to the initial passage, cells are split at a 1 : 4 ratio upon reaching confluence. For injection into the vitreous, confluent cells from the third to tenth passage are trypsinized with 0.25% trypsin/0.02% EDTA, centrifuged at 500–600 *g*, washed twice with the medium, then re-suspended in the medium and allowed to stand for 10–15 min to let cell clumps settle. The number of cells in suspension is determined using a Coulter counter. Tuberculin syringes are filled with 600 µl of cell suspension, which allows five injections in 0.01 ml steps.

Pigmented rabbits of either sex weighing 2–3 kg are anesthetized with 2.0–2.5 ml of a 1 : 1 Rompun-ketamine mixture. The eyes are dilated using one drop of 10% Neo-Synephrine, 1% Mydriacyl, and 1% atropine. Only one eye of each animal in injected using an operating microscope. Fifty thousand, 100 000 or 250 000 cells in a total volume of 0.1 ml medium are injected into the posterior portion of the midvitreous through a 27-gauge needle 5 mm from the corneoscleral limbus at the superonasal quadrant. The test drug or the vehicle is injected as a second injection through the same entrance site and is delivered to the same place in the vitreous. Both injections have to be done slowly to prevent posterior retinal holes or deformation of the injected cells by shearing forces. The needle is withdrawn slowly to prevent leakage of vitreous from the wound. A paracentesis is performed to equilibrate the intraocular pressure after the second injection. An ointment containing antibiotics and atropine is applied at the end of the procedure.

EVALUATION

The development of proliferative vitreoretinopathy in the injected eyes is followed by indirect ophthalmoscopy; the appearance of membranes and detachment is documented by fundus photography.

MODIFICATIONS OF THE METHOD

A survey of eye models of inflammation including conjunctivitis, corneal responses to injurious stimuli, uveitis models, and retinal diseases has been presented by Woodward et al. (1989).

Retinopathy in **rats** resembling lesions seen in human retinopathy of prematurity could be provoked in newborn rats by exposure to 80% O_2 for the first 5 days of life (Ricci et al. 1995, 2000).

Hikchi et al. (1996) described an experimental model of ocular inflammation induced by intravitreal injection of interleukin 1 beta in rabbits.

Chapter P
Pharmacological models in dermatology

P.1 Skin sensitization testing

P.1.1 Guinea pig maximization assay

PURPOSE AND RATIONALE

A variety of methods are available for the prospective identification of skin sensitizing chemicals. The methods that have been used are the Draize rabbit irritancy test (Draize et al. 1944; Phillips et al. 1972), the occluded guinea pig patch test (Buehler 1965), and the guinea pig maximization test (Magnusson and Kligman 1969; Magnusson 1980). The guinea pig maximization test is an adjuvant sensitization test requiring intradermal injections of the test substance, in combination with Freund's complete adjuvant, which stimulates non-specifically the immune system of treated animals, enhancing their ability to respond to sensitizing chemicals.

PROCEDURE

Groups of 15–20 guinea pigs (Hartley strain) are used. On day 0 an area of 4×6 cm over the shoulder region is clipped short with an electric clipper. Three pairs of intradermal injections are made simultaneously, so that on each side of the midline there are two rows of injections each. The injection sites are just within the boundaries of the 2×4 cm patch, which is applied one week later. Injections are (1) 0.1 ml Freund's adjuvant alone, (2) 0.1 ml test material, and (3) 0.1 ml test material in Freund's adjuvant. Control animals are given the same injections but without the test agent, i.e. Freund's adjuvant and vehicle.

On day 7, the same area over the shoulder region is again clipped and shaved with an electric razor. The test agent in petrolatum is spread over a 2×4 cm filter paper in an even, rather thick layer or, if liquid, to saturation. The patch is covered by an overlapping, impermeable plastic adhesive tape. This in turn is firmly secured by an elastic adhesive bandage, which is wound around the torso of the animal. The dressing is left in place for 48 h. Control animals are exposed to the vehicle without the test agent in the same way as the experimental group.

On day 21, in experimental and control animals the flanks are shaved on both sides on an area of 5×5 cm each. Filter paper pieces, 2×2 cm, are sealed to the flanks for 24 h with the same occlusive bandage as for topical induction: (1) left side: patch with the test agent in the highest non-irritant concentration. The same vehicle as for topical induction is used; (2) right side: path with the vehicle.

On day 23, reading is made 24 h after removing of the patches. By then, skin irritation due to the occlusive dressing has usually faded.

EVALUATION

If the challenge reactions in the experimental group clearly outweigh those in the control group, the agent is regarded to be a sensitizer. To grade the substances according to the percentage of animals sensitized, the substances are divided into 5 classes, ranging from weak (grade I) to extreme (grade V) sensitizers (Kligman 1966).

MODIFICATIONS OF THE METHOD

Improvement of the classical guinea pig maximization test was proposed by several authors: Maurer et al. (1980), Shillaker et al. (1989), Botham (1992), Kashima et al. (1993), Basketter et al. (1995), Frankild et al. (1996), Vohr et al. (2000), Steiling et al. (2001).

A predictive assay for contact allergens using human skin explant cultures has been described by Pistoor et al. (1996).

Use of **transgenic animals** to investigate drug hypersensitivity has been proposed by Moser et al. (2001).

P.1.2
Popliteal lymph node hyperplasia assay

PURPOSE AND RATIONALE

The popliteal lymph node assay in mice or rats has been recommended as a tool for predicting allergies (Kammuller et al. 1989; Bloksma et al. 1995; Koch et al. 2000; Pieters 2001). Moreover, the inhibition of popliteal lymph node hyperplasia can be measured (Schorlemmer et al. 1998; Mollison et al. 1999). The test can be used to study compounds potentially effective in allergic eczema.

PROCEDURE

Spleens from Brown-Norway rats are harvested aseptically, splenocytes expressed by compression with a hemostat in Dulbecco's phosphate buffered saline (DPBS), red blood cells lysed with Tris (0.16 M) buffered in ammonium chloride (0.17 M) buffer, washed twice (400 *g*), irradiated (20 Gy), washed in DPBS, and suspended in DPBS at 5×10^7 cells per ml. On day 0, recipient Lewis rats are injected subcutaneously into the plantar surface of the right hindpaw with 0.1 ml of the splenocyte suspension. Compounds are dissolved in an appropriate vehicle and dosed daily, 2 ml/kg, on days 0–3. Recipients are sacrificed on day 4 and popliteal lymph nodes (PLN) from both hind limbs from vehicle control rats, or the right popliteal lymph node from drug-treated rats, are dissected free and weighed individually on a microbalance (Mollison et al. 1993). The average weight of PLN from the left leg of vehicle-treated animals is used as background.

EVALUATION

Percent inhibition is calculated using the following formula:

$$100 - \frac{PLN_{\text{exp.}} - PLN_{\text{mean left}}}{PLN_{\text{mean right}} - PLN_{\text{mean left}}} \times 100$$

- $PLN_{\text{exp.}}$ = experimental PLN weight
- $PLN_{\text{mean left}}$ = mean vehicle control left PLN weight
- $PLN_{\text{mean right}}$ = mean vehicle control right PLN weight

ED_{50} values are derived by simultaneous least square regressive analysis.

P.1.3 Local lymph node assay

PURPOSE AND RATIONALE

More recently, the local lymph node assay in mice has been recommended for measurement of allergenic potency (Kimber and Weisenberger 1989; Kimber et al. 1995; Kimber 2001; Basketter and Scholes 1992; Basketter et al. 2001).

PROCEDURE

Groups of mice (CBA strain), weighing 20–25 g, receive topical applications of the test chemical on the dorsum of both ears, once a day for three consecutive days. In standard analyses, three concentrations of the test material are evaluated together with the relevant vehicle control. Five days after the initiation of exposure, all mice receive an intravenous injection of [^{3}H]-labeled thymidine into their tail vein. Five hours later, animals are sacrificed and draining auricular lymph nodes excised. A single cell suspension of lymph node cells is prepared by gentle mechanical disaggregation and the cells are washed and resuspended in trichloroacetic acid for at least 12 h at 4 °C. Precipitates are resuspended in trichloroacetic acid and transferred to an appropriate scintillation fluid. The incorporation by draining lymph node cells of [^{3}H]-labeled thymidine is measured by ß-scintillation counting and recorded as mean disintegrations per min (dpm).

EVALUATION

For each concentration of the test material a stimulation index (*SI*) is derived relative to the concurrent vehicle control. Those chemicals that at one or more test concentrations induce a *SI* of three or greater are classified as skin sensitizers.

Dose-response curves are plotted in order to provide information on the relative potencies of skin sensitizers. The concentration of the test chemical required to produce a stimulation index (*SI*) of three (named *EC3* value) is calculated using the formula:

$$EC3 = c + [(3 - d) / (b - d) \times (a - c)]$$

where the data points lying immediately above and below the *SI* value of three on the dose-response plot have the coordinates (a,b) and (c,d), respectively.

MODIFICATIONS OF THE METHOD

On the basis of a modified local lymph node assay, Horney et al. (1997) analyzed immunosuppressive effects of topically applied drugs. On four consecutive days, NMRI mice were treated on the dorsal surfaces of both ears with increasing concentrations of test compound. During the last three days, the mice received in addition the contact sensitizer, oxazolone (1%). On day 5, draining auricular lymph nodes were removed in order to assess lymph node cell counts and perform flow cytometric analysis of lymph cell subpopulations.

Hariya et al. (1998) developed a non-radioactive endpoint in a modified local lymph node assay.

P.2 Experimental dermatitis

Several methods involving skin reactions are discussed in other chapters, such as:

- Ultraviolet erythema in guinea pigs (H.3.2.2.1),
- Vascular permeability (H.3.2.2.2),
- Oxazolone-induced ear edema (H.3.2.2.4),
- Croton-oil ear edema in rats and mice (H.3.2.2.5),
- Spontaneous autoimmune diseases in animals (I.2.2.1),
- Passive cutaneous anaphylaxis (I.2.2.4),
- Arthus type immediate hypersensitivity (I.2.2.5),
- Delayed type hypersensitivity (I.2.2.6),
- Reversed passive Arthus reaction (I.2.2.7),
- Acute graft versus host disease (I.2.2.15),
- SLE-like disorder in MRL/lpr mice (I.2.2.16),
- Inhibition of allogenic transplant rejection (I.2.2.20).

P.2.1 Spontaneous dermatitis

P.2.1.1 NC/Nga mouse as model for atopic dermatitis

The NC/Nga mouse has been recommended as a model for atopic dermatitis (Matsuda et al. 1997; Tsudzuki et al. 1997; Suto et al. 1999; Vestergaard et al. 1999, 2000; Kotani et al. 2000; Aioi et al. 2001; Kohara et al. 2001). When kept in specific pathogen free conditions, it remains healthy, but when kept in non-sterile conditions, it spontaneously develops a disease resembling atopic dermatitis at the age of 6–7 weeks. The level of IgE in the blood gradually increases to very high levels, and peaks at the age of 16–18 weeks (Matsuda et al. 1997). This enhanced IgE production has been attributed to an increased sensitivity of the B cell to the CD40 ligand and to IL-4, which is the result of enhanced phosphorylation of Janus kinase 3, a feature found also in atopic dermatitis (Matsumoto et al. 1999). At 16–18 weeks, the mice develop dry skin, and, gradually, nodular lesions, which in turn become crusted wounds. The lesions are pruritic and they are located on the back, the neck, the ears and the face. Biophysical parameters show impairment of water retention and barrier function. The amount of ceramide in the skin decreases significantly (Aioi et al. 2001).

Histologically, the skin lesions in the NC/Nga mice are characterized by hyperkeratosis and parakeratosis, which resemble the lichenified lesions observed in atopic dermatitis patients. In the dermis, an infiltration is found, similar to that seen in atopic dermatitis patients, containing lymphocytes, eosinophils, mast cells and macrophages, in addition to a large population of dendritic cells (Vestergaard et al. 1999).

The lesions in the NC/Nga mouse improve after treatment with tacrolimus hydrate (FK506) ointment (Hiroi et al. 1998) and also with topical steroids (Vestergaard et al. 1999). Both treatments reverse the changes in the skin, block the expression of inflammatory cytokines and decrease the serum levels of IgE.

FURTHER DERMATITIS MODELS

Further animal models for atopic dermatitis were described, such as the NOA (Naruto Research Institute Otsuka Atrichia) mouse (Natori et al. 1999; Watanabe et al. 1999).

Barton et al. (2000) reported that mice lacking the transcription factor ReIB develop T cell-dependent skin lesions similar to human atopic dermatitis.

Herz et al. (1998) developed a human-SCID mouse model to analyze the possible role of bacterial superantigens in human allergic immune responses under *in vivo* conditions.

Atopic dermatitis-like symptoms were reported in hypomagnesaemic hairless rats by Neckermann et al. (2000).

P.2.1.2 Motheaten mice

Mice homozygous for the autosomal recessive motheaten (me) or the allelic viable motheaten (me^v) mutations develop severe and early-age onset of systemic autoimmune and inflammatory disease (Green and Shultz 1975; Shultz et al. 1984; Shultz 1988; Kovarik et al. 1994; Su et al. 1998). These mice show arthritis, patchy dermatitis and hemorrhagic pneumonitis; the latter is considered to be the cause of the early death of me and me^v mice at the age of 3 and 9 weeks, respectively.

Homozygous me^v mice are identified first at the age of 3–4 days by focal depigmentation of the skin, followed by patchy absence of hair and by necrotic lesions on paws, tail and ears.

P.2.1.3 Spontaneous erythema in hairless rats

The hairless rat (WBN/Kob-*Ht*) is a dominant mutant derived from the Wistar strain. With an incidence rate of about 4% in both male and female animals, at an age of 20 weeks an erythema appears spontaneously on the dorsal skin, gradually becoming widespread and progressive in nature (Tani et al. 1998). Histopathologically, erythema is characterized by dermatitis induced by an immunological reaction. Areas of erythema in the skin were decreased by treatment with dexamethasone (1 mg/kg) or cyclosporine (25 or 50 mg/kg) injected subcutaneously every other day for 2 weeks. The results suggested that erythema on the hairless rat could be used as an animal model of spontaneous dermatitis.

P.2.2 Contact dermatitis

P.2.2.1 Skin reaction in mice

PURPOSE AND RATIONALE

The phenomenon of contact hypersensitivity in animals is thought to mirror atopic dermatitis or eczema in patients (Corsini et al. 1979; Cooper 1994; Leung 1997).

PROCEDURE

Mouse contact hypersensitivity

CD1 mice are sensitized on the shaved abdomen with 20 µl of 0.5% 2,4-dinitrofluorobenzene (DNFB) in a vehicle consisting of 95% acetone/5% olive oil on days 0 and 1. On day 5, groups of 10 mice are challenged with 0.2% DNFB with or without co-dissolved drug, 10 µl on both the internal and external surface of both ears. Mice are sacrificed 24 h post-challenge, and a 7 mm diameter circle punched from each ear is weighed immediately on a microbalance.

EVALUATION

The mean ear plug weight from naïve mice challenged with 0.2% DNFB are used as background control.

Percent inhibition is calculated using the following formula:

$$100 - \frac{\text{plug}_{\text{exp.}} - \text{plug}_{\text{mean naïve}}}{\text{plug}_{\text{mean sens.}} - \text{plug}_{\text{mean naïve}}} \times 100$$

- $\text{plug}_{\text{exp.}}$ = experimental ear plug weight
- $\text{plug}_{\text{mean naïve}}$ = mean naïve ear plug weight
- $\text{plug}_{\text{mean sens.}}$ = mean sensitized vehicle control plug weight

ED_{50} values are derived by simultaneous least square regressive analysis.

MODIFICATIONS OF THE METHOD

Lowe et al. (1977) used oxazolone-sensitized Swiss Webster **mice** to evaluate anti-inflammatory properties of a prostaglandin antagonist, a corticosteroid and indomethacin in experimental contact dermatitis.

Further studies in mice on allergic contact dermatitis were performed by Ek and Theodorsson (1990), Fraginals et al. (1990), Katayama et al. (1990), Trenam et al. (1991), Stanley et al. (1991), Maguire (1996).

Grabbe et al. (1995) showed that removal of the majority of epidermal Langerhans cells by topical or systemic steroid application enhances the effector phase of contact hypersensitivity in BALB/c mice.

Koyama et al. (1998) used tenascin-C knockout mice and studied the effect on dinitrofluorobenzene-induced dermatitis.

A spontaneous mutation characterized by chronic proliferative dermatitis in C57BL mice was described by HogenEsch et al. (1993).

Guinea pig contact hypersensitivity

Guinea pigs, six per group, are sensitized on the dorsal surface of one ear pinna with 50 µl of 10% DBFB in 50% acetone: 50% olive oil on day 0, and then on the opposing ear on day 1. On day 5, animals are shaved and challenged with 0.5% 1-chloro-2,4-dinitrochlorobenzene (DNCB) with or without co-dissolved drug, 15 µl per site, 4.8 µl per cm^2, on the dorsolateral surface (Hsieh et al. 1996). Naïve animals are challenged with DNCB and serve as nonspecific controls. The response is scored visually in a blinded fashion 24 h after challenge (0: no change; 0.5: questionable erythema; 1: faint or scattered erythema; 2: mild, confluent erythema; 3: moderate erythema without edema or induration; 4: strong erythema with uniform induration or edema; 5: severe erythema with induration or edema, plus ulceration). Data are calculated as for mouse contact hypersensitivity.

Boyera et al. (1992) tested repeated application of dinitrochlorobenzene to the ears of sensitized guinea pigs as an animal model for contact eczema in humans.

The effect of a topical preparation of mycophenolic acid on experimental allergic contact dermatitis of guinea pigs induced by dinitrofluorobenzene was described by Shoji et al. (1994).

Contact hypersensitivity in pigs

Groups of 6–12 pigs are sensitized with 10% DNFB in acetone/DMSO/olive oil (45 : 5 : 50 by volume) to the shaved outer aspect of both ears and bilateral sites of the lower abdomen, 100 µl per site, on day 0, with a second application of 5% DNFB to the internal pinna and the lower thorax on day 3. On day 9, pigs are restrained on a webbed canvas cart and the test area carefully shaved with an electric clipper. A pilot challenge with 0.1, 0.15, and 0.2% DNCB in acetone/olive oil (95 : 5 by volume), 3.8 µl per cm^2, is used to determine conditions for obtaining submaximal average response in each animal cohort. Pigs are scored by a blinded observer, 24 h post-challenge on a scale from 0 to 4 (0: no change; 0.5: questionable erythema; 1: faint or scattered erythema; 2: moderate erythema without induration or edema; 3: strong erythema with focal areas of edema or induration: 4: extreme erythema with uniform induration or edema). Pigs having a mean DNCB control score <1.5 are excluded (Hsieh et al. 1997). Based on their pilot response on day 10, animals are stratified into two groups having comparable mean scores, challenged on duplicate sites with DNCB in 95 : 5, with or without co-dissolved drug, and scored on day 11. Scores for each challenge site are compared with the average of the control spots treated with DNCB alone on the same pig, and expressed as percentage inhibition.

Bilski and Thomson (1984) recommended allergic contact dermatitis in the domestic pig as a model for evaluating the topical anti-inflammatory activity of drugs and their formulations.

Vana and Meingassner (2000) described morphologic and immunohistochemical features of experimentally induced contact dermatitis in **Göttingen minipigs**.

P.2.2.2 Non-immunologic contact urticaria

PURPOSE AND RATIONALE

Contact urticaria is defined as a wheal-and flare reaction, appearing shortly after certain substances contact intact skin and disappearing within some hours, leaving normal appearing skin. Contact urticaria is divided into two main types, immunologic and non-immunologic (Maibach and Johnson 1975). Immunologic contact urticaria is mediated at least partially by specific IgE antibodies attached to mast cell membranes. Vasoactive substances, released from mast cells, elicit erythema and edema of the skin. Non-immunologic contact urticaria appears only on the contact area without previous sensitization. Specific antibodies against the causative substance are not found in serum. Lahti and Maibach (1984) investigated the suitability of the guinea pig for studies on non-immunologic contact urticaria.

PROCEDURE

Female Hartley strain guinea pigs weighing 350–500 g are used. Fifty µl of test substances is applied with a micropipette to both sides of the earlobe. One ear of the animal is challenged with the contact urticant, while the other ear serves as control with ethyl alcohol. Earlobe thickness is measured three times on four different sites using a string micrometer with round touching plates, 6 mm in diameter. The string of the instrument is adjusted so that the moving plate does not squeeze the tissue, but stops at once when it reaches the surface of the ear. The mean of 12 measurements is recorded as the pre-application thickness. All measurements after application of the test substance are performed once on the same four sites, and the mean is recorded as the post-application thickness.

The thickness of the ear is measured 5 min after application, and then every 10 min during the first h, every 15 min during the second, and every 30 min during the third h.

EVALUATION

The differences between post-application and pre-application values are recorded and plotted as time-response and dose-response curves.

MODIFICATIONS OF THE METHOD

Lauerma et al. (1997) used the trimellitic anhydride-sensitive mouse as an animal model for contact urticaria. BALB/c mice were sensitized with trimellitic anhydride by topical applications and treated with glucocorticosteroids, antihistaminics, or non-steroidal anti-inflammatory drugs. Ears were challenged with trimellitic anhydride and ear thickness was measured at baseline and 1, 2, 4, 8, and 24 h after challenge. Trimellitic anhydride caused a biphasic ear swelling response. However, there was also an early swelling by trimellitic anhydride in non-sensitized mice, suggesting that non-immunological as well as immunological mechanisms contribute to early swelling by trimellitic anhydride.

P.3 Pruritus models

P.3.1 Studies in cpdm/cpdm mice

PURPOSE AND RATIONALE

Pruritus is a common feature of many skin disorders. Since its pathogenesis in largely unknown, proper treat-

ment is not available. The development of new treatments is hampered by the lack of animal models for studying pruritus (Woodward et al. 1985). Kuraishi et al. (1995) have proposed that pruritogenic but not algesiogenic agents stimulate the scratching activity in mice. Scratching is usually registered by counting the number of scratches from direct visual observation or from a video recording (Gmerek and Cowan 1983; Larsen et al. 1994; Thomas et al. 1994). Elliott et al. (2000) developed a method, which allows the automated registration of the scratching activity of the hind legs of mice for periods longer than 24 h.

PROCEDURE

Mice with chronic proliferative dermatitis (cpdm/cpdm mice), a spontaneous mutation of C57BL/Ka mice showing a skin disorder accompanied by severe scratching (Gijbels et al. 2000), at an age of 6–12 weeks or normal C57BL/Ka mice treated subcutaneously with 100 µg/mouse compound 48/80 or 3 mg/mouse histamine hydrochloride, are used.

Metal rings made of soft 1-mm-diameter aluminum wire are placed around both hind legs of the animal just above the ankle. The ring has to be of sufficient diameter that it is just free enough to rotate around the limb. Mice are housed individually in cages ($12 \times 18 \times 13$ cm), which are placed on a scratch detection unit consisting of a plastic outer casing containing the circuit board, and, inset into the top, four ferrite rods with copper coils.

As the mouse scratches, the movement of the metal rings (fitted around its hind legs) in the field generated by the coils elicits a signal that can be transformed into peaks of different frequencies using fast Fourier transformation. Data are downloaded to memory every 3 s, filtered and a power spectrum constructed. The power spectrum is analyzed for a scratch pattern every 1.5 s. Scratching is routinely classified as a signal that gives rise to peaks with maximal amplitudes of around 200 mV and frequencies greater than 15 Hz. The amplitude of general motor activity peaks (movement from bedding using hind limbs, drinking from water bottle) is usually greater than 500 mV and at frequencies of less than 10 Hz. In order to obtain the best discrimination between scratching and general motor activity, any contribution to the scratch frequencies of high energy/low frequency peaks is filtered out by setting the upper detection limit at 0.5 mV for scratching.

EVALUATION

Data are expressed as mean ±SEM Statistical analysis is performed by one-way analysis of variance followed by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Larsen et al. (1994) studied the influence of ultraviolet irradiation on scratching behavior in hairless mice. Especially the wavelengths 315–330 nm were more itch-provoking than erythemogenic.

Sugimoto et al. (1998) studied the effects of histamine H_1 receptor antagonists on compound 48/80-induced scratching behavior in mice.

Inagaki et al. (1999, 2000) studied the participation of histamine H_1 and H_2 receptors in passive cutaneous anaphylaxis-induced scratching behavior in ICR mice and evaluated anti-scratch properties of drugs in BBLB/c, ICR, and ddY mice treated with dinitrofluorobenzene painting.

Ko and Naughton (2000) described an experimental itch model in **Rhesus monkeys**.

P.4 Psoriasis models

P.4.1 General considerations

Several authors reviewed the experimental models for psoriasis (Krueger and Jorgensen 1990; Boehncke 1997; Nickoloff 1999; Rosenberg et al. 1999; Schön 1999). In addition to studies in animals, various *in vitro* investigations were carried out with autopsy material from human psoriatic lesions. Several studies were devoted to the T-cell hypothesis of psoriasis (Bos and de Rie 1999). Lymphocytes may change epidermal growth homeostasis, leading to increased keratinocyte proliferation and abnormal differentiation of these apoptotic cells that end their life cycle as corneocytes.

P.4.2 *In vitro* studies with isolated cells

P.4.2.1 Cultured keratinocytes

PURPOSE AND RATIONALE

Cultured keratinocytes have been used to study the pathogenesis of psoriasis (Mils et al. 1994; Bata-Csörgö et al. 1993, 1995a,b; Ockenfels et al. 1996; Nylander-Lundqvist and Egelrud 1997a,b; Nylander-Lundqvist et al. 1998; Konger et al. 1998; Szabo et al. 1998; Dimon-Gadal et al. 2000; Karvonen et al. 2000; Segaert et al. 2000; Ting et al. 2000) and to evaluate antipsoriatic drugs (Chapman et al. 1990; Ockenfels et al. 1995; Medalie et al. 1996; Lin et al. 1999; Diaz et al. 2000; Farkas et al. 2001). Sampson et al. (2001) tested the *in vitro* keratinocyte antiproliferant effect of *Centella asiatica* extract and triterpenoid saponins.

PROCEDURE

The medium (FDMEM) consists of Dulbecco's Modified Eagle Medium supplemented with 10% fetal bovine serum (FBS), 1% penicillin and 2% streptomycin.

SVK-14 keratinocytes (Taylor-Papadimitriou et al. 1982) are cultured in FDMEM medium in flasks at 10% CO_2 and 37 °C. When confluent, cells are washed with magnesium- and calcium-free phosphate buffered saline (PBS). PBS is decanted and cells detached by adding 5 ml of trypsin (0.05%) in EDTA (0.02%). PBS is added to a volume of 50 ml. The cell pellet obtained by centrifugation (1 000 *g*, 5 min) is re-suspended in 10 ml of FDMEM. Cell counts in the final suspension are determined using a haemocytometer, and the cell density is adjusted to 25 000/ml with FDMEM.

For microtiter assays, cells (5 000 in 200 µl medium) are inoculated into the inner wells of 96-well plates. The outer edge wells of the plate contain 200 µl of 10% fetal bovine serum in PBS. After 24 h at 37 °C, 10% CO_2, plating medium is replaced with FDMEM containing test material or standard in 200 µl. Standard substances are: madecassoside (50 nM–5 mM), asiaticoside (100 nM–10 mM), dissolved in methanol, and dithranol (0.33–170 µM) dissolved on DMSO. Each sample concentration is tested with 6 replicates on each of three separate plates. Cells exposed to FDMEM alone provide 100% growth control. Cells are incubated for 7 days at 37 °C, 10% CO_2 prior to carrying out the sulphorhodamine B assay.

For the sulphorhodamine B (SRB) assay (Skehan et al. 1990), cells are fixed by layering 100 µl of ice-cold 50% trichloroacetic acid on top of the growth medium. Cells are incubated at 4 °C for 1 h, after which plates are washed 5 times with cold water, excess water drained off and the plates left to dry in air. SRB stain (50 µl; 0.4% in 1% acetic acid) (Sigma) is added to each well and left in contact with the cells for 10 to 30 min after which they are washed with 1% acetic acid, rinsing 4 times until only the dye adhering to the cells is left. The plates are dried and 100 µl of 10 mM Tris buffer added to each well to solubilise the dye. The plates are shaken gently for 5 in on a plate reader and the absorbance is read at 550 nm using a Titertek Multiscan MCC/340 II plate reader.

EVALUATION

Mean optical density (OD ±SD) is calculated for each concentration from the six replicate wells in a single plate. The data is used to plot a dose response curve from which IC_{50} values ±SD are obtained.

MODIFICATIONS OF THE METHOD

Fogh et al. (1993) described an *ex vivo* skin model. Keratomized psoriatic skin samples were incubated in the presence of the calcium ionophore a23 187 and

arachidonic acid for 45 min at 37 °C. After extraction of lipids, eicosanoids were determined by reversed-phase high-performance liquid chromatography in combination with specific radioimmunoassays.

P.4.2.2 Effect on T lymphocytes

PURPOSE AND RATIONALE

Psoriasis vulgaris is considered as an inflammatory cell-mediated autoimmune disorder (Uyemura et al. 1993; Gottlieb et al. 1994; Bata-Csörgö et al. 1995; Austin et al. 1999). Lesional skin T cells contribute pro-inflammatory/type 1 (T1) cytokines to initiate and maintain the cell-mediated keratinocyte hyperplasia in inflammatory lesions. Atopic dermatitis is characterized by the presence of Th2 cell and their respective cytokines (Cooper 1994; Leung 1997). A therapeutic agent down-regulating both Th1 and Th2 cytokine production would be desirable (Mollison et al. 1999; Santamaria et al. 1999).

PROCEDURE

Human mixed leukocyte reaction (MLR) assay

Fifty milliliters of sodium heparinized blood, obtained from normal, unrelated donors, is mixed with an equal volume of Dulbecco's phosphate buffered saline (DPBS). Peripheral blood mononuclear cells (PBMC) are isolated by density centrifugation at 400 *g* over Histopaque-1 077. A sufficient number of PBMC are washed three times in RPMI-1 640 medium and used as responder cells. The remaining PBMC (stimulator cells) are washed as above and treated with 25 μg/ml mitomycin C for 30 min at 37 °C in an atmosphere of 5% CO_2 and 100% humidity and then washed three times with RPMI-1 640 medium. The stimulator cells are pooled at $0.5–1.0 \times 10^6$ cells per ml per donor in RPMI-1 640 medium. Cells are cultured in medium consisting of RPMI-1 640 supplemented with 4 mM L-glutamine, 500 μM 2-mercaptoethanol, 10% fetal bovine serum, 25 units/ml penicillin, and 25 μg/ml streptomycin. Mixed leukocyte reactions are performed in 96 well flat-bottom plates (Corning, Acton MA) in a final volume of 220 μl, containing 20 μl of culture medium with or without test compound or standard (ascomycin, purified from a fermentation of *Streptomyces hygroscopicus* ssp. *ascomyceticus* ATCC 14 891 and characterized according to Or et al. 1993), 100 μl of responder cells (1×10^6 cells per ml) and 100 μl of stimulator cells ($2–4 \times 10^6$ cells per ml). Cultures are incubated at 37 °C in an atmosphere of 5% CO_2 and 100% humidity for 4 days. On day 4, 0.5 μCi of [^{3}H]thymidine is added to each well during the last 6 h of culture. Cultures are harvested onto glass-fiber mats using a 96 well harvester. [^{3}H]Thymidine uptake is measured by direct β-counting using a Matrix 9 600 β-counter (Packard, Meriden, CT).

Inhibition of IL-2 production in human whole blood and PBMC

Fifty milliliters of venous blood from normal donors is drawn into tubes containing sodium heparin. Twenty-five milliliters of blood is used directly. PBMC are isolated from the remaining sample as described above and cultured at 1×10^6 cells per ml with supplemented RPMI-1 640. Whole blood or PBMC are induced to secrete IL-2 with 50 ng PMA per ml plus 1 μg ionomycin per ml. Immunosuppressive potency of test compound vs. standard is determined by measuring the inhibition of IL-2 secretion. Assays are performed in 96 well flat-bottom plates in a volume of 210 μl, which includes 190 μl of whole blood or PBMC (1×10^6 cells per ml), 10 μl of PMA (1 μg/ml) and ionomycin (20 μg/ml) mixture and 10 μl of serially diluted test compound. Plasma or tissue culture supernatants are collected 24 h later and IL-2 concentrations determined by ELISA.

Porcine MLR assay

Fifty milliliters of sodium heparinized venous blood is drawn from pigs and diluted with an equal volume of 0.9% saline. PBMC are isolated by density centrifugation for preparation of responder and stimulator cells as described above. MLR are performed as described for human MLR, using 100 μl of responder cells (2×10^6 cells per ml) and 100 μl of stimulator cells ($0.5–4 \times 10^6$ cells per ml).

Rat MLR assay

Popliteal, inguinal, and mesenteric lymph nodes from newly sacrificed Lewis rats and spleens from Brown Norway rats are aseptically removed. Single cell suspensions of splenocytes and lymphocytes are prepared using forceps and a hemostat to macerate the tissues. Red blood cells in the splenocyte suspension are lysed by 2 min incubation at ambient temperature in red blood cell lysis buffer containing 0.14 M NH_4Cl in 0.0167 M Tris-HCl, pH 7.2. Responder cells from Lewis rat lymph nodes and stimulator cells from Brown Norway rat spleens are washed three times in RPMI-1 640 medium and then sedimented at 400 *g* for 10 min. Stimulator cells are prepared as for human, and the assay is conducted in serum-free AIM-V medium supplemented with 1% Antibiotic-Antimycotic solution and 50 μM 2-mercaptoethanol, using an optimized cell ratio of 100 μl of responder cells (2×10^6 cells per ml) and 100 μl of stimulator cells ($1–2 \times 10^6$ cells per ml) and an incubation period of 4 days.

Mouse MLR assay

Spleens are aseptically removed from newly sacrificed C_3H(C_3H/HeNCrIBR) and BALB/c mice. Splenocytes are prepared and the assay conducted as for rat, using an optimized cell ratio of 100 μl of responder cells (4×10^6 cells per ml) and 100 μl of stimulator cells (1×10^6 cells per ml).

Concanavallin A-induced guinea pig lymphocyte proliferation assay

Spleens are aseptically removed from newly sacrificed guinea pigs. Single cell suspensions of splenocytes are prepared as for rat using 4 min incubation in lysis buffer to remove red blood cells. Splenocytes are washed three times in RPMI-1 640 medium and adjusted to 6.25×10^5 cells per ml in culture medium consisting of RPMI-1 640 supplemented as described for human MLR. Concanavallin A-induced proliferation reactions are performed in a volume of 200 μl, containing 20 μl of culture medium with or without test compound or standard, 160 μl of guinea pig splenocytes and 20 μl concanavallin A (20 μg/ml). Cultures are incubated for 3 days, pulse labeled on the last day with [^{3}H]thymidine, harvested and counted as described.

Inhibition of cytokine secretion

Serially diluted test compound or standard is added to 96 well plates with PBMC in RPMI-1 640 medium at 1×10^6 cells per ml. PMA and ionomycin are added to effect 10 ng per ml and 500 ng per ml concentrations, respectively. Supernatants from these cultures are collected 24 h later after centrifugation and stored at –80 °C until use. Concentrations of IL-2 and IFN-γ in the supernatants are determined by ELISA. For assessing inhibition of IL-4 and IL-5 secretion in T cells by the test compound, $CD4^+$ cells are isolated from PBMC using a T cell subset enrichment column (RandD Systems, Minneapolis, MN). Purified $CD4^+$ cells are cultured with serially diluted test compound and PMA at 10 ng per ml in plates previously coated with 100 ng per ml solution of anti CD3 antibody (Immunotech, Westbrook, ME). Supernatants are collected after centrifugation 40 h later. IL-4 and IL-5 concentrations in the supernatants are determined by ELISA.

EVALUATION

Dose response curves for test compound and standard are established and IC_{50} values for inhibition calculated.

MODIFICATIONS OF THE METHOD

Gillitzer et al. (1996) studied neutrophil migration in psoriatic lesions as a model for neutrophil chemotaxis.

Kunstfeld et al. (1997) investigated the migration of inflammatory T cells from psoriasis through superficial vascular plexus and through deep vascular plexus endothelium. Superficial and deep plexus human skin was placed separately into SCID mice.

P.4.3
Psoriasis models in normal animals

P.4.3.1
Mouse tail model for psoriasis

PURPOSE AND RATIONALE

The mouse-tail test was introduced by Jarrett and Spearman (1964). The model is based on the induction of orthokeratosis in those parts of the adult mouse-tail, which have normally a parakeratotic differentiation. Quantification of orthokeratosis was achieved by morphometric evaluation of the scales with the aid of a semiautomatic evaluation unit (Bosman et al. 1992; Bosman 1994; Sebök et al. 1996).

PROCEDURE

Male albino NMRI mice weighing 25–27 g are used. The tails are treated locally with 0.1 ml ointment applied to the proximal part of the tail. For the contact time of 2 h a plastic cylinder is slipped over the tail and fixed with adhesive tape. At the end of contact time the cylinders are removed and the tails washed. Animals are treated once daily, 5 times a week, for 2 weeks. Five to 8 animals are used per dosage group. Two hours after the last treatment the animals are sacrificed and the tails prepared histologically (fixation in 4% formalin, paraplastic embedding). Longitudinal sections of about 5 µm thickness are prepared and stained with hematoxylin-eosin.

The epidermal thickness is measured as the distance between the dermo-epidermal borderline and the beginning of the horny layer. Five measurements per animal are made in each of 10 scales. Out of these 50 measurements the mean for the individual animals is calculated.

The sections are examined for the presence of a granular layer or isolated granular cells induced in the previously parakeratotic skin areas (10 sequential scales per animal). The measurements are carried out at the border of the scale with a semiautomatic image evaluation unit (VIDS III, AI TEKTRON). The distances are obtained in pixels (1 pixel = 1.2120 μm).

Quantitative values of orthokeratosis are obtained by measuring the length of the granular layer per scale (A) and the whole scale length (B). The whole scale length is defined as the length of the scale lying between two adjacent hair follicles, beginning and ending at the turning point between hair follicle and scale. Percent keratosis is calculated by the formula:

$$(A / B) \times 100$$

EVALUATION

Ten sequential scales per animal are measured and the results given in % orthokeratosis per scale. Five to 8 animals are taken for one drug concentration or control group. Thus 50–80 individual orthokeratosis values are obtained per test group. Mean and standard error of the mean are calculated per animal and per group. From the individual orthokeratosis values per dosage group (50–80 scales) a frequency distribution is constructed. Therefore the values (ranging from 0 to 100% orthokeratosis) are grouped into classes with a constant class interval of 10% (class 1: 0–10%; class 2: 10.1–20%; class 10: 90.1–100% orthokeratosis). The frequency per class is calculated in %:

$$\text{class frequency} = \frac{\text{no. of scales in the class}}{\text{total no. of scales}} \times 100$$

For every class the cumulative frequency is constructed by adding the frequencies of all foregoing classes.

Due to a non-Gaussian distribution of the orthokeratotic values (100% is the maximal effect), the Mann-Whitney U-test is used.

The efficacy of test compounds on epidermal differentiation is calculated from the mean length of orthokeratosis after treatment with the substrate (Ok_s) and with salicylic acid as control (Ok_c) using the formula:

$$(Ok_s - Ok_c) / (100 - Ok_c) \times 100$$

MODIFICATIONS OF THE METHOD

Nagano et al. (1990) studied the effect of tumor necrosis factor in the mouse-tail model of psoriasis.

Beyaert et al. (1992) induced a psoriasiform inflammatory reaction in mice by subcutaneous injection of a combination of tumor necrosis factor and lithium chloride.

Several studies were performed in **guinea pigs** (Miller and Ziboh 1990; Kumar et al. 1992; Maini et al. 1999). Tuzun et al. (1993) reported psoriasis lesions in guinea pigs receiving propranolol; however, their results could not be confirmed by Wolf et al. (1994).

P.4.3.2 Rat ultraviolet ray B photodermatitis model for psoriasis

PURPOSE AND RATIONALE

Rat ultraviolet ray B photodermatitis has been proposed as an experimental model of psoriasis vulgaris by Nagakuma et al. (1995).

PROCEDURE

Male Wistar rats weighing around 300 g are used. Hair on the dorsal skin is clipped and carefully shaved. An area (1.5 × 2.5 cm) on one side of the flank is irradiated for 15 min (1.5 J/cm^2) at a vertical distance of 20 cm with UV-B lamps. A biphasic erythema is observed. Immediately after irradiation, initial faint erythema appears, disappearing within 30 min. The second phase of erythema starts 6 h after the irradiation and gradually increases, peaking between 24 and 48 h. The color is brownish-red, and the reaction is confined to the exposed area with a sharp boundary. By 48–72 h after irradiation, dark-brown scale is formed on the erythematous lesion. Pieces of the scale are relatively thick. The scale separates and the erythema decreases daily. The skin sites return to normal about 10 days after irradiation.

The irradiated rats are sacrificed after various time intervals by decapitation under ether anesthesia. Skin biopsies are taken immediately, fixed in 10% formalin and embedded in paraffin. Tissue sections (4 μm thick) are stained with hematoxylin and eosin. The numbers of the keratinocyte layers, including the basal layer, are counted by direct microscopy.

For DNA labeling (Morimoto et al. 1991), 20 mg/kg 5-bromo-2-deoxyuridine (BrdU) is administered i.p. 8 h before decapitation. Frozen tissue sections (8 μm) are prepared with a cryostat. The sections are then fixed in acetone for 10 min, 4% paraformaldehyde containing 1% $CaCl_2$ (pH 7.0) for 10 min and 1% glutaraldehyde for 5 min. After fixation, sections are digested with 0.006% pepsin in 10 mM HCl for 10 min at 37 °C, and incubated in 4 M HCl for 30 min at ambient temperature to denature DNA. They are then incubated with anti-BrdU mouse monoclonal antibody and then with alkaline phosphatase-conjugated anti-mouse IgG sheep IgG antibody. Antibody-binding sites are visualized with naphthol and fast red at pH 9 in the dark. The number of labeled as well as unlabeled cells at the epidermal basal layer or outer root sheath cell layers of the hair follicles are counted in five high-power fields to a total of at least 100 cells. The intensity of BrdU incorporation is demonstrated as a labeling index (%) with the following formula:

$$\text{labeling index} = \frac{\text{no. of labelled cells}}{\text{total cell no. counted}} \times 100$$

EVALUATION

Chronological changes of thickness of keratinocytes at the epidermis and the hair follicles as well as of DNA labeling indices are plotted as time-response curves.

P.4.4 Psoriatiform skin diseases in spontaneous mice mutations

PURPOSE AND RATIONALE

Nearly 100 mouse mutations have been described as causing some type of abnormality of the skin or hair. These include "asebia", a mildly hyperkeratotic disorder with sebaceous gland hyperplasia, "ichthyosis", an example of abnormal hair growth associated with hyperkeratosis, "rhino" and "hairless", two related examples of congenital follicular malformations, and "flaky skin", a potential animal model of eruptive psoriasis.

P.4.4.1 Flaky skin (*fsn*) mouse

PURPOSE AND RATIONALE

Flaky skin (*fsn*) is an autosomal recessive mouse mutation that causes pathologic changes in the skin, yielding a papulosquamous disease resembling human psoriasis (Sundberg et al. 1993). In addition, this mutation, assigned to distal chromosome 17, causes anemia and gastric forestomach hyperplasia (Beamer et al. 1995).

The *fsn* mutation arose spontaneously in the A/J inbred strain at The Jackson Laboratory (Beamer et al. 1986). Psoriasiform skin lesions are first evident as focal epidermal hyperplasia and inflammation at 2 weeks of age. These lesions become confluent and diffuse by 3–4 weeks of age and are associated with marked dermal infiltration of lymphocytes and small numbers of neutrophils and macrophages. Mast cell numbers increase significantly in the dermis from 2 weeks of age onward. Diffuse dermal neovascularization accompanies these cutaneous changes (Sundberg et al. 1997). Systemic lesions in-

clude progressive and massive papillomatosis of the stratified squamous epithelium of the forestomach, hyperplasia and dysplasia of the glandular stomach, increased apoptosis of cecal enterocytes, renal glomerulopathy associated with inflammatory cell infiltrates and fibrosis around the portal triads in the liver, splenomegaly due to massive erythropoiesis, and granulomatous lymphadenitis.

Scanning microscope examination (Morita et al. 1995) reveals a greatly thickened epidermis, and sparsity of hairs and scale accumulations in the epidermal surface. Hair shafts have conspicuous pits, striations, and exophytic protrusions. Nails are bent at a 90-degree angle with surface irregularities and accumulation of scale at the nail base. Transmission electron microscopic examination shows increased epidermal thickness, mitochondrial aberrations, and intraepidermal invasion by neutrophils. Keratin abnormalities are detected using immunocytochemical staining for profilaggrin. At the dermal-epidermal junction, numerous macrophages and mast cells are seen in close proximity to focal dissolutions of the basement membrane. A high density of collagen fibers and cellular infiltrates are evident in the papillary dermis.

Besides lymphadenopathy and mast cell accumulation, elevated serum IgE levels (>7 000 fold increase compared with normal littermates), autoimmunity (evidenced by glomerulonephritis with immune complex deposition in the kidneys), are observed in flaky skin mutant mice (Pelsue et al. 1998).

Peripheral lymph nodes of adult mutant (*fsn/fsn*) mice were found to contain almost 10-fold more leukocytes than peripheral lymph nodes from phenotypically normal littermates. Analysis of peripheral lymph node cells using mAbs and flow cytometry revealed that this predominantly lymphoid hyperplasia is characterized by approximately equivalent increases of $CD3^+$ T cells and $C19^+$ B cells (Abernethy et al. 2000a). A dysregulated expression of CD69 and IL-2 receptor alpha and beta chains was found on $CD8^+$ T lymphocytes (Abernethy et al. 2000b). Expression and function of IL-1 beta is increased in psoriasiform skin lesions of flaky skin (*fsn/fsn*) mice (Schön et al. 2001).

However, neutrophils also played a critical role of for the generation of psoriasiform skin lesions in flaky skin mice (Schön et al. 2000). Intraperitoneal injection of the neutrophil-depleting RB6-85C monoclonal antibody resulted in a dramatic reduction of the epidermal thickness.

Similar to active human psoriatic lesions, an increase of epidermal growth factor receptors was observed in *fsn/fsn* mice (Nanney et al. 1996).

Sundberg et al. (1994a) transplanted full-thickness skin grafts from flaky skin mice on the dorsal skin of genetically athymic nude (*nu/nu*) mice. The grafts maintained the psoriatiform phenotype of the donors.

Backcrosses to different mouse strains suggested several modifier genes affecting the *fsn* phenotype (Sundberg et al. 1994b). As cyclosporine A, in contrast to glucocorticoids, was not effective when used for topical or systemic treatment of *fsn* lesions, it seems that there is no immunologic basis for these lesions. Therefore, it remains uncertain whether the flaky skin mouse can be used to test potential therapeutic compounds.

P.4.4.2 Asebia (*ab/ab*) mouse

PURPOSE AND RATIONALE

The asebia mouse was first described by Gates and Kasarek (1965) as hereditary absence of sebaceous glands. The asebia mouse represents a spontaneous mutation in BALB/c mice leading to hyperplasia of the epidermis and chronic inflammatory dermal changes, including enhanced cellularity, edema and elevated mast cell numbers (Josefowicz and Hardy 1978; Brown and Hardy 1988). The circadian rhythms in cell proliferation are suppressed in the chronically hyperproliferative epidermis of the asebia mouse (Brown et al. 1988a). UVB radiation as well as anthralin and tar with UVB further stimulate proliferation in the already hyperproliferative epidermis of the asebia mouse (Brown et al. 1988b, 1989). The gene for the enzyme stearyl-CoA desaturase 1, which is expressed in sebaceous glands, is disrupted in the asebia mouse (Parimoo et al. 1999; Zheng et al. 1999; Miyazaki et al. 2000). Besides Sdc1 and Sdc2, Zheng et al. (2001) identified Scd3 – a novel gene of the stearoyl-CoA desaturase family with restricted expression in the skin. Since T cell and neutrophil infiltrates are not observed in asebia mice, a pathogenesis distinct from psoriasis has been suggested (Schön 1999).

Asebia-2J (Scd1(ab2J)): a new allele and a model for scarring alopecia was described by Sundberg et al. (2000).

P.4.5 Psoriasiform skin diseases in genetically modified animals

PURPOSE AND RATIONALE

Based on expression in inflammatory skin disorders, several factors, such as cytokines, are considered to play a crucial role in the pathogenesis of psoriasis and other skin diseases. Transgenic animals are tools to analyze these factors (Meyer 1990; Rothnagel et al. 1990; Sellheyer 1996; Rosenberg et al. 1999).

Bullard et al. (1996) described a polygenic mouse model of psoriasiform skin disease in **CD18-deficient mice**. CD18 deficiency in patients results in recurrent microbial infections, leukocytosis, impaired wound healing, failure of granulocyte emigration, and lack of pus formation (Anderson et al. 1995). A hypomorphic mutation for CD18 was introduced by Wilson et al. (1993) into mice with homocygotes displaying mild leukocytosis, an impaired response to chemically induced peritonitis, and delays in transplantation rejection. When this CD18 mutation was crossed back onto PL/J strain of mice, the development of an inflammatory skin disorder was observed (Bullard et al. 1996). The disease is characterized by erythema, hair loss, and the development of crusts. The histopathology reveals hyperplasia of the epidermis, subcorneal microabscesses, orthohyperkeratosis, parakeratosis, and lymphocyte exocytosis similar to human psoriasis and other hyperproliferative skin disorders. The dermatitis rapidly resolved after subcutaneous administration of dexamethasone.

Dermal infiltrates of macrophages/monocytes within the dermis of clinically uninvolved skin were seen in transgenic mice with epidermal overexpression of K14/IL-1α, suggesting a role of IL-1α for macro-

phage attraction (Groves et al. 1995). In severely affected animals, inflammation reactions occur that are characterized by a mixed inflammatory infiltrate, and by acanthosis and parakeratosis. **IL-1α transgenic mice** support a primary role of IL-1α as an inducer of cutaneous inflammation, which may be helpful for clarifying pathogenesis of psoriasis.

Wilson et al. (1990) reported that expression of the **BNLF-1 oncogene** of Epstein-Barr virus in the skin of transgenic mice induces hyperplasia and aberrant expression of keratin 6.

Cook et al. (1997, 1999) found that overexpression of the heparin-binding EGF-related ligand amphiregulin in the epidermis of transgenic mice induces a psoriasis-like cutaneous phenotype. **Transgenic mice with a K14 enhancer/promoter-driven amphiregulin gene** targeted to the epidermis displayed a macroscopic phenotype that included extensive areas of scaling and erythematous skin with marked alopecia. Histological examination revealed hyperkeratosis, focal parakeratosis, acanthosis, mixed leukocytic infiltration that included both CD3-positive T cells in the dermis and epidermis, and a tortuous vasculature.

Two completely opposite phenotypes were observed in **mice expressing K10/BMP-6** (bone morphogenetic protein-6, a member of the TGF-β superfamily) within the epidermis (Blessing et al. 1996). Whereas keratinocyte proliferation was severely reduced in animals with strong and homogenous expression of the transgene, weaker and patchy expression led to marked hyperproliferation.

Rodriguez-Villanueva et al. (1998) reported that **human keratin-1.bcl-2 mice** aberrantly express keratin 6, exhibit reduced sensitivity to keratinocyte cell death induction, and are sensible to skin tumor formation.

The concept of vascular endothelial growth factor (VEGF) being an important angiogenic factor in psoriatic skin (Detmar et al. 1994) was supported by **transgenic mice with constitutive epidermal K14/VEGF expression**. These animals exhibited dilated and contorted dermal microvessels (Detmar et al. 1998). There was also an increased number of dermal mast cells, and leukocyte adhesion and extravasation was enhanced in VEGF transgenic mice.

Klement et al. (1996) found that **IκBα deficiency** results in a sustained NF-κB response and widespread dermatitis in mice.

Seitz et al. (1998) reported that alterations on NF-κB function in transgenic epithelial tissue demonstrate a growth inhibitory role for **NF-κB**.

To determine the role of κB-α deficient immunocytes in the pathogenesis of skin disease in adult mice, Chen et al. (2000) utilized the RAG2-deficient blastocyst complementation system to generate **RAG2–/–, IκB-α–/– chimeras**. These animals display a psoriasiform dermatitis characterized by hyperplastic epidermal keratinocytes and dermal infiltration of immunocytes, including lymphocytes. Skin grafts transferred from diseased chimeras to recipient nude mice produce hyperproliferative epidermal keratinocytes in response to stimulation.

Transgenic mice overexpressing suprabasal integrins α_2, α_5, and β_1 demonstrate a phenotype similar to psoriasis with cycles of flaking and inflamed skin, suggesting that disrupted keratinocyte integrin-ligand interactions may play a role in hyperproliferative states (Carroll et al. 1995).

Robles et al. (1996) found that **expression of cyclin D1 in epithelial tissue** of transgenic mice results in epidermal hyperproliferation and severe thymic hyperplasia.

Carroll et al. (1997) used the **involucrin promoter to overexpress IFN_γ** in the suprabasal layers of transgenic mouse epidermis. The mice exhibited striking hypo-pigmentation of the hair due to reduction of DOPA-positive melanocytes. Severely affected mice had reddened skin, growth retardation, hair loss, and flaky skin lesions. The skin was characterized by a dermal infiltrate of T lymphocytes and macrophages/monocytes.

When **scid/scid mice were reconstituted with MHC-matched, but minor histocompatibility mismatched $CD4^+/CD45RB^{hi}$ T lymphocytes**, almost all of the animals developed skin lesions similar to human psoriasis within 4–8 weeks after transfer (Schön et al. 1997). The psoriatiform skin lesions did not develop in recipients of unfractionated splenocytes or $CD4^+/CD45RB^{lo}$ T cells, indicating that T cell dysregulation is the primary pathogenic factor in this model. When recipients of $CD4^+/CD45RB^{hi}$ T cells were treated with either cyclosporine A or UVB irradiation, the psoriasiform lesions were dramatically improved demonstrating that immunosuppressive therapies are efficacious. The model was proposed as a T cell initiated murine model of inflammatory skin lesions (Schön and Parker 1997).

Mann et al. (1993) found that mice with a **null mutation of the TGF-a gene** have abnormal skin architecture, wavy hair, and curly whiskers and often develop corneal inflammation.

Turksen et al. (1992) described psoriasiform changes in the skin of transgenic mice with **overexpression of interleukin 6**.

Guo et al. (1993) reported that targeting expression of **keratinocyte growth factor** to keratinocytes elicits striking changes in epithelial differentiation in transgenic mice.

Hong et al. (1999) showed that IL-12, independently of IFN-gamma, plays a crucial role in the pathogenesis of a murine psoriasis-like disorder. Only a few *scid/scid* mice develop skin lesions when $CD4^+$/$CD45RB^{hi}$ are transferred alone. Coadministration of LPS plus IL-12 or staphylococcal enterotoxin B in *scid/scid* mice one day after **$CD4^+$/$CD45RB^{hi}$ cell transfer** greatly enhances disease penetrance and severity.

Schön et al. (2000) reported a cutaneous inflammatory disorder in **integrin alpha E (CD103)-deficient mice**. Skin inflammation correlated with alpha E deficiency in mice with a mixed 129/Sv×BALB/c background.

Transgenic rats expressing human HLA-B27 and β_2-microglobulin develop psoriasiform skin changes as part of a multi-organ inflammatory disease (Hammer et al. 1990). In the most severely affected lines, psoriasiform lesions first occurred at about 20 weeks of life and were observed in 10% to 80% of animals. Male appeared to be more prone to skin changes than females (Taurog et al. 1993, 1994, 1999). Similar to human pathogenesis, T cells seem to be the most important factor in HLA-B27 transgenic rats (Breban et al. 1996).

P.4.6 Xenotransplantation of human psoriatic skin

PURPOSE AND RATIONALE

Xenotransplantation models for psoriasis involve the transfer of human psoriatic skin to animals. First studies were performed by transplantation of involved psoriatic and non-psoriatic human skin onto congenitally athymic (nude) mice (Krueger et al. 1975, 1985; Baker et al. 1992). More recently, human psoriatic skin grafts were transplanted onto SCID mice (Nickoloff et al. 1995; Boehncke et al. 1994, 1997, 1999; Gilhar et al. 1997; Sugai et al. 1998; Dam et al. 1999; Raychaudhuri et al. 2001) allowing screening of anti-psoriatic drugs.

PROCEDURE

Keratome biopsies ($7 \times 2 \times 0.05$ cm containing both dermis and epidermis) are obtained from clinically symptomless skin of patients with psoriasis or from psoriatic plaques. Prior to the procedure, the skin is defined and infiltrated with 1% lidocaine and epinephrine 1 : 200. The full-thickness skin biopsy is dissected into 12 grafts. CB-17 SCID mice at an age of 6–8 weeks are anesthetized with an i.p. injection of 1.56 mg phenobarbital before transplantation of the human xenografts on the flank area. The grafts are sutured with absorbable 6-0 Vicryl Rapid suture and covered with Xeroform dressings for one week. Animals transplanted with the psoriatic plaque are then randomized into groups receiving PBS as negative controls or 0.15 mg cyclosporine A or the test compound intradermally into the xenografts. Within 4 weeks, the animals are sacrificed by CO_2 asphyxiation and 4 mm punch biopsies are obtained from each xenograft. Biopsies are fixed in 10% neutral-buffered formalin for paraffin embedding.

EVALUATION

A semiquantitative scale is used to indicate the extent of new vessel formation (angiogenesis) that can be seen between the xenograft and the underlying fascia muscularis. A calibrated eyepiece microscope is used for estimating the epidermal thickness in the vertical sections. Statistical differences are calculated using Student's *t*-test for multiple comparisons.

MODIFICATIONS OF THE METHOD

Nickoloff et al. (1995) studied severe combined immunodeficiency mouse and human psoriatic skin chimeras. Autologous blood-derived $CD4^+$ cells injected into symptomless transplanted psoriatic skin engrafted onto SCID mice produced full-fledged psoriatic lesions (Wrone-Smith and Nickoloff 1996; Nickoloff and Wrone-Smith 1999; Nickoloff et al. 1999; Nickoloff 2000).

Yamamoto et al. (1998) studied the effects of superantigen-driven peripheral blood mononuclear cells on the persistence of psoriasiform epidermis and on the cytokine gene expression of grafted psoriatic skin. Staphylococcal enterotoxin B-stimulated peripheral blood mononuclear cells from psoriatic patients were repeatedly injected under the grafted full-thickness involved psoriatic skin onto severe combined immunodeficient mice. A persistence of the psoriasiform epidermis was found after 5 weeks. E-selectin expression was observed on endothelial cells in the upper epidermis of the mice.

Tissue specificity of E- and P-selectin ligands in Th1-mediated chronic inflammation was studied by Chu et al. (1999).

P.5
Scleroderma models

P.5.1
Scleroderma models in chicken

Scleroderma is an autoimmune disorder which occurs in the severe systemic form, a localized scleroderma (morphoea) and as lichen sclerosus et atrophicus. Chickens of the University of California line 200 (**UCD-200 chickens**) developed an inherited inflammatory fibrotic disease, closely resembling human progressive systemic sclerosis (scleroderma) (Gershwin et al. 1981; Van de Water et al. 1984; Boyd et al. 1991; Gruschwitz et al. 1991, 1993; Herold et al. 1992; Needleman 1992; Brezinscheck et al. 1993; Ausserlechner et al. 1997; Nguyen et al. 2000). An acute inflammatory stage started at an age of about 60 days after hatching, leading to fibrosis with fast progression with severe lymphocytic infiltration and excessive accumulation of collagen in skin and internal organs. A sequential increase of type VI, type I and type II procollagen transcripts and a progressive increase of autoantibodies to histone, to ssDNA and to dsDNA was found.

A further strain of chickens with progressive systemic sclerosis (UCD 206) has been identified (Duncan et al. 1995; Sgonc et al. 1995).

P.5.2 Scleroderma models in mice

The **tight-skin mouse** is another experimental model for scleroderma (Walker et al. 1990; Muryoi et al. 1992; Delany and Brinkerhoff 1993; Kasturi et al. 1993, 1994; Wallace et al. 1994; Pablos et al. 1995; Frondoza et al. 1996). This mutant mouse develops autoantigens specific for scleroderma target tissues. The tight-skin disease was first discovered in 1967 at the Jackson Laboratory in the B10.D2(58N)/Sn mouse strain. The disease occurred spontaneously. Green et al. (1976) have identified the tsk locus and shown it to be linked to pallid locus. The tight skin character is transmitted as an autosomal dominant trait and homozygous tsk/tsk mice die *in utero*. The striking feature of the disease is the presence of thickened skin, firmly bound to subcutaneous and deep muscular tissue, with excessive accumulation of collagen in skin and internal organs (Menton et al. 1978; Osborn et al. 1983). Synthesis and accumulation of type I collagen is markedly increased (Jimenez et al. 1986; Ong et al. 1998). Biochemical studies have shown that the prolyl hydroxylase and glycosaminoglycan content of the affected tissue is increased (Ross et al. 1987).

Additionally, the **tight skin 2 mouse** has been described as an animal model of scleroderma displaying cutaneous fibrosis and mononuclear cell infiltration (Christner et al. 1995, 1996; Wooley et al. 1998; Sgonc et al. 1999).

Bleomycin-induced scleroderma in genetically mast cell deficient WBB6F1-W/W^V mice was described as an animal model of sclerotic skin by Yamamoto et al. (1999a–c).

Murine sclerodermatous graft-versus-host disease is considered as a model for human scleroderma (Claman 1990; Schiltz et al. 1994; McCormick et al. 1999).

A syndrome resembling human systemic sclerosis (scleroderma) in **MRL/lpr mice lacking interferon-receptor** was described by Le Hir et al. (1999).

A **mouse model for vitiligo** was described by Lerner et al. (1986), designated C57BL/6J-vit/vit. The vitiligo mouse has congenital dorsal and ventral white spots as well as progressive replacement of pigmented hairs with each spontaneous molt or after plucking.

P.6
Pemphigus models

P.6.1
Experimentally induced pemphigus in mice

PURPOSE AND RATIONALE

Pemphigus is defined as a group of spontaneously occurring disorders of skin and mucosae in which blisters and erosions form within the epidermis due to loss of intercellular contact (Marks 1987). Pemphigus occurs also spontaneously in domestic animals, such as dogs, cats, and horses (Hurvitz 1980; Scott et al. 1983; Sueki et al. 1997). Various attempts were made to study experimentally induced pemphigus in mice (Buschard et al. 1981; Takahashi et al. 1985; Anhalt et al. 1986a,b; Rock et al. 1990; Juhasz et al. 1993; Koch et al. 1997; Fan et al. 1999; Mahoney et al. 1999; Amagai et al. 2000; Zillikens et al. 2001).

Fan et al. (1999) screened four strains of female mice (BALB/c, DBA/1, SJL/J, and HRS/J) for their ability to produce pathogenic anti-desmoglein 3 antibodies. Only BLB/c mice immunized with full length desmoglein 3 can produce pathogenic antibodies capable of causing acantholysis in human foreskin in culture and blistering in neonatal mice.

PROCEDURE

Six- to 8-week-old female BALB/c, DBA/1, SJL/J, and HRS/J are immunized four times with 20 µg/mouse of purified desmoglein 3 protein in CFA (on days 1, 10, 20, and 30), four times with 20 µg/mouse of extracellular domain of desmoglein 3 (on days 40, 50, 60, and 70), and twice with 20 µg/mouse of refolded desmoglein 3 (on days 80 and 90), then they are boosted twice more with 20 µg/mouse of extracellular domain of desmoglein 3 in IFA by i.p. inoculation (on days 97 and 104). Control groups of mice are similarly immunized with BSA.

IGs from 10 ml of pooled serum from mice immunized with desmoglein 3 are precipitated with 40% ammonium sulfate, dialyzed against PBS twice, lyophilized, and reconstituted in water to 1 ml. One hundred µl of the reconstituted antibodies/mouse is injected into neonatal BALB/c mice.

EVALUATION

Mice are examined 18–24 h post injection for blister formation. Cross sections containing the blister and comparable areas in control animals are biopsied and frozen sections are prepared for routine histological examination.

P.7
Ichthyosis vulgaris models

P.7.1
Experimentally induced ichthyosis in mice

PURPOSE AND RATIONALE

Ichthyosis vulgaris is a heterogeneous autosomal skin disease characterized by dry, scaly skin, mild hyperkeratosis, and a decreased or absent granular layer that either lacks, or contains morphologically abnormal, keratohyalin granula (Anton-Lamprecht and Hofbauer 1972). Both the skin of ichthyosis vulgaris patients and keratinocytes cultured from affected individuals exhibit reduced or absent profilaggrin mRNA and protein levels (Sybert et al. 1985). The symptoms and the genetics of the ichthyotic (*ic/ic*) mouse were described by Spearman (1960), Green et al. (1974), Jensen and Esterly (1977), Holbrook (1989). Presland et al. (2000) demonstrated loss of normal profilaggrin and filaggrin in flaky tail (*ft/ft*) mice and proposed this as an animal model for the filaggrin-deficient skin disease ichthyosis vulgaris.

Elias et al. (1983) and Chung et al. (1984) induced ichthyosis in the hairless mouse by treatment with diazacholesterol and used this as an assay for comparative potency of topical retinoids.

PROCEDURE

Male hairless mice, 2–3 months old, are fed either a normal laboratory diet supplemented with 60 mg/kg/day of 20,25-diazacholesterol or normal laboratory diet. Diazacholesterol blocks the conversion of Δ^{24}-reduction of desmosterol to cholesterol (Anderson and Martt 1965), and as a result desmosterol accumulates in stratum corneum lipids rather than cholesterol. Ichthyotic changes generally become apparent after 8–12 weeks and are most pronounced over the back and tail. With the exception of some reduction in body weight in comparison with controls, the animals appear healthy. Since the tail manifests the most exaggerated scaling, this site is used for topical drug applications. As the animals become ichthyotic, the daily dose of diazacholesterol can be lowered to 30 mg/kg and maintained at that level.

The test substances (retinoids) are first solubilized in a small volume of dimethyl sulfoxide and then dissolved in Cremophore EL. A volume of ~100 µl of each test substance is applied once daily to circumscribed areas of the tail. Treatment groups consist of 3 animals each, and each animal serves as its own control. The drop is first placed on an investigator's gloved index fingers and then spread evenly around a designated band of the tail. Each animal is treated with two concentrations of the test drug. The most proximal and most distal portions of the tail are left untreated as control regions. Applications are continued for 2 weeks. At three- or four-day intervals, and at the termination of the experiment, the clinical response is graded from 0 to 4+, with 0 indicating no response and 4+ indicating removal of all visible scale, leaving a glistening surface.

Prior to biopsy, the skin surface is coated with a thin film of flexible collodion to prevent fragmentation during frozen sectioning. Perpendicular sections of biopsy samples are stained with aqueous 8-anilino-2-naphthalene sulfonic acid, which on fluorescence microscopy depict selectively stratum corneum hydrophobic membrane domains.

EVALUATION

Both control and drug-treated sections are measured in a double-blind manner. The mean and SE from a minimum of five separate regions are tabulated. Significant differences are determined by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Harlequin ichthyosis (ichq): a juvenile lethal mouse mutation with ichthyosiform dermatitis was described by Sundberg et al. (1997).

Knox and Lister-Rosenoer (1998) described an infantile ichthyosis in **rats** and proposed this as a new model of hyperkeratotic skin disease.

P.8
Xeroderma models

P.8.1
Experimentally induced xeroderma in mice

PURPOSE AND RATIONALE

Xeroderma pigmentosum is an autosomal recessive disorder characterized by hyperphotosensitivity and multiple cancers in association with abnormal DNA repair (Robbins et al. 1974; Satokata et al. 1992). Xeroderma pigmentosum group A (XPA) gene-deficient mice cannot repair UV-induced DNA damage and easily develop skin cancers by UV-irradiation (Nakane et al. 1995; Miyauchi-Hashimoto et al. 1996, 1999). Kuwamoto et al. (2000) tested the involvement of enhanced prostaglandin E_2 production in the photosensitivity in Xeroderma pigmentosum group A model mice and the influence of a prostaglandin synthesis inhibitor.

PROCEDURE

XPA gene-deficient homogeneous mice, age 8–12 weeks, are used (Nakane at al 1995). The UVB source consists of a bank of fluorescent sunlamps with an emission spectrum from 270 to 375 nm, peaking at 305 nm. The mice are anesthetized by i.p. injection of phenobarbital to keep them immobile during exposure. The ears are irradiated with 250 mJ per cm^2 of UVB. Immediately after irradiation, the test drug (20 µl of 1% solution of the prostaglandin synthesis inhibitor indomethacin) is applied to the ears. Ear thickness is measured with a dial thickness gauge immediately before irradiation and 1–4 days after irradiation. The amounts of PGD_2, PGE_2, and PGF_{2a} in mouse ears at 0, 24, 48, and 72 after UVB irradiation are determined by enzyme immunoassay.

EVALUATION

Student's *t*-test is employed to determine the statistical difference between means.

MODIFICATIONS OF THE METHOD

P.9 Acne models

P.9.1 Activity on sebaceous glands of rats

PURPOSE AND RATIONALE

Bioassays for topical antiandrogens are based on inhibition of sebum secretion. Sebum production is increased by endogenous or exogenous androgens in many species including humans. In the mouse (Lapière and Chèvremont 1953; Neumann and Elger 1966), the Mongolian gerbil (Mitchell 1965), and the golden hamster (Hamilton and Montagna 1950), the male sex hormone stimulates sebum production and sebaceous gland growth. Morphometric evaluation by light microscopy in the rat has shown that castration causes a large reduction in the volume of the glands (Sauter and Loud 1975). The administration of testosterone over several days produces an enlargement of the sebaceous glands. Early transformations, which take place in the morphology of the organelles in sebaceous cells, can be observed by electron microscopy. In the cytoplasm of intermediate cells a large number of vesicular elements derived from the smooth endoplasmic reticulum is formed, participating in the synthesis of lipids which appear as droplets of varying size (Karasek 1968; Morohashi 1968). Following an increase of lipid droplets, the cells increase in size, become totally differentiated and are pushed towards the apex of the gland where they break up and release their content (sebum) into the infundibulum. This effect is used for morphometric evaluation of topical anti-androgens.

PROCEDURE

Groups of 5 adult male Sprague-Dawley rats weighing 180–220 g are shaved in the interscapular area. Twenty-four hours later, the test preparation or the standard (cyproterone acetate) is applied locally to the shaved area at increasing doses (0.05, 0.5, and 5 mg/cm^2) in 20 µl ethanol. The treatment is continued for three weeks. Controls receive ethanol only. The animals are sacrificed 24 h after the last administration. Pieces of skin from the interscapular region are excised and processed for evaluation by electron microscopy. The volume density of the smooth endoplasmic reticulum vesicles is measured.

EVALUATION

Dose-response curves are established for volume density of vesicles of the smooth endoplasmic reticulum after various doses of antiandrogen and testosterone standard in order to calculate activity ratios. Statistical comparison with untreated controls allows calculation of threshold doses.

MODIFICATIONS OF THE METHOD

Ebling and Petrow (1993) tested 19-Aldehydo-4-androstene-3,17-dione, an estrogen precursor that inhibits sebaceous secretion in ovariectomized testosterone-treated rats.

De Young et al. (1984, 1985) described intradermal injection of *Propionibacterium acnes* as a model of inflammation relevant to acne. Intradermal injection of killed *P. acnes* into the rat ear induces a chronic acne-like inflammation characterized by edema and cell infiltration of several months' duration, formation of comedones, hypersensitization, and transepithelial elimination.

Shamoto et al. (1999) investigated the dermal histology and the regional draining superficial lymph node of a new mutant strain of hairless rats (ISh). The homocygote ISh rat was characterized as having naked and wrinkled skin. The comedo-like casts in the skin resembled human acne.

P.9.2
Activity on sebaceous glands of the fuzzy rat

PURPOSE AND RATIONALE

Fuzzy rats, a genetic mutant between hairless and haired albino rats, exhibit sexual dimorphism in the skin (Ferguson et al. 1979). A brown-colored, thick seborrhoeic coating on the entire back is characteristic of male rats while the female rats show clear skin with white fuzzy hairs. In male rats the hair follicles resemble human sebaceous follicles associated with hyperplastic glandular lobules, dilatation and microcomedo (Plewig and Kligman 1975). Castration caused a reduction in size of the sebaceous glands and ducts, and a testosterone implant in castrated rats resurrected glandular hyperplasia and ductal dilatation (Uno et al. 1990).

This rodent model for androgen-dependent hyperplasia of the sebaceous glands is useful for the study of many pharmacological aspects, comprising the rate of percutaneous absorption, stability, and affinity to target organs of the testing compounds and selection of adequate vehicles for topical application (Ye et al. 1997).

PROCEDURE

Peripubertal male fuzzy rats at an age of 25 days weighing about 40 g are kept in single cages at a temperature of 24 °C and a 12-h light-and-dark cycle. They are divided into several groups for local treatment with 5α-reductase inhibitors or androgen receptor antagonists. One group serving as control is castrated at an age of 25 days in anesthesia. Approximately 0.5 ml of a 1% solution of test compounds dissolved in 30% propylene glycol, 50% alcohol and 20% water are applied to the other groups in a 4×4 cm area on the lower back once per day 5 days per week. Vehicle solution alone is applied to the control and castrate groups. After 8 weeks of treatment, the animals are euthanized by anesthesia with ketamine HCl, 100 g/ml, xylazine HCl, 120 g/ml, acepromazine, 5 g/ml, 1 ml/kg intramuscularly.

Photographs of the backs are taken pre-treatment and every 2 weeks after the start of treatment.

Eight weeks after starting treatment, the animals in all groups are given an intraperitoneal injection of 200 mg/kg bromodeoxyuridine 2 h before euthanasia. A blood sample is then collected from the right ventricle of the heart under anesthesia with the ketamine-xylazine-acepromazine mixture. After euthanasia with an overdose of the same anesthesia solution, fresh skin tissues are taken by a punch (4 mm diameter) from the marked area of the back and immediately incubated with EDTA solution for the split-skin preparation. The rest of the skin in the marked area is cut and fixed with 10% neutral buffered formalin solution for morphometric analysis of the sebaceous glandular lobules. The ventral lobes of the prostate are dissected and the weight is measured.

For morphometric analysis of the sebaceous glands, the size of sebaceous glandular lobules is first determined. Using formalin-fixed skin, small skin samples are taken by punch (4 mm diameter) and serial frozen sections (40 μm thick), horizontal to the epidermal surface, are cut and collected in water-filled wells. Four to five free-floating sections containing sebaceous glandular lobules are selected and stained with 1% osmium and 2.5% potassium dichromate solution for 2–3 min. The sections are washed with distilled water and mounted on a glass slide with aqua mount. Darkly stained globular lobules are distinctively seen under the microscope or on microvideo images. The largest lobular area in each glandular image is measured by a computer-assisted microimage apparatus, using a program of image analysis.

Split preparations of the pilosebaceous organ are used to measure the size of the sebaceous lobule and duct, and the number of DNA synthesis sebocytes. Fresh skin samples, 4 mm punched, are incubated with 17 mM EDTA in phosphate buffer (0.1 M, pH 7.4) for 2 h at 27 °C. The pilosebaceous organs attached to the epidermis are manually split from the dermis. Follow-

ing fixation with 10% buffered formalin, free-floating split tissues are stained by the immunocytochemical method, using a monoclonal antibody against bromodeoxyuridine with the avidin-biotin complex method.

On viewing the split tissue under a stereomicroscope, the sebaceous glandular lobules with a duct attached to the follicular shaft are clearly visible. After mounting on a slide glass, these *in situ* images of the sebaceous glands are observed on a computer monitor with a microvideo apparatus, and the area of the lobes, the diameter of the duct and number of bromodeoxyuridine-stained nuclei in the sebocytes are measured.

EVALUATION

Group data are expressed as means ±standard error. The results are analyzed using the *t*-test.

MODIFICATIONS OF THE METHOD

Marit et al. (1995) presented anatomical and physiological parameters of the fuzzy rat, collected for each sex at five ages, including histological and clinical biochemical profiles, organ and body weights, and a characterization of gross and histopathological findings.

Yourick and Bronaugh (2000) studied percutaneous penetration and metabolism of 2-nitro-*p*-phenylendiamine in human and fuzzy rat skin.

Salcido et al. (1995) described an animal model and computer-controlled surface pressure delivery system for the production of pressure ulcers. A method for inducing dermal pressure lesions on the fuzzy rat was developed using a computer-controlled displacement column, which produced a constant tissue interface pressure.

P.9.3
Activity on ear sebaceous glands of Syrian hamsters

PURPOSE AND RATIONALE

The ear sebaceous glands of the Syrian hamster have been proposed as a model system for human sebaceous glands because of the similarities in morphology and in turnover time (Hamilton and Montagna 1950; Plewig and Luderschmidt 1977). As an androgen-sensitive structure, the ear sebaceous glands have been used to determine the effect of antiandrogenic compounds by the use of histoplanimetry on projections of sagittal sections of the ear (Luderschmidt and Plewig 1977). Matias and Orentreich (1983) developed a stripped skin planimetric method to measure the ear sebaceous gland areas in Syrian golden hamsters.

Seki et al. (1995) determined the effects of topically applied spironolactone on androgen stimulated sebaceous glands in the hamster pinna.

PROCEDURE

Adult female Syrian golden hamsters, 9–10 weeks of age and 110–120 g in weight, are kept at constant temperature and humidity and fed commercially prepared hamster food and water. The hamsters are divided at random into three groups. Testosterone propionate (80 µg dissolved in 1 ml sesame oil) is administered to two groups every other day over a two weeks period to stimulate androgen responses. Hamsters in the third group are injected with 1 ml sesame oil only as controls. The hamsters receive once daily applications of 0.1 g of a colorless clear hydrophilic gel preparation of 5% spironolactone, containing ethanol and isopropyl alcohol on the ventral side of the right pinna for two weeks. The left side is left untreated as control. On day 15, 4 mm punch biopsy specimens from each hamster are obtained from the central region of the bilateral pinnae where sebaceous glands are most developed.

The sebaceous gland size is measured by the whole mount technique (Motoyoshi 1988). After the biopsy specimens are immersed in physiological saline at 4 °C for 18 h, cartilages are removed. Then, each specimen is immersed in 2 N NaBr at 37 °C for one hour, and the epidermis is peeled off with fine forceps. The obtained dermis sheet containing sebaceous glands is stained with Susan III and mounted on a glass slide.

EVALUATION

An area of five or more sebaceous glands, including all the sebaceous acini attached to one pilosebaceous unit in each biopsy specimen, is measured with a computerized image analyzer (Olympus CIA-102) and shown as a mean value ± standard deviation ($mm^2/100$). The values are compared using Student's paired *t*-test.

MODIFICATIONS OF THE METHOD

Gollnick (1990, 1992) evaluated azelaic acid proposed for acne treatment, using comedo formation in the hamster ear model and recommended it as a new substance in the spectrum of antiacne agents.

Matias and Gaillard (1995) studied the local inhibition of sebaceous gland growth in the ventral ear pinna of sexually mature male Syrian hamsters by topically applied androgen receptor inhibitors.

Seki and Morohashi (1993) investigated the effect of some alkaloids, flavonoids and triterpenoids on the lipogenesis of sebaceous glands of the hamster ear. Lipogenesis was assayed by determining ^{14}C incorporation into sebaceous lipids extracted from the sebaceous glands, which were incubated with ^{14}C-acetate.

Morgan et al. (1993) studied the occurrence of zinc-induced synthesis of metallothionein in skin after topical application of the anti-acne drug Zineryt® lotion in hamster ears. The dinitrophenyl hapten-sandwich immunohistochemical method involving a monoclonal anti-metallothionein antibody was used to detect and localize zinc-binding metallothionein in the treated and untreated hamster skin.

P.9.4
Activity on ear sebaceous glands of rabbits

PURPOSE AND RATIONALE

Several authors used the rabbit ear model to study comedo formation (Weirich and Longauer 1974; Mills and Kligman 1975; Motoyoshi 1983a; Kligman 1989; Ito et al. 1985, 1991; Maeda 1991) in order to assess the comedogenicity of cosmetics, toiletries and drugs and to evaluate potential anti-acne drugs. Sebaceous follicles in the inner surface of rabbit ears are sensitive to many substances called comedogenes, which, when applied topically, induce comedo formation. This comedo induction takes place after about 2 weeks of repeated topical application of a chemical comedogen such as 1% coal tar, 50% oleic acid, or 50% tetradecane.

PROCEDURE

Male rabbits weighing 2.5–3.5 kg are used. Tetradecane, testosterone, and dimethyl sulfoxide are separately inuncted on rabbit pinnas once a day for 4 weeks. The pinnas are biopsied on days 1, 3, 7, and 28. Untreated pinnas and squalene-treated pinnas serve as controls. Three-dimensional images of sebaceous glands are reconstructed from their serial histological sections using a computer-image analysis system.

EVALUATION

The volumes of the sebaceous glands, the number of acini, and the volume of individual acini are compared between groups.

MODIFICATIONS OF THE METHOD

Motoyoshi (1983b) studied the correlation between surface microscopy and dermal histology in tetradecane-induced comedones in rabbit ear skin.

Kligman and Kligman (1994) used the rabbit ear to assay the comedogenic potentialities of an array of known tumorigens. Complete carcinogens and some tumor promoters were invariably strongly comedogenic at concentrations of 1.0% and below. The rabbit ear model was recommended to be an easy and reliable way to screen for carcinogenicity.

P.9.5
Activity on the hamster flank organ

PURPOSE AND RATIONALE

The flank organs of Syrian golden hamsters are located on each flank of the animal consisting mainly of sebaceous tissue. Like sebaceous glands in other species, these pigmented spots respond to androgens by an increase in size. This proliferation is inhibited by systemical or topical anti-androgens.

PROCEDURE

Female Syrian golden hamsters (*Mesocricetus auratus*), weighing 80–110 g are kept at constant temperature on a commercial diet and water ad libitum. They are castrated 24 h prior to the experiment. The costovertebral region is shaved; the horny layer is stripped the day prior to the tes and then every 3 days. For stimulation, animals receive a subcutaneous dose of 250 µg testosterone propionate in 25 µl peanut oil in the dorsal neck fold, for three weeks (weekdays only or continually). On the same days, the anti-androgen dissolved in water/ethanol (1 : 4, v/v) is applied locally to the left flank organ at increasing doses, using a micropipette under a continuous air stream to enhance the evaporation of the solvent. At least 5 animals are used per group. Controls receive vehicle only, and another group, testosterone propionate only. After treatment the animals are sacrificed under ether anesthesia. The 2 major perpendicular axes of the pigmented spot overlying each flank organ are measured and multiplied to obtain the surface area index. The flank organs are excised and divided into two halves along the major axis, immediately fixed in 10% formalin and embedded in paraffin. The 5 µm-thick sections are stained with haematoxylin-eosin. Sebaceous glands and hairs are measured in the first 2 sections of each half of the specimen, using a semiautomatic computerized image analyzer. The sebaceous gland area in each field is quantified in square millimeters. The diameter of all the hair under each flank organ is measured in micrometers.

EVALUATION

The local (topical) anti-androgenic activity of the test compound is estimated by the ability to inhibit the effects in the ipsilateral treated flank organ whereas the systemic activity is evaluated by the inhibition on the untreated contralateral flank organ. The values for surface area index, sebaceous gland area, and average of diameter of the hairs on the flank organ of the treated left and the untreated right side are compared for anti-androgen-treated animals with controls using two-way analysis of variance and *t*-test.

MODIFICATIONS OF THE METHOD

Wuest and Lucky (1989) studied the differential effect of testosterone on pigmented spot, sebaceous glands and hair follicles in the Syrian hamster flank organ.

Noto et al. (1991) quantified the antiandrogenic activity of topically applied canrenoic acid in the hamster flank organ. The flank organs of female Syrian hamsters were stimulated by subcutaneous administration of testosterone propionate. Sebaceous glands and hair follicles were measured by a computerized image analyzer. Using this method, the same authors (Noto et al. 1992) compared the activity of some topical antiandrogens.

Aricò et al. (1993) found no antiandrogenic effects of topical bifonazole on sebaceous glands and hair in the hamster flank organ.

Lucky et al. (1995) studied the autoradiographic localization of tritiated dihydrotestosterone in the flank organ of the albino hamster.

Foreman et al. (1984) found that in the hairless hamster, progesterone can antagonize dihydrotestosterone-mediated hypertrophy of the sebaceous gland.

CRITICAL ASSESSMENT OF THE METHOD

The relevance of the hamster flank organ model to man has been challenged by Franz et al. (1989).

P.9.6
Activity on the skin of the Rhino mouse

PURPOSE AND RATIONALE

The Rhino mouse has been widely used as an experimental acne model to evaluate topically active comedolytic and anti-keratinizing agents (Kligman and Kligman 1979; Ashton et al. 1984; Mezick et al. 1984; Chatelus et al. 1989; Bernerd et al. 1991; Bouclier et al. 1991; Tramposch et al. 1992; Zheng et al. 1993; Sundberg 1994; Fort-Lacoste et al. 1999).

Rhino mice are hairless mutants with a rhinoceros-like appearance, which carry the rhino gene, a recessive allele of the hairless gene ($hr^{rh}hr^{rh}$) (Howard 1941). This recessive mutation on chromosome 14 results in a mouse with wrinkled skin devoid of body hair by age of 25 days. At that time, the end of the first hair cycle, the follicular papillae fail to follow the regressing hair follicles and become isolated in the dermis. The papillae do not re-associate with the follicular epithelium to initiate a new hair follicle cycle. The upper remnants of the hair follicles are filled with sloughed, cornified cells and form utriculi with a small sebaceous gland at their base, resembling an open comedone. The Rhino skin becomes progressively loose, forming folds and ridges, due to the expansion of the surface, secondary to abortive hair follicles filling with cornified debris. The utriculi progressively enlarge, forming pillory cysts (pseudocomedones), which are dilated follicular infundibula filled with cornified debris (Mann 1971). The dermal cysts of the rhino mouse develop into unopened sebaceous glands (Bernerd et al. 1996).

Seiberg et al. (1997) studied the effects of trypsin on apoptosis, utriculi size and skin elasticity in the rhino mouse. González et al. (2000) measured the effect of graduated local doses of all-*trans* retinoic acid applied to the skin of rhino mice with fluorescence excitation spectroscopy and compared the data with histological findings.

PROCEDURE

Seven-weeks old female rhino mice ($hr^{rh}hr^{rh}$) obtained from Charles River Laboratories are divided into groups receiving graduated doses of test compound (all-*trans* retinoic acid) dissolved in an ethanol/propylene glycol mixture (70 : 30) or the solvent as controls. The solution is applied once per day in doses of 100 µl on the entire dorsal skin, for 5 consecutive days each week, for a total period of 2 weeks. Animals in all groups are sacrificed 24 h after the last treatment and biopsies are obtained immediately following sacrifice. Fluorescence excitation spectra are collected from dorsal skin on a daily basis during treatment. During the measurements, the animals are sedated with inhalation of methoxyflurane.

Fluorescence excitation spectra are obtained *in vivo* with a fluorescence spectrophotometer (SkinSkan, SPEX, Edison NJ) equipped with a 450 W Xenon lamp, double monochromators on the excitation and emission, a photomultiplier detector (R928P, Hamamatsu, Japan) connected to a single photon counting system and a bifurcated quartz fiber bundle (Model 1950; SPEX Ind., Edison, NJ) for light delivery and collection. The individual fibers are 100 µm in diameter and are randomly arranged to form a bundle 6 mm in diameter. The resolution is 4 nm, the intensity of the excitation radiation is in the range of 1–20 mW/cm^2, and the total delivered radiation dose is below the erythema threshold. Each fluorescence measurement consists of a set of eight serial excitation spectra collected by positioning the emission monochromator from 340 to 480 nm in increments of 20 nm and scanning the excitation monochromator from 260 to within 20 nm of the emis-

sion monochromator setting. Light from the excitation monochromator is focused into one leg of the bifurcated fiber bundle. The other leg of the fiber bundle is focused into the input of the emission monochromator. The joined end of the fiber bundle is brought into direct contact with the skin site measured. Care is taken to clean properly the fiber bundle end with an alcohol swab between measurements on different animals and that gentle pressure is applied to the animals during measurement.

Significant changes are observed in the fluorescence spectra as a result of the application of comedolytic agents. The first peak, located approximately at 295 nm, which is related to tryptophan, increases significantly, whereas the second peak at 340–370 nm, which is attributed to collagen links, exhibits a dramatic decrease.

For histology, skin samples approximately 5 mm in diameter are obtained from the skin of each animal following sacrifice, from the mid-line of the anterior portion of the skin. All specimens are fixed in 10% buffered formaldehyde for 24 h, and later embedded in paraffin. Tissue sections 5 µm thick are cut perpendicularly to the epidermal surface and stained with hematoxylin and eosin for light microscopic examination. For each animal, the epidermal and dermal thickness, utriculi diameter, and number of capillaries containing more than 5 erythrocytes are assessed with a micrometer eyepiece adapted to a microscope (Leitz SM-LUX, Ernst Leitz, Wetzlar, Germany) using a 40× objective for the measurement of epidermal and dermal thickness, and utriculi diameter, and a 20× objective for the count of dilated capillaries.

EVALUATION

Time-response curves and dose-response curves of the changes of fluorescence spectra are established compared with the changes of histological data.

MODIFICATIONS OF THE METHOD

In addition to image analysis, Seiberg et al. (1997) tested the effects of trypsin on skin elasticity and elastin expression in the Rhino mouse.

Beehler et al. (1995) studied gene expression of retinoic acid receptors and cellular retinoic acid-binding proteins in rhino and hairless mouse skin.

González et al. (1997) investigated DNA ploidy changes in rhino mouse skin after treatment with all-*trans* retinoic acid and retinol.

Petersen et al. (1984) developed an animal model using human face skin onto the nude mouse to study human sebaceous glands. The effects of androgens were evaluated.

Lesnik et al. (1992) reviewed agents that cause enlargement of sebaceous glands in hairless mice.

P.9.7 Activity on the skin of the Mexican hairless dog

PURPOSE AND RATIONALE

The Mexican hairless dog has been recommended as a model for the comedolytic and morphogenic activity of retinoids and other anti-acne agents (Loux et al. 1974; Schwartzman et al. 1996; Kimura and Doi 1996). A semilethal mutation of an autosomal dominant 'L' gene produces an animal with multiple developmental defects, including poor dentition, early degeneration of the thymus, hairlessness and numerous comedones (Yankell et al. 1970a; González-Diddi et al. 1971; Goto et al. 1987; Fukuda et al. 1991). The Mexican hairless dog is nearly bald, with sparse, flimsy hair most abundant on the limbs and head. In most hairy species, the primary hair is surrounded by 7 to 10 accessory hairs. In this species, the follicles are mainly single and not in clusters. The skin is tan-colored. A brownish, waxy material unevenly coats the surface; this can be removed easily by soap and lipid solvents. A great number of comedones cover the surface, and these are nearly all of the open variety. The majority is rather small (a few millimeters in diameter), and may be viewed as horn-filled shallow invaginations. Scattered among these, especially on the face, neck and thighs, are larger, black-tipped open comedones. These are hard, deep, horny impactions, which are expelled with difficulty. A few small, closed comedones occur on the neck and lateral aspect of the chest.

Papulopustules are rare, and are found mainly on the metacarpus and metatarsus. They apparently do not develop from the rupture of comedones as in humans. Thus, this animal mimics human acne only with regard to comedones. These, unlike the human variety, do not originate from pre-existing sebaceous follicles. They arise de novo, and completely lack sebaceous glands.

PROCEDURE

About 1-year-old female animals are used. Areas of 4–5 cm^2 on the dorsolateral aspects of the trunk are treated once daily (5 working days) for 14 weeks with test formulations or tretinoin formulations (0.025–0.1%) as standard.

Biopsies are taken from each site under local anesthesia at 5 weeks and again at 14 weeks.

EVALUATION

The clinical picture and the histology of biopsies are compared before, during, and after treatment.

MODIFICATIONS OF THE METHOD

Yankell et al. (1970b) used the Mexican hairless dog for sunscreen recovery studies.

Hunziker et al. (1978) compared percutaneous penetration of benzoic acid, progesterone and testosterone between Mexican hairless dogs and man.

Matsumura et al. (1992) described a burn wound-healing model in the hairless descendant of the Mexican hairless dog.

P.9.8 *In vitro* sebocyte model

PURPOSE AND RATIONALE

Cultured human sebocytes have been used by several authors to study sebum formation and to evaluate potential ant-acne drugs (Zouboulis et al. 1991a,b, 1993, 1994, 1998; Rosenfield 1989; Doran and Shapiro 1990; Doran et al. 1991; Akamatsu et al. 1993; Guy et al. 1996a,b; Rosenfield et al. 1998; Wauben-Penris et al. 1998; Tsukada et al. 2000; Fritsch et al. 2001).

PROCEDURE

Human sebaceous glands are isolated from facial skin and seeded on monolayer 3T3 cells (Xia et al. 1989). Primary sebocyte cultures are derived from the periphery of the gland lobules and are maintained to confluence before subcultivation. All experiments are performed using secondary sebocyte cultures, which consist of cells undergoing sebocytic differentiation.

Human sebocytes are seeded in 96-well culture plates at a concentration of 10^4 cells/well and are left to attach for 2 days at 37 °C with 5% CO_2 in culture medium consisting of Dulbecco's modified Eagle's medium and Ham's F12 medium (1 : 1) supplemented with 8% fetal calf serum, 2% human serum, 10 ng/ml epidermal growth factor, 10^{-9} M cholera toxin, 3.4 mM L-glutamine, 100 IU/ml penicillin, and 100 µg/ml streptomycin. The medium is then aspirated, and serum-free keratinocyte basal medium (KBM) (Clonetics, San Diego, CA) without additives, supplemented with steroids, e.g., testosterone (10^{-8}–10^{-5} M), 5a-dihydrotestosterone (10^{-8}–10^{-5} M), or spironolactone (10^{-12}–10^{-7} M) or their combinations are added to 6 wells at each concentration. KBM is concomitantly added to another 6 wells serving as controls. The plates are incubated at 37 °C for 10 days before evaluation. KBM with and without compounds is changed every 2 days.

Cell numbers of treated human sebocytes in 96-well culture plates are assessed over 9 days by counting single-cell suspensions in Neubauer chambers and compared with the absolute fluorescence units (AUF) of parallel wells obtained using the 4-methylumbelliferyl heptanoate (MUH)-fluorescence assay (Stadler et al. 1989). This assay is based on the hydrolysis of the fluorogenic substrate MUH by esterases of proliferating cells. A stock solution of 10 mg/ml MUH is prepared in DMSO and kept frozen at –20 °C until use. On the day of assessment, KBM is removed, and the cells are washed twice with phosphate-buffered saline without Ca^{2+} and Mg^{2+} (pH 7.2). The MUH stock solution is diluted in phosphate-buffered saline up to 100 µg/ml, and 100 µl of the final solution is added to each well. The plates are then incubated for 30 min at 37 °C and read automatically on a Titertek Fluoroscan II (Flow, Meckenheim, Germany).

EVALUATION

The results are given as absolute fluorescence units using 355-nm excitation and 460-nm emission filters. Statistical significance of the differences between the means is assessed by Student's *t*-test.

General considerations

PURPOSE AND RATIONALE

Fungal infections of the skin account for a large number of consultations to general practitioners and dermatologists. They are caused by dermatophytes, such as Trichophyton rubrum, Trichophyton tonsurans, Trichophyton mentagrophytes, Microsporum canis, Epidermophyton floccosum, Microsporum gypseum, and Trichophyton verrucosum. (Sinski and Kelley 1991).

Most fungal skin infections, such as tinea pedis and tinea cruris, respond to topical therapy, although widespread or chronic infections that do not respond to local measures may require systemic treatment, for example with griseofulvin, ketoconazole or terbinafine. Traditional topical products such as compound benzoic acid ointment (Whitfield's ointment) and tolnaftate preparations have largely been superseded by other topical-active antifungal agents, such as the imidazoles (e.g. clotrimazole, miconazole or econazole) or hydroxypyridones (e.g. ciclopirox), which are well tolerated and rapidly effective (Gupta et al. 1994). Fungal infections also affect the appendices, such as hair and nails. To evaluate antifungal agents not only the antimicrobial spectrum, but also the penetration plays a decisive role.

P.10.2
In vitro inhibitory activity

PURPOSE AND RATIONALE

In vitro tests are performed to investigate whether the test compound in comparison to standards covers the most relevant pathogens of dermal mycoses. The test conditions are rendered more difficult by addition of protein since the main infection site for fungi is the horny layer of the epidermis, which has a high protein content.

PROCEDURE

The studies are performed by means of conventional serial dilution procedures in test medium without and with addition of 4% bovine albumin. The test medium is Sabouraud dextrose broth containing 1% Neopeptone Difco (Difco Laboratories, Detroit, Mich., USA) and 2% glucose. The basic medium is sterilized in an autoclave at 121 °C for 15 min. The pH is adjusted to 6.5 with 1 N NaOH. The medium containing albumin is sterilized by filtration through a membrane filter. For preparation of the test series, the inhibiting substances are dissolved in methanol and then rapidly diluted with slightly warmed test medium, so that series with a continuous dilution factor of 2 are obtained: 125–0.03 µg/ml in medium without protein, 500–1 µg/ml in medium with protein. Each test tube contains 3 ml. The test organisms are various strains of dermatophytes (*Trichophytum mentagrophytes*, *T. rubrum*, *T. verrucosum*, *T. equinum*, *T. gallinum*, *Microsporum canis*, *Microsporum gypseum*) and yeasts (*Candida albicans*, *Ca. tropicalis*, *Ca. pseudotropicalis*, *Ca. krusei*, *Ca. parapsilosis*, *Ca. lipolytica*, *Ca. brumpti*, *Ca. utilis*, *Torulopsis glabrata*). The organisms are pre-cultured on a modified Grütz agar at 28 °C for periods of 1–4 weeks. The suspensions are adjusted by photometry that about 10^5 microconidia of dermatophytes and 10^4 yeast cells per ml are obtained in each inoculated test tube. The minimal inhibitory concentrations are measured after 14 days incubation at 28 °C.

EVALUATION

The percentage of strains of *Trichophytum mentagrophytes*, *Trichophytum rubrum*, and *Candida albicans* is plotted against dilution steps for each test compound with and without albumin and IC_{50} values are calculated.

P.10.3
In vivo activity in the guinea pig trichophytosis model

PURPOSE AND RATIONALE

The guinea pig trichophytosis model has been used by several authors to evaluate antimycotic compounds (Millberger and Gillert 1973; Dittmar et al. 1981; Plempel et al. 1983; Petranyi et al. 1987; Schaude et al. 1990; Garcia Rafanell et al. 1992; Arika et al. 1993).

PROCEDURE

Male albino guinea pigs (Pirbright White), bred mycosis-free, weighing 450–550 g are fed Altromin® pellets and tap water ad libitum. On both sides of the back, areas of 5 × 12 cm are shorn to a fur length of 1 mm.

Three areas with a diameter of 3 mm are inoculated with a pipette on either side. Per injection site, 10^4 spores of *Trichophyton mentagrophytes* 2 114 in 0.05 ml suspension in physiological saline solution are inoculated. Three days after inoculation, infections with redding and scale formations are observed. From days 3–7 after the infection, 1 ml of the test preparation or standard is applied onto the right animal sides and rubbed in once daily. The diameters (mm) of all alopecias are measured with a ruler 3.5 weeks after the infection.

EVALUATION

The values of alopecias, separated according to the treated group and animal side, are determined and statistically evaluated using Duncan's new multiple range test.

P.10.4 Skin penetration

PURPOSE AND RATIONALE

Cutaneous pathogenic fungi like dermatophytes or Candida ssp. present a particular affinity for the stratum corneum. Therefore the bioavailability of antimycotic drugs in the thick horny layer of the skin is an important element of treatment success. These studies can be performed in human cadaver skin (Dittmar 1981; Kligmann et al. 1987; Hänel et al. 1988)

PROCEDURE

Skin pieces, measuring 10×12 cm are removed from the back of corpses not later than 24 h after death. The subcutis is removed and the skin piece divided 3 to 5 parts. The edges (4 mm) of each individual piece are then taped with Tesa-film (adhesive tape) and the remaining surface is treated with the antimycotic compound. 0.05 ml of compound preparation or solution is rubbed into the skin for 10 s. For a period of one h, the pieces are placed on water agar, allowing for free admission of air. After this time, the compound is carefully wiped off with filter paper and water.

The skin area treated with the antimycotic is then stripped with Tesa-film tape as follows: (A) one third of the area remains unstripped; (B) one third of the area is stripped three times; (C) one third of the area is stripped six times. Then each piece of skin is placed into a Petri dish, which is heated in a water bath to 52 °C for 15 min. The epidermis is removed from all the skin pieces, which are then placed on slides (with the base turned upwards) and put into the upper parts of plastic Petri dishes. Each of the epidermis pieces is inoculated in 20 sites with a microconidia suspension of the dermatophyte Trichophyton mentagrophytes 109-FHM 1a. The spores had been rinsed off from three-week-old slant cultures, using distilled water. Approximately 50–100 viable spores are deposited at each inoculation site.

The upper parts of the Petri dishes (containing the slides with the epidermis pieces) are then covered with the bottom parts of Petri dishes, which contain 2% aqueous agar for producing a wet chamber. Holes in the covers serve to avoid excess humidity in the chamber. The chambers are incubated at 28 °C for 5 days. The fungal growth is recorded daily according to a three points score system.

EVALUATION

Growth is evaluated by visual scoring from days 2–5 after inoculation and calculation of AUCs from growth curves.

Inhibition values (%) are calculated according to the formula:

$$\text{inhibition} = \frac{\text{growth on controls} - \text{growth after treatment}}{\text{growth on contols}} \times 100$$

MODIFICATIONS OF THE METHOD

Ceschin-Roques et al. (1991) performed penetration studies on excised skin from the back of slaughtered pigs.

P.11
Biomechanics of skin

P.11.1
General considerations

Several attempts were made to describe the mechanical properties of skin by mathematical models (Ridge and Wright 1965; Harkness 1971; Hirsch and Sonnerup 1968; Jamison et al. 1968; Viidik 1968, 1969, 1973, 1979; Frisén et al. 1969a,b; Veronda and Westman 1970; Danielson 1973; Soong and Huang 1973; Wilkes et al. 1973; Jenkins and Little 1974; Lanir and Fung 1974; Vogel 1976, 1986; Barbanel and Evans 1981; Barbanel et al. 1978; Lanir 1979; Barbanel and Payne 1980; Burlin 1980, 1981; Fung 1981; Sanjeevi 1982; Potts and Breuer 1983).

Most of these authors used models derived from studies in polymers (Ferry 1970). The simplest mechanical model analogous to a viscoelastic system is a spring combined with a dashpot, either in series (**Maxwell element**) or in parallel (**Voigt or Kelvin element**). Combinations of these elements were used to explain the mechanical phenomena in connective tissue, such as stress-strain behavior, relaxation and mechanical recovery, hysteresis and creep phenomena (Jamison et al. 1968; Frisén et al. 1969a,b; Hirsch and Sonnerup 1968; Vogel 1976, 1993; Riedl and Nemetscheck 1977; Vogel and Hilgner 1979; Viidik 1968, 1969, 1973, 1977, 1979). Larrabee (1986), Larrabee and Sutton (1986).

Larrabee and Galt (1986) reviewed the theoretical and experimental mechanics of skin and soft tissue and proposed a mathematical model of skin deformation based on the finite element method. A finite element based method to determine the properties of planar soft tissue was also described by Flynn et al. (1998).

Unfortunately none of these models has been found to be sufficient to describe all properties of human and animal skin including the mechanical history before measurement and the time-dependence during measurement. There is no comprehensive and unequivocally accepted model to describe completely the biorheology of skin. Therefore, several methods are used in order to get insight into the physical properties of skin.

P.11.2 *In vitro* (*ex vivo*) experiments

P.11.2.1 Stress-strain behavior

P.11.2.1.1 Measurement of skin thickness, ultimate load, tensile strength, ultimate strain and modulus of elasticity

PURPOSE AND RATIONALE

Animal experiments are preferable when studying the biomechanical properties of the dermis, since only in animals can the values at higher extension degrees be studied, *ex vivo* or *in vivo* under anesthesia, whereas studies in humans are limited by pain threshold or to tests in cadaver skin. Skin thickness, ultimate load, tensile strength, ultimate strain and ultimate modulus of elasticity are the most informative parameters, which describe the mechanical properties of the dermis.

PROCEDURE

Groups of at least 10 male Sprague-Dawley rats with an initial weight of 120 ±5 g are treated subcutaneously or orally with test drugs or saline. The duration of treatment is usually 5 days; however, for special studies treatment can be prolonged up to 3 months. The animals are sacrificed under anesthesia. The back skin is shaved and a flap of 5×5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness. In this way, **skin thickness** can be measured reliably by calipers with an accuracy of 0.1 mm. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out (Vogel 1969, 1970, 1989, 1993a). The samples are kept in Peteri dishes until testing at room temperature on filter paper soaked with saline solution. The specimens are fixed between the clamps of an INSTRON® instrument a at gauge length of 30 mm. All measurements are carried out within at least 1 h. For long lasting test procedures, such as relaxation or cyclic loading, the samples are wrapped with saline soaked filter paper (Vogel 1976a,b 1989, 1993a,b).

Stress-strain curves are registered at an extension rate of 5 cm/min, showing a characteristic shape. During low strain values, there is a gradual increase of load; the curve has a concave part. The stress-strain curve ascends according to an exponential function (Vogel and Hilgner 1977). Afterwards an almost straight part is reached indicating the dependence on Hook's law. At this part the **ultimate modulus of elasticity** (Young's modulus) can be calculated (increase of load divided by the cross sectional area). Then some yielding of the curve occurs which ends in a sudden break of the specimen. This point indicates **ultimate strain** and **ultimate load**.

EVALUATION

From ultimate load divided by the cross sectional area (specimen width times original skin thickness measured at the beginning of the experiment), **tensile strength** can be calculated. The mean values of skin thickness, ultimate strain, ultimate load, tensile strength, and modulus of elasticity of treated animals are compared with controls using ANOVA and Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

The parameters: **skin thickness, ultimate strain, ultimate load, tensile strength, and modulus of elasticity** are influenced by many factors, such as hormones and desmotropic drugs. The most pronounced changes are seen after glucocorticosteroids, both after systemic and local application (Vogel 1969, 1970, 1974a). Sev-

eral studies were performed on age dependence of mechanical parameters in rat skin. Ultimate load, tensile strength and modulus of elasticity show a very sharp increase during puberty, a maximum at 12 months and a slight decrease thereafter (Vogel et al. 1970; Vogel 1976b, 1978, 1983, 1988, 1989, 1993a). Studies on age dependence show a similar pattern for skin thickness, ultimate load, tensile strength, ultimate extension, modulus of elasticity, hysteresis, relaxation, creep behavior and biochemical data both in animals and men (Holzmann et al. 1971; Vogel 1987a,b).

Therefore, extrapolations from animal studies to behavior of human skin are justified.

However, due to the anatomical conditions (haired skin in animals) the biomechanics of the epidermis can be studied better in human experiments than in animals.

MODIFICATIONS OF THE METHOD

Measurement of skin thickness, ultimate strain, ultimate load, tensile strength, and modulus of elasticity can be used in the evaluation of topical corticosteroids (Schröder et al. 1974; Alpermann et al. 1982; Vogel and Petri 1985).

Similarly, Töpert et al. (1990) measured skin atrophy and tensile strength of skin after 30 days local administration of corticosteroids in rats.

Oxlund and Manthorpe (1982) found an increase of strength and a decrease of extensibility of skin strips after long-term glucocorticoid treatment of rats. In agreement with studies by Vogel (1974b, 1978), these results were explained by a change in collagen cross-linking pattern.

Jørgensen et al. (1989) found a dose-dependent increase of mechanical strength in intact rat skin after treatment with biosynthetic human growth hormone.

Andreassen et al. (1981) studied the biomechanical properties of skin in rats with streptozotocin-induced diabetes. An increased stiffness and strength was found: maximal stiffness was increased by 20% and the strain rate at maximum stress was decreased by 10%.

Oxlund et al. (1980) found that the stiffness of rat skin was increased in the early postpartum period. This increase was also found in adrenalectomized animals.

Among desmotropic drugs, l*athyrogenic* compounds, such as amino-acetonitrile, and *D-penicillamine* decrease ultimate load, tensile strength without major influence on skin thickness (Vogel 1971a,b, 1974a). A decrease of the strength of skin strips in rats after treatment with D-penicillamine was also found by Oxlund et al. (1984).

A dose-dependent increase of tensile strength in skin after treatment with was found with **non-steroidal anti-inflammatory drugs** (Vogel 1977).

Strain rate influences the values of ultimate load, tensile strength and modulus of elasticity, but not the effect of age and of corticosteroids (Vogel 1972b). Changes in tensile strength are correlated with the content of insoluble collagen (Vogel 1974b).

Fry et al. (1964) prepared skin rings from the lower part of the leg in rats and studied the age-dependence of the mechanical properties.

Nimni et al. (1966) measured tensile strength of excised skin samples in rabbits during aging.

Pan et al. (1998) studied ultrasound, viscoelastic and mechanical properties in rabbit skin, including stress relaxation, creep and Young's modulus as a function of strain.

Lofstrom et al. (1973) described circadian variations of tensile strength in the skin of two inbred strains of mice.

The effect of radiation therapy on mechanical properties of skin was studied in mice by Hutton et al. (1977) and by Spittle et al. (1980).

Schneider et al. (1988) measured tensiometric properties in guinea pig skin from flaps of normal dorsal skin and after implantation of an ovoid **tissue expander** filled for four days with saline.

Belkoff et al. (1995) studied the mechanical properties of skin in pigs after subcutaneous implantation and inflation of silicone tissue expanders.

Mustoe et al. (1989) compared the effects of a conventional tissue expansion regimen of 6 weeks with an accelerated regimen of 2 weeks in a model in dogs and measured skin thickness, elasticity, creep and stress relaxation.

P.11.2.1.2 Measurement of mechanical properties at low extension degrees

PURPOSE AND RATIONALE

At low strain values, stress-strain curves of skin samples show a gradual increase of load, the curve has a concave part. The stress-strain curve ascends according to an exponential function (Vogel and Hilgner 1977).

PROCEDURE

Groups of at least 10 male Sprague-Dawley rats with an initial weight of 120 ±5 g are treated subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia; the back skin is shaved

and a flap of 5 × 5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out (Vogel 1969, 1970, 1981, 1989, 1993). The specimens are fixed between the clamps of an INSTRON® instrument at a gauge length of 30 mm. An extension rate of 5 cm/min is chosen. Tension is registered at 2, 5, 10, 20, 30, 40, 50, 60, 70, 80 and eventually 90% elongation. The registration is started with high sensitivity and switched to one tenth of the sensitivity in order to register the steep end of the curve.

EVALUATION

During registration with high sensitivity, the curve reaches an almost straight part. At this part, a tangent is drawn which is used for calculation of E_2. The distance from the start to the cross-point of this tangent with the baseline is measured and denominated as extension until the first rise (D). The angle between the tangent and the baseline is halved. At the cross-point with the stress-strain curve another tangent is drawn and used for calculation of E_1. At the second part of the curve registered with low sensitivity a further tangent is drawn for calculation of E_3, which is identical to the ultimate modulus of elasticity.

Mean values for $\boldsymbol{E_1}$, $\boldsymbol{E_2}$, $\boldsymbol{E_3}$, and ultimate stress of skin strips from treated animals are compared with controls using Student's *t*-test.

P.11.2.1.3 Step phenomenon

PURPOSE AND RATIONALE

Analysis of the low parts of the stress-strain curve revealed a "step"-phenomenon (Vogel and Hilgner 1977, 1979a,b; Vogel 1988). If samples obtained perpendicular to the body axis are extended, a gradual increase of load is observed at low degrees of extension, which is suddenly interrupted by a decrease of the registered curve. Then the curve increases again, being interrupted by a second or third step.

PROCEDURE

Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ±10 g are treated subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5 × 5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out. The ends of the skin strips are fixed in the clamps of an INSTRON® instrument resulting in a gauge length of 30 mm. The specimen is stretched with a strain rate of 50 mm/min. The first part of the stress-strain curve is registered with 10 times higher amplification than the second part. The steps are evaluated as follows.

EVALUATION

Tangents to the curves are drawn before and after each step. Then a vertical line is drawn in the middle of the step. The distance between the cross-points of this line with the tangents is measured and calculated as stress loss (ΔS). Furthermore, in the middle of each vertical line a horizontal line is drawn. The distance between the cross-point with the curves is measured and calculated as elongation due to the step (ΔE). Total stress loss is calculated by adding all values of ΔS and dividing by the number of specimens.

If this parameter is considered not only by itself but also in connection with tensile strength it can be calculated as percentage of ultimate stress (= % of breaking strength). In addition, the stress value, which would have been achieved without the step (= value S) and the elongation at which the step occurred (= value E) is registered. If stress loss at one step is multiplied with the elongation at this point, an indication of work loss is achieved (value ΔS times E). Taking into account the corresponding parameters indicating total work input (ultimate stress times ultimate strain), the relative work loss can be calculated.

Furthermore, elongation gain due to the steps is calculated by adding all values of ΔE and by dividing by the number of specimens.

Mean values of these parameters from treated animals are compared with controls using Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

The step phenomenon can be explained by the different orientation of collagen fibers in the dermis and by the presence of a muscular layer in rat skin. The muscular fibers are in a direction longitudinal to the body axis. If samples are obtained perpendicular to the body axis, the muscle bundles are cut transversally. In further studies the muscle layer was removed in one specimen and compared with a control still having the muscle layer. Investigation of the directional variation showed that the step phenomenon is mainly due to the muscular layer oriented longitudinal to the body axis and the connective tissue between the muscle bundles, whereas the anisotropic behavior of extensibility and ultimate strain is caused by the directional variation of the collagenous bundles in the dermis.

MODIFICATIONS OF THE METHOD

The step phenomenon could also be found in creep experiments (Vogel and Hilgner 1979b).

P.11.2.1.4 Anisotropy of skin

PURPOSE AND RATIONALE

As is the case with human skin indicated by Langer's lines (Langer 1861; Gibson et al. 1969; Wright 1971; Stark et al. 1977; Daly 1982), the skin of rats exhibits **directional differences** (Hussein 1972, 1973; Vogel and Hilgner 1979a,b; Vogel 1981, 1983a, 1985a,b, 1988; Belkoff and Haut 1991). Stress-strain curves of rat skin showed a different shape if excised perpendicularly or longitudinally to the body axis. Directional variations of mechanical parameters in rat skin were studied depending on maturation and age (Vogel 1981).

PROCEDURE

Male Sprague-Dawley rats are used at different age groups from 1 week up to 24 months. Young animals (1, 2 and 3 weeks) are delivered with their mothers from the breeder. Each age group is randomly divided into 2 blocks which are assigned as "perpendicular to body axis" or "longitudinal to body axis". The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5×5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material of known thickness to measure skin thickness by calipers. From each rat two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out either perpendicular or longitudinal to the body axis, allowing a gauge length between the clamps of an INSTRON® instrument of 30 mm. Stress-strain curves are measured at a strain rate of 50 mm/min, whereby the first part of the curve is registered with 10-fold amplification. Besides ultimate values, the extension is measured at given load interval for each curve:

0.05, 0.1, 0.2, 0.5, 1, 2, 10, 20, and 50 N

and at given stresses:

0.01, 0.02, 0.05, 0.1, 0.5, 1, 2, 5, and 10 N/cm^2.

EVALUATION

Each parameter is measured longitudinal and perpendicular to the body axis. The mean values are statistically compared within each age group using Student's *t*-test.

At low loads, extension is higher in the longitudinal than in the perpendicular direction. The situation is reversed at medium and high stress values. Ultimate extension shows remarkable differences between longitudinal and perpendicular samples. Specimens obtained perpendicular to the body axis showed an increase during maturation, a maximum at 4 months of age and a decrease during further aging. The behavior of samples obtained longitudinal to the body axis was quite different. After an initial rise a maximum was found at 3 weeks. Afterwards a slight decrease was noted. Between 1 and 4 weeks all values of ultimate extension were significantly higher in samples punched out longitudinally to the body axis; between 4 and 12 months they were considerably lower (Vogel 1981).

CRITICAL ASSESSMENT OF THE METHOD

The data indicate the importance of directional variations in all studies of biomechanics of skin.

MODIFICATIONS OF THE METHOD

Directional variations of rat skin were also found in hysteresis experiments (Vogel 1983a) and in relaxation experiments (Vogel 1985a).

Directional variations of the stress-strain curves were also described in the skin of tight-skin mutant mice (Menton et al. 1978).

P.11.2.1.5 Relaxation phenomenon

PURPOSE AND RATIONALE

In the relaxation experiment the viscous properties of rat skin are measured (Vogel 1973, 1976a,b, 1983, 1985, 1993a,b).

PROCEDURE

Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ±10 g are treated subcutaneously or orally with test drugs or saline. The animals are sacrificed in anesthesia, the back skin is shaved and a flap of 5×5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

Skin strips are fastened between the clamps of an INSTRON® instrument and extended with the high strain rate of 1 000 mm/min up to 20% extension. This extension is kept constant for 5 min. The chart speed is initially 1 000 mm/min, then 10 mm/min. In this way, the **initial tension** and the **stress values at 0.001, 0.01, 0.1, 1, and 5 min** can be measured. Due to relaxation, the stress values drop down roughly with the logarithm of time.

Furthermore, the **residual stress** after 5 min relaxation period is measured and calculated as percentage of the original stress. After 5 min the sample is returned to 90% of the original strain, for example, from 20% to 18%. The stress following such unloading is recorded and again calculated as percentage of the original stress. Immediately after unloading, the measured stress values rise again spontaneously, which is called **mechanical recovery**. Mechanical recovery is calculated as percentage of initial tension and as percentage of stress after unloading. The relaxation experiment is repeated with increasing degrees of extension of 40%, 60%, 80% and eventually 100% until the specimen breaks.

EVALUATION

For each sample, the relaxation is calculated according to the formula

$$\sigma(t) = A_1 + A_{2\times} \log t$$

resulting in two constants (A_1 and A_2) for each sample whereby A_1 is the stress at $t = 0$, and A_2 the slope of the relaxation curve.

The **ratio between the constants A_1 and A_2** has to be considered as the most characteristic parameter of the relaxation experiment.

The means of these parameters are compared between treated animals and controls using Student's *t*-test.

MODIFICATIONS OF THE METHOD

In studies of age dependence in rats skin, a definitive decrease of the **ratio A_2/A_1** was found at 40% and 60%

extension degrees indicating a decrease of plasticity with age. Mechanical recovery, as an indicator of secondary elasticity, was better in old animals at medium extension degrees than in young individuals. Stress relaxation was decreased after corticosteroids and increased after thyroid hormones and D-penicillamine (Vogel 1973, 1993a,b).

Purslow et al. (1998) suggested that relaxation processes within the collagen fibers or at the fiber-matrix interface might be responsible for the viscoelastic behavior of skin.

Vogel HG (1993b) Strength and viscoelastic properties of anisotropic rat skin after treatment with desmotropic drugs. Skin Pharmacol 6:92–102

P.11.2.1.6 Hysteresis experiment

PURPOSE AND RATIONALE

In the hysteresis experiment not only the elastic but also the viscous properties of skin are measured (Vogel 1978, 1983).

PROCEDURE

Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ±10 g are treated for 10 days subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5×5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material of known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

Using the INSTRON® instrument, the samples are stretched up to a given extension degree (e.g., 20%) with an extension rate of 20 mm/min. When the given extension is achieved the crosshead is immediately moved back to the starting position with the same velocity. From the upward curve the stress and the modulus of elasticity at the end of the loading phase at the given strain indicating the elastic properties can be measured. When the sample is unstretched the unloading curve shows a different pattern reaching the baseline much earlier than the curve left it during the upward phase. From this point the **residual extension** can be measured. Immediately after the first hysteresis cycle, the experiment is repeated up to an extension degree of 30%, than to 40% and 50% and finally up to 60%.

EVALUATION

By planimetry of the area below the upward curve the **energy input** and of the area between the hysteresis loop the **energy dissipation** can be calculated as well as the **ratio between energy dissipation and energy input** at each hysteresis cycle indicating the viscous properties. Stress and modulus of elasticity at the end of the hysteresis loop, energy input, energy dissipation and the ratio between energy dissipation and energy input at each hysteresis cycle are compared between treated animals and controls using Student's *t*-test.

MODIFICATIONS OF THE METHOD

In rat skin, a maximum of the ratio between energy dissipation and energy input was found at 30% to 40% extension. This ratio is influenced by age. At low extension degrees there was an increase with age, whereas at high extension degrees an age-dependent decrease was noted. The ratio dissipation/input was slightly decreased by prednisolone, but definitively increased by D-penicillamine (Vogel 1993b).

P.11.2.1.7 Isorheological point

PURPOSE AND RATIONALE

Buss et al. (1976) demonstrated the determination of the isorheological point to be a valuable parameter for the mechanics of connective tissue. This method has been modified and elaborated for the skin strips of rats (Vogel 1984, 1985, 1987).

PROCEDURE

Groups of 20 male Sprague-Dawley rats with an initial weight of 120 ±10 g are treated subcutaneously or orally with test drugs or saline. The groups are divided randomly into groups of 10 animals for examination of skin samples either perpendicular or longitudinal to the body axis. The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5×5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

Being fastened between the clamps of an INSTRON® instrument, the specimen is expanded rapidly up to 2 N and the corresponding strain is measured. Keeping this strain constant, the load decay (relaxation) is measured for 5 min. Then the sample is again loaded up to 2 N and a second relaxation period of 5 min is evaluated. In the third cycle, the sample is unloaded to 50% of the load observed after the 5-min relaxation period in the second cycle. The phenomenon of **mechanical recovery** is observed. With the crosshead driven up and down, the point is sought where neither immediate relaxation nor mechanical recovery can be observed. The load and strain at this point define the **isorheological point**, which is characterized by the fact that under isometric conditions, the measured load is constant for several minutes. Increasing and decreasing the load by 10% produces a saw-tooth-shaped curve from which the **modulus of elasticity at the isorheological point** can be calculated. The same procedure is performed at higher initial loads such as 10 N and 50 N. The product of percentage of strain multiplied by stress at the isorheological point indicates energy density.

EVALUATION

The means of these parameters are compared between treated animals and controls using Student's *t*-test.

The values showed a decrease during maturation, a minimum at 12 months and an increase during senescence. In studies with desmotropic compounds, the decreased viscosity after treatment with prednisolone acetate was more evident at the isorheological points than at the ultimate values. Likewise, the higher extensibility after treatment with D-penicillamine was indicated more clearly by the isorheological points than by the ultimate strain.

P.11.2.1.8 Creep experiments

PURPOSE AND RATIONALE

In creep experiments, viscous behavior of skin is studied. The strain under constant load is also denominated as retardation behavior. (Vogel 1977, 1987).

PROCEDURE

Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ±10 g are treated for 10 days subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5×5 cm removed. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis three dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

In a special apparatus, skin specimens are suddenly loaded with 100, 200 or 500 g and the extension degree measured. An immediate extension occurs which is followed by a slow and almost continuous creep being measured as **ultimate extension rate**. Furthermore, **extension achieved after 1 h** is registered.

EVALUATION

The means of these parameters are compared between treated animals and controls using Student's *t*-test.

An age-dependent decrease of these parameters was found in rat and human specimens indicating a decrease of viscosity or plasticity with maturation and age. Ultimate extension rate was decreased by prednisolone and increased by D-penicillamine.

P.11.2.1.9 Repeated strain

PURPOSE AND RATIONALE
By the method of using repeated strain, mainly the viscous properties of skin are measured (Vogel and Hilgner 1978; Vogel 1987).

PROCEDURE
Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ±10 g are treated for 10 days subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5 × 5 cm removed. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

Skin specimens are fastened between the clamps of an INSTRON® instrument, extended with a strain rate of 100 mm/min up to 20% extension and immediately unloaded followed by further cycles with the same strain rate and extension degree. The peak of the second cycle is considerably lower than the first, followed by a further decrease in the next cycles. The number of cycles is counted until the stress value is only one half of that of the first cycle. Immediately afterwards, the degree of extension is increased to 30%. Again the number of cycles is counted until the stress value was only one half of that of the first cycle. In this way, the **number of cycles indicating the half-life of tension** due to relaxation is counted at each step of 20%, 30%, 40%, 50%, 50%, 70%, 80%, 90% and eventually 100% extension. The number of cycles decreased from the first step (20%) to the third step (40%) and increased continuously until the last step. This increase was almost an exponential function of the number of steps.

EVALUATION
The means of the number of cycles indicating the half-life of tension due to relaxation at each step are compared between treated animals and controls using Student's *t*-test.

The parameters measured with this method are influenced by several factors: An increase was noted from an age of 1 month up to 24 months. The values were decreased by D-penicillamine and increased by prednisolone treatment. Again this method showed that plasticity of skin is decreased by age and by corticosteroids and increased by D-penicillamine.

MODIFICATIONS OF THE METHOD
Lafrance et al. (1998) tested mechanical properties of human skin equivalents submitted to cyclic forces. The *in vitro* production of disk-shaped (25.4 mm diameter) skin equivalents was based on the culture, under submerged conditions, of keratinocytes seeded on anchorage-based dermal equivalents, a human type I + III collagen gel supplemented with elastin and glycosaminoglycans. The specimens were submitted to quasi-static ramp-deflection cycles induced by means of an actuated hemispherical head. The effects of repeated loading were studied by monitoring the indentation load versus deflection and the relaxation of load over 1 000 s.

P.11.2.2 Thermocontraction

PURPOSE AND RATIONALE
If collagenous material such as skin or tendon is heated in a water bath, thermocontraction occurs. This phenomenon was already described by Wöhlisch (Wöhlisch and du Mesnil de Rochemont 1927; Wöhlisch 1932). Verzár and other authors used the phenomenon of thermocontraction of tendons and skin strips extensively to study the ageing process (Verzár 1955, 1957; Lerch 1951; Rasmussen et al. 1964; Boros-Farkas and Everitt 1967; Viidik 1969, 1977, 1979; Vogel 1969). With increasing temperature, a sudden increase of isometric force is found, which is followed by a decrease. To evaluate this phenomenon, either the **shrinkage temperature** or the **stress at and above the shrinkage temperature** can be measured. Furthermore, the decrease of sample strength can be measured.

PROCEDURE

Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ±10 g are treated for 10 days subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5 × 5 cm removed. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

The samples are attached to the clamps of a specifically modified INSTRON® instrument which allows the submersion of the test specimen into a beaker filled with 0.9% saline solution. This solution is kept at 58 °C or 60 °C by a thermostat. Immediately after immersion, the exerted tension is measured and the **maximum of tension** and **time until maximal tension** are recorded.

EVALUATION

The means of these parameters are compared between treated animals and controls using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Joseph and Bose (1962) tested the shrinkage temperature of skin in newborn rats, at 10 months and 2 years and found an increase from 51.2 °C to 61.1 °C.

Alain et al. (1977, 1980) tested pieces of dorsal skin of rats. Temperature of maximum tension was decreased from birth to 1 month, and then very slowly increased with age. A rapid relaxation was observed in young rats and in non-senescent adult rats.

Rundgren (1976) found changes of thermal contractility in skin of young and old female rats, and also changes due to repeated pregnancies.

Blackett and Hall (1980) found an increase of thermal shrinkage temperature in two strains of mice during the aging period.

Danielsen (1981) determined thermal stability measured as area shrinkage without tension during heating for membranes of collagen fibrils, reconstituted from solutions of highly purified rat skin collagen.

Allain et al. (1980) built a device, which measured not only hydrothermal shrinking but also swelling in rat skin.

Le Lous et al. (1982a,b, 1983), Flandin et al. (1984) applied the technique of differential scanning calorimetry to evaluate the denaturation process of collagen in rat skin.

P.11.3 *In vivo* experiments

P.11.3.1 Stress-strain curves *in vivo*

PURPOSE AND RATIONALE

In contrast to studies in human beings, animal experiments allow measurement of mechanical properties both *in vivo* under anesthesia and later on *in vitro* (*ex vivo*) at the same site. For this purpose, special methods had to be developed (Barbanel and Payne 1981; Vogel 1981a,b, 1982; Vogel and Denkel 1982, 1985; Denkel 1983).

PROCEDURE

Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ±10 g are treated for 10 days subcutaneously or orally with test drugs or saline.

The rats are anesthetized with 60 mg/kg Nembutal® i.p. The back skin is shaved mechanically. Skin thickness is measured by use of calipers on an elevated skin fold. Four small (14 × 14 mm) metal plates bearing a hook are used as tabs and are glued on the skin in both longitudinal and perpendicular direction at a distance of 25 mm with a cyanoacrylate preparation. An operation table is mounted on the crosshead of an INSTRON® instrument. The table can be turned to allow stretching of the skin in both perpendicular and longitudinal directions relative to the body axis. The anesthetized animals are fastened by their legs to the operation table. A triangle is attached to the load cell. At the end of the triangle, threads are fastened which are conducted by reels and hooked to the tabs. The cross head is moved down manually until the threads are stretched, however, no tension is measured yet. Then the crosshead is driven downwards with a rate of 50 cm/min, what means that the actual extension rate is 100 cm/min. The load is measured only to limited values in order to prevent damage of the skin. In each rat the stress-strain curve is recorded in both directions whereby the order (first longitudinal or first perpendicular) is changed from animal to animal. In this way, the influence of the first extension on the results of the second extension is eliminated. Stress-strain curves are recorded up to an elongation of 80%. Modulus of elasticity is calculated from the almost straight part of the curve.

EVALUATION

Average stress-strain curves with standard deviations are plotted for each treatment group perpendicular and longitudinal to the body axis. The stress values and the values for modulus of elasticity of the treated groups are compared with controls using Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

In spite of similar conditions, differences between the stress-strain curves from *in vitro* and *in vivo* experiments were found. These findings confirmed the statements of other authors (Barbanel and Payne 1981; Wijn 1980) of the importance of tab distance and tab geometry (Vogel 1981b). Analysis of the data showed that the higher the ratio of distance between the tabs to the area below the tabs, the higher were the stress values. These findings can be explained by the fact that skin consists of several layers. Only the upper layer (epidermis) is fastened to the tabs in the *in vivo* experiment. The forces transmitted to the lower layers are transmitted by a larger area if the area under the tabs is larger. The lower layer can slide over a larger area and is therefore less extended resulting in lower stress values. No sliding is possible if the sample is fastened from both sides as it is performed in the *in vitro* experiments. Taking into account all experimental conditions including the strain rate, the *in vivo* results are comparable with those obtained *in vitro*. This holds true for the age-dependence as well as for the influence of desmotropic compounds (Vogel and Denkel 1985).

MODIFICATIONS OF THE METHOD

Cook et al. (1977) compared tension/extension ratio curves *in vivo* and *in vitro* in rats using the suction-cup method. Baker et al. (1988) described an apparatus for testing mechanical properties of normal and irradiated **pig** skin *in vivo.* In this system, the pads were attached to the skin of the pig rump with double-sided tape. They were moved apart at a predetermined rate using a motorized unit. Force was assessed using a S-shaped, center point, double beam load cell mounted on a movable crosshead. Displacement of the pads was measured using a floating core linear variable displacement transducer. Using this system, Baker et al. (1989) studied the effect of single doses of X-rays on the mechanical properties of pig skin *in vivo*.

P.11.3.2 Repeated strain *in vivo*

PURPOSE AND RATIONALE

A special method has been developed to study the mechanical properties of rat skin after repeated strain *in vivo* and the course of recovery during different time intervals (Denkel 1983; Vogel and Denkel 1985; Vogel 1988).

PROCEDURE

Male Sprague-Dawley rats with an initial weight of 120 ±10 g are treated for 10 days subcutaneously or orally with test drugs or saline. Groups of 10 animals are used for each time interval tested and for the two directions of testing.

Tabs are fastened on the shaved back skin of anesthetized rats with a distance of 25 mm either perpendicular or longitudinal to the body axis with a cyanoacrylate preparation. With an extension rate of 100 mm/min, the skin is extended 30 times for a 50% strain under anesthesia. Load is recorded and stress calculated by dividing load by skin thickness measured from a skin fold obtained with calipers. The 1st, 5th, 10th, 20th, 25th and 30th cycles are recorded with faster paper speed in order to facilitate the evaluation of modulus of elasticity and stress values. Modulus of elasticity is calculated from the upper part of the stress-strain curve. The area under the curve of 30 cycles is evaluated by computerized calculation according to Simpson's formula (Hütte 1915; Denkel 1983; Vogel 1988).

EVALUATION

Average curves of stress vs. number of cycles with standard deviations are plotted for each treatment group perpendicular and longitudinal to the body axis. The stress values and the values for modulus of elasticity of the treated groups are compared with controls using Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

Stress values decreased after repeated loading approximately with the logarithm of number of cycles. Stress values and the area under the curve were higher perpendicular than longitudinal to the body axis, as found in other *in vivo* experiments (Vogel and Denkel 1985). During the experiment, modulus of elasticity increased in both directions from the first to the fifth cycle. This may be explained by the so-called "conditioning" of connective tissue (Nemetscheck et al. 1980). From the 5th to the 30th cycle, a decay of modulus of elasticity approximately with the logarithm of number of cycles was noted. The area under the curve calculated from stress values resembled closely the pattern of initial stress, indicating that this value dominates for the area under the curve and that the decay is only of secondary importance.

P.11.3.3 *In vivo* recovery after repeated strain

PURPOSE AND RATIONALE

A method was developed to study the *in vivo* recovery of mechanical properties of rat skin after repeated strain (Denkel 1983; Vogel and Denkel 1985; Vogel 1988, 1990, 1993a,b). Full recovery, i.e., ***restitutio ad integrum***, can be observed only by doing *in vivo* experiments but not by *in vitro* experiments.

PROCEDURE

Male Sprague-Dawley rats with an initial weight of 120 ±10 g are treated for 10 days subcutaneously or orally with test drugs or saline. Groups of 10 animals are used for each time interval tested and for the two directions of testing.

As in the experiment of repeated strain, tabs are fastened on the shaved back skin of anesthetized rats with a distance of 25 mm either perpendicular or longitudinal to the body axis with a cyanoacrylate preparation. With an extension rate of 100 mm/min, the skin is extended 30 times for a 40% strain under anesthesia. Load is recorded and stress calculated by dividing load by skin thickness measured from a skin fold obtained with calipers. The 1st, 5th, and 30th cycles are recorded with faster paper speed in order to facilitate the evaluation of modulus of elasticity and stress values. Modulus of elasticity is calculated from the upper part of the stress-strain curve. The area under the curve of 30 cycles is evaluated by computerized calculation according to Simpson's formula (Hütte 1915; Denkel 1983; Vogel 1988).

After the first run the animals are returned to their cages with the tabs still in position. A second run of repeated strain is applied after different time intervals at 1, 6, and 16 h. The stress values in the second run are definitively lower than in the first run.

When calculated as percentage of the first run, the differences diminish with extended time intervals. By this *in vivo* method not only the mechanical recovery, which can also be observed *in vitro*, but also the biological recovery, i.e., the restitutio ad integrum, can be measured. Almost full recovery is found after 16 h.

EVALUATION

Average curves of stress vs. number of cycles with standard deviations are plotted for each treatment group perpendicular and longitudinal to the body axis. The stress values and the values for modulus of elasticity of the treated groups are compared with controls using Student's *t*-test. Stress of the first and 30th cycle as well as the area under the curve at the second run are expressed as percentage of the first run after the 1, 6, or 16 h interval. Furthermore, the hours to reach certain percent levels up to 100% are calculated for the stress values during the first cycle and the area under the curve both longitudinally and perpendicularly to the body axis.

CRITICAL ASSESSMENT OF THE METHOD

In the late phase of recovery, an even better restitutio ad integrum was found in animals treated with 300 mg/kg p.o. D-penicillamine or 10 mg/kg s.c. prednisolone acetate. In contrast to other biomechanical parameters, the restoration process was found to be barely influenced by treatment with desmotropic compounds.

Surprisingly, in studies on age dependence restitutio ad integrum was the fastened in old animals. The ability of the dermis to reconstitute the fibrous structure is apparently not influenced negatively by age.

P.11.4 Healing of skin wounds

PURPOSE AND RATIONALE

Healing of skin wounds is a multiphasic process. The effect of drugs on the healing process was studied by measuring the mechanical strength at various time intervals after incision of the skin (Vogel 1970).

PROCEDURE

Groups of 10 to 20 male Sprague-Dawley rats weighing 120 ±5 g are used for each dosage or control and for each test interval. Under anesthesia the dorsal skin is shaved and an approximately 3 cm long incision is made down to the fascia in a cranio-caudal direction in the dorso-lumbar region. Immediately afterwards, the wound is closed with wound clips. The rats are treated subcutaneously with test drugs beginning on the day of surgery. The clips are removed the day before the tensile strength is tested or on the 10th postoperative day at the latest.

For the measurement of wound tensile strength, the rats are sacrificed under anesthesia on days 3, 6, 9, or 12 after surgery. Wound clips are fastened *in situ* on each side of the incision and connected by means of threads with the load cell and the crosshead of an INSTRON®-Instrument. Stress-strain curves are recorded at an extension rate of 5 cm/min. **Dehiscence of the wound** results in a sudden drop of the registered load. For experiments up to 3 weeks, bell-shaped skin strips are punched and tensile strength is tested, as described for evaluation of tensile strength in normal skin.

EVALUATION

Mean values of tensile strength of skin wounds in drug treated groups at each time interval are compared with controls using Student's *t*-test. To visualize the influence of drugs on the healing process, the changes following treatment with drugs are expressed as percentage of vehicle treated controls.

A dose-dependent decrease following treatment with corticosteroids is found after immediate postoperative treatment and a dose-dependent increase in prolonged experiments. This data serve as comparative parameters for new test compounds

MODIFICATIONS OF THE METHOD

Many authors measured tensile strength of skin wound to follow the course of wound healing under various conditions. Most experiments were performed in *rats* (Struck et al. 1967; Holm-Pedersen and Zederfeldt 1971; Holm-Pedersen and Viidik 1972a,b; Andreassen et al. 1977; Greenwald et al. 1993; Seyer-Hansen et al. 1993; Jyung et al. 1994; Adamson et al. 1996; Quirinia and Viidik 1998; Canturk et al. 1999; Gupta et al. 1999), with some of them also using the INSTRON®-Instrument (Phillips et al. 1993; Maxwell et al. 1998; Jimenez and Rampy 1999; Kim and Pomeranz 1999).

A biphasic effect of corticosteroids on wound healing in rats was also found by Oxlund et al. (1979).

Furthermore, **mice** (Butler et al. 1991; Celebi et al. 1994; Kashyap et al. 1995; Vegesna et al. 1995; Gonul et al. 1998; Matsuda et al. 1998), **guinea pigs** (Bernstein et al. 1991; Drucker et al. 1998; Silverstein and Landsman 1999), **rabbits** (Sandblom 1957; Wu and Mustoe 1995; Pandit et al. 1998, 1999; Knabl et al. 1999; Xia et al. 1999), **dogs** (Howes et al. 1929; Scardino et al. 1999), **pigs** (Langrana et al. 1983; Higashiyama et al. 1992; Chang et al. 1998; Fung et al. 1999) or **Yukatan miniature pigs** (Van Dorp et al. 1998) were used.

In some studies simultaneously polyvinyl alcohol sponges were implanted in which collagen accumulation was determined (Albina et al. 1993; Schaffer et al. 1996; Koshizuka et al. 1997; Bitar 1998; DaCosta et al. 1998; Witte et al. 1998).

Ågren and Mertz (1994) found excessive granulation tissue formation and retarded wound contraction in wounds in tight-skin mice.

Kyriakides et al. (1999) reported accelerated wound healing in mice with a disruption of the thrombospondin 2 gene.

P.12
Protection against UV light

PURPOSE AND RATIONALE

The mechanical parameters' skin thickness, ultimate strain, ultimate load, tensile strength and modulus of elasticity were used to evaluate the effects of UV-irradiation and the prevention of skin damage in hairless mice (Alpermann and Vogel 1978; Vogel et al. 1981).

PROCEDURE

Female hairless mice (strain mutant h/h) with an initial weight of 20 ±2 g are used. Groups of 20 animals are treated topically with 0.025 ml of the sunscreen

product or the base. One other group is not treated topically, but irradiated. A further group is neither treated nor exposed to UV-B.

A special light source (Osram Ultra-Vitalux No. 2) is used. This light source is almost free from UV-C. For UV exposure groups of 5, mice are immobilized under a fine wire net of 14×14 cm at a distance of from the lamp, resulting in an irradiation energy of 14 mW/cm^2 for UV-B and 33 mW/cm^2 for UV-A. Irradiation is performed once a day except Saturday and Sunday during 4 weeks. Exposure time is 45 s in the first week, 60 s in the second, 90 s in the third, and 120 s in the fourth week. The animals are sacrificed umder anesthesia 72 h after the last irradiation. A flap of back skin is removed, skin thickness measured by use of calipers and two dumb-bell shaped samples punched with a width of 4 mm in the middle of the specimen. Stress-strain curves are recorded with an INSTRON®-instrument at a strain rate of 5 cm/min. Ultimate load and ultimate strain are recorded and tensile strength as well as ultimate modulus of elasticity are calculated.

Furthermore, samples of skin are deep-frozen for chemical analysis of collagen and soluble collagen fractions as well as of elastin (Vogel 1978).

EVALUATION

The mean data from animals treated with sunscreen products are compared with those of animals treated with ointment base, irradiated and non irradiated controls using ANOVA and Student's *t*-test.

MODIFICATIONS OF THE METHOD

The effect of UV-irradiation on skin has been studied by several authors both in man and in animals.

Wolska (1974) recommended the hairless mouse as an experimental model for evaluating the effectiveness of sunscreen preparations.

Cook et al. (1979) investigated the changes in the mechanical properties of intact **guinea pig** skin resulting from ultra-violet irradiation.

Lowe and Breeding (1986) evaluated several sunscreen preparations by UVB irradiation of mice. Sunscreen solutions were applied to the back of 5–8 weeks old female skh/HR-1 mice one h before irradiation with FS40 sunlamps. Epidermal DNA synthesis assay was used to measure sunscreen efficacy. The amount of UVB required to achieve a 50% suppression of radiolabelled thymidine incorporation in treated and untreated mice was compared as a ratio to determine the protective factor. Furthermore, epidermal ornithine decarboxylase activity was determined by measuring the release of $^{14}CO_2$ from L-[1-^{14}C]ornithine 24 h after a single UVB exposure. Edema was estimated by the increase in double skin fold thickness measured by a caliper at 24 h post irradiation.

Benrath et al. (1995) reported that substance P and nitric oxide mediate wound healing of ultraviolet photodamaged skin in **rats**.

Muizzudim et al. (1998) studied the effect of topical application of antioxidants and free radical scavengers on protection of hairless mouse skin, exposed to suberythemal doses of ultraviolet B, three times a week, and measured epidermal thickness by microscopy.

Fullerton and Keiding (1997) quantified UV-B induced erythema in depilated Hartley-strain albino male guinea pigs and compared the results with a tristimulus colorimeter (Minolta ChromaMeter CR-200) and two spectrophotometers (Minolta Spectrophotometer CM-508i and CM-2 002). With the tristimulus colorimeter the color is expressed in a three-dimensional color space, which simulates the perception of color by the human eye.

Further description of ultraviolet erythema in animals see Sect. H. 3.2.2.1.

Transepidermal water loss (TEWL)

PURPOSE AND RATIONALE

The physical basis for the measurement of transepidermal water loss (TEWL) is the diffusion law discovered by A. Fick in 1855.

$$dm / dt = -D \times A \times dp / dx$$

where:

- A = surface (m^2),
- m = water transported (g),
- t = time (h),
- D = diffusion constant (= 0.0877 g/m × h × mm Hg),
- p = vapor pressure of the atmosphere (mm Hg),
- x = distance from skin surface to point of measurement.

Most of the recent studies are performed with commercially available instruments, such as Tewameter TM 210, Courage and Khazaka, Cologne, Germany, Evaporimeter EP1, Servo Med AB, Vallingby, Sweden, primarily designed for the used in human beings.

Several studies were performed in **rats**, e.g., in hairless rats (Doucet et al. 1991; Vanbever et al. 1998), neonatal rats (Wickett et al. 1995), in rats with experimentally induced condition of essential fatty acid deficiency (Basnayake and Sinclair 1956; Prottey et al. 1976; Hartop et al. 1976, 1978; Penneys 1992; Yamaguchi et al. 1998; Meguro et al. 2000), **hairless mice** (Grubauer et al. 1989; Mortz et al. 1997; Sato et al. 1998), essential fatty acid deficient hairless mice (Menton 1968; Lowe and Stoughton 1977), platelet-type 12-lipoxygenase deficient mice (Johnson et al. 1999), keratin 10 deficient mice (Jensen et al. 2000), **guinea pigs** (Frosch et al. 1993; Fuchs et al. 1998; Sagiv et al. 2000), **pigs** (Zhao and Singh (1999) **Yucatan microswine** (Gendimenico et al. 1995).

Löffler et al. (2001) evaluated irritant skin reaction in mice by measurement of auricular transepithelial water loss.

PROCEDURE

BALB/c mice aged 10–16 weeks are sensitized on day 0 by applying 50 µl 2,4-dinitro-flurobenzene (DNFB) solution (0.5% diluted in acetone/olive oil 4 : 1) to the shaved dorsal neck region. On day 5, the dorsal surface of one ear is challenged by applying 10 µl DNFB 0.3%; the other side is treated by acetone/olive oil alone.

Transepithelial water loss is measured with an evaporimeter (Tewameter TM 210, Courage and Khazaka, Cologne, Germany) with a measuring cylinder into which the whole ear of the mouse can be placed. The measurements are performed under isofluoran inhalation anesthesia. Measurements are performed before and 24 h after challenge.

EVALUATION

The comparison between the treated and untreated ears is calculated by the Wilcoxon test. The comparison between the tested groups is calculated by the Kruskal-Wallis *H*-test, after the Mann-Whitney *U*-test.

P.14
Influence on hair growth

PURPOSE AND RATIONALE

Several mutations affecting hair growth or quality have been reported in the laboratory mouse (Holland 1988), among them "alopecia" (Dicke 1955); "alopecia periodica" (Tutikawa 1952); "crinkled" (Falconer et al. 1951); "frizzy" (Falconer and Snell 1952); "fuzzy" (Mann 1964); "rhino" (Mann 1971); "naked" (Raphael et al. 1982); "nude" (Flenagen 1966; Buhl et al. 1990; Militzer 2001); "ragged" (Slee 1962); androchronogenetic alopecia (AGA) mouse (Matias et al. 1989); aging C3H/HeJ mice (Sundberg et al. 1994); SPF-ASH mice (Shimada et al. 1994); "nackt" (Benavides et al. 1998); transgenic mice overexpressing homeobox gene MSX-2 (Jiang et al. 1999). Kligman (1988) used the Skh-hairless mouse as a model for evaluating promoters of hair growth.

PROCEDURE

Six litters of Skh-hairless-1 albino mice with 5–8 animals are housed, with their mothers, in individual plastic cages. Food and water are supplied ad libitum. Beginning at 1 week of age, topical treatment is applied: two litters dorsal application of low dose (e.g., 0.2% minoxidil), two litters dorsal application of high dose, two litters abdominal application of high dose. Application is performed once daily five times a week at a rate of 20 µl/cm^2 of skin using a digital micropipette. Two control litters receive no treatment. All treatment continue for up to 17 weeks, after which mice are sacrificed and grossly examined for signs of toxicity.

Mice are observed daily for hair growth and weighed each week. Photographs are taken when hair growth appears to be maximum. At the time of maximal hair growth, two or three representative neonates from the treated and untreated groups are sacrificed for skin biopsies; all remaining mice continue on treatment to asses the extent of a third pelage. Biopsy specimens are fixed in formalin and stained with hematoxylin and eosin.

EVALUATION

In transverse sections, all active hair matrices or viable follicles, which contain keratin zed hairs located in the subcutis, are counted. Fourteen to 16 contiguous fields are examined over a surface distance of 1 cm at 250× magnification. Mean values of the groups are compared using Student's *t*-test.

MODIFICATIONS OF THE METHOD

A hair loss mutation on mouse chromosome 19, called **scraggly**, was described by Herron et al. (1999).

Several authors studied **chemotherapy-induced alopecia in mice, rats and rabbits** (Powis and Kooistra 1987; Paus et al. 1994a,b; Cece et al. 1996; Sredni et al. 1996).

The **Dundee experimental bald rat (DEBR)** was used as model for alopecia areata (Oliver and Lowe 1995; McElwee et al. 1997).

Kimura (1996) underlined the usefulness of studies in **hairless descendants of Mexican hairless dogs** in dermatological science.

The **balding stumptail macaque** is recommended as a model for androgenetic alopecia (Brigham et al. 1988; Diani et al. 1995; Pan et al. 1998).

The stimulating effect of drugs on hair growth has been studied using *in vitro methods.*

Kurata et al. (1996) investigated the effect of hypertrichotic agents on follicular from macaque and human skin and nonfollicular cells (normal kertainocyts and dermal fibroblasts) *in vitro*. Minoxidil induced a significant increase in all follicular cells in a dose-specific manner, whereas nonfollicular cells showed no response.

Lachgar et al. (1996) found inhibitory effects of bFGF, VEGF and minoxidil on collagen synthesis by cultured hair dermal papilla cells from rat vibrissa follicles.

Boyera et al. (1997) described biphasic effects of minoxidil on the proliferation and differentiation of normal human keratinocytes obtained form microdissected hairs of from plucked hairs. Minoxidil stimulated human keratinocyte proliferation at micromolar doses, while antiproliferative, pro-differentiative and partially cytotoxic effects were observed with millimolar concentrations.

Sato et al. (1999) reported that minoxidil increases 17â-hydroxysteroid dehydrogenase and 5á-reductase of cultured human dermal papilla cells from balding scalp.

P.15
Cutaneous microcirculation

P.15.1
General considerations

PURPOSE AND RATIONALE

Various techniques are used to determine cutaneous blood flow, such as radioactive microspheres, xenon clearances, plethysmography, laser Doppler velocimetry (Flagrell 1986; Guy et al. 1985), reflectance spectrophotometry (Kimura et al. 1988; Kakizoe et al. 1992).

P.15.2
Laser Doppler velocimetry

PURPOSE AND RATIONALE

Laser Doppler velocimetry and laser Doppler flowmetry are essentially identical procedures. With these methods, light is transmitted from a helium-neon laser source in the instrument to the skin via an optical fiber. The laser provides light of single frequency (wavelength 632.9 nm) and allows the Doppler effect to be exploited. The incident radiation enters the skin tissue and is multiply scattered and reflected by non-moving components and by the mobile red blood cells that are encountered as the radiation penetrates to a depth of 1–1.5 mm. A portion of scattered/reflected incident radiation exits the skin and is collected by second or third optical fibers that carry the light back to the instrument. The returning radiation falls on a photodetector and is converted to an electrical signal. Stationary skin tissue reflects and backscatters light at the same frequency as the incident source. Erythrocytes moving with certain velocity, however, reflect radiation that is slightly frequency-shifted, the shift increasing with increasing velocity.

Hirkaler and Rosenberger (1989) described simultaneous two-probe laser Doppler velocimetric assessment of topically applied drugs as a simple, non-invasive method for the determination of cutaneous blood flow in anesthetized rats.

PROCEDURE

Male Sprague-Dawley rats (400–500 g) are anesthetized with urethane (1.6 g/kg), the abdominal region carefully clipped and the remaining hair removed with a commercially available depilatory. Phthalate buffer (pH 4.0) is gently applied to neutralize the effects of the depilatory cream. The rat is placed on its back and allowed to stabilize for approximately 15 min. Cutaneous blood flow is measured using two standard Medpacific LD 5 000 capillary perfusion monitors and probes (1.9 cm diameter). The probes are modified to allow application of the drug without removal of the probe. This is achieved by enlarging the center opening of the adhesive pad to 1 cm, which creates a drug well of approximately 5 µl vol. The drug is introduced through a short length of polyethylene tubing (PE10) held in place by the adhesive pad and placed slightly off center to avoid interference with the sensing device.

The modified probes are attached to the lower abdominal region of the rat, approximately 1–2 cm from the midline. Cutaneous blood flow is recorded continuously from 30 min prior to drug application and for 5 h post-dosing. Various doses of standard (0.015 to 0.75 mg/kg minoxidil) or test compound or control vehicle (propylene glycol 15%, ethyl alcohol 65%, water 20%) are applied. At the end of the experiment, the animals are sacrificed.

EVALUATION

Post-dosing values are expressed as % change from control and analyzed using Student's paired *t*-test.

MODIFICATIONS OF THE METHOD

Knight et al. (1987) measured microvascular blood flow by a laser Doppler flow meter in **rabbit** epigastric island flaps made ischemic for various intervals of time.

P.15.3 Measurement of skin microcirculation by reflectance spectroscopy

PURPOSE AND RATIONALE

Kimura et al. (1988), Kakizoe (1992) developed reflectance spectrophotometric measurement to analyze the microcirculation of the skin in real time. The light reflected from the skin tissue containing information about hemoglobin, the injected dye, and other data, is continuously analyzed into the relative absorption spectrum and the changes in relative absorption values at specific wavelengths are used as indices of oxyhemoglobin content and capillary permeation.

PROCEDURE

Male Wistar rats weighing 300–400 g are anesthetized with pentobarbital (40 mg/kg i.p.). The skin of the back is shaved and the hair removed by a commercial hair remover. A polyethylene catheter (PE10) is inserted into the femoral artery to measure blood pressure on a polygraph. An other catheter is inserted into the femoral vein for injection of drugs or Evans blue.

To obtain the relative absorption spectra, a spectro-multi-channel-photodetector system (MCPD 110; Otsuka Electronics Co., Ltd., Osaka, Japan) is used. White light (halogen lamp 150 W) is projected onto the skin through an optical fiber. The light reflected from the skin is transmitted to the detector system via another optical fiber. The positions of the optical fibers are fixed independently. Each fiber is attached to a steel arm on the stand, and the height of the arms is adjusted so that the top of the fibers can be in gentle contact with surface of the skin. The angles of the fibers are adjusted so that the relative absorbance spectrum with the best peaks of oxyhemoglobin can be obtained. The reflected light is passed through a slit and illuminated on the grating surface to obtain the spectrum. Following amplification by an image intensifier, the component wavelengths are sampled by photodiode array in a short time interval. The relative absorbance spectra from the skin against the spectra for the white light are obtained at wavelengths ranging from 450 to 643 nm, arranging the initial relative absorbance at 640 nm to zero. The sampling time is 50 ms. The average of 10 measurements is indicated at 1-s intervals on the output unit. The spectrum at a point of time and time-dependent changes in relative absorbance values at selected wavelength are shown on the display and registered by an X-Y recorder.

After achieving a steady state under anesthesia, the relative absorbance spectrum is obtained from the skin, and two peaks ate wavelength of about 540 and 577 nm, corresponding to those of oxyhemoglobin, are observed. The relative absorbance spectrum is measured at the posterior part of the back near the backbone because the shape is relatively flat in this region and it is easy to fix the optical fibers.

To standardize the changes in oxyhemoglobin content in skin tissue, graduated doses of noradrenaline are injected intravenously and the effect on relative absorbance is measured.

To measure the content of oxyhemoglobin and permeation of the capillaries at the same time, 1.5 ml/kg 0.05% Evans blue solution is injected intravenously 10 min before measurement. Histamine (0.3–100 μg/50 μl/site) is injected intradermally into the skin of the back, and measurement is started 1 min after the injection. The changes in the relative absorbance values at 540 nm, an absorption peak in the oxyhemoglobin spectrum, and at 610 nm, an absorption peak in the Evans blue spectrum, are measured for 15 min, and the absorption values at baseline and the point of maximum change are compared.

EVALUATION

Results are expressed as mean ±SEM. Comparisons are made using the Student's *t*-test or Mann-Whitney's *U*-test.

MODIFICATIONS OF THE METHOD

Hertel (1986, 1992) measured cutaneous microcirculation in the pinnal of conscious rats. Erythrocyte flow velocities were measured by the 'flying spot technique' (Tyml and Ellis 1982) and the diameters of the capillaries were measured from a monitor with a ruler.

Da Costa et al. (1992) measured the fluctuations in the diameter of selected arterioles in the cutaneous microcirculation of **Syrian golden hamster** dorsal skin flap chambers. These ranged in size between 10 and 70 μm at different branching order sites, before burn, at the same site after burn and after injection of drugs.

Q.2 Techniques of blood collection in laboratory animals[3]

Q.2.1 Introduction

Blood is collected from laboratory animals for various scientific purposes, for example, to study the effects of a test drug on various constituents, such as hormones, substrates, or blood cells. In the field of pharmacokinetics and drug metabolism, blood samples are necessary for analytical determination of the drug and its metabolites. Blood is also needed for some *in vitro* assays using blood cells or defined plasma protein fractions.

The techniques for blood collection depend on specific factors which differ from one experiment to the other. There is a difference between terminal and non-terminal blood collection techniques. The conditions of blood collection at the end of an experiment which includes death of the animal (terminal experiment) are completely different (anesthesia, volume of blood) from those of single or repeated blood collections from a conscious animal. Terminal blood collection under anesthesia allows the use of techniques which are not acceptable for non-terminal blood collections.

Q.2.2 Aspects of animal welfare

Minimizing any pain and distress in laboratory animals during the procedure have to be as important as achieving the desired experimental results. This is important not only for humanitarian reasons but also as part of good scientific practice. Blood collection may be stressful to the animal due to the handling and the discomfort associated with a particular technique. Many biochemical and physiological changes are associated with stress which affect the results, e.g. increases in the blood levels of catecholamines, prolactin and glucocorticosteroids can influence certain metabolic parameters, such as glucose, as well as the counts of erythrocytes, white cells, and packed cell volume. Therefore, stress should be reduced to an absolute minimum if it is not possible to avoid it at all, this is not only in the interest of animal welfare but also in the interest of good science to obtain representative data. To minimize stress during blood collection, e.g.

[3] By A. W. Herling, J. Maas, K. Seeger (1st edition), revised by U. Albus (2nd edition).

from dogs or cats, it may be helpful for the animal as well as for the operator first to do some dummy runs and provide rewards to the animal.

During non-terminal blood collection it is important not to withdraw too much blood which could reduce total blood volume and lead to false results. A reduced total blood volume is accompanied by a reduced hemoglobin content and oxygen transport capacity (Gainer et al. 1955) as well as by a fall in blood pressure, and an increase in the concentrations of stress-related hormones. It may be further accompanied by other factors such as necrosis of the gastric mucosa.

The welfare of the individual animal should not be endangered by removal of too large a volume of blood or by too frequent collections. This may be the case more often when small laboratory animals, e.g. mice, gerbils, rats or hamsters are used. In these cases the study protocol should be adapted to use more animals to minimize distress for the individual animal.

Q.2.3 Total blood volume

The total blood volume is very difficult to determine (McGuill et al. 1989) and depends on species, sex, age and health as well as nutritional condition. Total blood volume is smaller in larger animals than in smaller animals of the same species in relation to body weight. It is also smaller in older and obese animals compared to normal weight and young animals. Total circulating blood volume is in the range of 55–70 ml/kg body weight.

Q.2.4 Terminal blood collection

Terminal blood collection represents (i) exsanguination as a single process of blood removal to collect as much blood as possible and (ii) multiple blood sampling during a terminal experiment under general anesthesia. Basically, exsanguination should only be performed after the animal has been rendered unconsciuos by another method, e.g. physical stunning or general anesthesia. This is due to the fact that stress occurs with extreme hypovolemia and accessing deeper blood vessels causes pain. Due to the anesthetized condition of the animal and the terminal nature of the experiment, methods can be used for exsanguination which can never be recommended for non-terminal blood collections with recovery of the animal. These include

- blood withdrawal from the V. cava caudalis or the aorta after laparatomy when as much blood as possible should be removed in a sterile manner,
- exsanguination after decapitation, incision of the jugular vein or carotid artery or techniques in the slaughterhouse, when a non-sterile collection is possible,
- retro-orbital bleeding of smaller laboratory animals like mice, gerbils, hamsters and rats which can also be a method of exsanguination.

Q.2.5 Non-terminal blood collection

Non-terminal blood collections can be differentiated into single and multiple blood withdrawals. Possible peripheral veins for blood withdrawal are listed in Table Q.2.

Q.2.5.1 Single blood removal

A single withdrawal of up to 15% of total blood volume does not influence the well-being of the animal. However, the removal of 15 to 20% might be accompanied by side effects such as fall in cardiac output or blood pressure. Haemorrhagic shock can be induced by the withdrawal of 30–40% of total blood volume and the loss of 40% causes mortality in up to 50% of pigs and rats (McGuill et al. 1989).

A single removal of up to 15% of total blood volume may be repeated after 3–4 weeks from normal and healthy animals with no detectable adverse effects. This does not mean that the animal does not experience any adverse effects, but it does not show any.

Symptoms of hypovolaemic shock are fast pulse, pale mucous membranes, hyperventilation and a subnormal body temperature including cold skin and extremities. In these animals therapeutic intervention consists of volume substitution with warm isotonic intravenous infusion.

Q.2.5.2 Multiple blood removal

Multiple withdrawal of blood samples should not exceed 1% of total blood volume every 24 h (0.6 ml/kg/d). More frequent withdrawals and/or removal of larger volumes of blood causes anemia.

Symptoms of anemia are pale mucous membranes of the conjunctiva or inside the mouth, intolerance to exercise and an increased respiratory rate in cases of severe anemia. Anemia can be easily detected by determination of erythrocyte cell count and packed cell volume (haematocrit), hemoglobin level as well as reticulocyte count in a blood sample. In case of anemia

the animal should be treated with iron and vitamin B12 and should be monitored for the above mentioned blood parameters during therapy until normal values are reached again.

Q.2.6 Technical aspects of blood removal

A common method in mice and rats for collecting up to 0.1 ml capillary blood is to remove the tip of the tail. For repeated blood sampling the blood clot on the tail has to be removed to get fresh capillary blood. This method is sufficient for multiple blood collections to determine, e.g. blood glucose or total radioactivity after the administration of radiolabeled drugs. In tail-less animals such as guinea pigs and hamsters, cardiac puncture under general anesthesia may be the preferred technique.

Blood collections from larger animals will preferably be performed from a superficial vein. The person holding the animal and raising the vein plays a key role in collecting blood without undue stress to the animal by talking to and stroking the animal. Some animals, e.g. dogs and some primates, may be trained to present a limb for blood removal without the use of any physical restraint.

It is important to locate the vessel accurately before insertion of the needle or the catheter. In most cases obstruction of the venous return is necessary for distension of the vessel and to successfully insert the needle. The bore of the needle should be as large as possible to ensure rapid blood withdrawal with minimal risk of blood clotting within the needle. When the sample is taken too quickly by a syringe, the vein will collapse. After the needle has been withdrawn, continuous pressure should be applied immediately to the puncture site and maintained for at least 30 s. The animal should be monitored 15 min later to check for after-bleeding.

Q.2.6.1 Permanent venous cannulation

For multiple blood collections a permanent venous access by chronic cannulation is often recommended. In most cases, particularly in rats, it is necessary to restrain the animal in harnesses or jackets to prevent it from damaging or removing the cannula. In these cases the signs of stress are often apparent by an increase in serum levels of stress hormones. However, a few days after implantation of catheters, hormone levels are normal in restrained rats (Tsukamoto et al. 1984; Wiersma and Kastelijn 1985). Such animals are usually housed alone and the tethering restricts normal movements such as lying on the back and rolling over. Such restrictions may be considered as potential sources of stress. This can be prevented by having the catheter exit the back of the animal for only 2 cm and capping it with a steel needle. At the time of the experiment, a longer catheter is attached for blood collections.

A simple device for serial blood collection has been described by Sir-Petermann et al. (1995).

One has to balance very carefully the distress and discomfort of the individual animal with a permanent cannulation under restraint conditions for a longer period with multiple blood samplings without permanent cannulation. In the first case, multiple values from the same animal can be obtained showing perhaps individual differences among a group of animals. In the latter case it may be necessary to use a larger number of animals but there is less discomfort for the individual animal.

Short-term cannulation (less than a day) of a peripheral blood vessel in larger animals is easy to perform. A butterfly needle can be inserted under aseptic conditions and multiple blood samples can readily be collected. Long-term cannulation (longer than two days) in larger and smaller animals often presents complications such as blockage of the cannula by thrombi. The infusion and administration of substances via the permanent cannula are much easier than the removal of blood. Thrombi attached to the end of the cannula function as a one-way valve. Clotting can be prevented by repeatedly filling the catheter with saline containing heparin.

Q.2.6.2 Retro-orbital bleeding

Blood sampling by orbital puncture is a controversial technique. The puncture of the orbital venous plexus is often performed in tail-less animals, e.g. hamsters. This technique is also used in rats and mice, when larger volumes are required which cannot be obtained from the tail vein. Basically, retro-orbital bleeding should always be performed under anesthesia. Pasteur pipettes, micropipettes or microcapillary tubes are used and pushed with a rotating movement through the conjunctiva laterally, dorsally or medially of the eye to the back wall of the orbit. In general, inflammatory reactions can be seen histologically in the puncture track four days after punction. After 4 weeks the lesions have healed without detectable scars (van Herck et al. 1992). However severe side-effects such as retro-orbital haematoma with subsequent pressure on the eye cannot be completely excluded. This pressure can dam-

age the optical nerve. The animal may be unable to close its eye. Bleeding from the orbital venous plexus should only be performed with recovery of the animal in exceptional circumstances when there is no other method available. The technique should be performed only by a well-trained staff and only one eye should be used.

Q.2.6.3 Cardiac puncture

The collection of blood by cardiac puncture has been performed in guinea pigs, gerbils and hamsters. In these species it is difficult to collect blood by alternative methods except retro-orbital bleeding. In general, cardiac puncture should be performed under general anesthesia with atropine as premedication to prevent cardiac arrhythmia. If cardiac puncture is used for a non-terminal blood withdrawal with recovery, the animal has to be separated from other animals until it is fully conscious. It should be carefully watched for adverse effects and sacrificed if found in distress due to complications like bleeding into the pericardium or into the thorax.

Q.3 Anesthesia of experimental animals[4]

Q.3.1 Introduction

In biomedical research, experiments should only be done with a conscious animal if it is not possible to do the study in an anesthetized one. Anesthetic conditions should always be chosen to exclude stress, discomfort and pain for the animal which could have negative influences on the pharmacological results and reproducibility of the data. Therefore, an experimental design causing minimal discomfort to the animal is always preferable. This is important not only for humanitarian reasons but also for good scientific practice.

Many pharmacological experiments are performed under anesthesia:

- terminal experiments under anesthesia followed by euthanasia,
- experiments under anesthesia with recovery at the end of the study, and
- experiments in which an animal is surgically prepared under anesthesia and continuation of the experiment occurs with the conscious animal after recovery.

Generally, two possibilities exist for immobilization of aggressive animals and to prevent escape: (i) physical restraint (e.g. immobilization cages or immobilization tubes) and (ii) chemical restraint with anesthetic compounds. As a rule of thumb it is recommended to use physical restraint for animal studies in which no anesthesia would be used in comparable studies in man. Physical restraint can be used for short and painless interventions like administration of substances or blood sampling from a vein.

In general, physical restraint produces fear, distress and anxiety in experimental animals with the result of stress symptoms which could affect the results of the study. To minimize pain for the animals, to obtain correct and reproducible results and to protect the handlers from aggression by the animals, it is often necessary to use chemical restraint. However, the chemical used can affect the biochemistry or physiology of the animal.

It is possible to anesthetize special areas of the animal (local anesthesia) or the whole animal (general anesthesia). Local anesthesia plays only a minor role for experimental animals as compared to general anesthesia.

[4] By J. Maas, A. W. Herling, K. Seeger (first edition), revised by U. Albus (second edition).

Q.3.2 Local anesthesia

Local anesthesia is the regional and reversible elimination of pain with chemical compounds. Circulatory, pulmonary and renal functions are not disturbed and the animals are conscious. Surface anesthesia has to be distinguished from the anesthesia produced after a local injection. The most common compounds for surface anesthesia are tetracaine and proparacaine. Procaine, butanilicaine, lidocaine, mepivacaine and etidocaine are commonly used injectable local anesthetics. Local anesthesia is only recommended for gentle and calm animals (cattle, sheep). For most laboratory animals, general anesthesia is the method of choice.

Q.3.3 General anesthesia

Q.3.3.1 Preparation

It is very important to check the general condition of the animal prior to anesthesia. This check should include a clinical examination (inspection, auscultation, palpation) of the animal concerned. Sometimes it could be useful to perform a few laboratory tests, e.g. hematocrit, hemoglobin, pH-value of blood and acid/base parameters.

Those animals with a vomiting reflex should be fasted prior to anesthesia. Most animal species should be fasted for a period of at least 12 h but pigs and cattle for at least 24 h. Water can be offered during the fasting period ad libitum.

Q.3.3.2 Premedication

Premedication is recommended prior to anesthesia for easier administration of the anesthetic and for elimination of side effects of the anesthetic used, such as disturbing autonomic reflexes.

Q.3.3.2.1 Hydration and base excess

Based on hematocrit, hemoglobin and erythrocyte values, the hydration of the animal should be normalized prior to anesthesia. Infusions of glucose or Ringer solution can be used for this purpose. To check the suc-

cess of the treatment repeated determinations of the above mentioned values are necessary.

In cases of acidosis (pH of blood <7.36), treatment of the animals with $NaHCO_3$ is recommended. If measurement of base excess is possible, the amount of $NaHCO_3$ can be determined from the following formula:

$$\text{Dose } NaHCO_3 \text{ (ml)} = \text{g body weight} \times \text{base excess} / 0.6$$

Q.3.3.2.2 Atropine

To avoid cardiopulmonary problems and to decrease saliva production, atropine should be administered intramuscularly prior to general anesthesia. The recommended dose varies considerably and is usually between 0.05 and 0.1 mg/kg body weight. Cats and rodents have a higher activity of atropine-esterase in the liver, and these species need higher amounts of atropine (up to 0.25 mg/kg).

Q.3.3.2.3 Sedation and pain elimination

Indications for sedation and elimination of pain are to calm the animals and to stabilize the autonomic nervous system.

For sedation the following compounds are used:

- minor tranquilizers without autonomic effects:
- meprobamate, diazepam,
- major tranquilizers with autonomic side effects:
- propionyl-promazine, acetylpromazine, azaperone, dehydrobenzperidol, xylazine, detamidone.

Anaesthesia does not necessarily lead to analgesia (elimination of pain). Although general anaesthesia produces loss of consciousness and pain is not perceived, the noxious stimuli will be transmitted to the CNS and will develop central hypersensitivity, leading to a postoperative heightened perception. To reduce the degree of central hypersensitivity analgesics have to be administered before noxious stimulation begins (pre-emptive analgesia). Analgesia should also reduce or eliminate peripheral inflammation, which aggravates central hypersensitivity.

For analgesia, the opioids used are mainly:

- methadone, meperidine, fentanyl.

In most species (dog, rabbit, guinea pig) a sedative effect is to be observed after administration of these compounds. In other species (pig, cat) an excitatory effect can occur.

Minor tranquilizers, major tranquilizers and analgesic compounds are often used in common with anesthetics. A compilation of such combinations is summarized in Table Q.3.

Q.3.3.3 Course of anesthesia

The animal has always to be observed very carefully during anesthesia. Various systems can be checked with technical equipment, e.g. circulatory system (heart rate, pulse, blood pressure, ECG, peripheral perfusion, temperature) or pulmonary system (respiratory rate).

A very important procedure during anesthesia is the determination of the depth of anesthesia. There are four stages of anesthesia:

I. Stage of analgesia (from the first effect to unconsciousness):
   - heart and respiratory rate increase, normal dilation of pupils.

II. Stage of excitation (from the beginning of unconsciousness to the start of regular respiration): respiration irregular, dilated pupils, increased motor reflexes, nystagmus, opisthotonus.

III. Stage of tolerance (from the beginning of regular respiration to the termination of spontaneous respiration):
   This stage is divided into four steps:
   A) regular respiration, narrow pupils, most reflexes present
   B) skeletal muscles relaxed, narrow pupils, no eyelid reflex, corneal reflex present, flat respiration, good analgesia.
      This is the optimal stage of anesthesia for surgery
   C) only corneal reflex present, respiration very flat, pupils dilated
   D) no reflexes, respiration very flat, pupils very dilated

IV. Stage of asphyxia (after termination of the spontaneous diaphragmatic respiration):

V. no reflexes, no respiration: danger of death, immediate use of antidotes is necessary to prevent death.

These various stages appear clearly in the case of ether. By using combinations of different anesthetics – mainly by using combinations with muscle relaxing agents – the reactions of animals will differ from this scheme.

Q.3.3.4 Routes of general anesthesia

In general, there are two different routes to induce general anesthesia: (i) injection and (ii) inhalation anesthesia. Sometimes combinations of both routes are used. The decision for one or the other route depends on the animal species, the purpose of the study and the necessity of control during anesthesia.

Q.3.3.4.1 Injection

By using this route of anesthesia the narcotic compound is dissolved in a liquid. The route of administration can be intravenous, intramuscular, subcutaneous or intraperitoneal. The mostly frequently used compounds are mentioned below:

Barbiturates

There are three groups of barbiturates: long acting, short acting and very short acting barbiturates. For laboratory animals short and very short acting barbiturates are used predominantly (sodium pentobarbitone, thiopental, hexobarbital).

Barbiturates are metabolized in the liver and mainly excreted via the bile. They are very fat soluble. Their short duration of action is caused by a distribution into adipose tissue. Fat represents a large compartment for these compounds with a relatively slow excretion. This can lead to prolongation of the narcotic effects after repeated dosing. The dosing of barbiturates should be adjusted according to the observed reactions of the individual animal as there are individual differences due to age, body weight, size, fat content and general condition of the animal. Barbiturates are not analgesic and should not be given without opioids.

Chloralhydrate

Chloralhydrate is a relatively old soporific compound. By using it for anesthesia cardiovascular side effects are often observed. The range of dosing is very narrow. Its use for laboratory animals is therefore limited. Intraperitoneal injections in rats can lead to paralysis of the ileus.

Combinations of analgesic with neuroleptic compounds

This method is often used for dogs and rodents. Strong analgesics (morphine, methadone, meperidine, fentanyl) are combined with neuroleptics like phenothiazine, acetylpromazine or butyrophenone. The anaesthesia can be rapidly terminated by available antagonists.

Ketamine

Ketamine is a neuroleptic compound with a very fast onset of action following intramuscular administration. It can be used for nearly all species. A side effect of this compound is an increased tonus of skeletal muscles but this can be prevented by the simultaneous administration of xylazine or diazepam.

Hypnotic agents

Hypnotics are compounds which produce a very deep sleep without analgesia (metomidate). Therefore combination with neuroleptic compounds is recommended (e.g. combination azaperone with metomidate for pigs). As a single compound, metomidate can only cause anesthesia in birds.

Xylazine

Xylazine is frequently used for anesthesia in combination with other substances (Table Q.3). As a single compound it is only used to produce anesthesia in cattle.

Urethane

Urethane was formerly used as a hypnotic agent, It can, at the appropriate dose, produce a long acting (about 10 h) anesthesia in rats. Urethane is liver toxic and therefore its use is limited to some pharmacological models in which liver metabolism is of no importance. Due to its carcinogenic properties it should be avoided wherever possible.

The important criteria of anesthesia are sedation, unconsciousness, analgesia and relaxation. These cannot be achieved with a single compound. Therefore, a combination of different compounds is necessary. The most common combinations for different species are listed in Table Q.3 with respect to the duration of anesthesia: short (up to 30 min), medium (up to 120 min) and long anesthesia (longer than 120 min).

Q.3.3.4.2 Inhalation

This kind of anesthesia plays only a minor role for small laboratory animals like rodents. Inhalation anesthesia is more common for the bigger laboratory animals such as dogs, cats, sheep, goats and monkeys. The advantages of this form of anesthesia are the possibilities of controlling exactly the depth of anesthesia and of fast management of complications.

The parts of an inhalation system include:

- Bottle with oxygen (blue bottles)
- Valve to regulate pressure (reduces the pressure of the oxygen-bottle)
- Flowmeter (monitors the gas flow to the animal)
- Evaporator (evaporation of liquid anesthetic compounds)
- Oxygen-bypass (fast supply of oxygen to the animal in case of need)
- Tube to the system

Different techniques are used for laboratory animals:

Technique of insufflation
Administration of anesthetic compounds is performed via a mask. Expiration occurs into the air of the room. Advantages are the simple procedure without valves and CO_2-absorber, and the very small dead volume of the system. Disadvantages are the waste of compounds, drying of the trachea of the animals, the impossibility of checking the respiration volume and the expiration of narcotic compounds into the room air (jeopardy to the staff).

Open system
Inspired and expired gases are separated by a valve. The inspired air consists of the fresh mixture of gases. The expiration reaches completely the atmosphere. The "Stephen slater" is the most used system of this group. It is recommended for smaller animals.

Half-closed and closed systems
In closed systems all of the expired air passes to a CO_2 absorber. The CO_2 is removed chemically and the air is inspired again with newly evaporated anesthetic compounds mixed with oxygen. In a half-closed system, part of the expired air reaches the atmosphere. Advantages of closed systems include the economic benefit, the decrease of fluid and body heat loss from the animal and no risk to the laboratory staff. Disadvantages are the necessity to change the absorber every 8–10 h during anesthesia, the production of heat and the increase of resistance to breathing.

Summary
If it is possible inhalation should be done by intubating the animal. The risk of aspiration of stomach contents with the danger of an aspiration pneumonia can then be minimized. It is very important to use a tube with the correct diameter and length. An animal should be unconscious for intubation (see Table Q.3). In order to avoid gulp or cough reflexes it is recommended to administer succinylcholine, a muscle relaxant. Atropine can also be administered to decrease saliva production. Generally, all methods of injection anesthesia mentioned (Table Q.3) can be combined with an inhalation method. Such a "balanced anesthesia" is recommended for long and highly sophisticated operations.

Q.3.3.4.3 Inhalation compounds

The inhalation mixture has to include 21% oxygen. Sometimes it is better to administer 33% oxygen. Despite the danger of explosion ether is one of the most frequently used anesthetic compounds, similarly, isoflurane, methoxyflurane and enflurane are widely used compounds for inhalation anesthesia. By using a mixture of N_2O and O_2 the amount of the evaporated compounds can be reduced drastically (Table Q.4).

Q.3.3.5 Termination of anesthesia

Inhalation anesthesia can be stopped by removing the supply of evaporated compounds. To hasten the elimination of anesthetic compounds, the concentration of oxygen in the system can be increased for a period of five min.

The elimination of injected compounds is difficult to influence. It may be possible to accelerate metabolism of the anesthetic by using agents which stimulate metabolism in the liver and excretion by the kidney.

It is very important to check the body temperature of the animal during and after anesthesia. In cases of low body temperature the use of heating lamps or pads is necessary. After termination of anesthesia the animals go through the same phases as mentioned above but in the reverse order (tolerance, excitation, analgesia).

During anesthesia it might be necessary to stimulate respiration or circulation. Stimulatory agents for respiration are doxapram, pentamethylentetrazole, nikethamide, methetarimide, lobeline or micoren. Stimulatory agents for circulation are adrenaline, effortil, dopamine and ephedrine. The application of pure oxygen via a mask is also recommended during an injection anesthesia. Antidotes to morphine and its derivatives are morphine-antagonists like naloxone. Yohimbine is an antagonist of xylazine. The antidote for diazepam is flumazenil. There are no direct antagonists for ketamine and barbiturates.

Table Q.3. Anesthesia of experimental animals (values are in mg/kg)

Species	Premedication	Sedation	Short anaesthesia	Medium anaesthesia	Long anaesthesia
Rat	Atropine (0.2 s.c.)	Diazepam (2.5 i.m.)	Alfentanyle + Etomidate (0.03 + 2 i.m.) or Inhalation (Isoflurane)	Xylazine + Ketamine (5 + 100 i.m.) or Pentobarbitone (50 i.p.)	Xylazine + Ketamine (16 + 100 i.m.) or Urethane (1 500 i.m.)
Mouse	Atropine (0.1–0.25 s.c.)	Diazepam (5 i.p.)	Alfentanyle + Etomidate (0.03 + 2 i.m.) or Inhalation (Isoflurane)	Xylazine + Ketamine (5 + 100 i.m.) or Pentobarbitone (50 i.p.)	Xylazine + Ketamine (16 + 100 i.m.)
Hamster	Atropine (0.1–0.2 s.c.)	Diazepam (5 i.p.)	Inhalation (Isoflurane or Ether)	Xylazine + Ketamine (5 + 50 i.m.) or Pentobarbitone (35 i.p.)	Xylazine + Ketamine (10 + 200 i.m.)
Guinea pig	Atropine (0.1–0.2 s.c.)	Diazepam (2.5–5 i.m.)	Inhalation (Isoflurane)	Xylazine + Ketamine (2 + 80 i.m.)	Xylazine + Ketamine (4 + 100 i.m.) or Pentobarbitone + Chloralhydrate (30 i.p. + 300 i.v.)
Rabbit	Atropine (0.1–0.2 s.c.)	Diazepam (1–5 i.m.)	Inhalation (Isoflurane)	Xylazine + Ketamine (5 + 25–80 i.m.)	Xylazine + Ketamine (5 + 100 i.m.) or Pentobarbitone + Chloralhydrate (30 i.p. + 300 i.v.)
Cat	Atropine (0.05–0.2 s.c.)	Diazepam (0.2–1 i.m.)	Acetylpromazine (0.5–1 i.v./i.m.) or Propionylpromazine 0.5–1 i.v.) or Xylazine (2 i.m.)	Xylazine + Ketamine (2 + 10 i.m.) or Ketamine (5 i.v.) or Inhalation (Isoflurane)	Pentobarbitone (35 i.v./i.p.)
Dog	Atropine (0.05 s.c.)	Xylazine (3 i.m.) or Acetylpromazine (0.5 i.m.) or Propionyl-promazine (0.5 i.m.) or Droperidol (1 i.m.) or Diazepam (1 i.m.)	Thiopental (17 i.v.) or Metomidate + Fentanyl (4 + 0.005 i.m.) or Alfentanil + Etomidat (0.03 + 1 i.m.) or Inhalation/Intubation (Isoflurane)	Xylazine + Methadone (2 + 1 i.m.) or Xylazine+Ketamine (2 + 10 i.m.) or comb. with Diazepam (0.6 i.m.) or Propionylpromazine + Methadone (0.5 + 1 i.v.) or Acetylpromazine + Methadone (0.5 + 0.5–1 i.v.)	Pentobarbitone (30 i.v.) or Xylazine + Ketamine (2 + 15 i.m.) or Intubation (Isoflurane)
Pig		Azaperone (1–2 i.m.) or Chlorpromazine (1–2 i.m.)	Thiopental (10 i.v; 5 % solution)	Azaperone + Metomidate (0.05–5 + 2.5–5 i.m. + i.v./i.p.) or Tiletamine + Zolazepam + Xylazine (2 + 2 + 0.5–1 i.m.)	Pentobarbitone (10–25 i.v.)
Sheep Goat		Xylazine (0.05–0.1 i.m.) or Diazepam (2 i.m.)	Xylazine + Ketamine (1–2 + 5–10 i.m.) or Thiopental (7.5–10 i.v.)	Pentobarbitone (20–30 i.m.)	Ketamine after pretreatment with Xylazine/ ketamine 3–4 h or Intubation (Isoflurane)
Monkey[a]	Atropine (0.05–0.1 s.c.)	Diazepam (1.0 i.m.) or Xylazine (1–2 i.m.) or Ketamine (10–30 i.m.)	Inhalation/Intubation (Isoflurane)	Xylazine + Ketamine (2 + 10 i.m.)	Pentobarbitone (20–30 i.v./i.p.) or Intubation (Isoflurane)

[a] Anaesthesia of monkeys depends very much on the monkey species.

Table Q.4. Inhalation compounds and their characteristics

Compound	Conc. with N_2O/O_2 (%)	Conc. without N_2O/O_2 (%)	MAC
Methoxyflurane	0.4–1	3.5	0.23
Isoflurane	1.0–2.5	1.5–3.5	1.4
Enflurane	0.5–1.5	2	2.2
Ether	3.5	5–10	3.2

MAC: minimal alveolar concentration for an anesthetic effect.

Q.3.4 Postoperative analgesia

To effectively reduce pain in animals a pain assessment has to be made using behavior, stress response etc. Pain assessment will be facilitated by

- a good knowledge of the species specific behaviors of the animal being assessed
- a knowledge and comparison of the individual animal's behaviour before and after the onset of pain (eg pre- and post-operatively)
- the use of palpation or manipulation of the affected area and assessment of the responses obtained
- examination of the level of function of the affected area: e.g. leg use following injury or limb surgery, together with a knowledge of any mechanical interference with function
- the use of analgesic regimens or dose rates that have been shown to be effective in controlled clinical studies, and evaluation of the change in behaviour this brings about
- a knowledge of the non-specific effects of any analgesic, anaesthetic or other drugs that have been administered

Analgesics can be broadly divided into two groups, the opioids or narcotic analgesics and the non-steroidal anti-inflammatory drugs (NSAID). Clinical pain involves several pathways, mechanisms and transmitter systems. To provide the most effective pain relief, drugs of different classes should be applied, acting on different parts of the pain system, for example combining opioids and NSAIDs.

Q.4 Euthanasia of experimental animals[5]

Q.4.1 Introduction

Biomedical research needs animals. This is most obvious in case of *in vivo* animal experiments. However, for other scientific purposes, e.g. *in vitro* studies, biological material is also necessary to study enzymes, membranes, receptors, cells, tissues, or organs which are obtained from dead animals. Therefore, animals have to be sacrificed in biomedical laboratories (i) at the end of an *in vivo* experiment, (ii) during experiments where sacrifice of the animals is not part of the study but must be done when pain, distress and suffering exceed acceptable levels or if it is likely for the animal to remain in pain or distress after cessation of the experiment, and (iii) to provide biological material for *in vitro* studies.

The following remarks are a summary of the *Recommendations for Euthanasia of Experimental Animals* of the *Commission of the European Communities* (1993) and the *Guidelines for Skillful and Human Euthanasia of Laboratory Animals* (1993) of Switzerland.

Q.4.2 Euthanasia

Euthanasia means a gentle death and should be regarded as an act of a human method of sacrificing an animal with a minimum of physical and mental suffering. The method of euthanasia should be appropriate for the species and the age of the animals. The method should be painless, avoid excitement and achieve rapid unconsciousness and death. Additionally, the method should be reliable, reproducible and irreversible.

Prior to euthanasia, it is important to recognize symptoms of fear, distress and anxiety; these symptoms are species specific. Depending on the species these symptoms may include distress vocalisation, attempts to escape, aggression, freezing, salivation, urination and defecation. Distress vocalization and release of certain odors or pheromones by a frightened

[5] By A. W. Herling (1st edition), revised by U. Albus (2nd edition).

animal may cause anxiety in other animals housed nearby. In this context it has to be stressed that many vocalisations of animals are in a range of frequencies which are out of the human hearing range. Therefore, animals should not be present during euthanasia of other animals, especially of their own species. If possible, an animal should not be killed in a room where other animals are housed, in particular in case of a bloody method of euthanasia, e.g. decapitation.

Euthanasia usually requires some physical control over the animals. Suitable control minimizes pain, distress, fear and anxiety in the animal and depends on animal species, size, state of domestication and method of euthanasia. Gentle handling, stroking and talking to the animal during euthanasia often have a calming effect on many animals. The use of sedating and immobilising drugs may be necessary in those cases, where capture or restraint may cause pain, injury or anxiety to the animal.

The person performing euthanasia is the most relevant factor during sacrificing an animal in order to cause a minimum of pain, fear and distress. A suitable method of euthanasia can be extremely harmful to the animal if it is badly performed. All persons performing euthanasia should be well trained, demonstrate professionalism and be sensitive to the value of animal life.

After euthanasia it is essential to confirm death. Signs of death are cessation of heartbeat and respiration, and absence of reflexes. Death must be guaranteed by exsanguination or removal of the heart, destruction of the brain, decapitation, evisceration or the presence of rigor mortis.

Methods for euthanasia of laboratory animals can be separated into physical and chemical methods.

Q.4.2.1 Physical methods recommended for euthanasia of laboratory animals

Physical methods are stunning (concussion, electrical stunning, and stunning with a captive bolt), cervical dislocation, decapitation, and microwave irradiation. The different methods of stunning as well as cervical dislocation cause a rapid loss of consciousness which must be followed immediately by a method to force and guarantee death of the animal.

Concussion may be sufficient in smaller animals, e.g. rodents, to achieve unconsciousness and is performed by a blow to the head. Electrical stunning is a common method in the slaughterhouse predominantly for pigs. Only specific equipment must be used for this method either in the slaughterhouse or in laboratory. Stunning with a captive bolt is also a common and an effective method for larger animals in the slaughterhouse to achieve unconsciousness. Adapted equipment can also be used for larger rabbits in biomedical laboratories. The correct localisation of the captive bolt is important in order to achieve immediate destruction of the brain. Cervical dislocation destroys the brainstem but the large vessels to the brain are often intact. All these methods have to be followed immediately by an act to force and guarantee death, e.g. exsanguination, removal of the heart or destruction of the brain.

During the decapitation process the head is separated from the neck which causes an immediate interruption of the blood circulation to the brain and a fall in blood pressure in the brain with subsequent loss of consciousness. This is valid only for warm-blooded animals. In cold-blooded vertebrates it is recommended to stun the animals prior to decapitation due to their higher resistance against anoxia. For decapitation of smaller laboratory animals specific guillotines have been developed.

Euthanasia by microwave irradiation is used by neurobiologists for fixation of brain metabolites without destruction of brain anatomy. Only specific equipment developed for this purpose must be used (no domestic microwave ovens). It is essential to localize correctly the microwave beam onto the brain of the animal.

Q.4.2.2 Chemical agents recommended for euthanasia of laboratory animals

Many chemicals can cause death due to their toxicity, but only a few are recommended for euthanasia. The most suitable chemicals for euthanasia are certain anesthetics in overdose. In this case, the anaesthetic agent causes unconsciousness, followed by death.

Volatile anesthetics such as halothane, enflurane, isoflurane and methoxyflurane should only be used in a gas scavenging apparatus. Carbon dioxide at high concentrations of 80 to 100% causes unconsciousness within a few seconds.

Injectable anesthetics, predominantly barbiturates such as sodium pentobarbitone, are the most widely used and the most appropriate agents for euthanasia for most animals. Three times the anesthetic dose causes generally rapid unconsciousness and death. Intravenous injection is the most reliable and rapid route. Intraperitoneal injection may also be used in smaller rodents but it needs more time for death to occur. The intracardial and intrapulmonal administration can only be recommended in unconscious animals, because it is painful and, in the case of intracardial injection, difficult to perform successfully on the first attempt.

The agent T61 is a mixture of a local anesthetic, a hypnotic and a curariform component. It is used only intravenously. Due to the curareform component it is not allowed in some countries but it has been demonstrated that unconsciousness and neuromuscular blockade occur simultaneously in dogs and rabbits. Nevertheless, prior sedation should be performed if possible.

Q.4.2.3 Methods and agents not to be used for euthanasia of laboratory animals

Physical methods not to be used for euthanasia are exsanguination, rapid freezing, pithing, decompression, hyperthermia, hypothermia, asphyxia, drowning and strangulation. Chemicals not to be used are carbon monoxide, nitrogen, nitrous oxide, cyclopropane, chloroform, trichloethylene, hydrogen cyanide, magnesium sulfate, potassium chloride, nicotine, strychnine, chloral hydrate, and ethanol. Some of the above mentioned chemicals are not recommended for euthanasia because they are extremely noxious and dangerous to the experimenter.

Neuromuscular blocking agents such as curare, succinylcholine or suxamethonium which do not cause rapid unconsciousness prior to death should also not be used. Ketamine is a very good anesthetic with a wide therapeutic safety margin for most animal species. Therefore, it is unsuitable for euthanasia.

However, non-acceptable methods of euthanasia can be used if animals are anaesthetized or rendered insensible and unconscious by a recommended method. This is used for, e.g. exsanguination, rapid freezing, and pithing. Exsanguination must not be performed in sight or smell of other animals. Rapid freezing is important to minimize enzymatic processes prior to subsequent biochemical determinations in tissues and organs. Pithing is a quick method of brain destruction achieved by insertion of a needle through the foramen magnum.

Q.4.2.4 Recommended methods for euthanasia for specific animal species

Mouse
- Decapitation
- Cervical dislocation with subsequent exsanguination
- Euthanasia within a 80% carbon dioxide atmosphere
- Euthanasia within an atmosphere of suitable volatile anesthetics
- Sodium pentobarbitone at a dose of 150 mg/kg i.p.

Rat
- Concussion, cervical dislocation (both with subsequent exsanguination), and decapitation, conducted only by well trained persons
- Euthanasia within a 80% carbon dioxide atmosphere
- Euthanasia within an atmosphere of suitable volatile anesthetics
- Sodium pentobarbitone at a dose of 100 mg/kg i.v. or 150 mg/kg i.p.
- Microwave irradiation

Hamster
- Decapitation; conducted only by well trained persons
- Euthanasia within a 80% carbon dioxide atmosphere
- Euthanasia within an atmosphere of suitable volatile anesthetics
- Sodium pentobarbitone at a dose of 300 mg/kg i.p.

Guinea pig
- Concussion (with subsequent exsanguination), and decapitation; conducted only by well trained persons
- Euthanasia within a 80% carbon dioxide atmosphere
- Euthanasia within an atmosphere of suitable volatile anesthetics
- Sodium pentobarbitone at a dose of 150 mg/kg i.p.

Rabbit
- Stunning with captive bolt
- Concussion (with subsequent exsanguination); conducted only by well trained persons
- Sodium pentobarbitone at a dose of 120 mg/kg i.v.
- T61 at a dose of 0.3 ml/kg strictly i.v. via a catheter

Cat
- Sodium pentobarbitone at a dose of 100 mg/kg i.v. or 200 mg/kg i.p.
- T61 at a dose of 0.3 ml/kg strictly i.v. via a catheter; it is recommended to anesthetize the animal beforehand with 20–30 mg/kg ketamine i.m. or 1–2 mg/kg xylazine plus 10 mg/kg ketamine i.m.

Dog
- Sodium pentobarbitone at a dose of 100 mg/kg i.v.
- T61 at a dose of 0.3 ml/kg strictly i.v., it is recommended to anesthetize the animal beforehand with 1–2 mg/kg xylazine plus 10 mg/kg ketamine i.m.

Ferret
- Sodium pentobarbitone at a dose of 120 mg/kg i.p.

Cattle, sheep, goat, horse, pig
- Sodium pentobarbitone at a dose of 100 mg/kg i.v.; for larger animals prior sedation is recommended (Xylazin).

- All other acceptable methods which are used for slaughtering

Primate

- Sodium pentobarbitone at a dose of 100 mg/kg i.v.; it is recommended to anaesthetize the animal beforehand with 1–2 mg/kg xylazine plus 10 mg/kg ketamine i.m.
- T61 at a dose of 0.3 ml/kg strictly i.v., it is recommended to anesthetize the animal beforehand with xylazine/ketamine i.m.
