The proteoglycan content is determined with the dimethyl-methylen blue (DMB) method modified after Farndale et al. (1986) and Chandrasekhar et al. (1987). The wet weight of the cartilage samples is determined immediately after preparation, and their dry weight is recorded after 3 day drying at 60 °C. Samples are then soaked overnight in 1 ml buffer (containing 20 mM disodium-hydrogen-phosphate, 1 mM EDTA, and 2 mM dithiothreitol in 500 ml aqua bidest at pH 6.8). Ten µl of papain, suspended in 0.05 M sodium-acetate (Sigma 9 001-73-4), are then added, and incubated at 60 °C for 6 h. Ten µl of standard (shark chondroitinsulfate C (Sigma C4 384) in a concentration range from 10–200 µg/ml buffer) and of each probe are then transferred into a 96 well microtiter-plate. Two hundred µl of DMB is added, and, after 1 min, the extinction recorded photometrically at 690/540 nm. The DMB solution is prepared by dissolving 16 mg DMB (Serva 20 335) in 2 ml methanol, adding 400 ml aqua bidest, 9.6 ml 1N HCl-solution, 3.04 g glycine, and 2.36 g NaCl, stirred and warmed until dissolved, and then diluted to a final volume of 1 000 ml with aqua dest (pH 3.0). The results are recorded as µg chondroitin-sulfate equivalents/mg cartilage dry weight.

EVALUATION

The histological appearance of the articular cartilage is assessed with a modified Mankin score, emphasizing more earlier changes, and separating degradative aspects, (e.g. loss of safranin staining), from repair aspects, (e.g. the occurrence of pericellular staining). The proteoglycan content is expressed as % change to the contralateral knee, or, comparing groups, to chymopapain-treated or. untreated control groups. To relate the proteoglycan content to cartilage dry weight has been found to be more reliable than choosing wet weight as baseline, as the cartilage water content is known to change in this model according to matrix composition.

CRITICAL ASSESSMENT OF THE TEST

In this model, hyaluronic acid preparations and some MMP inhibitors can be detected, NSAIDs do not change the parameters tested. The protocol can be modified to emphasize repair phenomena, or to assure a more severe course of cartilage loss (Williams et al. 1993).

MODIFICATIONS OF THE MODEL

To avoid interaction of a drug with the enzymatic nature of the chymopapain, other degradation mediators can be applied instead, as e.g. fibronectin fragments (Williams et al. 1988).

To ensure continuous synovial levels of a given drug, an osmotic minipump containing the drug can be implanted into the femoral muscles with a prolonged fine tube to insert into the patellar groove (Karbowski et al. in prep). This is an elaborate procedure in which a

Ketavet/Rampun anesthesia is needed, and postoperative plastic collars to prevent the rabbits to interfere with the operated region for the first three days. This results in highly consistent data compared to repeated injections.

Osteoarthritic lesions in the knee joints of male C57bl10 mice were induced by a single intra-articular injection of bacterial collagenase (Van der Kraan et al. 1990; Van den Berg et al. 1993).

Van Osch et al. (1995) developed a device to measure laxicity of knee joints in mice. Reproducible, non-linear S-shaped load displacement curves were determined from knee joints of normal mice. Parameters of anterior-posterior translation, varus-valgus rotation, and compliance were calculated from the curves. Laxicity was marked increased in animals with osteoarthritis induced by intra-articular injection of collagenase.

I.1.2.4 Spontaneous OA model in STR/1N mice

PURPOSE AND RATIONALE

This spontaneous model has the advantage of a gradually developing OA starting with cartilage surface erosion and fibrillation to osteophyte formation, subchondral bone remodeling, and finally eburnation, in a moderate time frame. All these steps, with only intermittent inflammatory flares, are similar to human pathology, and develop without any interference. The disadvantages are, however, the restriction to systemic drug application, due to the relative small animal size, and the variance in onset and severity of the disease among the animals.

PROCEDURE

The STR/1N mouse strain, characterized extensively by Walton (1977–1979) can be obtained from the National Institute of Health, Bethesda MA, USA. It is not identical to the STR/ORT strain as described by Benjamin et al. (1995), since it displays, in contrast to the ORT, no calcification in ligaments or tendons. Male mice develop OA earlier and more consistently than females, and, without dietary restriction, develop additionally obesity.

Beginning at the age of 10 weeks, male mice are trained to walk on a slowly rotating cylinder (or treadmill, manufactured by Ugo Basili, Italy) recording the mean walking time of each mouse. Mice with a moderate activity (neither dropping off too soon, nor staying on for hours) are then selected to enter the experiment. In groups of 8 to 10 animals, the drug is applied systemically for 8 weeks, and the mobility of each animal is recorded once or twice a week on the rotating cylinder. The body weight is recorded regularly as well. At the end of the experiment, the animals are sacrificed, both knee joints dissected, fixed, decalcified, and embedded in defined orientation for histology.

EVALUATION

The mean walking time decreases with age and disease progression, and is recorded in a time-dependent graph over the treatment period. The medial tibial plateau of the knee joints exhibits the most pronounced cartilage fibrillation and loss, and is, therefore, selected for histological evaluation, based on a modified Mankin grade.

CRITICAL ASSESSMENT OF THE TEST

Since this model is best suitable for oral drug application, experience with disease-modifying drugs for osteoarthritis is limited. Drugs with anti-inflammatory properties increase walking time, but do not alter the

morphological aspects of cartilage degradation in the joint. Analgesic drugs have no effect on either.

MODIFICATIONS OF THE TEST

Several authors (Nakamura 1990; Pataki, Witzemann 1990; Wilhelmi, Meyer 1983) have used the C57black mouse which, however, is reported to vary considerably in the incidence and severity of the disease, and also to develop the osteoarthritis only at older ages.

The STR/ORT strain differs in its calcification of fibrous cartilage (Benjamin et al. 1995), and seems to change the orientation of the proteoglycans in the hyaline cartilage (Dunham et al. 1989).

Brewster et al. (1998) tested an orally active collagenase inhibitor in STR/ORT mice. Microfocal X-ray-generated images of the hind limbs as well as histologic sections of the knees were scored for degradative changes and drug effects.

I.2 Methods for testing immunological factors[3]

I.2.1 *In vitro* methods

I.2.1.1 Inhibition of histamine release from mast cells

PURPOSE AND RATIONALE

Hypersensitivity reactions can be elicited by various factors: either immunologically induced, i.e. allergic reactions to natural or synthetic compounds mediated by IgE, or non-immunologically induced, i.e. activation of mediator release from cells through direct contact, without the induction of, or the mediation through immune responses. Mediators responsible for hypersensitivity reactions are released from mast cells. An important preformed mediator of allergic reactions found in these cells is histamine. Specific allergens or the calcium ionophore 48/80 induce release of histamine from mast cells. The histamine concentration can be determined with the *o*-phthalaldehyde reaction.

PROCEDURE

Preparation of mast cell suspension

Wistar rats are decapitated and exsanguinated. Fifty ml of Hank's balanced salt solution (HBSS) are injected into the peritoneal cavity and following massage of the body, the abdominal wall is opened. The fluid containing peritoneal cells is collected in a centrifuge tube and centrifuged at 2 000 rpm. The cells are resuspended in HBSS. Then the cell suspension is brought to a final concentration of 10^5 mast cells/100 µl.

Test compound administration and induction of histamine release

1 ml test drug (concentration range between 10^{-4} and 10^{-8} Mol) is added to the mast cell suspension (10^5 cells/100 ml) and the mixture is incubated at 37 °C for 15 min. The cells are made up to a volume of 3 ml with HBSS,

[3] With contributions in the first edition by R. R. Bartlett.

an equal volume of calcium-ionophore (10^{-6} g/ml), compound 48/80 or specific allergen is added. The suspension is incubated at 37 °C for 30 min followed by centrifugation at 2 500 rpm.

The following control solutions are needed

- *Spontaneous histamine release:* contains only mast cells and solutions used to determine baseline.
- *Histamine release:* contains mast cells and solutions and calcium-ionophore (10^{-6} g/ml).
- *Test compound control:* contains solutions and test compound to test the compound for native fluorescence.
- *Solution control:* contains only solutions used in the test to determine baseline.

Extraction of histamine

One ml of the top layer is transferred to a tube containing 300 mg NaCl and 1.25 ml butanol. The sample is alkalized to extract the histamine into butanol by adding 1 ml 3 N NaOH. Following mechanical shaking, the sample is centrifuged for 5 min. One ml of the top layer (butanol) is pipetted into a 5 ml tube containing 2 ml of n-heptane and 0.4 ml of 0.12 N HCl. The tube is mixed by inverting it several times. Following separation into aqueous and organic phases, 0.5 ml of the aqueous phase is transferred to another tube.

Induction of o-phthaladehyde complexing reaction

To each sample 100 µl 1 N NaOH is added under constant stirring immediately followed by administration of 100 µl 0.2% *o*-phthalaldehyde solution. After 2 min, the *o*-phthalaldehyde complexing reaction is stopped by addition of 50 µl 3 N HCl.

Determination of histamine release

The total sample is transferred to an autosampler vial and the histamine concentration is determined by a fluorescence detector (using excitation and emission wave lengths of 350 and 450 nm respectively).

EVALUATION

Percent histamine release (hist. rel.) can be expressed by the following formula:

$$\frac{\text{sample hist. rel.} - \text{spontaneous hist. rel.}}{100\%\ \text{hist. rel.} - \text{spontaneous hist. rel.}} \times 100$$

The statistical evaluation is carried out using the Student's *t*-test (comparison of 100% control to experimental group)

CRITICAL ASSESSMENT OF THE METHOD

Disodium cromoglycate has been reported to inhibit the release of histamine and the degranulation of rat mast cells (Orr and Cox 1969; Orr et al. 1971; Johnson and Bach 1975; Church and Young 1983). However, this effect of disodium cromoglycate and its analogues does not parallel the clinical efficacy (Kay et al. 1987).

MODIFICATIONS OF THE METHOD

Johnston et al. (1978) studied the increased superoxide anion production by immunologically activated and chemically elicited macrophages.

Flint et al. (1985) found a significant inhibition of histamine release by disodium cromoglycate in human mast cells recovered by bronchoalveolar lavage.

Ali et al. (1985) investigated the histamine release from rat peritoneal mast cells, human basophil and neutrophil leukocytes, mast cells from mesentery lung and heart of rats and guinea pigs by the skin irritating constituents thapsigargin and thapsigargicin from the resin of the umbelliferous plant *Thapsia gargania.*

Eady (1986) studied the reactivity of mast cells in bronchoalveolar lavage fluid of macaques repeatedly infected with *Ascaris suum*.

Wells et al. (1986) compared release of histamine, LTC_4, and PGD_2 from primate bronchoalveolar mast cells with that of rat peritoneal mast cells.

The release of β-hexosaminidase from mouse or rat bone marrow derived mast cells and from rat peritoneal mast cells was studied by Broide et al. (1986).

Peretti et al. (1990) recommended flow cytometry to investigate mast cell degranulation. Peptides, including substance P and bradykinin analogs release histamine from human skin mast cells (Lawrence et al. 1989).

Williams et al. (1991) studied the vancomycin-induced release of histamine from rat peritoneal mast cells and a rat basophil cell line (RBL-1).

A sensitive colorimetric assay for the release of tryptase from human lung mast cells *in vitro* has been described by Lavens et al. (1993).

I.2.1.2 Mitogen induced lymphocyte proliferation

PURPOSE AND RATIONALE

Cultured lymphocytes can be stimulated to a proliferative response and to DNA synthesis by various mitogens. Measurement of DNA synthesis can be accomplished by pulse-labeling the culture with tritiated thymidine (^{3}H-thymidine), a nucleoside which is incorporated into the newly synthesized DNA. Immunmodulating properties can be detected either by pretreatment of the animals *in vivo* or by adding the test drug to the cultured lymphocytes.

PROCEDURE

Mice of NMRI strain weighing 18–20 g or rats of Lewis strain weighing 180–200 g are used.

Materials

Sheep red blood cell (SRBC) specific antigen and/or the following mitogens:

- Lipopolysaccharide 10–0.1 µg/ml
- Dextran sulfate 30–7.5 µg/ml
- Phytohaemagglutinin 0.5–0.12 % stock solution
- Concanavallin A 0.5–0.12 µg/ml
- As standards levamisole, cyclosporine A, prednisolone or leflunomide are used.

Ex vivo

Animals receive the test compound once a day for 5 days. Thereafter, they are sacrificed, spleens are removed and a single cell suspension of 5×10^6 cells/ml is prepared. Mitogens are titrated (4 replicates/group) in 0.1 ml/well and 0.1 ml of the cell suspension is added. Plates are incubated at 37 °C in 5% CO_2 in air for 48–60 h and for another 8 h after addition of 0.25 µC ^{3}H-thymidine per well. Cells are harvested on glass fiber filters and after drying the degree of radioactivity is determined using a β-counter.

In vitro

Animals are sacrificed and their spleens removed. A single cell suspension of 10^7 cells/ ml is prepared and 0.05 ml placed in each microtiter well (4 replicates/ group). Then the test compound (4 times concentrated) is added in 0.05 ml. At last 0.1 ml of the double concentrated mitogen is added. Plates are incubated and processed as described above.

EVALUATION

Stimulation index = proliferation ratio according to positive control, either with or without mean spleen weight. Statistical evaluation is carried out using the Student's *t*-test (comparison of positive and/or negative control to experimental group).

I.2.1.3 Inhibition of T cell proliferation

PURPOSE AND RATIONALE

Activation and/or proliferation of clonal populations of T cells are critical for the initiation of an antigen-specific immune response. Thus, inhibition of T cell activation provides a potent means for suppressing specific immune response. A number of immunosuppressive agents exhibit the ability to suppress T cell activation.

PROCEDURE

Purification of peripheral blood leukocytes and T cells

Peripheral blood leukocytes from normal donors are separated on Ficoll-Hypaque (Pharmacia, Piscataway, NJ). Leukocyte suspensions are washed in HBSS and are resuspended in RPMI 1664 medium (Gibco, Grand Island, NY) containing 10% heat-inactivated fetal bovine serum and 100 U/ml penicillin/streptomycin. Leukocyte suspensions are resuspended in RPMI 1664 containing 10% heat-inactivated pooled human serum. Highly enriched T cells are obtained by passing leukocytes through a nylon wool column to remove macrophages and B cells and then depleted of NK and monocytes with anti-Leu 11 b (Becton Dickinson, Mountain View, CA) plus complement (Pel-Freeze, Brown Deer, WI). These highly enriched T cells are approximately 95% CD3+ cells, the remaining cells being B lymphocytes.

Mixed lymphocyte reaction

Peripheral blood leukocytes are incubated at 2×10^5/well with equal numbers of gamma-irradiated (3000 rads) allogenic peripheral blood leukocytes and various concentrations of test compounds. Assays are performed in triplicate in 96-well, U-bottom plates. After 6 days of coculture, the cells are pulsed for 6 h with 1 μC of [^{3}H]thymidine per well. [^{3}H]Thymidine incorporation is then measured by scintillation counting. Data are presented as:

$$\%\ \text{inhibition} = \frac{CPMexpt - CPMbckgrd}{CPMctrl - CPMbckgrd} \times 100$$

where *CPMexpt* are mean counts per min of experimental cultures, *CPMbckgrd* are mean counts per min of background well, unstimulated cultures, and *CPMctrl* are mean counts per min of uninhibited, stimulated cultures.

Lymphocyte stimulation and proliferation

Peripheral blood leukocytes and isolated T cells are cultured with anti-CD3 (5 ng/ml) plus PMA (5 ng/ml), anti-CD28 (1: 5 000 dilution) plus PMA (5 ng/ml), or 100 U/ml rhuIL-2 in RPMI 1644 containing 10% fetal bovine serum. Peripheral blood leukocytes or T cells are cultured at 2×10^5 cell per well in a total volume of 200 μl/well. Assays are performed in quadruplicate in 96-well, U-bottom plates. [^{3}H]Thymidine (1 μC) is added to each well after 48 h of coculture and after a 20 h pulse of [^{3}H]thymidine, the cells are harvested and the amount of [^{3}H]thymidine uptake is quantitated on a scintillation counter.

ELISA assays

Supernatants/well (100 mml) are harvested 24 h after initiation of cultures of peripheral blood leukocytes or T cells stimulated with anti-CD3 or anti-CD28 plus PMA. IL-2 in the coculture supernatant is quantitated using a commercially available IL-2 ELISA kit. All experiments are performed in duplicate.

IL-2R assays

The expression of IL-2R on T cells stimulated for 48 h with anti-CD3 or anti-CD28 plus PMA is determined using FITC-conjugated anti-CD25 mABs (Becton Dickinson, Mountain View, CA). T cells are washed in HBSS and then stained with phycoerythrin-conjugated anti-CD3 mAB and fluorescein-conjugated antiCD25 mAB. The percent of cells coexpressing CD3+ and CD25+ are determined from 2000 cells using an EPICS C flow cytometer (Coulter, Hialeah, FL).

EVALUATION

Dose response curves of inhibition of one-way mixed lymphocyte reaction and of IL-2 in the supernatant after stimulation with antiCD3 or anti-CD28 are established.

MODIFICATIONS OF THE METHOD

Zielinski et al. (1993, 1994) studied the influence of leflunomide on expression of lymphocyte activation ex-

pression markers (IL-2 and transferrin receptors) as well as on cell cycle and on IL-2 receptor gene expression.

Calcineurin was found to be a key signaling enzyme in T lymphocyte activation and the target of immunosuppressive drugs (Clipstone and Crabtree 1993).

I.2.1.4 Chemiluminescence in macrophages

PURPOSE AND RATIONALE

The stimulation of macrophages by antigen, complement, phorbol-esters, ect. leads to elaboration of O_2^- and other oxygen metabolites. Superoxide ion (O_2^-) and other highly reactive oxygen metabolites (radicals) form the basis for an efficient microbicidal system *in vivo*. Yet, when these radicals are released in response to self-antigens, tissue damage is often the result. Inhibition of this process can be regarded as a measure for immunmodulating effects of compounds. The oxygen metabolites can produce light-emitting reactions (chemiluminescence), which is measurable if amplified with suitable agents, such as the cyclic hydrazide luminol.

PROCEDURE

NMRI mice weighing 30 g or Sprague-Dawley rats weighing 250–300 g of either sex are used.

Positive control

1. Sensitized mice, receiving vehicle
2. Mice, developing an autoimmune disease, receiving vehicle
3. Rats, developing adjuvant arthritis, receiving vehicle

Negative control

1. Mice not sensitized, receiving vehicle
2. Mice, not developing an autoimmune disease, receiving vehicle
3. Rats without adjuvant arthritis.

Materials

- 5×10^8 SRBC (sheep red blood cells)/0.5 ml 0.9% NaCl solution (for sensitization)
- *Phorbolester:* Stock solution of 1 mg/ml phorbolmyristenacetate. This stock solution is diluted with Hank's balanced salt solution to a final concentration of 3.5 µM (working solution). For the induction of chemiluminescence, the working solution is diluted in the test tube 1 : 4, resulting in a final phorbolester concentration of 0.875 µM.
- Luminol (5-amino-2,3-dihydro-1,4-phthalazinedione, Sigma) final concentration 25 µg /ml

Ex vivo experiment

Groups of 6 animals are treated for 6 days orally or subcutaneously with test compound or the standard (prednisolone acetate or leflunomide). They are decapitated and exsanguinated. Macrophages are obtained by flushing the peritoneal cavity with 10 ml saline, containing 250 IU heparin. The cells are pooled, washed several times and suspended again at a final concentration of 2×10^6/200 µl.

For measurement in the luminometer the following mixture is prepared:

200 µl macrophages (2×10^6)
100 µl luminol solution (100 µg/ml)
100 µl phorbolmyristenacetate solution (3.5 µM)

Each sample is mixed thoroughly without the phorbolmyristenacetate solution, put into the luminometer and counted at 2 min intervals for 10 s. The addition of the phorbolester induces the reaction.

In vitro experiment

To 100 µl of macrophage suspension (2×10^6 cells) are 100 µl of the solution of the test compound added and incubated for 15 min at 37 °C.

Then, 100 µl of luminol solution (100 µg/ml) and 100 µl of the 3.5 µM phorbolester solution are added and the luminescence measured in the luminometer.

EVALUATION

The time of maximal counts for the positive control is recorded. For all groups the ratio of counts per 10 s is determined at that time, compared to the positive control counts per 10 s and the percent change is calculated. For statistical evaluation the experimental group is compared with the positive control group using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Bird and Giroud (1985) described a technique of polymorphonuclear leukocyte chemiluminescence as a means to detect compounds with anti-inflammatory activity. Inflammatory polymorphonuclear leukocytes were obtained by injecting rats intrapleurally with 1 ml of a 1% solution of calcium pyrophosphate and collection of the pleural exudate 4 h later. Chemoluminescence responses were measured using a Packard Picolite chemoluminometer and opsonized zymosan as the stimulus.

Seeds et al. (1985) found an independent stimulation of membrane potential changes and the oxidative metabolic burst in polymorphonuclear leukocytes.

A microtechnique for studying chemiluminescence response of phagocytes using whole blood was described by Selvaraj et al. (1982).

I.2.1.5 PFC (plaque forming colony) test *in vitro*

PURPOSE AND RATIONALE

Identification of antibody producing cells is based on the ability of the secreted IgM antibody to fix complement and thereby lyse the indicator erythrocytes. Spleen cells or peripheral blood lymphocytes, previously incubated with antigen, are mixed with sheep red blood cells (SRBC). After addition of compliment and incubation, plaques (clear areas) caused by the lysis of SRBC appear in the otherwise cloudy layer. Antibody forming cells can be detected by the appearance of plaques. The number of plaques obtained is proportional to the number of antibody producing lymphocytes in the cell population.

PROCEDURE

NMRI mice weighing 16–18 g or Lewis rats weighing 180–200 g of either sex are used.

Materials

- absorbed guinea pig complement
- SRBC stored in Alsever's solution

Positive control

Spleen cells incubated with antigen and medium

Negative control

Spleen cells incubated with medium alone. The animals are decapitated and the spleens are removed from the peritoneal cavity. A single cell suspension of 15×10^6 cells/ml is prepared. For the induction of PFC, a 0.5 ml splenocyte suspension is added to 0.5 ml of a suspension of SRBC, previously washed in medium and diluted to 8×10^6 cells/ml. Thereafter, 1 ml of the solution of the test compound is added and the limbrowells are incubated at 37 °C in a CO_2 incubator for 5 days. Per group 3 limbrowells are set up. On day 5, the 3 wells of each group are pooled, washed in medium and the number of cells is determined. For each cell pellet, 875 µl of washed SRBC and 125 µl absorbed guinea pig compliment are added. The suspension is mixed thoroughly and filled in chambers constructed of microslides. The chambers are placed in the incubator at 37 °C for 90–120 min. The plaque forming colonies are counted immediately after incubation.

EVALUATION

The activity of test compounds can be determined using the following formula:

1. PFC/3 wells:

$$x = \frac{\text{plaques} \times 100}{\mu\text{l}}$$

2. % change in the number of plaques:

$$x = \frac{\text{plaques} \times 100}{\text{plaques pos. control}}$$

$$d\% = x - 100$$

3. % change in number of cells:

$$x = \frac{\text{number of cells} \times 100}{\text{number of cells pos. control}}$$

$$d\% = x - 100$$

I.2.1.6 Inhibition of dihydro-orotate dehydrogenase

PURPOSE AND RATIONALE

Dihydro-orotate dehydrogenase catalyzes the fourth committed step in the de novo biosynthesis of pyrimidines. As rapidly proliferating human T cells have an exceptional requirement for de novo pyrimidine biosynthesis, small molecule dihydro-orotate dehydrogenase inhibitors constitute an attractive therapeutic approach to autoimmune diseases, immunosuppression, and cancer. The main mode of action of the immuno-suppressive compound leflunomide and its active metabolites is considered to be the inhibition of the enzyme dihydro-orotate dihydrogenase (Bruneau et al. 1998; Graul and Castañer 1998; Knecht and Löffler 1998; Rückemann et al. 1998; Schorlemmer et al. 1998; Herrmann et al. 2000; Liu et al. 2000).

PROCEDURE

A fragment of human dihydro-orotate dehydrogenase is expressed by means of the baculovirus expression vector system and purified to a specific activity greater than 50 U/mg (Knecht et al. 1996, 1997). Enzyme assays are performed with purified recombinant dihydro-orotate dehydrogenase at 30 °C. The oxidation of the substrate dihydro-orotate and the reduction of the co-substrate quinone is coupled to the reduction of the chromogen 2,6-dichlorophenolindophenol (DCIP). The reaction mixture contains 0.1 mM Q_D or 0.1 M Q_{10}, 1 mM L-dihydro-orotate, 0.06 mM DCIP, 0.1% Triton X-100 in 50 mM Tris-HCl buffer, 150 mM KCl, pH 8.0. The reaction is started by addition of the enzyme. The loss of absorbance of the blue DCIP is monitored at 600 nm; $\epsilon = 18.800\ \text{l mol}^{-1}\,\text{cm}^{-1}$. The enzyme activity in control assays without Q_D or Q_{10} which is approximately 1% of maximum enzyme activity is subtracted from the activity values measured. Stock solutions of the test compounds are prepared in dimethylsulfoxide with further dilutions in the buffer taken for the assays.

EVALUATION

To determine the inhibitory potency of the agents, the initial velocity of dihydro-orotate dehydrogenase reaction is measured at saturating substrate concentrations, 1 mM dihydro-orotate and 100 µM Q_D and varying concentrations of the drugs (1 nM through 100 µM). The equation is fitted to the initial velocities:

$$v = V / \{1 + [\text{I}]/IC_{50}\}$$

([I] is the inhibitor concentration) in order to find the concentration causing 50% inhibition of the enzyme activity (IC_{50}).

I.2.2
In vivo methods for testing immunological factors

I.2.2.1
Spontaneous autoimmune diseases in animals

Several spontaneous autoimmune diseases have been reported in several inbred animal strains:

New Zealand black mouse (NZB mouse) (Bielschowski et al. 1959; Howie and Helyer 1968; Barthold et al. 1974; Blanchard and Bach 1980). The NZB mouse develops a spontaneous autoimmune disease with autoimmune hemolytic anemia, splenomegaly, glomerulonephritis, lymphoproliferative disorders and peptic ulcerations.

New Zealand black/white F1 (B/W) mouse (Helyer and Howie 1963; Kessler 1968): These animals develop nephritis similar to that in human systemic lupus erythematosus and show mononuclear cell infiltration in salivary and lachrymal glands such as in human Sjögren's syndrome.

A substrain of the autoimmune-prone mouse, NZB/kl, was found to show spontaneous elevation of the auditory brainstem response threshold with age (Sone et al. 1995).

Immunodeficient alymphoplasia mice were recommended as a spontaneous model for Sjøgren's syndrome (Tsubata et al. 1996). Mice homozygous for an autosomal recessive mutation aly (alymphoplasia) lack both lymph nodes an Peyer's patches and show defects in both humoral and cellular immunity. Histo-pathological analyses revealed chronic inflammatory changes in exocrine organs such as the salivary gland, lacrimal gland and the pancreas.

The **Palmerston North autoimmune mouse strain** which exhibits both spontaneous systemic autoimmune disease and otic capsule bone formation has been proposed as a model for otic capsule osteogenesis and otosclerosis (Hertler and Trune 1990; Traynor et al. 1992).

In aging **BDF1 mice**, Hayashi et al. (1988) described spontaneous development of autoimmune sialadenitis.

Robison et al. (1994) examined the relationship between orchitits and aspermatogenesis in various strains of H_2 congenic mice and defined a genetic predisposition to spontaneous aspermatogenesis.

Motheaten mice. Mice homozygous for the autosomal recessive motheaten (me) or the allelic viable motheaten (me^v) mutations develop severe and early-age onset of systemic autoimmune and inflammatory disease (Green and Shultz 1975; Shultz et al. 1984; Shultz 1988; Su et al. 1998).

The genetic, hormonal and behavioural influence on spontaneously developing arthritis in normal mice has been reviewed by Holmdahl et al. (1992).

Non-obese diabetic mouse (NOD mouse) (Makino et al. 1980; Miyazaki et al. 1985; Leiter et al. 1987). The inbred NOD mouse is considered a good model for type I diabetes mellitus. Mononuclear cells infiltrate the pancreatic islets of Langerhans from 6–8 weeks of age, followed by a progressive and selective destruction of insulin-producing β-cells and the onset of IDDM from the 12^{th} week of age onwards.

Itoh et al. (1997) studied the requirement of Fas for the development of autoimmune diabetes in nonobese diabetic mice.

Quartey-Papafio et al. (1995) showed that aspartate at position 57 of nonobese diabetic I-A(g7) β-chain diminishes the spontaneous incidence of insulin-dependent diabetes mellitus in the NOD mouse.

The NOD mouse was also recommended to study the pathogenesis of autoimmune thyroiditis (Many et al. 1996).

Bio-breeding rat (BB rat) (Like et al. 1982; Field 1983; Yale and Marliss 1984). On the basis of clinical and histopathological parameters, the BB rat is considered a useful model for human IDDM. The disease in the BB Rat is characterized by infiltration of lymphocytes and macrophages into the islets of Langerhans.

Allen and Thupari (1995) described spontaneous autoimmune lymphocytic thyroiditis in *BB/Wor rats.*

Obese strain chicken (OS chicken) (van Tienhoven and Cole 1962; Cole 1966; Cole et al. 1968, 1970; Wick et al. 1974). The OS chicken is perhaps the best studied model for an organ-specific, spontaneously occurring autoimmune disease, viz. spontaneous autoimmune thyroiditis, which closely resembles human Hashimoto thyroiditis. The spontaneous autoimmune thyroiditis in obese chicken was further studied by Neu et al. 1986; Kroemer et al. 1989; Cihak et al. 1995; Hala et al. 1996; Dietrich et al. 1997.

Chickens of the University of California line 200 **(UCD-200 chickens)** develop an inherited inflammatory fibrotic disease that closely resembles human progressive systemic sclerosis (scleroderma) (Gershwin et al. 1981; Van de Water et al. 1984; Brezinscheck et al. 1993).

Schumm-Draeger and Fortmeyer (1996) described **autoimmune thyroiditis in the cat** as a spontaneous disease model.

Spontaneous autoimmune thyroiditis was found in **Mastomys** (*Praeomys coucha*) by Solleveld et al. (1985) and recommended as an animal model of human disease.

I.2.2.2 Acute systemic anaphylaxis in rats

PURPOSE AND RATIONALE

Rats are immunized with ovalbumin and *Bordetella pertussis* suspension as adjuvant. After 11 days the animals are challenged by intravenous injection of ovalbumin. The shock symptoms can by inhibited by corticosteroids and intravenous disodium cromoglycate.

PROCEDURE

Female Sprague-Dawley rats weighing 120 g are immunized by i.m. injection of 10 mg/kg highly purified ovalbumin. Simultaneously 1 ml of *Bordetella pertussis* suspension (2×10^{10} organisms) is injected intraperitoneally. IgE antibodies are induced and attached to the surface of mast cells and basophilic granulocytes. Eleven days later the animals are challenged by intravenous injection of 25 mg/kg highly purified ovalbumin. This results in formation of antigen-antibody-complexes on the surface of mast cells and basophilic granulocytes in blood and in all organs with immediate release of various mediators of anaphylaxis, such as histamine, serotonin, SRS-A, prostaglandins; in shock symptoms and 80% lethality. Corticosteroids, e.g. dexamethasone 1–10 mg/kg s.c. are given 18 h prior to challenge, or 30 mg/kg disodium cromoglycate i.v. before injection of ovalbumin. Ten–20 animals are used for each group.

EVALUATION

The shock symptoms are scored and mortality counted. Results after treatment are compared with untreated controls. Pretreatment with corticosteroids or disodium cromoglycate can inhibit death and ameliorate shock symptoms. Statistical calculation is performed using the χ^2-test.

MODIFICATIONS OF THE METHOD

Desensitization by repeated 'microshocks' of constant strength in guinea pigs has been reported by Herxheimer (1952).

Acute systemic anaphylaxis experiments have also been performed in guinea pigs and in mice. In guinea pigs anaphylactic bronchospasm can be measured with the Konzett and Rössler method (see D.2.2.1) (Davies and Evans 1973).

Moreover, anaphylactic bronchospasm can be measured in isolated guinea pig lungs according to the method of Bhattacharya and Delaunois (1955).

Anaphylaxis can be measured in the chopped guinea pig lung by assay of the supernatant in the isolated guinea pig ileum in the presence of 2×10^{-7} M atropine (Austen and Brocklehurst (1961).

Ufkes and Ottenhof (1984) sensitized Brown-Norway rats with a suspension of trinitrophenyl haptenized ovalbumin together with $AlPO_4$ as adjuvant. Bronchial and cardiovascular function were studied after treatment with anti-allergic agents and antigen challenge.

Elwood et al. (1992) studied the effect of dexamethasone and cyclosporin A on allergen-induced airway hyperresponsiveness and inflammatory cell responses in sensitized Brown-Norway rats.

I.2.2.3 Anti-anaphylactic activity (Schultz-Dale reaction)

PURPOSE AND RATIONALE

Guinea pigs are sensitized against egg albumin. Challenge after 3 weeks causes in isolated organs release of mediators, e.g. histamine, which induce contraction in isolated ileum.

PROCEDURE

Guinea pigs of either sex weighing 300–350 g are sensitized with alum precipitated egg albumin. Alum egg albumin is prepared by dissolving egg albumin (1 mg/ml) in six percent aluminum hydroxide gel, suspended in saline. The mixture is stirred and kept at room temperature. Each animal receives at the same time injections of 0.125 ml of this mixture in each foot pad and 0.5 ml subcutaneously. After 4 weeks the animals are killed and the ileum is dissected out. Cleaned pieces, about 2–3 cm long, are mounted in an organ bath containing Tyrode solution at 37 °C. The strips are allowed to equilibrate for 15 min. The contractility of the ileum strips is tested by adding 10^{-4} g/ml $BaCl_2$ solution. To one organ bath the standard (2×10^{-6} g/ml final concentration of Tribenosid = 1-O-ethyl-3,5,6-tri-O-benzyl-D-glucofuranoside = Glyvenol® CIBA) and to other vials the test compounds (final concentration up to 10^{-5} g/ml) are added. One organ bath serves as control. After 3 min ovalbumin in a final concentration of 2×10^{-6} g/ml is added. The contractions are recorded with strain gauges by a polygraph.

EVALUATION

The results are expressed as presence or absence of blocking activity (percentage inhibition). If anti-anaphylactic activity is observed, ED_{50} values using different doses are calculated.

CHRITICAL ASSESSMENT OF THE METHOD

Positive results can also be achieved with spasmolytics, local anesthetics, antihistaminics, and sympathicomimetics.

MODIFICATIONS OF THE METHOD

The method has been modified by testing histamine release in the lung after challenging with egg albumin. Either lung strips from sensitized guinea pigs are suspended in an organ bath and their contractions are measured after addition of egg albumin or the entire lung tissue is dissected out and washed free from blood by perfusing with warm oxygenated Tyrode solution via the pulmonary artery. The lung tissue is chopped and washed with Tyrode solution in order to remove the remaining blood. The chopped lung tissue is divided into 24 samples, each of approximately 100 mg wet weight. These are incubated at 37 °C in Tyrode solution for 15 min with continuous agitation by rocking, after which, 1 mg/ml of egg albumin is added to the reaction mixture. After shaking for 10 min at 37 °C, the supernatant is collected and assayed for histamine with guinea pig ileum. Atropine sulfate 2 mg/ml is added in Tyrode solution. The residual histamine is obtained by boiling the tissue in 5 ml Tyrode solution for 10 min. The tubes are then placed on ice for 1 h to allow complete diffusion. Released histamine is expressed as a percentage of total histamine content.

Koppel et al. (1981) developed a method to induce contraction of immunologically sensitized mouse trachea by antigen (Schultz-Dale reaction).

The trachea of sensitized guinea pigs was used by Omote et al. (1994).

I.2.2.4 Passive cutaneous anaphylaxis

PURPOSE AND RATIONALE

Passive cutaneous anaphylaxis is a immune reaction of the immediate type. By passive immunization of rats in the skin with rat anti-ovalbumin serum and a challenge 2 days later with ovalbumin at the same skin area antigen-antibody complexes are formed in the mast cells inducing release of mediators. This results in vasodilatation, increase in permeability of the vessel walls and leakage of plasma. To make the allergic reaction visible, Evan's blue dye is administered along with the antigen. Evan's blue dye is attached to the albumin fraction of plasma, producing a blue spot. This blue spot indicates that an anaphylactic reaction has taken place in the skin.

PROCEDURE

For preparation of antiserum male rats weighing 200–250 g are adrenalectomized and are allowed to recover for 3 days. Thereafter, animals are sensitized with egg albumin (1 mg/animal) using aluminium hydroxide gel (200 mg) as adjuvant. Alum egg albumin is prepared by dissolving 1 mg/ml of egg albumin in 20% aluminium hydroxide gel, suspended in saline. Each animal simultaneously receives 0.125 ml of the above solution in each foot pad and 0.5 ml subcutaneously. After 8 days, the animals are bled and antiserum is collected.

For the test, the antiserum is diluted in such a manner as to give a wheal of 15–20 mm diameter in a preliminary titration. Aliquots of 100 µl of appropriate dilution of antiserum are injected intradermally into the shaved dorsal skin of normal male rats weighing about 100 g. After 24 h of latent period each animal is challenged with the intravenous administration of 0.1 ml of 2.5% Evans blue dye containing 25 mg/ml of egg albumin. In the case of intravenous administration, the test compound is administered simultaneously with the antigen and the dye. In case of oral testing, the compound is given orally 1 h prior to challenge. The animals are sacrificed 30 min after the challenge. The amount of Evans blue dye leaked at the site of passive cutaneous anaphylactic reaction is extracted and determined colorimetrically at 620 mµ wavelength.

EVALUATION

The amount of Evans blue extracted from passive cutaneous anaphylactic reaction is taken as 100 percent. Percent inhibition of passive cutaneous anaphylactic reaction in the rats treated with the test compound is calculated. The standard disodium cromoglycate at a dose of 3 mg/kg i.v. or 30 mg/kg orally results in 80–100% inhibition. Using different doses, ED_{50} values can be calculated.

MODIFICATIONS OF THE METHOD

Goose and Blair (1969) used *Bordetella pertussis* and extracts of the worm *Nippostrongylus brasiliensis* as antigens in passive cutaneous anaphylaxis experiments in the rat.

Patterson et al. (1971) tested passive cutaneous reactivity to antihuman IgE in rhesus monkeys.

Without immunization, plasma extravasation after bradykinin injection can be tested in anesthetized Sprague-Dawley rats (Lembeck et al. 1991). Evans blue dye is injected to stain plasma proteins. After injection of bradykinin antagonists followed by bradykinin injection, the rats are perfused with physiological saline. The trachea, the urinary bladder, and the duodenum are resected, weighed and incubated for 48 h in formamide at 50 °C (Saria et al. 1983). The amount of Evans blue extracted is measured photometrically at 620 nm.

Vascular reactions to histamine, histamine-liberator and leukotaxine in the skin of guinea pigs using pontamine sky blue 6X as indicator were studied by Miles and Miles (1952).

I.2.2.5 Arthus type immediate hypersensitivity

PURPOSE AND RATIONALE

The immune complex induced Arthus reaction comprises inflammatory factors that have been implicated in the acute responses in joints of rheumatic patients. Complement and polymorphonuclear neutrophiles are activated via precipitating antigen-antibody complexes leading to an inflammatory focus characterized by edema, hemorrhage and vasculitis. Arthus reaction of the immediate type becomes maximal 2–8 h after challenge.

PROCEDURE

Ovalbumin suspension

1 700 mg ovalbumin are suspended in 100 ml paraffin oil. 4.38 ml pertussis vaccine are suspended in 70 ml 0.9% NaCl-solution. Both suspensions are mixed to form an emulsion.

Wistar or Sprague-Dawley rats of either sex weighing 220–280 g can be used. Seven days prior to start of the experiment rats are sensitized by i.m. administration of 0.5 ml of the ovalbumin suspension. They are housed in groups of eight with standard food and water ad libitum.

Twenty-four hours and one hour prior to induction of the Arthus reaction, test compounds are administered to groups of 8 animals. The rats are challenged by injection of 0.1 ml of 0.04% solution of highly purified ovalbumin in the left hind paw. Swelling of the paw occurs which reaches a maximum after a few hours. The footpad thickness can be measured by calipers. One group of sensitized animals treated with solvent alone serves as positive control, one group of nonsensitized animals treated with solvent alone serves as negative control. Standard doses are 30 mg/kg cortisone or 10 mg/kg prednisolone p.o.

EVALUATION

The change in footpad thickness is expressed as the percent change from the vehicle control group. Comparison of experimental group to positive control is evaluated statistically using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Instead of ovalbumin, sheep red blood cell suspensions can be used for immunization and for challenge in mice (Omote et al. 1994).

Nagakawa et al. (1990) sensitized mice by s.c. injection of bovine serum albumin in complete Freund's adjuvant and boosted on day 21 by an intradermal injection of BSA. On day 28, the Arthus reaction was elicited by intradermal injection of BSA. Four hours later, an erythematous skin reaction over an area of more than 8 mm^2 was regarded as positive.

Kamei et al. (1991) immunized guinea pigs by injection of a mixture of egg albumin and Freund's complete adjuvant subcutaneously into the food pad or i.m. into the hind leg. The injection was repeated 4 times at 7 day intervals. Ten days after the last immunization, 0.2 ml of 2.5% egg albumin was injected sc. into the dorsal skin of the animals. The intensity of the Arthus reaction was evaluated by measuring the inflamed area according to scores.

I.2.2.6 Delayed type hypersensitivity

PURPOSE AND RATIONALE

Delayed type hypersensitivity is a reaction of cell mediated immunity and becomes visible only after 16–24 h. The same methods as for testing immediate type hypersensitivity can be used.

PROCEDURE

Rats are sensitized in the same way by i.m. administration of 0.5 ml ovalbumin suspension 7 days prior to the start of the experiment as described for testing immediate type hypersensitivity. They are challenged by injection of 0.1 ml of 0.04% solution of highly purified ovalbumin in the left hind paw. Footpad thickness is measured immediately and 24 h after ovalbumin administration.

MODIFICATIONS OF THE METHOD

Mizukoshi et al. (1994) injected female CDF1 mice intradermally with a suspension of 2×10^8 sheep red blood cells/50 µl into the left foot pad. A second booster of the same dose was given to the right foot pad on day 4. The thickness of the foot pads was measured on the following day, and the difference in the thickness between the right and the left food pads was taken as the degree of swelling.

Kamei et al. (1991) immunized mice by applying 0.15 ml of 7% picryl chloride/ethanol solution to the skin of the shaved abdomen. The second immunization was performed 6 days later. One week after the second immunization, 1 drop of 1% picryl chloride olive oil solution was applied to the ear and the thickness of the ear was measured by a thickness gauge 24 h later.

I.2.2.7 Reversed passive Arthus reaction

PURPOSE AND RATIONALE

In the reversed passive Arthus reaction the antigen is injected intravenously followed by a local injection – either intradermally or into the pleural space – of the respective antibody. Generation of an immune-mediated reverse passive Arthus reaction in the rat pleural cavity results in a classic acute inflammatory response. The methods are used to evaluate new anti-inflammatory agents.

PROCEDURE

Male Lewis rats weighing 200–250 g are fasted overnight prior to use with free access to water. The animals receive 5 mg bovine serum albumin in 0.2 ml sterile saline intravenously, followed 30 min later by injection of 1 mg rabbit anti-BSA in 0.2 ml sterile saline into the right pleural cavity under light halothane anesthesia. Drugs or vehicle controls are administered by gastric gavage in 1 ml/100 g body weight at different times prior to the anti-BSA. The animals are sacrificed at various intervals after anti-BSA injections by CO_2 inhalation (after 5 min for thromboxane B_2 determination, after 10 min for leukotriene B_4 determination, and after 4 h at the peak time of neutrophil infiltration). The fluid exudate is removed from the pleural cavity by gentle vacuum aspiration and the volume is recorded. Eikosanoids in the pleural exudate are quantitated by commercial RIA kits.

EVALUATION

The values after treatment with various doses of test compounds are compared with those of vehicle controls.

MODIFICATIONS OF THE METHOD

The antibody can be injected intradermally into the shaved skin of rats after intravenous injection of the antigen (e.g., human albumin) together with Evans blue dye solution. Extravasated dye is determined in skin punches (Camussi et al. 1990; Burch et al. 1992; Okamoto et al. 1992).

Bailey and Sturm (1983) induced the reverse passive Arthus reaction in rats using bovine serum albumin as antigen into the tail vein and rabbit anti-bovine serum albumin into the skin site. One hour after oral dosing with vehicle or drug, animals were lightly anesthetized and their hair was shaved from the mid-dorsal region with electric clippers. Each animal was injected intradermally with 40 µl on the left side of the mid-dorsal line and with 40 µl of rabbit anti-bovine serum albumin (5.0 mg/ml antibody protein), diluted 1 : 4 with phosphate-buffered saline on the right side of the dorsal midline. Immediately following the intradermal challenge, each rat received 0.5 ml phosphate-buffered saline containing 1.0 mg bovine serum albumin injected in the tail vein. Four hours after intradermal challenge, the animals were sacrificed. The full thickness skin was removed from the back and discs 8 mm in diameter were punched out with a metal punch. Wet weight of the samples from the phosphate-buffered saline- and antibody-injected site was determined and the edema induced by the reverse passive Arthus reaction calculated as the difference between both weights.

I.2.2.8 Adjuvant arthritis in rats

PURPOSE AND RATIONALE

Adjuvant arthritis in rats has been described by Pearson and Wood (1959) exhibiting many similarities to human rheumatoid arthritis. Injections of complete Freund's adjuvant into the rat paw induces inflammation as primary lesion with a maximum after 3 to 5 days. Secondary lesions occur after a delay of approximately 11 to 12 days which are characterized by inflammation of non-injected sites (hindleg, forepaws, ears, nose and tail), a decrease of weight and immune responses. The procedure has been modified by several authors in order to differentiate between anti-inflammatory and immunosuppressive activity (e.g. Perper et al. 1971). Anti-inflammatory compounds do not inhibit secondary lesions, which are prevented or diminished by immunosuppressive agents. Two protocols, termed "preventative" (or "prophylactic") and "therapeutic" (or "established") adjuvant arthritis, have gained wide usage for assessing a drug's potential anti-arthritic activity (Schorlemmer et al. 1999).

PROCEDURE

The choice of the animal strain has been found to be very important for the performance of this test. Wistar-Lewis rats have been proven to be very suitable in contrast to other sub strains. Male rats with an initial body weight of 130 to 200 g are used. On day 1, they are injected into the sub plantar region of the left hind paw with 0.1 ml of complete Freund's adjuvant. This consists of 6 mg mycobacterium butyricum (Difco) being suspended in heavy paraffin oil (Merck) by thoroughly grinding with mortar and pestle to give a concentration of 6 mg/ml. Dosing with the test compounds or the standard is started on the same day and continued for 12 days. Paw volumes of both sides and body weight are recorded on the day of injection, whereby paw volume is measured plethysmographically with equipment as described in the paw edema tests. On day 5, the volume of the injected paw is measured again, indicating the primary lesion and the influence of therapeutic agents on this phase. The severity of the induced adjuvant disease is followed by measurement of the non-injected paw (secondary lesions) with a plethysmometer. Purposely, from day 13 to 21, the animals are not dosed with the test compound or the standard. On day 21, the body weight is determined again and the severity of the secondary lesions is evaluated visually and graded according the following scheme:

		score
ears:	absence of nodules and redness	0
	presence of nodules and redness	1
nose:	no swelling of connective tissue	0
	intensive swelling of connective tissue	1
tail:	absence of nodules	0
	presence of nodules	1
forepaws:	absence of inflammation	0
	inflammation of at least 1 joint	1
hind paws:	absence of inflammation	0
	slight inflammation	1
	moderate inflammation	2
	marked inflammation	3

EVALUATION

a) For primary lesions: The percent inhibition of paw volume of the injected left paw over vehicle control is measured at day 5.
b) For secondary lesions: The percentage inhibition of paw volume of the non-injected right paw over controls is measured at day 21.
c) An arthritic index is calculated as the sum of the scores as indicated above for each animal. The average of the treated animals is compared with the control group.
d) The total percentage change is calculated as follows by addition of:
percent inhibition of the injected paw on day 5 + percent inhibition of the non-injected paw on day 21 + percent change of the arthritic index.

Doses of 0.3 mg/kg indomethacin p.o. and 20–50 mg/kg phenylbutazone p.o. are effective on the primary lesions when dosage is started at the day of injection of the irritant. They are not effective on the secondary lesions.

In contrast, immunosuppressants like cyclophosphamide at a dose of 7 mg/kg inhibited the secondary lesions even when started at day 9 or later.

CHRITICAL ASSESSMENT OF THE METHOD

Evidence was given that adjuvant arthritis in the rat is associated with chronic pain (Colpaert 1987) The measure of pain in this model still presents some technical problems since the evaluation is based on the somewhat biased observation of the behavioral responses.

MODIFICATIONS OF THE METHOD

A review was given by Gardner (1960) on the experimental production of arthritis.

Moran et al. (1999) compared adjuvant arthritis and selected animal models of arthritis to rheumatoid arthritis with special emphasis on the mechanism of joint destruction.

Kazuna and Kawai (1975) and Rooks et al. (1982) used rats with established lesions to test analgesics in the arthritic flexion pain test. The method is claimed to be specific by detecting only central analgesics and nonsteroidal anti-inflammatory drugs but not other classes such as CNS-depressant or antihistaminic drugs.

Brackertz et al. (1977) established antigen-induced arthritis in the mouse by immunization with methylated bovine serum albumin in complete Freund's adjuvant with B pertussis vaccine.

A streptococcal cell wall-induced arthritis in rats has been described by Wilder et al. (1982, 1987) and Yocum et al. (1986).

Lewis et al. (1997) studied degradation of articular cartilage in a rat monoarthritis model induced by an intra-articular injection of *Propionibacterium acnes*.

Crossley et al. (1989) reported on a monoarticular antigen-induced arthritis in rabbits and mice.

α-2-Glycoprotein levels have been recommended as parameter for severity and inhibition of experimental immunoarthritis in the rat by Sandow et al. (1971).

Pircio et al. (1975) recommended a method for the evaluation of analgesic activity using adjuvant-induced arthritis in rats. The degree of vocalization was recorded from 5 rats placed together in a counting chamber.

Cruwys et al. (1994) sensitized rats on day 0 and 7 with multiple intradermal injections of methylated bovine serum albumin emulsified in Freund's complete adjuvant. On day 21, the animals were challenged by the intra-articular injection of 100 µl 0.5% solution of methylated bovine serum albumin into the right knee. The progress of the monoarticular arthritis was monitored by daily measurement of joint diameter.

Butler et al. (1991) described a limited arthritic pain model for chronic pain and inflammation studies using injections of 0.05 ml of complete Freund adjuvant into the left tibio-tarsal joint of Sprague-Dawley rats.

Esser et al. (1995) measured radiographic changes in adjuvant-induced arthritis in rats by quantitative image analysis. Digitized radiographs of the calcaneus were examined for changes in the mean and in the distribution of gray values. Periostal new bone formation was measured as an increase in image area of the calcaneus.

Mercuric chloride ($HgCl_2$) induces a syndrome of autoimmunity in Brown-Norway rats characterized by a variety of IgG antibodies, very high concentrations of serum IgE, proteinuria, leukocytoclastic vasculitis which predominantly affects the caecum, and an inflammatory polyarthropathy (Kiely et al. 1995, 1996).

Consden et al. (1971), Cook and Jasin (1972), Cook et al. (1972), Jasin and Cook (1977) produced a chronic experimental monoarthritis by intra-articular injection of antigens into previously immunized **rabbits**.

Henderson et al. (1990) induced monoarticular arthritis in ovalbumin-sensitized rabbits by intraarticular injection of ovalbumin (antigen-induced arthritis) or in naive rabbits by injecting hyaluronic acid mixed with the polycation poly-D-lysine (polycation-induced arthritis).

Arner et al. (1995) compared the alterations in proteoglycan metabolism in antigen-induced arthritis and polycation-induced arthritis in rabbits and determined the involvement of interleukin-1 in the cartilage degradation that occurs in these models of rheumatoid arthritis.

Lewthwaite et al. (1995) studied the antifibrotic action of interleukin-1 receptor antagonist in antigen-induced monoarticular arthritis in New Zealand White rabbits.

Arthritis occurs in **pigs** due to infection with *Erysipelothrix rhusiopathiae* (Ajmal 1969). Experimental erysipelothrix infection in pigs can be used as a model for rheumatism research (Schulz et al. 1975a,b, 1977). Infections are established by oral or parenteral administration of standardized serotype B erysipelas strains.

Erysipelothrix arthritis could also produced in rats and **rabbits** (White et al. 1975; Glynn 1977).

Arthritis due to infection with *Mycoplasma synoviae* occurs naturally among domestic poultry (Olson et al. 1954, 1964). Arthritis in **chickens** after mycoplasma infection has been used as experimental model (Kerr and Olson 1970; Cullen 1977).

Experimental models of arthritis due to streptococcal infections have been proposed for various species: **mice** (Cayeux et al. 1966; Hook et al. 1960; Ohanian et al. 1969), **rats** (Jasmin 1967; Koga et al. 1973), **rabbits** (Cecil et al. 1939; Cook and Fincham 1966; Ginsburg et al. 1968, 1977; Norlin 1960; Shimizu et al. 1958; Stein et al. 1973), **pigs** (Roberts et al. 1968, 1969).

I.2.2.9 Collagen type II induced arthritis in rats

PURPOSE AND RATIONALE

As reported by Trentham et al. (1977) intradermal injection of homologous or heterologous type II collagen in incomplete Freund's adjuvant results in an inflammatory polyarthritis in rats. The demonstration of antibodies to collagen in patients with rheumatic polyarthritis suggests that autoimmunity may contribute to the pathophysiology of synovitis and joint destruction. Because of the similarities of the symptoms in rats to human disease the test is considered to be useful to detect anti-inflammatory and immunosuppressive properties of test compounds.

PROCEDURE

Bovine type II collagen is prepared from nasal septum cartilage, which is cut into small fragments, frozen in liquid nitrogen, and pulverized in a freezer mill. Proteoglycans are extracted overnight by stirring 25 g of pulverized cartilage in 1 liter of 0.2 N NaOH. Following centrifugation at 20 000 *g* for 30 min, the residue is washed with 250 ml of absolute ethanol, the supernatant aspirated, and the residue vacuum dried. Hundred mg pepsin are added to 150 ml of 0.5 M acetic acid, after which 1.0 g of cartilage is added to reach a cartilage to pepsin ratio of 10 : 1 (w/w). The mixture is stirred 18 h at room temperature and centrifuged at 20 000 *g* for 1 h. Acid soluble collagen present in the supernatant is precipitated by adding NaCl to reach a final concentration of 0.9 M, followed by centrifugation at 20 000 *g* for 1 h. The precipitate from 1.0 g cartilage is dissolved in 100 ml 1.0 N NaCl/0.005 M Tris-HCl, pH 7.5, and stirred for 3 days. Then, the solution is dialyzed against 0.02 M Na_2HPO_4, pH 9.4, and the precipitate collected by centrifugation at 30 000 *g* for 1 h. The pellet is dissolved in 0.5 M acetic acid, dialyzed against 6 liters of 0.01 M acetic acid, and lyophilized. All procedures, unless otherwise stated are performed at 4 °C.

Test procedure. Collagen is dissolved in a concentration of 2.0 mg/ml in 0.1 M acetic acid overnight at 4 °C. This solution is added dropwise to an equal volume of chilled incomplete Freund's adjuvant. Six to 12 male Wistar rats with an initial weight of about 120 g are used for each group. On day 1, each rat receives a total of 0.5 mg collagen in 0.5 ml, equally divided, in 5 sites. All injections are intradermal, one at the base of each appendage and one in the nape of the neck. Seven days post-immunization, the animals receive identical booster injections. Control animals receive only the incomplete Freund's adjuvant diluted with 0.1 M acetic acid.

The volume of both hind paws is measured plethysmographically on day 20. To minimize the possibility of including animals with minimal transient disease, only animals with a paw volume of 1.8 ml or greater are used for further testing. From days 20–40, the animals receive the test compounds p.o. once a day. On day 41, the paw volumes are recorded again.

EVALUATION

The paw volumes of treated animals are recorded plethysmographically. The increase versus day 20 is calculated. The increase is compared with that of controls or animals treated with a standard drug. Otherwise, arthritic scores can be determined. Nonsteroidal anti-inflammatory drugs such as indomethacin in a dose of 2 mg/kg p.o. or phenylbutazone in a dose of 150 mg/kg p.o., but not acetylsalicylic acid in a dose of 50 mg/kg p.o. have been found to be active. Likewise, corticosteroids and immunosuppressives, but not D-penicillamine, were active.

CHRITICAL ASSESSMENT OF THE METHOD

Non-steroidal and steroidal anti-inflammatory compounds are detected by this method which, however, does not allow a separation between this two groups.

MODIFICATIONS OF THE METHOD

Hom et al. (1988), Takagishi et al. (1986, 1992), Cannon et al. (1990), Nemoto et al. (1992) and Carlson et al. (1992) described the effects of immunomodulating agents in collagen-induced arthritis in mice.

Wooley et al. (1993) investigated the anti-arthritic effect of recombinant human interleukin-1 receptor antagonist protein on type II collagen-induced arthritis and antigen-induced arthritis in mice.

Joosten et al. (1994) found an accelerated onset of collagen-induced arthritis in DBA_1 lac/J mice by remote inflammation.

Miesel et al. (1993, 1994a,b) studied the effects of an active center analogue of Cu_2Zn_2-superoxide dismutase in collagen type II-induced arthritis. Furthermore, the authors described a model potassium peroxochromate-induced inflammation in rats and mice. One to 3 µmol/kg K_3CrO_8 was administered by intraplantar application into the left hind-paws of anesthetized rats or mice. Arthritis index was assessed by a score system or the inflammatory response was quantified scintigraphically under a gamma camera by intravenous injection of 500 µCi $Na^{99m}TcO_4$.

From studies with a neutrophil elastase inhibitor Janusz and Durham (1997) concluded that of the destruction of the joints in rat collagen-induced arthritis is at least partially due to neutrophil elastase.

Kumar et al. (1997) compared the cellular mechanisms involved in the control of collagen II-induced

arthritis and experimental autoimmune encephalomyelitis.

I.2.2.10 Proteoglycan-induced progressive polyarthritis in mice

PURPOSE AND RATIONALE

Glant et al. (1987, 1992), Mikecz et al. (1987, 1990), Poole (1989) described a proteoglycan-induced progressive arthritis and spondylitis in BALB/c mice as an animal model displaying similarities to human rheumatoid arthritis and ankylosing spondylitis as indicated by clinical assessments, immunological parameters and histopathological studies of diarthrodial joints and spine.

PROCEDURE

High buoyant density cartilage proteoglycans are prepared from fetal and adult human, canine or bovine articular cartilages as well as from 1-week-old mouse epiphyseal cartilage. Fetal human articular cartilage proteoglycan digested with chondroitinase ABC (Hascall and Heinegård 1974) is used to induce arthritis in female BALB/c mice. The mice are sensitized by intraperitoneal injection of 100 µg of chrondroitinase ABC-treated proteoglycan in 100 µl of phosphate buffered saline, pH 7.2, and in Freund's complete adjuvant in a 1 : 1 emulsion. They are re-injected twice more with the antigen in incomplete Freund's adjuvant after one and three weeks. All BALB/c mice immunized with human articular cartilage proteoglycan develop arthritis in diarthrodial joints after the third antigen injection. Sera from mice with progressive polyarthritis are tested for antibodies to arthritogenic proteoglycans during weeks 12–18 of immunization. The limbs of all mice are examined daily to record clinical arthritic changes. Swelling and redness, as the first symptoms of arthritis, and the thickness (diameter) of the knee, ankle (intermalleolar diameter), wrist and

the dorsovo-lar thickness of the paw are recorded three times a week. The most objective joint diameter is the intermalleolar one. The animals are treated with test drug or vehicle for 12 weeks and serum samples taken by retroorbital puncture for determination of antibodies to proteo-glycans. Seven weeks later, the mice are sacrificed, limbs, tails and lumbar spine are fixed, decalcified and embedded in paraffin for histological examination.

EVALUATION

Mean values of intermalleolar diameter and antibody titers of treated and non-treated animals are compared by non-parametric statistics.

MODIFICATIONS OF THE METHOD

Stimpson and Schwab (1989) described a chronic remittent erosive arthritis in rats induced by bacterial peptidoglycan-polysaccharide structures.

I.2.2.11 Experimental autoimmune thyroiditis

PURPOSE AND RATIONALE

Immunization of rats or mice with porcine thyroglobulin results in thyroiditis (Vladutiu 1971, 1983; McGregor et al. 1983; Hassman et al. 1985; Salamero et al. 1987; Fournier et al. 1990).

PROCEDURE

Crude porcine thyroglobulin (PTg) solution is emulsified in complete Freund's adjuvant in a 1 : 1 ratio. Female mice (6–8 weeks old) are primed with 50 µg PTg given s.c. into four or five sites of injection and are boosted 14 days later with the same dose of PTg (s.c.) emulsified in incomplete Freund's adjutant. The test compounds are administered from day 0 (at priming) until day 21. Mice are bled on day 21 and on day 28 after priming. The sera are tested for the levels of anti-PTg antibodies using an enzyme-linked immunosorbent assay (ELISA). On day 28, the animals are sacrificed and the thyroid glands prepared. Five-micrometer thick sections are stained with Masson-Goldner's trichrome solution.

EVALUATION

The histological severity of experimental autoimmune thyroiditis is graded as a function of mononuclear cell thyroid infiltration indices:

1. interstitial accumulation of inflammatory cells distributed between two ore more follicles.
2. one or two foci of inflammatory cells reaching at least the size of one follicle
3. 10 to 40% of the thyroid replaced by inflammatory cells.
4. more than 40% of the thyroid replaced by inflammatory cells.

Mean values of treated animals are compared with controls.

MODIFICATIONS OF THE METHOD

Castagliola et al. (1994) induced autoimmune thyroid disease in BALB/c mice by immunizing with the extracellular domain of the human TSH receptor expressed as a maltose-binding protein fusion in bacteria. This type of thyroiditis could be transferred to naive BALB/c and NOD mice (Castagliola et al. 1996).

Green et al. (1995) described a spontaneous model of autoimmune thyroiditis in MRL-lpr/lpr mice.

Furthermore, Green et al. (1996) induced thyroiditis in Lewis rats by immunization with thyroid extract and thyroglobulin. A reduction of the gap junction proteins connexin 43, connexin 32 and connexin 26 was found in diseased thyroid tissue.

I.2.2.12 Coxsackievirus B3-induced myocarditis

PURPOSE AND RATIONALE

The effects of immunosuppressant drugs can be studied in the murine model of Coxsackie virus B-3 myocarditis.

PROCEDURE

Three week old male BALB/c mice are kept for 7 days before the experiment in a single, self-contained animal isolation unit to exclude pre-diseased animals. They are maintained in disposable, filter-topped cages and handled with gloves by gowned and masked personnel. The intraperitoneal route is used for injection of virus in a 0.5 ml volume.

The CVB3 virus strain is grown on either Hep-2 or VERO cells, aliquotted, and maintained at –70 °C until use. At the time of infection, seed virus is grown on either VERO or LLC-MK-2 cells with Dulbecco's modified Eagle medium, 12% fetal calf serum and gentamycin. Virus is harvested and adjusted to an inoculum of 1.75×10^7 plaque forming units/0.5 ml RPM-1640. The test drugs are given subcutaneously daily for 8 days. On day 8, the animals are sacrificed, the hearts rapidly removed and divided into two equal cross sections. The basal portion is snap frozen for isolation of virus and determination of drug level. The apical portion is fixed in 10% formalin, dehydrated and embedded in paraffin. Five mm sections are stained with hematoxylin-eosin and Masson's trichrome stains. The bases of the individual hearts are minced with a sterile scalpel, suspended in 1 ml RPMI-1640, and homogenized in a glass tissue grinder. The suspension is centrifuged at 8 000 *g* for 10 min at 4 ºC. Supernatants are harvested and frozen at –70 ºC until assay. Serial 10-fold dilutions of heart homogenates in minimum essential medium are layered on confluent, 72-h-old VERO cells, that had been grown in 96-well microtiter plates. Monolayers are checked daily for 7 days for presence or absence of virus and rate of cell destruction.

EVALUATION

The slides are examined by two observers blinded to the slide code, and inflammation and necrosis are quantitated.

MODIFICATIONS OF THE METHOD

Lane et al. (1991) showed that lipopolysaccharides promote CB3-induced myocarditis in otherwise resistant B10.A mice.

Beisel et al. (1991) identified a putative shared epitope between Cocksackie virus B4 and mouse alpha cardiac myosin heavy chain.

Gauntt et al. (1993) found that epitopes shared between Coxsackie virus B3 and normal heart tissue contribute to CVB3-induced myocarditis in mice.

Instead of Coxsackie virus B-3, Monrad et al. (1986) used encephalomyocarditis virus to induce experimental myocarditis in mice.

I.2.2.13 Porcine cardiac myosin-induced autoimmune myocarditis in rats

PURPOSE AND RATIONALE

Pummerer et al. (1991), Inomata et al. (1995), Suzuki 1995; Dimitrijevic et al. (1998) described autoimmune myocarditis in rats induced by porcine cardiac myosin.

PROCEDURE

Male Sprague Dawley or Lewis rats at the age of 8 to 10 weeks are immunized with porcine cardiac myosin either purchased from Sigma (St. Louis, MO, USA) or prepared from the ventricular muscle of porcine hearts according to Murakami et al. (1976). The cardiac myosin fraction is dissolved in phosphate buffer at a concentration of 10 mg/ml. The antigen solution is emulsified with equal volume of complete Freund's adjuvant supplemented with heat-killed mycobacterium tuberculosis. Rats are injected subcutaneously into the foot pad with an immunizing dose of 5 mg of antigen in complete Freund's adjuvant/kg of body weight. Rats are injected intraperitoneally with test compounds either from day 0 to 6 (early treatment group) or from day 14 to 20 (late treatment group).

Immunized rats are sacrificed on days 8, 16, 21, and 34, respectively. Disease course and severity are analyzed by macroscopic findings of the hearts, heart weight/bodyweight ratio, as well as by histological and immunohistochemical analysis. Macroscopic findings are scored as follows: 0: normal finding; 1: presence of focal discolored area on the surface; 2: presence of diffuse discolored areas (Kodama et al. 1995).

The hearts are removed and weighted immediately after the rats are sacrificed, fixed in 10% buffered formalin and embedded in paraffin. Serial section (5 μm in thickness) are stained with hematoxylin-eosin. The severity of myocarditis is determined according the following scoring system: 0, no inflammation; 1: histological cross section infiltrated up to 5%; 2: 5–10% infiltrates/section; 3: 10–20% infiltrates/section; more than 20% infiltrates/section.

For immunohistochemical staining, heart samples are embedded in OCT compound (Miles, Elkhart, IN) and rapidly frozen. Cryostat sections are cut sequentially at 7 μm in thickness, mounted on glass slides and prepared for immunoperoxidase staining. Sections are fixed in cold acetone for 10 min and extensively washed in 0.1 M Tris buffer solution, pH 7.6. Murine monoclonal antibodies specific for different rat molecules are added at appropriate concentrations. After incubation at 4 °C over night and further buffer washes, the sections are incubated with peroxidase-conjugated anti-mouse immunoglobulins for 60 min. Peroxidase reaction is visualized with 0.05% diaminobenzidine in 0.01% H_2O_2 for 7–8 min. The color development is stopped by washing slides in running water. All samples are lightly counterstained with hematoxylin, mounted in gelatin/glycerol medium and assessed by light microscopy.

EVALUATION

Macroscopic and microscopic scores are expressed as mean values. Body weights, heart weights and heart weight/body weight ratio are expressed as mean ±SD. Student's *t*-test for paired samples is used for comparison data within groups in reference to time, while two-sample *t*-test is used for comparison data between groups.

MODIFICATIONS OF THE METHOD

Koyama et al. (1995) immunized Lewis rats with human cardiac myosin suspended in complete Freund's adjuvant and induced severe active myocarditis with acute and chronic heart failure. The baseline left ventricular pressure was significantly lower in the chronic phase group and peak *dP/dt* was significantly lower in both the acute phase group and the chronic phase group than in the respective controls. The animal model was recommended to study both acute heart failure related to acute myocarditis and chronic heart failure due to diffuse myocardial fibrosis.

Neu et al. (1990, 1991ab; Penninger et al. 1993) induced severe autoimmune myocarditis in some mouse strains by immunization with cardiac myosin in complete Freund's adjuvant.

I.2.2.14 Experimental allergic encephalomyelitis

PURPOSE AND RATIONALE

Experimental allergic encephalomyelitis was first produced in laboratory animals by Rivers et al. in 1933. This pathological model is an immunologic disease arising from a delayed hypersensitivity reaction to nervous tissue. In many respects, the model resembles autoimmune diseases, especially demyelinating diseases, in man. The method is used for evaluation of immunosuppressive properties of drugs.

PROCEDURE

Preparation of the encephalitogen: 3 g of spinal cord from guinea pigs or rats are homogenized with 7.5 ml bidistilled water, 3.8 ml phenol and 7.5 ml complete Freund's adjuvant under cooling.

Groups of 6–12 male Wistar-Lewis rats with an initial body weight of 130–200 g are used. On day 0, experimental allergic encephalomyelitis is induced by subplantar injection of 0.1 ml of the encephalitogen into the left hind paw. An equal volume of *Bordetella pertussis* vaccine concentrate (200×10^9 organisms/ml) is injected into the same foot. From days 1–2, the animals receive the test compound or vehicle only or the standard drug by oral administration once a day. Body weights of the animals are recorded every second day. The clinical signs of experimental allergic encephalomyelitis consist of ataxia or paresis, i.e., grossly irregular gait and weakness of one or both hind legs followed by flaccid paralysis of the hindquarters, urinary incontinence, fecal impaction and abdominal wall flaccidity. Animals showing one of these clinical signs are considered positive for the purpose of evaluation.

EVALUATION

Starting from day 7, the severity of clinical signs and mortality are determined daily and scored according to the following scheme:

	score
per 20 g loss of weight	1
paralysis of the tail	1
paralysis of the hind paw	3
complete paralysis	5
death	6

Calculation of the results

The delay of onset of the paralytic symptoms is determined. The total score per day is recorded for treated and control groups. On the day of maximal clinical symptoms occurring among control animals, the total scores of the treated groups is compared to the total score of the control group. The percentage change is evaluated.

Doses of 0.5 mg/kg p.o. methotrexate, 1 mg/kg p.o. hydrocortisone, 2.5 mg/kg p.o. cyclophosphamide were found to be active, whereas non-steroidal anti-inflammatory compounds were inactive.

CHRITICAL ASSESSMENT OF THE METHOD

The model of experimental allergic encephalomyelitis in rats is suitable to distinguish between immunosuppressive and anti-inflammatory drugs.

MODIFICATIONS OF THE METHOD

The phosphodiesterase inhibitor pentoxifylline was found to prevent induction of experimental autoimmune encephalomyelitis in Lewis rats (Rott et al. 1993).

Martin and Near (1995) studied the protective effect of the interleukin-1 antagonist IL-1ra on experimental allergic encephalomyelitis in Lewis rats.

Experimental autoimmune encephalomyelitis in different strains of mice was described by Heremans et al. (1996), Glabinski et al. (1997), Liblau et al. (1997).

Baker et al. (1990, 1991, 2000) induced experimental allergic encephalomyelitis in Biozzi AB/H mice by sensitization with 1 mg of mouse spinal cord homogenate emulsified in Freund's complete adjuvant on days 0 and 7. The disease is characterized by relapsing-remitting episodes similar to multiple sclerosis in human beings. Biozzi AB/H mice also develop spasticity and tremor which can be antagonized by cannabinoids.

A chronic relapsing-remitting form of experimental autoimmune encephalomyelitis was induced in the common marmoset Callithrix jacchus following a single immunization with human white matter by Massacesi et al. (1995), Genain and Hauser (1997) and recommended as a new model for multiple sclerosis.

Experimental allergic neuritis in several animal species has been described by Waksman and Adams 1955, 1956; King et al. 1983; McCombe et al. 1990; Nakayasu et al. 1990). This disorder has been considered to show similarities to the Guillain-Barré syndrome in man. The demyelating process initiated by the injected antigens is a lymphocyte-mediated reaction in which activated macrophages strip myelin off the axons. Hartung et al. (1987) described the adoptive transfer experimental autoimmune neuritis in Lewis rats by injection of P2-reactive T lymphocyte cell lines.

Mix et al. (1992) studied the effect of stilbene-type anion channel blockers on the immune response during experimental allergic neuritis induced by bovine peripheral myelin.

Kojima et al. (1994) investigated the pathogenic potential of autoimmune T cell responses to nonmyelin autoantigens in the Lewis rat using the astrocyte-derived calcium-binding protein S100β, as a model nonmyelin autoantigen. In contrast to the experimental autoimmune encephalomyelitis induced by the adoptive transfer of myelin basic protein-specific T line cells, S100β-specific T cell transfer induced intense inflammation not only in the spinal cord but also throughout the entire CNS and also in the uvea and retina of the eye.

I.2.2.15 Acute graft versus host disease (GVHD) in rats

PURPOSE AND RATIONALE

The intravenous injection of a mixture of parental splenocytes into healthy inbred F_1-rats results in graft-versus-host (GVH) induced immune abnormalities. This is due to T-lymphocytes in the donor inoculum that recognize the major histocompatibility alloantigens expressed by the F_1-animals. The host F_1 T-cells are genetically unable to recognize antigens of the parental donor as foreign, thus the response involves only donor recognition of host and not host recognition of donor. The ensuing immune abnormalities lead to clinical symptoms of an acute, lethal GVH-disease (GVHD), i.e. profound immunodeficiency, anemia, hypogammaglobulinemia and runting.

PROCEDURE

Three to 4 month old, male F_1-hybrid rats of the inbred strains Lewis (Rt-1 l) and Brown Norway (BN, Rt-1n) (Zentralinstitut für Versuchstierkunde Hannover Germany) are used as hosts for cell grafts from the Lewis parental strain. The bone marrow cells are obtained by flushing hind femur bone shafts with culture medium. These cells are then pooled together with spleen cells (ratio 2 bones: 1 spleen). The cell viability, determined by trypan exclusion, has to be more than 90%. Each recipient is injected with about 40×10^7 cells in a 1.5 ml-suspension volume. The route of injection is the penis vein, allowing an optimal control of correct intravenous application.

Prophylactic drug application

For this experiment, 2 groups of 6 F_1-hybrids each are injected with the above mentioned bone marrow/spleen cell suspension. One group receives the test drug orally and daily until the end of the experiment, homogeneously suspended in 1% carboxy-methylcellulose (CMC) solution. The other group receives CMC alone and, thus, serving as the GVHD control group. The experiment is terminated two weeks after disease induction i.e. 1 week after the first appearance of GVHD-symptoms. All animals are sacrificed and clinical aspects documented, spleens weighed, histology of the skin, liver, spleen and lymph-nodes performed and organs photographed.

Therapeutic drug application

In this experiment, rats are separated into four groups treatment begins with the first sign of GVHD-symptoms (beginning of the second week). Because of the expected, greater therapeutic difficulty, the daily dose of the test drug has to be doubled, again for 2 weeks duration.

The experiment is terminated either by sacrificing those rats that are too sick to be able to move around the cage, or at the end of the 4 week observation period, regardless of the clinical condition of the animals. The clinical-chemical parameters are determined by routine procedures conducted with a HITACHI autotechnicon.

EVALUATION

The tested parameters of therapeutic success or disease, respectively, are survival rate (%), spleen weight (g), and body weight (g) as well as clinical-chemical parameters (bilirubin, alkaline phosphatase, creatinine, white cell count) after 2 and 3 weeks.

MODIFICATIONS OF THE METHOD

Gelpi et al. (1994) established a chronic graft vs host disease in (C5BL/10 x DBA/2)F_1 mice with an injection of lymphoid cells from the parent DBA/2 strain. Most of the animals developed antibodies against transfer RNA/protein particles.

Mosier et al. (1988) reported transplantation of human peripheral blood lymphocytes (PBL) into severe combined immunodeficient (scid) mice to construct hu-PBL-scid mice. Kim et al. (1997) suggested these mice for routine immunotoxicity investigations using lymph nodes of intestines as the lymphocyte sources.

Ford et al. (1970), Schorlemmer et al. (1997, 1998) used the popliteal lymph node assay to study the local graft vs. host reaction. The test is based on the enlargement of the draining popliteal lymph nodes as a result of injecting immuno-competent cells (1×10^8 parental Lewis spleen cells) into the hind foot pad of Lewis × Brown-Norway F1 recipients. The reaction is measured at day 6 after challenge as a gain in lymph node weights.

I.2.2.16 Influence on SLE-like disorder in MRL/lpr mice

PURPOSE AND RATIONALE

Systemic lupus erythematosus (SLE) is an autoimmune disease in man that affects multiple body organs and is characterized by the development of certain types of self antigens. Primarily, the antibodies formed against double-stranded DNA (dsDNA), the most prevalent in this ailment, complex together and, with complement, deposit in the small blood vessels, leading to widespread vasculitis. MRL Mpf lpr/lpr (MRL/lpr)-mice spontaneously develop a severe disease with many symptoms very similar to human SLE, i.e. hypergammaglobulinemia, and glomerulonephritis (Theofilopoulos and Dixon 1981).

PROCEDURE

Female MRL/lpr-mice (originally from Jackson Laboratories, USA), displaying distinct symptoms of SLE (between 12 and 13 weeks of age) are randomized and divided into groups of 12 animals each. At this age, the animals have already clinical manifestations of the SLE-like illness, as determined by the disease index, but have not yet developed proteinuria. Animals with

early symptoms of disease are treated with various drugs, e.g., leflunomide, cyclosporin A, azathioprine, cyclophosphamide or prednisolone for 11 weeks and the survival rate and disease index of these animals are followed for 24 weeks. The disease index and urine protein level are determined once weekly.

Disease index

The subsequent clinical parameters are taken into consideration:

1. Ears: reddening of the skin, deterioration of the pinna.
2. Nose: loss of hair, wasting of the skin.
3. Lymph nodes: detection of swollen lymph nodes on any part of the body, especially neck and extremities.
4. Fur: general condition of fur (e.g. shabby, mangy, etc.), loss of hair.
5. Skin: inflammation of the skin, scab and/ or granuloma formation.
6. Eyes: exophthalmos, deterioration due to inflammation, tumor formation around the eye, swelling of the eyelid with eventual closure of the eye.
7. Paws: reddening of the skin, swelling of the paw.

EVALUATION

A score for each of the above described parameters is given according to the severity of the symptoms as follows:

Points for clinical index

Involvement	*detectable*	*moderate*	*severe*
Ears (each)	0.5	1.0	1.5
Nose	1.0	2.0	3.0
Lymph node (each)	1.0	2.0	3.0
Fur	1.0	2.0	3.0
Skin	1.0	2.0	3.0
Eyes (each)	1.0	2.0	3.0
Paws (each)	0.5	1.0	1.5

Body weight (one point for 5 g difference from week to week)

The determination of the disease index is performed, weekly, by the same individual, but without knowledge of the group being evaluated. The points, for each animal, are registered and the total score, of each group, summarized. The average score for the group is calculated, significance between the experimental group and the untreated diseased group is determined using the Student *t*-test.

Proteinuria

Pooled urine is collected from each experimental group and the amount of protein in the urine is calculated.

MODIFICATIONS OF THE METHOD

In addition to a lupus-like syndrome and massive T cell proliferation. MRL-1pr/1pr (MRL/1) mice develop an arthritic process very similar serologically and histologically to human rheumatoid arthritis. Boissier et al. (1989) found that in these animals mouse type II collagen is antigenic, but not arthritogenic.

Holmdahl et al. (1991) studied the involvement of macrophages and dendritic cells in synovial inflammation of collagen induced arthritis in DBA/1 mice and spontaneous arthritis in MRL/Lpr mice.

Rordorf-Adam et al. (1985) used serum amyloid P component and autoimmune parameters in the assessment of arthritis in MRL/lpr/lpr mice.

Furukawa et al. (1996) studied the autoimmune disease-prone genetic background in relation to Fas-defect in MRL/lpr mice.

Kanno et al. (1992) found spontaneous development of pancreatitis in the MRL/Mp strain of mice.

Kusakari et al. (1992) compared hearing acuity and inner ear disorders of MRL/lpr mice with those of BALB/c mice and found a significantly higher auditory brain stem response threshold. They recommended this as a model of sensorineuronal hearing loss.

Bundick and Eady (1992) investigated the effects of an immunosuppressive agent on the development of spontaneous lupus disease in female NZBW F_1 hybrid mice.

Walker et al. (1996) reported a powerful suppressive effect of testosterone on the autoimmune disease analogous to systemic lupus erythematodes spontaneously developed by F1-hybrids of New Zealand Black (NZB) × New Zealand White (NZW) mice. A model was developed in which NZB dams carrying NZB/NZW fetuses were treated with testosterone in a dose adequate to masculinize the external genitalia in female fetuses.

Zoja et al. (1998) investigated bindarit, a compound devoid of immunosuppressive properties, in NZB/W F1 hybrid mice developing an immune complex glomerulonephritis with proteinuria and progression to renal insufficiency.

Kiberd and Stadnyk (1995) studied the role of endogenous interleukin-1 in established lupus nephritis in MRL lpr/lpr mice by administration of the IL-1 receptor antagonist IL-1ra.

Gleichmann et al. (1982), Schorlemmer et al. (1997) induced a systemic lupus erythematodes-like disease in mice by abnormal T- and B-cell cooperation. A chronic graft versus host reaction with the pathologic symptoms of severe glomerulonephritis is induced in B6D2 (C5Bl/6 × DBA/2) F1 hybrid mice receiving four i.v. injections (one per week) of 1×10^8 parental lymphoid spleen cells from DBA/2 donors. The inoculation of splenocytes into the BDF1 hybrid mice results in the

development of a chronic GvH reaction with lymphoid hyperplasia, autoantibody production and immune-complex glomerulonephritis.

Chan et al. (1995) described ocular changes occurring in mice with experimental lupus erythematodes. The ocular disease is characterized by bilateral subacute and chronic inflammation of the eyelids (blepharitis) and hypertrophic Meibomian glands. The severity of the ocular changes is strain dependent. The authors recommend this experimental eye disease as an animal model for chronic blepharitis in humans.

The changes of lacrimal and salivary glands found in MRL/lpr mice and other mouse strains with autoimmune disorders were also regarded as model of Sjögren's syndrome in human (Sullivan and Edwards 1997; Toda et al. 1999).

I.2.2.17 Prevention of experimentally induced myasthenia gravis in rats

PURPOSE AND RATIONALE

Myasthenia gravis is an organ specific autoimmune disease in man that results in skeletal muscles weakness. Typically, the sufferer has drooping eyelids, a blank facial expression, and weak, hesitant speech. This is due to the formation of autoantibodies against the nicotinic acetylcholine receptor (AChR). The formation of autoantibodies to acetylcholine's receptor leads to a gradual destruction of the receptors in skeletal muscles that receive nerve impulses and initiate muscle contractions. As a result, affected muscles fail to respond or react only weakly to nerve signals.

Experimental myasthenia gravis (EMG) can be induced in rats by injecting them with heterologous

AChR, or with recombinant α subunits (two) of the AChR (portion of the AChR to which acetylcholine mainly binds) (Lennon et al. 1991). The animals display symptoms of myasthenia (electrophysiological evidence of altered neuromuscular function) and detectable antireceptor antibodies. The two α-subunits are plausible targets of pathogenic autoantibodies because they would allow mechanisms that depend on cross-linking, complement-mediated lysis, or hindrance of acetylcholine binding to the receptor (Schwartz 1993). The severity of the disease can vary, but most animals display, at the very least, a weakness and fatigability of foot grip. The disease gradually leads to abnormal gait and eventually the inability of the animals to walk or even right themselves.

PROCEDURE

Female rats of AO strain, 6–10 weeks old, are used. Three groups of rats are included in the experiment:

1. immunized with acetylcholine receptor (AChR)-protein and treated with test drug;
2. immunized with AChR-protein without drug, and
3. nonimmunized, nontreated control rats. The test drug is applied per os daily. First dose is administered on the day of immunization and the last on the day of sacrifice.

Immunization with AChR-protein

AChR-protein isolated from Torpedo marmorata is emulsified with complete Freund's adjuvant and 100 µg/rat is injected intradermally in the hind foot pad. As additional adjuvant, 2.6×10^{10} *Bordetella pertussis* microorganisms is administered simultaneously by intramuscular injection in the hind leg.

Antibody determination

Anti-AChR-protein antibodies are measured by enzyme linked immunosorbent assay (ELISA) as described by Norcross et al. (1980). AChR-protein is diluted to a final concentration of 2.5 µg/ml in 0.05 M carbonate buffer, pH 9.6. Two hundred ml of this solution is placed in each well of a microtitration plate (Flow Laboratories Inc.). After an over night incubation at 4 °C, the plates are washed thoroughly with 0.01 M phosphate buffered saline (PBS) solution containing 0.05% Tween-20 (Sigma) subsequently referred to as PBS/T. Sera from all groups of rats are serially diluted in PBS/T and 200 µl is added to each micron well except in the background row (control row) and incubated at 4 °C for 2 h. After washing, 200 µl of 1:1 000 diluted peroxidase conjugated goat antirat immunoglobulin (Sera Lab. Sussex, England) in PBS/T are added to the micron wells and incubated for an additional 60 min at 4 °C. After plates are washed, 200 µl of substrate-citrate buffer and 0.2 µl of 10% H_2O_2 are added and then incubated in the dark at room temperature for 30 min. The reaction is stopped by addition of 50 µl of 2M H_2SO_4 and the OD determined by using Titert Multiscan.

Two-color flow cytometry

Thymic cell suspensions are obtained by mincing tissue and passing it through 80 mm stainless mesh. After being washed three times in PBS, the cells are resuspended in PBS at a cell density of 10^7 viable cells/ml. The cell viability is determined by the trypan blue exclusion test. Erythrocytes are removed by addition of ammonium chloride. Cell staining and flow cytometric analyses are done as described by Itoyama et al. (1989). Thymocyte subsets expressing CD4 and/or CD8 molecules are defined by staining with monoclonal antibodies obtained from Serotec, Oxford, England: phycoerythrin (PE)-conjugated anti-W3/25 (CD4) and fluoresceinisothiocyanate (FITC)-conjugated anti-MRC OX8 (CD8). Two $\times 10^5$ to 1×10^6 cells suspended in 100 ml of PBS are exposed sequentially for 30 min to FITC-conjugated anti-CD8 and PE-conjugated anti-CD4 monoclonal antibodies. Isotype matched control monoclonal antibodies are used to prove the specificity of binding. Cell analysis is performed using FACScan flow cytometer from Becton Dickinson. One $\times 10^4$ events per sample are analyzed by Consort 30 and Lysis software. All data are collected and displayed on a log scale of increasing green and orange fluorescence intensity. This is presented as two-dimensional contour maps and as percentage of thymocytes by integrating counts in selected areas of the contour plots.

Stereologic analysis of thymuses

Thymuses of animals of all groups are prepared for light microscopic analysis. For this purpose thymus tissue is fixed in Carnoy's solution, embedded in paraffin and 3–5 µm thin sections are stained with hematoxylin and eosin. Cortex and medulla are analyzed stereologically using the point counting method described by Weible (1963). Volume density (*Vv*) of the examined structures is determined by the following equation: $Vv=Pi/Pt$, where *Pi* represents the number of points of the examined structure, and *Pt* the total number of points. *Vv* refers to the volume fraction i.e. volume of a feature per unit test volume (Williams 1981).

EVALUATION

EMG is evaluated clinically by daily examination of muscle weakness and scored as follows:

\+ = weakness of grip with fatigability;
++ = abnormality of gait;
+++ = inability to walking and righting.

Immediately after appearance of clinical signs of EMG, rats are sacrificed, blood and thymuses are taken for determination of anti-AChR-protein antibodies, and histological analysis of thymuses and thymocyte subsets, respectively.

Statistical analysis of data is performed by Student's *t*-test (data of stereological analysis) and Mann-Whitney *U*-test (Results of flow cytometric analysis of thymocyte subsets).

MODIFICATIONS OF THE METHOD

McIntosh and Drachman (1987) described an *in vitro* suppressor assay using responder cells from the lymph nodes of Lewis rats immunized sc. with acetylcholine receptors emulsified in complete Freund's adjuvant and suppressor cells from spleens of rats immunized i.p. with acetylcholine receptors absorbed on bentonite. Antibodies were determined after stimulation with acetylcholine receptors from co-cultures of responder cells and putative suppressor cells treated previously with an immunosuppressant.

Araga and Blalock (1994) developed a method of altering B-cell-mediated autoimmune diseases by induction of anti-idiotypic antibodies by immunization with complementary peptides. A peptide encoded by RNA complementary to RNA for the Torpedo acetylcholine receptor main immunogenic region, AChR 67-16, was tested in the Lewis rat model of experimental auto-immune myasthenia gravis.

I.2.2.18 Glomerulonephritis induced by antibasement membrane antibody in rats

PURPOSE AND RATIONALE

Masugi nephritis and other nephritis models of immunological origin in rats have been used for evaluation of immunosuppressive activity (Heymann et al. 1959; Shibata et al. 1966; Ito et al. 1983; Thoenes et al. 1989; Ogawa et al. 1990, 1991).

PROCEDURE

Preparation of rabbit antiserum against rat glomerular basement membrane

Glomeruli are separated from the homogenate of rat renal cortex by successive use of 3 metal sieves (150-, 180-, and 200-mesh). The basement membrane fraction is obtained by centrifugation and ultrasonic disruption. It is then digested with trypsin, dialyzed, and lyophilized. The resultant substance is employed as antigen. An emulsion of 1 mg of the antigen in 0.2 ml saline with 0.2 ml of complete Freund's adjuvant is injected intracutaneously into white rabbits once a week for 6 weeks. One week later, production of the antibasement membrane antibody is confirmed in guinea pigs by the passive cutaneous anaphylaxis test. Blood is collected from the carotid artery, incubated at 56 °C for 30 min to inactivate components of the complement, and stored at –20 °C until use.

Induction of glomerulonephritis in rats

Male Sprague-Dawley rats weighing about 300 g are injected with 0.5 ml of the rabbit antiserum via the tail vein. On the following day, they are further injected subcutaneously with an emulsion (0.25 ml) of physiological saline solution containing 5 mg of rabbit gamma-globulin in an identical volume of complete Freund's adjuvant.

Treatment

The rat antibasement antibody is injected 5 days before the start of administration of the test compound. Before the first dose, urinary total protein is determined and rats with nephritis are so assigned as to provide almost equal distribution of severity of the disease per group. The test compounds are administered orally for 14 days. The urine is collected at 7 and 14 days of treatment. After 14 days, the animals are sacrificed, blood is collected and thymus and kidneys are removed. Histopathological and immunohistochemical studies are performed in kidney tissue.

EVALUATION

Scores are given for **microscopic findings in the glomeruli:**

- cell proliferation in glomeruli
- PAS-positive granules in the epithelium of glomeruli
- fibrin deposits in Bowman's space
- adhesion to Bowman's capsule

and in **the tubuli:**

- hyaline cast
- dilation of tubuli

as well as for **immunofluorescence findings** for rat IgG, rat C3, and rabbit IgG.

Furthermore, total urinary protein, plasma total cholesterol, plasma fibrinogen, thymus/body weight ratio are compared between drug treated animals and controls by statistical means.

MODIFICATIONS OF THE METHOD

Lan et al. (1995) investigated the pathogenic role of interleukin-1 in the progression of established rat crescentic glomerulonephritis by administration of the interleukin-1 receptor antagonist IL-1ra.

Giménez et al. (1987), Thoenes et al. (1987) induced autoimmune tubulointerstitial nephritis in the brown Norway rat by injection of bovine tubular basement membrane.

Development of a systemic T-lymphocyte dependent autoimmune syndrome in brown Norway rats including glomerulonephritis with high proteinuria was induced with mercuric chloride by Baran et al. (1986), Aten et al. (1988), Lillevang et al. (1992).

Kokui et al. (1992) induced nephrosis with proteinuria in rats by intraperitoneal injection of puromycin aminonucleoside.

Lundstrom et al. (1993) studied the Heymann nephritis antigenic complex using a rat yolk sac carcinoma cell line that expresses glycoprotein 330, the main antigen in this autoimmune disease.

I.2.2.19 Auto-immune uveitis in rats

PURPOSE AND RATIONALE

The mechanisms of certain types of uveitis have been studied in animals implicating autoimmunity. Uveitis has been produced in guinea pigs following injections with homologous uveal tissue.

The method is described in detail in the Sect. O.7.3.

I.2.2.20 Inhibition of allogenic transplant rejection

PURPOSE AND RATIONALE

Transplantation of allogenic organs to recipients results in rejection of the transplants. This effect can be suppressed or delayed by immunosuppressive agents. Various organs are used for allogenic transplantation in animal experiments, such as skin pieces (Schorlemmer et al. 1993), kidney (Lee 1967; Küchle et al. 1991), rat heart, rat small intestine (Xiao et al. 1944) and corneal buttons (Coupland et al. 1994). The immunosuppressive activity can be evaluated either by using a major histocompatibility complex variant strain combination or a strong allogenic system.

PROCEDURE

For **skin transplantation** male animals of inbred strains of Fischer (F334), Lewis (LEW), Brown Norway (BN), Dark Agouti (DA) rats are used. Rat tail skin (donor) is cut into square pieces of 0.5 to 1.0 cm and transplanted to the tails of recipient rats. Rejection is defined as the day when the skin graft is of red-brown color and hard consistency. As strain combination with a major histocompatibility variant, transplantation from LEW to F334 is performed. Using a strong allogenic system, the high responder DA to LEW donor recipient combination is used. The immunosuppressive agents, e.g., cyclosporine or leflunomide are given orally up to 20 days. Ten animals are used for each group.

EVALUATION

The mean values of rejection time of treated groups are compared statistically with vehicle treated controls using Student's *t*-test or the Mann Whitney U-test.

MODIFICATIONS OF THE METHOD

Schorlemmer and Kurrle (1997) used Lewis (LEW, Rtl*l) rats as receivers and Balb/c mice as donors in a xenotransplantation model of mouse-to-rat skin grafts. Rejection was defined as the day when the skin graft turned red-brown and became hard. For quantification of xeno-specific IgM and IgG antibody titers, the test sera (dilution 1 : 10) were incubated with 1×10^6 purified T-cells (by sheep anti-mouse dynabeads, Deutsche Dynal GmbH, Hamburg, Germany) from Balb/c donor spleens for 30 min at 4 °C. The cells were washed 3 times with phosphate buffered saline (pH 7.2) and then stained for IgG or IgM xenoantibodies; 50 µl of either FITC-conjugated goat antibodies, specific for the Fc-portion of rat IgG or specific for the µ-chain of rat IgM were added. After 30 min at 4 °C the cells were washed twice and analyzed by flow cytometry.

Techniques for transplantation of several organs have been elaborated.

For **kidney transplantation** male rats, 5–7 months of age, are used as donors and recipients for the orthotopic right kidney transplantation as described by Lee (1967) with a modification of ureter-ureter anastomosis (Thoenes et al. 1974). Because bilateral nephrectomy is performed at transplantation, animal survival is dependent upon the allograft's function. All rats that do not excrete urine on the first postoperative day are excluded from further studies. As a control concerning long survival, syngeneically transplanted rats are maintained up to 300 days.

Engelbrecht et al. (1992) described a new rapid technique for renal transplantation in the rat. The method

combines a special sleeve anastomotic technique for the renal artery, convential end-to end anastomosis of the renal vein, and implantation of the ureter into the bladder.

A porcine renal transplant model has been used by Almond et al. (1992).

Peters et al. (1993) reviewed the therapeutic potential of tacrolimus in renal and hepatic transplantation.

For studying **heart transplantation**, heterotopic implantation of hearts from BN to LEW rats is performed (Williams et al. 1993). The diagnosis of rejection is established once the palpable cardiac allograft impulse ceases. Further studies with rat cardiac allografts have been performed by Hancock et al. (1990). The Fischer 344 rat (donor)/Long Evans rat (recipient) combination was used by Kahn et al. (1991). Walpoth et al. (1993) used magnetic resonance spectroscopy for assessing myocardial rejection in the transplanted rat heart.

Shiraishi et al. (1995) evaluated the effectiveness of the interleukin-1 receptor antagonist IL-1ra in the immune and inflammatory responses to rat heart allografts.

Cardiac transplantation between inbred rat strains that differ for weak histocompatibility antigens is associated with the development of arteriosclerosis in arteries of the donor graft myocardium (Carmer et al. 1990; Adams et al. 1992).

A heterotopic rat **infection heart-transplant model** was described by Kobayashi et al. (1993).

The **hamster to rat cardiac xenograft** model has been used by several authors (de Masi et al. 1990; Steinbrüchel et al. 1991; van den Bogaerde et al. 1991; Woo et al. 1993; Fujino et al. 1994; Schuurman et al. 1994). The hearts from Syrian hamsters were implanted heterotopically in male Lewis rats, with anastomoses between the infrarenal abdominal aorta and inferior vena cava of the recipient and the donor aorta and right pulmonary artery, respectively.

Primate cardiac xenografts were performed by McManus et al. (1993) using cynomolgus monkeys (*Macaca fascicularis*) as donors and baboons (*Papio anubis*) as recipients.

Chronic rejection of rat **aortic allograft** was studied by Mennander et al. (1991). Administration of cyclosporin induced accelerated allograft arteriosclerosis.

Heterotopic transplantation of small intestine has been performed from BN to LEW rats. The mesenteric venous drainage is reconstructed either via the vena cava or the portal vein (Xiao et al. 1994). An isolated Thiry-Vella-loop was prepared by Xia and Kirkman (1990). Kellnar et al. (1990) described allogenic transplantation of fetal rat intestine with anastomosis to the normal bowel of the host. Langrehr et al. (1991) investigated under which circumstances graft versus host disease occurs following fully allogenic small bowel transplantation in the rat. Kirsch et al. (1991) studied the extent to which intestinal transplants in rats undergo functional and morphologic compensation.

Liver transplantation procedure has been described by Svensson et al. (1995) allowing measurement of bile secretion.

Orthotopic left **lung transplantation** was performed in inbred rats by Katayama et al. (1991).

Tracheal allografts were implanted into the abdomen of recipient rats (Davreux et al. 1993).

In vivo electrophysiology of rat **peripheral nerve transplants** was studied by Yu et al. (1990). A sciatic-tibial nerve graft was harvested from the donor rat between the sciatic notch and the ankle. In the recipient, the tibial nerve and the sural nerve were resected. The nerve graft was placed along the natural course of the native tibial nerve. Nerve repair was performed using standard end-to-end epineural microsuture technique.

A model of neurovascularized rectus femoris **muscle transplantation** in rats was established by Muramatsu et al. (1994).

The orthotopic **transplantation of vascularized skeletal allografts** (rat distal femur and surrounding muscular cuff) has been described by Lee et al. (1995).

Long-term surviving of **limb allografts** in rats was studied by Kuroki et al. (1991). The donor and recipient limbs were prepared simultaneously by amputation at midfemur. The donor limb was fixed orthotopically by Kirschner wire. The donor and recipient femoral arteries, veins and sciatic nerves were anastomosed using a microsurgical technique.

For **cornea transplantation** Brown Norway rats ($RT1^{1xn}$) serve as donors and Lewis rats ($RT1^{1}$) as recipients (Coupland et al. 1994). Both the donor and recipient rats are anesthetized with xylazine hydrochloride and ketamine hydrochloride. Twenty min prior to surgery the recipient rats also receive 0.5 mg/kg atropine sc. and phenylephrine hydrochloride 5% eyedrops. Under sterile conditions and using an operation microscope, two donor corneal buttons (3.5 mm) are harvested from the donor rat using a trephine and curved Castroviejo scissors. The donor animals are then sac-

rificed by ether inhalation. The left eyes of the recipient rats are prepared by removing a central 3.0-mm button using a trephine and curved Castroviejo scissors. A drop of sterile methylcellulose (1%) is placed over the 3.0-mm corneal opening before the donor cornea is fixed with 10 interrupted sutures. The anterior chamber is not re-established following surgery. Prior to closure of the eyelids with 3 or 4 interrupted sutures, Polyspectran® eyelid gel is placed over the operated eye. Forty-eight hours following surgery, the eyelid sutures are removed, allowing for the first time assessment of the cornea on the slit-lamp microscope. Slit-lamp evaluations are performed every 2–3 days under i.m. anesthesia with keta-mine, with assessment of the cornea by scoring graft opacity, edema and vascularization.

J.1
Salivary glands

J.1.0.1
Measurement of salivation

PURPOSE AND RATIONALE

Symptoms of several human diseases are manifested as increased salivation (e.g., Parkinson's disease) or decreased salivation (e.g., xerosis). Studies to find and to evaluate sialagogues, such as substance P and its synthetic derivatives, as well as to search for salivation inhibitors are necessary. Saliva excretion is greatly influenced by anesthetics. Wagner et al. (1991) proposed a simple method to study saliva secretion in conscious rats and to evaluate sialagogues and sialagogue antagonists.

PROCEDURE

Fed, male Sprague-Dawley rats (200–300 g) are weighed and distributed randomly into groups of 6 animals. Conscious rats are injected i.v., via the lateral tail vein, with either the vehicle or the sialagogue, e.g., sub-stance P (0.3–3 µg/kg in 1 ml saline/kg). The rat's oral cavity is swabbed immediately after i.v. injection by placing and holding a pre-weighed, absorbent foam cube (e.g., 5/16", Texwipe Company, Upper Saddle River, NJ) sublingually for 10 s using a Triceps foam pencil (Texwipe Company, Upper Saddle River, NJ). Conscious rats are restrained during the 10 s collection period by gently holding the animal and opening the mouth using a plastic coated snare, which is looped around the maxillary incisors and drawn back over the animal's head and the hand holding the rat, drawn around in front of the rat and looped around the mandibular incisors. Gentle pressure on the snare opens the rat's mouth allowing the placement of the absorbent cube. Foam cubes are re-weighed immediately after use. The difference between the initial weight of the cube and the weight of the cube after use represents saliva secreted.

EVALUATION

Data are analyzed with Dunnett's *t*-test that compares several treated groups with a control group. Regression analysis is used to determine dose response and relative potency.

MODIFICATIONS OF THE METHOD

Martinez et al. (1978, 1981) inserted appropriate plastic cannulae into the main excretory ducts of the two submandibular glands in **rats**.

Giuliani et al. (1988) studied the relative contributions of various neurokinin receptors (NK-1, NK-2, NK-3) to the sialogogic response after i.v. application in urethane-anesthetized rats.

Direct cannulation of the glandular duct with polyethylene tubing was performed by Bodner et al. (1983) and Kohn et al. (1992).

Bianciotti et al. (1994, 1996) cannulated the ducts of both the submaxillary and parotid glands in male Wistar rats anesthetized with 10% ethyl urethane. No basal flow of saliva was observed from either gland, however dose-response curves could be established after intravenous injection of sialogogic agents, such as methacholine (0.3 to 10.0 µg/kg), norepinephrine (3 to 60 µg/kg), isoproterenol (1 to 30 µg/kg), methoxamine (30 to 300 µg/kg), substance P (0.3 to 10.0 µg/kg). Atrial natriuretic factor enhanced the salivary response to methacholine, methoxamine and substance P.

Lohinai et al. (1997) determined salivary amylase secretion in conscious rats. Under ether anesthesia a catheter was introduced into the esophagus for salivary juice collection and a cannula was inserted into the jugular vein for infusions. After post-anesthesia recovery, submaximal carbachol infusion was given as a background to obtain steady secretion because of the low basal secretory rate. After application of drugs, volume and amylase were determined in saliva samples collected for 30 min.

Iwabuchi et al. (1994) studied salivary secretion after administration of a muscarinic agonist in MRL/lpr **mice**. Saliva were collected from the floor of the mouth of anesthetized rats with a capillary micropipette every 5 min for 60 min.

A method for the quantitative comparison of atropine substitutes on the salivary secretion of the **cat** has been published by Bülbring and Dawes (1945). Cats anesthetized with pentobarbitone were used. A cannula is tied into Wharton's duct and attached to a bottle containing tap-water. The tap-water, displaced by the saliva, passes out of the bottle through a tube which actuates a drop timer.

Ekström et al. (1994) used morphometric analyses to study the parotid acinar degranulation in cats after stimulation of the parasympathetic auriculo-temporal nerve.

Izumi and Karita (1994, 1995a,b) investigated the secretory and vasodilator effects of nerve stimulation in the submandibular gland of cats. Cats of either sex were anesthetized with ketamine and a mixture of chloralose and urethane, paralyzed by intravenous injection of pancuronium bromide and artificially ventilated. Blood flow changes in the submaxillary glands and lips of the cats were measured using a laser-Doppler flowmeter. The duct of the submandibular gland was cannulated with a polyethylene cannula inserted distal to the intersection between the chorda lingual nerve and the duct. The amount of saliva secreted in response

to nerve stimulation was determined gravimetrically by collecting the saliva in pre-weighed tubes.

Boldyreff (1925) described the preparation of salivary fistulae in the **dog**.

For preparing a **parotid fistula**, a fine sound is introduced through the orifice of the parotid duct, which is found opposite to the largest upper molar tooth, to the depth of 6–8 cm. Around the orifice and at a distance of about 0.5 cm from it, four sutures are laid on the mucosa at equal distances one from the other. After this, a round piece of mucosae, about 1 cm in diameter around the orifice, with the sutures at the edge of this piece, is cut out with small sharp scissors. The duct is then separated from surrounding tissues about 2 cm from the orifice in the direction of its length. Then an opening is made through the cheek into the mouth (from the point half way on the vertical line from the front or the back corner of the eye to the mouth) to the base of the prepared duct. The orifice of the duct is now led outside by pulling out with the forceps. Four sutures on the piece of mucosa are made around it. The piece of mucosa is sutured carefully to the skin with knot sutures. The wound inside the mouth is closed with a continuous suture. The piece of mucosa must be covered daily with vaseline to prevent drying. Sutures must be taken out slowly, beginning 3 days after operation. For the first 10 days after operation it is necessary to produce on the dog an intensive salivary secretion, twice a day, by introducing into the mouth of the animal, dry bread or meat powder or 0.5% solution of hydrochloric acid. Saliva is collected into graduated test tubes.

In a similar way, one can produce a **fistula of the submaxillary or sublingual glands**, usually a common fistula for both glands, because their ducts have a common orifice.

Lambert et al. (1994) **cultured acinar cells** from lacrimal and submandibular glands as well as epithelial cells from rat small intestine in supplemented, serum-free media and measured the secretory components after treatment with various agents by radioimmunoassay.

J.2 Esophagus

J.2.0.1 Tunica muscularis mucosae of esophagus *in vitro*

PURPOSE AND RATIONALE

The tunica muscularis mucosae preparation of the rat esophagus (Bieger and Triggle 1985; Ohia et al. 1992) has been recommended for evaluation of 5-HT_4 recep-

tor ligands since it possesses a homogeneous population of 5-HT_4 receptors which mediates a well defined relaxant response to 5-HT (Baxter et al. 1991, 1992; Reeves et al. 1991; Waikar et al. 1992; Eglen et al. 1993, 1995; Yang et al. 1993; Gale et al. 1994; Monge et al. 1994; Sagrada et al. 1994; Elz and Keller 1995; Hegde et al. 1995; Cohen et al. 1996, 1998; Wong and Eglen 1996; Nagakura et al. 1999; Takeda et al. 1999).

PROCEDURE

Male Sprague Dawley rats (200–300 g) are sacrificed by asphyxiation with CO_2, and 2 cm segments of intrathoracic esophagus, proximal to the diaphragm, are excised and placed in Tyrode solution of the following composition (mM): NaCl 136, KCl 2.7, $MgCl_2 \cdot 6\,H_2O$ 1.0, NaH_2PO_4 0.4, glucose 5.6, $NaHCO_3$ 11.9, $CaCl_2$ 1.8, pH 7.4. The external muscularis propria, containing the outer longitudinal and circular muscle layers of the esophagus, is carefully removed in order to isolate the inner smooth muscle tube of the tunica muscularis mucosae. The tunica muscularis mucosae is suspended in a 10 ml tissue bath containing Tyrode solution at 37 °C and aerated continuously with 95% O_2/5% CO_2. Tissues are placed under 2.5 mN tension and are left to equilibrate with Tyrode solution for 60 min (washing every 15 min) prior to starting the experiment. Responses are recorded isometrically using a Hugo Sachs Electronic (Biegestab K30) transducer coupled to a Graphtec (Linearcorder WR3 310) 4-channel chart recorder.

Preparation of tunica muscularis mucosae are contracted with carbachol (3 μM, approximate EC_{50}). Concentration-effect curves (relaxation) to 5-HT (or other agonists) are constructed in a cumulative fashion, followed by washout, with a 60-min interval between the first and second curve.

In antagonist studies, the antagonist is incubated with the tissue for 60 min following washout and the second concentration-effect curve is constructed in the presence of the antagonist. Responses are measured as decreases in isometric tension and are expressed as percentage relaxation of the carbachol-induced tone.

EVALUATION

Concentration-effect curves and agonist potencies

All agonist concentration-effect curves are fitted using an nonlinear, iterative curve fitting program according to the following relationship (Parker and Waud 1971):

$$E = E_{max}[A]^n/([A]^n + EC_{50}{}^n)$$

This relationship describes curves with a maximal response E_{max}, half-maximal response EC_{50} (both in terms of molar concentration), and a slope factor determined by the power n. [A] represents agonist concentration and E is response.

Antagonist potencies

pA_2 estimates of test compounds vs. 5-HT in the rat tunica muscularis mucosae are determined by the method of Arunlakshana and Schild (1959) and computed using Statview II (Brain Power Inc., Calabassas, CA). Concentration ratios are determined using the iterated EC_{50} values in the absence and the presence of the test compounds.

All remaining pA_2 estimates are determined by the method of Furchgott (1972) using a single concentration of agonist. The method assumes a competitive interaction and is calculated as follows:

$$pA_2 = -\log([\text{antagonist}] / [\text{concentration ratio} - 1])$$

Statistics

CL (95%) and statistical significance of the difference between samples (single comparisons; unpaired Student's t-test) are determined using Statview II.

MODIFICATIONS OF THE METHOD

De Boer et al. (1993) divided the **rat** esophagus into two parts, cervical and thoracic, each of a length of 10–15 mm. Both parts were cut longitudinally and pinned on a silicon mat with the outer, striated muscle coat up. After dissection of the striated muscle, the remaining muscularis mucosae was divided into 4 (5×2 mm, thoracic part) and 6 (5×1.5 mm, cervical part) strips. Strips from different parts showed no differences in pharmacological behavior.

Cohen et al. (1994) found 5-HT_4 receptors in rat but not guinea pig, rabbit or dog esophageal smooth muscle.

Several authors (de Boer et al. 1993, 1995; Kelly and Houston 1996; Lezama et al. 1996; Oriowo 1997, 1998) showed that β_3-adrenoceptors mediate the relaxation of the rat esophageal muscularis mucosae.

Eglen et al. (1996) studied the functional interactions between muscarinic M_2 receptors and 5-hydroxytryptamine 5-HT_4 receptors and β_3-adrenoceptors in the isolated esophageal muscularis mucosae of the rat.

Goldhill et al. (1997) investigated the 5-HT_4 receptor modulation of tachykinergic excitation of rat esophageal tunica muscularis mucosae.

The tunica muscularis mucosae of **guinea pigs** was used by various authors:

Yoshida et al. (1993) studied the effect of a gastroprokinetic agent on electrically-evoked contractions in tunica muscularis from isolated guinea pig esophagus.

Watson et al. (1995) investigated the interactions between muscarinic M_2-receptors and β-adrenoceptors in guinea-pig esophageal muscularis mucosae.

Uchida et al. (1998a,b) examined the effect of Ba^{2+} on acetylcholine- and KCl-induced contractions and characterized the endothelin-induced contraction of the guinea-pig esophageal muscularis mucosae.

Malmberg et al. (1991) studied muscle activity of isolated muscle strips from the middle pharyngeal constrictor, the inferior pharyngeal constrictor, the cricopharyngeal muscle, and the cervical esophagus from **rabbits** in organ baths in response to drugs and electrical field stimulation.

Kohjitani et al. (1993, 1996) divided the lower esophagus of rabbits into 3 regions (lower esophagus, transitional zone, lower esophageal sphincter) and studied the influence of anesthetics and peptides on contractions induced by acetylcholine or electrical field stimulation.

Percy et al. (1997) studied the pharmacological characteristics of rabbit esophageal muscularis mucosae *in vitro*.

Based on studies by Bitar and Mahklouf (1982), Biancani et al. (1987), isolated smooth muscle cells of the lower esophageal sphincter from **cats** were used by Hillemeier et al. (1996) to investigate the influence of protein kinase C on spontaneous muscle tone. Esophagus and stomach from sacrificed cats were removed and opened along the lesser curvature. The location of the squamocolumnar junction was identified, the mucosa was peeled and removed by sharp dissection under a microscope. The underlying circular muscle layer was cut into slices 0.5 mm thick with a tissue slicer. The last slices containing the myenteric plexus, longitudinal muscle and serosa were discarded. The slices of circular muscle were placed flat on a wax surface, and tissue squares were made by cutting twice with a 2-mm blade block, the second cut at right angle of the first. Isolated smooth muscle cells were obtained by enzymatic digestion with collagenase. Agonist-induced contraction of isolated muscle cells was achieved by exposing them to IP_3 and a protein kinase C agonist. The cells were fixed in acrolein at a final concentration of 1%. The length of 30 consecutive intact cells encountered at random was measured with a phase-contrast microscope and a closed-circuit video camera.

Muscle strips from *cat* lower esophageal sphincter were used by Dobreva et al. (1994), Kortezova et al. (1994), Preiksaitis and Laurier (1998).

Uy Dong Sohn et al. (1995) investigated muscle-type-specific signal transduction pathways in esophageal and lower esophageal sphincter circular smooth muscle of cats.

Tokuhara et al. (1993) studied the influence of adrenoceptor agonists on the striated muscle portion of the esophagus by use of isolated strips from **dogs**.

Saha et al. (1993) examined the effects of nitric oxide-containing compounds on **opossum** esophageal longitudinal smooth muscle *in vitro*.

La Rocca et al. (1992) examined the effects of metoclopramide in transverse muscular strips from **pigeon** esophagus.

J.2.0.2 Esophageal sphincter *in vivo*

PURPOSE AND RATIONALE

Salapatek et al. (1992), Xue et al. (1996) studied the control of esophageal peristalsis and function of the lower esophageal sphincter in anesthetized cats.

PROCEDURE

Adult cats of either sex are fasted overnight. Anesthesia is induced with 15 mg/kg ketamine i.m. and maintained with i.v. infusion of 15 mg/kg/h. The cats can tolerate intubation while continuing to swallow spontaneously or with pharyngeal stimulation. Esophageal motility is continuously monitored by a multi-lumen catheter passed orally. The catheter has a sleeve (Dent 1976) which is positioned within the lower esophageal sphincter, with recording ports 2, 4, 6, and 8 cm above the lower esophageal sphincter and one port just below the sleeve. The recording catheter channels are continuously perfused with distilled water at 0.3 ml/min by means of a pressurized infusion pump. At the recording ports within the esophageal body, the system is able to record a pressure rise of 300 mm Hg/s. Pressures are recorded using transducers. Respiration is continuously monitored with a belt pneumograph placed around the animal's chest. All pressures are recorded on a Beckman eight-channel direct writing chart recorder with input couplers, preamplifiers and amplifiers while simultaneously taped on an eight channel FM tape recorder. Drugs are administered intravenously.

For each esophageal contraction, amplitude is measured at each esophageal level, using mean intra-esophageal pressure as baseline. Onset of contraction is determined as the point of rapid upstroke at each level, and progression of the wave along the esophagus is expressed as the lag of time or delay (in seconds) between two adjacent recording sites. Basal lower esophageal sphincter pressure is measured using intragastric pressure as reference. Maximum lower esophageal sphincter relaxation and lower esophageal sphincter after-contraction are also assessed.

EVALUATION

Statistical analysis is performed by using one-way analysis of variance and a Student's *t*-test where appropriate.

MODIFICATIONS OF THE METHOD

Greenwood et al. (1992) used a similar multi-lumen catheter assembly system in **cats** and registered additionally the electromyogram of the mylohyoid muscle.

Further studies in cats were performed by Preiksaitis et al. (1994) and Lichtenstein et al. (1994).

Using a miniature perfused sleeve/sidehole catheter, Kawahara et al. (1994) measured gastric, lower esophageal sphincter and esophageal pressure in urethane anesthetized **rats**.

Rouzade et al. (1996) monitored manometrically esophageal, lower esophageal sphincter and fundus pressure in conscious **dogs**.

Blackshaw et al. (1995), Blackshaw and Dent (1997) measured responses of the lower esophageal sphincter in urethane-anesthetized **ferrets**.

Smid et al. (1998) studied lower esophageal sphincter function in a model of oesophagitis in ferrets. Oesophagitis was induced by acid (0.15 M HCl) and 1% pepsin infusions in anesthetized ferrets. Lower esophageal sphincter strip responses were measured *in vitro* after various agents and after electrical field stimulation.

Knudsen et al. (1994) measured esophageal pressured with a four-channel, perfused catheter assembly in lightly anesthetized **opossums**.

Further studies in opossums were performed by Harrington et al. (1991), de Arruda-Henry and Uchida-Athanasio (1994).

J.2.0.3
Permanent fistula of the esophagus in the dog

PURPOSE AND RATIONALE

Esophagostomy was made for the first time by Pavlov (1902) for the purpose of obtaining pure gastric juice from a dog. Pure gastric juice can obtained in great quantities only after shame feeding from a gastric fistula, so it is necessary that the dog shall have two fistulae: esophageal and gastric fistula. The technique to prepare a permanent gastric fistula in the dog was described by Boldyreff (1925).

PROCEDURE

It is necessary to obtain beforehand a well nourished dog with a gastric fistula. The operation must be done aseptically with the usual anesthesia. The incision on the neck is made on a median line 2–3 cm below the larynx and is 12–15 cm long. Th esophagus is found under the trachea and a little to the left. It is separated as little as possible from the surrounding tissue with a knife handle and pulled outside. The esophagus is now divided, cross-section, and the ends of the dissected esophagus are carefully sutured into the respective corners of the wound. In suturing the mucosa of the esophagus with the skin of the wound it is necessary to take into the suture the muscle layer of the esophagus also. After the ends of the esophagus are sutured into the corners of the wound, the part of the wound between them is closed. The wound should be covered with thick antiseptic ointment. After the operation it is necessary to examine the wound daily. The sutures must be taken out gradually beginning five or six days after the operation.

Oesophagotomy can be performed more simply, if the esophagus is not divided but a longitudinal incision, 12–15 cm long is made through its wall. The edges of this incision are sutured together with the edges of the wound in the neck. When the wound is healed this fistula can be temporarily closed during feeding by means of a bandage or with a special device. The dog can then eat and drink normally and the saliva is not lost through the fistula.

MODIFICATIONS OF THE METHODS

Boldyreff (1925) described also the preparation of crop fistulas in the **rooster**. A longitudinal incision 2–3 cm long is made through the skin in the middle part of the crop. Then, with the aid of a pair of surgical forceps the front wall of the crop is lifted up and an opening about 2 cm long is made in it with scissors. After this a fistular tube is introduced into the crop with the aid of a large hook and, if necessary, the opening of the crop is sutured with one suture tightly around the tube.

Acid secretion

J.3.1.1
Acid secretion in perfused rat stomach (Gosh and Schild rat)

PURPOSE AND RATIONALE

Gosh and Schild (1958) introduced a method for the continuous recording of acid gastric secretion in the rat. The acid secretion can be stimulated by histamine, acetylcholine and gastrin. Moreover, the stimulated secretion can be inhibited by anti-ulcer drugs.

PROCEDURE
(MODIFIED AFTER GOSH AND SCHILD 1958)

Male Sprague-Dawley or Wistar rats weighing about 250 g are used. They are withheld from food, but not from water 18 h prior to the experiment. Four animals are used per dose of test drug or standard. Anesthesia is induced by i.p. injection of 5 ml/kg of 25% urethane solution. Body temperature is artificially stabilized by means of a rectal thermometer and a heating pad. The trachea is exposed and cannulated for artificial respiration. The jugular veins are then exposed and cannulated with polyethylene tubes bevelled at the tip. The abdomen is opened through a midline incision, the

pyloro-duodenal junction exposed and a double perfusion cannula (with two lumina) is introduced through a cut in the duodenum up to the cardiac part of the stomach and secured firmly by placing a ligature around the pylorus, care being taken not to include blood vessels within the ligature. Using a peristaltic pump, the stomach is perfused continuously with 0.9% NaCl solution at 37 °C. In the effluent, pH is measured with a pH-meter and continuously recorded. Gastric secretion is stimulated by continuous intravenous infusion of 100 µg/kg/h of pentagastrin or 3 mg/kg/h histamine hydrochloride or 30 µg/kg/h carbachol. As soon as acid secretion has reached a plateau, test substances or standard are injected intravenously.

EVALUATION

The maximal inhibition of acid secretion (AI_{max}) and the inhibition of acid secretion during 1 h (AI_t) are calculated.

$AI_{max} = (pH_i - pH_s) \times (pH_b - pH_s)^{-1} \times 100$

$AI_t = 100 - F_i \times F_s^{-1} \times 100$

whereby,

pH_b = pH value at basal H^+ secretion

pH_s = pH value at stimulated H^+ secretion

pH_i = highest pH value after administration of test compound

F_s = integral of pH curve over 60 min before administration of test compound

F_i = integral of pH curve over 60 min after administration of test compound.

Moreover, using various doses of the test compound and of a standard, dose-response curves can be established and activity ratios with confidence limits can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method of Gosh and Schild being modified by several authors can be used for standardization of secretagogues, like gastrin, and for evaluation of acid secretion inhibiting anti-ulcer drugs.

MODIFICATIONS OF THE METHOD

Burn et al. (1952) described the evaluation of substances which affect gastric secretion using perfusion of the stomach in anesthetized **cats**.

Lawrence and Smith (1974) described the measurement of gastric acid secretion in the **rat** by conductivity. The stomach of an anesthetized rat is continuously perfused with 2 ml/min of an isotonic (0.308 molar) glucose solution at 37 °C. The conductance of a solution depends on the total ion concentration and is therefore not specific for hydrogen ions. Since hydrogen ions have an equivalent conductance nearly 5 times greater than any other ion found in gastric juice and since they are secreted in a far greater concentration than other ions, conductivity measurements can be regarded as a relatively specific measure of hydrogen ions. Using Mullard conductivity cells (type E 791/B) and a commercially available meter (Phillips PW 9 501) simultaneous measurements in 6 rats were performed.

Gallo-Torres et al. (1979) described in detail a method for the bioassay of antisecretory activity in the conscious rat with acute gastric fistula with additional collection of the biliary and pancreatic secretion by means of a catheter in the common bile duct. The gastric secretions are collected by gravity via a cannula in the most gravity dependent site of the glandular stomach.

Larsson et al. (1983) described studies in the acutely vagotomized rat. Truncal vagotomy is performed under ether anesthesia by cutting the dorsal and ventral branches of nervus vagus just below the diaphragm. The pylorus is then ligated and a polyethylene catheter (PP 200) is inserted into the duodenum, close to the pylorus. Each animal is placed in a modified Bollman cage and is allowed to recover at least 1 h before the experiment. Gastric juice is collected by free drainage in 30 min samples.

Herling and Bickel (1986) showed that gastric acid secretion in stomach-lumen perfused rats can be stimulated *in vivo* on the subreceptor level by IBMX (phosphodiesterase inhibitor) and forskolin (non-receptor activation of the adenylate cyclase). H^+/K^+-ATPase inhibitors and H_2-antagonists show, according to their different modes of action, also a different inhibitory profile in this assay.

Hammer et al. (1992) used anesthetized female Sprague-Dawley rats weighing 200–320 g. After insertion of a tracheal cannula, a 3-mm silicon tubing is placed through the mouth and advanced to the stomach. The tubing is tied to the esophagus at the neck. A 4-mm drainage tube is inserted into the stomach through a laparatomy incision and an incision in the duodenum, and ligated in place at the pylorus. Gastric perfusate (0.9% saline at 37 °C) is collected on ice every 5 min for titration to pH 7.0.

J.3.1.2 Isolated rat stomach

PURPOSE AND RATIONALE

The isolated whole stomach of the rat was recommended for evaluation of H_2-receptor antagonists (Bunce and Parsons 1976).

PROCEDURE

Fed immature rats of either sex weighing 38–42 g are anesthetized with sodium pentobarbitone i.p. The abdomen is opened and the esophagus ligated close to the stomach. An incision is made in the rumen of the stomach and the contents washed out with warm Krebs-Henseleit solution. A second incision is then made at the pyloric sphincter and polyethylene cannulae are inserted and tied into the stomach via these incisions. The stomach is rapidly dissected out and placed immediately into a 10 ml organ bath containing Krebs-Henseleit solution at 37 °C. The lumen of the stomach is perfused at a rate of 1 ml/min with a modified Krebs-Henseleit solution (without Na_2CO_3 and KH_2PO_4) at 37 °C. Both solutions are gassed with 95% O_2/5% CO_2. The effluent perfusate from the stomach is passed over a micro dual electrode. The changes in pH are converted to a function of hydrogen ion activity by an antilog function generator and continuously recorded on a potentiometric pen recorder. The drugs are added, in a volume not exceeding 0.5 ml, to the complete Krebs-Henseleit solution bathing the serosal surface of the stomach. After setting up the stomach preparation the basal H^+ output is allowed to stabilize, both under control conditions and in presence of the H_2-antagonist, before the secretory responses to histamine are investigated. The response to a dose of histamine is assessed by measuring the amount of acid secreted at peak response above the preceding basal level.

EVALUATION

The rate of acid secretion is expressed as [H^+] moles $\times 10^{-8}$ per min. The effect of the antagonist is assessed by measuring the potency of the agonist. An estimate of potency is firstly obtained using the agonist alone, and then a second estimate is obtained in the presence of the agonist-antagonist combination. The potency ratio is calculated according to Finney (1964).

MODIFICATIONS OF THE METHOD

A similar method was described by Szelenyi (1981) and Stanovnik et al. (1988) using the isolated stomach of the **mouse**.

Weigert et al. (1995) evaluated the effect of the opiate receptor antagonist naloxone on vagally stimulated secretion of bombesin-like immunoreactivity, somatostatin and gastrin from the isolated rat stomach which was perfused via the celiac artery with Krebs-Ringer buffer. Vagal stimulation was performed with 1 ms, 10 V and 2, 5, 0r 20 Hz, respectively.

J.3.1.3 Chronic gastric fistula in rats

PURPOSE AND RATIONALE

A permanent gastric fistula using an especially designed Pavlov's type of cannula in the rat has been

described by Lane et al. (1957) and Komarow et al. (1960, 1963). Moreover, the preparation of chronically denervated gastric pouches in the rat has been reported by Alphin and Lin (1959).

PROCEDURE

For a **permanent gastric fistula** in rats Komarow et al. (1960, 1963) developed a stainless steel cannula of the type extensively used in Pavlov's laboratories. The cannula is 10–12 mm in length with an inner bore of 3 mm diameter and a bevelled flange at each end. The inner bore at one flange is threaded to permit insertion of a removable screw which acts as a stopper between experiments. The lumen of the cannula permits a snug fit with a No. 8 French catheter.

Male Wistar rats weighing 280–300 g are used. Under ether anesthesia, the left upper quadrant of the abdomen is shaved and the animal placed on its right side. An incision of 5–10 mm in length is made about 5 mm below and parallel to the lower left costal margin between the parasternal and mammary lines and the deep abdominal muscles are divided. The area of the rumenal wall is then drawn up through the incision. This area should be close to the greater curvature but far enough away from the glandular portion of the stomach to avoid sacrificing secretory mucosa. A small incision is made in the exposed portion of the rumen and a purse string suture is loosely placed around the margin of the opening. The unthreaded flange of the cannula is inserted into the rumen and the suture is pulled tight around the shaft of the cannula and tied. The incision is then closed by two layers of interrupted sutures. The deep abdominal muscle is closed first by a suture at each side of the cannula, using a bit of rumen to ensure a tight fit. The incision is closed with skin sutures.

During the postoperative period of 2–3 weeks, the animals are conditioned to the experimental procedure by keeping them in a restraining cage for several hours each day. Food is withdrawn 18 h prior to the experiment. The animal is placed in a restraining cage, the stopper screw removed from the cannula and the stomach gently washed twice with 2–3 ml warm saline, and 6 cm length of rubber catheter is inserted through the lumen of the cannula. Hourly collections of gastric fluid in a graduated centrifuge tube are then started. The animal model can be used for physiological studies as well as for standardization of secretagogues and for measuring the inhibition of gastric secretion by antisecretory drugs.

For preparation of **chronic denervated gastric pouches** according to Alphin and Lin (1959) male Wistar or Sprague Dawley rats weighing 250–350 g are used. Under ether anesthesia, a mid-line incision is made along the abdominal wall and the stomach is gently pulled to the outside by means of a stainless steel hook. Two small clamps are then gently applied along the stomach between the smaller and greater curvature, care being taken not to injure the blood vessels supplying the glandular and the non-glandular portions of the stomach.

An incision is made between the clamps from one end to the other end of the greater curvature with as little involvement of the mesenteries as possible. The mucosa and the muscular wall are sewed up separately. A new opening is made midway along the greater curvature of the denervated pouch into which one end of a stainless steel cannula is secured by double purse-string sutures. The stainless steel cannula is 3 cm in length with an inside diameter of 3 mm. The other end of the cannula is led through a small puncture 1 cm on the left of the midline of the abdomen. The gastric end of the cannula is firmly anchored to the body wall by silk sutures. After closing the midline incision of the body wall by silk sutures, the animal receives 150 MU procaine penicillin. The animals receive a pasted diet for some days and are kept constantly in an air-conditioned room with constant temperature during the recovery period of 2–3 weeks.

For experiments, the animals are deprived of food, but not of water prior to the test, placed in restraining cages and the gastric juice is collected in graduated centrifugation tubes. The amount of secretion into the pouch and the acidity of the fluid are measured after secretagogues, e.g. 20 mg/kg histamine s.c., alone and then two hours later after administration of potential antisecretory drugs.

EVALUATION

The effect on volume and HCl secretion at 30 min intervals after administration of the test compound is compared with the control values. The decrease is expressed as percentage of control.

MODIFICATIONS OF THE METHOD

Larsson et al. (1983) described a modified technique for the chronic fistula rat. Under methohexital anesthesia a plastic cannula is implanted in the rumen of rats close to the glandular part of the stomach wall. At the same time, a polyethylene tube (PE 50) for compound administration is inserted into the upper part of duodenum and fixed to the cannula. The duodenal tube is subcutaneously guided to the neck, where the free end is guided through the skin. One week recovery is allowed before experiments. For the experiment, the rats are placed in modified Bollman cages and 6 consecutive 1-h samples of gastric juice are collected from the gastric cannulae. After the first two collection periods, the test compounds are given intraduodenally.

Altar (1980) described design and method of implantation of a chronic gastric cannula in adult rats.

Johnson et al. (1990) described a chronic gastric cannula for feeding ethanol liquid diet to rats.

Tsukamoto et al. (1984) reported an improved method for intragastric infusion in conscious rats with simultaneous implantation of a cannula into the jugular vein for blood sampling and drug administration.

Rossowski et al. (1997) measured the inhibition of gastric secretion by adrenomedullin, amylin, calcitonin-gene related peptide and their fragments in rats equipped with chronic gastric fistulas.

J.3.1.4 Chronic gastric fistula in dogs

PURPOSE AND RATIONALE

A simple technique for preparing chronic gastric fistulas in dogs which does not require placement of cannulae or tubes has been described by Foschi et al. (1984).

PROCEDURE

Male mongrel or Beagle dogs weighing 12–18 kg are used. After thiopental and halothane anesthesia, a round incision (2 cm) is made on the left side of the abdomen below the costal arch. The muscular fascial layers are cut across to either the peritoneum or the abdominal cavity. The stomach is grasped on the greater curvature, as high as possible, and is gently pulled through the abdominal wall. A round excision of the serous-muscular layer (0.5 cm diameter) is made, and then the mucosa is cut and sutured to the serous layer with catgut. A purse string of 3-0 silk is placed 1.5 cm around the gastrostomy hole to invert the opening and to form an antireflux flap. The stomach is also sutured to the peritoneum, the fascial layer, and the skin with catgut. After 5 days, a silver cannula has to be inserted once a week to avoid closure of the gastrostomy.

After 10–14 days, the animals are trained to lie in a cage to their left sides, supported by a 30° angle with the caudal part of the body raised to avoid the passage of gastric juice into the duodenum. For secretion studies, a short plastic tube is inserted through the fistula and gastric juice is collected for periods of 15 min. After 30 min, secretagogues (e.g., pentagastrin 6 µg/kg/min) are given as continuous infusion and samples collected every 15 min.

EVALUATION

The samples are titrated with 0.1 N NaOH to pH 7.0 by a pH meter. The results are expressed as volume (ml), pH, acid concentration (µE/ml), and output (mE/h).

CRITICAL ASSESSMENT OF THE METHOD

The technique described by Foschi et al. (1984) has the advantage of simplicity.

MODIFICATIONS OF THE METHODS

Boldyreff (1925) reported improvements and details of the technique described by Pavlov (1902).

Thomas (1941) described an improved cannula for gastric and intestinal fistulas using a removable flange being inserted separately into the stomach or intestine.

Emås (1960) reported on gastric secretory responses to repeated intravenous infusions of histamine and gastrin in non-anaesthetized and anesthetized cats with gastric fistula. A gastric cannula as well as a duodenal cannula were inserted.

Daly et al. (1980) described an apparatus for intragastric titration in the conscious dog. A titration display unit provides a record of the secretory response both as a digital printout and a bar chart display.

J.3.1.5 Heidenhain pouch in dogs

PURPOSE AND RATIONALE

The preparation of a chronic gastric pouch, as described by Heidenhain in 1878, is one of the classic techniques in experimental surgery. This model has much contributed to the understanding of the physiology and pathology of the stomach and to modern techniques of abdominal surgery in man. The surgical technique has been described again in detail by deVito and Harkins (1957). A preparation of chronic denervated pouches in the rat has been described by Alphin and Lin (1959). Both preparations can be used as pharmacological models for testing antisecretory drugs.

PROCEDURE

Short-haired mongrel dogs or Harrier dogs weighing 15–20 kg are fasted 24 h preoperatively. Intravenous pentobarbital sodium, 30 mg/kg, provides satisfactory anesthesia. It can be supplemented, if necessary, during operation. The abdominal part is shaved with electric clippers, then with a razor. The skin is disinfected with Zephiran®-70% alcohol. Sterile drapes are applied to cover the whole surgical field. A mid-line linea alba incision from xiphoid to umbilicus provides excellent exposure and ease for closure. As the posterior sheath is divided, the large ventral fat pad present in dogs should be excised completely. A self-retaining retractor is applied and the stomach is palpated for the absence of food. Then the spleen is displaced, wrapped in warm, moist pads and laid on the ventral wall below the incision.

The stomach is pulled into the operative field. The greater curvature is held at multiple points so that the stomach is stretched out and the line of incision for the pouch is selected. The pouch should be made from the corpus of the stomach so that true parietal cell juice can be obtained. A line projected from the incisura angularis perpendicular to the proximal lesser curvature will generally fall across the junction between corpus and antrum. Appropriate division of the gastric branches of the right gastroepiploic artery at the lower end of the proposed line of transsection clears the greater curvature for 1–2 cm. The gastroepiploic artery itself should be sectioned at this site and a long rent formed on the adjacent omentum, else the omentum vessels tend to tear during subsequent manipulations.

An index finger is then inserted through this defect dorsal to the stomach to emerge higher on the greater curvature through the gastrosplenic ligament at the upper end of the proposed line of transsection. This portion of the greater curve is cleared for 1–2 cm. Von Petz clamps with their staplings are used to control bleeding and to avoid leakage of gastric content. The stomach should be kept stretched and flattened while the clamps are applied. After division between the staples, any bleeding is controlled and the cut edges of the main stomach and pouch are then oversewn with continuous sutures of black silk. The suture should be of an inverting type. Surprisingly, leakage or excessive adhesions are not a problem when serosal apposition is neglected.

The pouch so formed is about 30% of the corpus volume and provides adequate secretory volume for further studies. A cannula, made of stainless steel, 3 cm long with a bevelled flange threaded at the other end is placed in the most ventral portion of the pouch through a small incision in the anterior wall. A single purse-string of silk holds it in place. A double sheet of omentum is then wrapped about the pouch and the cannula before being pulled through the abdominal wall, about 3 cm to the left of the mid-line subcostally. It is important that the cannula be held snugly by fascia, otherwise it will readily pull out of the pouch and abdominal wall. The linea alba is closed with a continuous suture of silk and the skin with subcuticular stitches of chromic catgut. On the outside of the cannula a stainless steel jacket is screwed. For further collections, a bag is connected to the cannula by a threaded adapter, facilitating removal for daily drainage of secretions.

At the end of surgery, 300 MU penicillin and 0.5 g of streptomycin are instilled intraperitoneally. Before recovery from anesthesia the dog receives 500 ml 5% glucose in saline intravenously. The same volume is given for 3 days postoperatively together with oral fluid ad libitum. From the 4th day onward, normal food is given. Twenty-four hours secretions are collected every morning and analyzed for free HCl. A period of 7–10 days is required for full recovery from the operation. Special care has to be taken for each animal being kept separately in a suitable cage with mesh bottom.

For pharmacological studies, food is withdrawn 18 h prior to the experiment with water ad libitum. The animals are placed in Pawlow stands and a continuous i.v. infusion of either pentagastrine at a dose of 8 µg/kg/h

or histamine at a dose of 0.1 mg/kg/h is administered. Secreted fluid is collected at 15 or 30 min intervals and analyzed for free HCl. As soon as the secretion has reached a plateau, test compounds are given orally or intravenously.

EVALUATION

The effect on volume and HCl secretion at 15 or 30 min intervals after administration of the test compound is compared with the control values. Maximal inhibition is calculated as percentage change against the pre-drug value. Secretin inhibits gastric secretion volume in a dose-dependent manner. Activity ratios for unknown preparations of secretin can be calculated by 2 + 2 point assays in comparison with the international standard. Gastric secretion can be stimulated by slow continuous infusion of pentagastrin, e.g., (Gastrodiagnost®) 8 µg/kg/h.

The Heidenhain pouch technique can also be used for evaluation and standardization of **gastrin analogues**. Two or more doses of the test compound and the standard are given intravenously. Dose-response curves are established using gastric juice secretion, acid secretion, or pepsin secretion, within two 15-min collection periods as parameters. Activity ratios with confidence limits can be calculated.

For evaluation of **H_2-antagonists**, a continuous infusion of histamine is given over a period of 45 min, starting with 3×10^{-8} M/kg/h. Then, the dose of histamine is doubled and infused for the next 45 min. This procedure is repeated until secretion has reached a plateau. Secretory response curves are constructed in the presence or the absence of a H_2-antagonist at a concentration between 2×10^{-6} and 5×10^{-7} M/kg/h.

To evaluate the **type of gastric acid secretion inhibition**, e.g., cholinergic, histaminergic, or gastrinergic mechanisms, either carbachol (8 µg/kg/h), or histamine (80 µg/kg/h), or pentagastrin (8 µg/kg/h), are administered as continuous i.v. infusion until a plateau of acid secretion is reached. The experiments are performed at weekly intervals with and without the administration of various doses of test compounds. Regression lines of antisecretory effects of various doses of test drugs are constructed and used for calculation of ID_{50} values. Relative potencies versus a standard, e.g., cimetidine, can be calculated by four- or six-point assays.

MODIFICATIONS OF THE METHOD

Boldyreff (1925) described a simplified method for isolation of a portion of the stomach as compared to the original method of Heidenhain (1878).

Gastric motility can be measured by balloon manometry of the Heidenhain pouch in the conscious dog. The animals are deprived of food for 18 h before the experiment, but water is allowed ad libitum. A latex balloon, connected via a polyethylene catheter to a pressure transducer (Statham P 23 BB), is introduced through the fistula cannula into the accessory stomach. Changes in intragastric pressure are measured on a frequency measurement bridge and are recorded continuously. The number and height of the pressure waves are used as indices of gastric motor activity. Secretin inhibits gastric motility dose-dependent. After injection of gastrin or gastrin analogues, a dose-dependent increase of pressure is noted over a wide dose-range.

Jacobson et al. (1966, 1967) studied gastric secretion in relation to mucosal blood flow by an antipyrine clearance technique in conscious dogs with vagally denervated gastric fundic (Heidenhain) pouches. A vagally denervated fundic pouch was so constructed that the entire arterial blood supply was delivered by the splenic artery. A non-cannulating transducer (electromagnetic flowmeter) and a hydraulic occluder were implanted on the vessel.

The Heidenhain pouch preparation was used by Carter and Grossman (1978), Kauffman et al. (1980) to study the effect of luminal pH on acid secretion evoked by topical and parenteral stimulants and the effect of topical and intravenous 16,16-dimethyl prostaglandin E_2 on gastric bicarbonate secretion.

Baker (1979) and Roszkowski et al. (1986) developed a modified Heidenhain dog pouch preparation for collecting gastric juice exclusively from the pouch during experimental periods but allowed the pouch to be an integral part of the gastrointestinal tract during non-experimental periods. The pouch is prepared using conventional techniques but, instead of being fitted with a simple cannula through the abdominal wall, a three-way cannula is used which provides passage between the exterior orifice, the pouch and the main body of the stomach. By inserting an appropriate adapter, passage is available only to the pouch and not to the main stomach or vice versa.

The Heidenhain pouch technique in dogs has been used for preclinical evaluation of various drugs, such as:

a histamine H_2 antagonist by Uchida et al. (1993),

dual histamine H_2 and gastrin receptor antagonists by Kawanishi et al. (1997),

a 5-HT_4 receptor antagonist by Bingham et al. (1995),

an other 5-HT_4 receptor antagonist by Wardle et al. (1996),

inhibition of motilin-induced phase III contractions by pentagastrin by Yamamoto et al. (1994),

peptide YY by Zai et al. (1996),

reversible K^+-competitive inhibitors of the gastric H^+/K^+-ATPase by Parsons et al. (1995),

the antiulcer agent SWR-215 by Kataoka et al. (1997),

a selective gastrin/CCK-B receptor antagonist by Yuki et al. (1997).

Descroix-Vagne et al. (1993) used Heidenhain pouch preparations in **cats** and **rabbits** to study the effect of perfusion at pH 5.5 on acid and pepsin secretion.

J.3.1.6 Gastrin activity

PURPOSE AND RATIONALE

Biological activity of gastrin and its analogues can be determined with a bioassay using the acid secretion as determined by pH-metry (Gosh and Schild 1955, 1958; Barrett 1966; Smith et al. 1970) or by measurement of conductivity according to Lawrence and Smith (1974).

Radioimmunoassays for gastrin have been developed (Jaffe and Walsh 1979) and are available as commercial kits.

PROCEDURE

Male Sprague-Dawley or Wistar rats weighing about 250 g are used. They are withheld from food, but not from water, 18 h prior to the experiment. Four animals are used per dose of test drug or standard. Anesthesia is induced by i.p. injection of 5 ml/kg of 25% urethane solution. Body temperature is artificially stabilized by means of a rectal thermometer and a heated pad. The trachea is exposed and cannulated. The jugular veins are then exposed and cannulated with polyethylene

tubes bevelled at the tip. The abdomen is opened through a midline incision, the pyloro-duodenal junction exposed and a catheter with two lumina is introduced through a cut in the duodenum up to the cardiac part of the stomach and secured firmly by tying a ligature around the pylorus. Care must be taken not to include blood vessels within the ligature.

Using a peristaltic pump, the stomach is perfused continuously with a phosphate-citrate buffer at 37 °C. In the effluent pH is measured with a pH-meter and continuously recorded. At the beginning, gastric secretion is stimulated by an intravenous injection of 0.5 µg/kg pentagastrin. Then, the injections are repeated in 1 h intervals with alternating doses between 0.2, 0.4, 0.8, and 1.6 µg/kg of standard or test compound. Since in this dose range linearity of the response to gastrin can be assumed a 2 + 2 point parallel assay is allowed. After each injection, pH or conductivity is measured for 45 min. The area under the curve after each dosage is evaluated by planimetry.

EVALUATION

Each of 4 animals receives two doses of standard and test compound in the order of a Latin square. The dose differences have to follow a logarithmic scale. The evaluation is performed with the 4×4 assay according to Gosh and Schild (1958).

MODIFICATIONS OF THE METHOD

Wan (1977), Chang and Lotti (1986) used CF_1 female **mice**. The whole stomach was placed in tissue baths and perfused. The effluent of the perfused stomachs was collected at 15 min intervals, and the hydrogen ion concentration was determined by titration with 0.01 M NaOH to pH 7.0, or continuously recording with a pH-meter.

J.3.1.7 Receptor binding for gastrin

PURPOSE AND RATIONALE

Binding to gastrin receptors can be determined in isolated guinea pig gastric glands (Praissman et al. 1983; Gully et al. 1993).

PROCEDURE

The gastric glands of male guinea pigs weighing between 300 and 400 g are isolated according to Berglindh and Obrink (1976). The animals are anesthetized with 30 mg/kg Nembutal®. The abdomen is opened and the aorta is cannulated in a retrograde direction. Heparin solution (250 IU/ml) is injected forcefully through the cannula. After one min, the animal is bled through the cannula and a ligature is placed around the mesenteric vessels. The chest is opened and the thoracic aorta clamped. A warm (37 °C) phosphate buffered saline solution is pumped into the aorta, whereupon the portal vein is opened to allow a free outflow of the perfusate. By this procedure, most of the solution is forced through the gastric blood vessels. When the stomach appears totally exsanguinated, it is rapidly removed, opened along the lesser curvature and emptied. The cardial and antral regions are discarded. The corpus is rinsed several times with phosphate buffered saline solution and blotted with filter paper.

The thoroughly washed fundic mucosa from two guinea pigs is minced with fine scissors in a standard buffer consisting of 15 mM HEPES, 130 mM NaCl, 12 mM $NaHCO_3$, 3.0 mM NaH_2PO_4, 2.0 mM $MgSO_4$, 1.0 mM $CaCl_2$, 5.0 mM glucose, 4.0 mM L-glutamine, pH 7.4. The minced tissue is washed and then incubated with 0.1% collagenase in the above mentioned standard buffer containing 0.1% bovine serum albumin in a shaker bath at 37 °C. After 40 min, the glands are liberated by a series of resuspensions through a 10 ml plastic pipette, filtered through 200 µ nylon mesh (Nytex), washed and collected by centrifugation. The glands are then resuspended in 40 ml of the standard binding buffer containing 0.1% bovine serum albumin at pH 7.4. Two ml aliquots are transferred into 15 ml plastic centrifuge tubes. The amount of protein contained in fundic glands is determined according to Lowry et al. (1951).

[^{125}I]Gastrin binding is measured in the presence of 0.4 ml of gland suspension in triplicate tubes that contain 50 µl of either buffer, unlabeled gastrin (1 µM), or displacers at the desired concentration and 50 µl of [^{125}I] gastrin (70 pM final concentration). After 90 min of incubation at 37 °C, the mixture is layered over 1 ml ice-cold incubation buffer in microcentrifuge tubes and is centrifuged at 10 000 *g* for 5 min. The supernatant is discarded and the radioactivity is measured in a γ-scintillation counter.

EVALUATION

IC_{50} values and K_i constants are calculated.

J.3.1.8 Gastrin releasing peptide/bombesin/ neuromedin

Bombesin is a tetradecapeptide originally isolated from frog skin by the group of Erspamer (Anastasi et al. 1971). Shortly before, Nakashima et al. (1970) isolated from the skin of *Rana pipiens* a peptide called ranatensin because of its contractile effects on smooth muscle. **Gastrin-releasing peptide**, which shares a C-terminus with amphibian bombesin, has been isolated from a variety of mammalian and non-mammalian species (Spindel et al. 1993). **Neuromedin B**, a decapeptide originally isolated from porcine spinal cord (Minamino et al. 1983), also shows sequence homology to bombesin and gastrin-releasing peptide. **Neuromedin N**, a six amino acid neurotensin-like peptide, shows a high affinity to brain neurotensin receptors and is rapidly inactivated by brain synaptic peptidases (Checler et al. 1990).

The peptides which belong to the bombesin family can be classified in three subgroups according to the sequence of their C-terminal tripeptide: bombesin (-His-Leu-MethNH_2), ranatensin and litorin (-His-Phe-MethNH_2), and phyllitorin (-Ser-Phe MethNH_2).

Bombesin and its homologues are known to affect a wide spectrum of biological processes (Tache et al. 1988; Parkman et al. 1994; Thomas et al. 1994; Konturek et al. 1995; Varga et al. 1994, 1995; Glad et al. 1996).

In the **gastrointestinal tract**, bombesin/gastrin-releasing peptide stimulates hormone and peptide release, stimulates gastric, pancreatic, bile and intestinal secretion, prevents gastric injury, causes smooth muscle contraction and induces epithelial growth (Dietrich et al. 1994; Kortezowa et al. 1994; Liu et al. 1995; Takehara et al. 1995; Wada et al. 1995; Weigert et al. 1995; Roberge et al. 1996; Yegen et al. 1996; Won Kyoo Cho 1997; Azay et al. 1998; Cox et al. 1998; Mercer et al. 1998; Milusheva et al. 1998; Nishino et al. 1998; Alvoro-Alonso et al. 1999; Bozkurt et al. 1999; Ladenheimer et al. 1999; Shahbazian et al. 1999).

Bombesin-related peptides inhibit **food intake** (Kirkham et al. 1994; Ladenheimer et al. 1996; Smith et al. 1997; Plamondon et al. 1998; Rushing and Gibbs 1998; Aalto et al. 1999; Edwards and Power 1999; Horstmann et al. 1999; Merali et al. 1999).

Several **central activities** of neuromedin B and gastrin-releasing peptide are reported, e.g. involvement in the hypothalamic-pituitary system (Pinski et al. 1992; Plamodon and Merali 1997; Garrido et al. 1998, 1999).

Autocrine actions of neuromedin B and gastrin-releasing peptide in small and non-small cell lung carcinomas are described (Gaudino et al. 1988; Siegfried et al. 1999).

J.3.1.9 Bombesin receptor binding

PURPOSE AND RATIONALE

Different types receptors have been described for bombesin-like peptides (von Schrenk et al. 1989; Battey et al. 1991; Severi et al. 1991; Fathi et al. 1993). The mammalian bombesin receptor subfamily of G protein coupled receptors consists of the gastrin-releasing peptide receptor (GRP-R), also called BB2, the neuromedin B receptor (NMB-R), also called BB1, and the bombesin receptor subtype 3 (BRS-3), also called bb3 (Donohue 1999; Jian 1999). A fourth subtype, bombesin receptor subtype 4, has been isolated from a cDNA library from the brain of the frog, *Bombina orientalis* (Katsuno et al. 1999). A ligand with high affinity to all four receptors has been identified (Pradhan et al. 1998).

Moody et al. (1978) studied the binding of the radiolabeled bombesin analogue [^{125}I]bombesin to rat brain membranes. Functional GRP-preferring bombesin receptors were identified in human melanoma cells by Pansky et al. (1997). Benya et al. (1995) expressed and characterized clones of human bombesin receptors.

PROCEDURE

BALB/3T3 fibroblasts devoid of gastrin-releasing peptide receptor (GRP-R) and neuromedin B receptor (NMB-R) are selected by clonal expansion after assaying for GRP-R or NMB-R by RNase protection and binding studies (Benya et al. 1992). These BALB/3T3 cells are stably transfected using a full length human GRP-R clone (huGRP-R transfected cells) or a full length human NMB-R clone (huNMB-R transfected cells) (Corgay et al. 1991). In both cases the receptor is subcloned into a modified version of the pCD2 plasmid and transfected using calcium phosphate precipitation. Stable transfectants are isolated in the presence of 800 µg/ml aminoglycoside G-418 (GIBCO, Waltham MA), identified by binding studies, and then maintained in DMEM containing 10% fetal bovine serum and 270 µg/ml G-418. Cells are passaged every 3–5 days at confluence by splitting 1 : 4.

[^{125}I-D-Tyr^0]NMB (2 200 Ci/mmol), ^{125}I-GRP (2 200 Ci/mmol), and [^{125}I-Tyr^4]Bn (2 000 Ci/mmol) are prepared using Iodo-Gen and purified using high pressure liquid chromatography. Binding studies are performed by suspending disaggregated cells in binding buffer containing 75 pM levels of either [^{125}I-D-Tyr^0]NMB or [^{125}I-Tyr^4]Bn and 3×10^6 cells/ml for 30 min at 22 °C. Nonsaturable binding of either radiolabeled peptide is the amount of radioactivity associated with transfected cells when the incubation mixture contains either 1 µM NMB of 1 µM Bn.

The ability of various bombesin related agonists or antagonists to inhibit the binding of [^{125}I-Tyr^4]Bn to huGRP-R transfected cells and of [^{125}I-D-Tyr^0]NMB to huNMB-R transfected cells is compared.

EVALUATION

Data are expressed as the percentage of saturably bound reactivity in the absence of nonradioactive peptide. For each experiment each value is determined in duplicate, and the results are expressed as the means ±standard errors of at least 3 separate experiments.

MODIFICATIONS OF THE METHOD

Radulovic et al. (1991) studied biological effects and receptor binding affinities of pseudononapeptide bombesin/CRP receptor antagonists.

Fanger et al. (1993) identified a 63-kDa serum protein that binds somatostatin and gastrin-releasing peptide but not bombesin.

Wada et al. (1997), Ohki-Hamazaki et al. (1999) generated mice lacking the gastrin-releasing peptide receptor, the bombesin subtype-3 receptor or the neuromedin B receptor.

Akeson et al. (1997) identified four amino acids in the gastrin-releasing peptide receptor that are required for high affinity agonist binding.

Ryan et al. (1998) studied the intracellular signaling of the human bombesin orphan receptor BRS-3 by various bombesin receptor agonists and antagonists.

Chave et al. (2000) analyzed the expression of bombesin-like peptides and their receptor subtypes in normal and neoplastic colorectal tissue.

Sun et al. (2000) investigated the presence and characteristics of the functional receptors for bombesin/GRP in human prostate adenocarcinoma specimens by radio-receptor assay and the mRNA expression of the three bombesin receptor subtypes by RT-PCR.

Weber et al. (2000) determined the structure of the mouse gastrin-releasing peptide receptor gene and investigated its basal promotor activity.

Radioligands for the **GRP receptor** are:

- [^{125}I][DTyr^{6}]bombesin-6-13-methylester, [^{125}I]GRP, [^{125}I][Tyr^{4}]bombesin,

for the **neuromedin B receptor:**

- [^{125}I]BH-NMB, [^{125}I][Tyr^{4}]bombesin,

for the **bombesin receptor subtype 3:**

- [^{125}I][Tyr^{6},βAla^{11},Phe^{13},Nle^{14}]bombesin-6-14 (Alexander et al. 2000).

J.3.1.10 Evaluation of bombesin receptor antagonists as anti-cancer drugs

PURPOSE AND RATIONALE

Bombesin and gastrin-releasing peptide affect the growth and differentiation of lung epithelium in the

fetus and the adult. Gastrin-releasing peptide is an autocrine growth factor for various small cell carcinoma cell lines. Bombesin/gastrin-releasing peptide receptors were also identified in other human cancer tissue (Halmos et al. 1995). Therefore, bombesin- and gastrin-releasing peptide-antagonists were synthesized and tested as antitumor agents (Heimbrook et al. 1991; Qin et al. 1994a, 1995; Thomas et al. 1994; Azay et al. 1996; Casanueva et al. 1996; Halmos and Schally 1997; Moody and Jensen 1998).

The procedure of Qin et al. (1994a) on the inhibitory effect of an bombesin receptor antagonist on the growth of human pancreatic cells *in vivo* and *in vitro* is described as example of various similar studies.

PROCEDURE

Cancer cell line

Cancer cells of the CFPAC-1 human pancreatic cell line, originally established from a well differentiated ductal pancreatic adenocarcinoma of a 26-year-old white male with cystic fibrosis, are routinely maintained in a monolayer culture in Costar T75 culture flasks with IMDM medium containing 10% FCS, 0.5 g/liter L-glutamine, 25 mM HEPES, 3.7 g/liter $NaHCO_3$, 100 units/ml penicillin, 100 µg/ml streptomycin, and 0.25 µg/ml amphotericin B under humidified 5% CO_2 at 37 °C. The cells growing exponentially are harvested by an incubation with 0.25% trypsin-EDTA in calcium- and magnesium-free Hank's balanced salt solution for 5 min at 37 °C. For tumor cell implantation, a cell suspension is prepared in serum-free IMDM by repeatedly passing the cells through a G-22 needle; then the cells are diluted to a concentration of 5×10^6 cells/ml.

Implantation of tumors in nude mice

Male athymic BALB/c (nu/nu) 6-week-old mice are housed in a laminar airflow cabinet under pathogen-free conditions throughout the experiments. Three nude mice receive s.c. injections in the flanks with 0.2 ml of cell suspension (1×10^6 cells) and serve as tumor donors. After 4 weeks, the implanted tumors grow to a size of about 5 mm in diameter and are removed from the mice. Tumor samples are dissected free of necrotic tissue and blood vessels and are cut into small fragments of about 8 mm^3. Under ether anesthesia, two pieces of tumor fragments are implanted s.c. by trocars on both sides of the flanks for each mouse. The mice bearing the implanted tumors are randomly divided into groups with 10 mice in each group.

The nude mice with implanted tumors start to receive injections of the bombesin antagonist or vehicle 7 days after the tumor cell injection. The treatment is continued for 25 days.

Evaluation of tumor growth

During the treatment, the size of the implanted tumors is measured by calipers in each mouse at 3–4 days intervals for 25 days to construct the tumor growth curve *in vivo*. Tumor volume is calculated by the formula: Tumor volume = length × width^2 × 0.5. Tumor volume doubling time is defined as the time required for the tumors to grow from 50 mm^3 to 100 mm^3 for the control group and from 35 mm^3 to 70 mm^3 for the treatment group, respectively. The tumor growth delay time is estimated as the time difference for the treated tumors and the controls to reach a volume of 70 mm^3. At the end of the experiment, the animals are sacrificed by an overdose of ether. The tumors are removed from the animals, weighed, and immediately frozen in liquid nitrogen for measurement of DNA and protein content in tumor tissues.

Determination of DNA and protein in tumor tissue

DNA in tumor tissue is determined by the method of Labara and Paigen (1979) which is based on the enhancement of fluorescence reaction upon binding bisbenzimidazole Hoechst 33 528 to DNA in cell nuclei in a high ionic strength solution. Tumors collected in each group are pooled and homogenized in 10 times their volumes in a buffer consisting of 0.05 M NaH_2PO_4, 2.0 M NaCl, and 2 mM EDTA (pH 7.4). Hoechst 33 528 is dissolved in the same buffer at a concentration of 1 µg/ml and filtered before use. An aliquot of tumor homogenate (0.4 ml) is suspended in 4 ml of Hoechst 33 528 solution, followed by incubation in a dark room for 30 min. The reaction is measured by a fluorescence spectrophotometer at excitation and emission wavelengths of 356 and 492 nm, respectively. Calf thymus DNA type I is used as a standard.

Measurement of cell growth *in vitro*

The effects of bombesin and the bombesin antagonist on the growth of CFPAC-1 human pancreatic cells *in vitro* is evaluated by direct cell counting and [^{3}H]thymidine incorporation assay.

Direct cell counting

CFPAC-1 cells collected from 60–70% confluent cultures are used for this study and seeded to 24-well culture plates (1×10^4 cells/well). After the cells are cultured in IMDM containing 10% FCS for 48 h, the medium is replaced by IMDM supplemented with 2.5% FCS and various concentrations of bombesin, bombesin antagonist, or a combination of both. The same volume of medium but without peptides is added to control wells. Following another 24 h of incubation, the culture is terminated by aspiration of the medium from the wells and washing with PBS (0.5 ml/well).

The cells are trypsinized by a 10-min incubation with (0.5 ml/well) 0.25% Trypsin-EDTA. The detached cells are dis-persed by repeated pipetting using a G-22 needle and syringe. The number of cells is counted by an automat-ed electronic cell counter (Coulter Counter Model ZF).

[^{3}H]Thymidine incorporation assay

Single cell suspension is prepared in IMDM with 10% FCS and seeded to 24-well culture plates (1×10^4 cells/well). After 46 h of culture, the medium is changed to IMDM (0.5 ml/well) containing 2.5% FCS and various concentrations of bombesin, bombesin antagonist, or a combination of both. The same volume of medium but without peptides is added to control wells. After 24 h of culture [methyl-^{3}H]thymidine (radioactivity 25 Ci/mg) is added to each well (1μCi/well) to pulse the cells. After a 4-h incubation, the medium is removed from the wells, and the cells are fixed by Camoy's solution (1 ml/well; methanol:glacial acetic acid, 3 : 1, v/v) for 20 min. After washing 3 times with PBS, the cells in each well are dissolved with 0.5 ml of 0.3 N NaOH for 15 min at room temperature. The cell lysate is collected and mixed with 3 ml of Universal scintillation cocktail. The radioactivity is measured for 1 min by a liquid scintillation beta counter.

Receptor binding assay

Receptor binding assay is performed using intact CFPAC-1 cells in monolayer cultures. Tyr^4-bombesin is labeled with ^{125}I-Na using a Bio-Rad enzymo-bead iodination kit. Mono-^{125}I-Tyr^4-bombesin is purified by high performance liquid chromatography resulting in a specific activity of ^{125}I-Tyr^4-bombesin of about 2 000 Ci/mmol. CFPAC-1 cells are seeded to 24-well culture plates (1×10^4 cells/well) and cultured with IMDM containing 10% FCS for 48 h. The cells in subconfluent culture are washed once with serum-free IMDM supplemented with 25 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid, 10 mM $MgCl_2$, 1 mM EGTA, 10 mM monothioglycerol, 0.25 mM phenylmethylsulfonyl fluoride, aprotinin 10 000 kallikrein inactivator units/liter, and 0.1% bovine serum albumin (pH 7.5), followed by an incubation for 2 h at 22 °C with the same medium containing (0.5 nM) ^{125}I-Tyr^4-bombesin in the presence or absence of various concentrations of bombesin, bombesin antagonists or structurally unrelated peptides. The binding reaction is terminated by adding 0.5 ml of ice-cold medium to each well. After washing four times with ice-cold PBS (pH 7.4) the cells in each well are dissolved with 0.5 ml of 0.3 N NaOH. The resultant cellular lysate is collected from each well for measurement of radioactivity by a gamma counter.

EVALUATION

All data are expressed as the mean ±SEM of duplicate or triplicate observations from at least 2–3 repeated experiments. Mean values between the treatment and control group are analyzed by the Student *t*-test, Mann Whitney *U*-test, or one-way analysis of variance.

Data from receptor binding assays are analyzed by a ligand-PC computerized curve-fitting program created by Munson and Rodbard as modified by McPherson (1985) to determine the types of binding sites, the dissociation constants (K_d) and the maximal binding capacity of receptors (B_{max}).

MODIFICATIONS OF THE METHOD

Similar studies, mostly by Schally's group, as with tissue derived from human pancreatic cancer were performed with nitrosamine-induced pancreatic cancers in hamsters (Szepeshazi et al. 1993, 1994, 1999), with human prostate cancer (Pinski et al. 1993a,b), with rat prostate cancer (Pinski et al. 1994a), with human gastric cancer (Halmos et al. 1994; Qin et al. 1994b), with human small-cell and non-small-cell lung carcinoma (Pinski et al. 1994b; Moody et al. 1996; Koppan et al. 1998; Kiaris et al. 1999a), with human breast cancer (Yano et al. 1994; Miyazaki et al. 1998; Kahan et al. 2000), with mouse mammary cancer (Szepeshazi et al. 1992, 1997), with human colon cancer (Radulovic et al. 1994), with human glioblastoma (Kiaris et al. 1999b), and with human renal adenocarcinoma (Jungwirth et al. 1998).

J.3.2 Mucus secretion

J.3.2.1 Isolated gastric mucosal preparation

PURPOSE AND RATIONALE

Main and Pearce (1978) described an isolated gastric mucosal preparation from rats for studying the pharmacology of gastric secretion and the synthesis or release of endogenous substances.

PROCEDURE

Rats of either sex weighing 100–120 g or guinea pigs weighing 400–600 g are anesthetized with 60 mg/kg pentobarbitone s.c. The abdomen is opened along the midline and the stomach exteriorized. The nonglandular portion is removed and the stomach rinsed with mucosal solution, containing 136 mM NaCl, 5 mM KCl, 3.6 mM $CaCl_2 \cdot 6\,H_2O$, 1.2 mM $MgCl_2 \cdot 6\,H_2O$, and 16.7 mM glucose. The muscular layer overlying the nonantral region is separated from the mucosa by blistering. The tip of a fine needle (27 gauge) is inserted just below the muscle and mucosal solution injected between the layers. The process is repeated as many times as is necessary to blister the whole area. Fine scissors are then used to cut the muscle along the greater curvature and then parallel to the cut edge. The muscle sheet is pulled back to expose the mucosa. The stomach is then removed, opened by cutting along the greater curvature, and rinsed with mucosal solution.

Two pieces are obtained from one stomach and each is placed, mucosal surface inwards, over a 1-cm^2-opening on a polyethylene vessel (titration cup). Both preparations, one each from the ventral and dorsal surfaces, are stretched lightly over the cup and tied in place. Each tissue is placed in an organ bath, at 37 °C, containing 35 ml of serosal solution (110 mM NaCl, 5 mM KCl, 3.6 mM $CaCl_2 \cdot 6\,H_2O$, 1.2 mM $MgCl_2 \cdot 6\,H_2O$, 26 mM $NaHCO_3$, and 16.7 mM glucose) being gassed with a 95% O_2/5% CO_2 mixture. The mucosal surface is superfused by means of a peristaltic pump at a rate of 0.5 ml/min with an unbuffered solution of similar ionic composition and gassed with 100% O_2. The volume of solution on the mucosal side is kept constant by suction via the same pump using larger diameter tubing, varying between 1.6 and 2.0 ml. This small volume is used in order to follow changes in acid secretion more closely. Secretion is recorded continuously via a dual microelectrode in the mucosal solution connected with a potentiometric pen recorder. The H^+-ion concentration is noted every 15 min and expressed as apparent secretion rate. Drugs are added to the serosal solution in volumes not exceeding 1 ml. Contact times for drugs and hormones (e.g., gastrin or histamine) are between 30 and 60 min. Recovery periods before the next response are between 45 and 60 min. Responses are readily reversible on replacing the solution in the bath with fresh, warmed serosal solution.

EVALUATION

The secretory response is calculated as the increase in secretion rate at the peak of the response over the preceding basal value. Dose-response curves and time-response curves are established for histamine, gastrin, and methacholine. The effects of drugs which inhibit acid secretion are evaluated by adding them either at the peak of a response, or 15 to 60 min prior to the secretagogue.

MODIFICATIONS OF THE METHOD

Wan et al. (1974) used the fundic glandular portion of the rat stomach mounted onto a glass tube without removing the muscular layer to study the inhibition of *in vitro* stimulated gastric acid secretion by a histamine H_2-receptor antagonist.

J.3.2.2 Primary culture of rat gastric epithelial cells

PURPOSE AND RATIONALE

Zheng et al. (1994) described an *in vitro* model for evaluation of antisecretory agents using primary cultures of rat gastric epithelial cells.

PROCEDURE

Gastric mucosal cells from 1- to 2-week-old Sprague-Dawley rats are isolated according to Terano (1982). Gastric mucosal surface is washed thoroughly with sterile cotton and Hank's balanced salt solution (HBSS) and then rinsed with HBSS before being minced into approximately 1-mm^3 pieces. The minced tissues are incubated in HBSS containing 0.1% collagenase and 0.05% hyaluronidase at 37 °C in a shaking water bath for 60 min, then pipetted several times and filtered through a sterile nylon mesh. The filtrate is washed twice with HBSS by centrifugation (200 *g* for 5 min) and resuspended in Coon's modified Ham's F-12 culture medium containing 100 µg/ml penicillin, 100 µg/ml streptomycin, 50 µg/ml gentamycine, 15 mM HEPES, 2 µg/ml fibronectin, and 10% fetal bovine serum. Cells are seeded at a density of $1.5–2 \times 10^5$ or $1–2 \times 10^4$ cells/cm^2 directly onto either 96-well plates or 6-well plates, and maintained in a Steri-Cult incubator at 37 °C in a humidified atmosphere with 5% CO_2. The medium is changed daily. The confluent monolayers are formed after 4–5 days in 96-well plates.

Drug treatment

To measure the effects of individual drugs on the viability of gastric mucosal cells, cells are incubated with

0.02–5 mg/ml drugs in culture medium for either 2 or 48 h for the uptake of MTT (3-[4,5-dimethyl-2-thiazolyl]-2,5-diphenyl-2*H*-tetrazolium bromide) or up to 8 days for the colony-forming efficiency assay. To measure the cytotoxicity of drugs, e.g., indomethacin, and acidified medium to gastric mucosal cells, cells are incubated in either serum-free medium containing 0.5–10 mM indomethacin for 1 h, or pH 3.5 at for 10–30 min.

To study the effect of various antacids, e.g., aluminium hydroxide or sucralfate preparations, cells are incubated for 1 h in culture medium containing these drugs. The drug suspensions are then aspirated away, followed by another hour of treatment with 3.5 mM indomethacin. Alternatively, cells are treated with drugs and 3.5 mM indomethacin concurrently for 1 h. The effects of antacids on acid-induced damage are investigated by incubating the cells with the agents for 2 h and then exposing them to pH 3.5 medium for 10 to 30 min.

MTT (3-[4,5-dimethyl-2-thiazolyl]-2,5-diphenyl-2H-tetrazolium bromide) colorimetric assay

Cells in 96-well plates are treated with the different drugs and then incubated in 100 µl of culture medium containing 10 µl of an MTT stock solution (5 mg/ml) for 4 h at 37 °C according to Mosmann (1983). Following the incubation, 100 µl acid-isopropanol (0.04 N HCl in isopropanol) is added to the wells and incubated overnight at room temperature. The color changes are recorded at 540 nm on a microplate reader. To exclude the disturbance of precipitates in some samples, the samples are centrifuged and only the supernatants are read. For each experiment, a standard curve is generated by measuring the relationship of absorbance to a series of viable cell numbers.

Neutral red uptake assay

Neutral red is prepared as a 1% stock solution in distilled water and diluted to 0.035% in HBSS immediately before each experiment. The cells are treated with the drugs and then stained with 0.1 ml of 0.035% neutral red for 30 min (Parish and Müllbacher 1983). The stain is discarded and the cells are washed twice in HBSS before the addition of 200 µl/well of acidified alcohol solution (50%, v/v, ethanol/water, containing 0.5% acetic acid). After a 2 h incubation period at room temperature, the color changes are measured in a microplate reader.

Colony-forming efficiency assay

The cells are seeded into 6-well plates and incubated in culture medium containing 0.02 to 5 mg/ml of individual drugs for 8 days. Cells are then fixed in 10% formalin and stained with 1% aqueous crystal violet (Sundqvist et al. 1989). Colonies formed on each well are counted (crystal violet stains cell nuclei) and compared with those formed on drug-free wells.

EVALUATION

Data are expressed as mean ± standard error. A one-way analysis of variance followed by Scheffe's post hoc test is used to test the significance between control and drug-treated samples. Differences are considered significant at $P < 0.05$.

MODIFICATIONS OF THE METHOD

Buchan et al. (1993) used cultured human antral epithelial cells enriched for D cells to study the effect of cholecystokinin and secretin on somatostatin release.

J.3.3 Gastric motility

J.3.3.1 Measurement of intragastric pressure in rats

PURPOSE AND RATIONALE

Gastric motor activity can be measured by recording intragastric pressure in anesthetized rats (Holzer 1992).

PROCEDURE

Sprague-Dawley rats of either sex weighing 220–240 g are deprived of food for 20 h prior experimentation but are allowed free access to tap water. After induction of anesthesia by i.p. injection of phenobarbital sodium (0.92 mmol/kg), the trachea is cannulated to facilitate spontaneous breathing. The left carotid artery is cannulated and connected to a pressure transducer to monitor mean arterial blood pressure. The left jugular vein is cannulated for i.v. injection of drugs and for continuous infusion of physiological saline at a rate of 0.6 ml/h to avoid dehydration of the animals. Intragastric pressure is measured by a catheter (outer

diameter 1.9 mm) passed down to the stomach via the esophagus. The position of the catheter tip in the corpus region is verified at the end of each experiment. The catheter has two side holes in its tip segment and is continuously perfused with physiological saline at a rate of 0.6 ml/h. To record intragastric pressure, the catheter is connected to a pressure transducer.

EVALUATION

The gastric motor effect is quantitated by calculation of the area under the curve versus baseline intragastric pressure, measured immediately before injection of the stimulant (e.g., neurokinin A). To test inhibitors, the area under the curve after the stimulant is set as 100% and the effect of application of the inhibitor with the stimulant is calculated as percentage.

MODIFICATIONS OF THE METHOD

Lotti et al. (1986) described a simple mouse assay for the *in vivo* evaluation of cholecystokinin antagonists which is based on visual determination of the gastric emptying of a charcoal meal.

J.3.3.2 Isolated smooth muscle preparation of guinea pig stomach

PURPOSE AND RATIONALE

Boyle et al. (1993) described a novel smooth muscle preparation from the guinea pig stomach for characterization of CCK receptors by use of selective antagonists.

PROCEDURE

Adult male guinea pigs weighing 330–400 g are sacrificed and the stomach rapidly removed. The fundus is discarded and the stomach is opened along the greater curvature, pinned on a Petri-dish with the mucosa pointing up. The mucosal and submucosal layers are removed by dissection to reveal the underlying smooth muscle layer. Strips of circular muscle (2×25 mm) from the corpus region of the stomach are obtained by cutting inwards, following the striations of the lesser curvature. Muscle strips are mounted in siliconized 3 ml organ baths containing Krebs-Henseleit solution. The buffer is modified to include 5 μM indomethacin. The solution is maintained at 37 °C and continuously gassed with a mixture of 95% O_2/5% CO_2. Isometric contractile responses are measured with force-displacement transducers (e.g., Grass FT.03) and recorded on a polygraph (e.g., Mark VII Graphtec Linearcorder).

Tissues are placed under 1 g tension and allowed to equilibrate for 30 min after which time they are contracted with a submaximal dose of carbamylcholine (10 nM). Using a 12 min dose cycle, concentration-response curves are established for agonists, e.g., gastrin, pentagastrin, CCK and CCK-analogues. For studies with antagonists, the tissues are exposed to antagonists for 15 min before re-exposure to agonists. The addition of 5 μM indomethacin removes the spontaneous activity due to the inherent myogenic tone existing in the tissue, but leaves the responses to the agonists unaffected.

EVALUATION

Contractile responses to exogenously applied agonists are expressed as absolute changes in tension and are transformed as a percentage of the maximal response achieved for that agonist in order to obtain potency values. EC_{50} values are obtained graphically for individual concentration-response curves. Responses to agonists in the presence of antagonists are expressed as a percentage of the control maximum response obtained in the same tissue preparation. Agonist concentration-response curves in the absence and presence of increasing concentrations of antagonists are obtained. The method of Arunlakshana and Schild (1959) is used to provide Schild plots of the data, and to obtain affinity constants for the antagonists.

MODIFICATIONS OF THE METHOD

Riazi-Farzad et al. (1996) described an improved preparation of the **isolated rat stomach fundus strip** based on the finding that the majority of the contractile response to 5-HT and carbachol was present in the left ventral longitudinal quartile of the tissue.

Van Nueten et al. (1978), Reyntjens et al. (1984), Schuurkes et al. (1985), Kishibayashi and Karasawa (1998) used an **isolated gastroduodenal preparation of the guinea pig**. After ligation of the esophagus, the stomach was filled with 20 ml saline and suspended in 200 ml of oxygenated Krebs-Henseleit solution, maintained at 37 °C. The duodenum was cannulated and connected with an ultrasonic transit time transducer to record changes in intraluminal volume and with a bottle of saline to ensure constant hydrostatic pressure of 6 cm H_2O. Spontaneous phasic activity was always present on the stomach and recorded as rhythmic changes in gastric volume. Gastric peristaltic waves either stopped at the pylorus or were propagated to the duodenum. Antroduodenal coordination was quantified as the relative number of antral waves that were propagated to

the duodenum. After 30 min stabilization, drugs were added in varying concentrations and the effects followed for 30 min. Three parameters were determined: (1) contractile amplitude, expressed as milliliters of expelled volume; (2) frequency, measured as number of contractions per minute; (3) percentage of antroduodenal coordination.

J.3.4 Absorption

J.3.4.1 Measurement of gastric absorption of drugs in rats

PURPOSE AND RATIONALE

Although the stomach is not the prime absorptive site of drugs, the absorption of some drugs from the gastric mucosa has been established (Doluisio et al. 1969; Welling 1977). Worland et al. (1983) described an *in situ* gastric pouch technique for direct measurement of the gastric absorption of drugs in the rat.

PROCEDURE

Male Wistar rats weighing 220–300 are anesthetized by i.p. injection of 50 mg/kg sodium pentobarbital. A cannula is placed in the jugular vein for administration of heparinized saline (3 000 IU/kg) and whole blood replacement during the experiment. The replacement blood is collected from heparinized donor rats immediately prior to the experiment. Another cannula is placed into the carotid artery of the experimental animal for the collection of systemic blood samples. A midline incision is made in the abdominal wall. Double ligatures are placed on the superior epigastric vessels and transverse incisions are made between the ligatures. The branches of the right gastroepiploic veins and arteries are then ligated using surgical silk and the gastrohepatic ligament between the stomach and the posterior surface of the left hepatic lobe and the caudal hepatic lobe is separated. The gastrosplenic mesentery is also severed. A strip of gauze is employed to keep the liver lobes out of the surgical field. Using appropriately sized surgical silk, double ties are placed around the short gastric vessels and the esophagus, which are then severed between the ties. The pylorus and pyloric vessels are then ligated and an incision is made in the forestomach to allow the removal of gastric contents.

The pouch is then rinsed with warm saline until clear and the remaining fluid is removed using an adsorbent tissue. A Luer adapter modified from a three-way tap is tied into the incision to enable drug administration via a syringe. The gastric pouch is then transposed to the right of the animal exposing the left gastric vein. The vein is cannulated above the junction with the lienal (splenic) vein using a 21-gauge needle connected to a 15-cm length of polyethylene tubing (i.d. 0.75 mm, o.d. 1.45 mm). A small Oxford clamp with foam rubber insets is employed to prevent dislocation of the cannula during the changing of the sample vials. The drug is administered into the stomach and blood draining from the gastric pouch is collected over timed intervals. To determine the volume (ml) of blood collected, the venous effluent is weighed and hematocrit (HCT) readings are taken for each sample and converted to units using the formula:

$$\text{Volume (ml)} = \frac{\text{mass blood collected (g)}}{\text{HCT} \times \text{blood cell density} + (1 - \text{HCT}) \times \text{plasma density}}$$

Rat blood cell and plasma density measurements are obtained from five determinations from four rats, blood samples being separated at 3000 *g* for 10 min. Samples from the gastric pouch are kept on ice until the plasma can be separated by centrifugation at 3000 *g* for 10 min and the plasma frozen until assay.

Blood replacement is delivered at a rate of 0.7 ml/min from a gently oscillating reservoir using a peristaltic pump.

The compound to be tested is administered in a volume of 0.5 ml to the gastric pouch. Plasma levels are determined with a method specific for the compound under investigation. Plasma samples are collected at 4 min intervals over a period of 30–60 min. At the end of the experiment, the fluid in the gastric pouch is collected for determination of the dose remaining in the stomach.

EVALUATION

Mean values ± standard deviation of plasma concentration are calculated from 4–6 experiments and plotted versus time to demonstrate the absorption profile.

J.3.5 Antacid activity

J.3.5.1 Evaluation of antacids

PURPOSE AND RATIONALE

Antacids have been used for the treatment of gastroduodenal ulcerations since a long time (Konturek 1993). The main action of antacids is to reduce the acidity of the gastric content through neutralization and increasing intragastric pH. Since pepsin is not active at higher pH levels, antacids reduce peptic activity (Goldberg et al. 1968) and may also adsorb pepsin (Sepelyak et al. 1984). Binding of bile salts (Clain et al. 1977) by antacids may also have a beneficial influence on peptic ulcer disease. Most antacids contain magnesium and aluminum hydroxide, in some cases also calcium carbonate and sodium bicarbonate. The acid-neutralizing potency can be measured *in vitro*.

PROCEDURE

0.1 M HCl is added to the antacid to be tested. The acid neutralizing capacity is defined as the amount of 0.1 M HCl that can be added to a liquid antacid without reducing the pH of the mixture below pH 3.0. The determination of the acid neutralizing capacity of antacid tablets is performed *in vitro* by stirring a mixture of crushed tablets and water. The time at which all antacid is consumed is much longer for antacid in tablet as compared with the same amounts of antacid in liquid form. Magnesium hydroxide is very insoluble in water, but is readily soluble in hydrochloric acid. In combined preparations, the magnesium hydroxide reacts first to produce an almost immediate neutralizing effect and an increase of the pH within a few minutes. Aluminum oxide, on the other hand, has a weaker antacid activity, reacting more slow with acid (Fordtran et al. 1973; Richardson et al. 1988).

EVALUATION

In vitro titration curves of 0.1 M HCl with 5 ml liquid antacid or one tablet are measured over 3 h and compared with the standard.

CRITICAL ASSESSMENT OF THE METHOD

Acid neutralizing potency may be not the only factor which contributes to the therapeutic effect of antacids. Damage and protection in the stomach are essentially represented by acid secreted by the parietal cells and by bicarbonate released by the surface epithelial cells and mucous neck cells. Among various neurohumoral factors most important in the bicarbonate-secretion appear the prostaglandins, mainly of the E series. Mucosal bicarbonate secretion may be stimulated through the activation of prostaglandins by aluminum hydroxide containing antacids. Aluminum containing antacids were found to protect against mucosal damage due to topical irritants and against stress or aspirin induced lesions. Gastroprotection of aluminum-containing antacids has been attributed to the biological activity of nitric oxide interacting with mucosal prostanoids on the mucosal microcirculation. Therefore, these antacids were found to be active in various experimental ulcer models and to exert cytoprotective activity against ethanol induced gastric injury in rats (Szylenyi et al. 1983; Domschke et al. 1986; Hollander et al. 1986; Konturek et al. 1989, 1992; DiJoseph et al. 1989; Vergin and Kori-Lindner 1990). Konturek (1993) reported that aluminum hydroxide containing antacids protect growth factors, involved in the healing of ulcers, against acid degradation.

J.3.6 Inhibition of HCl secretion

J.3.6.1 Anticholinergic activity

J.3.6.1.1 General considerations

Gastric motility and tonus, as well as gastric secretion are stimulated by cholinergic impulses. Anticholinergic compounds, such as the *Belladonna* alkaloid atropine, were the first drugs used in treatment of gastric ulcers. The doses that are necessary to reduce acid secretion also decrease mucus secretion and cause side effects, such as dry mouth, increase in heart rate and ocular disturbances. Inhibitors of specific muscarinic receptors responsible for gastric acid secretion were found. Receptors for acetylcholine which play a major role in central and peripheral transmission have been studied extensively (Karlin et al. 1976; Hulme et al. 1990; Jones et al. 1992; Kebabian and Neumeyer 1994).

J.3.6.1.2 Acetylcholine receptor binding

PURPOSE AND RATIONALE

The search of specific muscarinic antagonists for inhibition of gastric acid secretion lead to the discovery of pirenzepine, a tricyclic compound, originally tested as psychotropic agent. This compound has a greater gastrointestinal selectivity than other muscarinic antagonists (Carmine and Brogden 1985; Longdong 1986). The activity of pirenzepine has been localized to M_1 receptors.

This, and the involvement of acetylcholine in many physiological processes, has stimulated the research on the various types of muscarinic receptors. At present, 5 types have been described but further subdivisions can be envisaged (Hulme et al. 1990; Jones et al. 1992; Kebabian and Neumeyer 1994; Alexander et al. 2001). The subtypes of muscarinic receptors have been characterized by the use of organs with a predominant subtype receptor population, e.g., rabbit vas deferens stimulated with electric impulses for M_1, electrically stimulated left atria from guinea pigs for M_2, and longitudinal smooth muscle preparations of guinea pig ileum or salivary gland of the rat for M_3 (Doods et al. 1987; Lambrecht et al. 1993), or by the use of selective antagonists (Pitschner et al. 1989; Richards 1990; Svensson et al. 1992,) or agonists (Lambrecht et al. 1993). Further characterization has been achieved by studies of the transduction mechanisms (Brown and Brown 1984; Brown et al. 1985; Parekh and Brading 1992) and by voltage clamp techniques (Bernheim et al. 1992). The genes for the muscarinic acetylcholine receptor subtypes have been cloned and expressed in Chinese ovary hamster cells (Buckley et al. 1989; Dörje et al. 1991) or in fibroblasts (Kashihara et al. 1992).

Many organs, e.g., rat brain (Luthin and Wolfe 1984; El-Fakahani et al. 1986) have been used for studies on acetylcholine receptor subtypes. Only the method using Chinese ovary hamster cells is presented here.

PROCEDURE

Preparation of plasmid DNA

The coding sequences of the m1, m2, m3, m4, and m5 receptors are derived from a human genom library. The cDNAs are inserted into the Okayama/Berg pCD or pCD-PS expression vector (Bonner et al. 1987, 1988; Buckley et al. 1989). Plasmid DNA is isolated by two sequential density gradient centrifugations through CsCl (Maniatis et al. 1982).

Cell culture

Chinese hamster ovary cells are incubated at 37 °C in a humidified atmosphere (5% CO_2) as a monolayer cul-

ture in Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum, 100 units/ml each of penicillin G and streptomycin, and 4 mM glutamine.

Transfection procedures

Cells are transfected using a modified calcium phosphate procedure (Chen and Okayama 1987) involving the use of cotransfected pcDneo as a selectable marker. Selection with the neomycin analog G 418 (600 µg/ml; Gibco NY) is started 72 h after transfection and cont-in-ued for 2–3 weeks. Media are changed every 3 days. Clonal cell lines are obtained by single cell cloning and assayed for [^{3}H]NMS (N-methylscopolamine hydrochloride) binding capacity.

Membrane preparation

Cells are grown to about 80% confluency, scraped into ice-cold binding buffer and homogenized for 30 s using a Brinkman homogenizer (setting 5). Membranes are pelleted at 16 000 *g* for 15 min and re-homogenized. Membrane protein is determined using a Bio-Rad protein assay dye reagent. Membranes are stored frozen at –80 °C before use.

Radioligand binding studies

All membranes, drugs, and radioligands are made up in binding buffer consisting of 25 mM sodium phosphate (pH 7.4) containing 5 mM magnesium chloride. The assays are performed in 1 ml total volume. Final membrane concentrations are: m1 6 µg/ml; m2 10 µg/ml; m3 5 µg/ml; m4 3 µg/ml; and m5 4 µg/ml. In [^{3}H]NMS saturation experiments, 8–10 different concentrations of the radioligand (2–1 400 pM) are employed. For displacement experiments, [^{3}H]NMS in a concentration of 150 pM and 10 different concentrations of the displacer are used. Specific binding is defined as the difference in [^{3}H]NMS binding in the absence and presence of 1 µM atropine. Alternatively [^{3}H]pirenzepine is used. Incubations are carried out at 22 °C for 3 h. Assays are terminated by filtration through a Brandell cell harvester onto Whatman GF/C filters. Membranes are washed three times with 5 ml of ice-cold binding buffer before being dried. They are transferred to 10 ml of scintillant (New England Nuclear Aquasol) and counted in a LKB β-counter.

EVALUATION

Data from direct binding experiments are fitted to the equation:

$$\alpha = (B_{max}\, x^n / k) / (1 + x^n / k)$$

to derive the Hill coefficient n and to:

$$\alpha = (B_{max}\, x / K_D) / (1 + x / K_D)$$

to obtain the dissociation constant K_D and the total number of binding sites B_{max} (α = [^{3}H]NMS specifically bound; x = [^{3}H]NMS concentration).

Data from displacement experiments are fitted to the equation:

$$\%\ [^3\text{H}]\text{NMS bound} = 100 - [100\, x^n / k / (1 + x^n / k)]$$

to obtain the Hill number n and to:

$$\%\ [^3\text{H}]\text{NMS bound} = 100 - [100 \times IC_{50} / (1 + x / IC_{50})]$$

to derive the IC_{50} value (x = concentration of the cold inhibitor).

K_i values are calculated by the method of Cheng and Prussoff (1973):

$$K_i = IC_{50} / (1 + L / K_D)$$

where L is the concentration of the radioligand, IC_{50} is the concentration causing 50% inhibition of the specific radioligand binding and K_D the dissociation constant of the radioligand receptor complex. Data are analyzed by a non-linear least-squares curve fitting procedure.

Results are expressed as mean values ±SEM of n experiments. Statistical significance is assessed using Student's *t*-test or Scheffé's method. $P < 0.05$ is accepted as being significant.

MODIFICATIONS OF THE METHOD

The selectivity towards muscarinic receptor subtypes can be tested by radioligand binding assays using either selective ligands or tissues possessing only one receptor subtype (Giachetti et al. 1986; Pitschner et al. 1989; Bickel et al. 1990). M_1-receptors from bovine cortex which has also M_2-and M_3-receptors are tested with the M_1-selective radioligand ^{3}H-pirenzepine. M_2-receptor from porcine heart possessing only this receptor type can be tested with the unselective ligand ^{3}H-N-methylscopolamine. M_3-receptors from rat submaxillary gland are likewise labelled with the unselective ligand ^{3}H-N-methylscopolamine, because this subtype is present predominantly in this tissue.

Measurement of the contractions of rabbit vas deferens after electrical stimulation was used to study the effects of prejunctional M_1 heteroreceptors and postjunctional M_2 receptors (Eltze et al. 1988; Dörje et al. 1991), of guinea pig atria for M_2-receptors and of guinea-pig ileum for M_3-receptors (Lambrecht et al. 1989, 1995). Cardiac muscarinic $M_{2\alpha}$ receptors have been discussed (Wess et al. 1988).

Coexistence of M_2 and M_3 subtypes of muscarinic receptors in canine colonic circular smooth muscle was reported by Zhang et al. (1991).

Investigations on the nature of muscarinic receptors present on parietal cell membranes using binding studies and polymerase chain reaction amplification or parietal cell messenger RNA revealed the existence of only a M_3 receptor responsible for acid secretion (Kajimura et al. 1992).

The phenotypes of knockout mice or the responses lost in these animals were used to characterize the properties of the subtypes of muscarinic receptors (Birdsall et al. 2001).

Owicki et al. (1990, 1992), McConnell et al. (1991, 1992) used a special apparatus, the 'cytosensor microphysiometer' which measures the rate of proton excretion from cultured cells. Chinese hamster ovary cells were transfected with the m_1 muscarinic acetylcholine receptor. Sequential addition of increasing doses of carbachol every 2.5 min induced an increasing acidification allowing the determination of an EC_{50} value. The effect was antagonized by atropine.

J.3.6.2 H_2-antagonism

J.3.6.2.1 General considerations

Three classes of histamine receptors with subtypes for the H_3 receptor have been identified by selective antagonists (Haaksma et al. 1990; Hill 1990; West et al. 1990; Clapham and Kilpatrick 1992). H_2-antagonists inhibit competitively the interaction of histamine with H_2-receptors responsible for acid secretion in the stomach. Although H_2-receptors are present in many tissues, including vascular and bronchial smooth muscle and the right atrium, H_2-antagonists interfere remarkably little with physiological functions other than gastric secretion.

The H_2 receptor was reported to be spontaneously active in transfected CHO cells (Smit et al. 1996). Based on this concept, the H_2 antagonists were reclassified; cimetidine, ranitidine and famotidine are in fact inverse agonists, whereas burimamide acts in this model system as a neutral agonist.

J.3.6.2.2 Histamine H_2-receptor binding

PURPOSE AND RATIONALE

Histamine H_2-receptor binding can be determined using homogenates from guinea pig cerebral cortex and ^{3}H-tiotidine as labeled ligand (Gajtkowski et al. 1983; Norris et al. 1984; Hill 1990). Using the polymerase chain reaction, the gene encoding the histamine H_2 receptor has been cloned (Gantz et al. 1991).

PROCEDURE

Preparation of membranes

Guinea pigs of either sex weighing 400–600 g are sacrificed by exsanguination and the brains rapidly removed. The cerebral cortex is dissected away from the rest of the brain and homogenized in 50 mM sodium-potassium buffer, pH 7.4, using a Potter homogenizer. The homogenate is then centrifuged at 50 000 *g* for 10 min at 4 °C. The resulting pellet is washed three times by being resuspended in phosphate buffer followed by recentrifugation. The pellet is finally resuspended in phosphate buffer, pH 7.4, at a protein concentration of 5 mg/ml.

Assay

An aliquot of 100 µl of the homogenate is incubated with 2 nM ^{3}H-tiotidine and varying concentrations of competing test substance, in triplicate, in a total volume of 250 µl, for 30 min at room temperature. The reaction is stopped by the addition of 2 ml of ice-cold phosphate buffer and immediately filtered under reduced pressure through Whatman GF/B glass-fiber filters, followed by 3 times 3 ml washes with room temperature buffer.

Radioactivity is determined by allowing the filters to remain for at least 18 h in NE 260 scintillator (Nuclear Enterprise), followed by liquid scintillation counting.

EVALUATION

K_i values (µM) are calculated for displacement of specific H_2-binding from the relationship

$$K_i = IC_{50} / (1 + [L]\, K_d^{-1})$$

where IC_{50} is the concentration of the drug required for 50% inhibition of specific binding, [L] is the concentration of ^{3}H-tiotidine in the assay and K_d is the dissociation constant for ^{3}H-tiotidine.

Data can be analyzed using a computer program as described by McPherson (1985).

MODIFICATIONS OF THE METHOD

Hirschfeld et al. (1992) performed photoaffinity labeling studies of the H_2 receptor using the radioactive probes [^{125}I]iodoaminopotentidine and its photolabile azido analogue [^{125}I]iodoazidopotentidine.

Martinez-Mir et al. (1990) studied the distribution of histamine H_1, H_2, and H_3 receptors in postmortem human and rhesus monkey brain by receptor autoradiography using [^{125}I]iodobolpyramine, [^{125}I]iodoaminopotentine, and [^{3}H](R)α-methylhistamine as ligands to label H_1, H_2, and H_3 receptors, respectively.

Traiffort et al. (1992) used [^{125}I]iodoaminopotentidine for pharmacological characterization and autoradiographic localization of histamine H_2 receptors in human brain.

J.3.6.2.3 H_2-antagonism in isolated guinea pig right atria

PURPOSE AND RATIONALE

H_2-antagonism can be determined in isolated guinea pig right atria which contain predominantly H_2-receptors. Compounds that inhibit the positive chronotropic effect mediated by histamine H_2-receptors in the isolated right guinea pig atrium (Reinhardt et al. 1974) can be classified as specific histamine H_2-antagonists. The test can be used as screening method for H_2-antagonists.

PROCEDURE

Male guinea pigs, e.g., Hartley strain, are sacrificed by exsanguination. The right atria are dissected and suspended at 0.7 g tension in a 25 ml organ bath with Tyrode's solution bubbled with carbogen (5% CO_2/95% O_2) at 38 °C. After a stabilization period of 30 min, the contractions are recorded on a polygraph with a force-displacement transducer through a strain gauge. Cumulative concentration-response curves are obtained after sequential additions of histamine (10^{-7} to 10^{-4} M) in the absence of test drugs and the equilibration of test drugs or the standard (cimetidine).

EVALUATION

pA_2 values and relative potencies are calculated by a Schild plot (Arunlakshana and Schild 1959).

MODIFICATIONS OF THE METHOD

Hattori et al. (1990) studied the inotropic, electrophysiological and biochemical responses to histamine in rabbit papillary muscles and found evidence for coexistence of H_1- and H_2-receptors. Histamine increases force of contraction and decreases action potential duration in rabbit papillary muscles. H_2-antagonists antagonize the histamine-induced decrease in action potential duration, however, are less effective in antagonizing the increase in force of contraction produced by histamine. The positive inotropic response to histamine is abolished by sequential addition of a H_1-antagonist.

J.3.6.2.4 H_2-antagonism in isolated rat uterus

PURPOSE AND RATIONALE

Histamine inhibits spontaneous and electrically stimulated contractions of rat uterus horns. This effect can be antagonized by H_2-, but not by H_1-antagonists.

PROCEDURE

Adult, virgin Wistar rats weighing 180–200 g are used. By microscopic examination of vaginal smears, the stage of the estrus cycle is determined. Only animals in natural proestrus or metestrus are chosen. After sacrifice, the two uterus horns are removed and placed in modified de Jalon solution at room temperature and cleaned of mesenteric fat and connective tissue. Paired preparations from the same animal are used in parallel experiments. Two segments, about 2 cm in length, are taken from the ovarian end of the uterus horns and mounted separately on Perspex organ holders between two steel electrodes arranged at the end of the muscle. The organs are immediately superfused with modified de Jalon solution at 35 °C at a rate of 2–3 ml/min being continuously gassed with air. Basal muscle tension is maintained at 0.5 g. The contractions of the preparations are recorded isometrically with a force-displacement transducer linked to a multipen recorder. The intrinsic rhythm of spontaneous and regular contractions appears within 5–10 min after mounting the tissues in their holders.

Organs showing a frequency of only one contraction every two min or less are electrically stimulated with square wave impulses of 2 ms duration for 1 s every 1 min at 10 V and 80 Hz with a suitable stimulator. The organs are linked via a four-way stopcock to a set of reservoirs of modified de Jalon solution containing different concentrations of agonist and test substance. The preparations are superfused for 20–30 min with nutrient solution until mechanical activity of the uterus horns is stabilized in frequency and contraction height before addition of drugs.

The time interval between application of drugs is 15–20 min, the time of contact of the drugs with the uterus segments is about 4–5 min, being interrupted as soon as the contractions of the muscles reach a minimum. Logarithmic dose-response curves for histamine are constructed from mean effects of single doses, taking the average amplitude of 5 contractions immediately preceding the addition of histamine as 100% control activity. In experiments involving antagonists, a standard dose of histamine is used giving a response within the linear region of the log dose-response curve and is set as 100%. Reduction of histamine-induced inhibition is studied by superfusing increasing concentrations of antagonists in addition to the standard dose of histamine.

EVALUATION

Results are expressed in percentage of the reversal of initial depression of contraction height after histamine and plotted against –log mol/l concentration of the antagonist. pA_2 values are calculated according to Ariëns and van Rossum (1957).

J.3.6.2.5 Activity at histamine H_1- and H_2-receptors *in vivo*

PURPOSE AND RATIONALE

Owen and Pipkin (1985) described a technique that allows simultaneous and quantitative assay of the action of agonists and antagonists at histamine H_1- and H_2-receptors in anesthetized guinea pigs. The principle of the technique is based on H_1-receptor caused bronchoconstriction and H_2-receptor caused tachycardia.

PROCEDURE

Guinea pigs of either sex weighing about 500 g are anesthetized with 90 m/kg sodium pentobarbitone i.p. The trachea is cannulated to permit artificial respiration. Blood pressure is measured from a catheter tied into one carotid artery. Catheters are tied into one jugular and one femoral vein for the administration of drugs.

Airways resistance is measured using a modification of the Konzett-Rössler technique. By means of a small animal respiration pump, the lungs are inflated at a rate of 40 breaths/min. The inflow arm of the circuit includes a side-arm, the outlet of which is placed below 12 cm of H_2O. The volume of air used in the study has to be that which fills the lungs at a pressure of 12 cm H_2O, selected by adjusting the volume until no air escapes through the H_2O trap each time the lungs are filled. The side-arm is then clamped, and the animal is respired with the selected volume for the duration of the study. Airways resistance to inflow is measured using a pressure transducer connected to a second arm of the inflow circuit. Resistance is proportional to the maximum pressure required to inflate the lungs. Inflow pressure is registered on an electronic recorder.

Heart rate is measured from the blood pressure pulse using an instantaneous rate meter and is registered on an electronic recorder.

Intravenous injection of histamine causes simultaneously bronchoconstriction and tachycardia. The threshold dose needed to cause tachycardia may be less than that for bronchoconstriction, but both responses will be apparent over the dose range 1×10^{-8} to 5×10^{-7} mol/kg.

EVALUATION

Agonists

Dose-response curves for agonists compared to the dose-response curve for histamine for both parameters, bronchoconstriction and tachycardia, allow the calculation of potency ratios. Specific H_1-receptor agonists are more potent to cause bronchoconstriction than tachycardia, whereas H_2-agonists provoke tachycardia but are less active or inactive causing bronchoconstriction.

Antagonists

To evaluate antagonists, various doses of the test compound are injected i.v. and dose-response curves of histamine are established for both parameters to be compared with the dose-response curve of histamine without pretreatment. From the ratios of shift to the right dose-response curves for both parameters can be established. These are similar for mixed antagonists, but a definitively higher potency is shown for H_1-antagonists in bronchoconstriction and a higher potency for H_2-antagonists in tachycardia.

J.3.6.2.6 Inhibition of histamine stimulated adenylate cyclase from gastric mucosa

PURPOSE AND RATIONALE

The *in vitro* potencies of H_2-antagonists can be evaluated using determinations of adenylate cyclase activity in membrane preparations of guinea pig mucosa after stimulation with histamine.

PROCEDURE

Preparation of membranes

Guinea pigs of either sex weighing 400–600 g are sacrificed. The fundic portion of the stomach is rapidly removed. Food particles are washed away with ice-cold 50 mM Tris buffer, pH 7.4, containing 4 mM EDTA and 0.25 M sucrose (homogenization buffer). The tissue is stretched, mucosal side up, on a glass Petri dish supported on ice and the mucosal layer is scraped off the muscle layer using a scalpel blade. The mucosal scrapings are transferred to 10 ml ice-cold homogenization buffer in a glass homogenization tube, and homogenized using an Ultra-Turrax® homogenizer followed by four strokes using a Potter Teflon homogenizer. The resulting suspension is centrifuged at 700 *g* for 10 min at 4 °C. The supernatant is discarded, and the pellet resuspended in 50 mM Tris buffer, pH 7.4, containing 4 mM EDTA followed by a further period of centrifugation. The resulting pellet is finally resuspended in Tris/EDTA buffer at a protein concentration of 2.4 mg/ml as determined by the method of Lowry et al. (1951) using bovine serum albumin as standard.

Stimulation of adenylate cyclase

Adenylate cyclase activity is measured according to Hegstrand et al. (1976). Aliquots (120 µg) of fundic mucosal homogenate are incubated in 100 mM Tris buffer, pH 7.8, containing 0.6 mM EGTA (ethylene-glycol-bis-(β-aminoethyl ether)-N,N'-tetra-acetic acid), 1 mM IBMX (isobutyl-methyl xanthine), 2 mM $MgCl_2$, 0.1 mM GPT (guanosine triphosphate), histamine at various concentrations between 0.1 µM and 100 µM and the compound under investigation at varying concentrations between 0.1 µM and 1 mM for 10 min at 0 °C. The reaction is initiated by the addition of 1 mM ATP followed by a 10 min incubation at 30 °C. The reaction is terminated by placing the assay tubes in a boiling water bath for 3 min. After cooling, 40 mg of Alumina 90 (E. Merck, 70–230 mesh) are added to each tube prior to mixing and centrifugation at 700 *g* for 15 min at 4 °C.

Assay of cyclic AMP

The cyclic AMP content of each sample is determined according to Brown et al. (1971) using ^{3}H-cyclic AMP in a competitive protein binding assay. Fifty µl aliquots from the adenylate cyclase assay are incubated with 50 µl of ^{3}H-cyclic AMP (14 nC at a specific activity of 62 Ci/mmol) and 100 µl of previously prepared cyclic AMP binding protein at 4 °C. The bound and free ^{3}H-cyclic AMP are separated by the addition of 100 µl of charcoal reagent (2 g bovine serum albumin, 2.5 g Norit GSX charcoal in 100 ml of 50 mM Tris buffer, pH 7.4, containing 4 mM EDTA), followed by mixing and centrifugation at 1000 *g* for 15 min. Two hundred µl aliquots of the supernatant are decanted into scintillation vials containing 10 ml of NE 260 scintillator. Radioactivity is determined by liquid scintillation counting.

EVALUATION

Results are calculated from a standard curve using cyclic AMP as the standard. From these data IC_{50} values (µM) are derived.

J.3.6.3 H^+/K^+-ATPase (proton pump) inhibition

J.3.6.3.1 General considerations

The parietal cell of the stomach is activated by three major stimuli: histamine, acetylcholine, and gastrin. In addition to the direct action of gastrin and acetylcholine on the parietal cell, these two agents may release histamine from a histamine storage in the gastric mucosa. In this manner, histamine would act as the final

mediator of acid secretion. One of the first events leading to acid secretion is a massive membrane transformation that occurs in the parietal cell. When the cell is stimulated, the tubulovesicles in the cytoplasma of the cell fuse and form an expanded secretory cannaliculus in the apical membrane where the enzyme H^+/K^+-ATPase is located.

In this way, the ultimate mediator of acid secretion in the stomach is the proton pump H^+/K^+-ATPase which transports hydrogen in exchange for potassium. The rat stomach H^+/K^+-ATPase has been cloned by Shull and Lingrel (1986). Development of specific inhibitors of this enzyme is an approach to suppress acid secretion and ulcer formation since ulcers only exist in acidic medium.

Alderuccio et al. (1993) described an experimental autoimmune gastritis in BALB/c mice as a $CD4^+$ T cell-mediated organ-specific autoimmune disease induced by neonatal thymectomy. Transgenic expression of the gastric H^+/K^+-ATPase β subunit specifically prevented the onset of this form of autoimmune gastritis.

J.3.6.3.2 H^+/K^+-ATPase inhibition in membrane vesicles of stomach mucosa

PURPOSE AND RATIONALE

Several H^+/K^+-ATPase inhibitors contain a sulfhydryl group. At lower pH-values the compounds are protinated and rearrange to a sulphenic acid and a sulphenamide, that react with sulfhydryl groups in the enzyme. Therefore, the *in vitro* assays are performed both at neutral and at acidic pH levels.

PROCEDURE

Membrane vesicles containing H^+/K^+-ATPase are prepared from pig stomachs obtained from the local slaughter house (Ljungstrom et al. 1984). Pigs are fasted overnight before slaughter. The gastric mucosa of four stomachs is rinsed with cold saturated NaCl solution for 3–5 min. The superficial cells, cell debris plus the mucus are wiped off with the edge of a plastic ruler and with paper towels. The mucosa is scraped off. About 100 g scrapings are divided into portions of 10 g and homogenized in 0.25 M sucrose with seven strokes in a Potter-Elvehjem Teflon-glass homogenizer. The total volume is 600 ml which is centrifuged at 20 000 *g* for 40 min. The pellet is discarded. The supernatant is centrifuged at 75 000 *g* for 1 h. The resulting microsomal pellet is homogenized in 30 ml 0.25 M sucrose.

Aliquots of 15 ml are transferred to 100 ml centrifuge tubes and layered on top of step gradients, from the bottom comprising 25 ml 37% sucrose (w/v) and 45 ml 7.5% Ficoll (w/v) in 0.25 M sucrose. The tubes are centrifuged at 75 000 *g* for 1 h in a 6×100 ml ME angle rotor at 4 °C. The gradient is then fractionated by pumping Fluoroinert 70 through a narrow tubing in a fractionating cap down to the bottom of the tube. Fractions are collected from top through a center hole in the fractionating cap. The yield of vesicles in a typical preparation is about 50–75 mg protein. In order to maintain a stable vesicular structure for a long period of time, the vesicles are frozen at –70 °C under nitrogen. They can then be kept for several months without decrease of H^+/K^+-ATPase activity.

The ATPase activity is measured at 37 °C as the release of inorganic phosphate (P_i) from ATP. The test drug and the standard (omeprazole) are pre-incubated in concentrations of 0.01 to 100.0 µM in enzyme containing buffers in parallel at pH 6.0 and 7.4 for 30 min at 37 °C. Then, the medium of pH 6.0 is adjusted with HEPES/Tris buffer to pH 7.4. The enzyme reaction is started by addition of nigericin and Tris/ATP. The total reaction volume is 1 ml, containing 20 µg vesicular protein, 4 mM $MgCl_2$, 10 mM KCl, 20 µM nigericin, 2 mM Tris-ATP, 10 mM HEPES and additionally 2 mM Pipes for the pre-incubation medium at pH 6.0.

After 4 min at 37 °C, the reaction is stopped by the addition of 10 ml of 50% trichloroacetic acid. The denaturated protein is spun down and the P_i content is determined according to LeBel et al. (1978) based on the reduction of a phosphomolybdate complex by p-methyl-aminophenol sulfate in a copper acetate buffer or according to Carter and Karl (1982) based on the reaction of phosphomolybdate with the basic dye malachite green.

EVALUATION

IC_{50} values are calculated by probit analysis, whereby 0% corresponds to 4 mM Mg^{2+}-dependent and 100% to 4 mM Mg^{2+} plus 10 mM K^+-dependent ATP hydrolysis. IC_{50} values of the test compound at different pH values are compared with IC_{50} values of the standard. Statistical differences ($p < 0.05$) are calculated by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Proton transport in gastric vesicles can be measured by acridine orange fluorescence quenching (Lee and Forte 1978; Beil et al. 1990). Membrane protein (0.12 mg) is incubated at 37 °C in a volume of 2 ml containing: 10 mM Pipes/Tris buffer, pH 7.0 in the presence of 150 mM KCl, 2 mM $MgCl_2$, 2 mM ATP and 10 µM acridine orange. The pump reaction is started by the addition of valinomycine (ionophore for K^+). The decrease of fluorescence is studied at 530 mm as a measure for the intravesicular proton uptake.

CRITICAL ASSESSMENT OF THE METHOD

The pre-incubation period at the lowest possible pH of about 6 is used to initiate the acidic conversion of the test compound into its active principle. This reflects more the chemical instability of the test compound at neutral pH values than its effect during conditions of much higher acidity within the secretory cannaliculus of the parietal cell during acid secretion. Many chemically labile inhibitors are therefore very active in this test system. However, they do not cause an inhibition in more complex test systems and, therefore, are without any practical usefulness (Lindberg et al. 1990). Proton transport studies in gastric vesicles, using the acridine orange fluorescence quenching technique, where a pH gradient similar to *in vivo* conditions is formed (Lee and Forte 1978; Beil et al. 1990) are more suitable for studying the mechanism of action, acid-conversion, and structure-activity relationship of K^+/H^+-ATPase inhibitors (Herling and Weidmann 1994).

J.3.6.3.3 Effect of H^+/K^+-ATPase inhibitors on serum gastrin levels

PURPOSE AND RATIONALE

It is known from the H^+/K^+-ATPase inhibitor omeprazole that the total acid blockade initiates a gastric antral feed back mechanism resulting in an excessive hypergastrinaemia (Arnold et al. 1986; Creutzfeldt et al. 1986; Larsson et al. 1986) which is believed to cause diffuse endocrine cell hyperplasia, characterized as carcinoids, in the gastric corpus after 2 years of treatment in the rat (Ekman et al. 1985).

PROCEDURE

Groups of 10–15 female Wistar rats weighing 90–110 g are treated daily for 10 weeks with omeprazole (10 or 30 mg/kg p.o.) or the test compound or serve as controls. The compounds are suspended in potato starch mucilage (20 mg/ml) and administered in a volume of 2 ml/kg. On days 1–3, the rats receive the H^+/K^+-ATPase inhibitors by intraperitoneal injection in order to cause gastric acid inhibition and therefore to reduce the gastric acid degradation of subsequent oral doses. After treatment for 2, 4, 7, and 10 weeks, blood samples are collected under ether anesthesia by retroorbital puncture. Gastrin is determined by radioimmunoassay using a commercially available kit, e.g. Gastrin RIAKit II; Dainabot Co., Ltd. At the end of the study

of 10 weeks, the animals are studied for their gastric acid output using the pylorus ligation (Shay technique).

EVALUATION

Serum gastrin levels are determined as pg/ml. Statistical differences ($p < 0.05$) are calculated using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Katz et al. (1987) described a five-day test to predict the long-term effects of gastric antisecretory agents on serum gastrin in rats.

J.3.6.3.4 (^{14}C)-aminopyrine uptake and oxygen consumption in isolated rabbit gastric glands

PURPOSE AND RATIONALE

Isolated gastric glands from rabbits and other species can be used in studying the control of mechanism of gastric H^+ secretion (Berglindh and Öbrink 1967; Berglindh et al. 1967; Sack and Spenny 1982; Sewing et al. 1983; Herling et al. 1987, 1988, 1990). In isolated gastric glands and parietal cells, H^+ secretion cannot be directly measured by titration; therefore, accumulation of weak bases such as aminopyrine is used as an indirect probe of H^+ secretion. Moreover, glandular oxygen consumption can be measured with the Warburg technique.

PROCEDURE

Preparation of gastric glands

Rabbits are anesthetized with 40 mg/kg pentobarbital i.v. The abdomen is opened and the aorta is cannulated in a retrograde direction. Five ml of a heparin solution (250 IU/ml) are injected with force through the cannula. After one min the rabbit is bled through the cannula and a ligature is placed around the mesenteric vessels. The chest is quickly opened and the thoracic aorta clamped. Phosphate buffered saline solution (containing 149.6 mM NaCl, 3 mM K_2HPO_4, 0.64 mM NaH_2PO_4, pH 7.3) at 37 °C is pumped through the aorta, whereby the portal vein is opened to allow free outflow of the perfusate. By this procedure most of the solution is forced through the mesenteric vessels. The perfusion pressure, as measured proximal to the cannula, can be up to 600 mm Hg.

The stomach appears totally exsanguinated after perfusion with about 500 ml phosphate buffered saline solution and is then removed, cut open along the lesser curvature, and emptied. The cardial and antral regions are discarded. The corpus is rinsed several times with phosphate buffer solution and finally blotted with filter paper, whereby the remaining gastric content as well as some surface epithelial cells are removed. By blunt dissection the mucosa can easily be separated from the muscular and submuscular layers.

The mucosa is then minced into small pieces with a pair of scissors. The pieces are washed twice in warm oxygenated phosphate buffer solution and transferred to a 200 ml flask with 50 ml of a freshly prepared collagenase-enzyme solution containing 1 mg/ml collagenase (type I, Sigma), 1 mg/ml rabbit albumin (Sigma), 2 mg/ ml glucose in 130 mM NaCl, 10 mM $NaHCO_3$, 3 mM NaH_2PO_4, 3 mM Na_2HPO_4, 3 mM K_2HPO_4, 2 mM $MgSO_4$, 1 mM $CaCl_2$, and 10 mg/L phenol-red at pH 7.4. The flask is gassed with 100% oxygen, sealed, and kept in a 37 °C water bath under gently stirring with a magnet for 90 min. The cloudy suspension containing the separated glands and some cells is filtered through a nylon mesh into 15 ml test tubes with conical bottoms. The glands rapidly sediment to the bottom while the free cells remain in the solution. In this way centrifugation can be avoided and the glands can easily be washed free from isolated cells and collagenase by three washings with phosphate buffer at room temperature.

^{14}C-aminopyrine accumulation in gastric glands

The ability of gastric glands to form acid is measured based on aminopyrine accumulation. The glands are diluted to a final concentration of 2–4 mg dry weight/ml in a medium containing 100.0 mM NaCl, 5.0 mM KCl, 0.5 mM NaH_2PO_4, 1 mM Na_2HPO_4, 1.0 mM $CaCl_2$, 1.5 mM $MgCl_2$, 20.0 mM $NaHCO_3$, 20.0 mM HEPES, 2 g/ml glucose, 1 mg/ml rabbit albumin, adjusted with 1 M Tris to pH 7.4. Samples of 1 ml gland suspension are equilibrated in 1 ml medium containing 0.1 µCi/ml [^{14}C]aminopyrine at 37 °C in a shaking water bath to-

gether with the agent to be tested. After 20 min either histamine or dibutyryl-cyclic-AMP is added, followed by a 30 min incubation period for histamine and a 45 min incubation period for dibutyryl-cyclo-AMP.

The glands are then separated from the medium by brief centrifugation. The supernatant is withdrawn, the pellets are dried at 80 °C for 50 min, weighed and dissolved in 200 µl 1 M NaOH. Aliquots of the supernatant and the digested gland pellet are examined in a liquid scintillation counter. The ratio of intraglandular to extraglandular radioactivity is calculated. All determinations are made in triplicate.

Respiratory studies

Glandular oxygen consumption is measured at 37 °C using a Warburg respirometer and air as the gas phase. The 15 ml flasks with a central well 20% containing KOH solution on a filter paper as CO_2 adsorber are filled with 1 ml medium containing 100.0 mM NaCl, 5.0 mM KCl, 0.5 mM NaH_2PO_4, 1 mM Na_2HPO_4, 1.0 mM $CaCl_2$, 1.5 mM $MgCl_2$, 20.0 mM $NaHCO_3$, 20.0 mM HEPES, 2 g/ml glucose, 1 mg/ml rabbit albumin, adjusted with 1 M Tris to pH 7.4 and 1 ml gland suspension. After 20 min equilibration, the test compound and dbcAMP are added and the oxygen consumption is measured at 15 min intervals for the following 45 min. The recorded oxygen consumption is corrected according to the following formula:

$$O_2 \text{ consumption} = O_2 \text{ recorded} \times K$$

where

- $K = 273 \times (Pb / t + 273) \times 760$
- t = ambient temperature in °C around the manometers
- Pb = Atmospheric pressure (mm Hg)

The respiratory activity is expressed in µl O_2 consumed per mg dry weight and time.

EVALUATION

IC_{50} values are calculated by probit analysis. Statistical differences ($P < 0.05$) are assessed by Student's t-test, n = the number of different gland preparations.

CRITICAL ASSESSMENT OF THE METHOD

Studies on (^{14}C)-aminopyrine uptake and oxygen consumption in isolated rabbit gastric glands have become a valuable approach for studying the effect of various H_2-receptor antagonists and proton pump inhibitors. When studying gastric acid production with the ^{14}C-AP accumulation technique, the addition of basic drugs can be problematic (Fryklund and Wallmark 1986). The basic nature of a test compound can compete with accumulation of ^{14}C-AP. Nevertheless, it is generally accepted that oxygen consumption of gastric glands correlates well with acid formation (Berglindh et al. 1976).

MODIFICATIONS OF THE METHOD

Soll (1978) studied the actions of secretagogues on oxygen uptake by isolated mammalian parietal cells. Parietal cells were prepared from the stomach of dogs by collagenase digestion and counterflow centrifugation. Oxygen consumption was determined by polarography. Isobutyl methyl xanthine (IMX), carbamylcholine, histamine, and gastrin each independently stimulated oxygen uptake. The specificity of these responses was tested by use of an H_2-histamine receptor antagonist or atropine as anticholinergic agent.

Stoll (1980) investigated the [^{14}C]aminopyrine accumulation in isolated *canine* parietal cells when treated with histamine, gastrin and carbachol and the displacement by cimetidine or atropine.

Sewing et al. (1983, 1986) studied the effect of several benzimidazole derivatives on isolated and enriched guinea pig parietal cells using the ^{14}C-aminopyrine accumulation.

Schepp et al. (1994) determined the effects of exendin-4, a peptide from *Heloderma suspectum venom*, and exendin-(9-39)NH_2 on [^{14}C]aminopyrine accumulation in isolated rat parietal cells and compared these with those of glucagon-like peptide-1-(7-36)NH_2.

J.3.6.3.5 Gastric mucosal blood flow

PURPOSE AND RATIONALE

Hydrogen gas clearance has been used to measure blood flow in the basal portion of gastric mucosa in anesthetized rats (Leung et al. 1984, 1986; Pique et al. 1988).

PROCEDURE

Male Sprague Dawley rats are anesthetized with 1.5 g/kg of urethane subcutaneously. A tracheotomy is performed and a PE-250 tubing is inserted into the trachea to facilitate spontaneous breathing and for administration of 3% hydrogen in air. The right carotid artery is cannulated for blood pressure monitoring. A midline laparatomy is then performed and the stomach exteriorized. Through an incision in the forestomach the gastric contents are gently washed out with physiological saline. A double-lumen cannula (outer: Tygon with a diameter of 7 mm; inner: polyethylene with a diameter of 2 mm) are inserted into the stomach and secured by a ligature at the forestomach. The pylorus is ligated and a 0.9% sodium chloride solution is infused through the inner cannula at a rate of 0.8 ml/min and drained from the outer tubing. The gastric effluent is collected at 15-min intervals. Acid output (in micro-equivalents per min) is determined in the perfusate with 0.2 N NaOH with an automatic titrator.

An incision in the serosa and the muscularis externa is made in the gastric wall of the corpus, exposing 3–4 mm of the submucosa. Through this hole a platinum electrode is placed in contact with the exposed basal portion of the mucosa. The electrode is made with a ring of platinum wire, 125 µm in diameter, wound around a glass capillary tube and held in place inside a Teflon tube by epoxy. A Ag-AgCl reference electrode is placed inside the peritoneal cavity. The laparatomy incision is covered by Parafilm to minimize evaporation.

One femoral vein is cannulated for the infusion of saline or drugs. The rat is kept warm with a heat lamp to maintain rectal temperature at 37 °C.

Hydrogen gas clearance technique

Current is generated at the surface of a platinum electrode by oxidation of molecular hydrogen to hydrogen ions and electrons. This current, which is measured using a polarographic and amplifying unit, is proportional to the hydrogen tension gradient at the surface of the platinum electrode. When the experimental animal breathes 3% hydrogen in air, the current tracing, graphed on a recorder, gradually rises and reaches a plateau as the tissue adjacent to the electrode is saturated with hydrogen. After the external hydrogen source is removed, the current tracing gradually falls because of removal of tissue hydrogen by blood flow. The rate of dissipation of hydrogen estimates the tissue blood flow (Aukland et al. 1964).

The exponential decrease of the hydrogen gas clearing curves is evaluated by a computer program (Livingstone et al. 1986). Current from the platinum electrode is passed through an ADALAB analog-to-digital converter and discrete digitized values are sampled every 5 s. Blood flow is determined by an Newtonian-Gaussian nonlinear iterative regression program by means of a biexponential formula:

$$f(x) = A + B\, e^{-k1t(t-T)} + B\, e^{-k2t(t-T)},$$

where $f(x)$ is the electrode current, A is the baseline current, B is the initial current, e is the base of natural logarithms, k_1 is the rate constant for the fast component, k_2 is the rate constant for the slow component, t is the time at which the current is observed, and T is the time when hydrogen gas was removed.

Mucosal blood flow is expressed in milliliters per minute per 100 g of tissue.

Inhibition of acid secretion

Intravenous saline is infused during the first 45 min of the study. After this period, an infusion of 80 µg/kg·h of pentagastrin is administered for 135 min. During the last 75 min an intravenous infusion of the inhibitor or vehicle is administered simultaneously with pentagastrin. Corpus mucosal blood flow measurements are obtained during the resting period, 45 min after start for the pentagastrin infusion, and during the last 15 min of combined infusion of pentagastrin and inhibitor. Acid output is measured at 15 min intervals throughout the experiments.

EVALUATION

All data are expressed as mean ±standard error. The data are analyzed using a paired *t*-test for comparison

of basal versus stimulated condition within the same animal, analysis of variance with contrasts, and linear and polynomial regression analysis for comparison between animals in different groups. A probability level of $P < 0.05$ is considered significant.

MODIFICATION OF THE METHOD

The hydrogen gas clearance technique has been used by many authors in experimental gastroenterology, e.g.: Hirose et al. (1991), Holzer and Guth (1991), Lippe and Holzer (1992), Pique et al. (1992), Tsukamoto et al. (1992), Lazaratos et al. (1993), Petho et al. (1994), Tanaka and Guth (1994), Goldin et al. (1996), Hisanaga et al. (1996), Doi et al. (1998), Heinemann et al. (1999).

J.3.7 Anti-ulcer activity

J.3.7.1 Pylorus ligation in rats (SHAY rat)

PURPOSE AND RATIONALE

A simple and reliable method for production of gastric ulceration in the rat based on ligature of the pylorus has been published by Shay et al. (1945). The ulceration is caused by accumulation of acidic gastric juice in the stomach.

PROCEDURE

Female Wistar rats weighing 150–170 g are starved for 48 h having access to drinking water ad libitum. During this time they are housed single in cages with raised bottoms of wide wire mesh in order to avoid cannibalism and coprophagy. Ten animals are used per dose and as controls. Under ether anesthesia a midline abdominal incision is made. The pylorus is ligated, care being exercised that neither damage to the blood supply nor traction on the pylorus occurs. Grasping the stomach with instruments is to be meticulously avoided, else ulceration will invariably develop at such points. The abdominal wall is closed by sutures. The test compounds are given either orally by gavage or injected subcutaneously.

The animals are placed for 19 h in plastic cylinders with an inner diameter of 45 mm being closed on both ends by wire mesh. Afterwards, the animals are sacrificed in CO_2 anesthesia. The abdomen is opened and a ligature is placed around the esophagus close to the diaphragm. The stomach is removed, and the contents are drained in a centrifuge tube. Along the greater curvature the stomach is opened and pinned on a cork plate. The mucosa is examined with a stereomicro-

scope. In the rat, the upper two fifths of the stomach form the rumen with squamous epithelium and possess little protective mechanisms against the corrosive action of gastric juice. Below a limiting ridge, in the glandular portion of the stomach, the protective mechanisms are better in the mucosa of the medium two fifths of the stomach than in the lowest part, forming the antrum. Therefore, lesions occur mainly in the rumen and in the antrum. The number of ulcers is noted and the severity recorded with the following scores:

- 0 = no ulcer
- 1 = superficial ulcers
- 2 = deep ulcers
- 3 = perforation.

The volume of the gastric content is measured. After centrifugation, acidity is determined by titration with 0.1 n NaOH.

EVALUATION

An ulcer index U_I is calculated:

$$U_I = U_N + U_S + U_P \times 10^{-1}$$

- U_N= average of number of ulcers per animal
- U_S = average of severity score
- U_P = percentage of animals with ulcers

Ulcer index and acidity of the gastric content of treated animals are compared with controls. Using various doses, dose-response curves can be established for ulcer formation and gastric acid secretion. ID_{50} values can be calculated by probit analysis, whereby 0% corresponds to no and 100% to maximal stimulated gastric acid output.

CRITICAL ASSESSMENT OF THE METHOD

The "Shay-rat" has been proven to be a valuable tool to evaluate anti-ulcer drugs with various mechanisms of action.

J.3.7.2 Stress ulcer through immobilization stress

PURPOSE AND RATIONALE

Psychogenic factors, such as stress, play a major role in the pathogenesis of gastric ulcers in man. The first report of the use of restraint as stress factor was published by Selye (1936). Hanson and Brodie (1960) and Bonfils et al. (1966) described methods to study the effect of anti-ulcer drugs on immobilization stress in rats.

PROCEDURE

Groups of 10 female Wistar rats per dose of test drug and for controls weighing 150–170 g are used. Food and water are withdrawn 24 h before the experiment. After oral or subcutaneous administration of the test compound or the placebo solution the animals are slightly anesthetized with ether. Both lower and upper extremities are fixed together and the animals are wrapped in wire gaze. They are horizontally suspended in the dark at 20 °C for 24 h and finally sacrificed in CO_2 anesthesia. The stomach is removed, fixed on a cork plate and the number and severity of ulcers is registered with a stereo-microscope using the following scores:

- 0 = no ulcer
- 1 = superficial ulcers
- 2 = deep ulcers
- 3 = perforation

EVALUATION

An ulcer index U_I is calculated:

$$U_I = U_N + U_S + U_P \times 10^{-1}$$

- U_N = average of number of ulcers per animal
- U_S = average of severity score
- U_P = percentage of animals with ulcers

CRITICAL ASSESSMENT OF THE METHOD

The experimental model resembles the psychogenic factors in the pathogenesis of gastric ulcers in patients. Therefore, it is not surprising that not only antacids, anticholinergics, H_2-antagonists, proton-pump-inhibi-

tors, but also psychotropic drugs, like neuroleptics, have been found to be effective in this test. The test is being used in final drug evaluation only.

J.3.7.3 Stress ulcers by cold water immersion

PURPOSE AND RATIONALE

Cooling of rats in water during the restraint period accelerates the occurrence of gastric ulcers and shortens the time of necessary immobilization (Takagi et al. 1964; West 1982).

PROCEDURE

Groups of 8–10 Wistar rats weighing 150–200 g are used. After oral administration of the test compound, the rats are placed vertically in individual restraint cages in water at 22 °C for one hour. Then, they are removed, dried and injected intravenously via the tail vein with 30 mg/kg Evans blue. Ten min later, they are sacrificed in CO_2 anesthesia and their stomachs removed. Formol-saline (2% v/v) is then injected into the totally ligated stomachs for storage overnight. The next day, the stomachs are opened along the greatest curvature, washed in warm water, and examined under a 3-fold magnifier. The lengths of the longest diameters of the lesions are measured and summated to give a total lesion score (in mm) for each animal, the mean count for each group being calculated.

EVALUATION

The mean score in control rats is about 25 (range 20–28). Inhibition of the lesion production is expressed as percentage value.

CRITICAL ASSESSMENT OF THE METHOD

Like other stress models, the test resembling the psychogenic factor for ulcer disease in human beings, is used for final drug evaluation only.

J.3.7.4 Indomethacin induced ulcers in rats

PURPOSE AND RATIONALE

Nonsteroidal anti-inflammatory agents, like indomethacin and acetyl-salicylic acid, induce gastric lesions in man and in experimental animals by inhibition of gastric cyclo-oxygenase resulting in less formation of prostacyclin, the predominant prostanoid produced in the gastric mucosa.

PROCEDURE

Groups of 8–10 Wistar rats weighing 150–200 g are used. The test drugs are administered orally in 0.1% Tween 80 solution 10 min prior to oral indomethacin in a dose of 20 mg/kg (4 mg/ml dissolved in 0.1% Tween 80 solution). Six hours later, the rats are sacrificed in CO_2 anesthesia and their stomachs removed. Formol-saline (2% v/v) is then injected into the totally ligated stomachs for storage overnight. The next day, the stomachs are opened along the greater curvature, then washed in warm water, and examined under a 3-fold magnifier. The lengths of the longest diameters of the lesions are measured and summated to give a total lesion score (in mm) for each animal, the mean count for each group being calculated.

EVALUATION

The mean score in control rats is about 25 (range 20–28). Inhibition of the lesion production is expressed as percentage value.

MODIFICATION OF THE METHOD

Dose- and time dependency of the ulcerogenic action of indomethacin were studied by Djahanguiri (1969).

Instead of indomethacin, gastric lesions can be induced by intravenous or oral doses of aspirin which can be prevented by exogenous PGE_2 or PGI_2 (Konturek et al. 1981). Furthermore, reserpine at a dose of 8 mg/kg i.p., or cysteamine hydrochloride at a dose of 400 mg/kg s.c. was given in order to induce ulcers in rats (Tarutani et al. 1985).

Kitajima et al. (1993) studied the role of endothelin and platelet-activating factor in indomethacin-induced gastric mucosal injury in rats. Four hours after subcutaneous injection of 25 mg/kg indomethacin, the rats

were sacrificed after ether anesthesia, and the stomach was removed. The stomach was filled with 1.5 ml of 2% buffered formalin for 10 min and then opened along the greater curvature. The total length of the lesions was measured.

Wallace et al. (1989) studied the ulcerogenic activity of endothelin in indomethacin pretreated rats using an *ex vivo* gastric chamber.

Scarpignato et al. (1995) evaluated NSAID-induced gastric mucosal damage by continuous measurement and recording gastric potential difference in the rat.

CRITICAL ASSESSMENT OF THE METHOD

According to West (1982) the cold stress induced ulcer formation, but not the indomethacin- or aspirin-induced ulcers are inhibited by H_2-receptor antagonists, whereas other authors reported protective effects of H_2-receptor antagonists under these conditions (Tarutani et al. 1985).

J.3.7.5 Ethanol induced mucosal damage in rats (cytoprotective activity)

PURPOSE AND RATIONALE

Intragastric application of absolute ethanol is a reproducible method to produce gastric lesions in experimental animals (Robert et al. 1979; Szabo et al. 1981). These lesions can be at least partially inhibited by various drugs, such as some prostaglandins. The protective effect against various irritants has been called cytoprotective activity (Robert 1979; Robert et al. 1979). The method has been modified by several authors. Witt et al. (1985) described a method to objectively quantify the extent of ethanol-induced gastric lesions utilizing a transmission densitometer to measure the optical density of the photographic negative of the stomach mucosa.

PROCEDURE

Male Wistar rats weighing 250–300 g are deprived of food 18 h prior to the experiment but are allowed free access to water. During this time they are kept in restraining cages to prevent coprophagy. The rats are administered either the appropriate vehicle or the cytoprotective drug, e.g. a prostanoid, intragastrally 30 min prior to administration of 1 ml absolute ethanol. Untreated animals are included as controls. One hour after administration of ethanol, the animals are euthanized with CO_2, the stomachs are excised, cut along the greater curvature, and gently rinsed under tap water. The stomachs are stretched on a piece of foam core mat, mucosal site up.

The subjective scores of the treated tissues are recorded; the graded response is reflecting the least (0) to most (3) damage. A circular full thickness area, about 13 mm in diameter, is cut with a cork borer from each lobe of the fundus just below the ridge dividing the glandular from the non-glandular portion of the stomach. A Plexiglas template ($19 \times 14 \times 0.3$ cm), burnished on one side with emery cloth, and with four rows with six holes 13 mm in diameter is placed on a sheet of clear glass, burnished side up, and bound to the glass with photographic tape along the periphery. The excised pairs of tissue from each stomach are placed into the holes of the template.

Pairs of tissue from each stomach are examined to minimize sampling errors. The template is positioned on a rectangular central open area of an Aristo Model T-16 cold cathode transilluminator (38×38 cm) containing a W-45 blue-white lamp. A camera is mounted on a copy stand directly above the template. Photographs are taken, the film processed in a standard manner and a contact sheet is made from the negatives. A light transmission densitometer (e.g. MacBeth model TD-501) is used to evaluate the negatives. The optical density of the test tissues is determined by placing each area of the negative in sequence over the aperture through which the light is transmitted. The optical density is displayed on a digital read out and recorded. Hemorrhagic or damaged areas appear bright on the negative, whereas undamaged tissue appears dark. Hence, lower optical density values are indicative of

damage while higher optical densities are associated with little, or, as in the case of control, no damage.

EVALUATION

The significance of differences in optical density between control and ethanol-treated tissue is evaluated by nonpaired single-tail Student's *t*-test.

MODIFICATIONS OF THE METHOD

Cytoprotection by prostaglandins was studied in rats by prevention of gastric necrosis produced by various agents such as alcohol, HCl, NaOH, hypertonic NaCl, and thermal injury (Robert et al. 1979) and against gastric injury produced by nonsteroidal anti-inflammatory compounds (Robert 1979; Franzone et al. 1988). The animals are fasted 48 h prior to the experiment and placed 18 h before the administration of drugs into plastic tubes to prevent coprophagy. Fifteen min after application of the test drug, the animals are given 1 ml of the irritant orally. After an additional hour, the animals are sacrificed, the stomachs removed and immediately opened along the greater curvature. Lesions are counted and scored (0 = no lesion; 1 = mild lesions; 2 = severe lesions; 4 = necrosis).

Starrett et al. (1989) employed 3.0 ml/kg ethyl alcohol (100%) or 3.0 ml/kg 0.75 N HCl as necrotizing agent.

Borella et al. (1989) studied the cytoprotective and anti-ulcer activities of the anorganic antacid Magaldrate in the rat using absolute ethanol as irritant.

Masuda et al. (1993) investigated the role of endogenous endothelin in the pathogenesis of ethanol-induced gastric mucosal injury in rats.

CRITICAL ASSESSMENT OF THE METHOD

Several prostaglandins provide cytoprotection, particularly in rats, in a dose-range which has no antisecretory activity. However, clinical experience with prostaglandins showed that ulcer healing is only achieved at antisecretory doses (Lindberg et al. 1990). Therefore, it seems very likely that the cytoprotective property of a compound in rats has very limited relevance to prediction of its ulcer healing potential in humans if cytoprotection is really separated from its antisecretory potential (Herling and Weidmann 1994).

J.3.7.6 Subacute gastric ulcer in rats

PURPOSE AND RATIONALE

Ezer (1988) described a method for producing standard subacute gastric ulcers in rats and for the quantitative evaluation of the healing process.

PROCEDURE

Female Wistar rats weighing 120–150 g are fasted for 24 h having access to water at libitum in cages with wire sieves at the bottom. The rats are anesthetized with ether and a polyethylene catheter including a fine steel wire with a needle tip (1.2 mm diameter) at the lower end is orally inserted into the stomach. After the cannula reaches the gastric wall, the upper end of the steel wire is pressed in a definitive manner, so as to puncture the gastric wall. Each rat is kept in the same position during the intervention in order to localize the puncture at nearly the same region of the glandular part of the stomach. The test substances are administered orally, 30 min or 24 h after puncture. Free access to food and water is provided from 2 h up to the end of the experiment. Each group consists of 8–15 rats.

The animals are sacrificed by overdose of ether at definitive time intervals after puncture. The stomach is dissected and opened along the lesser curvature, extensively rinsed in tap water and fixed to the end of a

polyethylene tube of 10 mm diameter (plastic tip of an automatic pipette) in a position with the punched ulcer in the center. The end of the tube with the gastric wall is suspended in a beaker containing physiological saline, and the pressure in the tube is gradually increased with a valved rubber ball connected to the other end of the tube. The third part of the system is a tonometer calibrated up to 1 bar. The value of tension at which bubbles appear at the ulcerous gastric wall is noted. This value is termed as tensile strength and can be expressed in mm Hg.

EVALUATION

The extent of the healing of gastric ulcers can be characterized by the healing rate (*HR*) according the following equation:

$$HR = (A - B) / C \quad (\text{mm Hg/h})$$

with

- A = tensile strength (mm Hg) at C time-point after puncture
- B = tensile strength 30 min after puncture (the average value is 143 mm Hg)
- C = time course (h) of the experiment.

Anti-ulcer drugs, such as H_2 antagonists, significantly increase the healing rate, which is decreased by non-steroidal anti-inflammatory drugs.

CRITICAL ASSESSMENT OF THE METHOD

Similarly to the method of Takagi et al. (1969) who injected 50 µl of acetic acid into the stomach wall (Szelenyi et al. 1982), the method of Ezer (1988) allows to judge the time course of healing of the ulcers.

MODIFICATIONS OF THE METHOD

Okabe and Pfeiffer (1972) induced chronic gastric ulcer in rats by temporary instillation of acetic acid. In pentobarbital anesthesia, a cylindrical glass tube of 6 mm in diameter was tightly placed upon the anterior serosal surface of the glandular portion of the stomach one cm away from the pyloric end. A dose of 0.06 ml/animal of 50% acetic acid was instilled into the tube and allowed to remain one min on the gastric wall. After removal of the acid solution, the abdomen was closed in two layers and the animals brought back to their cages and fed normally. Test drugs were given orally on day 1 twice daily, 4 h after application of acetic acid and continued up to 10 days after induction of ulcer. The animals were sacrificed after 18 h of the last dose to assess ulcer size and healing. Ulcer index was calculated upon the product of length and width of ulcers.

Karmeli et al. (1996) induced gastric mucosal erosions in rats by addition of 0.1% iodoacetamide to the drinking water. The animals were sacrificed after various time intervals, the stomach was resected, washed, lesion area assessed, and mucosal inflammatory mediators determined. Myeloperoxidase was increased and nitric oxide synthase activity decreased. The damage induced by iodoacetamide was significantly ameliorated by treatment with a free radical scavenger, (4-hydroxy-2,2,6,6-tetramethyl-piperidine-1-oxyl, TEMPOL).

Konturek et al. (1999) described a mouse model of *Heliobacter pylori* infection. Gastric function and healing of chronic acetic acid-induced ulcers in BALB/c mice were studied after inoculation with CagA and VacA positive (type I) or CagA and VacA negative (type II) *Heliobacter pylori* strains. This infection caused immediate suppression of gastric secretion and delayed the healing of ulcers.

J.3.7.7 Gastric ischemia-reperfusion injury in rats

PURPOSE AND RATIONALE

Hassan et al. (1997) described the effect of an endothelin converting enzyme inhibitor on local gastric ischemia-reperfusion injury in rats. Endothelin-1 has potent ulcerogenic effects in the stomach (Wallace et al. 1988). Endogenous endothelin-1 has been implicated for ethanol-, indomethacin- and hemorrhagic shock-induced gastric ischemia-reperfusion injuries (Masuda et al. 1993; Kitajima et al. 1993; Michida et al. 1994; Kitajima et al. 1995).

PROCEDURE

Male Wistar rats weighing 200–250 g are fasted for 24 h with free access to water. The rats are anesthetized with 1.5 g/kg urethane i.p. The stomach is exposed by a medial laparatomy and instilled with 0.15 M HCl (1 ml/100 g) via the forestomach. The left gastric artery is clamped by a small vascular clamp for 5 min to induce ischemia and 30 min of reperfusion is done by releasing the clamp. Pretreatment with test drug or standard is given to groups of 5 rats immediately before the induction of ischemia. At the end of the experiment, the rats are sacrificed by cervical dislocation. The stomach is fixed with 10% buffered formalin and photographed for macroscopic evaluation of injuries. For the assessment of microscopic injuries, a sample of corpus 0.5 cm below the limiting ridge containing the entire width of the anterior wall is taken from each stomach and processed for subsequent histological evaluation.

A planimeter attached to a computer is used to trace the macroscopic mucosal injury from color photographs. The results are expressed as a percentage of the total glandular mucosal area.

Each histological section is stained with hematoxylin/eosin and examined under light microscope. An one cm length of each histological section is assessed for epithelial damage (score = 1), glandular disruption, vasocongestion or edema in the upper mucosa (score = 2), hemorrhagic damage in the mid to lower mucosa (score = 3) and deep necrosis and ulceration (score = 4). Each section is evaluated on a cumulative basis to give the histological index, the maximum score thus being 10.

EVALUATION

Data are expressed as mean ±SEM. Comparisons between different groups are made by one way analysis of variance followed by Fisher's least significant difference test. P-values of <0.05 are considered as statistically significant.

J.4 Intestinal functions

J.4.1 Intestinal secretion

J.4.1.1 Laxative activity in rats

PURPOSE AND RATIONALE

Laxatives of the sennoside type act mainly by acceleration of large intestine transit and inhibition of fluid absorption in the colon (Leng-Peschlow 1986).

PROCEDURE

For **measurement of large intestinal transit time**, female Wistar rats weighing approximately 200 g are anesthetized with ether. A PVC catheter is implanted into the caecum with the distal end fixed on the animal's neck. The animals are allowed to recover and are placed individually in a wire meshed cage to enable the feces to fall through onto blotting paper. Carmine red (10 mg in 0.4 ml distilled water per animal) is injected through the catheter immediately after administration of the test substance. The time until appearance of the first colored feces is registered.

For **measurement of fluid absorption in the colon**, female Wistar rats weighing approximately 200 g are anesthetized with 50 mg/kg pentobarbitone sodium. The colon is ligated and cannulated distal to the caecocolic junction (PE-tube, i.d. 1 mm) and, after a thorough rinse with 50 ml physiological saline to remove all contents, a second cannula (silicone, i.d. 3 mm) is inserted proximal to the rectum for fluid outflow. Four and 6 h after oral administration of the test compounds an open perfusion with an electrolyte solution (NaCl 6.72 g/l, KCl 0.37 g/l, $NaHCO_3$ 2.1 g/l, polyethylene glycol (PEG, mol wt 4 000) 2.0 g/l, [^{14}C]PEG 5 µCi/l; pH 6.5, osmolality 275 milliosmol/kg) is started at a rate of 12 ml/h for two consecutive 2 h periods. [^{14}C]PEG activity is measured by liquid scintillation counting, Na^+ and K^+ by flame photometry, Cl^- by coulometric titration, osmolality by freezing point depression and mucus as protein-bound total hexoses by the orcinol-sulphuric acid method. Net H_2O, Na^+, K^+ and Cl^- transport are calculated and expressed as ml or µmol/h and per 10 cm colon length.

EVALUATION

All values are expressed as mean ± standard deviation. Statistical significance is assessed with Student's *t*-test.

MODIFICATIONS OF THE METHOD

Ogunti and Elujoba (1993) tested the laxative activity of *Cassia alata* in rats. Male Charles River rats were kept in individual cages during one week. Any rat producing wet feces was rejected. After administration of the test compounds to groups of 5 rats per dose, the feces were examined for wetness hourly for 12 h. The results were expressed as the mean percent of total feces that were wet per kg rat.

J.4.1.2 Enteropooling test

PURPOSE AND RATIONALE

The enteropooling assay in rats has been developed by Robert et al. (1976) to test the diarrheogenic property of prostaglandins for prediction of this clinically relevant side effect of several synthetic prostaglandins.

PROCEDURE

Female Sprague Dawley rats weighing 190–215 g are used. The animals are fasted overnight having free access to water. The test compounds are administered orally, and the animals, 12 per group, are sacrificed one hour later. The fluid accumulation occurs in the small intestine which is cut at the pylorus and the ileocecal junction, and its contents, consisting of a thick fluid (in controls) and a very watery fluid (in prostaglandin-treated animals) are collected into a graduated test tube by milking the whole length of the small intestine with the fingers. The volume of fluid is recorded.

EVALUATION

Using various doses, dose-response curves can be established and potency ratios calculated. 16,16-dimethyl PGE_2 was found to be the most active compound.

CRITICAL ASSESSMENT OF THE METHOD

Some other diarrheogenic agents, like $MgSO_4$, castor oil, bile, taurocholate and taurochenodesoxy-cholate cause enteropooling, whereas mineral oil and tragacanth are ineffective. The anticholinergic agent methylscopolamine partially counteracted the enteropooling. The assay, therefore, can be used to test the laxative or the antidiarrheal activity of compounds (Shook et al. 1989).

MODIFICATIONS OF THE METHOD

Beubler and Badhri (1990) used the PGE_2-induced net fluid secretion in the jejunum and colon in the rat to evaluate the antisecretory effects of antidiarrheal drugs. Polyethylene catheters were placed into the jejunum and colon and Tyrode solution was instilled into the loops. Net fluid transfer rates were determined gravimetrically 30 min after instillation of Tyrode solution.

J.4.1.3 Inhibition of chloride secretion in rabbit colon[2]

PURPOSE AND RATIONALE

Epithelia have the ability to reabsorb or to secrete fluids and electrolytes. In 1958, Koefoed-Johnsen and Ussing first published a model of ion transport across frog skin epithelium. Ussing also introduced the measurement of the short-circuit current as a means of defining active ion transport (Koefoed-Johnsen and Ussing 1958). Mammalian colon is an example of epithelium which has the capacity to absorb and to secrete electrolytes.

Previous studies have shown that mammalian colon actively secretes chloride when exposed to prostaglandins and vasoactive intestinal peptides, which increase the cellular concentration of cAMP resulting in an electrogenic chloride secretion (Frizzell et al. 1976). The elevation of cAMP causes the opening of chloride channels, whereas the colonic epithelium absorbs sodium and chloride ions by an electroneutral mechanism under control conditions. In general it is assumed that absorption takes place mainly in the surface cells, whereas the crypts are the predominant site of secretion (Greger et al. 1985; Binder and Sandle 1987).

[2] Contributed in the first edition by M. Hropot.

PROCEDURE

Rabbits of either sex (2.0 to 4.0 kg body weight) are killed by cervical dislocation. The distal colon is removed, immediately opened into a flat sheet and washed in the standard electrolyte solution. The epithelium with an area of 1.0 cm^2 is stripped from its underlying musculature and mounted in an Ussing chamber. The tissue is mounted vertically and bathed on both sides by electrolyte solutions, which are circulated and oxygenated by a water-jacketed bubble-lift apparatus maintained at 37 °C. The carbogen gas used for bubbling contains O_2 and CO_2 in a mixture of 95% and 5%, respectively. The solutions used on the two sides have the following composition (in mmol/l): NaCl 120, $NaHCO_3$ 21, Na_2HPO_4 0.4, K_2HPO_4 1.6, $MgCl_2$ 1.2, glucose 5.

Tissues are continuously short-circuited by a four-electrode automatic voltage-clamp apparatus (AC-Microclamp, Aachen, Germany) which measures short-circuit current (I_{sc}) and automatically subtracts chamber fluid resistance. Transepithelial electrical potential difference is measured between Ag-AgCl electrodes, which make contact with the bathing solutions via agar bridges (5% agar in glucose-free standard electrolyte solution). I_{sc} is measured by passing sufficient current through Ag-AgCl electrodes to reduce the spontaneous transepithelial electrical potential difference to zero. Transepithelial conductance (G_t) is determined by passing 100-ms bipolar current pulses through the tissue.

The standard protocol consists of an initial equilibration period of 20 min. The I_{sc} measured in the presence of indomethacin (1 µmol/l, serosal and mucosal solution) corresponds mostly to the rheogenic reabsorption of sodium. In the next step, amiloride is added at 0.1 mmol/l to block sodium reabsorption. Then PGE_2 (1 µmol/l) is added to the serosal solution in the presence of amiloride in order to stimulate chloride secretion. After a further equilibration period of 20 min putative blockers of chloride secretion are added to the mucosal or serosal solution.

EVALUATION

Each compound is examined at least 3 times and at three different concentrations (usually 1, 10 and 100 µmol/l). From the mean values a concentration-response curve is constructed, and from this curve the IC_{50} value is read as the concentration producing 50% inhibition of the stimulated I_{sc}.

Data are presented as means ±SEM. Paired *t*-test with a significance level of $p < 0.05$ may be used.

CRITICAL ASSESSMENT OF THE METHOD

The method can be used to study the antidiarrhoic activity of a test compound, but also generally its influence on active electrolyte transport across the cell membrane.

MODIFICATIONS OF THE METHOD

Warhurst et al. (1996) studied the effects of somatostatin analogues on electrogenic ion secretion in isolated rat colonic mucosa mounted in Ussing chambers.

J.4.2 Antidiarrhea effect

J.4.2.1 Castor oil induced diarrhea

PURPOSE AND RATIONALE

The induction of diarrhea with castor oil results from the action of ricinoleic acid formed by hydrolysis of the oil (Iwao and Terada 1962; Watson and Gordon 1962). Ricinoleic acid produces changes in the transport of water and electrolytes resulting in a hypersecretory response (Ammon et al. 1974). In addition to hypersecretion, ricinoleic acid sensitizes the intramural neurons of the gut.

PROCEDURE

Female Wistar rats weighing 210–230 g are used after overnight food deprivation. For the experiment, the rats are housed in individual cages with no access to drinking water. The potential antidiarrhoic agents are administered orally by gavage in various doses. Controls receive the solvent only. Each dose is given to 10 animals. One hour after dosage, 1 ml of castor oil is administered orally. Stools are collected on non-wetting paper sheets of uniform weight up to 24 h after administration of the castor oil. Every 15 min during the first 8 h, urine is drained off by gravity, and the net stool weight, termed early diarrheal excretion, is recorded. The diarrhea-free period is defined as the time in minutes between castor oil administration and the occurrence of the first diarrheal output. The acute diarrheal

phase is the time between the first and the last diarrheal output of the 8-h observation period. Stools occurring between 8 and 24 h after castor oil administration are called late diarrheal excretion.

EVALUATION

With antidiarrheal agents dose-response curves are obtained for decrease of hypersecretion (stool weight) and for increase of the diarrhea-free period are obtained. Inhibitors of prostaglandin biosynthesis increase the diarrhea free period but do not affect early diarrheal secretion (Niemegeers et al. 1984).

MODIFICATIONS OF THE METHOD

Inhibition of castor oil-induced diarrhea in **mice** was tested by Bianchi and Goi (1977).

Dajani et al. (1977) tested antidiarrheal activity in castor-oil treated **monkeys**.

Mannitol-induced diarrhea was used as model in **calves** (Fioramonti and Buéno 1977) and in **pigs** (Théodorou et al. 1991).

J.4.2.2 Antidiarrheal effect in cecectomized rats

PURPOSE AND RATIONALE

Evaluation of antisecretory antidiarrheal agents in animal models is limited primarily to extrapolations of efficacy from enteropooling studies *in vivo* (DiJoseph et al. 1984), isolated intestinal loops (Nakaki et al. 1982), and Ussing flux chamber preparations *in vitro* (Dharmsathaphorn et al. 1984).These studies do not mimic secretory diarrhea. The method of Magnus (1915) using chronic diarrhea in cats induced by continuous milk diet and thereby proofing the antidiarrheal effect of morphine is of historical interest only.

Fondacaro et al. (1990) developed a model of secretory diarrhea utilizing conscious cecectomized rats by surgical resection of the cecum and by use of potent intestinal secretagogues. The rat has a pronounced cecum as part of its gastrointestinal tract. The rat cecum is not only a reservoir for intestinal contents where high concentrations of various microbial flora assist in the digestion of carbohydrates, cellulose and peptides through microbial fermentation processes (Ambuhl et al. 1979; Williams and Senior 1982) but also plays a role in handling of excess intestinal fluid.

PROCEDURE

Cecectomies are performed in unfasted rats weighing 200–250 g. Under anesthesia with methohexital (60 mg/kg i.p.) cecectomy is initiated with a 2-cm midventral incision. The cecum is lifted from the abdominal cavity and exteriorized onto a gauze drape. The cecal apex is freed by severing the avasclular area of the mesocecum. A ligature of no. 1 silk suture is positioned so as to occlude the cecum and its vasculature without compromising ileo-colonic patency. After the ligature is secured and ileo-colonic patency confirmed, the cecum is resected, and the remaining ex-

posed cecal mucosa is washed with saline and cauterized. The intestinal segment is then returned to the abdominal cavity and the abdominal muscle fascia closed with sutures. The dermal incision is closed with wound clips that are removed about 1 week postsurgery. Immediately following the surgical procedure, the animals are returned to their cages and allowed free access to food and water. The animals are permitted at least a 48-h recovery period before being used in an experiment.

For the diarrhea assay, cecectomized rats are put into individual wire-bottomed cages placed over sheets of clean paper, and deprived of food and water for the duration of the assay. Rats are given a two hour's acclimatization period prior to the start of the assay in order to eliminate sporadic episodes of anxiety-induced defecation. During this period, they are observed also for consistent occurrences of pelleted feces; an animal producing other than pelleted stool is disqualified from the study. Diarrhea is induced with oral administration of secretagogues: either 16,16 dimethyl prostaglandin E_2 (0.3 mg/kg) in 3.5% ethanol, carbachol (15 mg/kg) in water, or cholera toxin (0.5 mg/kg) in an aqueous vehicle of 2% $NaHCO_3$ plus 2% casamino acids. Antidiarrheal agents are administered by gavage after the onset of diarrheal episodes. The cage papers are removed and examined at 15 min intervals for carbachol-induced diarrhea, 30 min intervals for 16,16 dimethyl prostaglandin E_2 induced diarrhea, and hourly when cholera toxin is used as secretagogue. Fetal output is recorded at each interval and scored as follows:

- 1 = normal pelleted stool
- 2 = soft-formed stools
- 3 = water stool and/or diarrhea

Known antidiarrheal agents, such as chlorpromazine (10 mg/kg p.o.), or the alpha-2 receptor agonist clonidine (1.0 mg/kg p.o.), or morphine (10 mg/kg p.o.) reduce the fecal output and induce a cessation of diarrhea.

EVALUATION

The fecal output index is defined as the summation of the number of defecation periods and their ranked consistency score within an observation period and is expressed as mean ±SEM for each group. Student's *t*-test and analysis of variance are used for statistical comparisons of data points. Significance is accepted at $p < 0.05$ or less.

CRITICAL ASSESSMENT OF THE METHOD

The model of diarrhea induced by secretagogues in cecetomized rats has the advantage to mimic secretory diarrhea in man.

J.4.2.3 Evaluation of antidiarrheal effect in cold-restrained rats

PURPOSE AND RATIONALE

Barone et al. (1990) tested the effect of various antidiarrheal and other drugs on increased fecal pellet output in cold-restrained rats resembling clinical observations that stressful situations can produce diarrhea in humans.

PROCEDURE

Male Sprague-Dawley rats weighing 260–310 g are maintained on Purina lab chow and water. Since gastric ulcers are reduced if cold-restrained rats are allowed free access to food and water, for studies on fecal output food was not withdrawn prior to the experiment. The rats are studied in normal living cages at room temperature (control, non-stressed animals) or in wire-mesh restraining cylinders placed in a cold (4 °C) environment. Test drugs are administered by appropriate routes over optimal effective dose-ranges for their activities and at optimal pretreatment times to maximize their effects. The number of pellets expelled by each animal is measured at 1 and 3 h (fecal pellet output). Generally, the fecal pellets of stressed animals are less firm.

Fecal pellet fluid content is determined by weighing fecal pellets, drying them in an oven at 37 °C, and weighing them again.

EVALUATION

The dose in mg/kg that inhibits the cold restrained stress induced increase in fecal pellet output by 50% (ID_{50}) is determined using least-squares fit analysis directly from the regression line. If fecal pellet output is decreased by a drug but no clear dose-related effects occur, the maximum percent decrease is determined.

MODIFICATIONS OF THE METHOD

For colonic transit studies, rats are implanted with indwelling catheters in the proximal colon. Animals are anesthetized with 60 mg/kg pentobarbital i.p., and a chronic colonic catheter is positioned to enter the proximal colon 2 cm from the ileocecal junction. A catheter of about 20 cm of silicone tubing prepared with several drops of silicon rubber adhesive coating a 1-cm length along the catheter is positioned into the colon. The colon end of the tubing also is sealed with a 1-cm plug of petroleum jelly intraluminally. A small incision is made in the proximal colon, and the adhesive-coated portion of the Silastic tubing is tied in place with the use of a purse-string suture. The tubing is brought through the abdominal wall, led subcutaneously through the skin in the midscapular region and secured on the back of the neck with the use of a wound clip. The abdominal incision is closed with sutures and wound clips.

Experiments are performed in conscious animals 48–72 h after surgical preparation. At this time, the radiolabeled marker (^{51}Cr as sodium chromate) is instilled into the proximal colon via the indwelling catheter. After 35, 60, or 120 min, cold-restrained rats and controls are sacrificed and their colons and large intestines are removed. The cecum and equal segments of the colon are dissected, placed into vials and subjected to gamma counting.

Ikeda et al. (1995) investigated the effect of a neurokinin$_1$ receptor antagonist on stress-induced defecation in rats placed in special restraint cages.

Kishibayashi et al. (1993) studied distal colonic function using wrap-restrained stress-induced defecation as described by Williams et al. (1988). The rats were lightly anesthetized with ether, and the foreshoulders, upper forelimbs and the thoracic trunk were wrapped in paper tape to restrict, but not prevent, movement. The animals recovered from anesthesia within 2–5 min and immediately moved around in cages and ate and drank, but had been restricted from mobility of forelimbs, which prevented them from grooming the face, upper head and the neck. Fecal pellet output induced by wrap-restraint stress was weighed during the 1st h after stress. The test drugs were given p.o. 1 h before stress. The ID_{50} values were calculated as the doses that reduced stress-induced defecation by 50%.

J.4.3 Gut motility

J.4.3.1 Isolated ileum (MAGNUS technique)

PURPOSE AND RATIONALE

The isolated ileum, as first described by Magnus (1904), is probably the most widely used model in experimental pharmacology. Magnus already studied simultaneously the spontaneous contractions of the longitudinal and circular musculature and the inhibiting effect of atropine. The method has been used for many purposes, such as the study on the effects of adrenaline on the lower segments causing contraction and on the segments of the upper end causing relaxation by Munro (1951) or the study on the origin of acetylcholine released from guinea-pig intestine and longitudinal muscle strips by Paton and Zar (1968) either retaining or being denervated from Auerbach's plexus. The model is used as a basic screening procedure for spasmolytic activity, whereby an anti-acetylcholine or anticarbachol effect indicates antimuscarinic activity and an anti-$BaCl_2$-effect indicates a musculotropic, papaverine-like effect. In addition to the isolated ileum, other parts of the gut such as the isolated duodenum and colon, have been used widely.

PROCEDURE

Guinea pigs of either sex weighing 300 to 500 g are used. They are sacrificed by stunning and exsanguination. The abdomen is opened with scissors. Just distal to the pylorus, a cord is tied around the intestine which is then severed above the cord. The intestine is gradually removed, with the mesentery being cut away as nec-

essary. When the colon is reached, the intestine is cut. Below the cord, the intestine is cut halfway through, so that a glass tube can be inserted. Tyrode's solution is passed through the tube and the intestine until the effluent is clear. Mesentery is cut away from the intestine that was joined to the colon. Pieces of 2–3 cm length are cut. Preferable the most distal piece is used being the most sensitive one. This piece is fixed with a tissue clamp and brought into a 15 ml organ bath containing Tyrode's solution at 37 °C being oxygenated with 95% O_2/5% CO_2. The other end is fixed to an isometric force transducer (UC 2 Gould-Statham, Oxnard USA). A preload of 1 g is chosen. Responses are recorded on a polygraph. After a pre-incubation time of 30 min, the experiment is started.

The following agonists and antagonists (standards) are used (concentrations in g/ml bath fluid):

Agonist		Antagonist	
Acetylcholine	10^{-7} g/ml	Atropine	10^{-8}–19^{-9} g/ml
		Scopolamine	10^{-8}–10^{-9} g/ml
Carbachol	10^{-7} g/ml	Atropine	10^{-8}–10^{-9} g/ml
Histamine	10^{-6} g/ml	Histamine antagonists	
$BaCl_2$	10^{-4} g/ml	Papaverine	10^{-5}–10^{-6} g/ml
Serotonin	10^{-6} g/ml	Serotonin antagonists	
PGE_2	2×10^{-7} g/ml	PG-antagonists	

EVALUATION

Several methods for the quantitative evaluation of an antagonistic effect are available. One approach is the determination of pD_2' values according to van Rossum and van den Brink (1963). Acetylcholine or histamine is added in 1/2 $\log_{10}$ concentration increments until a maximum response is obtained. Control curves are recorded at 30 min intervals. After uniform control responses are obtained, the potential antagonist or the standard is added 5 min before the concentration-response curve is re-obtained. The potency of the antagonist is obtained by calculating the pD_2' value which is defined as the negative logarithm of the molar concentration of an antagonist that causes a 50% reduction or the maximal response obtained with an agonist.

MODIFICATIONS OF THE METHOD

Many modifications of the Magnus technique have been described in the literature, mainly with the isolated ileum (e.g., Koelle et al. 1950).

Okwuasaba and Cook (1980) dissected the myenteric plexus and longitudinal muscle free of the underlying circular muscle according to the method of Paton (1957), Paton and Zar (1968) and stimulated the preparation with trains of supramaximal rectangular pulses of 1.0 ms duration at a frequency of 0.2 Hz.

Kilbinger et al. (1995) studied the influence of 5-HT_4 receptors on [^{3}H]-acetylcholine release from guinea pig myenteric plexus.

De Graaf et al. (1983) described a fully automated system for *in vitro* experiments with isolated tissues. The apparatus consists of an organ bath equipped with (a) a gradient pump supplying a logarithmic concentration/time gradient of agonist; (b) pumps and valves for dispensing bath fluid, antagonist solutions, and an oxygenation gas mixture; and (c) a transducer with automatic baseline adjustment. The information coming from the preparation is fed into a mini-computer. The data of various experiments can be accumulated and Schild-plots obtained.

Furukuwa et al. (1980) studied the effects of thyrotropin-releasing hormone on the isolated small intestine and taenia coli of the guinea pig.

Paiva et al. (1988) studied the role of sodium ions in angiotensin tachyphylaxis in the guinea-pig ileum and taenia coli.

Barnette et al. (1990) used electrically stimulated strips of circular smooth muscle from the lower esophageal sphincter of dogs to study the inhibition of neuronally induced relaxation by opioid peptides.

Bradykinin antagonism can be studied in the isolated guinea pig ileum bathed in a solution containing atropine (1.5 mM), diphenhydramine (3.4 mM), indomethacin (2.8 mM), and captopril (0.9 mM) (Rubin et al. 1978; Kachur et al. 1987).

Griesbacher and Lembeck (1992) used the isolated guinea-pig ileum for analysis of bradykinin antagonists.

Hew et al. (1990) used field stimulated (95% of maximum voltage, 0.1 Hz, 0.5 ms) guinea pig ileum, bathed in physiological salt solution at 37 °C in the presence of 1 mM mepyramine for determination of histamine H_3 bioresponse. Reduction of contractile response by the test substance (>50% relative to control 0.3 mM R-α-methylhistamine) indicates possible H_3 agonism. At a test concentration where no significant activity is seen, ability to inhibit (>50%) R-α-methylhistamine-induced contractile reduction indicates antagonistic activity.

A similar technique was used by Conner et al. (1987) to study antagonist effects at functional 5-HT_{1A} receptors.

Feniuk et al. (1993) used the guinea-pig isolated ileum, vas deferens and right atrium to characterize somatostatin receptors. Transmural electrical stimulation was applied to guinea pig ileum (0.1 Hz, 0.1 ms continuously) and vas deferens (5 Hz, 0.5 ms for 1.5 s every 30 s) at supramaximal currents (approximately 800 mA) delivered from a Digitimer D330 multistimulator.

Radomirow et al. (1994) investigated opioid effects of short enkephalin fragments containing the Gly-Phe sequence on contractile responses of guinea pig ileum after addition of 10 nM acetylcholine or after electrical stimulation.

Coupar and Liu (1996) described a simple method for measuring the effects of drugs on intestinal longitudinal and circular muscle in **rats**. The preparation consists of a segment of rat ileum set up to measure the tension developed in the longitudinal muscle and intraluminal pressure developed in the circular muscle in response to transmural electrical stimulation.

Vassilev et al. (1993) exposed Wistar rats to subtoxic doses of Co^{2+} or Ni^{2+}, receiving $Co(NO_3)_2$ or $NiSO_4$ with drinking water for 30 days, and measured the changes in the contractile responses to carbachol and in the inhibitory effects of verapamil and nitrendipine on isolated smooth muscle preparations of the ileum and the trachea.

Pencheva and Radomirov (1993), Pencheva et al. (1999) studied the effects of GABA receptor agonists on the spontaneous activity of the circular layer in the terminal ileum of **cats**. Segments of the terminal ileum approximately 0.5 cm long were mounted in an organ bath along the axis of the circular layer through a cotton thread with a large knot situated at the inner part of the gut wall.

Similar preparations of cat ileum were used by Kortezova et al. (1994) and Chernaeva and Mizhorkova (1995).

Vassilev and Radomirov (1992) used an isolated preparation of **rat rectum**. The rectal region, 1–6 cm proximal to the anal sphincter was removed and a 20 mm long segment suspended in an organ bath. The influence of prostaglandins and antagonists on spontaneous mechanical activity and electrically stimulated responses was investigated.

J.4.3.2 Cascade superfusion technique

PURPOSE AND RATIONALE

The technique of isolated organ superfusion was developed by Gaddum (1953) for the assay of biologically active substances. Extension of the technique for multiple tissue superfusion with particular reference to the identification and the assay of prostaglandin-like activity was used by various authors (Vane 1964; Ferreira and Vane 1967; Ferreira et al. 1976; Gilmore et al. 1968; Hong 1974; Bult et al. 1977; Henman et al. 1978; Elliott and Adolfs 1984; Fournau et al. 1984).

PROCEDURE

The apparatus consists of a double-wall glass container (height 20–25 cm, inner diameter 7–8 cm) with an outlet at the bottom. A constant temperature of 38 °C is maintained by circulation of warm water through the outer jacket. Inside the glass container can be suspended up to 5 pieces of tissue of various origins. The multiple preparation tissue holder consists of a vertical rectangular rod and plastic platforms for attachment of the tissues and for accurate deflection of the superfusate on to the lower tissue. The rod is grooved at 10 mm intervals with 1 mm deep slots set at an angle of 20° to the horizontal. To the upper surface of the nonwettable platform a small plastic hook is cemented at such a distance from the rod that when the tissue is in position its attachment thread passes between the V-shaped notch cut into the margin of the upper tissue platform. The individual platforms are inserted on to the vertical rod by slotting into the requisite grooves appropriate to the tissue length.

Thus, the superfusate passes at a uniform flow rate down the tissues of the cascade and the tension recording threads are separated from each other by about a 5-mm gap so that the responses can be conveniently recorded. The threads from the organs are connected over isotonic levers to isometric tension transducers. The lever is used for preloads according to the individual organ. Tension exerted by each tissue is recorded on a polygraph. Various media can be used for superfusion, e.g., Krebs-Henseleit solution gassed with 95% O_2 and 5% CO_2.

Many tissue preparations can be used for the cascade, such as rat fundic strip, rat duodenum, rat colon, rat bladder strip, guinea-pig ileum, guinea-pig proximal colon, rabbit stomach strip, rabbit coeliac/mesenteric artery, or rabbit aorta strip. Moreover, donor tissue can be superfused and its effluent be tested in the organs of the cascade.

EVALUATION

Many agonists and antagonists can be tested by appropriate selection of organs. Threshold doses and ED_{50} or ID_{50} values can be determined.

MODIFICATIONS OF THE METHOD

The superfusion technique has been used for several purposes, e.g., for the assay of catecholamines (Armitage and Vane 1964), for detecting active substances in the circulating blood (Vane 1964). A simple and inexpensive piece of apparatus for cascade superfusion procedures has been described by Naylor (1977).

Mombouli et al. (1996) described a bioassay of endothelium-derived hyperpolarizing factor (EDHF) using a perfusion-superfusion cascade where canine carotid arteries were used as donors of vasoactive substances and rings of coronary arteries without endothelium as detectors.

J.4.3.3 *In vivo* evaluation of spasmolytic activity in rats

PURPOSE AND RATIONALE

Maggi and Meli (1982) described an *in vivo* procedure for estimating spasmolytic activity in the rat by measuring smooth muscle contractions to topically applied acetylcholine.

PROCEDURE

Male albino rats weighing 350–400 g are anesthetized with subcutaneous urethane (1.2 g/kg). The left jugular vein is cannulated for administration of test compounds. After laparatomy occluding silk ligatures are applied at a distance of 2 cm from each other in the gut (colon or rectum). Through a small incision the flanged tip of a polyethylene tubing (1 mm i.d., 1.5 mm o.d.) is inserted into the lumen of this pocket-like space and secured in place by a purse string ligature. The free end of the tubing is connected to a pressure transducer and the whole system filled with saline. The same procedure is performed with the urinary bladder. The organs are filled with warm saline (37 °C) to obtain a resting pressure of 4–12 mm Hg. Warm saline soaked cotton wool swabs are laid around the exteriorized organs which are maintained warm and moist with warm (37 °C) saline dropping from a reservoir at a rate of 10–15 drops/min.

After 15 min stabilization period, saline flow is stopped and a dose-response curve to acetylcholine determined. A volume of 0.5 ml (an amount sufficient to put the whole outer surface of the organ into contact with the bathing solution) of acetylcholine at the desired concentration is applied within 2–3 s from a syringe to the outer surface of the target organ. To construct a dose-response curve of acetylcholine, increasing concentrations are applied to the target organ until maximal contraction is obtained. After at least 3 or more control curves have been obtained at 10 min intervals, the antagonist is administered.

EVALUATION

The quantitative analysis of the data is carried out by plotting the results of each experiment as log (acetylcholine dose ratio-1) against log dose antagonist (Arunlakshana and Schild 1959). The regression line is calculated according to the method of least squares and ED_{50} values and 95% confidence limits according to Litchfield and Wilcoxon (1949). From ED_{50} values, the dose of the antagonist (mg/kg i.v.) to produce an acetylcholine dose ratio of 10 is calculated according to Daly et al. (1975). Parallel displacement to the right of the agonist dose response curve and a slope of unity for the regression line indicate competitive antagonism. The DR_{10} values from different organs are compared by means of Student's *t*-test for unpaired data.

MODIFICATIONS OF THE METHOD

In vivo registration of gut motility in guinea pigs was already described by Straub and Viaud (1933). A four cm long part of the gut was ligated and filled with Tyrode solution. Gut motility was measured at variable intraluminal pressure.

J.4.3.4 Colon motility in anesthetized rats

PURPOSE AND RATIONALE

The influence of spasmolytic drugs on carbachol induced increase of colonic motility can be measured in anesthetized rats. The method has also be used to study the stimulation of colonic motility by an enkephalin analogue pentapeptide (Bickel 1983).

PROCEDURE

Male Sprague-Dawley rats weighing 350–500 g are anesthetized with pentobarbital i.v. A pressure sensitive tip catheter is inserted into the colon ascendens and the signals of the intraluminal pressure changes

are recorded. The colonic contractions are stimulated by i.v. injection of 3 mg/kg carbachol. The height and the duration of the contractions are recorded. Then, the test compound is injected intravenously. The decrease of contractions is measured and the duration of the spasmolytic activity determined by repeated administration of carbachol at 15 min intervals, until the contractions are not significantly different from the response obtained with carbachol alone.

EVALUATION

Significant differences are calculated using Student's unpaired *t*-test.

MODIFICATIONS OF THE METHOD

Maggi and Meli (1984) used eserine-induced hypertonus of **guinea pig** distal colon *in vivo* as a pharmacological procedure for testing smooth muscle relaxants. Male albino guinea pigs weighing 240–300 g are anesthetized with 1.5 g/kg urethane s.c. Through a midline abdominal incision, the proximal part of the hypogastric loop of the distal colon is exposed and occluding silk ligatures are applied at a distance of 2 cm from each other, taking great care to avoid any lesion to the vascu-lar and nervous supply. Through a small incision, the flanged tip of a polyethylene tube (1 mm i.d., 1.5 mm o.d.) is inserted into the lumen and secured by means of a purse-string ligature. The free end of the tube is con-nected to a pressure transducer and the whole system is filled with saline. Intraluminal pressure and its variations are recorded on a polygraph. The effect of drugs is assessed as inhibition of eserine induced hypertonus.

Théodorou et al. (1991) studied the absorptive and motor components of the antidiarrheal action of loperamide in **pigs**. Motility was recorded by implantation of intraparietal electrodes into various parts of the gut.

Raffa et al. (1987) used a method utilizing the insertion of a 3 mm glass bead into the distal colon in **mice** to evaluate the activity of intracerebroventricularly administered μ- and δ-opioid agonists on colonic bead expulsion time.

J.4.3.5 Continuous recording of electrical and mechanical activity in the gut of the conscious rat

PURPOSE AND RATIONALE

Bueno et al. (1981) described a method for continuous electrical and mechanical activity recording in the gut of the conscious rat. In this study two methods for the continuous recording of motor events – microtransducers and the electromyogram – are compared for the rat stomach and intestine.

PROCEDURE

Male Wistar rats weighing 200–300 g are housed singly in wire-bottomed cages and allowed lab chow and water ad libitum during the training period of 30 days. Under halothane anesthesia pairs of electrodes are implanted along the greater curvature of the pyloric antrum 5 and 2 cm from the pylorus, on the antimesenteric border of the duodenum 2 and 5 cm beyond the pylorus, and along the jejunum, 4 cm from the pylorus using a procedure described by Ruckebusch and Fioramonti (1975).

The contractions of the circular muscle layer are recorded with strain gauge microtransducers sutured onto the serosa at less than 1 cm from each set of electrodes (Pascaud et al. 1978). The free ends of the electrodes and strain gauge wires are carried subcutaneously and exteriorized on the back of the neck. The wires are inserted into a glass tube (15 cm and 0.5 cm external diameter) to prevent twisting and any contact with the metallic lids of the cage.

EVALUATION

Both electrical and mechanical activities are continuously recorded starting 5–7 days after surgery on a multichannel recorder (e.g., 8-channel Dynograph®, Beckman, USA) using lead selector couplers (type 9 856, Beckman) at a constant time of 0.1 s for the electrical spiking activity and strain gauge couplers (type 9 863, Beckman) for the contractile force minitransducers. Simultaneously low frequency signals (frequency < 3 Hz) of the electromyogram are eliminated through filters and the spiking activity, integrated for each 20 s, is recorded on a potentiometric recorder. The electrical and

mechanical activities are also recorded simultaneously on a magnetic tape recorder.

The index of motility, expressed as mcoul/min is calculated from the integrated records of electrical activity. The index of mechanical motility is calculated as the area under all contraction waves occurring during 1 min, and is expressed as g s/min. Mechanical and electrical activities during a test period of 30 min after administration of stimulant drugs, e.g., the gastrointestinal hormones gastrin and cholecystokinin, or relaxing drugs, like anticholinergic agents, are compared with the values of a 30 min pretest period.

MODIFICATIONS OF THE METHOD

Wright et al. (1981) described a similar method for long-term recording of intestinal mechanical and electrical activity in the unrestrained rat. Mechanical activity is detected using miniaturized half-bridge metal foil strain-gauge force transducers. The electrical activity is monitored by silver/silver chloride bipolar electrodes. The lead wires from the recording units are encased in a metal compression spring and are permanently joint to a ball connector positioned on the top of the cage, such allowing the animal free access to all parts of the cage.

Stam et al. (1995) described computer analysis of the migrating motility complex of the small intestine recorded in freely moving rats. Myoelectric activity of the small intestine was recorded digitally in fasted, freely moving rats with multiple pairs of electrodes in the antimesenterial smooth muscle. A computer program was developed to distinguish the three characteristic phases of the migrating motility complex.

Fändriks (1993) measured duodenal wall motility, mucosal fluid transport and alkaline secretion in anesthetized **cats**. A triple-lumen tube supplied with two small balloons was positioned via the esophagus in the duodenal lumen and its distal end was led through a small incision in the antimesenteric border of the distal duodenum at the level of the ligament of Treitz. The most oral of the balloons was positioned immediately to the pylorus. After filling with air, the balloons occluded the lumen and isolated a 2 cm segment of the proximal duodenum. A double-lumen tube was inserted into the stomach for luminal perfusion.

Martinez et al. (1993), Jimenez et al. (1994) studied gastrointestinal motility and coordination in **chickens**. Animals were chronically implanted with electrodes in stomach, duodenum, ileum, caeca and rectum.

Nakajima et al. (1996) used a telemetric device (supplied by Data Sciences International, Inc., St Paul, MN) which can be implanted in the abdominal cavity of small animals. Gastric motility of freely moving rats could be continuously recorded for up to 60 days.

J.4.3.6 Propulsive gut motility in mice

PURPOSE AND RATIONALE

The passage of a charcoal meal through the gastrointestinal tract in mice is used as parameter for intestinal motility and to study the effect of laxatives.

PROCEDURE

Groups of 10 female mice (e.g., NMRI strain) weighing 15 g are fed an oat diet for 3 days. Eighteen hours prior to the experiment food, but not water, is withdrawn. The animals are treated either subcutaneously 15 min or orally 60 min before administration of the charcoal meal (0.2 ml of a 4% suspension of charcoal in 2% carboxymethylcellulose solution). The mice are sacrificed after various time intervals, 20 min, 40 min, 60 min and 120 min. Ten animals serve as controls for each time interval. The entire intestine is immediately removed and immersed in 5% formalin to halt peristalsis; then washed in running water. The distance the

meal has traveled through the intestine as indicated by the charcoal is measured and expressed as percent of the total distance from the pylorus to the caecum.

EVALUATION

Student's *t*-test is used to compare the control and the drug-treated group.

CRITICAL ASSESSMENT OF THE METHOD

The charcoal passage test can be used for evaluation of laxative activity as well as for inhibition of intestinal motility.

MODIFICATIONS OF THE METHOD

Instead of charcoal, unsubstituted Hostapermblau (CuPcB) suspended in gummi arabicum mucilage can be used.

Carmine red (15) suspended in a 1% tragacanth solution was used for measurement of small intestine transit in **rats** (Leng-Peschlow 1986).

Miller et al. (1981) measured the intestinal transit in the rat by the use of radiochromium (^{51}Cr). Female Sprague Dawley rats weighing approximately 200 g were implanted with indwelling silastic cannulae in the proximal duodenum. Following a 3 day recovery period, the animals were fasted for 18 h and then treated with the test compounds. Thirty min later, 0.2 ml of radiochromium (0.5 mCi $Na^{51}CrO_4$) was instilled into the small intestine via the indwelling silastic cannula. Twenty-five min after chromium instillation, the animals were sacrificed. The small intestine was carefully removed and divided into 10 equal segments. The radioactivity was determined with an automatic gamma counting system. The effect of drugs could be quantified by determining the geometric center of the distribution of chromium through the small intestine.

Shook et al. (1989) used radiolabeled chromium to measure gastrointestinal transit in mice.

Megens et al. (1989) used the charcoal test to study the *in vivo* dissociation between the antipropulsive and antidiarrheal properties of opioids in rats.

Lish and Peters (1957) recommended an intestinal antipropulsive test in intact insulin-treated rats providing certain advantages over the commonly used charcoal meal test for screening of synthetic antispasmodic and antipropulsive agents.

J.4.3.7 Nerve-jejunum preparation of the rabbit

PURPOSE AND RATIONALE

Perivascular nerve stimulation induces cessation of peristalsis of rabbit jejunum (Finkelman 1930). Effects of test compounds on this phenomenon can be tested.

PROCEDURE

Albino rabbits are sacrificed and the jejunal part of the gut prepared. The nerve lies in the mesentery along with the arterial blood supply. Nerve-jejunum preparations are suspended in an organ bath. The preparation is stimulated with pulses at a frequency of 20 Hz with 0.5 ms and about 5 volt for 10 s at 3 min intervals. Test compounds are applied to the organ bath in a cumulative manner at 6 min intervals. Peristalsis movements for each period of 3 min between drug application or of the period of cessation of peristalsis induced by nerve stimulation of the rabbit jejunum preparation are recorded. The effect of drugs on spontaneous peristalsis movement and on the cessation of peristalsis movement exerted by perivascular nerve stimulation is tested.

EVALUATION

The areas of peristalsis movement for each period of 3 min are measured using a planimeter. The effects are expressed as percentage of change between controls and test compound treated preparations.

Finkelman B (1930) On the nature of inhibition in the intestine. J Physiol 70:145–157

J.4.3.8 Motility of gastrointestinal tract in dogs

PURPOSE AND RATIONALE

Intraluminal pressure and motility of the small intestine can be measured in unanesthetized dogs with balloon catheter systems via a duodenal Mann-Bollman (1931) fistula according to Tasaka and Farrar (1976) or in the loop of a Thiry-Vella fistula (see below).

PROCEDURE

Fistulas of the small intestine are created in male Beagle dogs weighing 15–20 kg. The animals are anesthetized with 40 mg/kg pentobarbital i.v. and fixed on an operation table. After shaving and careful disinfection of the skin a midline incision is made. A 10–15 cm length of ileum, approximately 15 cm proximal to the caecum, is excised. The remaining ileum is anastomosed end-to-end. The excised ileum is anastomosed, end to side, to the proximal or middle jejunum. Radiopaque tantalum markers are sutured to the serosa distal to this anastomosis in order to guide the direction for subsequent intubation. The other end is sutured to the skin. To create a skin ileostomy which does not shrink rapidly, a small amount of muscle, fascia and subcutaneous tissue are excised from the abdominal wall.

For the measurement of the pressure inside the intestine, an air-filled system is employed. Air-filled latex balloons (Cementex), 5 mm in diameter, are attached to air-filled PE 190 polyethylene catheters (ID 1.19 mm) with a length of 120 cm. Three balloon-catheter pressure assemblies are tied together with the balloons 5 cm apart. The catheters are connected to Statham p23 db pressure transducers and to a polygraph. The transducers are rendered airtight by repeated applications of latex to all the connections.

The dogs are withheld from food, but not from water 18 h prior to the experiment. The balloon-catheter assemblies are introduced through the fistula and secured in an appropriate position. The system is filled with air to a pressure of 10 mm Hg. Similarly, balloon-catheter assemblies can be introduced into a Thiry-Vella fistula.

Intraluminal pressure is measured continuously; frequency and amplitude of pressure waves are recorded. After a period of 1 h, the test drug is administered orally or subcutaneously and the above mentioned parameters recorded for 10 min intervals.

EVALUATION

For 10 min intervals amplitude frequency (f_A), average degree and duration of amplitudes (A) and average pressure performance (PL_i) are calculated. Post-drug values are compared with pre-drug readings.

MODIFICATIONS OF THE METHOD

Goldenberg and Burns (1973) reported on a technique using rubber balloon catheters inserted in the duodenum, ileum, or colon of dogs, secured by purse-string sutures and filled with water to record intraluminal pressure monitored by Statham pressure transducers connected to a polygraph. Furthermore, an antispasmodic agent can be tested for relaxation of morphine sulfate (0.3 mg/kg i.v.) induced spasms of the intestinal tract.

Fox et al. (1985) implanted chronically extraluminal strain gage force transducers on the serosal surface of the gastrointestinal tract of dogs.

J.4.3.9 Thiry-Vella fistula

PURPOSE AND RATIONALE

As described first by Thiry (1864) and improved by Vella (1892), a part of the jejunum is isolated and the ends are exteriorized through the abdominal wall allowing to measure *in vivo* motility and function of the intestines in dogs and other species (Boldyreff 1925).

PROCEDURE

Male Beagle dogs weighing 15–20 kg are used. They are fasted 24 h preoperatively. Intravenous pentobarbital sodium, 30 mg/kg, provides satisfactory anesthesia. It can be supplemented, if necessary, during operation. The abdominal part is shaved with electric clippers, then with a razor. The skin is disinfected with Zephiran® –70% alcohol. Sterile drapes are applied to cover the whole operative field. A mid-line linea alba incision is made. A loop of the jejunum, about 70 cm in length, is separated leaving the blood supply through the mesenterium intact. Both distal and proximal ends are exteriorized through the abdominal wall and provided with stomata. An end-to-end jejuno-jejunal anastomosis is performed.

EVALUATION

The preparation can be used to evaluate intestinal motility. A latex balloon connected via a polyethylene catheter to a pressure transducer (Statham P 23 BB) is introduced through the proximal ostium. Changes in intragastric pressure are measured on a frequency measurement bridge and are recorded continuously. The number and height of the pressure waves are used as indices of intestinal motor activity. Secretin inhibits motility of the small intestine dose-dependent.

MODIFICATIONS OF THE METHOD

Sarr et al. (1981) and Bastidas et al. (1990) used **dogs** with Thiry-Vella loops to study jejunal absorption.

Bilchik et al. (1993) examined the effects of physiological doses of peptide YY in dogs with jejunal and ileal exteriorized, neurovascularly intact Thiry-Vella fistulas.

Ashton et al. (1996) created Thiry-Vella fistulas using a 20 cm segment of distal colon under general anesthesia in dogs. Colonic absorption of water and electrolytes was evaluated in awake, conscious animals.

Liu et al. (1996a) studied the effects of intravenous peptide YY on colonic water and electrolyte transport in awake dogs which had 20 cm neurovascularly intact colon Thiry-Vella fistulas.

In an other study, Liu et al. (1996b) evaluated the effects of cholecystokinin and peptide YY on intestinal absorption of water and electrolytes using colonic, ileal, or jejunal fistulas in dogs.

These authors (Liu et al. 1995) also examined the effects of intraluminal administration of a new substituted peptide YY analog on intestinal absorption of water and electrolytes in dog with jejunal, ileal and colonic Thiry-Vella fistulas.

Barry et al. (1995) investigated the effect of luminally administered dopamine, the D_1-receptor agonist SKF 38 393, the α_1-receptor antagonist terazosin, and the α_2-receptor antagonist yohimbine on ileal water and electrolyte transport in dogs with Thiry-Vella fistulas.

Walters et al. (1994) described the effect of a model of canine jejuno-ileal orthotopic autotransplantation on jejunal and ileal transport of water and electrolytes. For neurally intact jejunal loops, myoneural continuity between the loop and the proximal duodenum and jejunum was maintained by preserving a bridge of tunica muscularis devoid of mucosa between the proximal jejunum and the loop. All intrinsic neural and lymphatic continuity to the loop was carefully maintained by not transecting any of the mesentery to the loop.

For the autotransplanted jejunal loop the dogs underwent construction of an identical loop with the muscular bridge after preparation of an jejuno-ileal autotransplantation. For this purpose, all neural, lymphatic, myogenous, and connective tissue connections with the jejuno-ileum were transected except for the fully isolated and stripped superior mesentery artery and vein at the base of the small bowel mesentery. The perivascular and adventitial tissue of these two vessels were carefully dissected away and transected under optical magnification. From here, the mesenteries to the distal duodenum and to the distal ileum were transected in radial fashion and the distal duodenum and distal ileum 5 cm from the ileo-colonic junction were also transected. At this point, the jejuno-ileum was completely isolated from any neural/lymphatic continuity with the dog except for any neural/lymphatic elements travelling within the media of the mesenteric artery and vein.

Neurally intact and autotransplanted ileal loops were prepared in a similar way.

Remie et al. (1990) described in detail the preparation of a Thiry-Vella loop in the **rat**. After laparatomy the segment to be isolated has to be located carefully. The segment should be vascularized by two or more tributary arteries. For ligation of the arcade, two ligatures are placed around the blood vessels 2–3 mm from each other. The two ligatures are tightened, the gut wall is disinfected with iodine solution, and both the vessels of the arcade and the gut wall are cut. The same procedure is performed at the other end of the segment to be isolated. This segment is laid on gauze moistened with warm saline avoiding torsion of the vessels. For end-to-end anastomosis the remaining parts of the gut are approximated and two corner sutures are placed. A continuous suture with transfixing stitches is placed on the anterior and posterior wall. Using a pair of sharp scissors two holes are made in the abdominal wall and the skin. Subsequently, standard end-to-side anastomosis technique is used to sew the gut to the internal abdominal muscle. The two stay sutures are at 180° and the posterior wall is sutured first. Following this, the skin is sutured to the abdominal muscle, using a running suture.

Chu et al. (1995) used Thiry-Vella fistulas of either the jejunum or ileum in rats in order to determine whether the trophic effects of bombesin on the small bowel mucosa are mediated by nonluminal factors or endogenous luminal secretion.

Bárdos and Nagy (1995) prepared double Thiry-Vella fistulas in rats. The first Thiry-Vella loop was created from the lower duodenum. After 1 month or more, a similar fistula was prepared from the upper part of the colon. The two loops were positioned along the midline and formed a line of 4 openings of the abdominal wall providing an easy access for inserting stimulatory devices to either of the loops in the same animal. A rubber balloon made of latex rubber was tied to a

silicon rubber tube, inserted into the isolated loop via one of its orifices and then fixed to the body by a tape. Stimulation was performed by injection of various volumes of water into the balloon from an attached syringe. Behavioral reactions of the animals were recorded as scores during 10 s stimulation periods.

In order to purify the putative luminal cholecystokinin-releasing factor, Spannagel et al. (1996) collected intestinal secretions by perfusing a modified Thiry-Vella fistula of jejunum in conscious rats.

Gianotti and Tchervenkov (1992) used a Thiry-Vella loop in **guinea pigs** to study the stimulatory effect of intraluminal nutriment on burned guinea pig intestinal mucosa.

Philpott et (1993) created Thiry-Vella loops in 21 week old **rabbits** in order to study the influence of luminal factors on intestinal repair during refeeding of malnourished infant rabbits.

Silbart et al. (1996) examined the ability of several bacterial endotoxins and their subunits to act as adjuvants or carrier proteins in stimulating an intestinal secretory Ig4 response to 2-acetylaminoflourene using Thiry-Vella loops in rabbits.

J.4.3.10 Continuous recording of mechanical and electrical activity in the intestine of conscious dogs

PURPOSE AND RATIONALE

Cyclic motor activity occurring in almost all parts of the gastrointestinal tract is due to a migrating electric

complex (Szurszewski 1969; Fioramonti et al. 1980; Sarna and Condon 1984; Sarna et al. 1984; Sarna 1985). Smooth muscle cells of the gut show periodic oscillations of membrane potentials called electrically controlled activity; they are also named slow waves, basic electrical rhythm, or pacesetter potentials. If the membrane potential depolarizes beyond a certain threshold during such an oscillation, the smooth muscle contracts. This is usually associated with a rapid burst of electrical oscillations, called electrical response activities or spikes. Electrical response activity is, therefore, associated with contractions on a 1 : 1 basis.

Implantation of extraluminal force transducers allows the monitoring of contractile activity in conscious animals (Bass and Wiley 1972; Ormsbee and Bass 1976; Ormsbee et al. 1981). The data can be analyzed by computer (Ehrlein and Hiesinger 1982; Schemann et al. 1985). The effects of opiate agonists, morphine, natural enkephalins, endorphins, and synthetic enkephalins and opiate antagonists, like nalorphine, as well as other gastrointestinal hormones, such as motilin, can be studied (Bickel and Belz 1985, 1988; Bickel et al. 1985).

PROCEDURE

Male Beagle dogs weighing 15–20 kg are anesthetized with thiobarbital and anesthesia is then maintained with halothane and a mixture of N_2O and O_2 (3 : 1). Under aseptic conditions several miniaturized strain gauge force transducers are sutured onto the muscular layers of the gastrointestinal tract. Before implantation, the transducers are externally calibrated giving linear signals over a range from 10 to 300 mN. Each transducer has its recording axis perpendicular to the longitudinal axis of the intestine to record contractions of the circular smooth muscles. The proximal ends of the strain gauge transducers are fitted to a plug embedded in a stainless-steel cannula implanted into the abdominal wall. The signals are continuously recorded and stored in a HP 9 835A Hewlett Packard computer, allowing later analysis of the data.

For measuring electrical activity, bipolar electrodes are implanted at several parts of the intestinal tract. The lead wires from the electrodes are externalized via a stainless-steel cannula. Electromyogram is recorded on an electroencephalograph.

The animals are kept in a standardized environment with one daily feeding at 9:00 A.M. The dogs are trained to stand in a Pawlov stand. Eighteen hours prior to the beginning of the experiment, the animals are fasted with access to water. Motility data and electrical activity are first recorded for fasting dogs without drug treatment. Then the drug is injected intravenously during the period of quiescence of the migrating motor complex.

EVALUATION

Recordings are analyzed for duration of cycles (min) and motor complexes (min), mean height (mN) and frequency (*n*/min). The length of the cycles is measured from the beginning of one complex to the beginning of the next complex. Electromyogram is analyzed for slow waves (cycles/min), maximum amplitude of the spike bursts (mV), duration of the spike bursts (ms) and duration of the effect (min). The data before and after administration of various doses of the test compound are compared by statistical means (Student's *t*-test).

MODIFICATIONS OF THE METHOD

Itoh et al. (1977) and Nagakura et al. (1996) used extraluminal force transducers for recording contractile motility of the gastrointestinal smooth muscle in conscious dogs.

Nakada (1995) recorded gastrointestinal and gallbladder contractions in conscious dogs by chronically implanted strain gauge transducers and gallbladder volume changes by a chronically indwelling gallbladder catheter.

Orihata and Sarna (1994) investigated contractile mechanism of gastroprokinetic agents in conscious dogs. The spatial and temporal parameters of gastric, pyloric and duodenal contractions during the entire period of gastroduodenal emptying, during a 60-min period of drug infusion and during the post-drug-infusion period were analyzed by a computer method.

J.4.4 Absorption

J.4.4.1 Everted sac technique

PURPOSE AND RATIONALE

The everted sac technique is used to study the transport of substances from the mucosal to the serosal surface (Wilson and Wiseman 1954).

PROCEDURE

Male Wistar rats weighing 150–220 g are anesthetized with 30 mg/kg pentobarbitone s.c. A midline abdominal incision is made. The rats are sacrificed by cardiac puncture. The small intestine from the ligament of Treitz to the ileocaecal junction with a length of 6–7 cm is rapidly removed and everted with a glass rod. The sac is securely ligated at both ends and filled with Krebs-Henseleit bicarbonate buffer solution (pH 7.4) containing 0.4% glucose and pre-gassed with 95% O_2/5% CO_2. The sac is incubated at 37 °C in a glass vessel containing the same buffer solution and gassed with 95% O_2/5% CO_2.

After 5 min, the drug solution is added to the glass vessel and the preparation is further incubated. After given time intervals, the fluid from the everted sac is removed and the volume determined. The concentration of the drug transported from the mucosal to the serosal side is determined by appropriate analytical methods.

EVALUATION

Determinations of the drug in the everted sac at different time intervals allow evaluation of pharmacokinetic parameters.

MODIFICATIONS OF THE METHOD

Madar (1983) used the small intestine everted sac of **chicken** for demonstration of amino acid and glucose transport.

Harnett et al. (1989) used everted segments of distal ileum of **rats** to study taurocholate absorption.

Turner et al. (1990) used everted sacs of ileum in **sheep** to study selenate and selenite absorption.

Goerg et al. (1992) used the stripped descending colon of the **rat** as everted sac to study the inhibition of neuronally mediated secretion in rat colonic mucosa by prostaglandin D_2.

Under ether anesthesia, the descending colon is removed and transferred into ice-cold bathing solution. The colon is placed on a plastic rod. After a circular incision with a blunt scalpel, the serosa and muscularis propria are stripped away, leaving the mucosal-submucosal preparation consisting of the mucosa, the muscularis mucosae, and a part of the submucosa with the completely preserved submucosal plexus. The tube-like mucosal-submucosal preparation is mounted as an everted sac in a holding apparatus (volume of the outer compartment 25 ml). The potential difference between the outer mucosal side and inner serosal side is measured by two agar bridges. The tissue is short-circuited by a voltage clamp after correcting for the offset potential and compensating for the solution resistance.

Moreover, transmural ion fluxes can be determined with the everted sac technique. Net fluxes of sodium, chloride, and potassium are studied by direct measurements of volume changes and changes of electrolyte concentrations in the inner volume of the everted sacs. Unidirectional fluxes can be determined simultaneously with the direct measurement of net fluxes by adding the isotopes $^{22}Na^+$ and $^{36}Cl^-$ to one side of the everted sac.

Schilling and Mitra (1990) used the everted gut technique in rats to study enteral insulin absorption.

Mizuma et al. (1993) studied the active absorption in the intestine and metabolism of the β- and α-anomers of the glucoside and galactoside of p-nitrophenol to find a more suitable prodrug for poorly absorbed drugs. The everted sac technique was used to investigate the intestinal absorption of these glycosides from the mucosal to the serosal side of the rat jejunum.

Kitagawa et al. (1996) investigated the influence of various factors, such as temperature, on the absorption of methochlorpromazine in the small intestinal everted sac of rats.

Tanaka et al. (1996) estimated the transport characteristics of thyrotropin-releasing hormone (TRH) and

its chemically modified derivative with lauric acid (Lau-TRH) across the rat small or large intestine by means of an *in vitro* everted sac experiment.

Sasaki et al. (1995) studied the absorption characteristics of azetirelin, a new thyrotropin-releasing hormone analogue in rats by means of *in situ* closed loop and *in vitro* everted sac experiments.

Toskulkao et al. (1995) examined the effects of stevioside (a natural non-nutritive sweetening agent) and of steviol (a product of enzymatic hydrolysis of stevioside) on intestinal glucose absorption in hamster jejunum using the everted sac technique.

Motozono et al. (1994) determined the effect of age on gastrointestinal absorption of tobramycin in suckling, weanling and adult rats by an everted sac method.

J.4.4.2 Stomach emptying and intestinal absorption in rats

PURPOSE AND RATIONALE

Reynell and Spray (1956) described a method for the simultaneous measurements of gastric emptying, intestinal transit and absorption of test substances in the rat using phenol red as marker.

PROCEDURE

Adult male Wistar rats weighing 200–300 g are allowed water but are deprived of food 24 h before the experiment. They are treated orally or subcutaneously with the test compound 15 min prior to oral administration by gavage of 1.5 ml 0.07% phenol red in 2% carboymethylcellulose solution. Fifteen min later the animal is sacrificed and the stomach is immediately removed. The whole stomach including the stomach content is alkalized with 1 N NaOH and homogenized. The homogenate is filtered, and after precipitation of the protein with 10% trichloroacetic acid, centrifuged for 15 min at 3 000 rpm. The concentration of phenol red in the supernatant is measured colorimetrically in a photometer at 546 nm.

EVALUATION

Percentage of stomach emptying (S_e) is calculated according to the following formula:

$$S_e = 100 - P_s \times P_a^{-1} \times 100$$

- P_s = Concentration of phenol red in the stomach (µg/ml)
- P_a = Concentration of phenol red in the initial solution after addition of equal volumes of 1 N NaOH and trichloroacetic acid (µg/ml)

MODIFICATIONS OF THE METHOD

By selective ligations of the different parts of the gastrointestinal tract and analysis for phenol red contents and for drug substance, as well as by sacrificing the animals after various time intervals, the degree and time course of absorption can be studied.

Droppleman et al. (1980) described a simplified method for assessing drug effects on gastric emptying in **rats**. Three ml of a semi-solid test meal, based on

methylcellulose, are given to rats fasted 24 h prior to the experiment. At a specified time following the test meal, the rats are sacrificed, laparatomized, and the stomachs removed. The full stomachs are weighed on an analytical balance; they are opened and rinsed. Excess moisture is removed and the empty stomach weighed again. The difference is subtracted from the weight of 3 ml of the test meal, indicating the quantity emptied from the stomach during the test period. Gastric motor stimulants, e.g., metoclopramide increase, and anticholinergic compounds decrease gastric emptying.

Megens et al. (1990) used phenol red as marker to measure gastrointestinal propulsion after castor oil or paraffin oil challenge in **rats**.

Hedge et al. (1995) studied 5-HT_4 receptor mediated stimulation of gastric emptying in rats using a specially prepared semi-solid test meal containing charcoal.

Bonnafous et al. (1995) investigated benzodiazepine-withdrawal-induced gastric emptying disturbances in rats. Male Wistar rats, weighing 200–250 g, fasted for 16 h, received by gavage 2 ml of a test meal containing 1 µCi/ml of ^{51}Cr sodium chromate, 15 min after drug administration. Thirty min later, the animals were sacrificed by cervical dislocation. The stomach, small intestine (10 segments) and the colon were excised and placed into tubes. Radioactivity was determined by placing the tubes in a gamma counter. Gastric emptying was calculated as the percentage of total counts found in the small intestine and the colon.

Varga et al. (1995) determined gastric emptying in rats 5 min after a 3-ml intragastric load of 0.9% NaCl using phenol red as marker in order to define which bombesin receptors are involved in the delay of gastric emptying by bombesin-like peptides.

Lasheras et al. (1996) studied gastric emptying in rats. Sixty min after oral administration of vehicle or test compounds, the rats received by gavage 40 steel spheroids (1 mm diameter) in 2 ml 3% carboxymethylcellulose. Sixty min later, the animals were sacrificed and the spheroids remaining inside the stomach counted.

Yegen et al. (1996) studied the inhibitory effects of gastrin releasing peptide on gastric emptying in rats using methyl cellulose and phenol red as non-absorbable marker.

Haga et al. (1994) studied gastric emptying in **mice**. Male mice, weighing 18–22 g, had free access to food and water before the experiment. The test compounds were administered orally in 10 ml/kg 0.5% methylcellulose solution. The mice were deprived of food an water and sacrificed 4 h later by cervical dislocation. The stomachs were removed and opened. The contents of the stomach were mixed with 10% trichloroacetic acid, and centrifuged at 3 000 rpm for 30 min. The weight of the sediment was taken as the food remaining in the stomach.

Ding and Håkanson (1996) examined the effect of drugs on a cholecystokinin-A receptor-mediated response by gastric emptying of a charcoal meal in mice.

Costall et al. (1987) used the **guinea pig** to study the influence of a 5-HT_3 antagonist on gastric emptying.

Brighton et al. (1987) used scintigraphy following indium-111-labeled meals in Beagle **dogs** and **baboons**. Indium-111-labeled polystyrene beads (500 mCi per dog) were mixed into a meal consisting of 50 g of finely crushed commercial dog food and 50 ml of milk. Images of 1 min duration were taken every 5 min for a period of 1 h using a large field of view gamma camera (ON Sigma 410).

Gullikson et al. (1991, 1993) studied gastric emptying of a solid meal in dogs.

J.4.4.3 Intestinal drug absorption

PURPOSE AND RATIONALE

Doluisio et al. (1969) described an *in situ* rat gut technique to determine absorption rates of drugs.

PROCEDURE

Male Sprague-Dawley albino rats weighing 220–260 g are fasted 16–24 h prior to surgery allowing, however, drinking water ad libitum. They are kept in cages having wide mesh floors to prevent coprophagia. One hour prior to surgery, the animals are anesthetized with 1 g/kg ethylurethane i.p. The small intestine is exposed by a midline abdominal incision, and two L-shaped glass cannulae are inserted through small slits at the duodenal and ileal ends. Care has to be taken to handle the small intestine gently in order to maintain an intact blood flow. The cannulae are secured by ligation with silk suture, and the intestine is returned to the abdominal cavity. Four cm long segments of tubings are attached to the exposed ends of both cannulae, and a 30-ml hypodermic syringe fitted with a three-way stop-cock and containing perfusion fluid warmed to 37 °C is attached to the duodenal cannula. As a means of clearing the gut, perfusion fluid is passed slowly through it and out the ileal cannula to be discarded until the effluent is clear. The remaining perfusion solution is carefully expelled from the intestine by means of air pumped through from the syringe.

Immediately afterwards, 10 ml of drug solution are introduced into the intestine by means of a syringe. The stopwatch is started, and the ileal cannula is connected to another 30 ml syringe fitted with a three-way stopcock. This arrangement enables the operator to pump the lumen solution into either the ileal or the duodenal syringe, remove 0.1-ml aliquots, and return the remaining solution to the intestine within 10–15 s. To assure uniform drug solution concentrations throughout the gut segment, aliquots are removed from the syringes alternatively. Samples are collected every 5 min. Depending on the drug to be studied, the concentration is determined by chemical methods.

EVALUATION

The concentrations of the drug are plotted on a logarithmic scale on the ordinate versus time on the abscissa on a linear scale. Half-life values can be calculated.

MODIFICATIONS OF THE METHOD

Ochsenfahrt (1979) described a more sophisticated method to measure the absorption of drugs in the vascularly perfused, isolated intestine of the rat. Male rats weighing about 350 g are anesthetized with urethane. The abdomen is opened by a midline incision. The mesentery of the ascending and transverse colon is gently pulled away from the mesentery of the small intestine. The vessels to the colon are ligated and cut. The superior mesenteric artery is freed from the surrounding mesentery. The duodenal vessels are ligated and cut. A suitable segment of the jejunum of about 7 cm length is selected. The proximal cannula is tied into the lumen of this segment, and the duodenum is cut. The lumen of the segment is washed with 3–4 ml warm Krebs-Henseleit solution. Then, the distal cannula is tied. After the mesenteric vessels distal to the experimental segment are ligated, the rest of the small intestine, ileum, and colon is excised. Temporarily, the intestine is covered with gauze soaked with saline solution.

The preparation of the rat is interrupted for 8–10 min, while a second rat (donor rat), which has been anesthetized with urethane, is prepared. The donor rat supplies the arterial blood; the spontaneous respiration is supported with a respiration pump through a tracheal cannula. The right jugular vein of the donor rat is cannulated for the blood infusion and 2 mg heparin dissolved in 0.1 saline solution is administered. A cannula is placed into the left carotid artery of the donor rat; this tube is later connected to the superior mesenteric artery of the test segment. Blood lost by the donor rat is replaced with heparinized blood taken from other rats immediately before the beginning of the experiment.

In the test animal, a thin silicon tube is inserted in the left carotid artery. Two mg heparin, dissolved in 0.1 ml saline, are injected. The superior mesenteric vein is ligated distal to the splenic vein and a plastic cannula is inserted for venous outflow. The cannula is then connected to a drop counter. The luminal cannulae of the segment are connected to a recirculation unit which is filled with Krebs-Henseleit solution at 37 °C, and the luminal perfusion of the segment (mucosal solution) is started. The mucosal solution is oxygenated and recirculated. The superior mesenteric artery is ligated with a thread at its origin at the aorta and then cannulated. This cannula is first connected to the carotid artery of the test animal and later to the carotid

artery of the donor animal. The isolated vascularly perfused segment is suspended in a serosal bath containing Krebs-Henseleit solution at 37 °C. Venous blood outflow is collected in plastic vials at 15 min intervals. Samples are taken from the mucosal and serosal solutions at the beginning and the end of each period. By this way, the mucosal disappearance rate, the venous appearance rate, and the serosal appearance rate can be measured.

Schilling and Mitra (1992) measured insulin absorption from the distal duodenum/proximal jejunum and from the distal jejunum/proximal ileum in anesthetized rats by the closed-loop technique.

Schümann and Hunder (1996) described a modified device for the differentiated study of intestinal transfer in isolated intestinal segments from mice and suckling rats *in vitro*. A luminal perfusion system for small intestinal segments was adapted for the use in mice and rat pups to investigate longitudinal differences in drug and toxin transfer.

J.4.5 Duodenal ulcer formation

J.4.5.1 Cysteamine-induced duodenal ulcers in rats

PURPOSE AND RATIONALE

Duodenal ulcers can be induced in rats by repeated administration of cysteamine or propionitrile in rats (Dzan et al. 1975; Szabo 1978; Szabo et al. 1979).

PROCEDURE

Male Sprague-Dawley rats with an initial weight of 200 g are used. Cysteamine-HCl is administered three times on day 1 in a dose of 280 mg/kg orally. Protective drugs, such as H_2-antagonists, are given 30 min prior cysteamine treatment. The rats are sacrificed on the third day. For histological evaluation, the stomach and duodenum are fixed in 10% aqueous buffered formaldehyde and paraffin-embedded sections are stained with hematoxylin and eosin. Duodenal ulcers develop in the anterior (antimesenteric) and posterior wall of the proximal duodenum, about 2–4 mm from the pylorus. The more severe ulcers, located on the anterior wall, frequently perforate, resulting in focal or generalized peritonitis, or penetrate into the liver. The opposite ulcer invariably penetrates into the pancreas.

EVALUATION

The intensity of the duodenal ulcer is evaluated using scores from 0 to 3.

- 0 = no ulcer
- 1 = superficial mucosal erosion
- 2 = deep ulcer usually with transmural necrosis
- 3 = perforated or penetrated ulcer

CRITICAL ASSESSMENT OF THE METHOD

In view of the development of modern gastric K^+/H^+-ATPase inhibitors the predictive value of methods using experimental ulcers in the rat for clinical healing rates in man has been challenged (Herling and Weidmann 1994).

MODIFICATIONS OF THE METHOD

The cysteamine-induced duodenal ulcer has been used for pharmacological studies by many authors, e.g.: Evangelista et al. (1992), Krantis et al. (1993), Pascaud et al. (1993), Tanaka et al. (1993), Morimoto et al. (1994), Pendley et al. (1995), Sikiric et al. (1997), Drago et al. (1999).

Okabe et al. (1971), Sato et al. (1989) described a method for experimental, penetrating gastric and duodenal ulcers in rats. Rats were anesthetized with ether and an incision was made in the abdomen. A round metal mold, 6 mm in diameter, was placed in close contact with the serosal surface of the duodenal wall, about 7 mm distal to the pylorus. **Glacial acetic acid** (60 ml) war poured into the mold and was left in place for 20 s. After the acetic acid was removed, the treated surface was rinsed with 50 ml of 0.02 N NaOH and the abdomen was closed. A drug or the vehicle was given p.o. once a day for 14 consecutive days beginning 2 days after the operation. The animals were sacrificed on the 16th day after the operation and the ulcerated area (mm^2) was measured.

Mepirizole-induced duodenal ulcers were described by Okabe et al. (1982), Sato et al. (1989), Tanaka et al. (1989). A drug or the vehicle was given p.o. 30 min before mepirizole (200 mg/kg) was administered s.c. Twenty-four hours later, 1 ml of 0.5% Evan's blue solution was injected via the tail vein of each rat and the rats were sacrificed by CO_2 asphyxiation. The gastroduodenal region was removed and examined for lesions.

J.4.6
Models of inflammatory gut disease

J.4.6.1
Experimental ileitis

PURPOSE AND RATIONALE

An experimental model of inflammatory bowel disease produced by the intraluminal administration of the cytotoxic plant lectin ricin into the rabbit ileum was developed by Sjogren et al. (1994), Goldhill et al. (1995, 1997). *In vitro*, electric field stimulation results in larger non-cholinergic excitatory junction potentials in ricin-treated circular muscles than in controls.

PROCEDURE

Inflammation

Acute ileitis is induced with ricin in male New Zealand white rabbits. The animals are anesthetized with intramuscular xylazine (9 mg/kg) and ketamine (50 mg/kg) and maintained with intravenous pentobarbital (15 mg/kg). A midline incision is made, a ligated terminal ileal loop (~10 cm in length) is constructed in each animal and 1 ml of ricin (1 mg/ml) or vehicle is injected into the lumen. The loop is removed after 5 h, a time period that allows development of ileitis, abnormal myoelectric activity and increased response to electric field stimulation. Animals are sacrificed with an overdose of pentobarbital. The loop is opened along its length, gently flushed of luminal contents with cold oxygenated Krebs-bicarbonate-saline and prepared for contractility studies.

Contractility studies

Muscle strips (~1×0.4 cm) with mucosa removed are cut in the axis of the circular muscle and attached to isometric tension transducers in 10-ml organ baths with modified oxygenated Krebs-bicarbonate-saline at 37.5 ±0.5°C. Tissues are allowed to equilibrate at L_i (the length at which no tension can be measured) for 20 min. The strips are then stretched to L_0, which is

determined as the length at which maximum force is generated in response to acetylcholine (0.5–1 mM). Strips are then allowed to equilibrate for an additional 20 min.

Effect of inflammation on response to tachykinins

Concentration-response curves are constructed to substance P and neurokinin agonists (or analogues) on separate muscle strips in vehicle- and ricin-treated tissues. Studies are performed in the presence or absence of tetrodotoxin to distinguish between neural and non-neural effects of ricin treatment.

Effects of ricin treatment to responses to electrical field stimulation

Muscle strips are passed through a pair of ring electrodes (2-mm diameter) and stimulated for 10 s by square-wave pulses (0.5 ms duration, supramaximal voltage) at 1–10 Hz. Stimulation is performed in the presence of atropine (1 mM) and N^G-nitro-L-arginine methyl ester) (L-NAME) (0.1 mM).

EVALUATION

Maximum increases in muscle tone in response to tachykinin addition of electrical field stimulation are obtained through visual analysis of chart recorder outputs. Responses to tachykinins are expressed as absolute tension development. Electrical field stimulation data are expressed as a percentage of the response to 1 μM acetylcholine added at L_0 to reduce the variation of the data. Values are given as mean ±SEM Tachykinin concentration responses are fitted to sigmoid curves and EC_{50} values (with 95% confidence intervals) are determined from these curves. Differences between frequency or concentration-response curves are assessed statistically by multivariate analysis of variance, with adjustments made for multiple comparisons. In cases in which curves are significantly different to one another, maximal responses were compared statistically using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Miller et al. (1991) induced ileitis in **rabbits** by luminal perfusion with histamine monochloramine or with acetic acid.

Rachmilewitz et al. (1997) induced inflammation in the small intestine in **rats** by intrajejunal administration of 0.1 ml 2% iodoacetamide.

Sukumar et al. (1997) induced ileitis in rats by two doses of indomethacin (7.5 mg/kg) administered subcutaneously 24 h apart.

Ileitis in **guinea pigs** was induced by intraluminal trinitrobenzene sulfonic acid (Miller et al. 1993; Izzo et al. 1998; Mazelin et al. 1998).

Likewise, ileitis in **hamsters** was induced by intraluminal injection of trinitrobenzene sulfonic acid (Boyd et al. 1995).

Shibata et al. (1993) induced ileitis in **dogs** by administration of 10 ml 100% ethanol and 1 g trinitrobenzene sulfonic acid dissolved in 10 ml water through a tube inserted into the ileum.

J.4.6.2 Experimental colitis

PURPOSE AND RATIONALE

Inflammatory bowel diseases, ulcerative colitis and Crohn's disease, represent chronic alteration of the gastrointestinal tract of unknown etiology perhaps involving immunological events. The immunological parameters have been described as secondary but may possibly be attributed to the chronicity of the disease. Several compounds have been described to elicit cell-mediated immune responses in the gut, such as dinitrochlorobenzene

(DNCB) (Rosenberg and Fischer 1964; Norris et al. 1982; Norris 1989) or 2,4,6,-trinitrobenzene sulfonic acid (TNBS) (Morris et al. 1989; Selve and Wöhrmann 1992).

PROCEDURE

A three-step concept is realized to mimic the human disease, using 2,4,6-trinitrobenzene sulfonic acid (TNBS) as a defined hapten:

1. specific hypersensitivity by active immunization,
2. local inflammation by local challenge,
3. chronicity by chronic application of the immunogen.

Female Sprague Dawley rats weighing 150–200 g are sensitized by intradermal injection of 0.8% TNBS (Fluka, Neu-Ulm, Germany) solution into a shaved area on the back once daily for three consecutive days. TNBS is dissolved in 0.05 ml Freund's incomplete adjuvant together with 1 mg/ml ovalbumin. After 18 days, the animals receive a further intradermal booster injection. Intradermal challenge of 0.08% TNBS in 0.05 ml 0.9% NaCl solution with or without ovalbumin, or ovalbumin solution without TNBS, is given 14 days later in order to determine the type and specificity of the immunological reaction.

Ten days after the intradermal challenge, a flexible polyethylene tube of 0.5 mm diameter is implanted under ketamine (100 mg/kg i.p.) anesthesia 15 cm proximal to the cecum and emerging at the neck for TNBS or drug administration. After a 10-day recovery phase, the animals are treated daily for 3 weeks with 0.08% TNBS in saline (0.2 mg/rat) given through the catheter. Control groups receive only saline. Drugs are applied either by gavage twice a day. suspended in carboxymethyl cellulose, or intraluminally once a day, suspended in saline. The animals are sacrificed by CO_2 inhalation 24 h after the last intraluminal application of TNBS. The distal 10 cm of small intestine anterior to the ileo-caeco-colic junction (5 cm distance to the open end of the catheter) including Peyer's patches are dissected, cut open longitudinally and rinsed with saline.

Immediately after dissection, the distal small intestine is visually assessed for inflammation according to the following scores:

Enteritis score	*Gross morphology*
0	No visible damage of the whole 10 cm the small intestine
1	Slight inflammation, slight redness (hyperemia), villi visible under 15 fold magnification
2	Intermediate inflammation, discontinuous hyperemia, intermediate redness of villi
3	Intensive inflammation, intensive hyperemia, intensive redness of villi

The dissected gut segments, precisely 10 cm long, are weighed for measurement of edema formation. They are then incubated in Tris buffer for 30 min at 37 °C in a shaking water bath (1 ml/100 mg tissue, Tris 50 mM, pH 7.4, 100 mM NaCl, 1 mM $CaCl_2$, 1 mg/ml glucose). Following incubation, aliquots of the solutions are centrifuged (13 000 *g*, 2 min, 20 °C) for determination of leucotriene B_4 (TB_4) by a commercial radioimmuno-assay (e.g., Amersham Buchler, Brunswick).

EVALUATION

Results are expressed as means ±SEM of (*n*) experiments. Differences between control and inflamed tissue, and influence of drug treatment are compared. Statistical significance is calculated by Wilcoxon-Mann-Whitney *U*-test for unpaired data. The level of significance is taken as $p < 0.05$.

MODIFICATIONS OF THE METHOD

Several authors used the trinitrobenzene sulfonic acid model in *rats* with slight modifications (Kitano et al. 1996; Yue et al. 1996; Lora et al. 1997; Taniguchi et al. 1997; Cruz et al. 1998; Fries et al. 1998; Goldhill et al. 1998).

Zea-Ariate et al. (1994) studied chronic colitis in Wistar rats after intracolonic instillation of 20 or 42 mg of trinitrobenzene sulfonic acid in 30% and 40% ethanol and compared the effect with the administration of ethanol alone.

Alternatives to the 2,4,6-trinitrobenzene sulfonic acid model in **rats** were proposed:

Wallace et al. (1995), Hawkins et al. (1997) recommended dinitrobenzene sulfonic acid to produce experimental colitis in the rat.

Patterson and Colony (1983) tested sulphasalazine and 5-aminosalicylic acid in experimental colitis induced in **guinea pigs** by topical dinitrochlorobenzene.

Neurath et al. (1996) studied chronic intestinal inflammation induced by 2,4,6-trinitrobenzene sulfonic acid (TNBS) in **mice**.

These authors (Neurath et al. 1997) investigated the role of tumor necrosis factor in this mouse model and showed that no significant TNBS-induced colitis could be induced in mice in which the TNF-alpha gene had been inactivated by homologous recombination.

Antony et al. (1997), Oyen et al. (1997) used trinitrobenzene sulfonic acid to induce experimental colitis in **rabbits**.

Dams et al. (1998) compared gamma-camera imaging in rabbits with colitis after retrograde instillation of trinitrobenzene sulfonic acid with technetium-99m-labeled liposomes after various time intervals with macroscopically scored severity of inflammation.

A model of diffuse colitis in **rats** induced by intraluminal colonic instillation or serosal application of dilute **acetic acid** was described by MacPharson and Pfeiffer (1976, 1978). Ritzpatrick et al. (1990) tested the anti-inflammatory effects of various drugs on acetic acid induced colitis in the rat.

For instillation into the colon of rats, a 2 cm length of soft polyethylene tubing is fitted to a Luer stub adapter. The open end of the tubing is sealed with glue. The whole length of the tubing is perforated with a needle at 0.5 mm length by four holes, 90° apart. A 1 ml syringe containing 10% acetic acid in saline is fitted to the adapter. The tubing is inserted intrarectally into the colon of rats and 0.2 ml is injected into the lumen. After 10 s contact *in situ*, the remaining acid is withdrawn and the lumen washed with three successive 0.5 ml volumes of isotonic saline. Test drugs are administered daily during the following days. Diffuse colonic lesions appear after 3 days in control animals and the animals experience a bloody diarrhea. An initial mucosal inflammation develops into submucosal edema; petechial hemorrhages become enlarged with subsequent neutrophil invasion, and pseudopolyps become evident.

Terzioglu et al. (1997) studied the effect of prostaglandin E_1 on the experimental colitis induced by rectal instillation of 10% acetic acid in rats.

Fabia et al. (1994) induced colitis in rats in an exteriorized colonic segment by administration of 4% acetic acid for 15 s. Four days later, this colonic segment was examined using a morphological scoring system, and measurements of myeloperoxidase activity and plasma exudation into the colonic segment.

Eliakim et al. (1995) demonstrated that ketotifen ameliorated capsaicin-augmented acetic acid-induced colitis. Rats were pretreated with subcutaneous injections of 20, 30, and 50 mg/kg capsaicin. Colitis was induced 2 weeks later by flushing 2 ml 5% acetic acid into the proximal colon.

Higa et al. (1997) studied the role of neutrophils in the pathogenesis of acetic acid-induced colitis in mice.

Millar et al. (1996) evaluated the antioxidant potential of new treatments for inflammatory bowel disease using acetic acid-induced colitis in rats.

Myers et al. (1997) determined colonic transit in rats by calculating the geometric center of distribution of a radiolabeled marker (^{51}Cr) instilled into the proximal colon after induction of distal colitis by intracolonic administration of 4% acetic acid.

Several **other agents** can induce experimental colitis in animals (Kim and Berstadt 1992), such as

phorbol esters (Fretland et al. 1990),

carrageenan (Marcus and Watt 1969; Benitz et al. 1973; Watt and Marcus 1973; Abraham et al. 1974; Jensen et al. 1984. Kitano et al. 1994; Pricolo et al. 1996),

amylopectin-sulfate (Watt and Marcus 1972),

dextran sulfate (Ohkusa 1985; Okayasu et al. 1990; Axelsson et al. 1966; Shintani et al. 1997; Kanauchi et al. 1998),

the **chemotactic peptide FMLP** (Magnusson et al. 1985; *von Ritter et al. 1988;* LeDuc and Nast 1990).

Ekstrom (1998) described **oxazolone**-induced colitis in rats. Dark Agouti rats were skin-sensitized with oxazolone and further challenged intra-rectally with oxazolone dissolved in carmellose sodium/peanut oil.

Suzuki et al. (1997) developed a rat model for human ulcerative colitis by using **1-hydroxyanthraquinone** to cause severe inflammation of colonic mucosa.

Aiko et al. (1997), Satdnicki et al. (1998) induced chronic granulomatous colitis in female Lewis rats via intramural (subserosal) injections of **peptidoglycan-polysaccharide** into the distal colon.

Surfactants being used to enhance drug absorption may cause intestinal damage. Oberle et al. (1995) evaluated mucosal damage by surfactants in a single-pass *in situ* perfusion model in the rat. The release of LDH and mucus into the lumen of jejunum and colon following perfusion of the nonionic surfactants Tween 80 and Triton X-100 was determined.

Axelsson and Ahlstedt (1993) reviewed the actions of sulfasalazine and analogues in various animal models of experimental colitis, in particular in the hapten-, immune complex- and dextran models.

Bach et al. (1985) studied the inhibition of LTC synthetase and of rat liver glutathione *S*-transferases by sulfasalazine.

Stein et al. (1993) determined arachidonic acid oxidation and damage in the colon in rats stressed by the **cold-restraint** method.

Kirsner et al. (1959), Kraft et al. (1963) induced severe colitis in **rabbits** which had previously been sensitized to egg albumin and had mild colonic inflammation induced by intrarectal instillation of a small amount of diluted **formalin**.

Meenan et al. (1996) induced immune-complex colitis in rabbits by using various formalin concentrations (2%, 0.75%, and 0.5%).

Hodgson et al. (1978) induced colitis in rabbits by a modified technique. Preformed immune complex of human serum albumin and anti-HSA with antigen excess was injected to non-sensitized rabbits after provocation of mild inflammation in the colon with diluted formalin.

Kuroe et al. (1996a,b) induced granulomatous enterocolitis in rabbits by repeated submucosal injection

of **muramyl dipeptide** emulsion into the rectum and colon with a flexible endoscope. Extraintestinal manifestations, such as pericholangitis, were observed.

Walsh and Zeitlin (1987) studied the effects of salazopyrin, 5-aminosalicylic acid and prednisolone on immune complex-mediated colitis in **mice**.

A survey on various genetic and immune manipulations which lead to inflammatory bowel disease in mice was given by Powrie and Leach (1995).

$CD4^+$ T lymphocytes injected into severe immunodeficient (SCID) mice lead to an inflammatory and lethal bowel disease (Claesson et al. 1996; Leach et al. 1996; Rudolphi et al. 1996; Bregenholt et al. 1998).

Hermiston and Gordon (1995) described an inflammatory bowel disease in mice expressing a dominant negative N-cadherin resembling Crohn's disease.

Watanabe et al. (1998) reported that interleukin7 transgenic mice develop chronic colitis with decreased interleucin7 protein accumulation in the colonic mucosa.

Mitchell and Turk (1990) described a model of **gran-ulomatous bowel disease in guinea pigs**. Epithelioid cell granulomas and primary macrophage granulomas were induced by the inoculation of BCG (Pasteur) and irradiated Mycobacterium leprae, respectively, into the terminal ileum.

Wallace et al. (1998) induced colitis in guinea pigs and in rats by intracolonic administration of trinitrobenzene sulfonic acid.

Some **monkeys**, such as the cotton-top tamarin, *Saguinus oedipus* (Chalifoux and Bronson 1981; Madara et al. 1985; Lushbach et al. 1985; Podolsky et al. 1988; Hesterberg et al. 1996; Warren 1996), and juvenile rhesus monkeys (Adler et al. 1990), develop **spontaneous colitis**.

CRITICAL ASSESSMENT OF THE METHODS

The relevance of animal models for the pathogenesis and treatment of human inflammatory bowel disease was reviewed by Dieleman et al. (1997) and by Sartor (1997).

A critical review of *in vitro* models in inflammatory bowel disease was given by McKay et al. (1997).

J.5
Emetic and anti-emetic activity

J.5.0.1
Assessment of emetic and anti-emetic activity in dogs

PURPOSE AND RATIONALE

Emesis comparable to man occurs only in a few animal species. Among laboratory animals, the dog is a suitable species to test anti-emetic drugs. Apomorphine-induced emesis is also used to evaluate neuroleptic drugs (see E.5.3.8). Burkman (1982) described a technique relying upon the use of apomorphine either as a reference standard against which other emetics can be compared, or as a challenging agent against which anti-emetic compounds can be evaluated.

PROCEDURE

Beagle dogs weighing between 15 and 20 kg are used. Each dog is given 200 g food 30 min prior to an assay session. The threshold emetic dose of apomorphine

hydrochloride is established for each dog by administering single doses at 5 day intervals in gradually increasing amounts. The starting dose is 0.07 mM/kg (22 mg/kg) body weight, i.m., and is subsequently increased (or decreased) as required. Injection sites alternate between contralateral gluteus muscles. After every third or fourth dose of the emetic, the animals receive an equivalent volume of vehicle under similar conditions in order to detect the presence of a conditioned emetic response.

The threshold dose is defined as the concentration provoking an emetic episode and determined for each individual animal. The threshold emetic dose is relatively stable for a given group of dogs over a period of 2 months. Continued administration to the same dogs for longer periods of time is inadvisable as Pavlovian emetic conditioning becomes evident after 8–10 doses of apomorphine. Establishment of an emetic threshold for a test compound using a similar dosing schedule allows to quantitatively express the test compound's emetic potency as a ratio compared with the reference standard. Usually, 4–6 animals are sufficient to provide a reliable estimate of the test compound's emetic efficacy and potency.

In the anti-emetic assay, dogs whose apomorphine threshold emetic dose has been determined receive various concentrations of the potential anti-emetic drug at a given time interval prior to apomorphine. The dose initially selected for the anti-emetic is a fraction of the acute LD_{50} of this drug in mice. A new threshold dose is estimated in the presence of the test anti-emetic and compared to the threshold dose in the presence of the reference standard chlorpromazine.

EVALUATION

Using the threshold doses, the relative potency of an emetic compared to apomorphine, or the relative potency of an anti-emetic compared to chlorpromazine, is calculated.

MODIFICATIONS OF THE METHOD

Cisplatin-induced emesis in the **dog**, as described by Gylys et al. (1979), was used by Turconi et al. (1991) to test the anti-emetic properties of 5-HT_3 receptor antagonists.

Gupta and Sharma (1996) tested the activity of antioxidants against emesis induced by an intravenous dose of 3 mg/kg cisplatin in healthy mongrel dogs.

Szelenyi et al. (1994) described emesis in **domestic pigs** as a new experimental tool for detection of antiemetic drugs and for evaluation of the emetogenic potential of new anticancer agents. Healthy young, 12–15-week-old domestic pigs of either sex were lightly anesthetized with ketamine (10 mg/kg, i.v.) and xylazine (2 mg/kg, i.v.) and a cannula inserted into a superficial vein of one of the extremities. The challenging agents, e.g., cisplatin, carboplatin, cyclophosphamide, or ifosfamide were infused intravenously at different doses during a total administration time of 15 min. After removing of the cannula the animals were placed in their boxes for observation of emesis over 24 h. Drugs with anti-emetic potential were given intravenously 15 min prior cisplatin infusion.

Göthert et al. (1995) found a dose-dependent inhibition of cisplatin-induced emesis in pigs by anpirtoline, a mixed 5-HT_1 receptor agonist/5-HT_3 receptor antagonist.

Gardner et al. (1995, 1998) used the **house musk shrew** (*Suncus murinus*) to test antagonism against cisplatin-induced emesis.

J.5.0.2 Anti-emetic activity in ferrets

PURPOSE AND RATIONALE

The ferret is a well established animal model of emesis which responds to cancer chemotherapeutic agents in

a manner similar to that observed in man (Florczyk et al. 1982). The animals react with vomiting and retching after challenge with central (loperamide and apomorphine), peripheral ($CuSO_4$), or mixed central and peripheral (ipecacuanha, cisplatin) emetic stimuli. The model has been used to test the anti-emetic properties of 5-HT_3 receptor antagonists and tachykinin NK_1 receptor antagonists.

PROCEDURE

Adult male ferrets weighing 1 to 1.5 kg are randomly assigned to the different treatment groups. Each animal is anesthetized by inhalation with methoxyflurane. A jugular vein is cannulated and exteriorized from the outside of the neck. Following recovery from the anesthesia, the animals are dosed with the test drug or the standard or the vehicle 30 min prior i.v. administration of 10 mg/kg cisplatin. The numbers of retches and vomits occurring following the administration of the emetogen are recorded in each animal for 5 h. Retching is defined as rhythmic inspiratory movements against a closed glottis, and vomiting as forced expulsion of upper gastrointestinal contents.

EVALUATION

Duration of action of the compounds is assessed by determining the period of time for which the inhibitory effects remain significantly different from vehicle controls.

Statistical analysis of the data is performed by a repeated measure analysis of variance (ANOVA) followed by pairwise comparisons against control at each time period using Fisher's LSD multiple comparison test.

MODIFICATIONS OF THE METHOD

Fink-Jensen et al. (1992) reported that the excitatory amino acid receptor antagonists, 2,3-dihydroxy-6-nitro-7-sulphamoylbenzo(f)quinoxaline (NBQX) and 6-cyano-7-nitroqinoxaline-2,3-dione (CNQX), which preferentially block non-NMDA subtypes of excitatory amino acid receptors, effectively inhibit cisplatin-induced emesis in ferrets.

Emesis in ferrets was induced by X-irradiation or oral doses of copper sulfate (Andrews and Bhandari 1993).

Watson et al. (1995) studied the anti-emetic effects of a selective NK_1 receptor antagonist using the gag reflex in ferrets. The gag reflex is mediated by mechanoreceptors in the superior laryngeal nerve, which projects to the nucleus tractus solitarius. (Mifflin 1993). The gag reflex was evoked in conscious ferrets by gentle tactile stimulation of the pharynx and larynx and was recorded as an all or none response before and after drug administration.

Furthermore, the authors induced retching in the ferret by electrical stimulation of the vagal afferents under urethane anesthesia (Andrews et al. 1990). The dorsal or ventral abdominal vagus was isolated and ligated and the central cut-end stimulated before and after drug administration.

J.5.0.3 Assessment of emetic and anti-emetic activity in pigeons

PURPOSE AND RATIONALE

Emesis in pigeons can be induced by various agents. Formerly, the phenomenon has been used for standardization of cardiac glycosides (Hanzlik 1929). More recently, dose response curves of emesis have been determined for various agents and anti-emetic effects were evaluated (Wolff and Leander 1994, 1995).

PROCEDURE

Male White Carneaux pigeons are kept in individual stainless steel cages at constant temperature and humidity. They are maintained at 90% of their free-feeding body weights by once-daily feeding of approximately 20 g Purina Pigeon Checkers.

All testing is conducted during the illuminates phase of the light-dark cycle. On test days, the birds are fed 5 min before the start of an emetic trial. If vomiting occurs, the pigeons are given an additional 20 g of feed before being returned to their home cages at the conclusion of the observation period. Individual subjects are allowed a recovery period of at least 3 days between each drug test.

For the following compounds emetic doses are reported:

- Cisplatin 10 mg/kg, injected into a wing vein.,
- Ipecac syrup, 1 to 3 ml/kg, administered via a feeding needle passed through the crop to the opening of the proventriculus,
- emetine, 1 to 20 mg/kg, injected into the pectoralis muscle,
- m-(chlorphenyl)-biguanide (mCBG), 0.32 to 5 mg/kg, injected intramuscularly,
- ditolyganidine (DTG), 5.6 mg/kg, injected intramuscularly.

Test substances with potential anti-emetic activity are injected at various doses 15 min before the emetic challenge. The animals are observed for vomiting during 2 h.

EVALUATION

ED_{50} values for with 95% confidence limits are calculated for the activity of emetic substances, as well as for the inhibition of emesis by anti-emetic drugs after a high dose of the emetic compound.

J.5.0.4 Activity against motion-induced emesis

PURPOSE AND RATIONALE

The house musk shrew (*Suncus murinus*) is a small insectivore that has been shown to exhibits emesis when exposed to linear reciprocation motion (Ueno et al. 1988; Okada et al. 1994).

PROCEDURE

Adult male (body weight range 55–90 g) and female (body weight range 35–50 g) are used. The animals receive a dose of the test drug or vehicle in a volume of 4 ml/kg 15 min before motion testing. The animals are placed in a Perspex chamber (11 cm wide × 22 cm long

× 11 cm high) that is attached to the platform of a shaker set to execute a linear horizontal movement of 4 cm at a frequency of 1 Hz along the long axis of the chamber. The animals are allowed approximately 3 min to become accustomed to the chamber before exposure to motion for a period of 5 min, during which the number and timing of emetic episodes are recorded. An emetic episode usually consists of a short period of rapid retching followed by a vomit. A cross-over design is used for the experiment, with animals exposed to motion testing following treatment with vehicle control on one occasion, and following treatment with test drug on another. An interval of 12 days is allowed between treatments.

EVALUATION

Group results are expressed as mean ±SEM. Either Student's *t*-test or the Wilcoxon signed rank test is used as a measure of significance.

MODIFICATIONS OF THE METHOD

Gardner and Perren (1998) described a model of post-anesthesia-induced emesis in Suncus murinus.

Lucot (1989) used cats to test the activity of HT_3 antagonists against motion-induced sickness.

J.5.0.5 Foot tapping in gerbils

PURPOSE AND RATIONALE

Foot tapping in gerbils, a centrally mediated behavior (Graham et al. 1993; Bristow and Young 1994; Rupniak and Williams 1994; Vassout et al. (1994), has been claimed to be highly predictive for NK_1 antagonists to prevent cisplatin-induced retching in ferrets and to be a simple *in vivo* assay for CNS penetration (Rupniak et al. 1997).

PROCEDURE

Mongolian gerbils of either sex weighing 35–70 g are anesthetized by inhalation of an isoflurane/oxygen mixture to permit exposure of the jugular vein through a skin incision in the neck, using blunt dissection to clear surrounding salivary gland and connective tissues. Test compounds or vehicle are administered using an injection volume of 5 ml/kg i.v. The wound is closed and a second incision is made in the midline of the scalp to expose the skull. The highly selective, peptidase-resistant NK_1 receptor agonist GR73 632 (D-Ala-[D-Pro^9,Me-Leu^8]substance P-(1-17) (Hagan et al. 1991) is infused directly into the cerebral ventricles (3 pmol in 5 µl i.c.v.) by vertical insertion of a cuffed 27-gauge needle to a depth of 4.5 mm below bregma. The scalp incision is closed and the animal allowed to recover from anesthesia in a clear Perspex observation box (25 × 20 × 20 cm). The duration of hind foot stepping is then recorded continuously for 5 min using a stopclock. The time relapse from induction to recovery from anesthesia, with intervening i.v. and i.c.v. injections is about 3–4 min.

EVALUATION

Data are subjected to one-way analysis of variance (ANOVA), followed by Dunnett's or Newman-Keuls multiple comparison *t*-tests.

CRITICAL ASSESSMENT OF THE METHOD

The specificity of the method to predict anti-emetic activity has to be proven.

J.6 Gall bladder functions

J.6.1 Bile secretion

J.6.1.1 Cholagogic activity in mice

PURPOSE AND RATIONALE

A rapid method for standardization of cholagogues in mice by simple weighing the gall bladder filled with bile was published by Litvinchuk (1976).

PROCEDURE

Groups of 10 female mice (e.g., NMRI strain) weighing 15–20 g are used. Food, but not water, is withdrawn 24 h prior to the experiment. The test compound or the control solution is administered subcutaneously or orally. After 1 h, the animals are sacrificed and bled from the carotid artery. Laparatomy is performed, the liver exposed, and a No. 75 silk ligature is tied around the cystic duct, which is detached from the bile ducts and removed from the peritoneal cavity. If a large volume of bile has been accumulated, the full gall bladder is removed together with the bile ducts. The isolated gall bladder is weighed on a suitable balance, after which the contents are removed, the gall bladder walls are washed with distilled water, dried on filter paper, and the organ is weighed again. The difference in weight of the full and the empty gall bladder indicates the quantity of bile secreted during a measured time. The concentration of cholates, bilirubin, and cholesterol in the bile can be determined.

EVALUATION

The average of secreted bile in groups of 10 treated mice is compared with the average value of the control group using Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

The method has the clear advantage of simplicity but does not measure the true bile excretion since the outflow from the bile bladder during the test period is neglected.

MODIFICATIONS OF THE METHOD

Sterczer et al. (1996) studied the effect of cholagogues on the volume of the gallbladder in healthy dogs fasted for 24 h by two-dimensional ultrasonography. The volume was measured immediately before the administration of each test substance and at 10-min intervals for 120 min thereafter.

J.6.1.2 Choleretic activity in rats

PURPOSE AND RATIONALE

In contrast to other animals, rats do not possess a bile bladder. Therefore, cannulation of the bile duct in rats can be used as a suitable model to measure choleresis, i.e. bile production.

PROCEDURE

Male rats (e.g. Sprague-Dawley strain) weighing 300–500 g are used. Food, but not water, is withdrawn 18 h prior to the experiment. The animals are anesthetized with 5 ml/kg 25% urethane solution. The trachea is cannulated and the abdomen opened by a midline incision. The pylorus is ligated and the bile duct cannulated from the duodenum with a thin (0.05 mm diameter) polyethylene catheter which is pushed up to the liver. The secreted bile volume is measured for 30 min intervals and then the bile is returned to the duodenum. After a preperiod of 60 min, the test substances are administered subcutaneously or intraduodenally. The bile volume is registered in 30 min intervals for 2 h.

EVALUATION

The average values of the post-drug periods are compared with the pre-drug readings.

MODIFICATIONS OF THE METHOD

Several authors tested the choleretic activity of plant extracts and essential oils (De la Puerta et al. 1993; Peana et al. 1994; Trabace et al. 1994) and of synthetic compounds (Grella et al. 1992; Paglietti et al. 1994) in rats.

Tripodi et al. (1993) investigated the anticholelithogenic and choleretic activities of taurohyodeoxycholic acid by measurement of biliary flow and biliary solids content in rats.

Bouchard et al. (1993) induced cholestasis in rats by treatment with 17-α-ethinyl estradiol and studied

the influence of oral treatment with ursodeoxycholic and tauroursodeoxycholic acids.

Vahlensieck et al. (1995) studied the effect of *Chelidonium majus* herb extract on choleresis in the isolated perfused rat liver.

Miki et al. (1993) investigated the metabolism and the choleretic activity of homochenodeoxycholic acid in **hamsters** with bile fistula.

Pesson et al. (1959) recommended the **guinea pig** as the best choice among the common laboratory animals to study choleretic agents.

Cohen et al. (1992) reported a study in male **black-tailed prairie dogs** (*Cynomys ludovicianus*) weighing 1.0 ±0.2 kg anesthetized with 20 mg/kg xylazine i.m. and 20 min later with 100 mg/kg ketamine i.m. Through an abdominal incision, the cystic duct is ligated, and gallbladder bile is aspirated. A PE-50 polyethylene cannula is inserted into the common bile duct and secured with silk sutures, thereby completely diverting bile flow for collection. The bile duct cannula is externalized, the abdominal incision closed, and the prairie dog placed in a restraining cage with access to food and water.

Matsumura et al. (1996) analyzed hypercholeresis in **dogs** with pigment gallstones after cholate infusion.

J.6.1.3 Chronic bile fistula in rats

PURPOSE AND RATIONALE

Most of the techniques for collection of bile in rats use restrained or anesthetized animals. Such factors as well as the surgical intervention itself may profoundly influence the results. Therefore, Remie et al. (1990, 1991) developed a technique for a permanent double bile fistula in rats. The procedure is described in detail.

PROCEDURE

Preparation of cannulae

Cannulae are made of silicon rubber. The proximal bile cannula, which will be inserted into the common bile duct in the direction to the liver, is 18 cm long (Silastic tubing, Dow Corning, no. 605-135; 0.51 i.d. and 0.94 o.d.) and has one square cut and one bevelled end. Two silicon rings are wrapped around the cannula at 7 mm and 50 mm, respectively, from the bevelled end.

The distal bile cannula, which will be inserted into the common bile duct in the direction of the gut, is made of the same material, is also 18 cm long and has one square cut and one bevelled end. This cannula, however must have a smaller tip-diameter (Silastic tubing, Dow Corning, no. 605-105: 0.31 i.d. and 0.64 o.d.). To serve this purpose, the square cut end of the cannula is immersed in ether, causing the tubing to dilate. When the tubing is wide enough, a 13 mm piece of small diameter Silastic tubing is inserted. Subsequently, two silicon rings are wrapped around the cannula, one at the joint of the two tubes and the other 5 cm from the tip. The tip in then cut at a 45° angle, 7 mm from the first silicon ring.

The duodenal cannula (Silastic tubing, Dow Corning, no. 605–135) is also 18 cm long, and has one square and one bevelled end. An additional ring is placed 30 mm from the tip. Before the cannulae are fixed to the skull, they must be connected to a stainless steel needle bent in a 90° angle.

Anesthesia
The animal is anesthetized with halothane/N_2O/O_2.

Preparation of the crown of the head
The head of the animal is shaved and disinfected. An incision of about 1 cm is made and the bregma exposed. Three stainless steel screws (1.0 × 4.2 mm) are mounted in the crown, two in the left and one on the right side of the bregma. The screws are tightened that approximately 2 mm is left between the skull and the head of the screws.

Double cannulation of the bile duct
The abdominal wall is shaved and disinfected and the animal secured on the operation board with adhesive tape. A midline incision is made from the level of the pubic bones to the xyphoid cartilage. The abdomen is then opened by making an incision over the linea alba towards the sternum up to the distal part of the fourth sternebra, thus exposing the xiphoid cartilage.

Then, the intestines are lifted out and are laid next to the animal on moistened gauze. Using jewelers forceps, the bile duct is stripped off its surrounding tissue and ligated with a 7-0 suture. The duct is placed under tension with an artery forceps for cannulation. With the aid of a microscope, a V-shaped hole is made just cranial of the first ligature with iridectomy scissors. The sterile proximal cannula is inserted into the duct. The second ligature is tied and pulled tight ensuring that the cannula is not obstructed. The bile is now flowing into the cannula. The first ligature is released and the threads are tied behind the silicon ring. The rat is then turned and the ligature reclamped, thereby putting the distal part of the duct under tension. A third ligature is loosely introduced around the duct, distal to the first ligature. Another V-shaped aperture is made between the first and third ligature for insertion of the distal bile cannula. The third ligature is tied and pulled tight. The first ligature is released from the artery forceps and tied around the second cannula behind the silicon ring. All the loose threats are cut close to the knots. The sections of the cannulae which lie between the silicon rings are placed kink-free in the abdominal cavity. The cannulae are fixed using 7-0 silk suture to the abdominal muscle near the xiphoid cartilage.

Cannulation of the duodenum
After location of the place where the bile duct enters the duodenum (sphincter of Oddi), a four fine-stitch purse-string suture (7-0) is made in the wall of the duodenum at the outer border at about 1 cm proximal to the sphincter. Using a 20G needle, an incision is made inside the purse string. The cannula is inserted into the duodenum until the first, smaller silicon ring has entered the lumen, and the purse string is tightened between the first and the second ring. This cannula together with the bile cannula is placed kink-free in the abdominal cavity and anchored to the internal muscle.

The abdomen is closed of resorbable sutures leaving 1 cm of the skin unclosed.

Subcutaneous tunneling and anchoring of the cannulae
From the back of the neck, a slender needle holder is pushed subcutaneously through the connective tissue in caudal direction as near as possible to the skin down to the xiphoid cartilage. The cannulae are then grasped and pulled through to emerge at the crown of the head. The abdominal wall is closed completely.

With a 5 cm piece of polyethylene tubing (0.75 × 1.45 mm), the two long ends of the L-shaped stainless steel adapters are connected and the short ends inserted into the respective cannulae. The cannulae together with the tubing are fixed to the skull with acrylic glue flowing under the heads of the screws.

Postoperative care
The animals are allowed to recover in a warm and quiet place. They reach usually preoperative weight within 2–3 days, and display normal feeding and drinking behavior. Supplementation with saline besides the normal tap water may be necessary.

Collection of bile
The animals are housed in individual metabolic cages. For bile collection, they are attached to long swiveled PE-cannulae (0.75 × 1.45 mm). A stainless steel coil is used to protect the rats from gnawing on the tubing. For continuous collection of bile, the cannula can be connected to a fraction collector.

CRITICAL ASSESSMENT OF THE METHOD
Among other applications, the method is suited to study the enterohepatic circulation of compounds.

MODIFICATIONS OF THE METHOD
Castilho et al. (1990) studied the intestinal mucosal cholesterol synthesis in rats using a chronic bile duct-ureter fistula model. Male Wistar rats weighing 300–350 g were anesthetized with 50 mg/kg pentobarbital i.p. and submitted to a bile duct-right ureter fistula utilizing a PE-50 catheter after a right-kidney nephrectomy.

J.6.1.4 Chronic bile fistula in dogs

PURPOSE AND RATIONALE

Herrera et al. (1968) described a special cannula which can be used to obtain bile or pancreatic juice from a duodenal pouch after appropriate surgical procedures.

PROCEDURE

Male Beagle dogs weighing 15–20 kg are used. The abdomen is opened through a midline epigastric incision under barbiturate anesthesia. The duodenum is mobilized at the pyloric and jejunal ends, and a 5-cm duodenal segment containing the common bile duct is isolated. The distal stoma of the duodenum is closed and continuity restored by end-to-side duodeno-jejunostomy. The duodenal pouch is closed at both ends.

The cannula to be inserted is made of stainless steel and consists of 3 parts. The main casement measures 10.5 cm in length, with an external diameter of 1.0 cm. The internal end is flanged, and 1.5 cm from this point there is a short lateral limb, also 1.5 cm in length. The lateral limb is also flanged but, in addition, possesses a small V-shaped defect to facilitate insertion into the pouch. When not in use, the cannula is sealed from the exterior by inserting a threaded plug which allows bile to enter the duodenum in the normal manner. For collection of bile this plug is removed and a long obturator is inserted. The latter effectively isolates the bile secretion from duodenal contents. A similar hollow obturator is reserved for use when duodenal perfusion is studied, the obturator being connected via a plastic tube to the irrigating fluid.

Through a small antimesenteric incision in the duodenal pouch, the lateral limb of the cannula is inserted; the V-shaped defect in the flange facilitates entry into the pouch. A purse string secures the cannula in position. The defunctioned loop of duodenum is then brought anterior to the pancreas, and the remaining limb of the cannula inserted through a small duodenotomy and secured by a further purse-string suture. The whole system is then generously wrapped in omentum and the cannula exteriorized through a stab incision toward the flank. An external collar stabilizes the cannula. The cannula is left open to drain blood and secretions for 24 h postoperatively, after which time the plug is inserted. Physiologic saline is administered subcutaneously for a period of 3 days, after which the animals are permitted to drink water. Daily checks of the cannula are advisable to ensure that the plug remains tight. The animals receive normal kennel food and water ad libitum.

The dogs are allowed at least 4 weeks to recover. Eighteen hours prior to the experiment food is withdrawn but water allowed ad libitum. The long hollow obturator is inserted and bile collected for 15 min periods. After 1 h pretest time, the test compound is given either orally or intravenously.

EVALUATION

Secretion of bile is measured at 15 min intervals and volume and bile contents are determined from 1 ml samples. The values are compared with pretest data. The remaining bile is re-infused into the duodenum via the hollow obturator.

MODIFICATIONS OF THE METHOD

Boldyreff (1925) described several techniques for fistulae of the gall bladder and also for the fistula of the ductus choledochus in dogs.

An abdominal incision about 10 cm is made on the median line. The duodenum is pulled out and the orifice of the large (first) pancreatic duct is found. The orifice of the ductus choledochus with the orifice of the small (second) pancreatic duct is situated on the other side of the intestine some 2 or 3 cm nearer the stomach. The ductus choledochus goes straight from the gallbladder to the duodenum; further it lies parallel to is and at its end it is attached to the wall of the duodenum. The small pancreatic duct goes from the gland straight to the duodenum.

At the very beginning of the operation it is useful to cut the ligamentum that goes from the liver to the duodenum, because this facilitates orientation and operating. It is necessary to cut out a piece of the intestinal wall with the orifice of the ductus choledochus. But before this one must prepare off a little bit the intestine from the pancreas so as to be able to close conveniently and securely the hole in the intestine and divide between double ligatures the second pancreatic duct.

On the duodenum around the orifice of the ductus choledochus an incomplete oval figure is now marked with a knife, so that the duct enters this figure through the incomplete part of the oval and has its orifice in the middle of this figure. The length of the oval is about 1.5 cm and its width 1 cm. A suture is then made on the edge of this oval, which is cut out not completely but leaving a small bridge about 0.5 cm wide between the intestine and the oval; through the bridge the duct enters the oval. The mucosa of this bridge must be completely destroyed with a knife.

The oval piece of the intestine is now turned with the mucosa up and its serosa is sutured to the serosa of the intestine The hole in the intestine is very carefully closed with two layers of sutures. Two heavy threads are then passed underneath the intestine on either side of the place of operation; they are laid through the abdominal wall and tied after the operation is over. They serve as temporary supporting sutures. The oval piece of the intestine is now sutured with the skin of the abdominal wound and the wound is closed in the usual manner. The supporting sutures must be taken out one day or two days after the operation.

J.6.2 Gall bladder motility

J.6.2.1 Activity on isolated gall-bladder strips from guinea pigs

PURPOSE AND RATIONALE

Effects on the smooth musculature of the gall bladder can be studied in isolated strips of gall bladder from guinea pigs or cats (Chowdhury et al. 1975; Fara and Erde 1978; Cabrini et al. 1995).

PROCEDURE

Guinea pigs of either sex weighing approximately 400 g are anesthetized with 3 g/kg urethane i.p. The gall bladder is removed and cut into longitudinal strips 10×3 mm. The strips are suspended in a Krebs solution bath between a stationary hook and an isometric strain gauge. Tension is recorded on a polygraph. The bath is maintained at 37 °C and aerated with a gas mixture of 95% O_2 and 5% CO_2. After a half-hour stabilization period, test doses of acetylcholine (1 mg/ml) are added to determine viability of the preparation. Dose-response curves for the muscle strips are obtained by introducing one dose of the stimulating agent and waiting until the maximal response to that dose is reached (usually 5–15 min). The bath is then rinsed three times and 15 min allowed before a new dose is tested.

EVALUATION

Concentrations for the maximal response and ED_{50} values are calculated.

MODIFICATIONS OF THE METHOD

Eltze et al. (1997) found that contractions of the isolated guinea-pig gallbladder elicited by muscarinic stimuli are mediated by functional muscarinic M_3 receptors.

J.6.2.2 Gallbladder motility in dogs

PURPOSE AND RATIONALE

Gall bladder motility can be measured in anesthetized dogs with intraluminal manometry.

PROCEDURE

Beagle dogs weighing 15–18 kg are fasted for 16 h prior to the experiment. Median laparatomy is performed under pentobarbital anesthesia (25 mg/kg i.v.). An incision is made in the bile bladder and a 2 mm diameter polyethylene catheter introduced. The catheter is advanced as far as possible to the neck of the gall bladder and tied. The pressure in the interior of the gall bladder is recorded on a pen recorder via a Statham pressure transducer (P 23 BB) and a frequency measuring bridge.

EVALUATION

Cholecystokinin increases dose-dependent the intraluminal pressure. The preparation can be used for evaluation of cholecystokinin or cholecystokinin-like activity.

MODIFICATIONS OF THE METHOD

Ryan and Cohen (1976) used adult opossums (*Didelphis viginiana*) of either sex, weighing 2.5–3.0 kg.

REFERENCES

Ryan J, Cohen S (1976) Gallbladder pressure-volume response to gastrointestinal hormones. Am J Physiol 230:1461–1465

J.6.2.3 Cholecystokinin activity (isolated gallbladder or intestine)

PURPOSE AND RATIONALE

A sensitive bioassay for cholecystokinin utilizing strips of rabbit gall bladder has been described by Amer and Becvar (1969). Segments of ileum and colon have been used by Paton and Zar (1968) and by Zetler (1984).

PROCEDURE

Male albino rabbits weighing 1.5–2.5 kg are fasted 18 h prior to the experiment. The animals are sacrificed by cervical dislocation and the liver is quickly dissected out. The gallbladder is teased away from the liver and immediately placed in Locke-Ringer solution. The biliary contents are emptied and the gall bladder is cut spirally (right-handed spiral starting from the bile duct) into a strip of muscle tissue 30–40 mm in length and about 5 mm wide. The muscle strip is placed in an organ bath containing Locke-Ringer solution at 37 °C continuously bubbled with carbogen. The initial tension of the muscle is adjusted to 0.5 g. The bath fluid is changed every 30 min. The test compound and the standard (range 5–20 mIDU (Ivy dog units) are added alternatively. The maximum of contractions is usually reached after 5 min. Then, the bath fluid is changed. The next dose is applied when the tension has achieved again the starting value.

EVALUATION

The maximum of contraction is taken as endpoint. Using at least two doses of test compound and standard, parallel line assays can be carried out and potencies ratios can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

This bioassay has the advantage to be sensitive and less time consuming than *in vivo* assays, such as measuring gall bladder motility in the anesthetized dog (see J.6.2.2). However, the assay is not specific for cholecystokinin, since also gastrin and gastrin analogues cause contractions of the isolated bile bladder. This assay allows also to calculate potency ratios of different gastrin analogues.

MODIFICATIONS OF THE METHOD

The whole gallbladder of the mouse or a strip of guinea pig gallbladder is used for evaluation of cholecystokinin-like peptides, ceruletide, ceruletide analogues, and cholecystokinin octapeptide by Zetler (1979, 1984)

Paton and Zar (1968), Zetler (1984), Chang and Lotti (1986), Barthol and Holzer (1987) used isolated segments of ileum and colon from guinea pigs for determination of CCK-like activity.

Makovec et al. (1986), Tachibana et al. (1996) studied the *in vivo* activity of derivatives of CCK in emptying the gallbladder in mice.

Henke et al. (1997) tested CCK-A agonists in the isolated guinea pig gall bladder.

Singh et al. (1995) used gall bladder strips from guinea pigs to evaluate CCK receptor antagonists.

Fukamizu et al. (1998) tested the effect of a cholecystokinin-A receptor antagonist against CCK-8 induced contractions in isolated smooth muscle fibers of gall bladders and longitudinal fibers of ileum from guinea pigs.

J.6.3 Sphincter Oddi function

J.6.3.1 Relaxation of sphincter of Oddi *in vitro*

PURPOSE AND RATIONALE

The integrity of the relaxation function the sphincter of Oddi is a prerequisite for normal delivery of bile into the duodenum. Sphincter of Oddi relaxation is mainly executed by non-adrenergic, non-cholinergic (NANC) nerves that are essentially nitrergic in several species including guinea pigs (Pauletzki et al. 1993) and rabbits (Lonovics et al. 1994).

PROCEDURE

Biliary sphincter of Oddi muscle rings of approximately 6 mm length from adult male New Zealand white rabbits weighing form 3 500–4 000 g pretreated with various drugs or diet are prepared. The papilla Vater is eliminated and the ampullary part of the muscle rings of approximately 3 mm length are mounted horizontally on two small L-shaped glass hooks one of which is connected to a force transducer attached to a polygraph for measurement and recording of isometric tension. The experiments are carried out in an organ bath (5 ml) containing Krebs bicarbonate buffer which is maintained at 37 °C and aerated continuously with carbogen. The initial tension is set at 10 mN and the rings are allowed to equilibrate over 1 h during which period the sphincters develop characteristic 14–19 per min rhythmic contractions. Atropine (1 μM) and guanethidine (4 μM) are continuously present (NANC solution). Changes in isometric tension in response to two consecutive trains of impulses of electrical field stimulation (40 stimuli, 50 V, 0.1 ms and 20 Hz) are then studied.

EVALUATION

The data representing changes in isometric tension expressed as means ± standard deviation are evaluated by means of analysis of variance (ANOVA) followed by a modified Student's *t*-test for multiple comparisons according to Bonferroni's method. Changes are considered statistically significant at P-values smaller than 0.05.

MODIFICATIONS OF THE METHOD

In addition to studies with the isolated sphincter of Oddi of rabbits (Slivka et al. 1994; Sari et al. 1998; Jia and Stamler 1999) and guinea pigs (Harrington et al. 1992; Gocer et al. 1995; Lu et al. 1997), several pharmacological studies were reported with the isolated sphincter of Oddi of **opossum** (Perodi et al. 1990; Allescher et al. 1993), and of the **Australian brush-tailed possum** (*Trichosurus vulpecula*) (Baker et al. 1992, 1996).

J.6.3.2 Function of sphincter of Oddi *in vivo*

PURPOSE AND RATIONALE

Dogs were used for *in vivo* studies of the function of the sphincter of Oddi (Sarles 1986; Pozo et al. 1990; Matsumara et al. 1991; Kobayashi et al. 1994; Wang et al. 1998). Shima et al. (1998) recorded the spontaneous motility and the response to cerulein on the canine sphincter of Oddi using a constant-perfusion technique.

PROCEDURE

Mongrel dogs weighing 7–9 kg fasted overnight are anesthetized with 25 mg/kg intravenous pentobarbital sodium and are maintained under adequate anesthesia with 12.5 mg/kg intravenous pentobarbital sodium as required. Systemic blood pressure is monitored through a catheter placed into the femoral artery. A femoral vein is cannulated and used for systemic administration of Ringer's solution and drugs.

After an upper median laparatomy, a small longitudinal incision is made in the common bile duct. Two catheters (outer diameter 2.0 mm) are cannulated and tied in the bile duct to avoid any leaks and the occlusion of the orifice of the catheters. One is distally placed at 5 mm proximal to the choledochoduodenal junction and is used to perfuse the sphincter of Oddi with saline at a rate of 0.12 ml/min using an infusion pump. The other is proximally placed and used to siphon off the hepatic bile. Pressure changes are recorded on a polygraph through a pressure transducer which is placed between the infusion pump and the catheter.

EVALUATION

To evaluate the effects of intravenously administered drugs on the sphincter of Oddi, a motility index is calculated by measuring the square between the zero line and the trace of the sphincter of Oddi pressure changes per minute.

Results are expressed as means ±SEM; n is the number of independent observations of different animals. The paired and unpaired t-tests are used for statistical analysis. $P < 0.05$ is considered significant.

MODIFICATIONS OF THE METHOD

Thune et al. (1992, 1995) studied simultaneously the flow resistances in the common bile duct and main pancreatic duct sphincters in anesthetized **cats** using a perfusion technique.

Elbrønd et al. (1994) prepared the sphincter of Oddi and duodenum in anesthetized **rabbits** with perfused catheters and bipolar electrodes. Increasing, successive doses of cholecystokinin were administered intravenously every 15th min. The digitized recordings were scored on a computer in control and stimulatory cholecystokinin sequences.

Further studies in **rabbits** were performed by Nakamura (1996), Chiu et al. (1998).

Opossums were used by Calabuig et al. (1990), Hanyu et al. (1990),Cullen et al. (1996), Herrmann et al. (1999) to study the function of the sphincter of Oddi.

Several authors used the **Australian brush-tailed possum** (*Trichosurus vulpecula*) for studies of the function of the sphincter of Oddi *in vivo* (Baker et al. 1990; Saccone et al. 1992; Cox et al. 1998a,b; Huang et al. 1998).

The **prairie dog** was used by several authors to study the function of the sphincter of Oddi (Ahrend et al. 1992; Kaufman et al. 1993; Thierney et al. 1994).

Pasricha et al. (1995) reported a model in **pigs** for endoscopic biliary manometry, similar in technique to the procedure in humans.

J.7 Pancreatic function

J.7.0.1 Acute pancreatic fistula in rats

PURPOSE AND RATIONALE

The effect of exogenous hormones, e.g. secretin, or other drugs on pancreas secretion can be measured in rats with acute pancreas fistula.

PROCEDURE

Male Sprague Dawley rats weighing 150–200 g are used. Eighteen hours prior to the experiment food is withdrawn with free access to water. Groups of 4–5 rats are used for each dose of drug evaluation, the control group consists of at least 7 rats. The animals are anesthetized with 5 ml 25% urethane solution i.m. and the is trachea cannulated. The abdomen is opened by a mid-line incision and the pylorus ligated. The proximal part of the bile duct is ligated near the hepatic porta. The bile is drained via a thin polyethylene tube into the duodenum. The distal part of the bile duct with the orifices of pancreatic ducts is cannulated with another thin polyethylene tube. The pancreatic juice is collected in graduated microvessels. After a pre-test period of 60 min, the test compounds are applied intravenously or intraduodenally.

EVALUATION

The secretion after injection of the test compound is compared with the pre-test values. Secretin increases pancreatic secretion volume in a dose-dependent manner. Activity ratios for unknown preparations can be calculated by 2 + 2 assays in comparison with the international standard.

MODIFICATIONS OF THE METHOD

Guan et al. (1990) inserted two separate cannulae for bile and pancreatic juice to Wistar **rats** under methoxyfluorane anesthesia. Both fluids were returned to the intestine. Placing the rats in modified Bollman-type restraint cages, experiments could be performed after a few days in conscious animals.

Ito et al. (1994) studied the inhibition of CCK-8-induced pancreatic amylase secretion by a cholecystokinin type-A receptor antagonist in rats.

Niederau et al. (1989) compared the effects of CCK receptor antagonists on rat pancreatic secretion *in vivo*. Output of amylase in pancreatico-biliary secretion was measured after various doses of caerulein. The effects of high caerulein doses were dose-dependent inhibited by CCK-antagonists.

Alvarez and Lopez (1989) studied the effect of alloxan diabetes on exocrine pancreatic secretion in the anesthetized **rabbit**. After a 14–15 h fasting period, but with free access to water, rabbits weighing about 2.0 kg are anesthetized by intravenous injection of 1.0 g/kg urethane. After tracheotomy, a median laparatomy is performed, the main pancreatic duct is exposed and cannulated near its entrance to the duodenum following ligation of the pylorus and cannulation of the bile duct for deviation of bile to the exterior.

Kim et al. (1993) studied the effect of [(CH_2NH)4,5] secretin on pancreatic exocrine secretion in **guinea pigs** and rats using an acute pancreatic fistula preparation.

Niederau et al. (1990), Tachibana et al. (1996) determined pancreatic exocrine secretion in **mice**. Because the cannulation of mouse pancreatic duct is not possible for technical reasons, the amount of amylase was determined *in vivo*. Five min after i.v. administration of test drugs, mice were sacrificed and a 5 cm-duodenal loop was removed. The duodenal contents were washed out with 1.0 ml ice-cold saline and collected for amylase activity.

J.7.0.2 Exocrine secretion of isolated pancreas

PURPOSE AND RATIONALE

Procedures for isolation and perfusion of rat pancreas in order to record membrane potential and effective membrane resistance during the collection of perfusates and for simultaneous measuring of flow of pancreatic juice were described by Kanno (1972), Kanno and Saito (1976), Kanno et al. (1976), Saito et al. (1980). Similar techniques to measure exocrine secretion of the isolated pancreas have been used by other groups (Penhos et al. 1969; Mann and Norman 1984; Trimble et al. 1985; Norman and Mann 1986, 1987; Norman et al. 1989; Park et al. 1993).

PROCEDURE

Male Sprague Dawley rats weighing about 250 g are fasted for 24 h before the experiments but are allowed to drink water. Under ether anesthesia and after cannulation, the vascular system and the common duct are separately perfused. The rectum and the transverse colon are separated from the pancreas following ligation and sectioning of their vascular supply. Perfusion is performed through the hepatic end of the common duct with the outlet at the duodenal end. The **flushing preparation** is used when continuously recording the transmembrane potential and, in this preparation, the common duct is flushed at a constant pressure of 5 cm H_2O following cannulation of both ends with stainless steel tubes. The **draining preparation** is used during the electrical measurements are made from as many acinar cells as possible in every 10 min. In the draining preparation, the hepatic end of the duct is ligated and the pancreatic juice collected from the duodenal end following cannulation with a stainless steel tube. In both preparations, the inlets of the vascular perfusion are the superior mesenteric artery and the coeliac artery, and the outlet is the portal vein. The rate of vascular flow is kept constant at 1 ml/min with the aid of a roller pump. The animal is then killed by cutting the carotid arteries and the perfusion begins. The spleen is removed after section of its vascular supply close to the hilum, care being taken to avoid interference with the supply from the splenic artery. The blood supplying stomach and liver is stopped by tying the hepatic artery and gastric arteries. The superior mesenteric vein and the descending branch of the superior mesenteric artery are then ligated. The mesentery with its embedded whole pancreas and the attached duodenum is then removed and mounted on a paraffin block in a lucite chamber containing 20 ml of standard Krebs-Henseleit solution. The contents of the duodenum is then drained with a polyethylene tube. The level of the standard Krebs-Henseleit solution in the bath is kept constant with a siphon. The temperature of the preparation and perfusing Krebs-Henseleit solution containing 8 vol% erythrocytes is maintained at 37 °C. The perfusion solution in the reservoir is continuously bubbled with 5% CO_2 in O_2.

The rate of flow of pancreatic juice is measured by attaching a calibrated tube made of silicone-rubber to the free end of the pancreatic duct cannula. Every

10th min the tube is replaced and the rate of flow of pancreatic juice is noted. The sample is diluted with Krebs-Henseleit solution up to 100 ml and the amount of amylase assessed.

Intracellular recordings are made from the pancreatic acinar cells by manually advancing KCl-filled microelectrodes under direct visual control. The microelectrode is connected to the probe of a solid state preamplifier. Resting potentials are observed at the screen of a cathode ray oscilloscope and simultaneously recorded on a direct visual oscillograph.

Measurements are made every 10 min for half an hour as base level, followed by measurements every 10 min during infusion of drug for one hour.

EVALUATION

All results are expressed as mean ±SEM. Statistical analysis is performed using Student's *t*-test.

J.7.0.3 Chronic pancreatic fistula in rats

PURPOSE AND RATIONALE

Suguiyama et al. (1996) described the preparation of a chronic pancreatic fistula in the WBN/Kob rat, a strain which develops spontaneously chronic pancreatitis (Ohashi et al. 1990; see also J.7.0.14).

PROCEDURE

Male WBN/Kob rats at an age of 2 months are used. Before surgery, the rats have free access to chow and water. After an 18-h fast, laparatomy is performed through a midline incision under general anesthesia with ether. A polyethylene catheter (inside diameter 0.28 mm; outside diameter 0.61 mm, length 30 cm), as an external pancreatic fistula, is inserted into the common biliary pancreatic duct immediately proximal to the ampulla of Vater. The bile duct is ligated proximally to the pancreas. Another catheter is introduced into the bile duct distal to the confluence of the hepatic ducts, and the opposite end of the catheter is inserted into the duodenum near the ampulla through the stomach to drain the bile into the intestine. A third catheter is inserted in the duodenum through the stomach to return pancreatic juice. A fourth catheter is placed in the femoral vein, and 0.15 M sodium chloride is continuously administered at a flow rate of 1 ml/h with a syringe pump. All catheters are brought into the abdominal cavity or the femoral region through a subcutaneous tunnel starting in the middle portion of the tail. The rat is then placed prone in a cage with the proximal portion of the tail fixed to a side wall of the cage. When awakened, the rat is allowed access to food and water ad libitum. Pancreatic juice is collected and continually re-circulated with a syringe pump every 6 h until the secretion test.

The secretion test is started 3 days after surgery. After a 12-h fast, pancreatic juice is collected every 30 min in a plastic syringe. The juice volume is determined by weighing. A 50-µl sample is taken for the analysis of juice composition, and the remaining juice is returned to the duodenum for the next 30-min collection period.

After a 30-min basal period, the test compound is administered in graded doses, each dose for 30 min.

The bicarbonate concentration of pancreatic juice is measured with a microgasometer (Natelson 1958) in a sample size of 10 µl. Protein concentration is determined by measuring optical density at 280 nm with purified bovine trypsinogen as standard.

EVALUATION

All values are presented as mean ±SEM. Results are analyzed by means of the Wilcoxon test. Differences are considered significant at $p < 0.05$.

J.7.0.4 Acute pancreatic fistula in dogs

PURPOSE AND RATIONALE

The effect of exogenous hormones, e.g. secretin or gastrin, or of vagal stimulation, on pancreatic secretion can be measured in dogs with acute pancreas fistulas.

PROCEDURE

Beagle dogs of either sex weighing 12–20 kg are used. The animals are fasted for a 24-h period and then anesthetized with 25 mg/kg sodium pentobarbital i.v. After opening the abdomen along the mid-line, the pyloric sphincter is ligated and the common bile duct cannulated to prevent the entry of acid chyme and bile into the duodenum. The bile is allowed to drain. The pancreas is gently exposed and the major pancreatic duct ligated. A polyethylene tube of 2 mm diameter is inserted into the minor pancreatic duct for collection of the secretion. The left femoral vein is cannulated for continuous infusion or i.v. injection. The pancreatic juice is collected in an ice-bath in a special tapered tube with fine calibrations for measuring volumes of less than 1 ml.

At the end of each collection period, the volume is recorded, and the bicarbonate content determined titrimetrically. Furthermore, pancreatic enzymes, such as amylase, are determined in the samples. Determination of protein concentrations in the pancreatic juice can be used as end-point since the total protein concentration is proportional to the individual enzymes (Keller et al. 1958). In a pretest period of 10 min, samples are collected every 2 min. Then, the test compound is injected intravenously and the pancreatic juice is collected every 2 min.

EVALUATION

The secretion after injection of the test compound is compared with the pre-test values. Secretin increases pancreatic volume and bicarbonate secretion in a dose-dependent manner. Activity ratios for unknown preparations can be calculated by 2 + 2 points assays in comparison with the international standard.

Moreover, the model can be used for standardization of gastrin analogues.

MODIFICATIONS OF THE METHOD

Glad et al. (1996) tested the influence of gastrin-releasing peptide on acid-induced secretin release and pancreatobiliary and duodenal bicarbonate secretion in Danish country strain **pigs** weighing between 22 and 30 kg. The animals, starved overnight with free access to water, were premedicated with 4 mg/kg i.m azaperone, and with 5 mg/kg i.p. metomidate. After 20 min a cannula was placed in an ear vein, and 5–10 mg/kg metomidate was given i.v. followed by intubation and artificial respiration with 50% O_2 and 50% N_2O. Anesthesia was maintained with an intravenous bolus infusion of 0.53% α-chloralose.

Both external jugular veins were cannulated for infusion of saline or drugs. A femoral artery was cannulated for withdrawal of blood samples and recording of blood pressure. After laparatomy the cystic duct was ligated, and the common hepatic duct and the pancreatic duct were catheterized. The duodenal segment was defined as extending from the pylorus to the ligament of Treitz. A Foley catheter was passed through the pylorus into the proximal part of the duodenum and inflated. Distal to the pylorus the pancreaticoduodenal arteries, veins and nerves were dissected, and a double ligature was passed under these structures and tied around the duodenum. At the ligament of Treitz an inflated Foley catheter was placed in the distal part of the duodenum and tied with a suture around the duodenum. A catheter was placed through a splenic branch of the left gastroepiploic vein and advanced through the lienal vein to the portal vein.

The flow of pancreatic juice and bile was tested before and after the experiment by means of an intravenous bolus of 5 pmol/kg secretin. Before the experiment the duodenum was continuously perfused at a rate of 2 ml/min for 435 min with isotonic saline containing phenol red (10 mg/l) as a marker. After drug treatment (intravenous infusion of gastrin-releasing peptide or duodenal HCl perfusion) pancreatic and hepatic secretions were collected in 15-min periods and the volumes determined by weighing. Duodenal effluents were collected in 15-min periods and phenol red concentrations determined spectrophotometrically. Blood sampled were withdrawn for determination of secretin by radioimmunoassay.

J.7.0.5 Chronic pancreatic fistula in dogs

PURPOSE AND RATIONALE

Herrera et al. (1968) described a special cannula which can be used to obtain pancreatic juice or bile from a duodenal pouch after appropriate surgical procedures (Preshaw and Grossman 1965).

PROCEDURE

Male Beagle dogs weighing 15–20 kg are used. The abdomen is opened through a midline epigastric incision under barbiturate anesthesia. The duodenum is mobilized at the pyloric and jejunal ends, and a 5-cm duodenal segment containing the main pancreatic duct is isolated. The proximal level of the duodenal section lies immediately distal to the opening of the common bile duct and the distal level of section lies 2.5 cm distal to the main pancreatic duct. The distal stoma of the duodenum is closed and continuity restored by end-to-side duodeno-jejunostomy. The duodenal pouch is closed at both ends.

The cannula to be inserted is made of stainless steel and consists of 3 parts. The main casement measures 10.5 cm in length, with an external diameter of 1.0 cm. The internal end is flanged, and 1.5 cm from this point there is a short lateral limb, also 1.5 cm in length. The lateral limb is also flanged but, in addition, possesses a small V-shaped defect to facilitate insertion into the pouch.

When not in use, the cannula is sealed from the exterior by inserting a threaded plug which allows pancreatic juice to enter the duodenum in the normal manner. For collection of juice this plug is removed and a long obturator is inserted. The latter effectively isolates the pancreatic secretion from other duodenal contents. A similar hollow obturator is reserved for use when duodenal perfusion is studied, the obturator being connected via a plastic tube to the irrigating fluid.

Through a small antimesenteric incision in the duodenal pouch, the lateral limb of the cannula is inserted; the V-shaped defect in the flange facilitates entry into the pouch. A purse string secures the cannula in position. The defunctioned loop of duodenum is then brought anterior to the pancreas, and the remaining limb of the cannula inserted through a small duodenotomy and secured further by a purse-string suture. The whole system is then generously wrapped in omentum and the cannula exteriorized through a stab incision toward the flank. An external collar stabilizes the cannula.

The cannula is left open to drain blood and secretions for 24 h postoperatively, after which time the plug is inserted. Physiologic saline is administered subcutaneously for a period of 3 days, after which the animals are permitted to drink water. Checking the cannula daily is advisable to ensure that the plug remains tight. The animals receive normal kennel food and water ad libitum.

The dogs are allowed at least 2 weeks to recover. Eighteen hours prior to the experiment food is withdrawn but water allowed ad libitum. The long obturator is inserted and pancreatic juice collected for 15 min periods. After 1 h pretest time, the test compound is given either orally or intravenously.

EVALUATION

Secretion of pancreas juice is measured at 15 min intervals and volume and enzyme content determined. The values are compared with pretest data.

MODIFICATIONS OF THE METHOD

Boldyreff (1925) described details of the technique as recommended by Pavlov (1902) as well as his own modification.

Konturek et al. (1976, 1984) performed experiments with chronic gastric fistulas in **cats** as well as in **dogs** to compare the species-specific activities of vasoactive intestinal peptide and secretin in stimulation of pancreatic secretion.

Ninomiya et al. (1998) studied the effects of a cholecystokinin A receptor antagonist on pancreatic exocrine secretion stimulated by exogenously administered CCK-8 in conscious dogs with chronic pancreatic fistula.

Garvin et al. (1993) described distal pancreatectomy with autotransplantation and pancreaticocystostomy in dogs.

Kuruda et al. (1995) developed a new technique in dogs for pancreatico-gastrointestinal anastomosis that consists of pancreatectomy using the ultrasonic dissector and implantation of the pancreatic duct into the gastrointestinal tract without suturing the pancreatic parenchyma.

J.7.0.6 Somatostatin activity

PURPOSE AND RATIONALE

Somatostatin is a neuropeptide, also called somatotrophin release inhibiting factor (SRIF or SRIF-14), which occurs not only in the brain, but also in a variety of peripheral tissues. Two other related peptides somatostatin-28 (SRIF-28) and cortistatin (Vasilaki et al. 1999), also occur naturally (Humphrey 1998). Somatostatin acts via G-protein coupled receptors of which five subtypes are cloned (Hoyer 1998).

Somatostatin analogues and antagonists have been tried for a variety of indications (Bass et al. 1996; Coy and Taylor 1996; Papageorgiou and Borer 1996; Rohrer et al. 1998; Yang et al. 1998). The long-acting octapeptide somatostatin analog, octreotide, has been studied thoroughly (Ambler et al. 1996; Danesi and Del Tacca 1996; Hoffmann et al. 1996; Paran et al. 1996) and gained clinical use as gastric antisecretory agent.

Somatostatin inhibits basal pancreatic secretion as well as secretion stimulated by food, cholecystokinin, and secretin. Inhibition of pancreatic secretion can be used as bioassay to compare synthetic analogues with the original somatostatin.

PROCEDURE

Male Wistar rats weighing 300–400 g are anesthetized with methoxyfluorane and prepared with silastic cannulae. Two cannulae drain pancreatic juice and bile separately, one cannula is inserted into the duodenum for return of bile and pancreatic juice to the intestine and for intestinal infusion. Another cannula is located in the abdominal cavity and a fifth cannula into the right jugular vein for drug infusion. After surgery, the rats are placed into modified Bollman-type restrain cages. The rats have free access to food and water. During recovery and between the experiments, pancreatic juice and bile are collected and continuously returned to the intestine by a servo-system consisting of a collection tube in a liquid-level photodetector coupled to a peristaltic pump.

Experiments are performed on the third to eighth days postoperatively. The rats are assigned to treatment groups on a random basis and, treatment days are equally divided among the third to eighth postoperative days. The rats are fasted overnight before each experiment. Bile and pancreatic juice are collected separately every 30 min; the volume of pancreatic juice is measured, and 10 ml is taken for protein assay. Different doses of the test drug and the standard are given as continuous i.v. infusion over a period of 2 h.

EVALUATION

Inhibition of pancreatic fluid and protein output is calculated compared to control infusion and expressed as percentage. From dose-response curves activity ratios can be calculated.

MODIFICATIONS OF THE METHOD

Konturek et al. (1985) and Susini et al. (1980) studied the effect of somatostatin analogues on pancreas secretion in dogs.

Cai et al. (1986) reported on the biological activity of octapeptide analogs of somatostatin assaying GH concentrations in blood samples of anesthetized rats by RIA and studying the inhibition of gastric secretion on dogs.

Biological actions of prosomatostatin have been described by Meyers et al. (1980) using *in vitro* and *in vivo* GH bioassays.

Taylor et al. (1996) employed the technique of cytosensor microphysiometry for real-time evaluation of somatostatin subtype receptor activity in CHO-K_1 cells stably expressing the human sst_2 receptors.

Cytotoxic analogs of somatostatin have been synthesized and evaluated (Nagy et al. 1998).

Gilon et al. (1998) studied a synthetic receptor 5-selective somatostatin analogue *in vivo* in rats. The compound inhibited bombesin- and caerulein-induced amylase and lipase release from the pancreas without inhibiting growth hormone or glucagon release.

Jeandel et al. (1998) described the effects of two somatostatin variants on receptor binding, adenyl cyclase activity and growth hormone release from the frog pituitary.

Hofland et al. (1994) determined relative potencies of somatostatin analogs on the inhibition of growth hormone release by cultured human endocrine tumor cells and normal rat anterior pituitary cells.

Somatostatin analogs labeled with ^{99m}technetium, ^{111}indium, and ^{90}yttrium were developed for tumor diagnosis and therapy (O'Byrne and Carney 1996; Pearson et al. 1996; Stolz et al. 1996, 1998; Thakur et al. 1996).

Radioimmunoassays for somatostatin have been developed (Arimura et al. 1975; Gerich et al. 1979; Patel and Reichlin 1979; Patel 1984) and are available as commercial kits.

J.7.0.7 Receptor binding for somatostatin

GENERAL CONSIDERATIONS

A family of five somatostatin receptor subtypes from various species including man has been described (Yamada et al. 1992; Reisine and Bell 1995; Hoyer et al. 1995; Bruns et al. 1996; Liapakis et al. 1996; Patel et al. 1996; Nilsson and Folkesson 1997; Patel 1997; Pscherer et al. 1996; Shimon et al. 1997; Humphrey et al. 1998). There are several endogenous ligands, such as somatostatin-14, somatostatin-28 and the corticostatins (Meyerhoff et al. 1992; De Lecea 1996; Fukusumo 1997). A number of synthetic peptide analogues have been developed and their relative affinities at human recombinant receptors in radioligand receptor studies have been established (Raynor et al. 1992; Bass et al. 1996; Coy and Taylor 1996; Pearson et al. 1996; Piwko et al. 1996, 1997a,b).

Greenmman and Melmed (1994) evaluated the expression of three somatostatin receptor subtypes (SSTR3, SSTR4, and SSTR5) in pituitary tumor specimens. SSTR3 expression was studied by reverse transcription coupled to polymerase chain reaction, whereas SSTR4 and SSTR5 expression was determined by ribonuclease protection assay.

Somatostatin occurs not only in the hypothalamus and in the gut, but also in several other organs. Somatostatin$_1$ receptors in the nucleus accumbens have been found to mediate the stimulatory effect of somatostatin on locomotor activity in rats (Raynor et al. 1993a). Molecular cloning and expression of a pituitary somatostatin receptor with preferential affinity for somatostatin-28 has been described by O'Carroll et al. (1992).

Cloning and expression of a mouse somatostatin receptor (SSTR 2B) has been reported by Vanetti et al. (1992). Pharmacological properties of two cloned somatostatin receptors have been described by Rens-Domiano et al. (1992).

Subtype-selective peptides have been identified by Raynor et al. (1993b). The somatostatin receptor, SSTR3, coupled to adenyl cyclase, has been cloned by Yasuda et al. (1992). Somatostatin receptors SSTR4 and SSTR5 have been cloned and characterized by Raynor et al. (1993c).

The somatostatin receptor SST_1 mediates inhibition of central neurons (Viollet et al. 1997).

The somatostatin receptor SST_2 inhibits growth hormone release (Raynor et al. 1993b), inhibits parietal cell function and ion secretion in rat distal colon (McKeen et al. 1996; Warhurst et al. 1996; Wyatt et al. 1996), and inhibits neurons in the rat locus coeruleus (Chessell et al. 1996). High basal gastric acid secretion has been found in somatostatin receptor subtype 2 knockout mice (Martinez et al. 1998). The cytoplasmatic tail of the somatostatin receptor SST_2 undergoes alternative splicing giving rise to two isoforms, SST_{2A} and SST_{2B} (Schulz et al. 1998).

The somatostatin receptor sst_3 mediates relaxation of isolated gastric smooth muscle cells (Gu et al. 1995).

The fourth human somatostatin receptor has been cloned and characterized by Rohrer et al. (1993).

The somatostatin receptor sst_5 may have a role in inhibition of hormone release from the pituitary (Tallent et al. 1996) and pancreas (Rossowski and Coy (1994) and mediates the antiproliferative effect of somatostatin in vascular smooth muscle (Lauder et al. 1997).

PROCEDURE

Crude membrane preparations are obtained by homogenizing (Polytron, setting 6, 15 s) tumor cell cultures

(e.g. human SCLC line NCI-H69, rat pancreatic tumor AR42J) or rat tissues (lung, pancreas, cerebral cortex) in ice-cold 50 mM Tris-HCl and centrifuging twice at 39 000 *g* (10 min), with an intermediate resuspension in fresh buffer. The final pellets are resuspended in 10 mM Tris-HCl for assay. Aliquots of the membrane preparation are incubated for 25 min at 30 °C with [^{125}I-Tyr^{11}]SRIF (2 000 Ci/mmol, Amersham) in 50 mM HEPES (pH 7.4) containing bovine serum albumin (10 mg/ml; fraction V, Sigma), $MgCl_2$ (5 mM), Trasylol (200 KIU/ml), bacitracin (0.02 mg/ml), and phenyl-methyl-sulfonyl fluoride (0.02 mg/ml). The final assay volume is 0.3 ml. The incubations are terminated by rapid filtration through Whatman GF/C filters (presoaked in 0.3% polyethylenimine) under reduced pressure. Each tube and filter is then washed three times with 5 ml aliquots of ice-cold buffer. Specific binding is defined as the total [^{125}I-Tyr^{11}]SRIF bound minus that bound in the presence of 200 nM unlabeled SRIF.

EVALUATION

The binding parameters are calculated from the experimental data by non-linear least-squares regression analysis using an appropriate computer program.

CRITICAL ASSESSMENT OF THE METHOD

Somatostatin occurs in many organs and has more activities than anticipated at its discovery. Therefore, the occurrence of a family of receptors rather than a single receptor is not surprising.

MODIFICATIONS OF THE METHOD

Receptor scintigraphy with a radioiodinated somatostatin analogue has been described by Bakker et al. (1990).

The tissue-selective binding of somatostatin-14 and somatostatin-28 in rat brain was studied by Srikant et al. (1990).

Feniuk et al. (1993) characterized somatostatin receptors in guinea-pig isolated ileum, vas deferens and right atrium.

Yang et al(1998) reported synthesis and biological activities of potent peptidomimetics selective for somatostatin receptor subtype 2 by testing inhibition of forskolin-stimulated cAMP accumulation in a mouse cell line that contains a cAMP response element fused to the *E. coli* β-galactosidase gene and by measuring growth hormone release from primary cultures of rat anterior pituitary cells.

J.7.0.8 Secretin activity

PURPOSE AND RATIONALE

Synthetic derivatives of secretin can be tested for activity against the standard using the bioassay of a chronic pancreatic fistula in dogs. Moreover, stability of secretin preparations has to be checked when using this bioassay.

PROCEDURE

Dogs with a chronic pancreatic fistula prepared according to Preshaw and Grossman (1965), Herrera et al. (1968) (see J.6.1.4) are used. Eighteen hours prior to the experiment food is withdrawn but water allowed ad libitum. Pancreatic juice is collected for 15 min periods. After 1 h pretest time, a test dose of 0.2 KE/kg Karolinska-secretin is given intravenously. In one hour intervals the test preparation or the standard is given alternatively in logarithmic doses between 0.1 and 1.6 KE/kg intravenously. The volume of pancreas juice secreted during 30 min after injection is used as parameter.

EVALUATION

Using at least two doses of test compound and standard, parallel line assays can be carried out and potencies can be calculated. Each of 4 animals receives two doses test compound and two doses standard, the application scheduled according to a Latin square. Potency ratios with confidence limits are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method is time consuming and needs dogs with chronic fistula. Nevertheless, for final evaluation of a test compound this bioassay can not be avoided.

MODIFICATIONS OF THE METHOD

The standardization of secretin has been described as early as 1952 by Burn et al. using anesthetized **cats**. After laparatomy the pylorus and first duodenal loop are brought outside and turned to the animal's left side. The bile duct is identified by gently squeezing the bile-bladder. The pancreatic duct usually enters the duodenum about 2 mm below the entry of the bile-duct. Starting about 2 cm below the bile duct, the pancreas is separated from the duodenum by blunt dissection, the blood vessels being tied and divided where necessary. When the pancreatic duct is reached, two silk ligatures are placed around and a length of 5 mm is dissected. A dose of secretin is injected intravenously and one of the ligatures is then tied as near the duodenum as possible. The duct is then cut and a flow of juice is usually visible. A small cannula is tied into the duct and attached to a rubber tube and L-piece whose position is adjusted so that the flow of juice continues. The cannula and the L-piece are clamped in position and the abdomen is closed.

The relation between the dose injected and the number of drops of pancreatic juice secreted is almost linear, but the slope differs in different cats. In making a comparison between two preparations, the dose-response relation is first determined for the standard preparation by administration of three or more different doses. A dose of the test preparation is then injected and the effect compared with the curve of the standard. Further doses of the test preparation and comparison of the dose-response curves allow the calculation of the relative potency.

Izzo et al. (1989) studied the internalization of labelled secretin into isolated pancreatic acinar cells of **rats**.

J.7.0.9 Receptor binding for secretin

PURPOSE AND RATIONALE

Secretin receptor antagonists, such as reduced peptide bond pseudopeptide analogues of secretin, inhibit the binding of ^{125}I-secretin to secretin receptors in pancreatic acini (Haffar et al. 1991).

Radioimmunoassays for secretin have been developed (Boden and Wilson 1979; Chang and Chey 1980) and are available as commercial kits.

PROCEDURE

Dispersed acini from guinea pig pancreas are prepared according to Peikin et al. (1978) and Jensen et al. (1982). After sacrifice, the pancreas of a guinea pig is immediately removed and trimmed of fat and mesentery. A suspension of dispersed acini is prepared by injecting the pancreas 5 times with 5 ml of digestion solution composed of standard incubation solution plus purified collagenase (0.12 mg/ml). The pancreas is in-

cubated for 4 sequential 10-min periods at 37 °C in a Dubnoff incubator at 160 oscillations per min. The gas phase is 100% O_2. The digestion solution is discarded, and the tissue is washed 3 times with 5 ml of standard incubation solution. The tissue is dispersed by passing it 5 times through each of a series of siliconized glass pipettes of decreasing bore (3, 1, and 0.5 mm). Large fragments and the duct system are discarded. The suspension of dispersed acini is layered over standard incubation solution containing 4% albumin and centrifuged at 800 *g*. The supernatant is discarded, and the acini are washed twice with standard incubation solution containing 4% albumin.

^{125}I-Secretin and ^{125}I-labeled analogues are prepared using chloramine T and a method described by Chang and Chey (1980), Jensen et al. (1983), Zhou et al. (1989). They are separated from ^{125}I using a disposable C_{18} cartridge (Sep-Pak) and then separated from unlabeled peptide with reverse phase HPLC using a 4.6-mm × 25-cm column of mBondapak C_{18}. The column is eluated with a linear gradient of acetonitrile in 0.1% trifluoroacetic acid (v/v) from 0 to 54% acetonitrile in 60 min using a flow rate of 1.0 ml/min.

For binding of ^{125}I-secretin incubations are performed containing 0.25 ml of cell suspension of pancreatic acini (one pancreas in 10 ml of standard incubation buffer) and 50 pM ^{125}I-secretin with or without 1 mM secretin. Nonsaturable binding of ^{125}I-secretin is measured as the amount of radioactivity associated with acini when the incubation contains 50 pM ^{125}I-secretin plus 1 mM secretin. Secretin antagonists are added in various concentrations. Saturable binding of ^{125}I-secretin is expressed as percentage of radioactivity bound in the absence of the antagonists.

EVALUATION

K_i values are calculated from percent of controls of bound ^{125}I-secretin using the equation:

$$K_i = [R / (R - 1)]\,[S\,B / (S + A)]$$

where R = the observed saturable binding of ^{125}I-secretin in the presence of the antagonist (B) expressed as a fraction of that obtained when B is not present. A is the concentration of ^{125}I-secretin (0.05 nM), S is the k_d determined by Scatchard analysis.

MODIFICATIONS OF THE METHOD

Bawab et al. (1991) characterized the down regulation of the ^{125}I-secretin binding sites and the associated desensitization of the secretion receptor-cAMP system in rat gastric glands.

Molecular cloning and expression of a cDNA encoding the secretin receptor in COS cells was reported by Ishihara et al. (1991).

Steiner et al. (1993) localized secretin receptors mediating rat stomach relaxation by autoradiography of frozen sections of the rat stomach with ^{125}I-labeled porcine secretin.

Ulrich et al. (1993) studied the intrinsic photoaffinity labeling of native and recombinant rat pancreatic secretin receptors.

Vilardaga et al. (1994) investigated the properties and regulation of the coupling to adenylate cyclase of secretin receptors stabile transfected in Chinese hamster ovary cells.

Molecular cloning, expression and functional characterization of a human secretin receptor was reported by Chow (1995), Patel et al. (1995), of the rabbit secretin receptor by Svoboda et al. (1996). The full-length human secretin receptor cDNA was subcloned into the mammalian expression vector pRc/CMV and expressed in cultured CHO cells (Ng et al. 1999). Intracellular cAMP accumulation of the stably transfected cells was measured by a radioimmunoassay, while the extracellular acidification rate was measured by the Cytosensor microphysiometer.

J.7.0.10 Cholecystokinin activity (isolated rat pancreatic acini)

PURPOSE AND RATIONALE

Cholecystokinin (CCK) is one of the first discovered gastrointestinal hormones and one of the most abundant neuropeptides in the brain (Crawley and Corwin (1994). CCK is found in high concentrations in the mammalian brain and may be implicated in the neurobiology of anxiety and panic disorder (Bourin et al. 1996). Two types of CCK receptors have been identified: CCK-A receptors are mainly located in the periphery, but are also found in some areas of the CNS. CCK-B receptors are widely distributed in the brain. Major biological actions of CCK are the reduction of food intake and the induction of anxiety-related behavior. Inhibition of feeding is mainly mediated by the A-type receptors, whereas anxiety-like behavior is induced by stimulating B-type receptors (Fink et al. 1998).

Isolated pancreatic acini of rats can be used for evaluation of cholecystokinin activity of synthetic derivatives and for plasma CCK-like activity (Liddle et al. 1984; Höcker et al. 1990; Schmidt et al. 1991).

PROCEDURE

For plasma determinations, CCK or inhibitors are extracted from a plasma sample using PR-18 cartridges (Merck, Darmstadt, Germany). One ml plasma is diluted with 4 ml 0.1% trifluoroacetic acid and applied to a cartridge. After a wash (15 ml), CCK and inhibitor are eluted with acetonitrile/water (80 : 20, v/v) and lyophilized. Pancreatic acini are prepared from female Sprague-Dawley rats weighing 180–200 g, 1 to 2 weeks post ovarectomy, by enzymatic digestion of pancreas with collagenase (Jensen et al. 1982). Test compounds, or extracted material reconstituted with Krebs-Ringer HEPES buffer, or CCK standard is incubated with acini (final volume 0.25 ml). Lipase is measured with an autoanalyser (e.g., Hitachi type 705 or 805). Release is calculated as percent of the initial content determined in each incubation vial.

EVALUATION

CCK bioactivity is determined by comparison with a CCK-8 standard curve. Results are expressed as CCK-like bioactivity.

MODIFICATIONS OF THE METHOD

Amblard et al. (1998) evaluated cyclic cholecystokinin analogues for their ability to stimulate amylase secretion from isolated pancreatic acini.

Inhibition of CCK-8 induced release of amylase from pancreatic cells was used for measurement of CCK_A antagonism (Yamazaki et al. 1995; Akiyama et al. 1996; Patel et al. 1996; Taniguchi et al. 1996; Ballaz et al. 1997; Martin-Martinez et al. 1997).

Deyer et al. (1993) reported on acetylcholine and cholecystokinin induced acid extrusion in mouse isolated pancreatic acinar cells as measured by the microphysiometer. The microphysiometer continually measures the pH of the medium bathing a cell sample. EC_{50} values for the acidification rate were determined for CCK and CCK analogues. Dunlop et al. (1997) used the Cytosensor® microphysiometer to analyze the activity of cholecystokinin antagonists against the CCK-4-mediated response in hCCK-B CHO cells.

J.7.0.11 Receptor binding of cholecystokinin

PURPOSE AND RATIONALE

Receptor binding assays for CCK have been described by several authors, such as Innis and Snyder (1980) for rat pancreas; Gaisano et al. (1989), Doi et al. (1990), Blevis et al. (1990), Maletínská et al. (1992) for isolated pancreatic acini; Saito et al. (1981), Chang et al. (1983) for guinea pig cerebral cortex, Praissman et al. (1983) for guinea pig mucosa, Van Dijk et al. (1984) for rat brain and pancreas; Steigerwalt et al. (1984), Chang and Lotti (1986) for gallbladder membranes; Kaufmann et al. (1993) for guinea-pig cerebral cortex and rat pancreas.

Using transfected COS cells, Talkad et al. (1994) identified three different states of the pancreatic CCK receptor, with the very-low-affinity state being the most abundant.

A review on cholecystokinin receptors was given by Wank (1995).

Radioimmunoassays for cholecystokinin have been developed (Harvey 1979) and are available as commercial kits.

PROCEDURE

Membranes of rat (Sprague Dawley) pancreas, guinea pig (Hartley) cerebral cortex, and bovine gallbladder are prepared by homogenization in 50–100 vol of 50 mM Tris-HCl (pH 7.4 at 37 °C) using a Polytron (Brinkman, PT 10, setting 4 for 10 s for pancreas or brain and maximal speed for bovine gallbladder). Homogenates are centrifuged at 50 000 *g* for 10 min, and the pellets are resuspended in the same buffer and centrifuged as described above. The resulting pellets are resuspended in 4 000, 80, and 25 ml of binding assay buffer for each g of original tissue wet weight of pancreas, brain, and gallbladder, respectively. ^{125}I-CCK-8 binding assay buffer contains 5 mM dithiothreitol, 50 mM Tris-HCl (pH 7.4 at 37 °C), 5 mM $MgCl_2$, 2 mg of bovine serum albumin, and bacitracin at 0.14 mg/ml for pancreas; 10 mM HEPES, 5 mM $MgCl_2$, 1 mM EGTA, bacitracin at 0.25 mg/ml, and 130 mM NaCl (pH adjusted to 6.5 with NaOH) for brain; and 10 mM HEPES, 5 mM $MgCl_2$, 1 mM EGTA, bacitracin at 0.25 mg/ml, soybean trypsin inhibitors at 0.2 mg/ml, and 130 mM NaCl (pH 6.5) for bovine gallbladder.

^{125}I Bolton-Hunter labeled CCK-8 (New England Nuclear) is used. Free and bound ^{125}I-CCK-8 are separated by filtration using Whatman G/F B glass fiber filters that are presoaked with 50 mM Tris-HCl (pH 7.4) containing bovine serum albumin (1 mg/ml). Immediately after the filtration, the filters are washed rapidly three times with 4 ml of Tris-HCl containing bovine serum albumin (0.1 mg/ml). Radioactivity is counted with a gamma counter, e.g. Beckman Instruments. Specific ^{125}I-CCK-8 binding is defined as the difference between total binding and nonspecific binding in the presence of 1 mM CCK.

EVALUATION

IC_{50} values are determined by regression analysis of displacement curves. Inhibitor constants (K_i) are calculated from the formula

$$K_i = I / (K_{d'} / K_{d\text{-}1})$$

where I is the concentration of the inhibitor, and K_d and $K_{d'}$ are the dissociation constants of ^{125}I-CCK-8 in the absence and presence of the inhibitor, respectively.

MODIFICATIONS OF THE METHOD

Subtypes of the cholecystokinin receptor, forming a cholecystokinin receptor family, have been described, such as CCK_A from pancreas and other parts of the gastrointestinal tract and in a few discrete brain regions (Kachur et al. 1991; Poirot et al. 1992; Wank et al. 1992a).

According to the IUPHAR Compendium of Receptor Characterization and Classification 1998; CCK_A and CCK_B receptors are designated as CCK_1 and CCK_2, respectively.

A survey on ligands for cholecystokinin receptors was given by Trivedi (1994).

Van der Bent et al. (1994) described molecular modeling of **CCK-A receptors**.

For CCK_A receptor binding assays (Fossa et al. 1997), the pancreas from a male Hartley guinea pig is dissected and placed in saline. Fatty tissue and blood vessels are dissected away and the tissue placed in 20 vol of buffer (50 mM Tris HCl, pH 7.4, 0.35 mg/ml bacitracin and 0.5 mg/ml soybean trypsin inhibitor) at 4 °C and minced using scissors. The tissue is homogenized (Polytron, setting no. 9 for two 15-s bursts), strained through gauze and centrifuged at 100 000 *g* for 15 min at 4 °C. The supernatant is discarded and the pellet resuspended in 20 vol of buffer and recentrifuged. The final pellet is diluted to a concentration of 1.25 mg/ml (original wet weight) in buffer and kept on ice until used. The incubation reaction is initiated by the addition of 100 µl of tissue to 96-well plates containing 150 µl of incubation buffer (50 mM Tris HCl, pH 7.4, and a final concentration of 5 mM $MgCl_2$, 5 mM dithiothreitol and 1% DMSO) with 60 pM final concentration of ^{125}I-BH-CCK_{8S}, and drug or vehicle. After a 30-min incubation the reaction is terminated by rapid filtration using a Skatron cell harvester (Skatron Instruments, Inc. VA) onto GF/B filters that were soaked for 2 h in 50 mM Tris HCl, 0.1 mg/ml bovine serum albumin. The filters are dried and counted on a Betaplate counter (Wallac Inc. Gaithersburg, MD) for 45 s per sample.

Povoski et al. (1994) reported cholecystokinin receptor characterization and cholecystokinin A receptor messenger RNA expression in transgenic mouse pancreatic carcinomas and dysplastic pancreas.

Yule et al. (1993), Blevins et al. (1994) recorded intracellular Ca^{2+} concentration signaling stimulated by cholecystokinin or by a partial CCK agonist in Chinese hamster ovary-CCK-A cells or in isolated pancreatic acini.

Ghanekar et al. (1997) established a Chinese hamster ovary cell line bearing the mouse type A cholecystokinin receptor.

CCK-A agonists were evaluated as anorectic agents (Pierson et al. 1997; Simmons et al. 1998).

CCK_B receptors occur predominantly in the central nervous system indicating involvement in behavioral functions (Moran et al. 1986; Wank et al. 1992b; Derrien et al. 1994; Schäfer et al. 1994) but also in pancreatic cancer cells (Smith et al. 1993; Zhou et al. 1992) and small lung cell cancer lines (Sethi et al. 1993).

For CCK_B receptor binding assays (Fossa et al. 1997), guinea pig cortex is homogenized with a Teflon homogenizer in 20 vol of 50 mM Tris HCl (pH 7.4) containing 5 mM $MgCl_2$ at 4 °C and centrifuged at 100 000 *g* for 30 min. The supernatant is discarded and the pellet resuspended and spun again. The pellet is diluted to a concentration of 10 mg/ml (original wet weight) with assay buffer (10 mM HEPES, 5 mM $MgCl_2$, 1 mM EGTA, 130 mM NaCl, and 0.2 mg/ml bacitracin, pH 6.5) before use. The incubation reaction is initiated by the addition of 50 µl of tissue to 96-well plates containing 150 µl of assay buffer with 1% DMSO final concentration, 50 pM final concentration of ^{125}I-BH-CCK_{8S} and the appropriate concentration of drug or vehicle. Non-specific binding is estimat-ed using 1 µM CCK_{8S}. The reaction is terminated by spinning the plates using a H1 000B rotor at 3 000 rpm for 5 min at 4 °C. The pellet is washed with 200 µl of 50 mM Tris HCl and respun. The supernatant is again discarded, the pellet resuspended and the tissues harvested onto Betaplate filters soaked in 0.2% polyethylenimine for 2 h using a Skatron cell harvester (Skatron Instruments, Inc., VA). The filtermats are dried and counted on a Betaplate counter (Wallac Inc. Gaithersburg, MD) for 45 s per sample.

Lee et al. (1993) described cloning and characterization of the human brain cholecystokinin-B/gastrin receptor.

Kaufmann et al. (1993) studied the binding of a series of succinylated cholecystokinin tetrapeptide derivatives to different tissues and their effects on intracellular calcium mobilization ($[Ca^{2+}]_i$) in the human T-cell line Jurkat and rat pituitary (GH3) cells.

Durieux et al. (1989) described [^{3}H]pBC 264 as the first highly potent and very selective radioligand for CCK_B receptors.

Slaninova et al. (1995) recommended the radioiodinated CCK_8 analogue, SNF 8 702, as a selective radioligand for CCK_B receptors.

Knapp et al. (1990) found CCK-B receptor heterogeneity in various brain areas of the guinea pig using a highly selective CCK-B receptor radioligand.

Dunlop et al. (1996) described the functional characterization of a Chinese hamster ovary cell line trans-

fected with the human CCK-B receptor gene. Functional coupling in these cells was demonstrated using agonist stimulated mobilization of intracellular Ca^{2+}, measured with the FURA-2 technique.

CCK_A receptor antagonists have been described (Chang and Lotti 1986; Makovec et al. 1986; Evans 1993; Gully et al. 1993) as well as **CCK_B receptor antagonists** (Hill and Woodruff 1990; Ohtsuka et al. 1993; Pendley et al. 1993).

Selective non-peptide **CCK_B/gastrin receptor antagonists** have been described by Bertrand et al. (1994, Makovec et al. 1999; Takeuchi et al. 1999). Harper et al. (1999) analyzed some of them in radioligand binding assays in mouse and rat cerebral cortex.

Cholecystokinin dipeptoid antagonists with anxiolytic properties which bind preferably to CCK_B receptors have been reported by Boden et al. (1993).

CCK_A receptor antagonists (Ballaz et al. 1997) and **CCK_B receptor antagonists** (Revel et al. 1998) with anxiolytic-like activity in animal models were described.

J.7.0.12 Acute experimental pancreatitis

PURPOSE AND RATIONALE

Acute interstitial pancreatitis can be induced in the rat by excessive doses of a pancreatic secretagogue (Lampel and Kern 1987) such as caerulein (Renner et al. 1986; Ito et al. 1991; Yazu et al. 1991).

PROCEDURE

Induction of pancreatitis

Male Wistar rats weighing 200 g are used. Pancreatitis is induced by caerulein given as 5 intraperitoneal injections of 40 µg/kg each at hourly intervals on day 1. Controls receive saline injections only. Treatment with potential drugs is started at day 1 and continued for 7 or 14 days. The rats are sacrificed after 1 or 2 weeks following caerulein injection.

Preparation of pancreatic acini

The rats are decapitated after overnight fasting and the pancreata are quickly removed. The pancreata are injected with digestion medium containing 170 U/ml collagenase and incubated for 15 min at 37 °C. The medium is changed for the second incubation for 60 min with 15 ml digestion medium containing 200 U/ml collagenase. Acini are dissociated by sequential passage through 4 pipettes of different diameters in a standard medium containing 0,1% soybean inhibitor. The suspension is filtered through a single layer of gauze and layered over 15 ml of 4% bovine albumin. After centrifugation for 2 min at 400 rpm, the pellet is washed 3 times with 20 ml of incubation medium containing 0.5 mM $CaCl_2$. Finally, the acini are resuspended in 10–20 ml of the incubation medium containing 10 mM HEPES, 145 mM NaCl, 4.7 mM KH_2PO_4, 1.0 mM $CaCl_2$, 1.2 mM $MgCl_2$, 16.5 mM glucose, 0.1% bovine serum albumin, 0.01% soybean trypsin inhibitor, Eagles minimal essential amino acids and vitamins, adjusted to pH 7.4 and bubbled with 100% oxygen.

Measurement of [^{3}H]-thymidine uptake into pancreatic acini

Aliquots (5 ml) of the acini suspension are incubated at 37 °C for 30 min, and 6-[^{3}H]-thymidine (5 mCi/mmol) is added as a final concentration of 0.8 mCi/mol. After incubation for 60 min, 200 ml aliquots are filtered by vacuum through Whatman GF/B glass fiber filters. Filters which trapped the acini are washed with 15 ml ice-cold buffer. After adding 5 ml of Aquazol II to each vial, the radioactivity of the filters is counted with a scintillation spectrometer.

Measurement of amylase secretion from pancreatic acini

Acini are resuspended in 5 ml of the incubation medium and pre-incubated at 37 °C for 30 min. Carbachol at concentrations between 10^{-7} and 10^{-4} M or CCK-8 at concentrations between 10^{-11} and 10^{-8} M is added and the acini suspension is incubated at 37 °C for an additional 30 min. Triplicate 300 ml aliquots are centrifuged for 5 s at 3 000 rpm. The amylase activity in the supernatant is measured by a commercial amylase test. Triplicate 500 ml aliquots are sampled before adding the secretagogue and the amylase contents (total amylase) are measured after sonification.

EVALUATION

Thymidine uptake is compared between control, caerulein treated animals and animals treated with drugs. Dose-response curves of amylase secretion after carbachol and CCK-8 are established for each group. Moreover, amylase concentrations in the acini are compared.

MODIFICATIONS OF THE METHOD

Griesbacher and Lembeck (1992), Griesbacher et al. (1993) studied the prevention of **caerulein-induced** experimental acute pancreatitis in the rat by the bradykinin antagonist HOE 140.

Several authors (Ito et al. 1994; Ogden et al. 1994; Liu et al. 1995; Sledzinski et al. 1995; Weidenbach et al. 1995; Chen et al. 1996; Lembeck and Griesbacher 1996; Asano et al. 1997; Ito et al. 1997) used different dose regimens of caerulein administration to induce acute pancreatitis in rats.

Huch et al. (1995) induced necrotizing pancreatitis by intraductal infusion of low-dose glycodeoxycholic acid (10 mmol/l) followed by intravenous cerulein (6 µg/kg/h) for 6 h.

Several other chemicals and drugs may induced acute pancreatitis (Vogel 1994).

Merkord et al. (1997) studied the pathogenesis and the time course of lesions of acute interstitial pancreatitis in rats induced by intravenous injection of 6 mg/kg **dibutyltin dichloride** (DBTC), an organotin compound used in chemical industry and in veterinary medicine. First, the cytotoxic effects on the biliopancreatic duct epithelium lead to epithelial necrosis with obstruction of the duct, subsequent cholestasis, and interstitial pancreatitis; and second, the hematogenic effects of DBTC cause direct injury of pancreatic cells followed by interstitial edema and inflammation. A chronic course is found when the obstruction of the duct and cholestasis persist.

Destruction of acinar cells has been found after the administration of **ethionine** in rats (Herman and Fitzgerald 1962).

Niederau et al. (1985), Neuschwander-Tetri et al. (1994), Norman et al. (1995), Van Laethem et al. (1995), Taniguchi et al. (1996) described acute necrotizing pancreatitis induced by caerulein in **mice**.

Pancreatitis can be induced in mice by a **choline-deficient diet** (Lombardi et al. 1975; Niederau et al. 1990). Mice weighing 10–14 g are fed regular laboratory chow ad libitum before the experiment. A choline-deficient diet supplemented with 0.5% ethionine is given for a period of 66 h, after which it is replaced by regular chow.

Lake-Bakaar and Lyubsky (1995), Hirano (1997), Niederau et al. (1995) induced acute pancreatitis in female Swiss-Webster mice by feeding a choline- and methionine-deficient diet supplemented with 1% ethionine.

Emanuelli et al. (1994) demonstrated that a single injection of endotoxin (lipopolysaccharides, *E. coli* 0111-B4) into the superior pancreaticoduodenal artery of **rabbits** induced a dose-dependent acute necrotizing pancreatitis.

Watanabe et al. (1993) induced acute hemorrhagic pancreatitis in rats by surgically **closing a 1 cm length of duodenal loop** at points proximal and distal to the orifice of the pancreatic duct for 6 h with bypassing the bile from the liver hilus distal to the closed loop. The effects of Hoe 140, a bradykinin antagonist, were studied.

Ha et al. (1994, 1996) used the closed duodenal loop technique to study the role of endogenous and exogenous cholecystokinin in experimental pancreatitis and the effect of a cholecystokinin receptor antagonist on the early stage of the healing process in acute pancreatitis.

Kimura et al. (1988) found beneficial effects of a cholecystokinin A receptor antagonist in three methods of acute experimental pancreatitis: pancreatitis in mice induced by 6 intraperitoneal injections of 50 µg/kg caerulein, necrotizing pancreatitis in rats induced by injection of sodium taurocholate into the common bile duct followed by 4 subcutaneous injections of 50 µg/kg caerulein, and in closed duodenal loop induced pancreatitis in rats.

J.7.0.13 Taurocholate-induced pancreatitis in the rat

PURPOSE AND RATIONALE

Retrograde infusion of bile salts into the pancreatic duct induces severe necrotizing pancreatitis indicated by reduced amylase output and histological changes.

PROCEDURE

Male Sprague-Dawley or Wistar rats weighing 200–300 g are anesthetized by i.m injection of a mixture of 87 mg/kg ketamine and 13 mg/kg xylazine. After laparatomy, the pancreaticobiliary duct is cannulated through the duodenal papilla with a polyethylene catheter (P10, Clay Adams) which is introduced by means of a puncture in the duodenum. A precision pump is used to infuse 0.6 ml 5% sodium taurocholate into the pancreaticobiliary duct during a 10-min period at an infusion rate of 6 ml/h. The catheter is then withdrawn and the abdominal cavity surgically closed.

After various time intervals (several hours up to 2 weeks), the animals are anesthetized and the pancreaticobiliary duct is cannulated again. The response to various doses of caerulein is measured.

EVALUATION

The degree of amylase output (mg/h) is taken as parameter. Dose response curves after various doses of caerulein are established.

MODIFICATIONS OF THE METHOD

The effects of various agents on experimental pancreatitis induced by retrograde intraductal injection of **taurocholate** solution or bile acid in rats have been studied by various authors (Bielecki et al. (1994), Hietaranta et al. 1995; Nakae et al. 1995; Niederau et al. 1995; Kimura et al. 1996; Mithofer et al. 1996; Paran et al. 1996; Tachibana et al. 1996; Norman et al. 1997; Plusczyk et al. 1997; Manso et al. 1998).

Tanaka et al. (1995), Sakai (1996) induced necrotizing pancreatitis by retrograde injection of **deoxycholate** solution into the biliopancreatic duct of rats.

J.7.0.14 Chronic pancreatitis

PURPOSE AND RATIONALE

Chronic pancreatitis was induced by various means in rats (Zhou 1990, 1994; Goto et al. 1995; Puig-Diví et al. 1996), golden hamsters (Rutishauser et al1991, 1995), cats (Reber et al. 1992, 1999; Zhao et al. 1996), dogs (Hayakawa et al. 1993; Tanaka et al. 1994, 1998), and pigs (Vinter-Jensen et al. 1997).

Puig-Diví et al. (1996) induced chronic pancreatitis in rats by trinitrobenzene sulfonic acid infusion into the pancreatic ducts.

PROCEDURE

Male Sprague Dawley rats weighing 300–350 g are anesthetized with ketamine (100 mg/kg i.p.) after an overnight fast. Access to the pancreas is gained through a ventral midline incision. The duodenum is opened and the biliopancreatic duct cannulated through the papilla using polyethylene tubing (PE 10). The biliopancreatic secretion is allowed to drain freely for 15 min. To prevent liver damage, the duct is tied close to the liver. Retrograde infusion is initiated by means of a controlled pressure device that uses the height of a liquid column (trinitrobenzene sulfonic acid or vehicle) in a vertical pipette connected to the infusion cannula to control the intraductal pressure and infusion volume. Ductal pressure is never allowed to exceed 20 cm H_2O. In the treated group 0.4 ml of 2% trinitro-benzene sulfonic acid in phosphate buffered saline + 10% ethanol (pH 8) is infused. Ethanol is employed as an epithelial "barrier breaker" to facilitate trinitrobenzene sulfonic acid penetration into the tissue. Rats in the control group undergo the same procedure, except that trinitrobenzene sulfonic acid in absent from the infusion medium.

The total exposure time of the gland to the instillate is 60 min, followed by a washout period of 30 min. Ligatures are then released, the duodenum and the abdominal wall are sutured, and the animals are kept under observation for 2 h after surgery. Rats are then transferred to individual cages, where they are fasted for 24 h. Thereafter they receive standard chow and their weight gain is recorded weekly.

Blood is withdrawn after various time intervals by cardiac puncture under light ether anesthesia for determination of glucose and serum α-amylase (EPS test, Boehringer Mannheim GmbH).

Groups of treated rats and controls are sacrificed at 3, 4, and 6 weeks after the surgical procedure. Pancreata are fixed in 10% neutral buffered formaldehyde and embedded in paraffin. Several sections are cut and stained with haematoxylin-eosin for light microscopy evaluation. The degree of periductal and intralobular fibrosis, patchy acute and chronic inflammatory cell infiltrates, common duct stenosis, and segmentary gland atrophy is evaluated.

EVALUATION

Data are expressed as means ±SEM. A two-tailed Student's *t*-test for unpaired values is used for statistical comparison of mean values of serum amylase, glucose and rat weight.

MODIFICATIONS OF THE METHOD

Chung and Richter (1971), Zhou et al. (1990, 1994) induced chronic pancreatitis in rats by **ligation of the pancreatic duct**.

Injection of oleic acid (Goke et al. 1989; Goldstein et al. 1989; Andersen et al. 1994; Kakugawa 1996; Seymour et al. 1995, 1998) or of a viscous solution of zein – oleic acid – linoleic acid (Kataoka et al. 1998) into the pancreatic duct was used to induce chronic pancreatitis in rats.

Goto et al. (1995) described a chronic pancreatitis model with diabetes induced by intraperitoneal **cerulein** injection plus water immersion stress in rats.

Pancreatic blood flow was measured in **cats** with chronic pancreatitis induced by partial ligation of the pancreatic duct by Austin et al. (1980), Reber et al. (1992, 1999), Widdison et al. (1992).

Zhao et al. (1996, 1998) induced progressing lesions of chronic pancreatitis in cats by intraductal injection of alcohol or by a combination of intraductal and intraparenchymal injection of ethanol together with partial obstruction of the main pancreatic duct to 70% of its original lumen by fixation of a small catheter in the papilla.

Hayakawa et al. (1993) induced pancreatolithiasis in **dogs** by partial obstruction of the major pancreatic duct.

Rats of the diabetic strain WBN/Kob (Tsuchitani et al. 1985; Nakama et al. 1985) develop **spontaneously chronic pancreatitis** (Ohashi et al. 1990; Sato et al. 1993; Sugiyama et al. 1996a,b; Arai et al. 1998; Ito et al. 1998) with pancreatic fibrosis and parenchymal destruction and both endocrine and exocrine pancreatic dysfunction (see also K.2.0.2).

Transgenic mice overexpressing $TGF_{\beta 1}$ (Sanvito et al. 1995) develop tissue changes in the pancreas resembling changes found in chronic pancreatitis.

Shetzline et al. (1998) identified target tissues of pancreatic polypeptide using an *in vivo* radioreceptor assay in order to further elucidate the function of this hormone.

J.8 Liver function

J.8.1 Hepatocellular function

J.8.1.1 Hepatitis in Long Evans Cinnamon rats

PURPOSE AND RATIONALE

The Long Evans Cinnamon strain of rats has been recommended as a useful model to study genetically transmitted fulminant hepatitis and chronic liver disease (Yoshida et al. 1987; Hawkins et al. 1995). The underlying cause is thought to be due to excessive copper accumulation in the liver of Long Evans Cinnamon rats, thus making this animal a model for Wilson's disease in humans (Okayasu et al. 1992). Chelation therapy or feeding a copper-deficient diet can ameliorate the symptoms in Long Evans Cinnamon rats and Wilson's disease (Togashi et al. 1992).

PROCEDURE

Male Long Evans Cinnamon rats obtained from a commercial breeder at an age of 5 weeks are housed in temperature- und humidity-controlled rooms at a 12 : 12 light/dark cycle. Groups of 6–10 rats are given different diets based on a 15% purified egg protein diet and supplemented with vitamins or drugs. Drugs are applied via minipumps intraperitoneally implanted under ether anesthesia.

The occurrence of jaundice is easily observable as the time when the ears and tail turn yellow and the urine becomes bright orange, staining the fur in the lower abdominal region. Usually, the jaundice progressively worsens, ending in death of the animal within about a week. Incidence of jaundice and mortality vs. time are used as parameters.

EVALUATION

Statistics are performed using StatView II software package for Student's *t*-test, ANOVA, and the Scheffé F-test for comparison between means. All data are expressed as means. A p-value < 0.05 is used as the threshold of significance.

MODIFICATIONS OF THE METHOD

Several drugs which are known to be effective or which are potentially effective in treatment of Wilson's disease were studied in this animal model, such as D-penicillamine (Togashi et al. 1992; Yokoi et al. 1994; Shimizu et al. 1997), trientine (= triethylenetetramine) (Iseki et al. 1992; Sone et al. 1996; Yamamoto et al. 1997), tetrathiomolybdate (Ogra et al. 1995; Suzuki 1997; Sugawara et al. 1999), or the investigative drug TJN-101 (Yokoi et al. 1995).

The interferon-γ transgenic mouse which carries the mouse INF-γ gene develops chronic hepatitis from the age of 6–10 weeks and was recommended by Okamoto et al. (1999) as a model for **chronic hepatitis**.

J.8.1.2 Temporary hepatic ischemia

PURPOSE AND RATIONALE

Hepatocellular function is altered by temporary hepatic ischemia as occurring during surgical management of acute hepatic trauma and being essential during hepatic transplantation. To study this, total hepatic ischemia in rats is produced by placing a ligature around the hepatic artery, portal vein, and the common bile duct.

PROCEDURE

Hepatic ischemia procedure

Male albino Holtzman rats, weighing 300–350 g are fasted for 16 h prior to the experiment but are allowed water ad libitum. The rats are anesthetized lightly with ether and the abdominal cavity is opened through a midline incision. Splenectomy is performed following which a temporary extracorporal splenofemoral shunt is established between the splenic vein and the right femoral vein using a PE-190 tubing. To insure total hepatic ischemia, the portal vein as the hepatic artery and the bile duct are occluded by placing a tourniquet around the vessels. Blood pressure is measured via a catheter inserted into the right femoral artery. After heparinization (10 mg/kg), hepatic ischemia is produced for 60 min. During the ischemic period, 0.7 ml of saline is given i.v. at 20-min intervals for volume replacement. At the end of the 60-min ischemic period, the tourniquet around the portal vein, hepatic artery and the bile duct is removed in order to reestablish blood flow to the liver. The abdominal incision is then closed and the animals receive either saline (nontreated) or the drug. Following administration of saline or the drug the catheters are removed and the animals are returned to their home cages.

Sham-operated animals are prepared exactly in the same manner except that the tourniquet around the portal vein, hepatic artery, and the bile duct are not placed.

Measurement of indocyanine green clearance

Three hours following the end of ischemia, the experimental as well as the sham-operated rats are lightly anesthetized with ether and a femoral artery and vein of each animal cannulated. Sodium heparin (400 units) is given i.v. and the animals are allowed to awake. Indocyananine green is given i.v. at 5 mg/kg (low) or 25 mg/kg (high) to the animals via the femoral vein and 0.2 ml arterial blood samples are taken at 5, 6, 8, 10, 12, 15, 18, and 20 min later. The blood samples are diluted with 0.8 ml of 1% bovine serum albumin in normal saline and centrifuged at 6 000 rpm for 20 min at 4 °C. The spectrophotometric absorbance of the supernatant is read at 800 nm and the indocyanine green concentration determined from a standard curve.

EVALUATION

The $t_{½}$ of indocyanine green clearance is computed for each animal using a computer program which calculates the least square line of log indocyanine green vs. time. Mean and standard errors for each group are compared using the Student *t*-test.

MODIFICATIONS OF THE METHOD

Daemen et al. (1989) compared the electromagnetic versus the microsphere and the clearance method for liver blood flow measurement in the rat.

J.8.1.3 Model for direct transhepatic studies in dogs

PURPOSE AND RATIONALE

A chronic conscious dog model for repeated transhepatic studies over a period of 6–8 weeks was developed by O'Brien et al. (1991). This model can be applied to the study of the hepatic effects of pancreatic hormone secretion and glucose metabolism, to studies of the hepatic mechanisms associated with high first-pass metabolism and food interactions of drugs (Semple et al. 1990), and to studies of insulin balance in dogs that have undergone previous pancreatectomy and islet cell auto-transplantation.

PROCEDURE

Four silastic catheters, 0.062 in. ID × 0.125 in. OD (lengths: carotid 70 cm; jugular 70 cm; hepatic 80 cm; and portal 70 cm) and two ultrasonic transit time flow probes suitable for long-term implants (Burton and Gorewit 1984), 4 mm for the hepatic artery and 6 mm for the portal vein, are cleaned with chlorhexidine scrub and rinsed with distilled water. Double velour dacron cuffs are placed 15 cm from the external ends of all the devices.

Male dogs weighing 20–25 kg are sedated and anesthetized with a 2% halothane/L O_2 mixture. Skin interface sites and subcutaneous pockets for placement of catheters are prepared. After skin closure the external ends of the catheters are sealed. Then the catheters and flow probes are placed into the abdomen by retrieving them from the subcutaneous pockets. First, the hepatic artery flow probe is placed, then, the portal venous flow probe inserted. To eliminate extrahepatic blood flow, the gastroduodenal artery is ligated. Then, the portal vein and the hepatic vein catheters are placed. After ensuring catheter patency, the abdomen is closed. Finally, a carotid artery catheter and a jugular venous catheter are placed.

EVALUATION

Blood samples can be withdrawn from the catheters placed into the carotid artery, the right external jugular vein, the portal vein, and the hepatic vein. Blood flow is measured by flow probes in the hepatic artery and the hepatic portal vein.

The following values are measured:

- Plasma flow in the portal vein and plasma flow in the hepatic artery,
- drug concentration in the portal vein, in the hepatic artery, in the hepatic vein, and in the right external jugular vein.

From these data plasma flux in the portal vein, in the hepatic artery, and in the hepatic vein and the interval areas under the curve for these vessels are calculated.

J.8.2 Liver cirrhosis and necrosis

J.8.2.1 General considerations

Various factors induce liver cirrhosis in man, such as alcoholism, viral hepatitis, intoxications, bile duct dis-

orders, inborn diseases, and others. In the process leading to cirrhosis, accumulation of connective tissue and parenchymal regeneration are competing events. Excessive formation of connective tissue with collagen overproduction in the liver reduces hepatic blood flow, impairs the metabolic functions of the liver, and increases portal vein pressure. These mechanisms result in hepatic failure, esophageal bleeding, portal hypertension and ascites. Therefore, the search for agents to prevent liver cirrhosis is focused on inhibitors of excessive connective tissue formation in the liver (Kervar et al. 1976; Nolan et al. 1978). The main component of connective tissue formed as a response to chronic injury is collagen. The collagenous fibers consist of triple helical molecules. Their formation depends on the presence of hydrogen bonds involving the post-translationally hydroxylated amino acid hydroxyproline. If the number of hydrogen bonds is reduced due to a decrease of hydroxylated amino acids, the resulting collagen can not form the triple helix and is degraded instead of being deposited in the extracellular matrix.

Insoluble collagen is responsible for most of the mechanical functions of connective tissue, e.g., bone, tendon and skin, being influenced by hormones, desmotropic drugs, such as D-penicillamine, and by maturation and age (Vogel 1969, 1972, 1974a,b, 1976, 1978, 1980, 1989; Bickel et al. 1990, 1991). The aim of fibrosuppressive compounds is to reduce only the excessive formation of insoluble collagen in the liver leaving collagen synthesis and turnover in other tissues intact. Fibrosuppressive effects by inhibition of proline hydroxylation can be screened with *in vitro* methods, however, the desired organ specificity has to be tested in models of liver cirrhosis and fibrosis *in vivo* together with functional studies of the connective and supporting tissue. Detailed description of methods for studying collagen metabolism and mechanical function of connective tissue is given in the Sect. M.2.1.3 (hormones).

J.8.2.2 Inhibition of proline hydroxylation

PURPOSE AND RATIONALE

The thermal stability of the triple helix of collagenous proteins is crucially dependent upon the intramolecular hydrogen bonds involving the 4-hydroxyproline residues synthesized by the enzyme prolyl 4-hydroxylase. This makes the enzyme a possible target for therapeutic antifibrotic agents.

PROCEDURE

Enzyme activity is assayed in sealed test tubes. The reaction volume of 1 ml contains 50 mM Tris buffer, pH 7.5, 10–100 mM (60 000 d.p.m.) 2-oxo[1-^{14}C]glutarate, 1–50 mM $FeSO_4$, 0.1–1 mM ascorbate, 10–100 mg $(Pro\text{-}Pro\text{-}Gly)_{10}$, 0.1 mg catalase, 2 mg bovine serum albumin, 100 mM dithiotreitol, 0.05–0.2 mg enzyme, and inhibitors in various concentrations. After incubation at 37 °C for 30 min, the generated $^{14}CO_2$ is trapped and determined.

EVALUATION

Inhibition modes are determined by plotting 1/v versus 1/concentration of the variable substrate (Lineweaver-Burk plot). The K_i values are derived from a secondary transformation (slopes or intercepts vs. inhibitor concentrations). The lines of best fit for primary plots and secondary transformations are calculated by using the method of least squares. The mean K_i value of 4–6 experiments is calculated.

MODIFICATIONS OF THE METHOD

The collagen hydroxylases lysyl hydroxylase and prolyl 3-hydroxylase have similar reaction mechanisms as prolyl 4-hydroxylase, differing only in the specificity for the amino acid sequence of the substrate (Kivirikko and Myllylä 1982). Instead of $(Pro\text{-}Pro\text{-}Gly)_{10}$, 50–500 mg Arg-Ala-Gly-Ile-Lys-Gly-Ile-Arg-Gly-Phe-Ser-Gly are used.

The activity of prolyl 3-hydroxylase is assayed in a reaction volume of 1.5 ml containing 50 mM Tris buffer, pH 7.5, 1 000 000 d.p.m. of biologically obtained [2,3-^{3}H]proline-labeled protocollagen substrate in which all proline residues recognized by proline 4-hydroxylase are converted to hydroxyproline, 2 mM ascorbate, 0.2 mg/ml catalase, 2 mg/ml bovine serum albumin, 15 mM 2-oxoglutarate, 50 mM Fe^{2+}, 100 mM dithiothreitol, 0.2–2 mg enzyme, and inhibitors at various concentrations. After incubation at 37 °C for 30 min, the reaction is stopped by addition of 0.5 ml 10% trichloroacetic acid (w/v). The reaction mixture is then distilled, and 1.6 ml of ^3H_2O is counted for radioactivity.

J.8.2.3 Influence on collagen synthesis in human skin fibroblasts

PURPOSE AND RATIONALE

Secretion of collagen by fibroblasts and other cells capable of synthesizing extracellular matrix is dependent on the hydroxylation of proline residues by prolyl 4-hydroxylase. This enzyme is located in the cisternae of the endoplasmic reticulum. An agent aimed at inhibition of this enzyme must therefore pass both the external cell membrane and the endoplasmic reticular membrane. Organ specificity of a prolyl 4-hydroxylase inhibitor can be achieved by applying a prodrug which can be converted to the active agent only in cells of specialized tissues, e.g., in the liver, but not generally in fibroblasts.

PROCEDURE

Confluent cultures of human skin fibroblasts are preincubated for 24 h at 37 °C without serum in glutamine-free Dulbecco's minimal essential medium supplemented with 50 mg/ml sodium ascorbate, 60 mg/ml 3-aminopropionitrile, and 100 U/ml penicillin G. The cells are then exposed to the potential inhibitor at various concentrations for 20 min, followed by the addition of 2 mCi [U-^{14}C]proline/ml. The incubation is continued for 5 h at 37 °C. Then, the cells are separated from the medium. After removal of non-incorporated [^{14}C]proline, the proteins from medium and cells are hydrolyzed, and the hydroxyproline content is determined by amino acid analysis. The total incorporation of radioactivity serves as marker for protein synthesis.

EVALUATION

Two individual samples are taken for each concentration of the inhibitor and 6 samples for the controls. Proline incorporation is expressed as % of control radioactivity. Hydroxyproline synthesis is expressed as relative Hyp/Pro ratio according to the formula:

$$(Hyp/Pro_{sample} / Hyp/Pro_{control}) \times 100$$

J.8.2.4 Influence on collagen synthesis in chicken calvaria

PURPOSE AND RATIONALE

To find fibrosuppressive agents for therapeutic use, it is necessary to have prodrugs which cross cell membranes readily and are converted intracellularly to the active agent. Proinhibitors which are cleaved hydrolytically can suppress collagen synthesis in chicken calvaria.

PROCEDURE

Calvaria are removed from chicken embryos, age 15 days, and washed for 3 min with DMEM at 37 °C. They are then transferred into Pyrex tubes (8–10 calvaria/tube) containing 3 ml medium supplemented with 2 mM glutamine, 6 mCi [U-^{14}C-]proline, and various concentrations of the inhibitor. The samples are incubated for 1.5 to 6 h at 37 °C. The experiment is terminated by placing the tubes in ice and separation of calvaria from the culture medium. The calvaria are washed once with 3 ml of fresh medium, which is then pooled with the incubation medium. Bovine serum albumin and phenyl methyl sulfonyl fluoride are added (final concentration 1 mg/ml and 6 mg/ml, respectively). The calvaria are extracted for 16 h with 25 ml of 0.5 M acetic acid.

The following procedure is identical for the medium and the calvaria extracts. The samples are extensively dialyzed against 0.5 M acetic acid at 4 °C. Aliquots are withdrawn for SDS-PAGE1 and the triple-helix stability assay is performed. The remaining material is lyophilized, resuspended in 2 ml 6 N HCl and hydrolyzed at 105 °C for 24 h. After evaporation of the acid, the samples are dissolved in 2 ml H_2O, and the hydroxyproline content is determined according to Juva and Prockop (1967).

In order to study the degree of collagen hydroxylation and proportion of collagen biosynthesis, calvaria are incubated in the presence of 10 mCi [3,4-^{3}H]-proline/ml and 2 mCi [U-^{14}C]-proline/ml for 3 h under the conditions described above. After lyophilization, aliquots of media and calvaria samples are digested with collagenase according to Peterkofsky et al. (1982). The degree of hydroxylation is calculated from the ^{3}H/^{14}C ratio in the digested material; the amount of collagen as a proportion of total protein synthesis is determined by the relation of collagenase degradable vs. collagenase resistant radioactivity. The stability of the extracted collagenous material against digestion by a trypsin/chymotrypsin mixture is tested according to the procedure proposed by Bruckner and Prockop (1981): An aliquot of either culture medium or calvaria extract is incubated for 15 min at a temperature between 25 °C and 45 °C in a total volume of 800 µl of 0.04 M NaCl/0.1 Tris, pH 7.4. After quenching to 0 °C the sample is digested with 200 µl of a mixture of each 1 mg trypsin and chymotrypsin/ml buffer for 15 min at room temperature. One hundred µl of 1 mg BSA/ml buffer is added, and the protease-resistant radioactivity, consisting of triple-helical collagen, is precipitated with 100 µl 100% trichloroacetic acid (w/v). The sample is transferred in total to a Schleicher and Schüll OE 67 filter paper of 2.5 cm diameter. The digested material is removed by repeated washing with cold 5% trichloroacetic acid and methanol. The filters are then dried and the radioactivity is determined. Unhydrolyzed samples are studied by SDS-polyacrylamide gel electrophoresis, and autofluorography. The morphologic appearance of the control and treated cultures is studied by electron microscopy.

EVALUATION

IC_{50}-values of hydroxyproline synthesis are read graphically from concentration response curves. Total protein synthesis is estimated as the incorporation of proline; the mean ±standard deviation is calculated from four samples.

MODIFICATIONS OF THE METHOD

Canalis et al. (1977) used cultured calvaria from 21 day fetal rats to study the effects of insulin and glucagon on bone collagen synthesis.

J.8.2.5 Allyl alcohol induced liver necrosis in rats

PURPOSE AND RATIONALE

Administration of allyl alcohol induces focal liver necrosis in rats which can be partially prevented by treatment with several drugs such as antibiotics.

PROCEDURE

Female Wistar rats weighing 120–150 g are used. At 8:00 A.M. of the first day food but not water is withdrawn. At 3:00 P.M. the compounds to be tested for protective activity are administered i.p. or orally. One hour later, the animals are dosed orally with 0.4 ml/kg of a 1.25% solution of allyl alcohol in water. At 8:00 A.M. of the second day the treatment with the potentially protective drugs is repeated. Food but not water is withheld until the third day. At 8:00 A.M. of the third day the animals are sacrificed and the liver removed. The parietal sides of the liver (left, medium and right lobe and lobus caudatus) are checked using a stereomicroscope with 25 times magnification. Focal necrosis is observed as white-green or yellowish hemorrhagic areas clearly separated from unaffected tissue. The diameter of the necrotic areas is determined using a ocular-micrometer. These values are added for each animal to obtain an index for necrosis.

EVALUATION

Using 10 animals for controls and for each treatment group, the mean of necrosis index is calculated and compared with Student's *t*-test. The protective effect is expressed as percentage decrease of the necrosis index versus controls.

J.8.2.6 Carbontetrachloride induced liver fibrosis in rats

PURPOSE AND RATIONALE

Chronic administration of tetrachloride to rats induces severe disturbances of hepatic function together with histologically observable liver fibrosis.

PROCEDURE

Groups of 20 female Wistar rats with a starting body weight of 100–150 g are used. The animals are treated orally twice a week with 1 mg/kg carbontetrachloride, dissolved in olive oil 1 : 1, over a period of 8 weeks. The animals are kept under standard conditions (day/night rhythm 8:00 A.M. to 8:00 P.M., 22 °C room temperature, standard diet, e.g. Altromin® 1 321 pellets, and water ad libitum). Twenty animals serve as controls receiving olive oil only, 40–60 animals receive the carbontetrachloride only, and groups of 20 rats receive in addition the compound under investigation in various doses by gavage twice daily (with the exception of the weekends, when only one dose is given) on the basis of the actual body weight. The animals are weighed weekly.

At the end of the experiment (8 weeks), the animals are anesthetized and exsanguinated through the caval vein.

In the *serum*, the following parameters are determined:

- Total bilirubin,
- total bile acids,
- 7S fragment of type IV collagen,
- procollagen III N-peptide.

The following organs are prepared for determination of hydroxyproline:

- Liver,
- kidney,
- aortic wall, and
- tail tendons.

The specimens of the organs are weighed and completely hydrolyzed in 6 N HCl. Hydroxyproline is measured by HPLC and expressed as mg/mg wet weight of the organs.

To measure **mechanical properties of connective tissue**, the following organs are prepared: Femur and tibia of both sides, tail tendons, and strips from dorsal skin (Bickel et al. 1990, 1991; detailed description of the methods see N.2.1.3). Furthermore, the influence on the healing process of skin wounds is studied (Method see N.2.1.3.5).

For **histological analysis**, 3–5 pieces of the liver weighing about 1 g are fixed in formalin and Carnoy solution. Three – 5 sections of each liver are embedded, cut and stained with azocarmine aniline blue (AZAN) and evaluated for the development of fibrosis using a score of 0–IV.

Grade 0:	Normal liver histology.
Grade I:	Tiny and short septa of connective tissue without influence on the structure of the hepatic lobules.
Grade II:	Large septa of connective tissue, flowing together and penetrating into the parenchyma. Tendency to develop nodules.
Grade III:	Nodular transformation of the liver architecture with loss of the structure of the hepatic lobules.
Grade IV:	Excessive formation and deposition of connective tissue with subdivision of the regenerating lobules and with development of scars.

EVALUATION

For detection of significant differences ($p < 0.05$), the unpaired *t*-test is used. For comparison of the scores in the histological evaluation, the χ^2-test is used.

MODIFICATIONS OF THE TEST

Instead of chronic intoxication with carbontetrachloride resulting in liver fibrosis, acute hepatocellular damage can be achieved by short term application of carbontetrachloride.

Wistar rats with a starting body weight of 120–150 g are treated daily for 5 days with various oral doses of the compound under investigation. From day 2 to day 5 (4 applications) the rats receive by gavage a dose of 1 mg/kg carbontetrachloride dissolved in olive oil (1 : 1). Blood is withdrawn every day and the aminotransferases ALAT and ASAT, as well as total bilirubin are determined in the serum.

Kawaura et al. (1993) produced liver cirrhosis with ascites in **dogs** by administration of 2 ml carbontetrachloride per kg body weight once a week for 4 weeks. Eight weeks afterwards, the supradiaphragmatic inferior vena cava was constricted to 50% resulting in ascites formation of 500 to 1 000 ml. The dogs could be treated by ligation of the common hepatic artery and hepatocyte inoculation into the spleen.

Wirth et al. (1997) studied the effects of a bradykinin B_1 receptor antagonist in rats with CCl_4-induced liver cirrhosis.

J.8.2.7 Bile duct ligation induced liver fibrosis in rats

PURPOSE AND RATIONALE

Bile duct ligation in rats induces liver fibrosis which can be evaluated by histological means and by determination of serum collagen parameters.

PROCEDURE

Male Sprague Dawley rats weighing approximately 250 g are anesthetized with ketanest (Rompun®). Laparatomy is performed under antiseptic conditions. A mid-line incision in the abdomen is made from the xiphosternum to the pubis, exposing the muscle layers and the linea alba, which is then incised over a length corresponding to the skin incision. The edge of the liver is then raised and the duodenum pulled down to expose the common bile duct, which pursues an almost straight course of about 3 cm from the hilum of the liver to its opening into the duodenum. There is no gallbladder, and the duct is embedded for the greater part of its length in the pancreas, which opens into it by numerous small ducts. A blunt aneurysm needle is passed under the part of the duct selected, stripping the pancreas away with care, and the duct is divided between double ligatures of cotton thread. The peritoneum and the muscle layers as well as the skin wound are closed with cotton stitches.

The animals receive normal diet and water ad libitum throughout the experiment. Groups of 5–10 animals receive the test compound in various doses or the vehicle twice daily for 6 weeks. Then, they are sacrificed and blood is harvested for determination of bile acids, 7S fragment of type IV collagen, and procollagen III N-peptide. The liver is used for histological studies and for hydroxyproline determinations. Control animals show excessive bile duct proliferation as well as formation of fibrous septa. The picture is consistent with complete biliary cirrhosis.

EVALUATION

For detection of significant differences ($p < 0.05$), the unpaired *t*-test is used.

MODIFICATIONS OF THE METHOD

Alpini et al. (1994) found an upregulation of secretin receptor gene expression in rat cholangiocytes after bile duct ligation.

J.8.2.8 Galactosamine induced liver necrosis

PURPOSE AND RATIONALE

Single dose or a few repeated doses of D-galactosamine cause acute hepatic necrosis in rats (Decker and Keppler 1972). Prolonged administration leads to cirrhosis (Lesch et al. 1970).

PROCEDURE

For induction of acute experimental hepatotoxicity, divided doses of 100 to 400 mg/kg D-galactosamine are injected to rats i.p. or i.v. during one day.

For induction of liver cirrhosis, male Wistar rats weighing 110–180 g are injected intraperitoneally three times weekly with 500 mg/kg D-galactosamine over a period of one to 3 months. Potential protective substances are administered orally with the food or by gavage every day. The rats are sacrificed at various time intervals and the livers obtained by autopsy.

EVALUATION

The livers are evaluated by light microscopy and immunohistology using antibodies against macrophages, lymphocytes and the extracellular matrix components, e.g., laminin, fibronectin, desmin, collagen type I, III, and IV. The extent of liver cell necrosis and immunoreactivity for macrophages, lymphocytes and the extracellular matrix components is graded semiquantitatively on a 0 to 4+ scale (0 = absent, 1+ = trace, 2+ = weak, 3+ = moderate, and 4+ = strong). Furthermore, serum enzyme activities, such as GOT and GPT, are determined.

MODIFICATIONS OF THE METHOD

Other agents used to induce experimental cirrhosis are ethionine, thioacetamide (Dashti et al. 1996), dialkylnitrosamines, tannic acid, aflatoxins, pyrrolidizine alkaloids, and hepatotoxic components from mushrooms, such as amatoxins and phallotoxins (Zimmerman 1976).

Bruck et al. (1996) found an inhibition of thioacetamide-induced liver cirrhosis in rats by a nonpeptidic mimetic of the extracellular matrix-associated Arg-Gly-Asp epitope.

Intrahepatic cholestasis can be induced by alpha-naphthylisothiocyanate in rats (Krell et al. 1982).

J.9 Eviscerated animals

J.9.1 Evisceration in rats

PURPOSE AND RATIONALE

Eviscerated animals have been used to study the influence of hormones and other drugs on carbohydrate disposal (Russell 1942; Creutzfeldt et al. 1961; Wick and Drury 1963; Willms et al. 1969; Tanira and Furman 1999).

"Functional" evisceration has been performed by most authors (Russell 1942; Creutzfeldt et al. 1961; Creutzfeldt and Deuticke 1962; Willms et al. 1969; Penhos et al. 1970; Smith 1986; Smith et al. 1990; Tanira and Furman 1999). The abdominal viscera, with the exception of the liver, are removed, and the blood vessels supplying the liver – the coeliac axis and the portal vein – are tied and cut.

PROCEDURE

Male Wistar rats weighing 180 to 280 g are allowed free access to food and water until the experiment. They are anesthetized with 55 mg/kg pentobarbitone sodium i.p. Cannulae are placed in the left femoral vein and in the abdominal aorta via the left femoral artery.

The abdominal cavity is opened and the anterior mesenteric artery, posterior mesenteric artery and the coeliac axis are cut between double ligatures close to the abdominal aorta. The hepatic portal vein is ligated and cut in the same manner. After ligating and cutting the esophagus and the rectum, the abdominal portion of the gastrointestinal tract is removed, together with the pancreas and the spleen. The muscle and the skin incisions are sutured. After completion of the operation the rats are left for 15 min to equilibrate.

Drugs are injected intravenously through the venous cannula. Blood samples are withdrawn from the aortic cannula before and at various intervals after drug administration to be assayed for insulin, blood glucose and non-esterified fatty acids.

EVALUATION

All results are expressed as mean ±SEM. Statistical analysis is performed using ANOVA.

CRITICAL ASSESSMENT OF THE METHOD

The described "functional" evisceration can be performed within 2–3 min without any hemorrhage or any signs of shock, even in hypophysectomized or adrenalectomized animals. That the liver remaining *in situ* is effectively cut off from the blood stream is proven by the fact that rats eviscerated in this way will die within 1–2 h without infusion of glucose.

MODIFICATIONS OF THE METHOD

Some authors removed also the kidneys and the adrenals in rats (Creutzfeldt and Deuticke 1962).

Dogs were eviscerated and nephrectomized under sodium pentobarbital anesthesia by Levine et al. (1950).

J.9.2 Evisceration in rabbits

PURPOSE AND RATIONALE

Evisceration in rabbits was performed by Drury (1935), Wick and Drury (1963), Lippmann and Hommel (1968, 1969), Menzel and Haupt (1972). A detailed description of the technique was given by Lippmann and Hommel (1968).

PROCEDURE

Rabbits of both sexes weighing 2.6–3.2 kg kept on standard diet and tap water ad libitum are used. Food is withdrawn 12 h before surgery and the abdominal skin

is shaved. The animals are anesthetized with 50 mg/kg hexobarbital sodium intravenously. After fixation of the animal, the abdominal cavity is opened by electrocautery from the xyphoid process until 3 cm cranial of the symphysis. The rectum is cut between double ligatures as far caudally as possible. Bleeding from the arteria rectalis has to be avoided. The arteria mesenterica inferior, which is a tiny vessel in the rabbit, is ligated close to the aorta. The root of the mesentery is cut up to the superior mesenteric artery which is tightly ligated. Then the arteria coeliaca is ligated in the same manner allowing complete removal of the root of the mesentery. The esophagus is ligated close to the cardia. After double ligature of the portal vein the whole gastrointestinal tract including the pancreas and the spleen is isolated and the liver is functionally cut off. To eliminate the function of the kidneys, the renal arteries are ligated close to the aorta and the ureters close to the hilus. Cannulae are introduced into the caval vein via the renal veins. The right renal vein is ligated close to the hilus and the tip of a polyethylene catheter placed 4–6 cm caudal from the inferior caval vein for blood withdrawal; the left renal vein is also ligated close to the hilus and the tip of a polyethylene catheter placed 6 cm cranial from the inferior caval vein for infusion.

The animal receives via the catheter 750 IU heparin, 0.3 mg/kg lobeline hydrochloride, 3 mg/kg pentylenetetrazole, 0.01 mg/kg ouabain, and 1.3 mg/kg synephrine to stabilize the cardiovascular function.

Drugs are injected intravenously through the infusion cannula. Blood samples are withdrawn from the other cannula before and at various intervals after drug administration to be assayed for insulin and blood glucose.

EVALUATION

All results are expressed as mean ±SEM. Statistical analysis is performed using ANOVA.

MODIFICATIONS OF THE METHOD

Schäfer (1990) measured glucose disappearance rates into peripheral tissues *in vivo* in adult eviscerated, nephrectomized and adrenalectomiced rabbits, Wistar rats and non-diabetic sand rats with physiological insulin concentrations in the blood.

Chapter K
Antidiabetic activity[1]

[1] Contribution of the biochemical part by G. Müller, Review by A. W. Herling.

K.1 Methods to induce experimental diabetes mellitus

K.1.0.1 Pancreatectomy in dogs

GENERAL CONSIDERATIONS

Dysfunction of the visceral tract has been considered for a long time to be the cause of diabetes mellitus. Bomskov (1910) reported severe diabetic symptoms in dogs after cannulation of the ductus lymphaticus. This observation, however, could not be confirmed in later experiments (Vogel 1963). The technique was similar to that described by Gryaznova (1962, 1963) for ligation of the thoracic duct in dogs.

Von Mehring and Minkowski (1890) noted polyuria, polydipsia, polyphagia, and severe glucosuria following removal of the pancreas in dogs. The final proof for the existence of a hormone in the pancreas was furnished by Banting and Best (1922) who could reduce the elevated blood sugar levels in pancreatectomized dogs by injection of extracts of the pancreatic glands. The role of the pituitary gland in development of diabetes has first been elucidated by Houssay (1930, 1931) in pancreatectomized dogs (Survey by Beyer and Schöffling 1986).

PURPOSE AND RATIONALE

The technique of complete pancreatectomy in the dog as described in detail by Foà (1971) and by Sirek (1986) has been used by many scientists as a relevant animal model for diabetes mellitus in man. Some remarks of our own experiences are added to an abbreviated version of Sirek's description.

PROCEDURE

Male Beagle dogs weighing 12–16 kg are used. The animal is anesthetized with an intravenous injection of 50 mg/kg pentobarbital sodium and placed on its back. After removal of the fur and disinfection of the skin a midline incision is made from the xyphoid process reaching well below the umbilicus. Bleeding vessels are ligated and the abdomen is entered through the linea alba. The falciform ligament is carefully removed and the vessels ligated. A self-retaining retractor is applied. By passing the right hand along the stomach to the pylorus, the duodenum with the head of the pancreas is brought into the operating field. First, the mesentery at the unicate process is cut and the process itself is dissected free. The glandular tissue is peeled off from the inferior pancreatico-duodenal artery and vein. The vessels themselves are carefully preserved.

Along a line of cleavage which exists between the pancreas, the pancreaticoduodenal vessels and the duodenal wall, the pancreas is separated from the duodenum and from the carefully preserved pancreaticoduodenal vessels. The small vessels to the pancreas are ligated. The dissection is carried out from both sides of the duodenum. In the area of the accessory pancreatic duct the glandular tissue being attached very firmly has to be carefully removed in order to leave no residual pancreatic tissue behind.

The pancreatic duct is cleaned, doubly ligated and cut between the ligatures. The dissection proceeds until one encounters a small lobe containing the main pancreatic duct. The glandular tissue adheres here firmly to the duodenum. Blunt dissection and ligation of the vessels is followed by ligation of the pancreatic duct. By pulling on the pylorus and the stomach, the pyloric and the splenic parts of the pancreas are delivered into the wound. The duodenal part is placed back into the abdominal cavity. The mesentery of the body and tail of the pancreas is cut with scissors. The small vessels are doubly ligated and cut. The pancreatic tissue is bluntly dissected from the splenic vessels. The pancreatic branches of the splenic vessels are doubly ligated and cut. Working in direction from the spleen to the pylorus, the pyloric part of the pancreas is the last one to be dissected. Finally, all pancreatic tissue is removed.

The surgical field is checked once more for pancreatic remnants. The concavity of the duodenum and its mesentery is approximated by a few silk stitches and the omentum is wrapped around the duodenum. Retroperitoneal injection of 5 ml 1% procaine solution is given to prevent intussusception of the gut. 250 000 IU penicillin G in saline solution are instilled into the peritoneal cavity. The abdominal wall and the subcutaneous layer are closed by sutures and finally the skin is sutured with continuous everting mattress stitches.

After the operation, the animal receives via a jugular vein catheter for 3–4 days the following treatment: 1 000 ml 10% glucose solution with 10 IU human insulin Regular®, 3 ml 24% Borgal® (sulfadioxin/trimethoprim) solution, 2 ml 50% metamizol and 400 IU secretin. On the third day, the animal is offered milk. After the animal has passed the first milk feces, it is given daily dry food (e.g. Vipromix®, Nagut, Laage, Germany) together with a preparation of pancreatic enzymes (e.g. Viveral® or Festal®, Hoechst AG, Germany). Insulin is substituted with a single daily subcutaneous dose of 34 IU Retard-Insulin (e.g. Ultratard® HM). Vitamin D_3 is given every three months as a intramuscular injection of 1 ml Vigantol® forte.

MODIFICATIONS OF THE METHOD

Experiments performed by Houssay (1930, 1931) performing hypophysectomy in pancreatectomized dogs revealed amelioration of the diabetic state. These experiments contributed to the understanding of hormonal control in diabetes mellitus.

Rappaport et al. (1966), Lau et al. (1976) used a pedunculated subcutaneous autotransplant of an isolated pancreas remnant for the temporary deprivation of internal secretion in the dog.

Subtotal pancreatectomy in **rats** was described by Scow (1957), Scow et al. (1957), Wagner and Cardeza (1957), Bonner-Weir et al. (1983), Noguchi et al. (1994), Tanigawa et al. (1997). The pancreatic tissue between the common bile duct, duodenal loop, and portal vein in the duodenal segment, along the greater curvature in the gastric segment, and along the splenic vein in the splenic segment, was surgically excised in 3- to 4-weeks old rats weighing 80–100 g.

Greeley (1937) proposed a 3-stage procedure with 3–4 weeks intervening between operations for pancreatectomy in **rabbits**.

Itoh and Maki (1996) reported surgical removal of 90% of pancreatic tissue in 7 or 13 weeks old **mice**. Under sodium pentobarbital anesthesia (65 mg/kg i.p.), the pancreas and the spleen were surgically removed with careful conservation of the common bile duct and major vessels surrounding the duodenum. Approximately 10% (by weight and by insulin content) of the pancreas tissue was left intact adjacent to the lower duodenal loop.

K.1.0.2 Alloxan induced diabetes

PURPOSE AND RATIONALE

Surveys on chemically induced diabetes in animals were given by Frerichs and Creutzfeldt (1968, 1971).

Hyperglycemia and glucosuria after administration of alloxan has been described in several species, such as in dogs (Brunschwig et al. 1943; Tasaka et al. 1988), in rabbits (Baily and Baily 1943), in rats (Dunn and McLetchie 1943; Goldner and Gomori 1944) and in other species (Frerichs and Creutzfeldt 1968, 1971). Guinea pigs have been found to be resistant (Maske and Weinges 1957). Dosage and treatment regimen have been elaborated for the most frequently used species. In most species a triphasic time course is observed: an initial rise of glucose is followed by a decrease, probably due to depletion of islets from insulin, again followed by a sustained increase of blood glucose.

PROCEDURE

Rabbits weighing 2.0 to 3.5 kg are infused via the ear vein with 150 mg/kg alloxan monohydrate (5.0 g/100 ml, pH 4.5) for 10 min resulting in 70% of the animals to become hyperglycemic and uricosuric. The rest of the animals either die or are only temporarily hyperglycemic (Baily and Baily 1943; Pincus et al. 1954; Bänder et al. 1969).

Rats of Wistar or Sprague-Dawley strain weighing 150–200 g are injected subcutaneously with 100–175 mg/kg alloxan (Blum and Schmid 1954; Katsumata and Katsumata 1990; Katsumata et al. 1993).

Male **Beagle dogs** weighing 15–20 kg are injected intravenously with 60 mg/kg alloxan. Subsequently, the animals receive daily 1 000 ml 5% glucose solution with 10 IU Regular insulin for one week and canned food ad libitum. Thereafter, a single daily dose of 28 IU insulin (Ultratard HM®) is administered subcutaneously (Brunschwig at al 1943; Geisen 1988).

MODIFICATIONS OF THE METHOD

Kodoma et al. (1993) described a new diabetes model induced by neonatal alloxan treatment in rats. Male Sprague Dawley rats 2, 4, or 6 days of age were injected intraperitoneally with 200 mg/kg of alloxan monohydrate after a 16 h fast. The most severe diabetic symptoms occurred in rats injected on day 6.

Keikkila et al. (1974) reported the prevention of alloxan-induced diabetes by ethanol administration in mice.

K.1.0.3 Streptozotocin induced diabetes

PURPOSE AND RATIONALE

Rakieten et al. (1963) reported the diabetogenic activity of the antibiotic streptozotocin. The compound turned out to be specifically cytotoxic to beta-cells of the pancreas.

PROCEDURE

Male Wistar rats weighing 150–220 g fed with a standard diet are injected with 60 mg/kg streptozotocin (Calbiochem) intravenously. As with alloxan, three phases of blood glucose changes are observed. Initially, blood glucose is increased, reaching values of 150–200 mg% after 3 h. Six–eight h after streptozotocin, the serum insulin values are increased up to 4 times, resulting in a hypoglycemic phase which is followed by persistent hyperglycemia. Severity and onset of diabetic symptoms depend on the dose of streptozotocin. After the dose of 60 mg/kg i.v., symptoms occur already after 24–48 h with hyperglycemia up to 800 mg%, glucosuria and ketonemia. Histologically, the beta-cells are degranulated or even necrotic. A steady state is reached after 10–14 days allowing to use the animals for pharmacological tests.

CRITICAL ASSESSMENT OF THE METHOD

Streptozotocin induced diabetes in laboratory animals, mostly in rats, has become a valuable tool in diabetes research being used by many investigators.

MODIFICATIONS OF THE METHOD

A survey on susceptibility of various species to streptozotocin was given by Frerichs and Creutzfeldt (1971).

Multiple low doses of streptozotocin induce immune pancreatic insulitis in rats thereby mimicking immune type 1 diabetes in humans (Like and Rossini 1976; Rossini et al. 1977).

Miller (1990) described the effect of streptozotocin on the **golden Syrian hamster** using a single i.p injection of 50 mg/kg streptozotocin.

Enhancement of streptozotocin induced diabetes in **CD-1 mice** by cyclosporin A was reported by Iwakiri et al. (1987).

Grussner eat al (1993) induced long-lasting diabetes mellitus in **Yorkshire Landrace pigs** with a dosage of 150 mg/kg streptozotocin.

Stosic-Grujicic et al. (1999) described protection of **mice** from multiple low dose streptozotocin-induced insulitis and diabetes by the immunosuppressive drug leflunomide.

Bleich et al. (1999) found that elimination of leukocyte 12-lipoxygenase in mice ameliorates low dose streptozotocin-induced diabetes by increasing islet resistance to cytokines and decreasing macrophage production of nitric oxide.

Masutani et al. (1998) studied the role of poly(ADP-ribose)-polymerase (Parp) in streptozotocin-induced diabetes. Parp-deficient ($Parp^{-/-}$) mice were established by disrupting *Parp* exon 1 using the homologous recombination technique. These mice were almost resistant to streptozotocin-induced diabetes.

K.1.0.4 Other diabetogenic compounds

PURPOSE AND RATIONALE

Several other compounds have been found to induce symptoms of diabetes and/or obesity, such as dithizone (Maske and Weinges 1957; Frerichs and Creutzfeldt 1971; Hansen et al. 1989; Goldberg et al. 1991) or goldthioglucose (Stauffacher et al. 1967; Caterson et al. 1988; Silva and Hernandez 1989; Heydrick et al. 1995) or monosodium glutamate (Sartin et al. 1985).

PROCEDURE

Goldberg et al. (1991) injected various chelators, such as dithizone, 8-(p-toluene-sulfonylamino)-quinoline (8-TSQ), and 8-(benzenesulfanylamino)-quinoline (8-BSQ) in a single i.v. dose of 40–100 mg/kg to cats, rabbits, golden hamsters and mice. Dithizone injection causes a triphasic glycemic reaction in rabbits. A phase of initial hyperglycemia is detected after 2 h, followed by a normoglycemic phase after 8 h and a secondary permanent hyperglycemic phase after 24–72 h. Histologically, complete and partial degranulation of beta cells is observed.

K.1.0.5 Hormone induced diabetes

Growth hormone induced diabetes

Cotes et al. (1949) described the diabetogenic action of pure anterior pituitary growth hormone in cats. In intact adult dogs and cats the repeated administration of growth hormone induces an intensively diabetic condition with all symptoms of diabetes including severe ketonuria and ketonemia. Rats of any age subjected to a similar treatment do not become diabetic but grow faster (Young 1945) and show striking hypertrophy of the pancreatic islets.

Young FG (1945) Growth and diabetes in normal animals treated with pituitary (anterior lobe) diabetogenic extract. Biochem J 39:515–536

Corticosteroid induced diabetes

Ingle (1941) described hyperglycemia and glucosuria in forced fed rats treated with cortisone. In the guinea pig and in the rabbit, experimental corticoid diabetes could be obtained without forced feeding (Hausberger and Ramsay 1953; Abelove and Paschkis 1954). In the rat, the adrenal cortex, stimulated by corticotrophin, has the capacity to secrete amounts of steroids which induce steroid diabetes (Ingle et al. 1946).

K.1.0.6 Insulin deficiency due to insulin antibodies

PURPOSE AND RATIONALE

A transient diabetic syndrome can be induced by injection of guinea pig anti-insulin serum in various species (Moloney and Coval 1955; Wright 1968).

PROCEDURE

Bovine insulin, dissolved in acidified water (pH 3.0), is incorporated in a water-oil emulsion based on complete Freund's adjuvant or a mixture of paraffin oil and lanolin. A dose of 1 mg insulin is injected in divided doses subcutaneously to male guinea pigs weighing 300–400 g. Injections are given at monthly intervals and the guinea pigs are bled by cardiac puncture two weeks after the second and subsequent doses of antigen. It is possible to get 10 ml blood from every animal once a month.

Intravenous injection of 0.25–1.0 ml guinea pig anti-insulin serum to rats induces a dose-dependent increase of blood glucose reaching values up to 300 mg%. This effect is unique to guinea pig anti-insulin serum and is due to neutralization by insulin antibodies of endogenous insulin secreted by the injected animal. In this way a state of insulin deficiency is induced. It persists as long as antibodies capable of reacting with insulin remain in the circulation. Slow rate intravenous infusion or intraperitoneal injection prolongs the effect for more than a few hours. However, large doses and prolonged administration accompanied by ketonemia, ketonuria, glucosuria, and acidosis are fatal to the animals. After lower doses, the diabetic syndrome is reversible after a few hours.

K.1.0.7 Virus induced diabetes

Juvenile-onset (type I) diabetes mellitus may be due to virus infections and β-cell specific autoimmunity (Craighead 1978). The D-variant of encephalomyocarditis virus (EMC-D) selectively infects and destroys pancreatic β-cells in susceptible mouse strains similar to human insulin-dependent diabetes (Yoon et al. 1980; Giron and Patterson 1982; Giron et al. 1983; Vialettes et al. 1983). Adult, male ICR Swiss mice are susceptible to the diabetogenic effect of the D-variant of encephalomyocarditis virus in contrast to adult C3H/HeJ male mice which are relatively resistant. Pretreatment with cyclosporin A, a potent immunosuppressive drug, results in increased severity and incidence of diabetes in susceptible ICR Swiss mice and induction of diabetes in resistant C3H/HeJ mice (Gould et al. 1985).

MODIFICATIONS OF THE METHOD

Hirasawa et al. (1997) studied the possible role of macrophage-derived soluble mediators in the pathogenesis of encephalomyelitis virus-induced diabetes in **mice**. The inactivation of macrophages prior to viral infection resulted in the prevention of diabetes.

Utsugi et al. (1992) demonstrated that intraperitoneal inoculation with NDK25, a variant of encephalomyocarditis virus which has been cloned from the M variant of encephalomyocarditis virus, caused DBA/2 mice to develop non-insulin-dependent diabetes mellitus.

See and Tilles (1995) challenged CD-1 mice with a diabetogenic strain (E2) of coxsackievirus B4. Islet cell destruction was associated with chronic islet cell inflammation, elevation of islet cell antibody, and prolonged presence of viral RNA in the pancreas.

Stubbs et al. (1994) investigated the effect of Kilham rat virus (KRV) infection on GLUT2 expression in diabetes-resistant BB/Wor **rats**. Viral antibody-free diabetes resistant rats did not develop spontaneous diabetes, but inoculation with Kilham rat virus induced autoimmune beta cell-destruction and hyperglycemia.

Hayashi et al. (1995) investigated the role of adhesion molecules in the reovirus type2-induced diabetes-like syndrome in mice.

Ellerman et al. (1996) studied Kilham rat virus induced autoimmune diabetes in multiple strains of rat.

K.2 Genetically diabetic animals

K.2.0.1 General considerations

Several animal species, mostly rodents, were described to exhibit spontaneously diabetes mellitus on a hereditary basis. These findings were highly appreciated with the expectation to get more insight into the pathogenesis of diabetes in humans. During the last few years since the discovery of leptin (Zhang et al. 1994) and its downstream signal transduction cascade (Friedman and Halaas 1998) tremendous new insight of the genetics of diabetic and obese animal disease models derived. Up to now at least 6 genetically diabetic animal models exhibit defects in the leptin pathway: The *ob* mutation in the mouse resulted in leptin deficiency. The *db* mutation in the mouse and the *cp* and *fa* mutations in the rat are different mutations of the leptin receptor gene. The *fat* mutation in the mouse results in a biologically inactive carboxipeptidase E, which processes the prohormone conversion of POMC into α-MSH, which activates the hypothalamic MC4 receptor. Finally the Agouti yellow (*y*) mouse exhibit an ubiquitous expression of the Agouti protein which represents an antagonist of the hypothalamic MC4 receptor.

Symptoms of diabetes and obesity are overlapping in many animal models (see also L.2. Genetically obese animals).

CRITICAL ASSESSMENT

The pathophysiological mechanisms which finally lead to the diabetes phenotype (hyperglycemia, hyperinsulinemia and insulin resistance) exhibited of the various animal disease models for non-insulin dependent diabetes do not necessarily be identical to those in human disease. Therefore, detailed knowledge about the (patho-)physiology of these animal disease models is a prerequisite for interpretation of experimental results and their value for the human disease.

K.2.0.2 Spontaneously diabetic rats

The occurrence of spontaneous diabetes has been reported in several strains of rats:

BB RAT

The BB rat (Bio Breeding (BB) rat) is a model of spontaneous diabetes associated with insulin deficiency and insulitis due to autoimmune destruction of pancreatic beta cells. (Nakhooda et al. 1977, 1978, Like et al. 1982; Oschilewski et al. 1985; Lee et al. 1988; Solomon et al. 1989; Papaccio and Mezzogiorno 1989; Kolb et al. 1990; Velasquez et al. 1990; Lefkowith et al. 1990; Gottlieb et al. 1990; Ellerman et al. 1993). Diabetes is inherited as an autosomal recessive trait and develops with equal frequency and severity among males and females. The onset of clinical diabetes is sudden, and occurs at about 60–120 days of age. Within several days, diabetic animals are severely hyperglycemic,hypoinsulinemic, and ketotic unless insulin treatment is instituted.

Pipeleers et al. (1991) described the transplantation of purified islet cells in diabetic BB rats.

Hao et al. (1993) reported that the immunosuppressive agent mycophenolate mofetil can prevent the development of diabetes in BB rats.

Klöting and Vogt (1991) characterized the features of a subline of diabetes-prone BB rats (BB/OK rats). The circadian variations in blood pressure and heart rate of this strain were compared with spontaneously hypertensive rats (Berg et al. 1997).

WBN/KOB RAT

Spontaneous hyperglycemia, glucosuria and glucose intolerance have been observed in aged males of an inbred Wistar strain, named the WBN/Kob rat (Nakama et al. 1985; Tsuchitani et al. 1985; Koizumi 1989; Shimoda et al. 1993).These animals exhibit impaired glucose tolerance and glucosuria at 21 weeks of age. Obvious decreases in the number and size of islets are found already after 12 weeks of age. Fibrinous exudation and degeneration of pancreatic tissue are observed in the exocrine part, mainly around degenerated islets and pancreatic ducts in 16 weeks old males. These rats develop demyelinating, predominantly motor neuropathy, later accompanied by axonal changes (Yagihashi et al. 1993).

COHEN DIABETIC RAT

Diabetes in Cohen rats is characterized by hyperglycemia, glucosuria, and hyperinsulinemia, with late development of hypoinsulinemia, insulin resistance, and a decrease in the number and sensitivity of insulin receptors. The rats develop overt diabetes and diabetes related complications when fed a diet rich in sucrose or other refined sugars and poor in copper content, but not when fed a starch or stock diet (Cohen 1972; Velasquez et al. 1990).

GOTO-KAKIZAKI RAT

Non-obese, insulin-resistant Goto-Kakizaki (GK) rats are a highly inbred strain of Wistar rats that spontaneously developed type II diabetes. Defects in glucose-stimulated insulin secretion, peripheral insulin resistance, and hyperinsulinemia are seen as early as 2 to 4 weeks after birth. Impaired skeletal muscle glycogen synthase activation by insulin was observed, accompanied by chronic activation of diacylglycerol-sensitive protein kinase C.

ZUCKER-FATTY RAT

The Zucker-fatty rat is a classic model of hyperinsulinemic obesity. (Zucker 1965). Obesity is due to a simple autosomal recessive (*fa*) gene and develops at an early age. Obese Zucker rats manifest mild glucose intolerance, hyperinsulinemia, and peripheral insulin resistance similar to human NIDDM. However, their blood sugar level is usually normal throughout life (Bray 1977; Clark et al. 1983; McCaleb and Sredy 1992; Abadie et al. 1993; Alamzadeh et al. 1993; Kasim et al. 1993; Galante et al. 1994).

ZUCKER DIABETIC FATTY RAT (ZDF/DRT-FA)

The obese Zucker Diabetic Fatty rat originally derived from the Zucker fatty rat (Peterson et al. 1990). This strain develops diabetes with hyperglycemia of about 20 mmol/l. The males and females become diabetic at the age of 6 to 8 weeks and 9 to 11 weeks, respectively. Diabetes phenotype develops due to lipotoxicity to

the β-cell (Lee et al. 1994). These rats are characterized besides hyperglycemia by insulin resistance, moderate hyperinsulinemia, extreme hyperphagia due to the loss of calories by glucosuria and obesity.

WDF/TA-FA RAT

The WDF/Ta-fa rat, commonly referred to as the Wistar fatty rat, is a genetically obese, hyperglycemic rat established by the transfer of the fatty *(fa)* gene from the Zucker rat to the Wistar Kyoto rat. (Ikeda et al. 1981; Kava et al. 1989; Velasquez et al. 1990). The Wistar fatty rat exhibits obesity, hyperinsulinemia, glucose intolerance, hyperlipidemia, and hyperphagia similar to Zucker rats being, however, more glucose intolerant and insulin resistant than Zucker rats. Hyperglycemia is usually not observed in females but can be induced by addition of sucrose to the diet.

Kobayashi et al. (1992) found an increase of insulin sensitivity by activation of insulin receptor kinase by Pioglitazone in Wistar fatty rats (*fa/fa*).

Sugiyma et al. (1992) found a reduction of glucose intolerance and hypersecretion of insulin in Wistar fatty rats after treatment with pioglitazone for 10 days.

OLETF RAT

A spontaneously diabetic rat with polyuria, polydipsia, and mild obesity was discovered in 1984 in an outbred colony of Long-Evans rats. A strain of rats developed from this rat by selective breeding has since been maintained at the Tokushima Research Institute (Otsuka Pharmaceutical, Tokushima, Japan) and named OLETF. The characteristic features of OLETF rats are: (1) late onset of hyperglycemia (after 18 weeks of age), (2) a chronic course of disease, (3) mild obesity, (4) inheritance by males, (5) hyperplastic foci of pancreatic islets, and (6) renal complications (nodular lesions). The clinical and pathological features of disease in OLETF rats resemble those of human NIDDM.

Administration of diazoxide (0.2% in diet), an inhibitor of insulin secretion, to OLETF rats from the age of 4 to 12 weeks completely prevented the development of obesity and insulin resistance (Aizawa et al. 1995).

Ishida et al. (1995) found that insulin resistance preceded impaired insulin secretion in OLETF rats.

ESS-RAT

The occurrence of spontaneous diabetes in a colony of rats (Stilman Saldago), called eSS-rat was reported by Tarrés et al. (1981). The animals show abnormal glucose tolerance tests from the age of 2 months onwards. The syndrome consists of a mild type of diabetes that does not diminish the longevity of the animals. Six-months old rats show disruption of the islet architecture and fibrosis of the stroma (Dumm et al. 1990).

OBESE SHR RAT

The strain of obese SHR rats was developed by Koletsky (1973, 1975) by mating a spontaneous hypertensive female rat of the Kyoto-Wistar strain with a normotensive Sprague Dawley male. After several generations of selective inbreeding, these obese SHR exhibited obesity, hypertension, and hyperlipidemia. In addition, some rats developed hyperglycemia and glucosuria associated with giant hyperplasia of pancreatic islets.

From these rats, several substrains were developed, such as the JCR:LA-corpulent rat which exhibits a syndrome characterized by obesity, hypertriglyceridemia and hyperinsulinemia with impaired glucose tolerance (Russell et al. 1994).

Reduced insulin receptor signaling was found in the obese spontaneously hypertensive Koletsky rat (Friedman et al. 1997).

SHR/N-CP RAT

The congenic SHR/N-cp rat strain, developed at the National Institutes of Health, USA, (Hansen 1983; Michaelis et al. 1986; Hansen 1988; Adamo et al. 1989) was derived by mating a male Koletsky rat heterozygous for the corpulent gene (cp/+) to a female rat of the Okamoto strain. After a minimum of 12 backcrosses, homozygous (cp/cp) SHR/N-cp rats exhibit obesity, mild hypertension, hyperinsulinemia, and glucose intolerance.

BHE RAT

The BHE rat colony was originally developed by breeding black and white hooded rats of the Pennsylvania State College strain and albino rats of the Yale (Osborne Mendell) strain. The BHE rat is a model in which the diabetic state is manifested only at maturity. BHE rats have hyperinsulinemia at 50 days of age associated with glucose intolerance and tissue resistance to insulin. Later on, BHE rats have less hyperinsulinemia with reduced pancreatic insulin stores, and show mild hyperglycemia and hyperlipidemia.

K.2.0.3 Spontaneously diabetic mice

KK MOUSE

Nakamura (1962, 1967) reported on a diabetic strain of the KK-mouse. The animals were moderately obese and showed polyphagia and polyuria. Mice at the age of seven months or older showed glucosuria and blood sugar levels up to 320 mg%. The pancreatic insulin content was increased, but histologically degranulation of the beta-cells and hypertrophy of the islets were found. Sections of the liver showed a reduction of glycogen and an increase in lipid content.

KK-A^{Y} MOUSE

Iwatsuka et al. (1970) reported on yellow KK mice (also named KK-A^{y} mice), carrying the yellow obese gene (A^{y}). These mice develop marked adiposity and diabetic symptoms in comparison with their littermates, black KK mice. Blood glucose and circulating insulin levels as well as HbA_{1c} levels were increased progressively from 5 weeks of age. Degranulation and glycogen infiltration of B cells were followed by hypertrophy and central cavitation of islets. Lipogenesis by liver and adipose tissue were increased. Insulin sensitivity of adipose tissue was more remarkably reduced than in black KK mice to its complete loss at 16 weeks of age. Renal involvement is uniquely marked by early onset and rapid development of glomerular basement membrane thickening (Diani et al. 1987).

KK-A^{y} mice can be used to demonstrate the extrapancreatic action of antidiabetic drugs, such as glimepiride, a novel sulfonylurea (Satoh et al. 1994).

Sohda et al. (1990) evaluated ciglitazone and a series of 5-[4-(pyridylalkoxy)benzyl]-2,4-thiazolidinediones for hypoglycemic and hypolipemic activities in yellow KK mice.

Hofmann et al. (1992) evaluated the expression of the liver glucose transporter GLUT2 and the activity and the expression of phosphoenolpyruvate carboxykinase in the liver of obese KKA^{Y} mice after treatment with the oral antidiabetic agent pioglitazone.

NOD MOUSE

The NOD mouse strain was established by inbreeding diabetic CTS mice derived originally from the JCL-ICR strain. Like the BB rat, the NOD mouse is a model of insulin dependent diabetes mellitus and develops hypoinsulinemia secondary to autoimmune destruction of pancreatic β cells in association with insulitis and auto antibody production. NOD mice develop diabetes abruptly between 100 and 200 days of age, as well as rapid weight loss, polyuria, polydipsia, and severe glucosuria. Without insulin treatment, they do not survive for more than one month and usually die from ketosis. The onset of diabetes can be prevented by an immunmodulating drug (Baeder et al. 1992) or by a soluble interleukin-1 receptor (Nicoletti et al. 1994).

Hutchings and Cooke (1995) compared the protective effects afforded by intravenous administration of bovine or ovine insulin to young NOD mice.

Bergerot et al. (1997) reported that feeding small amounts (2–20 μg) of human insulin conjugated to cholera toxin B subunit can effectively suppress β-cell destruction and clinical diabetes in adult NOD mice.

Insulin-dependent diabetes mellitus in NOD Mice is the result of a CD4^{+} and CD8^{+} T cell-dependent auto-immune process directed against the pancreatic β-cells (Serreze and Leiter 1994; Verdaguer et al. 1997).

OBESE HYPERGLYCEMIC MICE

Ingalls et al. (1950), Mayer et al. (1951), Bleisch et al. (1952) observed hereditary diabetes in genetically obese mice. The obese hyperglycemic mice were glycosuric, the non-fasting blood sugar levels were about 300 mg%, but neither ketonuria nor coma were observed. One of the most interesting features was insulin-resistance; doses as high as 400 IU/kg had little effect on blood sugar. The serum insulin-like activity was high, the islands of Langerhans were hypertrophic, their insulin content was increased and the liver glycogen stores were decreased. Kidneys and other organs did not show pathological changes. Obviously, the diabetic condition of this and other strains of obese hyperglycemic mice is different from that of the human diabetic patient. The *ob* mutation was identified as a mutation in the leptin gene in adipose tissue (Zhang et al. 1994) and the substitution of leptin reverses the obese and diabetic phenotype completely (Halaas et al. 1995). Other strains or substrains of mice with obesity and hyperglycemia have been described by Dickie (1962), Westman (1968), Stein et al. (1970), Coleman and Hummel (1973), Herberg and Coleman (1977).

Gill and Yen (1991) studied the effect of ciglitazone on endogenous plasma islet amyloid polypeptide (amylin) and insulin sensitivity in obese-diabetic viable yellow mice (VY/Wfl-A^{vy}/a).

DIABETES MOUSE (*DB/DB*)

The diabetes *db/db* mouse strain is derived from an autosomal recessive mutation having occurred spontaneously in mice of the C57BL/KsJ strain which was identified as a mutation in the leptin receptor gene (Tartaglia et al. 1995). On this basis, the diabetes mouse (C57BL/6J *db/db*) consistently develops a severe diabetic syndrome similar to that found in the C57BL/KsJ *ob/ob* mouse, characterized by early onset of hyperinsulinemia, and hyperglycemia up to 20 to 25 mmol/l. (Hummel et al. 1966; Coleman and Hummel 1967; Like et al. 1972). The *db/db* mouse, in contrast to the *ob/ob* mouse, develops significant nephropathy (Gardner 1978). Mutations on the leptin receptor result in an obese phenotype identical to that of *ob* mice (Li et al. 1998). C57BL/KsJ *ob/ob* mice are phenotypically the same as other strains of *db* mice. The leptin receptor (Ob-R) gene encodes 5 alternatively spliced forms, Ob-Ra, Ob-Rb, Ob-Rc, Ob-Rd (Lee et al. 1996). In the C57BL/KsJ *ob/ob* mouse strain, the Ob-Rb transcript contains an insert with a premature stop codon as a result if abnormal splicing (Chen et al. 1996; Friedman and Halaas 1998).

Coleman and Hummel (1969) joined adult diabetic mice (*db/db*) of the C57BL/Ks strain in parabiosis with normal mice of the same sex. Little, if any, amelioration of the disease was observed in parabiont diabetics and no symptoms of diabetes were observed in the normal parabiont. Instead, the normal partners lost weight, became hypoglycemic, and died of apparent starvation 50 days after surgery. In contrast, the diabetic partners gained weight rapidly and remained diabetic.

Raizada et al. (1980) demonstrated a decrease of insulin receptors and impaired responses to insulin in fibroblastic cultures from the diabetic *db/db* mouse.

DIABETES OBESITY SYNDROME IN CBA/CA MICE

A spontaneous maturity onset diabetes obesity syndrome occurs in a small proportion (10–20%) of male CBA/Ca mice. Inbreeding can increase the incidence to 80%. It occurs at 12–16 weeks of age, and is characterized by hyperphagia, obesity, hyperglycemia, hypertriglyceridemia, hyperinsulinemia, and an impaired glucose tolerance. The mice are also resistant to exogenous insulin. Female mice remain normal except for a slight increase in serum insulin. The male obese diabetic mice have a normal life expectancy.

WELLESLEY MOUSE

The Wellesley mouse, described first by Jones (1964), is a hybrid with predisposition to diabetes mellitus. The diabetic animals have elevated levels of immunoreactive insulin in serum, enlarged pancreatic islets and reduced insulin responsiveness in peripheral tissues (Cahill et al. 1967; Gleason et al. 1967; Like and Jones 1967).

K.2.0.4 Chinese hamster

Meier and Yerganian (1959, 1961) described the occurrence of hereditary diabetes mellitus in the Chinese

hamster (*Cricetulus griseus*). Blood sugar levels of diabetic hamsters were elevated from a normal of 110 mg% up to 600 mg%. Severe polyuria, glucosuria, ketonuria, and proteinuria were observed. The diabetic condition could be improved by administration of insulin, and oral antidiabetic drugs were effective in mildly diabetic hamsters. Pathological changes were seen in histological sections of pancreas, liver and kidney. The number of pancreatic islets was decreased, and the cells of the remaining islets were abnormal. This animal model has been studied by several authors.

K.2.0.5 Other species with inherited diabetic symptoms

SAND RAT

The sand rat (*Psammomys obesus*) lives in the desert regions of North Africa and the Near East. In the laboratory the animals develop diabetic symptoms when fed Purina laboratory chow instead of an all vegetable diet (Hackel et al. 1965, 1967; Miki et al. 1967; deFronzo et al. 1967; Brodoff et al. 1967; Strasser 1968). The diabetic syndrome in the sand rat usually develops within 2–3 months with variations in severity between the animals. Severely hyperglycemic animals die prematurely from ketosis. Initially, the pancreatic islets appear normal. In the intermediate stage of the disease, degranulation of pancreatic β cells is observed. This is followed by β cell degeneration and necrosis with resultant insulinopenia and ketonuria.

Histological studies by Dubault et al. (1995) showed insulitis in animals who became insulin-dependent in later stages and recommended *Psammomys obesus* as a model of latent IDDM in NIDDM patients.

SPINY MOUSE

The spiny mouse (*Acomys cahirinus*) is a small rodent living in the semi-desert areas of the Eastern Mediterranean (Pictet et al. 1967). Diabetes occurs in about 15% of the animals under laboratory conditions accompanied by hyperplasia of the endocrine pancreas. Great variations in the appearance and severity of diabetes and obesity occur in this species. Some animals show obesity, mild hyperglycemia, and hyperinsulinemia. Others have frank hyperglycemia with glucosuria that leads to fatal ketosis. Regardless of the stage of the disease, all spiny mice characteristically have massive hyperplasia of pancreatic islets and increased pancreatic insulin content. Despite the large insulin stores, plasma insulin response to glucose is delayed or impaired suggesting an impairment of the insulin release mechanism.

AFRICAN HAMSTER (*MYSTROMYS ALBICAUDATUS*)

Spontaneous diabetes mellitus was described in South African hamsters (*Mystromys albicaudatus*) by Packer et al. (1970), Stuhlman et al. (1972, 1974, 1975), Schmidt et al. (1974). Characteristics established as part of the diabetic syndrome in this species include hyperglycemia, glucosuria, ketonuria, polyuria, polyphagia and polydipsia. Pancreatic lesions include β-cell vacuolization, glycogen infiltration, nuclear pycnosis, margination of organelles, and β-cell death.

TUCO-TUCO

The diabetic syndrome in Tuco-tucos (*Ctenomis talarum*) is similar to that in sand rats and spiny mice (Wise et al. 1972). However, Tuco-tucos tend to have less hyperglycemia and are less prone to ketosis. Many animals, mainly males, become hyperphagic and quite obese. Degranulation of β cell is the usual lesion in the pancreas, but amyloid hyalinization of islets has been observed in a few animals.

MACACA NIGRA

A high incidence of spontaneous diabetes mellitus was found in *Macaca nigra* (Celebes black apes) with analogies to human diabetes (Howard 1972, 1974a,b, 1975). Abnormal signs include hyperglycemia, decreased clearance of glucose, in intravenous tolerance tests, reduced insulin secretion and increased serum lipids. Insulin secretory capacity is lost concomitant with amyloid infiltration into the islets of Langerhans. Secondary manifestations are atherosclerosis, thickened basement membranes of muscle capillaries, and cataracts. The genetic predisposition in these monkeys is exacerbated by changes in diet and environment.

K.2.0.6 Transgenic animals

TRANSGENIC MICE

Schaefer et al. (1994) described a transgenic mouse model of chronic hyperglycemia. The extracellular ligand binding domain of the human insulin receptor can be expressed as a stable soluble protein that is efficiently secreted and binds insulin with high affinity. Expression under the mouse transferrin promoter of a transgene encoding a secreted derivative of the human insulin receptor in transgenic mice results in the accumulation of this high-affinity insulin-binding protein in the plasma. Alterations of glucose homeostasis are induced including postabsorptive hyperglycemia concomitant with increased hepatic glucose production and hyperinsulinemia.

Palmiter et al. (1987) developed a method of deleting specific cell lineages that entailed microinjection into fertilized eggs of a chimeric gene in which a cell-specific enhancer/promoter is used to drive the expression of a toxic gene product. Microinjection of a construct in which the elastase I promoter /enhancer is fused to a gene for diphtheria A polypeptide resulted in birth of mice lacking a normal pancreas because of the expression of the toxin in pancreatic acinar cells. A small pancreatic rudiment, containing islet and duct-like cells, was observed in some of the transgenic mice.

Aichele et al. (1994) used a synthetic peptide corresponding to an immunodominant epitope of lymphocytic choriomeningitis virus glycoprotein (LCMV GP) to prime or to tolerize $CD8^+$ T cells *in vivo*. Peptide-specific tolerance was then examined in transgenic mice expressing LCMV GP in the β islet cells of the pancreas. These mice developed $CD8^+$ T cell-mediated diabetes within 8–14 days after LCMV infection. Specific peptide-induced tolerance prevented autoimmune destruction of β islet cells and diabetes in this transgenic mouse model.

Oldstone et al. (1991) showed that virus infection triggers insulin-dependent diabetes mellitus in a transgenic mouse model.

Ablation of tolerance and induction of diabetes by virus infection in viral antigen transgenic mice was reported by Ohashi et al. (1991).

Von Herrath et al. (1994) investigated how virus induces a rapid or slow onset insulin-dependent diabetes mellitus in two distinct transgenic mouse models.

Von Herrath et al. (1995) evaluated the role of the costimulatory molecule B7-1 in overcoming peripheral ignorance in transgenic mice which expressed the glycoprotein or nucleoprotein of lymphocytic choriomeningitis virus as the self-antigen in pancreatic β-cells.

Von Herrath and Holz (1997) reported that pathological changes in the islet milieu precede infiltration of islets and destruction in β-cells by autoreactive lymphocytes in a transgenic model of virus-induced IDDM. RIP-LCMV transgenic mice that express the viral glycoprotein or nucleoprotein from lymphocytic choriomeningitis virus (LCMV) under control of the rat insulin promoter (RIP) in pancreatic β-cells develop autoimmune diabetes after infection with LCMV. Upregulation of MHC class II molecules associated with the attraction/activation of antigen presenting cells to the islets occurs as soon as 2 days after LCMV inoculation of transgenic mice, clearly before $CD4^+$ and $CD8^+$ lymphocytes are found entering the cells. Possibilities of treatment of virus-induced autoimmune diabetes were discussed (von Herrath et al. 1997).

Hebert et al. (1996) created transgenic mice to study the influence of overexpression of glutamine:fructose-6-phosphate amidotransferase on insulin resistance.

Moritani et al. (1996) reported the prevention of adoptively transferred diabetes in nonobese diabetic mice with IL-10-transduced islet-specific Th1 lymphocytes as a gene therapy model for autoimmune diabetes.

Birk et al. (1996) generated transgenic NOD mice carrying a murine Hsp60 transgene driven by the $H°2E_{\alpha}$ class II promoter in order to examine the hypothesis of a pathogenic role for self-reactive cells against the stress protein Hsp60 in autoimmune destruction of pancreatic cells in the diabetes of NOD mice.

Terauchi et al. (1997) reported development of non-insulin-dependent diabetes mellitus in double knockout mice with disruption of insulin receptor substrate-1 and β-cell glucokinase genes.

Insulin resistance and hyperinsulinemia in insulin receptor substrate-1 knockout mice was discussed by Jenkins and Storlien (1997).

Ueki et al. (2000) could restore insulin-sensitivity in IRS-1-deficient mice by adenovirus-mediated gene therapy.

Brüning et al. (1997) developed a polygenic model of NIDDM in mice heterozygous for IR and IRS-1 null alleles. Mice double heterozygous for null alleles in the insulin receptor and insulin receptor substrate-1 genes exhibit the expected ~50% reduction in expres-

sion of these two proteins, but a synergism at the level of insulin resistance with 5- to 50-fold elevated plasma insulin levels and comparable levels of β-cell hyperplasia.

Withers et al. (1998) showed that disruption of IRS-2 impairs both peripheral insulin signaling and pancreatic β-cell function. IRS-2-deficient mice showed progressive deterioration of glucose homeostasis because of insulin resistance in the liver and skeletal muscle and a lack of β-cell compensation for this insulin resistance.

Kulkarni et al. (1999) reported that in mice a tissue specific knockout of the insulin receptor in pancreatic β cells creates an insulin secretory defect similar to that in type 2 diabetes.

K.3
Assays of insulin and of insulin-like activity

K.3.1
Hypoglycemic effects

K.3.1.1
Blood sugar lowering effect in rabbits

PURPOSE AND RATIONALE

A biological assay of insulin preparations in comparison with a stable standard using the blood sugar lowering effect in rabbits has been proposed already in 1925 by Harrison et al.

The biological assay of insulin using the blood sugar lowering effect in rabbits has been until recently the official assay in several pharmacopoeias, such as European Pharmacopoeia, Second Edition 1980; Deutsches Arzneibuch 1986; British Pharmacopoeia 1988; Unit-

ed States Pharmacopoeia 23 and The National Formulary 18, 1995.

The rabbit blood glucose bioassay as well as the mouse convulsion assay and the mouse glucose assay were used for establishing international standards for highly purified human, porcine and bovine insulins (Bristow et al. 1988).

In several pharmacopoeias, the biological assays have been replaced by chemical methods (British Pharmacopoeia 1999; European Pharmacopoeia, 3rd Edition 1997; but the rabbit blood sugar method is still valid in the United States Pharmacopeia USP 24, 2000.

PROCEDURE

Four groups of at least 6 randomly distributed rabbits weighing at least 1.8 kg are kept in the laboratory and maintained on a uniform diet for not less than one week before use in the assay. About 24 h before the test each rabbit is provided with an amount of food that will be consumed within 6 h. The same feeding schedule is followed before each test day. During the test all food and water is withheld until the final blood sample has been taken. The rabbits are placed into comfortable restraining cages to avoid undue excitement.

Immediately before use two solutions of the standard preparation are made, containing 1 unit and 2 units of insulin per ml, respectively, and two dilutions of the preparation being examined which, if the assumption of potency is correct, contain amounts of insulin equivalent to those in the dilutions of the standard preparation. As diluent, a solution is used of 0.1–0.25% w/v of either m-cresol or phenol and 1.4 to 1.8 w/v of glycerol being acidified with hydrochloric acid to a pH between 2.5 and 3.5.

Each of the prepared solutions is injected subcutaneously to one group of rabbits, using the same volume, which should usually be between 0.3 and 0.5 ml for each rabbit, the injections being carried out according to a randomized block design. Preferably on the following day, but in any case not more than 1 week later, each solution is administered to a second group of rabbits following a twin crossover design. One hour and 2.5 h after each injection a suitable blood sample is taken from the ear vein of each rabbit.

Blood sugar is determined by a suitable method, preferably using glucose oxidase.

EVALUATION

The results of the assay are calculated by standard analytical methods (e.g., USP 23, 1995).

CRITICAL ASSESSMENT OF THE METHOD

The classical bioassay based on blood-sugar lowering activity in rabbits has been replaced by chemical methods in some pharmacopoeias (Underhill et al. 1994), but is still included in USP 24, 2 000; and will be still necessary for evaluation of synthetic insulin derivatives.

MODIFICATIONS OF THE METHOD

An assay of insulin activity after intraperitoneal injection in **rats** has been described by Rafaelsen et al. (1965), Young(1967).

Shults et al. (1994) reported as one of the first on an implantable potentiostat-radiotelemetry system for *in vivo* sensing of glucose, implanted into the paravertebral thoracic subcutaneous tissue of a **dog**. An enzyme electrode sensor measures the oxidation current of hydrogen peroxide formed by the stoichiometric conversion of the substrate glucose and oxygen as a cofactor in an immobilized glucose oxidase layer.

Salehi et al. (1996) described the development of a compact, low power, implantable system for *in vivo* monitoring of oxygen and glucose concentrations.

K.3.1.2 Hypoglycemic seizures in mice

PURPOSE AND RATIONALE

The biological assay of insulin using hypoglycemic seizures in mice has been suggested already in 1923 by Fraser. The biological standardization of insulin using the mouse convulsion method has been published in detail by the Health Organisation of the League of Nations in 1926 (Trevan and Boock; Hemmingsen and Krogh) and has been until recently the official assay in several pharmacopoeias, such as European Pharmacopeia, Second Edition 1980; Deutsches Arzneibuch 1986; British Pharmacopoeia 1988.

In most pharmacopoeias, the biological assays have been replaced by chemical methods (British Pharmacopoeia 1999; European Pharmacopoeia, 3rd Edition 1997).

PROCEDURE

Ninety-six mice of either sex (but not of mixed sexes) weighing 20 ±5 g are randomly distributed into 4 groups. The mice are deprived of food 2–20 h immediately preceding the test. Solutions of the insulin standard and of the test preparation containing 30 and 60 milliUnits/ml are prepared by diluting the original solution with 0.9% NaCl solution, pH 2.5. 0.5 ml/20 g mouse of these solu-tions are injected subcutaneously. The mice are kept at a uniform temperature, between 29 and 35 °C, in transparent containers within an air incubator with a transpar-ent front. The mice are observed for 1.5 h and the num-ber of mice is recorded that are dead, convulse or lie still for more than 2 or 3 s when placed on their backs.

EVALUATION

The percentage of mice of each group showing the afore mentioned symptoms is calculated and the relative potency of the test solution calculated using a 2 + 2 point assay.

CRITICAL ASSESSMENT OF THE METHOD

Attempts to replace the tests in mice and rabbits by *in vitro* tests, such as the rat diaphragm test, the rat epididymal fat pad test, or even the radioimmunoassay failed due to several reasons (Trethewey 1989). Nevertheless, for industrial production and for stability studies, the classical bioassays based on hypoglycemic seizures in mice or hypoglycemia in rabbits have been replaced by chemical methods (Stewart 1974; Underhill et al. 1994).

MODIFICATIONS OF THE METHOD

A modification of the mice seizure method using **rotating hollow cylinders** has been proposed by Young and Lewis (1947). A similar technique which increases the sensitivity of the mice seizure method has been used by Vogel (1964). The equipment consisted of seven perforated metal drums with a diameter of 15 cm. The drums were rotated in oblique position at 10 rotations per minute. Female mice weighing 16 to 20 g were deprived of feed at the afternoon before the test. On the test day, groups of 6 mice received doses of 0.5; 1.0 or 1.5 IU/kg of test preparation or standard subcutaneously and were placed after 20 min into the rotating drums. Controls received saline only. Mice with insulin-induced seizures dropped out from the rotating drum. The number of animals dropping out was counted after 15; 30; 45 and 60 min. Mice dropping out due to hypoglycemic seizures received 0.5 ml of 10% glucose solution intraperitoneally.

ED_{50} values and activity ratios were calculated according to Litchfield and Wilcoxon (1949).

K.3.1.3 Blood sugar determinations in mice

PURPOSE AND RATIONALE

Eneroth and Ahlund (1968, 1970a,b) recommended a twin crossover method for bio-assay of insulin using blood glucose levels in mice instead of hypoglycemic seizures giving more precise results. This test was induced into the British Pharmacopoeia 1980 and continued up to 1988. Moreover, the test is included as alternative in the European Pharmacopoeia, Second Edition 1980; and in Deutsches Arzneibuch, 9. Ausgabe, 1986.

PROCEDURE

Non-fasting mice of the same strain and sex are used having body masses such that the difference between the heaviest and lightest mouse is not more than 2 g. The mice are assigned at random to four equal groups of not less than 10 animals. Two dilutions of a solution of the substance or of the preparation to be examined and 2 dilutions of the reference solution are prepared using as diluent 0.9% NaCl solution adjusted to pH 2.5 with 0.1 N hydrochloric acid and containing a suitable protein carrier. In a preliminary experiment, concentrations of 0.02 IU and 0.10 IU are tested. Each of the prepared solutions (0.1 ml/10 g body weight) is injected subcutaneously to one group of mice according to a randomized block design. Not less than 2.5 h later, each solution is administered to a second group of mice following a twin crossover design. Exactly 30 min after each injection, a sample of 50 µl of blood is taken from the orbital venous sinus of each mouse. Blood glucose concentration is determined by a suitable method, such as described by Hoffman (1937).

EVALUATION

The potency is calculated by the usual statistical methods for the twin-cross-over assay.

K.3.2 Insulin target cells/tissues of rats[2]

K.3.2.1 Epididymal fat pad of rats

Insulin-like activity can be measured by the uptake of glucose into fat cells. Adipose tissue from the epididymal fat pad of rats has been found to be very suitable. Early studies (Beigelman 1959; Steelman et al. 1961) determined the difference of glucose concentration in the medium after incubation of pieces of epididymal rat adipose tissue or measured oxygen consumption in Warburg vessels (Ball and Merill 1961; Doisy 1963; Froesch et al. 1963). In experiments with radiolabelled ^{14}C glucose, the $^{14}CO_2$ is trapped and counted (Martin et al. 1958; Slater et al. 1961; Gliemann 1965, 1967). The principle used by Martin et al. (1958) in the first publication was measurement of $^{14}CO_2$-production from 1-^{14}C-labelled glucose by epi-didymal fat pads from the rat. This method has been used by various authors (Humbel 1959; Ditschuneit et al. 1959) and described in detail by Renold et al. (1960) and Siess et al. (1965). Sönksen et al. (1965) found a close correlation between "suppressible" insulin-like activity measured by the fad pad method and insulin concentration determined by immunoassay.

The presence of factors other than insulin in this test was proven by the persistence of serum insulin-like activity after pancreatectomy (Steinke et al. 1962).

Ball and Merrill (1961) used the manometric measurement of the net gas exchange of rat adipose tissue to quantitate small amounts of insulin.

Steinke et al. (1965) tested insulin-like activity on adipose tissue of various species, rat, mouse and guinea pig.

The epididymal fat pad assay, originally developed as bioassay of insulin-like activity in serum samples, can be used for measuring activity of synthetic insulin derivatives as well as for evaluation of peripheral insulin-like effects of compounds such as sulfonylureas. Several modifications (isolated fat cells, primary cultured adipocytes, 3T3 adipocytes) broadened the value of this assay.

A survey of the biological assays of insulin-like serum activity was given by Faulhaber and Ditschuneit (1975).

The influence of insulin on the uptake of ^{14}C glucose in cultured rabbit coronary microvessel endothelium was studied by Gerritsen and Burke (1985).

[2] Contributions by G. Müller.

K.3.2.2 Fat cells isolated by digestion with collagenase

Rodbell (1964), Gliemann (1965, 1967) used fat cells isolated by digestion with collagenase. The conversion of (3 ^{3}H) glucose to total lipids has been used as a sensitive parameter in an improved free fat cell assay for insulin-like activity by Moody et al. (1974).

Preparation of rat adipocytes

Male Wistar rats weighing 160–180 g are sacrificed and both epididymal fat pads are removed under sterile conditions. The fat pads are cut into pieces and incubated for 20 min at 37 °C with 1 mg/ml collagenase (e.g. type CLS II, Worthington, Freehold, NJ) in KRHB (Krebs-Ringer bicarbonate buffer), 25 mM HEPES/KOH (pH 7.4), 0.1 mM glucose, 1% wt/vol BSA (bovine serum albumin). The cell suspension is filtered through a 100 µm nylon screen and washed 3 times by flotation (accumulation of a thin cell layer on top of the medium after centrifugation at 1 000 *g* for 1 min in a swing-out rotor) with KRHB lacking glucose and finally suspended in the same solution. The suspension is adjusted to a final titer of 4×10^5 cells/ml.

Stimulation of rat adipocytes with insulin

Adipocytes are suspended in buffer S (Dulbecco's minimal essential medium [DME] containing 5 mM glucose, 0.5 M mM sodium pyruvate, 4 mM L-glutamine, 200 nM 1-methyl-2-phenylethyl)adenosine, 100 µg/ml gentamycine, 1% BSA and 25 mM Hepes/KOH, pH 7.4) at 5% cytocrit (corresponding to about 7×105 cells/ml). For determination of the packed cell volume, small aliquots of the cell suspension are aspirated into capillary hematocrit tubes and centrifuged for 90 s in a microhematocrit centrifuge in order to measure the fractional occupation of the suspension by the adipocytes (= cytocrit). A 20-ml portion of the adipocyte suspension (5% cytocrit) is added to 20 ml of buffer S containing human insulin as indicated. Incubations (20 min, 37 °C) are performed under 5% CO_2 in 200-ml polyethylene vials during shaking at 110 cycles/min with a stroke length of 3.5 cm.

Electroporation of rat adipocytes

For studying the molecular mechanism of insulin action and its interference by a certain compound/drug it may be useful to block known signaling or metabolic pathways in adipocytes by introduction of specific inhibitory antibodies (against key proteins/enzymes) or peptide substrates (competing for the endogenous protein substrate; e.g. synthetic peptide as kinase substrate) prior to stimulation of the adipocytes with the compounds/drugs. The antibodies and peptides can be introduced into isolated rat adipocytes by the method of electroporation without significant loss of cell viability and insulin sensitivity. 0.4 ml of buffer E (4.74 mM NaCl, 118 mM KCl, 0.38 mM $CaCl_2$, 1 mM EGTA, 1.19 mM $MgSO_4$, 1.19 mM KH_2PO_4, 25 mg/ml bovine serum albumin, 3 mM sodium pyruvate and 25 mM Hepes/KOH, pH 7.4) is placed in a 0.4-cm gap-width electroporation cuvette (Bio-Rad, Munich, Germany) together with the antibodies or peptides. 0.4 ml of adipocyte suspension (50% cytocrit in buffer E) is added to each cuvette and gently mixed. Electroporation is performed using a Gene Pulser Transfection Apparatus (Bio-Rad, Munich, Germany) which is set at a capacitance of 25 µF and voltage of 800 V (2 kV/cm), at 25 °C for six shocks (Shibata et al. 1991; Quon et al. 1993). After the third treatment, the adipocyte suspension is gently stirred with a plastic stick and the electric polarity is reversed. The time constant of electroporation is typically 0.6 ms during the final shock. Routinely, 4 ml of adipocyte suspension (25% cytocrit) is electroporated in five cuvettes. The time required for treatment of the five cuvettes is about 3 min. After electroporation, the cells from five electroporations are pooled and transferred to 50-ml polystyrene tubes. After incubation (30 min, 37 °C) in 5% CO_2/95% O_2, the cells are centrifuged (200 *g*, 1 min, swing-out-rotor) and the infranatant is aspirated. Thereafter the cells are washed once with 40 ml of buffer E containing 5 mM glucose and 4% BSA, suspended in 20 ml of the same buffer and then incubated (1 h, 37 °C) under 5% CO_2 prior to stimulation with insulin/compound.

MODIFICATIONS OF THE METHOD

Etherton and Chung (1981), Etherton and Walker (1982) characterized insulin sensitivity of isolated *swine* adipocytes.

K.3.2.3 Primary culture of rat adipocytes

Insulin resistant rat adipocytes can be generated *in vitro* by incubation of freshly isolated cells in primary culture in the presence of 25 mM glucose and 10 nM insulin for 20 h at 37 °C under slow shaking. When assayed for insulin-stimulated glucose transport, these cells show a right-ward shift of the dose-response curve (decreased insulin sensitivity) and a reduced maximal glucose transport velocity (decreased insulin responsiveness).

K.3.2.4 3T3 Adipocytes

Green and Kehinde (1974) isolated from an established mouse fibroblast line 3T3 two subclonal sublines that

accumulate large amounts of triglycerides when the cells are in the resting state. The cell line 3T3-L1 has been used extensively by many authors (Spooner et al. 1979; Frost and Lane 1985; Zuber et al. 1985; Chan et al. 1988; Clancy and Czech 1990; Wieland et al. 1990; Müller et al. 1993).

Kletzien et al. (1992) studied the effect of pioglitazone, an insulin-sensitizing agent, on the expression of the adipocyte fatty acid-binding protein in *ob/ob* mice and 3T3 L1 cells.

Preparation of adherent 3T3-L1 adipocytes and stimulation with insulin/compound

3T3-L1 fibroblasts (American Type Culture Collection, Rockville, MD) are seeded in 12-well (60 000 cells/well) plates and maintained in DME (high glucose) plus 10% fetal bovine serum (FBS), 5 mM L-glutamine and 2% BSA. Following three days at 100% confluence, differentiation is initiated by the addition of DME containing 10% FBS, 400 nM human insulin, 1 µM dexamethasone and 1 mM isobutylmethylxanthine. Three days later, the medium is replaced with DME plus 10% FBS and 100 nM insulin. After additional two days, the medium is changed to DME (low glucose) plus 10% FBS. Adipocytes are used 5 to 12 days after completion of the differentiation protocol, when more than 85% of the cells expressed the adipocyte phenotype. Prior to experiments, the cells are rinsed two times with low serum medium (DME containing 5 mM glucose, 0.5% BSA, 0.1% FBS, 25 mM Hepes pH 7.4, 10 mM glutamine, 100 units/ml streptomycin/penicillin), then incubated (12 to 14 h) in this medium and finally washed twice with phosphate-buffered saline [PBS] containing 2 mM sodium pyruvate prior to incubation (30 min, 37 °C) with insulin/compound.

Preparation of non-adherent 3T3-L1 adipocytes and stimulation with insulin/compound

Adherent 3T3-L1 adipocytes are serum-starved for 12 h in serum-free DME, 10 mM glutamine, 0.5% BSA, 50 units/ml streptomycin/penicillin, thereafter washed twice with PBS containing 1 mM EDTA, and then removed gently from the dishes using a rubber policeman. After washing once in PBS, the cells are maintained in suspension (30 min, 37 °C) in 4 ml of PBS containing 5 mM glucose, 1% BSA, 200 nM phenylisopropyladenosine before the addition of insulin/compound and further incubation (30 min, 37 °C).

Attachment of 3T3-L1 adipocytes to fibronectin-coated dishes

Cell culture dishes (12-well plates) are coated (4 °C, overnight) with fibronectin (10 µg/ml) or poly-L-lysine (10 µg/ml) together with vitronectin (2 µg/ml) in PBS containing 2.7 mM KCl, 6.5 mM Na_2HPO_4 and 1.5 mM KH_2PO_4 (pH 7.4), blocked (1 h) with 0.1% BSA in PBS and then dried (1 h, 37 °C) prior to plating of the cells. Confluent 3T3-L1 adipocytes are serum-starved for 12 h in serum-free DME, 10 mM glutamine, 0.5% BSA, 50 units/ml streptomycin/penicillin and then detached by adding EDTA-trypsin (0.05 mM, 0.025%). The detached adipocytes are washed three times with PBS containing 1% BSA and then held in suspension (30 min, 37 °C) in 4 ml of buffer S prior to addition of insulin as indicated. After incubation (10 min, 37 °C), the cells are replated on dishes coated with fibronectin/polylysine in the absence or presence of 25 µg/ml peptide as indicated and further incubated (20 min, 37 °C) under 5% CO_2 (Guilherme and Czech 1998; Guilherme et al. 1998).

K.3.2.5 Lipogenesis assay

PURPOSE AND RATIONALE

This assay measures the insulin-stimulated glucose transport and conversion into lipid-soluble products (triglycerides, phospholipids, fatty acids) including the signal cascade. According to TLC-analysis of the products after enzymatic digestion, the majority of the label appears in the glycerol backbone at low glucose concentration (0.1 mM) when glucose transport is rate-limiting. At higher glucose concentrations (2 mM) when transport is not rate-limiting, two thirds of the label is incorporated into the fatty acids of the lipids.

PROCEDURE

For measurement of lipogenesis, adipocytes are incubated with D-[^{3}H]glucose (0.55 mM final concentration). The cells are lysed. The lipids separated from water-soluble products and the medium by addition of toluene-based scintillation cocktail. After phase separation, radioactivity incorporated into lipids is determined by liquid scintillation counting directly without removal of the lipid phase.

The assay is performed according to the method of Moody et al. (1974). Incorporation of D-[3-^{3}H]glucose into toluene-extractable acylglyceroides is measured after incubation of adipocytes with 1 ml Krebs-Ringer-phosphate buffer in the absence or presence of insulin or test compound.

The reaction is started by the transfer of 0.2 ml of adipocyte suspension to scintillation vials containing the following ingredients:

0.1 ml [3-^{3}H]glucose (2 µCi/ml) 0.1 mM
0.4 ml Krebs-Ringer bicarbonate solution 2-fold

0.3 ml of substance with insulin-mimetic activity or insulin

The scintillation vials are placed under a stream of carbogen for 10 s, then closed and placed in a very slowly shaking water bath (37 °C).

After incubation for 90 min, the reaction is terminated by the addition of 10 ml of toluene-based scintillation cocktail. The vials are mixed rigorously using a vortexer and subsequently left standing for 2–4 h to allow phase separation.

The ^{3}H-radioactivity is determined with a liquid scintillation counter.

EVALUATION

Blank values obtained from a typical reaction mixture containing buffer and [3-^{3}H]glucose but lacking adipocytes and substance (or insulin) have to be included in each experiment. Since the quality of the cells decreases with time (that is increase of lipid synthesis in the basal state), it is recommended to set up 2 basal incubations for every 20–25 test mixtures. The blank values (usually 500–600 dpm) are subtracted from the values measured for the corresponding set of test mixtures to correct for ^{3}H-radiation originating from the aqueous phase (i.e. [^{3}H]glucose).

Due to the very limited number of pipetting steps (the most critical one being the transfer of an equal number of cells to each assay), the standard deviations are rather low. Usually, 2–4 measurements per point are sufficient.

An insulin-dose/response curve should be performed for each experiment to test the insulin sensitivity (and thus the quality) of the cells. Appropriate insulin concentrations are 0.02, 0.04, 0.06, 0.1, 0.5, 1, 5 nM (final concentration in the assay). The maximal insulin stimulation factor for lipogenesis (at 5 nM), calculated as the ratio between [^{3}H]lipid in the presence of insulin minus [^{3}H]lipid in the absence of insulin and [^{3}H]lipid in the absence of insulin, lies in the range of 10–20-fold over the basal incorporation (absence of insulin). Half-maximal insulin stimulation is observed at 0.1–0.5 nM. The insulin-mimetic activity of substances can be expressed as % of the maximal insulin stimulation (that is as ratio between the stimulation factor for the insulin-mimetic substance and the insulin stimulation factor) to correct for the varying quality of the cells from different preparations.

MODIFICATIONS OF THE METHOD

Grunfeld and Jones (1983) explored the ability of insulin to stimulate amino acid uptake in 3T3-L1 cells using the non-metabolizable amino acid analog methylaminoisobutyric acid.

K.3.2.6 Assays of glucose transport

Total uptake of glucose

Adipocytes are incubated with D-[U-^{14}C]glucose (0.2 mM final concentration) for 20 min. Cells are separated from the medium by centrifugation on silicon oil, removed and counted for radioactivity.

This assay measures the total insulin-stimulated glucose uptake (signal cascade, glucose transport, glucose metabolism) irrespective whether the glucose is utilized via the oxidative or non-oxidative pathway. Conversion into lipids, glycogen or membrane-impermeable intermediary products (glucose-6-phosphate) will be detected. Production of lactate can not be followed.

Bypass of the insulin receptor

Adipocytes are incubated with trypsin (4 mg/ml) for 15 min at 4 °C. After addition of soy bean trypsin inhibitor (8 mg/ml) the cells are washed three times by flotation and used for determination of total uptake of glucose (see above).

This assay measures the total glucose uptake into cells with inactivated insulin receptor. Thus only compounds that bypass the first step in the insulin signal transduction cascade (binding of insulin to its receptor) will provide positive results.

Transport of 2-deoxy-glucose

The transport of 2-deoxy-D-[1-^{3}H]glucose (Amersham, specific activity 20–30 Ci/mmol, aqueous solution) by isolated rat adipocytes or 3T3 adipocytes is measured as described by Gliemann et al. (1972), Foley and Gliemann (1981), Müller and Wied (1993).

All incubations are performed in a 25 °C shaking water bath. A 50 µl adipocyte cell suspension is pipetted into minisorp tubes (Nunc, Denmark) and equilibrated at 25 °C for 30 min. Insulin (80 nM stock in KRH/5% BSA) and substances (lyophilized, 2 mg/ml) are added in 50 µl KRHB and incubated for 30 min at 25 °C. To cor-rect for 2-deoxyglucose unspecifically associated with the cell surface or entrapped in extracellular spaces, 2 µl of cytochalasin B (20 µM final conc.) from a 1 mM stock solution (in 10% ethanol, diluted with H_2O from a 10 mM stock in ethanol at the day of use) and, as a control, 2 µl of 20% ethanol were added prior to addition of radiolabeled 2-deoxy-glucose and incubated under identical conditions.

The transport assay is started by addition of 50 µl of 0.1 mM 2-deoxy-[^{3}H]glucose (2 µCi per ml of KRHB containing 10 µl/ml of ^{3}H-stock, 0.2 mCi/ml), is added and the incubation continued for another

10 (max. 20) min at 25 °C (total volume of the final incubation mixture = 150 µl).

The assay is terminated by centrifugation of 100 µl samples on top of 250 µl dinonylphthalate (Merck, Darmstadt, FRG) in 500 µl plastic tubes (Beckman) in a microfuge (10 000 *g*, 1 min, room temperature). The adipocytes remain on top of the oil, while the buffer is below the oil. The tube is cut just below the adipocyte layer, which is transferred into 5 ml aqueous scintillation cocktail (Zinsser Nr. 312 or Beckman Ready Safe) and counted.

Specific transport is calculated as the difference between total cell-associated radioactivity (absence of cytochalasin B) and unspecifically entrapped radioactivity (presence of cytochalasin B). Under the conditions used, 2-deoxyglucose transport is linear with time up to 20 min. The glucose transport stimulation factor is calculated as ratio between stimulated specific transport (presence of insulin or extract) minus basal specific transport (absence of insulin or extract) and basal specific transport. For insulin (2 nM), this factor usually lies in the range between 15 and 25.

This assay measures the insulin-stimulated specific transport of glucose across the plasma membrane via facilitated diffusion (glucose carriers) including the signal cascade irrespective of glucose utilization (as revealed by the non-metabolizable deoxyglucose). Moreover, the effect of sulfonylureas on 2-deoxyglucose transport can be demonstrated (Maloff and Lockwood 1981; Müller et al. 1994).

Clarke et al. (1984) investigated the insulin-stimulated uptake of 2-deoxy-D-glucose in cultured glial cells of rat brain.

Hernvann et al. (1987) studied the effects of human, bovine and porcine insulin on 2-deoxy-D-glucose uptake in cultured chicken embryo fibroblast monolayers.

Liu and Stock (1995) used 2-deoxy-[^{3}H]glucose uptake into various tissues for determination of tissue utilization after acute treatment with a β_3-adrenoceptor agonist.

Transport of 3-O-methylglucose

The rate of 3-*O*-methylglucose transport is determined according to Whitesell and Gliemann (1979), Karnieli et al. (1981), Basi et al. (1992) by a modification of the L-arabinose uptake method described by Foley et al. (1978).

Five ml polyethylene miniscintillation vials are prepared with 50 µl of incubation medium containing L-[1-^{3}H]glucose and 3-*O*-[methyl-^{14}C]glucose such that their concentration is 0.5 mM (58.2 and 11.6 µCi/µmol, respectively). L-Glucose is included as a marker for the extracellular space. Sugar uptake is initiated by the rapid addition of 200 µl of adipose cell suspension and then rapidly stopped by the subsequent addition of 10 µl of a 10 mM solution of cytochalasin B in 25% ethyl alcohol. The duration of this 'pulse' incubation is adjusted from 3 to 25 s so that the uptake achieved will be approximately one third of the equilibrium level. The equilibrium level of uptake is determined by incubating cells for 5 to 6 min in the presence of 3-*O*-methylglucose only and then for 1 additional min following the addition of L-glucose. Experimental blanks are obtained by adding cytochalasin B to the labeled sugar solution prior to the addition of cells. Following incubation, 200-µl samples of cells are separated from incubation medium by centrifugation through dinonylphthalate, and the separated cells and incubation medium are counted. The net uptake of 3-*O*-methylglucose is then counted, and the initial uptake velocity or rate of transport is determined.

K.3.2.7 Adipocyte plasma membranes

Preparation of rat adipocyte plasma membranes

Adipocytes are isolated from epididymal fat pads of 160–180 g male Wistar rats by collagenase digestion under sterile conditions as described above. The subcellular fractionation is performed according to McKeel and Jarett (1970), Simpson et al. (1983) with the following modifications: The postnuclear supernatant is centrifuged (12 000 *g*, 15 min). The washed pellet is suspended in 35 ml of buffer and recentrifuged (1 000 *g*, 10 min). The washed pellet (12 000 *g*, 20 min) is suspended in 5 ml of buffer, layered onto a 20 ml cushion of 38% (w/v) sucrose, 20 mM Tris/HCl (pH 7.4), 1 mM EDTA and centrifuged (110 000 *g*, 60 min, 4 °C). The membranes at the interface between the two layers (1 ml) are removed by suction, diluted with three volumes of buffer and layered on top of a 8 ml cushion of 24% Percoll, 250 mM sucrose, 20 mM Tris/HCl (pH 7.4), 1 mM EDTA. After centrifugation (45 000 *g*, 30 min) the plasma membranes are withdrawn with a Pasteur pipette from the lower fourth of the gradient (1 ml), diluted with 10 volumes of buffer and recentrifuged (150 000 *g*, 90 min, 4 °C). The pellet is suspended, recentrifuged, finally dissolved in buffer at 0.5 mg protein/ml and stored at –80 °C.

Preparation of 3T3 adipocyte homogenate and membrane fractions

Prior to homogenization, 150-mm plates are washed with DMEM as above and then once with 10 ml of PBS containing 1 mM EDTA, 0.25 M sucrose. Monolayers from four plates are scraped into 24 ml of ice-cold Tris/EDTA/sucrose buffer (10 mM Tris/HCl, pH 7.4, 1 mM EDTA, 0.25 M sucrose) and immediately homogenized with 10 strokes of a motor-driven

Teflon-in-glass homogenizer. PMSF (final concentration 0.2 mM) is added to the cell suspension prior to homogenization.

The homogenate is centrifuged (16 000 *g*, 20 min). The pellet is resuspended in 6 ml of 10 mM Tris/HCl (pH 7.4), 1 mM EDTA and applied onto a sucrose cushion (1.12 M sucrose in Tris/EDTA). After centrifugation (100 000 *g*, 1 h), the plasma membranes are removed from the top of the sucrose cushion, suspended in 25 ml of Tris/EDTA, 0.1 mM PMSF, recovered by centrifugation (30 000 *g*, 30 min) and resuspended in 0.5 ml of Tris/EDTA, 0.1 mM PMSF. The initial 16 000 *g* supernatant is centrifuged (48 000 *g*, 30 min). LDM are recovered from the supernatant by centrifugation (200 000 *g*, 2 h). The pellet is suspended in 0.5 ml of Tris/EDTA, 0.1 mM PMSF. The membrane fractions are assayed for the activity of the plasma membrane marker enzyme, 5'-nucleotidase that is enriched 7.5-fold (plasma membranes) and 0.4-fold (LDM) towards the homogenate.

K.3.2.8 Effect on glucose transporter translocation

PURPOSE AND RATIONALE

The transport of glucose across the plasma membrane of mammalian cells represents one of the most important nutrient transport events, since glucose plays a central role in cellular homeostasis and metabolism. Apparently, rather than mediated by a single transporter molecule, glucose transport is mediated by a family of highly related transporters (Assimacopoulos-Jeannet et al. 1991; Gould and Holman 1993; Mueckler 1994):

GLUT1: the erythrocyte-type glucose transporter,
GLUT2: the liver-type glucose transporter,
GLUT3: the brain-type glucose transporter,
GLUT4: the insulin-responsive glucose transporter
GLUT5: the small intestine sugar/fructose transporter
GLUT6: a pseudogene-like sequence

GLUT4 occurs in muscle and adipose tissue. In both animal and human tissues, insulin induces a several fold increase of glucose transport. GLUT4 remains localized in intracellular vesicles in the absence of insulin. Addition of insulin recruits the transporter to the cell surface. GLUT4 is inactivated by phosphorylation in the insulin-resistant state and activated by dephosphorylation indicating an important role in the signal transduction cascade (Reusch et al. 1993).

PROCEDURE

Translocation of glucose transporters to the plasma membrane

The insulin-stimulated movement of glucose transporter molecules from intracellular stores to the plasma membrane is assayed by determination of the amount of GLUT4 protein in the plasma membrane of rat adipocytes which have been incubated for 20 min at 37 °C with insulin prior to homogenization and fractionation of the cells The isolated and purified membranes are subjected to immunoblot analysis and immunoprecipitation of GLUT4.

Immunoblot analysis of GLUT4

Polyclonal affinity-purified rabbit antibodies were raised against a synthetic peptide corresponding to the COOH-terminal domain of rat GLUT4 (residues 495–509), (James et al. 1989). The plasma membrane and LDM fractions are subjected to SDS-PAGE (25 µg protein/lane) and electro-phoretically transferred onto nitrocellulose filters (Towbin et al. 1979). Incubations of the filters with primary and secondary antibodies (^{125}I-anti-rabbit IgG from goat), autoradiography and quantitative evaluation of the immunoreactive material by densitometry are carried out as described Müller and Wied (1993).

Immunoprecipitation of GLUT4

Immunoprecipitation of GLUT4 is performed according to Müller and Wied (1993) with the following modifications: 200 µl of homogenate (100 µg of protein) is centrifuged (150 000 *g*, 60 min, 4 °C). The pellet is dissolved in 50 µl of 10 mM Tris/HCl (pH 8.0), 1 mM EDTA, 6 M urea, 5% SDS, heated (60 °C, 5 min) and again centrifuged. The supernatant is supplemented with 2.5 ml of immunoprecipitation buffer containing 1% TX-100 and then with 50 µl anti-GLUT4 antibody that has been adsorbed to protein A-Sepharose (50 µl of antiserum is incubated with 50 mg protein A-Sepharose beads in 450 µl immunoprecipitation buffer for 2 h at 4 °C under head-over rotation. The beads are centrifuged, washed two times with buffer and finally suspended in 0.5 ml of buffer). After incubation (10 h, 4 °C, head-over rotation), the immunoprecipitates are collected by centrifugation (12 000 *g*, 30 s), washed sequentially with 2 ml of immunoprecipitation buffer containing 0.5 and 0.1% TX-100 and finally dissolved in 50 µl of 10 mM Tris/HCl (pH 8.0), 1 mM EDTA, 6 M urea, 2% SDS.

The supernatant of a centrifugation is analyzed by SDS-PAGE and fluorography. The relative amount of immunoprecipitated GLUT4 is calculated from spectrophotometric analysis of the silver grains eluted from the darkened areas (bands) of the film (Suissa 1983).

The number of insulin-sensitive glucose transporter molecules in the plasma membrane is determined either indirectly by the glucose transport activity of the isolated vesicles or directly by binding of cytochalasin B (inhibitor of glucose transport that binds to the glucose transporter) to the vesicles.

Determination of cytochalasin B-binding sites

(Mühlbacher et al. 1988)

The vesicles are incubated with [4(n)-^{3}H]cytochalasin B and cytochalasin E in the presence or absence of 0.5 M D-glucose. The mixtures are rapidly spotted onto Whatman filter papers. The filters are washed, dried and counted for radioactivity. The D-glucose inhibitable cytochalasin B-binding (specific binding) is calculated as difference between total binding (– glucose) and non-specific binding (+ glucose).

Transport of glucose into plasma membrane vesicles

(Baldwin et al. 1981)

The vesicles are incubated with 0.1 mM each of D-[3-^{3}H]glucose and L-[1-^{14}C]glucose (same specific radioactivity). The incubation mixtures are spotted rapidly onto nitrocellulose filters. The filters are washed extensively, dried and counted for radioactivity. Specific transport is calculated as difference between the [^{3}H] and the [^{14}C] counts.

Both assays measure the insulin-dependent increase in total transporter number of the plasma membrane. It is generally assumed that insulin stimulates the translocation of small intracellular Golgi vesicles containing the glucose transporter molecules (low density microsomes) to the plasma membrane. Thus, the assays reflect movement to and fusion with the plasma membrane of those vesicles (including the corresponding signal transduction cascade).

MODIFICATIONS OF THE METHOD

Li end McNeill (1997) reviewed various quantitation methods for the insulin-regulatable glucose transporter (Glut4) including reconstituted glucose transport, cytochalasin B binding assays, immunocytochemistry, immunoblots, ELISA, and exofacial labels.

The effect of streptozotocin-induced diabetes on GLUT-4 phosphorylation in rat adipocytes has been studied by Begum and Draznin (1992).

The effect on glucose transporters by sulfonylureas was studied by Jacobs and Jung (1985), Jacobs et al. (1989), that of metformin by Matthei et al. (1991).

Cusin et al. (1990) found that hyperinsulinemia increases the amount of GLUT4 mRNA in white adipose tissue and decreases that of muscles.

Hofmann et al. (1991) determined GLUT4 content by Western immunoblot protein analysis and by Northern blot analysis of GLUT4 mRNA in epididymal fat

or soleus muscle tissue of streptozotocin-treated rats and of obese male KKA^Y mice after treatment with pioglitazone.

The effect of *in vivo* thyroid hormone status on insulin signaling and GLUT1 and GLUT4 glucose transport systems in rat adipocytes was studied by Matthei et al. (1995).

Galante et al. (1994) studied insulin-induced translocation of GLUT4 in skeletal muscle of insulin-resistant Zucker rats.

Recycling of GLUT4 was studied by Laurie et al. (1993), Rampal et al. (1995).

Bähr et al. (1995) studied the stimulation of myocar-dial glucose transport and glucose transporter-1 (GLUT1) and GLUT4 protein expression in cultured cardiomyocytes from rats.

Teresaki et al. (1998) studied the influence of an insulin sensitizer on GLUT4 translocation in adipocytes of rats fed a high fat diet.

Ren et al. (1995) evaluated the effect of increased GLUT4 protein expression in muscle and fat on the whole body glucose metabolism by the euglycemic hyperinsulinemic clamp technique in conscious mice.

Uphues et al. (1995) used cardiac ventricular tissue of lean and genetically obese (fa/fa) Zucker rats to study the expression, subcellular distribution and insulin-induced recruitment of the glucose transporter GLUT4.

Zeller et al. (1995) studied the GLUT1 distribution in adult rat brains using a newly developed immunoautoradiographic method.

Abe et al. (1997) reported molecular cloning of bovine GLUT4.

K.3.2.9 Influence on further metabolic functions

Esterification

(Sooranna and Saggerson 1976)

Adipocytes are treated with low concentrations of saponin to permeabilize the plasma membrane (without disrupting internal membranes) and subsequently incubated with L-[U-^{14}C]glycerol-3-phosphate for 10 min at 25 °C. Toluene-based scintillation cocktail is added and the lipid and aqueous phases are separated by centrifugation. The lipid phase is removed and counted for radioactivity.

This assay measures the insulin-stimulated esterification of glycerol-3-phosphate into lipid-soluble products (triglycerides, phospholipids) including the signal cascade. Glucose transport does not interfere as revealed by lack of inhibition of basal esterification by cytochalasin B.

Glycerol-3-phosphate-acyltransferase (GPAT)

Vila et al. (1990) showed that insulin activates glycerol-3-phosphate-acyltransferase through a phospholipid-derived mediator.

Glycerol-3-phosphate-acyltransferase is assayed as follows: The incubation mixture contains 50 mM Tris/HCl (pH 7.4), 200 mM KCl, 1 mM DTT, 150 µM palmitoyl-CoA, 2 mg/ml BSA, 0.2 mM [^{3}H]glycerol-3-phosphate (2 µCi) and homogenate from 3T3 adipocytes in a final volume of 0.5 ml. The reaction is started by addition of homogenate. After incubation (3 min, 37 °C) the reaction is stopped with 2 ml of water-saturated butanol, followed by 1.5 ml of butanol-saturated water. The butanol phase is separated and washed twice. An aliquot is counted for radioactivity. Under these conditions the rate of product formation is linear for at least 15 min. The radiolabeled products formed are primarily phosphatidic acid (65–70%) and lyso-phosphatidic acid (20–25%) as determined by thin layer chromatography.

Time- and concentration dependence of sulfonylurea-stimulated glycerol-3-phosphate-acyltransferase was tested by Müller et al. (1994).

Measurement of lipolysis as release of NBD-FA

For fluorescent labeling of adipocyte lipids, 200-µl portions of adipocyte suspension in 1.5-ml plastic cups are incubated with 200 µl of KRH containing 0.75% BSA and 1 mM glucose in the presence of 50 µl insulin (5.5 nM or as indicated) for 15 min at 37 °C prior to addition of 50 µl of 12-((7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino) dodecanoic acid (NBD-FA; 500 µM, prepared daily by dissolving 39.8 mg NBD-FA in 1 ml ethanol under moderate heating and subsequent 1 : 200 dilution with KRH containing 0.75% BSA) and further incubation for 60 min at 37 °C under mild shaking (thermomixer 5 436, setting 10, Eppendorf, Hamburg, Germany). For removal of the free NBD-FA left in the incubation medium, the adipocyte suspensions are combined in 50-ml plastic vials and centrifuged (500 *g*, 1 min, swing-out rotor). The infranatant below the cell layer is aspirated. The adipocytes are suspended in 30 ml of Medium 199 (HEPES modification) containing 4 mM L-glutamine, 10 mg/ml glucose, 30 mg/ml BSA. After two further cycles of centrifugation and resuspension, the washed adipocytes are finally adjusted to 5% lipocrit with Medium 199. For initiation of lipolysis, 400-µl portions of adipocyte suspension are supplemented with 500 µl of Medium 199 containing glutamine, glucose and BSA as indicated above and incubated in a total volume of 1 ml in the presence or absence of isoproterenol, adenosine deaminase or insulin and for periods of time indicated in plastic scintillation vials at 37 °C under mild shaking in a water bath. Methods I and II: The samples are transferred into pre-cooled Eppendorf cups containing 500 µl chloroform, mixed vigorously and centrifuged (12 000 *g*, 2 min). Aliquots of the lower phase is removed and 5- or 10-µl portions analyzed by TLC

using Si-60 plates and diethylether/petrolether/acetic acid (78 : 22 : 1, v/v) as solvent system. Quantitative evaluation of the amount of NBD-FA released is performed by fluorescent imaging (Molecular Dynamics, Storm 840) using imaging software (Molecular Dynamics, Program Image Quant) (Method I). Alternatively, 200-µl aliquots of the lower phase are supplemented with 3.25 ml of methanol/chloroform/heptane (10 : 9 : 7, v/v) and 1.05 ml of 0.1 M potassium carbonate, 0.1 M boric acid (pH 10.5), vortexed and centrifuged (800 *g*, 20 min). Aliquots of the upper phase (1.5 ml) are removed and measured for fluorescence in an automatic fluorometric analyzer (Cobas Bio, Roche Diagnostic, Welwyn, UK) (Method II). Method III: 300-µl aliquots of the samples are filtered under vacuum over GF/C-glass microfiber filters (Whatman, Maidstone, UK) that had been pre-wetted with butanol-saturated water. The filters are washed once with 300 µl butanol-saturated water and once with 300 µl water-saturated butanol. After centrifugation, portions of the water phase are used for glycerol determination (see below).

Measurement of lipolysis as release of glycerol or generation of cAMP

400 µl of adipocyte suspension (lipocrit 10%) are suspended in 600 µl KRH containing 0.75% BSA, 1.5 mM glucose, and incubated in the absence or presence of isoproterenol, adenosine deaminase or insulin at 37 °C in a mildly shaking water bath. 200-µl aliquots are transferred into Eppendorf cups containing 20 µl $HClO_4$ (70%), vortexed vigorously and centrifuged (12 000 *g*, 15 min, room temperature). 110 µl of the infranatant is removed, taking care not to aspirate any of the precipitate, supplemented with 60 µl of 1 M Tris/HCl (pH 7.5), incubated for 15 min on ice and then centrifuged (13 000 *g*, 15 min, 4 °C). 150 µl of the infranatant is removed for glycerol determination, frozen in liquid N_2 and stored at –20 °C prior to determination of glycerol and cAMP levels. Glycerol is measured fluorometrically by a modified version of the enzymatic method by Wieland (Wieland 1974). The reaction mixture contained 0.1 M Tris/HCl (pH 9.3), 0.9 mM ATP, 1.25 mM NAD, 0.1 M $MgCl_2$, 0.25% (v/v) hydrazine hydrate, 5–50 µl sample or standard, and a mixture of glycerokinase (0.2 U/ml final conc.) and glycerol 3-phosphate dehydrogenase (0.7 U/ml final conc.) in a total volume of 240 µl. Fluorescence is determined using an automatic fluorometric analyzer. cAMP is determined by a modification of the protein kinase binding procedure. Samples and standards are incubated with 8 µg of R-subunit of protein kinase A and 175 nCi [8-^{3}H]cAMP in a buffer composed of 50 mM Tris/HCl (pH 7.4), 4 mM EDTA in a final volume of 200 µl for 4 h at 4 °C to reach equilibrium. Charcoal suspension (30 g/l) is added and after vortexing, the mixture is centrifuged at 16 000 *g*, 2 min, 4 °C). The supernatant is transferred into scintillation vials, supplemented with 5 ml water-compatible scintillation fluid and counted for radioactivity using a liquid scintillation counter. The concentration of endogenous unlabelled cAMP in the samples is determined from a linear standard curve.

Measurement of lipolysis as PKA activity ratio

500-µl samples are withdrawn from the fluorescent labeled adipocytes, transferred to 2-ml microfuge tubes, pre-cooled to 4 °C, containing at final concentrations: 20 mM Tris/HCl (pH 7.4), 10 mM EDTA and the cAMP phosphodiesterase inhibitor, Ro 20-1 724 (100 µM). The mixture is vortexed briefly, decanted into a 5-ml Teflon-in-glass homogenizer and homogenized with 10 strokes of the rotating (1 500 rpm) Teflon pestle. The homogenate is transferred to pre-cooled microfuge tubes and centrifuged (16 000 *g*, 10 min, 4 °C). The infranatant is removed and immediately assayed for PKA activity. 25 µl of assay medium (20 mM MOPS/KOH, pH 7.0, 10 mM $MgCl_2$, 0.1 mM ATP, 0.5 mg/ml histone H1, 5 mM DTT, 50 µCi/ml [γ-^{32}P]ATP) is added to 25 µl infranatant. After vortexing and incubation for 20 min at 30 °C, the reaction is terminated by addition of 1 ml of ice-cold 20% TCA containing 5 mM sodium pyrophosphate and incubation (1 h, 4 °C). The precipitates are sedimented by centrifugation (16 000 *g*, 5 min, 4 °C) and, after removal of the supernatant, dissolved in 100 µl of cold 1 N NaOH and re-precipitated with 20% TCA and 5 mM sodium pyrophosphate. The precipitate is then filtered under vacuum over GF/C-glass microfiber filter that had been pre-wetted with 5% TCA, 5 mM sodium pyrophosphate. The filters are washed with 4 ml of the same medium, dried and counted for radioactivity. Each adipocyte infranatant is assayed in quadruplicate under four separate conditions: (I) with no further additions; (II) in the presence of 15 µM cAMP; (III) in the presence of 2 µM A-kinase inhibitor synthetic peptide and (IV) in the presence of 15 µM cAMP and 2 µM A-kinase inhibitor synthetic peptide. The results are expressed as corrected PKA activity ratios (I)–(III)/(II)–(IV) (Honnor et al. 1985a; Honnor et al. 1985b; Londos et al. 1985).

Protein phosphatase 2A (PP2A) activity

Insulin inhibits lipolysis by decreasing the phosphorylation and thus the activation state of hormone-sensitive lipase in adipose tissue via both inhibition of PKA and stimulation of protein phosphatase 2A (PP2A) by at present unknown mechanisms. For measurement of PP2A activity, the adipocytes (3×10^7 cells) are washed once with 25 ml of ice-cold 100 mM Tris/HCl (pH 8.5), 10 mM EDTA, 25 mM DTT and immediately resuspended in 0.5 ml of 100 mM Tris/HCl (pH 7.0), 2 mM

EDTA, 10 mM DTT, 0.5 mM benzamidine, 0.2 mM PMSF, 2 µg/ml leupeptin, 5 µg/ml pepstatin. After addition of the same volume of ice-cold glass beads, cell extracts are prepared by vigorous vortexing (5 times 5 s each with cooling intervals on ice) and centrifuged (13 000 *g*, 5 min, 4 °C). The supernatant (S13) is diluted with 3 volumes of the same buffer containing 1% BSA. Protein phosphatase activity is assayed as the ability to dephosphorylate ^{32}P-labeled myelin basic protein. 10 µl of S13 is added to an assay mixture (total volume 50 µl) containing 50 mM Tris/HCl (pH 7.5), 1 mM EDTA, 0.5 mM EGTA, and 0.2 nmol ^{32}P-labeled myelin basic protein (900 dpm/pmol) for 20 min at 30 °C in the absence or presence of 2 nM okadaic acid. The reaction is terminated by the addition of 50 µl of ice-cold 10% TCA. After incubation for 15 min on ice and centrifugation (12 000 *g*, 5 min, 4 °C), the supernatant is neutralized with NaOH and measured for radioactivity by liquid scintillation counting (10 ml Aquasol). PP2A activity is determined as the difference between ^{32}P-radiolabel measured in the presence of okadaic acid (10 nM) corresponding to the PP2A independent phosphatase portion and the label determined after uninhibited incubation corresponding to the total phosphatase activity. Under these conditions, release of $^{32}P_i$ is linear for 10 min. One unit of activity is defined as the amount of enzyme that catalyzes the release of 1 µmol of $^{32}P_i$-radiolabel from labeled myelin basic protein in one min under conditions of the standard assay (Müller et al. 2000).

cAMP-dependent protein kinase (PKA)

Insulin inhibits PKA by an at present unknown mechanism.

cAMP-dependent protein kinase is assayed according to Roskoski (1983, Honnor et al. 1985): The reaction mixture contains 25 µl of rat adipocyte cytosol, 0.4 µM kemptide, 40 mM Tris/HCl (pH 7.2), 2 mM DTT, 12.5 mM $MgCl_2$, 0.1 mM PMSF, 1 mM IBMX, 100 µM [γ-^{32}P]ATP (1 µCi) with or without 1 µM cAMP in a total volume of 100 µl. After incubation (10 min, 30 °C) the reaction mixture is chilled on ice, then supplemented with 3 ml of 75 mM phosphoric acid, 100 mM NaF, 10 mM ATP and immediately spotted on phosphocellulose filters (Whatman P18). After extensive washing with 75 mM phosphoric acid, the filters are dried and counted for radioactivity. The PKA activity is expressed as the ratio between ^{32}P-incorporation into kemptide without and with cAMP. This activity ratio is a parameter for the portion of PKA active *in vivo* toward total cellular PKA at the time point of homogenization.

The inhibition of isoproterenol-stimulated proteinkinase A by sulfonylureas was tested by Müller et al. (1995).

The effect of tolbutamide and glyburide on cAMP-dependent protein kinase activity in rat liver cytosol was investigated by Okuno et al. (1988).

Insulin-sensitive cAMP-specific phosphodiesterase (PDE)

Membrane-bound phosphodiesterase of rat epididymal fat cells is stimulated when intact cells are exposed to insulin. The localization and properties of the insulin-sensitive cAMP phosphodiesterase have been described by Kono et al. (1975), Osegawa et al. (1982), Saltiel and Steigerwalt (1985), Solomon et al. (1986).

The low density microsomal fraction of 3T3 adipocytes is incubated with insulin or test compounds at various concentrations for 20 min. For the assay of cAMP-specific PDE up to 50 µl of low density microsomal fraction (LDM) from rat adipocytes are incubated (5 min, 30 °C) with 500 nM [2,8-^{3}H]cAMP (100 nCi) in 50 mM Tris/HCl (pH 7.4), 0.5 mM DTT, 5 mM $MgCl_2$, 50 µM PMSF in a total volume of 0.25 ml. The incubation is terminated by the sequential addition of 30 µl of 10 mM IBMX and 120 µl of 0.1 N HCl and heating (5 min, 95 °C). After neutralization (120 µl of 0.1 N KOH, 80 ml of 250 mM Tris/HCl pH 7.4), 10 µl of crude 5'-nucleotidase (5 mg/ml) (*Crotalus atrox*) is added to the mixture. The reaction (30 min, 37 °C) is terminated by the addition of 60 µl of 200 mM EDTA, 5 mM adenosine. Unreacted cAMP is removed by the addition of 1 ml of a 1 : 3 slurry of Dowex AG-1X8 (Biorad, München, FRG). Solutions are shaken (5 min, 4 °C) and centrifuged (1 000 *g*, 5 min). Radiolabeled adenosine left in the supernatant is determined by liquid scintillation counting. The assay is proportional up to 100 µg of protein and linear throughout 20 min.

Calculation of insulin-mimetic activity

Data from metabolic assays are calculated as stimulation factor above basal activity (absence of insulin/compound) (e.g. for lipogenesis, glycerol-3-phosphate acyltransferase, glucose transport and GLUT4 translocation) or as difference between the basal and insulin/compound-induced values for inhibition of lipolysis or vice versa for stimulation of glycogen synthase and in each case normalized to the basal (set at 0%) and maximal insulin action (set at 100%; elicited at 10 nM insulin). At least three different cell preparations with two to four independent incubations with insulin/compound for each preparation should be performed. Each incubation should be assayed at least in triplicate. Concentration/response curves can be fitted to the equation

$$y = a + b\,[x / (x + k)]$$

using a Marquardt-Levenberg nonlinear least squares algorithm. When plotted on linear-log axes, this equa-

tion gives a sigmoidal curve where the parameters are associated with the following properties:

a = basal response;
$a + b$ = maximal response;
k = half-maximal concentration (EC_{50});
x = concentration of insulin.

PURPOSE AND RATIONALE

Bipartite metabolic-mitogenic signaling by insulin

Upon binding of insulin to the insulin receptor in insulin-responsive cells (adipocytes, myocytes, hepatocytes), the insulin signal transduction machinery, a complex network of protein-protein interactions and protein (serine/threonine/tyrosine) phosphorylation cascades between a multitude of cellular signaling components, is activated and transmits the insulin signal to a variety of metabolic (predominantly) and mitogenic (to a minor degree) effector systems (e.g. Glut4 translocation, gene expression) (Myers and White 1995; Saltiel 1996; Yenush and White 1997; White 1998). For compounds/drugs with insulin-mimetic/sensitizing activity, it is important to differentiate between metabolic and mitogenic signaling in insulin-responsive cells, such as adipocytes.

Two pathways within the insulin signaling pathway have been dissected and are thought to mediate the different biological functions of the hormone: (I) Activation of phosphatidylinositol-3'-kinase (PI 3-K) plays a pivotal role for regulation of glucose transport and cellular trafficking as well as glycogen synthesis and lipolysis by insulin. (II) Formation of the Shc-Grb2 complex leads to activation of the Ras-pathway which has been linked to insulin regulation of both cell growth and gene expression, although this has been questioned recently. Many of the proteins involved in these two pathways have been identified at the molecular level (White 1996; White 1997; Holman and Kasuga 1997). The insulin receptor is a transmembrane tyrosine kinase which when activated by insulin binding, undergoes rapid autophosphorylation and phosphorylates a number of intracellular substrates, among them one or more 50- to 60-kDa proteins including Shc, a 15-kDa fatty acid binding protein and several so-called insulin receptor substrate proteins, IRS-1/2/3/4. Following tyrosine phosphorylation, the IRS polypeptides act as docking proteins for several Src homology 2 domain-containing adaptor molecules and enzymes, including PI 3-K, Grb2, SHP2, Nck, and Fyn. The interaction between the IRS proteins and PI 3-K occurs through the p85 regulatory subunit of the enzyme and results in an increase in catalytic activity of the p110 subunit. PI 3-K is essential for many insulin-sensitive metabolic processes including stimulation of glucose transport and glycogen synthesis. In all cases in which there is stimulation of tyrosine phosphorylation of IRS proteins, there is concomitant docking of these proteins to the p85 subunit of PI 3-K and this

docking is associated with stimulation of the PI 3-K activity.

It is generally accepted that one branch of acute metabolic insulin signalling is initiated by activation of PI 3-K (Yeh el al 1997; Alessi and Downes 1998; Shepherd et al. 1998). This may be necessary for insulin stimulation of GS and glucose transport and even be sufficient for the latter (Cheatham et al. 1994; Herbst et al. 1995; Yeh et al. 1997). Further, there is experimental evidence for protein kinase B (PKB) being an element of the signalling cascade leading from PI 3-K to activation of glycogen synthase (GS) and glucose transport in isolated rat adipocytes, various cell culture models and human skeletal muscle (Burgering and Coffer 1995; Hurel et al. 1997; Shepherd et al. 1997). The experimental data available favor a model for a cascade which assumes the following sequence of events (Gustafson et al. 1998): PI 3-K activation results in the production of phosphatidylinositol (3,4,5)-trisphosphate and phosphatidylinositol (3,4)-bisphosphate. The binding of the pleckstrin-homology domain of PKB to these phosphoinositides both recruits PKB to the plasma membrane and directly and/or indirectly (via phosphorylation by the membrane-associated serine/threonine protein kinases, PDK1/2) stimulates its kinase activity. Activated PKB phosphorylates substrate proteins (e.g. GSK-3 which is thereby inhibited, leading to dephosphorylation and activation of GS), resulting in a variety of biological effects possibly including stimulation of glycogen synthesis and GLUT4 translocation. Thus the current knowledge favors the view that most metabolic insulin signals emerge from insulin-dependent tyrosine phosphorylation of the IRS proteins whereas the mitogenic insulin action is apparently coupled to tyrosine phosphorylation of the Shc proteins. These serve as docking sites for the Grb-SOS complex which possesses GDP-GTP exchange activity for the small G-protein Ras and is activated by binding to Shc. GTP-loaded Ras interacts with and activates the Raf serine kinase which phosphorylates the dual specificity kinase mitogen/extracellular signal-activated kinase MEK (= MAPKK). Activated MEK phosphorylates the mitogen-activated protein kinases MAPK, ERK1 (p44) and ERK2 (p42), which in turn phosphorylate and activate a number of transcription factors (e.g. c-jun, c-fos) ultimately leading to increased gene and protein expression as well as DNA synthesis in insulin-like fashion (Gustafson et al. 1998).

In addition to the identification of the signal transduction pathways directly leading from the insulin receptor to downstream targets, several cross talks have been delineated between signalling transmission by insulin and other hormones/growth factors or diverse exogenous stimuli which either mimic (to a certain degree) or modulate in a positive or negative fashion metabolic and/or mitogenic insulin action in various cellular systems. Since none of these ligands activates the insulin receptor kinase directly, their signalling pathways may converge with that of insulin at a more distal signalling step (Argetsinger et al. 1995; Huppertz et al. 1996; Kowalski-Chauvel et al. 1996; Velloso et al. 1996; Ricort et al. 1997; Verdier et al. 1997; Baron et al. 1998). Soluble phosphoinositolglycan molecules which have been shown to exert partial insulin-mimetic effects in diverse cellular and subcellular systems (Müller et al. 1997; Kessler et al. 1998; Frick et al. 1998) can also be classified into the latter category. Interestingly, the second-generation sulfonylureas, glibenclamide and, in particular, glimepiride have been demonstrated to stimulate glucose transport and non-oxidative metabolism in adipose and muscle cells *in vitro* by causing insulin receptor-independent tyrosine phosphorylation of IRS-1/2 and stimulating the downstream located insulin signaling events (Müller et al. 1994; Müller and Geisen 1996). This insulin-mimetic signaling in cells of peripheral tissues may explain the insulin-independent blood glucose-lowering activity of glimepiride/glibenclamide as has been reported in a number of animal studies (Geisen 1988; Müller et al. 1995), which supplements the potent blood glucose decrease via insulin release provoked by these anti-diabetics.

PROCEDURES USING CULTURED ADIPOCYTES

Preparation of cell lysates

Stimulated adherent or non-adherent 3T3-L1 cells are placed on ice and then washed twice with 50 mM HEPES/KOH, pH 7.5, 150 mM NaCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 10 mM EDTA, 10 mM glycerol-3-phosphate, 10 mM $Na_4P_2O_7$, 2 mM Na_3VO_4, 100 mM NaF (in case of non-adherent cells by flotation [200 *g*, 2 min] and aspiration of the infranatant). Cells are solubilized in the above buffer containing 1% (vol/vol) Triton X-100, 0.1% sodium deoxycholate, 10% glycerol and protease inhibitors (20 µg/ml leupeptin, 10 µg/ml pepstatin A, 50 µg/ml aprotinin, 10 µM E-64, 0.5 mM phenylmethylsulfonylfluoride (PMSF) = lysis buffer) for 30 min on ice (non-adherent cells) or by scraping with a Teflon policeman (adherent cells). Total lysates are centrifuged (25 000 *g*, 20 min, 18 °C). The infranatant is aspirated taking care to avoid contamination by the upper fat layer and re-centrifuged to obtain the defatted cell lysate. Stimulated rat adipocytes are washed once with PBS containing 2 mM sodium pyruvate by flotation (200 *g*, 2 min) and aspiration of the infranatant and immediately homogenized in lysis buffer containing 4 mM benzamidine by 10 strokes/200 rpm in a medium-fitting Teflon-in-glass homogenisator (2 ml vessel vol.) at 18 °C. Defatted cell lysate is prepared as described above.

Immunoprecipitation

Defatted cell lysates (standardized for 5 to 10 µg protein) are precleared (1 h, 4 °C) with protein G/A-Sepharose and then supplemented with appropriate antibodies (often 0.5–5 µg/sample) preadsorbed on protein G-Sepharose (monoclonal antibodies) or protein A-Sepharose (rabbit antibodies) in a total volume of 100 µl of lysis buffer. After incubation (4 h, 4 °C, end-over-end rotation) and centrifugation (13 000 *g*, 2 min, 4 °C), the collected immune complexes are washed twice with 1 ml each of immunoprecipitation buffer (50 mM HEPES/KOH, pH 7.4, 500 mM NaCl, 100 mM NaF, 10 mM EDTA, 10 mM $Na_4P_2O_7$, 1 mM Na_3VO_4) containing 1% NP-40 (omitted for sequential immunoprecipitation), then twice with 1 ml each of immunoprecipitation buffer containing 150 mM NaCl and 0.1% NP-40 and once with 1 ml of immunoprecipitation buffer lacking salt and detergent and finally suspended in 50 µl of Laemmli buffer (2% SDS, 5% 2-mercaptoethanol), heated (95 °C, 2 min) and centrifuged. The supernatant samples are analyzed by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE; 4–12% Bis-Tris precast gel, pH 6.4, morpholinoethanesulfonic acid (MES)/SDS running buffer, Novex, San Diego, Ca) under reducing conditions. For sequential immunoprecipitation, the supernatant samples (50 µl) are supplemented with 1 ml of immunoprecipitation buffer containing 1% NP-40 and 1–10 µl of the relevant antiserum. After incubation (12 h, 4 °C), 50 µl of protein A-Sepharose (100 mg/ml in immunoprecipitation buffer) is added and the incubation continued (4 h, end-over-end rotation). The immune complexes are collected, washed and processed for SDS-PAGE as described above.

Immunoblotting

Proteins are transferred to polyvinylidene difluoride membranes (Immobilon, Millipore, Eschborn, Germany). The blocked membrane is incubated (2 h, 25 °C) with the appropriate antibodies (often 1 : 200–1 : 5 000; or e.g. against phosphotyrosine [2 µg/ml]), washed (four times with Tris-buffered saline [TBS] containing 1% (vol/vol) Nonidet-P40 [NP-40] and 0.5% Tween 20, twice with TBS containing 0.5% Tween 20, twice with TBS) and then incubated (1 h, 25 °C) with appropriate horseradish peroxidase-coupled detection (anti-mouse or rabbit) antibodies (1 : 15 000 dilution; enhanced luminescence, Pierce, Rockford, IL, USA) in TBS containing 5% (wt/vol) BSA, washed (five times with TBS containing 1% NP-40 and 0.5% Tween 20, three times with TBS containing 0.05% Tween 20 and finally processed with chemiluminescent reagents (Renaissance Chemiluminescence Detection System, NEN/DuPont, Bad Homburg, Germany) and subjected to phosphorimaging.

Immune complex kinase assays

The kinase immune complexes are washed in kinase buffer (50 mM Hepes/KOH, pH 7.4, 100 mM NaCl, 5 mM $MnCl_2$, 1 mM $MgCl_2$, 0.5 mM DTT, 1 mM Na_3VO_4) and then suspended in 50 µl of kinase buffer. The kinase reactions are started by addition of ATP (unlabeled or ^{32}P-labeled; final conc. often 40 µM, 0.2 mCi/ml – 100 µM, 0.5 mCi/ml) and incubated (often 3–15 min; 22 °C) in the absence (autophosphorylation) or presence of recombinant substrate protein (often 0.1–1 µg). Autophosphorylation reactions are terminated by addition of 50 µl of ice-cold stop buffer (50 mM Hepes/KOH, pH 7.4, 150 mM NaCl, 100 mM ATP, 0.05% Triton X-100) and washing of the beads twice with 1 ml of stop buffer prior to addition of 20 µl of Laemmli buffer and boiling (95 °C, 5 min). Substrate phosphorylation reactions are terminated by addition of 10 µl of four-fold concentrated Laemmli buffer and boiling. The phosphoproteins are separated on SDS-PAGE (10% Bis-Tris resolving gel, morpholinopropanesulfonic acid/SDS running buffer) and analyzed by phosphorimaging directly (use of [^{32}P]ATP) or after immunoblotting with anti-phosphotyrosine antibody (use of unlabeled ATP). Under these conditions the kinase reactions are linear with time for the assay period. Protein concentration is determined by the bicinchoninic acid protein assay protocol from Pierce (Rockford, IL, USA) with crystalline BSA as standard. Phosphorimaging is performed with a phosphorimager Storm 860 and quantitatively evaluated using ImageQuant software (Molecular Dynamics). Differences in recovery in the amounts of immunoprecipitated protein during a specific experiment are corrected in each case (data on fold- or % stimulation) for the amount of protein actually applied onto the gel by homologous immunoblotting. The data should be confirmed by running independent experiments with different batches of adipocytes several times each with two to five parallel independent immunoprecipitation/kinase assay/immunoblotting analyses.

K.3.2.11 Insulin signaling in the liver

PURPOSE AND RATIONALE

In NIDDM patients with moderate fasting hyperglycemia, the liver production of glucose is increased by about 0.5 mg/kg/min, or about 50 g/d above normal (DeFronzo et al. 1992). This modest increase is the consequence of reduced suppression of hepatic glucose production by insulin (Firth et al. 1987) and could be nullified by reducing dietary carbohydrate by 50 g/d. The increased hepatic glucose production in NIDDM is probably caused by a combination of lack of an insulin-mediated reduction in glucagon secretion (Müller et al. 1970) and hepatic resistance to insulin action at the level of both the insulin signaling transduction cascade and its coupling to the metabolic end effector enzymes of gluconeogenesis. The importance of increased hepatic glucose production is underlined by the fact that when phosphoenolpyruvate carboxykinase (PEPCK), the key rate-limiting regulatory enzyme of gluconeogenesis, is overexpressed in mice carrying a transgene expressing the protein hyperglycemia results (Valera et al. 1994). Independent of whether increased

hepatic glucose production plays a primary or only secondary role in the pathogenesis of human NIDDM, analysis of insulin signaling and action in liver is important for gaining a complete picture of the pathophysiology of NIDDM. The model of the isolated perfused rat liver offers advantages determining insulin action, which, compared to primary and cultured liver cells, are the intact tissue, the near physiological function of the liver, and, compared to the *in vivo* situation, the separation from other effects which may also affect hepatic metabolism, like basal glucagon secretion from β-cells, increased sympathetic activity and/or hypothalamic effects (Nonogaki 2000).

Preparation of rat liver cytosol

Portions of frozen liver (0.2–1 g wet weight), which has been perfused as described in K.6.2.1., are homogenized in a buffer containing 50 mM Hepes/KOH (pH 7.4), 140 mM NaCl, 250 mM sucrose, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 2 mM EDTA, 2.5 mM Na_3VO_4, 10 mM glycerol-3-phosphate, 20 mM $NaPP_i$, 20 mM NaF, 1 mM phenylphosphate, 5 µM okadaic acid (sodium salt), 1% Nonidet P-40, 10% glycerol and protease inhibitors (10 µg/ml leupeptin, 5 µg/ml pepstatin A, 75 µg/ml aprotinin, 100 µM benzamidine, 2 µg/ml antipain, 10 µg/ml soybean trypsin inhibitor, 5 µM microcystin, 5 µM E-64, 0.2 mM PMSF) using an Ultraturrax T25 basic (three 10-s cycles at 2 000 rpm on ice) and then a tight-fitting Teflon-in-glass homogenizer (5 strokes at 500 rpm on ice). The total homogenate was centrifuged (30 min, 48 000 *g*, 4 °C). The supernatant was carefully removed to avoid contamination with the upper fat layer and re-centrifuged. The fat-free supernatant obtained was stored in liquid N_2 and used as cytosol (3–5 mg protein per ml) for immunoprecipitations and PEPCK activity measurements.

Immunoprecipitation of IRß, IRS-1/2 and GSK3

Up to 1 ml portions of cytosol (equal amounts of protein) are precleared (30 min, 4 °C) with protein A-Sepharose (50 mg, Pharmacia) and then supplemented with appropriate antibodies (anti-IRS-1 [rabbit, polyclonal, protein A-purified, raised against a peptide corresponding to amino acids 1 220–1 235 of rat IRS-1, Upstate Biotechnology]: 3 µg/ml; anti-IRS-2 [raised against peptide mixture corresponding to amino acids 618–747 and 976–1 094 of mouse IRS-2]: 1 : 100; anti-IRß [raised against a peptide corresponding to the 100 carboxy-terminal amino acids of human IR, Upstate Biotechnology]: 5 µg/ml; anti-GSK3ß [mouse monoclonal, protein G-purified, raised against a peptide corresponding to amino acids 203–219 of Drosophila GSK3, Upstate Biotechnology, Lake Placid, NY]: 2.5 µg/ml, preadsorbed on protein A-Sepharose. After incubation (4 h, 4 °C, end-over-end rotation) and centrifugation (3 000 *g*, 2 min, 4 °C), the collected immune complexes are washed twice with 1 ml each of immunoprecipitation buffer (50 mM Hepes/KOH, pH 7.4, 500 mM NaCl, 100 mM NaF, 10 mM EDTA, 10 mM $NaPP_i$, 2.5 mM Na_3VO_4) containing 1% Nonidet P-40, then twice with 1 ml each of immunoprecipitation buffer containing 150 mM NaCl and 0.2% Nonidet P-40 and once with 1 ml of immunoprecipitation buffer lacking salt and detergent and finally suspended in 50 µl of Laemmli buffer, heated (95 °C, 2 min) and centrifuged. The supernatant samples are analyzed by SDS-PAGE (4–12% Bis-Tris Novex precast gel, pH 6.4, morpholinoethanesulfonic acid/SDS running buffer) under reducing conditions.

Immunoblotting

Immunoblotting is performed as described previously (Frick et al. 1998; Müller et al. 2000) with minor modifications. Briefly, after SDS-PAGE and transfer of the proteins to polyvinylidene difluoride membranes (2 h, 400 mA in 20% methanol, 192 mM glycine, 25 mM Tris, 0.005% SDS), the blocked membrane (1 h in blotting buffer containing 20 mM Tris/HCl, pH 7.6, 150 mM NaCl, 0.05% Tween 20, 0.1% Brij, 0.01% NP-40 and with 1% ovalbumin and 1% BSA (anti-phosphotyrosine, anti-IRß, anti-GSK-3) or with 5% non-fat dried milk (anti-p85, anti-IRS-1/2) was incubated (2 h, 25 °C) with anti-IRß (3 µg/ml), anti-IRS-1 (rabbit polyclonal, immunoaffinity-purified, raised against a peptide corresponding to the 14 carboxyterminal amino acids of rat IRS-1, 1 : 500), anti-IRS-2 (1 : 250), anti-p85α (rabbit, polyclonal, protein A-purified, raised against full-length rat p85 PI-3K, Upstate Biotechnology, 1 µg/ml), anti-GSK3 (phosphoserine 21- and 9-specific; New England Biolabs 9 331, 1 : 250) or anti-phosphotyrosine (1 : 1 000, Transduction Laboratories, pY20) antibodies, and then washed five times with blotting buffer containing the corresponding blocking reagent. After incubation (1 h, 25 °C) of the membranes [^{125}I]protein A (5 µCi/ml, Amersham-Buchler) in the same blocking medium, the membranes were washed five times and then subjected to autoradiography (Kodak X-Omat AR) or phosphorimaging (Molecular Dynamics, Storm 860). Quantitative analysis of the blots was performed by using IMAGEQUANT software. The recovery in the amounts of immunoprecipitated protein was corrected (data on fold- or % stimulation) for the amount of protein actually applied onto the gel as revealed by homologous immunoblotting. Each experiment was performed with samples from four different liver perfusions (as indicated in the figure legends) with three to five independent immunoprecipitation/kinase assay/immunoblotting procedures.

Determination of PI-3K activity

IRS immunecomplexes are incubated (10 min, 22 °C) in 50 µl of 20 mM Tris/HCl (pH 7.0), 50 µM [γ-^{33}P]ATP (5 µCi, New England Nuclear), 10 mM $MgCl_2$, 2 mM MnCl, 100 mM NaCl, 2 mM EDTA, 0.5 µM wortmannin (for control incubations, only) containing 10 µg of phosphatidylinositol (PI, Avanti Polar Lipids, Alabaster, AL) and 1 µg of phosphatidylserine (Folli et al. 1993). After addition of 10 µl of 8 M HCl and 160 µl of a 1 : 1 mixture of methanol/chloroform, the extracted phospholipids are resolved by TLC on plates coated with 1% oxalate and developed in chloroform:methanol: water:ammonia (60 : 47 : 11.3 : 3.2, v/v). Radiolabeled phosphatidylinositol 3-phosphate (PI 3-P) is visualized by autoradiography and quantitated by phosphorimaging of the [^{32}P]phosphate-containing TLC spot reflecting PI 3-P. For calculation of wortmannin-sensitive PI-3K, all values are corrected for PI 3-P radiolabeled in the presence of wortmannin.

Determination of GSK3 activity

GSK3ß activity is determined using immune complex assay with phospho-glycogen synthase peptide 2 (P-GS 2) as a substrate (Eldar-Finkelman et al. 1996; Wang et al. 1994). The GSK3ß immunoprecipitates are washed twice with homogenization buffer and once with assay buffer (20 mM Tris/HCl, pH 7.4, 1 mM DTT) and then suspended in 20 µl of assay buffer containing 0.4 mg/ml BSA, 10 mM $MgCl_2$, 30 µM [γ-^{32}P]ATP (3 000 Ci/mmol, 1 mCi/ml) and 20 µM P-GS 2. After incubation (15 min, 30 °C), the reactions are terminated by addition of 20 µl of 20% trichloroacetic acid and centrifugation (10 000 *g*, 5 min). Then, 15-µl portions of the supernatant are spotted on 2.5 × 3-cm pieces of Whatman P81 phosphocellulose paper. 20 s later, the filters are washed five times with 0.75% phosphoric acid (for at least 5 min each time) and once with acetone. The dried filters are counted for radioactivity in the presence of 5 ml of scintillation fluid (ACS, Amersham Pharmacia Biotech). $^{32}P_i$ incorporation into the negative control peptide (glycogen synthase peptide 2 [Ala21]) is subtracted from values obtained using P-GS 2. No activity was measured with immunoprecipitates using nonimmune IgG. Each activity value is corrected for the amount of immunoprecipitated GSk3ß according to immunoblotting.

Determination of PEPCK activity

PEPCK is measured using the $NaH^{14}CO_3$ fixation assay as described by Noce and Utter (1975); Burcelin et al. (1995) with some modifications. 490 µl of rat liver cytosol is added to 500 µl of reaction buffer containing 150 µmol Tris/acetate (pH 7.2), 5 µmol sodium IDP, 10 µmol $MnCl_2$, 250 µmol KCl, 10 mM DTT, 2 mM GSH, 400/150 µmol $KHCO_3$ and 15 µCi $NaH[^{14}C]O_3^-$ (10 µmol; Amersham-Buchler). The reaction is started by the addition of 10 µl of 0.4 M phosphoenolpyruvate and terminated after 10 min incubation at 25 °C by addition of 1 ml of 6 N HCl and placing the tube on ice. After dilution with 1 ml of deionized water, unreacted CO_2 ($H[^{14}C]O_3^-$) is removed by bubbling with N_2 and CO_2 for 30 min each. The reaction mixture is supplemented with 10 ml of aqueous scintillation cocktail (Beckman ReadySafe) and measured for radioactivity by liquid scintillation counting (Beckman LS6 500). From each value appropriate blanks are subtracted containing the same ingredients but lacking either cytosol or IDP. Under these conditions and up to the maximal amount of cytosol used, the incorporation rates are linear with both cytosol concentration and time during the first 15 min at least.

K.3.2.12 Insulin receptor substrate

PURPOSE AND RATIONALE

The principal substrate for the insulin and insulin-like growth factor-1 receptors is the cytoplasmatic protein insulin-receptor substrate-1 (IRS-1). IRS-1 undergoes multisite tyrosine phosphorylation and mediates downstream signals by 'docking' various proteins that contain Src homology 2 domains. Insulin derivatives can be characterized by phosphorylation and dephosphorylation kinetics of the insulin receptor, insulin receptor substrate-1 and Shc which is implicated in mitogenic signal transduction. Further members of the insulin receptor substrate family are identified (Fantin et al. 1998).

PROCEDURE

Phosphorylation and dephosphorylation kinetics of insulin receptor and insulin receptor substrates

Rat embryo fibroblasts (Rat-1) stable overexpressing the human receptor isoform A are grown in Dulbecco's modified Eagle's/F12 Mix medium supplemented with 200 nM methotrexate and 10% FCS to confluence in 6 well culture plates and subsequently incubated for 18 h in Dulbecco's modified Eagle's/F12 Mix medium without FCS.

For phosphorylation kinetic studies, cells are incubated with human insulin or the insulin derivatives for various times (0–120 min), subsequently rinsed once with ice-cold buffered saline and solubilized in lysis buffer (50 mM HEPES, 150 mM NaCl, 1.5 mM $MgCl_2$, 1 mM EGTA, 15 mM $Na_4P_2O_7$, 100 mM NaF, 10% v/v glycerol, 1% v/v Triton X-100, 1 200 trypsin inhibitory units/liter aprotinin, 1 mM PMSF, 1 mM Na_3VO_4, pH 7.5).

For the dephosphorylation kinetics, the cells are incubated with insulin or the test preparations for 3 min and dephosphorylation of the insulin receptor is initiated by dilution of the ligand. The monolayers are then kept for various times at 37 °C. After washing with ice-cold buffered saline, cells are solubilized in lysis buffer. After centrifugation (10 min at 16 000 *g*) the supernatants are diluted in Laemmli buffer (50 mMDTT) and the proteins separated by SDS-polyacrylamide gel electrophoresis.

Tyrosine phosphorylation of IRS-1 in rat diaphragms

After incubation with insulin/compounds, the hemidiaphragms (80–100 mg wet weight) are rapidly liberated from the rib cage, rinsed once with homogenization buffer (25 mM Hepes/KOH, pH 7.4, 140 mM NaCl, 10% glycerol, 1 mM EDTA, 1 mM sodium vanadate, 50 mM sodium pyrophosphate, 100 mM NaF, 10 mM glycerol-3-phosphate, 0.2 mM PMSF, 10 µg/ml leupeptin, 10 µg/ml pepstatin, 5 µg/ml antipain, 25 µg/ml aprotinin), frozen in liquid N_2 and then homogenized in 2 ml of ice-cold homogenization buffer in a porcelain mortar on ice. After centrifugation (1 500 *g*, 10 min, 4 °C), the fat-free supernatant is supplemented with TX-100 (0.5% final conc.), incubated (30 min, 4 °C) and centrifuged (18 000 *g*, 20 min, 4 °C). The supernatant is precleared by addition of 50 µl of protein A/G-Sepharose (50 mg/ml of the same buffer) and centrifugation (see above). The supernatant is incubated with rabbit anti-rat carboxy-terminal IRS-1 antibodies (Upstate Biotechnology, Lake Placid, USA; 1 : 500) for 2 h at 4 °C and then with protein A/G-Sepharose (5 mg) for 16 h at 4 °C. The precipitates are collected by centrifugation (12 000 *g*, 2 min), washed three times with 1 ml, each, of homogenization buffer containing 1% TX-100, 250 mM NaCl and lacking glycerol and then twice with homogenization buffer lacking TX-100 and all salt ingredients. The immunoprecipitates are suspended in Laemmli sample buffer, heated (95 °C, 5 min) and centrifuged (12 000 *g*, 2 min). The supernatant is subjected to SDS-PAGE (8%) and immunoblotting with either mouse monoclonal anti-phosphotyrosine antibodies (Biomol, Hamburg, Germany; clone 3B12, 1 : 2 000) or anti-IRS-1 antibodies (see above, 1 : 200) using decoration with [^{125}I]protein A (15 µCi/5 ml; Amersham-Buchler, Freiburg, Germany) and autoradiography according to published procedures. Quantitative evaluation is performed by phosphorimaging (Molecular Dynamics, Storm 840).

Tyrosine phosphorylation of the insulin receptor and IRS-1/2/3 in rat adipocytes

Adipocytes (2.8×10^5) incubated with insulin/-compound are separated from the medium by flotation and lysed in 1 ml of chilled buffer containing 20 mM Tris/HCl (pH 7.4), 150 mM NaCl, 10% glycerol, 2 mM EDTA, 1 mM Na_3VO_4, 50 mM $Na_4P_2O_7$, 10 mM NaF, 10 mM glycerol-3-phosphate, 0.2 mM PMSF, 20 µg/ml leupeptin, 10 µg/ml pepstatin, 25 µg/ml aprotinin by 10 strokes in a loose-fitting Teflon-in-glass homogenizer on ice. The fat-free homogenate, prepared by centrifugation (1500 *g*, 3 min, 15 °C), is supplemented with TX-100 (1% final conc.) and sodium deoxycholate (0.5% final conc.), incubated for 30 min at 4 °C and finally centrifuged (13 000 *g*, 10 min). The soluble fraction is precleared by addition of 100 µl of protein A/G-Sepharose (50 mg/ml of the same buffer) and centrifugation as above. The supernatant is incubated with anti-human insulin receptor β-subunit (from guinea pig; Transduction Laboratories, Lexington, USA, 1 : 200), anti-rat carboxy-terminal IRS-1, anti-rat IRS-2 (from rabbit; Upstate Biotechnology, Lake Placid, USA,

1 : 200) or anti-phosphotyrosine (from rabbit; Biomol, Hamburg, Germany, 1 : 400) or nonimmune rabbit IgG for 4 h at 4 °C and then with protein A/G-Sepharose (5 mg) overnight at 4 °C. The precipitates, collected by centrifugation, are washed three times with 1 ml each of lysis buffer containing 1% TX-100 and lacking glycerol and finally twice with buffer lacking TX-100 and NaCl. The anti-insulin receptor and anti-IgG as well as portions of the anti-IRS-1/2 and anti-phosphotyrosine immunoprecipitates are subjected to SDS-PAGE and immunoblotted using mouse monoclonal anti-phosphotyrosine primary antibodies (1 : 2 000 dilution, Biomol, Hamburg, Germany; clone 3B12) or anti-rat PI 3-kinase antibodies raised against a peptide corresponding to residues 500–519 of p85 protein (from rabbit; 1 : 500, Upstate Biotechnology, Lake Placid, USA) followed by decoration with horseradish peroxidase-coupled secondary antibodies and chemiluminescence detection with the ECL kit (performed according to the instructions from Amersham-Buchler, Braunschweig, Germany), or, alternatively, with [^{125}I]protein A (Amersham-Buchler, Braunschweig, Germany). Quantitative evaluation is performed by phosphorimaging (Molecular Dynamics, Storm 840).

PI 3-kinase activity

Portions of the anti-IRS-1/2 immunoprecipitates (see above) are assayed for PI 3-kinase activity by incubating in 100 µl of 20 mM Tris/HCl (pH 7.0), 50 µM [γ-^{32}P]ATP (5 µCi), 10 mM $MgCl_2$, 2 mM $MnCl_2$, 100 mM NaCl, 2 mM EDTA, 0.5 µM wortmannin (for control incubations, only) containing 10 µg of phosphatidylinositol and 1 µg of phosphatidylserine for 15 min at 22 °C. After addition of 20 µl of 8 M HCl and 160 µl of a 1 : 1 mixture of methanol/chloroform, the extracted phospholipids are resolved by TLC on plates (Silica Gel 60, Merck, Darmstadt) coated with 1% oxalate and developed in chloroform : methanol : water : ammonia (60 : 47 : 11.3 : 3.2, v/v). Radiolabeled PI 3-P (average R_f value of 0.41 under these conditions) is visualized by autoradiography and quantitated by phosphorimage analysis. For calculation of wortmannin-sensitive PI 3-kinase, all values are corrected for PI 3-P radiolabeled in the presence of wortmannin.

Protein kinase B (PKB) activity

Adipocytes (5×10^5) incubated with insulin/compound are washed with KRP-Hepes by flotation and then extracted in 1 ml of 50 mM Hepes/KOH (pH 7.6), 0.2 mM EDTA, 2.2 mM EGTA, 2 mM DTT, 100 mM KCl, 100 mM NaF, 10 mM $Na_4P_2O_7$, 2 mM Na_3VO_4, 15% glycerol, 1% Nonidet P-40, 0.5% deoxycholate, 1 µM microcystin, 10 µg/ml pepstatin, 25 µg/ml leupeptin, 1 µg/ml antipain. 900 µl of cell extract is incubated with 10 µl of PKB antiserum (raised in rabbits by immunization with a synthetic peptide corresponding to residues 465–480 of the human PKB sequence) precoupled to 10 mg of protein A-Sepharose in 100 µl of extraction buffer for 2 h at 4 °C. The immunoprecipitates are collected by centrifugation (12 000 *g*, 2 min, 4 °C), washed twice with 1 ml each of PKB assay buffer (20 mM Mops, pH 7.0, 1 mM EDTA, 1 mM EGTA, 10 mM $Na_4P_2O_7$, 50 mM NaF, 1 mM Na_3VO_4, 10 µg/ml aprotinin, 0.1 mM PMSF, 0.01% Brij35, 5% glycerol) containing 1% Nonidet P-40, 0.5 M NaCl and three times with 1 ml each of assay buffer lacking salt and detergent. The immunoprecipitates are finally resuspended in 45 µl of PKB assay buffer containing 10 mM $MgCl_2$, 1 mM DTT, 2.5 µM cAMP-dependent protein kinase inhibitor peptide (IP_{20}) and either the synthetic peptide, Crosstide (100 µM final conc.), which is based on the sequence surrounding the serine phosphorylation site of GSK-3 (Ser21 of GSK-3α and Ser9 of GSK-3β) or alternatively, histone 2B (150 µg/ml). The assay is initiated by the addition of 5 µl of [γ-^{32}P]ATP (50 µM, 4 µCi) and terminated after incubation for 15 min at 30 °C by placing the test tubes on ice. For determination of Crosstide phosphorylation, the 10-µl portions of the samples are adsorbed on p81 phosphocellulose paper and extensively washed as described below for the MBPK assay. The radioactivity associated with the paper is counted by liquid scintillation counting. For determination of histone 2B phosphorylation, the samples are separated on a 12% SDS-PAGE. The autoradiogram is quantitated by densitometry. Exposure times are chosen which guaranteed that the intensity of the bands is linearly related to the quantity of protein contained in the bands.

Protein kinase B (PKB) phosphorylation using immunoblotting

For demonstration of phosphorylation by a size shift in SDS-PAGE analysis, a fat-free homogenate is prepared from adipocytes treated with insulin/compound, supplemented with TX-100 (1% final conc.) and sodium deoxycholate (0.5% final conc.), incubated for 30 min at 4 °C and finally centrifuged (13 000 *g*, 10 min). The supernatant (100 µg protein) is immunoprecipitated with 5 µg of rabbit anti-PKB antibodies coupled to protein G-Sepharose beads. Immune pellets are washed three times with 1 ml each of immunoprecipitation buffer (20 mM Tris/HCl [pH 7.4], 5 mM EDTA, 100 mM NaF, 10 mM $Na_4P_2O_7$, 2 mM Na_3VO_4, 1% TX-100) and three times with 1 ml each of 50 mM Tris/HCl, pH 7.4, 10 mM $MgCl_2$, 1 mM DTT. The final immune pellets are suspended in Laemmli sample buffer, heated (95 °C, 2 min) and centrifuged (12 000 *g*, 2 min), and proteins contained in the supernatant separated on SDS-PAGE. PKB is visualized by immunoblotting using a polyclonal anti-rat PKB antibodies from sheep directed

against the N-terminal part of the protein (Santa Cruz Biotechnology, Santa Cruz, USA) and [^{125}I]protein A followed by autoradiography.

Protein kinase B phosphorylation using phosphate incorporation

For demonstration of phosphorylation by $^{32}P_i$ incorporation, isolated rat adipocytes are incubated with [^{32}P]phosphate and then with insulin/compound. A fat-free homogenate is prepared (see above) and centrifuged (150 000 *g*, 60 min, 4 °C). 1-ml portions of the supernatant are immunoprecipitated with 10 µg anti-PKB antibodies coupled to protein G-Sepharose beads. The immunoprecipitates are washed and finally suspended in 50 µl of Laemmli sample buffer (2% SDS), heated (95 °C, 2 min) and centrifuged (12 000 *g*, 2 min). One half of each supernatant is separated by SDS-PAGE and radiolabeled PKB is visualized by phosphorimaging. The other half is diluted with 1 ml of immunoprecipitation buffer containing 10 µg/ml aprotinin, 20 µg/ml pepstatin, 10 µg/ml leupeptin, 1 mM PMSF and centrifuged again (12 000 *g*, 2 min). The supernatant is supplemented with 20 µg of a kit containing four different monoclonal anti-phosphoserine antibodies (Biomol, Hamburg, Germany; clones 1C8, 4A3, 4A9, 4H4) and the monoclonal anti-phosphothreonine antibodies (clone 1E11). After incubation (4 h, 4 °C), the antibodies complexes are precipitates during a 2-h incubation with 50 µl of 50 mg protein A-Sepharose per ml of 50 mM Hepes/KOH (pH 7.4), 0.1% TX-100. The collected immunoprecipitates (12 000 *g*, 2 min) are washed three times with 1 ml each of 50 mM Hepes/KOH (pH 7.4), 150 mM NaCl, 100 mM NaF, 0.2 mM Na_3VO_4, 0.1% SDS, 1% TX-100 and finally twice with buffer lacking TX-100. Phosphoproteins are eluted from the washed precipitates by incubation with 500 µl of 50 mM Hepes/KOH (pH 7.4) containing 50 mM p-nitrophenylphosphate for 30 min at 4 °C. The supernatants obtained by centrifugation are precipitated with TCA. The acetone-washed pellets are suspended in 50 µl of Laemmli sample buffer and analyzed by SDS-PAGE and phosphorimaging of the gel.

PKB serine phosphorylation

One hundred-fifty–200 µg of soluble adipocyte fraction (about 0.5 ml) is supplemented with the same volume of immunoprecipitation buffer (2% NP-40, 25 mM HEPES/KOH pH 7.4, 50 mM NaF, 1 mM Na_3VO_4, 50 mM $Na_4P_2O_7$, 50 mM NaF, 5 mM glycerol-3-phosphate, 1 mM PMSF, 20 µg/ml leupeptin, 10 µg/ml pepstatin, 25 µg/ml aprotinin) and then incubated on ice for 1 h. After addition of 35 µg of anti-PKB antibody and further incubation for 4 h, the mixtures are incubated with 50 µl of protein A-Sepharose (50 mg/ml) overnight with end-over-end rotation at 4 °C. The collected immunoprecipitates (13 000 *g*, 2 min) are washed two times with immunoprecipitation buffer containing 140 mM NaCl, two times with the same buffer lacking NP-40 and finally with immunoprecipitation buffer lacking NP-40. The immunoprecipitated proteins are dissolved in 50 µl of 2-fold Laemmli buffer, separated by SDS-PAGE and immunoblotted with anti-phospho-PKB antibody (1 : 400). Quantitative evaluation is performed by phosphorimaging.

Glycogen synthase-3 (GSK-3) activity

Adipocytes (5×10^5) incubated with insulin/compound are washed with KRP-Hepes by flotation and homogenized in 2 ml of 10 mM Tris/HCl (pH 7.4), 50 mM NaCl, 30 mM $Na_4P_2O_7$, 10 mM glycerol-3-phosphate, 50 mM NaF, 0.1 µM microcystin, 200 µM Na_3VO_4, 0.5 µg/ml leupeptin, 2 µg/ml aprotinin, 1 µg/ml pepstatin, 1 mM PMSF by 10 strokes in a Teflon-in-glass homogenizer. A clear and fat-free cytosol is prepared by three sequential centrifugations at 1 000 *g* for 2 min and twice at 20 000 *g* for 15 min at 4 °C. 100 µl of cytosol is incubated with 5 µl of GSK-3α antiserum (raised in sheep by immunization with a synthetic peptide corresponding to amino acids 471–483 of rat GSK-3α coupled to BSA) for 2 h at 4 °C. The immunocomplexes are precipitated with 2 mg of anti-sheep IgG coupled to agarose in 50 µl of homogenization buffer (under rotation for 2 h at 4 °C) after which the beads are collected by centrifugation (12 000 *g*, 2 min), washed once with 1 ml of 100 mM Tris/HCl (pH 7.4) containing 0.2% Nonidet P-40, 0.5 M NaCl, 0.5 M LiCl, once with 10 mM Tris/HCl and twice with GSK-3 assay buffer (20 mM Hepes/KOH, pH 7.4, 10 mM $MgCl_2$, 1 mM DTT, 10 mM NaF, 10 mM $Na_4P_2O_7$). The kinase reaction is started by the addition of 50 µl of assay buffer containing 125 µM [γ-^{32}P]ATP (8 µCi), 300 µg/ml P-GS1 peptide and 10 µg/ml heparin to the washed beads. After incubation for 15 min at 30 °C, 10-µl aliquots of the supernatant (obtained by centrifugation as above) are spotted on p81 phosphocellulose papers (1 × 1 cm), which are then washed four times in 75 mM orthophosphoric acid. The radioactivity associated with the papers is measured by liquid scintillation counting. In some experiments recombinant PP2AI (1 µg, Calbiochem, Bad Soden, Germany) is used as substrate instead of P-GS1 or autophosphorylation of GSK-3 is assayed in the absence of exogenous substrate. In these cases the kinase reaction (conditions as above) is terminated by rapid centrifugation (12 000 *g*, 1 min, 4 °C) and separation of the supernatant from the immune pellet. The precipitated (10% TCA for 1 h on ice, 15 000 *g*, 15 min 4 °C) supernatant (for phosphorylated PP2AI) or immune pellet (for phosphorylated GSK-3) is suspended in 50 µl of 2× Laemmli sample buffer, heated (95 °C, 5 min) and

centrifuged (12 000 *g*, 2 min). The supernatants are run on SDS-PAGE and phosphorylated PP2AI and GSK-3 are visualized by autoradiography and quantitated by phosphorimaging.

Glycogen synthase (GS) phosphorylation

Adipocytes are washed twice by flotation in low phosphate medium composed of KRP-HEPES modified to contain 50 µM KH_2PO_4, 2 mM glucose, 2% BSA and then suspended in the same medium (7.5×10^5 cells/ml). 5-ml portions are incubated with [^{32}P]phosphate (0.2 mCi/ml) for 2 h prior to addition of insulin/compound and of 0.5 ml of 50 mM glucose. After incubation for 20 min at 37 °C, the cells are floated by centrifugation (1 000 *g*, 1 min) and the infranatant is aspirated. The cells are suspended in 1.5 ml of cold 50 mM Tris/HCl (pH 7.6), 100 mM KF, 20 mM glycerol-3-phosphate, 10 mM $K_4P_2O_7$, 10 mM EDTA, 1 mM benzamidine, 0.2 mM PMSF and homogenized by 10 strokes using a tight-fitting Teflon homogenizer in the same Eppendorf cup. The homogenate is centrifuged (18 000 *g*, 30 min, 4 °C). 1 ml of the post-mitochondrial supernatant is incubated with 10 µl of GS antiserum raised in guinea pigs by immunization with purified GS from rabbit skeletal muscle [29]. After incubation for 2 h at 4 °C, 50 µl of protein A-Sepharose (10% w/v in TES, see below) is added and the incubation continued overnight. The immunoprecipitates are collected by centrifugation (12 000 *g*, 2 min, 4 °C) and washed twice with 1 ml each of TES (50 mM Tris/HCl, pH 7.4, 1 mM EDTA, 150 mM NaCl) containing 1% TX-100, twice with TES and finally once with 50 mM Tris/HCl (pH 7.4). The beads are suspended in 25 µl of 2xLaemmli sample buffer, heated (95 °C, 5 min) and centrifuged. The supernatant is subjected to SDS-PAGE (8% resolving gel). The amount of [^{32}P] contained in GS is determined by excising the corresponding gel pieces and measuring their radioactivity by liquid scintillation counting.

Glycogen synthase (GS) activity

GS activity is assayed by measuring the incorporation of D-[^{14}C]glucose from UDP-[^{14}C]glucose into glycogen. 10 ml of adipocytes in KRB (about 3×10^5 cells) are incubated with insulin/compound in a shaking water bath under an atmosphere of 5% CO_2 for 30 min at 37 °C. Washed cells are frozen in liquid N_2 and then homogenized in 0.5 ml of 10 mM Tris/HCl (pH 7.5) containing 10 mM EDTA, 150 mM KF, 5 mM DTT by ten strokes in a Teflon-in-glass homogenizer on ice. The homogenate is centrifuged (5 500 *g*, 2 min, 10 °C). The infranatant below the lipid layer is cleared from residual lipids by two additional centrifugations and served as source for GS. The reaction is started by adding 30 µl of the homogenate to 60 µl of a reaction mixture (prewarmed at 30 °C) containing 33 mM Tris/HCl (pH 7.8), 0.2 mM UDP-[U-^{14}C]glucose (4 µCi), 6.7 mg glycogen, 150 mM KF and 0.1 mM/10 mM glucose-6-P. After incubation for 20 min at 30 °C, the reaction is terminated by addition of 2 ml of 66% ethanol, 10 mM LiBr (–20 °C), rapid mixing and filtration over pre-wetted Whatman GF/C glass-fiber discs. The filters are washed 5 times with 5 ml of 66% ethanol each at 25 °C, dried and measured for radioactivity. Blank values determined by adding the homogenate to tubes containing the complete reaction mixture plus ice-cold ethanol are subtracted from the total values each. The fractional velocity is calculated as the ratio of GS activity in the presence of 0.1 mM and 10 mM glucose-6-P. Measurements of GS activity in homogenates from adipocytes which had been incubated in the presence of 0.1 mM glucose instead of 5 mM glucose (the concentration routinely used) did not reveal significant differences with respect to both the activity ratio and the effect of insulin. Presumably, the dilution of the limited amount of glucose-6-P, which accumulates during incubation with 5 mM extracellular glucose, during the subsequent preparation of the homogenate and the GS assay is high enough to prevent allosteric activation of GS. According to our experience incubation of the isolated rat adipocytes in the presence of 5 mM glucose has a positive impact on their viability, in general, and insulin sensitivity (glucose transport, glycogen synthesis), in particular.

Myelin basic protein kinase (MBPK) activity

Adipocytes (2.5×10^5) incubated with insulin/compound are quickly washed with ice-cold KRP-HEPES by flotation and then homogenized in 200 µl of 20 mM HEPES/KOH (pH 7.2), 20 mM EGTA, 15 mM $MgCl_2$, 1 mM DTT, 40 mM p-nitrophenylphosphat, 50 mM glycerol-3-phosphate, 5 mM $Na_4P_2O_7$, 20 mM NaF, 0.2 mM PMSF, 25 µg/ml leupeptin, 25 µg/ml aprotinin by 10 strokes of a rotating tight-fitting Teflon pestle in the same Eppendorf cup at 4 °C. The homogenate is centrifuged (2 000 *g*, 5 min, 4 °C). The infranatant below the fat cake is removed and centrifuged (30 000 *g*, 5 min, 4 °C). After careful removal of the residual fat layer, the supernatant is used for measurement of MBPK by combining 5-µl portions (about 10 µg protein) with 45 µl of kinase buffer (50 mM glycerol-3-phosphate, pH 7.3, 5 mM $Na_4P_2O_7$, 10 mM NaF, 0.5 mM EDTA, 15 mM $MgCl_2$, 2 mM DTT, 4.4 mM protein kinase inhibitor peptide) containing 0.5 mg/ml myelin basic protein (MBP). The kinase reaction is initiated by the addition of 5 µl of 1 mM [γ-^{32}P]ATP (700 mCi/mmol). Following a 10-min incubation at 30 °C, reactions are terminated by spotting 10 µl of the reaction mixture onto p81 phosphocellulose papers (Whatman), which are immediately immersed in

0.85% orthophosphoric acid under stirring and washed once in 95% ethanol for 5 min. Papers are dried and ^{32}P is quantitated by liquid scintillation counting.

Mitogen-activated protein kinase (MAPK) activity

Adipocytes (5×10^5) incubated with insulin/compound are washed with KRP-HEPES by flotation and then lysed in 1 ml of 50 mM HEPES/KOH (pH 7.2), 100 mM NaCl, 2 mM EDTA, 1% Nonidet P-40, 0.5 mM Na_3VO_4, 40 mM p-nitrophenylphosphate, 10 mM glycerol-3-phosphate, 10 mM NaF, 0.2 mM PMSF, 25 µg/ml leupeptin, 25 µg/ml aprotinin by incubation for 30 min on ice and vigorous vortexing three times for 10 s at 10-min intervals. Lysates are cleared by centrifugation (12 000 *g*, 10 min, 4 °C). The infranatant below the fat cake is removed using a syringe, recentrifuged and used for measurement of MAPK by addition of 250-µl portions to 250 µl of protein A Sepharose (50 mg/ml of 50 mM Hepes/KOH, pH 7.2, 100 mM NaCl), which had been precoupled with 10 µl of rabbit anti-p42MAPK antiserum (raised against rat p42MAPK) and 5 µl of rabbit anti-p44MAPK antiserum (raised against the C-terminal 14 amino acids of rat p44MAPK), and incubation for 2 h at 4 °C. The beads are collected by centrifugation (12 000 *g*, 2 min, 4 °C), washed three times with 1 ml each of lysis buffer and three times with 1 ml each of 10 mM HEPES/KOH (pH 7.4), 10 mM $MgCl_2$ and then resuspended in 20 µl of the same buffer containing 2 mg MBP per ml. The kinase assay is initiated by the addition of 20 µl of 40 mM HEPES/KOH (pH 7.4), 200 µM [γ-^{32}P]ATP (25 mCi/mmol), 40 mM $MgCl_2$, 20 mM NaF, 0.2 mM Na_3VO_4. After incubation for 30 min at 30 °C, the reaction is terminated by the addition of 20 µl of 4× Laemmli sample buffer. Samples are subjected to SDS-PAGE using a 15% resolving gel. The gel is dried and the radiolabeled MBP is quantified by phosphorimaging.

Preparation of detergent-insoluble complexes

Many components of the insulin signaling cascade (e.g. insulin receptor) are localized in special areas of the plasma membrane of adipocytes and myocytes, the so-called caveolae (Rothberg et al. 1992; Anderson 1993a and b, Kurzchalia et al. 1994; Parton 1996; Anderson 1998). Caveolae serve as special signaling compartment keeping the corresponding components in a basal inactive state but competent for future activation (Lisanti et al. 1994; Couet et al. 1997; Schlegel et al. 1998; Okamoto et al. 1998). Thus, the analysis of insulin signaling processes may be facilitated by using caveolae instead of total cell extracts. Caveolae can be isolated simply as detergent-insoluble complexes since they resist solubilization by non-ionic detergents in the cold due to their high content of glyco(sphingo)lipids and cholesterol (Brown and Rose 1992; Brown and London 1997). Furthermore, certain sulfonylureas seem to accumulate at caveolar plasma membrane regions of adipose cells due to spontaneous intercalation between glycosyl-phosphatidylinositol (GPI) lipids. Thereby a non-receptor tyrosine kinase attached to the cytoplasmic face of caveolae and the GPI-specific phospholipase is activated which then leads to phosphorylation of IRS-1/2 initiating metabolic insulin signaling (see above; Müller and Geisen 1996; Müller and Frick 1999; Müller 2000).

For preparation of detergent-insoluble complexes, 9×10^7 adipocytes are lysed on ice in 2 ml of isotonic lysis solution (25 mM Tris/HCl pH 7.4; 140 mM NaCl, 1% NP-40, 30 mM sodium pyrophosphate, 50 mM NaF, 1 mM Na_3VO_4, 1 mM PMSF, 2 µM leupeptin, 5 µM pepstatin, 2 mM EDTA, 5 mM iodoacetamide by 10 strokes of a Dounce homogenizer and five 10-s bursts of a bath sonicator. After removal of nuclei by centrifugation (3 000 *g*, 3 min), the supernatant is mixed on ice 1 : 1 with 80% sucrose in lysis solution. The sample (1 ml of detergent cell lysate in 40% sucrose) is overlaid with 5 ml of 30% sucrose in lysis solution followed by 5 ml of 5% sucrose in lysis solution and finally by 1 ml of lysis solution lacking sucrose. After centrifugation (20 h, 40 000 rpm, 4 °C, Beckman SW41 rotor), the gradient is fractionated into 12 fractions of identical volume. A light-scattering band is confined to fraction 2 and 3 (from the top of the gradient) corresponding to the 5–30% sucrose interface.

K.3.2.13 Effect of insulin on glycosyl-phosphatidylinositol-specific phospholipase C

PURPOSE AND RATIONALE

A low molecular weight substance was identified that was released from hepatic plasma membranes in response to insulin which may be a second messenger to insulin (Saltiel and Cuatrecasas 1986). The generation of this substance by insulin can be reproduced by addition of a phosphatidylinositol-specific phospholipase C. This enzyme is known to selectively hydrolyze phosphatidylinositol and release from membranes several proteins that are covalently linked to a glycosyl-phosphatidylinositol (GPI) anchor (Low and Saltiel 1988; Low 1989; Ferguson and Williams 1988; Cross 1990). In addition to the released diacylglycerol, phosphoinositolglycans (PIG) are therefore considered as precursor for an insulin specific second messenger (Larner 1988; Romero et al. 1988; Saltiel 1990).

During the past two decades a large body of evidence has accumulated that PIG molecules can exert some insulin-mimetic activity on glucose and lipid metabolism on insulin target cells *in vitro*. They have been demonstrated to stimulate glucose transport, glycolysis, glycogen synthesis, lipid synthesis and to inhibit glucagon-induced gluconeogenesis and isoproterenol-induced lipolysis in isolated or cultured muscle, fat and liver cells to a partial degree (Saltiel 1990; Romero and Larner 1993; Varela-Nieto et al. 1996; Jones and Varela-Nieto 1998). The molecular basis of these PIG actions seems to rely on the appropriate modulation of the activity of the corresponding key metabolic and

regulatory enzymes/proteins, like pyruvate dehydrogenase, glycogen synthase, glycerol-3-phosphate acyltransferase, glycogen phosphorylase, protein kinase A, cGMP-inhibitable cAMP-specific phosphodiesterase, protein phosphatase 1 and 2C (Varela-Nieto et al. 1996; Jones and Varela-Nieto 1998). This partial insulin-mimetic metabolic activity together with the mechanistic findings that (I) some metabolic insulin actions can be inhibited by anti-PIG antibodies in intact BC_3H-1 myocytes (Romero et al. 1990), (II) insulin stimulation of glycogen synthesis is blocked in mutant K562 erythroleukemia cells which are totally deficient in GPI synthesis (Lazer et al. 1994), (III) isolated PIG can exert acute hypoglycemic activity in normal and streptozotocin diabetic rats (Fonteles et al. Asplin et al. 1993), (IV) PIG can be isolated from normal subjects and in reduced amounts from NIDDM patients (Shashkin et al. 1997), suggests but does not prove the involvement of GPI structures, GPI cleavage or PIG molecules in metabolic insulin signalling. The partial insulin-mimetic activity of PIG structures in cellular and cell-free assay systems (Farese 1990; Gaulton and Pratt 1994) in combination with the possibility of the generation of PIG molecules from GPI structures by regulated lipolytic or combined lipolytic/proteolytic cleavages (Müller et al. 1993 and 1994; Romero et al. 1988; Movahedi and Hooper 1997) prompted P. Cuatrecasas, J. Larner, M. G. Low, J. Mato, and A. Saltiel in the late 80s to assign PIG molecules a function as soluble mediators of metabolic insulin action (Low and Saltiel 1988; Romero et al. 1988; Larner 1987; Saltiel et al. 1988; Mato 1989). According to this hypothesis, PIG molecules are generated in response to insulin through lipolytic cleavage of free GPI lipids and/or GPI proteins by a phospholipase/protease at the extracellular face of the plasma membrane of insulin-sensitive cells and are then transported into the cytosol, where they directly affect key metabolic enzymes and/or their regulatory proteins in an allosteric fashion.

In fact, it has been demonstrated that insulin stimulates a GPI-specific phospholipase C in cultured and isolated adipocytes as well as muscle cells in a concentration-dependent and rapid fashion. The GPI-PLC cleaves glycosyl-phosphatidylinositol (GPI) lipids, which exist either in free form or as membrane anchors covalently bound to GPI-anchored proteins (GPI proteins), cell surface ectoproteins of eucaryotic cells, embedded in the outer leaflet of the plasma membrane by the covalently linked GPI moiety (Nosjean et al. 1997), such as the cAMP-binding ectoprotein, Gce1, of rat and mouse adipocytes (Müller et al. 1994). Many cell types including adipose and muscle cells harbor an endogenous GPI-specific PLC (GPI-PLC) which upon activation causes the release of the protein moiety of GPI proteins from the cell surface into the cellular environment due to lipolytic cleavage of its GPI anchor (Saltiel et al. 1986; Romero et al. 1988). In isolated and cultured adipocytes certain GPI proteins, such as lipoprotein lipase, are released from the cell surface into the incubation medium by the action of an endogenous GPI-PLC which is activated by both insulin and Amaryl (Romero et al. 1988; Müller et al. 1993 and 1994; Movahedi 1997).

PROCEDURE

Glycosyl-phosphatidylinositol-specific phospholipase C is assayed as the conversion of glycosyl-phosphatidylinositol-anchored plasma membrane protein lipoprotein lipase (LPL) from its amphiphilic version (containing the intact glycosyl-phosphatidylinositol anchor) into its hydrophilic version (containing the lipolytically cleaved glycosyl-phosphatidylinositol anchor).

Metabolic labeling of rat adipocytes

Adipocytes are cultured, as described by Marshall et al. (1984). After collagenase digestion, the cells (3×10^7 cells/ml) are washed three times with 4 ml/ml cell suspension of Dulbecco's modified Eagle's medium (DMEM) containing 1% BSA, 5% fetal bovine serum, 100 units of penicillin/ml, 100 µg of streptomycin/ml and 1 mg of Fungizone/ml and finally suspended in the same buffer supplemented with 5 mM glucose at $3–5 \times 10^5$ cells/ml. The radiolabelling is performed by the addition of 250 µCi of myo-[^{14}C]inositol or 400 µCi of [^{14}C]stearic acid to 20 ml of cell suspension and incubation for 14 h or 1 h, respectively. Subsequently, the cells were concentrated by flotation (1 000 *g*, 2 min, 25 °C), washed three times with 20 ml of DMEM, 0.5% BSA, 1 mM myo-inositol or 10 mM stearic acid per ml of packed cells and finally suspended in buffer for preparation of plasma membranes. Labeling with [^{35}S]methionine is performed according to Lawrence et al. (1986) with following modifications: Adipocytes are washed and suspended in methionine-free DMEM containing the same ingredients as indicated above. After addition of [^{35}S]methionine (1 mCi/10 ml of cell suspension, approximately 1 000 Ci/mmol), the cells are incubated for 1 h at 37 °C, then floated by centrifugation (1 000 *g*, 2 min) and washed twice in DMEM containing 10 mM unlabeled methionine.

The cells are incubated with standard insulin or test compounds at various concentrations for 30 min at 37 °C. Subsequently, the cells are concentrated by flotation (1 000 *g*, 2 min, 25 °C), washed three times with DMEM, 0.5% BSA, 1 mM *myo*-inositol per ml of packed cells and finally suspended in buffer for preparation of plasma membranes. Plasma membranes are isolated and subjected to partitioning between a TX-114 phase and aqueous phase (Bordier 1981; Pryde and

Phillips 1986). Metabolically labeled lipoprotein lipase (LPL) is analyzed in the aqueous phase by immunoprecipitation with anti-LPL antibodies and fluorography (Müller et al. 1993).

Assay for insulin-specific phospholipase

(Müller and Bandlow 1991; Müller et al. 1993)

Adipocytes are photoaffinity-labeled with 8-N_3-[^{32}P]cAMP to specifically label the regulatory subunit of a cAMP-dependent ectoprotein kinase of the plasma membrane.

The labeling is performed in 24-well culture plates. Cells are washed twice with 2 ml of DMEM containing 1% BSA, 1 mM EDTA, 100 mM NaCl, without glucose, serum and antibiotics. To each monolayer, 10 µCi 8-N_3-[^{32}P]cAMP (0.5 nM) or 2 µCi 8-N_3-[^{3}H]cAMP in 0.5 ml of phosphate-buffered saline (250 mM sucrose, 1 mM EDTA, 50 mM KCl, 10 mM $MgCl_2$, 2 mM $MnCl_2$, 1 mM IBMX, 1 mM dithiothreitol, 1 mM AMP, 0.1 mM PMSF) is added. The cells are incubated for 30 min at 4 °C and then irradiated with UV light at 254 nm (8 000 µW/cm^2) at a distance of 2 cm for 2 min. Subsequently, the cells are washed twice with 2 ml of the same buffer containing 1 mM unlabeled cAMP instead of 8-N_3-[^{32}P]cAMP and then for incubation with the test compound supplemented with 1 ml of high glucose DMEM, 10% FCS, 0.5% BSA 50 units/ml penicillin, 50 µg/ml streptomycin sulfate.

The cells are separated from the medium by centrifugation on silicon oil. The cells as well as the medium are subjected to TX-114 partitioning. The detergent phase is separated from the aqueous phase by centrifugation. The aqueous phases are removed, dried and subjected to SDS gel electrophoresis and autoradiography. The labeled bands are excised and counted for radiography.

The assay measures the insulin-stimulated release of a glycosyl-phosphatidylinositol anchored plasma membrane protein into the medium. It has been proposed that phosphoinositolglycan structures derived from glycolipids or glycosyl-phosphatidylinositol modified plasma membrane proteins (e.g. alkaline phosphatase) by insulin-dependent lipolytic cleavage (phospholipase C) act as second messengers for a variety of insulin-dependent metabolic reactions. Therefore, the insulin-stimulated phospholipase determined by this assay may reflect an early step in the signal transduction cascade.

EVALUATION

Concentration-response curves are established using various concentrations of standard (human insulin) and the test compounds, e.g. sulfonylureas, allowing calculation of ED_{50} values and potency ratios.

K.3.2.14
Preparation of caveolae and detergent-insoluble glycolipid-enriched raft domains (DIGs)

PURPOSE AND RATIONALE

Caveolae are flask- or bulb-shaped invaginations (50 to 100 nm diameter) of the plasma membrane abundantly expressed in terminally differentiated cells, such as endothelial, epithelial, muscle and adipose cells which play important roles in intracellular transport and signaling processes (Anderson 1998; Engelman et al. 1998; Okamoto et al. 1998; Parton 1996). They are characterized by a unique lipid composition consisting of cholesterol, glycosphingolipids and glycosyl-phosphatidylinositol (GPI). These detergent-resistant (in the presence of 1% Triton X-100 at 4 °C for 1 h) liquid-ordered domains purified from mammalian cells and tissues (by means of sucrose gradient centrifugation due to low buoyant density) are referred to as detergent-insoluble glycolipid-enriched rafts (DIGs) (Brown and London 1997 and 1998) and have been demonstrated by several independent methods to exist in living cells (Harder et al. 1998; Rietveld and Simons 1998). Caveolins, 21- to 25-kDa integral membrane proteins with three isoforms (Glenney 1992; Rothberg 1992; Parton 1996; Scherer et al. 1997), are the structural and marker proteins of caveolae and are dramatically enriched in DIGs. DIGs lacking caveolin may represent the biogenetic precursors for caveolae (precaveolae) and DIGs containing caveolin can be considered as the biochemical correlate of caveolae (Okamoto et al. 1998; Schlegel et al. 1999).

Caveolae and DIGs harbor a number of components of various intracellular signal transduction pathways including G protein-coupled receptors, heterotrimeric G proteins, receptor tyrosine kinases (Src family tyrosine kinases), components of the Ras-mitogen-activated protein kinase (MAPK) pathway, protein kinase C isoforms, and endothelial nitric oxide synthase (eNOS) (Schlegel et al. 1999; Shaul and Anderson 1998; Smart et al. 1999). As a consequence, they may function as locations for the direct physical interaction of signaling elements where the cross-talk between the corresponding signaling pathways takes place (Okamoto et al. 1998). Lisanti and coworkers demonstrated direct binding of a common domain within caveolin, the caveolin

scaffolding domain (CSD) to the corresponding caveolin binding domain (CBD) of a variety of signaling proteins which are thereby kept in a basal inactive state, however competent for future activation (Couet et al. 1997a; Ju et al. 1997; Mineo et al. 1998; Moffett et al. 2000). The inhibitory interaction between caveolin and signaling molecules should be accessible for modulation in response to extracellular/intracellular signals. Activation of signaling pathways engaging CBD-harboring signaling molecules requires their relief from binding to/inhibition by caveolin both in short and long term. The molecular mechanism for the long term response may be based on the regulation of caveolin gene expression. Consistent with this hypothesis, caveolin-1 mRNA and protein expression as well as the number of caveolae are dramatically diminished upon cell transformation by activated oncogenes, such as H-Ras (Koleske et al. 1995). Some putative physiological mechanisms for short term regulation of the caveolin-signaling component interaction have been described (Feron et al. 1996; Garcia-Cardena et al. 1997), among them the coordination of the interaction of receptors and a variety of downstream signal transducing molecules that localize to the plasma membrane following cell stimulation (Müller and Frick 1999; Okamoto et al. 1998; Smart et al. 1999). Agonist stimulation has been demonstrated to result in redistribution of receptors for contractile agonists (e.g. bradykinin, de Weerd et al. 1997; acetylcholine, Feron et al. 1997), hormones (e.g. insulin, Gustavsson et al. 1999; angiotensin II, Ishizaka et al. 1998) and growth factors (e.g. EGF, Couet et al. 1997) as well as of downstream elements (e.g. PKCα, Mineo et al. 1998; and rhoA, Taggert et al. 2000) to caveolin-containing subcellular fractions. A pathway for insulin activation of glucose transport has been identified in insulin-sensitive cells which involves DIGs/caveolae and the in- and out- movement of signaling proteins (Baumann et al. 2000; Ribon et al. 1998). Thus, DIGs/caveolae seem to harbor signaling components for insulin-stimulated glucose transport and regulate their activity by interaction with caveolin and additional caveolar structural proteins that may serve as scaffolding proteins for concentrating and activating/inhibiting specific insulin signaling components.

However, small molecules, which manage to modulate the interaction of caveolin/caveolae with CBD-containing signaling proteins and, in consequence, the activation state of the corresponding downstream signaling cascades have not been described so far with one important exception (Scherer and Scherer 1997). A study by Müller et al. (2001) demonstrated that in isolated rat adipocytes, the non-receptor tyrosine kinases, $pp59^{Lyn}$ and $pp125^{Fak}$, are down-regulated by localization in caveolae/binding to caveolin and upregulated by release from caveolae/dissociation from caveolin in response to phosphoinositolglycans (PIG), degradation products of GPI membrane protein anchors (Jones and Varela-Nieto 1999; Müller and Frick 1999), and the sulfonylu-rea drug, glimepiride (Langtry and Balfour 1998). The short term redistribution of these kinases from caveolae/DIGs induces insulin-independent activation of the me-tabolic insulin signaling cascade. These findings suggest that the concentration of signaling proteins at cave-olae/caveolin may be regulated by diverse physiological and pharmacological stimuli thereby integrating cross-talk to various signal transduction pathways.

PROCEDURE

For studying signal transduction processes which involve caveolae, these structures are isolated as DIGs by biochemical methods (carbonate or detergent extraction) from primary or cultured differentiated cells, such as muscle and fat cells, after incubation with external stimuli. DIGs can be prepared either directly from total cells, or total cell lysates or (preferably) isolated (purified) plasma membranes. The use of DIGs from total cells or lysates may obscure subtle changes in signaling since the (considerable) fraction of DIGs present in membranes of the Golgi apparatus (where their biogenesis takes place) may respond differently (or not at all) toward external stimuli compared to the plasma membrane DIGs. Subsequent analysis for the presence in/cofractionation with caveolae, direct interaction with caveolin and changes in activity of signaling proteins in response to the external stimuli requires the methods of enrichment/purification of DIGs, photoaffinity labeling (of GPI proteins), coimmunoprecipitation with caveolin (of signaling proteins), immunoblotting (of signaling proteins) and immune complex kinase assays (in case of kinase activity of signaling proteins).

Preparation of DIGs from total cells

Carbonate method

Washed adipocytes (0.5×10^7 cells) are suspended in 2 ml of sodium carbonate buffer (0.5 M Na_2CO_3, pH 11) containing protease inhibitors and homogenized sequentially using a loosely fitting Dounce homogenizer (10 strokes) and a sonicator (3×20 s bursts). The homogenate (2 ml) is then adjusted to 45% sucrose by addition of 2 ml of 90% sucrose, 50 mM MES/KOH (pH 6.5), 150 mM NaCl (final pH of the mixture 10.2). A discontinuous sucrose gradient is formed by overlaying this solution with 4 ml of 35% sucrose and 4 ml of 5% sucrose, both in the same buffer containing 0.25 M Na_2CO_3. After centrifugation (see above), 0.85-ml gradient fractions are collected to yield a total of 14 fractions. The individual gradient fractions are pooled into

DIGs (Fr. 4–7) and non-DIG areas (Fr. 10–14). The membranes from each pooled gradient fractions obtained by either method are diluted 2- to 3-fold with 25 mM MES (pH 6.5), 150 mM NaCl, 1% TX-100, collected by centrifugation (50 000 *g*, 30 min, 4 °C) and resuspended in non-dissociating buffer (10 mM Tris/HCl, pH 7.4, 150 mM NaCl, 1% Nonidet P-40, 5 mM EDTA, 0.5 mM EGTA, 1 mM sodium orthovanadate, 50 mM NaF and protease inhibitors) or dissociating buffer (= non-dissociating buffer supplemented with 60 mM β-octylthioglucoside, 0.3% deoxycholate) as indicated, incubated (1 h, on ice) and used for (co)immunoprecipitation, immunoblotting or photoaffinity labeling.

Detergent method

Washed adipocytes (3.5×10^6) are suspended in 1.5 ml of lysis buffer (25 mM MES, pH 6.0, 150 mM NaCl, 5 mM EDTA, 1% TX-100, 0.2 mM sodium orthovanadate, and protease inhibitors) and incubated for 20 min on ice. The cells are lysed with 10 strokes in a manual Teflon-in-glass homogenizer over the course of 1 h at 4 °C. The lysate is centrifuged (1 300 *g*, 5 min) to pellet unbroken cells, cellular debris, nuclei and large unsoluble material. One ml of the postnuclear supernatant is subjected to sucrose gradient centrifugation by mixing with an equal volume of 85% sucrose, 25 mM MES (pH 6.0), 150 mM NaCl, 5 mM EDTA at the bottom of a 12-ml centrifuge tube which is overlayed with 5.5 ml of 35% sucrose, and then 3.5 ml of 5% sucrose in the same medium. After centrifugation (230 000 *g*, Beckman SW41 rotor, 18 h, 4 °C), 0.9-ml fractions are collected from top to bottom, and termed fraction Fr. 1, 2, 3, etc. The bottom fraction is Fr. 12. Fr. 5 appears as a white, light-scattering band under illumination located at 5–7% sucrose at the 35-% sucrose interface. The DIGs contained in Fr. 5 are pelleted by dilution of the sucrose with 5 volumes of 50 mM HEPES/KOH con-taining protease inhibitors and centrifugation (200 000 *g*, 2 h).

Preparation of plasma membranes appropriate for subsequent generation of DIGs

Basal or stimulated rat adipocytes (5×10^7 cells) are washed once with PBS containing 2 mM sodium pyruvate by flotation (200 *g*, 2 min) and aspiration of the infranatant and immediately homogenized in 10 ml of lysis buffer (25 mM Tris/HCl, pH 7.4, 0.5 mM EDTA, 0.25 mM EGTA, 0.25 M sucrose, 50 mM NaF, 5 mM sodium pyrophosphate, 25 mM glycerol-3-phosphate and 1 mM sodium orthovanadate, supplemented with protease inhibitors [10 µg/ml leupeptin, 2 µM pepstatin, 10 µg/ml aprotinin, 5 µM antipain, 5 mM iodo-acetate, 100 µM phenylmethylsulfonyl fluoride, 4 mM benzamidine]) using a motor-driven Teflon-in-glass homogenizer (10 strokes with a loosely fitting pestle) at 22 °C. The following procedures are performed at 4 °C (Müller and Wied 1993). After centrifugation (1 500 *g*, 5 min), the postnuclear infranatant is separated from the fat cake, and the pellet fraction (containing adipocyte ghosts and cell debris) by suction with a needle. For preparation of plasma membranes, the postnuclear infranatant is centrifuged (12 000 *g*, 15 min). The pellet is suspended in 10 ml of homogenization buffer and re-centrifuged (1 000 *g*, 10 min). The supernatant is centrifuged (12 000 *g*, 20 min). The washed pellet is suspended in 1 ml of homogenization buffer, layered onto a 5-ml cushion of 38% (w/v) sucrose, 25 mM Tris/HCl (pH 7.4), 1 mM EDTA, and centrifuged (110 000 *g*, 1 h). The membranes at the interface between the two layers (0.5 ml) are removed by suction, diluted with four volumes of homogenization buffer, and layered on top of an 8-ml cushion of 28% Percoll, 0.25 M sucrose, 1 mM EDTA, 25 mM Tris/HCl (pH 7.0). After centrifugation (45 000 *g*, 30 min), the plasma membranes are withdrawn from the lower third of the gradient (0.5 ml) with a Pasteur pipette, diluted with 10 volumes of homogenization buffer and centrifuged (200 000 *g*, 90 min). The washed pellet is suspended in the same buffer at 0.5 mg protein/ml.

Preparation and purification of DIGs from plasma membranes

Plasma membranes (200 µg) are pelleted (200 000 *g*, 90 min) and suspended in 1.5 ml of 0.5 M Na_2CO_3 (pH 11) containing protease inhibitors and sonicated (3×30-s bursts with 1-min intervals on ice, Branson B-12, power stage 4). The suspension is then adjusted to 45% sucrose in 15 mM Mes/KOH (pH 6.5), 75 mM NaCl, 0.25 M Na_2CO_3, overlayed with 2 ml each of 35, 25, 15, and 5% sucrose in the same medium, and centrifuged (230 000 *g*, Beckman SW41 rotor, 18 h). The light-scattering band of flocculent material just below the 15–25% sucrose interface is collected as DIGs using a 19-gauge needle and a syringe (about 1.5 ml).

Coimmunoprecipitation

Total cell lysates (25–50 µg protein) or DIGs in non-dissociating buffer (10–15 µg protein) are precleared (1 h, 4 °C) with protein G/A-Sepharose (50 mg/ml) in a total volume of 100 µl and then supplemented with appropriate antibodies ($pp125^{Fak}$: 2 µg/sample; IRS-1: 1 : 50 dilution; IRS-2: 10 µg/sample; $pp59^{Lyn}$: 5 µg/sample; caveolin: 0.7 µg/sample; IRβ: 1 : 175 dilution) preadsorbed on protein G-Sepharose (monoclonal antibodies) or protein A-Sepharose (rabbit antibodies) in a total volume of 100 µl. After incubation (4 h, 4 °C, end-over-end rotation) and centrifugation (3 000 *g*, 2 min,

4 °C), the collected immune complexes are washed twice with 1 ml each of immunoprecipitation buffer (50 mM HEPES/KOH, pH 7.4, 500 mM NaCl, 100 mM NaF, 10 mM EDTA, 10 mM sodium pyrophosphate, 1 mM sodium orthovanadate) containing 0.2% Nonidet P-40 and 0.3% deoxycholate, then twice with 1 ml each of immunoprecipitation buffer containing 150 mM NaCl and 0.2% Nonidet P-40 and once with 1 ml of immunoprecipitation buffer lacking salt and detergent and finally suspended in 50 µl of Laemmli buffer (4% SDS, 115 mM Tris/HCl, pH 6.8, 1 mM EDTA, 10% glycerol, 4 mg/ml bromophenol blue) supplemented with 1.2% β-mercaptoethanol (except for anti-caveolin immunoprecipitates), heated (95 °C, 2 min) and centrifuged. The supernatant samples are analyzed by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE; 4–12% Bis-Tris precast gel, pH 6.4, morpholinoethanesulfonic acid/SDS running buffer under reducing conditions. The centrifugation conditions for collection of the protein A/G Sepharose-bound immune complexes, do not lead to sedimentation of (non-dissociated DIGs) to any significant degree according to immunoblotting with anti-caveolin antibody. The coimmunoprecipitation of proteins with caveolin from non-dissociated DIGs is specific for DIG-associated components, such as the GPI protein, Gce1, and the dual-acylated non-receptor tyrosine kinase, $pp59^{Lyn}$, since the use of non-immune IgG instead of anti-caveolin antibody or of dissociated DIGs and anti-caveolin antibody do not result in immunoprecipation of Gce1 and $pp59^{Lyn}$.

Immunoblotting

Immunoblotting is performed as described above with minor modifications. After SDS-PAGE and transfer of the proteins to polyvinylidene difluoride membranes (2 h, 400 mA in 20% methanol, 192 mM glycine, 25 mM Tris, 0.005% SDS), the blocked membrane (1 h in 20 mM Tris/HCl, pH 7.6, 150 mM NaCl, 0.05% Tween 20, 0.1% Brij, 0.01% NP-40 and with 1% ovalbumin and 1% BSA (anti-phosphotyrosine, anti-$pp59^{Lyn}$, anti-IRβ) or with 5% non-fat dried milk (anti-caveolin, anti-IRS-1/2) is incubated (2 h, 25 °C) with antibodies against IRS-1 (1 : 500), IRS-2 (1 : 750), caveolin (1 : 2 000), $pp59^{Lyn}$ (1 µg/ml) or IPβ (2 µg/ml) diluted in the same medium, and then washed five times with the same medium. After incubation of the membranes (1 h, 25 °C) with horseradish peroxidase-coupled goat anti-mouse IgG antibody or goat anti-rabbit IgG antibody diluted in the appropriate blocking buffer (1 : 5 000 or 1 : 2 500) and subsequent washing with detergent-containing (two times) and detergent-free (two times) buffer (20 mM Tris/HCl, pH 7.6, 150 mM NaCl), the labeled proteins are visualized by the enhanced chemiluminescence method.

Immune complex kinase assays

Immune complex kinase assays are performed as described above with minor modifications. $pp59^{Lyn}$ immune complexes are suspended 30 µl of kinase buffer (50 mM HEPES/KOH, pH 7.4, 100 mM NaCl, 1.25 mM $MnCl_2$, 12.5 mM $MgCl_2$, 1.25 mM EGTA, 0.5 mM DTT, 1 mM Na_3VO_4) containing [γ-^{32}P]ATP (final conc. 40 µM, 0.2 mCi/ml) or 1 mM ATP and incubated ($pp59^{Lyn}$: 15 min, 22 °C) in the presence of 1 µg heat-denatured enolase. Phosphorylation is terminated by addition of 10 µl of four-fold concentrated Laemmli buffer and boiling. The phosphoproteins are separated on SDS-PAGE (10% Bis-Tris resolving gel, morpholinopropanesulfonic acid/SDS running buffer) and analyzed for phosphotyrosine by phosphorimaging ([γ-^{32}P]ATP) or immunoblotting (ATP). Under these conditions the kinase reactions are linear with time for the assay period. IRS-1 immune complexes were assayed for phosphatidylinositol-3 kinase (PI-3'K) by incubating (10 min, 22 °C) in 50 µl of 20 mM Tris/HCl (pH 7.0), 50 µM [γ-^{33}P]ATP (5 µCi), 10 mM $MgCl_2$, 2 mM $MnCl_2$, 100 mM NaCl, 2 mM EDTA, 0.5 µM wortmannin (for control incubations, only) containing 10 µg of phosphatidylinositol (PI) and 1 µg of phosphatidylserine. After addition of 10 µl of 8 M HCl and 160 µl of a 1 : 1 mixture of methanol/chloroform, the extracted phospholipids are resolved by TLC on plates coated with 1% oxalate and developed in chloroform: methanol:water:ammonia (60 : 47 : 11.3 : 3.2, v/v). Radiolabeled PI 3-P is quantitated by phosphorimage analysis. For calculation of wortmannin-sensitive PI-3'K, all values are corrected for PI 3-P radiolabeled in the presence of wortmannin.

Photoaffinity labeling of plasma membranes and DIGs for detection of the GPI protein, Gce1

Solubilized plasma membranes and DIGs (5–10 µg protein) are incubated (30 min, 4 °C) with 50 µCi 8-N_3-[^{32}P]cAMP (0.5 nmol) in 50 µl of 10 mM Tris/HCl (pH 7.4), 1 mM EDTA, 0.5 mM EGTA, 140 mM NaCl, 10 mM $MgCl_2$, 2 mM $MnCl_2$, 1 mM isobutylmethylxanthine, 1 mM DTT, 1 mM AMP, and protease inhibitors in the wells of microtiter plates (96-formate) and then irradiated with UV light (254 nm, 8 000 µW/cm^2) at a distance of 0.5 cm for 1 min (Müller et al. 1993, 1994a and b). Subsequently, the photoaffinity labeling reaction is quenched by addition of 100 µl of the same buffer containing 10 mM cAMP. Gce1 is precipitated (5% trichloroacetic acid, 1 h on ice, 10 000 *g* for 15 min) and solubilized in sample buffer for SDS-PAGE. Protein concentration is determined using the BCA protein determination kit from Pierce (Rockford, IL). Autoradiographs and direct photoimages are processed and quantified by computer-assisted video densitometry using the Storm 860 Phosphor-Imager system

(Molecular Dynamics, Gelsenkirchen, Germany). Figures of autoradiographs and photoimages are constructed using the Adobe Photoshop software (Adobe Systems Inc., Mountain View, CA). The recovery in the amounts of immunoprecipitated protein has to be corrected (data on fold- or % stimulation) for the amount of protein actually applied onto the gel as revealed by homologous immunoblotting. Each experiment/incubation should be performed with different batches of adipocytes with two to four independent immunoprecipitation/kinase assay/immunoblotting analyses.

K.3.3 Isolated diaphragm of rats or mice[3]

GENERAL CONSIDERATIONS

The determination of insulin based on the stimulation of glucose uptake by the isolated diaphragm from mice and rats has been used by many investigators. Formerly, the method has been used for determination of serum insulin (Groen et al. 1952; Randle 1954; Vallance-Owen 1954, 1960; Wright 1957; Willebrands et al. 1958; Antoniades 1961; Moody and Felber 1964; Stock 1973) but the epididymal fat pad assay (see above) turned out to be more sensitive and the immunological methods based on the findings of Yalow and Berson (1960) are more specific. Nevertheless, the isolated diaphragm of rats or mice is still useful to study the effects of insulin and insulin-mimetic substances on muscle tissue.

Instead of the isolated rat diaphragm, Adolfsson et al. (1967) recommended the use of the intact levator ani muscle of rats to study the incorporation of labelled proline into protein.

K.3.3.1 Glycogen synthesis

PROCEDURE

Male Sprague Dawley rats weighing 70–100 g are used. The animals are sacrificed during anesthesia and the diaphragms are carefully removed, spread out and divided into two equal pieces. The hemidiaphragms are incubated in Krebs-Henseleit buffer gassed with carbogen (95% O_2/5% CO_2) with 5 µM [U-^{14}C] glucose (0.5 µCi/ml), insulin or the compound to be tested. After 30 min, the hemidiaphragms are blotted on tissue, frozen in liquid nitrogen, and ground in a porcelain mortar and pestle chilled with liquid nitrogen. Samples of the powdered tissue are weighed and dissolved by heating for 45 min at 100°C in 30% KOH (1 ml/100 mg tissue) before ethanol is added to a concentration of 70%. After 4 h at –20°C, the samples are centrifuged at 2 000*g* for 10 min. The glycogen pellets are washed 3 times with 70% ethanol before the amount of ^{14}C labelled glycogen is determined by liquid scintillation counting. Total glycogen is determined according to Lowry and Passo-neau (1972) after hydrolysis to glucose (1 N HCl at 100°C for 3 h). The incorporation of [^{14}C]glucose into radiolabeled glycogen is normalized for the total amount of glycogen.

EVALUATION

The concentration dependence of [U-^{14}C] glucose uptake and conversion into glycogen by insulin or insulinomimetic compounds is determined.

The isolated diaphragm of rats or mice is the preferable organ to study the effect of insulin and substances with insulin-mimetic effects, such as sulfonylureas, on muscle tissue or the influence of denervation (Standing and Foy 1970; Smith and Lawrence 1984; Ishizuka et al. 1990; Hothersall et al. 1990).

K.3.3.2 Glucose transport

Intact washed rat diaphragms are incubated (30 min, 37 °C) in HEPES-buffered saline (25 mM HEPES, 120 mM NaCl, 5 mM KCl, 1.5 mM $CaCl_2$, 1 mM $MgCl_2$, 5 mM glucose, 0.5 mM sodium pyruvate, 1.5 mM KH_2PO_4, pH 7.4) under constant bubbling with 95% O_2/5% CO_2. The diaphragms are then washed two times with the same buffer lacking glucose and further incubated (30 min) in 5 ml of glucose-free buffer in the presence of test compounds or insulin. Glucose transport is initiated by addition of 50 µl of 10 mM 2-[1-^{3}H]deoxyglucose (10 µCi/ml) in the absence or presence of 25 µM cytochalasin B (control). After 15 min, the diaphragms are rinsed four times with ice-cold buffer containing 10 mM glucose, 25 µM cytochalasin B, blotted with filter paper and homogenized. Portions of the homogenate are used for protein determination. One-ml portions of the supernatant of a centrifugation at 10 000 *g* for 15 min are mixed with 10 ml scintillation cocktail and counted for radioactivity.

Specific glucose transport (dpm/mg of protein) is calculated as the difference between diaphragm-associated radioactivity measured in the absence (total

[3] Contributions by G. Müller.

uptake) and presence of cytochalasin B (non-specific uptake). Under these experimental conditions, transport is linear for 30 min.

K.3.3.3 Glycogen synthase

Glycogen synthase is assayed according to Oron and Larner (1979), Guinovart et al. (1979), Altan et al. (1985) with the following modifications: Intact hemidiaphragms are dissected from male Wistar rats and incubated in DMEM (10 ml/hemidiaphragm) with constant bubbling of $O_2 : CO_2$ (95 : 5). For treatment with test compounds or insulin, the hemidiaphragms are incubated (37 °C) in the same medium plus 5 mM glucose. For preparation of a homogenate, the diaphragms are blotted and frozen in liquid nitrogen. The frozen diaphragms (pool of four) are manually ground in a porcelain mortar and then homogenized at 0 °C in 10 vol of 25 mM Tris/HCl (pH 7.4), 100 mM NaF, 5 mM EDTA, 0.1 mM PMSF. The homogenate is centrifuged (10 000 *g*, 20 min). The supernatant is used for the glycogen synthase assay.

After addition of 10 µl of diaphragm homogenate to 200 µl of 25 mM Tris/HCl (pH 7.4), 50 mM NaF, 10 mM EDTA (pre-incubated at 30 °C) containing either 0.1 or 10 mM glucose-6-phosphate, the reaction is initiated by supplementing 0.2 mM [U-^{14}C]UDP-glucose (10 µCi) and terminated after 15 min by the addition of 2.5 ml of ice-cold 66% ethanol and filtration over pre-wetted Whatman GF/C glass fiber disks. The filters are washed, dried and counted for radioactivity. Blanks are assayed by adding the homogenate to tubes containing the complete reaction mixture plus ice-cold ethanol. The fractional velocity as parameter for the portion of glycogen synthase active *in vivo* (l-form) toward the total enzyme contents (l- + d-forms) at the time point of homogenization is calculated as ratio between the activities measured at 0.1 (l-form) and 10 mM glucose-6-phosphate (l- + d-forms).

The concentration-dependence of sulfonylurea stimulated glycogen synthase and the potentiation of insulin were studied by Müller et al. (1994).

K.3.4 Binding assays

K.3.4.1 Immunoassay

PURPOSE AND RATIONALE

The first description of an immunoassay of endogenous plasma insulin in man has been given by Yalow and Berson (1959, 1960), Yalow et al. (1960) providing evidence that the bioassays hitherto being used (isolated rat diaphragm, epididymal fat pad tissue) measure insulin-like activity but not true insulin levels in blood. Since that time, the method has been used and modified by many investigators, e.g., Grodsky and Forsham (1960), Morgan and Lazarow (1963), Melani et al. (1965, 1967), Wright et al. 1968). Survey on the radioimmunoassay of insulin have been given by Ditschuneit and Faulhaber (1975), Freedlender et al. (1984).

PROCEDURE

Immunization

Semisynthetic or biosynthetic human insulin is used as immunogen and as standard. Formerly, porcine insulin has been used since Yalow and Berson (1960) and subsequently many other authors have shown that antisera raised against porcine insulin react identically with human and porcine insulin. Guinea pigs weighing 350–450 g are injected subcutaneously with 0.4 ml of an emulsion of 5 mg human insulin dissolved in 1.0 ml 0.01 N HCl and 3.0 ml complete Freund's adjuvant (Difco Laboratories). For boostering, 0.2 ml of an identically prepared emulsion is injected in monthly intervals. Fourteen days after the third booster injection, the animals are slightly anesthetized and 8–10 ml blood are withdrawn by cardiac puncture. Boosting is continued at monthly intervals and the animals are bled 2 weeks following each booster injection.

Antiserum

The optimal antiserum titer for use in the radioimmunoassay is determined using conditions identical to those employed in routine immunoassays. The percentage binding of 1 μU ^{125}I insulin is determined for dilutions of antisera ranging from 10^3 to 10^6 fold. The steepness of the antisera dilution curve is a measure of the affinity of the antiserum and therefore the potential sensitivity of the radioimmunoassay. Antisera with the steepest slopes, but not necessarily the highest titer, are selected for further study. The selected antisera dilutions are then run in an immunoassay using a full range of standards. A reduction in the percent ^{125}I-insulin bound to antibody from 50% (in the absence of unlabeled insulin) to 45% (in the presence of unlabeled insulin) (B/Bo = 0.9) is a reasonable measure of assay sensitivity.

Preparation of ^{125}I-insulin

Most investigators use the "chloramine-T procedure" to iodinate insulin.

The reaction is carried out in a 20 ml glass vial in an ice-bath with continuous magnetic stirring. To 2.5 ml 0.05 M phosphate buffer, pH 7.5, 2.0 mCi Na^{125}I, and 15 μl of a 1 mg/ml insulin solution are added. Then, 0.5 ml of a chloramine T (50 mg/ml) solution is added dropwise over the course of 1 min. After 10 min, 0.7 ml of a freshly prepared sodium metabisulfite solution (50 mg/ml in 0.05 M phosphate buffer, pH 7.5) is added. One ml of this reaction mixture is transferred to 10 ml 2% bovine serum albumin for determination of specific activity. In order to absorb unreacted ^{125}I and damaged products 2.0 g 20–50 mesh AG 1X-8 resin (BioRad Laboratories) are added (equilibrated in 1 ml 0.05 M phosphate buffer, pH 7.5, containing 0.1 mg/ml thiomerosal and 20 mg/ml crystalline bovine serum albumin). The reaction mixture is stirred for 10 min, decanted from the resin and diluted to a concentration of less than 25 μC/ml in a solution of 0.8 M glycine, 0.2 M NaCl, 0.05 M phosphate (pH 7.5), and 2.5 mg/ml crystalline BSA. The final solution is stored in multiple aliquots at –70 °C.

Assay procedure

The antibody-bound ^{125}I-insulin can be separated from free ^{125}I-insulin in various ways, such as by paper electrophoresis, as originally described by Yalow and Berson (1960), or by a two-antibody system, as described by Morgan and Lazarow (1963), Starr et al. (1979). In this method, the soluble insulin-anti-insulin complex is precipitated by an anti-guinea pig serum antibody.

The following procedure is recommended (Freedlender et al. 1984):

- A buffer is prepared from a solution of 8.25 g boric acid and 2.70 g NaOH dissolved in 1 l water. After dissolving 5.0 g of purified bovine serum albumin, pH is adjusted with concentrated HCl to 8.0.
- In disposable plastic tubes, 10 × 75 mm, the following volumes are added:
  100 μl serum or standard
  900 μl buffer
  100 μl 1 mU ^{125}I-insulin in assay buffer
  100 μl guinea pig anti-insulin antiserum diluted in assay buffer (at a concentration to bind 50% of the ^{125}I-insulin in the absence of unlabeled hormone)
- The mixture is incubated at 4 °C for 72 h. Then, the following solutions are added:

100 µl normal guinea pig serum diluted 1 : 400 in the assay buffer
100 µl rabbit anti-guinea pig globulin serum diluted in assay buffer

- The mixture is again incubated at 4 °C for 72 h and then centrifuged at 4 °C and 2 000 *g* for 20 min. The supernatant is decanted and radioactivity counted in the precipitate for 5 min.

Calculation

Counts in the nonspecific binding tubes are subtracted from counts in all other tubes. Data are linearized using an unweighted logit-log transformation (Rodbard and Frazier 1975). Micro-units insulin in a logarithmic scale are plotted against the ratio B/Bo ^{125}I-insulin on a logit scale. The range of B/Bo between 0.4 and 0.9 is the most suitable for determination of insulin concentration in plasma.

CRITICAL ASSESSMENT OF THE METHOD

The immunoassay of insulin as described by Yalow and Berson (1960) has been a break-through for many immunological assays of peptide hormones and other drugs. At present, not only guinea pig anti-insulin antisera, but also complete RIA kits are available from a number of commercial firms.

MODIFICATIONS OF THE METHOD

Cam and McNeill (1996) published a sensitive radioimmunoassay optimized for reproducible measurement of rat plasma insulin. Relatively small volumes (25 µl) of plasma from control, diabetic, and fasted rats can be assayed reproducibly with charcoal in the final separation step.

K.3.4.2 Insulin receptor binding

PURPOSE AND RATIONALE

Insulin receptor binding studies have been performed with various animal tissues and isolated cells as well as with cells of human origin. Human adipocytes can be used to study simultaneously insulin receptor binding and metabolic effects of insulin (Hjøllund 1991). The binding tests are of value to characterize newly synthesized insulin derivatives (Schwartz et al. 1987; Ribel et al. 1990; Vølund et al. 1991; Robertson et al. 1992).

PROCEDURE

Subcutaneous adipose tissue (about 4–5 g) is obtained from the abdomen of patients undergoing gastroenterological surgery. Patients suffering from any endocrine or metabolic disorder or taking drugs known to affect metabolism have to be excluded. Other exclusion criteria are impaired glucose tolerance measured by determination of fasting blood glucose and the 2 h value after a 75 g oral glucose load. The adipose tissue is finely chopped and incubated for 90 min at 37 °C in a HEPES buffer (pH 7.4), containing human serum albumin (25 g/l) and collagenase (0.5 g/l). The isolated adipocytes are subsequently washed five times in a HEPES buffer containing 50 g/l human albumin. The diameters of adipocytes are measured at 200-fold magnification using an eyepiece micrometer. Surface and volume are calculated for every cell diameter.

Insulin receptor binding studies with isolated human adipocytes are performed in a 300 µl cell suspension containing about 1×10^5 cells/ml in a HEPES buffer (10 mmol/l HEPES, 50 g/l human serum albumin, (pH 7.4) at 37 °C. The iodine labelled ligand ([^{125}I]Tyr^{A14}-monoiodinated insulin, specific activity about 350 mCi/mg) in a final concentration of 20 pmol/l

is incubated with increasing amounts of unlabeled human insulin and the insulin derivative to be tested. The reaction is stopped by adding 10 ml of chilled 0.154 mol/l NaCl and subsequent centrifugation with silicone oil (Pederson et al. 1981; Zeuzem et al. 1984). Non-specific binding is measured by incubating tracer in the presence of a large excess of unlabelled insulin.

For association studies the ^{125}I-labelled ligand is incubated for various times (1 to 240 min) and the reaction is terminated as described above. At each time point, the non-specific binding is measured and subsequently subtracted from the corresponding data for total binding.

Dissociation rates are determined by first incubating isolated human adipocytes at 37 °C with either [^{125}I]Tyr^{A14}-insulin or the test compound labelled in the same position for 90 min to achieve steady-state binding conditions. Each incubation mixture is then centrifuged for 60 s The adipocytes are rapidly washed twice by diluting with buffer to the original volume at 4 °C and the centrifugations and aspirations are repeated. After the third aspiration, the cells are diluted to the original volume with buffer alone or native insulin or the insulin derivative to be tested at a final concentration of 0.2 µmol/l at 22 °C. At this hormone concentration a maximal effect of ^{125}I-insulin dissociation is reported (Podlecki et al. 1984; DeMeyts et al. 1976). The reaction is stopped at various times between 10 and 180 min and cell-associated radioactivity is determined.

EVALUATION

Results are expressed as percentage specific binding per 10 cm^2 plasma membrane surface area (Olefsky 1976; Pedersen et al. 1982).

MODIFICATIONS OF THE METHOD

Koch and Weber (1981) described the preparation of insulin receptors from rat liver membranes. The membranes are prepared from normal male or female Sprague-Dawley rats weighing about 130 g and starved 12–15 h before decapitation. The livers are cut into small pieces on ice. The whole procedure is performed at 4 °C. Five g of liver in 1 000 ml 0.01 M phosphate buffer (pH 7.4) containing 0.25 M sucrose are homogenized first with an Ultra-Turrax® and then in a glass-Teflon homogenizer with 10 strokes up and down at 100 rotations per min. The homogenate is centrifuged for 10 min at 600 *g*. The pellets are discarded and the supernatant centrifuged at 12 000 *g* (30 min) and 40 000 *g* (80 min). The pellet is suspended in phosphate buffer and again centrifuged at 40 000 *g* for 60 min. This washing step is repeated twice. The pellets are resuspended in 30 ml 0.01 M phosphate buffer. At least 8 concentrations of test substance and standard are used for the binding test.

Heterogeneity of insulin receptors in different tissues has been emphasized by Gammeltoft (1988), Breiner et al. (1993).

Simonescu et al(1985) described a radioreceptor assay of insulin using **human erythrocytes**.

Kergoat et al. (1988) studied the properties of the liver insulin receptor and the activity of the insulin receptor tyrosine kinase in rats with non-insulin-dependent diabetes induced by neonatal streptozotocin administration.

Hurrell et al. (1989) prepared solubilized purified insulin receptors from livers of Zucker fatty rats and Sprague-Dawley rats with dietary obesity.

Olichon-Berthe et al. (1994) studied insulin receptor dephosphorylation by phosphotyrosine phosphatases obtained from liver and muscle of goldthioglucose-treated insulin-resistant obese mice.

Standaert et al. (1984) studied the development of high affinity insulin receptors and insulin-stimulated responses in the differentiating **nonfusing muscle cell line BC3H-1**.

Bornfeldt et al. (1991) studied receptor binding and growth promoting effects of insulin, insulin analogues and insulin-like growth factors in **cultured rat aortic smooth muscle cells**.

DeMeyts (1976) described insulin and growth hormone receptors in human cultured lymphocytes and **peripheral blood monocytes**.

Wyse and Chang (1981) characterized insulin receptors in the established **Chinese hamster kidney epithelial cell line CHK-AC$_{E\text{-}100}$**.

Klein et al. (1986) studied insulin activation of insulin receptor tyrosine kinase in intact rat adipocytes.

Weiland et al. (1990) described antagonistic effects of a covalently dimerized insulin derivative on insulin receptors in **3T3-L1 adipocytes**.

Levy and Belsky (1990) studied insulin receptors in cultured **hepatoma HepG2 cells**.

Drejer et al. (1991) studied receptor binding and tyrosine kinase activation by insulin analogues in human hepatoma HepG2 cells. The kinetic studies showed that differences in affinities between analogues were due to differences in both dissociation and association constants.

Markussen et al. (1991) purified the **soluble ectodomain of the human insulin receptor**, produced in transfected baby hamster kidney cells, by affinity chromatography on immobilized insulin.

Kurose et al. (1994) studied the binding of an insulin derivative to **human insulin receptor overexpressed on a transfected Chinese hamster ovary cell line**.

Schäffer et al. (1993) produced chimeric insulin/type I insulin-like growth factor receptors to study the interaction of a hybrid insulin/insulin-like growth factor-I analog.

Schumacher et al. (1993) **generated chimeric receptors** in which the structurally defined subdomains of the insulin receptor and insulin growth factor-I receptor a-subunits were exchanged for their respective receptor backbone structures.

Burke et al. (1980) showed a divergence of the *in vitro* biological activity and receptor binding affinity (liver plasma membranes and fat cells) of a synthetic insulin analogue, [21-asparaginamide-A]insulin.

Müller et al. (1991) showed that hyperglycemia induces an acute inhibition of the insulin receptor tyrosine kinase in rat-1 fibroblasts overexpressing the human insulin receptor. This effect is paralleled by translocation of several protein kinase C (PKC) isoforms, and it can be prevented by PKC inhibitors. The glucose-induced inhibition of the insulin receptor kinase could also be prevented by incubation with troglitazone (Kellerer et al. 1994).

Shah et al. (1995) described a method for electronic microscopic visualization of insulin binding and insulin translocation into the cytoplasm and nuclei of intact H35 hepatoma cells using covalently linked nanogold-insulin.

Whitcomb et al. (1985a,b) described an *in vivo* **radioreceptor assay** for identification of tissue insulin receptors.

Awasthi et al. (1994) used ^{99m}Tc-insulin for distribution studies in animals.

K.4
Assays of other glucose regulating peptide hormones

K.4.0.1
Bioassay of glucagon

PURPOSE AND RATIONALE

Glucagon is a 29-amino-acid, single-chain polypeptide which is secreted by the α cells in the islets of Langerhans. It is synthesized from preproglucagon, a 180-amino-acid precursor (Bell et al. 1983). Proglucagon is processed in islet and intestinal cell lines (Tucker et al. 1996). Glucagon interacts with a 60-kDa glycoprotein receptor on the plasma membrane of target cells (Sheetz and Tager 1988).

A biological assay of glucagon is described in the British Pharmacopoeia 1988. The potency of glucagon is estimated by comparing its hyperglycemic activity with that of the standard preparation of glucagon using the rabbit blood sugar assay as performed for insulin determinations.

PROCEDURE

Rabbits of either sex, weighing 1.8 to 2.8 kg are maintained under uniform conditions and an adequate uniform diet for at least one week. Forty-eight hours before the beginning of the test, each rabbit is injected with 1 ml of cortisone acetate injection. The animals are deprived of food, but not water, from 16 h before each test day until the withdrawal of the last blood sample on that day. The rabbits are randomly distributed into 4 groups of at least 6 animals.

The standard preparation to be used is the 1st International Standard for Glucagon, porcine, established in 1973, consisting of freeze-dried porcine glucagon with lactose and sodium chloride (supplied in ampoules containing 1.49 Units), or another suitable preparation the potency of which has been determined in relation to the International Standard.

The entire contents of one ampoule of the standard preparation are reconstituted with 2 ml of saline solution, acidified to pH 3.0 with hydrochloric acid and diluted with the same solvent to a convenient concentration, for example 100 milliUnits per ml. Two dilu-

tions are made containing 24 and 6 milliUnits per ml, respectively, and at the same time two dilutions are made of the preparation being examined. The rabbits are injected subcutaneously with doses of 1 ml of each of the four solutions, giving the doses in random order following a twin cross-over design on two consecutive days at the same time each day. At 20 and 60 min after injection, a blood sample is taken from a marginal ear vein of each rabbit.

Blood glucose concentrations are determined using a suitable method, such as the glucose-oxidase procedure.

EVALUATION

The result of the assay is calculated by standard statistical methods using the means of the two blood glucose levels found for each rabbit.

MODIFICATIONS OF THE METHOD

Glucagon can be determined by radioimmunoassay (Unger 1959; Harris et al. 1978; von Schenk 1984). Commercial kits are available.

K.4.0.2 Receptor binding and *in vitro* activity of glucagon

PURPOSE AND RATIONALE

The binding of glucagon to its receptor is assayed with rat liver plasma membranes (Neville 1968; Pohl et al. 1971; Goldstein and Blecher 1976). Displacement of ^{125}I-labeled glucagon is measured for synthetic glucagon analogues in comparison to natural glucagon. Cyclic AMP formation as the first step in glucagon action on liver is measured as a bioassay in liver plasma membranes.

PROCEDURE

Preparation of membranes

Male Sprague-Dawley rats weighing 160–200 g are decapitated and the livers rapidly removed and trimmed of fat and connective tissue. The pooled livers are placed on a pre-chilled glass plate and chopped finely with a stainless steel blade. Ten-gram portions of the mincate are suspended in 35 ml of ice-cold 1 mM $NaHCO_3$ and homogenized in a loose fitting Dounce homogenizer. Two homogenates are combined, brought to 500 ml with ice-cold medium, stirred magnetically for 5 min, and finally filtered once through two layers of cheesecloth. The filtrate is centrifuged at 1 500 *g* for 10 min. Supernatant fluid is aspirated to waste using a serum pipette attached to a water pump. Homogenizations and centrifugations are continued until all of the tissue has been processed. The pooled pellets are again homogenized. The suspension is adjusted to 44 ±0.1% (wt/wt) sucrose solution by the addition of 70% sucrose solution. Sucrose gradients are prepared in 1 × 3.5-in. tubes by pipetting 26 ml of the tissue suspension followed by an overlay of 13 ml of 42.3 ±0.1% sucrose. Centrifugation is carried out at 95 100 *g* for 2 h. The float containing the plasma membranes can be removed by pinching the tube slightly above the float, then lifting off the float with a spoon-shaped Teflon-coated spatula. These floats are transferred to a preweighed plastic centrifuge tube (50 ml), and the well-mixed suspension centrifuged at 40 000 *g* for 30 min. Following aspiration of the supernatant to waste, the tubes are reweighed in order to estimate the yield of plasma membranes. After addition of an equal volume of medium, the pellet is aspirated repeatedly through a 20-gauge needle fitted to a syringe. The plasma membrane suspension is distributed in 0.2 or 1.0 ml aliquots to screwcap plastic vessels for storage in liquid nitrogen.

Radioiodination of glucagon

Three nmol glucagon are allowed to react with a 1.0 nmol sample of carrier-free $Na^{125}I$ (2.0 mC) in the presence of 1.5 nmol chloramine-T, added at a regular interval of 30 s (0.5 nmol each time). Reaction is terminated by addition of 0.5% sodium metabisulfite solution (Hagopian and Tager 1983). By chromatographic purification (Jørgensen and Larsen 1972), fractions of 2 ml are collected, and the monoiodinated glucagon as determined by reverse phase HPLC is stored at –20 °C for receptor binding assays.

Receptor binding

Membrane suspensions adjusted to 50 µg protein in 400 µl of Tris-HCl buffer (25 mM, pH 7.5, with 1% BSA) are incubated for 10 min with 50 µl peptide solution (Tris-HCl buffer) and 50 µl of [^{125}I]glucagon (1 000 000 cpm, 25 fmol). The samples are then filtered through Oxoid filters and washed three times with 1 ml of Tris-HCl buffer. The radioactivity retained in the filters is counted by a γ-counter.

Adenylate cyclase assay

The assay is carried out with a membrane suspension containing 25–30 µg protein in a volume of 0.1 ml of Tris-HCl buffer 25 mM, pH 7.5 containing BSA 1%, ATP 1 mM, $MgCl_2$ 5 mM, cAMP 1 nM, (containing 10 000 cpm of [^{3}H]cAMP), GTP 10 mM, phosphocreatine 20 mM, with 4×10^6 cpm [α^{32}P]ATP and 0.72 mg/ml creatinine phosphokinase (100 U/ml). Assays are run in triplicate.

EVALUATION

Results are expressed as the percentage inhibition of [^{125}I]glucagon specific binding for receptor binding assays. For adenylate cyclase assays the results are expressed as percent potency relative to the maximal stimulation by glucagon which is defined as 100%.

MODIFICATIONS OF THE METHOD

Azizeh et al. (1995, 1997) synthesized and tested a glucagon antagonist and multiple replacement analogues of glucagon by adenylate cyclase assay according to Lin et al. (1975) and receptor binding assay according to Wright and Rodbell (1979).

K.4.0.3 Glucagon-like peptide I

PURPOSE AND RATIONALE

Several intestinal peptides have been described to have insulinotropic or incretin activity, e.g. GIP (gastric inhibitory peptide, glucose-dependent insulin releasing peptide) (Creutzfeldt 1985; Baer and Dupré 1989; Volz et al. 1995). More recently, glucagon-like peptide-1 (7-37) or the (7-36)amide is described as a new incretin (Kreymann et al. 1987; Fehmann et al. 1989, 1990, 1991a, 1992, 1995; Holz et al. 1993). The insulinotropic activity has been confirmed in diabetic and non diabetic subjects (Gutniak 1992; Nathan et al. 1992; Nauck et al. 1993; Ørskov 1993). The insulin stimulatory effect of glucagon-like peptide-1(7-36)amide is glucose-dependent (Göke et al. 1993a). The peptide does not only stimulate insulin release but also inhibits glucagon secretion (Komatsu et al. (1989). Cloning and functional expression of the rat (Thorens 1992) and human (Dillon et al. 1993) glucagon-like peptide1 (GLP-1) re-

ceptor has been achieved. The sequence of glucagon-like peptide-1 (7-36)amide is completely conserved in all mammalian species studied, implying that it plays a critical physiological role. Intracerebroventricular administration of GLP-1 powerfully inhibits feeding in fasted rats, which is blocked by the GLP-1-receptor antagonist exendin(9-39) (Turton et al. 1996).

Peptides isolated from reptile venoms, like exendin-4, were found to have similar activity as glucagon-like peptide-1(7-36)amide (Göke et al. 1993b; Adelhorst et al. 1994; Schepp et al. 1994). Analogues and antagonists of glucagon-like peptide-1(7-36)-amide have been synthesized and evaluated in pharmacological experiments (Watanabe et al. 1994; Hjorth and Schwartz 1996; Montrose-Rafizadeh et al. 1997). Besides insulin release from perfused pancreas (see K.6.1.1), the receptor binding according to Göke and Conlon (1988) on rat insulinoma-derived cells (RINm5F cells), the cAMP formation and the insulin release were studied (Göke et al. 1989a,b).

PROCEDURE

Binding studies with RINm5F cells

The RINm5F cell line is derived from a radiation-induced insulin-producing rat tumor (Gazdar et al. 1980). The RINm5F cells are grown in plastic culture bottles (Praz et al. 1983). They are detached from the surface of the bottles before the experiment using phosphate-buffered saline (136 mmol NaCl/l, 2.7 mmol KCl/l, 8.1 mmol Na_2HPO_4/l, 1.5 mmol KH_2PO_4/l, pH 7.3) containing 0.7 mmol EDTA/l, and centrifuged at 100 *g* for 5 min. The pelleted cells are resuspended in an incubation buffer (2.5 mmol Tris-HCl/l, 120 mmol NaCl/l, 1.2 mmol $MgSO_4$/l, 1.5 mmol KCl/l, and 15 mmol CH_3COONa/l, pH 7.4) containing 1% human serum albumin, 0.1% bacitracin and 1 mmol EDTA/l. Approximately 3×10^6 cells/tube are incubated for 5 min at 37 °C, followed by the addition of unlabelled peptide (final concentration range from 10 pmol to 1 mmol) and radiolabelled tracer (approximately 40 000 c.p.m.). Iodination of the glucagon-like peptide-1(7-36)amide is carried out using the lactoperoxidase method. The total volume of incubation is 0.3 ml. After incubation for 60 min, aliquots (200 µl) of the cell suspensions are centrifuged (11 500 *g* for 2 min) through an oil layer (dibutylphthalate:dinonylphthalate; 10 : 4, v/v). Cell-surface associated radioactivity in the pellet is counted using a γ-counter (e.g. Gamma 5 500, Beckman).

Determination of cAMP production from RINm5F cells

Approximately 1×10^6 cells in 0.45 ml buffer (113 mmol NaCl/l, 4.7 mmol KCl/l, 1.2 mmol KH_2PO_4/l, 10 mmol HEPES/l, 2.5 mmol $CaCl_2$/l and 1.2 mmol $MgSO_4$/l; pH 7.4) containing 1% human serum albumin are pre-incubated for 10 min at 37 °C, and then incubated for 10 min after the addition of 2 µl 3-isobutyl-1-methyl-xanthine (50 mmol/l) in order to prevent the breakdown of cAMP. The reaction is then started by the addition of 50 µl of a peptide solution dissolved in the above buffer (final concentration range from 10 pmol/l to 1 µmol/l). After incubation for 10 min at 37 °C, the reaction is stopped by the addition of 200 µl 12% trichloroacetic acid. The reaction mixture is sonicated for 30 s at 25 W (e.g., Heat system, Ultrasonics) and centrifuged (11 500 *g* for 2 min). HCl (25 µl; 1 mol/l) is added to 0.5 ml supernatant. Trichloroacetic acid dissolved in the supernatant is removed by diethyl ether (3×1 ml) and the resulting supernatant is stored at –40 °C until cAMP assays being performed by use of a RIA kit.

Determination of insulin release from RINm5F cells

One day prior to the experiment, approximately 1×10^6 cells are seeded into 24-well test plates. At the time of the experiment, the culture medium is aspirated, and the cells are washed with 1 ml of a modified Krebs-Ringer bicarbonate buffer containing 10 mmol HEPES/l, 5 mmol $NaHCO_3$/l, 0.5% BSA, and 8.3 mmol glucose/l (pH 7.4). After pre-incubation for 30 min at 37 °C with the above buffer, glucagon-like peptide-1(7-36)amide and its analogues dissolved in the above buffer, are added (final concentration range from 10 pmol/l to 1 µmol/l) and incubated for 30 min at 37 °C. The incubation is stopped by aspiration of the buffer which is stored at –40 °C until measurement of insulin by radioimmunoassay. After the aspiration, the cells are washed with the phosphate-buffered saline used in the binding study, and dissolved in 0.5 ml NaOH (0.1 mol/l). After overnight incubation, the resulting solution is collected for assay of cellular protein content.

EVALUATION

Displacement curves of ^{125}I-labelled glucagon-like peptide-1(7-36)amide are established for various concentrations of glucagon-like peptide-1(7-36)amide and its analogues as well as dose-response curves for cAMP production and insulin release. The data are analyzed by analysis of variance followed by group comparisons (Duncan's multiple comparisons).

MODIFICATIONS OF THE METHOD

Similar experiments were performed with other insulinoma cell lines such as HIT-T15 cells and βTC-1 cells (Fehmann and Habener 1991a,b, 1992). Active glucagon-like peptide-1(7-36)amide receptors have been solubilized from RINm5F plasma membranes (Göke et al. 1992).

Valverde et al. (1993) reported the presence and characterization of glucagon-like peptide-1(7-36) amide receptors in solubilized membranes of rat adipose tissue.

Jehle et al. (1995) found that in RINm5F insulinoma cells GLP-1 potently stimulates insulin secretion and insulin content and improves insulin receptor binding.

Fehmann et al. (1991b) evaluated the effects of helodermin, a peptide isolated from the lizard Gila monster, in isolated rat pancreas.

Schepp et al. (1996) studied binding of oxyntomodulin, an intestinal peptide hormone derived from proglucagon, to the receptor for glucagon-like peptide-1 (7-36)NH_2.

Van Delft et al. (1997) developed a sensitive radioimmunoassay for C-terminally amidated forms of glucagon-like peptide-1.

K.4.0.4 Insulin-like growth factors

PURPOSE AND RATIONALE

Three different lines of research have led to the discovery of insulin-like growth factors (Froesch et al. 1985): Growth hormone does not stimulate growth processes by itself but induces factors, named sulfation factors or **somatomedins**, that mediate the message of growth hormone (Salmon and Daughaday 1957; Nevo 1982; Laron 1999). Pierson and Temin (1972) extracted factors from serum with multiplication-stimulating activity (MSA) for chicken fibroblasts in the cell culture and with non-suppressible insulin-like activity. Serum exerts insulin-like effects on insulin target tissues such as muscle and adipose tissues to a much greater extent than it can be expected on the basis of the insulin content in serum. The activity of factors other than insulin in the epididymal fat pad assay was proven by the persistence of serum insulin-like activity after pancreatectomy (Steinke et al. 1962). Since this activity could not be suppressed by insulin antibodies, the factors were called **'non-suppressible insulin-like activity'** or **NSILA**.

They were finally identified as **insulin-like growth factors I and II** (Rinderknecht and Humbel 1978a,b) structurally related to insulin. These polypeptide hormones are present in serum in high concentrations but are bound to specific carrier proteins (Zapf et al. 1975). Most of IGF and also the IGF-binding protein are synthesized and secreted, but apparently not stored by the liver (Schwander et al. 1983).

Insulin-like growth factor 1 (IGF-1) is a polypeptide of 70 amino acids, whose function of is more or less clarified (Cascieri et al. 1988; Moxley et al. 1990; Salamon et al. 1991; Schmitz et al. 1991; Vikman et al. 1991; Laron 1999). The metabolic activity of IGF-1 is regulated by at least 6 IGF-binding proteins, the most important being IGFBP-3. The effects of growth hormone on protein metabolism are mediated by IGF-1, whereas these 2 hormones are antagonistic in their effects on insulin and some aspects of lipid metabolism. IGF-1 has been shown to improve glycemic control and to reduce insulin requirements in both IDDM and NIDDM (Simpson et al. 1998). One important clinical use is replacement therapy in primary IGF-1 deficiency, such as Laron syndrome, which is characterized by dwarfism due to primary GH resistance or insensitivity (Laron 1999). IGF-1 improves bone healing *in vivo* (Kobayashi et al. 1996). A truncated variant of human IGF-1 with the tripeptide Gly-Pro-Glu absent from the N-terminus, has been isolated from bovine colostrum, human brain and porcine uterus which is about 10-fold more potent than IGF-1 at stim-ulating hypertrophy and proliferation of cultured cells (Ballard et al. 1999).

The function of insulin-like growth factor II is less defined (Roth 1988). IGF-II has an insulin-like effect *in vitro* and *in vivo* (Shizume et al. 1996; Burvin et al. 1998). IGF-II, administered acutely, affects glucose homeostasis in a manner very similar to insulin, probably via the insulin receptors, although with significantly lower potency.

Two subtypes of IGF receptors exist which are different from the insulin receptor and different in their affinity for IGF I and IGF II (Rechler 1985; Verspohl et al. 1988). They belong to the insulin receptor family of receptor tyrosine kinases (Ullrich and Schlessinger 1990; Schlessinger and Ullrich 1992; Fantl et al. 1993). Although insulin and IGF bind with high affinity to

their own specific receptors, each can also bind to the heterologous receptor with reduced binding affinity.

With recombinant DNA technology insulin analogues with modified amino acid sequence can be produced which may bind differently to the insulin and IGF receptor resulting in different biological activities (Drejer 1992; Schäffer 1993). It has been speculated whether the unexpected carcinogenic effect of an insulin analogue (Dideriksen et al. 1992) is related to the mitogenic effect in mouse NIH 3T3 fibroblasts which express IGF receptors but not insulin receptors (Gammeltoft and Drejer 1991). Biosynthesis of 10 kDa and 7.5 kDa insulin-like growth factor II in a human rhabdomyosarcoma cell line has been described by Nielsen et al. (1993).

For new insulin analogues the kinetics of association and dissociation to the receptors should be studied and *in vivo* metabolic activity should be compared with insulin and IGF I.

The *in vivo* metabolic action of insulin-like growth factor I can be compared with insulin in adult rats using the following methods (Schmitz et al. 1991):

Dose-dependence and time-dependence of blood sugar decrease after intravenous injection,

antilipolytic effect (decrease of non-esterified fatty acids) after i.v. injection,

stimulation of glucose disposal during euglycemic clamping after intravenous infusion.

Furthermore, all other assays described for insulin can be applied.

Gazzano-Santoro et al. (1998) described a cell-based potency assay for insulin-like growth factor-1.

PROCEDURE

Cells from the human cell line HU-3, established from the bone marrow of a patient with acute megakaryoblastic leukemia, are adapted to grow in the presence of human thrombopoietin. Removal of thrombopoietin results in decreased proliferation and rapid loss of viability. Cells are cultured in RPMI-1 640 medium with 2% heat-inactivated human serum, 2 mM glutamine, 10 mM HEPES (pH 7.2) and 5 ng/ml thrombopoietin in culture flasks. They are grown in suspension at 37 °C in a humidified 5% CO_2 incubator and are routinely subcultured every two or three days when densities reach $0.8–1.5 \times 10^6$ cells/ml.

The cell growth assay is performed under serum-free conditions in Assay Medium consisting of RPMI-1 640 supplemented with 0.1% BSA, 10 mM HEPES (pH 7.2) and 50 µg/ml gentamycin. Cells are washed twice in the Assay Medium and resuspended at a density of 0.25×10^6 cells/ml. In a typical assay, 100 µl of a cell suspension (25 000 cells/well) and 100 µl of IGF-1 at varying concentrations are added to flat bottomed 96-well tissue culture plates at 37 °C and 5% CO_2 and cultured for 2 days. Forty microliters of Alamar Blue™ (undiluted) are then added and the incubation continued for 7–24 h. The plates are allowed to cool to room temperature for 10 min on a shaker and the fluorescence is read using a 96-well fluorometer with excitation at 530 nm and emission at 590 nm.

EVALUATION

Results, expressed as relative fluorescence units, are plotted against IGF-1 concentrations using a 4-parameter curve-fitting program. Test compounds are compared with the standard.

MODIFICATIONS OF THE METHOD

Boge et al. (1994) described an enzyme immunoreceptor assay for the quantitation of insulin-like growth factor-1 and insulin receptors in bovine muscle tissue.

Hodgson et al. (1995) tested mutations at positions 11 and 60 of insulin-like growth factor-1 using (a) quantification of affinities for the human insulin receptor overexpressed on NIH 3T3 cells, (b) quantification of affinities for the type 1 IGF receptor via competition for binding to a monolayer of MDA-MB-231 cells, (c) promotion of the *in vitro* mitogenesis of growth-arrested MCF-7 cells in the presence of 17-β-oestradiol, and (d) a competition assay for binding to IGF-binding proteins secreted by MCF-7 cells.

In order to investigate the influence of insulin-like growth factor-1 and IGF-binding protein-1 on wound healing, Lee et al. (1996) measured the contraction of collagen gels with embedded fibroblasts.

Ernst and White (1996) studied the hormonal regulation of IGF-binding protein-2 expression in C_2C_{12} myoblasts.

Frystyk and Baxter (1998) described a competitive assay for rat insulin-like growth factor (IGF)-binding protein-3 (rIGFBP-3) based on the ability of IGFBP-3 to form a ternary complex with the acid labile subunit (ALS) in the presence of IGF. Human ALS was bound to test tubes pre-coated with anti-human ALS antibody. The assay depends on a competition between a covalent complex of ^{125}I-hIGF-I and hIGFBP-3, added as tracer, and hIGFBP-3 or rIGFBP-3 in standards or test samples, for binding to the immobilized hALS. Purified natural hIGFBP-3 served as standard.

Damon et al. (1997) used the C_2 skeletal myogenic cell line to characterize an insulin-like growth factor-binding protein, named Mac25/IGFBP-7.

To explore the possible relationship between insulin-like growth factor I and diabetic retinopathy, Naruse et al. (1996) examined the effects of glucose on IGF-I stimulated thymidine incorporation into DNA and IGF-I binding in cultured bovine retinal pericytes.

Jonsson et al. (1997) used a fluorometric proliferation assay with AlamarBlue to study the proliferative capacity of isolated human osteoblasts which were dose-dependently stimulated by IGF-I.

K.4.0.5 Amylin

K.4.0.5.1 General considerations

PURPOSE AND RATIONALE

Amylin, also named islet amyloid polypeptide, is a pancreatic islet peptide consisting of 37 amino acids with a role in the maintenance of glucose homeostasis. The peptide is predominantly present in the β-cells of the pancreas and to a lesser extent in the gastrointestinal tract and in the nervous system, where amylin mRNA is also present along with specific binding sites.

Amylin has structural and functional relationships to two other messenger proteins, calcitonin and calcitonin gene-related peptide (Rink et al. 1993; Pittner et al. 1994; van Rossum et al. 1997; Wimalawansa 1996).

Amylin inhibits food intake in rodents when given centrally as well as peripherally (Morley et al. 1997; Lutz et al. 1998). Bhavsar et al. (1998) found a synergy between amylin and cholecystokinin for inhibition of food intake in mice.

Amylin reduces insulin-stimulated incorporation of glucose into glycogen in skeletal muscle. Young et al. (1992) found that increasing concentrations of amylin progressively depressed the maximal insulin-stimulated radioglucose incorporation into soleus muscle glycogen.

Castle et al. (1998) reported an inhibition of 3-O-methyl-D-glucose transport in perfused rat hindlimb muscle under hyperinsulinemic conditions.

Bryer-Ash et al. (1995) found that amylin-mediated reduction in insulin sensitivity corresponds to reduced insulin receptor kinase activity in the rat *in vivo*.

Transgenic mice expressing human islet amyloid polypeptide develop diabetes mellitus by 8 weeks of age, which is associated with selective β-cell death and impaired insulin secretion (Janson et al. 1996).

Mulder et al. (2000) showed that amylin-deficient mice develop a more severe form of alloxan-induced diabetes.

In single β-cells exhibiting normal glucose sensing, amylin causes membrane hyperpolarization, increases net outward current and reductions in insulin secretion. In contrast, in cells with abnormal glucose sensing (e.g., from *db/db* diabetic mice) amylin has no effect on electrical activity or secretion (Wagoner et al. 1993).

Amylin suppressed the cAMP generation induced by glucagon-like peptide 1 (GLP-1) in RINm5F cells dose-dependently (Göke et al. 1993).

Amylin, also named human islet amyloid polypeptide (hIAPP) according to van Hulst et al. (1997), may be implicated in the pathogenesis of pancreatic islet amyloid formation and type 2 diabetes mellitus (Wimalawansa 1997). Hulst et al. (1997) used transgenic mice for the study of (patho)physiological roles of hIAPP *in vivo*. Leckstrom et al. (1997) studied plasma levels and immunoreactivity of insulin and islet amyloid polypeptide in *Psammomys obesus* (sand rat) under low-energy and high-energy diet.

Amylin given peripherally or centrally inhibits acid gastric secretion in a dose dependent manner and has a protective effect against indomethacin- or ethanol-induced ulcers only when injected centrally. Subcutaneous or central injection of amylin produces a dose-dependent inhibition of gastric emptying, which may contribute to the activity of amylin in the regulation of carbohydrate absorption. In addition, amylin inhibits food intake both when injected peripherally or centrally. Amylin is considered to take part in the rapid endocrine response during digestion to maintain euglycemia (Guidobono 1998).

Amylin slows the rate of gastric emptying in spontaneously diabetic BB/Wistar rats (Macdonald 1997) and inhibits gastric acid secretion in rats (Rossowski et al. 1997).

Guidobono et al. (1997) reported a cytoprotective effect of amylin against indomethacin- and ethanol-induced ulcers when given intracerebroventricularly, but not when given subcutaneously.

Clementi et al. (1997) found a protective, dose-dependent effect of amylin against reserpine- and serotonin-induced gastric damage in rats, however, no anti-ulcer effect after pylorus ligation.

The search for a superior compound with the biological actions of human amylin resulted in the identification of [Pro^{25,28,29}]human amylin, assigned the USAN name pramlintide. Young et al. (1996) compared this compound with human and rat amylin in various pharmacological tests, such as receptor assays (binding to rat nucleus membranes, amylin receptors; binding to membranes from SK-N-MC cells, CGRP receptors; binding to membranes from T46D cells, calcitonin receptors), gastric emptying in rats, plasma glucose after oral glucose gavage. When studying glycogen metabolism in the isolated soleus muscle of rats, pramlintide was slightly more potent than human amylin, but not different from rat amylin in inhibiting insulin-stimulated incorporation of [U-^{14}C]glucose into muscle glycogen. After intravenous infusion of amylin or pramlintide, a dose-dependent increase of plasma glucose, plasma lactate and ionized calcium was found. Mean arterial blood pressure decreased with higher doses.

Clementi et al. (1995) found an anti-inflammatory activity of amylin in mouse ear edema induced by Croton oil and acetic acid-induced peritonitis in the rat, but not in serotonin-induced rat paw edema and plasma protein extravasation induced by dextran in rat skin.

Bell et al. (1995), Bell and McDermont (1995) reported that amylin has an hypertrophic effect in rat ventricular cardiomyocytes and exerts the contractile response via $CGRP_1$-preferring receptors.

In anesthetized rats, amylin increased after intravenous infusion urine flow, sodium excretion, glomerular filtration rate and renal plasma flow (Vine et al. 1998).

Clementi et al. (1996) reported that intracerebroventricularly injected amylin induced in rats a dose-dependent decrease of locomotor activity without affecting grooming and sniffing.

Amylin dose-dependently stimulated cell proliferation of human osteoblast like (hOB) cells and increased osteocalcin production (Villa et al. 1997). Cornish et al. (1998) found in adult male mice after daily subcutaneous injection of amylin for 4 weeks an increase of histomorphometric indices of bone formation and a reduction of bone resorption.

K.4.0.5.2 Receptor binding of amylin

PURPOSE AND RATIONALE

Binding sites with high affinity for amylin are present in several brain regions, with the nucleus accumbens and surrounding tissue containing more than twice as many banding sites as any other regions (Beaumont et al. 1993).

PROCEDURE

Membranes are prepared from male Sprague-Dawley rats (150–200 g). Following decapitation, the basal forebrain regions (nucleus accumbens) are removed to phosphate buffered saline (PBS), pH 7.4 at 4 °C. The tissues are weighted, then placed in 10 ml/g tissue of ice-cold 20 mM HEPES buffer, pH 7.4 and homogenized with a Polytron (10 s at setting 4). An addi-tional 30 ml of cold HEPES is added, and the homogenate centrifuged at 48 000 *g* for 15 min. After discarding the supernatant fluid, membrane pellets are resuspended by homogenization in 40 ml of fresh HEPES buffer and centrifuged as before. Membranes are washed again by homogenization in buffer and centrifugation. The final membrane pellet is resuspended in a volume of 20 mM HEPES containing 0.2 mM PMSF added immediately before use from a stock 0.2 M solution in ethanol. A volume of buffer is used to yield a concentration of about 80 mg original tissue/ml. Membranes are kept frozen at –80 °C until use.

Membranes from 4 mg of original wet weight of tissue are incubated with ^{125}I-BH-amylin (rat amylin, BH-labeled at the amino-terminal lysine, (Amersham Corp.) in 20 mM HEPES buffer, containing 0.5 mg/ml bacitracin, 0.5 mg/ml bovine serum albumin, and 0.2 mM phenylmethylsulfonyl fluoride, for 60 min at 23 °C. Incubations are carried out in duplicate tubes and are started by addition of membranes. Incubations are terminated by filtration through glass fiber filters that have been presoaked in 0.3% polyethylene-imine, followed by washing with 15 ml of cold phosphate-buffered saline.

EVALUATION

Competition curves are generated by measuring binding of 13 pM ^{125}I-BH-amylin in the presence of 10^{-11} to 10^{-6} unlabeled peptide. Data are fitted to a four-parameter logistic equation to derive half-maximal inhibitory concentrations (IC_{50} values) and slope factors (Hill coefficients).

MODIFICATIONS OF THE METHOD

Sheriff et al. (1992) characterized amylin binding sites in the human hepatoblastoma cell line, HepG2.

Perry et al. (1997) studied amylin and calcitonin receptor binding in the mouse α-thyroid-stimulating hormone thyrotroph cell line.

K.5 Blood glucose lowering activity of antidiabetic drugs

K.5.0.1 Blood glucose lowering activity in rabbits

PURPOSE AND RATIONALE

The rabbit has been used since many years for standardization of insulin (see K.3.1.1.). Therefore, it has been chosen as primary screening model for screening of blood glucose lowering compounds as well as for establishing time-response curves and relative activities (Bänder et al. 1969; Geisen 1988).

PROCEDURE

Groups of 4–5 mixed breed rabbits (e.g. Hoe:BASK, SPFWiga) of either sex weighing 3.0–4.5 kg are used. For insulin evaluation, food is withheld overnight. For evaluation of sulfonylureas and other blood glucose lowering agents the animals are on a normal diet (e.g. Era® mixed feed 8 300) prior to the experiment. The animals are gently placed into special restraining boxes allowing free access to the rabbit's ears.

Oral blood glucose lowering substances are applied by gavage in 1 ml/kg of 0.4% starch suspension or intravenously in solution. Several doses are given to different groups. One control group receives the vehicle only. By puncture of the ear veins, blood is withdrawn immediately before and 1, 2, 3, 4, 5, 24, 48, and 72 h after treatment. For time-response curves values are also measured after 8, 12, 16, and 20 h. Blood glucose is determined in 10 µl blood samples with the hexokinase enzyme method (Glucoquant® test kit).

MODIFICATIONS OF THE METHOD

For special purposes the effect of blood sugar lowering agents is studied in glucose loaded animals. Rabbits of either sex weighing 3.0–4.5 kg are treated either once (0.5 h after test compound) or twice (0.5 and 2.5 h after test compound) orally with 2 g glucose/kg body weight in 50% solution.

EVALUATION

Average blood sugar values are plotted versus time for each dosage. Besides the original values, percentage data related to the value before the experiment are calculated. Mean effects at a time interval are calculated using the trapezoidal rule. The values of the experimental group are compared statistically with the t-test or the WILCOXON test for each time interval with those of the control group. Differences between several treated groups and the control group are tested using a simultaneous comparison according to Dunnett or Nemenyi/Dunnett (1966). Dose dependencies and relative activities are determined by means of linear regression analysis after Fieller (1944) and Sidak (1967). All data for statistical comparisons have to be tested for homogeneity of variances according to Levene (1960) and for normal distribution according to Shapiro and Wilk (Miller 1965). In the case of regression analyses, the lines are additionally tested for parallelism according to Tuckey (1966) and for linearity according to Scheffé (1959). The level of significance for all procedures is chosen as 5%.

K.5.0.2 Blood glucose lowering activity in rats

PURPOSE AND RATIONALE

Rats are used for screening as well as for quantitative evaluation of blood glucose lowering agents.

PROCEDURE

Male Wistar rats (e.g. Hoe:WISKf, SPF 71) weighing 180–240 g are kept on standard diet (e.g. Altromin® 1 324). Groups of 4–7 non-fasted animals are treated orally or intraperitoneally with various doses of the test compounds suspended in 0.4% starch suspension. One control group receives the vehicle only. Blood is withdrawn from the tip of the tail immediately before, and 1, 2, 3, 5, and 24 h after administration of the test compound. Blood glucose is determined in 10 µl blood samples with the hexokinase enzyme method (Glucoquant® test kit).

EVALUATION

Average blood sugar values are plotted versus time for each dosage. Besides the original values, percentage data related to the value before the experiment are calculated. Mean effects over a time period are calculated using the trapezoidal rule. Statistical evaluation is performed as described for tests in rabbits.

MODIFICATIONS OF THE METHOD

Studies in glucose loaded rats

For special purposes the effect of blood sugar lowering agents is studied in glucose loaded animals. One g glucose/kg body weight is given in a 50% solution either orally 5 min after oral administration or subcutaneously 5 min after intraperitoneal administration of the test compound.

Studies in streptozotocin-diabetic rats

Male Wistar rats (e.g. Hoe:WISKf, SPF 71 strain) weighing 170–220 g are kept on standard diet (e.g. Altromin® 1 324). Ten–fourteen days prior to the study they are injected with 60 mg/kg streptozotocin (Calbiochem) intravenously. Blood sugar levels rise from 5.5–6.0 mmol/l up to 25.0–28.0 mmol/l and glucosuria occurs. Plasma insulin levels fall below 4 µU/ml.

Compounds which release insulin from pancreatic islets as sole hypoglycemic activity are not effective in rats with severe streptozotocin induced diabetes.

Studies in guinea pigs

Instead of rats male guinea pigs (e.g., Pirbright white, Hoe:DHPK, SPF Lac) weighing 250–380 g can be used. Blood is withdrawn by puncture of ear veins before, and 1, 3, and 5 h after administration of the test compound or the vehicle. Blood sugar determinations and statistical evaluations are performed as described for rabbits and rats.

Studies in genetically diabetic animals

Genetically obese and diabetic yellow KK mice have been used by Sohda et al. (1990) for evaluation of hypoglycemic activity of potential antidiabetic drugs.

Gill and Yen (1991) studied the effect of ciglitazone in obese-diabetic viable yellow mice (VY/Wfl-A^{vy}/a).

K.5.0.3 Blood glucose lowering activity in dogs

PURPOSE AND RATIONALE

Besides experiments in rats and rabbits studies in dogs are necessary to predict the effect of a new compound in man due to differences in species related metabolism.

PROCEDURE

Male Beagle dogs weighing 15–20 kg are kept on standard diet (e.g. Erka mixed feed 8 500). Food is withdrawn 18 h prior to the administration of the test compound which is given either orally or intravenously in various doses. Control animals receive the vehicle only. Blood is collected at different time intervals up to 48 h. Blood glucose is determined with the hexokinase enzyme method (Glucoquant® test kit) and plasma insulin with an immunological method (Riagnost®-kit).

EVALUATION

Average blood sugar values are plotted versus time for each dosage. Besides the original values, percentage data related to the value before the experiment are calculated. Mean effects over a time period are calculated using the trapezoidal rule. Similarly, plasma insulin levels are plotted versus time and compared with control values. Statistical evaluation is performed as described for tests in rabbits.

MODIFICATIONS OF THE METHOD

Studies in pancreatectomized dogs

The surgical technique of pancreatectomy in dogs is described in Sect. K.1.0.1. The animals are pancreatectomized up to 2–3 years prior to the study. They are kept on dry feed (Vipromix®) together with 2–3 g pancreatic enzymes (Viveral®). Insulin is substituted with a single daily subcutaneous dose of 32 IU Insulin Ultratard HM®. For substitution of vitamin D an intramuscular dose of 1 ml Vigantol® is given every 3 months.

On the day before the study, the animals receive 32 IU of the shorter acting Basal-H® insulin. This insulin is administered at the same time when food and test compound are given in the morning. The test drug

is applied as oral suspension in tap water. Blood glucose is determined before and up to 6 h after treatment in hourly intervals. Control animals receive tap water only.

Studies in alloxan-diabetic dogs

Chemical diabetes can be induced by a single intravenous dose of 60 mg/kg alloxan. Afterwards, the animals receive infusions of 1 000 ml 5% glucose together with 10 IU Regular® Insulin via a jugular vein catheter daily during one week and canned food ad libitum. Thereafter, a single dose of 28 IU Insulin Ultratard HM® is given daily and the animals are fed commercial diet (Altromin® pellets). On the day before the study, the dogs receive 28 IU of the shorter acting Basal-H® insulin. This insulin is given at the same time as food and test compound in the morning. The test drug is applied as oral suspension in tap water. Blood glucose is determined before and up to 6 h after treatment in hourly intervals. Control animals receive tap water only.

Continuous blood glucose monitoring

A device for continuous blood glucose monitoring and infusion in freely mobile dogs was described by Geisen et al. (1981).

K.5.0.4 Euglycemic clamp technique

PURPOSE AND RATIONALE

The euglycemic glucose clamp technique has provided a useful method of quantifying *in vivo* insulin sensitivity in humans (DeFronzo et al. 1979). In this technique a variable glucose infusion is delivered to maintain euglycemia during insulin infusion. Whole-body tissue sensitivity to insulin, as determined by net glucose uptake, can be quantitated under conditions of near steady state glucose and insulin levels. Kraegen et al. (1983, 1985) developed the euglycemic glucose clamp technique for use in the intact conscious rat.

PROCEDURE

Male Wistar rats weighing 150–200 g are fasted overnight and anesthetized with pentobarbital (40 mg/kg, i.p.). Catheters are inserted into a jugular vein and a femoral vein for blood collections and insulin and glucose infusion, respectively. To evaluate the insulin action under physiological hyperinsulinemia (steady state plasma insulin concentration during the clamp test around 100 μU/dl), and maximal hyperinsulinemia (under which maximal insulin action may appear) two insulin infusion rates, 6 and 30 mU/kg/min, are used. The blood glucose concentrations are determined from samples collected at 5-min intervals during the 90-min clamp test. The glucose infusion rate is adjusted so as to maintain the blood glucose at its basal level during the clamp test. The final glucose infusion rate is calculated from the amount of glucose infused for the last 30 min (from 60 to 90 min after start of the clamp) in which the blood glucose levels are in a steady state. The glucose metabolic clearance rate is obtained by dividing the glucose infusion rate by the steady state blood glucose concentration. The steady state plasma insulin concentration is calculated from the insulin concentrations at 60 and 90 min after the start of the clamp. At the start and end of the euglycemic clamp test, free fatty acid concentration is also determined and the free fatty acid suppression rate is calculated.

EVALUATION

All values are analyzed by one-way ANOVA.

When the steady state plasma insulin is maintained at submaximal concentration by the euglycemic clamp technique, the glucose infusion rate and glucose metabolic clearance rate value are considered to reflect the state of receptor binding levels in the peripheral tissue as an index for insulin sensitivity. Under maximal hyperinsulinemia these values are thought to reflect the state of the enzymes and glucose transport system activated after the binding to receptors, indicating mainly insulin responsiveness.

MODIFICATIONS OF THE METHOD

Burnol et al. (1983) used the euglycemic insulin clamp technique coupled with isotopic measurement of glucose turnover to quantify insulin sensitivity in the anesthetized rat.

Bryer-Ash et al. (1995) used this technique to demonstrate reduction of insulin sensitivity by amylin corresponding to reduced insulin receptor kinase activity.

The effects of counterregulatory hormones on insulin-induced glucose utilization by individual tissues in rats, using the euglycemic hyperinsulinemic clamp technique combined with an injection of 2-[1-^{3}H]-deoxyglucose, were studied by Marfaing et al. (1991).

Lang (1992) determined the insulin-mediated glucose uptake in normal and streptozotocin-diabetic rats using the euglycemic-hyperinsulinemic clamp technique.

Hirshman and Horton (1990) reported increased insulin sensitivity and responsiveness in peripheral tissues of the rat after glyburide as determined by the glucose clamp technique.

Lee et al. (1994) studied the metabolic effects of troglitazone on fructose-induced insulin resistance with the euglycemic hyperinsulinemic clamp technique in rats.

Tominaga et al. (1992, 1993) studied the influence of insulin antibodies in anesthetized rats and of thiazolidinediones on hepatic insulin resistance in streptozotocin-induced diabetic rats by the glucose clamp technique.

Gelardi et al. (1991) used the hyperinsulinemic-euglycemic clamp technique to evaluate the insulin sensitivity in the obese offspring of streptozotocin-induced mildly hyperglycemic rats.

Hulman et al. (1993) studied insulin resistance in the conscious spontaneously hypertensive rat with the euglycemic hyperinsulinemic clamp technique.

Cheung and Bryer-Ash (1994) described a modified method for the performance of glucose insulin clamp studies in conscious rats under local anesthesia.

Burvin et al. (1994) developed a modification of the euglycemic insulin clamp technique and used it to repeatedly assess *in vivo* insulin effects in awake streptozotocin-induced diabetic rats.

Xie et al. (1996) described a modified euglycemic clamp technique in **cats**.

Finegood et al. (1987) estimated endogenous glucose production during hyperinsulinemic-euglycemic glucose clamps using unlabeled and labeled glucose infusates in **dogs**.

Xie et al. (1996) described an insulin sensitivity test using a modified euglycemic clamp in **cats** and rats. This test uses the amount of glucose required to be infused to maintain euglycemia over a 30-min period in rats and 60 min in cats following a bolus administration of insulin as the index of insulin sensitivity. Glucose levels are determined a short intervals and variable glucose infusion is used to hold glucose levels within a few percentage points of the basal pre-test glucose level. A new blood sampling technique is described that allows each insulin sensitivity test to be carried out using a total of only 0.5 ml of blood.

K.5.0.5 Effects of insulin sensitizer drugs

PURPOSE AND RATIONALE

Insulin sensitizer drugs are reported to improve symptoms in patients with established NIDDM (non-insulin dependent diabetes mellitus) (Colca 1995; Kuehnle 1996). In contrast to sulfonylureas, these compounds do not lower blood glucose in normal animals. Various animal models resembling type II diabetes are used for evaluation. Details of these models are described in the respective chapters. *In vitro* techniques showed an increased glucose uptake of into muscle tissue and into adipocytes.

PROCEDURES

In vivo studies

Chang et al. (1983) studied ciglitazone in *ob/ob* and *db/db* mice, diabetic Chinese hamsters, and normal and streptozotocin-diabetic rats.

Fujita et al. (1983) investigated the effects of ciglitazone in obese-diabetic yellow *KK* (*KK-A*^{y}) mice and obese Zucker-fatty rats.

Diani et al. (1984) treated C5BL/6J-*ob/ob* and C57BL/KsJ-*db/db* mice for several weeks with ciglita-zone and studied the morphological effects on pancreatic islets.

Fujiwara et al. (1988) performed studies in *KK* and *ob/ob* mice and Zucker fatty rats.

Moreover, Fujiwara et al. (1991) studied the effects of CS-045 on glycemic control and pancreatic islet structure at a late stage of the diabetes syndrome in C57BL/KsJ-*db/db* mice.

Ikeda et al. (1990), Sohda et al. (1990) used insulin resistant animals (yellow *KK* mice, Zucker fatty rats, and obese Beagle dogs with moderate insulin resistance).

Gill and Yen (1991) studied the effects on endogenous plasma islet amyloid polypeptide and insulin sensitivity in obese-diabetic viable yellow mice.

Hofmann et al. (1991, 1992) treated insulin resistant KKA^y mice.

Stevenson et al. (1991) studied the effects of englitazone in nondiabetic rats and found no overt hypoglycemia but an enhancement of insulin action.

Kobayashi et al. (1992) found an increase of insulin sensitivity by activating insulin receptor kinase in genetically obese Wistar fatty rats treated with various doses of pioglitazone.

Sugiyma et al. (1992) found a reduction of glucose intolerance and hypersecretion of insulin in Wistar fatty rats after treatment with pioglitazone for 10 days.

Tominaga et al. (1993) used the glucose clamp-technique in streptozotocin-induced diabetic rats.

Yoshioka et al. (1993) found antihypertensive effects in obese Zucker rats.

Lee et al. (1994) studied the metabolic effects on fructose-induced insulin resistance in rats.

Apweiler et al. (1995) administered BM 13.09143 to lean and obese Zucker rats and performed hyperinsulinemic-euglycemic clamp studies in these animals.

Fujiwara et al. (1995) found a suppression of hepatic gluconeogenesis in long-term troglitazone treated diabetic KK and C57BL/ksJ-*db/db* mice.

Lee and Olefsky (1995) studied the effects of troglitazone in normal rats with the euglycemic glucose clamp technique.

In vitro studies

Kirsch et al. (1984) found a reversal of cAMP-induced post-insulin receptor resistance in rat adipocytes *in vitro*.

Ciaraldi et al. (1990) performed *in vitro* studies using cultured hepatoma cells (Hep G2) and muscle cells (BC3H-1) and found an increased glycogen synthase I activity in both cell types.

Murano et al. (1994) found a stimulation of fructose-2,6-bisphosphate production in rat hepatocytes.

Kellerer et al. (1994) reported the prevention of glucose-induced insulin resistance of insulin receptor in rat-1 fibroblasts.

Bader et al. (1993) found an increased [^{32}P]incorporation in the 95 kD β-subunit of the insulin receptor and an increased phosphorylation of the synthetic substrate Poly[GluNa4 : 1Tyr] in receptors isolated from skeletal muscle of obese Zucker rats treated with CS 045.

Teboul et al. (1995) found that thiazolidinediones convert myogenic cells (C_2C_{12}N myoblasts, a subclone of the C_2C_{12} cell line) into adipose-like cells. Thiazolidinediones or fatty acids prevented the expression of myogenin, α-actin, and creatine kinase and abolished the formation of multinucleated myotubes. In parallel, these treatments induced the expression of a typical adipose differentiation program including acquisition of adipocyte morphology and activation of adipose-related genes.

Tafuri (1996) reported that troglitazone enhanced the rate and percent differentiation of fibroblasts to adipocytes. Basal glucose transport and synthesis of GLUT1 transporter messenger RNA were increased.

Stevenson et al. (1990) examined the effects of racemic englitazone (CP 68 722) in adipocytes and soleus muscles from *ob/ob* mice and in 3T3-L1 adipocytes. Administration of the drug in various doses lowered plasma glucose and insulin dose-dependently without producing frank hypoglycemia in either diabetic or nondiabetic animals. Basal and insulin-stimulated lipo-

genesis were enhanced in adipocytes from *ob/ob* mice. Glycogenesis and basal glucose oxidation in isolated soleus muscles were stimulated.

Kreutter et al. (1990) used 3T3-L1 adipocytes and found a stimulation of 2-deoxyglucose uptake.

Masuda et al. (1995) found an insulinotropic mechanism distinct from glibenclamide in isolated rat pancreatic islets and HIT cells.

K.5.0.6 Effects of thiazolidinediones on peroxisome proliferator-activated receptor-γ

PURPOSE AND RATIONALE

Peroxisome proliferator-activated receptors (PPARs) compose a subfamily of the nuclear hormone receptors. Three distinct PPARs, termed α, δ, and γ, each encoded by a separate gene and showing a distinct tissue distribution pattern, have been described (Keller and Wahli 1993; Green 1995; Devchand et al. 1996; Lemberger et al. 1996; Schoonjans et al. 1996a,b, 1997). Ligands that induce the transcriptional activity of PPARα and γ have been identified (Forman et al. 1995; Devchand et al. 1996; Lehmann 1995). PPARγ is a central regulator of adipocyte gene expression and differentiation (Tortonoz et al. 1995; Brun et al. 1996; Wu 1998). Thiazolidinedione derivatives which are antidiabetic agents are potent and selective activators of PPARγ (Young et al. 1997; Murakami et al. 1998; Reginato et al. 1998; Ribon et al. 1998). Berger et al. (1996) found a correlation of antidiabetic actions of thiazolidinediones in *db/db* mice with the conformational change in peroxisomal proliferator-activated receptor-γ: Murphy and Holder (2000) suggested a therapeutic potential of PPARγ agonists in the treatment of inflammatory diseases and certain cancers.

Steppan et al. (2001), Berger (2001) showed that adipocytes secrete a signaling molecule which they called resistin (for resistance to insulin). Circulating resistin levels in mice are decreased by thiazolidindiones and are increased in diet-induced and genetic forms of obesity.

PROCEDURE

Plasmids

The pSG5-haPPARγ1 expression construct is generated by inserting the hamster PPARγ complementary DNA into the EcoRI site of the pSG5 expression vector (Strategene, La Jolla, CA). As reporter construct, pPPRE-chloramphenicol acetyltransferase (CAT) is used containing two copies of the peroxisomal proliferator response element from the enhancer region of the murine acyl coenzyme A-oxidase gene adjacent to the glutathione-S-transferase minimal promotor and the CAT gene.

Cell culture and transfections

COS-1 cells are seeded at 2.1×10^5 cells per dish in 35-mm dishes (for transactivation assays) and 3×10^6 cells/dish in 150-mm dishes (for binding assays) in DMEM (high glucose) containing 10% charcoal-stripped fetal calf serum, nonessential amino acids, 100 U/ml penicillin G, and 100 µg/ml streptomycin sulfate at 37 °C in a humidified atmosphere of 10% CO_2. After 24 h, transfections are performed with Lipofectamine (Life Technologies, Gaithersburg, MD). For transactivation experiments, transfection mixes are used containing 1 µg receptor expression vector, and 1 µg pCH110 (Pharmacia, Piscataway, NJ) as an internal control and, for binding studies 20 µg receptor expression vector.

Binding assay

Transfected cells are grown for 48 h after transfection with the receptor expression vector. Receptor preparation is performed according to Tilley et al. (1989). Cell lysates containing receptor are prepared in TEGM (10 mM Tris-HCl, pH 7.2; 1 mM EDTA; 10% glycerol; 7 µl/100 ml β-mercaptoethanol; 10 mM Na molybdate; 1 mM dithiothreitol; 5 µg/ml aprotinin; 2 µg/ml leupeptin; 2 mg/ml benzamide; and 0.5 mM phenylmethylsulfonylfluoride). Plates are placed on ice, rinsed with TEG (10 mM Tris-HCl, pH 7.2; 50 mM EDTA; and 10% glycerol), and scraped into 0.5 ml TEGM. The material is pooled, frozen in liquid nitrogen to lyse the cells, and thawed on ice. The lysate is centrifuged at 22 000 *g* for 20 min at 4 °C to remove the debris and stored frozen (–80 °C) until use. For each assay, an aliquot of receptor-containing lysate (0.1–0.25 mg protein) is incubated with 10 nM ditritiated AD-5 075 (21 Ci/mmol) with or without test compound for ~16 h at 4 °C in TEGM (300 µl final volume). Unbound ligand is removed by incubation on ice for ~10 min after the addition of 200 µl dextran/gelatin-coated charcoal. After centrifugation at 3 000 rpm for 10 min at 4 °C, 200-µl aliquots of supernate are counted in an liquid scintillation counter.

Transactivation assay

After transfection, cells are incubated for 48 h in culture medium with or without increasing concentrations of test compounds. Cell lysates are produced using reporter lysis buffer (Promega Corp., Madison, WI). CAT activity is determined using radiolabeled butyryl CoA as substrate in a diffusion based assay. β-Galactosidase activity is determined according to Hollons and Yoshimura (1989).

Protease digestion assay

The protease digestion assay is performed according to the method of Allan at al (1992) with minor modifications. The plasmid pSG5-haPPARγ1 is used to synthesize ^{35}S-radiolabeled PPARγ1 in a coupled transcription/translation system. The transcription/translation reactions are subsequently aliquoted into 22.5-µl vol-

umes, and 2.5 µl PBS with or without a thiazolidinethione are added. The mixtures are incubated for 20 min at 25 °C, separated into 4.5-µl aliquots, and 0.5 µl distilled water or distilled water-solubilized trypsin are added. The protein digestions are allowed to proceed for 10 min at 25 °C, then terminated by the addition of 20 µl denaturing gel loading buffer and boiling for 5 min. The products of the digestion are separated by electrophoresis through a 1.5-mm 12% polyacrylamide-SDS gel. After electrophoresis, the gels are fixed in 10% acetic acid-40% methanol for 30 min, treated in EN^{3}HANCE for an additional 30 min. and dried under vacuum for 2 h at 80 °C. Autoradiography is then performed to visualize the radiolabeled digestion products.

EVALUATION

Binding assays

For binding assays, competition curves are generated by incubation of 10 nM [^{3}H]AD-5075 with hamster PPARg1 produced by transient transfection of COS-1. The percentage of ligand bound after incubation in the presence of the indicated concentration of each unlabeled compound for 16 h is plotted.

Activation assays

For activation assays of PPARg in COS-1 cells transiently cotransfected with pSG5-haPPARg1 and pPPRE-CAT, normalized CAT activity is plotted after incubation in the presence of the indicated concentration of each compound for 48 h.

Protease digestion assay

For evaluation of the protease digestion assay, the partially protease-resistant conformation product of PPARg is visualized by autoradiography on SDS-PAGE after incubation with the thiazolidinedione and increasing concentrations of trypsin.

K.6 Activity in isolated organs, cells, and membranes

K.6.1 Effects on pancreas

K.6.1.1 Perfusion of isolated rat pancreas

PURPOSE AND RATIONALE

The *in vitro* perfusion of the isolated rat pancreas as described by Anderson and Long (1947) and by Grodsky et al. (1963, 1984; Muñoz et al. 1995) offers the advantage to study the influence of carbohydrates, hormones and drugs such as sulfonylureas not only on insulin but also on glucagon and somatostatin secretion without interference of secondary effects resulting from changes in hepatic, pituitary or adrenal functions.

PROCEDURE

Male Wistar rats (e.g. Hoe:WISKf, SPF 71-strain) weighing 200–250 g serve as donors. Prior to the experiment, the animals have free access to food and water. The pancreas is removed under pentobarbital (50 mg/kg i.p.) anesthesia. The mesenteric artery is doubly ligated and cut, and the entire intestine below the duodenum is separated and removed from the rat to simplify the exposure. The esophagus is ligated as high as possible and cut above the ligature. A loose ligature is placed, but not tied, around the entire gastrohepatic ligament. The aorta is cautiously exposed through the crura of the diaphragm well above the point of origin of the celiac axis. The ligature around the gastrohepatic ligament is then tied as tightly as possible, and the ligament cut above the ligature. The aorta is cut between the double clamps and below the lower clamp, and the preparation is lifted out from the abdomen. The clamps are removed from the aorta which is slit open on the side opposite to the origin of the celiac axis, revealing the opening of the latter. The arterial cannula is inserted and tied in place. An opening is made close to the ligature, as near as the end of the portal vein as possible.

Circulation through the preparation is initiated and fluid is observed to flow from the slit in the portal vein. After a minute or two, the flow is stopped and a cannula is inserted into the portal vein and tied in place. Flow is then resumed at a perfusion pressure of about 100 mm Hg. Carbogenated Krebs-Ringer bicarbonate buffer with 2% bovine albumin and 5.5 mmol/l glucose is used as perfusion medium at a temperature of 37.5 °C with a perfusion rate of 1.75 ml/min. The perfusate is collected every minute for 30 min. After 5 min perfusion with 5.5 mM glucose, the test compound is added until the 15th min (concentrations between 0.05 and 0.5 mM for highly active substances), followed by perfusion with 5.5 mM glucose and finally with 16.6 mM glucose.

The perfusate medium samples are stored at –20 °C until further processing.

EVALUATION

The hormones: insulin, glucagon and somatostatin are determined radioimmunologically: insulin with the RIAgnost®-kit and rat insulin as standard; glucagon with a rabbit antibody, ^{125}I-glucagon as tracer, and polyethylene glycol as precipitant; somatostatin with a rabbit antibody, ^{125}I-tyrosyl-somatostatin as tracer and charcoal dextran for separation of free and bound hormone. At least 3 experiments per concentration are performed. The values of each collection period of 1 min are averaged and plotted versus time. The effects of the test compound (increase or decrease of the secreted hormones) are compared with the control periods and the effect of elevated glucose.

CRITICAL ASSESSMENT OF THE METHOD

The isolated perfused rat pancreas has been proven to be a useful tool to study the degree and time course of secretion of the pancreatic hormones insulin, glucagon and somatostatin under the influence of sulfonylureas.

MODIFICATIONS OF THE METHOD

Penhos et al. (1969) described a technique for *in situ* perfusion of **rat** pancreas alone or with a small intestine preparation which is suitable for studying insulin and/or glucagon secretion and the role intestinal factors have upon it.

Silvestre et al. (1996) studied in the perfused pancreas of the rat the effect of $^{8-32}$salmon calcitonin, an amylin antagonist, on insulin, glucagon and somatostatin release.

Weir et al. (1979) used the isolated perfused pancreas of **dogs** to study the influence of glucagon, insulin and arginine on somatostatin and pancreatic polypeptide secretion.

Retrograde perfusion of the isolated perfused pancreas of dogs was used as a model for testing the relative effects of glucose versus insulin on the A cell by Stagner and Samols (1986).

K.6.1.2 Perifusion of isolated rat pancreatic islets

PURPOSE AND RATIONALE

An assay with isolated pancreatic islets to study the dynamic response and transitions between various metabolic states has been recommended by Idahl (1972). A further description and discussion of the method were given by Malaisse-Lagae and Malaisse (1984).

PROCEDURE

Male Wistar rats weighing 200–250 g serve as donors. Before the study, the animals have free access to food and water. Two donor rats are used for each test. The pancreas is removed under pentobarbital anesthesia. The islets are obtained by the collagenase (e.g. collagenase type IV, Worthington, Freehold) method and collected under a stereomicroscope. In each test, up to 10 chambers each with 15 islets are perifused. Cut-off Microfuge® tubes, sealed with Tuohy-Borst® adapters, serve as perfusion chambers. Two thick-walled, small-diameter Teflon® catheters are passed through the adapter into the chamber. One of the catheters extends to the bottom of the chamber and acts as the perifusate inlet, the other extends to the lower edge of the adapter cone and acts as outlet. The latter is connected to a multi-channel peristaltic pump which delivers the perifusate to a fraction collector. The chamber volume is 0.15 ml. The perifusate flow rate is 0.1 ml/min. The perifusate consists of a carbogenated Krebs-Ringer bicarbonate buffer with 1.0 mmol/l glucose, 0.25% bovine albumin, and 5 mmol/l theophylline. The storage vessels for the perifusate, the chambers, and the inlet catheters are immersed in a water bath of 37 °C.

After a pre-perifusion phase of one hour, the perifusate is collected every min for 46 min. From the 2nd until the 18th min, the test compound is added at concentrations between 0.1 and 2.5 µmol/l, and from the 34th to the 46th min, the glucose concentration is raised to 20.0 mmol/l.

Insulin is determined with the RIAgnost® kit using rat insulin as standard in every second sample. The determination is done immediately after the end of an experiment.

EVALUATION

The raw data are expressed in µU insulin per islet/min. Mean and standard error of the mean of each time interval are calculated for graphical representation. The values under exposure to drug are compared with the values under perifusion with glucose only, and with the effect of elevated glucose.

MODIFICATIONS OF THE METHOD

Lernmark (1974) described a method using free cell suspensions from **mouse** pancreatic islets. The glucose response was found to be lower compared to that of intact isolated islets.

A microperifusion system with especially designed microperifusion chambers was described by Panten et al. (1977).

Details of islet cell purification have been reported by Pipeleers (1984).

Tissue culture of dispersed islet cells has been described by Fletcher and Weir (1984).

A simple method for **human pancreatic β cell cultures** has been described by Yoon et al. (1984).

Islet cell membrane isolation and characterization have been described in detail by McDaniel et al. (1984).

Kaiser and Cerasi (1991) described the long term monolayer culture of adult rat islet of Langerhans as an experimental model for studying chronic modulation of b-cell function.

Horaguchi and Merrell (1981) described a method for preparation of viable islet cells from **dogs**.

This method has been used by Marincola et al. (1983) to study the effect of insulin on its own secretion.

Marchetti et al. (1989) used isolated islets of Langerhans of adult **pig** pancreata obtained from slaughterhouses to evaluate the insulin secretion in response to glucose and arginine and inhibition of insulin secretion by the presence of purified insulin.

K.6.1.3 Insulin producing tumor cells

PURPOSE AND RATIONALE

Chick et al. (1977) described a transplantable insulinoma in the rat which was originally observed as primary tumor in the pancreas of an old male NEDH albino rat being previously irradiated during a parabiosis experiment. Fragments of this tumor were transplanted to young NEDH rats in many passages inducing severe hypoglycemia in host rats. Gazdar et al. (1980) reported the establishment of a continuous cell line of a rat islet cell tumor which secretes primarily insulin and some somatostatin. Bhatena et al. (1982) studied insulin, glucagon, and somatostatin receptors on cultured cells and clones from rat islet cell tumor.

PROCEDURE

The insulinoma is transplanted when the tumor has reached a diameter of about 2 cm and the carrier animal exhibits distinct manifestations of insulin excess. The tumor is removed, cut open, mixed briefly in a mortar and one tenth to one twentieth is injected between the shoulder blades of another animal. No metastases are observed. The histological examination also shows a nonmalignant adenoma. The tumors grow only in rats of the strain NEDH (New England Deaconess Hospital).

Insulin producing cells from the RINm5F cell line are grown in RPMI medium containing 10% (v/v) heat inactivated fetal calf serum, 50 IU/ml penicillin, 0.25 µg/ml amphotericin B, and 50 µg/ml streptomycin at 37 °C in an atmosphere of humidified air/CO_2 (19 : 1) (Praz et al. 1983). The cells are seeded at a density of 3.5×10^4 cells/ml in 20 ml of medium (75 cm^2 culture flasks). The medium is replaced 4 times a week (one passage). Thereafter, the cells are treated with trypsin (0.02% trypsin in 0.9% NaCl/0.2 mM EDTA) for 2–5 min at 37 °C. The trypsin-treated cells are diluted, re-seeded at a density of 2×10^6 cells per 75 cm^2 culture flask and grown to 70% confluency.

The cells are used for preparation of cell membranes (Müller et al. 1994).

MODIFICATIONS OF THE METHOD

The cell lines **RIN-m** and **RINm5F** have been used by several authors e.g. for receptor studies or for patch clamp experiments (Gögelein et al. 1998). RINm5F

cells were maintained in RPMI 1 640 tissue culture media, containing 11 mM glucose, supplemented with 10% fetal calf serum, 2 mM glutamine and 50 µg/ml gentamycine. Cells were seeded out every 2–3 days onto Petri dishes and kept in a humidified atmosphere of 95% O_2 and 5% CO_2 at a temperature of 37 °C. For patch-clamp experiments, cells were isolated by incubation in a Ca^{2+}-free medium containing 0.25% trypsin for about 3 min. Single cells and clusters of 2–3 cells were obtained after centrifugation with 800 rpm and were stored on ice until use. The tight-seal whole-cell patch-clamp technique was applied to single cells.

Several other insulin secreting cell lines were reported in the literature (Review by Poitout et al. 1996).

The insulin secreting **HIT cell line** was developed by Santerre et al. (1981) by isolating pancreatic islets from the hamster, dispersing the islets into single cells, transforming the cell isolates with the simian virus 40 (SV40), and cloning out the insulin-secreting cell lines. These clonal cells retain a differentiated function and respond to secretagogues and inhibitors of insulin secretion (Boyd et al. 1991).

Experiments for assessment of glucose transport activity in HIT cells and Western blot analysis for GLUT2 in these cells after incubation with glibenclamide and troglitazone were performed by Masuda et al. (1995).

Asfari et al. (1992) derived **INS-1 cells** and **INS-2 cells** from parental RINm5f cells. In the course of a coculture of lymphocytes and RIN cells in the presence of 2-mercaptoethanol, the authors observed the formation of free-floating cell aggregates which appeared to be morphologically different from the parental cells. These clusters were isolated and gave rise to the INS-cell lines, whose viability is dependent on the presence of 2-mercaptoethanol in the media and whose secretory characteristics are similar to those of native islets.

Hanahan (1985) applied gene transfer technology to the establishment of β-cell lines. In order to target the expression of viral DNA to the β-cell, recombinant oncogenes were designed by fusion of the 5' regulatory region of the rat insulin II gene with the early coding region of SV40. The transgenes were microinjected into fertilized mice embryos, which were then implanted in the oviduct of pseudo-pregnant females. The offspring specifically expressed SV40 in their β-cells and spontaneously developed β-cell tumors at 10–20 weeks of age. Tumors were subsequently excised, isolated and propagated in culture, giving rise to β-tumor cell (**β-TC**) lines (Erfrat et al. 1988). Because these cells do not grow in culture at low density, the have not been cloned, and several subpopulations have been derived.

Similarly, the **MIN6 cell** was derived from transgenic mice expressing a comparable transgene (Miyazaki et al. 1990).

Hamaguchi et al. (1991) applied this technique to the development of the **NIT1 cell line** from transgenic NOD mice in order to establish an immortalized source of NOD β-cells.

The **betacyte**, also called the **HEP G2ins/g cell**, is a genetically engineered insulin-secreting human liver cell line that is glucose responsive (Simpson et al. 1995, 1996; Tuch et al. 1997). The clone was constructed by doubly transfecting the HEP G2 cell line with insulin cDNA under the control of the constitutive CMV promoter and the cDNA for the glucose transporter 2, which is specific to β-cells and hepatocytes. This cell is capable not only of synthesizing, storing and secreting insulin in a regulated fashion when challenged with physiological concentrations of glucose, but also of acting as a liver cell and secreting albumin.

Tuch et al. (1997) studied the effect of β-cell toxins (streptozotocin, alloxan and pentamidine) on betacytes.

K.6.1.4 Isolation of membranes

PURPOSE AND RATIONALE

For receptor binding studies, membranes are isolated from adenoma tissue suspension, cerebral cortex of Wistar rats (Kaubisch et al. 1982; Geisen et al. 1985) or from RINm5F cells (Müller et al. 1994).

PROCEDURE

Cerebral cortex homogenates are prepared from decapitated Wistar rats. The cortices are immersed in ice-cold buffer, pH 7.5, and are homogenized under cooling in an Ultraturrax® tissue homogenizer. The cell membranes are centrifuged at 50 000 *g*, resuspended in fresh phosphate buffer and recentrifuged at the same speed. The resulting pellet is suspended in phosphate buffer, the final dilution being 1 : 50, based on wet weight of the cerebral cortex. One ml aliquot of this cell suspension is used for the incubations.

β-Cell adenoma tissue, dissected from rats of the strain NEDH, is homogenized in 25 mM HEPES/KOH, pH 7.4, 0.25 M sucrose, 0.5 mM EDTA, 100 μM PMSF (50 ml/g tissue) under cooling with ice (3 × 5 s) with an Ultraturrax® homogenizer. After centrifugation (5 min at 3 000 *g*) the supernatant is transferred into new tubes and centrifuged (60 min at 200 000 *g* at 4 °C). The pellet is washed with 2 × 5 ml of the same buffer, resuspended in 2 volumes of the same buffer and centrifuged again (30 min at 75 000 *g*). The pellet is resuspended again in the membrane buffer.

Insulin producing cells from RINM5F cell culture (one culture flask) are washed twice with 25 mM HEPES/KOH (pH 7.4), 0.25 M sucrose, 0.5 mM EDTA, scraped with 20 ml of the same buffer and homogenized with 10 strokes of a tight fitting Potter-Elvehjem homogenizer followed by sonication (bath sonicator, 4 °C, 10 s, maximal power). After centrifugation (45 min at 200 000 *g*, 4 °C) the pellet is suspended in 10 ml of 25 mM HEPES/KOH (pH 7.4), 0.25 M sucrose, 100 mM NaCl, 0.5 mM EDTA, 200 μM PMSF and recentrifuged (10 min at 1 000 *g*). The supernatant is transferred to a new tube and centrifuged (30 min at 50 000 *g*, 4 °C). The pellet is washed once with 25 mM HEPES/KOH (pH 7.4) and finally suspended in membrane buffer (25 mM HEPES/KOH pH 7.4, 150 mM NaCl, 1 mM EDTA, 100 μM PMSF, 10 μg/ml soybean/trypsin inhibitor, 10 μM leupeptin, 1 mM iodoacetamide at 5 mg protein/ml). Aliquots are stored at –80 °C.

K.6.1.5 Receptor binding of sulfonylureas[4]

PURPOSE AND RATIONALE

Sulfonylureas block ATP-dependent K^+ channels in the β-cell plasma membrane (Schmid-Antomarchi et al. 1987). Binding to the receptor and depolarization of

[4] Contributions by G. Müller.

the membrane initiates a chain of events leading to the release of insulin (Boyd 1992). The high affinity sulfonylurea receptor is considered to be an integral part of the ATP-sensitive K^+ channel (Aguilar-Bryan et al. 1992). Binding studies of sulfonylureas and other drugs can be performed on isolated pancreatic islets, isolated insulinoma cells, isolated intact membranes or solubilized membranes (Geisen et al. 1985; Gaines et al. 1988; Panten et al. 1989, 1992, 1993; Müller et al. 1994).

PROCEDURE

Binding to intact RINm5F cells

Cells seeded in culture flasks at a density of 2×10^6 cells and grown to 70% confluency are treated with trypsin (0.02% trypsin in 0.9% NaCl/0.2 mM EDTA), washed with 3×10 ml HEPES based Krebs-Ringer buffer containing 20 mM HEPES/KOH (pH 7.4), 125 mM NaCl, 5 mM KCl, 7.5 mM $NaHCO_3$, 2 mM $CaCl_2$, 0.8 mM $MgSO_4$, suspended at a density of 2×10^7 cells/ml in the same buffer and then incubated for 45 min at 4 °C at a density of 4×10^6 cells per 0.5 ml assay volume with labelled sulfonylurea, e.g., [^{3}H]glibenclamide or [^{3}H] glimepiride at concentrations between 0.1 and 20 nM. For determination of non-specific binding, 1 µM unlabeled ligand is included. The incubation mixture is rapidly filtered on Whatman GF/C filters soaked with ice-cold buffer under reduced pressure. Filtration and washing has to take less than 30 s. The filters are washed three times with 6 ml ice-cold buffer containing 100 µM PMSF, 0.5 µg/ml leupeptin, 0.75 mg/ml pepstatin, 1 µg/ml aprotinin, 50 mg/ml antipapain dihydrochloride, placed in 10 ml of ACSII scintillation cocktail and after incubation overnight counted for radioactivity in a liquid scintillation counter.

Binding to intact membranes

Filter binding assays are performed in a total volume of 1 ml containing 5 mg membrane protein, 25 mM MOPS/KOH (pH 7.4), 0.1 mM $CaCl_2$ and labelled sulfonylurea, e.g. [^{3}H] glibenclamide or [^{3}H] glimepiride at concentrations between 0.1 and 20 nM. After incubation for 45 min at 25 °C, the binding reaction is terminated by rapid filtration through Whatman GF/F filters soaked with the same buffer. The filters are washed three times with 5 ml of ice-cold 25 mM HEPES/KOH (pH 7.4), 100 mM NaCl, 1 mM EDTA, 200 µM PMSF, 0.5 µg/ml leupeptin, 0.75 µg/ml pepstatin and two times with 5 ml of ice-cold HEPES/KOH (pH 7.4), placed in 10 ml of ACSII scintillation cocktail and after incubation overnight counted for radioactivity in a liquid scintillation counter. Non-specific binding is determined in parallel samples in the presence of 1 µM unlabeled ligand.

Binding to solubilized membranes

Isolated β-cell tumor membranes are diluted with 25 mM MOPS/KOH (pH 7.4), 100 mM NaCl, 0.1 mM $CaCl_2$, 200 µM PMSF, 0.5 µg/ml leupeptin, 0.75 µg/ml pepstatin, 50 µg/ml antipapain dihydro-chloride, 1 mg/ml aprotinin at 1 µg protein/ml and solubilized by addition of 1/10 vol. of 10% digitonin and subsequent incubation for 30 min at 4 °C. After centrifugation for 30 min at 200 000 *g* and 4 °C, the supernatant is incubated with the radioactive ligand, e.g. [^{3}H] glibenclamide or [^{3}H] glimepiride at concentrations between 0.1 and 20 nM in a final volume of 1 ml. After 30 min at 25 °C, 3 ml of ice-cold PEG 8 000, 25 mM MOPS/KOH (pH 7.4), 100 mM NaCl, 0.5 mM EDTA, 200 µM PMSF is added. After further incubation for 15 min at 4 °C, the incubation mixture is filtered through nitrocellulose filters (Millipore, HAWP, 0.22 µm), soaked with 5 ml ice-cold 10% PEG 8 000 and 4 times 5 ml 6% PEG 8 000, dried, placed in 10 ml of ACSII scintillation cocktail and counted for radioactivity in a liquid scintillation counter. From all values, radioactivity retained on the filter in the absence of protein during the binding reaction is subtracted (up to 1% of total radioactivity added). Non-specific binding is determined in the presence of 1 µM unlabeled ligand.

Binding to intact HIT-T15 cells

Cultured cells producing the β-cell sulfonylurea receptor, SUR1, include the hamster insulin secreting tumor cell line, HIT-T15 (passage 65–75; CRL1 777 ATCC, Rockville, MD). Cells are maintained in T-175 culture flasks (Falcon) as monolayers in DMEM containing high glucose supplemented with 10% fetal bovine serum, 100 U, 7 ml penicillin and 0.1 mg/ml streptomycin. Cells are grown in 5% CO_2 at 37 °C, maintained in subconfluent cultures, fed three times a week, and subcultured as needed. To subculture, confluent cells are detached with 0.05% trypsin/EDTA, resuspended in supplemented DMEM/-high glucose and replated at 1/10 of the original density.

Kinetic studies

For studying the association kinetics, the binding reaction is started by addition of radiolabeled ligand and terminated after predetermined periods of time by rapid filtration. For studying the dissociation kinetics, displacement of radiolabeled ligand at equilibrium (60 min incubation) is initiated by addition of unlabeled drug (final concentration 1 µM) and terminated after given periods of time. For termination, the incubation mixtures are rapidly chilled to 2–4 °C by placing the assay tube in a dry ice/methanol bath for 1 s immediately prior to filtration in a filtration apparatus located in a cool bench.

EVALUATION

K_d as well as B_{max}-values are calculated from Scatchard plot analyses and K_{on} and K_{off} values from kinetic studies. Curvilinear Scatchard plots allow the assumption of more than one binding site. IC_{50} values for half maximal inhibition of [^{3}H] glibenclamide binding can be calculated from competition-inhibition plots.

MODIFICATIONS OF THE METHOD

Masuda et al. (1995) tested the effect of troglitazone on sulfonylurea receptor binding in rat pancreatic islet cells and in HIT cells (a hamster β-cell line). They concluded that troglitazone has a non-competitive binding site at, or in the vicinity of, the sulfonylurea receptor.

K.6.1.6 Interaction of sulfonylureas with β-cells

PURPOSE AND RATIONALE

It is now established that increasing the closed probability of the β-cell ATP-dependent potassium channel (K_{ATP}) is the major mechanism through which sulfonylureas as well as glucose (via transport, phosphorylation and metabolism for generation of ATP) stimulate insulin release from pancreatic β-cells (Ashcroft and Ashcroft 1992). The resulting reduction in potassium ion efflux causes depolarization of the β-cell plasma membrane which in turn leads to opening of voltage-sensitive Ca^{2+} channels of the L-type. The increased influx of Ca^{2+} and thus the elevated cytosolic Ca^{2+} levels trigger the fusion of insulin-containing secretory granules with the plasma membrane, presumably mediated by Ca^{2+}/calmodulin-dependent protein kinase and additional unknown mechanisms (Philipson 1995; Aquilar-Bryan and Bryan 1999). The β-cell K_{ATP} consists of the regulatory sulfonylurea receptor subunits (SUR), such as SUR1, and the physically associated pore-forming potassium ion inwardly rectifying subunit, KIR6.2, in a multimeric assembly with the SUR and KIR6.2 subunits in 1 : 1-stoichiometry and four identical SUR/KIR6.2 complexes per functional channel unit (size of the channel holocomplex $[SUR/KIR6.2]_4$ about 1 000 kDa; Skeer et al. 1994; Clement et al. 1997; Bryan and Aquilar-Bryan 1999). SUR1, which is predominantly expressed in neuronal/pancreatic β-cells, is an ATP-binding cassette (ABC) protein or transport ATPase, which closely resembles members of the multidrug resistance associated protein family with 17 predicted transmembrane domains (TMD) and two nucleotide-binding folds (NBF), which bind specifically (Mg^{2+})ATP/ADP (Bryan et al. 1995; Inagaki et al. 1996; Ueda et al. 1999). The KIR6.2 subunits have two TMDs which somehow contribute to the K^+ conductivity and selectivity (Babenko et al. 1998). The glibenclamide-binding site of SUR1 is proposed to consist of a benzamido (meglitinide)-binding site on TMDs

1–5 and the sulfonylurea (tolbutamide)-binding site on TMDs 12–17 based on photolabeling with [^{125}I]iodoglibenclamide and chimeric receptors (Ashfield et al. 1999; Babenko et al. 1999). Interaction with both the benzamido- and sulfonylurea-binding sites could account for the several thousand-fold increase in affinity of glibenclamide vs. tolbutamide. SUR2A/B are splice variants of a single SUR2 gene differing in 42 amino acids at the carboxy-terminus, exclusively, with SUR2A expressed mainly in cardiac/skeletal muscle cells and SUR2B in vascular/non-vascular smooth muscle cells (Aquilar-Bryan et al. 1998). K^+-channel openers (KCOs) bind to SURs at the tolbutamide-binding site encompassing those (flanking) TMDs 12–17 which surround the central core region of the tolbutamide-binding site (Uhde et al. 1999). SURs define the sensitivity of the K_{ATP} channel holocomplex for its sensitivity toward both sulfonylureas and KCOs with SUR1 mediating high sensitivity for sulfonylureas/low sensitivity toward KCOs and vice versa SUR2A/2B medi-ating low sensitivity for sulfonylureas/high sensitivity for KCOs. Chimeric SURs can be engineered by recombinant DNA technology (harboring TMDs 12–17 from both SUR1 and SUR2A/B) with high sensitivity for both sulfonylureas and KCO arguing for a modular structural and functional organization of SURs (Uhde et al. 1999).

The cooperative interactions between NBFs 1 and 2 of SUR1 in the open state of the K_{ATP} channel are disrupted by the conformational change induced by glibenclamide-binding which encompasses TMD 12–17 and especially TMD 1–5 (Babenko et al. 1999). This conformational change repositions TMD 2 of KIR6.2 (M2), which is in close contact to TMD 1–5 of SUR1, to a closed state via a mechanism that requires the intact N-terminus of KIR6.2. Thus sulfonylurea-binding to SUR1 apparently induces a subtle relaxation of the intimate association between SUR1 and KIR6.2, which is required for keeping KIR6.2 in a (partly) open state. Compatible with this simplified view are recent findings that certain mutations in both SUR1 and KIR6.2 cause recessive forms of familial hyperinsulinism or persistent hyperinsulinemic hypoglycemia of infancy due to permanent closure of K_{ATP} presumably in course of weakening of the interaction between SUR1 and KIR6.2 to a certain degree (Thomas et al. 1995; Thomas et al. 1996; Kane et al. 1996). Binding of ATP to the carboxy-terminal domain of KIR6.2 facilitates and/or stabilizes the glibenclamide-induced relative dissociation of SUR1 and KIR6.2 and thereby favors the closed state of the K_{ATP} which may explain (in part) the stimulation of glucose- (i.e. ATP-) induced insulin release by sulfonylureas. In contrast, interaction of ATP with NBF-1 and Mg^{2+}ADP with NBF-2 is relieved upon glibenclamide binding.

PROCEDURE

Analysis of recombinant SUR1

Heterologous expression of SUR1

Chinese hamster ovary and COS (1, m6, 7) cell lines do not produce SUR1 and are used for heterologous SUR1 expression. For transient transfection, COS cells are plated at 50–60% confluence. Cells are transfected using either a DEAE-dextran or a lipofectamine protocol. 3-day-old cultures of COS cells are trypsinized and replated at a density of 3.5×10^5 cells per 35-mm well (six-well dish) and allowed to attach overnight. Typically, 5 µg of a SUR1 plasmid is mixed with 5 µg of a KIR6.2 plasmid and brought up to 7.5 µl final volume in TBS (8 g/l NaCl, 0.4 g/l KCl, 0.2 g/l Na_2HPO_4, 3 g/l Tris base, 0.2 g/l $CaCl_2$, 0.1 g/l $MgCl_2$, pH 7.5) before addition of DEAE-dextran (30 µl of a 5 mg/ml solution in TBS). The samples are vortexed, collected by spinning in a microfuge, then incubated (15 min, 22 °C) prior to addition of 0.5 ml of 10% FBS in TBS. Cells are washed twice with Hanks' balanced salt solution (HBSS), the DNA mix is added, and the cells are maintained in a 37 °C CO_2 incubator. After 4 h incubation, the DNA mix is decanted and the cells shocked for 5 min in 1 ml HBSS + 10% dimethyl sulfoxide, then placed in 2 ml of DMEM/high glucose containing 2% FBS and 10 µM chloroquine and kept in the incubator for 4 h. Thereafter the cells are washed three times with HBSS and incubated in normal growth media until assayed.

Alternatively, lipofectamine is used for transfection instead of DEAE-dextran. COS cells are plated in six-well dishes (see above) and are used at 70–80% confluency. Typically 1 µg of a SUR1 plasmid and 1 µg of a KIR6.2 plasmid are mixed with 375 µl of Opti-Mem reduced serum medium (Life Technologies, Inc.), then added to 375 µl of Opti-Mem containing 9 µl of lipofectamine. After 1 h incubation, the mixture is supplemented with Opti-Mem to 1 ml final volume and added to the cells, which had been washed twice with 3 ml of Opti-Mem each. After 5 h incubation, the Opti-Mem is replaced with DMEM/high glucose containing 10% FBS. Transfections are scaled up based on the area of the plates used. For instance, 150-mm plates used for membrane isolations are transfected with 100 µg of each plasmid using the DEAE-dextran protocol. Transfected cells are used for determination of sulfonylurea binding and photolabeling or $^{86}Rb^+$ efflux 36–72 h posttransfection.

Membrane isolation from HIT-T15 cells

Membranes are prepared from 15–25 150-mm dishes. Cells are washed three times in phosphate-buffered saline (PBS), pH 7.4, then scraped in PBS and collected

in 10-ml plastic tubes. The cells are pelleted, resuspended in 10 ml of hypotonic buffer (10 mM Tris/HCl, pH 7.4, 1 mM EDTA), and allowed to swell for 1 h on ice. Cells are then homogenized, transferred to a 15-ml glass tube, and spun at 2 000 *g* for 20 min at 4 °C to remove nuclei and unbroken cells. The supernatant is then transferred to a polycarbonate centrifuge tube and membranes are collected by centrifugation (50 000 rpm, 90 min, Ti80 fixed-angle rotor). The pelleted membranes are resuspended in 5–200 µl of membrane buffer (25 mM Tris/HCl, pH 7.4, 2 mM EDTA, 250 mM sucrose, 0.2 mM PMSF, 10 µg/ml leupeptin) and stored frozen in aliquots in liquid N_2.

Membrane solubilization

Membranes are rapidly thawed, resuspended using a Teflon-in-glass homogenizer, and mixed with ice-cold digitonin (25% w/v, in deionized water, prepared daily) to a final protein concentration of 3 mg/ml and 1% digitonin. Subsequent steps are performed at 25 °C in the presence of 0.2 mM PMSF, 10 µg/ml leupeptin, 20 µg/ml pepstatin, 0.2 mM phenanthroline). After 30 min of incubation, solubilized membrane proteins are separated from insoluble material by centrifugation (100 000 *g*, 1 h, 4 °C). Alternatively, the thawed and rehomogenized membranes are mixed with the same volume (resulting in 3 mg/ml protein) of ice-cold 0.2% (w/v) phosphatidylcholine, 20% (w/v) glycerol, 280 mM KCl, 4 mM EDTA, 0.4 mM PMSF, 20 µg/ml leupeptin, 50 mM Hepes/KOH, pH 7.4, 2.5% (w/v) Triton X-100 or CHAPS, incubated on ice for 1 h (under gentle stirring) and then centrifuged (150 000 *g*, 1 h, 4 °C). The supernatants are collected and stored frozen in liquid N_2.

Partial purification of SUR1

For purification of the 140-kDa core glycosylated species of SUR1, 4-ml aliquots of digitonin-solubilized membranes are cycled for times over a 1-ml concanavalin A-Sepharose column equilibrated with 40 mM Tris/HCl (pH 7.5), 0.2 M NaCl, 1 mM EDTA, 1% digitonin. The column is washed with 8 ml of the equilibrating buffer and eluted with 4 ml of the equilibrating buffer containing 0.5 M methyl α-methylmannopyranoside. The eluted protein is stored in liquid N_2. For purification of the 150-kDa complex glycosylated SUR1, wheat germ agglutinin-Sepharose is used instead of concanavalin A-Sepharose. The procedure is the same as described with the exception of elution of the receptor using 0.3 M N-acetylgluosamine.

The eluate for the lectin columns is cycled twice over a 1-ml column of Reactive Green 19-agarose equilibrated with 40 mM Hepes/KOH (pH 8.5), 1 mM EDTA, 0.5% (w/v) digitonin. After washing with 10 ml of equilibrating buffer, and 10 ml of the same buffer supplemented with 0.5 M NaCl, the protein is eluted with 4 ml of equilibrating buffer containing 1.5 M NaCl. The eluate from the Reactive Green-19 purification step is diluted 1 : 2 with 40 mM Hepes/KOH (pH 8.5), 1 mM EDTA, 0.2% digitonin, then cycled twice over a 1-ml phenylboronate-10 Sepharose column. The phenylboronate column is washed with 10 ml of the HEPES buffer, followed by 2 ml of 0.1 M Tris/HCl (pH 7.5), 1 mM EDTA, and 0.2% digitonin. The protein is eluted with 4 ml of 0.1 M Tris/HCl (pH 7.5), 1 mM EDTA, 0.15% (w/v) sodium dodecyl sulfate. Prior to binding measurements, pooled samples from the various column steps are concentrated by centrifugation (3 000 *g*, 30 min, 4 °C) through 100 000 molecular weight cut-off filters (Amicon), which have been pretreated with 5% (v/v) Tween 20 for 14 h at 4 °C.

Analysis of SUR1 in extrapancreatic tissues

In addition to β-cells and hypothalamic neurons, SUR1 is also expressed in human adipocytes (Shi et al. 1999). Closure of the K_{ATP} by sulfonylurea binding to the adipocyte SUR1 leads to depolarization of the plasma membrane, opening of voltage-dependent Ca^{2+} channels and concomitant increase of the cytosolic Ca^{2+} concentration. Thus, adipocytes and determination of intracellular Ca^{2+} may be used for assaying the potency of sulfonylureas with regard to binding to SUR1.

Prior to fluorometric Ca^{2+} measurement, the adipocytes are washed three times (by flotation) with HBSS (140 mM NaCl, 0.8 mM $MgSO_4$, 1.8 mM $CaCl_2$, 0.9 mM NaH_2PO_4, 4 mM $NaHCO_3$, 5 mM glucose, 2 mM sodium pyruvate, 2 mM glutamine, 20 mM Hepes, 1% BSA). The cells are then loaded with Fura-2-acetoxymethyl ester (10 µM) in the same buffer for 45 min at 37 °C in the dark with continuous shaking. For removal of extracellular dye, the cells are washed three times with HBSS and resuspended in HBSS at 3.5×10^5 cells/ml. Cytosolic Ca^{2+} is determined using dual excitation (340 and 380 nm) and single emission (510 nm) fluorometry. After establishment of a stable baseline in the absence or presence of the K_{ATP} channel openers, diazoxide and nitrendipine, the response to sulfonylureas is determined. Digitonin (25 µM) and Tris/EGTA (100 mM) are used to measure maximal and minimal fluorescence to calibrate the signals. Cyto-solic Ca^{2+} is calculated by the equation of Grynkiewicz et al. (1985).

K.6.1.7 Photoaffinity labeling of β-cell membranes[5]

PURPOSE AND RATIONALE

Binding sites of sulfonylureas have been identified in pancreatic β-cell membranes and in other tissues such as brain (Bernardi et al. 1988). The technique of photoaffinity labeling allows the identification and purification of membrane receptors (Yip 1984; Kramer et al. 1994).

PROCEDURE

For photoaffinity labeling of β-cell membranes, samples of membrane suspension are prepared as described above. 600 µg of β-cell membranes, suspended in 100 mM sodium phosphate buffer (pH 7.4), are incubated in a total volume of 200 µl with 40–60 nM (0.3–0.4 µCi) [^{3}H]glibenclamide at 20 °C in the dark for 60 min. Irradiation is performed in a Rayonet RPR 100 photochemical reactor (Southern Ultraviolet Co., Hamden, CT), equipped with RPR 2 530 Å lamps at a distance of 10 cm from the lamps. After irradiation at 254 nm for 2 min the membranes are diluted with 1 ml of 10 mM Tris-HEPES buffer (pH 7.4) containing 4 mM EDTA, 4 mM iodoacetamide, 4 mM PMSF and centrifuged at 48 000 *g* for 30 min. The resulting pellet is resuspended in 200 µl water and protein precipitated according to Wessel and Flügge (1984).

For inhibition of [3H]glibenclamide photo-labeling of the receptor protein by test compounds as compared with glibenclamide, 600 µg of β-cell membranes are incubated with various concentrations (10^{-9} to 10^{-4} M) of glibenclamide or the test compounds. After incubation with 60 nM (0.37 µCi) [^{3}H]glibenclamide in the dark, the membranes are photolabeled at 254 nm for 2 min. After washing of the membranes, the proteins are separated by SDS gel electrophoresis.

For SDS gel electrophoresis, the protein precipitates are dissolved in 70 µl of 62.5 mM Tris-HCl buffer (pH 6.8) containing 2% SDS, 5% mercaptoethanol, 0.005% bromophenol blue by shaking on a mixer for 60 min. After centrifugation at 15 000 g for 10 min the clear supernatants are subjected to SDS gel electrophoresis on 150 × 180 × 1.5 mm slab gels (Kramer et al. 1983). After fixing and staining, the gels are scanned with a CD-50 densitometer (Desaga, Heidelberg). The

[5] Contributions by G. Müller.

radioactivity is determined by liquid scintillation counting after slicing the gels into 2 mm pieces and after digestion of proteins with Biolute.

EVALUATION

The radioactive peak of [^{3}H]glibenclamide bound to the receptor protein is decreased depending on the concentration of unlabeled glibenclamide or test compounds. IC_{50} values can be calculated.

K.6.1.8 $^{86}Rb^+$ efflux measurements

PURPOSE AND RATIONALE

The binding of sulfonylureas to the receptor inhibits ATP-sensitive K^+ channels, decreasing the K^+ efflux and leading to membrane depolarization. This opens voltage-gated calcium channels. The rise in [Ca^{2+}] triggers the exocytosis of insulin. $^{86}Rb^+$ efflux can be used as marker for K^+ efflux.

PROCEDURE

RINm5F cells are grown and plated at a density of 200 000 cells/well (Falcon 24-well tissue culture plates). $^{86}Rb^+$ efflux experiments are performed at 37 °C and overnight equilibration of cells in RPMI 1 640 medium supplemented with 10% fetal calf serum, 0.1 µCi/ml ^{86}RbCl, and 0.2 µCi/ml L-[^{3}H]leucine (internal marker of cell recovery). After removing the medium, cells are preincubated in a medium containing 120 mM NaCl, 1.8 mM $CaCl_2$, 0.8 mM $MgCl_2$, 10 mM KCl, with 20 mM HEPES/NaOH buffer, at pH 7.5, supplemented with 0.1 µCi ^{86}RbCl, 0.24 mg/ml oligomycin, 1 mM 2-deoxy-D-glucose and several concentrations of various sulfonylureas. $^{86}Rb^+$ efflux studies are initiated by removing the pre-incubation medium and incubating the cells with 200 µl of the same medium/well without $^{86}Rb^+$, oligomycin, and 2-deoxy-D-glucose. Efflux is stopped by removing this medium and washing the cells three times with 1 ml of 0.1 M $MgCl_2$ at 37 °C. Cells are extracted with 2 × 1 ml of 0.1 N NaOH and counted. Total intracellular concentrations of ATP are measured after extracting the cells with 1% Triton X-100 by using the luciferase-luciferin technique.

EVALUATION

Inhibition is measured as percent of maximum $^{86}Rb^+$ efflux. Half maximum inhibition constants can be calculated.

MODIFICATIONS OF THE METHOD

Daniel et al. (1991) recommended a high through-put ^{86}Rb efflux assay in human medulloblastoma cells TE671 for screening of potassium channel modulators.

Hu et al. (1995) cloned a voltage-regulated K channel from human hippocampus for transfection into Chinese hamster ovary (CHO) cells. The authors recommended this method as a high through-put assay to identify isotype-specific K-channel modulators.

K.6.1.9 Membrane potential (measurement of the ATP sensitive potassium channel by voltage-clamp technique)

PURPOSE AND RATIONALE

The insulin secretion of β-cells is regulated by ATP sensitive K^+ channels (Bryan and Aguilar-Bryan 1997) which act as a switch that responds to glucose or sulfonylureas to initiate depolarization (Boyd 1992). This depolarization opens voltage-dependent calcium channels to increase the amplitude of free cytosolic Ca^{2+} levels, which triggers exocytosis of insulin (Nelson et al. 1987). The depolarization can be measured with the voltage-clamp technique.

PROCEDURE

Rat insulinoma cells RINm5F (Gögelein et al. 1998) or cultured pancreatic β-cells from NMRI mice (Rorsman and Trube 1985; Zünkler et al. 1985) or HIT T15 β-cells (Niki et al. 1989) are used. Whole cell patch-clamp experiments are performed according to Hamill et al. (1981), Rajan et al. (1993), Lindau and Neher (1988) at room temperature with cells bathed in an external solution of 140 mM NaCl, 4 mM KCl, 10 mM HEPES, pH 7.4. The patch pipettes are mounted on a suction pipette holder. The outlet is connected to silicon rubber tubing through which the suction is applied. The pipette solution contains 135 mM KCl, 1 mM $MgCl_2$, 1 mM EGTA, 10 mM HEPES, 0.3 mM NaATP, pH 7.5. Pipettes are prepared by pulling from borosilicate glass, coated with silicon rubber, and heat polished at the tip. Pipette resistances are ranging between 4 and 7 MΩ. A patch-clamp amplifier (e.g. EPC 7, List Electronic, Darmstadt, FRG) is used which allows capacitance and series resistance compensation. The series resistance after achieving the whole cell recording configuration is 5–20 MΩ and 50% series resistance compensation is used to keep the voltage error during current flow below 2 mV. The cell membrane potential is held at –70 to –80 mV and hyper- and depolarizing voltage pulses of 10 mV amplitude are applied alternatively every 2 s. Voltage-dependent currents, i.e., the Ca^{2+} inward current and the delayed K^+ outward current are not activated by these low pulse amplitudes and, therefore, most of the current is flowing through ATP-dependent K^+ channels. Inside-out patches are prepared according to Hamill et al. (1981) by disrupting the outer vesicle membrane.

EVALUATION

The current and voltage signals are stored on magnetic tape or filtered by a 4-pole Bessel filter and displayed on a digital oscilloscope. Outward currents flowing from the cell to the bath are indicated by upward deflections and inward currents by downward deflections. Half maximal effective concentrations are calculated as EC_{50} values.

MODIFICATIONS OF THE METHOD

Henquin and Meissner (1984), Henquin et al. (1984, 1884), Meissner (1990) measured membrane potential of mouse pancreatic β-cells.

Hu et al. (2000) compared the effects of netaglinide, a non-sulfonylurea hypoglycemic agent, with sulfonylureas on pancreatic β-cell K_{ATP} channel activity with the whole-cell configuration of the patch-clamp technique in primary cultures of rat pancreatic β-cells.

Wang and Giebisch (1991) reported a dual modulation of the renal ATP-sensitive K^+ channel by protein kinases A and C in cells of the cortical collecting duct of rabbit kidneys using the cell-attached and inside-out modification.

Shieh et al. (2000) characterized K_{ATP} channel opener-activated currents in pig and guinea pig bladder smooth muscle cells using the whole-cell patch-clamp technique.

Shindo et al. (2000) examined with the whole-cell configuration of the patch-clamp technique the effects of a vascular relaxing agent on the heterologously expressed pancreatic-type ATP-sensitive K^+ channels SUR1/Ki6.2, SUR2A/Ki6.2, and SUR2B/Ki6.2 in human embryonic kidney 293T cells.

Using whole-cell and single-channel patch-clamp recording, Gomora and Enyeart (1999) studied pharmacological properties of a cyclic AMP-sensitive potassium channel, I_{AC}, which is distinctive among K^+ channels both in its activation by ATP and inhibition by cyclic AMP.

K.6.2 Effects on liver

K.6.2.1 Perfusion of isolated rat liver

PURPOSE AND RATIONALE

The technique of liver perfusion has been described extensively by Ross (1972), mentioning in his introductory remarks that the isolated liver was first used by Claude Bernard in 1885. Derived from several modifications, the perfusion of rat liver from the portal vein is the most widely used technique.

PROCEDURE

Male Wistar rats weighing 200–250 g are anesthetized with 150 mg/kg hexobarbital intraperitoneally. After opening the abdomen, two ligatures are tied around the stomach, one around the esophageal end to include the adjacent blood vessels and the other around the pylorus. The stomach is removed between these ligatures, a procedure that facilitates the remaining dissection and the subsequent removal of the liver from the animal. A ligature is placed around the bile duct. The portal vein is tied and cannulated with PP10 tubing. The thorax is opened and the vena cava is cannulated via the right atrium. The lower vena inferior cava is tied and the liver is removed from the animal. From the portal vein the liver is washed with 100 ml hepari-

nized (5 IU/ml) physiological saline solution at 37 °C for 3 min whilst the outflow occurs via the vena cava. The preparation is then transferred to a perfusion apparatus, where the portal vein cannula is attached to tubing containing the oxygenated medium.

Krebs-Ringer bicarbonate buffer with 25% bovine erythrocytes, 1.6% bovine serum albumin, and 22.5 mmol/l Na-L-lactate is used as perfusion medium. The perfusion rate is 30 ml/min. Seventy ml are used for recirculation over 2 h. The test compounds are added in a concentration of 40–100 µmol/l to the perfusate medium.

The central element of the perfusion apparatus is a gas-tight, thermostatized, double-walled suction filter with an insertable sieve base as support of the organ. The discharge tube is elongated with a Plexiglas® tube of 18 cm length and 10 mm inside diameter. The lower end of this tube is connected to a peristaltic pump by means of a Luer® safety joint. The suction filter for perfusion of the liver has an internal diameter of 95 mm. On the return of the perfusate to the organ, it passes through a heat exchanger (glass spiral) and a filter holder with a sieve membrane of stainless steel (diameter 25 mm, mesh size 50 µm). A variable carbogen/oxygen mixture, the ratio of which is depending on the pH value of the perfusate, is used for gassing. The perfusate in the Plexiglas tube is bubbled with 70 ml gas mixture/min. To avoid foam formation, a detergent (14 µl/ml 0.1% Genapol® PF-10) has to be added to the perfusate. Samples for analyses are withdrawn by catheter immediately in front of the Luer joint in the Plexiglas tube.

EVALUATION

Several parameters can be determined in the effluate, such as net glucose production from lactate and net lactate utilization. The values are plotted against time before and after addition of the test compounds, such as insulin or sulfonylureas.

MODIFICATIONS OF THE METHOD

Alexander et al. (1992) studied hepatic blood flow regulation in an isolated dual-perfused rabbit liver preparation.

Alexander et al. (1995) described a miniaturized perfusion circuit using a novel design of organ bath, to maintain a buoyant preparation, and a high-efficiency miniaturized membrane tubing oxygenator for testing hepatic function during prolonged isolated rat liver perfusion.

K.6.2.2 Isolated hepatocytes

PURPOSE AND RATIONALE

Isolated hepatocytes can be used to study the effect of drugs on hepatic gluconeogenesis and other hepatic metabolic reactions such as ketone body formation and the tricarboxylic acid cycle.

PROCEDURE

Male Wistar rats weighing 200–300 g are used. The hepatocytes are isolated by perfusion of the liver with collagenase (Berry and Friend 1969; Alvarez et al. 1987). The viability of the isolated hepatocytes can be evaluated by the Trypan blue test; usually 90–95% of the cells exclude the stain. The isolated hepatocytes (20×10^6 cells/vial) are suspended in 3.0 ml of Krebs-Ringer bicarbonate buffer containing 4% bovine albumin (pH 7.4). The cell suspension is pre-incubated for 15 min at 37 °C in a Dubnoff metabolic shaking incubator gassed with carbogen.

The following substrates are added in various combinations, and each sample is incubated for 60 min: (1) alanine, fructose, glycerol, lactate, pyruvate (10 mM), or (2) palmitate (0.5 mM, as sodium palmitate bound to albumin). Test drugs, such as sulfonylureas and biguanides are added in concentrations between 0.05 and 5.0 mM.

At the end of the 60-min incubation period, 0.2 ml of 70% $HClO_4$ is added into the medium to stop the reaction. The reaction mixture is then centrifuged, and the supernatant obtained is used to determine the intermediate metabolites. Glucose is assayed by the glucose-oxidase method; lactate (Gutmann and Wahlefeld 1974), pyruvate (Czok and Lamprecht 1974), acetoacetate (Mellanby and Williamson 1974), and β-hydroxybutyrate (Williamson and Melanby 1974) by enzymatic methods.

In order to measure the influence on the tricarboxylic acid cycle, (U-^{14}C) alanine, (1-^{14}C) glutamate,

(1-^{14}C) pyruvate, (1-^{14}C) palmitate, or (1-^{14}C) glucose is added after pre-incubation together with various combinations of compounds and substrates, and incubated for 60 min. The radioactivity is measured by the $^{14}CO_2$ capturing method (Gliemann 1965).

EVALUATION

Values are expressed as means ±SEM. Means are compared by the Student *t*-test.

MODIFICATIONS OF THE METHOD

Agius et al. (1986) isolated parenchymal hepatocytes from male Wistar rats by collagenase perfusion of the liver to prepare hepatocyte monolayer cultures to study regulation of ketogenesis, gluconeogenesis, and glycogen synthesis by insulin and proinsulin.

Fukuda et al. (1992) used primary cultures of rat hepatocytes to study nutritional and hormonal regulation of mRNA levels of lipogenic enzymes, such as acetyl-CoA carboxylase, fatty acid synthase, malic enzyme, and glucose 6-phosphate dehydrogenase.

Instead of isolated hepatocytes, cultures of Hep G2 cells can be used. The Hep G2 line is a minimal deviation of human hepatoma that maintains liver cell morphology and function (Podskalny et al. 1985). Hep G2 cells express insulin receptors, display a number of metabolic responses to insulin and insulin-like growth factor I (Wade et al. 1988; Verspohl et al. 1988) and have been used for various studies (Forsayeth et al. 1986, 1988; Caro et al. 1988). Ciaraldi et al. (1990) found that troglitazone (CS-045) increased glycogen synthase I activity in Hep G2 and BC3H-1 muscle cells.

Benelli et al. (1994) used Zajdela rat ascites hepatoma cells to demonstrate the role of protein kinase C in the activation of the pyruvate dehydrogenase complex by insulin.

K.6.2.3 Fructose-2,6-bisphosphate production in rat hepatocytes

PURPOSE AND RATIONALE

Glycogenesis in hepatocytes is regulated by the cytosolic level of fructose-2,6-bisphosphate (Van Schaftingen 1993). Insulin induces an increase of fructose-

2,6-bisphosphate through inhibition of a proteinkinase A-dependent phosphorylation of the bifunctional enzyme 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase (Richards and Uyeda (1982), Gabbay and Lardy (1987), Pilkis and El-Maghrabi (1987). Hepatic fructose-2,6-bisphosphate is elevated by various sulfonylureas (Hatao et al. 1985; Kaku et al. 1986; Mori et al. 1992). Moreover, CS-045 (troglitazone), a non-sulfonylurea oral antidiabetic agent, stimulated fructose-2,6-bisphosphate production in rat hepatocytes (Murano et al. 1994).

PROCEDURE

A suspension of hepatic cells is adjusted to 10^6 cells/ml and pre-perfused with Hanks 10 mM-HEPES buffer solution (pH 7.5, containing 0.5% BSA and 1 mM palmityl oleate) at 37 °C for 10 min. The cells are then centrifuged at 40 *g* for 15 s, and the supernatant is removed. To the remainder, the same buffer and various concentrations of the sulfonylurea are added and the mixtures are then incubated at 37 °C for 10 min. The reaction is stopped by cooling on ice. The mixture is centrifuged at 170 *g* at 4 °C for 60 s. The pellet is homogenized with buffer solution containing 1 mM EGTA and 10 mM $MgCl_2$. After heating at 80 °C for 20 min, the homogenate is mixed with an equal volume of 400 mM Tris-HCl buffer (pH 7.5), and the mixture is centrifuged at 17 500 *g* at room temperature for 5 min. In the supernatant fructose-2,6-bisphosphate is measured according to the method of Furuya and Uyeda (1980) by adding a solution of 54 mM Tris-HCl, 1 mM fructose-6-phosphate, 0.2 mM NADH, 7.5 mM dithiothreitol, 0.5 mM EDTA, 0.01 U phosphofructokinase, 0.4 U aldolase, 1 U glycerin-3-phosphate dehydrogenase, and 3 U triosephosphate isomerase. The concentration of fructose-2,6-bisphosphate in the sample solution is measured by colorimetry and compared with the reaction rate of a known concentration of fructose-2,6-bisphosphate.

EVALUATION

Dose-response curves of fructose-2,6-bisphosphate content of isolated hepatocytes after various concentrations of test compound and standard (tolbutamide) are established.

K.6.3 Effects on muscle

K.6.3.1 Perfused hind limb in rats

PURPOSE AND RATIONALE

Ruderman et al. (1977) proposed the use of the isolated perfused hindquarter of the rat for the study of muscle metabolism.

PROCEDURE

Female Wistar rats weighing 170–230 g are starved 48 h before the experiment. They are anesthetized by i.p. injection of 50 mg/kg pentobarbital. After an midline incision, the skin is reflected and the superficial epigastric vessels are ligated. The abdominal wall is then incised from the pubic symphysis to the xyphoid process using electrocautery. After ligation of the uterine, ovarian and inferior mesenteric arteries, the upper half of the uterus, the ovaries and part of the descending colon are excised, together with adhering adipose tissue. Next, branches of the hypogastric and pudoepigastric trunks supplying pelvic viscera are ligated. Ligatures are also placed around the neck of the bladder and the residual portions of the uterus and descending colon. Adipose tissue in the perineal and retroperitoneal regions is removed.

Two pairs of ligatures are placed around the aorta and the vena cava, one just above the origin of the iliolumbar vessels and the other above the origin of the renal vessels. The inferior epigastric, iliolumbar and renal vessels are then ligated as are the coeliac axis and the portal vein. A ligature is also placed around the tail. The ligatures previously placed around the vena cava and aorta above the origin of the renal vessels are then tied. The aorta is incised between the left renal and iliolumbar vessels and a no. 18 polyethylene catheter filled with 0.85% NaCl containing 200 units of heparin/ml is introduced, passed to a point midway between the iliolumbar vessels and the aortic bifurcation, and after flushing with heparin-NaCl solution finally tied in place. The vena cava is cannulated with a no. 16 needle which is secured in a position so that its tip is at the same level as the aortic catheter. The needle is connected with a transparent vinyl tubing. The preparation is then transferred to a perfusion apparatus, where the aorta cannula is attached to tubing containing the oxygenated medium.

Krebs-Ringer bicarbonate buffer with 25% bovine erythrocytes, 4% bovine serum albumin, and 10 mmol/l D-glucose is used as perfusion medium. The perfusion rate is 8 ml/min. Seventy ml are used for recirculation over 2 h. The test compounds are added in a concentration of 40–100 µmol/l to the perfusate medium.

The central element of the perfusion apparatus is a gas-tight, thermostatized, double-walled suction filter with an insertable sieve base as support of the organ. The discharge tube is elongated with a Plexiglas® tube of 18 cm length and 10 mm inside diameter. The lower end of this tube is connected to a peristaltic pump by means of a Luer® safety joint. The suction filter for perfusion of the hind limb has an internal diameter of 145 mm. On the return of the perfusate to the organ, it passes through a heat exchanger (glass spiral) and a filter holder with a sieve membrane of stainless steel (diameter 25 mm, mesh size 50 µm). A variable carbogen/oxygen mixture, the ratio of which is depending on the pH value of the perfusate, is used for gassing. The perfusate in the Plexiglas tube is bubbled with 70 ml gas mixture/min. To avoid foam formation, a detergent (14 µl/ml 0.1% Genapol® PF-10) has to be added to the perfusate. Samples for analyses are withdrawn by catheter immediately in front of the Luer joint in the Plexiglas tube.

EVALUATION

Several parameters can be determined in the effluate, such as glucose for net uptake or lactate for metabolic formation. The values are plotted against time before and after addition of the test compounds, such as insulin or sulfonylureas.

CRITICAL ASSESSMENT OF THE METHOD

The isolated hindquarter of the rat has been proven to be a useful tool to study muscle metabolism under nearly physiological conditions after treatment with hormones and drugs as well as after electrical stimulation.

See K.3.3.

K.6.3.3 Activity on isolated muscle cells

PURPOSE AND RATIONALE

Several types of cultured muscle cells haven been used in diabetes research:

BC_3H1 myocytes, the L6 cultured myogenic cell line, and rat cardiomyocytes.

The **BC_3H1 cell line** is a nonfusing spontaneously and reversibly differentiating mouse muscle cell line derived from a mouse neoplasm (Schubert et al. 1974). As for other cultured cell lines, the BC_3H1 myocytes demonstrate intermediate characteristics, possessing electron-microscopic features of both smooth and skeletal muscle but with a nicotinic acetylcholine receptor and an action potential more characteristic of skeletal muscle (Standaert et al. 1984).

The **L6 cultured myogenic cell line**, cultured from the thigh of a 1-day-old rat (Yaffe 1986) has many features of skeletal muscle (Pardridge et al. 1978).

Gorray et al. (1990) studied the antiproteolytic effects of glyburide by measuring the release of ^{14}C-tyrosine from intact L_6 myoblasts.

C_2C_{12} cells, a mouse skeletal muscle cell line has been isolated from dystrophic mouse muscle by Yaffe and Saxel (1977), McMahon et al. 1994; Ernst and White 1996).

Cardiomyocytes are isolated by perfusion of hearts from adult rats with collagenase (Eckel et al. 1983, 1991; Bähr et al. 1995).

Primary human muscle cell cultures were established by Sarabia et al. (1992).

PROCEDURE

BC_3H1 myocytes are cultured to confluence in 100 mm dishes over 10–14 days in Dulbecco's modified Eagle's medium (DMEM) supplemented with 15% Process Serum Replacement-I (Sigma, St. Louis, MO) and 25 mM glucose are added 18 h before the experiment. Cells are rinsed and pre-incubated at 37 °C for 20 min in Dulbecco's phosphate buffered saline with 0.1 mM $CaCl_2$ and 1 mg/ml BSA, then treated with buffer (controls) or agonists in buffer for 30 min.

Direct effects of sulfonylurea agents on glucose transport (Rogers et al. 1987), insulin-induced decrease in 5'-nucleotidase activity in skeletal muscle membranes (Klip et al. 1987), sulfonylurea-stimulated glucose transport association with diacylglycerol-like activation of protein kinase C (Cooper et al. 1990) were studied in this cell line.

L6 muscle cells are grown in 75-cm^2 flasks in Ham's F-10 medium containing 15% horse serum, 2.5 fetal calf serum, 0.87% glutamine, 0.87% penicillin-streptomycin, and 7.5% $NaHCO_3$ at 37 °C under a 5% CO_2 atmosphere. After 2–4 days, the cells are in a monolayer, confluent, aligned, and fused, but usually no myotubes are present. The medium is changed, and test substances are added.

Augmentation of the effects of insulin and insulin-like growth factors I and II on glucose uptake by sulfonylureas (Wang et al. 1987), coordinate regulation of glucose transporter function, and gene expression by insulin and sulfonylureas (Wang et al. 1989), glyburide-stimulated glucose transport via protein kinase C-mediated pathway (Davidson et al. 1991) were studied in this cell line.

C_2C_{12} cells, a mouse skeletal muscle cell line, have been shown to be suitable for stable transfection experiments of exogenous cDNA, making this cell line a candidate for stable transfections of cDNAs that encode mutant skeletal muscle and cardiac protein isoforms. The cells are available from CRL 1772 stock, American Type Culture collection. The cells are seeded into 100-mm diameter, collagen coated, tissue culture dishes at 5×10^4 cells/ml and plated in growth medium consisting of Dulbecco's modified Eagle's medium containing 20% fetal bovine serum, 0.5% chick embryo extract, and 1% penicillin/streptomycin. Cells are grown in this medium to between 75% and 85% confluence and then induced to differentiate by switching them to medium containing Dulbecco's modified Eagle's medium supplemented with 2% adult horse serum and 1% penicillin/streptomycin.

K.6.4 Effects on adipose tissue

See K.3.2.

K.7 Inhibition of polysaccharide degrading enzymes

K.7.0.1 General considerations

Starch as the predominant ingredient of human food is rapidly degraded in the gastrointestinal tract by salivary and pancreatic α-amylaseα to maltose which is further hydrolyzed by maltase localized in the brush border of the small intestine to glucose. Glucose is immediately absorbed leading to hyperglycemia and consequently to hyperinsulinemia. Both phenomena are undesirable in diabetics and in obese patients. Inhibition of the digestion of starch leads to a decrease and a retardation of glucose absorption. In nature, α-amylase inhibitors are found in wheat and other grains (Shainkin and Birk 1970). Several inhibitors of amylase and α-glucosidase have been developed (Bischoff 1991). Animal experiments with high doses of absorbable α-glucosidase inhibitors indicate that lysosomal storage of glycogen may occur (Lembcke et al. 1991).

K.7.0.2 Inhibition of α-amylase *in vitro*

PURPOSE AND RATIONALE

α-Amylase activity can be measured by determination of the reducing groups arising from hydrolysis of soluble starch by isolated pancreatic α-amylase. The reduction of 3,5-dinitrosalicylic acid to nitro-aminosalicylic acid produces a color shift which is followed photometrically by changes in the absorbance at 546 nm. Inhibition of starch hydrolysis by an α-amylase inhibitor results in a diminished absorbance at 546 nm in comparison with the controls.

PROCEDURE

Commercially available pancreatic α-amylase (E. Merck, Darmstadt, Germany) is used. Various concentrations of the α-amylase inhibitor are dissolved in 1 ml 20 mM Sörensen buffer, pH 6.9 and 10 mM NaCl. 0.1 ml pancreatic α-amylase solution in 0.4% BSA is added. After prior incubation at 25 °C, the enzymatic reaction is started by addition of 1.0 ml soluble starch solution. The reaction is stopped after 10 min with 1.0 ml of dinitrosalicylic acid reagent. The mixture is heated in a boiling water bath for 10 min, and after cooling measured at 546 nm against the reagent blank.

EVALUATION
Dose-response curves of enzyme inhibition are determined.

K.7.0.3 Inhibition of glucosidase *in vitro*

PURPOSE AND RATIONALE
Inhibition of glucosidase can be measured *in vitro* using glucosidase from porcine small intestinal mucosa.

PROCEDURE
Glucosidase is prepared from rat or porcine small intestinal mucosa or porcine pancreas. The enzyme activity is assayed according to Dahlqvist (1964). The inhibitory activity is determined by incubating a solution (20 µl) of an enzyme preparation with 80 mM sodium phosphate buffer, pH 7.0 (500 µl) containing 37 mM sucrose or maltose, or 3.7 mM isomaltose and a solution (20 ml) containing various concentrations of the inhibitor at 37 °C for 20 min. The reaction mixture is heated for 2 min in a boiling water bath to stop the reaction. The amount of liberated glucose is measured by the glucose oxidase method.

EVALUATION
IC_{50} values of enzyme inhibition are determined.

K.7.0.4 Evaluation of α-glucosidase inhibitors using the everted sac technique

PURPOSE AND RATIONALE
The everted sac technique allows to study the effects of intestinal enzymes on substrates in an incubation vial.

PROCEDURE
Male rats weighing 120–140 g are sacrificed and the small intestines removed by cutting across the upper end of the duodenal junction. The intestine is stripped of the mesentery and the entire intestinal content is rinsed with cold saline solution. The intestine is divided into 7 to 8 cm-segments and turned inside out using a Pasteur pipette. The everted intestine is ligated at one end with a cotton thread and a second ligature is placed loosely around the opposite end ready for tying. A 1 ml syringe with Krebs-Henseleit-buffer is introduced into the lumen sac. The end of the sac is ligated and placed in a 25 ml Erlenmeyer flask containing 6 ml of 1% starch, dissolved in Krebs-Henseleit-buffer, with or without various concentrations of the α-amylase inhibitor. Pork α-amylase (4 000 U/g starch) is also included in the 6 ml starch solution. Following gassing with 95% O_2/5% CO_2, the flask is tightly capped and incubated in a shaking bath at 37 °C for 120 min. The reaction is terminated by the addition of 10 µl 1 N HCl. At the end of the incubation period, the sac is removed from the flask and the inner fluid is collected by cutting one end of the sac. The final volumes of the solute in the serosal and the mucosal side and the level of glucose liberation are measured.

EVALUATION
Glucose liberated in the presence of various concentrations of the α-amylase inhibitor is expressed as percentage of glucose found without the inhibitor. Dose-response curves can be drawn plotting percent inhibition versus concentration of the inhibitor

K.7.0.5 Inhibition of glucose absorption *in vivo*

PURPOSE AND RATIONALE
The inhibition of glucose absorption can be determined by measuring blood glucose after administration of starch or disaccharides with and without the inhibitor. In addition, non-absorbed starch or disaccharides can be determined in the intestine.

PROCEDURE
Male Wistar rats are kept on a standard diet with free access to tap water at constant temperature (24 ±1 °C). Sixteen hours prior to the experiment food but not wa-

ter is withheld. Groups of rats receive by stomach tube 2.5 g/kg raw starch in a water suspension without or with various doses of the α-amylase inhibitor. After 10, 20, 30, 60, 120 and 240 min, blood is withdrawn for determination of blood glucose and non-esterified fatty acids. The animals are sacrificed after these intervals and the residual starch in the stomach and the intestine determined. Definitely more starch is found in the intestine after simultaneous application of the α-amylase inhibitor. Similar experiments are performed in dogs for determination of serum insulin. The increase of blood glucose and serum insulin as well as the decrease of NEFA are inhibited.

EVALUATION

The values of starch content in stomach and intestine, as well as the blood glucose-, serum insulin- and NEFA-values are compared between control and treated animals.

MODIFICATIONS OF THE METHOD

In order to test the inhibition of glucosidase in addition, loading tests with sucrose or other disaccharides are performed (Puls et al. 1977; Matsuo et al. 1992).

Matsuo et al. (1992) performed experiments with genetically or experimentally obese rats (female Zucker fatty rats or female ventromedial hypothalamic nucleilesioned rats) and male yellow *KK*-mice.

LeMarchand-Brustel et al. (1990) studied the effect of an α-glycosidase inhibitor on experimentally induced obesity in mice. Male Swiss albino mice were rendered obese by injection of goldthioglucose at the age of 3 weeks. Since goldthioglucose treatment does not produce obesity in all injected mice, pro-obese mice were selected at 8 weeks of age on the basis of their body weight gain. They were divided in a control group receiving chow without drug and a treated group receiving chow containing the glycosidase inhibitor. Weight gain, glycemia and insulinemia were followed over 120 days.

Madar and Omusky (1991) studied the inhibition of intestinal α-glucosidase activity and postprandial hyperglycemia by α-glucosidase inhibitors in *fa/fa* rats. Various starch sources were used. Blood samples were taken at various intervals after starch load.

Takami et al. (1991) studied the antidiabetic actions of a disaccharidase inhibitor in spontaneously diabetic (GK) rats.

Okada et al. (1992) reported anti-obesity and antidiabetic actions of a new potent disaccharidase inhibitor in genetically obese-diabetic mice.

K.8
Effect on secondary diabetes symptoms

K.8.1
Inhibition of aldose reductase

K.8.1.1
General considerations

Secondary symptoms of long lasting diabetes mellitus are diabetic neuropathy with sensory symptoms, motoric disturbances due to reduced nerve conduction velocity and diabetic cataracts. Both are related to enhanced conversion of glucose to polyols, such as sorbitol, by the enzyme aldose reductase (van Heyningen 1959; Clements 1979). Sorbitol is converted to fructose by sorbitol-dehydrogenase. A low activity of this enzyme enhances the accumulation of sorbitol, thus contributing to cellular damage. Inhibitors of aldose reductase have been developed with positive results in diabetic patients (Kador et al. 1985).

There are even some experimental hints for the benefit of aldose reductase inhibitors in diabetic cardiomyopathy (Cameron et al. 1989). Experimental data provide also evidence for possible beneficial effects in diabetic neuropathy, retinopathy, measured by nerve conduction velocity or electroretinography, lens cata-

ract formation, vascular permeability and filtration (Williamson et al. 1987; Tilton et al. 1989; Pugliese et al. 1990) and nephropathy (Sarges and Oates 1993).

Geisen et al. (1994) reported on sorbitol-accumulating pyrimidine derivatives which inhibited sorbitol dehydrogenase, induced a dose-dependent increase of tissue sorbitol and accelerated cataract development. Surprisingly, an acceleration of motor nerve conduction velocity in normal and diabetic rats and a normalization of glomerular filtration rates in diabetic rats were found.

K.8.1.2 Aldose reductase inhibition *in vitro*

PURPOSE AND RATIONALE

The enzyme aldose reductase from bovine lens has been characterized by Hayman and Kinoshita (1965). Using this preparation, the *in vitro* effectiveness of various aldose reductase inhibitors can be determined (Varma and Kinoshita 1976; Billon et al. 1990).

PROCEDURE

Aldose reductase from lenses of calf eyes is isolated from the homogenates by ammonium sulfate precipitation of the concomitant proteins and by column chromatography on DEAE-cellulose. DL-Glyceraldehyde is used as substrate. The activity is expressed as the rate of OD_{340} [nm] due to the utilization of NADPH in the reaction:

$$\text{glyceraldehyde} + \text{NADPH} \xrightarrow{\text{aldose reductase}} \text{glycerol} + \text{NADP}$$

The reaction mixture contains: 0.1 M phosphate buffer, pH 6.2; NADPH 2.5×10^{-4} M; DL-glyceraldehyde 1.5×10^{-3} M; and the enzyme. The total volume of the reaction mixture is 1 ml. The reference blank consists of all the above compounds except the substrate. The effects of inhibitors on the enzyme activity are determined by including the compound being tested at the desired concentration in the reaction mixture. Appropriate blanks are used to correct for nonspecific reduction of NADPH and absorption by the compounds being tested. The test compounds are added first in 10^{-3} M solution and diluted as desired.

EVALUATION

Percentage of inhibition is tested at various concentrations and IC_{50}-values are calculated.

K.8.1.3 Effect on nerve conduction velocity

PURPOSE AND RATIONALE

Aldose reductase inhibitors can be tested in rats with diabetes induced with streptozotocin by measuring nerve conduction velocity (Miyoshi and Goto 1973; Mayer and Tomlinson 1983; Tomlinson et al. 1882, 1984; Yue et al. 1982) and resistance to ischemic conduction block (Price et al. 1988).

PROCEDURE

Male Wistar rats weighing 100–150 g are rendered diabetic with an i.v. injection of 60 mg/kg streptozotocin. Diabetes is confirmed by the presence of glucosuria and elevated blood glucose levels 24 h after injection. The rats are kept on standard diet and water ad libitum for 28 days after streptozotocin treatment. Groups of rats are treated with the test compound (aldose reductase inhibitor) or the vehicle once daily by gavage starting 24 h after streptozotocin injection. One group of age-matched rats serves as control.

For measurement of sciatic **nerve conduction velocity**, rats are anesthetized with 2% halothane in oxygen and placed in a Perspex chamber that is maintained at a constant temperature by a copper coil in the base through which warm water is circulated. A fine needle thermocouple is inserted in the lateral aspect of the left hind limb, and the subcutaneous temperature is measured with an electronic thermometer. The conduction velocity of the left sciatic-tibial nerve is measured by a modification of the method of Sharma and Thomas (1974). Two fine platinum stimulating electrodes are inserted in the sciatic notch, and two more are inserted through the skin of the ankle to lie adjacently to the tibial nerve. The electrodes are 5 mm apart, the distal end being the cathode. A recording electrode is inserted under the skin of the lateral side of the foot and another between the third and fourth toes. A ground electrode is inserted under the skin on the dorsum of the foot. Both stimulation and recording are carried out with a neurophysiological unit (e.g., model MS92a, Medelec, Old Woking, Surrey, UK). The nerve is stimulated supramaximally with square-wave pulses of 0.1 ms duration. The conduction velocity is calculated as the distance between the distal electrodes divided by the difference between the latencies at the two stimulation points. The mean of three recordings is taken. The coefficient of variation of nerve conduction velocity is calculated by measuring nerve conduction velocity six times in one rat from each treatment group, withdrawing and reinserting the electrodes each time.

To measure **resistance to ischemic conduction block**, two fine platinum stimulating electrodes (1 cm apart) are inserted in the lateral aspect of the tail 3 cm from the base. Two recording electrodes are inserted near the tip, and a ground electrode is inserted midway between these and the stimulating electrodes. A thermocouple is attached to the middle of the tail. Both stimulation and recording are carried out as described above. To render the tail ischemic, a small sphygmomanometer cuff is inflated to 240 mm Hg around the base of the tail. The nerve is stimulated at 2.5 min intervals until the action potential disappears. The tail temperature is maintained at 32 °C. At the end of the experiment, 5 ml blood is taken by cardiac puncture. The animal is then sacrificed, the sciatic nerves are removed, cleaned, weighed, snap-frozen in liquid nitrogen and stored at –20 °C for subsequent estimation of polyol level.

Nerve polyol estimation is performed by the method of Stribling et al. (1985). Frozen nerves are thawed, placed in 1 ml water containing 60 µg of α-methylmannoside as an internal standard, and boiled for 20 min. Zinc sulfate (200 µl of a 5% solution) is added, samples are homogenized with a Polytron homogenizer, 200 µl 0.3 N barium hydroxide solution is added, and the samples rehomogenized. After centrifugation, the supernatant is freeze-dried overnight. The residue is silylated with 250 ml of a mixture of pyridine, hexamethyldisilazane, and trimethylchlorosilane (10 : 2 : 1; Pierce, Rockford, IL) at room temperature for 24 h. The reaction is stopped by adding 2 ml water, and 200 µl cyclohexane is added. Samples are shaken and 2 µl of the organic phase is injected into a gas chromatograph.

Plasma glucose levels are measured with the use of a glucose analyzer. Plasma fructosamine, which reflects plasma protein glycosylation, is measured with the use of a commercial kit.

Plasma glucose, plasma fructosamine and nerve sorbitol are increased and nerve conduction velocity decreased in streptozotocin treated rats.

EVALUATION

Results are expressed as means ±SE. Data from diabetic rats treated with the aldose-reductase inhibitor are compared with the values of untreated diabetic rats and normal controls. Statistical comparisons are made by use of the Mann-Whitney *U* test.

MODIFICATIONS OF THE METHOD

Sima et al. (1990) studied motor nerve conduction velocity and neuroanatomical abnormalities in insulin-deficient diabetic Bio-Breeding rats (BB-rat) with and without long-term administration of an aldose reduct-

ase inhibitor. Their findings of a significant, but incomplete prevention of neuropathy in these animals by aldose reductase inhibition suggest that additional mechanisms besides polyol-pathway activation may be of importance in the pathogenesis of diabetic neuropathy.

Carrington et al. (1991) studied effects on impulse conduction after aldose reductase inhibition with imirestat in sciatic nerves of streptozotocin-diabetic rats both *in vivo* and *in vitro*.

Cameron et al. (1991) studied nerve blood flow monitored by microelectrode polarography and hydrogen clearance in experimental diabetes in rats in relation to conduction deficits.

Schmidt et al. (1991) performed ultrastructural studies in mesenteric nerves of streptozotocin-induced diabetic rats.

K.8.1.4 Effect on nerve blood flow (Doppler flux)

PURPOSE AND RATIONALE

In addition to nerve conduction studies, Calcutt et al. (1994) described a method to measure nerve blood flow by laser Doppler flowmetry in rats with streptozotocin induced diabetes treated with aldose reductase inhibitors.

PROCEDURE

Diabetes is induced in female Sprague-Dawley rats weighing 200–280 g by a single i.p. injection of 50 mg/kg streptozotocin after an overnight fast and is confirmed 2 days later by blood glucose determinations. Aldose-reduct-

ase inhibitor treated rats receive the test compound orally by gavage once a day for 2 months. For the experiment, the animals are anesthetized with an intraperitoneal injection (2 ml/kg) consisting of pentobarbital (12.5 mg/ml) and diazepam (1.25 mg/ml) in 0.9% NaCl. For estimation of nerve blood flow, a laser Doppler flowmeter (TSI model BPM 403A, St. Paul, MN) with a wavelength of 780 nm is used. Flow determinations are made with a filter frequency of 30 Hz to 18 kHz and, depending on the magnitude of the reflected signal, one of four band widths (30 Hz to 1.3 kHz, 30 Hz to 3 kHz, 30 Hz to 7.5 kHz, or 30 Hz to 18 kHz). The flow meter continuously displays a moving average for the preceding 5 s in units of $Hz \times 10^2$. For flow measurements, the sciatic nerve is exposed and the probe tip of the flowmeter placed 1 mm above the mid-thigh region of the nerve using a micromanipulator. After a 10 s stabilization period, the first measurement is recorded. The probe is then advanced 1 mm distally for a second measurement and this process repeated until 10 readings are recorded over 1 cm of nerve. The mean of 10 values is taken as average nerve laser Doppler flow. Blood flow velocity, expressed in m/s, is reduced in diabetic rats.

EVALUATION

The effects of streptozotocin diabetes and of aldose reductase treatment are assessed by one factor analysis of variance (ANOVA). Individual post-hoc comparisons are made with the Newman-Keuls method when the F ratio is $P < 0.05$.

K.8.1.5 Electroretinogram in diabetic hyperglycemia and galactosemia

PURPOSE AND RATIONALE

Diabetic neuropathy is one of the important symptoms of long-lasting diabetes (Engerman 1989).

Several animal studies with aldose reductase inhibitors have been performed (Lightman et al. 1987; Hotta et al. 1988; Nagata and Robison 1988). Segawa et al. (1988) measured the development of electroretinogram abnormalities and the possible role of polyol pathway activity in diabetic hyperglycemia and galactosemia in the rat.

PROCEDURE

Male Sprague-Dawley rats weighing 310–400 g are dark-adapted for 20 min and anesthetized with i.p injections of ketamine, 50–80 mg/kg and atropine sulfate, 2 mg/kg. Electroretinography is performed monocularly with the pupil maximally dilated. Photic stimulation is delivered with an intensity of one J in 20 s interstimulus intervals. Using a contact lens-type electrode, electroretinograms (ERG) evoked by strong flushes are amplified by a preamplifier, displayed on an oscilloscope and summed using a signal averager which also provides a copy of the averaged ERG. The amplitudes of the a- and b-waves are measured from the base line to the trough of the a-wave and from the trough of the a-wave to the crest of the b-wave, respectively. The amplitudes of the oscillatory potentials are measured. The peak latencies are measured as the intervals between the stimulus onset and the peak of the corresponding a- and b-waves and oscillatory potentials. The oscillatory potentials (designated O_1, O_2, and O_3 in order of appearance on the ascending limb of the b-wave) are added together. The sum of these amplitudes is expressed as the wavelet index.

For inducing galactosemia, male Sprague-Dawley rats weighing 140–185 g at the beginning of the study, receive a diet of 30% galactose. Test compounds are given as 0.1% to the diet.

EVALUATION

Data are calculated as mean ±SEM and significance levels are estimated using the Wilcoxon rank sum test for unpaired data (two-sided). Linear regression is calculated by the least square method. A p-value of < 0.05 is regarded as statistically significant.

K.8.1.6 Effect on streptozotocin induced cataract

PURPOSE AND RATIONALE

The increased incidence of cataracts, i.e., changes in the transparency or of the refractory index of the lens, in diabetic patients is well known. Evidence has accumulated for the involvement of polyol metabolism and the enzyme aldose reductase in diabetic cataractogenesis (van Heyningen 1959; Pirie and van Heyningen 1964). The enzyme aldose reductase catalyzes the reduction of aldoses such as glucose and galactose to the corresponding polyols, i.e., sorbitol and dulcitol. Sugar-induced cataractogenesis has been shown to parallel lenticular polyol accumulation (Kinoshita 1965). Since polyols do not readily diffuse through intact cellular membranes, they create a severe osmotic stress within the lenticular cells which leads to cellular swelling and loss of integrity of the cellular membrane (Kinoshita 1974). Aldose reductase inhibitors have been shown to prevent sugar induced cataracts (Dvornik et al. 1973; Varma and Kinoshita 1976; Kinoshita et al. 1979; Muller et al. 1985).

PROCEDURE

Experimental diabetes is induced in Wistar rats weighing 150–180 g by intravenous injection of 50 mg/kg streptozotocin (Griffin et al. 1984).

EVALUATION

The values of animals treated with the aldose reductase inhibitor are compared with the values of rats treated with streptozotocin only.

MODIFICATION OF THE METHOD

Instead of systemic application, the aldose reductase inhibitor is applied twice daily for 6 weeks in solution as eye drops to female Sprague-Dawley rats with a starting weight of 120–140 g after diabetes induction with 70 m/kg streptozotocin i.v. Body weight and blood sugar are registered twice a week. The progression of cataractous changes is followed by slit-lamp and Scheimpflug photography analysis every second week. At the end of the experiment, the animals are sacrificed and the lenses analyzed for their content of ATP, ADP, AMP, glucose, sorbitol, fructose, glucose-6-phosphate, and fructose-6-phosphate.

K.8.1.7 Determination of aldose reductase in rat lens

PURPOSE AND RATIONALE

The effect of aldose reductase inhibitors can be tested by determining the level of aldose reductase, NADPH

and $NADP^+$ in the lenses of galactose treated or streptozotocin diabetic rats after treatment with the inhibitor compared to controls.

PROCEDURE

Cataract formation can be induced by galactose feeding to young rats. Male Sprague-Dawley rats weighing 40–50 g are randomly divided into 2 groups. One group is fed a laboratory chow, the other group is fed a galactose diet containing 50% galactose, 20% cornstarch, 15% casein, 9% hydrogenated oil, 4% salt mixture, and 2% cod liver oil.

Diabetes is induced in male Sprague-Dawley rats weighing 80–90 g by a single intravenous dose of 100 mg/kg streptozotocin.

The progression of cataracts is observed in controls and in rats treated with the aldose reductase inhibitor.

At appropriate times, the rats are sacrificed and the lenses are dissected. They are frozen on solid CO_2 and stored at –70 °C until analysis.

Single rat lenses are homogenized in 200 µl of 10 mM sodium phosphate buffer containing 5 mM 2-mercaptoethanol (pH 7.0) for 0.5 min at 0 °C. A cell-free extract is obtained by centrifuging the total lens homogenate at 17 300 *g* for 10 min. The enzyme reaction mixture (final volume 1 ml) contains 0.4 M $(NH_4)_2SO_4$, 0.1 M HEPES buffer adjusted to pH 7.0 with sodium hydroxide, 10 mM DL-glyceraldehyde and 0.12 mM NADPH. A 20 ml aliquot of supernatant is added to initiate the reaction. Decrease in absorbance at 340 nm is followed spectrophotometrically. Enzymatic activity is expressed as nM of NADPH oxidized per min.

EVALUATION

Results are expressed as aldose reductase units/mg lens (wet weight). Means ±SE are calculated and compared using Student's non-paired *t*-test.

MODIFICATIONS OF THE METHOD

Naeser et al. (1988) studied sorbitol metabolism in the retina, optic nerve, and sural nerve of diabetic **rats** treated with an aldose reductase inhibitor. Activities of aldose reductase, sorbitol-dehydrogenase, and content of sorbitol were assayed in these tissues.

Freeze-dried tissue samples are sonicated for 5–10 s in 215 µl 0.04 M Tris(hydroxymethyl)-aminomethane, pH 6.8. For determination of aldose reductase, the homogenate is centrifuged for 45 min at 37 000 rpm and 100 µl is taken from the supernatant for analysis. The remaining sample is centrifuged further for 2 h at 96 000 rpm and the supernatant used for sorbitol determination. For determination of aldose reductase, 10 µl of the sample are mixed with 15 µl buffer solution containing 0.14 mol/L Tris(hydroxymethl)-aminomethane, 151 µmol/L NADH, and 0.6 mol/L glucose. After incubation in a water bath for 20 min at 38 °C, the incubation is stopped by transfer to ice. Samples mixed with buffer solution without glucose serve as blanks. Twenty µl of the incubated material are then mixed with 1.25 ml 0.04 mol/L NaOH solution containing 1.7 mmol/L NaCl. Fluorescence is measured in a Farrand Ratio Fluorometer with primary filters 5 860 and 5 970 (Corning Glass Works) and secondary filters 2A (Turner Optical Co), 4 308 and 3 387 (Corning Glass Works). The amount of NADPH consumed serves as measure for aldose reductase activity.

Sorbitol-dehydrogenase is measured by adding 5 µl of fresh homogenate to 20 µl of a buffer composed of 0.1 mol/L Tris(hydroxymethyl)-aminomethane, 1.25 mmol/L NAD and 50 mmol/L sorbitol at pH 6.8. After incubation for 30 min at 38 °C, the reaction is stopped by the addition of 5 µl 0.1 N NaOH and transfer to ice. The amount of NAD^+ converted to NADH is determined luminometrically in 10 µl samples with 100 µl of NAD(P)H reagent (Boehringer Mannheim, Germany) containing 5 mg/L luciferase, 25 mmol/L potassium phosphate, 100 mmol/L dithiothreitol, 38 U/L Triton-X 100, and 20 mmol/L myristic aldehyde. The flux of light is instantly registered, using a photomultiplier.

Sorbitol is determined in the centrifugation supernatant. After immersion in boiling water for 5 min, aliquots of 15 µl are added to 10 µl buffer containing 0.1 mol/L Tris, 3.5 mmol/L NAD, and 2.7 U/ml sorbitol-dehydrogenase at pH 8.6. Tissue blanks are run without sorbitol-dehydrogenase. The incubation is terminated and the amount of NADH formed is determined as for the sorbitol-dehydrogenase assay.

Gonzales et al. (1986) studied the effect of an aldose reductase inhibitor on integration of polyol pathway, pentose phosphate pathway and glycolytic route in diabetic rat lens. Diabetes was induced in male Wistar rats weighing about 230 g by subcutaneous injection of 200 mg/kg alloxan monohydrate. After one week, in the diabetic rat lens was an apparent increase in the flux of glucose through the pentose phosphate pathway, as measured by the difference in the yields of $^{14}CO_2$ from [1-^{14}C]glucose and [6-^{14}C]glucose [C1–C6]. Treatment with the aldose reductase inhibitor reduced the values toward normal. With glucose tritiated on carbons 2 or 3, it has been shown that the flux of glucose through the polyol route is increased, whereas the flux through the glycolytic pathway is decreased in the diabetic rat lens. Both parameters were restored to normal in diabetic rats treated with the aldose reductase inhibitor.

Meydani et al. (1994) investigated the onset and progression of cataract in weanling Sprague Dawley rats fed 10, 15, 20 and 30% dietary galactose for 45–226 days.

Ohta et al. (1999) studied cataract development in 12-months-old rats fed a 25% galactose diet and its relation to osmotic stress and oxidative damage.

Using phosphorus-31 nuclear magnetic resonance spectroscopy, Sakagami et al. (1999) investigated the metabolic kinetics of organophosphate compounds in the rat lens during cataract development induced by different doses of galactose added to rat chow.

Mackic et al. (1994) developed a model of galactose-induced cataract formation in **guinea pigs** and studied the morphologic changes and accumulation of galactitol.

Sato et al. (1998) demonstrated that the formation and progression sugar cataracts in galactose-fed **dogs** can be dose-dependently inhibited by the aldose reductase inhibitors.

K.8.1.8 Effect on naphthalene induced cataract

PURPOSE AND RATIONALE

Systemic application of naphthalene induces cataract in Brown-Norway rats. Aldose reductase inhibitors are tested for prevention of the cataract changes by parallel systemic or topical application (as eye drops).

PROCEDURE

Female Brown-Norway rats at an age of 6–7 weeks with a starting weight of 70–100 g are used. They are fed standard lab chow and receive water ad libitum. Naphthalene is dissolved in warm paraffin oil (10 g/100 ml) and is administered orally by gavage every second day in a dose of 1 g/kg. The test com-pound is administered orally every day or applied topically as suspension every day once, twice or four times to the right eye. The duration of the treatment is 6 weeks. Slit lamp microscopy (Zeiss photo slit lamp) during mydriasis with 1% atropine eye drops is performed in weekly intervals, including a baseline examination before the start of the treatment and a final examination prior to sacrifice. Scheimpflug photography of the anterior eye segment (Topcon SL-45 Scheimpflug camera) is carried out at the baseline examination, after 3 weeks of treatment and at the end of the experiment. Prior to sacrifice blood samples are taken by cardiac puncture under ether anesthesia. After sacrifice, lens fresh weight, concentration of oxidized and reduced glutathione, and the concentration of the aldose reductase inhibitor in the lenses and in blood samples are determined.

EVALUATION

The values of animals treated with the aldose reductase inhibitor are compared with the values of rats treated with naphthalene only.

MODIFICATIONS OF THE METHOD

Rathbun et al. (1996a) induced rapid-onset cataracts in SPF C57 bl/6 mice by i.p. administration of naphtha-

lene following cytochrome P-450 induction with phenobarbital.

Rathbun et al. (1996b) assessed the activity of a L-cysteine prodrug suitable for glutathione biosynthesis rat lenses *in vitro* and as an agent for the prevention of acetaminophen- and naphthalene-induced murine cataract in genetically susceptible mice.

Holmen et al. (1999) compared different methods of photographic evaluation of cataract formation in rats in response to different regimes of naphthalene treatment.

Chapter L
Anti-obesity activity[1]

[1] Review by M. Bickel, contributions by A. W. Herling.

L.1 Methods to induce experimental obesity

L.1.0.1 General considerations

Influence of the central nervous system, in particular of the hypothalamus, on development of obesity has been suspected since the early clinical observations of Babinski (1900) and Fröhlich (1901), Biedl 1916). Experiments reported by Smith (1927, 1930) showed that injections of chromic acid into the suprasellular region of rats with lesion of the hypothalamus induced obesity in rats (Bomskov 1939). Hetherington and Ranson (1939) found that electrolytic lesions, restricted to the ventromedial region of the hypothalamus, could be associated with the development of obesity.

A virally induced obesity syndrome in mice was described by Lyons et al. (1982).

Chan (1995) gave a review on β-cell stimulus-secretion coupling defects in rodent models of obesity.

Leiter and Herberg (1997) reviewed the advances in understanding the molecular bases for monogenic obesity mutations capable of producing obesity-induced diabetes, or diabesity in mice.

Astrup and Lundsgaard (1998) discussed pharmacological mechanisms of anti-obesity drugs.

L.1.0.2 Food induced obesity

PURPOSE AND RATIONALE

Obesity can be induced in rats by offering a diet containing corn oil and condensed milk.

PROCEDURE

Male Sprague Dawley rats are housed in individual wire-bottom suspended cages in rooms maintained at 22–23 °C with 12 h light-dark cycles. At the age of 6 months (body weight about 450 g) the animals are divided in 2 groups: group I is fed ordinary Purina Rodent Chow, group II a special diet containing Purina Rodent Chow, corn oil and condensed milk, resulting in a composition of 14.7% protein, 44.2% carbohydrate, 15.8% lipid, 2.5% fiber, 1.2% vitamin mixture, and 19% water. Body weight and food intakes are measured, and diet replaced, every 3 to 4 days.

Three months from the start of the experiment, the rats are sacrificed by decapitation for determination of adipose tissue cell size and number, carcass composition and plasma lipids, and hormone and glucose levels.

The dorsal subcutaneous (inguinal) pad, the retroperitoneal pad, and one epididymal fat pad are sampled for determination of lipid content by the method of Folch et al. (1957). The method consists of homogenizing the tissue with a 2 : 1 chloroform-methanol mixture and washing the extract by addition to it of 0.2 its volume of water. The resulting mixture separates into two phases. The lower phase is the total pure lipid extract. Cell number in each pad is determined by the osmium fixation method of Hirsch and Gallian (1968) using a Coulter counter. Total epididymal pad weights are based on doubling the weight of the individual pads sampled.

EVALUATION

Intergroup comparisons are made with the use of a two-tailed Student's *t*-test.

MODIFICATIONS OF THE METHOD

Scalfani and Springer (1976) induced obesity in adult female rats by adding a variety of supermarket foods to lab chow (**"cafeteria diet"**). In behavioral tests, the authors found similarities to hypothalamic and human obesity syndromes.

Rothwell et al. (1982) compared the effects of feeding a cafeteria diet on energy balance and diet-induced thermogenesis in four strains of rats.

Stock and Rothwell (1979) discussed the influence of various forms of feeding, high-fat diets, insulin injections, tube-feeding, and cafeteria feeding on energy balance in laboratory animals.

Rolls et al. (1980) found persistent obesity in rats following a period of consumption of a mixed, high energy diet. When the high energy foods were withdrawn after 90 days and just chow was available, the obese rats maintained their elevated body weights.

Hill et al. (1992) studied the influence of amount and composition of dietary fat on development of obesity in rats. Adult male Wistar rats were fed high fat (HF; 60% of calories) or low fat (LF; 20% of calories) diets for 28 weeks. Half of the rats in each condition received diets with saturated fat (lard) or with polyunsaturated fat (corn oil). There was some indication that unsaturated fat diets were associated with greater accumulation of fat in subcutaneous tissue depots than saturated fat diets. The effects of the type of fat were less than those of the amount of dietary fat.

Wade and Gray (1979) reviewed the gonadal effects on food intake and adiposity in rats. Estradiol and testosterone decrease adiposity, while progesterone increases carcass fat content.

Thermogenesis induced by various diets has been discussed by Rothwell and Stock (1986).

Harris (1993) studied the impact of high- or low-fat cafeteria foods on nutrient intake and growth of rats consuming a diet containing 30% energy as fat.

Segues et al. (1994) studied long-term effects of cafeteria diet feeding on young female Wistar rats by comparing the circulating levels of glucose, lactate, glycerol, 3-hydroxybutyrate and urea, and liver glycogen.

Llado et al. (1997) studied fatty acid composition of brown adipose tissue in dietary obese rats. Long time exposure to a hypercaloric high-fat diet such as the cafeteria diet induced an important fatty acid accumulation in brown adipose tissue, mainly for the major saturated and monounsaturated fatty acids.

LeBlanc and Labrie (1997) investigated the role of palatability of the food in diet-induced thermogenesis.

Selective breeding for diet-induced obesity and resistance in Sprague-Dawley rats was reported by Levin et al. (1997).

Herberg et al. (1974) reported the effects of either a high-carbohydrate diet or a high-fat diet over prolonged periods in metabolically intact and in obese NZO **mice**.

West et al. (1992) evaluated the effects of a 7 week consumption of a diet containing 32.6% of kilocalories as fat (condensed milk) on body composition and energy intake in nine strains of inbred mice. Relative to Chow diet controls, the condensed milk diet significantly increased carcass lipid content in six strains (AKR/J, C57L/J, A/J, C3H/HeJ, DBA/2J, and C57BL/6J), but had no or a marginal effect on adiposity in 3 strains of mice (SJL/J, I/STN, and SWR/J).

West et al. (1994) studied the genetics of dietary obesity in AKR/J x RWR/J mice. Pups were weaned between the ages of 29 and 34 days onto Purina Chow ad libitum until they were switched to a high fat, condensed milk diet containing 32.6%, 15.0%, and 52.4% of kilocalories as fat, protein, and carbohydrate, respectively.

Strain-specific response to β_3-adrenergic receptor agonist treatment of diet-induced obesity in mice was reported by Collins et al. (1997).

L.1.0.3 Hypothalamic obesity

PURPOSE AND RATIONALE

Hyperphagia in rats has been reported after hypothalamic lesions (Liu and Yin 1974). Surgical techniques were described by Leibowitz et al. (1981), Vander Tuig et al. (1985).

PROCEDURE

Female Sprague Dawley rats, weighing about 190 g body weight, receive during a 5–9 days initial period of adjustment a high-fat diet. They are then fasted overnight, anesthetized with 35 mg/kg pentobarbital sodium and additionally 1 mg atropine methyl nitrate intraperitoneally. Bilateral wire knife cuts or electrolytic lesions are sterotaxically positioned in the hypothalamus (David Kopf Instruments, CA). With the incision bar positioned at –3.0 mm, parasagittal wire knife cuts are placed between the medial and lateral hypothalamus using a retractable wire knife according to Gold et al. (1973). The cuts are made 1.0 mm lateral to the midline and extended from 8.5 to 5.5 mm anterior to the ear bars and from the base of the brain dorsally 3.0 mm.

To produce electrolytic lesions in the ventromedial hypothalamus, the incision bar is positioned at +5.0 mm and a stainless steel electrode, insulated except for 0.5 mm at the tip, is lowered 0.6 mm lateral to the midline and 5.8 mm anterior to the ear bars. With the tip of the electrode 0.7 mm above the base of the brain, lesions are made by passing 2.0 mA of anodal current for 20 s to a rectal electrode.

Sham-operated rats serve as controls. Separate rats that are fasted overnight are killed at the time of surgery to provide data on initial body composition.

Histological verification of placement of knife cuts and lesions is made in brains fixed in 10% buffered formaldehyde solution and embedded in paraffin. Serial sections through the hypothalamic area of the brain are examined histologically.

EVALUATION

Not only food consumption and increase of body weight can be determined after hypothalamic lesions, but also brown adipose tissue enzymes and guanosine diphosphate binding to brown adipose tissue mitochondria and noradrenaline turnover in various organs.

MODIFICATIONS OF THE METHOD

A survey on hypothalamic and genetic obesity in experimental animals was given by Bray and York (1979).

Caloric compensation to gastric loads in rats with hypothalamic hyperphagia was reported by Liu and Yin (1974).

Sclafani and Aravich (1983) adapted adult female Sprague Dawley rats to a macronutrient self-selection regimen which allowed them ad libitum access to separate sources of protein, carbohydrate, and fat. The rats were then given either ventromedial hypothalamic lesions, paraventricular hypothalamic lesions, parasagittal knife cuts through medial hypothalamus or sham lesions. Following surgery, all lesioned rats overate and became obese as compared to sham operated controls. The group with parasagittal knife cuts through medial hypothalamus gained more weight than the groups with ventromedial hypothalamic lesions and paraventricular hypothalamic lesions.

Enhanced expression of rat obese (ob) gene in adipose tissue of ventromedial hypothalamus (VMH)-lesioned rats was described by Funahashi et al. (1995).

Elmquist et al. (1999) discussed the role of leptin and other peptide hormones in different areas of the hypothalamus in controlling food intake and body weight.

L.1.0.4 Goldthioglucose-induced obesity

PURPOSE AND RATIONALE

Intraperitoneal or intramuscular injection of goldthioglucose induces obesity in mice. The effect is related to destruction of hypothalamic and extra-hypothalamic areas of the brain (Perry and Liebelt 1961).

PROCEDURE

Swiss albino mice of either sex are fed with commercial mouse chow (Altromin R®) ad libitum. At the age of 6 weeks, the animals receive a single intraperitoneal injection of 30–40 mg/kg gold-thioglucose.

EVALUATION

Food intake is registered for 2 weeks and body weight for a period of 3 months and compared with untreated controls.

MODIFICATIONS OF THE METHOD

Debons et al. (1962, 1968, 1977) administered 800 mg/kg gold thioglucose by a single intraperitoneal injection to female CBA mice.

Obesity was induced in rats by implants of gold thioglucose in the hypothalamus (Smith and Britt 1971; Smith 1972).

Several other compounds produce obesity concomitantly with brain lesions.

Single intraperitoneal injection of bipiperidyl mustard (N,N'-bis-[β-chloroethyl]-4,4'-bipiperidine) in doses between 5 to 50 mg/kg induced obesity in mice (Rutman et al. 1966). Brain lesions and obesity by bipiperidyl mustard could also produced in rats (Laughton and Powley 1981).

Massive and persistent obesity was induced in mice by a single intracerebral injection with 4-nitroquinoline 1-oxide (Mizutani 1977).

L.1.0.5 Monosodium glutamate-induced obesity

PURPOSE AND RATIONALE

Adiposity can be induced in mice by repeated subcutaneous injections of monosodium-L-glutamate at an early stage of life (Olney 1969).

PROCEDURE

Male Charles River mice are treated immediately after birth with daily subcutaneous injections of 2 g/kg monosodium-L-glutamate for 5 consecutive days. Control mice are treated with physiological saline. The animals are weaned at 3 weeks of age, housed under controlled temperature and artificial light/dark cycle and provided with commercial powdered chow and tap water at libitum.

EVALUATION

Food consumption and weight gain is measured at weekly intervals.

MODIFICATIONS OF THE MEDTHOD

Tokuyama and Himms-Hagen (1986) studied brown adipose tissue thermogenesis, torpor, and obesity in glutamate-treated C57B1/6J mice offered either normal chow or a cafeteria diet and found that the high metabolic efficiency and obesity of the glutamate-obese animals are principally a consequence of their maintenance of a hypothermic torpid state for more than 50% of the time.

Seress (1982) injected young albino **rats** with either single or repeated doses of 0.1–6.0 mg/g body weight of monosodium L-glutamate between the ages of 2 and 40 days. The smallest, single effective dose was 0.25 mg/g body weight administered during the first week of life. The sensitivity to monosodium L-glutamate decreased with age. In adult rats an 80–90% loss of neurons in the anterior part of the arcuate nucleus was found.

Remke et al. (1988) reported on development of hypothalamic obesity after subcutaneous administration of monosodium glutamate to neonate rats.

L.2 Genetically obese animals

L.2.0.1 General considerations

Obesity and diabetes are syndromes quite often linked in patients (maturity onset diabetes) and hereditary animal models. Hunt et al. (1976) described animal models of diabetes and obesity including the PBB-Ld mouse. A survey on hypothalamic and genetic obesity in experimental animals was given by Bray and York (1979). The inheritance of obesity in animal models of obesity was discussed by Festing (1979). Cawthorne (1979) discussed the use of animal models in the detection and evaluation of compounds for the treatment of obesity. The regulation of body weight in animals by leptin was reviewed by Friedman and Halaas (1998).

Symptoms of diabetes and obesity are overlapping in many animal models (see also K.2: Genetically diabetic animals).

L.2.0.2 Spontaneously obese rats

The occurrence of spontaneous obesity has been reported in several strains of rats:

WBN/KOB RAT

Spontaneous hyperglycemia, glucosuria and glucose intolerance have been observed in aged males of an inbred Wistar strain, named the WBN/Kob rat (Nakama et al. 1985; Tsuchitani et al. 1985; Koizumi 1989). These animals exhibit impaired glucose tolerance and glucosuria at 21 weeks of age. Obvious decreases in the number and size of islets are found already after 12 weeks of age. Fibrinous exudation and degeneration of pancreatic tissue are observed in the exocrine part, mainly around degenerated islets and pancreatic ducts in 16 weeks old males.

ZUCKER-FATTY RAT

The Zucker-fatty rat is a classic model of hyperinsulinemic obesity. (Zucker 1965). Obesity is due to a simple autosomal recessive (*fa*) gene and develops at an early age. Obese Zucker rats manifest mild glucose intolerance, hyperinsulinemia, and peripheral insulin resistance similar to human NIDDM. However, their blood sugar level is usually normal throughout life (Bray 1977; Clark et al. 1983; McCaleb and Sredy 1992; Abadie et al. 1993; Alamzadeh et al. 1993; Kasim et al. 1993; Galante et al. 1994).

Truett et al. (1991) found evidence that the rat obesity gene fatty (*fa*) has homology with the mouse gene diabetes (*db*).

Triscari and Sullivan (1987) reported a normalizing effect of an inhibitor of thromboxane synthase on the hyperinsulinemic state of obese Zucker rats and diet-induced obese rats.

Rouru et al. (1993) described the effect of chronic treatment with a 5-HT_1 receptor agonist on food intake, weight gain, plasma insulin and neuropeptide Y mRNA expression in obese Zucker rats.

Santti et al. (1994) studied the potentiation of the anti-obesity effect of a β_3-adrenoceptor agonist in obese Zucker rats by exercise.

Savontaus et al. (1997) investigated the anti-obesity effect of a imidazoline derivative in genetically obese (fa/fa) Zucker rats.

Zhang et al. (1996) reported downregulation of the expression of the *obese* gene by an antidiabetic thiazolidinedione in Zucker diabetic fatty rats and *db/db* mice.

Lynch et al. (1992) identified several adipocyte proteins, among them pyruvate decarboxylase contributing to the increased lipogenic capacity of young obese Zucker adipocytes.

WDF/TA-FA RAT

The WDF/Ta-fa rat, commonly referred to as the Wistar fatty rat, is a genetically obese, hyperglycemic rat established by the transfer of the fatty (*fa*) gene from the Zucker rat to the Wistar Kyoto rat. (Ikeda et al. 1981; Kava et al. 1989; Velasquez et al. 1990). The Wistar fatty

rat exhibits obesity, hyperinsulinemia, glucose intolerance, hyperlipidemia, and hyperphagia similar to Zucker rats being, however, more glucose intolerant and insulin resistant than Zucker rats. Hyperglycemia is usually not observed in females but can be induced by addition of sucrose to the diet.

Kobayashi et al. (1992) found an increase of insulin sensitivity by activation of insulin receptor kinase by Pioglitazone in Wistar fatty rats (*fa/fa*).

Mazusaki et al. (1996) found an augmented expression of the *obese* (*ob*) gene during the process of obesity in genetically obese-hyperglycemic Wistar fatty (*fa/fa*) rats.

OLETF RAT

A spontaneously diabetic rat with polyuria, polydipsia, and mild obesity was discovered in 1984 in an outbred colony of Long-Evans rats. A strain of rats developed from this rat by selective breeding has since been maintained at the Tokushima Research Institute (Otsuka Pharmaceutical, Tokushima, Japan) and named OLETF. The characteristic features of OLETF rats are: (1) late onset of hyperglycemia (after 18 weeks of age), (2) a chronic course of disease, (3) mild obesity, (4) inheritance by males, (5) hyperplastic foci of pancreatic islets, and (6) renal complications (nodular lesions). The clinical and pathological features of disease in OLETF rats resemble those of human NIDDM.

Administration of diazoxide (0.2% in diet), an inhibitor of insulin secretion, to OLETF rats from the age of 4 to 12 weeks completely prevented the development of obesity and insulin resistance (Aizawa et al. 1995).

Ishida et al. (1995) found that insulin resistance preceded impaired insulin secretion in OLETF rats.

Umekawa et al. (1997) determined induction of uncoupling protein and activation of GLUT4 in OLETF rats after administration of a specific β_3-adrenoceptor agonist.

OBESE SHR RAT

The strain of obese SHR rats was developed by Koletsky (1973, 1975) by mating a spontaneous hypertensive female rat of the Kyoto-Wistar strain with a normotensive Sprague Dawley male. After several generations of selective inbreeding, these obese SHR exhibited obesity, hypertension, and hyperlipidemia. In addition, some rats developed hyperglycemia and glucosuria associated with giant hyperplasia of pancreatic islets.

JCR:LA-CORPULENT RAT

Several substrains were developed from obese SHR rats, such as the JCR:LA-corpulent rat which exhibits a syndrome characterized by obesity, hypertriglyceridemia and hyperinsulinemia with impaired glucose tolerance and is susceptible to vascular arteriosclerotic lesions (Russell et al. 1986a,b, 1994).

Compared to fatty Zucker rats, the JCR:LA-corpulent rats have higher levels of the insulin releasing hormone gastric inhibitory polypeptide and higher insulin levels (Pederson et al. 1991).

Vydelingum et al. (1995) found an overexpression of the obese gene in the JCR:LA-corpulent rat.

L.2.0.3 Spontaneously obese mice

YELLOW OBESE (A^YA) MOUSE

The yellow obese mouse in the only example of obesity inherited through a dominant gene and was described as early as 1883 by Lataste and in 1905 by Cuenot. It is located on chromosome 2 at linkage group 5, the agouti locus (Bateson 1903). Since the genes controlling obesity and the agouti coat colors are so closely linked, the obesity is associated with a change of pigmentation from black to yellow. Such an association allows the early identification of pre-obese mice as soon as the coat hair begins to grow.

Since the original description of the yellow (A^ya) mouse, a number of additional alleles have appeared at the agouti locus. The homozygous dominant yellow mutation (A^y/A^y) is lethal in utero (Robertson 1942; Eaton and Green 1962) with approximately 25% of any litter from A^ya matings dying from an abnormal development after the trophoblast stage (Pedersen 1974).

Yellow (A^ya) mice develop a moderate form of obesity and diabetes. Increased body weight first appears at the time of puberty (8–12 wk) (Dickie and Wooley 1946; Carpenter and Mayer 1958), after which body weight increases slowly to reach values of approximately 40 g. In contrast to other forms of obesity, yellow mice are characterized by increased linear growth. Plasma insulin concentrations are increased and food is stored more efficiently than in lean mice (Dickerson and Gowan 1967). Food intake returns to normal in older A^ya mice and the animals lose body weight (Hollifield and Parson 1957). The obesity may be exaggerated by being fed high-fat diets (Fenton and Chase 1951; Silberberg and Silberberg 1957; Carpenter and Mayer 1958). Food restriction may normalize body weight but the animals still remain obese (Fenton and Chase 1951; Hollifield and Parson 1957). Metabolic rate of A^ya mice is depressed when related to body surface, although oxygen consumption per animal is identical to the homozygous recessive agouti (a/a) mouse (Bartke and Gorecki 1968).

Gill and Yen (1991) studied the effect of ciglitazone on endogenous plasma islet amyloid polypeptide (amylin) and insulin sensitivity in obese-diabetic viable yellow mice (VY/Wfl-A^{vy}/a).

KK-A^Y MOUSE

Iwatsuka et al. (1970) reported on yellow KK mice (also named KK-A^y mice), carrying the yellow obese gene (A^y). These mice develop marked adiposity and diabetic symptoms in comparison with their littermates, black KK mice. Blood glucose and circulating insulin levels as well as HbA_{1c} levels were increased progressively from 5 weeks of age. Degranulation and glycogen infiltration of B cells were followed by hypertrophy and central cavitation of islets. Lipogenesis by liver and adipose tissue were increased. Insulin sensitivity of adipose tissue was more remarkably reduced than in black KK mice to its complete loss at 16 weeks of age. Renal involvement is uniquely marked by early onset and rapid development of glomerular basement membrane thickening (Diani et al. 1987).

KK-A^y mice can be used to demonstrate the extrapancreatic action of antidiabetic drugs, such as glimepiride, a novel sulfonylurea (Satoh et al. 1994).

Sohda et al. (1990) evaluated ciglitazone and a series of 5-[4-(pyridylalkoxy)benzyl]-2,4-thiazolidinediones for hypoglycemic and hypolipemic activities in yellow KK mice.

Hofmann et al. (1992) evaluated the expression of the liver glucose transporter GLUT2 and the activity and the expression of phosphoenolpyruvate carboxykinase in the liver of obese KKA^Y mice after treatment with the oral antidiabetic agent pioglitazone.

Yoshida et al. (1991) compared brown adipose tissue thermogenesis, resting metabolic rate, insulin receptors in adipocytes, and blood glucose and serum insulin levels during a glucose overloading test in yellow KK mice with C57B1 control mice after a β_3-adrenoceptor agonist.

Yoshida et al. (1996) determined body weight, food intake, white adipose tissue weight, brown adipose tissue weight and its thermogenesis, noradrenaline turnover, blood glucose and serum insulin levels and GLUT4 in diabetic yellow KK mice compared with C57B1 mice after mazindol.

OBESE HYPERGLYCEMIC (OB/OB) MICE

Ingalls et al. (1950), Mayer et al. (1951), Bleisch et al. (1952) observed hereditary diabetes in genetically obese mice. The obese hyperglycemic mice were glycosuric, the non-fasting blood sugar levels were about 300 mg%, but neither ketonuria nor coma were observed. One of the most interesting features was insulin-resistance; doses as high as 400 IU/kg had little effect on blood sugar. The serum insulin-like activity was high, the islands of Langerhans were hypertrophic, their insulin content was increased and the liver glycogen stores were decreased. Kidneys and other organs did not show pathological changes. Obviously, the diabetic condition of this and other strains of obese hyperglycemic mice is different from that of the human diabetic patient.

Reduced oxygen consumption has been noted as early as 10–18 days of age in *ob/ob* mice (Boissenault et al. 1976; Trayhurn 1977).

Other strains or substrains of mice with obesity and hyperglycemia have been described by Dickie (1962), Westman (1968), Stein et al. (1970), Coleman and Hummel (1973), Herberg and Coleman (1977).

Strautz (1970) implanted *ob/ob* mice with Millipore diffusion chambers containing islets isolated from pancreas of normal littermates.

Trayhurn et al. (1977) found a thermogenic defect in pre-obese *ob/ob* mice. Rectal temperature of 17 days old pre-obese mice in response to an environmental temperature of 4 °C fell much more than in lean controls.

Chlouverakis (1972) performed parabiotic experiments of obese-hyperglycemic mice (*ob/ob*) with lean littermates and determined body weight, glucose, serum insulin and triglycerides as well as insulin-sensitivity of diaphragm muscle and epididymal fat pad.

Parabiosis of obese (*ob/ob*) with diabetes (*db/db*) mice caused the obese partner to become hypoglycemic, to lose weight and to die of starvation, while no abnormal changes were observed in the diabetic partner (Coleman 1973).

Cresto et al. (1977) compared the rate of insulin degradation in normal and in *ob/ob* mice.

Zhang et al. (1994) succeeded in positional cloning of the mouse *obese* gene and its human homologue.

Pelleymounter et al. (1995) investigated the effects of the *obese* gene product on body weight regulation in *ob/ob* mice. The OB protein was expressed in *E. coli* and purified to homogeneity as a 16-kilodalton monomer. Daily intraperitoneal injections of the recombinant OB protein to *ob/ob* mice lowered their body weight, percent body fat, food intake, and serum concentrations of glucose and insulin.

Halaas et al. (1995) reported that daily intraperitoneal injections of either mouse or human recombinant OB protein reduced the body weight of *ob/ob* mice but had no effect on *db/db* mice.

Campfield et al. (1995) found that peripheral and central administration of microgram doses of recombinant mouse OB protein reduced food intake and body weight of *ob/ob* and diet-induced obese mice but not in *db/db* obese mice.

Trayhurn et al. (1996) studied the effects of fasting and refeeding on *ob* gene expression in white adipose tissue of lean and obese *(ob/ob)* mice using a 33-mer antisense oligonucleotide as a probe for the rapid chemiluminescence-based detection of *ob* mRNA.

Sterility defect in homozygous obese female mice could be corrected by treatment with the human recombinant OB protein leptin (Chehab et al. 1996).

Roupas et al. (1990) used isolated adipocytes from *ob/ob* mice to study the diabetogenic action of growth hormone.

BL/6 OBESE MICE

An obese mutation occurred in a noninbred stock (Ingalls et al. 1950) but was established later, and has been maintained, in the C5BL/6J (BL/6) strain. BL/6 obese mice are characterized by marked obesity, hyperphagia, transient hyperglycemia and markedly elevated plasma insulin concentrations associated with an increase in number and size of beta cells in the islets of Langerhans (Coleman and Hummel 1973; Genuth et al. 1971). The mutation is autosomal recessive and homozygous mutants of both sexes are infertile. Obese mutants are obtained by mating known heterozygotes. A primary metabolic disturbance in the adipocyte has been postulated since increased adipocyte size has been observed as early as 14 days of age well before any obesity or hyperinsulinemia are observed (Joosten and van der Kroon 1974).

NZO MOUSE

The New Zealand obese (NZO) mouse was first described in 1953 by Bielschowsky and Bielschowsky. The strain was developed by selective inbreeding of obese mice from a mixed colony, beginning from a pair of agouti mice, which also gave rise to the NZB black strain (Melez et al. 1980). NZO mice develop obesity, mild hyperglycemia, glucose intolerance, hyperinsulinemia, and insulin resistance. The adult NZO mouse normally attains a body weight of 50–70 g by 6–8 months, although weight gain continues slowly after this age (Crofford and Davis 1965; Herberg et al. 1970). Hyperglycemia and glucose intolerance increase continuously with advancing age of the animals.

Renal disease in NZO mice is seen by 6 months of age. NZO mice have a high prevalence of autoimmune disorders.

DIABETES OBESITY SYNDROME IN CBA/CA MICE

A spontaneous maturity onset diabetes obesity syndrome occurs in a small proportion (10–20%) of male CBA/Ca mice. Inbreeding can increase the incidence to 80%. It occurs at 12–16 weeks of age, and is characterized by hyperphagia, obesity, hyperglycemia, hypertriglyceridemia, hyperinsulinemia, and an impaired glucose tolerance. The mice are also resistant to exogenous insulin. Female mice remain normal except for a slight increase in serum insulin. The male obese diabetic mice have a normal life expectancy.

FAT/FAT MICE

Fat mice carry an autosomal recessive mutation and display a rang of abnormalities, including progressive adult onset obesity, hyperinsulinemia and infertility (Coleman and Eicher 1990). The mutant allele of *fat* was identified and shown to be a missense (serin → proline) mutation in carboxypeptidase E which abolishes enzyme activity in a variety of neuroendocrine tissues (Naggert et al. 1995). Carboxypeptidase E is required for both sorting and proteolytic processing of a variety of prohormones including proinsulin and POMC (Cool et al. 1997). As carboxypeptidase E is expressed in the CNS, defective processing of a variety of hypothalamic neuropeptides – such as POMC and MCH – may trigger obesity in these animals (Rovere et al. 1996).

TUBBY MICE

Tubby is an autosomal recessive mutation in mice (Coleman and Eicher 1990) which display a tripartite phenotype of blindness, deafness and maturity onset obesity. In response to weight gain, these mice gradually increase their food intake in proportion to body weight and increase plasma insulin levels thereby maintaining normoglycemia. The progressive retinal degeneration in *tubby* mice results from apoptotic loss of photoreceptor cells, with abnormal electroretinograms detected as early as 3 weeks of age (Heckenlively et al. 1955). The mouse obesity gene *tubby* has been identified and characterized (Noben-Trauth et al. 1996; Kleyn et al. 1996).

L.2.0.4 Transgenic animals

PURPOSE AND RATIONALE

Transgenic animals will offer a new approach to study development of obesity and therapeutic possibilities. Lowell et al. (1993) used a transgenic toxigene approach to create transgenic mice with primary deficiency of brown adipose tissue.

The potential for inserting new genetic material into mammals has produced numerous transgenic mice with increased or decreased quantities of body fat (Bray and Bouchard 1997*)*.

Jensen et al. (1997) reported prevention of diet-induced obesity in transgenic mice overexpressing skeletal muscle lipoprotein lipase. The authors hypothesized that the potential to increase lipoprotein lipase activity in muscle by gene or drug delivery may prove an effective tool in preventing and/or treating obesity in humans.

L.3 Assays of anti-obesity activity

L.3.1 Anorectic activity

L.3.1.1 Food consumption in rats

PURPOSE AND RATIONALE

Food intake is measured in acute experiments in normal or obese rats. Additionally, in semichronic experiments body weight gain is recorded.

PROCEDURE

Female Zucker rats weighing 250–350 g are maintained under standard conditions (temperature, light-dark cycle, ground rodent pellet chow, tap water). Measurements of food intake begin on day –2. The food is offered in special dishes to reduce spillage. Food intake and body weight are measured daily between 8:00 and 9:00 A.M. At this time any spilled food from the collecting paper under the cage is gathered, air-dried if necessary, and weighed. Individual food intakes in grams are recorded. The tests compounds are either administered with the food or injected intraperitoneally. Groups of 5–10 animals are used for control or treatment with various doses of the test compound or the standard. Mazindol, 3 m/kg i.p. or 10 mg/kg p.o. can serve as standard. Treatment is continued for 7 days.

EVALUATION

Average food intake and body weight is recorded for each day. Average values of test drugs are compared statistically for each day with the control group. Results after oral administration have to be confirmed by parenteral route in order to exclude errors due to palatability.

MODIFICATIONS OF THE METHOD

Hull and Maher, Maher and Hull (1990) used male Sprague-Dawley rats placed on a mush diet composed of equal parts of ground rodent chow and of 4% nutrient agar solution. The agar-based chow allows a more accurate measurement of food intake and has been shown to be sufficient for maintaining normal growth in rats. The rats were made hyperphagic by food deprivation for 4 h at the beginning of the dark cycle.

Mennini et al. (1991) and Anelli et al. (1992) studied the anorectic activity of various compounds in different species, such as mice, rats, and guinea pigs.

Bowden et al. (1988) used metabolism cages equipped with automated feeding monitors. Food was provided as 45 mg pellets which were singly delivered to a feeding trough. A photodetector sensed the removal of the pellet, and the number of pellets delivered over a specified time interval was recorded.

Samanin et al. (1979) described anorexia in rats induced by the central serotonin agonist m-chlorophenylpiperazine.

Dourish et al. (1985) investigated the effects of the serotonin agonist 8-OH-DPAT on food intake in nondeprived male rats. This effect was prevented by p-chlorophenylalanine (Dourish et al. 1986).

The anxiolytics gespirone, buspirone and ipsapirone increased free feeding in rats and did not inhibit feeding induced by 8-OH-DPAT (Gilbert and Dourish 1987).

Jackson et al. (1997) investigated the mechanisms underlying the hypophagic effects of the 5-HT and noradrenaline reuptake inhibitor, sibutramine, in the rat.

Simansky and Vaidya (1990) tested the anorectic action of a serotonin uptake inhibitor by measuring the volume of milk consumed by food-deprived rats.

Stevens and Edwards (1996) induced anorexia by subcutaneous injection of 5 mg/kg 5-hydroxytryptamine in Wistar rats habituated to a restricted feeding regime and tested the effects of a 5-HT_3 antagonist.

Rouru et al. (1992) investigated in genetically obese male Zucker rats the effect of subchronic metformin treatment on food intake, weight gain and plasma insulin and corticosterone levels and somatostatin concentrations in the pancreas.

Robert et al. (1989) found an enhanced food intake after intracerebroventricular administration of the tetrapeptide FMRF-amide (Phe-Met-Arg-Phe-NH_2) in obese "cafeteria" rats.

Cooper et al. (1990a,b) used non-deprived rats to study anorectic effects in a test of palatable food consumption and in nocturnal free-feeding.

Cooper et al. (1990c) tested not only food consumption but also the frequency of feeding bouts and duration of individual feeding episodes.

Eberle-Wang and Simansky (1992) studied the influence on the anorectic action of CCK and serotonin by measuring the uptake of sweetened mash mixture in rats.

Voigt et al. (1995) studied the involvement of the 5-HT_{1A} receptor in CCK induced satiety by recording food intake during a 2 h test meal in food deprived and in freely feeding rats.

Influence on postprandial satiety in rats was tested by Rosofsky and Geary (1989). Rats were given pelleted chow and water ad libitum. Near the middle of the bright phase of the light-dark cycle, pellets were removed, the animals treated and condensed milk presented 30 min later. Milk consumption was measured at 4-min intervals for 40 min.

Rats show a dramatic and reliable reduction of food intake if they are prefed a low-protein basal diet and then offered a diet that is imbalanced in any of the essential amino acids (Leung and Rogers 1969). This anorectic response has been used by Hammer et al. (1990) to test serotonin_3 receptor antagonists.

Tail pinch is an effective stimulant of eating in rats (Antelman and Szechtman 1975; Fray et al. 1982). Clark et al. (1992) reported that N-methyl-D-aspartate lesions of the lateral hypothalamus do not reduce amphetamine or fenfluramine anorexia but enhance the acquisition of eating in response to tail pinch in the rat.

Thurlby and Samanin (1981) studied the effect of anorectic drugs on food-rewarded runway behavior.

Ferrari et al. (1992) studied the effects on anorexia induced by ACTH and immobilization in rats in an X-maze with alternate open and covered arms, each baited with laboratory chow.

Cooper et al. (1993) studied dopamine D-1 receptor antagonists in rats with chronic gastric fistula which were trained to sham-feed a 10% sucrose solution in a 60 min test.

In wild rodents, **hoarding of food** covers the long term alimentary need. In the laboratory, hoarding behavior does not occur in ad libitum fed rats. On the contrary, rats whose energy balance is threatened by previous food restriction hoard as soon as experimental conditions allow to do so. When such a rat gets free access to a food stock (placed outside its usual territory), it carries food into its shelter and accumulates an amount proportionate to its body weight. Fantino et al. (1980, 1986, 1988), Nishida et al. (1990) used the reduction of the amount of food hoarded during a period of 3 h as parameter for anorectic activity of drugs.

Caccia et al. (1993) studied the anorectic effect of D-fenfluramine in the **marmoset** (*Callithrix jacchus*).

Knoll (1979, 1984) described satietin, a anorectic substance which has been isolated from serum of humans and several animal species. Satietin has been reported to be a 50 000–70 000 dalton MW glycoprotein, containing 14–15% amino acids and 70–75% carbohy-drates, surviving digestion with proteases and boiling. Purification of bovine serum satietin was reported by Nagy (1994). These factors suppressed feeding in rats after peripheral and after intracerebroventricular administration.

L.3.2 Metabolic activity

L.3.2.1 GDP-binding in brown adipose tissue

PURPOSE AND RATIONALE

Brown adipose tissue is the major site for non-shivering thermogenesis in rodents (Ricquier and Mory 1984; Foster 1986). Drugs activating brown adipose tissue thermogenesis via β-adrenoceptors cause uncoupling of oxidative phosphorylation from electron transport (Arch et al. 1984; Nicholls et al. 1986). The binding of the nucleotide guanosine diphosphate (GDP) to brown adipose tissue membrane protein, the uncoupling protein or thermogenin (Ricquier and Bouillaud 1986), is an established indicator of the thermogenetic activity of brown adipose tissue (Milner et al. 1988).

PROCEDURE

Obese male fatty Zucker rats at the age of 13 weeks weighing about 450 g receive various doses of the test compound in the drinking water or tap water as control for 21 days. Food intake is measured every day and body weight every other day. At the end of the treatment, the rats are sacrificed by decapitation and interscapular brown adipose tissue is quickly dissected from surrounding tissue.

According to the method published by Nicholls (1976) brown adipose tissue is minced, diluted with 250 mM sucrose and homogenized with a Potter S homogenizer (B. Braun Melsungen, Germany). The homogenate is centrifuged for 10 min at 8 500 *g*. The pellet is diluted with 250 mM sucrose and centrifuged at 700 *g* for 10 min. The supernatant is collected and centrifuged at 8 500 *g* for 10 min. Bovine serum albumin at 0.2% is added to wash the suspension of the pellet, which now consists of mitochondria. After centrifugation (8 500 *g*) the resulting pellet is suspended in albumin-free sucrose buffer. The binding of [3H]-GDP (DuPont NEN, Boston MA) to mitochondria of single rats is determined by incubating mitochondria in a basic medium containing 100 mM sucrose, 20 mM TES (*N*-tris-[hydroxymethyl]-methyl-2-aminoethane-sulphonic acid), 1 mM EDTA, 10 mM choline chloride, 2 μM rotenone, [^{14}C]sucrose (0.125 μCi ml^{-1}) and 10 μM [^{3}H]-GDP (0.53 Ci mmol^{-1}) at room temperature. Non-specific binding is assessed in the presence of unlabelled GDP (1 mM). After 10 min of incubation, the reaction is terminated by filtration the mixture through Thomas A/E glass fibre filters by using a Brandel cell harvester. The radioactivity is measured with the Opti Phase 'High Safe' II scintillation cocktail and a scintillation counter enabling the samples to be counted for both ^{3}H and ^{14}C. The protein content of the mitochondrial suspensions is assayed according to the method of Peterson (1977).

EVALUATION

GDP binding is assessed from ^{3}H radioactivity with a correction for trapped medium using [^{14}C]-sucrose. Two way analysis of variance (ANOVA) is performed.

MODIFICATIONS OF THE METHOD

Glucose is a minor substrate for isolated brown adipocytes, fuelling thermogenesis by a maximum of 16% (Isler et al. 1987).

The mechanism of anti-obesity action of a dihydropyridine calcium antagonist was studied by Yoshida et al. (1994b). Obesity was induced by subcutaneous injection of 2 g/kg monosodium-L-glutamate immediately after birth for 5 consecutive days in ICR female mice. Binding of GDP and cytochrome c oxidase activ-ity in brown adipose tissue mitochondria were significantly increased after 4 weeks drug treatment incorporated in the diet.

Yoshida et al. (1984, 1985) found a reduced norepinephrine turnover in brown adipose tissue of mice with monosodium glutamate-induced obesity.

Kajita et al. (1994), Takahashi et al. (1994) determined regional blood flow in brown adipose tissue by the microsphere method in anesthetized rats.

Yoshida et al. (1996) determined the effect of mazindol on noradrenaline turnover in brown adipose tissue of yellow KK mice and C57B1 control mice.

L.3.2.2 Uncoupling protein and GLUT4 in brown adipose tissue

PURPOSE AND RATIONALE

Uncoupling proteins (UCPs) are a family of inner mitochondrial membrane transporters which dissipate the

proton gradient, releasing stored energy as heat. UCP1 is expressed exclusively in brown adipocytes, UCP2 is expressed widely, while UCP3 is found in skeletal muscle and brown adipose tissue (Vidal-Puig et al. 1997; Fleury et al. 1997; Masaki et al. 1997; Matsuda et al. 1997; Boss et al. 1997; Gong et al. 1997; Larkin et al. 1997). They are upregulated by thyroid hormones (Larkin 1997; Masaki 1997; Branco et al. 1999; Lanni et al. 1999). Mao et al. (1999) identified and characterized a novel member of the human uncoupling protein family, termed uncoupling protein-4 (UCP4).

In addition to the binding of the nucleotide guanosine diphosphate (GDP) to brown adipose tissue membrane protein, the uncoupling protein itself, and the glucose transporter 4 (GLUT4) were determined by RNA (Northern blot) analysis and by protein (Western blot) analysis as indicators of the thermogenetic activity of brown adipose tissue.

PROCEDURE

Male fatty (OLETF fatty) rats at the age of 10 weeks are given subcutaneous injection of test compound or solvent once daily. After 14 weeks treatment, the rats are sacrificed and brown and white adipose tissue samples rapidly removed.

Northern blot analysis

Total RNA is extracted from 0.1–1 g of tissue using TRIzol (Gibco) and the concentration determined from the absorbance at 260 nm. Total RNA (20 mg) is separated on a 1.5% agarose/formaldehyde gel, and transferred to and fixed on a nylon membrane. A 488 bp uncoupling protein cDNA probe corresponding to the coding region of rat uncoupling protein is prepared by digesting the whole uncoupling protein cDNA with BamHI. The uncoupling protein probe and GLUT4 cDNA are labeled with α-[^{32}P]dCTP (deoxy-cytidine-triphosphate). The blots are hybridized to the labeled probes at 42 °C for 20 h in the presence of 500 µg/ml salmon sperm DNA, and exposed to an X-ray film for autoradiography and an imaging plate of BAS1 000 (Fuji Film) for quantitative analysis.

Western blot analysis

Each tissue is homogenized in 5–10 volumes of a solution containing 10 mmol/l Tris-HCl and 1 mmol/l EDTA (pH 7.4) for 30 s with a Polytron. After centrifugation at 1 500 *g* for 5 min, the fat cake is discarded, and the infranatant (fat-free extract) is used for protein determination according to Lowry et al. (1951) and cytochrome C oxidase activity (Yonetani and Ray 1965). Uncoupling protein and GLUT4 protein in the fat-free extract is measured by Western blot analysis. The fat-free extracts (10 µg protein of brown adipose tissue, 20 µg of white adipose tissue) are solubilized, subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis, and transferred to a nitrocellulose filter. After blocking with 5% non-fat dry milk, the filter is incubated with rabbit antiserum against rat uncoupling protein or GLUT4. The rabbit antisera against rat uncoupling protein and GLUT4 are prepared by immunizing purified rat uncoupling protein (Lin and Klingenberg 1980) and a 12-amino acid peptide corresponding to GLUT4 (residues 498–509, TELEYLGPDEND) (Shimizu et al. 1993) respectively, coupled with keyhole limpet hemocyanin. Then the filter is incubated with [^{125}I]protein A (ICN). The dry blot is exposed to an X-ray film for autoradiography and an imaging plate of BAS1 000 (Fuji Film) for quantitative analysis.

EVALUATION

Data are expressed as means ±SEM and are analyzed by two-way ANOVA followed by Bonferroni *t*-test.

MODIFICATIONS OF THE METHOD

A radioimmunoassay to measure uncoupling protein was used by Milner et al. (1988).

Scarpace et al. (2000) performed unilateral surgical denervation of the interscapular BAT in rats under pentobarbital anesthesia according to Bartness et al. (1986). A transverse incision was made just anterior to the BAT, separating the BAT from the muscles of the scapulae. The BAT was raised to expose the five intercostal nerve bundles entering each pad. On one side, a section of each nerve bundle was removed with scissors. Denervation can be verified by assessing norepinephrine levels in the innervated compared with the denervated BAT pads (Scarpace and Matheny 1996).

Puigserver et al. (1996) studied the effects of retinoic acid isomers on the appearance of uncoupling protein in primary cultures of brown adipocytes, in the brown adipocyte cell line HIB 1B and directly in intact mice.

Shimabukuro et al. (1997) reported the induction of uncoupling protein-2 mRNA in the pancreatic islets of Zucker diabetic fatty rats by troglitazone.

Foellmi-Adams et al. (1996) found a synergy between norepinephrine and pioglitazone in induction of uncoupling protein in mice.

Kotz et al. (2000) determined uncoupling protein 1 (UCP1) in brown adipose tissue, UCP2 in white adipose tissue and UCP3 in muscle of male Sprague Dawley rats after injection of neuropeptide Y into the hypothalamic paraventricular nucleus.

Great efforts have been devoted to study the influence of **β_3-adrenergic agonists** on formation of uncoupling protein.

Umekawa et al. (1997) found an induction of uncoupling protein and activation of GLUT4 in white fat

of Otsuka Long-Evans Tokushima fatty rats after treatment with a specific β_3-adrenoceptor agonist.

Ghorbani and Himms-Hagen (1997) found appearance of abundant densely-stained brown adipocytes expressing uncoupling protein in white adipose tissue during reversal of obesity and diabetes in Zucker fa/fa rats induced by the β_3-adrenoceptor agonist CL316,243.

Nagase et al. (1996) found in yellow obese KK mice after treatment with a β_3-adrenergic agonist a significant reduction of body weight, associated with a marked decrease of white fat pad weight and hypertrophy of the interscapular brown adipose tissue with a sixfold increase in mitochondrial uncoupling protein content.

Liu et al. (1995, 1996), Stock (1997) reported an increase of glucose utilization in rat brown adipose tissue after treatment with a β_3-adrenoreceptor agonist or with sibutramine, a serotonin and noradrenaline reuptake inhibitor.

Savontaus et al. (1998) reported an increase of UCP3 and UCP1 in brown adipose tissue of obese fa/fa Zucker rats after chronic administration of a β_3-adrenoreceptor agonist.

The effects of β_3-adrenoceptor agonists on uncoupling protein-1 and leptin in culture-differentiated rat brown fat cells are antagonized by a β_3-adrenoreceptor antagonist (Tonello et al. 1998).

Berraondo et al. (2000) found an up-regulation of muscle UCP2 gene expression by a β_3-adrenoreceptor agonist in obese rodents, but down-regulation in lean animals.

Paulik and Lennard (1997) found an increased expression of uncoupling protein in C3H10T1/2 cells, a pluripotent stem-cell line, after addition of **thiazolidinediones**.

L.3.2.3 Resting metabolic rate

PURPOSE AND RATIONALE

Resting metabolic rate can be influenced by various drugs both in normal and obese animals.

PROCEDURE

Female yellow KK mice and female C57B1 mice at the age of 12 weeks are housed under controlled temperature and artificial light/dark conditions and are fed with commercial powdered chow and tap water ad libitum. Groups of each strain are treated with doses of test drug or solvent by daily intramuscular injections for 2 weeks. Daily food intake and body weight is measured.

Resting metabolic rate is estimated by means of a closed-circuit metabolic system (Molnar et al. 1986). The system consists of a chamber, circulating pump, desiccant and CO_2-absorbent canisters, solenoid valve, regulated gas source, and modified liquid crystal display calculator. The internal volume of a chamber for a single rat should be 4.5 liters. Food cups are placed on the door for convenient access when refilling. Water is supplied in a tray filled intermittently by means of a stopcock in the chamber wall. A shallow stainless steel funnel-shaped tray for urine collection is located in the bottom of the chamber.

Animals are placed in the chamber and the door is sealed airtight. Chamber air circulates by means of a peristaltic pump at a rate of 2.3 l/min through an external loop containing canisters of desiccant and CO_2-absorbent. In this manner, water vapor pressure remains constant and the respiration by-product, CO_2, is removed. Consumption of O_2 produces a pressure drop in the sealed system which actuates the pressure sensor for O_2 replacement.

The pressure sensor has two input ports, low and high, producing a simple contact closure whenever the high pressure exceeds the low by ~1 Torr. The low port is connected to the interior of the metabolic chamber by a length of tubing attached to a threaded connector, whereas the high port is open to the atmosphere. Thus the contact closes whenever the pressure within the chamber falls to more than 1 Torr below atmospheric pressure.

The contact closure is routed to the control unit where a precise pulse of fixed duration is triggered. This pulse activates a solid-state relay through an emitter-follower transistor circuit. The relay output is in series with a solenoid valve and line voltage, so that contact closure results in opening of the valve for a fixed duration. Since the input port of the valve is at a constant pressure, a predictable, highly repeatable volume of gas flows into the chamber. This raises the chamber pressure and opens the pressure sensor contacts. The entire cycle repeats after sufficient metabolism to again decrease the chamber pressure and close the sensor contacts.

After a stable baseline has been achieved after 30 min, drugs are administered and resting metabolic rate is measured for one hour at an ambient temperature of 22 °C.

EVALUATION

Data are presented as means ±SEM. Statistical analysis is performed by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Poon and Cameron (1978) measured oxygen consumption utilizing a standard Machlett manometer connected to a desiccator that accommodated a single mouse. The desiccator was placed in a 20 °C water bath to ensure constant temperature throughout and CO_2 was absorbed by means of soda lime UPS. After a 5-min equilibration period, measurements of oxygen consumption were obtained over a 5-min period. The procedure was repeated twice within 1 h for each mouse.

In order to study differential antagonism to amphetamine-induced oxygen consumption and agitation by psychoactive drugs Niemegeers and Janssen (1979) placed groups of 3 rats with a total weight of 235 ±5 g consisting of 2 parts, a bottom and a cover, both made up from clear glass. The cover, containing a thermometer, was used to seal the chamber airtight. Inside the chamber a perforate plate was placed as animal platform. Containers filled with calcium oxide were placed below and above the animal holder. The chamber was flushed with oxygen for 3 min at an overpressure of 50 units as measured by a manometer connected to one outlet of the chamber. Test drugs were administered subcutaneously 60 min before the animals were placed in the test chambers and 45 min before 2.5 mg/kg amphetamine were injected. Oxygen consumption was measured as decrease of manometer pressure over one hour.

Rothwell (1989) measured central activation of thermogesesis by prostaglandins by resting oxygen consumption in individual closed-circuit calorimeters (Stock 1975) and by registration of colonic temperature in conscious rats.

Jensen et al. (2001) described a self-correcting indirect calorimeter system for the measurement of energy balance in small animals.

Himms-Hagen et al. (1994) tested the effect of a thermogenic β_3-agonist on energy balance in rats. Twenty-four hours energy expenditure, resting metabolic rate, and thermic effect of food were measured using open-circuit indirect calorimetry. The rat was placed in a respiration chamber ($44 \times 22 \times 18$ cm), airflow was measured with a Brooks thermal mass flowmeter (Brooks Instrument Division, Emerson Electric, Hatfield, PA), and the flow of outside air through the chamber was controlled at a variable rate by two adjustable peristaltic pumps that maintained CO_2 concentration at <1%. Temperature was maintained at 23 ±1.0 °C. Humidity was measured by an electronic psychrometer, barometric pressure was recorded, and feeding activity was monitored by an infrared detector. The rat was placed into the chamber at 09:30 and removed at 08:30 at the following morning. Food was available to the rat only between 16:30 and 07:30. Total energy expenditure was measured for 23. Resting metabolic rate was determined from the lowest energy expenditure at rest between 11:00 and 16:00. Thermic effect of food was determined from the difference between resting metabolic rate and the lowest energy expenditure at rest between 24:00 and 07:00. For the measurement of minimum metabolic rate, the rat was anesthetized (pentobarbital sodium, 60 mg/kg) and then placed in a small chamber filled with warm circulating water in which it was submerged except for the head. Core temperature was measured with a digital thermometer immediately after induction of anesthesia, and this temperature was maintained (±0.1 °C) by adjusting the temperature of the circulating water bath. The chamber was sealed and minimum metabolic rate determined with the same equipment as was used for the 24-h energy expenditure. Measurements of minimum metabolic rate were made for 5–15 min between 08:30 and 09:30 after a stabilization period of 5–10 min.

Ghorbani et al. (1997) tested the effect of a β_3-adrenoreceptor agonist on resting metabolic rate in rats by placing the animal in a water-jacketed chamber at 28 °C, volume 1 liter, through which air, also at 28 °C, was drawn at a rate of 1 l/min. Oxygen entering and leaving the chamber was measured with an oxygen analyzer (Beckman Industrial Oxygen Analyzer, model 755).

Paulik et al. (1998) described a robust technique to measure thermogenesis of **yeast cells** cultured in microtiter plates using infrared thermography. Thermogenesis increased after exposing yeast to uncoupling protein-2, or troglitazone or β_3-adrenoreceptor agonists.

L.3.2.4 β_3-adrenoceptor

PURPOSE AND RATIONALE

β_3-adrenoreceptor agonists produce weight loss in obese rodents (Yoshida et al. 1994; Weyer et al. 1999) which is almost entirely accounted for a reduction in body fat. As this effect is observed without a decrease in food intake, it is thought to be due to increased thermogenesis in brown adipose tissue, increased lipolysis in white adipose tissue, and suppression of leptin gene expression and serum leptin levels (Arch and Wilson 1996; Kumar et al. 1999).

The β_3-adrenoreceptor has been cloned and characterized in animals (Granneman et al. 1991; Nahmias et al. 1991; Evans et al. 1996) as well as from man (Emorine et al. 1989; Strosberg 1997). However, the physiological function of the human β_3-adrenoreceptor, the significance of animal data with β_3-adrenoreceptor agonists, and even the presence of a putative fourth β-adrenoreceptor in human adipose tissue are still a matter of debate (Emorine et al. 1994; Galitzky et al. 1998; Kaumann et al. 1998; Sarsero et al. 1998; Strosberg et al. 1998; Weyer et al. 1999).

The development of a Chinese hamster ovary cell transfection system, using the human β_3-adrenoreceptor gene resulted in potential new selective β_3-agonists being identified (Carruba et al. 1998). Human β_1-, β_2- and β_3-adrenoreceptors expressed in Chinese hamster ovary (CHO) cells were used to evaluate potential β_3-adrenoreceptor agonists by He et al. (2000).

PROCEDURE

cAMP response element-luciferase receptor gene assay

CHO cells stably expressing human β_1-, β_2- or β_3-adrenoreceptor populations are transfected with cAMP response element-luciferase plasmids using electroporation with a single 70-ms, 150-V pulse (Vansal and Fellner 1999). The transfected cells are seeded at a density of 40 000/well in 96-well microtiter plates and allowed to grow for 20 h. After 20 h, the cells are treated with varying drug concentrations (10^{-11} to 10^{-4} M) for 4 h. Following drug exposure, the cells are lysed and luciferase activity is measured using the LucLite assay kit (Packard). Changes in light production are measured by a Topcount luminometer (Packard).

EVALUATION

Data are analyzed in duplicate at each concentration and expressed as percent luciferase response relative to the maximum response to (–)-isoproterenol (10^{-6} M). Results are expressed as the mean ±SEM.

MODIFICATIONS OF THE METHOD

Gettys et al. (1996) reported that the β_3-adrenergic receptor inhibits insulin-stimulated leptin secretion from isolated rat white adipocytes.

Using reverse transcription-polymerase chain reaction, Evans et al. (1998) compared levels of β_3-adrenoreceptor mRNA in white adipose tissue, brown adipose tissue, ileum and colon from genetically obese (*ob/ob*) and lean (+/+) C57BL/6J mice.

Bioassays

Tomiyama et al. (1998) studied β-adrenoreceptor subtypes mediating ureteral relaxation in rats, rabbits and dogs. β_3-adrenoreceptor agonists were more effective in relaxing canine ureter than β_1- and β_2-adrenoreceptor agonists.

Koike et al. (1997) reported that the relaxant responses in the guinea pig taenia caecum are mediated by both the β_2- and β_3-adrenoreceptors.

L.4 Assays of obesity regulating peptide hormones

L.4.0.1 Hormonal regulation of food intake

Food intake and fat deposition are regulated by neurotransmitters peptides, most of the located in the brain, particularly in the hypothalamus (Elmquist et al. 1999; Kalra et al. 1999) and in the gut. This includes peptides that are **orexigenic** (appetite-stimulating) signals and **anorectic** peptides.

Neuropeptide Y (NPY), orexins A and B, galanin, melanin concentrating hormone (MCH), and **agouti-related peptide (AgRP)** all act to stimulate feeding, while **alpha-melanocyte stimulating hormone (αMSH)**, (see N.10.1), **corticotropin releasing hormone (CRH)**, (see N.9.4), **cholecystokinin (CCK)**, (see J.7.0.10), **cocaine and amphetamine regulated transcript (CART), neurotensin, glucagon-like peptide 1 (GLP_1)**, (see K.4.0.3), **calcitonin gene related peptide (CGRP)**, (see N.10.3), **bombesin** (see J.3.1.8) and **ciliary neurotropic factor** (Xu et al. 1998) have anorectic actions (Tritos et al. 1999).

Mutations reducing the functional activity of leptin, the leptin receptor, α-MSH, and the melanocortin-4 receptors lead to obesity in animals. *Mc4r*-deficient ($Mc4r^{-/-}$) mice do not respond to the anorectic actions of MTII, an MSH-like antagonist, suggesting that α-MSH inhibits feeding primarily by activating Mc4r (Marsh et al. 1999).

Leptin, (see L.4.1) is a 167 amino acid protein that is synthesized and secreted primarily by white adipose tissue, circulates in the blood and acts on receptors in the hypothalamus to decrease food intake and increase energy expenditure (Friedman and Halaas 1998; Trayhurn et al. 1999). Leptin and its derivatives are candidates for treatment of obesity, however, clinical studies (Considine et al. (1996) showed that most of obese humans have higher plasma levels of leptin than non-obese individuals, suggesting that obesity is associated with leptin resistance rather than leptin deficiency.

Neuropeptide Y (NPY) (see L.4.2) is a 36 amino acid peptide that is widely distributed throughout both the central and peripheral nervous systems and which plays a key role in the control of body weight. Central administration of NPY increases food intake (Stanley et al. 1992), while a reduction in endogenous neuropeptide Y leads to a decrease of food intake (Lambert et al. 1993). NPY antagonists are candidates for anti-obesity drugs.

Orexin-A and orexin-B (see L.4.3) are 33- and 28-residue peptides, also called hypocrites, which were originally isolated from rat hypothalamus (Sakurai et al. 1998). These peptides are located predominantly in the hypothalamus and locus coeruleus but are also found elsewhere in the brain. The orexins have a broad range of physiological functions, including the control of feeding and energy metabolism. Food consumption is dose-dependently increased after intracerebroventricular infusion of orexin A and orexin B to rats (Jain et al. 2000). Orexin antagonists are potential anti-obesity drugs (Parker 1999).

Galanin (see L.4.4) is 29 amino acid C-terminally amidated peptide (30 amino acids in humans) which is localized mainly in the mammalian CNS, but also in other organs. Central administration of galanin increases and administration of galanin receptor antagonists (Crawley et al. 1990; Leibowitz and Kim 1992) decreases food intake. These data suggest the use of galanin receptor antagonists as anti-obesity agents.

Agouti-related protein affects pigmentation when its expression is limited to the skin, but ubiquitous expression causes obesity (Ollmann et al. 1997). The hypothalamic expression of agouti related protein is regulated by leptin, and overexpression of agouti related protein results in obesity and diabetes (Rosenfeld et al. 1998). Recombinant Agouti-related protein is a potent, selective antagonist at MC3R and MC4R, melanocortin receptor subtypes implicated in weight regulation (Fong et al. 1997; Shutter et al. 1997; Tota et al. 1999). Ubiquitous expression of human Agouti-related protein complementary DNA in transgenic mice caused obesity without altering pigmentation. Agouti-related protein is a neuropeptide implicated in the normal control of body weigh downstream of leptin signaling. Ollmann et al. (1998) used a sensitive bioassay based on *Xenopus* melanophores to characterize pharmacological properties of recombinant Agouti protein.

Melanin concentrating hormone (MCH) is a cyclic 19 amino acid neuropeptide that was originally found to regulate pigmentation in fish. It plays a role in the central feeding behavior increasing food consumption (Qu et al. 1996; Rossi et al. 1999). Mice carrying a targeted deletion of the MCH gene are hypophagic and lean (Shimada et al. 1998). Among other factors, MCH may be a target of leptin signaling in the hypothalamus (Sahu 1998; Huang et al. 1999). Melanin-concentrating hormone is a functional melanocortin antagonist in the hypothalamus (Ludwig et al. 1998). MCH has been identified as the natural ligand for the orphan somatostatin-like receptor 1 (SLC-1) (Bacher et al. 1999; Chambers et al. 1999; Shimomura et al. 1999) which has been characterized by Saito et al. (1999). High binding capacity for MCH was found in human keratinocytes (Burgaud et al. (1997). Radioligands for the mammalian MCH receptor were described by Hintermann et al. (1999).

Cocaine- and amphetamine-regulated transcript (CART), a brain located peptide, has potent appetite suppressing activity and is closely associated with the actions of leptin and neuropeptide Y (Lambert et al. 1998; Kuhar and Dall-Vechia 1999). When injected intracerebroventricularly into rats, recombinant CART peptide inhibits both normal and starvation-induced feeding, and completely blocks the feeding response induced by neuropeptide Y (Kristensen et al. 1998). In the rat the CART gene encodes a peptide of either 129 or 116 amino acids whereas only the short form exists in humans (Thim et al. 1998a,b). A role of CART peptides in substance abuse and addiction is suggested by psychomotor-stimulant regulation of CART transcription in the striatum, as well as its localization within neural circuits that mediate reward and reinforcing behaviors (Couceyro and Lambert 1999). CART has been found not only in the hypothalamus and other brain areas (Broberger 1999; Koylu et al. 1998, 1999) but also in other organs, such as the pancreas (Jensen et al. 1999), in the rat sympatho-adrenal axis (Dun et al. 2000), or in the vagal afferent neurons sensitive to cholecystokinin (Broberger et al. 1999). CART can cross the blood-brain barrier (Kastin and Akerström 1999). CART receptor agonists are potential anti-obesity drugs (Couceyro and Lambert 1999).

Steppan et al. (2001), Berger (2001) showed that adipocytes secrete a signaling molecule with 114 amino acids in length which is called **resistin** (for resistance to insulin) and which links obesity to diabetes. Circulating resistin levels in mice are increased in diet-induced and genetic forms of obesity and are decreased by thiazolidindiones (see K.5.0.6). Administration of anti-resistin antibody improves blood sugar and insulin action in mice with diet-induced obesity. Treatment of normal mice with recombinant resistin impairs glucose tolerance and insulin action. Insulin-stimulated glucose uptake by adipocytes ins enhanced by neutralization of resistin and is reduced by resistin treatment. Resistin with slightly modified amino acid sequence has also been found in humans.

L.4.1 Leptin

L.4.1.1 General considerations on the obese gene product leptin

The obese gene product leptin is a cytokine-like nonglycosylated peptide of 146 amino acids that is secreted from adipose tissue. It is an important circulating hormone for the regulation of body weight (Arch and Beeley 1996; Hamann and Matthaei 1996; Friedman and Halaas 1998; Trayhurn 1999). MacDougald et al. (1995) described the expression of the obese gene product (leptin) in white adipose tissue and 3T3-L1 adipocytes.

The mouse obese gene and its human homologue which show approximately 85% amino acid homology have been cloned by Zhang et al. (1994). Leptin binding was first reported in rat hypothalamic membranes (Stephens et al. (1995).

A **leptin receptor** was subsequently identified by expression cloning from a mouse chorioid plexus cDNA library (Tartaglia et al. 1995). Several transcripts of the leptin receptor as a result of alternative splicing which have different length of cytoplasmatic region have been identified in mice and rats (Guan et al. 1997; Igel et al. 1997; Murakami et al. 1997) as well as leptin receptors in man (Maffei et al. 1995, 1996; Liu et al. 1997; Strosberg and Issad 1999). There are at least five different isoforms of the leptin receptor in mice. Mutations in the leptin receptor lead to massive obesity in *db* mice and *fa* rats (Friedman and Halaas 1998).

Administration of recombinant human leptin to mice increases thermogenesis and lipid oxidation in brown fat coupled with increased lipolysis and decreased fat synthesis in white and brown fat, which lead to a rapid reduction in the body weight (Sarmiento et al. 1997).

Leptin increases uncoupling protein expression in brown adipose tissue and oxygen consumption in mice (Scarpace et al. 1997).

Intracerebroventricular injection of recombinant murine leptin produces a dose-dependent reduction of laboratory diet in normal rats. This effect is attenuated in rats with diet-induced obesity (Widdowson et al. 1997).

The role of leptin in human obesity is controversial. Rare forms of human obesity have been identified where mutations in leptin or its receptor play a major role in the development of the disease. Leptin may be a signal for the onset of puberty in humans (Strosberg and Issad 1999). Leptin activates leptin-receptor expressing neurons in the arcuate region of the hypothalamus. Projections from these neurones stimulate melanocortin MC_4 receptors and neuropeptide Y-containing neurones to activate the sympathetic nervous system which controls lipolysis in white adipose tissue. The firing of gonadotrophin-releasing hormone-containing neurons and secretion of gonadotrophin-releasing hormone to the pituitary is elicited by leptin-mediated activation of leptin-receptor-expressing neurons and by other factors that control the reproductive axis (Chebab 2000).

Grasso et al. (1997, 1999) found inhibitory effects of leptin-related synthetic peptides on food intake and body weight gain after intraperitoneal administration in female C57BL/6J*ob/ob* mice which may have potential application to the treatment of human obesity.

L.4.1.2 Determination of leptin mRNA level in adipose tissue

PURPOSE AND RATIONALE

Leptin mRNA levels in adipose tissue can be determined by Northern blot analysis (Friedrich et al. 1995; Harris et al. 1996; Zachwieja et al. 1997; Kochan et al. 1999).

PROCEDURE

Male Wistar rats weighing approximately 230 g treated for 14 days with test drug are sacrificed by decapitation. Liver, epididymal white adipose tissue and intracapsular brown adipose tissue are rapidly removed and frozen in liquid nitrogen. Total RNA is extracted from frozen tissues by a guanidinium thiocyanate-phenol/chloroform method (Chomczynski and Sacchi 1987). The RNA (10 µg per lane) is fractionated by horizontal gel electrophoresis. The RNA is transferred to a positively charged nylon membrane and fixed with UV-light. Pre-hybridization is performed at 42 °C for 45 min in pre-hybridization solution containing 7% sodium dodecyl sulfate, 50% formamide, 5 × saline-sodium citrate buffer, 2% blocking reagent (Boehringer Mannheim, Mannheim, Germany), 50 mM sodium phosphate (pH 7.0) and 0.1% N-laurylsarcosine. Hybridization is performed at 42 °C overnight in pre-hybridization solution containing oligonucleotide probe (25 ng/ml) specific to leptin, malic enzyme or 185 RNA. The following post-hybridization washes are performed: twice for 5 min in 2 × saline-sodium citrate buffer/0.1% sodium dodecyl sulfate (at room temperature): twice for 15 min in 0.1 × saline-sodium citrate buffer/0.1% sodium dodecyl sulfate (at 48 °C). The membranes are then rinsed briefly with washing buffer containing 0.1 M maleic

acid (pH 7.5), 0.15 M NaCl and 0.3% Tween 20. They are blocked by incubation for 30 min at room temperature with blocking buffer (1% blocking agent, 0.1 M maleic acid (pH 7.5), 0.15 M NaCl) and incubated (at the same conditions as described above) with blocking buffer containing a polyclonal antibody against digoxigenin conjugated to alkaline phosphatase. After washing twice for 15 min with washing buffer, the membranes are rinsed for 5 min with detection buffer (0.1 M Tris-Cl, pH 9.5, 0.1 M NaCl) and immersed for 5 min in CDP-Star solution (Boehringer Mannheim, Mannheim, Germany). Membranes are exposed to Kodak XAR film for 15 min to 1 h (Karbowska et al. 1999).

EVALUATION

Signals are scanned and quantified using the NIH-Image software. The level of mRNA for leptin and malic enzyme as well as for 185 RNA is estimated using PeakFit software (Jandel Scientific). The values for leptin and malic enzyme mRNA are normalized to the corresponding amount of 185 RNA. Results expressed in arbitrary units are presented as means ±SEM of samples of 10 rats. The statistical difference between groups is assessed by one-way analysis of variance (ANOVA) followed by Student's *t*-test or by Mann-Whitney test.

MODIFICATIONS OF THE METHOD

Richards et al. (2000) described quantitative analysis of leptin mRNA using competitive reverse transcription polymerase chain reaction and capillary electrophoresis with laser-induced fluorescence detection.

Shintani et al. (2000) determined leptin mRNA levels in primary cultured rat adipocytes.

Li et al. (1999) used an anti-leptin polyclonal antiserum to detect leptin-immunoreactivity in the central nervous system in rats.

L.4.1.3 Determination of plasma leptin

PURPOSE AND RATIONALE

Plasma leptin levels are determined by radioimmunoassay using a rat-specific antibody (Ciba-Geigy, Basel, Switzerland) (Zachwieja et al. 1997) or with a double-antibody radioimmunoassay kit based on a mouse standard (Linco Research, St. Louis, MO) (Surwit et al. 1997; Van Heek et al. 1997). A radioimmunoassay for leptin in human plasma was described McGregor et al. (1996).

PROCEDURE

The peptide VPIQKVQDDTKTLIKTIVT representing the first twenty amino acids of the predicted sequence of mature leptin protein (leptin 1–20) was synthesized with 9-fluorenyl methyl oxycarbonyl-(Fmoc)-protected L-amino acids on a applied Biosystems peptide synthesizer and purified by HPLC on a Dynamax column developed with a 0.1% trifluoroacetic acid (TFA)/H_2O/acetonitrile (8% to 40%) gradient. The peptide is conjugated to thyroglobulin using carbodiimide as coupling reagent. Rabbits are immunized by intradermal injections and boosted at 4 weeks intervals.

A peptide identical to the one used for antibody generation except for a tyrosine residue added to the C-terminal end is labelled with ^{125}I using the oxidizing agent Iodogen (Pierce, USA) and purified on HPLC. For radioimmunoassay, the buffer consists of Tris-HCl 1 M, pH 7.4; 0.1% gelatin; 0.1% Triton X-100, and 0.01% NaN_3. Unlabelled ob peptide is used for standards. 100 µl of standard or unknown, 200 µl buffer, 100 µl antibody at a final concentration of 1 : 80 000 and 100 µl ^{125}I-leptin peptide (approximately 5 000 cpm) are added to polystyrene tubes and incubated for 48 h at 4 °C. Antibody-bound and unbound peptide are sepa-

rated by addition of goat anti-rabbit immunoglobulin antibody followed by centrifugation. The precipitates are counted on a computer-linked gamma-counter and the leptin concentrations of the samples are obtained using the "RIA-Calc" program.

EVALUATION

Results are expressed as means ±SD, and statistical comparisons are made with the use of Student's *t*-test. Linear regression analysis is performed with the method of least squares.

MODIFICATIONS OF THE METHOD

Maffei et al. (1995) used an immunoprecipitation assay to measure plasma leptin levels. A quantitative increase of the signal intensity was seen on Western blots when increasing amounts of recombinant protein were added to *ob* mouse serum, which does not have leptin. Densitometry was used to compare the signal intensity of the native protein in mouse plasma to the standard. The level of leptin-like immunoreactivity was quantified as nanograms per ml.

L.4.2 Neuropeptide Y

L.4.2.1 General considerations on neuropeptide Y and related peptides

Neuropeptide Y (NPY), peptide YY (PYY) and pancreatic polypeptide (PP) are endogenous 36-amino acid peptides belonging to the same family, which is characterized by a tertiary structure termed 'PP-fold' (Larhammar 1996). They have different tissue distributions (Sundler et al. 1993) and act in different physiological systems, mostly neuronal for NPY and endocrine for PYY and PP (Wettstein et al. 1995; Playford and Cox 1996; Goumain et al. 1998).

Neuropeptide Y plays a key role in the control of body weight (Leibowitz 1994). Central administration of neuropeptide Y increases food intake and decreases thermogenesis in satiated animals (Billington et al. (1991, Stanley et al. 1992), while a reduction in endogenous neuropeptide Y leads to a decrease of food intake (Lambert et al. 1993). Hypothalamic neuropeptide Y and mRNA levels are increased after fasting and in genetically obese mice (Stephens et al. 1995). Neuropeptide Y is required for the maintenance of the obese phenotype of the leptin-deficient *ob/ob* mice (Erickson et al. 1996). Conversely, leptin appears to decrease food intake and body weight in part by decreasing neuropeptide Y synthesis and release (Stephens et al. 1995). These data suggest that neuropeptide Y is a key modulator of body weight and that neuropeptide Y receptor antagonists may be useful anti-obesity agents.

Neuropeptide Y mediates its physiological effects via interaction with at least six distinct G protein-coupled receptors, designated Y_1, Y_2, Y_3, Y_4, Y_5 and Y_6.(Marsh et al. 1998; Michel et al. 1998; Wyss et al. 1998; Iyengar et al. 1999).

Central administration of peptide analogues of neuropeptide Y has been used to study the physiological roles of neuropeptide Y, especially the role of the peptide in feeding behavior. Kanatani et al. (1999) demonstrated an anorexogenic effect against NPY induced feeding in rats by an Y_1 antagonist with high selectivity and potency for the Y_1 receptor. Central administration of peptides that activate the Y_5 receptor, peptide YY (PYY), PYY(3-36), [Leu^{31},Pro^{34}]NPY, and human pancreatic polypeptide elicit feeding, whereas central administration of central administration of peptides that are inactive at the Y_5 receptor do not elicit feeding (Gerald et al. 1996). While other neuropeptide Y analogues or fragments interacts with several neuropeptide Y receptors, [D-Trp^{32}]NPY is a completely selective Y_5 agonist that elicits feeding at relatively high doses (Gerald et al. 1996). Peptides with activity on the Y_1 receptor produce conflicting effects on feeding. DesAA$^{10–17}$ [Cys$^{7–21}$,Pro^{34}]NPY is a Y_1 receptor agonist with a potency equivalent to neuropeptide Y, but does not elicit feeding after central administration (Kirby et al. 1995).

Schaffhauser et al. (1997) described inhibition of food intake after intracerebroventricular injection of neuropeptide Y Y_5 receptor antisense oligodeoxynucleotides in rats.

Criscione et al. (1998) reported inhibition of food intake in rats by an Y_5 receptor antagonist under vari-

ous conditions. Several neuropeptide Y antagonists were synthesized which inhibit food intake in rodents and may be used as anorectic agents (Matthews et al. 1997; Kask et al. 1998; Parker et al. 1998; Shigeri et al. 1998; Wieland et al. 1998; Zarrinmayeh et al. 1998).

Besides the stimulation of feeding, NPY and PYY show several other activities: influence on gastric motility (Chen et al. 1997), antisecretory effects in the gastrointestinal tract (Souli et al. 1997), central and peripheral control of the cardiovascular system (Lew et al. 1996; Tadepalli et al. 1996; Hudspith and Muglani 1997; McCloskey et al. 1997), effects on renal function (Blaze et al. 1997; Bischoff et al. 1997), antinociceptive effects (Broqua et al. 1996), or release of ACTH (Small et al. 1997). NPY receptor agonists show anxiolytic effects in rat conflict tests (Britton et al. 1997); neuropeptide Y_1 antagonists have anxiogenic-like effects (Kask et al. 1996).

Goumain et al. (1998) generated a rat Y_5 clone by reverse transcription from rat brain, polymerase chain reaction and transfection to COS-7 cells. Isolated jejunal crypt and villus cells and colon epithelial cells were analyzed for the Y_5 receptor by reverse transcription and polymerase chain reaction. Inhibition of binding of [^{125}I]peptide YY in these cells by various peptides was studied.

L.4.2.2 Receptor assay of neuropeptide Y

PURPOSE AND RATIONALE

At least six distinct G protein-coupled receptors of neuropeptide Y have been identified, designated Y_1, Y_2, Y_3, Y_4, Y_5 and Y_6.(Marsh et al. 1998; Michel et al. 1998; Bischoff and Michel 1999).

Sheikh et al. (1989) described a receptor binding assay for neuropeptide Y.

PROCEDURE

^{125}I-labeling

^{125}I-labeled NPY is prepared using carrier-free Na^{125}I and 1,3,4,6-tetrachloro-3α,α6-diphenylglycouril (Serva Heidelberg, Germany) as oxidizing agent. Synthetic porcine NPY (7 nmol) in 40 µl of sodium phosphate buffer (pH 7.4, 0.1 M) and 1 mCi of Na^{125}I in 10 µl of dilute NaOH is added to a reaction vial which has been coated with 20 µg of chlorglycouril by evaporation of 20 µl of a solution of glycouril in methylene chloride. Following incubation in ice for 5 min, 50 µl of 35% acetonitrile is added prior to HPLC.

Purification by reverse phase-high performance liquid chromatography

A prepacked Nucleosil 300-5 C_{18} cartridge is used. The chromatography is performed at 50 °C with a flow rate of 1 ml 35% acetonitrile/min. Fractions of 0.5 ml are collected into tubes containing 0.1 ml of acetic acid (0.5 M) containing 10 mg/liter bovine serum albumin. Aliquots of 10 µl are counted in a γ-counter, and fractions containing the radiolabeled peptide are pooled and stored at −20 °C.

Preparation of synaptosomal membranes

Synaptosomal membranes are prepared from the hippocampus of Danish LYY-strain landrace/Yorkshire pigs. The tissue is homogenized in 0.32 M sucrose in a Sorval Omni-Mixer at 0 °C for 5 min, followed by centrifugation (1 000 *g*, 10 min). The supernatant is removed and centrifuged (20 000 *g*, 30 min) to form the crude mitochondrial fraction. After resuspension in 3 ml of sucrose, this fraction is subfractionated on a discontinuous density gradient consisting of 0.8 M and 1.2 M sucrose (3 ml of each) in a SW 27 rotor and a Beckman ultracentrifuge (100 000 *g*, 90 min). The syn-aptosomes which concentrate at the interface between the two sucrose concentrations are collected and recentrifuged (50 000 *g*, 10 min). The resulting pellet is washed with HEPES buffer (pH 7.4, 25 mM) containing $CaCl_2$ (2.5 mM) and $MgCl_2$ (1 mM), centrifuged (50 000 *g*,

10 min), and resuspended in HEPES buffer. The protein concentration is determined using the Bio-Rad protein assay with bovine serum albumin as standard. The membrane preparation is diluted in binding buffer to a protein concentration of 2 g/liter and stored at −80 °C.

Receptor binding assay

The binding buffer is a HEPES buffer (pH 7.4, 25 mM) containing $CaCl_2$ (2.5 mM) and $MgCl_2$ (1 mM), bovine serum albumin (10 g/liter), and bacitracin (0.5 g/liter). The incubation mixture consists of 0.5 ml of membrane suspension, diluted with binding buffer to a protein concentration of 200 mg/liter, 0.05 ml of unlabeled peptide, and 0.5 ml of ^{125}I-labeled peptide (40 000 cpm). After 1 h of incubation, triplicate aliquots of the incubation medium are transferred to polypropylene tubes (0.4×4.5 cm), containing 200 µl of ice-cold buffer. Membrane-bound, radiolabeled peptide is separated from the free peptide by centrifugation (7 500 *g*, 2 min) in a Beckman Microfuge B. The supernatant is aspirated, and the tube and pellet are gently washed with buffer (0.5 ml). The tip of the tube is the cut off and counted in the γ-counter.

EVALUATION

The specific binding is calculated as the difference between the amount of ^{125}I-labeled peptide bound in the absence (total binding) and presence (nonspecific binding) if 10 µM unlabeled peptide.

The concentration dependence of the receptor binding is determined by incubating the membranes with increasing concentrations of radiolabeled peptide in the absence or presence of unlabeled peptide.

MODIFICATIONS OF THE METHOD

Gehlert et al. (1996) recommended [^{125}I][Leu^{31},Pro^{34}] peptide YY as selective radioligand for the neuropeptide Y Y_1 receptor and for human pancreatic polypeptide 1 receptors.

Robin-Jagerschmidt et al. (1998) investigated the ligand binding site of neuropeptide Y at the rat Y_1 receptor by construction of mutant receptors and [^{3}H]NPY binding studies.

Dumont et al. (1998) investigated the respective distribution of neuropeptide Y Y_1, Y_2, Y_4, and Y_5 receptor subtypes in rodents (rat and mouse), guinea pig, and primates (marmoset and vervet monkey and human) brains, representing three orders of mammals.

Primus et al. (1998) measured guanyl 5'(γ[^{35}S]-thio)-triphosphate binding to NPY receptor-activated G-proteins in adult rat brain sections in order to determine the neuroanatomical distribution of NPY receptor subtypes.

Wyss et al. (1998) administered various doses of synthetic neuropeptide Y agonists intracerebroventricularly to rats in order to establish dose-response curves and to estimate ED_{50} values of feeding. These values were compared with binding affinities (IC_{50}) for rat NPY receptor subtypes Y_1, Y_2, Y_4, and Y_5 *in vitro*. Mouse fibroblast cell lines (LMTK−) were stably transfected with the rat Y_1, Y_2 and the Y_4 receptor, whereas human embryonic kidney HEK-293 cells were used for transfection with the rat Y_5 receptor.

Parker et al. (1998) determined the agonist and antagonist potency of neuropeptide Y and various analogues for cloned human and rat neuropeptide Y receptors expressed in CHO or 293 cells.

Wieland et al. (1998) studied the subtype selectivity of a nonpeptide Y_1 receptor antagonist using membranes from rat hypothalamus, from SK-N-MC (neuroblastoma) cells and from SMS-KAN (neuroblastoma) cells; human Y_1 receptor stably expressed in baby hamster kidney (BHK) cells, rat Y_1 receptor expressing human embryonic kidney (HEK) 293 cells, human Y_2 receptor stably expressed in BHK cells, rat Y_4 stably transfected in BHK cells, and human Y_5 receptor stably transfected in HEK 293 cells.

Savontaus et al. (1998) measured expression of preproneuropeptide Y mRNA in the arcuate nucleus and preprocorticotropin-releasing factor mRNA in the paraventricular nucleus by *in situ* hybridization technique after short and long-term treatment with a β_3-adrenoreceptor agonist.

Bioassays have been used for characterization and classification of neuropeptide Y receptors (Hedge et al. 1995; Pheng and Regoli 1998; Dumont et al. 2000a,b). Some isolated organs appear to be "monoreceptor" systems, e.g., the rat tail artery (Gicquiaux et al. 1996), the rabbit saphenous vein (Pheng and Regoli 1998; Feletou et al. 1999) or the isolated perfused kidney of the rat (Hedge et al. 1995) for the Y_1 receptor. The dog saphenous vein, the rat vas deferens and the rat colon can be used for the Y_2 receptor, the rat colon for the Y_4 receptor, and the rabbit ileum for the Y_5 receptor (Pheng et al. 1997).

L.4.3 Orexin

L.4.3.1 General considerations on orexin

Orexin-A and orexin-B are 33- and 28-residue peptides, also called hypocretins, which were originally isolated from rat hypothalamus (Sakurai et al. 1998). Both peptides are derived from a 130 amino acid precursor, prepro-orexin, which is encoded by a gene localized to chromosome 17q21 in humans. These peptides are located predominantly in the hypothalamus and locus coeruleus (Evans et al. 1999), but are also found elsewhere in the brain, and in the spinal cord (Smart 1999; Van den Pol 1999). The orexins have a broad range of physiological functions, including the control of feeding and energy metabolism (Dube et al. 1999; Mondal et al. 1999; Sakurai 1999), modulation of neuro-endocrine function (Date et al. 1999), regulation of the sleep-wake cycle (Piper et al. 2000) stress and anxiety, behavioral activities (Ida et al. 1999), cardiovascular (Shirasaka et al. 1999; Chen et al. 2000), sexual and reproductive functions (Pu et al. 1998; deLecea and Sutcliffe 1999; Tamura et al. 1999). Food consumption is dose-dependently increased after intracerebroventricular infusion of orexin A and orexin B to rats which can be suppressed by a NPY Y_1 antagonist (Jain et al. 2000). Food intake could inhibited by central injection of an anti-orexin antibody in fasted rats (Yamada et al. 2000). Novak et al. (2000) found an increase of insulin secretion after subcutaneous injection of orexins to rats.

Orexin antagonists are potential anti-obesity drugs (Parker 1999).

L.4.3.2 Receptor assay of orexin

PURPOSE AND RATIONALE

The peptides orexin A and orexin B bind both to two receptors, orexin-1 (OX_1) and orexin-2 (OX_2), although orexin B has a low affinity for OX_1 (Sakurai et al. 1998).

PROCEDURE

Orexin OX_1 and OX_2 receptors are produced by polymerase chain reaction from foetal and adult brain cDNA libraries, using primers located across the start and stop codons. The receptors are subcloned into the pCDN vector (with neomycin resistance) and transfected into CHO cells using lipofectamine (Life Technologies). Clones are selected using 400 µg/ml G418 (Life Technologies) and single clones are produced by limiting dilution cloning.

CHO-OX_1 and CHO-OX_2 cells are routinely grown as monolayers in MEM-Alpha medium supplemented with 10% fetal calf serum and 400 µg/ml G418 and maintained under 95% O_2/5% CO_2 at 37 °C. Cells are passaged every 3–4 days.

Synthetic human orexin A is ^{125}I-labeled at Tyr17 by chloramine-T oxidation in the presence of $Na^{125}I$ (2 000 Ci/mmol). Monoiodinated peptide is purified by C^{18} reverse-phase HPLC (Takigawa et al. 1995). Stable transfectant CHO cell lines expressing human OX_1R or OX_2R are each seeded onto 12-well plates at a density of 3×10^3 cells per well. After an overnight culture, medium is discarded and cells are incubated at 20 °C for 90 min with binding buffer (HEPES-buffered saline/5% bovine serum albumin) containing 10^{-10} M [^{125}I]orexin A plus designated concentrations of unlabeled competitors. Cells are then washed three times with ice-cold phosphate-buffered saline and lysed in 0.1 N NaOH. Cell-bound radioactivity is determined by a γ-counter.

EVALUATION

Data are expressed as the percentage of saturably bound reactivity in the absence of nonradioactive peptide. For each experiment each value is determined in duplicate, and the results are expressed as the means ±standard errors of at least 3 separate experiments.

MODIFICATIONS OF THE METHOD

Smart et al. (1999) studied the pharmacology of recombinant orexin receptors using the fluorescence imaging plate recorder (FLIPR). CHO-OX_1 or CHO- OX_2 cells were seeded into black walled clear base 96 well plates at a density of 20 000 cells per well in MEM-Alpha medium supplemented with 10% fetal calf serum and

400 µg/ml G418 and cultured overnight. The cells were then incubated with MEM-Alpha medium containing the cytoplasmatic calcium indicator, Fluo-3AM (4 µM) and 2.5 mM probenecid at 37 °C for 60 min. The cells were washed four times with, and finally resuspended in, Tyrode's medium containing 2.5 mM probenecid and 1% gelatin, before being incubated for 30 min at 37 °C with either buffer alone (control) or buffer containing various signal transduction modifying agents. The plates were then placed into an FLIPR (Molecular Devices, U.K.) to monitor cell fluorescence ($\lambda = 488$ nM, $\lambda = 540$ nM) (Sullivan et al. 1999) before and after the addition of orexin A or orexin B.

L.4.3.3 Radioimmunoassay for orexin

PURPOSE AND RATIONALE

A radioimmunoassay for orexin A has been developed by Mitsuma et al. (2000).

PROCEDURE

Synthetic orexin A is conjugated on an equal weight basis to BSA using glutaraldehyde. New Zealand white rabbits are immunized with an emulsion of this conjugate in one ml of water and complete Freund's adjuvant (1 : 2, v/v) which is injected into the foot pad at intervals of 3 weeks. Blood is withdrawn one week after each injection, and the presence of anti-orexin is checked by radioimmunoassay.

Radioiodination of orexin A is performed with the chloramine T method. The radioiodinated materials are chromatographed on Sephadex G-25, eluted with 0.01 M phosphate buffer (pH 7.4), and collected in 1.0 ml fractions. The first peak is orexin A-I^{125}.

For determination of tissue concentrations, brain tissues of rats are dissected into the hypothalamus, cerebral cortex, thalamus, striatum, hippocampal formation, brain stem and cerebellum.

For the extraction of orexin A, the freshly obtained tissues are weighed and placed in 5.0 ml acid-acetone, homogenized and centrifuged.

For the double antibody radioimmunoassay, 0.1 ml of standard or samples, 0.1 ml of antibody (1 : 1 000), 0.1 ml orexin A I^{125}, and 0,5 ml buffer are incubated for 24 h at 4 °C. Then 0.1 ml of the second antibody solution is added and incubated again for 24 h at 4 °C. The samples are centrifuged, the supernatants decanted and radioactivity counted in the precipitates.

EVALUATION

Bound/total count is calculated and standard curves versus synthetic orexin A are established.

MODIFICATIONS OF THE METHOD

Using separate radioimmunoassays for orexin A and orexin B, Mondal et al. (1999) determined their distribution in microdissected nuclei of the diencephalon and brainstem of rats.

L.4.4 Galanin

L.4.4.1 General considerations on galanin

Galanin is a neuropeptide of 29 amino acids in length (30 amino acids in humans) which was first isolated from porcine intestine (Tatemoto et al. 1983) and is localized mainly in the mammalian CNS (Skofitsch and Jacobowitz 1985; Melander et al. 1986), but also in

other organs (Baltazar et al. 2000). Central administration of galanin increases food intake in satiated rats (Crawley et al. 1990). Conversely, reduction of central galanin levels by antisense oligonucleotide techniques (Akabayashi et al. 1994) or central administration of galanin receptor antagonists (Leibowitz and Kim 1992) decreases food intake. The activity of galanin in the hypothalamus is modulated by metabolic hormones and by the ingestion of nutrients (Wang et al. 1998).

These data suggest the use of galanin receptor antagonists as anti-obesity agents.

Physiological actions of peripherally administered galanin include contraction of smooth muscle (Ekblad et al. 1989; Ahtaridis et al. 1998; Korolkiewicz et al. 1998; Niiro et al. 1998), inhibition of glucose-stimulated insulin release (McDonald et al. 1985; Leonhardt et al. 1989), influence on learning and memory behavior (McDonald and Crawley 1997; McDonald et al. 1998a,b; Gleason et al. 1999; Ögren et al. 1999; Zachariou et al. 1999), antinociceptive activity in rats with experimentally induced neuropathy (Burazin and Gundlach 1998; Ma and Bisby 1999; Yu et al. 1999; Kerr et al. 2000; Wang et al. 2000).

Galanin has been found to influence secretion of growth hormone (Ottlecz et al. 1988; Murakami et al. 1987), LH (Todd et al. 1998), luteinizing hormone (Finn et al. 1998), and prolactin (Koshiyama et al. 1987; Cai et al. 1998; Wynick et al. 1998), to inhibit dopamine release from the median eminence (Nordström et al. 1987), to influence ACh release from rat brain (Fisone et al. 1987; Kasa et al. 1998), to inhibit norepinephrine release from the hypothalamus (Tsuda et al. (1989) and to modulate 5-HT_{1A} receptors in the ventral limbic cortex of the rat (Diaz-Cabiale et al. 2000).

A fragment of the galanin precursor protein, galanin message-associated peptide (GMAP), is present in dorsal root ganglion cells and influences the spinal nociceptor flexor reflex in rats (Xu et al. 1996).

A galanin-like peptide, named GALP, was isolated by Ohtaki et al. (1999) from porcine hypothalamus.

Various **galanin receptor antagonists**, such as galantide (Lindskog et al. 1992; Sahu et al. 1994; Arletti et al. 1997; Ceresini et al. 1998), and other compounds (Bartfai et al. 1991; Pramanik and Ögren 1992; Kask et al. 1995; Xu et al. 1995; Kakuyama et al. 1997; Pooga et al. 1998; Koegler et al. 1999; Park and Baum 1999; Katoh and Ohmori 2000; Kisfalvi et al. 2000) were synthesized and tested.

L.4.4.2 Receptor assay of galanin

PURPOSE AND RATIONALE

Galanin mediates its physiological effects via interaction with at least three G protein-coupled receptors, designated GAL1, GAL2, and GAL3 receptor (Wang and Parker 1998; Branchek et al. 2000).

The first known galanin receptor GAL1 has been isolated from the human Bowes melanoma cell line (Habert-Ortoli 1994). Human GAL1 contains 349 amino acids with the structure of a G protein-coupled receptor. A rat GAL1 homologue, cloned from Rin14B cells, contains 346 amino acids (Parker et al. 1995). Human GAL1 mRNA has been detected by northern blot analysis in fetal brain and small intestinal tissue, and also by reverse transcriptase-polymerase chain reaction in the human gastrointestinal tract from the esophagus to the rectum. Rat GAL1 mRNA has been detected by northern blot analysis in the brain, spinal cord and Rin14B cells. Human and rat GAL1 share similar binding profiles in [^{125}I]galanin binding assays (Sullivan et al. 1997).

The rat GAL2 receptor has been cloned and characterized by Wang et al. (1997), Ahmad et al. (1998), the mouse GAL2 receptor by Pang et al. (1998) and the human GAL2 receptor by Bloomquist et al. (1998) and Fathi et al. (1998). Unlike GAL1, mRNA encoding rat GAL2 is widely distributed in all tissues examined including the brain and peripheral tissues. Likewise, the human GAL2 receptor is detectable by RT-PCR in several central and peripheral tissues. Rat GAL1 and GAL2 share similar pharmacological profiles in that they possess high affinity for full-length and N-terminal fragments of galanin.

Rat and human GAL3 receptors were described by Kolakowski et al. (1998), Smith et al. (1998). Human and rat GAL3 share similar profiles in [^{125}I]galanin receptor binding assays.

Lee et al. (1999) reported the isolation of a cDNA clone named GPR54 which encodes a G-protein coupled receptor related to the galanin receptors.

PROCEDURE

Preparation of the radioligand ^{125}I-galanin is performed by iodination of galanin at room temperature by the chlor-amine-T method. Galanin, 10 µg, in 20 µl 0.05 M sodi-um phosphate buffer (pH 7.5) and 20 µl chloramine-T (5 mg/ml) are added in a batch containing 2 mCi Na^{125}I (245 mCi/ml). The reaction is terminated by adding 100 µl of a solution of sodium metabisulfite (1.2 mg/ml). The reaction mixture is transferred onto a column packed with SP-Sephadex C25, equilibrated with a solution of 100 µg/ml BSA, then washed and equilibrated with 0.05 M sodium phosphate buffer (pH 5.0). The excess of Na^{125}I is first eluted with 0.05 M sodium phosphate buffer (pH 5.0), while the iodinated galanin is eluted as a single peak with 0.05 M sodium phosphate buffer (pH 8.1). Fractions corresponding to a peak of ^{125}I-ga-lanin are pooled, the pH adjusted to 6.0 with acetic acid, and the aliquots stored at −18 °C until use.

Male Sprague-Dawley rats are sacrificed and their brains quickly removed. The hypothalamus is dissected for **preparation of membranes**. The tissue is homogenized (10% mass/vol) in 0.32 M sucrose buffered with 5 mM HEPES (pH 7.4). The homogenate is diluted 10-fold and centrifuged at 1 000 *g* for 10 min. The supernatant is centrifuged at 10 000 *g* for 45 min, and the pellet is resuspended in 5 mM HEPES-buffered Krebs-Ringer solution (pH 7.4).

Displacement experiments are carried out with various test compounds in a final volume of 400 µl HEPES/Krebs-Ringer solution, 0.05% BSA (pH 7.4), containing 1 mM ^{125}I-galanin and 70–100 µg membrane preparation. Samples are incubated for 30 min at 37 °C. Incubation is terminated by the addition of 10 ml ice-cold HEPES/Krebs-Ringer solution, followed by rapid filtration over Whatman GF/B filters, precoated for 5–6 h in 0.3% polyethyleneimine solution. Specific binding is defined as that displaceable by 1 mM rat galanin1–29.

EVALUATION

Bound/total count is calculated and displacement curves versus the standard are established.

L.4.5 Adipsin

L.4.5.1 General considerations on adipsin

Proteins of the alternative complement pathway are secreted by adipose tissue (Choy et al. 1992; Peake et al. 1997). **Adipsin (complement D)** was the first to be cloned from an adipose tissue cell line and shown to be synthesized and secreted by adipose tissue (Cook et al. 1987; Flier et al. 1987; Johnson et al. 1991; White et al. 1992). Adipsin is markedly suppressed in *ob/ob, db/db,* monosodium glutamate-induced obese mice, in obese JCR:LA-cp rats and in cafeteria-fed rats (Rosen et al. 1989; Dugail et al. 1990; Shillabeer et al. 1992; Spurlock et al. 1996), and is regulated by glucocorticoids, retinoic acid, sympathomimetic drugs and insulin (Kitagawa et al. 1989; Spiegelman et al. 1989; Lowell and Flier 1990; Lowell et al. 1990; Moustaid et al. 1990; Antras et al. 1991; Miner et al. 1993). In contrast to rodents, adipsin increases with adiposity in humans and in response to feeding and is decreased during fasting, cachexia and lipatrophy (Napolitano et al. 1994).

Adipsin is required for the synthesis of **acylation stimulating protein (ASP)**, a protein implicated in fat metabolism (Sniderman and Cianflone 1994; Cianflone et al. 1999; van Harmelen et al. 1999). ASP is produced by the cleavage of C3a by carboxypeptidase and is highly expressed by mature adipocytes. The synthesis of C3a from C3 requires complement factor B and adipsin. Plasma ASP increases with meals and facilitates the synthesis and storage of triglycerides. Consistent with its role as a mediator of lipogenesis, ASP deficiency increases postprandial fatty acid levels and decreases weight gain and trigylceride synthesis in mice (Murray et al. 1999, 2000).

Several other factors, such as adiponectin (Takahashi et al. 2000) are involved in the function of adipose tissue acting as target as well as an endocrine organ (Ahima and Flier 2000).

L.4.5.2 Adipsin expression in mice

PURPOSE AND RATIONALE

Adipsin expression at the protein and mRNA levels was studied in mice (Flier et al. 1987; Spiegelman et al. 1989; Lowell et al. 1990; Dugail et al. 1990) and rats (Miner et al. 1993).

PROCEDURE

Various strains of mice (CD-1 mice, C57BL6 *ob/ob* mice, C57BL/Ks misty diabetes (m db/m db) mice, and mice with monosodium glutamate induced obesity are treated with drugs, e.g., ephedrine (1 g/kg chow) and caffeine (1.4 g/kg chow) mixed in the diet. The effects of these regimens on fat pad weight, specific mRNAs in white epididymal and brown adipose tissue and serum adipsin concentrations are assessed.

RNA is extracted from epididymal adipose tissue, brown intercapsular adipose tissue, 3T3-F422A adipocytes and isolated rat adipocytes by the guanidium-cesium chloride technique. Total RNA is denaturated, electrophoresed in 1.5% agarose, transferred to nylon filters, and hybridized to random primed adipsin, uncoupling protein (UCP), or actin cDNAs (Flier et al. 1987).

Serum adipsin and adipsin released by 3T3-F442A cultured adipocytes are assessed by RIA. Mouse adipsin purified from Chinese hamster ovary cells stably transfected with an adipsin expression vector is iodinated using the Bolton-Hunter reagent. The labeled protein is separated from unincorporated ^{125}I using G-50 Sephadex chromatography. The first rabbit polyclonal antibody is raised to purified mouse adipsin overexpressed using a baculovirus expression system. The assay is carried out in PBS, pH 7.4, supplemented with $CaCl_2$ (0.1 g/liter), $MgCl_2$ (0.1 g/liter), and BSA (0.1%). Serum adipsin is assessed in a dilution of 1 : 1 000–1 : 5 000 and in culture media at a dilution of 1 : 100. After adding tracer, standards, and serum, the tubes are mixed and the first antibody is added at a dilution of 1 : 800. After an overnight incubation, the bound and unbound tracer are separated using goat anti-rabbit immunoglobulin C fixed to heat killed staphylococcus at a ratio 1 : 1.2.

EVALUATION

Standard curves are generated using mouse adipsin purified from stably transfected CHO cells. Serial dilutions of standards, serum, and culture media are compared.

MODIFICATIONS OF THE METHOD

Dugail et al. (1989) showed that, in sharp contrast with genetically obese mice, adipsin mRNA is not suppressed in genetically obese Zucker rats.

Platt et al. (1994) found that a tissue-specific transcription factor that regulates adipsin expression is less active in the adipose tissue of obese animals.

Napolitano et al. (1994) determined concentrations in blood and rates of adipsin secretion by adipose tissue in humans using a two-monoclonal 'sandwich' ELISA assay.

Chapter M
Anti-atherosclerotic activity[1]

[1] With contributions for this edition by H.-L. Schäfer.

M.1 Induction of experimental atherosclerosis

M.1.0.1 General considerations

Experimental atherosclerosis was first successfully induced in rabbits by Saltykow (1908) and Ignatowski (1909). During the following years, various scientists found that dietary cholesterol was the responsible stimulus for development of atherosclerosis. Other species are also susceptible to diet-induced atherosclerosis (Reviews by Kritchevsky 1964; Hadjiinky et al. 1991). A unifying hypothesis of the pathogenesis of atherosclerosis has been proposed by Schwartz et al. (1991).

M.1.0.2 Cholesterol-diet induced atherosclerosis in rabbits and other species

PURPOSE AND RATIONALE

Rabbits are known to be susceptible to hypercholesterolemia and arteriosclerosis after excessive cholesterol feeding. Therefore, this approach has been chosen by many authors to study the effect of potential anti-arteriosclerotic drugs.

PROCEDURE

Several modifications of the protocol have been described. Usually, male rabbits from an inbred strain, e.g., white New Zealand, at an age of 8–10 weeks are used. Body weight variation should be as low as possible. At the beginning of the experiment, blood is withdrawn from the marginal ear vein for determination of total cholesterol, total glycerides, and blood sugar. Groups of 10 animals are used for treatment with drugs or as controls. The rabbits are switched from commercial food to a diet supplemented with 0.3–2% cholesterol and kept on this regimen for a period of 10–12 weeks. One group is kept on normal diet. During and at the end of the experiment blood is taken for analysis. Usually, cholesterol and triglyceride levels increase several-fold over the original values.

The animals are sacrificed and the thoracic aorta is removed, cleaned of surrounding tissues, and longitudinally cut and opened for fixation with formaldehyde. The tissue is stained with oil red. The percentage of the intimal surface covered by the oil red positive lesions is calculated with a computerized planimeter. In animals fed a normal diet, the aorta does not show any staining, whereas in cholesterol-fed rabbits the aorta shows severe atherogenic lesions.

EVALUATION

Data are expressed as means ± standard deviation. Statistical evaluation is performed by Dunnett's or Scheffé's test. A p-value of < 0.05 is regarded as statistically significant.

MODIFICATIONS OF THE METHOD

Shore and Shore (1976) studied two **different strains of rabbits** (New Zealand White and Dutch Belt) as models of hyperlipoproteinemia and atherosclerosis.

Studies of Kritchevsky et al. (1989) on experimental atherosclerosis in **rabbits** fed **cholesterol-free diets** revealed a greater influence of animal protein and of partially hydrogenated soybean oil on development of atherosclerosis than plant protein and unsaturated soybean oil.

Cockerels (Tennent et al. 1960) and **turkeys** (Simpson and Harms 1969) are very susceptible to cholesterol feeding and develop marked hypercholesterolemia in rather short periods. Atherosclerosis could also be induced in cockerels by high doses of estrogen without atherogenic diet (Caldwell and Suydam 1959).

Spontaneous arteriosclerosis in **pigeons** has been described by Clarkson and Lofland (1961).

The **Japanese sea quail** (*Coturnix coturnix japonica*) is highly susceptible to the rapid development of severe experimental atherosclerosis (Day et al. 1975, 1977, 1979, 1990; Chapman et al. 1976).

Out of 13 strains of **mice**, Roberts and Thompson (1976) selected the C57BR/cdJ and the CBA/J strain und used these strains and their hybrids as models for atherosclerosis research.

Paigen et al. (1987) described quantitative assessment of atherosclerotic lesions in mice. After 14 weeks on an atherogenetic diet C57BL/6J female mice had aortic lesions at each of the coronary arteries, at the junction of the aorta to the heart and in scattered areas of the aortic surface. The lesions increased after 9 months of atherogenic diet. Methods of evaluating the number and size of lesions were compared including sizing with a microscope eyepiece grid and computer-assisted planimetry.

Atherosclerosis susceptibility differences among progenitors of recombinant inbred strains of mice were described by Paigen et al. (1990).

Yamaguchi et al. (1993) found that addition of 10% linoleic acid to a high-cholesterol diet enhanced cholesterol deposition in the aorta of male ICR strain mice.

In **rats** hypercholesterolemia can be induced by daily administration by gavage of 1 ml/100 g body weight of a cocktail containing in 1 l peanut oil: 100 g cholesterol, 30 g propylthio-uracil, and 100 g cholic acid over a period of 7 days. The test compounds are administered simultaneously with the cocktail (Fillios et al. 1956; Lustalot et al. 1961).

Inoue et al. (1990) induced experimental atherosclerosis in the rat carotid artery by balloon de-endothelialization and atherogenic diet. A balloon catheter was introduced into the rat's carotid arteries from the iliac arteries and the endothelium was denuded.

The **hamster** is susceptible to atherosclerosis. Nistor et al. (1987) fed male hamsters a hyperlipidemic diet consisting of standard chow supplemented with 3% cholesterol and 15% commercial butter for 12 months. Serum total cholesterol doubled after 3 weeks and attained a 17-fold value after 10 months. Up to 6 months, smooth muscle cells in the intima and media of the aorta as well as endothelial cells began to load with lipids. After 10 months the affected zones looked like human atherosclerotic plaque with huge cholesterol crystal deposits, calcium deposits and necrosis.

Especially the hybrid hamster strain Bio™ F_1B (Bio Breeders Fitchburg, MA, USA) is more susceptible to dietary induced atherosclerosis than other strains (Kowala et al. 1991). Early atherosclerotic lesions can be induced within a 3-months-feeding of a cholesterol/butter enriched diet. In these animals simvastin dose-dependently inhibited the development of hyperlipidemia and the plaque formation by cholesterol synthesis inhibition The histopathological examination of the aortas showed that the cholesterol/butter fed F_1B hamster developed atherosclerotic lesions and functional changes in the aorta which are closely related to man (Schäfer et al. 1999).

Soret et al. (1976) studied the diet-induced hypercholesterinemia in the diabetic and non-diabetic Chinese hamster.

Beitz and Mest (1991) used cholesterol-fed **guinea pigs** to study the antihyperlipemic effects of a potentially anti-atherosclerotic drug.

Malinow et al. (1976) recommended the **cynomolgus monkey** as a model for therapeutic intervention on established coronary atherosclerosis.

This species was used by Hollander et al. (1978) to study the development atherosclerosis after a cholesterol and fat enriched diet.

Beere et al. (1992) described experimental atherosclerosis at the carotid bifurcation of the cynomolgus monkey by a cholesterol-enriched diet.

Eggen et al. (1991) studied the progression and the regression of diet-induced atherosclerotic lesions in aorta and coronary arteries on **rhesus monkeys**.

Howard (1976) recommended the **baboon** as model in atherosclerosis research because of the similarity of cholesterol metabolism and composition of the lipoproteins to man.

Kushwaha et al. (1991) determined the effect of estrogen and progesterone on plasma cholesterol concentrations and on arterial lesions in ovarectomized and hysterectomized baboons fed a high-cholesterol/high-saturated-fat diet.

Blaton an Peeters (1976) reported studies on the **chimpanzee**, the **baboon** and the **rhesus macacus** as models for atherosclerosis.

Ming-Peng et al. (1990) studied high density lipoproteins and prevention of experimental atherosclerosis in **tree shrews** (*Tupaia belangera yunalis*). In contrast to rabbits, no increased lipid deposition in aortic intima after cholesterol feeding was found in tree shrews.

CRITICAL ASSESSMENT OF THE METHOD

Diet-induced hypercholesterolemia is useful only for detection of agents interfering with the adsorption, degradation and excretion of cholesterol. Agents interfering with cholesterol biosynthesis are less probable to be detected.

The use of normal adult **marmosets**, a species with a lipoprotein profile similar to that of man, may be an alternative (Crook et al. 1990; Baxter et al. 1992).

M.1.0.3 Hereditary hypercholesterolemia in rats

A strain of genetically hypercholesterolemic rats (RICO) was described by Müller et al. (1979). In contrast to Zucker-rats, these animals are normotriglyce-ridemic and non-obese. The hypercholesterolemia of the RICO rat is related to a decreased rate of catabolism of chylomicrons and LDL, but more specifically to an excessive production of these two types of lipoproteins. This strain has been proposed to study hypolipidemic drugs, particularly those designed to decrease the plasma concentrations of chylomicrons and LDL. Hypolipidemic effects of β-cyclodextrin were found in this model (Riottot et al. 1993).

M.1.0.4 Hereditary hyperlipemia in rabbits

Watanabe et al. (1977, 1980) described a strain of rabbits with hereditary hyperlipemia (WHHL rabbit) which has been used by several scientists to study development of atherosclerosis, as well as for histological and functional changes of the aorta. At the age of 10–14 months homozygous animals exhibit an atheromatous plaque, distributed heterogeneously over the luminal surface of the aorta. Serum cholesterol is increased up to 400–600 mg/dl. The increased levels of LDL have been studied in detail (Kita et al. 1981, 1982).

M.1.0.5 Transgenic animals

Several transgenic animals as disease model were created during the last decade, mice (Stoltzfus and Rubin 1993), rats and rabbits.

The widely used model is the Apo E knockout mouse originally created by Nubuyo Maeda, University of North Carolina, Chapell Hill, NC. These Apo E knockout mice have spontaneously elevated plasma cholesterol levels, and develop atherosclerosis even on regular chow within 3–4 months. The time dependent progression of atherosclerosis leads to lesions similar in histopathology to those observed in humans. This

animal model is used as background for atherosclerosis research and target validation.

Walsh et al. (1989) and Rubin et al. (1991) integrated human apolipoprotein A-I gene in transgenic mice resulting in an increase of HDL levels.

Linton et al. (1993) described the development of transgenic mice expressing high levels of human apolipoprotein B48 and human apolipoprotein B100 which are considered to be atherogenic.

Transgenic mice lacking apolipoprotein E showed severe hypercholesterolemia and atherosclerosis (Plumpp et al. 1992; Zhang et al. 1992).

Overexpression of apolipoprotein E in transgenic mice reduced plasma cholesterol and triglyceride levels, prevented hypercholesterolemia and inhibited the formation of fatty streak lesions (Harada et al. 1996).

M.1.0.6 Evaluation of endothelial function in rabbits with atherosclerosis

PURPOSE AND RATIONALE

Cholesterol feeding of rabbits impairs the endothelium-dependent relaxation evoked by acetylcholine in the aorta. This phenomenon can be used to study the influence of vasodilators as well as the prevention by ACE-inhibitors (Becker et al. 1991).

PROCEDURE

Male white New Zealand rabbits weighing 3–4 kg receive a hypercholesterolemic diet containing 0.25 to 1% cholesterol and 3% coconut oil. Rabbits of the same weight receiving standard diet serve as controls. After several weeks, the serum cholesterol levels are increased from 30–40 mg/dl in the control group up to 900–1 000 mg/dl in the cholesterol-fed group. At the end of the treatment period, the animals are sacrificed by intravenous injection of sodium pentobarbital and a complete autopsy is performed.

Intact proximal parts of the thoracic aorta are sectioned into 2 mm wide rings, cut off to strips, and suspended at 2 g gauge in 25 ml organ chambers filled with a buffer solution of 37 °C comprising 113.8 mM NaCl, 20 mM $NaHCO_3$, 4.7 mM KCl, 1.2 mM KH_2PO_4, 1.1 mM $MgSO_4$, 2.5 mM $CaCl_2$, and 5.5 mM glucose being gassed with a 95% O_2/5% CO_2 mixture to achieve a pH of 7.4. After 2 h, when a stable contractile tone is established, norepinephrine is added at a final concentration of 1×10^{-8} M, which produces a stable submaximum isotonic contraction. Then, acetylcholine is added in 10 fold incremental doses from 1×10^{-8} M up to final concentrations of 10^{-5} M. Relaxation of aortic strips is assessed as percentage decrease in contraction. Acetylcholine induced concentration-dependent relaxation is greatly impaired in aorta rings from cholesterol-fed rabbits whereas contractions to norepinephrine are only slightly diminished.

EVALUATION

The data are expressed as mean ±SEM and compared by Student's *t*-test for unpaired data.

MODIFICATIONS OF THE METHOD

Verbeuren et al. (1986, 1990) and Tagawa et al. (1991) used a bioassay for the determination of EDRF (Rubanyi et al. 1985). The donor thoracic aorta segments (3 cm long) are mounted horizontally in perfusion chambers filled with physiological salt solution which contains indomethacin (3×10^{-6} M) at 37 °C; the solution is gassed with a mixture of 20% O_2, 5% CO_2, and 75% N_2. The aortas (control and atherosclerotic tissue) and a piece of glass tubing are perfused continuously with the same solution at 3 ml/min. The perfusate is dripping directly onto a segment (5 mm long) of either a control or an atherosclerotic abdominal aorta from which the endothelium was mechanically removed. The detector abdominal aortas are mounted vertically over two hooks and the development of isometric tension is monitored continuously. The initial tension of the detector aortas is set at 8 g. The perfusate of each donor aorta is analyzed both on a control and on an

atherosclerotic detector preparation: the order of this double analysis is selected at random. A control and an atherosclerotic donor aorta are always analyzed in parallel and thus on the same detector tissue. Drugs are added to the perfusion medium. Before the start of the experiments, the tissues are allowed to equilibrate for 45 min in the perfusion chambers. By means of a three-way system, placed at the outlet of the donor aortas, atropine (10^{-6} M) is added to the perfusate to block any muscarinic contractile effect of acetylcholine on the detector tissue. Noradrenaline (2×10^{-6} M) is infused into the perfusate via this 3-way system causing a sustained contraction in the detector tissue.

After the stabilization of the contraction to noradrenaline, the highest dose of acetylcholine (1.6×10^{-8} mol) is added to the solution for perfusion of the tubing in order to confirm no change in the contractile response to noradrenaline in the detector tissues. Moreover, the perfusate from the control and atherosclerotic donor aortas under basal conditions does not significantly affect the contraction of the detector tissues. The tissues are allowed to equilibrate and then increasing doses of acetylcholine (0.01 to 160×10^{-10} mol) are injected into the perfusion medium close to the donor aortas. Relaxation is less pronounced in the detector tissues when atherosclerotic aortas are stimulated with acetylcholine indicating that the cholinergic agent causes a smaller release of EDRF from atherosclerotic donor aortas than from control donor aortas. The degree of the arteriosclerotic lesion can be assessed by this functional assay.

M.1.0.7 Intimal reactions after endothelial injury

PURPOSE AND RATIONALE

Several attempts have been made to induce intimal injury in animals which is followed by proliferation and formation of fatty streaks similar to the alterations found in human atherosclerosis. One approach is the "balloon catheterization".

PROCEDURE

Male New Zealand White rabbits weighing 2.0–3.5 kg or male Sprague-Dawley rats weighing 350–400 g are used. An embolectomy catheter (Edwards Laboratories, size 4 French for rabbits, size 2 French for rats) is introduced into the right femoral artery under surgical anesthesia and passed to the aortic arch. After inflation with room air, the catheter is withdrawn to the iliac bifurcation, deflated and removed.

The incorporation of [^{3}H]thymidine into DNA of rabbit or rat aorta is measured 48 h after balloon catheterization. Animals are sacrificed 45 min after intravenous injection of [^{3}H]thymidine. Intima-media is prepared from whole aorta by scraping with blunt forceps. The specific activity of ^{3}H in DNA is determined after extraction of the DNA in the washed tissue homogenate using hot dilute perchloric acid. DNA is assayed by the diphenylamine method. ^{3}H Incorporation is measured in a liquid scintillation counter.

For histological examination, rabbits are injected 2 weeks after balloon catheterization intravenously with heparin (500 U/kg) and then sacrificed. Fixative (2% glutaraldehyde in 0.15 M phosphate buffer, pH 7.4) is infused at a constant pressure of 100 mm Hg via a carotid cannula and the aorta is pressure fixed *in situ* for 60 min. Intimal proliferation is quantified in the upper abdominal aorta, in the lower abdominal aorta and half-way between these points.

EVALUATION

[^{3}H]Thymidine incorporation and intimal proliferation is compared between drug treated animals and controls.

MODIFICATIONS OF THE METHOD

DeCampli et al. (1988) studied the effects of various drugs on accelerated myointimal proliferation in canine veno-arterial allografts by histological methods. An 8-cm length of femoral vein was removed, reversed, divided, and sewn end-to-end into carotid or femoral arteries of a recipient dog.

Berkenboom et al. (1989) induced experimental atherosclerosis in **canine** and **porcine** coronary arteries by endothelial denudation followed by a high-cholesterol diet.

Kawata et al. (1990) described the detection of regenerating cells in the aorta after ballooning by immunocytochemical demonstration of the thymidine analogue 5-bromo-2'-deoxyuridine.

Manderson et al. (1990) described changes in vascular reactivity of carotid arteries in rabbits following endothelial denudation.

Bocan et al. (1991) tested an ACAT inhibitor and selected lipid-lowering agents for anti-atherosclerotic activity in iliac-femoral and thoracic aortic lesions. Atherosclerotic lesion comparable in composition to human fatty streaks were induced by chronic endothelial denudation in the iliac-femoral artery inserting a sterile, indwelling, 18-cm nylon filament with a diameter of 200 µm into the lumen of the right femoral artery in hypercholesterolemic New Zealand White rabbits. Naturally occurring fatty streaks developed in the thoracic aorta following cholesterol feeding. The effect of treatment on lesion regression was evaluated in the iliac-femoral artery, while changes in the lesion progression were evaluated in the thoracic artery.

Davies et al. (1993) performed right common carotid artery bypass grafting using the ipsilateral external jugal vein in New Zealand White rabbits and studied the response to endothelin-1 in normolipidemic and hyperlipidemic animals.

Groves et al. (1993) studied platelet adhesion and thrombus formation in a **porcine** model of balloon angioplasty.

ACE inhibitor treatment reduced the neointima formation after endothelial denudation in the carotid artery of **rats** using a balloon catheter (Farhy et al. 1992; Linz and Schölkens 1992; Linz et al. 1993, 1994).

Lyle et al. (1995) tested the effect of inhibitors of factor X_a or platelet adhesion, heparin, and aspirin on platelet deposition in an atherosclerotic rabbit model of angioplastic injury. Acute ^{111}indium-labelled platelet deposition and thrombosis were assessed 4 h after balloon-injury in femoral arteries subjected to prior endothelial damage (air desiccation) and cholesterol supplementation (1 month).

M.2 Influence on lipid metabolism

M.2.0.1 General considerations

Elevated lipid levels, especially hypercholesterolemia, result from increased absorption from the gut or enhanced endogenous synthesis. Therefore, two ways are feasible to reduce hyperlipidemia: to block endogenous

synthesis or to decrease absorption. Both factors can be evaluated in normal animals without artificial diets. Clinically used lipid lowering compounds like fibrates can be tested in this way, being investigated with additional tests. Earlier attempts to interfere with endogenous cholesterol synthesis resulted in accumulation of other sterols than cholesterol (Holmes 1964). The most extensively studied approach to inhibit cholesterol biosynthesis is with HMG-CoA reductase inhibitors. Inhibition of other enzymes of cholesterol biosynthesis, such as lanosterol 14α-methyl demethylaseα and squalene synthetase, is considered. The inhibition of cholesterol absorption by ACAT-inhibitors is a widely followed approach. Furthermore, the interruption of bile acid recirculation resulting in reduction of LDL cholesterol is being used.

Protective effects of calcium antagonists against experimental arteriosclerosis acting mainly on other mechanisms than lipid metabolism have been claimed by various authors but the clinical relevance is still questionable (Kjeldsen and Stender 1989; Fronek 1990; Knorr and Kazda 1990; Fleckenstein-Grün et al. 1992).

M.2.0.2 Hypolipidemic activity in rats

PURPOSE AND RATIONALE

Hyperlipoproteinemia with increased concentrations of cholesterol- and triglyceride-carrying lipoproteins is considered to be the cause of arteriosclerosis with its dual sequelae of thrombosis and infarction. Lipoproteins are divided into 6 major classes: chylomicrons, chylomicron remnants, VLDL (very low density lipoproteins), IDL (intermediate density lipoproteins), LDL (low density lipoproteins), and HDL (high density lipoproteins). HDL promotes the removal of cholesterol from peripheral cells and facilitates its delivery back to the liver. Therefore, increased levels of HDL are desirable. On the contrary, high levels of VLDL and LDL promote arteriosclerosis. LDL, especially in its oxidized form, is taken up by macrophages via a scavenger mechanism. Therefore, anti-arteriosclerotic drugs should reduce VLDL and LDL and/or elevate HDL.

PROCEDURE

Groups of 10 male Wistar rats weighing 180–200 g are used. They are given once daily in the morning over a period of 8 days the test compounds or the standard in various doses ranging from 1 to 100 mg/kg via stomach tube in a volume of 5 ml/kg. The control group is given the solvent (e.g., PEG 400) only. Body weight of each animal is registered at the beginning and at the end of the experiment. Twenty hours prior to the experiment, food but not water is withdrawn. On the morning of the first day, blood samples are taken under light ether anesthesia by retroorbital puncture. Then, the first dose is applied. During the whole period, the animals have free access to food and water. Twenty hours prior the end of the experiment, food is again withdrawn and blood samples are taken by retroorbital puncture. Immediately thereafter, the animals are sacrificed and the liver removed, blotted free from blood and weighed. Samples of liver are frozen in liquid nitrogen and stored at –25 °C for lipid analysis. The blood samples are centrifuged for 2 min at 16 000 *g*. Total cholesterol and total glycerin as a measure of triglycerides are determined in each blood sample.

To estimate the serum lipoproteins, the serum of each rat group is pooled. The serum lipoproteins are separated by means of a preparative ultracentrifuge (e.g., KONTRON TGA 65, Rotor TFT 456).

The separation of fractions VLDL, LDL, HDL, and of the subnatant of HDL is carried out as follows:

VLDL	native density of the serum (1.006), 16 h at 40 000 rpm,
LDL	density range from 1.006 to 1.04, 18 h at 40 000 rpm,
HDL	density range from 1.04 to 1.21, 18 h at 40 000 rpm,
Subnatant of HDL	density > 1.21.

The density is adjusted by addition of a calculated amount of NaBr solution.

Cholesterol is determined using Boehringer Mannheim test combinations by the CHOD-PAP high performance method (Siedel et al. 1983) and triglycerides by means of an enzymatic assay (Eggstein and Kreutz 1966; Wahlefeld 1974). The method of Lowry et al. (1951) is applied to determine protein content.

Frozen samples of liver are thawed and extracted with chloroform/methanol 2 : 1 (v/v) in a Teflon Potter-Elvehjem homogenizer. The extracts are purified according to Folch et al. (1957). Solvents of aliquots of the extracts are evaporated for determinations of cholesterol and triglycerides.

EVALUATION

Average values of body weight, cholesterol and triglycerides are expressed as percentage of initial values for each group at the end of the experiment. Statistical differences between the controls and the treatment groups are evaluated by covariance analysis.

CRITICAL ASSESSMENT OF THE METHOD

Studies with normocholesterinemic animals are faced with the difficulty that starting cholesterol levels are relatively low, and to achieve significance for lowering of cholesterol levels requires large groups of animals.

MODIFICATIONS OF THE METHOD

Similar tests can be performed in various species, e.g.:

- Male NMRI mice, weighing 25–30 g,
- male New Zealand obese (NZO) mice, weighing 35–40 g,
- male Syrian golden hamsters, weighing 70–100 g,
- male Pirbright guinea pigs, weighing 200–250 g,
- male miniature pigs, weighing 14–22 kg.

To study long term effects, the experiments are extended for 4 weeks or 3 months.

Schurr et al. (1976) proposed high volume screening procedures for hypobetalipoproteinemic activity in rats.

März et al. (1993) described fast lipoprotein chromatography as a new method of analysis for plasma lipoproteins.

Adipokinetic actions of several hormones in slices of perirenal adipose tissue of various species were determined by Rudman et al. (1963).

M.2.0.3 Hypolipidemic activity in Syrian hamsters

PURPOSE AND RATIONALE

The Syrian hamster (*Mesocricetus auratus*) is a widely used animal to study the effects of drugs and diet on lipoprotein metabolism. Several in human approved lipid lowering drug like HMG-Co A reductase inhibitors, or cholestyramine lower plasma cholesterol in hamster. The lipoprotein and bile acid metabolism of the hamster is closer to human than the lipoprotein and bile acid metabolism of rats and mice (Bravo et al. 1994; Suckling et al. 1991; Kris-Etheron and Dietschy 1997). The hamster has in contrast to pig, rat and mouse CETP (Cholesteryl Ester Transfer Protein) activity, similarly as seen in humans (Ha and Barter 1982, 1986; Ahn et al. 1994).

Increase in plasma cholesterol can be easily induced by adding small, physiological amounts of cholesterol to the diet (0.05–0.01 weight%). Additional saturated fat like coconut oil (5–10 weight%) has synergistic effects for induction of hyperlipidemia. (Kowala et al. 1991) A stable hyperlipidemia with a human like lipoprotein pattern can be induced in hamster within 2–3 weeks by adding 10 weight% coconut butter and 0.2% cholesterol into the diet. Hamster HDL cholesterol can be easily measured after precipitation of VLDL+LDL cholesterol with phoshotungstic acid/$MgCl_2$ (Weingand and Daggy 1990, 1991). LDL and HDL cholesterol can also be measured directly with Kits from Roche Diagnostics. A complete separation of all lipoprotein fractions can be done by FPLC on Superose 6 columns (Pharmacia) according the method of März et al. (1993).

PROCEDURE

Male Syrian hamsters weighing 95–125 g at the start of the experiment are randomly assigned to form groups of 6 animals each. For each group a different diet is prepared: Controls receive powdered lab chow only, for the other groups test drug or standard (cholestyramine 0.1 to 2%) is added to the diet. After 1 week on these diets, the animals are anesthetized with diethyl ether, a blood sample is taken from the superior vena cava and the liver is removed and weighed. Microsomes are prepared by ultracentrifugation from the livers.

Preparation of plasma lipoprotein profiles

The blood is centrifuged at 600 *g* for 5 min and the plasma removed. The plasma is analyzed for total cholesterol using a colorimetric enzymatic assay (Merck, CHOD-iodine, BDH). The cholesterol content of HDL is determined using a precipitation kit (Merck, BDH).

Quantification of high-density-lipoprotein cholesterol by differential precipitation

Weingand and Daggy (1990) compared the validity of differential precipitation with Mg^{2+}-phosphotungstate for quantification of plasma high-density-lipoprotein cholesterol with ultracentrifugal flotation.

As precipitating agent, 0.55 mmol/l phoshotungstic acid and 25 mmol/l magnesium chloride is added. Cholesterol is determined spectrophotometrically with an enzymatic cholesterol reagent containing microbial cholesterol esterase, in a Hitachi 705 clinical chemistry analyzer.

Fast lipoprotein chromatography

März et al. (1989, 1993) developed fast lipoprotein chromatography for rapid and quantitative analysis of lipoprotein fractions.

Fast lipoprotein chromatography is carried out with a chromatography system from Kontron consisting of two Model 420 pumps, a Model 432 variable-wavelength detector, and a Model 450 data system. Without using a pretreatment, 20 µl of plasma are applied to a 300-mm Superose column 6 equilibrated with 100 mmol/l Na_2HPO_4, pH 7.4, and 200 mmol/l NaCl. Lipoproteins are detected on-line at 500 nm after post-column derivatization with CHOD-PAP cholesterol reagent (Boehringer Mannheim, Germany). The column eluate and the cholesterol reagent are mixed in a motor-driven microchamber attached to the column outlet, and the mixture is then passed through a "knitted" capillary (20–22). The flow rate of the reagent is 70 µl/min; the run time is 80 min. Under these conditions, it takes the column eluate 2 min to pass the derivatization capillary. VLDL-C, LDL-C and HDL-C are calculated on the basis of relative peak areas and total cholesterol.

Tissue preparation

The liver is homogenized in a KCl (0.104 M) solution containing NaF (50 mM) using a glass Teflon homogenizer. The homogenate is centrifuged at 30 000 *g*, 5 °C for 25 min. The supernatant is then centrifuged at 100 000 *g*, 5 °C for 60 min to pellet the microsomes, which are resuspended in potassium phosphate buffer (50 mM) containing NaF (50 mM) adjusted to pH 7.4.

Determination of enzyme activities in microsomal fractions

Protein for all the following assays is determined using the method described by Bradford (1976).

HMG-CoA reductase activity is determined by quantifying the conversion of [^{14}C]HMG-CoA to [^{14}C]mevalonic acid lactone, based on the method described by Ingebritsen and Gibson (1981). ACAT activity in liver microsomes and intestinal cell homogenates is determined by the method described by Suckling et al. (1982), measuring the incorporation of [^{14}C]oleoyl-CoA into cholesteryl oleate. The cholesterol 7α-hydroxylase activity in the microsomes is quantified by determination of the percentage conversion of [^{14}C]cholesterol to 7α-hydroxy[^{14}C]cholesterol. 3 mg of microsomal protein is diluted to a volume of 5.3 ml with a potassium phosphate buffer (50 mM, pH 7.4) containing NaF (50 mM), cysteamine (31.4 mM), glucose-6-phosphate (12.7 mM) NADP (1.4 mM) and [^{14}C]cholesterol (0.22 µCi, 55 Ci/mol). After a short pre-incubation (5 min at 37 °C), the reaction is started by the addition of glucose-6-phosphate dehydrogenase suspension (7 µg). The reaction is stopped 1 h later by adding methanol (5 ml). The cholesterol and 7α-hydroxy-cholesterol are extracted into a mixture of chloroform and methanol (2 : 1, v/v, 2 × 5 ml). The product and substrate are separated by thin-layer chromatography on silica gel eluting with toluene/ethyl acetate (3 : 7, v/v). The radioactive regions corresponding to cholesterol and 7α-hydroxy-cholesterol are scraped off the plates and quantified by liquid scintillation counting.

EVALUATION

Dose-response curves for standard and test drug are established using the control data as zero.

M.2.0.4 Triton-induced hyperlipidemia

PURPOSE AND RATIONALE

The systemic administration of the surfactant Triton to mice or rats results in a biphasic elevation of plasma cholesterol and triglycerides (Frantz and Hinkelman 1955; Garattini et al. 1958, 1961; Holmes 1964; Tamasi et al. 1968).

PROCEDURE

Male Sprague Dawley or Wistar rats weighing 200–350 g are starved for 18 h and then injected intravenously with 200 mg/kg Triton WR 1 339 (isooctyl-polyoxyethylene phenol). Serum cholesterol levels increase sharply 2–3 times after 24 h (phase I). The hypercholesterolemia decreases nearly to control levels within the next 24 h (phase II). The test drugs employed or the solvent for the controls are administered simultaneously with the Triton injection or 22 h thereafter. Serum cholesterol analyses are made 6, 24, and 48 h after Triton injection. The mechanism of the Triton-induced hypercholesterolemia in phase I is thought to be due to increased hepatic synthesis of cholesterol through the ability of Triton to interfere with the uptake of plasma lipids by the tissues. Drugs interfering with cholesterol biosynthesis were shown to be active in phase I, while drugs interfering with cholesterol excretion and metabolism were active in phase II.

EVALUATION
Mean values ± standard deviation are calculated for each group and time interval and compared statistically with the controls.

CRITICAL ASSESSMENT OF THE METHOD
The method employing Triton hypercholesterolemia is rather simple and rapid for detection of compounds interfering with the synthesis and excretion of cholesterol. Since the test is rather artificial, the results have to be validated by other methods.

M.2.0.5 Fructose induced hypertriglyceridemia in rats

PURPOSE AND RATIONALE
Rats switched from a diet low in carbohydrates and high in protein to a high intake of fructose, develop an acute hypertriglyceridemia. Compounds are tested for inhibition of this phenomenon.

PROCEDURE
Male Sprague Dawley rats weighing 200–250 g are fed over a period of one week a diet enriched in protein with reduced carbohydrate content, e.g., Altromin® C1 080 or C1 009. Groups of 10 animals are treated for 3 days daily with the test compound or the standard (clofibrate 100 mg/kg) or the vehicle (polyethylene glycol) by oral gavage. From the second to the third day water is withheld for a period of 24 h. Immediately afterwards, the animals are offered 20% fructose solution ad libitum for a period of 20 h. After this time which is also 20 h after the last application of the test compound, the animals are anesthetized with ether and 1.2 ml blood is withdrawn by retroorbital puncture. The blood is centrifuged for 2 min at 16 000 *g*. Total glycerol is determined in the serum according to Eggstein and Kreutz (1966) and total cholesterol according to Richterlich and Lauber (1962).

EVALUATION
The average values of total glycerol of the treated groups are compared with the control group using Student's *t*-test.

M.2.0.6 Intravenous lipid tolerance test in rats

PURPOSE AND RATIONALE
Intravenous injection of a lipid emulsion results in an increase of triglycerides in serum. The lipolytic activity can be determined by measuring lipid elimination.

PROCEDURE
Male Wistar rats weighing 200–240 g are treated daily with various doses of the test compound or the vehicle over a period of 5 days. On the fifth day, two hours after the last administration of the test compound, the animals are anesthetized with 125 mg/kg sodium hexobarbital i.p. Then they are injected intravenously with 2 ml/kg of a 10% lipid emulsion (Intralipid® Vitrum, Hausmann AG, St. Gallen, Switzerland). Prior to the injection and 10, 20, 30, and 40 min thereafter blood is withdrawn by retro-orbital puncture for determination of triglycerides.

EVALUATION
Peak levels as well as elimination constant and half life are determined.

M.2.0.7 Influence on lipoprotein-lipase activity

PURPOSE AND RATIONALE

Postheparin plasma lipolytic activity is performed by at least two lipase activities: hepatic triglyceride lipase and extrahepatic lipoprotein lipase. Hypothyroid rats show a selective decline of postheparin plasma hepatic triglyceride lipase (Murase and Uchimura 1980). For patients with familial lipoprotein lipase deficiency a rapid diagnostic test was developed (Gotoda et al. 1991). The method was used to study the influence of drugs on lipoprotein lipase activity (Tsusumi et al. 1993).

PROCEDURE

Male Wistar rats weighing 180–200 g receive either various single doses or one daily dose of test compounds over a period of several days. Blood samples are drawn from the tail vein into tubes containing 1 mg EDTA/ml. The animals are then injected with 100 U/kg heparin via the tail vein and blood samples are collected 5 min later. Plasma samples are used to determine lipoprotein lipase and hepatic triglyceride lipase activity.

Lipoprotein lipase activity in postheparin plasma is measured using glycerol tri[1-^{14}C]oleate as substrate and selective blocking of hepatic lipase activity with antiserum to rat hepatic lipase. Hepatic triglyceride lipase activity in postheparin plasma is obtained by subtracting lipoprotein lipase activity from total plasma lipase activity.

EVALUATION

The dose-related increase of plasma lipoprotein lipase activity and the time course after drug administration are evaluated.

M.2.0.8 Influence on several steps of cholesterol absorption and formation

PURPOSE AND RATIONALE

Cholesterol levels in the body result from two sources: absorption from the gut and endogenous *de novo* synthesis. Certain natural and synthetic compounds inhibit cholesterol absorption and reduce plasma cholesterol levels in experimental animals and are therefore of potential pharmacologic interest in the treatment of hypercholesterinemia. Cholesterol absorption can be decreased by inhibition of acyl coenzyme A:cholesterol acyltransferase (ACAT). Inhibition of cholesterol resorption results in a compensatory increase of hepatic 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) activity reductase activity which can be decreased by (HMG-CoA) reductase inhibitors. Harwood et al. (1993) studied the pharmacologic consequences of cholesterol absorption inhibition: alteration in cholesterol metabolism and reduction in plasma cholesterol concentration induced by a synthetic saponin β-tigogenin cellobioside.

PROCEDURE

Male golden Syrian hamsters, weighing 100–120 g, are housed in a reversed light-dark cycle room (light between 3:00 P.M. and 3:00 A.M.) and receive a cholesterol poor diet and water ad libitum 1 week prior to use. The animals are assigned to groups of 6 animals each and are given free access to water and chow that contains the compounds to be tested in appropriate concentrations for 4 days. At 9:00 A.M. of the fourth day of the study, the animals receive a 1.0 ml oral bolus of liquid hamster diet containing 15 mg of [^{3}H]cholesterol (2.25 μCi) and 7.5 mg cholic acid for determining cholesterol absorption. At 9:00 A.M. of the fifth day (peak of the diurnal cycles of HMG-CoA reductase and cholesterol 7α-hydroxylaseα activities) animals are anesthetized with pentobarbital and blood samples are obtained by cardiac puncture for determining plasma cholesterol and triglyceride levels, and cholesterol absorption.

Livers are removed, weighed, rinsed in 4 °C saline, and apportioned for determining hepatic cholesterol levels, hepatic HMG-CoA reductase, cholesterol 7α-hydroxylase activities, hepatic LDL receptor concentration, and cholesterol absorption.

Hepatic microsomes for measurement of hepatic HMG-CoA reductase activity and cholesterol 7α-hydroxylase activity are prepared according to Harwood et al. (1984) and Junker and Story (1985). For measurement of HMG-CoA reductase activity, 0.5 g liver are immediately homogenized at 4 °C in 1 ml TEDK buffer (containing 50 mM Tris (pH 7.5), 1 mM EDTA, 5.0 mM dithiothreitol, and 70 mM KCl) using 15 strikes in a Dounce homogenizer. For measurement of cholesterol 7α-hydroxylase activity, 0.5 g liver pieces are immediately homogenized at 4 °C in 1 ml PEDSKF buffer (containing 40 mM phosphate (pH 7.4), 5 mM EDTA, 5 mM DTT, 250 mM sucrose, 50 mM KCl, and 50 mM KF) using 20 strokes of a Dounce homogenizer. Homogenates are first centrifuged at 4 °C for 20 min at 10 000 *g* and the resultant supernatant is then centrifuged at 4 °C for 90 min at 178 000 *g*. The resulting microsomal pellets are resuspended in either 1.0 ml TEDK per g liver (HMG-CoA reductase determination) or 1 ml PEDSKF per g liver (cholesterol 7α-hydroxylase determination) by 5 strokes of a Potter-Elvehjem pestle and are stored frozen in liquid nitrogen.

For measurement of hepatic HMG-CoA reductase activity, 50 µg of microsomal protein is incubated for 30 min at 37 °C in a final volume of 75 µl of TEDK buffer containing 3.4 mM $NADP^+$, 30 mM glucose-6-phosphate, 66.7 µM [^{14}C]HMG-CoA (10 cpm/pmol), 15 000–20 000 cpm [^{3}H]mevalonate (0.6–1.2 Ci/mmol) as an internal standard, and 68 mM EDTA to prevent conversion of mevalonate to phosphomevalonate during incubation. After incubation, 10 µl of 6 M HCl are added to terminate the enzyme reaction and to convert the newly formed mevalonate to mevalonolactone. The mevalonolactone is then separated from unreacted substrate by silica gel thin-layer chromatography. After development in toluene-acetone 1 : 1, the region of the chromatogram corresponding to $R_f = 0.4–1.0$ is removed, immersed in liquid scintillation fluid, and counted using a dual channel $^3H/^{14}C$ program. HMG-CoA reductase activity is expressed as pmoles of mevalonate formed from HMG-CoA per min of incubation at 37 °C per mg of microsomal protein.

Cholesterol 7α-hydroxylase activity is measured in liver microsomes according to Junker and Story (1985) with increased specific activity of the added radiolabeled cholesterol in order to enhance the sensitivity of the method. An aliquot of 0.5 µg of microsomal protein, in a final volume of 200 µl PEDKF buffer (containing 40 mM phosphate (pH 7.4), 5 mM EDTA, 5 mM DTT, 50 mM KCl, and 50 mM KF), is mixed in a 16 × 125 mm test tube with 100 µl PEDKF containing 0.5 µCi [^{14}C]cholesterol, 0.5 mg Triton WR-1 339, and 5 µl acetone. The mixture is incubated in a covered, shaking water bath at 37 °C for 1 h to allow exogenously added [^{14}C]cholesterol to equilibrate with the unlabeled microsomal cholesterol pool.

The enzymatic reaction is initiated by addition of 250 µl of 70 mM phosphate buffer (pH 7.4) containing 1.25 mM $NADP^+$, 10 mM glucose-6-phosphate, 2 U glucose-6-phosphate dehydrogenase, and 10 mM β-mercaptoethyleneamine. After a 30 min-incubation at 37 °C, the reaction is terminated by addition of 7.5 ml chloroform:methanol 2 : 1 and vigorously mixed for 20 s. One ml distilled water is then added and the mixtures are vigorously shaken for an additional 10 s. After centrifugation at 2 500 rpm for 5 min at 4 °C, the chloroform layer is transferred to a test tube and evaporated to dryness under nitrogen. The resultant lipid residue is dissolved in 100 µl chloroform and 20 µl aliquots are applied to silica gel thin-layer plates and developed in toluene:ethylacetate 1 : 9. The region of the chromatogram corresponding to 7α-hydroxycholesterol is removed from the plate, mixed with 10 ml of liquid scintillation fluid and assessed for radioactivity. Cholesterol 7α-hydroxylase activity is expressed as pmoles of 7α-hydroxycholesterol formed from cholesterol per min of incubation per mg microsomal protein. The substrate specific activity for each microsomal sample is calculated by dividing the total substrate radioactivity by the total amount of cholesterol present in the assay.

Hepatic LDL receptor levels are measured by enzyme immune blotting (Cosgrove et al. 1992). One hundred –150 µl of the soluble extracts containing 100–600 µg protein are adjusted to 2% SDS and 0.2 M sucrose by addition of 0.33 volumes of electrophoresis sample buffer (containing 320 mM Tris (pH 6.8), 8% SDS, and 0.8 M sucrose). Mixtures are applied without heating and without addition of β-mercaptoethanol to 6-mm wells of a 7.5% (w/w) 0.1% SDS-containing polyacrylamide slab gel of 1.5 mm thickness. Electrophoresis is conducted at room temperature with a constant current of 15 mA/gel. Prestained molecular weight markers are included in a separate lane to monitor separation. After electrophoresis, proteins migrating into the gel are electrophoretically transferred to S&S BA85 nitrocellulose membranes at 18 °C with a con-

stant voltage of 120 V for 6–8 h in 25 mM Tris, 192 mM glycine buffer (pH 8.3), containing 20% methanol.

After transfer, the nitrocellulose paper is incubated with 100 ml of Tris buffered saline containing 3% gelatin for 30 min at room temperature with gentle shaking. After incubation, the nitrocellulose sheet is removed from the blocking solutions, immersed without rinsing into 50 ml Tris buffer solution (TBS) containing 1% gelatin and 250 µl of anti-LDL receptor peptide antiserum (final dilution 1 : 200) and incubated for 2 h at room temperature with gentle shaking. The nitrocellulose sheet is washed twice for 10 min each with TBS containing 0.05% Tween-20 and once for 10 min with TBS. The washed nitrocellulose sheet is incubated with 50 ml TBS containing 1% gelatin and 100 µl of goat anti-rabbit IgG-horseradish conjugate (final dilution 1 : 500) at room temperature for 1 h with gentle shaking. After incubation, the nitrocellulose is washed again as described above. During this final wash, 40 mg of 4-chloro-1-naphthol is dissolved in 10 ml methanol, and 50 µl cold 30% hydrogen peroxide is added to 50 ml TBS containing 1% gelatin. After draining the final TBS wash from the nitrocellulose, the two solutions are mixed and immediately added to the nitrocellulose. The mixture is incubated at room temperature with gentle shaking until the desired color development is observed. The nitrocellulose sheet is washed with running tap water for 15 min. The nitrocellulose is dried between pieces of filter paper and the intensity of color formation is quantitated by reflectance densitometry using a suitable instrument (e.g., Hoefer Scientific Instruments GS300 Transmittance/Reflectance Scanning Densitometer). Color intensity, which is a linear function of the number of LDL receptors in the analyzed fraction, is expressed in terms of mm peak height (arbitrary reflectance units).

Intestinal cholesterol absorption is estimated from the sum of radioactivity present in the liver and plasma 24 h after an oral bolus of [^{3}H]cholesterol. For assessment of hepatic radioactivity, 1.0-g liver pieces are placed in 50-ml polypropylene tubes and incubated with 2.5 ml of 2.5 M KOH for 2 h at 75 °C. After allowing the saponification mixture to cool to room temperature, 5.0 ml of 80% ethanol, 0.1 ml [^{14}C]cholesterol (40 000 dpm, 15 dpm/nmol) as carrier and extraction standard and 10 ml of hexane are added. Tubes are capped and shaken vigorously for 1 min. Mixtures are permitted to stand to allow phase separation, and are shaken vigorously for an additional minute. Mixtures are the centrifuged at 1 000 *g* for 5 min. Duplicate 3.0-ml aliquots of each hexane layer are removed, transferred to 20-ml liquid scintillation vials, mixed with 10 ml liquid scintillation fluid, and counted using a dual channel ^{3}H/^{14}C program.

After correction for recovery losses, hepatic radioactivity is calculated based on total liver weights. For assessment of total plasma radioactivity, 200-µl aliquots of plasma are added to 20 ml liquid scintillation vials and decolorized by addition of 25 µl of hydrogen peroxide. Ten ml aqueous scintillation fluid is added and the mixture assessed for radioactivity. Total radioactivity in the plasma is calculated based on the assumption that hamsters possess approximately 4.0 ml plasma per 100 g body weight. The degree of cholesterol absorption is expressed as a percentage of the total radioactivity administered that is present in the liver plus plasma 24 h after bolus administration.

For determination of **hepatic cholesterol concentration**, a 200-µl aliquot of the liver homogenate obtained after Dounce homogenization in TEDK buffer is mixed with 350 µl of TEDK buffer in a test tube. Chloroform-methanol 2 : 1 (7.5 ml) is then added and the suspension is vigorously mixed for 1 min. The sample is allowed to stand for 20 min, then 1 ml deionized water is added and the mixture vigorously shaken for 10 s. The mixture is centrifuged at 6 000 rpm for 15 min at room temperature. The chloroform-methanol layer is removed, placed in a 13 × 100 mm test tube, and evaporated to dryness under nitrogen at 37 °C. The lipid residue is resuspended in 200 µl isopropanol and the cholesterol concentration determined according to Assmann et al. (1983). Total hepatic cholesterol concentrations are expressed as µg cholesterol per mg hepatic protein.

For **plasma lipid and lipoprotein determinations**, blood plasma samples are treated either with EDTA or heparin to prevent clotting and are then centrifuged at 2 500 rpm for 30 min at 4 °C. The resultant plasma is removed and analyzed for cholesterol and triglyceride content using commercially available kits. HDL-cholesterol concentration is measured directly after precipitation with phoshotungstic acid/$MgCl_2$ of apoB-containing lipoproteins (Assmann 1983). Non-HDL cholesterol concentration (LDL + IDL + VLDL) is estimated by subtraction.

EVALUATION

Inhibition of cholesterol resorption results in a decrease of hepatic cholesterol and a compensatory increase of hepatic HMG-CoA reductase activity resulting from de novo cholesterol synthesis and an increase of hepatic LDL receptor levels.

MODIFICATIONS OF THE METHOD

Ogishima and Okuda (1986) described an improved method for assay of cholesterol 7α-hydroylase activityα. Cholesterol 7α-hydroxylation is performed in liver microsomes utilizing cholesterol as substrate. 7α-Hydroycholesterol is converted by the action of cholesterol oxidase into 7α-hydro-4-cholesten-3-one having an intense absorption at 240 nm.

Hylemon et al. (1989) reported a modified HPLC-spectrophotometric method for measuring cholesterol 7α-hydroxylase activity by using a C-18 reverse-phase column to separate 7α-hydroxy-4-cholesten-3-one and 4-cholestene-3-one and by adding 7β-hydroxycholesterol to each reaction mixture as an internal recovery standard. This method measures simultaneously cholesterol 7α-hydroxylase activity using endogenous cholesterol and exogenous [4-^{14}C]cholesterol as substrate.

Princen and Meijer (1990) measured cholesterol 7α-hydroxylase activity in cultured rat hepatocytes.

M.3
Inhibition of cholesterol biosynthesis

M.3.1
General considerations on cholesterol biosynthesis

The following steps are involved in cholesterol biosynthesis:

- HMG-CoA synthase (hydroxymethylglutaryl-coenzyme A synthase)
- forming **hydroxymethylglutaryl-CoA** from acetyl-CoA and acetoacetyl-CoA
- HMG-CoA reductase (hydroxymethylglutaryl-coenzyme A reductase)
- forming **mevalonic acid** from hydroxymethylglutaryl-CoA.

Inhibition of cholesterol synthesis on this step is used at present successfully for therapy (see below)

- Mevalonate kinase forming **5-phospho-mevalonic acid** from mevalonic acid,
- Phospho-mevalonate kinase forming **5-pyrophospho-mevalonic acid** from 5-phospho-mevalonic acid,
- Pyrophospho-mevalonate decarboxylase forming **3-isopentyl-pyrophosphate** from 5-pyrophospho-mevalonic acid,
- Isopentyl-pyrophosphate isomerase forming **3,3-dimethyl-pyrophosphate** from 3-isopentyl-pyrophosphate,
- Dimethylallyl-transferase forming in a two step process **geranyl pyrophosphate** from 3,3-dimethyl-pyrophosphate, and
- **farnesyl pyrophosphate** from geranyl pyrophosphate,
- Squalene synthetase forming **squalene** from farnesyl pyrophosphate,
- Squalene epoxidase forming **2,3 oxidosqualene** from squalene,
- 2,3-Oxidosqualene cyclase forming **lanosterol** from 2,3 oxidosqualene.

Following the formation of lanosterol (4,4,14α-trimethylcholesta-8(9),24-dien-3β-ol), a series of enzyme reactions is required to produce cholesterol (Bae et al. 1999):

- to 4,4,14α-trimethylcholesta-8(9)-en-3β-ol,
- to 4,4-dimethylcholesta-8(9),14-dien-3β-ol,
- to 4,4-dimethylcholesta-8(9)-en-3β-ol,
- to cholesta-8(9)-en-3β-ol,
- to cholesta-7-en-3β-ol,

- to cholesta-5,7-dien-3β-ol (7-dehydrocholesterol), and finally
- to cholesta-5-en-3β-ol (cholesterol) by 7-dehydrocholesterol reductase.

Besides **inhibition of HMG-CoA reductase** (detailed description below) other approaches to inhibit biosynthesis of cholesterol are reported:

- **inhibition of HMG-CoA synthase** (Goldstein and Brown 1990; Miller et al. 1980; Greenspan et al. 1987; Grayson and Westkaemper 1988);
- **inhibition of squalene synthase** (Biller et al. 1991a,b; Oehlschlager et al. 1991; Baxter et al. 1992; Ciosek et al. 1993; Ness et al. 1994; Harris et al. 1995; Chan et al. 1996; Dufresne et al. 1996; McTaggart et al. 1996; Amin et al. 1997; Sliskovic and Picard 1997; Rosenberg 1998; Vaidya et al. 1998; Hiyoshi et al. 2000; Ugawa 2000);

  Squalene synthase plays an important role in sterol biosynthesis by catalyzing the head-to-head condensation of two molecules of farnesylpyrophosphate. The enzyme is a single 47 000 Da polypeptide that is bound to the subcellular membranes of the endoplasmatic reticulum in yeast and mammalian liver;
- **inhibition of squalene epoxidase** (Horie et al. 1990, 1991; Moore et al. 1992; Ryder 1992);

  Squalene epoxidase catalyzes the conversion of squalene to (3*S*)-2,3-oxidosqualene, an essential step in the biosynthesis of sterols in mammals, plants, and microorganisms.

  A simplified squalene epoxidase assay based on HPCL separation and time-dependent UV/visible determination of squalene was published by Grieveson et al. (1997);
- **inhibition of 2,3-oxidosqualene cyclase** (Gerst et al. 1986; Cattel et al. 1989; Sen and Prestwich 1989; Dollis and Schuber 1994; Mark et al. 1996; Eisele et al. 1997; Morand et al. 1997; Abe et al. 1998a);

  The enzyme 2,3-oxidosqualene cyclase is of special interest due to its dual function: cyclization of 2,3-monoepoxysqualene to lanosterol and 2,3:22,23-diepoxysqualene to oxylanosterol.

  An orally active oxidosqualene:lanosterol cyclase inhibitor (Ro48-8 071) showed potent noncompetitive inhibition of bacterial squalene:hopene cyclase from *Alicyclobacillus acidocaldarius*. A tritium-labeled isotopomer of this nonterpenoid inhibitor, which possesses a benzophenone photophore, was chemically synthesized as a photoaffinity label (Abe et al. 1998b);
- **inhibition of 7-dehydrocholesterol reductase** (Amin et al. 1996);

  Deficiency of this enzyme causes a severe developmental disorder with multiple congenital and morphogenic abnormalities, the Smith-Lemli-Opitz syndrome (Waterham and Wanders 2000).

Search and development of new cholesterol-lowering drugs is continued (Abe and Prestwich 1998). Whether the efficacy and safety of these agents in man will be on the long run superior to currently available therapies remains to be determined.

M.3.2
Determination of HMG-CoA-reductase inhibitory activity

M.3.2.1
General considerations on HMG-CoA reductase

More than 70% of the total production of body cholesterol in humans is derived from de novo synthesis. 3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase is the rate limiting enzyme governing cholesterol biosynthesis and the synthesis of other isoprenoids in mammalian cells (Rodwell et al. 1976). The development of HMG-CoA reductase inhibitors offers an advance in the treatment of hypercholesterolemia by interfering with the crucial step of cholesterol biosynthesis. When inhibiting hepatic HMG-CoA reductase, the inhibitors trigger an increased production of LDL receptors in the liver. As LDL receptor activity increases, more LDL is extracted from the

blood and thus the level of circulating LDL-cholesterol is reduced. Pharmacological evaluation of HMG-CoA reductase inhibitors is based on studies on the inhibition of the isolated enzyme HMG-CoA -reductase *in vitro*, on the inhibition of the incorporation of ^{14}C sodium acetate into cholesterol in isolated liver cells, and on the effect of HMG-CoA -reductase inhibitors *in vivo*. HMG-CoA reductase activity has a diurnal rhythm in liver and intestine which has to be considered for *in vivo* studies (Shapiro and Rodwell 1969; Shefer et al. 1972).

HMG-CoA reductase inhibitors have been associated with skeletal myopathy in humans and experimental animals (Flint et al. 1997). The search for other inhibitors of cholesterol biosynthesis without myotoxicity seems to be worthwhile.

M.3.2.2 Inhibition of the isolated enzyme HMG-CoA-reductase *in vitro*

PURPOSE AND RATIONALE

For screening purposes, studies on the inhibition of HMG-CoA reductase obtained from rat liver microsomal fraction can be used (Avigan et al. 1975; Philipp and Shapiro 1979).

PROCEDURE

The inhibitory activity of the test compound on HMG-CoA reductase is estimated with soluble enzyme preparations obtained from the microsomal fraction of rat liver (Philipp and Shapiro 1979). The enzyme reaction is carried out with 50 µl partially purified HMG-CoA reductase in buffer containing 25 mM Tris, 10 mM EDTA, and 10 mM dithiothreitol at pH 7.5, 20 µl of 910 µM HMG-CoA solution containing 100 nCi (3.7 KBq) of ^{14}C-HMG-CoA and 20 µl of NADPH regenerating system (5.2×10^{-2} M glucose-6-phosphate, 1 unit glucose-6-phosphate dehydrogenase, 5.3×10^{-3} M NADP), with the actual concentration of 50 mM NADPH. The final incubation volume is 200 µl. The main reaction is preceded by 20 min preincubation with the NADPH regenerating system at 37 °C, followed by 20 min incubation at 37 °C of the completed samples with the test compound or the standard and stopped by addition of 75 µl 2 N $HClO_4$. After 60 min at room temperature, the samples are cooled in an ice-bath and neutralized by addi-

tion of 75 µl 3 N potassium acetate. Supplementing the volume with water to 500 µl, the precipitate is centrifuged and 250 µl of the clear supernatant are applied to a column (0.6 × 8.0 cm) of BIORAD AG 1-X8 (100–200 mesh). Mevalonolactone is eluted with water discarding the first 750 µl and collecting the next 3 500 µl. Five hundred µl of the eluate are used for measurement in duplicate, mixed in vials with 10 ml Quickscint (Zinsser) and measured in a liquid scintillation counter (Beckman). The assay is generally performed in triplicate. Lovastatin sodium is used as standard.

EVALUATION

The mean values with and without inhibitors are compared for the calculation of inhibition. IC_{50} values are calculated.

M.3.2.3 Inhibition of the incorporation of ^{14}C sodium acetate into cholesterol in isolated liver cells

PURPOSE AND RATIONALE

De novo synthesis of cholesterol from labelled acetate can be measured in isolated liver cells. This synthesis can be inhibited by incubation with HMG-CoA reductase inhibitors.

PROCEDURE

Monolayers of primary cell cultures from hepatocytes of female rats or of cultures of HEP-G2 cells (human hepatoma cells) are incubated in a lipoprotein deficient medium for 1 h with various concentrations of the potential HMG-CoA reductase inhibitor or the standard (Lovastatin). Thereafter, the labelled precursor ^{14}C sodium acetate is added to the medium and the incubation continued for further 3 or 24 h. To one part of the cells an internal standard of ^{3}H-cholesterol is added and the cells are saponified by alkaline. The lipids of these saponified cells are extracted with chloroform/methanol. The lipid mixture is separated by preparative thin layer chromatography. The localization of cholesterol is identified by exposure to iodine vapor and the amount of newly synthesized ^{14}C-cholesterol is determined in a scintillation counter.

Cell protein is determined in another part of the cells. A third part of the cell culture is used to control the integrity of the cells by light microscopy and tested biologically by determination of the release of lactate dehydrogenase into the incubation medium.

EVALUATION

The amount of newly synthesized cholesterol per mg cell protein is calculated. The inhibitory capacity of the test drug is estimated against a solvent control. IC_{50} values are calculated from the results of various concentrations.

MODIFICATIONS OF THE METHOD

Chen and Kandutsch (1976) studied the effects of cholesterol derivatives on sterol biosynthesis in cultures of various cell types.

Liver specificity of inhibition of sterol synthesis is studied by *in vitro* uptake into hepatocytes and human skin fibroblasts (Scott 1990) or in slices of various tissues after oral treatment with HMG-CoA reductase inhibitors (Tsujita 1990).

Shaw et al. (1990), however, caution against the use of HEP-G2 cells which may not be the cell system of choice to demonstrate liver selectivity of inhibitors of HMG-CoA reductase.

Cultures of HEP-G2 cells have also be used to test inhibition of cytoplasmic acetoacetyl-CoA thiolase (Greenspan et al. 1989) or inhibition of squalene epoxidase (Hidaka et al. 1991).

Pearce et al. (1992) used HEP G2 cells to study the hypocholesterolemic activity of synthetic and natural tocotrienols *in vitro*.

Raiteri et al. (1997) investigated drugs acting at different steps of the mevalonate pathway on arterial smooth muscle cell proliferation. Competitive HMG-CoA reductase inhibitors dose-dependently decreased smooth muscle cell proliferation.

M.3.2.4 *Ex vivo* inhibition of cholesterol biosynthesis in isolated rat liver slices

PURPOSE AND RATIONALE

Inhibition of cholesterol biosynthesis in rat livers can be measured in an *ex vivo* assay after oral treatment with HMG-CoA reductase inhibitors by cholesterol synthesis from labelled sodium octanoate.

PROCEDURE

Male Sprague Dawley rats weighing 110–130 g are kept on a reverse light cycle (lights 3:00 P.M. to 3:00 A.M.) for 14 days prior to use. Throughout the period of adaptation, the rats have free access to a low cholesterol diet and tap water. On the day of the experiment, the test compounds are given orally between 9:00 and 11:00 A.M. as suspensions in 0.5% methylcellulose. After one hour, the rats are sacrificed, the livers removed and transferred to chilled oxygenated Krebs-Ringer-bicarbonate buffer (pH 7.4). The livers are then chopped into 0.8-mm^2 pieces using a McIlwain tissue chopper (e.g., Brinkmann Instr., Westbury, USA) and are suspended in the same buffer. Aliquots of the suspension are pipetted, in triplicate, into culture tubes which contain [^{14}C]sodium octanoate (300 µM/l, 6.67 Ci/M). The assay volume is 1 ml. The tubes are gassed with 95% O_2/5% CO_2 for 10 s, stoppered with a serum cap, and incubated at 37 °C in a metabolic shaker at 150 oscillations/min for 90 min.

The reaction is stopped by addition of 1 ml 15% KOH in ethanol. An aliquot of the mixture is assayed for protein concentration. An internal standard [^{3}H]cholesterol (30 000 dpm) is added to determine recovery, which ranges from 70–80%. The tubes are saponified at 75 °C for 2 h and then extracted with 10 ml of petroleum ether for 30 min. The lower aqueous phase is frozen in a dry ice/alcohol mixture, and the ether phase is removed, washed with 2 ml glass-distilled water and then evaporated to dryness. The [^{14}C]cholesterol synthesized is separated by thin layer chromatography on plastic silica gel plates using chloroform as eluent. After visualization with iodine, the cholesterol spots are cut out, and radioactivity quantitated by liquid scintillation counting.

EVALUATION

Results are expressed as percentage inhibition compared to vehicle-treated control values. Using various doses, ED_{50} values of inhibition can be calculated from dose-response curves.

MODIFICATIONS OF THE METHOD

Koga et al. (1990) tested the tissue-selective inhibition of cholesterol synthesis *in vivo* by pravastin sodium in mice. Drugs were orally administered to mice 2 h prior to an intraperitoneal injection of [^{14}C]acetate. The animals were sacrificed 1 h afterwards and the cholesterol synthesis determined in various organs.

M.3.2.5 Effect of HMG-CoA-reductase inhibitors *in vivo*

PURPOSE AND RATIONALE

A strain of rabbits with heritable hyperlipidemia, the WHHL strain, has been described by Watanabe et al. (1980, 1985, 1988). These animals develop digital xanthoma and aortic and coronary atherosclerosis already at an early age. This animal is considered to be a suitable model for the evaluation of preventive or even regressive effects of drugs on hyperlipidemia and atherosclerosis.

PROCEDURE

Male heterozygous WHHL rabbits weighing 1.8 to 2.5 kg at an age between 8 and 20 weeks are used. The animals are housed individually under standard conditions (standard rabbit diet and water ad libitum) and are allowed to accommodate 2 weeks prior to treatment. The test compounds are suspended in 0.5% methylcellulose and are administered each day orally by gavage in the afternoon to insure an increased plasma level at night, since in man HMG-CoA reductase activity has been found to be higher at night than during daytime (Shapiro and Rodwell 1969; Shefer et al. 1972) similar to the enzyme in rodents. The treatment is continued for 14 days.

Blood samples are taken in the morning without previous feeding. Two ml of blood are drawn from the outer ear vein 5 days prior to the beginning of treatment, on days 3 and 8 of treatment and 30 days after the end of treatment for the determination of biochemical parameters. In addition, 6 ml blood are drawn at the first and the last day of treatment and 10 days after the end of treatment for determination of biochemical parameters and lipoprotein profile. In order to obtain serum, blood is allowed to clot at room temperature and then centrifuged twice at 10 000 rpm.

The following biochemical parameters are determined in non-frozen samples (kept at 4 °C): total cholesterol, HDL-cholesterol, triacylglycerol, as well as creatinine, total bilirubin, alkaline phosphatase, alanine amino transferase (ALAT), aspartate amino transferase (ASAT), and γ-glutamyl transferase (γ-GT) using commercially available kits.

The separation of serum lipoproteins by gel permeation chromatography is performed according to Ha and Barter (1985). This method is particularly well suited for the metabolic studies of lipoproteins, because the elution profile can be obtained from the same sample under more gentle conditions than by sequential ultracentrifugation. According to their descending particle size, the elution profile of lipoproteins in the same fraction of density (<1.21 g/ml) shows, as the elution progresses, three major peaks which correspond to very low density lipoproteins (VLDL), low density lipoproteins (LDL) and high density lipoproteins (HDL), respectively.

Since the amount of serum collected from one rabbit is too low to determine the lipoprotein profile from each sample, the total lipoproteins are isolated by ultracentrifugation at a density < 1.21 g/ml and the lipoproteins thus obtained in each group are pooled two by two prior to injection onto the cross-linked agarose HR 50 column (Superose 6B). As a result, each lipoprotein profile represents the lipoprotein size distribution of an equal volume of lipoproteins obtained from two rabbits. Cholesterol and triacylglycerol concentrations are determined in each 1 ml elution fraction.

EVALUATION

The data at 5 days before beginning of treatment and of day 0 of each animal are pooled and the mean is taken as reference value. Student's paired *t*-test is used to calculate for each group the significance of difference between mean values.

MODIFICATIONS OF THE METHOD

Extension of the treatment period up to 24 weeks allows to evaluate the meanwhile apparent atherosclerotic lesions in the aorta and the coronaries by gross observation and light microscopy (Tsujita 1990).

Kasim et al. (1993) studied the effect of lovastatin on the secretion of very low density lipoprotein lipids and apolipoprotein B in the Zucker obese rat

which is basically a model for genetic hypertriglyceridemia.

Soma et al. (1993) studied the effects of HMG-CoA reductase inhibitors on carotid intimal thickening induced by placing a nonocclusive, biologically inert, soft, hollow Silastic collar around both carotid arteries in normocholesterolemic rabbits (Booth et al. 1989).

Bocan et al. (1994) assessed atherosclerotic lesion development in the thoracic artery and chronically denuded iliac-femoral artery of hypercholesterolemic New Zealand White rabbits using inhibitors of HMG-CoA reductase.

M.4 Inhibition of cholesterol absorption

M.4.1 Inhibition of ACAT (Acyl coenzyme A:cholesterol acyltransferase)

M.4.1.1 General considerations

Acyl coenzyme A:cholesterol acyltransferase (ACAT), which catalyses the intracellular formation of cholesteryl esters, plays an important role in the intestinal absorption of cholesterol, foam cell formation within the arterial wall and VLDL production in the liver. Cholesterol is absorbed from the gut exclusively in the unesterified form, but appears in the lymph esterified with various long-chain unsaturated fatty acids. The enzyme responsible is ACAT, a microsomal enzyme, that utilizes long-chain fatty acyl coenzyme A and cholesterol as substrates. ACAT inhibitors also have potential actions beyond inhibition of cholesterol absorption. Inhibition of hepatic ACAT could reduce the production of cholesteryl esters for packaging into lipoproteins, while inhibition of ACAT in the arterial wall could reduce the deposition of cholesteryl esters in atherosclerotic lesions.

Human ACAT cDNA was cloned from a human macrophage cDNA library and expressed in an ACAT deficient line of Chinese hamster ovary cells. The cDNA, labelled K1, encoded an integral membrane protein of 550 amino acids (Chang et al. 1993). The inhibition of ACAT as treatment for hypercholesterolemia and atherosclerosis is an attractive target.

M.4.1.2 *In vitro* ACAT inhibitory activity

PURPOSE AND RATIONALE

In vitro ACAT inhibitory activity can be determined in microsomal preparations from liver or intestine of rabbits.

PROCEDURE

Hepatic or intestinal microsomes are prepared from rabbits. Prior to sacrifice, the animals receive chow supplemented with 2% cholesterol and 10% safflower oil for 6 weeks. Each assay contains 0.2 mg of microsomal protein and fatty acid-poor bovine serum albumin (3 mg/ml) in 0.04 M KH_2PO_4 buffer, pH 7.4, containing 0.05 M KCl, 0.03 M EDTA, and 0.3 M sucrose. Drug dilutions are made in DMSO (5 µl DMSO/200 µl total incubation volume). The reaction is started by the addition of [^{14}C]oleyl CoA (50 µM, 7 dpm/pmol). After 3 min the reaction is stopped by the addition of chloroform-methanol 2 : 1. [^{3}H]Cholesteryl oleate is used as an internal standard. Lipid extracts are dissolved in chloroform, spotted on TLC plates (silica gel G) and developed in hexane-petroleum ether-acetic acid 80 : 20 : 1. Unlabeled, carrier cholesterol oleate is added to the internal standard to aid band visualization with iodine vapor. The band corresponding to cholesteryl esters is then scraped into scintillation vials and radioactivity is determined by liquid scintillation spectroscopy.

EVALUATION

For each compound four concentrations are evaluated in duplicate. IC_{50} values are determined by performing a nonlinear least-squares fit of the data to a log dose-response curve.

MODIFICATIONS OF THE METHOD

Rothblatt et al. (1977) studied ACAT activity in Fu5 rat hepatoma cells under the influence of hyperlipemic serum lipoproteins.

Mathur et al. (1981) studied ACAT activity in hepatic microsomes of cynomolgus monkeys during diet-induced hypercholesterolemia.

Einarsson et al. (1989) studied acyl-CoA:cholesterol acyltransferase activity in human liver microsomes.

Largis et al. (1989) found CL 277,082 to be a potent inhibitor of ACAT in microsomes from a variety of tissues and smooth muscle cells in culture.

Heffron et al. (1990) studied ACAT inhibition in microsomal fractions of the transformed mouse macrophage J774.

Bell et al. (1992) measured ACAT inhibition in cultured Fu5AH cells.

Field et al. (1991), Krause et al. (1993) tested the inhibition of ACAT in CaCo-2 cells.

M.4.1.3 *In vivo* tests for ACAT inhibitory activity

PURPOSE AND RATIONALE

Most authors test the *in vivo* anti-atherosclerotic and antihyperlipemic effect of ACAT inhibitors in cholesterol-fed hypercholesterolemic animals (Balasubramaniam et al. 1990; Harris et al. 1992; Tanaka et al. 1944). Krause et al. (1993a) used the Zilversmit dual isotope technique (Zilversmit 1972; Cayen and Dvornik 1979) for determining cholesterol absorption in rats.

PROCEDURE

Male Sprague-Dawley rats weighing 200–225 g are fed with a diet containing 5.5% peanut oil, 0.5% cholic acid and 1.5% cholesterol with or without (controls) drugs for 1 week. On the last day, food is removed at 8:00 A.M. and the isotopes are administered beginning at 2:00 P.M. [^{3}H]cholesterol (13 μCi/rat) is given by oral gavage and [^{14}C]cholesterol (1.5 μCi/rat) is given is given by tail vein injection. The [^{3}H]cholesterol is prepared as an emulsion by dissolving 125 mg cholesterol in 1 625 mg olive oil. The oil phase is suspended by sonication in 25 ml of water containing 156 mg taurocholate (sodium salt). Each animal receives 1 ml. The intravenous dose is prepared by drying the labeled cholesterol (50 μCi), and then adding 300 μl warm ethanol followed by 12.5 ml of saline. Each animal receives 0.5 ml of this colloidal suspension. The rats are allowed to consume their respective diets at 3:00 P.M., and are sacrificed 48 h after the isotope administration.

EVALUATION

The percentage of an oral dose of cholesterol absorbed is calculated from the plasma isotope ratio (% of the oral dose in 2 ml plasma/of the intravenous dose in 2 ml plasma × 100).

FURTHER IN VIVO METHODS

Heider et al. (1983) measured cholesterol absorption via the Zilversmit dual isotope method in rabbits.

Gillies et al. (1990) studied the regulation of ACAT activity by a cholesterol substrate pool during the progression and regression phases of atherosclerosis in rabbits with dietary induced atherosclerosis.

Krause et al. (1993b) compared the activities of two ACAT-inhibitors in normocholesterolemic and hypercholesterolemic rats, rabbits, guinea pigs and dogs.

Nagata et al. (1995) tested a new ACAT inhibitor in diet-induced atherosclerosis formation in female C57BL/6J mice.

Bocan et al. (1993) described a reduction of VLDL and vessel wall cholesteryl ester content in Yucatan micropigs after treatment with an ACAT inhibitor.

M.4.1.4 Lymph fistula model for cholesterol absorption

PURPOSE AND RATIONALE

Direct evidence for an inhibitory effect on cholesterol absorption can be obtained by the lymph-fistula model in rats. This model also provides an indication as to the duration of inhibition and the relative selectivity of the compound on the absorption of cholesterol versus triglyceride and phospholipid.

PROCEDURE

Rats are anesthetized by an intramuscular injection of tiletamine/zolazepam (Telazol, 40 mg/kg). Silicon rubber cannulae are placed into the main mesenteric lymph duct and into the duodenum and secured with sutures. Animals are allowed to recover from surgery overnight in restraining cages while infused intraduodenally with 2% dextrose in saline containing 0.03% KCl (2.5 ml/h). Drinking water is allowed at libitum during this recovery period.

At 6:00 A.M. the following day, the drinking water is removed and a 2-h basal lymph sample is collected. Then, the animals are given the ACAT inhibitor at a specified dose as a single bolus into the duodenal cannula using a aqueous CMC/Tween suspension vehicle. Controls receive a bolus injection of the vehicle alone. Immediately after the drug dose, a lipid emulsion containing 0.1% cholesterol, 0.11% sodium taurocholate, 15% Intralipid (20%, Kabivitrium Inc.), 2.4% safflower oil, and 82.6% saline is infused into the duodenal cannula (3 ml/h). Then, four 2-h lymph collections are obtained. The lymph samples are extracted into hexane in the presence of a stigmasterol internal standard. Total and free cholesterol are quantitated by liquid gas chromatography.

EVALUATION

Esterified cholesterol of lymph is determined from difference between total and free cholesterol.

MODIFICATIONS OF THE METHOD

The lymph fistula model can also be used to examine the effect of ACAT inhibitors on the absorption of endogenous (i.e. biliary) cholesterol. Cannulated rats are infused intraduodenally with the saline/dextrose solution to which 2% whole rat bile is added containing [^{14}C]cholesterol. No nonradiolabeled lipid other than that in bile is infused into the animals, and hence, lymph cholesterol is exclusively of biliary origin. Hourly collections of lymph are obtained with the use of fraction collectors. Lymph is extracted with 3 volumes of ethylacetate-acetone 2 : 1 (Slayback et al. 1977). The total ^{14}C label of an aliquot of lymph extract is determined by liquid scintillation spectroscopy. The lymph extracts are resuspended in 100 µl chloroform-methanol 2 : 1 and spotted on Whatman LK6D TCL plates. The plates are developed in hexane-diethylether-acetic acid 85 : 15 : 1. The distribution of ^{14}C label between the cholesteryl ester and cholesterol bands are visualized and quantified by exposing the plates to phosphor imaging plates for 16 h and then scanning the imaging screens on a Molecular Dynamics Phosphorimager.

Clark and Tercyak (1984) studied the absorption of cholesterol during inhibition of mucosal acyl-CoA: cholesterol acyltransferase in mesenteric lymph fistula rats with normal pancreatic function.

Åkerlund and Björkhem (1990), Björkhem et al. (1993) used the lymph-fistula model in rats for studies on the link between HMG-CoA reductase and cholesterol 7α-hydroxylase. The thoracic lymph duct was cannulated just proximal to the cisterna magna through an abdominal approach. The proximal part of the lymph duct was ligated. The cannula exited at the back of the animal. The lymph was allowed to flow freely from the animal to the bottom of the metabolic cages. Under these conditions, the rats could move freely in the cages during the lymphatic drainage.

CRITICAL ASSESSMENT OF THE METHOD

Gallo et al. (1987) found normal cholesterol absorption in rats in which intestinal acyl co-enzyme A:cholesterol acyltransferase activity was significantly reduced by ACAT-inhibitors. This challenges the value of ACAT-inhibition at least in normal individuals.

M.5
Interruption of bile acid recirculation

M.5.0.1
Cholestyramine binding

PURPOSE AND RATIONALE

Cholesterol is metabolized in the liver by oxidation to bile acids which undergo enterohepatic circulation. In the untreated state, approximately 95% of the bile acids that are secreted are reabsorbed and returned to the liver, while the small loss is replaced by de novo biosynthesis from cholesterol. Increased excretion of bile acids with the feces increases the rate of oxidation of cholesterol in the liver leading to a partial depletion of the hepatic cholesterol pool. A compensatory increase in uptake via the LDL receptors results in lower serum LDL levels. This can be achieved by addition of a bile acid binding resin, e.g., cholestyramine, to the food. The binding of unconjugated and conjugated bile-salt anions can be tested *in vitro* (Johns and Bates 1969).

PROCEDURE

Rabbits weighing 2.5–3 kg are switched from standard food to a diet containing 10–20% polymeric basic-anion exchanging resin, e.g. cholestyramine. Cholesterol levels in serum are measured at the beginning and at the end of a 4 weeks feeding period.

EVALUATION

Cholesterol levels as means ±SD are calculated for controls and treated animals and compared by statistical analysis.

MODIFICATION OF THE METHOD

Tennent et al. (1960) tested polymeric organic bases for action on blood cholesterol in 4-day experiments and in experiments of 7–8 weeks duration in cholesterol-fed White Leghorn cockerels. The birds were given a diet containing 2% cholesterol and 5% cotton-seed oil with or without addition of polymeric bases. The increase of cholesterol and the incidence of aortic atheromatosis was decreased by polymeric organic bases.

Day (1990) compared the hypocholesterolemic activities of the bile acid sequestrants cholestyramine and cholestipol hydrochloride in cholesterol fed sea quail.

Quaternary ammonium conjugates of bile acid inhibited cholic acid binding and transport in everted ileal sacs of guinea pigs *in vitro* (Fears et al. 1990).

M.6
Inhibition of lipid oxidation

M.6.0.1
General considerations

Oxidative modification of the low density lipoproteins (LDL) has been shown to cause accelerated degradation of LDL via the scavenger receptor pathway. Under conditions of high serum LDL levels, LDL particles can migrate into the subendothelial space where oxidation of LDL can occur. The actual oxidation process is believed to begin with lipid peroxidation, followed by fragmentation to result in short-chain aldehydes. These aldehydes can form adducts with the lysine residues of apo B, creating a new epitope which is recognized by the scavenger receptor of macrophages.

During the same process, lecithin is converted to lysolecithin, which is a selective chemotactic agent for monocytes. The monocytes adhere to the arterial wall and penetrate through to the subendothelium. Once there, the monocyte changes to a tissue macrophage which takes up the oxidized LDL via the scavenger receptor. The uptake of oxidized LDL continues until the macrophage is engorged with cholesteryl esters ultimately forming a foam cell. Groups of these foam cells constitute a fatty streak. By inhibiting the oxidation of LDL, it is hoped that the modification of apo B and the production of chemotactic lysolecithin can be prevented.

The family of receptors for mammalian low-density proteins has been reviewed by Hussain et al. (1999).

M.6.0.2
Inhibition of lipid peroxidation of isolated plasma low density lipoproteins

PURPOSE AND RATIONALE

Hypercholesterolemic Watanabe rabbits are considered to be a suitable model to study the effect of antioxidants as anti-atherosclerotic agents (Carew et al. 1987; Kita et al. 1987; Steinberg et al. 1988; Dresel et al. 1990). Plasma of Watanabe heritable hyperlipidemic (WHHL) rabbits is used to test the inhibition of Cu^{2+}-induced lipid peroxidation of isolated low density lipoproteins (LDL).

PROCEDURE

Animals of a modified Watanabe heritable hyperlipidemic rabbit strain (Gallagher et al. 1988) are used. The animals are fed over a period of 12 weeks with Purina rabbit chow diet with or without 1% of test compound or standard (probucol). Plasma samples are collected in Na_2EDTA (0.1% final concentration). LDL are isolated from each rabbit plasma using a sequential ultracentrifugation technique at d = 1.019–1.063 g/ml (Mao et al. 1983). LDL are then dialyzed against phosphate buffered saline (PBS, 0.01 M sodium phosphate, 0.12 M NaCl, pH 7.4) at 4 °C for 24 h.

For determination of LDL lipid peroxidation induced by Cu^{2+}, 100 µg of each LDL sample is adjusted to a volume of 1.5 ml with distilled water. Lipid peroxidation is initiated by addition of $CuSO_4$ to a final concentration of 5 µM followed by an incubation at 37 °C for 3 h. The reaction is stopped by adding 100 µl of 50 mM Na_2EDTA. Fifty micrograms of LDL from the reaction mixture are added to 1.5 ml of 20% trichloroacetic acid and vortexed. Finally, 1.5 ml of 0.67% thiobarbituric acid (TBA) in 0.05 N NaOH is added and the mixture is incubated at 90 °C for 30 min. Samples are centrifuged at 1 500 rpm for 10 min. The absorbance of the supernatant fractions is determined at 532 nm to estimate the content of lipid peroxides

(thiobarbituric acid-reactive substances). A standard curve (0–5 nmol) of malondialdehyde is generated using malondialdehyde bis(dimethyl acetal) as reference to determine the lipid peroxidation content in Cu^{2+}-treated LDL.

EVALUATION

The content of lipid peroxide in LDL is plotted against the drug concentration in LDL fractions. The extent of Cu^{2+}-induced peroxidation decreases with increasing drug concentrations. The effects of test compounds are compared to the standard.

MODIFICATIONS OF THE METHOD

Inhibition of iron-dependent lipid peroxidation by test compounds was measured by Braughler et al. (1987), Yoshioka et al. 1989).

Yamamoto et al. (1986) studied the effects of probucol on lipid storage in macrophages *in vitro* in the presence of acetylated low density lipoprotein using macrophage-like cells (UE-12) established from a human histiocytic lymphoma cell line.

Barnhart et al. (1989) used LDL from human plasma to study the concentration-dependent anti-oxidant activity of probucol.

Parthasarathy et al. (1986) incubated LDL from human plasma samples with rabbit aortic endothelial cells and measured the increase in electrophoretic mobility, the increase in peroxides, and the increase in subsequent susceptibility to macrophage degradation.

Mansuy et al. (1986) studied the inhibition of lipid peroxidation induced in liver microsomes either chemically by $FeSO_4$ and reducing agents (cysteine or ascorbate) or enzymatically by NADPH and CCl_4.

M.6.0.3 Internalization of labeled LDL into HepG2 cells

PURPOSE AND RATIONALE

Enhanced uptake of low density lipoproteins (LDL) via the LDL receptor into liver cells results in reduced plasma cholesterol levels. This can be tested in the cultured hepatoma cell line HepG2.

PROCEDURE

Heterozygous WHHL rabbits are treated with the test compound over a period of 4 weeks. Blood is withdrawn twice weekly before, during, and after treatment for determination of total plasma cholesterol, low density lipoprotein cholesterol, total triglycerides, and high density lipoprotein cholesterol. Lipoprotein-deficient serum is prepared by ultracentrifugation (Goldstein et al. 1983). Serum of treated and untreated animals is used for the uptake assay being prepared by centrifugation to remove the clots, followed by heat inactivation of the complement system and sterilization through a 0.45-µm filter. In each preparation, 2 mg LDL (*d*, 1.019 to 1.050 g/ml) at 10 mg/ml are iodinated by the monochloride method to a specific activity of 300 cpm/ng (Huettinger et al. 1984).

HepG2 cells are grown in 5 cm dishes in Eagle's minimum essential medium to 60% confluence. Serum prepared from treated animals and from the same animals in the pretreatment period is added from 1% to 50% to the medium used to grow HepG2 cells. After incubation of 18 h, cells are washed and incubated in Eagle's minimum essential medium plus 2% bovine serum albumin and 8 µg labeled LDL for 3 h. The cells are then washed and solubilized in sodium hydroxide, and the content of each dish is counted for radioactivity. An aliquot is used to determine protein content.

EVALUATION

Values are given for specific uptake, which is calculated from the difference of total uptake minus uptake measured when a 40-fold excess of unlabeled LDL is present in the incubation medium of duplicate or triplicate incubations. The effect of the test drug is demonstrated by an increase of uptake with increasing percentage of serum of treated animals containing the active drug.

MODIFICATIONS OF THE METHOD

Sprague et al. (1993) measured the inhibition of scavenger receptor-mediated modified low-density lipoprotein endocytosis in cultured bovine aortic endothelial cells.

Takano and Mowri (1990) produced a monoclonal antibody which recognizes peroxidized lipoproteins.

Chapter N
Endocrinology[1]

[1] Review of this edition by J. Sandow.

N.1 Endocrine survey

PURPOSE AND RATIONALE

The effect of steroid and peptide hormones as well as the influence of drugs on the endocrine system are detected by repeated administration of the test substances. After administration during a period of 1–4 weeks, the endocrine glands and the organs depending on hormonal influences are weighed. Furthermore, the hormonal content of the endocrine glands and blood levels of hormones determined.

PROCEDURE

Separate groups of 5–10 male and female Sprague-Daw-ley rats weighing 55–65 g are used. For some compounds, groups of 200 or 300 g body weight may be required. They are treated daily over a period of 6–12 days with the test compound by the intended route of orally) or by subcutaneous injections. For toxicological studies, a treatment period of 4 weeks is preferable. A similar protocol is applied in chronic toxicity studies in rats and dogs. On the day after the last application, the animals are sacrificed, weighed, and the following parameters determined:

Parameter	Optional
Pituitary-adrenal axis	
Pituitary weight	Corticotropin-releasing hormone in hypothalamus
Adrenal weight	Pituitary content of adrenocorticotropin and vasopressin
Thymus weight	Adrenal content of corticosterone and aldosterone; Corticosterone and aldosterone blood level; Electrolyte (Na^+, K^+, Ca^{2+}, Cl^-) concentrations in serum; Urinary excretion of corticosterone and aldosterone
Pituitary-gonadal axis	
Male reproduction	
Pituitary weight	LH-RH in hypothalamus
Weight of testes	Pituitary content of FSH, LH and prolactin
Weight of seminal vesicles	Blood levels of FSH, LH and prolactin
Weight of ventral prostate	Testosterone content in testes and serum
Weight of musculus levator ani	Growth hormone in pituitary and serum
Female reproduction	
Pituitary weight	LH-RH in hypothalamus
Weight of ovaries	Pituitary content of FSH, LH and prolactin
Weight of uterus	Blood levels of FSH, LH and prolactin; Content of estradiol and progesterone in ovaries and serum
Pituitary-thyroid axis	
Pituitary weight	TRH in hypothalamus
Thyroid weight	Pituitary content of thyrotropin; Serum content of TSH, T3 and T4

After dissection, organ weights are recorded, serum or plasma and the endocrine glands are stored frozen at –20 °C for further determination of hormonal content. This method may include histology, *in situ* hybridization etc. as required.

EVALUATION

The mean value of each parameter of the treated groups are compared with the values of the vehicle control group.

MODIFICATIONS OF THE METHOD

Many modifications are possible, e.g., extension of the treatment period up to 4 weeks in order to detect toxicological effects after long-term administration, inclusion of supplementary parameters, satellite groups. Further specific tests are necessary to clarify the mode of action.

N.2
Adrenal steroid hormones

N.2.0.1
Adrenalectomy in rats

PURPOSE AND RATIONALE

The classical evaluation of hormone functions is the surgical ablation of the hormone producing endocrine gland and the substitution with exogenously administered substances. Most studies on the physiological role of adrenocortical hormones and the pharmacological effects of corticosteroids were performed in adrenalectomized rats.

PROCEDURE

Sprague-Dawley or Wistar rats of either sex weighing 120–150 g are used. The dorsal fur is shaved, the rat is anesthetized with ether and placed on a block ($8 \times 3 \times 2$ cm) in order to elevate the viscera. A transverse incision about 5 mm long is made in the midline at the costovertebral angle. To remove the left adrenal gland, the skin is retracted to the ventral side and the lumbar muscles incised just superior and anterior to the splenic shadow. In this way, the adrenal gland appears directly beneath the incision and no exteriorization of the kidney is necessary. The periadrenal tissue is grasped between the kidney and the adrenal by small curved forceps and the intact gland together with the periadrenal fat and the mesenteric attachments is removed in toto. The adrenal gland and its capsule are not touched and any remnants of the capsule to which cortical tissue may adhere are removed. The bleeding is negligible in young animals so that no vessels need be tied off.

After ablation of the left adrenal, the animal is turned around and the right gland is removed through the original skin incision. A small incision through the lumbar muscles is made just above and anterior to the prominent lumbocostal artery which is seen near the costal margin. The curved forceps are inserted over the kidney and by elevating the liver, which covers the adrenal on this side, the gland is brought into view and grasped by the forceps removing again the intact gland with the periadrenal fat and the mesenteric attachments. The incisions made in the lumbar muscles need not exceed 3 mm in length and may be made by spreading the blades of a pair of scissors, hemostasis or closure by sutures is not necessary. The incision is closed by a skin clip. The entire procedure is done in a time sufficiently short to avoid long-acting anesthetics. The animals appear normal in every aspect within a few min following the operation.

N.2.1
Glucocorticoid activity

N.2.1.1
In vitro methods for glucocorticoid hormones

N.2.1.1.1
Corticoid receptor binding

PURPOSE AND RATIONALE

Steroid hormone receptors are intracellular metalloproteins which bind steroids with high affinity and high specificity. The lipophilic steroids enter the cell by diffusion. The binding of the hormone to its specific receptors results in a series of conformational changes,

leading to an increase in affinity for specific DNA regulatory elements (steroid responsive elements). After binding, transcription of target genes is enhanced and mRNAs are produced. These mRNAs are then translocated to the cytoplasm and translated into proteins regulating cellular metabolism and initiating the cellular responses. The structure and functions of the steroid receptor superfamily have been reviewed by Carson-Jurica et al. (1990), Lazar (1991), Barnes and Adcock (1993), Distelhorst (1993), Power et al. (1993), Brinkmann (1994), Ojasoo et al. (1994, 1995), Wittliff and Raffelsberger (1995), Beato et al. (1996), Jensen (1996). The relative binding affinities for the glucocorticoid receptor of rat liver or thymus cytosol can be measured by competitive displacement of [^{3}H]-dexamethasone (Raynaud et al. 1979; Wojnar et al. 1986; Ueno et al. 1991).

PROCEDURE

The steroid receptor preparation is obtained from rats. Male Wistar rats weighing 140–150 g are adrenalectomized under anesthesia. Two days later, the liver is excised and homogenized in a 10 fold buffer containing 50 mM Tris-HCl, 1 mM EDTA, 2 mM dithiothreitol, 10 mM Na_2MO_4, and 10% glycerol (pH 7.4). The homogenate is centrifuged for 1 h at 105 000 *g* at 4 °C and collected as the supernatant fraction. The cytosol is mixed with 5 nM [^{3}H]-dexamethasone in the presence or absence of appropriate concentrations of competitors and incubated for 2 h at 4 °C. The reaction is terminated by the addition of hydroxyapatite in order to separate the receptor-steroid complex from the free [^{3}H]-dexamethasone. The radioactivity bound to the receptors is determined by liquid scintillation spectrometry.

EVALUATION

IC_{50} values are estimated by probit analysis.

MODIFICATIONS OF THE METHOD

Various modifications of the glucocorticoid receptor assay have been reported in the literature. Cytosols have been prepared from rat liver, from cultured rat hepatoma cells (Rousseau and Schmit 1977), from normal human lymphocytes (Steiner and Wittliff 1985), thymocytes from rat thymus gland (Lefebvre et al. 1988), human leukemic lymphoid cell line, CEM C7 (Srivastava and Thompson 1990), rat lung (Druzgala et al. 1991; Hochhaus et al. 1991), human lung (Rohdewald et al. 1985), rat hippocampus (Jacobson et al. 1993) and other sources.

Differentiation of type I (mineralocorticoid) and type II (glucocorticoid) receptors has been attempted (Spencer et al. 1990; Jacobson et al. 1993).

A new affinity label for glucocorticoid receptors was described by Lopez and Simons (1991).

The solution structure of the glucocorticoid receptor DNA-binding domain has been determined (Härd et al. 1990).

Berger et al. (1992) used transient co-transfection of receptor cDNA and suitable reporter genes to study human glucocorticoid receptor function in a CV-1 mammalian cell line. A variety of natural and synthetic steroids were analyzed for their ability to activate gene expression through the human glucocorticoid receptor and to bind to extracts of cells expressing the human glucocorticoid receptor cDNA. A good correlation between both *in vitro* parameters and *in vivo* anti-inflammatory activity was reported for most of the tested steroids.

Guo et al. (1995) tested the binding of various steroids to the synaptic plasma membrane which may be a novel type of glucocorticoid receptor on neuronal membrane being significantly different from the cytosolic glucocorticoid receptors.

A general survey on steroid hormones, receptors and antagonists was given by Jensen (1996).

Teutsch et al. (1995) discussed structure-activity correlation of hormone antagonists ("antihormones").

N.2.1.1.2 Transactivation assay for glucocorticoids

PURPOSE AND RATIONALE

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1995, 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor interacts with hormone responsive elements of hormone-regulated genes, thereby inducing a cascade of transcriptional events (Green and Chambon (1988). The hormone-dependent transcriptional activation can be determined in tissue culture by transfection of the steroid receptor under investigation and a reporter gene linked to a hormonally responsive promotor into cells. The transactivation assay allows determination of the agonistic and also the antagonistic potency of a given compound, by induction or inhibition of reporter gene activity (Fuhrmann et al. 1992).

PROCEDURE

Vector construct

The expression plasmid pHGO containing the full-length coding sequence of the human glucocorticoid receptor driven from the SV 40 early promotor is prepared according to Hollenberg et al. (1985). The pMMTV-CAT plasmid containing the mouse mammary tumor virus promotor linked to a chloramphenicol acetyltransferase gene is prepared according to Cato et al. (1986).

Cell culture and transfections

CV-1 cells and COS-1 cells for transient infections are cultured in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal calf serum, 4 mmol/L L-glutamine, penicillin and streptomycin. Stable and transient transfections are performed using Lipofectin reagent (Gibco BRL) according to a procedure recommended by Felgner and Holm (1989), Felgner et al. (1987). Stable transfections are carried out according to Fuhrmann et al. (1992). For transient

transfection, 1×10^6 COS-1 or CV-1 cells, respectively, are plated onto 100-mm dishes one day prior to transfection. Cells are typically about 80% confluent after 24 h. Before transfection, cells are washed twice with 1 ml Opti-MEM (Gibco BRL) per dish. For each dish, 5 µg pHGO (hGR expression plasmid) and 5 µg pMMTV-CAT are diluted with 1 ml Opti-MEM; in addition, 50 µg Lipofectin Reagent is diluted with 1 ml Opti-MEM. Next, DNA and Lipofectin Reagent dilutions are combined in a polystyrene snap-cup tube to obtain 2 ml of transfection solution per dish, gently mixed, incubated at room temperature for 5 min, and added to the washed cells. After 5 h the transfection solution is replaced by 6 ml DMEM supplemented with 10% fetal calf serum.

To study the effect of the test hormones, transiently transfected cells are trypsinized, pooled and replated onto 60-mm dishes at a density of 4.5×10^5 per dish 24 h after transfection. Stably transfected cells are seeded onto 6-well dishes (1×10^5 cells per dish). Cells are cultured in medium supplemented with 3% charcoal-stripped fetal calf serum and the appropriate hormones for 48 h. As negative control for the reporter gene induction, cells are cultured with 1% ethanol. Transactivation assays with transiently or stably transfected cells are carried out at least three times.

CAT assay

Transiently transfected cells and stably transfected cells are disrupted by freezing (ethanol/dry ice bath) and thawing (37 °C water bath) three times. Protein concentrations of the cell extract are determined according to Bradford (1976). The CAT assay is performed according to Gorman et al. (1982). After the cells are spun for 15 min in an Eppendorf microfuge at 4 °C, the supernatants are removed and assayed for enzyme activity. The assay mixture contains (in a final volume of 180 µl) 100 µl of 0.25 M Tris-hydrochloride (pH 7.5), 20 µl of cell extract, 1 µCi of [^{14}C]chloramphenicol (50 µCi/mmol; New England Nuclear Corp.), and 20 µl of 4 mM acetyl coenzyme A. Controls contain CAT (0.01 U; P.L. Biochemicals Inc.) instead of cell extract. All of the reagents except coenzyme A are preincubated together for 5 min at 37 °C. After equilibration is reached at this temperature, the reaction is started by adding coenzyme A. The reaction is stopped with 2 ml cold ethyl acetate, which is also used to extract the chloramphenicol. The organic layer is dried and taken up in 30 µl of ethyl acetate, spotted on silica gel thin-layer plates, and run with chloroform-methanol (95 : 5), ascending). After autoradiography of the separated acetyl chloramphenicol forms, the spots are cut out and counted. Data are expressed as the amount of chloramphenicol acetylated by 20 µl of extract.

EVALUATION

CAT activity is calculated as percent conversion from chloramphenicol to acetylated chloramphenicol. Concentration-response curves for CAT induction are established to determine the potency of the test hormone. Dexamethasone (10^{-10} to 10^{-6} mol/l) serves as standard.

For antiglucocorticoid activity, CAT activity in the presence of 10^{-8} mol/l dexamethasone is set as 100% and relative CAT activity is calculated as percentage of this value. Concentration-response curves for CAT inhibition are established with increasing concentrations of the antihormone RU 486as the standard inhibitor.

CRITICAL ASSESSMENT OF THE METHOD

Hollon and Yoshimura (1989) examined the causes for high variability in data from enzymatic transient gene expression assays. Their results strongly suggested that variation in transfection efficacy is the major cause of data variation and can seriously compromise valid interpretation of data.

MODIFICATIONS OF THE METHOD

White et al. (1994) described a simple and sensitive **high-throughput assay** for steroid agonists and antagonists. A DNA cassette, containing a synthetic steroid-inducible promotor controlling the expression of a bacterial chloramphenicol acetyltransferase gene (GRE5-CAT), was inserted into an Epstein-Barr virus episomal vector which replicates autonomously in primate and human cells. This promotor/reporter system was used to generate two stably transfected human cell lines. In the cervical carcinoma cell line HeLa, which expresses high level of glucocorticoid receptor, the GRE5 promotor is inducible over 100-fold by the synthetic glucocorticoid dexamethasone. In the breast carcinoma cell line T47D, which expresses progesterone and androgen receptors, the GRE5 promotor is inducible over 100-fold by either progesterone or dihydrotestosterone. These cell lines can be used to screen large numbers of natural and synthetic steroid agonists and antagonists in microtiter wells using a colorimetric chloramphenicol acetyltransferase assay.

Dias et al. (1998) recommended the use of Cre recombinase in mammalian cells for high through-put screening of chemical libraries to identify new receptor ligands. A translational fusion of Cre recombinase and the ligand binding domain of the human glucocorticoid receptor was transfected into mammalian cells with the *loxP*/luciferase reporter gene. A stable transfected clone was isolated and used to characterize the kinetics, ligand specificity, and dose response to various receptor ligands.

Vayssière et al. (1997) studied synthetic glucocorticoids that dissociate transactivation and AP-transrepression.

N.2.1.1.3 Induction of tyrosine aminotransferase in hepatoma cells

PURPOSE AND RATIONALE

The synthesis of tyrosine aminotransferase in hepatoma tissue culture (HTC) cells (Thompson et al. 1966) can be induced by glucocorticoids. This effect can be abolished by glucocorticoid antagonists.

PROCEDURE

Hepatoma tissue culture (HTC) cells are grown in suspension to a density of about 8×18^5 cells/ml. The cells are washed 3 times at 0 °C in a total volume of buffered saline equivalent to half of the culture medium. The suspension is centrifuged and cell pellets resuspended in serum free medium containing 0.1% BSA and 0.1% $NaHCO_3$. Ethanol solutions of standard (dexamethasone) and test steroids in various concentrations are added to 10 ml aliquots of cell suspension, final ethanol concentration not to exceed 0.5%. After 16 h of incubation in tightly capped flasks on a rotary shaker (100 rev/min) at 37 °C, the cells are harvested and tyrosine aminotransferase determined. The cells are washed twice and then disrupted with an ultrasonicator. The enzyme is assayed at 37 °C by conversion of p-hydoxyphenylpyruvate to p-hydroxybenzaldehyde (Diamondstone 1966). One unit of activity represents the conversion of 1 µmole of p-hydroxy-phenylpyruvate/min.

EVALUATION

Enzyme specific activity is expressed in milliunits of tyrosine aminotransferase/mg of cell protein. Dose-response curves are established for the standard and the test preparation allowing the calculation of potency ratios with confidence limits.

N.2.1.1.4 Effect on T-lymphocytes

PURPOSE AND RATIONALE

Corticosteroids as immunosuppressive agents influence T-lymphocyte function. Snijdewint et al. (1995) determined *in vitro* dose-dependent inhibition of Th1- and Th2-type cytokine production by various corticosteroids.

PROCEDURE

Culture media

T-lymphocyte clones are maintained and expanded in Iscove's modified Dulbecco's medium (IMDM) supplemented with 10% pooled c-inactivated human serum and gentamycin (80 µg/ml). Experiments are performed in IMDM supplemented with 10% FCS, human transferrin (35 µg/ml) 2-ME (3.5 µg/l) and human insulin (1.75 IE/ml).

Peripheral blood lymphocytes and T-lymphocyte clones

Peripheral blood mononuclear cells are prepared from heparinized venous blood of healthy volunteers by flotation on Lymphoprep (Nycomed, 1.077 g/ml) and the peripheral blood lymphocytes are separated by centrifugation on a discontinuous Percoll density gradient. Peripheral blood lymphocytes are collected form the interface between densities 1.977 g/ml and 1.061 g/ml, washed three times in HBSS plus 2% FCS and suspended in IMDM plus 10% FCS. Isolated peripheral blood lymphocytes (0.5×10^6 cells/ml) are stimulated with CD2 mAb plus CD28 mAb (1.1000 final dilution of ascites) in the absence or presence of corticosteroids (Van der Pouw-Kraan et al. 1992). Supernatants are collected after 48 h for IFN-γ and IL-2 measurement, and after 96 h for IL-4 measurement.

Housedust mite (*Dermatophagoides pteronyssinus*)-specific T-lymphocyte clones are generated from peripheral blood and skin of atopic individuals (Van der Heijden et al. 1991). These clones are Th0 typed, capable of producing both IFN-γ and IL-4 (Kapsenberg et al. 1988). T-lymphocyte clone cells (0.5×10^6 cells/ml) are stimulated with CD2 and CD28 mAb (1.1000) plus 1 ng/ml PMA to induce optimal levels of cytokine production. Corticosteroids are added at the start of the stimulation. 24 h after stimulation, supernatants are collected and stored at –20 °C until cytokine production is analyzed.

Proliferation assay and cytokine measurements

Proliferation by peripheral blood lymphocytes is measured 48 or 96 h after stimulation in 96-well flat-bottom culture plates using 10^4 cells/well, the last 16 h in the presence of 13 kBq (0.33 µC)/well of [^{3}H]TdR (Radiochemical Centre, Amersham, UK). T-lymphocyte clones proliferation (10^4 cells/well) is similarly measured after stimulation for 40 h, again the last 16 h in the presence of [^{3}H]TdR. Incorporation of [^{3}H]TdR is determined by liquid scintillation spectroscopy.

Measurement of IFN-γ and IL-4 in the peripheral blood lymphocytes and T lymphocyte clones supernatants is performed with specific solid-phase sandwich ELISA systems (Van der Pouw-Kraan et al. 1992). For quantification of IL-2 production, a commercial ELISA kit is used.

IL-2R expression by T cells of peripheral blood lymphocytes is determined 48 h after stimulation by labelling with mouse anti-human CD25 mAb.

EVALUATION

Dose-response curves of inhibition of IFN-γ, IL-4 and IL-2 production as % of initial values in peripheral blood lymphocytes and in different T-lymphocyte clones are established for various corticosteroids in the range of 10^{-10} to 10^{-6} M.

All measurements are performed in duplicate of triplicate. Data are expressed as mean ±SEM and are evaluated statistically using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Mollison et al. (1999) compared a macrolactam inhibitor of T helper type 1 and T helper type 2 cytokine biosynthesis in various animal models with several steroid preparations, used for topical treatment of inflammatory skin diseases.

N.2.1.1.5 Inhibition of cartilage degradation

PURPOSE AND RATIONALE

The efficacy of glucocorticosteroids after intra-articular injection has been clearly demonstrated in several animal models of osteoarthritis (Van den Berg et al. 1992; Pelletier et al. 1995). Augustine and Oleksyszyn (1997) used *in vitro* experiments to study the inhibition of degradation in bovine cartilage explants stimulated with concomitant plasminogen and interleukin-1α by various glucocorticosteroids.

PROCEDURE

Preparation of bovine articular cartilage explants

Bovine (calf) radiocarpal joints are acquired from a local abattoir immediately after sacrifice and transported on ice. The specimens are washed thoroughly and placed on ice containing 25% Povidine (10% Povidone-iodine topical solution). The specimens are then dissected in a sterile hood using good sterile technique. Media (DMEM containing 4.5 g/l D-glucose and L-glutamine, without sodium pyruvate) is supplemented with HEPES buffer(3.57 g/l) and sodium bicarbonate (3.7 g/l), and the pH adjusted to 7.4. The media is further supplemented with penicillin (100 U/ml), streptomycin (100 µg/ml) and 50 µg/ml L-ascorbic acid. The articulating cartilage surfaced are exposed, and the synovial fluid is wiped away with sterile gauze. A sterile cork-borer with a diameter of 3.5 mm is used to remove uniform cores of cartilage. The cores are placed in a sterile flask, washed for times with sterile media, and then placed in an incubator (37 °C, 5% CO_2/95% air, adequate humidity) and allowed to equilibrate for 1 h.

The cartilage disks are then labeled en mass with [^{35}S] sulfate at a concentration of 10 µC/ml for approximately 72–96 h, with hand-stirring every few hours. After labeling, explants are equilibrated with fresh media (minimum of 2 washes before use in experiments).

Inhibition of IL-1-induced cartilage degradation in bovine articular cartilage in the presence of human plasminogen

Individual explants are transferred to 96-well plates containing 250 µl of fresh media per well, with or without plasminogen and IL-1α, and with or without glucocorticosteroids. A negative control consists of media alone, while two positive controls are IL-1α alone, and plasminogen with IL-1α. All other groups contain the glucocorticosteroids along with recombinant human IL-1α (0.4 ng/ml) alone or concomitant human plasminogen (0.4 µM) plus IL-1α. Glucocorticosteroids are added in concentrations between 10 and 10 000 pM.

Control and experimental explants are incubated for approximately 96 h (four days) prior to counting a 50 µl sample of supernatant from each well. A 50 µl sample of a papain-digest of each explant is also counted.

EVALUATION

From the counts released into the supernatant over four days, and calculation of the total counts present (determined by digest counts), the data is expressed as % glycosaminoglycane release over the four days. The values for all groups with glucocorticosteroids present are then compared to the values for concomitant plasminogen and IL-1a without glucocorticosteroids, and percent inhibitions are calculated. Dose-response curves are established for each glucocorticosteroid.

N.2.1.2 *In vivo* methods for glucocorticoid hormones

N.2.1.2.1 General considerations

Muscle work tests have been used in early stages of adrenal gland research (Bomskov 1937; Ingle 1944). The method is based upon the fact that muscular responsiveness is lost within a few hours following the removal of the adrenal glands and can be maintained by the administration of corticosteroids. Since the 11-oxygenated steroids are quite active and compounds such as desoxycorticosterone are practically without activity, it appears that the principal effect monitored is on carbohydrate metabolism. In view of more specific methods, the muscle work tests have only historical interest.

N.2.1.2.2 Adrenal and thymus involution

PURPOSE AND RATIONALE
Repeated administration of corticosteroids causes both central and peripheral effects. In the immature rat, thymus involution is observed. The secretion of pituitary ACTH is blocked resulting in atrophy of the adrenal glands.

PROCEDURE
Groups of 6–10 immature male Sprague Dawley rats weighing 60–70 are injected subcutaneously daily for 6 days with 0.2 ml of a homogenized suspension of different doses of the test compound in 0.5% aqueous carboxymethylcellulose solution. The standard, hydrocortisone acetate is given in daily doses of 0.05 and 0.2 mg per animal. Controls receive the vehicle only. On the seventh day, the animals are sacrificed and the adrenal and thymus weights determined.

EVALUATION
The degree of involution of the thymus gland is a measure of the catabolic activity of the compound. Involution of the adrenals is a measure of the ability of the compound to inhibit the secretion of ACTH. Dose-response curves are established for both parameters and compared with hydrocortisone in order to calculate potency ratios.

MODIFICATIONS OF THE METHOD
The sensitivity of the test can be increased if the product of thymus and adrenal weight is calculated. Dose-response curves of the product are steeper than those of the individual glands (Laschet and Hohlweg 1960).

Inhibition of uridine incorporation into ribonucleic acid of thymocytes has been used as parameter for agonistic and antagonistic glucocorticoid activity (Gaignault et al. 1977).

N.2.1.2.3 Eosinopenia test in adrenalectomized mice

PURPOSE AND RATIONALE
Glucocorticoids decrease the eosinophilic cell blood count in laboratory animals as well as in man. This effect was used to quantitate the potency of corticosteroids in adrenalectomized mice.

PROCEDURE
Male mice weighing 20–25 g (e.g., of Jax C57 Brown, subline cd strain) are adrenalectomized and maintained at 28 °C with 1% sodium chloride solution in water. Fifteen mg pellets of desoxycorticosterone acetate are implanted at the time of operation. Steroids are dissolved in benzyl alcohol and mixed with sesame oil (1 : 10). Three days after operation, the mice receive 5 µg epinephrine by subcutaneous injection and 4 h later 1–6 µg of hydrocortisone (or the test substance) in 0.03 ml oil. Three doses of the unknown substance and standard are tested, using 6 animals per dose. Blood samples are taken from the tail before and 3 h after steroid injection. Mice with fewer than 100 eosinophils per cubic millimeter of blood before injection are discarded.

EVALUATION
The percentage decrease of eosinophil blood count after 3 h is averaged per group. From dose-response curves, potency ratios are calculated.

CRITICAL ASSESSMENT OF THE METHOD
The test is relatively simple and has the advantage of requiring little material.

N.2.1.2.4 Liver glycogen test in rats

PURPOSE AND RATIONALE

The liver glycogen deposition test, as described by Stafford et al. (1955) is a simple and specific test for glucocorticoid activity.

PROCEDURE

Male Sprague-Dawley rats weighing 140–160 g are adrenalectomized. They are fed stock laboratory diet and 1% sodium chloride solution. On the morning of the fourth postoperative day, food is withdrawn. On the morning of the fifth day, the drinking fluid is withdrawn and the rats are given the test compound by a single subcutaneous injection in appropriate dosages suspended in 0.5 ml sesame oil. Seven hours later, the rats are sacrificed. The livers are removed and blotted on filter paper to remove blood, weighed, dropped into flasks containing 10 ml hot 30% potassium hydroxide and digested on a hot plate. The digest is diluted to 100 ml and a 50-fold dilution of an aliquot is used for analysis.

Ten ml 0.2% anthrone in 95% sulfuric acid is slowly added to 5 ml of liver digest dilution with cooling. The mixture is heated in a boiling water bath for 10 min and then placed into cold water. Optical density is measured in a spectrophotometer at 620 µm using the anthrone-reagent as blank. Calibration curves are established using glucose as standard. Groups of 5 animals are used for each dose and for the vehicle controls. Three doses of test compound and of standard are used to find dose-response activities. Standard doses of hydrocortisone are 0.5, 1.0, and 2.0 mg per animal subcutaneously or 1.25, 2.5, and 5.0 mg per animal orally.

EVALUATION

The content of glycogen expressed as glucose is calculated per g liver weight. Dose-response curves are established for each compound and for the standard in order to calculate potency ratios.

MODIFICATIONS OF THE METHOD

The method can be used to determine the time course of activity and the duration of action of derivatives such as corticosteroid esters compared to the free alcohol (Vogel 1963, 1965) and for evaluation of topical and systemic activity (Alpermann et al. 1982).

The liver glycogen deposition in the **adrenalectomized mouse** has been used by Dorfman et al. (1946) and by Venning et al. (1946) to evaluate glucocorticoid activity.

Liver tryptophan peroxidase activity in the rat is decreased after adrenalectomy and increased after administration of corticosteroids (Knox and Auerbach 1955) indicating an early effect of corticoids.

The enzyme activity of tryptophane pyrrolase in **guinea pig liver** is increased by systemic administration of corticoids, but this effect is short-lived and achieved only with high s.c. doses (Albrecht et al. 1979). In contrast, the enzyme is markedly reduced by high-dosed and protracted epicutaneous application of dermatocorticoids.

N.2.1.2.5 Anti-inflammatory tests

GENERAL CONSIDERATIONS

Most of the tests described in the Sect. H.3 (anti-inflammatory activity) have been used for evaluation of corticosteroids.

The measures of **acute inflammation**, such as

- **Ultraviolet erythema in guinea pigs** (see H.3.2.2.1),
- **Vascular permeability in rats** (see H.3.2.2.2), and
- **Paw edema in rats** (see H.3.2.2.6)

are less suitable, whereas the methods measuring **subacute inflammation** are very well suited, such as

- **Granuloma pouch test in rats** (see H.3.2.2.8),
- **Cotton granuloma test in rats** (see H.3.2.3.1),
- **Glass rod granuloma test in rats** (see H.3.2.3.3),
- **Sponge implantation technique** (see H.3.2.3.2).

The molecular mechanisms of the anti-inflammatory actions of glucocorticoids were reviewed by Barnes (1998). Development of dissociated steroids which are more active in transrepression (interaction with transcription factors) than transactivation (binding to glucocorticoid response elements) as reported by Vayssiere et al. (1997) was recommended.

N.2.1.3 Influence of steroids on mechanical properties of connective tissue

N.2.1.3.1 Breaking strength of bones

PURPOSE AND RATIONALE

Patients with Cushing's disease or after long term treatment with corticosteroids have an increased susceptibility for bone fractures. The test was developed as a model for corticosteroid induced osteoporosis. Surprisingly, in chicken as well as in rats, low and medium doses of glucocorticosteroids increased breaking strength of bones dose-dependently whereas high, almost lethal doses induced a decrease of breaking strength.

PROCEDURE

White Leghorn chicken at an age of 14 days weighing 170 ±20 g are used. The animals are sacrificed after 14 days of treatment by intramuscular injections of doses from 0.2 up to 100 mg/kg cortisol (reference compound) or equivalent doses of glucocorticoids in oily solution. Body weight and comb weight are registered and the femur and tibia bones from both sites are freed from surrounding tissue and weighed. Length of bone (l) and outer diameter (D) of the diaphysis are measured using calipers. The bone is fastened on both ends, supported on edges 5 mm distant from the ends, and broken in the central portion of the diaphysis by a special apparatus assembled to an Instron®-instrument. Breaking load (P) is registered. The contralateral bone is cut by a small saw at the middle of the diaphyseal shaft into rings. Using a stereomicroscope, inner (d) and outer diameter (D) are measured in two perpendicular directions.

EVALUATION

Breaking strength (σ) of the hollow bones is calculated according to the technical formula for hollow cylinders:

$$\sigma = \frac{8}{\pi} \times \frac{P \times l \times D}{D^4 - d^4}$$

Doses between 0.2 and 2.0 mg/kg cortisol and 0.05 and 1.0 mg/kg prednisolone show a parallel increase of breaking strength allowing the calculation of potency ratios. With higher doses, the response changes to an inhibition of breaking strength. Excessive doses of 50 and 100 mg/kg cortisol which are in the range of the LD_{50} induce a decrease of breaking strength. It is concluded that the catabolic effect of glucocorticoids on bone matrix and mineral in this test can only be measured when using toxic doses.

MODIFICATIONS OF THE METHOD

In young and adult rats, 10 days of treatment with cortisol and other corticosteroids induce a dose-dependent increase of breaking strength, whereas with longer treatment (30 days) a bell-shaped dose-response (increase with low doses, decrease with high doses) is seen.

N.2.1.3.2 Tensile strength of femoral epiphyseal cartilage in rats

PURPOSE AND RATIONALE

Epiphyseal cartilage of rats is very sensitive to treatment with hormones and other desmotropic drugs. Tensile strength of the distal femoral epiphyseal plate is decreased after adrenalectomy and restored or increased by treatment with low doses of corticosteroids.

PROCEDURE

Male Sprague-Dawley rats weighing 120 ±10 g are treated with several doses of corticosteroids or other hormones for periods between 1 and 14 days. After sacrifice, the hind legs are exarticulated in the hip joint and fastened at the collum femoris. Longitudinal tension always results in rupture of the distal femoral epiphyseal cartilage (Ther et al. 1963; Vogel and Ther 1964; Vogel 1969). The ultimate load of the femoral epiphyseal plate is registered by an Instron® instrument at an extension rate of 5 cm/min.

Single injections of doses between 10 and 100 mg/kg cortisol acetate or 2.5 and 40 mg/kg prednisolone acetate induce dose-dependent increase of tensile strength up to twice of the control levels after 24–48 h which subsides after 96 h. Repeated administration up to 15 days also results in a dose-dependent increase. However after administration of subtoxic doses for more than 2 months, the tensile strength falls below the age-matched control values. There is a maturation-dependent increase of tensile strength in untreated rats.

The effect of other hormones, e.g. gonadal steroids, on cartilage is much smaller than that of glucocorticosteroids.

EVALUATION

Dose-response curves for steroids can be established allowing the calculation of potency ratios in experiments with single dose or repeated dose administration.

N.2.1.3.3 Tensile strength of tail tendons in rats

PURPOSE AND RATIONALE

The thread-like tail tendons of rats are very suitable for studying the mechanical properties of connective tissue. They are easy to prepare and consist predominantly of collagen. Like other organs of connective tissue, such as bone, cartilage, and skin, tensile strength of tail tendons is reduced after adrenalectomy and dose-dependently increased after short-term treatment with glucocorticosteroids.

PROCEDURE

Male Sprague-Dawley rats weighing 120 ±10 g are treated with increasing doses of corticosteroids or other hormones for periods between 1 and 14 days. After sacrifice, the tail is amputated at its basis. The tail skin and the last few coccygeal vertebrae are removed. Single tendons are pulled out from the dorsal and ventral bundles and kept in saline solution. Tendons of the same diameter (0.25 mm) are selected with a stereomicroscope. Since the diameter of the tendons may be influenced by long-term treatment of the animals, tendons of the same vertebral insertion are tested, alternatively. For this purpose, the 10^{th} vertebra is counted from the tail tip. All 6 tendons (4 on the ventral and 2 on the dorsal side) inserting on this vertebra are removed and tested. The tendons are fixed in special clamps at a distance of 2.0 cm and immersed in physiological saline. Stress-strain curves and ultimate loads are determined with an Instron®-instrument with an extension rate of 5 cm/min.

A single injection of cortisol acetate in doses from 10 to 100 mg/kg or prednisolone acetate in doses between 2 and 20 mg/kg prednisolone acetate causes a dose-dependent increase of tensile strength allowing the calculation of a potency ratio of 1 : 4 for prednisolone versus cortisol. Repeated injections of cortisol acetate in doses between 1.0 and 50 mg/kg sc or prednisolone acetate in doses between 0.05 and 50 mg/kg sc show the same dose-dependence and potency ratio. Tensile strength of tail tendons is similarly changed by treatment with gonadal steroids, depending on dose and duration of treatment, but to a much lesser degree than by corticosteroids.

EVALUATION

The potency ratios of glucocorticoids versus cortisol as the standard are calculated.

MODIFICATIONS OF THE METHOD

In addition to tensile strength, several other biophysical parameters can be determined in tail tendons, such

as hysteresis behavior (Vogel 1984). The ratio of energy input versus energy dissipation is calculated. Furthermore, dependence on strain rate and relaxation behavior under the influence of corticosteroids (Vogel 1989) as well as retardation (strain rate under constant load) has been studied (Vogel and Schorning 1990).

N.2.1.3.4 Tensile strength of skin strips in rats

PURPOSE AND RATIONALE

Clinical experience shows unequivocally a decrease of skin thickness after long-term systemic or local treatment with corticosteroids. The mechanical properties of human skin after treatment with corticosteroids, however, have not been measured. Like with other connective tissues, in animal experiments a clear increase of tensile strength of skin has been found after short term administration of corticosteroids.

PROCEDURE

Male Sprague-Dawley rats with an initial weight of 120 ±10 g are treated with increasing doses of corticosteroids or other substances for periods between 1 and 14 days. After sacrifice, the back of the animals is shaved and a flap of skin measuring about 5×5 cm is removed. The skin flap is placed between 2 pieces of plastic material with known thickness. By these means, the actual thickness of the excised skin is measured by calipers. Two dumb-bell shaped specimens are cut with a special punch in perpendicular direction to the body axis having in the middle a width of 4 mm. They are fixed between the clamps of an Instron® instrument. In the usual experiments, stress-strain curves and ultimate loads are registered at a strain rate of 5 cm/min. From stress-strain curves, the values of ultimate load and ultimate extension are registered. The stress-strain curves show an almost linear part allowing the calculation of modulus of elasticity. Tensile strength is calculated from ultimate load divided by original cross-sectional area.

Dose response curves between 10 and 100 mg/kg cortisol acetate or 2 and 20 mg/kg prednisolone acetate show a sharp increase of ultimate load and tensile strength until 5 days, a continuous decrease of skin thickness upon longer treatment, and a decrease of ultimate load up to 2 months, which is below controls for ultimate load, but not for tensile strength (Vogel 1970a).

EVALUATION

Dose-response curves are established for various corticosteroids versus the standard cortisol allowing the calculation of potency ratios with confidence limits.

For a more detailed description of this method see Sect. P.11.2.1.1.

MODIFICATIONS OF THE METHOD

With a similar method, tensile strength of skin wounds after treatment with corticosteroids was studied in rats (Vogel 1970a,b). See also Sect. P.11.4.

Strain rate influences the values of ultimate load, tensile strength and modulus of elasticity, but not the effect of corticosteroids (Vogel 1972).

In contrast to parameters indicating strength and elasticity of collagen, the parameters indicating plasticity, like relaxation, hysteresis, strain at constant load (creep experiments), and isorheological behavior, are less dramatically changed by corticosteroids but indicate a decrease of viscosity or an increase of stiffness.

For a more detailed description of **relaxation experiments** (Vogel 1973) see Sect. P.11.2.1.5,

of **hysteresis experiments** (Vogel 1976, 1989) see Sect. P.11.2.1.6,

of **creep experiments** (strain at constant load) (Vogel 1977, 1989) see Sect. P.11.2.1.8,

of measurement of **isorheological behavior** (Vogel 1987, 1989) see Sect. P.11.2.1.7,

of ***in vivo* experiments** in rat skin (Vogel and Denkel 1985; Vogel 1989, 1993a). see Sect. P.11.3.

N.2.1.4 Topical activity of glucocorticosteroids

N.2.1.4.1 Skin thickness and tensile strength

PURPOSE AND RATIONALE

From clinical experience it is known that a decrease of skin thickness occurs after long-term local treatment with corticosteroids. The mechanical properties of human skin after treatment with corticosteroids, however, have not been sufficiently measured. A clear increase of tensile strength of skin after short term local administration of corticosteroids has been found in animal experiments, whereas skin thickness decreased.

PROCEDURE

Male Sprague-Dawley rats with an initial weight of 150 ±10 g are used. The animals are shaved before and once again during treatment. The animals are treated once daily during 10 days with various concentrations of the test compound or the standard or with fixed concentrations of the test compound in different galenical preparations. The test material is applied in a volume of 0.2 ml to an area of 4 cm^2 to the shaven back skin. The animals are kept in individual cages to avoid systemic absorption by mutual licking. Two days after the last treatment the animals are sacrificed, a flap of skin measuring about 5×5 cm is removed and skin thickness is determined. The skin flap is placed between 2 pieces of plastic material with known thickness. By these means, the actual thickness of the excised skin is measured by calipers. Perpendicular to the body axis 2 dumb-bell shaped specimens are punched out. Stress-strain curves are recorded using an Instron® instrument. The following parameters are determined:

- load at rupture (ultimate load)
- extension at rupture (ultimate strain)
- skin thickness
- tensile strength (ultimate load divided by cross sectional area)
- modulus of elasticity (calculated from the straight part of the stress-strain curve).

EVALUATION

Dose-response curves are established for the parameters ultimate load, ultimate strain, skin thickness, tensile strength, and modulus of elasticity for the standard (prednisolone acetate) and the test compound allowing the calculation of potency ratios with confidence limits.

CRITICAL ASSESSMENT OF THE METHOD

In addition to corticosteroid-induced atrophy of the skin after topical application, mechanical parameters can be determined by this assay.

MODIFICATIONS OF THE METHOD

Kapp et al. (1977) used a special devised apparatus for **rats** covering the site of substance application, which guarantees an exclusive dermal absorption and excludes an oral ingestion of the steroid.

In addition to skin thickness and breaking strength, Töpert et al. (1990) determined thymus weight, water and glycosaminoglycan content in skin of rats after topical application of steroids over 30 days.

Iwasaki et al. (1995) measured the skin atrophy in Wistar rats by locally applied clobetasol-17-propionate, a synthetic glucocorticoid, and the influence of

simultaneously applied RU 486. Twenty-four h after the last application, the thickness of the skin was measured with a dial skin thickness gauge, with an accuracy of 0.01 mm. The treated skin was pinched lengthwise, and both skin surfaces were held vertically between two plastic discs of the gauge.

Hartop et al. (1978) measured transepithelial water loss (TEWL) in the skin of **essential fatty acid-deficient rats** (Prottey et al. 1976; Lowe and Stoughton 1977) after local treatment with corticosteroids.

Woodbury and Kligman (1992) recommended the **hairless mouse** as model for assaying the atrophogenicity of topical steroids. Epidermal atrophy was determined by the number of cell layers of viable epidermis on 5 fields under 400× magnification. Dermal thickness was determined under 400× magnification. The total number of sebocytes in all visualizable sebaceous glands was counted in 10 fields at 250× magnification.

Van den Hoven et al. (1991) used the hairless mouse as a model to distinguish between local and systemic atrophogenic effects of topical steroids. Male hairless mice (strain h/h-NMRI) were treated on the left flank with test preparations once daily for 3 weeks. During this time, body weight was measured and skinfold thickness of treated and untreated sides was determined using a graduated micrometer. On day 21, the animals were sacrificed and dermal thymidine uptake and weights of the thymus were determined.

Corticosteroid-induced skin atrophy in hairless mice can be prevented by tretinoin (Lesnik et al. 1989; Schwartz et al. 1994). In these studies, albino Skh-hairless-1 mice were treated topically twice daily with corticosteroids or the combination with tretinoin. At the end of the treatment, all mice were sacrificed and specimens of the dorsal skin were frozen for light microscopy and quantification of glycosaminoglycans, fibronectin, and collagen.

Wrench (1980) applied commercially available topical corticosteroid preparations to the proximal halves of albino mouse tail for 21 days and measured epidermal thickness by histology. All steroids caused epidermal thinning, except clobetasone butyrate.

Altmeyer and Buhl (1981) tested the antiacanthogenic effect of topically applied steroids after long-term treatment of **guinea pigs** (up to 118 days) by histological measurement of epithelial thickness. For delimitation of the measuring lines, the upper boundary was taken as that between the stratum granulosum and the stratum corneum, and the lower boundary as that between the basal cell layer and the corium.

Kajita et al. (1986) tested epidermal beta-adrenergic adenylate cyclase responses in **pigs** after topical application of glucocorticoids. A significant increase of this receptor response was observed 24 h following topical application of potent glucocorticoid ointments. Domestic white-haired pigs were anesthetized with 30 mg/kg Nembutal i.p. Four 5 × 5 cm areas were chosen and the following treatments were administered to each area: (1) topical administration of glucocorticoid ointments; (2) UVB irradiation alone (230 mJ/cm^2); (3) topical application of glucocorticoid ointments following UVB irradiation; (4) no treatment as a control. After 24 h the treated pigs were anesthetized again and skin specimens were obtained from the 4 areas by means of a Castroviejo keratome (Storz Instrument Co., St. Louis, Missouri) adjusted to 0.3 mm setting. Each skin slice obtained by the Castroviejo keratome was cut into 5 × 5 cm squares, which were washed 3 times in RPMI 1 640 medium and preincubated in the RPMI 1 640 medium for 37 °C to standardize the cyclic AMP level (Yoshikawa et al. 1975). After the preincubation, 2 pieces of skin squares were randomly selected and were incubated with various adenylate cyclase stimulators (Iizuka et al. 1985). The concentrations of epinephrine, adenosine, and histamine added to the incubation medium were 50 μM, 2 mM and 1 mM, respectively. The cyclic AMP content in skin squares was measured by radioimmunoassay using a Yamasa cyclic AMP assay kit (Yamasa Shoyu Co., Tokyo, Japan) after partial purification (Yoshikawa et al. 1975). The cyclic AMP phosphodiesterase activities in skin squares were measured by the method of Adachi et al. (1976) who purified multiple forms of pig epidermal cyclic nucleotide phosphodiesterases by DEAE-cellulose column chromatography.

In vitro experiments measuring the effects of retinoids and glucocorticoids on the beta-adrenergic adenylate cyclase system of pig skin epidermis were performed by Iizuka et al. (1985).

N.2.1.4.2 Assay of topical glucocorticoid activity in transgenic mice

PURPOSE AND RATIONALE

Katchman et al. (1995) proposed a transgenic mouse model as biological assay of topical glucocorticosteroid potency.

PROCEDURE

A homozygous line of transgenic mice expressing 5.2 kilobases (kb) of the human elastin promoter region linked to the chloramphenicol acetyltransferase (CAT) reporter gene was developed (Hsu-Wong et al. 1994). For this purpose, 5.2 kb of human elastin 5'-flanking DNA is linked to a 0.7-kb CAT gene, followed by 0.3 kb of DNA with a polyadenylation signal. This linearized construct is injected into fertilized oocytes, and a line of transgenic mice expressing the human elastin promotor, as detected by CAT activity, is developed. These transgenic mice have no clinical phenotype and they do not express human elastin protein, as no part of the coding sequence is contained within the transgene. The human elastin promotor/CAT construct is expressed in a tissue-specific and developmentally regulated manner.

Four- or 5-day-old hairless pups, homozygous for the transgene, are used as test animals. In each experiment, pups of the same litter are used for comparison between glucocorticosteroid and control preparation in parallel. Steroid preparations are tested by applying 0.03 g uniformly on their dorsal surface (≈14 mg/cm^2). Control animals receive the same amount of creme base. The test animals are separated from each other and from their mothers and are sacrificed at different time points. Skin biopsies are removed immediately from the treated area.

For the CAT assay, skin is homogenized with a Polytron tissue homogenizer in 0.25 M TRIS hydrochloride (pH 7.5). The homogenates are then freeze-thawed three times and centrifuged at 10 000 *g* for 15 min. The protein content of the supernatant is determined by a commercial kit and aliquots, containing 100 mg of protein, are assayed for CAT activity in the linear range of the assay (Gorman et al. 1982) (see N.2.1.1.2).

EVALUATION

The significance of differences between different treatment groups is evaluated by Student's *t*-test.

N.2.1.4.3 Effect on epidermal DNA synthesis

PURPOSE AND RATIONALE

Du Vivier et al. (1978), Marshall and Du Vivier (1978), Marshall et al. (1981), Clement et al. (1983) evaluated the local and systemic effects of topically applied corticosteroids on epidermal DNA synthesis in hairless mice.

PROCEDURE

Hairless mice of either sex, 2–4 months old, are dosed in groups of six with test preparations or control base. 0.03 ml of test drug formulation is spread over 3 cm^2 of the anterior dorsal skin. The posterior half of the dorsal surface of the animal is left untreated. Animals are injected subcutaneously with 25 mCi (methyl-^{3}H) thymidine, specific activity 5 Ci/mM in the right thigh 1 h before being sacrificed 6 or 24 h after application of test formulation.

The neck and back skin samples, with at least 2 cm unsampled skin left between them (to avoid inclusion of treated skin in the back sample) are removed. The epidermis is separated from the dermis by placing the sample, dermis downwards, on a stain-less steel plate at 57 °C for 25 s. The epidermis can then easily be separated from the dermis with a scalpel blade. The epidermal samples are wrapped in aluminum foil and stored at –20 °C until analysis.

Approximately 30 mg of epidermis in 5 ml of a 0.24 M sodium phosphate buffer solution, containing 8 M urea, 1% sodium lauryl sulfate and 1 mM EDTA at pH 6.8, is lysed using an ultrasonic disintegrator. DNA is extracted from the cell lysate by column chromatography using hydroxylapatite. The epidermal cell lysate is added to the hydroxylapatite column and washed with a buffer containing 0.24 M sodium phosphate and 8 M urea at pH 6.8 to remove RNA and protein. The urea is then removed with 50 ml of 0.14 M sodium phosphate buffer at pH 6.8. Double stranded DNA, which binds to hydroxylapatite under low salt buffer conditions, is eluted with 0.48 M sodium phosphate buffer at pH 6.8, and a 2 ml sample is collected.

The DNA concentration in the sample is determined by UV absorption at 260 nm in a spectrophotometer. 0.5 ml aliquots of the sample are added to 12 ml scintillation cocktail and 0.2 ml N HCl in scintillation vials. Each sample is prepared in triplicate and counted for 20 min/vial in a scintillation counter.

EVALUATION

The results are initially expressed as mean counts per minute (c.p.m.) for the vial triplets. The efficacy of counting for each sample is determined from the relevant channels ratio for that sample using a counting efficacy/channels ratio (quench correction) curve for this counting system. Mean c.p.m. are thus converted to mean disintegrations per minute (d.p.m.) and the results expressed as d.p.m./μg DNA. The significance of differences between different treatment groups is evaluated by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Marks et al. (1973) described a method for the assay of topical corticosteroids in mice. Sticky tape was applied five or six times to the dorsal skin of mature male hairless mice of the Harwell strain to remove the horny layer. A similar quantity of topical test preparations (about 70 mg) was applied on the stripped dorsal skin of each mouse. A dressing of cotton gauze lined with a plastic film was applied and secured with strapping staying for periods from 5 to 156 h. Four h before sacrifice the mice were intraperitoneally injected with 0.15 ml of a 0.1% colcemid solution together with 30 μCi of tritiated thymidine. After sacrifice the dorsal skin to which the preparation had been applied, was removed, fixed in 10% buffered formalin and stained with haematoxylin and eosin. For estimation of the mitotic index, cells in the prophase, anaphase, and metaphase stages were counted. To quantitate the labelling index, the number of labelled basal and suprabasal cells was estimated as a proportion of the total number of basal cells.

N.2.1.4.4 Induction of drug metabolizing enzymes

PURPOSE AND RATIONALE

Finnen et al. (1984, 1985) evaluated the effects of topical application of glucocorticosteroids on the

activity of drug metabolizing enzymes in the skin of adult hairless mice. The ability of steroid preparations to induce enzyme activity was related to their clinical potency.

PROCEDURE

Adult male and female hairless mice are treated with 0.3 g of test creams or cream base applied to the dorsal skin and rubbed in until no visible traces remain. Sixteen to 18 h after treatment, the animals are sacrificed, the treated area of skin removed, placed epidermis down on a curved surface and subcutaneous fat and muscle removed using a scalpel blade. Epidermis and dermis are separated by a heating technique (Thompson and Slaga 1976). The tissue is then placed in 0.1 M phosphate buffer pH 7.4 and minced finely using surgical scissors. Scissors minced tissue is then homogenized in ice-cold 0.1 M phosphate buffer pH 7.4 using a Polytron homogenizer. Whole skin homogenates are then centrifuged at 9 000 *g* for 20 min and the resulting supernatant used as source for the determination of ethoycoumarin O'dealkylase (Greenlee and Poland 1978). For the determination of ethoxyresorufin O'dealkylation (Pohl and Fouts 1980) the 9 000 *g* supernatants are further centrifuged at 100 000 *g* for 1 h, the resulting microsomal pellet resuspended in 0.1 M phosphate buffer pH 7.4, and used as the enzyme source. DNA content of the 9 000 *g* pellet is estimated by the diphenylamine reaction (Burton 1956).

EVALUATION

Results are shown as mean ±SE. The significance of differences between different treatment groups is evaluated by Student's *t*-test.

N.2.1.4.5 Cornea inflammation in rabbits

PURPOSE AND RATIONALE

Leibowitz et al. (1974, 1978, 1992), Cantrill et al. (1975) studied the anti-inflammatory efficacy of topical corticosteroids for treatment of glaucoma in rabbits.

PROCEDURE

New Zealand albino rabbits weighing 1.8–2.3 kg are anesthetized for approximately 5 min with 15 mg/kg i.v. thiamylal sodium. A corneal inflammatory response is produced by intralamellar inoculation of 0.03 ml of laboratory-grade clove oil. Before the induction of corneal inflammation, the rabbits are given three intravenous inoculations of 1.85×10^6 Bq/kg of an aqueous solution of tritiated thymidine (24.79×10^{10} Bq/mol) at 24-h intervals. The intracorneal injection of clove oil is given concomitantly with the third thymidine injection. Twenty-four hours later, therapy is initiated. A standard drop (0.05 ml) of drug is instilled hourly for a total of six doses, and then, after a lapse of 18 h, one drop is administered hourly for an additional total of seven doses.

Various corticosteroid preparations are tested in different concentrations. A control group is run with each experimental trial; control rabbits are handled in the same manner as experimental rabbits, except that the control rabbits receive either prednisolone acetate (positive control) or no treatment (negative control). Following completion of the treatment protocol, a 10-mm penetrating corneal button is removed by trephination, and tissue samples are placed in a commercially available solubilizing agent (Soluene 350, Packard Instrument Co.), 1 ml per cornea, until dissolved. The soluble samples are counted in a scintillation counter for a minimum of 10 min, quantitatively measuring the amount of radioactivity in each cornea.

EVALUATION

The significance of differences between different treatment groups is evaluated by Student's *t*-test.

N.2.1.4.6 Endotoxin-induced uveitis in rats

PURPOSE AND RATIONALE

When injected into the footpad of rats, *Salmonella* endotoxin, a lipopolysaccharide, produces uveitis. This is manifested in the anterior uvea and characterized by miosis with iris hyperemia, increase of protein content in aqueous humor and inflammatory cell accumulation in the anterior uvea and aqueous humor. Glucocorticoids strongly inhibits release of inflammatory mediators and this type of endotoxin-induced uveitis (Cousins et al. 1982; Tsuji et al. 1997).

PROCEDURE

Female inbred Lewis rats weighing about 160 g are used. Five hundred µg/kg Salmonella endotoxin dissolved in saline are injected into the footpads. Twelve hours later, the animals are sacrificed and both eyes of each animal used in the experiments. The anterior chamber of the eye is punctured, using a 27 gauge needle to collect the aqueous humor. Five-microliter aqueous humor samples are placed into 495 µl of phosphate-buffered saline containing 1% paraformalde-hyde. Cell number in the aqueous humor is then counted using a flow cytometry system. The cell number of both eyes of each animal is averaged for the statistical analysis of the results.

In topical applications, glucocorticoids are instilled (5 µl/eye) three times at 1 h before and 3 and 7 h after lipopolysaccharide injection. For systemic application, glucocorticoids are injected subcutaneously 3 h after lipopolysaccharide injection.

Total RNA is isolated from the iris-ciliary body with a mRNA purification kit (Pharmacia Biotech, Uppsala, Sweden). Each RNA sample is extracted from the pooled iris-ciliary bodies of both eyes of each animal. The extracted RNA is quantified after which 4 µg is used for DNA synthesis via polymerase chain reaction.

EVALUATION

Dunnetts's multiple comparison test is adopted for the statistical analysis of the results.

Further methods measuring local or **topical activity** of corticosteroids described in Sect. H.3 **"Anti-inflammatory activity"**, such as

- **Oxazolone induced ear edema in mice** (see Sect. H.3.2.2.4),
- **Croton-oil induced ear edema in rats or mice** (see Sect. H.3.2.2.5),

are very suitable for evaluation of local corticosteroid activity

Furthermore, methods described in Chapter I **"Anti-arthrotic and immunmodulatory activity"**

- I.2.2.4 **Passive cutaneous anaphylaxis**
- I.2.2.6 **Delayed type hypersensitivity**

are recommended as models for testing topical corticosteroid potency.

N.2.1.5 Anti-glucocorticoid activity

N.2.1.5.1 Adrenal and thymus involution

PURPOSE AND RATIONALE

The involution of thymus and adrenal glands induced by hydrocortisone can be antagonized by compounds with antiglucocorticoid activity.

PROCEDURE

Groups of 6–10 immature male Sprague-Dawley rats weighing 60–70 are injected subcutaneously daily for 6 days with 0.2 ml of a suspension of different doses of the test compound in 0.5% aqueous carboxymethylcellulose solution, with hydrocortisone acetate as the agonist in daily doses of 0.2 mg per animal. Controls receive hydrocortisone acetate only. On the seventh day, the animals are sacrificed and the adrenal and thymus weights determined.

EVALUATION

The relative weight (quotient of adrenal or thymus weight (mg) and body weight (g)) is calculated for each rat. Means of the antagonist-treated groups are compared with the means of hydrocortisone only controls. Increase of thymus and adrenal weight relative to the hydrocortisone control indicates antiglucocorticoid activity.

MODIFICATIONS OF THE METHOD

Inhibition of tyrosine aminotransferase induced by corticosterone or dexamethasone was used by Vicent et al. (1997) to characterize the antiglucocorticoid properties of a novel synthetic steroid.

N.2.2 Mineralocorticoid activity

N.2.2.1 *In vivo* methods

N.2.2.1.1 General considerations

Very early bioassays ("Survival tests") have been used to standardize extracts of adrenal cortex for mineralocorticoid activity. Several animal species do not survive after adrenalectomy. However, they can be kept alive by administration of mineralocorticoids. The first animal species used successfully was the adrenalectomized drake (Bülbring 1937). The methods employing adrenalectomized rats and mice (Dorfman 1962) suffer from the fact that in these species aberrant adrenal cortical tissue may occur, which is not removed by the classical adrenalectomy. In contrast, male Syrian golden hamsters weighing 50–60 g are very suitable to test adrenocortical activity (Junkmann 1955). For evaluation of mineralocorticoid activity these tests have been replaced by bioassays measuring electrolyte excretion in the urine.

N.2.2.1.2 Electrolyte excretion

PURPOSE AND RATIONALE

Mineralocorticosteroids enhance sodium retention and potassium excretion. The sodium excretion in adrenalectomized rats is dose-dependently decreased. This parameter can be used for mineralocorticoid activity of test compounds (Kagawa et al. 1952).

PROCEDURE

Male Sprague-Dawley rats weighing 140–160 g are adrenalectomized. They are maintained on 1% NaCl solution as drinking fluid. On the morning of the fourth postoperative day, food and drinking fluid are withdrawn. On the following day, each rat is given 5 ml water by stomach tube; one hour later 5 ml 0.9% NaCl orally. Test compounds may be injected s.c. in 0.2 ml of vehicle suspension. The rats are lightly anesthetized with ether to induce emptying of the bladder and placed in metabolic cages, 2 rats per cage, 3 cages per dosage group, for 4 h, again anesthetized with ether and removed from the cages. Urine volume is recorded and cages rinsed over the collection cylinders with a distilled water spray. Collections are diluted to 100 ml and appropriate dilutions analyzed for sodium with a flame photometer. Sodium is expressed as percent of excretion of control animals. Desoxy-corticosterone acetate in doses between 1 and 40 µg per rat is used as standard.

EVALUATION

Percent reduction of sodium excretion compared with controls is calculated for each dosage group. Dose-response curves are compared with the dose-response curve of desoxycorticosterone acetate to calculate potency ratios.

MODIFICATIONS OF THE METHOD

Simpson and Tait (1952) measured both urinary sodium and potassium and used the sodium-to-potassium ratio as an index of electrolyte activity of corticoids. Nikisch et al. (1991) infused glucocorticoid-substituted adrenalectomized rats with saline-glucose solution containing aldosterone and measured sodium and potassium concentrations in 1 h fractions of urine. The anti-aldosterone activity was assessed by the ability of test compounds to reverse the aldosterone effect on the urinary Na/K ratio.

N.2.2 *In vitro* methods

N.2.2.1 Mineralocorticoid receptor binding

PURPOSE AND RATIONALE

Rat kidney receptor preparations and radioactive labeled aldosterone are used to test binding to the mineralocorticoid receptor (Raynaud et al. 1975; Pasqualini and Sumida 1977; Ojasoo and Raynaud 1978).

PROCEDURE

Kidney homogenates of adrenalectomized rats are centrifuged at 0 °C for 10 min at 800 *g* in a buffer solution (10 mM Tris, 0.25 M saccharose, HCl, pH 7.4). Following addition of RU 28 362 at 0.001 mM (to inhibit binding of aldosterone to the glucocorticoid receptor) the supernatant is centrifuged again at 105 000 *g* for 60 min. The supernatant (cytosol) is removed and incubated at 0 °C with ^{3}H-aldosterone (5 nM) and increasing concentrations of test compounds (0–25 000 nM). Non-specific binding is determined in the presence of 1 µM aldosterone.

Free ^{3}H-aldosterone is removed from the incubation medium by the charcoal-dextran technique after 1 h or 24 h of incubation (Raynaud 1978). Following centrifugation, concentration of receptor bound ligand is determined in the supernatant by liquid scintillation counting.

EVALUATION

The following parameters are calculated:

- total binding of ^{3}H-aldosterone
- non-specific binding in the presence of 1 µM aldosterone
- specific binding = total binding – non-specific binding
- % inhibition: 100 – specific binding as percentage of the control value.

Compounds are first tested at a single high concentration (25 000 nM) in triplicate. For those showing more than 50% inhibition a displacement curve is determined using 7–8 different concentrations of compound. Binding potency of compounds is expressed as binding affinity (RBA), relative to the standard compound (aldosterone).

MODIFICATIONS OF THE METHOD

Affinity for the mineralocorticoid receptor was tested in the cytosol of rabbit kidneys (Claire et al. 1993) or rat kidney slices (Funder et al. 1974). It is also useful to use overexpressed human mineralocrticoid receptor.

Monkey kidney COS-1 cells were transfected with plasmids containing the human mineralocorticoid receptor – being cloned by Arriza et al. (1987) – and glucocorticoid receptor for binding studies with various steroids (Rupprecht et al. 1993a,b).

A survey on mineralocorticoid receptor ligands has been given by Sutano and de Kloet (1991).

Specific bioluminescent *in vitro* assays for selecting potential antimineralocorticoids were developed by Jausons-Loffreda et al. (1994).

Wehling (1994) found evidence for a membrane-bound mineralocorticoid receptor in human mononuclear leukocytes.

The human mineralocorticoid receptor was used by Grassy et al. (1997) to study structure-activity relationships of steroids with antimineralocorticoid activity.

Davioud et al. (1996) described synthesis and biological activities of new steroidal diazo ketones as potential photoaffinity labeling reagents for the mineralocorticoid receptor.

Fagart et al. (1997a) recommended [^{3}H-2]-21-diazoprogesterone as a potent photoaffinity labeling reagent for the mineralocorticoid receptor.

Fagart et al. (1997b) proposed a three-dimensional model for antagonism in the human mineralocorticoid receptor.

The biological and clinical relevance of glucocorticoid and mineralocorticoid receptors has been reviewed by Funder (1997).

N.2.2.2.2 Transactivation assay for mineralocorticoids

PURPOSE AND RATIONALE

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1995, 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor acts with hormone responsive elements of hormone-regulated genes, thereby inducing a cascade of transcriptional events (Green and Chambon (1988). The hormone-dependent transcriptional activation can be determined in tissue culture by transfection of the steroid receptor under investigation and a reporter gene linked to a hormonally responsive promotor into cells. The transactivation assay allows determination of the agonistic and also of the antagonistic activity of a given compound, by either induction or inhibition of reporter gene activity (Fuhrmann et al. 1992).

PROCEDURE

Vector construct

The expression plasmid pRShMR containing the full-length coding sequence of the mineralocorticoid receptor expressed from the long terminal repeat of the Rous sarcoma virus is prepared according to Arriza et al. (1987). The pMMTV-CAT plasmid containing the mouse mammary tumor virus promotor linked to a chloramphenicol acetyltransferase gene is prepared according to Cato et al. (1986).

Cell culture and transfections

CV-1 cells and COS-1 cells for transient infections are cultured in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal calf serum, 4 mmol/L L-glutamine, penicillin and streptomycin. Stable and transient transfections are performed using Lipofectin reagent (Gibco BRL) according to a procedure recommended by Felgner and Holm (1989). Stable transfections are carried out according to Fuhrmann et al. (1992). For transient transfection, 1×10^6 COS-1 or CV-1 cells, respectively, are plated onto 100-mm dishes one day prior to transfection. Cells are typically about 80% confluent after 24 h. Before transfection,

cells are washed twice with 1 ml Opti-MEM (Gibco BRL) per dish. For each dish, 5 µg pRShMR (hMR expression plasmid) and 5 µg pMMTV-CAT are diluted with 1 ml Opti-MEM; in addition, 50 µg Lipofectin Reagent is diluted with 1 ml Opti-MEM. Next, DNA and Lipofectin Reagent dilutions are combined in a polystyrene snap-cup tube to obtain 2 ml of transfection solution per dish, gently mixed, incubated at room temperature for 5 min, and added to the washed cells. After 5 h the transfection solution is replaced by 6 ml DMEM supplemented with 10% fetal calf serum.

To study the effect of the test hormones, transiently transfected cells are trypsinized, pooled and replated onto 60-mm dishes at a density of 4.5×10^5 per dish 24 h after transfection. Stably transfected cells are seeded onto 6-well dishes (1×10^5 cells per dish). Cells are cultured in medium supplemented with 3% charcoal-stripped fetal calf serum and the appropriate hormones for 48 h. As negative control for the reporter gene induction, cells are cultured with 1% ethanol. Transactivation assays with transiently or stably transfected cells are carried out at least three times.

CAT assay

Transiently transfected cells and stably transfected cells are disrupted by freezing (ethanol/dry ice bath) and thawing (37 °C water bath) three times. Protein concentrations of the cell extract are determined according to Bradford (1976). The CAT assay is performed according to Gorman et al. (1982).

EVALUATION

CAT activity is calculated as percent conversion from chloramphenicol to acetylated chloramphenicol. Concentration-response curves for CAT induction are established to demonstrate the potency of the test hormone. Aldosterone (10^{-10} to 10^{-6} mol/l) serves as standard.

For antimineralocorticoid activity, CAT activity in the presence of 10^{-8} mol/l aldosterone is set as 100% and relative CAT activity is calculated as percentage of this value. Concentration-response curves for CAT inhibition are established with increasing concentrations of the antihormone.

CRITICAL ASSESSMENT OF THE METHOD

See N.2.1.1.2.

MODIFICATIONS OF THE METHOD

White et al. (1994) described a simple and sensitive high-throughput assay for steroid agonists and antagonists. A DNA cassette, containing a synthetic steroid-inducible promotor controlling the expression of a bacterial chloramphenicol acetyltransferase gene (GRE5-CAT), was inserted into an Epstein-Barr virus episomal vector, which replicates autonomously in primate and human cells. This promotor/reporter system was used to generate two stably transfected human cell lines. In the cervical carcinoma cell line HeLa, which expresses high level of glucocorticoid receptor, the GRE5 promotor is inducible over 100-fold by the synthetic glucocorticoid dexamethasone. In the breast carcinoma cell line T47D, which expresses progesterone and androgen receptors, the GRE5 promotor is inducible over 100-fold by either progesterone or dihydrotestosterone. These cell lines can be used to screen large numbers of natural and synthetic steroid agonists and antagonists in microtiter wells directly using a colorimetric chloramphenicol acetyltransferase assay.

Rupprecht et al. (1993a,b) examined the functional agonistic and antagonistic activity of several steroids by co-transfecting human mineralocorticoid or human glucocorticoid receptor expression vectors, together with a mouse mammary tumor virus-luciferase (MTV-LUC) reporter gene into the human neuroblastoma cell line SK-N-MC. Transfections were performed using an electroporation system (Biotechnologies and Experimental Research, San Diego, CA).

Lombès et al. (1994) used a cotransfection assay in CV-1 cells to study the discrimination of aldosterone from natural and synthetic glucocorticoids by the human mineralocorticoid receptor. Cells were transfected by the calcium phosphate method with pRShMR, a plasmid that contains the entire coding sequence of the human mineralocorticoid receptor; pFC31Luc, which contains the mouse mammary tumor virus (MMTV) promotor driving the luciferase gene; pCH110 encoding the β-galactosidase as an internal transfection control; and pSP72 as plasmid carrier.

Lim-Tio et al. (1997) studied the determinants of specificity of transactivation by the mineralocorticoid or glucocorticoid receptor in three cell lines: CV-1 cells; a porcine renal epithelial cell line, LLC-PK1; a pig kidney cell strain, and RN33B; a neuronal medullary raphe cell line. The reporter gene used was MMTV-LUC (the long terminal repeat of the mouse mammary tumor virus promotor linked to the luciferase reporter gene). RSV-CAT (Rous sarcoma virus promotor-chloramphenicol acetyl transferase gene) was used as internal control for transfection efficacy.

N.2.2.3 Antimineralocorticoid activity

N.2.2.3.1 Electrolyte excretion

PURPOSE AND RATIONALE

The method is based on mineralocorticoid activity of desoxycorticosterone acetate reversed by simultaneous administration of antimineralocorticoids.

PROCEDURE

Male Sprague-Dawley rats weighing 140–160 g are adrenalectomized and maintained on 1% NaCl solution as drinking fluid. On the morning of the fourth postoperative day, food and drinking fluid are withdrawn. On the following day, each rat is given 5 ml water by stomach tube; one hour later it is given 5 ml 0.9% NaCl orally and injected with 40 µg desoxycorticosterone acetate. At a separate site, the antagonistic test compound is injected s.c. in 0.2 ml of vehicle suspension. Spironolacton 50 µg and 500 µg is injected as the standard to separate reference groups. The rats are placed in metabolic cages and lightly anesthetized with ether to induce emptying of the bladder, 2 rats per cage, 3 cages per dosage group, for 4 h, and again anesthetized with ether before being removed from the cages. Urine volume is recorded and cages rinsed over the collection cylinders with a distilled water spray. Collections are diluted to 100 ml and appropriate dilutions analyzed for sodium and potassium with a flame photometer.

EVALUATION

The amount of excreted water, sodium and potassium per 100 g rat is calculated. The product of water volume and sodium excretion is divided by the potassium excretion. This quotient is compared with the values of untreated adrenalectomized rats and animals treated with desoxycorticosterone acetate only.

MODIFICATIONS OF THE METHOD

Antimineralocorticoid activity of spironolactone and its analogues has been tested in adrenalectomized golden hamsters treated simultaneously with daily injections desoxycorticosterone acetate over a period of 3 weeks (Vogel 1965). Mean survival of adrenalectomized animals of 4.7 days was prolonged to 13.5 days by daily subcutaneous injections of 2 mg desoxycorticosterone acetate. Additional injection of 0.5 or 1.0 mg spironolactone reduced the survival time.

Losert et al. (1985) tested the ability of several steroids with progestogenic potency to inhibit the renal actions of aldosterone in adrenalectomized, glucocorticoid-treated rats. The rats were continuously infused with an isotonic solution of low sodium content (0.05% NaCl + 5.2% glucose, 3 ml/rat/h) supplemented with d-aldosterone (1 µg/kg/h) resulting in a long-lasting reduction in renal sodium excretion, increase in renal potassium excretion and hence decrease in the urinary Na/K ratio. The test drugs were administered either subcutaneously or orally 1 h before start of infusion. The antimineralocorticoid activity was judged by the increase in the aldosterone-lowered Na/K ration in urine collected at hourly intervals up to 21 h.

De Gasparo et al. (1987) evaluated epoxy-spironolactone derivatives for their antimineralocorticoid activity (Kagawa test) and their antiandrogenic and progestogenic side effects *in vitro* and *in vivo*.

Gómez-Sánchez et al. (1990) reported the effect of intra-cerebroventricular infusion of mineralocorticoid antagonists on the hypertension in rats produced by chronic subcutaneous administration of aldosterone.

N.3 Ovarian hormones

N.3.0.1 Castration of female rats

PROCEDURE

Ovariectomy is performed in immature female rats weighing less than 60 g. The animal is slightly anesthetized with ether. A single transverse incision is made in the skin of the back. This incision can be shifted readily from one side to the other so as to lie over each ovary in turn. A small puncture is then made over the site of the ovary, which can be seen through the abdominal wall, embedded in a pad of fat. The top of a pair of fine forceps is introduced and the fat around the ovary is grasped, care being taken not to rupture the capsule around the ovary. The tip of the uterine horn is then crushed with a pair of artery forceps and the ovary, together with the fallopian tube, is removed with a single cut by a pair of fine scissors. Usually, no bleeding is observed. In older rats, the tip of the uterine horn may be ligated and the ovary removed distally from the ligature. The ovary of the other side is removed in the same way. The skin wound is closed by one or two clips. The animal recovers immediately. With some skill, the operation can be performed very rapidly.

N.3.1 Estrogens

N.3.1.1 *In vitro* methods

N.3.1.1.1 Estrogen receptor binding

PURPOSE AND RATIONALE

This assay is used to estimate estrogenic activity and potency of test compounds. Estradiol-17β is used as the reference compound. Estrogen receptors are prepared from mouse uteri or from human endometrium. Measurements of association rates and dissociation rates at different temperatures allow evaluation of relative binding affinities (Bouton and Raynaud 1977, 1978). Binding to the cytosolic and the nuclear fraction is measured.

PROCEDURE

Cytosol preparation. Uteri from 18-day old female Swiss mice are removed and homogenized at 0 °C in 1 : 50 (w/v) of 10 mM Tris-HCl (pH 7.4), 0.25 M sucrose buffer in a conical homogenizer. Human endometrium from menopausal women is frozen within 2 h of hysterectomy and stored in liquid nitrogen until use. The frozen endometrium is pulverized and homogenized in 1 : 5 (w/v) Tris-sucrose buffer. Homogenates are centrifuged for 1 h at 105 000 *g*.

Dextran-coated charcoal (DCC) adsorption technique. Binding is measured as follows. A 100 µl aliquot of incubated cytosol is stirred for 10 min at 0 °C in a micro-titer plate with 100 µl of Dextran-coated charcoal (DCC) suspension (0.625% Dextran 80 000, 1.25% charcoal Norit A) and then centrifuged for 10 min at 800 *g*. The concentration of bound steroid is determined by measuring the radioactivity in a 100 µl aliquot of supernatant.

Determination of specific binding in mouse uterus cytosol as a function of steroid concentration, incubation time and temperature. Triplicate aliquots of 125 µl of cytosol are incubated with 5 or 25 nM labelled steroid (estardiol-17ß) either for 2 or 24 h at 0 °C or for 2 or 5 h at 25 °C in the absence (total binding) or presence (non-specific binding) of a 100-fold excess of radio-inert steroid. Bound steroid is measured by DCC adsorption.

Measurement of association rate at 0 °C. 1 or 5 nM concentration of labelled steroid is added to cytosol maintained at 0 °C. Every 5 min for 1 h after addition of the labelled steroid, a 100 µl aliquot is transferred into a 5 000 nM radio-inert steroid solution in a microtiter plate to stop the reaction. Bound radioactivity is determined by DCC adsorption.

Measurement of dissociation rate at 25 °C. Dissociation rate is measured by the isotopic dilution technique. Radio-inert steroid (2 500 nM) is added to crude cytosol previously incubated with 5 nm labelled steroid for 15 h at 0 °C. After different times of incubation at 25 °C, 100 µl samples are treated with DCC at 0 °C in order to determine bound radioactivity. Specific binding is evaluated by subtracting non-specific binding from total binding.

Nuclear uptake. Homogenate samples (0.5 ml; 2 uteri/0.5 ml) are incubated with 2.5, 5 or 25 nM labelled steroid for 5 or 60 min at 25 °C, then cooled on ice and centrifuged at 800 *g* for 10 min at 0 °C. The pellet (crude nuclei) is washed 3 times with 1 ml Tris-sucrose buffer, dissolved in 0.5 ml Soluene (Packard) and counted.

Nuclear extract preparation. After incubation with 25 nM labelled steroid for 1 h at 25 °C, the crude nuclei are resuspended in 0.5 ml Tris-sucrose buffer, to which 50 µl of 4 M KCl are added. The suspension is stirred (Vortex), left for 30 min at 0 °C and then centrifuged for 30 min at 105 000 *g*. The radioactivity in a 100 µl supernatant sample (nuclear extract) is counted.

EVALUATION

For calculation of **relative binding affinity**, the percentage of radioligand bound in the presence of competitor compared to that bound in its absence is plotted against the concentration of unlabeled competing steroid. A standard curve for the competition of the unlabeled radioligand is constructed with the use of 9–10 concentrations; 5 or 6 concentrations of the competitor are tested. These are chosen to provide a linear portion of the semilog plot which crosses the point of 50% competition. From this plot, the molar concentration of unlabeled radioligand or steroid competitor that reduces radioligand binding by 50% is determined.

The relative affinity of a test compound is established as the ratio of unlabeled radioligand concentration to competitor concentration, at 50% competition. This ratio is multiplied by 100.

Association rate (k_{+1}) is calculated by the slope of the line

$$k_{+1}\, t = (2.3 / E_0 - R_0) \log (E\, R_0 / R\, E_0)$$

where E_0 and E represent free steroid and R_0 and R free receptor at time $t = 0$ and time t, respectively.

Dissociation rate (k_{-1}) is calculated from the slope of the line

$$k_{-1} = -2.3 \log B / B_0$$

where B_0 and B represent bound steroid at time $t = 0$ and time t, respectively.

MODIFICATIONS OF THE METHOD

Sheep uteri were used for the preparation of cytosol by Shutt and Cox (1972).

Pons et al. (1990) described receptor binding of estrogens and anti-estrogens in the estrogen receptor-positive breast cancer cell line MCF-7, using the firefly luciferase assay (Brasier et al. 1989) as endpoint.

Ludwig et al. (1990) described a microliter well assay for quantitative measurement of estrogen receptor binding to estrogen-responsive elements.

Hwang et al. (1992) studied the use of tetrahydrochrysenes, inherently fluorescent, which are high-affinity ligands for the estrogen receptor.

Estrogen receptor binding has also been used to study the mechanism of action of non-steroidal anti-estrogens (Jordan et al. 1977; Wakeling and Slater 1980; Astroff and Safe 1988).

Sequence and expression of human estrogen receptor complementary DNA has been reported by Greene et al. (1986).

Solution structure of the DNA-binding domain of the estrogen receptor has been described by Schwabe et al. (1990).

Cloning, chromosomal localization, and functional analysis of the murine estrogen receptor β has been reported by Tremblay et al. (1997).

Nichols et al. (1998) showed that agonists and antagonists differently position the C-terminus of the ligand-binding domain (helix 12) and the F domain of the estrogen receptor.

N.3.1.1.2 Transactivation assay for estrogens

PURPOSE AND RATIONALE

Transient transfection of a suitable cell culture with an estrogen-responsive-element (ERE)-controlled reporter gene has become a convenient assay for estrogens.

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1995, 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor interacts with hormone responsive elements of hormone-regulated genes, thereby inducing a cascade of transcriptional events (Green and Chambon 1988).

The assay in the estrogen-receptor-positive human breast cancer cell line MCF-7, described by Meyer et al. (1994) as a rapid luciferase transfection assay

for transcription activation of estrogenic drugs, has been used for evaluation of synthetic estrogen antagonists by von Angerer et al. (1994, 1995), Biberger and von Angerer (1996).

PROCEDURE

MCF-7 cells used for transfection are grown in Dulbecco's Modified Essential Medium supplemented with 10% fetal calf serum, 100 U penicillin, 100 µg streptomycin and 150 mg L-glutamine in 500 ml of medium without phenol red. Shortly before confluence, the cells are washed with 10 ml of PBS. Cells are gently shaken for a few seconds with trypsin-EDTA solution (4 ml) and after removal of the solution incubated for 2 min at 37 °C. After addition of 10 ml of medium, the cell suspension (0.5 ml/well) is transferred to 6-well plates containing 2 ml of medium. Cells are grown until the density of the monolayer is about 50% (1–2 days) before 2 µg of the luciferase reporter plasmid EREwtc luc, harboring the luciferase gene from Photinus pyralis, are added. For a successful transfection, it is necessary to generate a very fine precipitate of the DNA by subsequent dilution with 45% water, 5% M $CaCl_2$, and 50% HBS buffer and continuous shaking. After 20 min at room temperature, an opalescent solution should be obtained.

After addition of the DNA solution, the medium is removed and the cells are washed with 2 ml of PBS, followed by treatment with glycerol (15% in PBS) for 2 min. After washing with PBS, fresh medium containing the test substances is added. The maximum of luciferase expression is reached 18 h after addition of the transfection solution. At this time, the medium is removed and cells are washed with PBS. Cell lysis and quantification of luminescence is performed according to the procedure described in the luciferase assay system E1 500 of PROMEGA (Serva, Heidelberg, Germany). Luminescence is measured in a luminometer Lumat LB (Berthold, Wildbad, Germany) as relative light units, which are converted into fg luciferase by a calibration curve.

EVALUATION

Dose response curves of luciferase activity after induction by the test substances and estradiol as control (10^{-14} to 10^{-9} M) are established.

CRITICAL ASSESSMENT OF THE METHOD

See N.2.1.1.2.

MODIFICATIONS OF THE METHOD

With the same method as for MCF-7 cells, von Angerer et al. (1994), Biberger and von Angerer (1996) transfected HeLa-cells using the estrogen expression receptors HE0, HEG0, HE15 and HEG19, together with the receptor plasmid EREwtc luc.

Bergmann et al. (1994) determined estrogenic activity by a transient transfection assay in ER-deficient CHO cells transfected with an expression vector encoding the estrogen receptor using an estrogen-responsive reporter gene construct, $(ERE)_2$-TATA-CAT, containing two estrogen response elements linked to a TATA promotor and the chloramphenicol transferase reporter gene.

For assessing environmental chemicals for estrogenicity, Shelby et al. (1996) recommended a transcriptional activation assay in ER-transfected HeLa cells using the estrogen responsive reporter, ERE81CAT, and the pRSV vector containing the mouse ER cDNA without the neomycin resistance cassette. Triplicate samples for each hormone concentration were harvested at 28 h post-transfection and assayed for CAT protein using the CAT-ELISA kit (Boehringer Mannheim).

Several authors used yeast for assays of estrogenicity (McDonnell et al. 1991; Pierrat et al. 1992; Kohno et al. 1994; Bush et al. 1996; Tran et al. 1996; Odum et al. 1997)

Pierrat et al. (1992) constructed yeast strains in which the *Saccharomyces cerevisiae* URA3 gene is induced by the human estrogen receptor. Promotor sequences required for both basal and activated transcription of URA3 were replaced with estrogen-response elements positioned upstream of the native TATA box. These constructs were integrated at the TRP1 locus of a yeast strain in which the natural URA3 gene has been deleted and the integrants were transformed with shuttle plasmids expressing wild-type or truncated derivatives of human estrogen receptor. Transformants were assayed for growth on uracil-deficient medium plus or minus estradiol, for resistance to 5-fluoroorotic acid, and for activity of orotidine-5'-monophosphate decarboxylase, the product of the URA3 gene.

Tran et al. (1996) used the yeast strain ER(wt) expressing human estrogen receptor and an estrogen-sensitive reporter to characterize the estrogenic or antiestrogenic activities of polynuclear aromatic hydrocarbons.

Gaido et al. (1997) described a yeast-base steroid hormone receptor gene transcription assay to evaluate estrogenic and androgenic activity. The yeasts contain two separate plasmids: (1) an expression plasmid which contains the CUP1 metallothionein promotor fused to the human estrogen receptor cDND, and (2) a receptor plasmid carrying two estrogen response elements or a reporter plasmid carrying two copies of a progesterone/androgen responsive element upstream of the structural gene for β-galactosidase.

N.3.1.1.3
Estrogen dependent cell proliferation

PURPOSE AND RATIONALE

Specific cell proliferation induced by estrogens is the principle of these assays. Some human breast cancer cell lines, such as MCF-7 and T47-D cells, respond to estrogens with proliferation. This effect has been used for assays of estrogenic and antiestrogenic activity (Scholl et al. 1983; Miller and Katzenellenbogen 1983, Thompson et al. 1984; Palkowith et al. 1997; Zacharewski 1997).

PROCEDURE

MCF-7 breast adenocarcinoma cells are maintained in MEM (Minimal Essential Medium), minus phenol red (which is estrogenic at high concentrations) supplemented with 10% fetal bovine serum (FBS), 2 µM L-glutamine, 1 µM sodium pyruvate, 10 µM HEPES, nonessential amino acids and 1 mg/ml bovine insulin. Ten days prior to assay, MCF-7 cells are switched to maintenance medium supplemented with 10% dextran-coated FBS in place of 10%FBS to deplete internal stores of steroids. MCF-7 cells are removed from maintenance flasks using cell dissociation medium (Ca^{2+}/Mg^{2+} free HBSS, (phenol red-free) supplemented wit 10 µM HEPES and 2 nM EDTA). Cells are washed twice with assay medium and adjusted to 80 000 cells/ml. Approximately 100 µl (8 000 cells) is added to flat-bottomed microculture wells and incubated at 37 °C in a 5% CO_2 humidified incubator for 48 h to allow for cell adherence and equilibration transfer. Serial dilutions of test compounds, or DMSO as a diluent control, are prepared in assay medium and 50 µl transferred to triplicate microcultures, followed by 50 µl assay medium for a final volume of 200 µl. After an additional 48 h incubation, microcultures are pulsed with 1 µCi [^{3}H]thymidine (specific activity 6.7 Ci/mmol) for the last 5 4–6 h of culture and the assay terminated by freezing at –70 °C. Microcultures are then thawed and harvested using a Skatron semi-automatic cell harvester. Samples are counted by liquid scintillation using a Wallace BetaPlate β-counter.

EVALUATION

Plotting of dpm versus compound concentration is used to determine the half maximal effective concentrations EC_{50} or inhibitory concentration IC_{50}.

N.3.1.2 *In vivo* methods

N.3.1.2.1 Vaginal cornification

PURPOSE AND RATIONALE

This is an early bioassay for estrogenic activity based on epithelial proliferation. The Allen-Doisy test for vaginal cornification in rodents (Allen and Doisy 1923) is based on the observations of Stockard and Papanicolaou (1917), who first reported the cyclic vaginal cornification in guinea pigs.

PROCEDURE

Immature female Sprague-Dawley rats weighing about 55 g are ovariectomized. They are kept for about one week on standard laboratory diet and water ad libitum. The test compounds are administered orally or subcutaneously in 0.5% solution of carboxymethyl-cellulose or in cotton seed oil injected at several doses to groups of 10–20 rats. Doses of 0.02, 0.1, and 0.5 µg estradiol per animal are used as standard. The compounds are dosed e.g. twice daily on two following days at 10:00 A.M. and 5:00 P.M. At 5:00 P.M. of the third day and at 10:00 A.M. of the fourth day vaginal smears are taken using cotton swabs moistened with saline. The smears are transferred to a glass slide and stained for 10 min with 5% aqueous methylene blue solution. They are evaluated microscopically according to the following scores:

0 diestrus smear, mainly leukocytes, few epithelia cells
1 mixture of leukocytes and epithelial cells
2 proestrus smear, nucleated or nucleated plus cornified cells
3 estrus smear, cornified cells only.

Only animals showing score 2 or 3 are considered to be positive.

EVALUATION

The number of positive animals in each dosage group is recorded. ED_{50} values can be calculated and compared with the standard estradiol-17β.

MODIFICATIONS OF THE METHOD

The sensitivity of the assay is increased by local applications of estrogens into the vagina of castrated rats or mice (Emmens 1969).

N.3.1.2.2 Uterus weight

PURPOSE AND RATIONALE

This is an early bioassay for estrogenic activity based on myometrial/endometrial proliferation. Repeated administration of estrogens induces a dose-dependent increase of uterine weight in castrated female rats.

PROCEDURE

Immature female Sprague-Dawley rats weighing about 55 g are ovariectomized. Groups of 5–10 animals are injected daily with several doses of the test compound or the standard (estradiol 0.03 to 0.06 µg per animal s.c.) for seven days. The test compound is administered orally or subcutaneously in 0.5% solution of carboxymethylcellulose or in cotton seed oil. Controls receive the vehicle only. On the 8th day, the animals are sacrificed and uterine weights determined.

EVALUATION

Using at least two doses of test compound and standard each, dose-response curves are established and potency ratios calculated.

MODIFICATIONS OF THE METHOD

Rubin et al. (1951) used albino mice 23–25 days of age weighing approximately 8 g. The mice are given subcutaneous injections once daily for 3 days of an oil solution of the hormone. Twenty-four hours after the last injection, the animals are sacrificed and uterine and body weights recorded. The uterine ratio is calculated by dividing uterine weight in milligrams by body weight in grams, multiplied by 100 (relative uterine weight). Two groups receive a standard preparation and two groups the unknown.

Bhakoo and Katzenellenbogen (1977) showed that one of the earliest biosynthetic tissue responses after estrogen binding in the rat uterus, the synthesis of a specific uterine protein, called 'induced protein', is antagonized by progesterone.

In addition to uterus weight, Branham et al. (1993) studied luminal and glandular epithelium height in cross-sections of the uterine horns of rats by histological means.

Uterine peroxidase activity was proposed as a marker for estrogen action by Lyttle and DeSombre (1977), Astroff and Safe (1991).

Odum et al. (1997) compared the rodent uterotrophic assay with a yeast estrogenicity assay.

N.3.1.2.3 Chick oviduct method

PURPOSE AND RATIONALE

This is an early bioassay for estrogenic activity based on proliferation of the oviduct. The weight of the oviduct of young chicken is increased dose-dependently by natural and synthetic estrogens (Tullner and Hertz 1956).

PROCEDURE

Seven-day old pullet chicks are injected subcutaneously twice daily with solutions of the test compound in various doses for 6 days. Doses between 0.02 and 0.5 μg estradiol-17β per animal serve as standard. Six to 10 chicks are used for each dosage group. On the day after the last injection, the animals are sacrificed and weight of the body and oviduct determined.

EVALUATION

The ratio oviduct weight/body weight is calculated for each animal (relative weight). Mean values are plotted as dose-response curves in order to calculate potency ratios.

MODIFICATION OF THE METHOD

The assay can be used for evaluation of anti-estrogenic activity using simultaneous injection of 0.6 μg estradiol-17β or stilbestrol and the inhibitor, e.g., progestagens, and calculation of the percentage of oviduct weight in estrogen/antiestrogen treated animals versus the values of estrogen treatment only.

Tullner WW, Hertz R (1956) The effect of 17-alpha-hydroxy-11-desoxycorticosterone on estrogen-stimulated chick oviduct growth. Endocrinology 58:282–283

N.3.1.3 Anti-estrogenic activity

N.3.1.3.1 Antagonism of uterus weight increase due to estrogen treatment

PURPOSE AND RATIONALE

These assays are modifications of estrogen bioassays. The increase of uterine weight in castrated female rats induced by estradiol can be antagonized by anti-estrogenic compounds.

PROCEDURE

Immature female Sprague-Dawley rats weighing about 55 g are ovariectomized. Groups of 5–10 animals are injected daily for seven days with estradiol 0.03 to 0.06 µg per animal s.c. and various doses of the test compound or estradiol alone. The test compound is administered in 0.5% solution of carboxymethylcellulose or in cotton seed oil either orally or injected subcutaneously. On the 8th day, the animals are sacrificed and the uterine weights determined.

EVALUATION

Mean values of each group are calculated. The anti-estrogenic effect is expressed as percent reduction of estrogen-stimulated uterine weight by test compounds compared to rats treated with estradiol alone.

MODIFICATIONS OF THE METHOD

Three-week old female NMRI mice can be used for determination of uterus weight (Lerner et al. 1958).

The inhibition by anti-estrogens of vaginal cornification induced by estradiol can be used as parameter.

The chick oviduct weight can be adapted for the assay of anti-estrogenic activity (Tullner and Hertz 1956).

Castrated immature male rats show an increase in weight of the seminal vesicles when treated with 20 µg estradiol for 5 days, the effect is counteracted by anti-estrogenic steroids (Byrnes et al. 1953).

N.3.1.3.2 Aromatase inhibition

PURPOSE AND RATIONALE

Estrogen synthesis by aromatase occurs in various tissues including estrogen dependent tumors. Specific aromatase (estrogen synthetase) inhibitors are potentially useful therapeutic agent for estrogen dependent tumors, such as some breast cancers. 4-Hydroxyandrostandione (4OHA) inhibits aromatase completely but also causes destruction of the enzyme. Test compounds can be evaluated both *in vitr*o (Häusler et al. 1989) and *in vivo* (Geelen et al. 1991). Tests are based on stimulation of estrogen biosynthesis by LH and inhibition of this effect by aromatase inhibitors.

PROCEDURE

For *in vitro* experiments, ovarian tissue from adult golden hamsters (*Mesocricetus auratus*) is used. Estrus cycle is monitored for at least 3 consecutive 4-day estrus cycles prior to the experiment. The experiments for evaluating inhibitor effects are performed with ovaries obtained from animals sacrificed on day 4 (proestrus), at the time of preferred estrogen synthesis. The ovaries are excised, freed from adhering fat tissue and quartered. The quarters are transferred into plastic incubation flasks with 2 ml of Krebs-Ringer-bicarbonate (KBR) salt solution, pH 7.6, containing 8.4 mM glucose. The flasks are gassed with O_2/CO_2 (95%/5%), tightly closed and placed in a shaker/water bath (37 °C) for incubation of the fragments. The in-

cubation media are replaced with fresh KBR after preincubation for 1 h.

The ovaries are further incubated for 4 h in the presence or absence of ovine LH (100 ng/ml) and inhibitors to be tested. 4-OH-Androstendione is used as standard in concentrations between 0.33 and 330 µM/L. At the end of the experiment, the incubation media are removed and centrifuged. In the supernatant, estrogen, progesterone and testosterone are determined by radioimmunoassays.

EVALUATION

The results are expressed as percentage of inhibition relative to control incubations containing 100 ng/ml LH for estrogen stimulation in the absence of inhibitor. Statistical analyses are performed using Dunnetts's *t*-test.

MODIFICATIONS OF THE METHOD

Geelen et al. (1991) determined the *in vivo* aromatase activity of test compounds in hypophysectomized rats treated with the estrogen precursor dihydroepiandrosterone sulfate, using the inhibition of cornification of vaginal epithelium and estradiol levels in plasma as parameters. Furthermore, aromatase activity was determined in homogenized ovaries. To the supernatant, [1β-^{3}H]androst-4-ene-3,17-dione was added. Incubation was performed with a NADPH generating system for 1 h at 37 °C. Incubations were terminated by placing the tubes on ice followed by an extraction with chloroform. After phase separation by centrifugation, the aqueous phase was diluted with an equal volume of dextran coated charcoal suspension. Following centrifugation, the ^3H_2O content was determined by liquid scintillation counting. The amount of ^3H_2O is a measure of the amount of estrogen produced.

Zaccheo et al. (1989) studied the antitumor activity of aromatase inhibitors in rats with 7,12-dimethylbenzanthracene (DMBA)-induced tumors.

Wouters et al. (1993) studied the inhibition of aromatase activity in FSH-stimulated rat granulosa cells by vorozole, a selective, non-steroidal aromatase inhibitor.

Suzuki et al. (1996) described changes in prostate volume and histopathological findings in androstenedione-treated castrated beagle dogs as a bioassay for an aromatase inhibitor.

Takahashi et al. (1997) tested the inhibition of aromatase activity in the microsomes from fresh human placentae by the amount of tritiated water released from [1β-^{3}H]androstenedione. For biological proof, the dose-dependent suppression of androstenedione-induced uterine hypertrophy in immature rats was measured.

N.3.1.3.3 Anti-estrogenic effect on MCF-7 breast cancer cells

PURPOSE AND RATIONALE

The MCF-7 cell line, derived from a pleural effusion of a malignant breast cancer, is a widely studied model for hormone-dependent human breast cancer. These cells contain functional estrogen receptors and show a pleiotropic response to estrogen which can be used to evaluate antiestrogenic effects (Miller and Katzenellenbogen 1983; Scholl et al. 1983; Thompson et al. 1988). These cells proliferate and invade through an artificial basement membrane. Antiestrogens reduce both the proliferation and invasiveness of these cells.

PROCEDURE

MCF-7 cells are maintained in T75 flasks in IMEM (Biofluids, Rockville, MD) supplemented with 2 mM glutamine and 10% fetal bovine serum. To deplete estrogen, the cells are passaged for at least 2 weeks in IMEM supplemented with 5% calf serum which has been treated sequentially with sulfatase and dextran coated charcoal (DCC) to remove endogenous estrogen.

Estrogen and antiestrogen treatment

Cells are trypsinized, reseeded in tissue culture dishes (1×10^6 cells/10-cm-diameter Falcon dish), and allowed to adhere overnight in a humidified incubator (37 °C, 5% CO_2, 95% air). The cells are treated the next day with either 17β-estradiol (10^{-9} M) or the antiestrogen or 0.1% ethanol alone. Four days later,

the cells are harvested with trypsin, washed twice in IMEM containing 0.1% BSA, counted with a Coulter cell counter and tested for chemotaxis and chemo-invasion activities.

Chemoinvasion assay

Boyden chambers are used (Albini et al. 1987). Polycarbonate filters (12-µm pore, polyvinylpyrrolidone-free, Nucleopore) are coated with matrigel (25 µg/filter), a mixture of basement membrane components (Kleinman et al. 1986), which is dried and then reconstituted at 37 °C into a solid, even layer over the surface of the filter. Fibroblast-conditioned medium, obtained by incubating confluent NIH-3T3 cells for 24 h with IMEM, is used as the chemoattractant. Cells are harvested with trypsin, washed twice with BSA/IMEM, and added to the top chamber (300 000 cells/chamber). Chambers are incubated in a humidified incubator at 37 °C in 5% CO_2 in air for 6, 9, or 12 h. The cells which have traversed the matrigel and attached to the lower surface of the filter are stained with Diff-Quick (American Scientific Products) and quantitated electronically with the Optimax V image analyzer.

Chemotaxis assay

Chemotaxis assays are performed as described for the chemoinvasion studies with the single exception that the filter surfaces are coated with 5 µg collagen IV instead of the layer of matrigel. This coats the interstices of the filters but does not form a barrier over the surface. Chemotaxis assays are performed in parallel to the chemoinvasion assays using the same cells and conditioned medium.

EVALUATION

One-way analysis of variance is performed on the data from each experiment.

N.3.2
Progestional activity

N.3.2.1
In vitro methods

N.3.2.1.1
Gestagen receptor binding

PURPOSE AND RATIONALE

Progesterone receptor may be obtained from uterine tissue or cultured cells. Uteri from estrogen primed rabbits (Ojasoo and Raynaud 1978; Boonkasemsanti et al. 1989; Phillips et al. 1990; Cook et al. 1992), castrated and estrogen treated mice or rats (Philibert and Raynaud 1977; Li et al. 1997), MCF-7 cells derived from human breast tumor (Bergink et al. 1983; Kloosterboer et al. 1988a,b; Kloosterboer et al. 1994), breast cancer T47D cells (Meyer et al. 1990), the quail fibroblast cell line QT6 (Schowalter et al. 1991) or human uteri obtained after hysterectomy (Jänne et al. 1976; Pollow et al. 1989a,b, 1992). Tritium labeled progesterone or R 5020 ([6,7-^{3}H]17,21-dimethyl-19-nor-pregna-4,9-diene-3,20-dione), are used as ligands (Moguilewsky and Raynaud 1979).

PROCEDURE

Relative binding affinities. Human uteri obtained after hysterectomy are snap frozen in liquid nitrogen and stored at –80 °C until use. For cytosol preparations, uterine tissues are minced and homogenized with an Ultra-Turrax at 0–4 °C in ice-cold buffer composed of 10 mM KH_2PO_4, 10 mM K_2HPO_4, 1.5 mM EDTA, 3 mM NaN_3, 10% glycerol, pH 7.5 (PENG buffer). The homogenates are then centrifuged at 105 000 *g* at 4 °C for 30 min. The supernatant is taken as cytosol. The cytosol preparations are incubated with ^{3}H-R 5020 as radioligand at a concentration of 8 nmol/l and increasing concentrations (1×10^{-10} to 1×10^{-5} mol/l) of the competitor steroids overnight at 4 °C. Then, unbound steroids are adsorbed by incubating with 0.5 ml of DCC (0.5% Norit A, 0.05% dextran T400 in PENG buffer) for 10 min at 4 °C. After centrifugation (10 min at 1 500 *g* at 4 °C) 0.5 ml of the supernatant is withdrawn and counted for radioactivity.

Association rate and dissociation rate are determined as described for the estrogen receptor.

EVALUATION

For calculation of **relative binding affinity**, the percentage of radioligand bound in the presence of competitor compared to that bound in its absence is plotted

against the concentration of unlabeled steroid. A standard curve for the unlabeled radioligand (progesterone) is constructed with of 9–10 concentrations; 5 or 6 concentrations of the competitor are tested. The molar concentrations of unlabeled radioligand and steroid competitors that reduce radioligand binding by 50% are determined. The ratio of unlabeled radioligand and competitor for 50% competition multiplied by 100 is calculated for relative binding affinity.

Association rate (k_{+1}) is calculated by the slope of the line

$$k_{+1}\, t = (2.3 / E_0 - R_0) \log (E\, R_0 / R\, E_0)$$

where E_0 and E represent free steroid and R_0 and R free receptor at time $t = 0$ and time t, respectively.

Dissociation rate (k_{-1}) is calculated from the slope of the line

$$k_{-1} = -2.3 \log B / B_0$$

where B_0 and B represent bound steroid at time $t = 0$ and time t, respectively.

MODIFICATIONS OF THE METHOD

For screening procedures homogenates of rabbit uteri may be used (Philibert et al. 1977).

The binding of the progesterone agonist R 5 020 and of the progesterone antagonist RU486 to the progesterone receptor from calf uterus was characterized by Hurd and Moudgil (1988).

A high affinity ligand and novel photoaffinity labeling reagent for the progesterone receptor ([^{3}H]DU41 165) was described by Pinney et al. (1990).

Different DNA-binding properties of the calf uterine estrogen and progesterone receptors were explained by different dimerization constants (Skafar 1991).

Mutations of the progesterone receptor were found to be responsible for species specificity and have been used for evaluation of agonistic and antagonistic activity (Benhamou et al. 1992; Garcia et al. 1992).

The complete amino acid sequence of the human progesterone receptor has been deduced from cloned cDNA by Misrani et al. (1987).

Structural requirements of the ligand and mapping of the hormone-binding site of the progestin receptor have been discussed by Ojasoo and Raynaud (1990).

Allan et al. (1992) studied conformational changes in the ligand binding domain induced by various progestins and antiprogestins.

Collins (1994) recommended the ratio between the affinity of a compound to progesterone receptors to the affinity to androgen receptors as a selection criterion for new oral contraceptives.

Comparative pharmacology of newer progestagens has been reviewed by Kuhl (1996).

Oñate et al. (1994) found that the DNA-binding protein HMG-1 enhances progesterone receptor binding to its target DNA sequences.

The concept of two categories of progestin antagonists based on differences how the interact with and inactivate the progestin receptor has been discussed by Edwards et al. (1995).

N.3.2.1.2 Transactivation assay for gestagens

PURPOSE AND RATIONALE

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995, 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor acts with hormone responsive elements of hormone-regulated genes, thereby inducing a cascade of transcriptional events (Green and Chambon (1988).

Transactivation assays were used by several authors to test the progestional and antiprogestional activity of steroidal and non-steroidal compounds (Pathirana et al. 1995; Sobek et al. 1994; Jones et al. 1996; Dijkema et al. 1988; Edwards et al. 1998; Schoonen et al. 1998; Zhi et al. 1998)

PROCEDURE

CV-1 cells (African green monkey kidney fibroblasts) are grown in Dulbecco's modified Eagle medium containing 10% charcoal resin-stripped fetal bovine se-

rum, 2 mM glutamine, and 55 µg/ml gentamycin. Cells are maintained in an environment of 4% carbon dioxide and routinely passaged from T-255 flasks to 96-well microtiter plates (1.5×10^5 cells/well, 70% confluent) 1 day before transfection.

Cells are transiently transfected, by the standard calcium phosphate co-precipitation procedure with 50 ng/well of plasmids coding for: hPR(human progesterone receptor)-B (hPR-B1) and pRS-β-Gal under constitutive control and a reporter (MTV-LUC) containing a response element for the progesterone receptor. After 6 h, the medium is replaced with medium containing progesterone at concentrations between 10^{-11} and 10^{-5} M or another progestagen. After a 40 h incubation, wells are washed with phosphate buffered saline and the cells are lysed with Triton X-100-based buffer. An aliquot of lysate (20 µl) is then transferred to Dynatech 96-well plates containing 1.6 mM ATP. LUC activity (chemiluminescence upon addition of luciferin substrate) is determined using a Dynatech ML1 000 luminometer, according to the equation:

$$\text{LUC units} = \text{relative LUC units} \times 10^4$$

β-Gal activity is determined from the remaining lysate in the original 96-well plates. The substrate, o-nitro-phenol-β-galactoside, is added to the plates, followed by incubation at 37 °C. The incubation is terminated by addition of sodium carbonate when the average absorbance, as determined by visual observation of the yellow product (o-nitrophenol), is within a standard range. Absorbance at a wavelength of 415 nm is then quantified spectrophotometrically. β-Gal rates are calculated according to the following equation:

$$\beta\text{-Gal rate} = \frac{\beta\text{-Gal absorbance} \times 10^5}{\beta\text{-Gal incubation time}}$$

For each set of replicate wells, normalized response is calculated according the following equation:

$$\text{Normalized response} = \text{LUC units} / \beta\text{-Gal rate}$$

EVALUATION

Agonist activity is determined by examining the amount of LUC expression (normalized response). The effective concentration that produces 50% of the maximal response (EC_{50}) is quantified. The efficacy is a function of the LUC expression relative to the maximal LUC expression produced by the reference agonist, e.g., progesterone. Antagonist activity is determined by testing the amount of LUC expression in the presence of a fixed concentration (equal to its agonist EC_{50}) of reference agonist. The concentration of test compound that inhibits by 50% the gene expression induced by the reference compound is quantified (IC_{50}). In addition, the efficacy of antagonists is determined as a function of maximal inhibition (LUC expression = basal activity).

CRITICAL ASSESSMENT OF THE METHOD

See N.2.1.1.2.

MODIFICATIONS OF THE METHOD

For transactivation studies, hPRA-A-MMTV-LUC and hPR-B-MMTV-LUC and stably co-transfected CHO cells were used by Dijekema et al. (1998), Schoonen et al. (1998).

N.3.2.1.3 Alkaline phosphatase assay

PURPOSE AND RATIONALE

Progestins induce the *de novo* synthesis of alkaline phosphatase (Di Lorenzo et al. 1991, 1993). The progestin in-duction of the nonspecific tissue alkaline phosphatase is not altered by other steroid hormones or synthetic analogs. This finding has been used by Sobek et al. (1994), Pathirana et al. (1995), Li et al. (1997) to measure the progestogenic and antiprogestogenic actions in a microplate assay.

PROCEDURE

T47D cells are grown in 96-well plates near confluence and then treated with 0.1–0.2% alcohol (control) or steroid agonists; otherwise R 5 020 plus potential antagonist for 2 days. The cells are then fixed with 3.7% formaldehyde in phosphate buffered saline for 15 min at 15 °C, washed with 200 µl phosphate buffered saline and stored at –90 °C. After thawing, each well is incubated with 100 µl *p*-nitrophenyl phosphate (1 mg pNPP/ml) in DEAM (1 M diethanolamine, pH 9.8, containing 0.5 mM $MgCl_2$, and 20 µM $ZnSO_4$). The enzyme reaction is allowed to proceed in the dark at 37 °C. Formation of *p*-nitrophenol is monitored periodically at 405 nm in a microplate reader. In each microtiter plate, blanks, *p*-nitrophenol, and alkaline phosphatase standards are measured together with the samples. One unit of alkaline phosphatase is defined as the amount of enzyme capable of transforming 1 µmole of substrate in 1 min at 37 °C. Enzyme assays are performed under conditions of linearity relative to the substrate and to the concentration of proteins.

EVALUATION

Progestin concentrations corresponding to half the maximal increase in alkaline phosphatase activity (ED_{50}) are calculated graphically and by computer assisted analysis using the ImmunoFit EIA/RIA analysis software (Beckman Instruments, Inc.).

N.3.2.2 *In vivo* methods

N.3.2.2.1 Clauberg (McPhail) test in rabbits

PURPOSE AND RATIONALE

For this historical bioassay, Clauberg (1930a–d) first described the histological changes of the endometrium in estrogen pretreated rabbits after administration of progestional compounds. This test was further studied by Butenandt et al. (1934) and systematically examined by McPhail (1934) who introduced scores for the changes of the endometrium.

PROCEDURE

Immature female rabbits (Yellow Silver or New Zealand strain), weighing 550–650 g, receive daily injections of 5.0 µg estradiol benzoate per animal in sesame oil solution for a period of 6 days (priming). From the 7th until the 12th day (treatment for 5 days) the rabbits are administered the test drug or the standard in several doses. 3 to 4 animals are used for each dosage group. Standard doses are: 0.02, 0.08 and 2.0 mg progesterone per day and animal s.c. in sesame oil solution, or 0.01, 0.02, and 0.04 mg medroxyprogesterone acetate orally. Controls receive either the vehicles or estradiol benzoate only. On the 15th day, the animals are sacrificed, both horns of the uterus removed and fixed in 10% formalin. Sections are made from the middle part of each horn for histological examination.

EVALUATION

Rabbits treated with estradiol benzoate have an increased uterine weight (priming), progestagens induce further proliferation and secretory transformation. The following scores are established:

0 ramification of the uterus mucosa, but no proliferation (estrogen treatment only)
1 slight proliferation of the uterus mucosa
2 medium proliferation of the uterus mucosa, slight additional ramification
3 pronounced proliferation of the uterus mucosa
4 very pronounced proliferation of the uterus mucosa, pronounced ramification.

The scores from each dosage group are averaged. Dose-response curves are constructed in order to calculate potency ratios versus the standard (progesterone).

The evaluation needs some experience of the investigator. Preliminary experiments with standard drugs and photographical documentation of the histological findings are recommended.

MODIFICATIONS OF THE METHOD

In order to study the prolonged activity, the animals are pretreated with estradiol for 6 days, followed by a single subcutaneous injection of the test compound or hydroxyprogesterone capronate as standard. Daily treatment with estradiol is continued and the rabbits sacrificed at various intervals up to 4 weeks.

McGinty et al. (1939) established a local **progestional test** which involves the direct injection of progesterone into an uterine segment. The test is performed in immature rabbits primed for 6 days with estrogen. On the 7th day, the uterus is exposed by lapa-rotomy. The upper middle segment of each horn is ligated without disturbance of blood circulation. A solution of the gestagen in oil is injected into the lumen of one segment through the lower ligature, which is drawn tight after the injection. In the opposite horn, only the vehicle is injected. Three days later, the animals are sacrificed and sections of the horn are evaluated histologically according to the McPhail scores (Tayama et al. 1979).

Pincus et al. (1957) improved the quantitative aspects of the McPhail test with the planimetric measurement of the endometrial proliferation.

N.3.2.2.2 Endometrial carbonic anhydrase

PURPOSE AND RATIONALE

Carbonic anhydrase activity in the endometrium is increased after administration of progesterone. Carbonic anhydrase activity in the endometrium of rabbits is used for a quantitative progestin assay (Lutwak-Mann 1955; Miyake and Pincus 1958).

PROCEDURE

Immature female rabbits are estrogen primed and progestin treated as described in the Clauberg-test. After sacrifice of the animals, the uteri are opened longitudinally. Endometrium is dissected, weighed and homogenized with 10-fold volume in a glass homogenizer. After centrifugation, carbonic anhydrase is determined in the supernatant with the colorimetric method of Philpot and Philpot (1936) using bromo-thymol as indicator.

EVALUATION

Mean values of carbonic anhydrase activity/g wet tissue are calculated and potency ratios for test compound and standard established.

N.3.2.2.3 Deciduoma formation

PURPOSE AND RATIONALE

This is a classical bioassay for progestagens. The deciduoma tests are based on the fact that the endometrium of the estrogen-primed, progesterone-treated rodent is sensitive to local stimuli such as scratching (Astwood 1939), chemical irritation, and electrical stimulation, and produces a deciduoma, as the equivalent of a maternal placental tumor.

PROCEDURE

Adult female Sprague-Dawley rats weighing 200 to 250 g are ovariectomized and 1 week later treated with 0.5 μg estradiol/animal once daily subcutaneously for 4 days, followed by 9 days of progesterone or the test compound in various doses. The uterus is exposed on the fifth day of progesterone treatment and 1.0 mg histamine dihydrochloride is injected into the lumen of one horn. The animals are sacrificed after the last treatment. Both uterine horns are removed and weighed. The degree of deciduoma formation is evaluated by the percent increase in the weight of the histamine-injected uterine horn as compared with the control horn.

EVALUATION

Dose-response curves are established plotting % increase in weight of the treated uterus horn versus logarithm of dose of test compound and standard in order to calculate potency ratios.

N.3.2.2.4 Pregnancy maintenance

PURPOSE AND RATIONALE

This is a historical bioassay for progestational activity. In the rat, ovariectomy performed during the first half of pregnancy terminates gestation, but when performed during the second half of pregnancy does not result in abortion, because of the capacity of the placenta to produce progestin and estrogen. Maintenance of pregnancy after ovariectomy in early pregnancy can be achieved by sufficient exogenous progestin with and without estrogen.

PROCEDURE

Mature Sprague-Dawley female rats are inseminated by being placed with males overnight. The day that sperms are found, is considered to be day one of pregnancy. On day 8, the females are ovariectomized if found pregnant upon examination of the uterus. Test compounds are administered once daily, subcutaneously, for 13 days beginning immediately after ovariectomy. Estradiol (0.1 μg/day) is administered concomitantly with the test compound. On day 21, the animals are sacrificed and autopsied. Presence or absence of implantation sites, and the numbers of live embryos are recorded.

EVALUATION

Normal pregnant rats have an average of 11 implantation sites and about 10 live embryos. A net success index is calculated as percentage of this theoretical maximum effect of pregnancy maintenance.

MODIFICATIONS OF THE METHOD

Similar tests have been performed in rabbits (Elton and Edgren 1958), in mice (McGinty 1959), and in hamsters (Shipley 1965). In rabbits, abortion can be induced by intravenous injection of oxytocin from day 30 of gravidity onwards. This effect can be suppressed by potent gestagens.

N.3.2.3
Anti-progestional activity

N.3.2.3.1
Progesterone antagonism

PURPOSE AND RATIONALE

The anti-progestional activity of a test compound may be determined by antagonism against the effect of progesterone in the Clauberg/McPhail assay in rabbits (N.3.2.2.1) or the McGinty test (N.3.2.2.1) and in the deciduoma formation assay in rats (N.3.2.2.3).

MODIFICATIONS OFTHE METHOD

Progesterone control of cervical ripening in the guinea pig and the tree shrew *Tupaja belangeri* has been used for the evaluation of progesterone antagonists (Chwalisz et al. 1991; Chwalisz 1994). The effects of progesterone antagonists on surgically induced endometriosis in rats have been studied by Stöckemann and Chwalisz (1993).

Michna et al. (1991) developed a bioassay which allows quantification of the antiproliferative potency of progesterone antagonists on the mammary gland in rats. Female Wistar rats with a body weight of 100 g were ovarectomized under anesthesia. One week after ovariectomy the rats were substituted with 10 µg estrone and 3 mg progesterone for 3 days. The animals in the experimental groups simultaneously received the progesterone antagonist. The animals were sacrificed and the inguinal mammary glands dissected: the right gland for biochemical analysis (DNA), the left for morphometrical analysis. The entire inguinal mammary gland was prepared for conventional paraffin sections and stained with ferric ammonium sulfate. Microphotographs were taken in transmitted light. The number of tubulo-alveolar buds was counted in the whole mount preparations using a 40-fold magnification. In the neighborhood of the inguinal node, a square of 2.5 mm^2 was quantified and calculated for a tissue volume of 100 mm^3 in more than 10 animals. The antiproliferative action of progesterone antagonists on the amount of tubulo-alveolar buds was estimated for a 80% confidence interval of mean inhibition.

N.3.2.3.2 Luteolytic effect of prostaglandins

PURPOSE AND RATIONALE

Synthetic prostaglandins are used for synchronization of estrus and for treatment of anestrus caused by a persistent corpus luteum in cattle. Furthermore, synthetic prostaglandins were studied for termination of early pregnancy in humans (Karim et al. 1977; Takagi et al. 1977, 1978; Toppozada et al. 1979). The most useful animal model for luteolytic activity is the hamster (Gutknecht et al. 1971; Labhsetwar 1971, 1972a; Dukes et al. 1974; Bartmann et al. 1979; Galliani et al. 1984; Roy et al. 1987). Other species such as rat (Fuchs et al. 1974), mouse (Labhsetwar 1972b), and guinea pig (Blatchley and Donovan 1969) have also been studied.

PROCEDURE

Adult female golden hamsters (*Mesocricetus auratus*), weighing approximately 100 g with regular, 4-day estrus cycles, are housed under controlled light and temperature conditions and given a standard diet. They are caged with fertile males on the day before expected vaginal discharge and the next morning vaginal smears are taken. If clumps of spermatozoa are found in the smear, this day is designated as day 1 of pregnancy. Groups of 10 animals are treated on days 4, 5, and 6 with four different doses of standard (prostaglandin F2α) or test compound. On day 13 of pregnancy, the hamsters are sacrificed and tested for pregnancy by counting the number of implantation scars.

EVALUATION

The luteolytic activity is expressed as the median effective dose, at this dose pregnancy can be terminated in 50% of the treated animals (ED_{50}).

MODIFICATIONS OF THE METHOD

The mode of action of luteolysis by prostaglandins has been studied by various authors both *in vitro* (Speroff and Ramwell 1970; O'Grady et al. 1972; Henderson and McNatty 1975; Kenny and Robinson 1986; Brambaifa 1988) and *in vivo* (Pharriss and Wyngarden 1969; Johnston and Hunter 1970; McCracken et al. 1970; Chatterjee 1973; Buhr et al. 1983; Torjesen and Aakvaag 1984, 1986).

Cao and Chan (1993) investigated the effects of oxytocin and luteal prostaglandins on the functional regression of the corpus luteum in pseudopregnant rats.

Motta et al. (1996) studied the effect of an oxytocin receptor antagonist on ovarian and uterine synthesis and release of prostaglandin $F_{2\alpha}$ in pseudopregnant rats.

Stocco and Deis (1998) examined the participation of intraluteal progesterone and prostaglandin $F_{2\alpha}$ in LH-induced luteolysis in pregnant rats.

Luteolysis by prostaglandins in the rhesus monkey has been studied by Auletta and Kelm (1994) and Auletta et al. (1995).

The ewe as a model for regulation of luteal regression has been recommended by Hoyer (1998).

N.4 Testicular steroid hormones

N.4.0.1 Castration of male rats

PROCEDURE

Castration of young male rats is performed with minimal bleeding in animals weighing less than 60 g. The animal is anesthetized. A small transversal incision is made in the skin on the ventral site over the symphysis. The testis lying in the scrotum is gently pushed into the abdominal cavity. With a pair of fine forceps, the abdominal wall is opened. The epididymal fat pad, easily to be seen, is grasped with the forceps and the testis with the epididymis is pulled out from the wound. The ductus deferens with the testicular vessels is crushed with an artery forceps and the testis together with the epididymal fad pad cut off with a pair of fine scissors. There is almost no bleeding in young animals. In older animals, ligation of the testicular vessels together with the ductus deferens may be necessary. The same procedure is performed on the other side. The skin wound is closed with one or two wound clips. The animal recovers immediately. With some skill, the operation can be performed very rapidly.

MODIFICATIONS OF THE METHODS

Dorfman (1969) recommended to remove the testes through an incision in the tip of the scrotum. In our hands, the procedure described above was preferable.

N.4.0.2 Caponizing of cockerels

PROCEDURE

This is a classical bioassay for androgens. White Leghorn cockerels are used for surgery at approximately 6 weeks of age. The animals being fasted 24 h prior to surgery are anesthetized with ether and placed on their sides. An incision is made between the last two ribs, the muscle layer is divided, and the incision is pulled apart with small retractors. The testis is found close to the midline of the posterior abdominal wall, alongside

the vena cava. The capsule enclosing the testis is cut and the gonad is removed. It is imperative to remove the testis intact, as fragments left behind are usually vascularized and persist, giving rise to incompletely caponized animals. The incision is closed by suture. The second testis is removed in a similar fashion.

N.4.1
Androgenic and anabolic activity

N.4.1.1
In vitro methods

N.4.1.1.1
Androgen receptor binding

PURPOSE AND RATIONALE

Rat ventral prostate (Bonne and Raynaud 1974; Liao et al. 1974; Grover and Odell 1975; Ojasoo and Raynaud 1978; Raynaud et al. 1979; Winnecker et al. 1989; Duc et al. 1995) or mouse kidney (Isomaa et al. 1982) serve as sources for androgen receptors. Moreover, human androgen receptors have been prepared from transfected COS-1 cells (Teutsch et al. 1994). As ligands, labeled androstanolone, 5α-dihydrotestosterone, testosterone, and, more recently, methyltrienolone (R 1 881) have been used.

PROCEDURE

Androgen receptor assay. Cytosol is prepared from ventral prostate glands of adult male rats castrated approximately 24 h before use. The tissue is homogenized in TMDG buffer (10 mM Tris, 20 mM sodium molybdate, 2 mM dithiothreitol, 10% glycerol, pH = 7.4) at room temperature using a motor driven glass homogenizer and centrifuged at 135 000 *g* for 1 h. Aliquots of the supernatant (cytosol) are diluted to contain 40 mg tissue/ml and incubated for 1 h or overnight with [17α-methyl-^{3}H]R 1 881 (methyltrienolone, 5 nM final concentration, 87 Ci/mmole, New England Nuclear) in either the absence or presence of increasing concentrations (1 nM–10 μM) of R 1 881 or test compounds. Because R 1 881 binds weakly to progesterone and glucocorticoid receptors, cytosols are pretreated with 1 μM triamcinolone acetonide to block these interactions. After 1 or 18 h incubation period, a suspension of dextran-coated charcoal (1% charcoal, 0.05% dextran T-70, 0.05% BSA) is added to the ligand-cytosol mixture and incubated for 5 min. The charcoal is removed by centrifugation at 1 500 *g* for 10 min and the supernatant (protein-bound [^{3}H]R 1 881) counted using 10 ml of Biofluor liquid scintillation fluid (New England Nuclear) in a liquid scintillation spectrometer.

Nuclear androgen receptor exchange assay. Ventral prostates are homogenized at 100 mg/ml in hexylene glycol buffer (1 M hexylene glycol, 1 mM $MgCl_2$, 2.0 mM dithiothreitol, 5.0 mM EGTA, 1.0 mM PIPES, pH = 7.4) using a motor driven ground glass homogenizer. Homogenates are centrifuged at 1 500 *g* for 10 min. The nuclear pellet is washed 3 times in homogenization buffer by gently resuspending the pellet in a Dounce homogenizer and centrifugation at 1 500 *g* for 10 min. The washed nuclear pellet is resuspended in pyridoxal-5'-phosphate extraction buffer (20 mM sodium barbital, 5 mM pyridoxal-5'-phosphate, 5.0 mM dithiothreitol, 1.5 mM EDTA, 150 mM KCl, 20% glycerol, pH = 7.4) for 60 min at a final concentration of 60 mg tissue/ml. The extracted nuclei are centrifuged at 25 000 *g* for 30 min with the resulting supernatant being used in the same single saturating dose assay as described for prostate cytosol.

EVALUATION

The binding of test substances to the androgen receptor is quantified by calculating relative binding affinity (ratio of the molar concentration of unlabeled R 1 881 to test substance required to inhibit the binding of [^{3}H]R 1 881 by 50% after correction for non-specific binding) and equilibrium inhibitory binding constant ($K_i = IC_{50}/(1 + C / K_d)$, where C = the concentration of [^{3}H]R 1 881 and the K_d for R 1 881 is 1.3 nM.

In the nuclear androgen receptor exchange assay treatment group means are compared to control means, using ANOVA and Dunnett's multiple comparison tests.

MODIFICATIONS OF THE METHOD

Cells assays and animal assays were described.

Brown et al. (1981) studied anti-androgen effects on androgen receptor binding in cultured human newborn foreskin fibroblasts.

Tezón et al. (1982) studied the intracellular distribution of the androgen receptor in the rat epididymis under the influence of androgens and anti-androgens.

The use of tritiated 7α,17α-dimethyl-19-nortestosterone for the assay of androgen receptors was recommended by Schilling and Liao (1984).

Characterization and expression of a cDNA encoding the human androgen receptor was described by Tilley et al. (1989).

Hoyte et al. (1993) recommended 7a-methyl-17α-(E-2'-[^{125}I]iodovinyl)-19-nortestosterone as radioligand for the detection of the androgen receptor.

Structure-affinity relationships of various steroids structurally related to nomegestrol and progesterone for [3H]testosterone binding to rat ventral prostate cytosol were reported by Botella et al. (1987).

Molecular cloning of human androgen receptor complementary cDNA has been reported by Chang et al. (1988), and Lubahn et al. (1988).

DNA-binding of androgen receptor overexpressed in COS-1 cells has been reported by von Krempelhuber et al. (1994).

Thoth et al. (1995) studied *in vitro* binding of 16-methylated C-18 and C-19 steroid derivates to the androgen receptor using cytosol of castrated rat prostate and [^{3}H]R 1 881 as radioligand.

Chang et al. (1995) reviewed the structure and function of the androgen receptor and its role playing in the function of the mammalian system.

The interaction of androgen receptors with the androgen response element in intact cells was investigated by Karvonen et al. (1997).

N.4.1.1.2 Transactivation assay for androgens

PURPOSE AND RATIONALE

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1995, 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor acts with hormone responsive elements of hormone-regulated genes, thereby inducing a cascade of transcriptional events (Green and Chambon (1988). The hormone-dependent transcriptional activation can be determined in tissue culture by transfection of the steroid receptor under investigation and a reporter gene linked to a hormonally responsive promotor into cells. The transactivation assay allows determination of the agonistic and also the antagonistic potency of a given compound, by either induction or inhibition of reporter gene activity (Fuhrmann et al. 1992).

PROCEDURE

Vector construct

CV-1 cells are stably transfected with the rat androgen receptor and pMMTV-CAT7. The pMMTV-CAT plasmid containing the mouse mammary tumor virus promotor linked to a chloramphenicol acetyltransferase gene is prepared according to Cato et al. (1986).

Cell culture and transfections

The culture medium of CV-1 cells stably transfected with the rat androgen receptor and pMMTV-CAT7 is supplemented with 400 µg/ml G418 (Gibco BRL) and 5 µg/ml puromycin.

Stable and transient transfections are performed using Lipofectin reagent (Gibco BRL) according to a procedure recommended by Felgner and Holm (1989). Stable transfections are carried out according to Fuhrmann et al. (1992). For transient transfection, 1×10^6 COS-1 or CV-1 cells, respectively, are plated onto 100-mm dishes one day prior to transfection. Cells are typically about 80% confluent after 24 h. Before transfection, cells are washed twice with 1 ml Opti-MEM (Gibco BRL) per dish. For each dish, 5 µg hAR expression plasmid and 5 µg pMMTV-CAT are diluted with 1 ml Opti-MEM; in addition, 50 µg Lipofectin Reagent is diluted with 1 ml Opti-MEM. Next, DNA and Lipofectin Reagent dilutions are combined in a polystyrene snap-cup tube to obtain 2 ml of transfection solution per dish, gently mixed, incubated at room temperature for 5 min, and added to the washed cells. After 5 h the transfection solution is replaced by 6 ml DMEM supplemented with 10% fetal calf serum.

To study the effect of the test hormones, transiently transfected cells are trypsinized, pooled and replated onto 60-mm dishes at a density of 4.5×10^5 per dish 24 h after transfection. Stably transfected cells are seeded onto 6-well dishes (1×10^5 cells per dish). Cells are cultured in medium supplemented with 3% charcoal-stripped fetal calf serum and the appropriate hormones for 48 h. As negative control for the reporter gene induction, cells are cultured with 1% ethanol. Transactivation assays with transiently or stably transfected cells are carried out at least three times.

CAT assay

Transiently transfected cells and stably transfected cells are disrupted by freezing (ethanol/dry ice bath) and thawing (37 °C water bath) three times. Protein concentrations of the cell extract are determined according to Bradford (1976). The CAT assay is performed according to Gorman et al. (1982).

EVALUATION

CAT activity is calculated as percent conversion from chloramphenicol to acetylated chloramphenicol. Concentration-response curves for CAT induction are established to demonstrate the potency of the test hormone. The synthetic androgen R 1 881 (10^{-10} to 10^{-6} mol/l) serves as standard.

For antiandrogenic activity, CAT activity in the presence of 0.5 nmol/l R 1 881 is set as 100% and relative CAT activity is calculated as percentage of this value. Concentration-response curves for CAT inhibition are established with increasing concentrations of the antihormone.

CRITICAL ASSESSMENT OF THE METHOD

See N.2.1.1.2.

MODIFICATIONS OF THE METHOD

Warriar et al. (1993) examined the ability of dehydrotestosterone and various antiandrogens to stimulate or to inhibit the transcription activation of mouse mam-

mary tumor virus-bacterial chloramphenicol acetyltransferase (MMTV-CAT) in CV-1 cells.

White et al. (1994) described a simple and sensitive high-throughput assay which can be adapted for several classes of steroid agonists and antagonists. A DNA cassette, containing a synthetic steroid-inducible promotor controlling the expression of a bacterial chloramphenicol acetyltransferase gene (GRE5-CAT), was inserted into an Epstein-Barr virus episomal vector which replicates autonomously in primate and human cells. This promotor/reporter system was used to generate two stably transfected human cell lines. In the cervical carcinoma cell line HeLa, which expresses high level of glucocorticoid receptor, the GRE5 promotor is inducible over 100-fold by the synthetic glucocorticoid dexamethasone. In the breast carcinoma cell line T47D, which expresses progesterone and androgen receptors, the GRE5 promotor is inducible over 100-fold by either progesterone or dihydrotestosterone. These cell lines can be used to screen large numbers of natural and synthetic steroid agonists and antagonists in microtiter wells directly using a colorimetric chloramphenicol acetyltransferase assay.

N.4.1.2 *In vivo* methods

N.4.1.2.1 Chicken comb method

PURPOSE AND RATIONALE

This classical bioassay based on growth of the capon comb has been used by many authors for androgenic activity and found to be extremely useful for the isolation and structural elucidation of natural androgens. Many modifications have been published (Dorfman 1969).

PROCEDURE

Prior to assay, the surface area (sum of the length plus height of each individual comb) is determined by a millimeter rule placed directly on the comb. The capons are injected daily intramuscularly for 5 consecutive days with a solution or suspension of the test compound or the standard in 1 ml olive oil. Twenty-four hours after the last injection, the combs are re-measured and the growth of the comb is expressed as the sum of length and height in millimeters. Groups of 8 animals are used for at least 2 doses of the test compound and the standard.

EVALUATION

The mean values of each group are calculated and plotted as dose-response curve for the test compound and the standard in order to calculate potency ratios.

MODIFICATIONS OF THE METHOD

The hormones, dissolved in oil, have been applied locally to the capon's comb. A greater sensitivity has been achieved with this modification (Fussgänger 1934; McCullagh and Cuyler 1939).

Newly hatched chicks of either sex have been used to study the growth of combs after systemic or local administration (Frank et al. 1942; Dorfman 1948). White Leghorn chicks are used at an age of 2–3 days. They are kept in a brooder with a thermostatic control. An oily solution (0.05 ml) of the test compound or the standard is applied on the comb daily for a period of 7 days. Twenty-four hours after the last application, the animals are autopsied. Body weights are determined. The combs are removed by two longitudinal incisions along the base of the comb at its juncture with the scalp. The comb is freed from the scalp, touched lightly on a towel to remove blood and weighed. Dose-response curves are established.

N.4.1.2.2 Weight of ventral prostate, seminal vesicles and musculus levator ani

PURPOSE AND RATIONALE
Androgens affect the development of secondary sex organs in the male. In the rat, the growth of the ventral prostate, the seminal vesicles and the musculus levator ani is dependent on the presence of male sexual hormones. Weight increase of the musculus levator ani is considered to indicate anabolic activity.

PROCEDURE
Immature male Sprague-Dawley rats weighing about 55 g are orchidectomized as described above. The animals are administered the test compound in various doses orally in 0.5 ml 0.5% carboxymethylcellulose or subcutaneously in 0.2 ml sesame oil suspension daily over a period of 10 days. Testosterone is given in doses of 0.02, 0.1, and 0.5 mg per animal subcutaneously or methyltestosterone in doses of 0.25, 1.5, and 5 mg per animal serve as standards. Controls receive the vehicle only. Ten animals are used for each group. On the 11^{th} day, the animals are sacrificed and the seminal vesicles, the ventral prostate, and the musculus levator ani carefully dissected and weighed. The seminal vesicles are squeezed between filter paper to remove the fluid.

Dissection of the levator ani muscle is performed after removal of the skin in the scrotal area between the base of the penis and the anus. The posterior aspect of the perineal complex is cleared of fat and connective tissue with forceps, particular care being taken to expose the constrictions at either end of the levator ani where it joins the bulbocavernosus muscle. The rectum is transected just caudad to the point where the musculus levator ani loops around it dorsally. The body of the levator ani is then freed of the rectum and is removed by incisions at the points of attachment to the bulbocavernosus muscle. The levator ani is cleared of any connective tissue and weighed to the nearest 0.1 mg. Body weight of the animals is registered at the beginning and at the end of the experiment.

EVALUATION
The ratio organ weight/body weight is calculated for each organ and for each animal (relative organ weights). Dose-response curves are constructed for each organ comparing the test compound with the standard in order to calculate potency ratios. Increase in weight of seminal vesicles and ventral prostate indicates androgenic activity, whereas increase in weight of musculus levator ani is considered to indicates anabolic activity. In evaluating steroids for possible use as anabolic agents, Hershberger et al. (1953) suggested the use of the levator ani: ventral prostate ratio, which is defined as the ratio of the increase in levator ani weight divided by the increase in ventral prostate weight.

N.4.1.2.3 Nitrogen retention

PURPOSE AND RATIONALE
Anabolic agents induce positive nitrogen balance in the living organism. Many modifications of this assay

principle have evolved. Stafford et al. (1954) suggested a method involving the measurement of nitrogen excretion in the castrated rat fed a liquid diet and in nitrogen balance.

PROCEDURE

Twenty-five day old rats are castrated and kept untreated for 67 days, reaching about 300 g in body weight on normal laboratory diet. After 67 days, they are changed to a liquid diet-force feeding regime. Besides carbohydrates and fat, the diet contains casein and brewer's yeast as nitrogen source. At the start, the rats receive 10 ml per day, and this is increased to 26 ml per day. This feeding is continued for 30 days with simultaneous administration of the test drug once a day. Twenty-four hour urine specimens are collected 3 times weekly and analyzed for total nitrogen.

EVALUATION

Indices are calculated, such as greatest daily retention which is defined as the difference between the lowest daily nitrogen value after beginning of treatment and the pre-injection mean, the total nitrogen retention which is the sum of the differences between the pre-injection excretion and the daily values during the retention period, and the number of days in the retention period.

MODIFICATIONS OF THE METHOD

A method for the assay of anabolic steroids in the monkey (*Macaca mulatta*) has been suggested by Stucki et al. (1960). Nitrogen retention expressed as total nitrogen retained per day during the treatment period is chosen as end point.

CRITICAL ASSESSMENT OF THE METHOD

The assays can be used for demonstration of the anabolic effect but are cumbersome for quantitative comparisons test compounds and standard.

N.4.2
Anti-androgenic activity

N.4.2.0.1
General considerations

Anti-androgens exhibit their activity both on a peripheral and a central site (Neumann et al. 1970; Mainwaring 1977; Neri 1977; Neumann et al. 1977; Raynaud et al. 1977; Neumann 1985; Moguilewski and Bouton 1988). They compete with the peripheral androgen receptors and thus inhibit the effect of endogenous or exogenous androgens. They inhibit gonadotropin secretion and thus diminish testosterone production by the gonads. In addition to their effects on reproduction and accessory sexual organs, anti-androgens are tested for inhibition of sebum production as potential anti-acne drugs. The methods for gonadotropin inhibition are described in Sect. N.7.1.8.

Inhibition of 5α-reductase, an enzyme located in tissues such as the prostate, where 5α-dihydrotestosterone is the specific androgenic hormone, is one mechanism to inhibit benign prostate hyperplasia in men.

N.4.2.1
In vitro methods

N.4.2.1.1
Inhibition of 5α-reductase

PURPOSE AND RATIONALE

Testosterone is converted to 5α-dihydrotestosterone (DHT) by the enzyme 5α-reductase which is specifi-

cally localized in some androgen-target tissues, such as prostate, seminal vesicle, epididymis and skin, whereas in other androgen-sensitive tissues, such as the skeletal muscles and the central structures, the androgenic stimulus is mediated by testosterone itself. Inhibition of 5α-reductase provides a selective approach to androgen deprivation in DHT-target tissues, such as the prostate. Therefore, 5α-reductase inhibitors are proposed for therapy of benign hyperplasia of the prostate.

PROCEDURE

5α-Reductase can be prepared from prostates of various species, such as human, dog, and rat.

Frozen human prostates obtained from benign prostatic hyperplasia patients are thawed and minced with a pair of scissors into small pieces. The minced tissue is homogenized in 3 tissue volumes of medium A (20 mM potassium phosphate, pH 6.5, containing 0.32 M sucrose, 1 mM dithiothreitol and 50 µM NADPH) with a Brinkmann Polytron and a glass-glass homogenizer. The homogenate is centrifuged at 140 000 *g* for 60 min and the pellets are washed with approximately 3 tissue volumes of medium A. The washed pellets are suspended at a concentration of 5–10 mg protein/ml in 20 mM potassium phosphate, pH 6.5, containing 20% glycerol and 1 mM dithiothreitol.

Dog prostatic particulates are prepared from either fresh or frozen prostates from male mature mongrel dogs as described for human prostate. The washed pellets are suspended in medium A at a concentration of 30–60 mg protein/ml.

Ventral prostates from male Sprague-Dawley rats weighing 400 g are processed as described for human prostate, except that medium A without NADPH is used throughout the procedures. NADPH prevents inactivation of human and dog 5α-reductases during the preparation, but the rat enzyme is stable without the coenzyme.

For the 5α-reductase assay, reaction solutions are prepared in duplicate tubes containing 1 µM [^{14}C]testosterone, 1 mM dithiothreitol, 40 mM buffer (potassium phosphate, pH 6.5, for the rat and for the dog enzymes; Tris-citrate, pH 5.0, for the human enzyme), prostatic particulate (1 mg protein), and NADPH (50 µM for reaction with rat enzyme, 500 µM for reaction with human and dog enzyme) in a final volume of 0.5 ml. Test compounds or standard as inhibitors are added in 5 µl ethanol at concentrations between 10^{-9}–10^{-5} M. The control tubes receive the same volume ethanol. The reactions for the rat and dog enzymes are started by the addition of the prostatic particulates. The human prostatic particulate is premixed with NADPH before starting the reaction. The reactions are linear for at least 1 h at 37 °C. The reactions are carried out for 10–30 min and are stopped with 2 ml ethyl acetate containing testosterone, 5α-dihydrotestosterone, and andostandione (10 µg each). After centrifugation at 1 000 *g* for 5 min, the ethyl acetate phase is transferred to a tube and evaporated under nitrogen to dryness. The steroids are taken up in 50 µl ethyl acetate. The solutions are applied to Whatman LK5DF silica plates and the plates are developed in either ethyl acetate-cyclohexane (1 : 1) at 25 °C or chloroform-methanol (96 : 4) at 4 °C. The plates are air-dried and the chromatography is repeated. Nonradioactive steroid standards are located by UV and by spraying with 1% $CeSO_4$/10% H_2SO_4 solution followed by heating. The radioactivity profiles are determined by scanning the plates or by scraping the silica in sections and counting in a scintillation counter. 5α-Dihydrotestosterone is the only radioactive product for the rat and human enzymes. With the dog enzyme 5α-dihydrotestosterone, 3α,17β-androstanediol, androstan-3,17-dione, and androstenedione are formed. The radioactivities of the first 3 products are combined for the calculation of the 5α-reductase activity.

EVALUATION

IC_{50} values are calculated based on at least 5 dilutions of test preparations or standard.

MODIFICATIONS OF THE METHOD

Using human genital skin fibroblasts and simian COS cells, specific inhibition of 5α-reductase type 1 has been observed (Hirsch et al. 1993).

Wennbo et al. (1997) reported that **transgenic mice** overexpressing the prolactin gene develop dramatic enlargement of the prostate gland.

Sigimura et al. (1994) described age-related changes of the prostate gland in the senescence-accelerated mouse and recommended this strain as a model of age-related changes in the prostate gland.

Neubauer et al. (1993) measured prostatic 5α-reductase in rats both *in vitro* and *ex vivo* and determined *in vivo* uptake of [^{3}H]testosterone by the prostate.

At least 2 isoforms of 5α-reductase have been isolated (Andersson and Russell 1990; Jenkins et al. 1992). Recombinant human prostatic 5α-reductase type I and II were expressed using the baculovirus-directed insect cell expression system (Iehlè et al. 1993).

Iehlè et al. (1995), di Salle et al. (1998) tested synthetic 5α-reductase inhibitors against both isoforms.

Tolman et al. (1995) identified a 4-azasteroid as a scalp isoenzyme selective inhibitor.

N.4.2.2 *In vivo* methods

N.4.2.2.1 Chick comb method

PURPOSE AND RATIONALE

This description is purely of historical interest. Several modifications of the chick comb method were described for the androgen as well as the anti-androgen applied either systemically or locally.

PROCEDURE

One- to 3-day old male or female White Leghorn chicks are housed at constant temperature in a heated incubator. Testosterone is incorporated into the finely ground chick starting mash at a concentration of 80 mg per kilogram of food. The chicks are placed on this diet on day one. The test compound is dissolved in sesame oil. Each day for 4 days 0.1 ml of the oil solution is injected subcutaneously. Control chicks receive only the vehicle. Groups of 10 chicks are treated with various doses of the test compound or the standard. Twenty-four hours after the last injection, the animals are sacrificed, the combs removed and, after blotting of the cut edge, weighed rapidly to the nearest 0.5 mg. Body weights are also determined.

EVALUATION

The results are either expressed as absolute comb weights or as mg of comb per g of body weight. Results of groups treated with various doses of the inhibitor are statistically compared with controls receiving the vehicle only.

N.4.2.2.2
Antagonism of the effect of testosterone on weight of ventral prostate, seminal vesicles and musculus levator ani

PURPOSE AND RATIONALE
In this modification, anti-androgens are administered to inhibit testosterone-stimulation of androgen-dependent organs in castrated rats.

PROCEDURE
Male Sprague-Dawley rats weighing 50–70 g are castrated. Starting one day after surgery, the rats are injected once daily for 7 days with 0.15 mg testosterone propionate in 0.1 ml sesame oil (standard stimulus). The test compound (antiandrogen) is dissolved or suspended in sesame oil at various doses and injected subcutaneously daily at a separate site for 7 days. Six to 10 animals are used per group. On the 8th day, the animals are sacrificed and weights of ventral prostate, seminal vesicles and musculus levator ani as well as body weight are recorded.

EVALUATION
The organ weight/body weight ratios is (relative organ weights are determined. The inhibition by the anti-androgen as compared with the group receiving testosterone propionate alone is calculated. Dose-response curves may be plotted for each organ by the percent inhibition versus the ratio of agonist to antagonist.

MODIFICATIONS OF THE METHOD
Dorfman (1962) described an anti-androgen assay using the castrated mouse. Weights of prostate and seminal vesicles were determined after injection of the antiandrogen test compounds and simultaneous injections of 2 mg testosterone over a period of 7 days.

APPLICATIONS OF THE METHOD
The degree of anti-androgenic activity is an important parameter in evaluation of the pharmacological activity of H_2-receptor antagonists (Winters et al. 1979; Broulik 1980; Baba et al. 1981; Sivelle et al. 1982; Foldesy et al. 1985; Takeda et al. 1982; Neubauer et al. 1990).
