E.1.3.4 Rotarod method

PURPOSE AND RATIONALE

The test is used to evaluate the activity of drugs interfering with motor coordination. In 1956, Dunham and Miya suggested that the skeletal muscle relaxation induced by a test compound could be evaluated by testing the ability of mice or rats to remain on a revolving rod. This forced motor activity has subsequently been used by many investigators. The dose which impairs the ability of 50% of the mice to remain on the revolving rod is considered the endpoint.

PROCEDURE

The apparatus consists of a horizontal wooden rod or metal rod coated with rubber with 3 cm diameter attached to a motor with the speed adjusted to 2 rotations per minute. The rod is 75 cm in length and is divided into 6 sections by plastic discs, thereby allowing the simultaneous testing of 6 mice. The rod is in a height of about 50 cm above the table top in order to discourage the animals from jumping off the roller. Cages below the sections serve to restrict the movements of the animals when they fall from the roller. Male mice (CD-1 Charles River strain) with an weight between 20 and 30 g undergo a pretest on the apparatus. Only those animals which have demonstrated their ability to remain on the revolving rod for at least 1 minute are used for the test. The test compounds are administered intraperitoneally or orally. Thirty minutes after intraperitoneal or 60 min after oral administration the mice are placed for 1 min on the rotating rod. The number of animals falling from the roller during this time is counted.

Using different doses, ED_{50} values can be calculated. Moreover, testing at various time intervals, time-response curves can be obtained.

CALCULATION

Percent animals falling from the rotarod within the test period is calculated for every drug concentration tested. ED_{50} is defined as the dose of drug at which 50% of the test animals fall from the rotarod.

CRITICAL ASSESSMENT OF THE TEST

Many central depressive drugs are active in this test. Benzodiazepines, such as diazepam and flurazepam, have ED_{50} values below 1 mg/kg i.p. The activity of neuroleptics, such as chlorpromazine or haloperidol, is in the same range. In this way, the test does not really differentiate between anxiolytics and neuroleptics but can evaluate the muscle relaxant potency in a series of compounds such as the benzodiazepines. Moreover, the test has been used in toxicology for testing neurotoxicity.

MODIFICATIONS OF THE METHOD

A comparison of the rotarod method in rats with other tests, such as blockade of morphine-induced rigidity in rats, decerebrate rigidity in cats, and polysynaptic-monosynaptic reflex preparations in cats was published by Novack and Zwolshen (1983).

Rozas et al. (1997) described a drug-free rotarod test that was used to evaluate the effects of unilateral 6-hydroxydopamine lesions, nigral grafts, and subrotational doses of apomorphine. The rotarod unit was automated and interfaced with a personal computer allowing automatic recording of the time that each rat was able to stay on the rod at different rotational speeds.

E.1.3.5 Influence on polysynaptic reflexes

PURPOSE AND RATIONALE

Inhibition of polysynaptic reflexes is considered to be the major mode of action of muscle relaxants. Polysynaptic transmission can be measured by the flexor reflex of the hindpaw in anesthetized rats, whereas the monosynaptic Hoffmann reflex is measured by electromyographic recordings from the plantar foot muscle (Block and Schwarz 1994; Schwarz et al. 1994, 1996).

PROCEDURE

Male Wistar rats (250–280 g) are anesthetized with urethane (400 mg/kg i.p.) and α-chloralose (80 mg/kg i.p.). For the flexor reflex a hindpaw is stimulated with a pair of fine subcutaneous needle electrodes (5 square-wave shocks at 500 Hz, 0.2 ms duration and 3.0 reflex threshold). Electromyographic recordings are made with a pair of fine needle electrodes inserted into the ipsilateral tibialis muscle. Seven consecutive electromyographic recordings are amplified, and band-pass filtered (8–10 Hz), collected at a sample rate of 10 Hz, averaged and evaluated using a Signal Averager (CED, Cambridge, UK) on an IBM-compatible personal computer. Ten consecutive responses are averaged before and 20 min after i.p. application of drug.

For stimulation of the Hoffmann reflex a pair of needle electrodes is transcutaneously inserted into the surrounding of the tibial nerve (single square-wave shocks, 0.2 ms duration at 2.0 threshold). Electromyographic recordings are made with a pair of skin clip surface electrodes from the plantar foot muscle. Low intensity electrical stimulation of the tibial nerve elicits a reflex response similar to the human Hoffmann (H) reflex, which has been attributed to monosynaptic excitation of spinal α-motoneurons predominantly by primary muscle spindle afferent fibers. With increasing stimulus strength, the H-wave is preceded by an electromyographic wave, the M wave, which is due to a direct excitation of axons of α-motoneurons.

In all reflex experiments, values measured after solvent or drug application are expressed as a percentage of the corresponding pre-injection value.

EVALUATION

Statistical evaluation of group differences is performed using the Mann-Whitney U-test. Statistical analysis for dose dependency of drug effects is carried out by the Kruskal-Wallis test.

MODIFICATIONS OF THE METHOD

Ono et al. (1990), Farkas and Ono (1995), Hasegawa and Ono (1996), Otsu et al. (1998) recorded spinal reflexes from spinalized and non-spinalized rats anesthetized with α-chloralose and urethane. Laminectomy was performed in the lumbo-sacral region. Ventral and dorsal roots of the segments L4 and L5 were isolated. A skin pouch was formed at the site of the dissection to cover the exposed tissues with liquid paraffin kept at 36 °C. The dorsal root of L5 was placed on bipolar silver wire electrodes for stimulation (0.2 Hz, 0.05 ms, supramaximal). The ipsilateral ventral root of L5 and the dorsal root of L4 were placed on bipolar wire electrodes for recording. Monosynaptic and polysynaptic reflexes and dorsal root-dorsal root reflexes were evoked in the L5 ventral root and in the L4 dorsal root, respectively. These reflex potentials were amplified, displayed on an oscilloscope and averaged 8 times by an averaging computer.

Turski and Stephens (1993) recorded monosynaptic Hoffman reflexes in NMRI **mice** anesthetized with 80 mg/kg α-chloralose i.p. +400 mg/kg urethane i.p. The tibial nerve was stimulated with single square-wave pulses, 0.2 ms duration at 1.2–1.6 times the nerve threshold. Electromyogram recordings were made with a pair of skin clip surface electrodes from the plantar foot muscle. For recording polysynaptic flexor reflexes, the tibial nerve was stimulated with five square-wave pulses at 500 Hz, 0.2 ms duration at 3.0 times the nerve threshold. Electromyogram recordings were made with a pair of wire electrodes inserted percuteneously into the ipsilateral tibial muscle.

Furthermore, these authors used **genetically spastic rats**. A mutant strain of Wistar rats, which carries an autosomal recessive gene defect, is characterized by a progressive paresis of the hindlimbs with increased tone on the extensor muscles (Pittermann et al. 1976). This genetically determined syndrome of spasticity in the rat permits quantitative evaluation of the effect of drugs on muscle tone by recording activity in the electromyogram from a hindlimb extensor muscle (Klockgether et al. 1985; Turski et al. (1990).

Farkas et al. (1989), Tarnava et al. (1989) studied the effects of drugs on the reflex potentials evoked by afferent nerve stimulation and recorded from the spinal roots in unanesthetized spinal **cats**. An analog integrating method was used for quantitative evaluation of the reflex potentials. The amplified and band-pass filtered signals from the ventral root (monosynaptic reflex and polysynaptic reflex) and from the dorsal root (dorsal root reflex and dorsal root potential) were fed into signal-selectors, which transmitted the input signals only within the chosen post-stimulus intervals. Thus, the various components of the reflex potentials were separated according to their latencies.

Shakitama et al. (1997) recorded ventral root reflex potential in anesthetized rats and ventral and dorsal root potentials in anesthetized intact and spinalized cats.

Suzuki et al. (1995) studied the recovery of reflex potentials after spinal cord ischemia produced by occlusion of the thoracic aorta and the bilateral internal mammary arteries for 10 min in cats.

E.1.3.6 Masticatory muscle reflexes

PURPOSE AND RATIONALE

The temporomandibular joint dysfunction syndrome, characterized by pain and clicking in the temporomandibular joint and limitation of function, involves a condition caused by hypertonia combined with parafunctional habits, such as clenching or grinding of teeth and hyperreflexia (Laskin and Block 1986) which may be treated by muscle relaxants. Ozawa et al. (1996) studied the effects of a centrally acting muscle relaxant on *masticatory* muscle reflexes in rats. Both monosynaptic and polysynaptic reflexes can be studied using this model.

PROCEDURE

For recording the **monosynaptic tonic vibration reflex** of the masseter muscle, Wistar rats are anesthetized with ether, intubated with a tracheal cannula and fixed into a stereotactic apparatus. Decerebration is performed by radiofrequency lesion of the midbrain using a Lesion Generator (Radionics, RFG-4, USA) and a lesioning electrode inserted into the midbrain. After lesioning, ether anesthesia is discontinued. The tonic vibration reflex of the masseter muscle, recorded as electromyogram, is induced every 10–12 s by a sinusoidal vibration (100–500 Hz, 2 s) which is applied to the mandi-bula, and is delivered by a vibration generator driven by a low frequency oscillator and an amplifier. The evoked electromyogram is amplified by a biophysical amplifier and recorded on a thermal array recorder. The root mean square of the electromyogram is also recorded through an integrator.

For recording the **polysynaptic jaw opening reflex**, the animals are anesthetized by intraperitoneal pentobarbital-Na (50 mg/kg), fixed into position on their back and intubated with a tracheal cannula. Intrapulpal stimulation (0.5 Hz, 0.2 s in pulse duration, supramaximal intensity) delivered by an electrical stimulator is performed via a dental reamer inserted into the dental pulp of the mandibula. The jaw opening reflex recorded as phasic component of the electromyogram evoked in the ipsilateral digastric muscle is amplified by a biophysical amplifier and recorded on a thermal array recorder.

For recording of the **polysynaptic tonic periodontal masseteric reflex** (Funakoshi and Amano 1974) the animals are anesthetized by intraperitoneal injection of pentobarbital-Na (35 mg/kg), which is supplemented as required, intubated with a tracheal cannula and fixed onto a stereotaxic apparatus. The maxillary incisor is stimulated by pressing for 5 s every 5 min using a vibration generator driven by a trapezoid generator. The electromyogram responses to this stimulation are amplified by a biophysical amplifier and recorded on a thermal array recorder. The evoked electromyogram is transformed into square-wave pulses, fed into a staircase generator and recorded on a thermal array recorder.

EVALUATION

The significance of differences between the control and the drug-treated groups is evaluated with Dunnett's test.

MODIFICATIONS OF THE METHOD

Boucher et al. (1993) performed microinfusions of excitatory amino acid antagonists into the trigeminal sensory complex of freely moving rats while record-

ing the long latency jaw opening reflex elicited by electrical stimulation of the dental pulp.

Bakke et al. (1998) studied in anesthetized rats neurokinin receptor mechanisms in the increased jaw muscle activity which can be evoked by injection of the small fiber excitant and inflammatory irritant mustard oil into the temporomandibular joint region.

Alia et al. (1998) preformed intra-oral administration of a NK_1 antagonist in freely moving guinea pigs during recording the short- (6–10 ms) and long-latency (18–26 ms) jaw-opening reflex elicited by electrical stimulation of the lower incisor tooth pulp.

Huopaniemi et al. (1988) determined the threshold of the tooth-pulp evoked jaw-opening reflex after naloxone in barbiturate-anesthetized cats.

E.2 Tests for anxiolytic activity

E.2.0.1 General considerations

Definitions in psychopharmacology have been coined by the activity of special compounds or chemical classes found in patients. This is not only true for the term "neuroleptic" but also for the term "anxiolytic". Other terms have been "ataractic" or "psycholeptic". Anxiolytics are derived from "tranquilizers", such as meprobamate which was used widely until the advent of benzodiazepines. The property which these drugs have in common is the alleviation of anxiety, thus explaining the term "anxiolytic". These agents are used for the relatively minor disorders of the nonpsychotic or neurotic type, whereas the antipsychotic agents (phenothiazines, butyrophenones) are given mainly to combat the more severe psychotic or schizophrenic reactions. Thus, the terms anti-anxiety and antipsychotic indicate a qualitative distinction in the clinical use and mode of action of the drug. Pathological anxiety in man has been defined by its interference with normal functions, by manifestations of somatic disorders, emotional discomfort, interference with productivity at work, etc. This complex characterization of anxiety in man already indicates the difficulties to find appropriate pharmacological models. Therefore, several tests have to be performed to find a spectrum of activities which can be considered to be predictive for therapeutic efficacy in patients. For *in vivo* studies, most investigators use a battery of anticonvulsive tests, anti-aggressive tests and evaluation of conditioned behavior.

Most of the actions of benzodiazepines are thought to be mediated by potentiation of g-amino-butyric acid (GABA). Two subtypes of GABA receptors ($GABA_A$ and $GABA_B$) have been described. Moreover, specific binding sites for benzodiazepines have been discovered near these GABA receptors in various areas of the brain. These sites occur in a macromolecular complex that includes GABA-receptors, benzodiazepine receptors and receptors for other drugs, and a chloride channel. The benzodiazepines potentiate the neurophysiological actions of GABA at the chloride ion channel by increasing the binding of GABA to $GABA_A$ receptors. This implies that the $GABA_A$ receptor is involved in anxiety and that its direct activation would have an anxiolytic effect. Based in these findings various *in vitro* tests have been developed.

More recently, research has focused on the therapeutic potential of blocking excitatory amino acids – in particular glutamate. Excitatory amino acid receptors have been classified into at least three subtypes by electrophysiological criteria: NMDA, quisqualic acid (QA) and kainic acid (KA) (Cotman and Iversen 1987; Watkins and Olverman 1987). Some methods are described in Sect. E.3 Anti-epileptic activity.

Serotonin may play a role in anxiety, since treatment with drugs that reduce serotoninergic function, including benzodiazepines, have anxiolytic effects in animal models (Dourish et al. 1986). Several subtypes of serotonin receptors have been elucidated, e.g. $5\text{-}HT_{1A}$, $5\text{-}HT_{1B}$. $5\text{-}HT_{1C}$, $5\text{-}HT_{1D}$, $5\text{-}HT_2$, $5\text{-}HT_3$. Further differentiation is underway. $5\text{-}HT_{1A}$, $5\text{-}HT_{1B}$, and $5\text{-}HT_3$ receptors are considered to be involved in the effect of anti-anxiety and novel antipsychotic drugs (Peroutka 1988; Costall et al. 1988). Some *in vitro* methods are described in Sect. E.6 Antidepressant activity and Sect. E.5 Neuroleptic activity.

E.2.1 *In vitro* methods

E.2.1.1 *In vitro* assay for GABAergic compounds: [^{3}H]-GABA receptor binding

PURPOSE AND RATIONALE

GABA is known to be an important inhibitory neurotransmitter in the brain. Abnormalities in the GABA-system have been found in neurological and psychiatric diseases such as Huntingdon's chorea, anxiety, panic attacks, schizophrenia and epilepsy. GABA is also implicated in the mechanism of benzodiazepines and related CNS-drugs. Radiolabeled GABA is bound to synaptic membrane preparations of mammalian brain. The labeling of the synaptic receptor with ^{3}H-GABA requires careful attention to possible interference from nonsynaptic binding since ^{3}H-GABA can also bind nonspecifically to plasma membranes. The most prominent of which is the sodium dependent binding of GABA to brain membranes, a process which appears to be associated with the transport (uptake) sites of GABA. Sodium-independent binding of ^{3}H-GABA has characteristics consistent with the labeling of GABA receptors. In addition, the relative potencies of several amino acids in competing for these binding sites parallel their abilities to mimic GABA neurophysiologically. Therefore, the sodium-independent binding of ^{3}H-GABA provides a simple and sensitive method to evaluate compounds for GABA-mimetic properties.

GABA receptors have been divided into $GABA_A$ and $GABA_B$ receptor subtypes which by themselves form receptor families (Matsumoto 1989; Knott and Bowery 1991; Möhler 1992).

PROCEDURE

Reagents

- 0.05 M Tris-maleate buffer (pH 7.1)
- 6.05 g of Tris-base are dissolved in distilled water and made up to 1 000 ml. 5.93 g of Tris- maleate are dissolved in 500 ml of water. The 0.05 M Tris maleate, pH 7.1 buffer is prepared by slowly adding Tris maleate to the Tris-base solution until the pH reaches 7.1.
- 0.32 M Sucrose: 109.5 g of sucrose are dissolved in distilled water and filled up to 1 000 ml. The solution is stored at 4 °C.
- ^{3}H-GABA (specific activity approximately 40 Ci/mmol) is made up to a concentration of 780 nmol in distilled water and 20 µl is added to each test tube (yielding a final concentration of 15 nmol in the assay). Isoguvacine or muscimol is prepared by dissolving 8.35 mg of isoguvacine or 6.40 mg of muscimol in 10 ml water. Twenty µl of these solutions when added to 1 ml of incubation medium give a final concentration of 0.1 mM isoguvacine or muscimol.
- Test drugs: 1 mM stock solutions are initially prepared. These are serially diluted to the required concentrations prior to the addition to the incubation mixture. Final concentrations are usually from 2×10^{-8} to 1×10^{-5} M.

Tissue preparation

Male Charles-River rats (100–150 g) are decapitated and their whole brains rapidly removed and homogenized in 15 vol of ice-cold 0.32 M sucrose. The homogenate is centrifuged at 1000 *g* for 10 min. The pellet (nuclear fraction) is discarded and the supernatant fluid is recentrifuged at 20 000 *g* for 20 min. The supernatant is discarded and the crude mitochondrial pellet is resuspended in 15 vol distilled water using a Tekmar homogenizer. The suspension is centrifuged at 8 000 *g* for 20 min. The supernatant is collected and used to carefully resuspend, using a gentle squirling motion, the pellet's soft, upper, buffy layer. This sus-

pension is then centrifuged at 48 000 *g* for 20 min. The final crude synaptic membrane pellets are resuspended (without homogenization) in 15 volumes of distilled water and centrifuged at 48 000 *g* for 20 min. The supernatant is discarded, and the centrifuge tubes containing the pelleted membranes are capped with parafilm and stored frozen at –70 °C.

Assay procedure

A frozen membrane pellet from one whole rat brain is resuspended in 15 volumes of 0.05 M Tris-maleate buffer (pH 7.1) by homogenization at 4 °C. Triton X-100 is added to a final concentration of 0.05%. This suspension is then incubated at 37 °C for 30 min followed by centrifugation at 48 000 *g* for 10 min. The supernatant is discarded and the pellet resuspended by homogenization in the same volume of 0.05 Tris-maleate buffer (pH 7.1) at 4 °C. The preincubation with Triton enhances specific GABA receptor binding while lowering non-specific binding.

For the standard Na-independent ^{3}H-GABA binding assay procedure, aliquots of the previously frozen, Triton treated crude synaptic membranes are incubated in triplicate at 4 °C for 5 min in 0.05 M Tris-maleate buffer (pH 7.1) containing 15 nM ^{3}H-GABA alone or in the presence of 0.1 mM isoguvacine or muscimol, or the test drug.

The procedure is as follows:

- 1 ml of the 0.05 M Tris-maleate homogenate
- 20 µl of ^{3}H-GABA
- 20 µl of test drug or 20 ml of 0.1 mM isoguvacine or muscimol.

After incubation at 4 °C for 5 min, the reaction is terminated by centrifugation for 15 min at 5 000 rpm. The supernatant fluid is aspirated and the pellet washed twice with 1 ml of the Tris-maleate buffer. Two ml of liquiscint are added to each tube which is then vigorously vortexed. The contents of the tubes are transferred to scintillation vials, and the tubes rinsed with an additional 2 ml of cocktail. An additional 6 ml of liquiscint are added to each scintillation vial. The radioactivity is measured by liquid scintillation photometry.

EVALUATION

Specific ^{3}H-GABA binding is defined as the radioactivity which can be displaced by a high concentration of unlabeled GABA and is obtained by subtracting from the total bound radioactivity the amount of radioactivity bound in the presence of 0.1 mM isoguvacine. Results are converted to percent of specifically bound ^{3}H-GABA displaced by a given concentration of test drug. IC_{50} values with 95% confidence limits are then obtained by computer derived linear regression analysis.

E.2.1.2 $GABA_A$ receptor binding

PURPOSE AND RATIONALE

Two subtypes of GABA receptors have been identified:

1. $GABA_A$ receptor for which muscimol is the typical agonist, whereas bicucculine, picrotoxin, and SR 95 531 are antagonists, and
2. $GABA_B$ receptor, for which baclofen is the typical agonist.

The $GABA_A$ receptor directly gates a Cl^- ionophore and has modulatory binding sites for benzodiazepines, barbiturates, neurosteroids and ethanol. By contrast, $GABA_B$ receptors couple to Ca^{2+} and K^+ channels via G proteins and second messenger systems; they are activated by baclofen and are resistant to drugs that modulate $GABA_A$ receptors.

Several subtypes of $GABA_A$ receptors have been identified by ligand binding studies (Kleingoor et al. 1991; Turner et al. 1992; Gusti et al. 1993). Molecular biology techniques revealed the $GABA_A$ receptor to be assembled as a pentameric structure from different subunit (α, β, γ and δ subunit) families making it possible that a very large number of such heteromeric $GABA_A$ receptors exist in the mammalian central and peripheral nervous system (Krogsgaard-Larsen et al.

1994; Lambert et al. 1995; Smith and Olsen 1995; Costa 1998). A total of 19 genes encoding $GABA_A$ receptor subunits are known, while several additional isoforms can occur as splicing variants of some of these (Barnard 1998). Probably more than 500 distinct $GABA_A$ receptor subtypes exist in the brain (Sieghart 2000). Sequences of six α, three β, three γ, one δ, three ρ, one ε, one π and one θ $GABA_A$ receptor subunits have been reported in mammals (Barnard 2000; Alexander et al. 2001). More insight into the pharmacological functions of $GABA_A$ receptor subtypes is expected from studies in gene-knockout mice and by knock-in point mutations (Rudolph et al. 2001).

$GABA_C$ receptors were described as a pharmacologically distinct group by Bormann and Feigenspan (1995), Johnston (1996), Bormann (2000), Zhang et al. (2001). These receptors are Cl^- pores that are insensitive to both bicucculine and baclofen. An IUPHAR Committee has recommended in 1998, that the term $GABA_C$ should be avoided and classified bicucculine- and baclofen-insensitive GABA receptors as a minor subspecies of $GABA_A$ receptors of the 'AO' type.

In rat brain membranes, only the $GABA_A$ receptor is labeled with the $GABA_A$ selective radioligand ^{3}H-SR 95 531 in the given concentration range. The assay allows specifically the estimation of the test drug's binding characteristics to the $GABA_A$ receptor subpopulation.

PROCEDURE

Materials

Radioligand: ^{3}H-SR 95 531 (^{3}H-2-(3-carboxypropyl)-3-amino-6-(4-methoxyphenyl)-pyridazinium bromide (New England Nuclear, Boston)

Membrane preparation

Rats are killed by decapitation, the brains are quickly dissected and after separation from the cerebellum placed into ice-cold sucrose solution. The brains (approximately 20 g wet weight) are then homogenized in a glass Teflon potter (1 g brain weight/15 ml 320 mM D(+)-sucrose solution), and centrifuged at 1 000 *g* at 4 °C for 10 min. The pellets are discarded and the supernatants centrifuged at 20 000 *g* for 20 min. The resulting supernatants are discarded and the pellets are lysed by hypoosmotic shock (addition of 20 volumes of ice-cold bidistilled water). After homogenization in a glass Teflon homogenizer, the suspension is stirred under cooling for 20 min, and centrifuged at 48 000 *g* for 20 min. The resulting pellets are resuspended in ice-cold bidistilled water, the suspension is stirred and recentrifuged as before. The final pellets are resuspended in the incubation buffer (50 mM Tris-HCl and 100 mM $MgCl_2 \times 6\ H_2O$, pH 7.4) corresponding to 1 g brain wet weight/1 ml buffer. The membrane suspension is immediately stored in aliquots of 1 ml at –20 °C. Protein content of the membrane suspension is determined according to the method of Lowry et al. (1951) with bovine serum albumin as standard.

At the day of the experiment, the required volume of the membrane suspension is slowly thawed and diluted 1 : 20 with bidistilled water. After stirring for 10 min, the membrane suspension is centrifuged at 50 000 *g* for 10 min. The resulting pellets are resuspended in ice-cold incubation buffer, yielding a membrane suspension with a protein content of 1 mg/ml.

Assay

For each concentration, assays are performed in triplicate. The total volume of each incubation sample is 200 µl (microtiter plates).

Saturation experiments

Total binding:

- 50 ml ^{3}H-SR 95531 (12 concentrations, 2×10^{-9} to 1×10^{-7} M)
- 50 ml incubation buffer

Non-specific binding:

- 50 ml ^{3}H-SR 95531 (4 concentrations, 2×10^{-9} to 1×10^{-7} M)
- 50 ml (+) bicucculine (10^{-4} M)

Competition experiments

- 50 ml ^{3}H-SR 95531 (1 constant concentration, $8–10 \times 10^{-9}$ M)
- 50 ml incubation buffer without or with non-labeled test drug (15 concentrations, 10^{-10} to 10^{-3} M)

The binding reaction is started by adding 100 µl membrane suspension per incubation sample. The samples are incubated for 30 min at 4 °C. The reaction is stopped by subjecting the total incubation volume to rapid vacuum filtration over glass fiber filters. Thereby, the membrane-bound radioactivity is separated from the free radioactivity. Filters are washed immediately with approximately 20 ml ice-cold rinse buffer (50 mM Tris HCl, pH 7.4) per sample. The membrane-bound radioactivity is measured after addition of 2 ml liquid scintillation cocktail per sample in a Packard liquid scintillation counter.

EVALUATION

The following parameters are calculated:

- total binding
- non-specific binding
- specific binding = total binding – non-specific binding.

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{3}H-SR 95 531 versus non-labeled drug by a computer-supported analysis of the binding data.

$$K_i = \frac{K_D{}^3\mathrm{H} \times IC_{50}}{K_D{}^3\mathrm{H} + [^3\mathrm{H}]}$$

IC_{50} = concentration of the test drug, which inhibits 50% of specifically bound ^{3}H-SR 95 531 in the competition experiment.
$[^3\mathrm{H}]$ = concentration of ^{3}H-SR 95 531 in the competition experiment.
$K_D{}^3\mathrm{H}$= dissociation constant of ^{3}H-SR 95 531, determined from the saturation experiment.

The K_i-value of the test drug is that concentration, at which 50% of the receptors are occupied by the test drug.

MODIFICATIONS OF THE METHOD

Binding to the agonist site of the $GABA_A$ receptor can be measured with [^{3}H]muscimol (Snodgrass 1978; Williams and Risley 1979; Martini et al. 1983).

A membrane fraction of whole brains (except cerebellum) from male Wistar rats is prepared by standard techniques. Ten mg of membrane preparation is incubated with 1 nM [^{3}H]muscimol for 10 min at 0 °C. Non-specific binding is estimated in the presence of 100 nM muscimol. Membranes are filtered and washed 3 times and the filters are counted to determine specifically bound [^{3}H]muscimol.

The $GABA_A$ receptor chloride channel can be studied by binding with [^{3}H]t-butylbicycloorthobenzoate ([^{3}H]TBOB) (Schwartz and Mindlin 1988; Lewin et al. 1989).

A membrane fraction of whole brains (except cerebellum) from male Wistar rats is prepared by standard techniques. 0.4 mg of membrane preparation is incubated with 3 nM [^{3}H]TBOB for 15 min at 15 °C. Non-specific binding is estimated in the presence of 200 µM picrotoxin. Membranes are filtered and washed 3 times and the filters are counted to determine [^{3}H]TBOB specifically bound.

E.2.1.3 $GABA_B$ receptor binding

PURPOSE AND RATIONALE

Baclofen, as an analogue of the inhibitory neurotransmitter γ-aminobutyric acid (GABA), binds as agonist to the subtype B of the GABA receptor. Baclofen is effective in the treatment of spasticity caused by multiple sclerosis or other diseases of the spinal cord, particularly traumatic lesions. Studies of similar compounds may lead to other effective antispasmodic drugs.

In rat cerebellar membranes, only the $GABA_B$ receptor is labeled in the given concentration range of the $GABA_B$ selective agonist ^{3}H-(–)baclofen. The assay allows specifically the estimation of the test drug's binding characteristics at the $GABA_B$ subtype receptor population.

The receptor on which baclofen acts is coupled via G_i/G_o proteins to Ca^{2+} and K^+ channels as well as adenyl cyclase in neurons and hence is classified as a metabotropic receptor.

As in other receptor families, heterogeneity of the $GABA_B$ receptor has been found (Scherer et al. 1988; Bittiger et al. 1992; Bonanno and Raiteri 1992, 1993a,b; Bowery 1993; Lanza et al. 1993). At least 3 distinct subtypes have be identified:

a) the postsynaptic receptor linked via a G-protein to a K^+ channel which upon stimulation by GABA hyperpolarizes the neuron,
b) the presynaptic autoreceptor at GABA nerve endings; blockade of this receptor augments the release of GABA in electrically stimulated rat cortical slices,
c) the presynaptic heteroreceptor at glutamate nerve endings; blockade with $GABA_B$ antagonists increases release of glutamate from K^+ stimulated cortical slices.

The structure of $GABA_B$ receptors was identified when isoforms were detected (Kaupmann et al. 1997). Potent $GABA_B$ antagonists were described (Bittiger et al. 1992, 1993; Froestl et al. 1996).

PROCEDURE

Materials

Radioligand: ^{3}H-(–)baclofen, specific activity 1.11–1.85 TBq/mmol (30–50 Ci/Mmol) New England Nuclear, Boston

Membrane preparation

Rats are killed by decapitation, the cerebella quickly removed, and placed into ice-cold preparation buffer (50 mM Tris-HCl, pH 7.4). Approximately 5 g wet weight of the cerebella are homogenized using a glass Teflon potter, corresponding to 1 g cerebellum wet weight/50 ml buffer, and centrifuged at 48 000 *g* at 4 °C for 10 min. The pellets are resuspended in approximately 270 ml preparation buffer, and centrifuged as before. The final pellets are dissolved in preparation buffer, corresponding to 1 g cerebellum wet weight/30 ml buffer. The membrane suspension is immediately stored in aliquots of 5–10 ml at –77 °C. Protein content of the membrane suspension is determined according to the method of Lowry et al. with bovine serum albumin as a standard.

At the day of the experiment, the required volume of the membrane suspension is slowly thawed, and centrifuged at 50 000 *g* for 20 min. The pellets are resuspended in the same volume of incubation buffer, and stirred for 45 min at room temperature. The suspension is recentrifuged as before. This washing step is repeated 3 times. The resulting pellets are resuspended in ice-cold incubation buffer in a volume, yielding a membrane suspension with a protein content of 1 mg/ml. The membrane suspension is stirred under cooling for 20–30 min until the start of the experiment.

Assay

For each concentration samples are used in triplicate. The total volume of each incubation sample is 200 µl (microtiter plates). The concentration of ^{3}H-(–)baclofen is constant in all samples ($1.8–2 \times 10^{-8}$ M).

Saturation experiments
Total binding:
- 50 µl ^{3}H-(–)baclofen
- 50 µl non-radioactive racemic baclofen (15 concentrations, 0–1.2×10^{-6} M)

Non-specific binding:
The measurement of the non-specific binding is performed at the lowest concentration of the saturation range, i.e. 1.8×10^{-8} M of the ^{3}H-(–)baclofen without non-radioactive racemic baclofen.

- 50 µl ^{3}H-(–)baclofen
- 50 µl gamma-aminobutyric acid.

Competition experiments
- 50 µl ^{3}H-(–)baclofen
- 50 µl incubation buffer without or with labeled test drug (15 concentrations, 10^{-10}–10^{-3} M)

The binding reaction is started by adding 100 µl membrane suspension per incubation sample (1 mg protein/1 ml). The samples are incubated for 60 min at 4 °C. The reaction is stopped by subjecting the total incubation volume to rapid vacuum filtration over glass fiber filters. Thereby, the membrane bound is separated from the free radioactivity. The filters are washed with approximately 20 ml ice-cold buffer. The retained membrane bound radioactivity on the filter is measured after addition of 0.3 ml ethylene glycol monomethyl ether and 2 ml liquid scintillation cocktail per sample and an equilibration time of 1 h in a Packard liquid scintillation counter.

EVALUATION
The following parameters are calculated:

- total binding
- non-specific binding
- specific binding = total binding – non-specific binding.

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{3}H-(–)baclofen versus non-labeled drug by a computer-supported analysis of the binding data.

$$K_i = \frac{K_D{}^3\mathrm{H} \times IC_{50}}{K_D{}^3\mathrm{H} + [^3\mathrm{H}]}$$

IC_{50} = concentration of the test drug, which inhibits 50% of specifically bound ^{3}H-(–)baclofen in the competition experiment.
$[^3\mathrm{H}]$ = concentration of ^{3}H-(–)baclofen in the competition experiment.
$K_D{}^3\mathrm{H}$ = dissociation constant of ^{3}H-(–)baclofen, determined from the saturation experiment.

The K_i-value of the test drug is the concentration, at which 50% of the receptors are occupied by the test drug.

CRITICAL ASSESSMENT OF GABA BINDING TESTS

Without any doubt, GABA is the most important inhibitory transmitter in the central nervous system. One may expect important new developments by attempts to influence the GABAergic system specifically by synthetic compounds. In general, $GABA_A$ receptor agonists are central nervous system depressants, muscle relaxants, and possess some nociceptive properties, whereas the receptor antagonists are convulsants. Most benzodiazepine binding sites seem to be associated with $GABA_A$ receptors combined with a chloride channel. Among $GABA_B$ receptor agonists, only baclofen has achieved success in clinical use. Results of ongoing research with receptor subtypes will result in the development of new therapeutic agents.

E.2.1.4 Benzodiazepine receptor: [^{3}H]-flunitrazepam binding assay

PURPOSE AND RATIONALE

Experiments using ^{3}H-diazepam or ^{3}H-flunitrazepam have demonstrated specific binding sites in CNS membrane preparations that satisfy the criteria for pharmacological receptors, e.g. saturability, reversibility, stereoselectivity and significant correlation with *in vivo* activities of the drugs in this class.

Heterogeneity of benzodiazepine receptors has been reported (Klepner et al. 1979; Supavilai and Karobath 1980; Hafely et al. 1993; Davies et al. 1994). There are four classes of benzodiazepine and non-benzodiazepine high affinity ligands for benzodiazepine recognition sites associated with $GABA_A$ receptors: The first class (e.g. diazepam, flunitrazepam, alprazolam) facilitates the action of GABA, increasing the opening frequency of Cl^- channels. These ligands are called full positive allosteric modulators, or full agonists. A second class of ligands, which includes the β-carbolines, can decrease the opening frequency of Cl^- channels. These ligands are known as full negative allosteric modulators, or full inverse agonists. A third class (e.g. flumazenil) binds with high affinity to benzodiazepine recognition sites, but it can also prevent the GABA modulations elicited by positive or negative allosteric modulators; this class is called a modulator antagonist. A fourth class of ligands for benzodiazepine recognition sites is known to elicit either partial amplification or partial attenuation of GABA action at various $GABA_A$ receptors, and comprises the class called partial positive and partial negative allosteric modulators or partial agonists and partial inverse agonists, respectively.

The names **ω_1, ω_2, and ω_3-receptor subtypes** have been proposed to replace the nomenclature of benzodiazepine BZ_1, BZ_2, and BZ_p receptors (Langer and Arbilla 1988; Langer et al. 1990; Griebel et al. 1999a,b).

PROCEDURE

Reagents

- [Methyl-^{3}H]-Flunitrazepam (70–90 Ci/mmol) can be obtained from New England Nuclear.
- Clonazepam HCl can be obtained from Hoffmann La Roche

Tissue preparation

Male Wistar rats are decapitated and the brains rapidly removed. The cerebral cortices are removed, weighed and homogenized with a Potter-Elvejhem homogenizer in 20 volumes of ice-cold 0.32 M sucrose. This homogenate is centrifuged at 1 000 *g* for 10 min. the pellet is discarded and the supernatant is centrifuged at 30 000 *g* for 20 min. The resulting membrane pellet is resuspended in 40 volumes of 0.05 M Tris buffer, pH 6.9.

Assay

1 ml 0.05 Tris buffer, pH 6.9
560 µl H_2O

70 µl 0.5 M Tris buffer, pH 6.9
50 µl ^{3}H-Flunitrazepam
20 µl vehicle (for total binding) or 0.1 mM Clonazepam (for non-specific binding) or appropriate drug concentrations.
300 µl tissue suspension.

The tubes containing ^{3}H-flunitrazepam, buffer, drugs and H_2O are incubated at 0–4 °C in an ice bath. A 300 µl aliquot of the tissue suspension is added to the tubes at 10-s intervals. The timer is started with the addition of the mixture to the first tube. The tubes are then incubated at 0–4 °C for 20 min and the assay stopped by vacuum filtration through Whatman GF/B filters. This step is performed at 10-s intervals. Each filter is immediately rinsed with three 5-ml washes of ice-cold buffer, pH 6.9. The filters are counted in 10 ml of liquid scintillation counting cocktail.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of clonazepam. Specific binding is approximately 97% of total ligand binding. The percent inhibition at each drug concentration is the mean of triplicate determinations. IC_{50} calculations are performed using log-probit analyses.

CRITICAL ASSESSMENT OF THE METHOD

Binding to the benzodiazepine receptor is not absolutely predictive for anxiolytic activity. A range of compounds have been discovered that do not have the benzodiazepine structure but that do interact with the benzodiazepine receptors (Gardner 1988; Byrnes et al. 1992). They may have a different pharmacological profile *in vivo*.

MODIFICATION OF THE METHOD

Takeuchi et al. (1992) developed a non-isotopic receptor assay for benzodiazepine drugs using the biotin-1 012-S conjugate. The free conjugate in the supernatant was determined with a solid-phase avidin-biotin binding assay.

E.2.1.5 Serotonin receptor binding

E.2.1.5.1 General considerations

Several surveys on 5-HT receptors and their classification have been published, e.g., by Humphrey et al. (1993), Peroutka (1993), Boess and Martin (1994), Hoyer et al. (1994), Kebabian and Neumeyer (1994), Martin and Humphrey (1994), Saxena (1994), Brancheck (1995), Sleight et al. (1995), Bockaert et al. (1997), Branchek and Zgombick (1997), Briley et al. (1997), Costal and Naylor (1997), Glennon and Dukat (1997), Göthert and Schlicker (1997), Hamon (1997), Hartig (1997), Hoyer and Martin (1997), Jacobs and Fornal (1997), Roth and Hyde (1997), Uphouse (1997), Martin (1998), Martin and Eglen (1998), Saxena et al. (1998).

The classification has evolved from a scheme recognizing three classes (5-HT_{1like}, 5-HT_2 and 5-$HT_{3)}$ to one accepted by the NC-IUPHAR subcommittee for 5-hydroxytryptamine (serotonin) receptors in which seven classes embrace 14 distinct receptor subtypes (Martin 1988; Martin and Eglen 1998). Some revisions of the nomenclature were made:

Renaming the 5-HT_{1C} receptor to 5-HT_{2C} on the basis of recognitory, transductional and structural identity with the 5-HT_2 family.

Alignment of the classification scheme with the human genome, meaning that human receptors are given pre-eminence in the nomenclature.

Renaming the 5-$HT_{1D\alpha}$ and 5-$HT_{1D\beta}$ subtypes to 5-HT_{1D} and 5-HT_{1B}, respectively.

Recognition that the '5-HT_{1like}' positively coupled to adenylate cyclase and mediating smooth muscle relaxation, is the 5-HT_7 receptor.

Use of a lower-case notation to describe a putative receptor defined only by gene product, with 'promotion' to a upper-case notation when the receptor is fully defined in terms of operational, recognitory and structural properties.

Up to 7 functional isoforms of the 5-HT_{2C} receptor, two functional isoforms of the 5-HT_4 receptor and four isoforms of the 5-HT_7 receptor were recognized.

Murphy et al. (1999) reviewed molecular biology-based alterations in 5-HT receptors including altered characteristics of mice lacking different 5-HT receptors, e.g., 5-HT_{1B}-receptor-deficient mice, 5-HT_{2C} receptor-deficient mice, 5-HT_{1A}-receptor-deficient mice, 5-HT cell-membrane-transporter deficient mice and vesicular monoamine-transporter-deficient mice.

The role of 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1F}, 5-HT_{2B}, and 5-HT_7 receptors in cardiovascular physiology and pharmacology was discussed by Watts and Cohen (1999).

5-HT receptor types and subtypes

5-HT_1 subtypes. At least five *5-HT_1 subtypes* are described (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5HT_{1e}, 5HT_{1f}), which share 41–63% overall sequence identity and couple preferentially to $G_{i/o}$ to inhibit cAMP formation.

Hartig et al. (1996) suggested a revised nomenclature for 5-HT_{1B}, 5-$HT_{1D\alpha}$ and 5-$HT_{1D\beta}$ receptor subtypes.

5-HT_{1A} receptor agonists were described by Sills et al. (1984), Porsolt et al. (1992), Foreman et al. (1994), Wolff et al. (1997), Hamon (1997), 5-HT_{1A} receptor antagonists by Allen et al. (1997), 5-$HT_{1B/D}$ receptor antagonists by de Vries et al. (1997), 5-HT_{1D} receptor agonists by Macor et al. (1994), van Lommen et al. (1995), Valentin et al. (1996), 5-HT_{1D} receptor antagonists by Clitherow et al. (1994), de Vries et al. (1996), Rollema et al. (1996), Briley et al. (1997).

Presynaptic receptors may be preferably involved in the anxiolytic effects of 5-HT_{1A} receptor agonists, whereas in the antidepressant effects postsynaptic receptors are strongly involved (De Vry 1991, 1995).

5-HT_1 receptors are involved in learning and memory processes (see F.3.3.7 and F.3.4.1).

An endogenous peptide interacting specifically with the serotonergic 1B receptor subtypes was identified (Rousselle et al. 1996).

5-HT autoreceptors, mainly of the 5-HT_{1D} subtype, were studied by Starke et al. (1989), Fink et al. (1995), Bühlen et al. (1996), Glennon et al. (1996), Roberts et al. (1996), Price et al. (1996).

Cushing et al. (1994) studied the role of a 5-$HT_{1D\text{-}like}$ receptor in serotonin-induced contraction of canine coronary artery and saphenous vein.

See E.2.1.5.2 and E.2.1.5.3 for binding assays of 5-HT_1 receptors.

5-HT_2 receptors. *5-HT_2 receptors* have been subdivided into 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C} receptors, which exhibit 46–50% overall sequence identity and couple preferentially to $G_{q/11}$ to increase the hydroly-

sis of inositol phosphates and elevate cytosolic [Ca^{2+}]. (Humphrey et al. 1993; Hoyer et al. 1994; Kebabian and Neumeyer 1994; Martin and Humphrey 1994; Saxena 1994; Shih et al. 1994; Tricklebank 1996; Martin 1998). The human 5-HT_2 receptors were cloned and characterized (Chen et al. 1992; Carey et al. 1996). Species differences in receptors were described (Johnson et al. 1995). 5-HT_2 receptors play a role in the action of antipsychotics and hallucinogens.

See E.5.1.9. and E.5.1.10 for binding assays to 5-HT_2 receptors.

5-HT_3 receptor. The *5-HT_3 receptor* is a pentameric, ligand-gated ion channel, activation of which promotes entry of Na^+ and Ca^{2+}, egress of K^+ and hence neuronal depolarization. It belongs to the transmitter-gated cation super-family of receptors and appears to be located exclusively in neuronal tissue where it mediates fast depolarization (Malone et al. 1991). Responses are blocked by a wide range of potent antagonists, which are highly selective with respect to other 5-HT receptors (Silverstone and Greenshaw 1996). The Bezold-Jarisch-reflex can be elicited by 5-HT_3 receptor agonists and be blocked by 5-HT_3 antagonists (see A.1.3.19). 5-HT_3 receptor antagonists are used as anti-migraine drugs. 5-HT_3 receptors are involved in feeding behavior (see L.3.1.1) Furthermore, gastric emptying (see J.4.4.2) and emesis (see J.5.0.1, J.5.0.2, J.5.0.3 and J.5.0.4) can be influenced by 5-HT_3 antagonists.

See E.2.1.5.4 for binding assays to the 5-HT_3 receptor.

5-HT_4 receptors. The *5-HT_4 receptors* couple preferentially to G_S protein and activate adenylate cyclase, thereby increasing intracellular cAMP levels (Martin 1998). This induces long-term modulation of ion-channel activity, which is fundamental in learning and memory (Eglen et al. 1995; Eglen and Hedge 1996). Excitatory responses were found in guinea pig ileum and colon, inhibitory responses in rat esophagus (Ford and Clarke 1993).

The tunica muscularis mucosae preparation of the rat esophagus has been recommended for evaluation of 5-HT_4 receptor ligands since it possesses a homogeneous population of 5-HT_4 receptors which mediates a well defined relaxant response to 5-HT (see J.2.0.1)

5-HT_4 receptors may mediate arrhythmias (Kaumann 1994). Two splice variants have been identified (Gerald et al. 1995). Several selective 5-HT_4 receptors agonists and antagonists were described (Gaster et al. 1995; Eglen and Hedge 1996; Eglen 1997).

Radioligand binding assays for 5-HT_4 receptors using [^{3}H]-GR113 808 have been described by Grossman et al. (1993), Domenech et al. (1994), Schiavi et al. (1994), Katayama et al. (1995), Ansanay et al. (1996).

A survey on molecular biology and potential functional role of **5-HT_5, 5-HT_6, and 5-HT_7 receptors** was given by Branchek and Zoombick (1997).

5-HT_6. The rat *5-HT_6* receptor has been cloned by Ruat et al. (1993). The distinguishing features of this receptor are the high affinity for a series of antipsychotic compounds as well as affinity for a number of cyclic antidepressants (Branchek 1995).

Bourson et al. (1995) used antisense oligonucleotides to determine the role of the 5-HT_6 receptor in the rat brain.

Boess et al. (1998) reported labelling of 5-hydroxytryptamine binding sites in rat and porcine striatum by the 5-HT_6 receptor-selective ligand [^{3}H]Ro 63-0563.

5-HT_7. Lovenberg et al. (1993), Shen et al. (1993), Gobbi et al. (1996), Villalón et al. (1997) described an adenyl cyclase-activating serotonin receptor (*5-HT_7*) implicated in the regulation of mammalian circadian rhythms.

A receptor autoradiographic and hybridization analysis of the distribution of the 5-HT_7 receptor in rat brain was reported by Gustafson et al. (1996).

Stowe and Barnes (1998) used [^{3}H]5-carboxamidotryptamine for selective recognition sites in rat brain.

Three different splice variants of the 5-HT_7 receptor have been described both in rat and human tissues (Vanhoenacker et al. 2000).

E.2.1.5.2 Serotonin (5-HT_{1A}) receptor: binding of [^{3}H]-8-hydroxy-2-(di-n-propylamino)-tetralin ([^{3}H]-DPAT)

PURPOSE AND RATIONALE

Determination of the affinity of test compounds for the 5-HT_{1A} receptor in brain may be useful for predicting compounds with novel anxiolytic or atypical anti-psychotic profiles.

The existence of at least two populations of 5-HT_1 receptors in rat brain was shown by differential sensitivity to spiroperidol (Pedigo et al. 1981). The spiroperidol-sensitive receptors were designated as the 5-HT_{1A} subtype and the insensitive receptors were referred to as the 5-HT_{1B} subtype (Middlemis and Fozard 1983). Other 5-HT binding sites (5-HT_{1C}, 5-HT_{1D}, 5-HT_3 and 5-HT_4) have subsequently been identified in various species, based on differential sensitivity to 5-HT antagonists (Peroutka 1988).

Schlegel and Peroutka (1986) identified [^{3}H]DPAT as a selective ligand for the 5-HT_{1A} receptor. These authors reported that [^{3}H]DPAT labeled an autoreceptor. Lesion studies suggest that [^{3}H]DPAT labeled receptors are not terminal autoreceptors, but may be somatodendritic autoreceptors (Gozlan et al. 1983). Although DPAT decreases the firing rate in the raphe nucleus and inhibits 5-HT release, the actual location and function is somewhat controversial (Verge et al. 1986). These studies and the sensitivity of [^{3}H]DPAT binding to guanine nucleotides and effects on adenylate cyclase suggest that DPAT acts as an agonist at the 5-HT_{1A} receptor (Schlegel and Peroutka 1986).

Serotonin may play a role in anxiety, since drugs which reduce serotoninergic function have anxiolytic effects in animal models (Dourish et al. 1986). Since buspirone and its analogs have relatively higher affinity for the 5-HT_{1A} receptor than other receptors and no effect on the benzodiazepine site, their anxiolytic properties are attributed to activity at the 5-HT_{1A} receptor (Verge et al. 1986; Iversen 1984; Traber and Glaser 1987).

Besides 5-HT_{1A} receptor agonists (Misslin et al. 1990; Griebel et al. 1992; Hascoet et al. 1994; Stanhope and Dourish 1996), 5-HT_{1A} receptor antagonists (Traber and Glaser 1987; Cao and Rodgers 1998), 5-HT_{2A} receptor antagonists (Griebel 1996), 5-HT_{2C} receptor antagonists (Jenck et al. 1998), mixed receptor agonists/antagonists (Kleven et al. (1997), 5-HT_3 re-ceptor antagonists (Artais et al. 1995; Roca et al. 1995) and 5-HT_4 receptor antagonists (Kennett et al. 1997) exhibit anxiolytic properties (Handley and McBlane 1993).

Fletcher et al. (1995) described visualization and characterization of 5-HT receptors and transporters *in vivo* and in man.

PROCEDURE

Reagents

1. Tris buffers, pH 7.7
   a) 57.2 g Tris HCl
      16.2 g Tris base
      q.s. to 1 liter with distilled water
      (0.5 M Tris buffer, pH 7.7)
   b) Make a 1 : 10 dilution in deionized H_2O
      (0.05 M Tris buffer, pH 7.7)
   c) 0.05 M Tris buffer, pH 7.7 containing
      10 µM pargyline, 4 mM $CaCl_2$ and
      0.1% ascorbic acid.
      0.49 mg pargyline HCl
      111 mg $CaCl_2$
      250 mg ascorbic acid
      q.s. to 250 ml with 0.05 M Tris buffer,
      pH 7.7 (reagent 1b)
2. [^{3}H]-DPAT (2-(N,N-Di[2,3(n)-^{3}H]propylamino)-8-hydroxy-1,2,3,4-tetrahydronaphthalene) (160–206 Ci/mmol) was obtained from Amersham.
   For IC_{50} determinations: a 10 nM stock solution is made up and 50 µl are added to each tube (final concentration = 0.5 nM).
3. Serotonin creatinine sulfate. 0.5 mM stock solution is made up in 0.01 N HCl and 20 µl added to 3 tubes for determination of nonspecific binding (final concentration = 10 µM).
4. Test compounds:
   For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentrations in the assay range from 2×10^{-5} to 2×10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used based on the potency of the drug.

Tissue preparation

Male Wistar rats are sacrificed by decapitation. Hippocampi are removed, weighed and homogenized in 20 volumes of 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 48 000 *g* for 10 min and the supernatant is discarded. The pellet is resuspended in an equal volume of 0.05 M Tris buffer, incubated at 37 °C for 10 min and recentrifuged at 48 000 *g* for 10 min. The final membrane pellet is resuspended in 0.05 M Tris buffer containing 4 mM $CaCl_2$, 0.1% ascorbic acid and 10 µM pargyline.

Assay

800 µl Tissue
130 µl 0.05 M Tris + $CaCl_2$ + pargyline + ascorbic acid
20 µl vehicle/5-HT/drug
50 µl [^{3}H]DPAT

Tubes are incubated for 15 min at 25 °C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed 2 times with 5 ml of ice-cold 0.05 M Tris buffer. The filters are then placed into scintillation vials with 10 ml of Liquiscint scintillation cocktail and counted.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 10 µM 5-HT. IC_{50} values are calculated from the percent specific binding at each drug concentration. The K_i value may then be calculated by the Cheng-Prusoff equation:

$$K_i = IC_{50} / 1 + L / K_D$$

The K_D value for [^{3}H] DPAT binding was found to be 1.3 nM by Scatchard analysis in a receptor saturation experiment.

MODIFICATIONS OF THE METHOD

Yocca et al. (1987) described BMY 7 378, a buspirone analog with high affinity, selectivity and low intrinsic activity at the 5-HT_{1A} receptor in rat and guinea pig hippocampal membranes.

Instead of the selective 5-HT_{1A} agonist 8-hydroxy-2-(di-n-propylamino)-tetralin (DPAT), a selective antagonist to the 5-HT_{1A} receptor, 4-(methoxyphenyl)-1-[2'-(n-2"-pyridinyl)-p-iodobenzamido]-ethyl-piperazine ([^{125}I]p-MPPI) has been recommended (Kung et al. 1994a,b, 1995).

Several other selective 5-HT_{1A} receptor radioligands were recommended:

[^{3}H]lisuride (Sundaram et al. 1995); [^{3}H]WAY-100 635 ([O-methyl-^{3}H]-N-(2-(4-(2-methoxyphenyl)-1-piperazinyl)ethyl)-N-(2-piridinyl)cyclohexane carboxamide trihydrochloride) (Laporte et al. 1994; Gozlan et al. 1995; Hume et al. 1995; Khawaja 1995; Khawaja et al. 1997); [^{3}H]Alnespirone (Fabre et al. 1997); [Carbonyl^{11}C]-Desmethyl-WAY 100 635 (Pike et al. 1998); [^{3}H]S 15 535 (4-(benzodioxan-5-yl)-1-(indan-2-yl)piperazine) (Newman-Tancredi et al. 1998a); NAD-299 (=(R)-3-N,N-dicyclobutylamino-8-fluoro-[6-^{3}H]-3,4-dihydro-2H-1-benzopyran-carboxamide) (Jerning et al. 1998; Sandell et al. 1999).

Newman-Tancredi et al. (1998b) performed autoradiographic studies with [^{35}S]-GTPγS and the selective radioligand [^{3}H]S 15 535 for parallel evaluation of localization and functionality of the 5-HT_{1A} receptor.

E.2.1.5.3 Serotonin (5-HT$_{1B}$) receptors in brain: binding of [^{3}H]5-hydroxytryptamine ([^{3}H]5-HT)

PURPOSE AND RATIONALE

The purpose of this assay is to determine the affinity of test compounds for the serotonin (5-HT$_{1B}$) receptor in brain.

The existence of two populations of 5-HT$_1$ receptors in rat brain was shown by differential sensitivity to spiroperidol (Pedigo et al. 1981). The spiroperidol-sensitive receptors were designated as the 5-HT$_{1A}$ subtype and the insensitive receptors were referred to as the 5-HT$_{1B}$ subtype (Middlemiss and Fozard 1983). The 5-HT$_{1B}$ subtype has been identified in the brain of rats and mice (Peroutka 1986) and can be selectively labeled by 5-HT in rat striatum when spiroperidol is included to mask the 5-HT$_{1A}$ and 5-HT$_2$ receptors. In contrast to the situation in rats and mice, [^{3}H]5-HT binding in the basal ganglia of other mammals displays a pharmacological profile characteristic of 5-HT$_{1D}$ sites. The distribution of 5-HT$_{1B}$ sites in rat brain is similar to that of 5-HT$_{1D}$ sites in human brain (Segu et al. 1991; Boulenguez et al. 1992; Palacios et al. 1992).

By comparing the results in the 5-HT$_{1B}$ assay with those in the 5-HT$_{1A}$, 5-HT$_2$ and the 5-HT$_3$ receptor binding assays the relative affinity of a test compound for the major subclasses of 5-HT receptors in the rat brain can be determined.

PROCEDURE

Reagents

1. Tris buffers, pH 7.7
   a) 57.2 g Tris HCl
      16.2 g Tris base
      q.s. to 1 liter with distilled water
      (0.5 M Tris buffer, pH 7.7)
   b) Make a 1 : 10 dilution in deionized H_2O
      (0.05 M Tris buffer, pH 7.7)
   c) 0.05 M Tris buffer, pH 7.7 containing 10 mM pargyline, 4 mM $CaCl_2$ and 0.1% ascorbic acid.
      0.49 mg pargyline HCl
      110.99 mg $CaCl_2$
      250 mg ascorbic acid
      q.s. to 250 ml with 0.5 M Tris buffer, pH 7.7.
2. 5-Hydroxy[G-^{3}H]tryptamine creatinine sulfate (17–20 Ci/mmol) (Amersham). For IC_{50} determinations: a 40 nM stock solution is made up and 50 ml added to each tube (final concentration = 2.0 nM).
3. Serotonin creatinine sulfate. A 0.5 mM stock solution is made up in 0.01 N HCl and 20 ml added to 3 tubes for determination of nonspecific binding (final concentration = 10 µM).
4. Spiroperidol is dissolved in dilute glacial acetic acid. A 20 µM stock solution is prepared and 50 µl added to each tube to prevent binding to 5-HT$_{1A}$ and 5-HT$_2$ receptors (final concentration in the assay = 1 µM).
5. Test compounds:
   For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 2×10^{-5} to 2×10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used based on the potency of the drug.

Tissue preparation

Male Wistar rats are sacrificed by decapitation. Striata are removed, weighed and homogenized in 20 volumes of 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 48 000 *g* for 10 min and the supernatant is discarded. The pellet is resuspended in an equal volume of 0.05 M Tris buffer, incubated at 37 °C for 10 min and recentrifuged at 48 000 *g* for 10 min. The final membrane pellet is resuspended in 0.05 M Tris buffer containing 4 mM $CaCl_2$, 0.1% ascorbic acid and 10 mM pargyline.

Assay

800 µl tissue
80 µl 0.05 M Tris + $CaCl_2$ + pargyline + ascorbic acid
20 µl vehicle/ 5-HT/ drug
50 µl [^{3}H]5-HT
50 µl spiroperidol

Tubes are incubated for 15 min at 25 °C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed 2 times with 5 ml of ice-cold 0.05 M Tris buffer. The filters are then placed into scintillation vials with 10 ml of Liquiscint scintillation cocktail and counted.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 10 µM 5-HT. IC_{50} values are calculated from the percent specific binding at each drug concentration. The K_i value may then be calculated by the Cheng-Prusoff equation:

$$K_i = IC_{50} / 1 + L / K_D$$

The K_D value for [^{3}H] 5-HT binding was found to be 16.5 nM by Scatchard analysis of a receptor saturation experiment.

MODIFICATIONS OF THE METHOD

[^{3}H]CP-96,501 = 3-(1,2,5,6-Tetrahydro-4-pyridyl-5-n-propoxyindole was recommended as a selective 5-HT_{1B} receptor radioligand (Koe et al. 1992; Lebel and Koe 1992).

Domenech et al. (1997) characterized human serotonin 1D and 1B receptors using [^{3}H]-GR-125 743, a novel radiolabelled serotonin 5-$HT_{1D/1B}$ receptor antagonist.

[^{3}H]mesulergine has been used as radioligand for 5-HT_{1C} receptor binding (Jenck et al. 1993, 1994).

[^{3}H]-5-carboxytryptamine was recommended as label for 5-HT_{1D} binding sites (Mahle et al. 1991; Novak et al. 1993).

Massot et al. (1998) described molecular, cellular and physiological characteristics of 5-HT-moduline, a tetrapeptide (Leu-Ser-Ala-Leu), acting as endogenous modulator of the 5-HT_{1B} receptor subtype.

E.2.1.5.4 5-HT$_3$ receptor in rat entorhinal cortex membranes: binding of [^{3}H]GR 65630

PURPOSE AND RATIONALE

The purpose of this assay is to determine the affinity of test compounds for the 5-HT$_3$ binding site in the brain. This assay may be useful for predicting the potential of compounds to exhibit anti-emetic, anxiolytic or atypical antipsychotic profiles.

The 5-HT$_3$ binding site has also been characterized on operational, transductional and structural characteristics. Originally it was believed that 5-HT$_3$ binding sites existed only in the periphery (Costall et al. 1988). However, with the introduction of potent and selective 5-HT$_3$ antagonists such as GR65630, zacopride, ICS 205 930 and MDL 72222, and agonists, data from binding studies have indicated that 5-HT$_3$ binding sites are also located in selected areas of the brain (Kilpatrick et al. 1987, 1989; Barnes et al. 1988, 1990, 1992; Watling et al. 1988; Miller et al. 1992). The highest levels of 5-HT$_3$ binding sites have been detected in limbic and dopamine containing brain areas (entorhinal cortex, amygdala, nucleus accumbens and tuberculum olfactorium) (Costall et al. 1988). Besides possessing selective binding in dopamine rich areas, 5-HT$_3$ antagonists have been reported to block behavioral effects associated with certain drugs of abuse (nicotine and morphine) and to be active in behavioral tests predictive of anxiolytic activity. Based on these selective regional binding results and behav-ioral studies, it has been speculated that 5-HT$_3$ antagonists may have a therapeutic benefit in disease states believed to be associated with excessive dopaminergic activity; i.e., schizophrenia, anxiety and drug abuse.

Several authors described synthesis, pharmacology and therapeutic potential of H$_3$ receptor agonists and antagonists (Leurs et al. 1995, 1998; Stark et al. 1996).

PROCEDURE

Reagents

1. 0.05 M Krebs-HEPES buffer, pH 7.4
   11.92 g HEPES
   10.52 g NaCl
   0.373 g KCl
   0.277 g $CaCl_2$
   0.244 g $MgCl_2 \cdot 6H_2O$
   q.s. to 1 liter with distilled H_2O
   bring pH up to 7.4 (at 4 °C) with 5N NaOH
2. [^{3}H]GR65 630 (87.0 Ci/mmol) is obtained from New England Nuclear. For IC_{50} determinations: [^{3}H]GR65 630 is made up to a concentration of 1.0 nM in Krebs-HEPES buffer such that when 100 µl is added to each tube a final concentration of 0.4 nM is attained in the 250 µl assay.
3. Ondansetron HCl (GR 38 032F) is made up to a concentration of 500 µM in Krebs-HEPES buffer. 50 µl is added to each of 3 tubes for the determination of nonspecific binding (yielding a final concentration of 100 µM in the 250 µl assay.
4. Test compounds. For most assays, a 50 µM stock solution is made up in a suitable solvent and serially diluted with Krebs-HEPES buffer such that when 50 µl of drug is combined with the total 250 µl assay, a final concentration from 10^{-5} to 10^{-8} M is attained. Characteristically seven concentrations are studied for each assay; however, higher or lower concentrations may be used, depending on the potency of the drug.

Tissue preparation

Male Wistar rats (150–200 g) are decapitated, the entorhinal cortex removed, weighed and homogenized in 10 volumes of ice-cold 0.05 M Krebs-HEPES buffer, pH 7.4. The homogenate is centrifuged at 48 000 *g* for 15 min at 4 °C. The resulting pellet is rehomogenized in fresh Krebs-HEPES buffer and recentrifuged at 48 000 *g* for 15 min at 4 °C. The final pellet is resuspended in the original volume of ice-cold Krebs-HEPES buffer. This yields a final tissue concentration of 1.2–1.6 mg/ml with the addition of 100 ml to the assay. Specific binding is approximately 55–65% of total bound ligand.

Assay

100 µl Tissue suspension
100 µl [^{3}H]GR65 630
50 µl Vehicle (for total binding) or 500 mM ondansetron HCl (for nonspecific binding) or appropriate drug concentration

Sample tubes are kept on ice for additions, then vortexed and incubated with continuous shaking for 30 min at 37 °C. At the end of the incubation period, the incubate is diluted with 5 ml of ice-cold Krebs-HEPES buffer and immediately vacuum filtered through What-man GF/B filters, followed by two 5-ml washes with ice-cold Krebs-HEPES buffer. The filters are dried and counted in 10 ml of liquid scintillation cocktail.

EVALUATION

Specific GR65 630 binding is defined as the difference between the total binding and that bound in the presence of 100 µM Ondansetron HCl. IC_{50} calculations are performed using computer-derived log-probit analysis.

MODIFICATIONS OF THE METHOD

Dunn et al. (1991) found that preclinical data with 5-HT$_3$ antagonists predict anxiolytic rather than antipsychotic activity.

Davies et al. (1999) found that the 5-HT$_{3B}$ subunit is a major determinant of serotonin receptor function.

Reiser and Hamprecht (1989) reported that substance P and serotonin (via 5-HT$_3$ receptors) act synergistically to activate the cation permeability as measured by [^{14}C]guanidinium uptake in neuroblastoma × glioma hybrid cells.

Bönisch et al. (1993) studied the 5-HT$_3$ receptor-mediated cation influx into N1E-115 mouse neuroblastoma cells by the use of the organic cation [^{14}C]-guanidinium.

Emerit et al. (1993) assessed the [^{14}C]guanidium accumulation in cells of the hybridoma (mouse neuroblastoma × rat glioma) clone NG 108-15 exposed to serotonin 5-HT$_3$ receptor ligands and substance P.

Bonhaus et al. (1993) characterized the binding of [^{3}H]endo-N-(8-methyl-8-azabicyclo[3.2.1.]oct-3-yl)-2,3-dihydro-3-ethyl-2-oxo-1H-benzimidazolone-1-carboxamide hydrochloride ([^{3}H]BIMU-1), a benzimidazolone with high affinity to 5-HT$_3$ and 5-HT$_4$ receptors in NG 108 cells and guinea pig hippocampus.

Kooyman et al. (1994) studied the specific binding of [^{3}H]GR65 630 to 5-HT$_3$ recognition sites in cultured N1E-115 mouse neuroblastoma cells.

Several other selective 5-HT$_3$ receptor radioligands were recommended:

[^{3}H]Quipazine (Perry 1990); tritium-labeled 1-methyl-N-[8-methyl-8-azabicyclo[3.2.1]oct-3-yl)-1H-indazole-3-carboxamide (Robertson et al. 1990); [^{125}I]-(S)-iodozacopride (Gehlert et al. 1993); [^{3}H]-BRL46 470 (Steward et al. 1995); [^{3}H]YM060 (Azukawa et al. 1995); (^{125}I)iodophenpropit (Jansen et al. 1994), (^{125}I)iodoproxyfan (Ligenau et 1994), (S)-Des-4-amino-3-[^{125}I]iodozacopride (Mason et al. 1996; Hewlett et al. 1999).

Tairi et al. (1998) and Hovius et al. (1999) studied ligand binding to the serotonin 5-HT$_3$ receptor with a novel fluorescence ligand and developed a total internal reflection fluorescence assay which is suitable for high-through-put screening.

E.2.1.6 Histamine H$_3$ receptor binding in brain

PURPOSE AND RATIONALE

Histamine modulates its own synthesis and release from depolarized brain slices or synaptosomes by interacting with H$_3$ autoreceptors with a pharmacology distinct from that of H$_1$ and H$_2$ receptors (Arrang et al. 1985, 1987, 1990; Hill 1990, 1992; Hill et al. 1997; Leurs et al. 1991, 1998). The R-isomer of α-methylhistamineα (α-MeHA) was identified as a highly selective H$_3$-receptor agonist active at nanomolar concentrations. Furthermore, this compound in ^{3}H-labeled form is a suitable probe for the H$_3$-receptor.

PROCEDURE

The cerebral cortex from guinea pigs is dissected and homogenized in 50 volumes ice-cold 50 mM KH_2PO_4/Na_2HPO_4 buffer, pH 7.5, in a Potter homogenizer. The

homogenate is centrifuged for 15 min at 750 g. The pellet is discarded and the supernatant centrifuged at 42 000 *g* for 15 min. The supernatant is discarded and the pellet washed superficially with and then resuspended in fresh buffer. The protein concentration of the membrane suspension as determined according to Lowry et al. (1951) is about 0.3–0.4 mg/ml.

Aliquots of the membrane preparation are incubated for 60 min at 25 °C with ^{3}H(R) α-MeHA and unlabeled substances in a final volume of 1 ml. The assay is stopped by dilution with 2 × 3 ml ice-cold medium, followed by rapid filtration under vacuum over Millipore AAWP filters which are then rinsed twice with 5 ml of ice-cold medium. Radioactivity retained on the filters is measured by liquid scintillation spectroscopy.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 10 μM unlabeled α-MeHA. IC_{50} values are calculated from the percent specific binding at each drug concentration. The K_i value may then be calculated by the Cheng-Prusoff equation:

$$K_i = IC_{50} / 1 + L / K_D$$

MODIFICATIONS OF THE METHOD

Jansen et al. (1992) described [^{125}I]iodophenpropit as a radiolabeled histamine H_3 receptor antagonist.

E.2.2 Anticonvulsant activity

E.2.2.1 Pentylenetetrazole (Metrazol) induced convulsions

PURPOSE AND RATIONALE

This assay has been used primarily to evaluate antiepileptic drugs. However, it has been shown that most anxiolytic agents are also able to prevent or antagonize Metrazol-induced convulsions.

PROCEDURE

Mice of either sex with a body weight between 18 and 22 g are used. The test compound or the reference drug is injected sc. or i.p. or given orally to groups of 10 mice. Another group of 10 mice serves as control. Fifteen min after sc.-injection, 30 min after i.p.-injection, or 60 min after oral administration 60 mg/kg MTZ (Metrazol) are injected subcutaneously. Each animal is placed into an individual plastic cage for observation lasting 1 h. Seizures and tonic-clonic convulsions are recorded. At least 80% of the animals in the control group have to show convulsions.

EVALUATION

The number of protected animals in the treated groups is calculated as percentage of affected animals in the

control group. ED_{50}-values can be calculated. Furthermore, the time interval between MTZ-injection and occurrence of seizures can be measured. The delay of onset is calculated in comparison with the control group.

CRITICAL ASSESSMENT OF THE METHOD

The method is widely accepted as a screening procedure and has been modified by many investigators. Chlordiazepoxide (20 mg/kg i.p.), diphenylhydantoin (10 mg/kg i.p.) and phenobarbitone sodium (20 mg/kg i.p.) were found to be effective. Predominantly, the muscle relaxant and anticonvulsant effects of benzodiazepines are measured by this test. Stimulant, anti-depressant, neuroleptic and some anti-epileptic drugs do not show MTZ-antagonism at tolerable doses (Lippa et al. 1979). Nevertheless, the antagonism of MTZ-induced seizures appears to be a suitable procedure for detecting compounds with potential anxiolytic activity. Among a battery of tests, the MTZ-antagonism has been proposed to study centrally acting skeletal muscle relaxants (Bastian et al. 1959; Domino 1964).

MODIFICATIONS OF THE METHOD

Different routes of administration (i.p., i.v., s.c.) have been used by various investigators. Moreover, the dose of MTZ which causes seizures in 80 to 90% of the animals varies with the strain being used.

Bastian et al. (1959) published a modification, whereby mice are infused with a MTZ-solution through a small-diameter polyethylene tubing into the tail vein. In the same animal 3 end-points are registered: 1. Onset of persistent clonic convulsions, 2. beginning of the tonic flexor phase, and 3. time to death. The three endpoints are affected differently by various drugs providing the basis for the determination of drug specificity.

Löscher et al. (1991) tested 8 clinically established antiepileptic drugs in three pentylentetrazole seizure models: (1) the threshold for different types of pentylentetrazole seizures, i.e., initial myoclonus twitch, generalized clonus with loss of righting reflexes and tonic backward extension of forelimbs (forelimb tonus) in mice; (2) the traditional pentylentetrazole seizure test with s.c. injection of the CD97 for generalized clonic seizures in mice; and (3) the s.c. pentylentetrazole seizure test in rats. Various factors may cause misleading predictions from pentylentetrazole seizure models.

E.2.2.2 Strychnine-induced convulsions

PURPOSE AND RATIONALE

The convulsing action of strychnine is due to interference with postsynaptic inhibition mediated by glycine. Glycine is an important inhibitory transmitter to motoneurons and interneurons in the spinal cord, and strychnine acts as a selective, competitive antagonist to block the inhibitory effects of glycine at all glycine receptors. Strychnine-sensitive postsynaptic inhibition in higher centers of the CNS is also mediated by glycine. Compounds which reverse the action of strychnine have been shown to have anxiolytic properties.

PROCEDURE

Groups of 10 mice of either sex with a weight between 18 and 22 g are used. They are treated orally with the test compound or the standard (e.g. diazepam 5 mg/kg). One hour later the mice are injected with 2 mg/kg strychnine nitrate i.p. The time until occurrence of tonic extensor convulsions and death is noted during a 1 h period. With this dose of strychnine convulsions are observed in 80% of the controls.

EVALUATION

ED_{50}-values are calculated using various doses taking the percentage of the controls as 100%. For time-response curves the interval between treatment and strychnine injection varies from 30 to 120 min.

CRITICAL ASSESSMENT OF THE METHOD

The method has been proven to be useful in a battery of tests to characterize CNS-active drugs. (Costa et al. 1975).

MODIFICATIONS OF THE METHOD

McAllister (1992) induced spinal seizures in mice by rotating them along the body axis clockwise and anticlockwise alternatively three times following pretreatment with a subconvulsive dose of strychnine.

Lambert et al. (1994) tested the antagonism of a glycine derivative against seizures induced by 3-mercaptopropionic acid (3-MPA).

McAllister KH (1992) N-Methyl-D-aspartate receptor antagonists and channel blockers have different effects upon a spinal seizure model in mice. Eur J Pharmacol 211:105–108

E.2.2.3 Picrotoxin-induced convulsions

PURPOSE AND RATIONALE
Picrotoxin induced convulsions are used to further evaluate CNS-active compounds. Picrotoxin is regarded as a $GABA_A$-antagonist modifying the function of the chloride ion channel of the $GABA_A$ receptor complex.

PROCEDURE
Groups of 10 mice of either sex with a weight between 18 and 22 g are treated either orally or i.p. with the test compound or the standard (e.g. 10 mg/kg diazepam i.p.). Thirty min after i.p. treatment or 60 min after oral administration the animals are injected with 3.5 mg/kg s.c. picrotoxin and are observed for the following symptoms during the next 30 min: clonic seizures, tonic seizures, death. Times of onset of seizures and time to death are recorded.

EVALUATION
For time-response curves the animals receive the drug 30, 60 or 120 min prior to picrotoxin. Protection is expressed as percent inhibition relative to vehicle control. The time period with the greatest percent inhibition is said to be the peak time of drug activity. ED_{50}-values are calculated taking the percentage of seizures in the control group as 100%.

CRITICAL ASSESSMENT OF THE METHOD
The method has been proven to be of value amongst a battery of tests for CNS-activity.

MODIFICATIONS OF THE METHOD
Buckett (1981) describes an intravenous bicuculline test in mice (see Sect. E.3.2.6). The compound bicuculline antagonizes the action of GABA by competition on postsynaptic receptors. In the whole animal bicuculline reproducibly induces myoclonic seizures. An intravenous dose of 0.55 mg/kg was found to induce myoclonic seizures in 90–100% of mice with less than 10% mortality. GABAergic compounds such as benzodiazepines at relatively low doses antagonize the bicuculline-induced myoclonic seizures.

E.2.2.4 Isoniazid-induced convulsions

PURPOSE AND RATIONALE
Isoniazid can precipitate convulsions in patients with seizure disorders. The compound is regarded as a GABA-synthesis inhibitor (Costa et al. 1975). Clonic-tonic seizures are elicited in mice which are antagonized by anxiolytic drugs.

PROCEDURE
Ten mice of either sex with a weight of 18 to 22 g are treated with the test compound or the standard (e.g. diazepam 10 mg/kg i.p.) by oral or intraperitoneal administration. Controls receive the vehicle only. 30 min after i.p. or 60 min after p.o. treatment the animals are injected with a subcutaneous dose of 300 mg/kg isoniazid (isonicotinic acid hydrazide). During the next 120 min the occurrence of clonic seizures, tonic seizures and death is recorded.

EVALUATION
The percentage of seizures or death occurring in the control group is taken as 100%. The suppression of these effects in the treated groups is calculated as percentage of controls. ED_{50}-values are calculated.

CRITICAL ASSESSMENT OF THE METHOD
The method has been proven to be of value amongst a battery of tests for CNS-activity.

REFERENCES
Costa E, Guidotti A, Mao CC (1975) Evidence for involvement of GABA in the action of benzodiazepines: Studies on rat cerebellum. In: Costa E, Greengard P (eds) Mechanisms of Action of Benzodiazepines. Advances in Biochemical Psychopharmacology, Vol 14. Raven Press, New York,pp 113–151

E.2.2.5 Yohimbine-induced convulsions

PURPOSE AND RATIONALE

Antagonism against yohimbine-induced seizures in mice is considered to be a model predictive of potential anxiolytic and GABA-mimetic agents (Dunn and Fielding 1987).

PROCEDURE

Male Swiss-Webster mice (20–30 g) are individually placed in clear plastic cylinders and test compounds are administered i.p. 30 min prior to 45 mg/kg s.c. of yohimbine HCl. The animals are observed for the onset and number of clonic seizures for 60 min.

EVALUATION

ED_{50} values with 95% confidence limits are calculated for the antagonism of yohimbine-induced clonic seizures by means of the Lichtfield-Wilcoxon procedure.

CRITICAL ASSESSMENT OF THE METHOD

The antagonism against yohimbine-induced seizures can be regarded as an useful test amongst a battery of tests for anxiolytic activity.

Current and Future Trends in Anticonvulsant, Anxiety, and Stroke Therapy, Wiley-Liss, Inc., pp 495–512

E.2.3 Anti-aggressive activity

E.2.3.1 Foot-shock induced aggression

PURPOSE AND RATIONALE

Since the discovery of the taming effects of benzodiazepines in vicious monkeys (Heise and Boff 1961; Randall et al. 1961) tests for agents with anti-aggressivity activity have been developed for various animal species. These tests include foot-shock induced aggression in mice and rats, fighting behavior of isolated mice and aggressiveness of rats which become extremely vicious after lesions in the septal area of the brain (Brady and Nauta 1953).

Foot-shock induced aggression is used for further characterization of centrally active drugs. Irwin et al. (1971) have attempted to compare drug classes with this method.

PROCEDURE

Male mice (NMRI, Ivanovas) with a weight between 20 and 30 g are used. Two mice are placed in a box with a grid floor consisting of steel rods with a distance of 6 mm. A constant current of 0.6 or 0.8 mA is supplied to the grid floor by a LVE constant current shocker with an associated scrambler. A 60-Hz current is delivered for 5 s followed by 5 s. intermission for 3 min. Each pair of mice is dosed and tested without previous exposure. The total number of fights are recorded for each pair during the 3-min period. The fighting behavior consists of vocalization, leaping, running, rearing and facing each other with some attempt to attack by hitting, biting or boxing. The test compound or the standard are applied either 30 min before the test i.p. or 60 min before the test orally. For a time response, the drug is given 30, 60 and 120 min prior to testing. Six pairs of drug-treated and two pairs of vehicle-treated animals are utilized for each time period. A dose range is tested at the peak of drug activity. A minimum of 3 doses (10 pairs of mice/dose) is administered for a range of doses. Control animals receive the vehicle.

EVALUATION

The percent inhibition of aggression is calculated from the vehicle control. ED_{50}-values are calculated.

CRITICAL ASSESSMENT OF THE METHOD

Not only anxiolytics but also other classes of drugs where found to be active in this test such as sedatives like meprobamate and phenobarbital, neuroleptics such as perphenazine, analgesics such as methadone, and ethyl alcohol.

MODIFICATIONS OF THE METHOD

A survey of aggressive behavior in the **rat** has been given by Blanchard and Blanchard (1977).

Induction of aggressive behavior by electrical stimulation in the hypothalamus of male rats was described by Kruk et al. (1979).

Mos and Olivier (1991) reviewed the concepts in animal models for pathological aggressive behavior in human.

E.2.3.2 Isolation-induced aggression

PURPOSE AND RATIONALE

Male mice, submitted to prolonged isolation, develop aggressive behavior against animals of the same sex. Compounds can be tested for their ability to suppress this isolation-induced aggression.

PROCEDURE

Male mice of NMRI-strain with an initial weight of 12 g are kept isolated in small Makrolon®-cages for a period of 6 weeks. Prior to the administration of the test drug, the aggressive behavior of the animals is tested. A male mouse being accustomed to live together with other animals is placed into the cage of an isolated mouse for 5 min. Immediately, the isolated mouse will start to attack the "intruder". The aggressive behavior of the isolated mouse is characterized by hitting the tail on the bottom of the cage, screaming and biting. The reaction time until the first attack is less than 10 s for most of the isolated mice and relatively constant for one individual. After these initial tests, the isolated mice receive the test compound, the standard drug or the vehicle either orally or subcutaneously. The aggressive behavior is evaluated 60, 120 and 240 min after oral and 30, 60 and 120 min after sc. treatment. After treatment with certain centrally acting compounds the aggressive behavior of the isolated mice is changed. The reaction time until the first attack can be prolonged or shortened. The fighting reaction can be attenuated. Then, additional mechanical stimuli can be used to elicit the fighting behavior. With highly effective drugs the aggressive behavior is completely suppressed.

EVALUATION

The number of animals with complete suppression of the fighting behavior is calculated. In animals with diminished aggressiveness the reaction time is registered. A gradual scale of inhibition of aggressiveness is established.

CRITICAL ASSESSMENT OF THE METHOD

The fighting behavior of isolated mice is not only altered by sedative and anxiolytic compounds but also by neuroleptics and antidepressants. For example, active doses are:

Lorazepam	2.5	mg/kg p.o.
Clonazepam	2.5	mg/kg sc.
Haloperidol	1.0	mg/kg p.o.
Chlorpromazine	10.0	mg/kg s.c.
Imipramine	25.0	mg/kg s.c.

In this way, anti-aggressive activity of several classes can be detected.

MODIFICATIONS OF THE METHOD

Krsiak (1974, 1979) described the effects of various drugs on behavior of aggressive **mice**.

Olivier and van Dalen (1982) discussed the social behavior in rats and mice as an ethologically based model for differentiating psychoactive drugs.

McMillen et al. (1987) tested the effects of drugs on aggressive behavior and brain monoaminergic neurotransmission.

Krsiak (1975) showed that about 45% of single-housed male mice showed timidity instead of aggres-

sion on interactions with group-housed male mice. Several drugs, such as benzodiazepines, chlorpromazine and barbitone inhibited the isolation induced timidity without reducing other motor activities in the timid mice.

Andrade et al. (1988) tested the effect of insulin-induced hypoglycemia on the aggressive behavior of isolated mice against intruders made anosmic by application of 25 µl of 4% zinc sulfate solution to the nasal tract 3 and 1 days before the encounters.

White et al. (1991) tested the effects of serotoninergic agents and other psychotropic compounds on isolation-induced aggression in mice at doses below those which produced debilitation in the rotarod performance.

Francès (1988), Francès et al. (1990), Francès and Monier (1991) described an other phenomenon of isolation in rodents which can be used for evaluation of psychotropic drugs: the **isolation-induced behavioral deficit**. Male Swiss NMRI mice were either housed in groups of 6 in home cages or isolated at the age of 4–5 weeks for 7 days. Mice were tested in pairs (one isolated and one grouped mouse) under a transparent beaker. The number of escapes was counted for the first 2 min of observation. An attempt to escape was defined as one of the following: (1) the two forepaws were placed against the wall of the beaker, (2) the mouse was sniffing, its nose at the spout of the beaker, (3) the mouse was scratching at the glass floor. Behavioral observations were taped by an observer, blind to the treatment.

E.2.3.3 Resident-intruder aggression test

PURPOSE AND RATIONALE

Sijbesma et al. (1991), Mos et al. (1992), Muehlenkamp et al. (1995) studied the effects of drugs in a test for offensive aggression, the isolation-induced resident intruder aggression model (Flannelly and Lore 1975; Brain et al. 1979), in the rat.

PROCEDURE

Sprague-Dawley rats weighing 250 to 450 g are housed in a light-dark (12L:12D)-, temperature (ca. 22 °C)- and humidity (ca. 55%)-controlled room.

Resident male rats (about 450 g) are tested in their home cages for aggression against a smaller (250 g) male intruder. They are treated by intraperitoneal injection of test drug or saline 15 min before the test. The resident female is removed from the cage 30 min prior to the start of the test period. After placing the intruder rat in the territorial cage, the behavior of the resident male is observed. The time until the first attack (in seconds), number of attacks, and duration of each attack (in seconds) are recorded for the next 15 min by a blind observer. Furthermore, a total of 49 different behavioral elements are scored and grouped into 7 behavioral categories: offensive, exploration, social interest, inactivity, avoidance, body care, defense.

EVALUATION

Paired and unpaired *t*-tests are used for comparisons of means of absolute values.

E.2.3.4 Water competition test

PURPOSE AND RATIONALE

The competitive water consumption test in rats (Baenninger 1970; Syme 1974) can be used to study the influence of drugs on defensive aggression and dominance (Muehlenkamp et al. 1995).

PROCEDURE

Male Sprague-Dawley rats weighing 250 to 400 g are kept in a light-dark (12L:12D)-, temperature (ca. 22 °C)- and humidity (ca. 55%)-controlled room.

Animals of equal weight are paired and housed in one cage. After 6 days, the animals are deprived of water for 23 h. Then, one water bottle is introduced with a shielded spout so that only one animal of a pair can drink at a time. Time (in seconds) and frequency of spout possession and water consumption are recorded in numbers with a special computer program for 5 min. Animals are then allowed another 55 min for water consumption. This test is repeated on 3 subsequent days. Saline or test substances are injected intraperitoneally 15 min before tests 3 and 4. The animal with the longest duration of water consumption and frequency of spout possession is considered to be the more aggressive and/or dominant animal.

EVALUATION

Paired and unpaired *t*-tests are used for comparisons of means of absolute values, as well as means of differences of the absolute value of the two rats.

E.2.3.5 Maternal aggression in rats

PURPOSE AND RATIONALE

The model of 'maternal aggression' in rats was described by Olivier et al. (1985), Olivier and Mos (1986, 1992), Mos et al. (1987, 1989). Introduction of an intruder (male or female) in the cage of a parturient female rat, induces high levels of aggression against such intruders. Maternal aggression is characterized by short latency attacks of high intensity, mostly directed toward the head or neck of the intruder and is particularly pronounced during the first part of the lactating period. The behavior can be suppressed by several drugs, e.g., 5-HT_1 agonists (Mos et al. 1990; Olivier and Mos 1992).

PROCEDURE

Female rats weighing 250–350 g are placed with a breeding male in their home cages. On the bottom of each cage an iron gauze is placed which enables the collection of ejaculation plugs. After an ejaculation plug is detected the male is left for an other week with the female after which she is placed in the observation

cage provided with nesting material where she stays for the rest of the experiment. These cages are situated in an observation room under a reversed day-night rhythm. The day of birth is marked as day 0. Every parturient female is tested each day against a naive male intruder which has about 25 g less body weight than the female. Tests are performed during the first part of the dark period under red light conditions. One male intruder is placed in the female's home cage for 5 min. The ongoing behavior is videotaped and analyzed later. Each intruder is used only once and sacrificed immediately afterwards with an i.p. overdose of pentobarbital, followed by shaving and describing the wounds on wound charts (Mos et al. 1984).

The aggressive behavior of the female is scored for:

- bite attack on the head (fierce biting on head and snout often causing severe wounds),
- bite attack on the body (mostly directed to the back),
- lateral threat (the animal kicks with a hindleg at the opponent),
- upright posture (accompanied by boxing),
- nipping (short and low intensity bite on the head of the opponent),
- pulling (the opponent is held by the teeth and drawn through the cage),
- lunge (very rapid movement toward the opponent, mostly followed by bite attacks),
- on top (the female holds down the opponent which lies on its back).

Besides the frequency and the duration of the elements, also the latency of the first attack and the number of attacks are recorded.

Drug experiments are performed on postpartum days 3, 5, 7, and 9 using a Latin-square design of dosage. Preceding days (day 1 and 2), intervening (4, 6 and 8) and following (10, 11, 12, and 13) days are used to establish an aggression base line and as wash-out days. Drugs are administered orally 60 min before testing.

EVALUATION

Analysis of variance is employed to detect overall significance, followed by Wilcoxon matched pairs comparison between dosages. Kruskal-Wallis analysis is used to test the differences in the bite target areas after drug treatment.

MODIFICATIONS OF THE METHOD

Postpartum aggression in rats did not influence threshold currents for electrical brain stimulation-induced aggression in rats (Mos et al. 1987).

Maternal aggression can be observed not only in rats but also in **mice** and **hamsters** (Mos et al. 1990).

Palanza et al. (1996) examined the effects of chlordiazepoxide on the differential response pattern in aggressive-naive and aggressive-experienced lactating female mice confronting intruders of either sex in a 10-min test.

Olivier et al. (1990) highlighted ethopharmacology as a creative approach to identification and characterization of novel psychotropics.

Olivier et al. (1995) gave a review on serotonin receptors and animal models of aggressive behavior.

E.2.3.6 Rage reaction in cats

PURPOSE AND RATIONALE

An emotional aggressive behavior (rage reaction) can be elicited in unrestrained cats by high frequency electrical stimulation of the hypothalamus. Benzodiazepines have been reported (Malick 1970; Mursaki et al. 1976) to elevate the stimulus threshold for eliciting this rage reaction.

PROCEDURE

Emotional aggressive behavior is evoked by stimulation of the perifornical area of the lateral hypothalamus through chronically implanted stainless steel bipolar concentric electrodes by using threshold impulses of 1.0–2.6 mA, delivered at 50 Hz, to evoke a control attack response. Stimulation is discontinued immediately after the slowly rising current has reached threshold strength, and is performed once before drug administration as well as every 30 min thereafter. Drugs are injected by intraperitoneal route.

EVALUATION

Post-drug values are expressed as percentage of the pre-drug control value. Student's paired *t*-test is used for each time interval.

CRITICAL ASSESSMENT OF THE TEST

The method has been used for evaluation of new drugs. Most studies were devoted to the role of neurotransmitters regulating feline aggression (Siegel and Schubert 1995; Siegel et al. 1998) and the neural bases of aggression and rage in the cat (Siegel et al. 1997, 1999).

E.2.4 Effects on behavior

E.2.4.1 Anti-anxiety test (Light-dark model)

PURPOSE AND RATIONALE

Crawley and Goodwin (1980) Crawley (1981) described a simple behavior model in mice to detect compounds with anxiolytic effects. Mice and rats tend to explore a novel environment, but to retreat from the aversive properties of a brightly-lit open field. In a two-chambered system, where the animals can freely move between a brightly-lit open field and a dark corner, they show more crossings between the two chambers and more locomotor activity after treatment with anxiolytics. The numbers of crossings between the light and dark sites are recorded.

PROCEDURE

The testing apparatus consists of a light and a dark chamber divided by a photocell-equipped zone. A polypropylene animal cage, $44 \times 21 \times 21$ cm, is darkened with black spray over one-third of its surface. A partition containing a 13 cm long $\times$ 5 cm high opening separates the dark one third from the bright two thirds of the cage. The cage rests on an Animex® activity monitor which counts total locomotor activity. An electronic system using four sets of photocells across the partition automatically counts movements through the partition and clocks the time spent in the light and dark compartments. Naive male mice or rats are placed into the cage. The animals are treated 30 min before the experiment with the test drugs or the vehicle intraperitoneally and are then observed for 10 min. Groups of 6–8 animals are used for each dose.

EVALUATION

Dose-response curves are obtained and the number of crossings through the partition between the light and the dark chamber are compared with total activity counts during the 10 min.

CRITICAL ASSESSMENT OF THE METHOD

It has been shown that a variety of anxiolytics, including diazepam, pentobarbital and meprobamate produce

a dose-dependent increase in crossings, whereas non-anxiolytic agents do not have this facilitatory effect. Furthermore, the relative potency of anxiolytics in increasing exploratory behavior in the two-compartment chamber agrees well with the potency found in clinical trials.

The test has the advantage of being relatively simple with no painful stimuli to the animals. The specificity of the method remains open.

MODIFICATIONS OF THE METTHOD

Using a similar method, called black and white test box, Costall et al. (1987, 1988, 1989) studied the effects of anxiolytic agents and reported an anxiolytic effect of dopamine receptor antagonists, such as sulpiride and buspirone.

Sanchez (1995) presented a fully automated version of the black and white two-compartment box for mice.

Barnes et al. (1992) used this model to study the interaction of optical isomers modifying rodent aversive behavior.

Kilfoil et al. (1989) used a similar apparatus to test compounds for anxiogenic and anxiolytic activity.

Animal models of anxiety and their relation to serotonin-interacting drugs have been reviewed by Broekkamp et al. (1989) and by Griebel (1995).

Laboratory rats prefer to dwell on a solid floor rather than an grid one, particularly when resting. Manser et al. (1996) described an operant test in rats to determine the strength of preference for flooring. The apparatus consisted of a grid-floored cage and a solid-floored cage, joined via a central box containing a barrier whose weight was adjustable. The rats had to lift the barrier in order to explore the whole apparatus or were confined on the grid floor and then had to lift the barrier in order to reach the solid floor.

E.2.4.2 Anticipatory anxiety in mice

PURPOSE AND RATIONALE

When group-housed mice are removed one by one from their home cage, the last mice removed have always higher rectal temperatures than those removed first (Borsini et al. 1989; Lecci et al. 1990). This phenomenon is interpreted as being caused by anticipatory fear for an aversive event (handling causes stress-induced hyperthermia). Consequently, this test is thought to be a model of anticipatory anxiety. The anticipatory increase in temperature was prevented by prior treatment with diazepam and buspirone, whereas several other drugs did not affect this phenomenon (Lecci et al. 1990). The usefulness of this model for obsessive-compulsive disorder in man is discussed.

PROCEDURE

Groups of 18 male albino Swiss mice weighing 25–30 g are housed at constant room temperature and relative

humidity for at least 7 days in Makrolon cages to adapt to the environment. Test drugs or standard (diazepam) or solvent are administered orally in various doses to groups of 18 mice prior to the test. Thirty min later, the first 3 mice are removed from the cage and the rectal temperature registered by inserting a silicone lubricated thermistor probe (2 mm diameter) for 2.5 cm into the rectum. The average temperature of these 3 mice is taken as basal value. Mice number 4 through 15 are simply removed and again returned to the cage, and thereafter body temperature is determined in the remaining three animals. The difference of the mean value of these mice and the basal values is calculated as increase. Vehicle treated test groups display increases of 1.1 to 1.3 °C.

EVALUATION

The mean increase values of treated groups ±SEM are compared by ANOVA statistics with the controls.

MODIFICATIONS OF THE METHOD

Van der Heyden et al. (1997) adapted the group-housed stress-induced hyperthermia paradigm to single housed animals in order to drastically reduce the number of animals used. Repeated, but not single, disturbance of animals resulted in a strong hyperthermia (Δt) within 10 min. The final test paradigm chosen involved repeated temperature measurements at 10 min intervals, thus providing both information on basal temperature and Δt in each animal within a short time frame.

E.2.4.3 Social interaction in rats

PURPOSE AND RATIONALE

In an unfamiliar and brightly lit environment, the normal social interaction of rats (e.g. sniffing, nipping, grooming) is suppressed. Anxiolytics counteract this suppression.

PROCEDURE

Male Sprague-Dawley rats (225–275 g body weight) are housed in groups of 5 animals The apparatus used for the detection of changes in social behavior and exploratory behavior consists of a Perspex open-topped box (51×51 cm and 20 cm high) with 17×17 cm marked areas on the floor. One hour prior to the test, two naive rats from separate housing cages are treated with the test compound orally. They are placed into the box (with 60 W bright illumination 17 cm above) and their behavior is observed over a 10-min period by remote video recording. Two types of behavior can be noted:

- social interaction between the animals is determined by timing the sniffing of partner, crawling under or climbing over the partner, genital investigation of partner, and following partner,
- exploratory motion is measured as the number of crossings of the lines marked on the floor of the test box.

Six pairs are used for each dose.

EVALUATIO N

The values of treated partners are compared with the data from 6 pairs of untreated animals using single factor analysis of variance followed by Dunnett's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

In spite of the fact that there may be some analogy between "social anxiety" in humans and the behavior of rats in the social interaction test, there appear some potential complications with this test, such as an increase of social interaction after anxiolytics independent from the environment, dependence on external variables such as time of the day, and the complicated nature of social interaction.

MODIFICATIONS OF THE TEST

Sams-Dodd (1995) described the automation of the social interaction test in rats by a commercially available video-tracking system.

Gheusi et al. (1994) studied the effects of tetrahydroaminoacridine (THA) on social recognition in rats indicating a dissociation of cognitive versus non-cognitive processes.

Doses of 1.0 to 4.0 mg/kg i.p. phencyclidine (PCP) reduce the social interaction time in rats in a dose-dependent fashion. Reversal of the PCP-induced social withdrawal has been used as an animal model for neuroleptic resistant schizophrenia (Carlsson and Carlsson 1990; Corbett et al. 1995).

Olfactory investigation of ovarectomized females by adult male mice decreases during repeated confrontations with the same female intruder, whereas aggressive behavior gradually increases (Winslow and Camacho 1995). Administration of scopolamine blocked decrements in olfactory investigation in repeated confrontations and significantly reduced aggression. Acetylcholinesterase inhibitors enhanced the rate of decrement of olfactory investigation, but had differential effects on aggression.

Wongwitdecha and Marsden (1996) investigated the effects of isolation rearing on anxiety using the social interaction paradigm and compared the effects of diazepam on social interactive behaviors in isolation and socially reared rats.

Sams-Dodd (1997) studied the effect of novel antipsychotic drugs on phencyclidine-induced stereo-typed behaviour and social isolation in the rat social interaction test.

The rat social interaction model has been used by various authors to characterize the potential anxiolytic effects of serotonin receptor antagonists, such as 5-HT_{1C} receptors antagonists (Kennett et al. 1989; Kennett 1992), 5-HT_2 receptor antagonists (Kennett et al. 1994, 1995, 1996a,b, 1997; Costall and Naylor 1995), 5-HT_3 receptor antagonists (Costall et al. 1990; Costall and Naylor 1992; Blackburn et al. 1993), 5-HT_4 receptor antagonists Kennett et al. (1997), cholestystokinin receptor antagonists (Hughes et al. 1990; Costall et al. 1991; Singh et al. 1991) and of nitric oxide synthase inhibitors (Volke et al. 1997).

File and Johnston (1989) reported a lack of effects of 5-HT_3 receptor antagonists in the social interaction test in the rat.

Woodall et al. (1996) described a **competition procedure** in rats. On the first week of experimentation groups of 3 rats (triads) are familiarized with the test box and sweetened milk from a drinking spout located on the end wall. The drinking spout is surrounded by a Perspex tube (4.5 cm diameter) which ensures that only one animal is able to drink at a time. All animals are deprived of water overnight and on the following day placed into the testing box and given access to the sweetened milk for 15 min. On the second week of testing, the rats are not longer water deprived and are given access to the testing box and sweetened milk for 5 min. During the testing period, the rats are observed every 5 s, and a note is made which animal is drinking. This procedure is carried out twice a week for a period of 5 weeks. Drugs are administered to either the dominant or subordinate rat in each triad 15 min prior to testing. Following the drug study, all triads are tested for 2 trials to ensure that their rank orders return to baseline levels. The access of the subordinate member to sweetened milk is increased after administration of an anxiolytic drug.

E.2.4.4 Elevated plus maze test

PURPOSE AND RATIONALE

Out of many possibilities to modify maze tests (e.g. water maze (Danks et al. 1991), the Y-mace, the radial maze (Di Cicco 1991), and the elevated plus maze (Montgomery 1958; Pellow et al. 1985; Corbett et al. 1991) have found acceptance in many laboratories. The test has been proposed for selective identification of anxiolytic and anxiogenic drugs. Anxiolytic compounds, by decreasing anxiety, increase the open arm exploration time; anxiogenic compounds have the opposite effect.

For effects on learning and memory see Sect. F.3.3.3.

PROCEDURE

The plus-maze consists of two open arms, $50 \times 10 \times 40$ cm, and two enclosed arms, $50 \times 10 \times 40$ cm, with an open roof, arranged so that the two open arms are opposite to each other. The maze is elevated to a height of 50 cm. The rats (200–250 g body weight) are housed in pairs for 10 days prior to testing in the apparatus. During this time the rats are handled by the investigator on alternate days to reduce stress. Groups consist of 6 rats for each dose. Thirty min after i.p. administration of the test drug or the standard, the rat is placed in the center of the maze, facing one of the enclosed arms.

During a 5 min test period the following measures are taken: the number of entries into and time spent in the open and enclosed arms; the total number of arm entries. The procedure is conducted preferably in a sound attenuated room, with observations made from an adjacent room via a remote control TV camera.

EVALUATION

Motor activity and open arm exploratory time are registered. The values of treated groups are expressed as percentage of controls. Benzodiazepines and valproate decrease motor activity and increase open arm exploratory time.

CRITICAL ASSESSMENT OF THE METHOD

The method is rather time consuming, but can be regarded as a reliable measure of anxiolytic activity. Computerized automatic systems are available for elevated plus maze, radial maze, Y-maze, and T-maze (e.g., Technical and Scientific Equipment GmbH, D-61348 Bad Homburg, Germany) and may help to overcome these difficulties.

MODIFICATIONS OF THE METHOD

Latency to enter a mirrored chamber by mice has been described as a behavioral assay for anxiolytic agents (Toubas et al. 1990).

Handley and McBlane (1993) provided an assessment of the elevated X-maze for studying anxiety and anxiety-modulating drugs.

Lapin (1995) studied the effect of handling, sham injection, and intraperitoneal injection of saline on the behavior of mice in an elevated plus-maze. These procedures produce behavior considered to be typical for anxiety inducing drugs. Saline-treated groups taken as controls possess the behavioral profile of stressed and anxious animals.

Pokk et al. (1996) described a method of small platform-induced stress whereby mice were individually placed for 24 h on a small platform (3 cm high, 3.5 cm in diameter) which was fixed at the center of a plastic chamber (20 cm diameter, 40 cm high) and was surrounded by water (1 cm deep) at 22 °C.

E.2.4.5 Water maze test

PURPOSE AND RATIONALE

Spatial learning of rats can be tested in a water maze as described by Morris (1984) and McNaughton and Morris (1987).

For effects on learning and memory see Sect. F.3.3.5.

PROCEDURE

The water maze consists of a circular tank with 100 cm diameter and a wall 20 cm above the water level. A circular platform (9 cm diameter, covered with white linen material for grip) is hidden 2 cm below the water level. The water is made opaque using titanium dioxide suspension and is kept at about 23 °C during the experiment. Training takes place on three consecutive days, with the rats receiving 4 consecutive trials per day with an inter-trial interval of 6–10 min. Each trial is started from one of four assigned polar positions with a different sequence each day. The latency to find the platform is measured as the time of placement of the rat in the water to the time it finds the platform. If the animal fails to find the platform in any trial within 3 min it is placed on it for 10 s.

EVALUATION

On day four a probe test is performed. The platform is removed and the time spent in the target quadrant (the quadrant in the center of which the platform has been located) and the number of annulus crossings (across the actual location where the platform has been located) in the first 60 s of exposure are measured. The time to the first annulus crossing is also taken as a measure of performance on the 13^{th} (i.e. probe) trial.

Buspirone (Rowan et al. 1990) as well as benzodiazepines (McNaughton and Morris 1987) increase the latency to find the platform in the training period and impair the number and the time of annulus crossings.

CRITICAL ASSESSMENT OF THE METHOD

The water maze test measures learning and memory rather than the anxiolytic activity. If the test is used for memory, rats which have learned quickly and consistently to find the platform are kept in their cages for 2 weeks and then re-tested. Rats which solve the escape immediately, are considered to have retained memory (see also Sect. F.3.3.5).

MODIFICATIONS OF THE METHOD

Bane et al. (1996) used the Morris water maze to study the adverse effects of the non-competitive NMDA receptor antagonist dextromorphan on the spatial learning of rats.

E.2.4.6 Staircase test

PURPOSE AND RATIONALE

The staircase test for evaluating anxiolytic activity was originally described for rats by Thiebot et al. (1973). When introduced into a novel environment, rodents experience a conflict between anxiety and exploratory behavior manifested by increased vigilance and behavioral activity. In the staircase paradigm, step-climbing is purported to reflect exploratory or locomotor activity, while rearing behavior is an index of anxiety state. The number of rearings and steps climbed are recorded in a 5 min period. The dissociation of these parameters is considered to be characteristic for anxiolytic drugs. The test was modified for rapid screening of anxiolytic activity in mice (Simiand et al. 1984).

PROCEDURE

For experiments with mice the staircase is composed of five identical steps 2.5 cm high, 10 cm wide and 7.5 cm deep. The internal height of the walls is constant along the whole length of the staircase. Naive male mice (Charles River strain) with a weight between 18 and 24 g are used. Each animal is used only once. The drug or the standard is administered orally 1 h or 30 min subcutaneously before the test. The animal is placed on the floor of the box with its back to the staircase. The number of steps climbed and the number of rears are counted over a 3-min period. A step is considered to be climbed only if the mouse has placed all four paws on the step. In order to simplify the observation, the number of steps descended is not taken into account. After each test, the box has to be cleaned in order to eliminate any olfactory cues which might modify the behavior of the next animal.

EVALUATION

Twelve mice are used for the untreated control group, each drug group, and for the group receiving the standard. The average number of steps and rearings of the control group is taken as 100%. The values of treated animals are expressed as percentage of the controls.

CRITICAL ASSESSMENT OF THE METHOD

The staircase test has been proven as a simple and reliable method for screening of anxiolytics in several laboratories. Many applications and modifications have been described in the literature (Houri 1985; Steru et al. 1987; Keane et al. 1988; Emmannouil and Quock 1990; Simiand et al. 1993).

E.2.4.7 Cork gnawing test in the rat

PURPOSE AND RATIONALE

Cork gnawing behavior in the rat has been proposed as a screening method for buspirone-like anxiolytics by Pollard and Howard (1991).

PROCEDURE

Adult male Evans rats serve as subjects. They are housed 4 per cage on a regular light/dark cycle with free access to food and water except for the period between injection and the end of a test session. For the test session one animal is placed in a stainless steel cage with wire mesh bottom. A session consists of placing the subject in the test cage with a cork stopper weighing between 2–3 g for 30 min. Initially, the amount gnawed is relatively high and variable within and between subjects. After 30 training sessions, the amount is low and stabilized. The test compounds are injected 30 min before the test and food is withdrawn.

EVALUATION

Each cork is weighed to the nearest 0.01 g before and after the session. The average cork loss during the previous control days is taken as baseline and the amount after drug treatment is expressed as percentage of baseline. Buspirone-related compounds as well as benzodiazepines and meprobamate show a dose dependent increase of cork gnawing, but amphetamine, chlorpromazine, imipramine and morphine do not.

CRITICAL ASSESSMENT OF THE METHOD

The test is worthwhile to be mentioned, since buspirone – whose anxiolytic action was discovered during clinical trials to assess possible antipsychotic action and not by use of animal tests for anxiolysis – is active in this test but not in most other classical tests for anxiolytic activity.

E.2.4.8 Distress vocalization in rat pups

PURPOSE AND RATIONALE

Measurement of ultrasonic vocalization induced by tail-holding in rat pups was proposed as a simple screening method for anxiolytic drugs by Gardner (1985).

PROCEDURE

Wistar rat pups are bred on site and left undisturbed with their mother, except for cage-bedding replacement, until the day of testing. The pups are tested at 9–12 days of age. On the day of testing the pups are separated from their mother and taken in their home cage to the quiet experimental room. In the morning all pups are subjected to handling stress and the magnitude of their ultrasound emission is observed. The stress consists of holding the pup by the base of the tail, between forefinger and thumb of the experimenter, and thus suspending it 5 cm above the bench for 30 s. A prior control recording (30 s) is taken when the pup is held gently in the experimenter's hand, whereby the pups emit only a few ultrasounds. Responses when held by the tail are more than 10 times higher. This entire hand-holding-tail-holding procedure is immediately repeated.

Ultrasounds are recorded with suitable detectors with 42 kHz as the center of a 10 kHz recording range. The output of the detectors is fed into pen recorders. The total number of ultrasonic cries in the two sessions of hand holding and the two sessions of tail holding are calculated and used as the control activity of each pup. Any pup producing a total of less than 50 ultrasounds when held by the tail is excluded from the drug study. The pups are kept in the home cage in the test laboratory until the afternoon. Three to four hours after the first test the pups are randomly allocated to several equally seized groups, weighed, marked, and dosed intraperitoneally either with the vehicle or drug and placed back in the home cage. Thirty min after dosing, each pup is subjected to the same handling stress as that used in the morning session, and the total number of sounds produced is calculated in the same way.

EVALUATION

The afternoon response to tail holding is expressed as a factor of the morning response. The mean factor for the saline-treated animals is taken to be 100% in calculations of percentage changes in ultrasound emission by drugs.

CRITICAL ASSESSMENT OF THE METHOD

Anxiolytic benzodiazepines dose-dependent inhibit vocalization. Amitriptyline and haloperidol have no effect. Chlorpromazine, muscimol and prazosin reduce sound at doses which also induce overt sedation. Therefore, the method can be regarded as relatively specific for anxiolytic activity.

E.2.4.9 Schedule induced polydipsia in rats

PURPOSE AND RATIONALE

Food deprived rats exposed to a procedure in which food is delivered intermittently will drink large amounts of water if given the opportunity to do so. This behavioral phenomenon is termed schedule-induced polydipsia and is an example of a more general class of behaviors termed adjunctive behaviors (Falk 1971; Pellon and Blackman 1992). Adjunctive behaviors have been cited as potential animal models of human obsessive-compulsive disorders (Pitman 1989).

PROCEDURE

Male Wistar rats weighing 180–250 g are individually housed at a 12 h/12 h light/dark cycle for a 1 week acclimation period with free access to food and water. Then they are placed on a restricted diet which maintains 80% of their free feeding body weight. To induce polydipsia, rats are placed in test chambers housed in sound attenuated boxes where a pellet dispenser automatically dispenses two 45 mg pellets on a fixed time 60-s (FT-60s) feeding schedule over a 150 min test session. Water is available at all times in the test chambers. After 4 weeks exposure to the FT-60s feeding schedule, approximately 80% of the rats meet the pre-determined criterion for water consumption (greater than 60 ml water per session) and are considered to have polydipsic behavior.

Rats receive the test compounds in various doses daily or the vehicle intraperitoneally 60 min prior to testing. They are tested once a week to assess schedule induced polydipsia. Water bottles are weighed before and after the 150-min test sessions.

EVALUATION

The experimental data comparing the effects of chronic administration of compounds on schedule-induced polydipsia are analyzed with the Mann Whitney *U*-test.

MODIFICATIONS OF THE METHOD

Yadin et al. (1991) proposed spontaneous alternation behavior in rats as an animal model for obsessive-compulsive disorder. Food-deprived rats were run on a T-maze in which both a white and a black goal box were equally baited with a small amount of chocolate milk. Each rat was given 7 trials every other day during which it was placed in the start box and allowed to make a choice. The mean number of choices until an alternation occurred was recorded. After a baseline of spontaneous alternation was achieved the rats were treated with the non-selective serotonin agonist

5-methoxy-N,N-dimethyltryptamine (5-MeODMT) (1.25 mg/kg i.p.) or the selective 5-HT_{1A} agonist 8-hydroxy-2-(di-n-propylamino)-tetralin hydrobromide (8-OH-DPAT) (2 mg/kg i.p.) which both disrupted the spontaneous alternation. A course of chronic treatment (2 × 5 mg/kg for 21 days) with the selective 5-HT uptake blocking agent fluoxetine had a protective effect on the 5-MeODMT-induced disruption of spontaneous alternation behavior. The authors speculated that serotonergic manipulations of spontaneous alternation may be a simple animal model for the perseverative symptoms or indecisiveness seen in patients with obsessive-compulsive disorder.

E.2.4.10 Four plate test in mice

PURPOSE AND RATIONALE

The four plate test in mice has been described by Aron et al. (1971), Boissier et al. (1968) as a method for the rapid screening of minor tranquilizers.

PROCEDURE

The test box has the shape of a rectangle (25 × 18 × 16 cm). The floor is covered with 4 identical rectangular metal plates (8 × 11 cm) separated from one another by a gap of 4 mm. The plates are connected to a source of continuous current which applies to 2 adjacent plates a mild electrical shock of 0.35 mA for 0.5 s. This evokes a clear flight reaction of the animals.

Adult male Swiss albino mice, weighing 17 to 23 g, are randomly divided into different groups. Thirty min before the test the animals are injected intraperitoneally with the test drug or the vehicle.

At the beginning of the test, the mouse is gently dropped onto a plate and is allowed to explore the enclosure for 15 s. After this, every time the animal crosses from one plate to another, the experimenter electrifies the whole floor for 0.5 s, which evokes a clear flight-reaction of the mouse which often crosses 2 or 3 plates. If it continues running, no new shock is delivered during the following 3 min.

EVALUATION

The number of times the apparatus is electrified is counted each minute for 10 min. The delivery of shocks decreases dramatically the motor activity. The number of shocks received during the first min is taken as parameter. This number is increased by minor tranquilizers, such as benzodiazepines, but not by neuroleptics and psychoanaleptics.

CRITICAL ASSESSMENT OF THE METHOD

The test is of value to differentiate minor tranquilizers, such as benzodiazepine anxiolytics, from neuroleptics. However, some stimulants (e.g. amphetamine) produce an increase in punished plate crossings and some anxiolytics do not.

E.2.4.11 Footshock induced freezing behavior in rats

PURPOSE AND RATIONALE

Footshock-induced freezing behavior in rats has been proposed as a model for anxiolytics by Conti et al. (1990).

PROCEDURE

Male Sprague-Dawley rats with a weight between 200 and 350 g are used. The animals receive a single i.p. injection of the test compound or the vehicle 30 min prior to being placed in a standard conditioning chamber (e.g., Coulborn Instruments) for a 6.5 min session. Two and 2.5 min after the start of the session, a scrambled footshock (0.5 mA, 0.5 s) is delivered through the grid floor of the chamber. Using an assembly of push buttons interfaced with a computer, an observer monitors the amount of time each animal spends engaged in the following mutually exclusive behaviors:

- Freezing: immobility with rigid body posture
- Sedated posture: sitting or sleeping
- Small exploratory movements: movements involving the torso or front paws only, vertical movements of the head, or sniffing.
- Locomotion: activity involving hind paws, grooming or rearing.

Frequency of rearing is also counted. All behaviors are monitored for the entire 6.5 min session.

EVALUATION

Duration of foot-shock induced freezing after the second shock is taken as the critical parameter. Time spent in freezing posture after administration of test compounds is compared with the controls. Anxiolytics like diazepam and buspirone show dose-dependent effects, but not haloperidol.

CRITICAL ASSESSMENT OF THE METHOD

The method seems to discriminate anxiolytics including buspirone from other centrally acting drugs.

MODIFICATIONS OF THE METHOD

Footshock-induced ultrasonic vocalization has been suggested as another model of anxiety (Tonoue et al. 1986; Kaltwasser 1990; Miczek et al. 1991; De Vry et al. 1993; Nielsen and Sánchez 1995; Schreiber et al. 1998). Test cages ($22 \times 22 \times 22$ cm) made of grey Perspex are equipped with a metal grid floor (distance between the bars = 1 cm). Electric footshocks are delivered from a 12 bit programmable shock source and ultrasounds are picked up by a microphone (range 18–26 Hz) placed in the center of the cage lid. The total vocalization time is measured. The rats are placed individually in the test cages and immediately receive a series of 0.5 mA inescapable footshocks each of 1 s duration with a shock interval of 5 s. The vocalization is measured for a 10 min period starting 1 min after the last shock. Drugs or saline are given subcutaneously 30 min before the test.

E.2.4.12 Experimental anxiety in mice

PURPOSE AND RATIONALE

Ogawa et al. (1966, 1990, 1993) designed a communication box to induce experimental anxiety in mice by employing intraspecies emotional communication. The inside of the communication box was divided into foot-shock and non-foot-shock compartments by transparent plastic boards. The animals, which were individually placed into each compartment, were unable to make physical contact with one another, but were able to receive other cues such as visual, auditory and olfactory sensations. During the foot shock period, the animals placed in the non-foot-shock compartments were exposed to the emotional cues from foot-shocked animals, such as shrieks, smell of feces or urine, and jumping response.

PROCEDURE

The floor of the communication box is equipped with grids for electric shock. The inside is divided into small compartments (10×10 cm), consisting of foot-shock compartments with a grid floor and non-foot-shock compartments with a grid floor covered by transparent plastic boards. The foot-shock compartments are arranged such as to surround the non-foot shock compartments.

The experimental groups consist of the following 3 groups: sender group, responder group, and food-yoked group to responder. Sender animals receive a foot shock of 10-s duration at intervals of 50 s for 3 h. The

electric current for the shock is increased step-wise from 1.6 mA to 2.0 mA at a rate of 0.2 mA per 1 h. Responders are exposed daily to the emotional responses of sender animals, 3 h per day for 3 days. Sender animals are changed daily to naive mice to prevent a reduced emotional response to foot shock based on adaptation or learned helplessness due to repeated exposure. Both sender and responder animals are placed individually in each compartment of the communication box 15 min before beginning of the shock period. On day-1, responder animals are returned to their home cages after the 3-h foot shock period. An day-2, after completing the foot-shock period, they are transferred to metal cages and are housed in the cages with 4 animals per cage under food-deprivation condition. Food-yoked control animals are maintained to the metal cage during the foot-shock period under the aggregated housing condition (5 animals each) and then they are returned to the home cages after the foot shock period. From beginning of the day-2 experiment to completion of the day-3 experiment, they are maintained in the metal cages under aggregating housing. On day-3, just after completing the foot-shock period, the responders are sacrificed by chloroform, and their stomachs are removed. The stomachs are visually inspected for lesions.

Drugs are administered orally at different doses either with a single dose on day-3 or daily 30 min before the shock period.

EVALUATION

Data are reported as the incidence of mice with gastric lesions characterized by slight erosions or bleeding. Active anxiolytics reduce the incidence of gastric ulcers found in food-deprived animals. The incidence in food-yoked animals is much lower. The data are analyzed by Fisher's exact probability test.

E.2.4.13 mCPP induced anxiety in rats

PURPOSE AND RATIONALE

The metabolite of the antidepressant drug trazodone 1-(3-chlorphenyl)piperazine (= mCPP), classified as 5-HT_{1C} agonist (Rocha et al. 1993; Gibson et al. 1996) or 5-$HT_{1B/2C}$ agonist (Dryden et al. 1996), has been shown to be anxiogenic both in man and in rats (Curzon et al. 1991). The compound induces hypophagia (Samanin et al. 1979; Dryden et al. 1996; Yamada et al. 1996) and hypolocomotion (Kennett et al. 1996, 1997a), inhibits social interaction in rats, diminishes exploratory activity of rats in the open field test (Czyrak et al. 1994; Meert et al. 1997) and in the light-dark box test (Bilkei-Gorzo et al. 1998), induces hyperthermia (Aulakh et al. 1995; Kennett et al. 1997b) and reduces ultrasound-induced defensive behavior in the rat (Beckett et al. (1996). Antagonism against these symptoms has been proposed as a screening model for anxiolytic drugs (Bilkei-Gorzo et al. 1996, 1998; Wallis and Lal 1998).

PROCEDURE

Male Sprague Dawley rats (220–250 g) are housed in groups of 6 under a 12 h light/dark cycle with free access to food and water.

mCPP-induced locomotion

Rats are placed in a room adjacent top the experimental room on the day of the procedure. They are dosed either orally 1 h, or i.p. 30 min before the locomotion test with test compound or vehicle, and injected 20 min before the test with 7 mg/kg mCPP i.p. or saline in groups of four. Rats are returned to their home cages after dosing. At 0 h they are each placed in automated locomotor activity cages made of black Perspex with a clear Perspex lid and sawdust covered floor under red light for 10 min. During this time, locomotion is recorded by means of alternately breaking two photocell beams traversing opposite ends of the box 3.9 cm above floor level.

mCPP-induced hypophagia

Rats are individually housed on day 1 and on day 3 they are deprived of food. Twenty-three hours later, the are orally treated with the test drug or vehicle and returned to their home cages. Forty min later, they are given 5 mg/kg mCPP or saline i.p. and again returned to their home cages. After a further 20 min, weighted amounts of their normal food pellets are placed in their food hoppers and the amount remaining after 1 h is measured.

EVALUATION

The effect of the test compound on mCPP-induced hypolocomotion is determined by one-way ANOVA and Newman-Keuls test. The dose producing 50% disinhibition of mCPP is also estimated. Feeding test data are subjected to one-way ANOVA and Dunnett's test.

MODIFICATIONS OF THE METHOD

Griebel et al. (1991) described neophobic and anxious behavior in mice induced by m-CPP.

Czyrak et al. (1994) measured the antagonism of anti-psychotics against the mCPP-induced hypothermia in mice.

E.2.4.14 Acoustic startle response in rats

PURPOSE AND RATIONALE

The acoustic startle reflex is a relatively simple behavior that occurs naturally in mammals and is affected by a variety of treatments. It consists of a series of rapid movements beginning at the head and moving caudally involving contraction and extension of major muscle groups in response to auditory stimuli with a rapid onset, or rise time. Responses are graded in amplitude in relation to stimulus intensity, and may show habituation and sensitization. Startle response can be used to determine sites and mechanisms of drug action (Davis 1982).

PROCEDURE

Male Wistar rats weighing about 200 g are used. Acoustic startle reflexes are measured in a specially build apparatus, e.g., Coulborn Instruments Acoustic Response Test System. The animals are individually placed in $8 \times 8 \times 16$ cm open air cages that restrict locomotion but do not immobilize the animal, and are placed on one of four platforms within a sound-attenuating acoustic chamber. A ventilating fan provides an ambient noise level. Acoustic stimuli consist of white noise bursts lasting 20 ms at 98 dB and 124 dB SPL. Simultaneously with the rapid onset of each stimulus, the animal's physical movement within the cage on the platform is measured for 200 ms as an electrical voltage change via a strain gauge which is converted to grams of weight change following analog to digital conversion. Data are recorded automatically by an interfaced microcomputer.

Pre-tests are performed with all animals to obtain control values. The animals are treated 2 h prior the experiment with test drugs or vehicle given orally or subcutaneously.

EVALUATION

The results are given as percentage of the change, related to the values obtained in the pre-test and assessed by a one-way ANOVA, followed by Dunnett's test when appropriate.

MODIFICATIONS OF THE METHOD

The test has been modified in various ways, e.g., inhibition by a prepulse (Keith et al. 1991; Rigdon and Viik 1991; Taylor et al. 1995) or fear-induced potentiation (Davis 1986, 1992).

Sipes and Geyer (1995) studied the disruption of prepulse inhibition of the startle response in the rat by DOI (2,5-dimethoxy-4-iodophenylisopropylamine) which is mediated by 5-HT_{2A} receptors. The authors suggested that studies of the serotonergic substrates of prepulse inhibition may provide a model of the possible serotonergic role in the sensorimotor gating abnormalities in schizophrenia and obsessive compulsive disorder patients.

Schulz et al. (1996) performed acoustic startle experiments in rats with a potent and selective non-peptide antagonist of the corticotropin releasing factor receptors.

Walker and Davis (1997) found that the amplitude of acoustic startle response in rats was increased by high illumination levels.

Devices to register the intensity of fear-potentiated startle response in rats were described by Hijzen et al. (1995).

E.2.4.15 Unconditioned conflict procedure (Vogel test)

PURPOSE AND RATIONALE

Vogel et al. (1971) described a simple and reliable conflict procedure for testing anti-anxiety agents. Thirsty, naive rats were administered shocks while licking water.

PROCEDURE

The apparatus is a clear Plexiglas box (38 × 38 cm) with a black Plexiglas compartment (10 × 10.5 cm) attached to one wall and an opening from the large box to the small compartment. The entire apparatus has a stainless-steel grid floor. A water bottle with a metal drinking tube is fitted to the outside of the small compartment, so that the tube extended into the box at a height 3 cm above the grid. Rats lick in bursts with a relatively constant rate of 7 licks per sec. A drinkometer circuit is connected between the drinking tube and the grid floor of the apparatus, so that the rat completes the circuit whenever it licks the tube. Shock is administered to the feet of the animal by switching the connections to the drinking tube and grids from the drinkometer to a shocker which applies an unscrambled shock between the drinking tube and the grid floor.

Naive adult male rats are used. Thirty min after intraperitoneal injection, the rat is placed in the apparatus and allowed to find the drinking tube and to complete 20 licks before shock (available at the tube for 2 s) is administered. The rat controls shock duration by withdrawing from the tube. A 3-min timer is automatically started after the termination of the first shock. During the 3-min period, shocks are delivered following each twentieth lick. The number of shocks delivered during the 3-min session is recorded for each animal.

EVALUATION

The number of shocks received after treatment is compared with untreated animals. Benzodiazepines increase dose-dependent the number of shocks. Barbiturates in low doses and meprobamate, but not d-amphetamine or scopolamine, are active in this test.

CRITICAL ASSESSMENT OF THE METHOD

The method is far more simple and less time consuming than the methods using conflict behavior after intensive training. The specificity may be less than that of the Geller paradigm.

MODIFICATIONS OF THE METHOD

The method and the apparatus have been slightly modified by Patel and Malick (1982), Patel et al. (1983) and Sanger et al. (1985).

Miklya and Knoll (1988) showed an increase of sensitivity of the method using rats deprived of food but supplied with tap water ad libitum for 96 h, than fed with dry pellets and punished for drinking during feeding. The punished drinking test has not only be used for identifying and studying anxiolytic agents, but also as a method for measuring anxiogenic activity (Uyeno et al. 1990).

La Marca and Dunn (1994) studied α_2-antagonists after intravenous administration in the Vogel lick-shock conflict paradigm.

E.2.4.16 Novelty-suppressed feeding

PURPOSE AND RATIONALE

Placing a hungry rat into an unfamiliar environment with access to food results in a suppression of feeding behavior relative to the condition when the test environment is familiar. This effect has been termed hyponeophagia (Shephard and Broadhurst 1982) and occurs because of the novelty of the test environment. The avoidance of novel foods is termed food neophobia. Both hyponeophagia and food neophobia have been assumed to measure emotionality or anxiety by eliciting a conflict situation arising from a fear of the novel setting and foods, and the drive to eat (Porschel 1971). A number of investigators have adopted these paradigms to explore the behavioral effects of anxiolytics (Soubrie et al. (1975;Cooper and Crummy 1978; Borsini et al. 1993).

PROCEDURE

The testing apparatus consists of individual Plexiglas open fields, 76 × 76 × 46 cm. Thirty Purina lab chow pellets are placed in a pile directly in the center of the open field.

Animals are handled for 3 weeks prior the behavioral testing. Forty-eight hours prior to testing, all food is removed from the home cage, although water is still

available ad lib. One h prior to testing, animals receive an intraperitoneal injection of test drugs or vehicle. At the time of testing, the animals are placed into individual open fields containing the food, and the latency to begin eating is measured. If the animal has not eaten within 720 s, the test is terminated and the animal is assigned a latency score of 720 s.

EVALUATION

The data are analyzed by a one-way analysis of variance followed by Fisher Last Significant Difference post hoc tests. An anxiolytic effect is defined as a significant decrease in mean latency to begin eating compared with vehicle controls.

CRITICAL ASSESSMENT OF THE METHOD

The test has the advantage of simplicity for screening procedures.

E.2.4.17 Shock probe conflict procedure

PURPOSE AND RATIONALE

The shock probe conflict procedure, an assay responsive to benzodiazepines, barbiturates and related compounds, was described by Meert and Colpaert (1986). Rats being placed in a novel test environment containing a probe, explore the environment and also the probe. The exploration of the probe, quantified as the number of times that the animal makes physical contact with it, is reduced when the probe is electrified. Rats treated with anxiolytics continue to touch the electrified probe.

PROCEDURE

Apparatus: The test environment consists of a Plexiglas chamber, measuring $40 \times 40 \times 40$ cm, and having a metal grid floor. A Teflon probe (∅: 1 cm) with two uninsulated wires (∅: 0.5 mm) each independently wrapped 25 times around it, is inserted from the front panel protruding for a length of 6.5 cm into the test box, 3 cm above the floor of the chamber. The wires are connected to a shocker. Whenever the animal touches both wires simultaneously with some part of its body, a DC current flows through the animal. At the same time, a counter is triggered. Normally, a shock intensity of 0.9 mA is used.

Sixty min after treatment with saline or test substance, the animal is placed in a back corner of the testbox facing away from the probe. The test session starts from the moment makes the first contact and receives the first shock. The number of responses the animal makes during the subsequent 5-min episode is counted.

EVALUATION

Dose-response curves can be established for various drugs at different shock intensities. The Mann-Whitney *U*-test is used to evaluate differences between experimental conditions. To control whether a drug treatment increases responding above the saline control level, an one-tail *t*-test is used; a two-tail test in other cases.

CRITICAL ASSESSMENT OF THE METHOD

The procedure requires neither behavioral training nor expensive equipment and overcomes some of the limitations that are typical for other conflict procedures. However, the procedure still uses electric shock as inhibitory stimulus.

E.2.4.18 Ultrasound induced defensive behavior in rats

PURPOSE AND RATIONALE

Rats exposed to aversive stimuli display specific defence behavior as a part of their natural survival strategy. One component of this behavior is the production of ultra-

sonic calls in the 20–27 kHz range, which are thought to serve a communication role. Artificially gen-erated ultrasound produces intensity-related locomotion, characteristic of defensive behavior (Beckett et al. 1996).

PROCEDURE

The apparatus (Beckett and Marsden 1995) consists of a circular open field arena, 75 cm in diameter, 46 cm high walls, with a video camera suspended above. Locomotor behaviors are recorded and analyzed using a computer automated tracking system capable of following rapid movements (VideoTrack, CPL Systems, Cambridge, UK). This allows the ultrasound-induced change in locomotor behavior to be quantified in maximum speed, average speed and distance traveled by the animals. Data are expressed as 15 sequential 20-s bins over the duration of the experiment.

Ultrasound (continuous tone, square wave, 20 kHz) is produced using a multifunction signal generator at sound pressure intensities of 65, 72 and 75 dB, as measured from the arena, 20 cm horizontally from the speaker. Sound is delivered to the testing arena via a high frequency piezo electric speaker mounted at a height of 40 cm on the wall of the testing arena. The signal frequency and intensity delivered to the speaker are monitored using a digital oscilloscope. White noise is generated using a standard generator and the sound intensity measured as above.

Animals are placed in the test arena 20 min after intraperitoneal injection of drug or vehicle and locomotor activity is measured. After 2 min they are exposed to a 1-min, 20 kHz, square wave ultrasound tone (65, 72 or 75 dB sound pressure intensity, randomized) followed by a further 2 min without sound. This procedure is repeated for each intensity with a 1-min inter-procedure interval. Locomotor activity values are then calculated for the maximum speed, average speed and total distance traveled throughout the 5-min test period and expressed as a series of 15–20-s time epochs.

EVALUATION

Maximum speed is analyzed using a two-way ANOVA. Significant interactions between treatment and time are followed by one-way ANOVAs for individual time points with post-hoc Duncan's new multiple range test.

MODIFICATIONS OF THE METHOD

Moleweijk et al. (1995) evaluated ultrasound vocalizations of adult male rats in association with aversive stimulation as a screening method for anxiolytic drugs.

E.2.4.19 Anxiety/defense test battery in rats

PURPOSE AND RATIONALE

Blanchard et al. (1989, 1990, 1992) described a set of procedures designed to assess the defensive reactions of rats to a natural predator, the cat. These tests involve a brief confrontation of laboratory rats with an unconditioned threat stimulus (cat) which, to preclude physical contact, is presented behind a wire mesh barrier. The primary measures, taken both during and after cat presentation, include movement arrest and risk assessment (proxemics/activity test) and the inhibition of non-defensive behaviors (eat/drink or freezing test).

PROCEDURE

The test apparatus for both the proxemics/activity and eat/drink procedures consists of two parallel subject chambers ($53 \times 20 \times 25$ cm). The inside walls of each chamber are constructed of opaque black Plexiglas, while outer walls and lids are clear Plexiglas to allow video recording from lateral and overhead views. The end wall of each chamber, constructed of wire mesh, adjoins a separate cat compartment. Subject movements are monitored by five photocells mounted at equal distances over the length of each chamber, and a food hopper and drinkometer are positioned 2.5 cm to each side of the central photocell. Access to the food hopper/drinkometer can be prevented by insertion of Plexiglas gates.

Each rat (Long-Evans strain, female or male, about 100 days old) receives the same injection (drug or saline) in each of the two successive paradigms. The initial study assesses the effects of cat exposure on proxemics/activity, followed 7 days later by analysis of eat/drink behavior during and after cat exposure. Both procedures are carried out under dim red light.

Proxemic/activity testing. Rats are individually placed in each compartment of the test apparatus. Following a 5-min pre-cat period, the cat is introduced to the cat compartment for 5 min. Following removal of the cat, behavior is recorded for a further 15 min post-cat period, for which measures are summed in three, 5-min blocks. The test session is video recorded for analysis of lying, crouching, rearing, locomotion and grooming. Proxemic location is measured by a digitizing sys-

tem which divides the length of the subject compartment into thirds, indicating animal's location near the cat compartment, in the midsection of the box, or far from the cat compartment. Assessment of transits indicate movement from one section to another.

Eat/drink testing. Rats are individually given 2 g of finely crushed chocolate cereal on the 2 days after the proxemic/activity test, to familiarize them with this highly preferred food. In order to induce a mild water deprivation, water bottles are removed, 24 h prior to eat/drink testing. On the test day, animals are individually placed in the subject compartments for a 5-min pre-cat period, during which the food hopper and water dispenser are concealed with Plexiglas gates. At the beginning of the 5-min cat period, these gates are removed allowing free access to the crushed chocolate cereal and water. After removal of the cat, the rats are monitored for a further 15-min post-cat period. Measures of eating frequency and duration, and drinking frequency are taken for the cat and post-cat periods.

EVALUATION

The data are analyzed by analysis of variance (ANOVA). Subsequent comparisons between treatment groups and control are carried out using Newman-Keuls procedures.

MODIFICATIONS OF THE TEST

Blanchard et al. (1986a,b, 1989) developed a battery of tests designed to elicit a wide range of active and passive defensive activities in *wild rats*.

Griebel et al. (1997, 1998a,b) designed a mouse defense test battery in which Swiss mice were confronted with a natural threat (a rat) and behaviors associated with this threat were recorded.

E.2.4.20 Marmoset human threat test

PURPOSE AND RATIONALE

The behavior of the common marmoset (*Callithrix jacchus*) as described by Stevenson and Poole (1976) can be used for evaluation of potential anxiolytic drugs (Costall et al. 1988).

PROCEDURE

Male or female laboratory bred common marmosets weighing 350–400 g are housed in single sex pairs. Holding rooms are maintained at 25 °C at a humidity of 55% on a 12 h light/dark cycle. Tests are conducted between 13:30 and 15:30 in the normal holding room. The holding cages are 75 cm high, 50 cm wide and 60 cm deep.

A behavioral change characterized by retreat from, and posturing toward a human threat is initiated by a human observer standing in close proximity in front of the holding cage. Changed behavior is recorded over a 2 min period by the observer. The behavioral measures selected are:

i the % of time spent on the cage front in direct confrontation with the human threat,
ii the number of body postures, primarily shown as raising the tail to expose the genital region with varying degrees of piloerection, anal scent marking and slit stare with flattened ear tufts.

The animals are used at 7 day intervals and are subject to a random cross-over of treatments.

Drugs are administered 45 min before exposure to the human threat situation.

EVALUATION

Statistical analysis is performed with one-way analysis of variance followed by Dunnett's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

The human threat test in marmosets has the advantage of using primates instead of rodents. However, it is subject to individual scoring of the observer.

MODIFICATIONS OF THE TEST

Borsini et al. (1993) used female **cynomolgus monkeys** to test aggressiveness against the observer.

Cilia and Piper (1997) developed a method of measuring conspecific confrontation-induced behavioral changes in common marmosets together with automated monitoring of locomotor activity as a possible model of anxiety.

E.2.4.21 Aversive brain stimulation

PURPOSE AND RATIONALE

Electrical stimulation of brain aversive areas, in particular the midbrain central gray, induces defensive reaction and/or flight behavior in several species and, therefore, may be viewed as an animal model of anxiety or of panic attack. Most studies used intracerebral microinjections of neurotransmitters, their agonists and antagonists to elucidate the mechanisms of aversive or antiaversive effects (Schütz et al. 1985; Graeff et al. 1986, 1990, 1991 1993, 1997; Audi et al. 1988, 1991; Brandão et al. 1991, 1993; Broekkamp et al. 1991; Nogueira and Graeff 1991, 1995; Motta and Brandão 1993; Aguiar and Brandão 1994, 1996; Melo and Brandão 1995; Motta et al. 1995; De Araujo et al. 1998). Other groups evaluated the effect of drugs, e.g., serotonin receptor antagonists, on periaqueductal gray stimulation induced aversion after peripheral application (Bovier et al. 1982; Clarke and File 1982; Jenck et al. 1989, 1996, 1998; Beckett and Marsden 1997).

PROCEDURE

Surgery. A stainless steel bipolar twisted electrode, insulated to the tip which is cut square to the shaft, is implanted to the dorsal part of the periaqueductal gray matter of male Wistar rats weighing 370–450 g under pentobarbital anesthesia. According to the atlas of Paxinos and Watson (1982), the coordinates for the electrode tip are 5.8 mm posterior to the bregma, 0.2 mm lateral to the midline and 5.0 mm ventral to the surface of the skull. The electrode is held in place with dental cement and five screws threaded into the skull.

Behavioral procedure. Animals are placed in a rectangular cage ($20 \times 36 \times 20$ cm high) with a grid floor and a 2 cm high barrier dividing the cage in half. They are allowed to explore freely for 10–15 min before the stimulation begins.

Strain stimulation consists of constant current square wave, 0.1 ms duration, monophasic pulses conducted from the neurostimulator (Grass S88 + stimulus isolation unit SIU8) to the electrode by way of flexible wire leads. Pulse duration, pulse frequency and stimulation intensity are monitored by an oscilloscope. Animals are screened for stimulation-induced aversion using a fixed stimulation frequency of 50 Hz; current is raised slowly until aversive behavioral signs are observed. Aversive effects are first characterized by visible autonomic reactions (increase in respiratory rates, piloerection, eventually mydriasis) in animals which are behaviorally frozen. Increasing the intensity induces, following a freezing period, active behavioral signs, ranging from ear dressing and head weaving to sudden running and attempts to escape out of the cage.

With this fixed stimulation intensity, aversive behavior is shaped into an operant escape response: rats are trained to stop the stimulation by escaping from one compartment to the opposite compartment of the cage. Brain stimulation is switched off when the rat crosses the middle line separating the two compartments or after a maximal cut-off time of 20 s. A trial is applied every min. Three to 10 daily sessions of 30 trials are required to obtain stable responses.

Once an animal displays steady performances during 3 consecutive days on this task with fixed intensity and fixed stimulation frequency, it undergoes the next step of training aimed at determining its stimulation frequency threshold for escape reaction. This consists of testing the animals in a threshold procedure in which the frequency is varied while stimulation inten-

sity is held constant. This procedure keeps the size of the stimulation field around the electrode tip constant.

A stimulation intensity is chosen and defined as the threshold intensity eliciting escape when the stimulation frequency is 50 Hz. With this intensity held fixed, a method of limits is employed to determine the frequency threshold for escape: the stimulation frequency is either decreased or increased depending on the response displayed by the animal on the previous trial. Starting from 50 Hz, stimulation frequency is decreased by 5 Hz steps following a trial in which the rat responds to the stimulation, and is increased by 5 Hz steps, in case the animal fails to respond to the stimulation. When a response is made, the time elapsing between the onset of the stimulation and the moment the animal crosses the midline barrier is also recorded as escape latency; no response is associated with the maximum cut-off time of 20 s.

Frequency threshold is calculated as the average frequency eliciting an escape reaction during a 20-min pre-injection session; an average escape latency is calculated the same way. Drugs are then injected intraperitoneally at various doses and 35 min following administration, frequency threshold is determined again over a 25–30 min post-injection session. Drug effects can be estimated by comparing thresholds and latencies for each animal before and after injection. Doses are injected at least 4 days in a counterbalanced order. Animals serve as their own controls and can undergo several treatments.

EVALUATION

Data are analyzed by means of analysis of variance, followed by paired *t*-tests. Dose-response curves are established for active drugs.

MODIFICATIONS OF THE METHOD

The group of Graeff and Brandão (1986) used an electrode-cannula, called chemitrode, for electrical stimulation and microinjection of drugs or neurotransmitters at the same place of the periaqueductal gray. This chemitrode was made of stainless steel cannula (outside diameter 0.6 mm, length 12.5 mm) glued to a brain electrode made of stainless steel (diameter 250 mm) enamel insulated except at the cross-section of the tip, reaching 1 mm below the lower end of the cannula (Nogueira and Graeff 1995).

E.2.5 Conditioned behavioral responses

E.2.5.1 Sidman avoidance paradigm

PURPOSE AND RATIONALE

Sidman (1953) described an apparatus for the evaluation of two temporal parameters (shock-shock interval and response-shock interval) of the maintenance of avoidance behavior by the white rat. The procedure has been widely used to evaluate CNS depressant compounds, neuroleptics, anxiolytics and sedatives.

PROCEDURE

The test cage is equipped with a single lever and a light. This cage is enclosed in a sound-attenuating chamber with a fan and with a speaker emitting a white-noise auditory background. The test cage has a grid floor of steel bars which are attached to a scrambled shock source. The data are recorded in an adjacent room. Male Sprague-Dawley rats with a starting weight of 250 to 300 g are housed in individual cages. They are trained to avoid an unsignalled shock by repetitive lever-pressing responses. A shock (1.5 mA for 0.5 s) is delivered to the grid floor every 15 s if no responses occur (shock-shock interval of 15 s = SS-15 s). A lever press (response) will delay the oncoming shock for 30 s (response-shock interval of 30 s = RS-30 s). The responses do not accumulate for delays of shock; a shock will be delivered 30 s after the last response is made even if 10 responses are made 31 s prior. Every 30 min, the total number of shocks received and the total number of responses made are accumulated and constitute the basic data. The animals are trained until they maintain a stable response rate and receive no more than 100 shocks/five hour test session. After reaching these criteria of performance, experimental compounds are administered and their effects on the performance of this learned avoidance behavior are evaluated. The experimental compounds or the standard are usually administered by i.p. injection immediately prior to testing in volumes of 1 ml/kg of body weight. Depressant drugs lower the rate of lever presses and increase the number of shocks received. Stimulant drugs increase the rate of lever pressing.

EVALUATION

The effect of a drug on the performance of an animal is compared to the data generated in the previous non-drug sessions. Each animal thereby serves as its own control. The basic measures of performance during a specific time interval, responses and shocks are used for evaluation. Responses are reported both as total and as percent of control responses. Shocks are reported as totals and as shock-avoided (SHA) as percent of control. This latter measure is computed by subtracting the number of shocks received from the total number of possible shocks if no responses had been made. In the initial screening of experimental compounds, the results are reported in terms of the total effect during a five-hour test. However, an ED_{50} is usually estimated during a representative time of peak activity.

CRITICAL ASSESSMENT OF THE METHOD

Anxiolytics show activity in this test, however, it has been proven to be more reliable for neuroleptic activity. Apparently, the present conditioned active avoidance paradigms do not constitute a reliable method for screening anxiolytic agents, in spite of their homologies with human anxiety.

MODIFICATIONS OF THE METHOD

Heise and Boff (1962) and Galizio et al. (1990) extended the method by using two levers, an "avoidance lever" and an "escape lever" for calculating ratios between shock rate, escape failure rate and avoidance rate.

Balfour (1990) described the effect of drugs on rat behavior in an unsignalled Sidman avoidance schedule.

Wadenberg et al. (1998) described and evaluated a newly designed apparatus for the assessment of conditioned avoidance response performance in rats.

Patel and Migler (1982) reported a sensitive and selective conflict test in **squirrel monkeys**.

Szewczak et al. (1995) tested antipsychotic agents using continuous avoidance behavior in adult male squirrel monkeys.

E.2.5.2 Geller conflict paradigm

PURPOSE AND RATIONALE

Experimentally induced conflict by punishing food-rewarded behavior has been used to differentiate between various psychoactive drugs by Geller and Seifter (1960). The basic principle has been used and modified by many authors to reveal possible anti-anxiety effects of experimental compounds.

PROCEDURE

Male albino rats with a starting body weight of 300–400 g are housed individually. They are food deprived until the body weight is gradually reduced by approximately 20% of original and it is maintained at this level by restricted food diet. Conditioning is carried out in commercially available Skinner boxes (e.g. Campden Instruments, London, UK) equipped with a house light, a single lever, cue lights, a liquid dripper, and a grid-floor connected to a shocker. Sweetened condensed milk delivered by the liquid dipper serves as the positive reinforcer. The data are recorded on cumulative recorders.

The animals are trained to lever press for the milk reward in two distinct response-reward sections. In the anxiety or "conflict" segment (signalled by onset of both tone and cue lights), a dipper of milk is delivered in response to each lever press (continuos reinforcement schedule = CRF) However, lever presses during this period are also accompanied by a 40-ms pulse of aversive foot-shock through the grid floor. This creates a conflict between milk reward and the a painful foot shock. This conflict period is 3 min in duration.

During the other segment of this paradigm, the lever presses produce a drop of milk only at variable intervals of time from 60 to 210 s with an average reward of once per 2 min (variable interval = VI-2 min). No shocks are administered during this variable interval phase of testing which is 15 min in duration.

The test procedure consists of four 15 min nonshock variable interval segments where reinforcement is available on a restricted basis. Each variable interval period is followed by a three minute CRF-conflict period phase when reinforcement is constantly available but always accompanied by an aversive footshock. The shock level is adjusted for each subject to reduce the CRF responding to a total of less than 10 lever presses during the entire test. The rats are tested 2 to 4 days a week. Drugs are administered once per week and the performance is compared to the previous day's control trial. The VI responses are used to evaluate any general debilitating drug effects while the CRF responses are used to evaluate any anti-anxiety effects as indicated by the increased responding during the CRF conflict period.

The test compounds are administered intraperitoneally 30 min or orally 60 min before the test period.

EVALUATION

The total number of lever presses during the conflict periods (CRF) and the non-conflict periods (VI) are counted. Values of treatment sessions are expressed as percentage of values of the preceding non-treatment day. An increase of lever presses in the conflict period is regarded as indication of an anti-anxiety effect, and a decrease of lever presses in the non-conflict period as an indication for a sedative effect. In this procedure linear dose-response curves are rarely found. Therefore, minimal effective doses (MED) are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method is suitable to distinguish anxiolytics from other centrally active drugs, such as sedatives and neuroleptics. The relative potency of various anxiolytic agents in a number of species compares favorably with their relative potency in humans. The negative aspects are the time consuming procedure, the high expenses for the apparatus and the difficulty to obtain ED_{50}-values.

The relevance of this test and other models has been challenged by Bignami (1988).

MODIFICATIONS OF THE METHOD

The method has been modified by many authors.

Davidson and Cook (1969), Cook and Davidson (1973) introduced a schedule of 10 lever presses for the delivery of one food pellet together with an electric foot-shock. In the variable interval reinforcement period, responses were reinforced by food delivery at varying intervals of time; the mean interval was 30 s. Also under these conditions differentiation of various psychotropic drugs could be achieved.

Iorio et al. (1986) and Chipkin et al. (1988) used a procedure during which a tone (5 s) preceded and then overlapped for 10 s with scrambled footshocks. After the start of the tone, the rat has the option to avoid (in the no shock period) or escape (in the shock period) the shock by jumping onto a platform located 17 cm above the grid floor.

Thiébot et al. (1991) developed the method further by introducing "safety signal withdrawal", a behavioral paradigm in rats sensitive to both anxiolytic and anxiogenic drugs.

Commissaris and Fontana (1991) published a potential animal model for the study of antipanic treatments. Rats were trained to drink their daily water ration during 10-minute sessions. These sessions were characterized by alterations of silence (unpunished periods) and the presence of a tone (punished periods). Tube contact during the tone periods resulted in a 0.25–0.5 mA shock delivered to the mouth of the animal for the duration of the tube contact. After 4 weeks of training, subjects received either chronic post-test treatment with an antidepressant or vehicle, twice daily, seven days per week. Acute pre-test administration of traditional anxiolytics (benzodiazepines, barbiturates) increased dramatically the number of punished contacts made in a dose-dependent manner. Typical antidepressants were not active after pre-test administration, however, active after chronic post-test treatment.

The conflict test has also be adapted to the **mouse** (Prado de Carvalho et al. 1986).

The conflict behavior and anticonflict effect of anxiolytics has been demonstrated in a variety of species, including **pigeons** (Morse 1964; Wuttke and Kelleher 1970; McMillan 1973; Gleeson et al. 1989; Barrett et al. 1989; Barrett 1991; Schipper et al. 1991; Pollard et al. 1992; Barrett et al. 1994; Mos et al. 1997).

Patel and Migler (1982) described a sensitive and selective conflict model in male squirrel **monkeys** in which anti-anxiety agents exhibit pronounced anticonflict activity.

Ervin et al. (1987), Ervin and Cooper (1988), van Heest et al. 1991; Simiand et al. (1993) used **conditioned taste aversion** as a conflict model. Moderate taste aversions were induced by pairing the initial consumption of 0.25% sodium saccharin with either 25 mg/kg 5-hydroxytryptophan or 30 mg/kg i.p. LiCl. Antagonism was found with benzodiazepines and non-benzodiazepine-anxiolytic drugs.

E.2.5.3 Conditioned defensive burying in rats

PURPOSE AND RATIONALE

Besides the well known defensive reactions of animals in typical laboratory settings, like freezing, fleeing, and attacking, rats tested in the presence of bedding material develop a peculiar behavior when shocked through a stationary prod by burying the shock source. This behavior has been proposed as a new paradigm for the study of anxiolytic agents (Pinel and Treit 1978, 1983; Treit et al. 1981).

PROCEDURE

Male adult rats weighing 250–400 g are used. The testing is performed in $44 \times 30 \times 44$ cm Plexiglas test chambers, the floor of which is covered with 5 cm of a commercial bedding material. In the center of each of the four walls, 2 cm above the level of the bedding material, is a small hole though which a $6.5 \times 0.5 \times 0.5$ cm wire-wrapped wooden dowel (i.e., the shock prod) can be inserted. Electric current is administered through the two uninsulated wires wrapped around the prod. The behavior of each rat is monitored for 15 min from a separate room via closed circuit television.

Before each of the experiments, the rats are placed in the Plexiglas test chamber in groups of 5 or 6 for 30-min periods on each of 4 consecutive days. In the experiments, groups of 10 animals are used for each dose and control. The rat is injected intraperitoneally with the test drug or saline before being placed into the test chamber in which the shock prod is inserted. The animal is placed into the center of the chamber so that is faces away from the prod. When the rat first touches the prod with its forepaw, it receives a brief electric shock (1 mA) which typically elicits a flinch away from the prod and withdrawal towards the back of the chamber. Afterwards, the rat moves directly towards the prod, pushing and spraying a pile of bedding material ahead with rapid shoveling movements of its snout and alternating pushing movements of its forepaws. The prod is buried in a pile of bedding material. The duration of burying is recorded.

EVALUATION

The mean duration of burying in treated animals is compared with controls. Anxiolytics as well as neuroleptics shorten the burying behavior dose-dependent at low shock intensity (1 mA). A second measure is the height of the bedding material. At high shock intensity (10 mA) only neuroleptics but not benzodiazepines are active.

CRITICAL ASSESSMENT OF THE METHOD

The method of conditioned defensive behavior can be regarded as a simple and reliable method to detect anxiolytic activity of benzodiazepines and neuroleptics. However, using higher shock intensity – where only chlorpromazine was found to be active – a separation between benzodiazepines and neuroleptics has been demonstrated.

The drug-class specificity of the test has been challenged by Craft et al. (1988).

MODIFICATIONS OF THE METHOD

Diamant et al. (1991) used telemetry to register autonomic and behavioral responses in the shock-prod burying test in rats.

Wiersma et al. (1996) reported that microinfusion of corticotropin-releasing hormone in the central amygdala of freely moving rats enhanced the active behavior responses in the conditioned defensive burying paradigm.

Fernandez-Guasti and Lopez-Rubalcava (1998) used the rat burying behavior test to study the effect of various potential anxiolytics.

Broekkamp et al. (1986), Njung'e and Handley (1991a,b; Gacsályi et al. 1997) described burying of marbles by *mice* as harmless objects without punishment by electrical shocks as a model for detection of anxiolytics. Thirty min after treatment with drugs, male Swiss mice, weighing 20–24 g, were individually placed in a $23 \times 17 \times 14$ cm cage with 25 glass marbles, 1.5 cm in diameter. The glass marbles were placed in close contact in the middle of the cage on a 5 cm layer of sawdust. The mice were left in the cage with the marbles for 30 min after which the test was terminated by removing the mice and counting the number of marbles that were more than two thirds covered with sawdust.

E.2.5.4 Taste aversion paradigm

PURPOSE AND RATIONALE

When ingestion of a taste stimulus is paired with internal malaise the animal remembers the taste and rejects its ingestion thereafter. This phenomenon is called a conditioned taste aversion or taste aversion learning. In the classical experiment in rats, the conditioned stimulus is a 0.01 M drinking solution of saccharin paired with an intraperitoneal injection of 0.15 M LiCl solution as unconditioned stimulus. The underlying neural mechanisms (Yamamoto 1993; Agüero et al. 1993, 1996; Swank et al. 1995) as well as facilitating and

inhibiting factors (Lipinski et al. 1995; Sobel et al. 1995) were investigated. Moreover, drugs by themselves can be studied. Rats are presented a fluid with palatable taste and immediately after consumption of this liquid injected with a drug, whose effect the animals have not experienced before. Subsequently, on a later occasion and under non-drug conditions, avoidance of the taste associated with the drug is measured (De Beun et al. 1996).

PROCEDURE

Male Wistar rats weighing 220–250 g are housed in groups of four per cage under a normal 12L:12D regime at 22–23 °C with free access to food and water. Twenty-four hours before the first conditioned taste aversion session, the animals are water deprived and fluid access is from then on restricted to daily experimental sessions of 15 min which takes place individually in a test cage. After each session, the animals are returned to their home cages. Food is freely available in the home cages throughout the procedure, but not available during the sessions. For a given subject, all six session required to complete a conditioned taste aversion experiment take place in the same test cage. Animals designated to the same experimental group are run in parallel. During the first four sessions (day 1 through day 4), both bottles contain plain tap water. During this phase of the procedure, the animal learns to drink a reasonable amount of fluid in a short period of time. For the 5th session (day 5, conditioning session), both bottles are filled with a 0.1% saccharin solution and immediately after completion of this session the animals are injected with either the vehicle or different doses of the test drug. Per animal, only one dose (or the vehicle) of a particular drug is tested. On days 6 and 7, no sessions are conducted (washout period) and the animals have free access to tap water in the home cages from the end of day 5 until the morning of day 7, when the animals are again deprived of water, 24 h prior to the final 6th session (day 8, test session). During this last session, one bottle contains the saccharin solution and the other bottle is filled with tap water. To control for location bias, the saccharin is presented in the left bottle for half of the animals in each group and in the right bottle for the other half. By measuring the amount of fluid consumed from both bottles separately, drug-induced conditioned taste aversion can be determined by comparison of the relative saccharin intake in the drug treated groups and their vehicle-treated controls.

EVALUATION

Data of test drugs are submitted separately to one-way analysis of variance, with the between-subjects factor DOSE. The dependent variable is the ratio of (saccharin solution/saccharin solution + tap water) intake. Fluid intake scores are calculated in grams. Post hoc analyses are used with Tukey HSD multiple comparisons. Results are considered significant when $p < 0.05$.

MODIFICATIONS OF THE METHOD

Besides LiCl, several other drugs were used to induce taste aversion, such as ethanol (Gauvin and Holloway 1992; June et al. 1992; Thiele et al. 1996; Bienkwoski et al. 1997), morphine (Miller et al. 1990; Bardo and Valone 1994), cocaine (Van Haaren and Highes 1990; Glowa et al. 1994), naloxone (Mucha 1997), apomorphine (McAllister and Pratt (1998), caffeine (Brockwell et al. 1991), d-amphetamine (Davies and Wellman 1990; Lin et al. 1994), nicotine (Shoaib and Stolermman 1996), quinine (Parker 1994), cisplatin (Mele et al. (1992), benzodiazepine and non-benzodiazepine anxiolytics (Neisewander et al. 1990), 5-hydroxytryptamine (Rudd et al. 1998), dopamine D_3 agonists (Bevins et al. 1996), cyclosporine A (Exton et al. 1998), cholecystokinin (Ervin et al. 1995; Mosher et al. 1996) and Δ9-tetrahydrocannabinol (Parker and Gillies 1995).

Turenne et al. (1996) found individual differences in reactivity to the aversive properties of drugs. Rats were assigned to high conditioned taste avoidance and low conditioned taste avoidance groups on the basis of their intake of saccharin solution previously paired with morphine, amphetamine, lithium, or fenfluramine.

Willner et al. (1992) investigated the influence of drugs on taste-potentiated odor aversion learning in rats.

Rabin and Hunt (1992) studied taste aversion learning in **ferrets**.

E.2.6
Effects on the endocrine system

E.2.6.1
Plasma catecholamine levels during and after stress

PURPOSE AND RATIONALE

A wide variety of stressors causes significant biochemical, physiological, and behavioral changes. These changes include marked increases in plasma catecholamines, heart rate and blood pressure. Treatment with anxiolytic drugs can attenuate the stress induced increases of norepinephrine and epinephrine in plasma (Vogel et al. 1984; Livesey et al. 1985; Taylor et al. 1989; de Boer et al. 1990; Krieman et al. 1992).

PROCEDURE

Male Sprague-Dawley rats, 300–350 g, are individually housed and given food and water ad libitum. After 1 week of acclimatization, an aortic catheter is surgically implanted in each animal, running on top of the psoas muscle and brought out through an incision at the back of the neck. The catheters are flushed

daily with heparinized saline. After a recovery period of 48 h baseline (time –15) blood samples are drawn and blood pressure recordings are taken using a Grass model 7 polygraph. The animals are then given an i.p injection of the test compound or the vehicle. 15 min after the injection (time 0), blood samples, and heart rate and blood pressure measurements are taken. Animals in control and treatment groups are then stressed by immobilization for 1 h and blood samples, heart rate and blood pressure recordings are taken at time 15, 30 and 60 min during stress. Immobilization is performed by taping the legs of the animals to the laboratory bench. After the stress period of 1 h, the animals are released, returned to the home cage for recovery and 1 h post-stress samples and recordings are taken. Non-stressed, compound or vehicle treated animals remain in the home cage for the entire test period and are sampled in the same manner as the stressed animals. Approximately 0.3 ml blood is withdrawn for each sample and an equal amount of 0.9% saline is re-infused to prevent changes in blood volume.

EVALUATION

Determinations of norepinephrine and epinephrine in plasma are made using an radio-enzymatic assay. Heart rate and systolic and diastolic blood pressure are determined directly from the polygraph tracings. The data are analyzed using a three-way analysis of variance (ANOVA) with repeated measures, two-way ANOVA, Students *t*-test, Student-Newman-Keuls and the trapezoidal rule for the area under the curve.

CRITICAL ASSESSMENT OF THE METHOD

Reduction of catecholamine levels but no changes of the cardiovascular parameters could be found after treatment with anxiolytics. The test can be used as a method for evaluation of the influence of psychoactive drugs on the endocrine system (Krieman et al. 1992).

E.2.6.2 Plasma corticosterone levels influenced by psychotropic drugs

PURPOSE AND RATIONALE

Corticosterone levels in the blood of rats are elevated not only after stress but also after application of selective 5-HT receptor agonists (Koenig et al. 1987). This has been used to differentiate typical and atypical neuroleptics (Nash et al. 1988).

PROCEDURE

Male Sprague Dawley rats weighing 200–250 g are housed 6 per cage under temperature and light/dark controlled conditions with free access to food and water. On the day prior to an experiment, the animals are transferred to the experimental room. On the day of the experiment, various doses of test drugs or saline are injected intraperitoneally. After 60 min 2.5 mg/kg 6-chloro-2-(1-piperazinyl)pyrazine (MK-212) are injected intraperitoneally followed by decapitation after further 60 min. Trunk blood is collected and allowed to clot. Serum is obtained following centrifugation and stored at –20 °C for the radioimmunoassay of corticosterone.

EVALUATION

Data are analyzed with a two-way analysis of variance. Differences between treatment groups are evaluated using the Student-Newman-Keuls test.

MODIFICATIONS OF THE METHOD

Korte et al. (1991) studied the effect of a 5-HT_{1A} agonist on behavior and plasma corticosterone levels in male Wistar rats before and after psychological stress of defeat.

Broqua et al. (1992) measured corticosterone and glucose levels in blood together with parameters of 5-HT metabolism in brain in stressed animals treated with the anti-depressant tianeptine.

Rittenhouse et al. (1992) measured plasma concentrations of renin, corticosterone, ACTH, and prolactin in rats after treatment with a 5-HT_{1A} agonist in three

stress paradigms: immobilization, forced swim and conditioned fear.

Groenink et al. (1995) studied the corticosterone secretion in rats after application of 5-HT_{1A} receptor agonists and antagonists.

Aulakh et al. (1988, 1993) reported higher baseline levels of plasma corticosterone in fawn-hooded rats relative to Wistar and Sprague-Dawley strain rats. Long-term treatment (21 days) with antidepressant drugs significantly decreased plasma corticosterone in fawn-hooded rats. The authors recommended this strain as a genetic model of depression.

E.2.7 Benzodiazepine dependence

E.2.7.1 General considerations

Benzodiazepine dependence is a hypothetical construct for the adaptive changes that occur as a result of chronic drug exposure. Two measures are usually considered to reflect dependence: the development to a drug's effects, and the abstinence signs of drug withdrawal.

REFERENCES

File SE, Hitcott PK (1991) Benzodiazepine dependence. In: Briley M, File SE (eds) New Concepts in Anxiety. McMillan Press Ltd., London, pp 237–255

E.2.7.2 Benzodiazepine tolerance and dependence in rats

PURPOSE AND RATIONALE

Induction of benzodiazepine tolerance and physical dependence has been reported for several animal species, such as rats, mice, dogs and monkeys. Ryan and Boisse (1983) and Boisse et al. (1986) developed a reproducible model exemplified for chlordiazepoxide in rats.

PROCEDURE

Male Sprague Dawley rats weighing 350–575 g are used. Chordiazepoxide hydrochloride is administered as solution 75 mg/ml by gavage after an initial loading dose of 450 mg/kg given at 7:00 A.M. and 5:00 P.M. Impairment of motor function is evaluated by a neurological screen including five different ladder and open field tests.

Neurological test	Maximum depression points
Ladder, head down	2
Ladder, head up	4
Ladder, grasp reflex	1
Motor activity	3
Walking	5
Maximum	15

The animals are rated by three independent observers. Once dependence is revealed, lower doses are used which are then increased in appropriate steps to induce an average depression rating of about five. Treatment is continued for 5 weeks during which time the dose has to be increased. The degree of increase (about 5-fold for in the case of chlordiazepoxide) reflects the **tolerance** of the test compound.

To test **dependence**, rats are challenged with the benzodiazepine receptor antagonist Ro 15-1 788 (flumazenil; ethyl-8-fluoro-5,6-dihydro-5-methyl-6-oxo-4H-

imidazo(1,5a)(1,4)benzodiazepine-3-carboxylate) at a dose of 25 mg/kg i.p. Withdrawal reactions are recorded just before, and 5, 15, 30 and 60 min after administration of the antagonist. Motor, autonomic and behavioral signs are monitored by operational defined criteria, such as position of the claws, salivation and diarrhea. The total withdrawal expression for each observation and each animal is estimated by summing the grades of all signs as recorded by three independent observers.

EVALUATION

For each animal and observation time, the scores are estimated by the average of all co-observers. From these estimates group means are computed and compared by *t*-test between control and test and by paired *t*-test for self-control comparisons before and after antagonist administration

MODIFICATIONS OF THE METHOD

Further studies in *rat* with benzodiazepines were preformed by Vellucci and File (1979), Treit (1985) and Nath et al. (1997).

File (1985) found very different rates at which tolerance develops to the sedative, anticonvulsive and anxiolytic actions of benzodiazepines.

Bonnafous et al. (1995) studied the increase of gastric emptying induced by benzodiazepine withdrawal in rats. Gastric emptying was measured with a test meal containing ^{51}Cr sodium chromate administered in rats, either previously receiving 15 mg/kg diazepam or DMSO i.p. for 7 days.

Benzodiazepine-like dependence potential of a putative 5-HT_{1A} agonist anxiolytic was assessed in rats by Goudie et al. (1994).

Studies in *mice* on tolerance and physical dependence with benzodiazepines were performed by Patel et al. (1988), Gallaher et al. (1986), Stephens and Schneider (1985), Nutt and Costello (1988) and Piot et al. (1990).

These phenomena were studied in *dogs* by McNicolas et al. (1988) and Löscher et al. (1989).

Studies in monkeys were performed by Lukas and Griffiths (1982), Yanagita (1983), Lamb and Griffiths 1984) and France and Gerak (1997).

E.3 Anti-epileptic activity

E.3.0.1 General considerations

Epilepsy is a disease of high prevalence, being well known since thousands of years as “morbus sacer”. In spite of intensive investigations, the pathophysiology of epilepsy is still poorly understood. Studies with various animals models have provided ample evidence for heterogeneity in the mechanisms of epileptogenesis.

New evidence derives from investigations of kindling, which involves the delivery of brief, initially subliminal, electrical or chemical stimuli to various areas of the brain. After 10 to 15 days of once-daily stimulation, the duration and intensity of after-discharges reach a stable maximum and a characteristic seizure is produced. Subsequent stimulation then regularly elicits seizures.

Surveys of methods being used to test compounds with anticonvulsant properties have been provided by Toman and Everett (1964), Woodbury (1972), Hout et al. (1973), Swinyard (1973), Koella (1985), Meldrum (1986), Rump and Kowalczyk 1987; Löscher and Schmidt (1988), Fisher (1989), Rogawski and Porter (1990), Porter and Rogawski (1992).

Several biochemical hypotheses have been advanced, involving the inhibitory GABAergic system and the system of the excitatory amino acids glutamate and aspartate. Excitatory receptors have been divided into subtypes according to the actions of specific agonists or antagonists. Agents which reduce $GABA_A$ synaptic function provoke convulsions. A convulsive state is induced by the direct blockade of $GABA_A$ receptors (e.g. to the action of bicuculline) or a reduction in the GABA-mediated opening of the chloride ion channel (e.g., by picrotoxin). One major factor in epileptogenesis seems to be a decreased function of $GABA_A$ synapses.

More recently, research has focused on the therapeutic potential of blocking excitatory amino acids – in particular glutamate. Of the three receptors of glutamate, the NMDA (N-methyl-D-aspartate)-receptor is considered the one of most interest in epilepsy and competitive NMDA receptor antagonists are proposed as potential anti-epileptic drugs. Excessive excitatory amino acid neurotransmission is thought to be associated with the neuropathologies of epilepsy, stroke and other neurodegenerative disorders. Antagonism of NMDA receptor function appears to be the mechanism of action of some novel anticonvulsant and neuroprotective agents. Excitatory amino acid receptors have been classified into at least three subtypes by electrophysiological criteria: NMDA, quisqualic acid (QA) and kainic acid (KA) (Cotman and Iversen 1987; Watkins and Olverman 1987).

E.3.1.4 ^{3}H-GABA uptake in rat cerebral cortex synaptosomes

PURPOSE AND RATIONALE

Roberts (1974) and others have proposed that the inhibitory action of the amino acid γ-aminobutyric acid (GABA) is the fine tuning control for pacemaker neurons. Disruption of this interplay due to inadequacies of the GABA system result in various disorders, in particular convulsive seizures (Roberts 1974; Korgsgaard-Larsen 1985). The nonspecific action of GABA-mimetics makes inhibition of the uptake mechanism, which terminates the neurotransmitters action, the ideal choice for increasing GABA's concentration at specific sites (Roberts 1974; Tapia 1975; Meldrum et al. 1982; Brehm et al. 1979). Demonstration of the high affinity mechanism that best reflects the *in vivo* condition utilizes GABA depleted cerebral cortex synaptosomes (Ryan and Roskoski 1977; Iversen and Bloom 1972; Roskoski 1978). Although the physiological role of GABA transport systems is still unclear, uptake inhibitors such as THPO [4,5,6,7-tetrahydroisoxazolo- (4,5-C)pyrid-3-ol], nipecotic acid, cis-4-hydroxynipe-cotic acid, and guvacine exhibit anticonvulsant effects (Meldrum et al. 1982; Brehm et al. 1979). Furthermore, a number of neuroleptics have been shown to inhibit GABA uptake (Fjalland 1978). In particular, fluspirilene was found to be equivalent to the most potent uptake inhibitors known.

The assay is used as a biochemical screen for potential anticonvulsants or GABA (γ-aminobutyric acid) mimetic compounds that act by inhibiting GABA uptake.

PROCEDURE

Reagents

1. 0.5 M Tris buffer, pH 7.4
2. Ringer's solution + 10 mM Tris buffer, pH 7.4 containing
   - glucose 10.0 mM,
   - NaCl 150.0 mM,
   - KCl 1.0 mM,
   - $MgSO_4$ 1.2 mM,
   - Na_2HPO_4 1.2 mM.
3. Depolarizing Ringer's solution, pH 7.4 reagent 2 containing
   - KCl 56 mM,
   - $CaCl_2$ 1 mM.
4. 0.32 M sucrose
5. ^{3}H-GABA is diluted to 2.5×10^{-4} M with distilled water. Forty µl of this solution in 1 ml of reaction mixture will yield a final concentration of 10^{-5} M.
6. Test compounds
   A 10 mM stock solution is made up in distilled water, ethanol, or DMSO and serially diluted, such that the final concentration in the assay ranges from 10^{-3} to 10^{-8} M. Total and nonspecific controls should use solvent of test compound.

Tissue preparation

Male Wistar rats are decapitated and the brains rapidly removed. Cerebral cortex is weighed and homogenized in 9 volumes of ice-cold 0.32 M sucrose using a Potter-Elvejhem homogenizer. The homogenate is centrifuged at 1000 *g* for 10 min. The supernatant (S_1) is decanted and recentrifuged at 1000 *g* for 10 min. The pellet (P_2) is resuspended in 9 volumes of 0.32 M sucrose and centrifuged at 24000 *g* for 10 min. The washed pellet is resuspended in15 volumes of depolarizing Ringer's solution, incubated at 25 °C for 10 min and centrifuged at 3000 *g* for 10 min. The resulting pellet is resuspended in 15 volumes of Ringer's solution and is ready for use.

Assay

60 µl Ringer's solution,
100 µl vehicle or appropriate drug concentration,
800 µl tissue suspension.

Microcentrifuge tubes are set up in triplicate. Nonspecific controls are incubated at 0°C and totals at 25 °C for 10 min. Forty µl of ^{3}H-GABA are added and the tubes are reincubated for 10 min. All tubes are centrifuged at 13000 *g* for 1 min. The supernatant is aspirated and 1 ml of solubilizer (Triton X-100 + 50% EtOH, 1:4, v/v) is added and mixed to dissolve pellets. Tubes are incubated at 90 °C for 3 min, then centrifuged at 13000 *g* for 15 min. 40 µl of supernatant is counted in 10 ml Liquiscint scintillation cocktail.

EVALUATION

Active uptake is the difference between cpm at 25 °C and 0 °C. The percent inhibition at each drug concentration is the mean of three determinations. IC_{50} values are derived from log- probit analysis.

E.3.1.5 GABA uptake and release in rat hippocampal slices

PURPOSE AND RATIONALE

The GABA transporter, the subsynaptic $GABA_A$-receptor, and the $GABA_B$-autoreceptor are therapeutically the most relevant targets for drug actions influencing GABAergic synaptic transmission. Uptake inhibitors are potential anticonvulsants.

PROCEDURE

For measurement of GABA uptake, rat hippocampal slices are cut with a McIlwain tissue slicer (100 µm-thick prisms) and dispersed in ice-cold Krebs-Ringer solution with HEPES buffer (pH 7.4). Following two washes, slices (15 mg) are incubated at 37 °C for 15 min in the presence or absence of test compound. [^{3}H]-GABA is added and samples are incubated for an additional 5 min before filtration through Whatman GF/F filters. Samples are then washed twice with 5 ml ice-chilled 0.9% saline. Distilled water is added and samples are allowed to sit at least 60 min before measured for radioactivity by liquid scintillation spectroscopy. Blanks are treated in an identical manner but are left on ice throughout the incubation.

For measurement of GABA release, rat hippocampal slices are prepared and dispersed in ice-cold HEPES-buffered (pH 7.2) Krebs Ringer solution and incubated with 0.05 µM [^{3}H]-GABA for 15 min at 37 °C. Following two washes, the slices are incubated for an additional 15 min and finally resuspended in medium. Tissue (10 mg) is incubated at 37 °C for a 15 min release period in the presence or absence of test compound. At the end of the release period, the medium is separated from tissue by centrifugation at 500 *g* for approximately 1 min and poured into 0.5 ml of perchloric acid (0.4 N). The tissue is homogenized in 0.13 N perchloric acid. Radioactivity in the samples is measured by using liquid scintillation spectroscopy.

EVALUATION

For GABA-uptake, IC_{50}-values (µM) are determined.

In GABA-release experiments, results are expressed as the amount of radioactivity released as a percent of the total radioactivity.

MODIFICATIONS OF THE METHOD

Roskoski (1978) studied the net uptake of GABA by high affinity synaptosomal transport systems.

Nilsson et al. (1990, 1992) tested GABA uptake in astroglial primary cultures.

E.3.1.6 Glutamate receptors: [^{3}H]CPP binding

PURPOSE AND RATIONALE

This assay is used to assess the affinity of compounds for the excitatory amino acid binding site of the NMDA (N-methyl-D-aspartate) receptor complex. [^{3}H]CPP (3-[(±)-2-carboxypiperazin-4-yl]-1-phosphonic acid) is a structurally rigid analog of the selective NMDA receptor antagonist 2-AP7 (2-amino-7-phosphonoheptanoic acid).

Excessive excitatory amino acid neurotransmission has been associated with the neuropathologies of epilepsy, stroke and other neurodegenerative disorders (Cotman and Iversen 1987; Watkins and Olverman 1987; Parsons et al. 1998). Antagonism of NMDA receptor function appears to be the mechanism of action of some anticonvulsant and neuroprotective agents (Loscher 1998; Tauboll and Gjerstad 1998). Excitatory amino acid receptors have been classified into at least three subtypes by electrophysiological criteria: NMDA, quisqualic acid (QA) and kainic acid (KA) (Cotman and Iversen 1987; Watkins and Olverman 1987; Collingridge and Lester 1989; Monaghan et al. 1989; Carlsson and Carlsson 1990; Young and Fagg 1990; Nakanishi 1992; Cunningham et al. 1994; Herrling 1994; Iversen and Kemp 1994; Mayer et al. 1994; Meldrum and Chapman 1994; Monaghan and Buller 1994; Watkins 1994; Bettler and Mulle 1995; Fletcher and Lodge 1995; Becker et al. 1998; Danysz and Parsons 1998; Meldrum 1998; Chittajallu 1999; Dingledine et al. 1999; Hatt 1999; Gallo and Ghiani 2000; Lees 2000; Meldrum 2000). The binding site for [^{3}H]2-amino-4-phosphonobutyric acid (AP4) may represent a fourth site which is less well characterized (Thomsen 1997). NMDA receptors are believed to be coupled to a cation channel which converts to an open state with NMDA receptor activation (Kemp et al. 1987; Mukhin et al. 1997). The opening and closing of this cation channel are also modulated by glycine, Mg^{2+} and Zn^{2+}. Dissociative anesthetics, such as phencyclidine (PCP) and ketamine, and novel anticonvulsants, such as MK-801, block the ion channel and are noncompetitive NMDA receptor antagonists. Competitive NMDA receptor antagonists, such as CPP and the phosphono analogs of L-glutamate, AP7 and AP5 (2-amino-5-phosphonopentanoic acid), are inhibitors at the excitatory amino acid binding site (Olverman et al. 1986; Davies et al. 1986; Harris et al. 1986; Murphy et al. 1987; Lehmann et al. 1987).

PROCEDURE

Reagents

1. Buffer A: 0.5 M Tris HCl, pH 7.6
   60.0 g Tris HCl
   13.9 g Tris Base
   q.s. to 1 liter with distilled water
2. Buffer B: 50 mM Tris HCl, pH 7.6
   Dilute buffer A 1 : 10 with distilled water
3. L-Glutamic acid, 5×10^{-3} M
   Dissolve 7.36 mg of l-glutamic acid (Sigma G1 251) with 10.0 ml distilled water. Aliquots of 20 µl to the assay tube will give a final concentration of 10^4M.
4. [^{3}H]CPP is obtained from New England Nuclear, specific activity 25–30 Ci/mmol. For IC_{50} determinations, a 200 nM stock solution is made with distilled water. Aliquots of 50 µl are added to each tube to yield a final concentration of 10 mM.
5. Test compounds. A stock solution of mM is made with a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Higher or lower concentrations may be used, depending on the potency of the drug.
6. Triton-X 100, 10% (v/v) (National Diagnostics, EC-606) A stock solution of Triton-X100, 10%, can be prepared and stored in the refrigerator. Dilute 1.0 ml of Triton-X100 to 10.0 ml with distilled water. On the day of the assay, the tissue homogenate (1 : 15 dilution) is preincubated with an aliquot of Triton-X 100, 10%, to give a final concentration of 0.05% (v/v).

Tissue preparation

Cortices of male Wistar rats are dissected over ice and homogenized in ice-cold 0.32 M sucrose, 15 volumes of original wet weight of tissue, for 30 s with a Tissumizer setting at 70. The homogenate is centrifuged at 1 000 *g* for 10 min. (SS34, 3 000 rpm, 4 °C). The supernatant is centrifuged at 20 000 *g* (SS34, 12 000 rpm, 4 °C) for 20 min. Resuspend the pellet in 15 volumes of ice-cold distilled water (Tissumizer setting 60, 15 s) and spin at 7 600 *g* (SS34, 8 000 rpm, 4 °C) for 20 min. Save the supernatant, swirl off the upper buffy layer of the pellet and add to the supernatant. Centrifuge the supernatant at 48 000 *g* (SS34, 20 000 rpm, 4 °C) for 20 min. Resuspend the pellet with 15 volumes of cold distilled water and centrifuge. Discard the supernatant and store the pellet at –70 °C.

On the day of the assay, resuspend the pellet in 15 volumes ice-cold 50 mM Tris buffer, pH 7.6. Preincubate the homogenate with Triton-X in a final concentration

0.05% (v/v) for 15 min at 37 °C with agitation. Centrifuge the homogenate at 48 000 *g* (SS34, 20 000 rpm, 4 °C for 20 min. Wash the pellet an additional 3 times by resuspension with cold buffer and centrifugation. The final pellet is resuspended in a volume 20 times the original wet weight.

Assay

1. Prepare assay tubes in triplicate.
   - 380 µl distilled water
   - 50 µl buffer A, 0.5 M Tris HCl, pH 7.6
   - 20 µl 1-glutamic acid, 10^{-4} M, or distilled water or appropriate concentration of inhibitor
   - 50 µl [^{3}H]CPP
   - 500 µl tissue homogenate
2. Following the addition of the tissue, the tubes are incubated for 20 min at 25 °C with agitation. Place the tubes in an ice bath at the end of the incubation. Terminate the binding by centrifugation (HS4, 7 000 rpm, 4 °C) for 15 min. Return the tubes to ice. Aspirate the discard the supernatant. Carefully rinse the pellet three times with 1 ml ice-cold buffer, avoiding disruption of the pellet. Transfer the pellet to scintillation vials by vortexing the pellet with 2 ml scintillation fluid, rinse the tubes twice with 2 ml and add an additional 4 ml scintillation fluid.

EVALUATION

Specific binding is determined from the difference of binding in the absence of presence of 10^{-4} M L-glutamic acid and is typically 60–70% of total binding. IC_{50} values for the competing drug are calculated by log-probit analysis of the data.

MODIFICATIONS OF THE ASSAY

Glutamate (non selective)

The assay measures the binding of glutamate, which binds non selectively to ionotropic glutamate receptors including the NMDA, AMPA, and kainate subtypes (Foster and Fagg 1987). In addition, glutamate binds to a family of metabotropic glutamate receptors.

Whole brains (except cerebellum) are obtained from male Wistar rats. A membrane fraction is prepared by standard techniques. Ten mg of membrane preparation is incubated with 1.6 nM [^{3}H]L-glutamate for 10 min at 37 °C. Non-specific binding is estimated in the presence of 50 µM L-glutamate. Membranes are filtered and washed 3 times to separate bound from free ligand and filters are counted to determine [^{3}H]L-glutamate bound.

Convulsions induced in mice by intravenous injections of 2.0 mmol/kg L-glutamic acid can be inhibited by glutamate antagonists (Piotrovsky et al. 1991).

Glutamate AMPA

The assay measures the binding of [^{3}H]AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid), a selective agonist which binds to the AMPA receptor subtype of glutamate-gated ion channels (Honore et al. 1982; Olsen et al. 1987; Fletcher and Lodge 1995).

Membranes are prepared from male rat brain cortices by standard techniques. Fifteen mg of membrane preparation is incubated with 5 nM [^{3}H]AMPA for 90 min at 4 °C. Non-specific binding is estimated in the presence of 1 mM L-glutamate. Membranes are filtered and washed 3 times and the filters are counted to determine [^{3}H]AMP bound.

Mutel et al. (1998) recommended [^{3}H]Ro 48-8 587 as specific for the AMPA receptor.

Fleck et al. (1996) described AMPA receptor heterogeneity in rat hippocampal neurons. AMPA receptor antagonists were described by Kohara et al. (1998), Wahl et al. (1998), Kodama et al. (1999), Nielsen et al. (1999) and reviewed by Chimirri et al. (1999).

Glutamate Kainate

The assay measures the binding of [^{3}H]kainate, a selective agonist that binds to the kainate subtype of the ionotropic glutamate receptors in rat brain (London and Coyle 1979; Clarke et al. 1997).

Whole brains (except cerebellum) are obtained from male Wistar rats. Fifteen mg of a membrane fraction prepared by standard techniques is incubated with 5.0 nM [^{3}H]kainate for 1 h at 4 °C. Non-specific binding is estimated in the presence of 1 mM L-glutamate. Membranes are filtered and washed 3 times to separate free from bound ligand and filters are counted to determine [^{3}H]kainate bound.

Toms et al. (1997), Zhou et al. (1997) recommended [^{3}H]-(2S,4R)-4-methylglutamate as kainate-receptor selective ligand.

Irreversible inhibition of high affinity [^{3}H]kainate binding by a photoactivatable analogue was reported by Willis et al. (1997).

Worms et al. (1981) described the behavioral effects of systemically administered kainic acid.

Glutamate NMDA-agonist site

The assay measures the binding of CGS 19755, a selective antagonist, to the agonist site of the NMDA receptor (Lehmann et al. 1988; Murphy et al. 1988; Jones et al. 1989)

E.3.1.7 NMDA receptor complex: [^{3}H]TCP binding

PURPOSE AND RATIONALE

The purpose of this assay is to determine the binding affinity of potential noncompetitive NMDA antagonists at the phencyclidine (PCP) binding site which is believed to be within or near the NMDA-regulated ion channel. TCP, 1-[1-(2-thienyl)cyclohexyl]-piperidine, is a thienyl derivative of PCP.

Excessive activity of excitatory amino acid neurotransmitters has been associated with the neuropatholo-

gies of epilepsy, stroke and other neurodegenerative disorders (Cotman and Iversen 1987; Watkins and Olverman 1987). Antagonism of NMDA receptor function appears to be the mechanism of action of some novel anticonvulsant and neuroprotective agents. Excitatory amino acid receptors have been classified into at least three subtypes by electrophysiological criteria: NMDA, quisqualic acid (QA) and kainic acid (KA) (Cotman and Iversen 1987; Watkins and Olverman 1987). The binding site for [^{3}H]2-amino-4-phosphonobutyric acid (AP4) may represent a fourth site which is less well characterized. NMDA receptors are believed to be coupled to a cation channel which converts to an open state following activation (Kemp et al. 1987). The opening and closing of this cation channel are also modulated by glycine, Mg^{2+}, Zn^{2+} and polyamines (Loo et al. 1986; Snell et al. 1987; Reynolds et al. 1988; Thomson 1989; Snell et al. 1988; Sacaan and Johnson 1989; Thedinga et al. 1989; Williams et al. 1989). Dissociative anesthetics, such as phencyclidine (PCP) and ketamine, and the neuroprotective agent MK-801 block the ion channel and are noncompetitive NMDA receptor antagonists. Competitive NMDA receptor antagonists, such as 3-[(±)-2-carboxypiperazin-4-yl]-1-phosphonic acid (CPP), and the phosphono analogs of L-glutamate, 2-amino-7-phosphonoheptanoic acid (2-AP7) and 2-amino-5-phosphonopentanoic acid (2-AP5), are inhibitors at the excitatory amino acid recognition site.

Molecular cloning and functional expression of rat and mouse NMDA receptors (Moriyoshi et al. 1991; Meguro et al. 1992), a family of AMPA-selective glutamate receptors (Keinänen et al. 1990) and the metabotropic glutamate receptors mGluR1–mGluR6 (Schoepp et al. 1990; Masu et al. 1991; Abe et al. 1992; Bashir et al. 1993; Nakajima et al. 1993; Tanabe et al. 1993) have been reported.

PROCEDURE I

Reagents

1. Buffer A: 0.1 M HEPES, pH 7.5
   Weigh 23.83 g HEPES
   Add approximately 900 ml distilled water.
   Adjust pH to 7.5 with 10 N NaOH.
   q.s. to 1 liter with distilled water.
2. Buffer B: 10 mM HEPES, pH 7.5
   Dilute buffer A 1 : 10 with distilled water and adjust pH to 7.5.
3. L-Glutamic acid, 5×10^{-3} M
   Dissolve 7.36 mg with 10.0 ml distilled water.
   Aliquots of 20 µl to the assay tube will give a final concentration of 10^{-4} M.
4. Glycine, 5×10^{-4} M
   Dissolve 3.75 mg with 10.0 ml distilled water.
   Dilute 1 : 10 with distilled water.
   Aliquots of 20 µl to the assay tube will give a final concentration of 10^{-5} M.
5. Phencyclidine HCl (PCP) is used for nonspecific binding.
   Dissolve 0.7 mg in 0.5 ml distilled water.
   Aliquots of 20 µl to the assay tube will give a final concentration of 10^{-4} M.
6. [^{3}H]TCP is obtained from New England Nuclear, specific activity 42–60 Ci/mmole. For IC_{50} determinations, a 50 nM stock solution is made with distilled water. Aliquots of 50 µl are added to each tube to yield a final concentration of 2.5 nM.
7. Test compounds. A stock solution of 5 mM is made up with a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Higher or lower concentrations may be used, depending on the potency of the drug.

Tissue preparation

Cerebral cortex of male Wistar rats, 7–10 weeks of age, is dissected over ice and homogenized in ice-cold 0.32 M sucrose, 30 volumes of original tissue weight, for 60 s with a Tissumizer setting at 70. The homogenate is centrifuged at 1 000 *g* for 10 min. (SS34, 3 000 rpm, 4 °C). The supernatant is centrifuged at 20 000 *g* for 20 min. (SS34, 12 000 rpm, 4 °C). The pellet is resuspended with cold distilled water, to 50 volumes of original tissue weight, using the Tissumizer, 60 s at setting of 70. The homogenate is incubated at 37 °C for 30 min, transferred to centrifuge tubes, and centrifuged at 36 000 *g* for 20 min. (SS34, 16 500 rpm, 4 °C). The pellet is again resuspended in 50 volumes distilled water, incubated and centrifuged. All resuspensions with the Tissumizer are for 60 s at a setting of 70. The resulting pellet is resuspended in 30 volumes of ice-cold 10 mM HEPES buffer, pH 7.5, centrifuged, and washed once again (resuspension and centrifugation) with buffer. Following resuspension in 30 volumes of buffer, the homogenate is frozen in the centrifuge tube and stored at –70 °C until the day of the assay.

On the day of the assay, the homogenate is thawed and centrifuged at 36 000 *g* for 20 min. (SS34, 16 500 rpm, 4 °C). The pellet is washed three times by resuspension with ice-cold 10 mM HEPES buffer, pH 7.5, centrifuged and finally resuspended in 30 volumes of buffer. Aliquots of 500 µl are used for each assay tube, final volume 1 000 µl, and correspond to approximately 0.2 mg protein.

Assay

1. Prepare assay tubes in triplicate. For each test compound, inhibition of [^{3}H]TCP binding is measured

both in the absence (basal) and presence (stimulated) of 100 µM L-glutamic acid and 10 mM glycine.

Basal	Stimulated	
380 µl	340 µl	Distilled water
50 µl	50 µl	Buffer A, 0.1 M HEPES, pH 7.5
20 µl	20 µl	PCP (reagent A5) or distilled water, or appropriate concentration of inhibitor
0 µl	20 µl	L-glutamic acid (reagent A3)
0 µl	20 µl	Glycine (reagent A4)
50 µl	50 µl	[^{3}H]TCP (reagent A6)
500 µl	500 µl	Tissue homogenate

2. Following the addition of the tissue, the tubes are incubated for 120 min at 25 °C with agitation. The assay is terminated by separating the bound from non-bound radioligand by rapid filtration with reduced pressure over Whatman GF/B filters, presoaked in 0.05% polyethylene-imine, using the Brandell cell harvesters. The filters are rinsed once with buffer before filtering the tubes, and rinsed two times after filtration. The filters are counted with 10 ml Liquiscint.

EVALUATION

Specific binding is determined from the difference of binding in the absence or presence of 10^{-4} M PCP. Specific binding is typically 50% of total binding in basal conditions, and 90% of total binding when stimulated by L-glutamic acid and glycine. L-Glutamic acid and glycine typically increase specific binding to 300% and 200% of basal binding, respectively. The combination of L-glutamic acid and glycine typically produce a greater than additive effect, increasing specific binding to 700% of basal binding. IC_{50} values for the competing drug are calculated by log-probit analysis of the data.

Protocol modification for crude membrane homogenates

This modified procedure for the preparation of membrane homogenates does not use extensive lysing and washing of the tissue to remove endogenous L-glutamate, glycine and other endogenous compounds which enhance [^{3}H]TCP binding. This procedure may be used for rapid screening of compounds for inhibition of [^{3}H]TCP binding site without specifically defining an interaction at the ion channel or modulatory sites of the NMDA receptor complex.

PROCEDURE II

Reagents

1. Buffers A and B are prepared as described above.
2. Phencyclidine HCl is used for nonspecific binding and is prepared as described above.
3. [^{3}H]TCP is prepared as described above.
4. Test compounds are prepared as described above.

Tissue preparation

Cortical tissue is dissected, homogenized in 30 volumes of 0.32 M sucrose and a crude P_2 pellet is prepared as described above. The pellet is resuspended in 30 volumes of 10 mM HEPES, pH 7.5, centrifuged at 36 000 *g* (SS34, 16 500 rpm, 4 °C) for 20 min, and again resuspended in 100 volumes of buffer. This homogenate is used directly in the assay in aliquots of 500 µl.

Assay

1. Prepare assay tubes in triplicate.

Volume	Solution
380 µl	Distilled water
50 µl	Buffer A, 0.1 M HEPES, pH 7.5
20 µl	PCP (reagent A5) or distilled water, appropriate concentration of inhibitor
50 µl	[^{3}H]TCP (reagent A6)
500 µl	Tissue homogenate

2. Following the addition of the tissue, the tubes are incubated for 120 min at 25 °C with agitation. The assay is terminated by rapid filtration as described above. The filters are rinsed and counted for bound radioactivity as above.

EVALUATION

Specific binding is determined from the difference of binding in the presence or absence of 10^{-4} M PCP. Specific binding is typically 90% of total binding. IC_{50} values for the competing drug are calculated by log-probit analysis.

MODIFICATIONS OF THE METHOD

Instead of [^{3}H]TCP, radiolabeled [^{3}H]MK-801 has been used as ligand (Wong et al. 1988; Javitt and Zukin 1989; Williams et al. 1989).

Sills et al. (1991) described [^{3}H]CGP 39 653 as a N-methyl-D-aspartate antagonist radioligand with low nanomolar affinity in rat brain.

Nowak et al. (1995) reported that swim stress increases the potency of glycine to displace 5,7-[^{3}H[di-

chlorokynurenic acid from the strychnine-insensitive glycine recognition site of the *N*-methyl-D-aspartate receptor complex.

NMDA receptor cloning studies have shown that NMDA receptors contain at least one of seven different NMDAR1 subunits (NR1A–NR1G) (Sugihara et al. 1992) and at least one of four NMDAR2 subunits (NR2A–NR2D) (Kutsuwada et al. 1992; Ishii et al. 1993). While the NR1 subunits are generated by alternative splicing of a single gene, the NR2 subunits are products of four highly homologous genes. Thus, there are thousands of potential subunit combinations yielding complexes of four or five subunits.

Grimwood et al. (1996) reported generation and expression of stable cell lines expressing recombinant human NMDA receptor subtypes, two cell lines expressing NR1a/NR2A receptors and one cell line expressing NR1a/NR2B receptors.

NR2B selective NMDA antagonists were described by Fischer et al. (1997), Kew et al. (1998), Reyes et al. (1998), Chenard and Menniti (1999).

E.3.1.8 Metabotropic glutamate receptors

PURPOSE AND RATIONALE

In addition to ionotropic (AMPA, kainate and NMDA) receptors, glutamate interacts with a second family of receptors, metabotropic or mGlu receptors (Tanabe et al. 1992, 1993; Schoepp and Conn 1993; Hollmann and Heinemann 1994; Nakanishi and Masu 1994; Okamoto et al. 1994; Watkins and Collingridge 1994; Knöpfel et al. 1995, 1996; Pin and Duvoisin 1995; Conn and Pin 1997; Alexander et al. 2001; Skerry and Generver 2001; DeBlasi et al. 2001). Three groups of native receptors are distinguishable on the basis of similarities of agonist pharmacology, primary sequence, and G protein-effector coupling: Group I ($mglu_1$ and $mglu_5$ and splice variants) are coupled via $G_{q/11}$ to phosphoinositide hydrolysis. Group II ($mglu_2$ and $mglu_3$) are negatively coupled via G_i/G_o to adenylyl cyclase and inhibit the formation of cAMP following exposure of cells to forskolin or activation of an intrinsic G_s-coupled receptor (e.g. adenosine A_2 receptor). The group III receptors ($mglu_4$, $mglu_6$, $mglu_7$, and $mglu_8$) also inhibit forskolin-stimulated adenylyl cyclase.

Various agonists and antagonists for metabotropic glutamate receptors were described (Ishida et al. 1990, 1994; Porter et al. 1992; Jane et al. 1994; Watkins and Collingridge 1994; Knöpfel et al. 1995; Annoura et al. 1996; Bedingfield et al. 1996; Thomsen et al. 1996; Acher et al. 1997; Doherty et al. 1997; Brauner-Osborne et al. 1998; Kingston et al. 1998; Monn et al. 1999; Jane and Doherty 2000).

Several radioligands for metabotropic glutamate receptors were described:

- for subtype mGluR4a receptor by Eriksen and Thomsen (1995),
- for group II mGlu receptors by Cartmell et al. (1998), by Ornstein et al. (1998), and by Schaffhauser et al. (1998).

Riedel and Reymann (1996) discussed the role of metabotropic glutamate receptors in hippocampal long-term potentiation and long-term depression and their importance for learning and memory. Furthermore, possible roles in the treatment of neurodegenerative disorders (Nicoletti et al. 1996; Bruno et al. 1998), and of Parkinson's disease (Konieczny et al. 1998) were discussed. Anticonvulsive properties (Attwell et al. 1998; Thompson and Dalby 1998; Gasparini et al. 1999) as well as anxiolytic properties (Helton et al. 1998) of metabotropic glutamate receptor ligands were reported. Christoffersen et al. (1999) found a positive effect on short-term memory and a negative effect on long-term memory of the class I metabotropic glutamate receptor antagonist, AIDA, in rats.

PROCEDURE

Cultured cells are prepared from cerebral cortex of 17-day embryos of Wistar rats. Prior to the experiments, the culture is maintained for 8–12 days with minimum essential medium (MEM) containing 5% fetal calf serum and 5% horse serum.

For **cyclic AMP assays**, the cultured cells are preincubated with HEPES-buffered Krebs-Ringer solution containing 5.5 mM glucose (HKR) for 1–1.5 h, then exposed to various agonists for 15 min in the absence or presence of 10 μM forskolin. The content of cyclic AMP is measured using a radioimmuno-assay kit after homogenization with 0.1 M HCl.

For **phosphoinositide turnover assays**, the cultured cells are prelabeled with myo-1,2-[^{3}H]inositol in MEM for 8–10 h. The cells are washed twice with HKR containing 10 mM LiCl, and then exposed to various agonists in HKR containing 10 mM LiCl for 30 min. The reaction is terminated with 2% trichloroacetic acid, and the homogenized samples are analyzed for inositol constituents by anion exchange chromatography (Berridge et al. 1982). The extracts are applied to columns containing 1 ml of Dowex 1 in the formate form. The phosphate esters are then eluted by the step-wise addition of solutions containing increasing concentrations of formate. Glycerophosphoinositol and inositol 1 : 2-cyclic phosphate are eluted with 5 mM-sodium tetraborate plus 150 mM sodium formate. The penultimate solution contains 0.1 M-formic acid plus 0.3 M-ammonium formate, followed by 0.1 M-formic acid plus 0.75 M-ammonium formate, each of which removes more polar inositol phosphates.The 1 ml fractions eluted from the columns are count-ed for radioactivity after addition of 10 ml of Biofluor.

The percentage of radioactivity of inositol phosphates to the total applied to the column is calculated.

EVALUATION

Dose-response curves for inhibition of forskolin-stimulated cAMP formation and for percentage of phosphoinositide hydrolysis are established for each test compound.

MODIFICATIONS OF THE METHOD

Thomsen et al. (1993, 1994) used baby hamster kidney (BHK) cells stably expressing $mGluR_{1\alpha}$, $mGluR_2$ or $mGluR_4$ for measurements of phosphoinositol hydrolysis or cAMP formation.

Varney and Suto (2000) recommended functional high throughput screening assay for the discovery of subtype-selective metabotropic glutamate receptor ligands.

E.3.1.9 Excitatory amino acid transporters

PURPOSE AND RATIONALE

Glutamate is not only the predominant excitatory neurotransmitter in the brain but also a potent neurotoxin. Following release of glutamate from presynaptic vesicles into the synapse and activation of a variety of ionotropic and metabotropic glutamate receptors, glutamate is removed from the synapse. This is achieved through active uptake of glutamate by transporters located prebut also post-synaptically, or glutamate can diffuse out of the synapse and be taken up by transporters located on the cell surface of glial cells. The excitatory amino acid transporters form a gene family out of which at least 5 subtypes were identified (Robinson et al. 1993; Seal and Amara 1999). A role for glutamate transporters has been postulated for acute conditions such as stroke, CNS ischemia, and seizure, as well as in chronic neurodegenerative diseases, such as Alzheimer's disease and amyotrophic lateral sclerosis. Glutamate transport is coupled to sodium, potassium and pH gradients across the cell membrane creating an electrogenic process. This allows transport to be measured using electrophysiological techniques (Vandenberg et al. 1997).

PROCEDURE

Complementary DNAs encoding the human glutamate transporters, EAAT1 and EAAT2, are subcloned into pOTV for expression in X. laevis oocytes (Arriza et al. 1994; Vandenberg et al. 1995). The plasmids are linearized with BAMHI and cRNA is transcribed from each of the cDNA constructs with T7 RNA polymerase and capped with 5',7-methyl guanosine using the mMESSAGE mMACHINE (Ambion, Austin TX). cRNA (50 ng) encoding either EAAT1 or EAAT2 is injected into defolliculated Stage V X. laevis oocytes. Two to 7 days later, transport is measured by two-electrode voltage-clamp recording using a Geneclamp 500 amplifier (Axon Instruments, Foster City, CA) and a MacLab 2e recorder (ADI Instruments, Sydney, Australia) and controlled using a pCLAMP 6.01 interfaced to a Digidata 1 200 (Axon Instruments). Oocytes are voltage-clamped at –60 mV and continuously superfused with ND96 buffer (96 mM NaCl, 2 mM KCl, 1.8 mM $CaCl_2$, 1 mM $MgCl_2$ and 5 mM HEPES, pH 7.5). For transport measurement, this buffer is changed to one containing the indicated concentration of substrate and/or blocker. The voltage dependence of block of glutamate transport is measured by clamping the membrane potential at –30 mV and then applying a series of 100 ms voltage pulses from –100 mV to 0 mV and measuring the steady state current at each membrane potential. This protocol is applied both before and during the application of the compound in question and then the base-line current at each membrane potential is subtracted from the current in the presence of the compounds to get a measure for the transport specific current at the various membrane potentials.

EVALUATION

Current (I) as a function of substrate concentration ([S]) is fitted by least squares to

$$I = I_{max}\,[S] / (K_m + [S])$$

where I_{max} is the maximal current and K_m is the Michaelis transport constant. The I_{max} values for the various substrates are expressed relative to the current generated by a maximal dose of L-glutamate in the same cell. I_{max} and K_m values are expressed as mean ± standard error and are determined by fitting data from individual oocytes. The potent competitive blockers are characterized by Schild analysis (Arunlakshana and Schild 1959) and the K_b estimated from the regression plot. The less potent blockers are assumed to be competitive and K_i values calculated from IC_{50} values using the equation

$$K_i = IC_{50} / (1 + [\text{glutamate}] / K_m)$$

where K_i is the inhibition constant, IC_{50} is the concentration giving half maximum inhibition, K_m is the transport constant and [glutamate] is 30 μM. The fraction of the membrane electric field sensed by transport blockers when bound to the transporters is estimated using the Woodhull equation (Woodhull 1973),

$$K_i = K_i^0 \exp(-\zeta\,\delta\,\mathrm{F}\,E / \mathrm{R}\,T)$$

where K_i is the inhibition constant, K_i^0 is the inhibition constant at 0 mV, ζ is the charge on the blocker, δ is the fraction of the membrane field, F is Faraday's constant, E is the membrane potential, R is the gas constant and T is temperature in °K.

E.3.1.10 [^{35}S]TBPS binding in rat cortical homogenates and sections

PURPOSE AND RATIONALE

To screen potential anticonvulsant agents which interact at the convulsant binding site of the benzodiazepine/GABA/chloride ionophore complex by measuring the inhibition of binding of [^{35}S]TBPS to rat cortical membranes.

TBPS, t-butylbicyclophosphorothionate, is a potent convulsant which blocks GABA-ergic neurotransmission by interacting with the convulsant (or picrotoxin) site of the GABA/benzodiazepine/chloride ionophore receptor complex (Casida et al. 1985; Gee et al. 1986; Olsen et al. 1986; Squires et al. 1983; Supavilai and Karabath 1984). Picrotoxin, pentylenetetrazol and the so-called "cage convulsants" are believed to change the state of the chloride channel to a closed conformation, and thereby block GABA-induced increases in chloride permeability. Anticonvulsants such as the barbiturates and the pyrazolopyridines, cartazolate, etazolate and tracazolate, appear to interact at depressant sites allosterically coupled to the convulsant sites, and facilitate the effects of GABA on chloride permeability, by converting the ionophore to the open conformation. Benzodiazepines interact at a separate recognition site to modulate the actions of GABA. Convulsant compounds and some anticonvulsants can inhibit [^{35}S]TBPS binding. These two classes can be differentiated by their effects on dissociation kinetics (Macksay and Ticku 1985; Trifiletti et al. 1984, 1985). [^{35}S]TBPS dissociates slowly, half-life approximately 70 min, in a monophasic manner in the presence of convulsant compounds; anticonvulsants produce a biphasic dissociation, with rapid and slow phase components. It has been postulated that the rapid and slow phases of [^{35}S]TBPS dissociation may correspond to the open and closed conformation of the chloride ionophore.

PROCEDURE

Reagents

1. Buffer A 0.05 M Tris with 2 M KCl, pH 7.4
   6.61 g Tris HCl
   0.97 g Tris Base
   149.1 g KCl
   q.s. to 1 liter with distilled water
2. Buffer B
   a 1 : 10 dilution of buffer A in distilled water (5 mM Tris, 200 mM KCl, pH 7.4)
3. [^{35}S]TBPS is obtained from New England Nuclear with a high initial specific activity, 90–110 Ci/mmol. For an inhibition assay with a 2 nM final concentration of TBPS, a specific activity of 20–25 Ci/mmol will provide sufficient counts due to a high counting efficiency (87%) for ^{35}S. The specific activity of [^{35}S]TBPS can be reduced with the addition of 3–5 vol-umes (accurate measurement with a Hamilton syringe) of an equimolar ethanolic solution of non-radiolabeled TBPS (7.9×10^{-6} M). The new specific activity (Ci/mmol) is calculated by dividing the number of Curies by the number of mmoles TBPS. Since [^{35}S]TBPS has a relatively short half-life, 87.1 days, the specific activity is calculated for each assay, based on the exponential rate of decay:

   A_0 = initial specific activity
   A = specific activity at time t
   t = days from date of initial calibration of specific activity
   $t_{1/2}$ = half-life of [^{35}S] in days (87.1)

   For IC_{50} determinations, a 40 nM stock solution is made with distilled water and 25 µl is added to each tube to yield a final concentration of 2 nM in the assay.
4. Unlabeled TBPS is available from New England Nuclear. A stock dilution of 7.923×10^{-6} M is prepared in ethanol.
5. Picrotoxin, is obtained from Aldrich Chemical Company. A solution of 5×10^{-4} M is prepared with distilled water, with sonication if necessary. Aliquots of 10 µl are added to assay tubes to give a final concentration of 10^{-5} M.
6. Test compounds. A stock solution of 1 mM is made up with a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Higher or lower concentrations may be used, depending on the potency of the drug.

Tissue preparation

Whole cerebral cortex of male Wistar rats is dissected over ice and homogenized with a Tekmar Tissumizer, 20 s at setting 40, in 20 volumes of 0.32 M sucrose, ice-cold. The homogenate is centrifuged at 1 000 *g* for 10 min (SS34, 3 000 rpm, 4 °C). The supernatant is then centrifuged at 40 000 *g* for 30 min (SS34, 20 000 rpm, 4 °C). The resulting pellet is resuspended in 20 volumes of ice-cold distilled water with two 6-s bursts of the Tissumizer, setting 40. The homogenate is centrifuged at 40 000 *g* for 30 min. The pellet is washed (resuspended and centrifuged) once with 20 volumes ice-cold buffer (Tris HCl 5 mM, KCl 200 mM, pH 7.4). The resulting pellet is resuspended with 20 volumes buffer and frozen at –70 °C overnight. The following day, the tissue homogenate is thawed in a beaker of warm water, approximately 15 min, and then centrifuged at 40 000 *g* for 30 min (SS34, 20 000 rpm, 4 °C). The pellet is washed twice with 20 volumes of ice-cold buffer, and then resuspended and frozen at –70 °C for future use. On the day of the assay, the homogenate is thawed and centrifuged at 40 000 *g* for 30 min. The resulting pellet is washed once with 20 volumes ice-cold buffer and finally resuspended in 30 volumes buffer. Aliquots of 250 µl are used for each assay tube, final volume 500 µl, and correspond to 8.35 mg original wet weight tissue per tube, approximately 0.2 mg protein.

Assay

1. Prepare assay tubes in triplicate:
   - 190 µl distilled water
   - 25 µl Tris 0.05 M, KCl 2M, pH 7.4
   - 10 µl picrotoxin, 10^{-5} M final concentration or distilled water or inhibitor 25 µl [^{35}S]-TBPS, final concentration 2 nM
   - 250 µl tissue preparation, 1 : 30 homogenate
2. Following the addition of the tissue, the tubes are incubated at 25 °C for 150 min with agitation. The assay is terminated by rapid filtration over Whatman GF/B filter circles, presoaked in buffer, with 5 × 4 ml rinses of ice-cold buffer. Vacuum filtration is performed with the 45-well filtration units to avoid contamination of the Brandell harvesters with [^{35}S]. The filters are counted with 10 ml Liquiscint.

EVALUATION

Specific binding is determined from the difference between binding in the absence or presence of 10 mM picrotoxin, and is typically 85–90% of total binding. The percent inhibition at each drug concentration is the mean of triplicate determinations. IC_{50} values for the competing drug are calculated by log-probit analysis of the data.

Modifications for dissociation experiments

1. Prepare assay tubes as follows:
   - 185 µl distilled water
   - 25 µl Tris 50 mM, KCl 2 M, pH 7.4
   - 10 µl test compound or vehicle
2. Add 250 ml tissue homogenate to tubes. Vortex. Preincubate 30 min at 25 °C.
3. Add 25 ml [^{35}S]-TBPS. Vortex. Incubate 180 min at 25 °C.
4. Add 5 ml picrotoxin (10^{-3} M) to give a final concentration of 10^{-5} M. Vortex.
5. At various times after the addition of picrotoxin (0–120 min) tubes are filtered and rinsed as described above.

Modification for [^{35}S]-TBPS autoradiography

1. Sections of rat brain, 20 mm thickness, are collected onto gel-chrome alum subbed slides, freeze-dried for approximately 1 h and stored at –70 °C until used.
2. After thawing and drying at room temperature, the sections are preincubated for 30 min in buffer B.
3. Preparation of slide mailers for incubation:
   a) for scintillation counting:
      - 2.47 ml distilled water
      - 0.325 ml buffer A
      - 3.25 ml buffer B
      - 0.13 ml picrotoxin, 10^{-5} M final concentration or distilled water or inhibitor
      - 0.325 ml [^{35}S]TBPS, final concentration 2 nM
      - 6.50 ml final volume

   b) for autoradiography:
      - 4.56 ml distilled water
      - 0.60 ml buffer A
      - 6.00 ml buffer B
      - 0.24 ml picrotoxin, 10^{-5} M final concentration or distilled water or inhibitor
      - 0.60 ml [^{35}S]TBPS, final concentration 2 nM
      - 12.0 ml final volume
4. Sections are incubated in slide mailers at room temperature with [^{35}S]TBPS in the absence or presence of appropriate inhibitors for 90 min.
5. Slides are transferred to vertical slide holders and rinsed in ice-cold solutions as follows: dip in buffer B, two 5 minute rinses in buffer A and a dip in distilled water.
6. Slides are dried under a stream of cool air and desiccated overnight at room temperature.
7. Slides are mounted onto boards with appropriate [^{35}S] brain mash standards.
8. In the dark room under safelight illumination (GBX filter), slides are opposed to Kodak X-OMAT AR film and stored in cassettes for 7–10 days.
9. Develop films as described in "X-OMAT AR Film Processing".

E.3.1.11 [^{3}H]glycine binding in rat cerebral cortex

PURPOSE AND RATIONALE

This assay is used to assess the affinity of compounds for the glycine binding site associated with the N-methyl-D-aspartate (NMDA) receptor complex using [^{3}H] glycine as the radioligand.

The amino acid glycine modulates and may activate the excitatory amino acid receptors of the NMDA-subtype (Thomson 1989). Glycine has been shown *in vitro* to potentiate the effects of l-glutamate or NMDA on the stimulation of [^{3}H]TCP binding (Snell et al. 1987, 1988; Bonhaus 1989) and [^{3}H]norepinephrine release (Ransom et al. 1988), and *in vivo* to act as a positive modulator of the glutamate-activated cGMP response in the cerebellum (Danysz et al. 1989; Rao et al. 1990). The activation of NMDA receptors requiring the presence of glycine is necessary for the induction of long-term potentiation (LTP), a type of synaptic plasticity which may be fundamental to learning processes (Oliver et al. 1990). A [^{3}H]glycine binding site in the brain has been identified and characterized as a strychnine-insensitive site associated with the NMDA receptor complex (Kessler et al. 1989; Monahan et al. 1989; Cotman et al. 1987). Autoradiographic studies have shown a similar distribution of [^{3}H]glycine and [^{3}H]TCP (NMDA ion channel radioligand) binding sites (Jansen et al. 1989). Compounds which interact with the glycine site offer a novel mechanism of action for intervention with NMDA receptor function.

PROCEDURE

Reagents

1. Buffer A: 0.5M Tris maleate, pH 7.4
   59.3 g Tris maleate
   q.s. to 0.5l
   Adjust pH to 7.4 with 0.5M Tris base.
2. Buffer B: 50 mM Tris maleate, pH 7.4
   Dilute buffer A 1 : 10 with distilled water; adjust pH with 50 mM Tris maleate (acid) or 50 mM Tris base.
3. Glycine, 5×10^{-2} M
   Dissolve 3.755 mg of glycine (Sigma G7 126) with 1.0 ml distilled water. Aliquots of 20 µl to the assay tube will give a final concentration of 10^{-3} M
4. [^{3}H]Glycine is obtained from New England Nuclear, specific activity 45–50 Ci mmol. For IC_{50} determinations, a 200 nM stock solution is made with distilled water. Aliquots of 50µl are added to yield a final assay concentration of 10 nM.
5. Test compounds. A stock solution of 5 mM is prepared with a suitable solvent and serially diluted, such that the final concentrations in the assay ranges from 10^{-4} to 10^{-7} M. Higher or lower concentrations may be used, depending on the potency of the compound.
6. Triton-X 100, 10% (v/v) (National Diagnostics, EC-606). A stock solution of Triton-X 100, 10% can be prepared and stored in the refrigerator. Dilute 1.0 ml of Triton-X 100 to 10.0 ml with distilled water. On the day of the assay, the tissue homogenate (1 : 15 dilution) is preincubated with an aliquot of the 10% solution to give a final concentration of 0.04% (v/v).

Tissue preparation

Cortices of male Wistar rats are dissected over ice and homogenized in ice-cold 0.32 M sucrose, 15 volumes of original wet weight of tissue, for 30 s with a Tissumizer setting at 70. Three cortices are pooled for one preparation. The homogenate is centrifuged at 1 000 *g* for 10 min (SS34, 3 000 rpm, 4 °C). The supernatant is centrifuged at 20 000 *g* (SS34, 12 000 rpm, 4 °C) for 20 min. Resuspend the pellet in 15 volumes of ice-cold distilled water (Tissumizer setting 70, 15 s) and spin at 7 600 *g* (SS34, 8 000 rpm 4 °C) for 20 min. The pellet is resuspended with 15 volumes of cold distilled water and centrifuged. Discard the supernatant and store the pellet at –70 °C.

On the day of the assay, the pellet is resuspended in 15 volumes ice-cold 50 mM Tris maleate, pH 7.4. Preincubate the homogenate with Triton-X in a final concentration of 0.04% (v/v) for 30 min at 37 °C with agitation. Centrifuge the suspension at 48 000 *g* (SS34, 20 000 rpm, 4 °C) for 20 min. Wash the pellet an additional 3 times by resuspension with cold buffer and centrifugation. The final pellet is resuspended in a volume 25 times the original wet weight.

Assay

1. Prepare assay tubes in quadruplicate.
   380 µl distilled water
   50 µl buffer A, 0.5 M Tris maleate, pH 7.4
   20 µl glycine, 10^{-3} M final concentration, or distilled water or appropriate concentration of inhibitor
   50 µl [^{3}H] glycine, final concentration 10 nM
   500 µl tissue homogenate.
   1 000 µl final volume
2. Following the addition of the tissue, the tubes are incubated for 20 min in an ice-bath at 0–4 °C. The binding is terminated by centrifugation (HS4, 7 000 rpm, 4 °C) for 20 min. Aspirate and discard the superna-tant. Carefully rinse the pellet twice with 1 ml ice-cold buffer, avoiding disruption of the pellet. Transfer the pellet to scintillation vials by vor-texing the pellet with 2 ml scintillation fluid, rinse the tubes twice with 2 ml and add an additional 4 ml scintillation fluid.

EVALUATION

Specific binding is determined from the difference of binding in the absence or in the presence of 10^{-4} M glycine and is typically 60–70% of total binding. IC_{50} values for the competing compound are calculated by log-probit analysis of the data.

MODIFICATIONS OF THE METHOD

Baron et al. (1996), Hofner and Wanner (1997), Chazot et al. (1998) described [^{3}H]MDL 105,519 as a high affinity ligand for the NMDA associated glycine recognition site.

E.3.1.12 [^{3}H]strychnine sensitive glycine receptor

PURPOSE AND RATIONALE

The strychnine-sensitive glycine receptor is a member of the family of ligand-gated ion channel receptors. Within this family, the glycine receptor is most closely related to the GABA-receptor. Like the $GABA_A$-receptor, the glycine receptor has an inhibitory role, mediating an increase in chloride conductance. However, in contrast to the $GABA_A$-receptor, the glycine receptor is located mainly in the spinal cord and lower brainstem, where glycine appears to be the major inhibitory neurotransmitter. Purification and molecular cloning has shown that the glycine receptor is an oligomeric transmembrane protein complex composed of three α and two β subunits. The inhibitory actions of glycine are potently blocked by strychnine. In addition to strychnine, the steroid derivative RU5 135 (Simmonds and Turner 1985), phenylbenzene-ω-phosphono-α-amino acid (Saitoh et al. 1996), and 5,7-dichloro-4-hydroxyquinoline-3-carboxylic acid (Schmieden et al. 1996) antagonize glycine responses in cultured neurons or cells expressing recombinant glycine receptors.

A glycine receptor agonist may be a potential antispastic agent.

PROCEDURE

Male Wistar rats weighing about 200 g are sacrificed. About 220 mg of frozen pons and medulla are homogenized in 2×10 ml ice-cold 50 mM potassium phosphate buffer, pH 7.1, by an Ultra-Turrax homogenizer. The homogenate is centrifuged for 10 min at 30 000 *g* at 0–4 °C in a refrigerated centrifuge. The pellet is rehomogenized in another 2×10 ml portion of the same buffer and recentrifuged as before. This washing procedure is repeated a total of four times. The final pellet is resuspended in 200 vol/g original tissue in ice-cold 50 mM potassium phosphate buffer, pH 7.1, with or without 1 000 mM NaCl, and used directly for binding assays.

Binding assays consist of 1 ml tissue homogenate, 50 µl test solution (water or 5% v/v ethanol/water is used for serial dilutions), 50 µl water, 5% ethanol/water or glycine solution (40 mM final concentration), and 25 µl [^{3}H]strychnine working solution, final concentration 2 nM. The samples are mixed well and incubated for 20 min in an ice bath. Free and bound radioactivity are separated by filtration through Whatman GF/C glass fiber filters followed by washing with 2×10 ml ice-cold 50 mM potassium phosphate buffer, pH 7.1. Tritium on the filters is monitored by convential scintillation counting in 3 ml Hydroluma. Nonspecific binding is binding in the presence of 40 mM glycine and is

always subtracted from total binding to give specific binding.

EVALUATION

K_i values are calculated as

$$K_i = IC_{50} / (1 + [K_D] / [L])$$

whereby: IC_{50} are the concentrations that inhibit by 50% the specific binding of [^{3}H]strychnine determined in two independent experiments using at least 3 concentrations of the agent in duplicate assays, [L] is the concentration of the radioligand, K_D is the affinity constant in the absence or the presence of 1 000 mM NaCl.

NaCl shift used for differentiating glycine agonists from glycine antagonists is the ratio K_i 1 000 mM NaCl versus K_i 0 mM NaCl.

E.3.1.13 Electrical recordings from hippocampal slices *in vitro*

PURPOSE AND RATIONALE

The transverse hippocampal slice has been described as a well-defined cortical structure maintained *in vitro* (Skrede and Westgard 1971). The hippocampus slice has the advantage that each slice may contain all hippocampal structures: The chain of neurons goes from the perforant path to granule cells of the dentate gyrus, through mossy fibres to CA-3 pyramidal cells and then through Schaffer collaterals to CA-1 cells with their axons leaving the hippocampus through the alveus. The pyramidal cells lie close together and can be easily seen and penetrated with fine microelectrodes.

PROCEDURE

Male guinea pigs weighing 300–400 g are anesthetized with ether, the brains removed and the hippocampi dissected. Transverse slices of the hippocampus (300–400 µm thick) are cut in parallel to the alvear fibres. After preparation, the slices are submerged in 28 °C warm saline which is equilibrated with 95% O_2 and 5% CO_2. After a preincubation period of 2 h, slices are transferred in a Perspex chamber (1.5 × 4 cm) and attached to the bottom consisting of optically plain glass. The chamber is mounted on an inverted microscope allowing detailed inspection of the excised tissue. The slices are superfused by an approximately 3 mm thick layer of 32 °C warm saline. Intracellular recordings are achieved by means of micropipettes with tip diameters of less than 0.5 µm which are filled with 3 mol/l potassium chloride. Under microscopic control the tips of the micropipettes are placed within the stratum pyramidale and moved by means of a step motor driven hydraulic microdrive. For intracellular injections of drugs, e.g., pentylenetetrazol, via the recording microelectrode, a passive bridge is used. Alternatively, drugs are added to the incubation bath.

EVALUATION

The resting membrane potential and paroxysmal depolarizations are recorded before and after application of drugs.

CRITICAL ASSESSMENT OF THE METHOD

The hippocampal slice has been one of the most useful models for the study of basic mechanisms underlying the epilepsies. The model has also been recommended for screening of putative anticonvulsant drugs.

MODIFICATIONS OF THE METHOD

Harrison and Simmonds (1985) performed quantitative studies on some antagonists of N-methyl-D-aspartate in slices of rat cerebral cortex consisting of cerebral cortex and corpus callosum.

Tissue culture models of epileptiform activity were described by Crain (1972).

Oh and Dichter (1994) studied the effect of a GABA uptake inhibitor on spontaneous postsynaptic currents in cultured rat hippocampal neurons by the whole cell patch clamp method.

Blanton et al. (1989) described whole cell recordings from neurons in slices of reptilian and mammalian cerebral cortex. Synaptic currents and membrane properties could be studied in voltage and current clamps in cells maintained within their endogenous synaptic currents.

Gähwiler (1988), Stoppini et al. (1991) described methods for organotypic cultures of nervous tissue. Hippocampal slices from 2–23-day old rats were maintained in culture at the interface between air and the culture medium. They were placed on a sterile, transparent and porous membrane and kept in Petri dishes in an incubator. This yielded thin slices which remained 1–4 layers thick and were characterized by a well preserved organotypic organization. Excitatory and inhibitory synaptic potentials could be analyzed using extra- or intracellular recording techniques. After a few days in culture, long-term potentiation of synaptic responses could reproducibly be induced.

Using this method, Liu et al. (1995) studied dopaminergic regulation of transcription factor expression in organotypic cultures of developing striatum of newborn rats.

Stuart et al. (1993) reported the implementation of infrared differential interference contrast video microscopy to an upright compound microscope and a procedure for making patch-pipette recordings from visually identified neuronal somata and dendrites in brain slices.

Bernard and Wheal (1995) described an *ex vivo* model of chronic epilepsy using slices of rat hippocampus previously lesioned by stereotactic injections of kainic acid. Extracellular population spikes were recorded from the stratum pyramidale of CA1 after stimulation by bipolar twisted wire electrodes placed in the stratum radiatum of CA1 area proximally to stratum pyramidale near the recording electrode.

Using hippocampal slices prepared from brain tissue of patients undergoing neurosurgery for epilepsy, Schlicker et al. (1996) showed that the serotoninergic neurons of the human hippocampus are endowed with presynaptic inhibitory autoreceptors.

E.3.1.14 Electrical recordings isolated brain cells

PURPOSE AND RATIONALE

The use of the cell-attached patch clamp configuration to record action potential currents has shown to have utility in the testing for drug actions on ion channels in excitable cell membranes (Kay and Wong 1986; McLarnon 1990, 1991).

PROCEDURE

Preparation of cultured cells

The cultured cells are obtained from the hippocampus or the hypothalamus of rat brain. The isolation of the hippocampal CA1 neurones is performed according the procedure of Banker and Cowan (1977). The dissociated hypothalamic neurons are prepared according to Jirikowski et al. (1981). The hippocampal and hypothalamic neurons that are selected for electrophysiological recording are bipolar in shape with the long axis dimension between 10–15 µm. The neurons are studied over a period of 5–10 days after isolation.

Electrophysiology

The cell-attached patch clamp configuration is used to record spontaneous action potentials in the cultured neurons. The bath solution contains 140 mM NaCl, 5 mM KCl, 0.5 mM $CaCl_2$, 1 mM $MgCl_2$, 5 mM HEPES, pH 7.3. The composition of the patch pipette solution is the same as the bath solution. The drugs used in the experiments are added to the bath solution.

The patch pipettes (Corning 7 052 glass) are fabricated using a specific patch pipette puller (PP-83; Narishige, Tokyo) are fire-polished and filled immediately prior to use. The resistance of the pipettes is in the range 4–8 MΩ and the tip diameters are between 1 and 2 µm. An axopatch amplifier (Axon Instruments, Foster City, CA), with low-pass filter set at 5 kHz, is used to record the capacitative currents. After recording, at a sampling frequency of 5 kHz, the data are stored on hard disc or video tape for subsequent analysis. All data are obtained at room temperature (21–24 °C).

EVALUATION

The capacitative component of current recorded by the patch pipettes is proportional to the rate of change of membrane potential and can be expressed as $I_C = C\,dV/dt$, where C is the specific membrane capacitance. Assuming a value of C of 1 µF/cm^2 and a tip diameter of the patch pipette of 2 µm, the membrane area isolated by the patch pipette is about 3×10^{-8} cm^2. Using a value of dV/dt of 100 mV/ms gives an approximate expected magnitude of I_C near 3 pA. When a class III antiarrhythmic drug that blocks a delayed rectifier K^+ channel is added to the bath, the portion of I_C corresponding to the after-hyperpolarization component of the action potential is completely abolished. The Na^+ spike is not altered by the drug. The cell-attached recordings of I_C can also be used to determine effects on the Na^+ spike when tetrodotoxin is included in the bath solution. Thus, the spontaneous action potential can be used for evaluation of drug effects on both K^+ and Na^+ channels in excitable membrane.

MODIFICATIONS OF THE METHOD

Chen et al. (1990) measured current responses mediated by $GABA_A$ receptors in pyramidal cells acutely dissociated from the hippocampus of mature guinea

pigs according to the procedure of Kay and Wong (1986) using whole-cell voltage-clamp recordings.

Caulfield and Brown (1992) studied inhibition of calcium current in NG108-15 neuroblastoma cells by cannabinoid receptor agonists using whole-cell voltage-clamp recordings.

Gola et al. (1992, 1993) performed voltage recordings on non-dissociated sympathetic neurones from rabbit coeliac ganglia using the whole-cell configuration of the patch clamp technique (Neher and Sakmann 1976; Sakmann and Neher 1983).

Stolc (1994) used the voltage-clamp technique in internally dialyzed single neurones isolated from young rat sensory ganglia to study the effects of pyridoindole stobadine on inward sodium and calcium currents and on slow non-inactivating components of potassium outward current.

McGivern et al. (1995) examined the actions of a neuroprotective agent on voltage dependent Na^+ currents in the neuroblastoma cell line, NIE-115, using the whole cell variant of the patch clamp technique.

Smith (1995) reviewed the use of patch- and voltage clamp procedures to study neurotransmitter transduction mechanisms.

Using whole-cell and perforated-patch recordings, Delmas et al. (1998) examined the part played by endogenous G-protein $\beta\gamma$ subunits in neurotransmitter-mediated inhibition of N-type Ca^{2+} channel current in dissociated rat superior cervical sympathetic neurones.

Gonzales et al. (1985) registered membrane potentials with intracellular electrodes in cultured olfactory chemoreceptor cells.

E.3.1.15 Isolated neonatal rat spinal cord

PURPOSE AND RATIONALE

The spinal cord of the neonatal rat is a useful *in vitro* preparation, originally proposed by Otsuka and Konishi (1974). In this preparation, ventral root potentials of ten seconds of duration can be recorded after supramaximal electrical stimulation of the lumbar dorsal root. Variously implicated in the generation of these slow ventral root potentials are tachykinins, such as substance P and neurokinin B (Yanagisawa et al. 1982; Akagi et al. 1985; Otsuka and Yanagisawa 1988; Guo et al. 1998) and agonists at the glutamate receptor sites (Evans et al. 1982; Ohino and Warnick 1988 1990; Shinozaki et al. 1989; Ishida et al. 1990, 1991, 1993; Woodley and Kendig 1991; Bleakman et al. 1992; King et al. 1992; Thompson et al. 1992; Zeman and Lodge 1992; Pook et al. 1993; Jane et al. 1994; Boxall et al. 1996). These long lasting reflexes are thought to reflect a nociceptive reflex for several reasons; the threshold of activation corresponds to that of C fibre primary afferents (Akagi et al. 1985); they can be depressed by opioids (Yanagisawa et al. 1985; Nussbaumer et al. 1989; Faber et al. 1997) and α_2-adrenoceptor agonists (Kendig et al. 1991) and a similar response can be evoked by peripheral noxious stimulation (Yanagisawa et al. 1995).

PROCEDURE

Preparation of spinal cord

Male Wistar rats aged 6–9 days are used. Under ether anesthesia the spinal column is quickly removed from the animal and placed in a Petri dish, filled with oxygenated physiological solution. A laminectomy is performed on the dorsal surface of the spinal column at room temperature. The spinal cord of the mid-thoracic to mid-sacral level is then carefully removed from the column and hemisected in the longitudinal plane under a dissecting microscope. After removal of the dura mater, the hemisected cord is completely submerged in the recording chamber (total volume: approximately 0.5 ml), which is perfused with physiological solution (124 mM NaCl, 5 mM KCl, 1.3 mM $MgSO_4$, 2.5 mM $CaCl_2$, 1.2 mM KH_2PO_4, 15 mM $NaHCO_3$, 11 mM glucose) at a flow rate of 1.5 to 2.5 ml/min. The perfusion medium is continuously bubbled with a gas mixture of 95% O_2 and 5% CO_2 and the temperature is kept at 25 ±0.5 °C. The cut ends of the corresponding dorsal and ventral roots in an $L_{3\text{-}5}$ segment are fixed to a pair of suction electrodes for stimulating and recording. The preparation is stabilized in the recording chamber for at least 90 min to allow recovery from the dissection and the sealing of the roots to suction electrodes.

Recording of monosynaptic reflexes

Test stimulations, composed of square wave pulses of 0.05–0.2 ms duration and 5–30 V, are applied to the dorsal root every 10 s. The discharges of the corresponding ventral root are recorded with a suction electrode, amplified and monitored on an oscilloscope and stored on an analog data recorder or computer discs for later analysis. The mean values for the waveform of the monosynaptic reflex (amplitude, area and latency) are obtained from 6–18 successive responses in each experiment before and during application of drugs.

Recording of single motoneuron activity

Test pulses (0.01–0.1 ms duration and 5–15 V) are applied to the dorsal or ventral root every 2 s. The activity of single motoneurons is recorded extracellularly using glass microelectrodes (electrical resistance approximately 10–30 MΩ) filled with 3 M sodium chloride or 2 M sodium acetate. The microelectrode is inserted into the ventral part of the cord through the hemisected surface while monitoring the field potential. The motoneurons in the ventral horn are identified by the short and consistent latency of antidromic spikes (1.66 ±0.46 ms, $n = 5$), following the stimulation of the ventral root. The motoneurons also produce transsynaptic spikes with orthodromic stimulation of the dorsal root, of which the latency is 10.26 ±1.05 ms upon supramaximal stimulation. The spike generation of motoneurons is displayed on an oscilloscope and stored on magnetic tapes. The spontaneous firing of the motoneuron is also monitored on an oscilloscope and recorded through a window discriminator and spike counter. The mean number and latency of spikes and latency of the dorsal root-elicited spikes are obtained from 20–40 successive responses in each experiment. Comparisons are made before and 3–5 min after application of drugs.

EVALUATION

All data are expressed as the mean ±SEM. Statistical significance of the data is determined by repeated measures analysis of variance (ANOVA) and, when appropriate, Student's *t*-test. A *P* value of less than 0.05 is considered statistically significant.

MODIFICATIONS OF THE METHOD

Smith and Feldman (1987), Wong et al. (1996) described an *in vitro* neonatal rat brainstem/spinal cord preparation. The brainstem and cervical spinal cord were isolated from 0–4 days old ether anesthetized Sprague Dawley rats. The en bloc neuraxis was pinned down with ventral surface upward in a recording chamber and superfused continuously with artificial cerebrospinal fluid. Respiratory activity was recorded with suction electrodes from the C_4 ventral root.

E.3.1.16 Cell culture of neurons

PURPOSE AND RATIONALE

Cell culture of neurons, especially of hippocampal neurons, has become a widely used tool in pharmacological studies (Banker and Cowan 1977; Skaper et al. 1990, 1993, 2001; Araujo and Cotman 1993; Brewer 1997, 1999; Brewer et al. 1998; Li et al. 1998; Mitoma et al. 1998; Semkowa et al. 1998, 1999; Chaudieu and Privat 1999; May et al. 1999; Hampson et al. 2000; Novitskaya et al. 2000; Pickard et al. 2000; Vergun et al. 2001).

The basic information on methodology of cell culture of rat hippocampal neurones was given by Banker and Cowan (1977). One modification used by Skaper et al. (1990, 2001) studying the role of mast cells on potentiation by histamine of synaptically mediated excitotoxicity in cultured hippocampal neurones is described below.

PROCEDURE

Preparation of hippocampus

Timed pregnancies are obtained in female Sprague Dawley rats by daily checking vaginal washings for sperm, the day on which sperm is found being regarded as day 0. At the appropriate stage of gestation the pregnant rats are anesthetized and the uterus removed to a sterile dish. The remainder of the cell preparations is performed in a sterile hood.

The brains are removed from the fetuses with a pair of fine scissors, and the cerebral hemispheres separated from the brain stem. When the hemisphere of an 18- to 19-day-old fetus in viewed in a dissecting microscope the hippocampus can be clearly seen on its medial surface. The hippocampal fissure, usually marked by a conspicuous group of blood vessels, indicates the approximate junction between the hippocampus and the adjoining subicular and entorhinal cortex. The developing fimbria is seen as a white translucent band along the free margin of the hippocampus. Before separating the hippocampus from the hemisphere,

the meninges and adherent chorioid plexus are carefully pulled off with fine forceps. At this stage the full depth of the hippocampal fissure can be seen. Then with iridectomy scissors the hippocampus is separated from the adjoining cortex by a cut parallel to the hippocampal fissure, and by transverse cuts at its rostral and caudal ends.

Cell culture

Hippocampi isolated from embryonic rats (gestational age 17.5 days) are incubated with 0.08% trypsin, and dissociated in Neurobasal medium containing 10% heat-inactivated calf serum. Cells are pelleted by centrifugation (200 *g*, 5 min) and resuspended in Neurobasal medium containing B27 (Life Technologies, Inc.) supplements (with antioxidants), 25 µM glutamate, 1 mM sodium pyruvate, 2 mM L-glutamine, 50 U/ml penicillin, and 50 µg/ml streptomycin. The cell suspension is plated onto poly-D-lysine (10 µg/ml) coated 48-well culture plates at a density of 4.5×10^4 cells per cm^2. Cultures are maintained at 37 °C in a humidified atmosphere of 5% CO_2-95% air. After 5 days, one-half of the medium is replaced with an equal volume of maintenance medium (plating medium but containing B27 supplements without antioxidants, and lacking glutamate). Additional medium exchanges (0.5 volume) are performed every 3–4 days thereafter. Cells are used between 14 and 16 days in culture. During this period, neurones develop extensive neuritic networks, and form functional synapses.

Mast cells are collected from the peritoneal lavage of male Sprague Dawley rats and isolated over a bovine serum albumin gradient to >90% purity, as judged by toluidine blue and safranin staining.

Neurotoxicity assays

Cultures are washed once with Locke's solution (pH 7.0–7.4) with or without 1 mM $MgCl_2$. Drug treatments are carried out for 15–30 min (25 °C) in a final volume of 0.5 ml. In the case of mast-cell-neurone cocultures, transwell inserts (3-µm pore size, 9 mm diameter) are seeded with 5×10^4 mast cells in RPMI-1 640 medium and placed in 24-well plates overnight. Inserts with mast cells are then placed into wells with hippocampal cells. Mast cells activation is achieved using an antigenic stimulus (0.3 µg/ml anti-DNP IgE/0.1 µg/ml DNP albumin). The mast cell containing inserts are removed at the end of the Mg^{2+}-free incubation. After this time all cell monolayers are washed with complete Locke's solution and returned to their original culture medium for 24 h. Cytotoxicity is evident during 24 h after the insult. Viable neurons have phase-bright somata of round-to-oval shape, with smooth, intact neurites. Neurones are considered nonviable when they exhibit neurite fragmentation and somatic swelling and vacuolation. Cell survival is quantified 24 h after the insult by a colorimetric reaction with 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT).

EVALUATION

Data are analyzed by one-way ANOVA with Student-Newman-Keuls *post hoc* test for differences between groups.

MODIFICATIONS OF THE METHOD

Brewer (1997) reported the isolation and culture of adult rat hippocampal neurons. Using different proteases and special separation techniques, about 90 000 viable neurons could be isolated from each hypothalamus at any age rat from birth to 24–36 months. Neurons were cultured for more than 3 weeks.

Flavin and Ho (1999) found that propentofylline protects hippocampal neurons in culture from death triggered by macrophage or microglia secretory products.

To study neurite outgrowth in cultured hippocampal cells from Wistar rat embryos, 5 000 cells/well were seeded in 8-well LabTec tissue culture slides with a grown surface of permanox plastic and grown in Neuro-basal medium supplemented with B27 (Life Technologies, Inc.), 20 mM HEPES, 0.4% bovine serum albumin, penicillin (100 IU/ml), and streptomycin (100 µg/ml). (Novitskaya et al. 2000). For image analysis, cells were fixed in 4% paraformaldehyde and stained for 20 min with Coomassie Blue R250. Cover slides were observed in an inverted microscope using phase contrast optics. To measure neurite outgrowth from hippocampal neurons, an unbiased counting frame containing a grid with a number of test lines was superimposed on the images of cells. The number of intersections of cellular processes with the test lines was counted and related to the number of cell bodies, thereby allowing quantification of neurite length per cell.

Cell culture experiments were also performed with **neuronal cells from other areas of the brain** besides the hippocampus.

Brain tissue samples of rat embryos containing either septum plus preoptic area or retrochiasmatic hypothalamus were dissociated and cultured for 14 and 21 days by Jirikowski et al. (1981). By means of immunofluorescence, LHRH, α-MSH, vasopressin and neurophysin-containing hormones could be identified.

Sinor et al. (2000) studied NMDA and glutamate evoked excitotoxicity at distinct cellular locations in rat cortical neurones *in vitro*.

Canals et al. (2001) examined neurotrophic and neurotoxic effects of nitric oxide on neuronal enriched fetal midbrain cultures from embryonic Sprague Dawley rats.

López et al. (2001) investigated the release of amino acid neurotransmitters in cultured cortical neurons obtained from gestation day 19 rats by nicotine stimulation.

Ehret et al. (2001) studied the modulation of electrically evoked acetylcholine release in cultured septal neurones from embryonic Wistar rats.

Tang et al. (2001) found a lack of replicative senescence in cultured rat oligodendrocyte precursor cells.

Yamagishi et al. (2001) used cultured rat cerebellar granule neurons as a model system for studying neuronal apoptosis.

Noh and Koh (2000) prepared mixed **mouse** cortical cultures containing both neurons and astrocytes, and pure astrocyte cultures, from fetal (15 d of gestation) and neonatal (1–3 postnatal days) mice.

Ushida et al. (2000) succeeded to directly isolate clonogenic **human** central nervous system stem cells from fresh human brain tissue, using antibodies to cell surface markers and fluorescence-activated cell sorting.

For further studies with brain cell cultures see Sect. F.2.0.10.

E.3.2 *In vivo* methods

E.3.2.1 Electroshock in mice

PURPOSE AND RATIONALE

The electroshock assay in mice is used primarily as an indication for compounds which are effective in grand mal epilepsy. Tonic hindlimb extensions are evoked by electric stimuli which are suppressed by anti-epileptics but also by other centrally active drugs.

PROCEDURE

Groups of 6–10 male NMRI mice (18–30 g) are used. The test is started 30 min after i.p. injection or 60 min after oral treatment with the test compound or the vehicle. An apparatus with corneal or ear electrodes (Woodbury and Davenport 1952) is used to deliver the stimuli. The intensity of stimulus is dependent on the apparatus, e.g. 12 mA, 50 Hz for 0.2 s have been used. Under these conditions all vehicle treated mice show the characteristic extensor tonus.

EVALUATION

The animals are observed closely for 2 min. Disappearance of the hindleg extensor tonic convulsion is used as positive criterion. Percent of inhibition of seizures relative to controls is calculated. Using various doses, ED_{50}-values and 95% confidence interval are calculated by probit analysis.

ED_{50}-values after oral administration are:

- Diazepam 3,0 mg/kg
- Diphenylhydantoin 20,0 mg/kg

CRITICAL ASSESSMENT OF THE METHOD

The electro-shock test in mice has been proven to be a useful tool to detect compounds with anticonvulsant activity.

MODIFICATIONS OF THE METHOD

Cashin and Jackson (1962) described a simple apparatus for assessing anticonvulsant drugs by the electroshock seizure test in mice.

Kitano et al. (1996) developed the increasing-current electroshock seizure test, a new method for assessment of anti- and pro-convulsant activities of drugs in mice. A single train of pulses (square wave, 5 ms, 20 Hz) of linearly increasing intensity from 5 to 30 mA was applied via ear electrodes. The current at which tonic hindlimb extension occurred was recorded as the seizure threshold. The method allows the determination of seizure threshold current for individual animals.

These tests, already described for evaluation of the anticonvulsive activity of anxiolytics, can be used and show activity for anti-epileptics.

Many other agents induce seizures in animals and have been used to test the anticonvulsant activity of drugs (Stone 1972), e.g. glutarimides (Hahn and Oberdorf 1960), pilocarpine (Tursky et al. 1987), methionine sulfoximine (Toussi et al. 1987), *N*-methyl-D-aspartic acid (Leander et al. (1988), γ-hydroxybutyrate (Snead 1988).

Shouse et al. (1989) described mechanisms of seizure suppression during rapid-eye-movement (REM) sleep in cats. Spike-wave paroxysms in the EEG accompanied by bilateral myoclonus of the head and the neck were induced by i.m. injection of 300 000 to 400 000 IU/kg sodium penicillin G.

E.3.2.6 Bicuculline test in rats

PURPOSE AND RATIONALE

Seizures can be induced by the $GAGA_A$-antagonist bicuculline and are antagonized by known anti-epileptics.

PROCEDURE

Female Sprague-Dawley rats are injected i.v. with 1 mg/kg bicuculline. At this dose, a tonic convulsion appears in all treated rats within 30 s after injection. Test compounds are administered orally 1 or 2 h before bicuculline injection. Dose-response curves can be obtained.

EVALUATION

Percentage of protected animals is evaluated. ED_{50}-values and 95% confidence limits are calculated by probit analysis.

CRITICAL ASSESSMENT OF THE METHOD

Like the electroshock test, the bicuculline test is considered to be relatively specific for anti-epileptic activity.

MODIFICATIONS OF THE METHOD

Czuczwar et al. (1985) studied the antagonism of N-methyl-D,L-aspartic acid-induced convulsions by antiepileptic drugs and other agents.

E.3.2.7 4-aminopyridine-induced seizures in mice

PURPOSE AND RATIONALE

The K^+ channel antagonist 4-aminopyridine is a powerful convulsant in animals and in man. The drug read-

ily penetrates the blood-brain barrier and is believed to induce seizure activity by enhancing spontaneous and evoked neurotransmitter release. Although both excitatory and inhibitory synaptic transmission is facilitated by 4-aminopyridine, the epileptiform activity induced by the drug is predominantly mediated by non-NMDA type excitatory amino acid receptors. In mice, parenterally administered 4-aminopyridine induces clonic-tonic convulsions and lethality.

PROCEDURE

Male NIH Swiss mice weighing 25–30 g are allowed to acclimatize with free access to food and water for a 24-h period before testing. Test drugs are administered in various doses intraperitoneally 15 min prior to s.c. injection of 4-aminopyridine at a dose of 13.3 mg/kg which was found to be the LD_{97} in this strain of mice. Controls treated with 4-aminopyridine only exhibit characteristic behavioral signs, such as hyperreactivity, trembling, intermitted forelimb/hindlimb clonus followed by hindlimb extension, tonic seizures, opisthotonus and death. The mean latency to death at the LD_{97} is about 10 min. Groups of 8 mice are used for each dose.

EVALUATION

The percentage of protected animals at each dose is used to calculate ED_{50} values. Phenytoin-like anti-convulsants such as carbamazepine and broad spectrum anticonvulsants such as phenobarbital and valproate are effective whereas GABA-enhancers such as diazepam, several NMDA antagonists, and CA^{2+} channel antagonists such as nimodipine are not.

CRITICAL ASSESSMENT OF THE METHOD

The profile of drugs effective in this seizure model is distinct from other chemoconvulsant models and more similar to those that prevent tonic hindlimb extension in the maximal electroshock seizure test. The test is useful to differentiate the mode of action of anticonvulsant drugs.

MODIFICATIONS OF THE METHOD

Morales-Villagran et al. (1996) described protection against seizures induced by intracerebral or intra-cerebroventricular administration of 4-aminopyridine by NMDA receptor antagonists.

E.3.2.8 Epilepsy induced by focal lesions

PURPOSE AND RATIONALE

Intrahippocampal injections of noxious agents or certain cerebral lesions can induce seizures in animals. Cavalheiro et al. (1982) studied the long-term effects of intrahippocampal kainic acid injections in rats.

PROCEDURE

Adult male Wistar rats are anesthetized with a chloral hydrate/Nembutal® mixture and placed in a stereotactic apparatus. For injections, a 0.3 mm cannula is inserted through a burr hole in the calvarium. The coordinates for hippocampal injections are based on a stereotactic atlas, e.g., Albe-Fessard et al. (1971). Kainic acid is dissolved in artificial serum and infused in various doses (0.1 to 3.0 µg) in a volume of 0.2 µl over a period of 3 min. For recording, bipolar twisted electrodes (100 µm) are positioned stereotaxically and fixed on the skull with dental acrylic cement. Depth recording sites include the dorsal hippocampus and amygdala ipsilateral to the injected side. Surface electrodes are guided from jeweler's screws over the occipital cortex. An additional screw in the frontal sinus serves as indifferent electrode for grounding. Signals are recorded by an EEG polygraph.

EVALUATION

EEG recordings and observations of convulsive seizures are performed during the acute phase and during the chronic phase (up to 2 months) with and without drug treatment.

MODIFICATIONS OF THE METHOD

Several agents have been used as convulsants after topical administration, e.g., application of alumina cream (Kopeloff et al. 1942, 1955; Ward 1972; Feria-Velasco et al. 1980), implantation of cobalt powder (Dow et al. 1962; Fischer et al. 1967), injection of a colloidal gel of tungstic acid (Blum and Liban 1960; Black et al. 1967), topical application of penicillin (Matsumoto and Marsan 1964), subpial injection of saturated $FeCl_3$ solution (Reid et al. 1979; Lange et al. 1980), intracer-

ebral injections of zinc sulfate (Pei et al. 1983), intracerebral injection of antibodies to brain gangliosides (Karpiak et al. 1976, 1981), microinjections of cholinergic agonists (Ferguson and Jasper 1971; Turski et al. 1983), topical application of atropine (Daniels and Spehlman 1973), injection of tetanus toxin into the hippocampus (Mellanby et al. 1984; Hawkins and Mellanby 1987), injection of strychnine in the visual or somatosensory cortex (Atsev and Yosiphov 1969), electrophoretic application of bicuculline from a fluid filled microelectrode (Campell and Holmes 1984).

Bernhard et al. (1955, 1956) evaluated the anticonvulsive effect of local anaesthetics in cats and monkeys. The head was fixed in light Nembutal anaesthesia, the parietal areas exposed and covered with paraffin oil. Stimulating electrodes were placed at the surface of the parietal region. The cortex was stimulated with repetitive square wave shocks (duration 1–3 ms) with a frequency of 25 per s for 5 s. In order to avoid muscular movements, d-tubocurarine was given. Cortical afterdischarge was registered before and after injection of local anaesthetics.

Cortical epileptic lesions were produced by local freezing (Stalmaster and Hanna 1972; Hanna and Stalmaster 1973; Loiseau et al. 1987).

Repetitive electrical stimulation of discrete regions of the central nervous system has been used as a convenient method for reproduction of the ictal phenomena of epilepsy (Marsan 1972; Racine 1972).

Remler and Marcussen (1986), Remler et al. (1986) studied the pharmacological response of systemically derived focal epileptic lesions. A defined area of left hemisphere of rats was radiated by α-particles from a cyclotron destroying the blood brain barrier. After a period of 150 days following irradiation, bicuculline was injected intraperitoneally resulting in focal lesions with EEG spikes and convulsions. Anticonvulsant drugs decreased these effects.

Walton and Treiman (1989) and Walton et al. (1994) described a model of cobalt-lesioned rats in which status epilepticus was induced by injection of homocysteine thiolactone.

Anderer et al. (1993) pointed out that restriction to a limited set of EEG-target variables may lead to misinterpretation of pharmaco-EEG results.

E.3.2.9 Kindled rat seizure model

PURPOSE AND RATIONALE

Kindling, first described by Goddard et al. (1969), results from repetitive subconvulsive electrical stimulation of certain areas of the brain. Initially, local afterdischarge is associated with mild behavioral signs; however, with continued stimulation electrical activity presumably spreads, and generalized convulsions occur. Although the pathogenesis of kindled seizures is not fully understood, it serves as a useful tool for investigating the efficacy of experimental anticonvulsant agents.

PROCEDURE

Adult female Sprague-Dawley rats (270–400 g) are used. The rats are implanted with an electrode in the right amygdala according to the coordinates of Pellegrino et al. (1979): frontal, 7.0; lateral, –4.7; horizontal, 2.5. At least 1 week has to elapse before electrical stimulation of the brain is started. After discharge threshold is determined for each rat. Duration and amplitude, behavioral seizure duration and seizure stage are recorded with increased stimuli afterdischarges. Seizure severity is classified into 5 stages (Racine 1972). Rats are considered to be kindled on the first stimulation causing a stage 5 seizure which is followed by at least 2 consecutive stage 5 seizures.

The animals are tested on the day before and after treatment with the test compound (i.p. or orally). Amygdala stimulation is applied at various time intervals.

EVALUATION

The occurrence and the degree of seizures are compared between control results and the those after administration of the test compound.

CRITICAL ASSESSMENT OF THE METHOD

The kindled seizure model offers an approach to study anticonvulsive drugs on the basis of a pathophysiological model. This method may give more relevant results than the simpler methods using maximal electroshock or chemically induced convulsions.

MODIFICATIONS OF THE METHOD

Generalized convulsive seizures have been induced by daily amygdaloid stimulation in **baboons** (Wada and Osawa 1976), and in **rhesus monkeys** (Wada et al. 1978).

The kindling effect can be produced by intermittent administration of small doses of pentylenetetrazol (Mason and Cooper 1972).

Dürmüller et al. (1994) tested a competitive (NBQX) and a non-competitive (GYKI 52 446) AMPA antagonist, and a competitive NMDA antagonist (D-CPPene) against the development of kindling and against fully kindled seizures in amygdala-kindled rats.

Croucher et al. (1996) described a chemical kindling procedure in rats by daily focal microinjection of NMDA into the right basolateral amygdala and the inhibition of seizures by a NMDA receptor antagonist.

Suzuki et al. (1996) studied the anticonvulsant action of metabotropic glutamate receptor agonists in kindled amygdala of rats.

The kindling procedure can also be used to evaluate antidepressant drugs (Babington 1975).

E.3.2.10
Posthypoxic myoclonus in rats

PURPOSE AND RATIONALE

The syndrome of posthypoxic myoclonus in man was described by Lance and Adams (1963). Lance (1968), Fahn (1986). Troung et al. (1994), Jaw et al. (1994, 1995, 1996) reported on a model in rats resembling this human disorder.

PROCEDURE

Male Sprague Dawley rats fasted 12–24 h prior surgery are anesthetized with 100 mg/kg ketamine i.p., supplemented by 0.4 mg/kg atropine. The animal is placed on a circulating water pad and kept at a constant body temperature by a heating lamp. The rat is intubated and ventilated with 30% O_2 in N_2O. A femoral artery and vein are cannulated for monitoring blood pressure and delivery of drugs, respectively. Electrocardiogram and blood pressure are recorded with a polygraph. The rat is then paralyzed with 2 mg/kg succinlycholine i.v. and ventilator settings are adjusted to a rate of 60 strokes/min and a volume of 7.5 ml/kg, which yields blood gases of >150 mm Hg pO_2, 35–40 mm Hg pCO_2, and a pH of 7.35–7.40. N_2O is replaced with N_2 and an equilibrium period of 5 min is allowed.

Cardiac arrest is accomplished with a trans-thoracic intracardiac injection of KCl and cessation of the respiration. Resuscitation is begun 10 min after the arrest by turning on the ventilator (100% O_2), manual thoracic compressions, and i.v. injections of 20 µg/kg epinephrine hydrochloride and sodium bicarbonate (4 mEq/kg). The rat is then weaned from the ventilator over 2–4 h and extubated.

Auditory-induced myoclonus: Rats are presented with a series of 45 clicks from a metronome (1 Hz, 95 dB, 40 ms), and the response to each click is scored as follows: 0 = no response, 1 = ear twitch, 2 = ear and head jerk, 3 = ear, head, and shoulder jerk, 4 = whole body jerk, 6 = whole body jerk of such severity that it causes a jump. The total myoclonus score of each rat is determined by summing up the scores yielded over 45 clicks.

Since rats ranging from 3 to 14 days post cardiac arrest show similar susceptibility to audiogenic stimulation, animals within this period are used for pharmacological tests. Myoclonus scores are assessed 30 min before and 60 min after intraperitoneal drug application.

EVALUATION

Changes in myoclonus scores are analyzed by paired two-tailed Student's *t*-test.

CRITICAL ASSESSMENT OF THE TEST

Some anticonvulsant drugs, such as clonazepam and valproic acid were reported to be active in this test; however, phenytoin is not. Posthypoxic myoclonus may present a special pathological condition.

E.3.2.11 Genetic animal models of epilepsy

PURPOSE AND RATIONALE

Several animal species exhibit epilepsy with spontaneous recurrent seizures such as dogs, rats, and mice (Löscher 1984). Serikawa and Yamada (1986) described spontaneous epileptic rats which are double mutants and exhibit both tonic and absence-like seizures.

PROCEDURE

Spontaneous epileptic rats are obtained by mating the tremor heterozygous rat (*tm/+*) with the zitter homozygous rat (*zi/zi*) found in a Sprague-Dawley colony. The behavior of the spontaneous epileptic rats is recorded weekly for 2 h on videotapes. The frequency of tonic convulsions and wild jumping occurring in the absence of external stimuli are recorded. Under anesthesia silver ball-tipped and monopolar stainless-steel electrodes are chronically implanted in the left frontal cortex and hippocampus. An indifferent electrode is placed on the frontal cranium. The frequency of absence-like seizures and tonic convulsions, as well as the duration of each seizure, are measured on the EEG. A mild tactile stimulus is given on the back of the animal every 2.5 min to induce consistent tonic convulsions. Compounds are given i.p. or orally.

EVALUATION

The number of seizures and the duration of each seizure are obtained and the total duration of the seizures (number × duration) is calculated every 5 min before and after injection of the drug. Percent changes between values before and after drug administration are calculated.

CRITICAL ASSESSMENT OF THE TEST

Studies in spontaneous epileptic rats and other genetic models are of value for an in depth investigation of a potential anti-epileptic drug.

MODIFICATIONS OF THE METHOD

The **genetically epilepsy-prone rat GEPR-9** has been described by Faingold et al. (1992, 1994) and by Jobe et al. (1992). The inferior colliculus is strongly implicated as a critical initiation site within the neuronal network for audiogenic seizures.

Several other genetic animal models have been described (Löscher and Frey 1984; Löscher and Meldrum 1984) showing epilepsy with spontaneous recurrent seizures, such as

dogs (Cunningham 1971; Edmonds et al. 1979),

rats with petit mal epilepsy (Vergnes et al. 1982), rats with two mutations, zitter and tremor (Serikawa and Yamada 1986; Xie et al. 1990), rats with absence-like states and spontaneous tonic convulsions (Sasa et al. 1988),

tottering mice (Green and Sidman 1962; Noebels 1979; Noebels and Sidman 1979; Fletcher et al. 1966),

leaner mutant mice with severe ataxia and atrophic cerebellum (Herrup and Wilczynnski 1982; Heckroth and Abbott 1994),

the **quaking mouse** (Sidman et al. 1966; Chermat et al. 1981) having deficiencies in myelinization in the nervous system (Hogan 1977; Li et al. 1993; Bartoszewicz et al. 1995) and alterations in the dopaminergic (Nikulina et al. 1995) and α_2-adrenergic (Mitrovic et al. 1992) brain system,

epilepsy with reflex seizures, such as

baboons with photomyoclonic seizures (Killam et al. 1966, 1967; Stark et al. 1970; Naquet and Meldrum 1972; Smith et al. 1991; Chapman et al. 1995),

photosensitive **fowls** (Crawford 1969, 1970),

audiogenic seizure susceptible mice (Collins 1972; Seyfried 1979; Chapman et al. 1984; Stenger et al. 1991),

mechanically stimulated mice (Imaizumi et al. 1959; Oguro et al. 1991),

audiogenic seizure susceptible rats (Consroe et al. 1979; Reigel et al. 1986; Smith et al. 1991; Patel et al. 1990),

gerbils with reflex seizures (Thiessen et al. 1968; Loskota et al. 1974; Majkowski and Kaplan 1983; Bartoszyk and Hamer 1987).

E.4 Hypnotic activity

E.4.0.1 General considerations

The term "hypnotic" has to be defined. In man, the purpose of taking hypnotics is to obtain a "normal" night's sleep from which the patient can be aroused without any subsequent hangover. In animal experiments, the term "hypnotic" has been applied to a much deeper stage of central depression of drug induced unconsciousness associated with loss of muscle tone and of righting reflexes. Therefore, most of the pharmacological models are questionable in regard to their predictivity to find an ideal hypnotic for human therapy. Many of the pharmacological tests are based on the potentiation of sleeping time induced by barbiturates or other sedative agents.

Since the biochemical events during sleep are rather unknown no *in vitro* method exists for testing compounds with potential hypnotic activity.

E.4.1 *In vivo* methods

E.4.1.1 Potentiation of hexobarbital sleeping time

PURPOSE AND RATIONALE

The test is used to elucidate CNS-active properties of drugs. Not only hypnotics, sedatives, and tranquilizers but also antidepressants at high doses are known to prolong hexobarbital induced sleep after a single dose of hexobarbital. The loss of righting reflex is measured as criterion for the duration of hexobarbital-induced sleeping time. Mice are used in this test, since metabolic elimination of hexobarbital is rapid in this species.

PROCEDURE

Groups of 10 male NMRI-mice with an average weight of 18–22 g are used. They are dosed orally, i.p. or s.c. with the test compound or the reference standard (e.g. 3 mg/kg diazepam p.o.) or the vehicle. Thirty min after i.p. or s.c. injection or 60 min after oral dosing 60 mg/kg hexobarbital is injected intravenously. The animals are placed on their backs on a warmed (37 °C) pad and the duration of loss of the righting reflex (starting at the time of hexobarbital injection) is measured until they regain their righting reflexes. Injection of 60 mg/kg hexobarbital usually causes anesthesia for

about 15 min. If there is any doubt as to the reappearance of the righting reflex, the subject is placed gently on its back again and, if it rights itself within one minute, this time is considered as the endpoint.

EVALUATION

Mean values of duration of anesthesia (min) are recorded in control and experimental groups. The percent change in duration of anesthesia is calculated in the experimental groups as compared to those of the controls. ED_{50} values can be calculated. ED_{50} is defined as the dose of drug leading to a 100% prolongation in duration of anesthesia in 50% of the animals.

CRITICAL ASSESSMENT OF THE METHOD

The anxiolytic agents of the benzodiazepine type show an uniform pattern with oral ED_{50} values of less than 1 mg/kg. This is in agreement with the fact that barbiturates also show anxiolytic activity in anti-anxiety tests with animals as well as in patients. Neuroleptics, such as chlorpromazine and haloperidol, also prolong hexobarbital sleeping time in low doses. The test is considered to be unspecific since compounds which inhibit liver metabolism of hexobarbital also prolong time of anesthesia. Balazs and Grice (1963) discussed the relationship between liver necrosis, induced by CCl_4 or nitrosamines, and pentobarbital sleeping time in rats.

OTHER USES OF THE TEST

Hexobarbital sleeping time is not only prolonged by the simultaneous administration of many compounds but also shortened under special conditions. Several CNS-active compounds (analeptics and stimulants like amphetamine and related compounds and methylxanthines) reduce hexobarbital sleeping time. Standard compounds for this kind of procedure are pentylenetetrazol, methamphetamine and aminophylline.

After repeated administrations, induction of metabolic enzymes in the liver is caused by many compounds and leads to an increased destruction of hexobarbital. Due to the accelerated metabolism of hexobarbital, sleeping time is reduced.

MODIFICATIONS OF THE TEST

Instead of hexobarbital, another barbiturate, thiopental can be used which has been proven in clinical use to be a short acting anesthetic. Test compounds or the standard are given 60 min before i.v. injection of 25 mg/kg thiopental to mice with a weight between 18 and 22 g. The animals are placed on their backs and the re-appearance of the righting reflex is observed. The ED_{50} which results in a 100% prolongation in duration of anesthesia is between 2.5 and 4.0 mg/kg diazepam p.o.

Simon et al. (1982) tested the interaction of various psychotropic agents with sleep induced by barbital or pentobarbital in mice. Pentobarbital (50 mg/kg) or barbital (180 mg/kg) were injected i.p. and the latency and duration of sleep (loss of righting reflex) were recorded. The test compound was usually administered i.p. 30 min before the injection of the barbiturate. The test was recommended for detecting sedative or anti-sleep activity. Since pentobarbital is metabolized by the liver whereas barbital is not, a comparative study using the two compounds can be useful for determining whether an eventual potentiation or antagonism can be ascribed to enzymatic inhibition or induction.

Fujimori (1965) recommended the use of barbital-Na instead of hexobarbital for the sleeping time test since barbital is not biotransformed by the liver microsomal system.

E.4.1.2 Experimental insomnia in rats

PURPOSE AND RATIONALE

James and Piper (1978) described a method for evaluating potential hypnotic compounds in rats. Usually, the compounds are tested in normal animals where they do not significantly decrease wakefulness. Footshock induced "insomnia" in rats is proposed as suitable model for insomnia in patients.

PROCEDURE

Male Wistar rats (200–275 g) are prepared for chronic electroencephalographic and electromyographic recordings. Four silver/silver chloride epidural electrodes and two disc nuchal electrodes are implanted. A mini-

mum of 10 days is allowed for recovery from surgery. The animals are placed into sound-attenuated recording chambers with grid floors. The frontal-occipital electroencephalogram and the electromyogram are recorded via nonrestraining recording leads on a polygraph and a tape recorder.

On the control day, the animals are dosed with the vehicle and a control nonstress recording is obtained for 8 h. On the next day, the animals are again injected with the vehicle and then exposed to electric footshocks for 8 h. The footshock is delivered through the grid floor of the recording chamber using the EMG leads as indifferent electrodes, in the form of a 0.5 mA pulse of 15 ms width for 30 s at 1 Hz. During the footshock the EEG and EMG recording circuits are automatically interrupted. The delivery of electric footshock is triggered automatically by two adjustable timers. In this way, each shock period of 30 s is followed by an interval of 30 min. On the next day the rats are dosed with the test compound or the standard and recordings are obtained during a shock session of 8 h.

EVALUATION

The sleep-wake cycle is definitely altered by the stress procedure. The amounts of arousal and of slow wave sleep I are increased, whereas slow wave sleep II and paradoxical sleep are decreased. Phenobarbital and benzodiazepines antagonize these changes at least partially.

CRITICAL ASSESSMENT OF THE METHOD

For screening procedures, the method is too expensive and time-consuming. However, the EEG-parameters in a situation of insomnia similar to men can indicate the usefulness of a new compound.

MODIFICATIONS OF THE METHOD

Gardner and James (1987) described a modified shortened protocol in which a 2.5-h nonstressed control period is followed by drug or vehicle administration and a further 5.5-h recording of the electrocorticogram in the presence of intermittent footshock.

Laval et al. (1991) studied the effect of anxiolytic and hypnotic drugs on sleep circadian rhythms in the rat.

E.4.1.3 EEG registration in conscious cats

PURPOSE AND RATIONALE

The effect of hypnotics on sleep pattern of EEG tracings can be studied in conscious, freely moving cats with chronically implanted electrodes (Heinemann et al. 1970, 1973; Wallach et al. 1976; Hirotsu et al. 1988).

PROCEDURE

Female cats weighing 2.5–3.5 kg are anesthetized and prepared with bipolar subcortical electrodes in the reticular formation (A3, L3, H –1), dorsal hippocampus (A5, L –5, H8), and either amygdala (A12, L –9, H –5), or caudate nucleus (A11, L9.5, H –2). Cortical screw electrodes are placed over the anterior suprasylvian, lateral, medial suprasylvian and ectosylvian gyri. Two Teflon coated steel wires are placed in the cervical neck muscles. All wires are connected to a subminiature socket and implanted in dental acrylic. Cats of this chronic colony are then intermittently utilized for drug experiments at interdrug intervals of at least two weeks.

On experimental days, the cats are taken into an experimental chamber $70 \times 80 \times 80$ cm high. The box is lighted and ventilated with room air at 21 °C. The cat is immediately connected to a cable which exits through the top center of the cage into a mercury swivel. This prevents the cable from becoming twisted and restricting the cat's movement. Recordings of the cortical EEG, cervical neck muscle tone and reticular formation multiple unit activity are obtained. Continuous recordings for up to 96 h are amplified and stored in a recorder. The recordings of cortical EEG, cervical neck muscle tone and reticular formation multiple unit activity are analyzed for REM sleep, slow wave sleep, and wakefulness. Undefined periods which can not be identified either as slow wave sleep or as wakefulness are included in the awake total. Since a first night effect was observed (Wallach et al. 1996) drugs are given at the third or fourth day.

EVALUATION

The data are analyzed by analysis of variance with subjects, days, and drug as factors.

MODIFICATIONS OF THE METHOD

Schallek and Kuehn (1965) measured the effects of benzodiazepines on spontaneous EEG and arousal responses in cats with implanted electrodes.

In addition to EEG and electromyogram, Holm et al. (1991) registered the electro-oculogram in conscious cats.

EEG studies in immobilized cats were performed by Ongini et al. (1982) for evaluation of a benzodiazepine hypnotic. Adult mongrel cats of both sexes were anesthetized with halothane. A tracheal cannula was inserted and artificial respiration was maintained throughout the experiment. The spinal cord was transected at C_2 level (Encephalè isolè preparation). The femoral vein was cannulated for i.v. injection of drugs. Cortical electrodes were inserted into the skull in the frontal, parietal and occipital areas. All incisions were infiltrated with mepivacaine 1% to produce local anes-thesia. The body temperature was maintained at 36.5–38.0 °C by an electrical heat pad. After recovery from surgery and anesthesia, a continuous EEG recording of 2 h was taken prior to drug administration. Test drugs were injected intravenously at various doses. Electrocortical activity was recorded using a 8-channel electroencephalograph. In addition, two electrodes were connected with an EEG-analyzer for the on-line evaluation of the EEG power spectrum. This was computed by the Fast Fourier Transform at a frequency range of 0–32 Hz. Power spectral plots averaging 30 s of electrocortical activity were derived during the experiment.

Shibata et al. (1994) administered various local anesthetics intravenously with constant rates of equipotent doses to cats with implanted electrodes until EEG seizures appeared. During slow rates of infusion, a tetraphasic sequence of changes was found.

Wetzel (1985) evaluated EEG recordings in freely moving **rats** by visual analysis for wakefulness, slow wave sleep or paradoxical sleep.

Krijzer et al. (1991) presented a subclassification of antidepressants based on the quantitative analysis of the electrocorticogram in the rat.

Sarkadi and Inczeffy (1996) described an integrated quantitative electroencephalographic system for pharmacological and toxicological research in the rat. Peak latencies and amplitudes of visual-evoked potentials, occurrence, duration, and linear excursions of photically evoked afterdischarges, activity, mobility, complexity according to Hjorth (1970), and absolute spectral powers of delta, theta, alpha, and beta frequency bands of background activity of visual cortex and frontal-visual leads were measured in freely moving rats.

Rinaldi-Carmona et al. (1992) performed temporal EEG analysis of the sleep-waking cycle in rats with implanted electrodes after administration of a 5-hydroxytryptamine$_2$ receptor antagonist.

Lozito et al. (1994) compared loss of righting with EEG changes in rats with implanted electrodes after single and multiple infusions of fentanyl analogues.

Jones and Greufe (1994) described a quantitative electroencephalographic method in **dogs**.

E.4.1.4 Automated rat sleep analysis system

PURPOSE AND RATIONALE

Ruigt et al. (1988a,b, 1993) described an automated rat sleep classification system in rats which allows classification of psychotropic drugs such as potential antidepressants, antipsychotics and stimulants (Ruigt and von Proosdij 1990; de Boer and Ruigt 1995).

The system records and analyzes bioelectrical signals from several animals over extended periods of time. The analysis is based on 3 signals, the parieto-occipital EEG, nuchal EMG and a movement indicator signal.

PROCEDURE

Epidural screw electrodes are implanted over the parieto-occipital cortex of male rats weighing 250–300 g for the recording of EEG against a frontal electrode. Stainless-steel wire electrodes are inserted in the dorsal neck musculature for recording the electromyogram (EMG). After recovery from surgery animals are separately housed in a light- (12 : 12 h light-dark cycle) and temperature- (21 °C) controlled room. Twenty-nine hour EEG and EMG recordings are made in sound-attenuated Faraday cages from 32 rats simultaneously. Movements of the rats are detected as capacitative artefacts generated in an open-ended wire of the non-restraining flat cable connecting the rats to a swivel commutator and to amplification and A/D conversion units, which are hooked up through a data controller to a dedicated PDP-11/83 minicomputer system for on-line spectral EEG analysis and data compression.

Off-line sleep staging on a micro VAX is done per 2-s epoch based on 5 spectral EEG band values (1.0–3.0, 3.0–6.0, 6.0–9.0, 9.5–20.0, 20.0–45.0 Hz), the integrated EMG level and the movement level. A first sleep stage assignment per epoch is done by application of a discriminant function to these epoch values. The discriminant function is derived from a discriminant analysis of visually classified representative recording segments from different sleep stages recorded during a separate calibration experiment for each rat. A moving average EEG smoothing procedure and a set of syntactic classification rules are then used to give a final sleep stage assignment to each specific EEG epoch.

Six sleep-wake stages are distinguished including 2 waking stages: (1) active waking characterized by movement, theta activity and high EMG, and (2) quiet waking without movement. Four sleep stages are discriminated: (3) quiet sleep, characterized by EEG spindles; (4) deep slow-wave sleep with prominent delta activity; (5) pre-REM sleep with spindles against a background of theta activity and low EMG, and (6) REM sleep with theta activity and low EMG.

Each experiment consists of 32 rats divided over maximally 4 groups, including various drug treatment groups (generally several doses of the same drug) and always one placebo group. Drug administration is done at the beginning of the light cycle of the rats. After each experiment 2–3 weeks are allowed for wash-out. Drug effects on sleep-waking behavior are assessed on several parameters extracted from the hypnogram, among which percentage time spent in each of the sleep stages per 30-min period and per rat. This gives for each compound a profile of changes over sleep stages and over time.

EVALUATION

Sleep stage-dependent and sleep-independent parts of the EEG power spectrum are defined by a procedure originally developed by Fairchild et al. (1969, 1971, 1975). First, a normal canonical discriminant analysis is done on 4 EEG frequency bands (1–3, 3–6, 6–9, 9.5–20 Hz) from representative segments of only 3 visually classified sleep stages (quiet waking, deep sleep and REM sleep), the sleep stage being the dependent variable. This results in 2 sleep stage-dependent canonical variables covering 100% of the variance in the data set and two residual canonical variables which are independent of sleep stage assignment. These 2 residual variables are subsequently used in a second canonical discriminant analysis in which the

presence or absence of the drug is used as the dependent variable, resulting in a single canonical variable (the drug score) associated with the drug effect on the sleep stage-independent variance of the EEG spectral parameters.

CRITICAL ASSESSMENT OF THE METHOD

According to the author's own judgment, antidepressants, antipsychotics and stimulants can be discriminated from each other and from placebo successfully from each other and from placebo by this method, whereas nootropics classified as placebo. Unfortunately, anxiolytics, hypnotics and anticonvulsants are classified poorly.

E.5 Neuroleptic activity

E.5.0.1 General considerations

Neuroleptics have been defined as therapeutics effective against schizophrenia. One has to bear in mind that the effect of certain drugs has not been predicted by pharmacological tests but has been found in clinical trials by serendipity. The clinical discoveries were followed by pharmacological studies in many laboratories (Courvoisier 1956).

Various studies have demonstrated the blockade of postsynaptic catecholamine receptors, especially D_2-receptors to be the main mode of action of most neuroleptics. Several *in vitro* methods measure the receptor blockade by neuroleptics.

Pharmacological models in the development of antipsychotic drugs were reviewed by Costall et al. (1991).

E.5.1 *In vitro* methods

E.5.1.1 D_1 Receptor assay: [^{3}H]-SCH 23390 binding to rat striatal homogenates

PURPOSE AND RATIONALE

Dopamine receptors are the primary targets in the development of drugs for the treatment of schizophrenia, Parkinson's disease and Huntington's chorea (Seeman and Van Tol 1994).

Reviews on dopamine receptors and their subtypes were given by Baldessarini and Tarazi (1996, Missale et al. 1998), and by the NC-IUPHAR subcommittee on dopamine receptors (Schwartz et al. 1998).

Multiple dopamine receptors are known. Two groups are most studied, designated as D_1 and D_2. In the group of D_1-like dopamine receptors the subtypes D_{1A} and D_5/D_{1B} have been described. To D_2-like dopamine receptors belong the D_{2S}, the D_{2L}, the D_3, and the D_4 receptor (Sokoloff et al. 1990; Civelli et al. 1991; Grandy et al. 1991; Van Tol et al. 1991; Lévesque et al. 1992; Baldessarini et al. 1993; Ginrich and Caron 1993; Todd and O'Malley 1993; Waddington and Deveney 1996).

D_1 receptors are positively linked to adenylate cyclase and the D_2 receptor has been shown to be negatively linked to adenylate cyclase. For typical neuroleptic agents, like butyrophenones, a good correlation was found between D_2 receptor binding and clinically effective doses. Atypical neuroleptics, like clozapine, were found to be potent inhibitors of D_1 and D_4 receptor binding, renewing interest in these receptor types. The compound SCH 23390 was found to be selective for the D_1 receptor.

PROCEDURE

Reagents

[N-Methyl-^{3}H] Sch 23 390 (Amersham Lab., specific activity 67–73 Ci/mmol). For IC_{50} determinations, ^{3}H-Sch 23 390 is made up to a concentration of 10 nM and 50 µl is added to each tube. This yields a final concentration of 0.5 nM in the assay.

d-Butaclamol (Ayerst Laboratories). A 1 mM stock solution is made and diluted 1 : 20.

20 µl are added to 3 tubes for the determination of nonspecific binding.

For the test compounds a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assays ranges from 10^{-5} to 10^{-8} M.

Tissue preparation

Male Wistar rats are decapitated, brains rapidly removed, striata dissected and weighed. The striata are homogenized in 100 volumes of 0.05 M Tris buffer, pH 7.7, using a Tekmar homogenizer. The homogenate is centrifuged at 40 000 *g* for 20 min and the final pellet is resuspended in the original volume of 0.05 Tris buffer, pH 7.7, containing physiological ions (NaCl 120 mM, KCl 5 mM, $MgCl_2$ 1 mM and $CaCl_2$ 2 mM).

Assay

50 µl	0.5 M Tris buffer, pH 7.7, containing physiological ions
380 µl	H_2O
20 µl	vehicle or butaclamol or appropriate concentration of test compound
50 µl	^{3}H-SCH 23 390
500 µl	tissue suspension.

The tubes are incubated at 37 °C for 30 min. The assay is stopped by rapid filtration through Whatman GF/B filters using a Brandell cell harvester. The filter strips are then washed 3 times with ice-cold 0.05 M Tris buffer, pH 7.7, and counted in 10 ml Liquiscint scintillation cocktail.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 1 µM d-butaclamol. IC_{50} calculations are performed using log-probit analysis. The percent inhibition at each drug concentration is the average of duplicate determinations.

MODIFICATIONS OF THE METHOD

Wamsley et al. (1992) recommended the radioactive form of a dopamine antagonist, [^{3}H]SCH39 166 as ligand for obtaining selective labeling of D_1 receptors.

Sugamori et al. (1998) characterized the compound NNC 01-0012 as a selective and potent D_{1C} receptor antagonist.

E.5.1.2
D_2 Receptor assay: [^{3}H]-spiroperidol binding

PURPOSE AND RATIONALE

The neuroleptic compound haloperidol has been used as binding ligand to study the activity of other neuroleptics. The use of haloperidol has been superseded by spiroperidol. Dopamine receptor binding assays employing dopaminergic antagonists in mammalian striatal tissue, a dopamine-enriched area of the brain, have been shown to be predictive of *in vivo* dopamine receptor antagonism and antipsychotic activity. Significant correlations exist between neuroleptic binding affinities and their molar potencies in antagonism of apomorphine- or amphetamine-induced stereotypy, apomorphine-induced emesis in dogs, and antipsychotic activity in man. Spiroperidol is considered to be an antagonist specific for D_2 receptors.

PROCEDURE

Tissue preparation

Male Wistar rats are decapitated, their corpora striata removed, weighed and homogenized in 50 volumes of ice-cold 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 40 000 *g* for 15 min. The pellet is rehomogenized in fresh buffer and recentrifuged at 40 000 *g*. The final pellet is then resuspended in Tris buffer containing physiological salts (120 mM NaCl, 5 mM KCl, 2 mM $CaCl_2$ and 1 mM $MgCl_2$) resulting in a concentration of 10 mg/ml.

Assay

The membrane preparations are incubated with ^{3}H-spiroperidol (0.25 nM) and various concentrations of test drug at 37 °C for 20 min in a K/Na phosphate buffer (50 mM, pH 7.2), followed by cooling in an ice bath for 45 min. To determine non-specific binding, samples containing 10 mM (+)-butaclamol are incubated under identical conditions without the test compound.

Bound ligand is separated by rapid filtration through Whatman GF/B glass fiber filters. The filters are washed three times with ice-cold buffer, dried, and shaken thoroughly with 3.5 ml scintillation fluid. Radioactivity is determined in a liquid scintillation counter. Specific binding is defined as the difference between total binding and the binding in the presence of 2.0 mM (+)-butaclamol.

EVALUATION

The following parameters are determined:

- total binding of ^{3}H-spiroperidol
- non-specific binding: binding of samples containing 2 mM butaclamol
- specific binding = total binding – non-specific binding
- % inhibition: 100 – specific binding as percentage of the control value.

IC_{50} values are determined using at least 3–4 different concentrations of the test compound in triplicate. Results are presented as mean ± standard deviation.

Dissociation constants (K_d) are determined, using ^{3}H-spiroperidol concentrations ranging between 0.1 and 1.0 nM. K_i values (inhibitory constants) are calculated using the following equation:

$$K_i = \frac{IC_{50}}{1 + c/K_d}$$

c = ^{3}H-spiroperidol concentrations used to determine IC_{50}

Standard values: K_i of haloperidol = 6.0 ±1.2 nM

MODIFICATIONS OF THE METHOD

Two isoforms of the D_2 receptor were found by alternative splicing: the long (D_{2L}) and the short (D_{2S}) isoform (Dal Toso et al. 1988; Giros et al. 1989; Monsma et al. 1989; Itokawa et al. 1996).

Niznik et al. (1985) recommended [^{3}H]-YM-09 151-2, a benzamide neuroleptic, as selective ligand for dopamine D_2 receptors.

Hall et al. (1985) used [^{3}H]-eticlopride, a substituted benzamide, selective for dopamine-D_2 receptors, for *in vitro* binding studies.

Radioactive ligands for the D_2 and the D_3 receptor were described by Seeman and Schaus (1991), Chumpradit et al. (1994), Booze and Wallace (1995), Gackenheimer et al. (1995), Seeman and van Tol (1995), Van Vliet et al. (1996).

Vessotskie et al. (1997) characterized binding of [^{125}I]S(–)5-OH-PIPAT to dopamine $D_{2\text{-like}}$ receptors.

Neve et al. (1992) used a special apparatus, the 'cytosensor microphysiometer' which measures the rate of proton excretion from cultured cells (McConnell et al. 1991, 1992; Owicki and Parce 1992). In C_6 glioma cells and L fibroblasts expressing recombinant dopamine D_2 receptors, the dopamine D_2 receptor agonist, quinpirole, accelerated the rate of acidification of the medium dose-dependent up to 100 nM quinpirole. The response was inhibited by the D_2 antagonist spiperone. The D_2 receptor stimulated acidification was due to transport of protons by a Na^+/H^+ antiporter which was verified by the inhibition with amiloride or methylisobutyl-amiloride.

Human recombinant dopamine D_{2A} and D_{2B} receptors

Hayes et al. (1992) described functionally distinct human recombinant subtypes of the dopamine D_2 receptor, D_{2A} and D_{2B}.

D_{2A} receptor binding

In a radioligand binding assay the binding of [^{3}H]-spiperone to membranes prepared from COS cells transiently expressing a recombinant human dopamine D_{2A} receptor is measured.

Twenty mg of membrane is incubated with [^{3}H]-spiperone at a concentration of 2.0 nM for 2 h at 25 °C. Non-specific binding is estimated in the presence of 10 mM haloperidol. Membranes are filtered and washed 3 times with binding buffer, and filters are counted to determine [^{3}H]-spiperone bound.

D_{2B} receptor binding

In a radioligand binding assay the binding of [^{3}H]-spiperone to membranes prepared from COS cells transiently expressing a recombinant human dopamine D_{2B} receptor is measured.

Fifteen mg of membrane is incubated with [^{3}H]-spiperone at a concentration of 0.7 nM for 2 h at 37 °C. Nonspecific binding is estimated in the presence of 10 mM haloperidol. Membranes are filtered and washed 3 times with binding buffer, and filters are counted to determine [^{3}H]-spiperone bound.

E.5.1.3 Dopamine D_2 receptor autoradiography (^{3}H-Spiperone binding)

PURPOSE AND RATIONALE

Autoradiography of ^{3}H-spiperone binding sites using selective labeling conditions permits the visualization of the anatomical locations of D_2-dopamine receptors

(Palacios et al. 1981). Quantitative measurements of the binding to receptors can be obtained with computer-assisted video analysis of the autoradiograms with a greater anatomical resolution and sensitivity than in membrane homogenates (Altar et al. 1984, 1985). Using autoradiographic techniques, it has been demonstrated that striatal D_2 receptors are present on intrinsic neurons (Trugman et al. 1986; Joyce and Marshall 1987) and that the distribution of D_2 receptors within the striatum is not homogeneous (Joyce et al. 1985). Anatomically discrete interactions of drugs with D_2 receptors can be examined *in vitro* with inhibition experiments and *ex vivo* following acute or chronic drug treatment of the whole animal.

Since ^{3}H-spiperone labels serotonin-2 (5-HT_2) sites in many brain regions, a masking concentration of a 5-HT_2 receptor blocker, e.g. ketanserin, is included to selectively define binding to D_2 receptors. This is necessary if the test compound inhibits 5-HT_2 binding, or if the brain region of interest has a low D_2 receptor density.

The assay is used to determine potential antipsychotic activity of compounds via direct interaction with the D_2 dopamine recognition site in discrete regions of the rat brain.

PROCEDURE

Reagents

1a. 0.5 M Tris + 1.54 M NaCl, pH 7.4
1b. 0.05 M Tris + 0.154 M NaCl, pH 7.4
2. ^{3}H-spiperone (specific activity 70–90 Ci/mmol) is obtained from Amersham (TRK.818).

   For IC_{50} determinations: ^{3}H-spiperone is prepared at a concentration of 8 nM and 0.55 ml is added to each slide mailer (yields a final concentration of 0.4 nM in the 11.0 ml assay volume).

   For saturation experiments: ^{3}H-spiperone is prepared at a concentration of 20 nM. The final concentrations should range from 0.2–1.0 nM. Typically, six concentrations are used by adding 0.55 ml or less to each mailer (for smaller volumes, add water to bring total addition of 0.55 ml).
3. Sulpiride is obtained from Sigma. A stock solution of 5×10^{-4} M is made by dissolving the sulpiride in 1.0 ml of 0.01 N acetic acid and bringing the final volume to 10 ml with distilled water. 0.22 ml of the stock solution is added to the nonspecific binding slide mailers (final concentration 10 µM). All other mailers receive 0.22 ml of vehicle (1 ml of 0.01 N acetic acid in a final volume of 10 ml with distilled water).
4. Ketanserin (free base or tartrate salt) is obtained from Janssen. A stock solution of 10^{-3} M is made by dissolving the ketanserin in 0.5 ml 1 N acetic acid and bringing the final volume to 10 ml with distilled water. The tartrate salt is water-soluble. This is further diluted to 5×10^{-6} M (50 µl q.s. to 10 ml). 0.22 ml is added to all mailers.
5. Test compounds (for IC_{50} determinations). For most assays, a 5×10^{-3} M stock solution is made up in a suitable solvent and serially diluted, such that the final concentrations in the assay range from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the drug.

Tissue preparation

Rat brain sections are collected from plates 9 (rostral nucleus accumbens) through plate 17 (caudal striatum) of "The Rat Brain Atlas in Stereotaxic Coordinates" by Paxinos and Watson.

1. For *in vitro* inhibition experiments, 3–5 sets of 10 slides are collected with 3–4 sections per slide.
2. For saturation experiments, 3–5 sets of 12 slides are collected with 3–4 sections per slide.
3. For *ex vivo* inhibition experiments, a set of 8 slides is used, 4 for total binding and 4 for nonspecific binding.
4. For experiments in which the tissue sections will be swabbed and counted with scintillation fluid, 2 sections per slide are collected.

Assay

1. Preparation of slide mailers (11.0 ml volume/slide mailer):

   Note: If slides with sections are to be wiped for scintillation counting, a final volume of 6.5 ml is sufficient to cover 2 sections. A proportional adjustment of the volumes to be pipetted is made.

a) *In vitro* inhibition experiments

Separate mailers are prepared for total binding, nonspecific binding and 7–8 concentrations of test compound. Ketanserin is included in all mailers to mask binding of [^{3}H]-spiperone to 5-HT_2 sites so that inhibition of binding is D_2-selective.

5.50 ml	buffer 1b
0.55 ml	buffer 1a
0.55 ml	[^{3}H]-spiperone, 0.4 nM final concentration
3.96 ml	distilled water
0.22 ml	ketanserin, 5×10^{-6} M, final concentration 100 nM or vehicle
0.22 ml	test compound, final concentration 10^{-8}–10^{-5} M or sulpiride 5×10^{-4}, final conc. 10 µM or vehicle

b) *Ex vivo* inhibition experiments

Separate mailers are prepared for total and nonspecific binding, as described above, including ketanserin to mask 5-HT_2 receptor binding.

c) Saturation experiments

Separate mailers are prepared for total and non-specific binding at each radioligand concentration. Ketanserin is not included in the mailers, in saturation experiments, since specific binding is defined as sulpiride-displaceable.

5.50 ml buffer 1b
0.55 ml buffer 1a
0.55 ml [^{3}H]-spiperone, final concentration 0.2–1.0 nM
4.18 ml distilled water
0.22 ml 5×10^{-4} M sulpiride, final concentration 10 µM or vehicle

2. Slides are air-dried for 10–15 min at room temperature, preincubated in 0.05 M Tris + 0.154 M NaCl, pH 7.4 for 5 min and further incubated for 60 min with [^{3}H]-spiperone. Slides are then rinsed with ice-cold solutions as follows: dipped in buffer 1b, rinsed in buffer 1b for 2×5 min, and dipped in distilled water.

Slides used for wipes: both sections are wiped with one Whatman GF/B filter and radioactivity is counted after addition of 10 ml of scintillation fluid.

Slides used for autoradiography: slides are dried under a stream of air at room temperature and are stored in a desiccator under vacuum at room temperature (usually over night). Slides are then mounted onto boards, along with ^{3}H-standards (Amersham RPA 506).

In the dark room under safelight illumination (Kodak GBX-2 filter), slides are exposed to Amersham Hyperfilm or LKB Ultrofilm for 14–17 days.

E.5.1.4 Binding to the D_3 receptor

PURPOSE AND RATIONALE

Sokoloff et al. (1990) reported molecular cloning and characterization of a dopamine receptor (D_3) as a potential target for neuroleptics. The D_3 receptor is localized in limbic areas of the brain which are associated with cognitive, emotional and endocrine functions. Together with the D_{2S}, the D_{2L} and the D_4 receptor, the D_3 receptor belongs to the group of D_2-like dopamine receptors (Ginrich and Caron 1993). 7-[^{3}H]hydroxy-*N*,*N*-di-n-propyl-2-aminotetralin (Lévesque et al. 1992), R(+)-7-OH-DPAT (Baldessarini et al. 1993; and [^{125}I]trans-7-OH-PIPAT-A (Kung et al. 1993) have been recommended as ligands for receptor binding studies.

Chio et al. (1993) compared the heterologously in Chinese hamster ovary cells expressed D_3 dopamine receptors with D_2 receptors.

Damsma et al. (1993) described R-(+)-7-OH-DPAT (R-(+)-7-hydroxy-2-(N,N-di-n-propylamino)tetralin) as a putative dopamine D_3 receptor ligand.

Functional correlates of dopamine D_3 receptor activation in the rat *in vivo* and their modulation by the selective agonist, (+)-S 14 297, have been described by Millan et al. (1995).

Isoforms of the D_3 receptor have been described (Pagliusi et al. 1993).

Akunne et al. (1995) described binding of the selective dopamine D_3 receptor agonist ligand [^{3}H]PD 12 8907 = 4aR,10bR-(+)-trans-3,4,4a,10b-tetrahydro-4-n-propyl-2H,5H-[1]benzopyrano[4,3-b]1,4-oxazin-9-ol.

PROCEDURE

Human dopamine D_3 receptor is expressed in Chinese hamster ovary cells. Cells are grown in Dulbecco's modified Eagle's medium containing 10% fetal bovine serum. Cells are harvested by trypsin treatment (0.25%) for 4–5 min and centrifugation at 2000 *g* for 5 min. They are homogenized with a Polytron in 10 mM Tris-HCl (pH 7.5) containing 1 mM EDTA and are centrifuged at 35 000 *g* for 15 min. The pellet is then resuspended by sonication in a buffer containing 50 mM NaHepes, 1 mM EDTA, 50 µM 8-hydroxyquinoline,

0.005% ascorbic acid, and 0.1% bovine serum albumin (pH 7.5) (incubation buffer). Membrane suspensions (15–25 µg protein) are added to polypropylene test tubes containing [^{3}H]7-OH-DPAT (7-[^{3}H]hydroxy-*N*,*N*-di-n-propyl-2-aminotetralin) for the D_3 receptor assay. Competing drugs are dissolved in incubation buffer, the final volume being 1 ml. Tubes are incubated in triplicate for 1 h at room temperature. The incubations are stopped by rapid filtration under reduced pressure through Whatman GF/C glass filters coated with 0.1% bovine serum albumin, followed by 3 rinses with 3–4 ml ice-cold buffer. Non-specific binding is measured in the presence of 1 µM dopamine.

EVALUATION

Saturation curves are analyzed by computer non-linear regression using a one-site cooperative model to obtain equilibrium dissociation constants (K_D) and maximal density of receptors (B_{max}). Inhibition constants (K_i) are estimated according to the equation

$$K_i = IC_{50} / 1 + L / K_D$$

E.5.1.5 Binding to D_4 receptors

PURPOSE AND RATIONALE

Van Tol et al. (1991) reported cloning of the gene of a human dopamine D_4 receptor with high affinity for the antipsychotic clozapine. Together with the D_{2S}, the D_{2L} and the D_3 receptor, the D_4 receptor belongs to the group of D_2-like dopamine receptors (Ginrich and Caron 1993). Recognition and characterization of this dopamine binding site may be useful in the design of new types of antipsychotic drugs.

Dopamine D_4 receptors have been localized in GABAergic neurons of the primate brain (Mrzljak et al. 1996).

PROCEDURE

A plasmid construct of a 3.9-kb gene-cDNA hybrid subcloned into the expression vector pCD-PS is introduced into COS-7 cells by calcium phosphate mediated transfection. Cells are cultivated and homogenized (Teflon pestle) in 50 mM Tris-HCl (pH 7.4 at 4 °C) buffer containing 5 mM EDTA, 1.5 mM $CaCl_2$, 5 mM KCl, and 120 mM NaCl. Homogenates are centrifuged for 15 min at 39 000 *g*, and the resulting pellets resuspended in buffer at a concentration of 150–250 µg/ml. For saturation experiments, 0.25 ml of tissue homogenate are incubated in duplicate with increasing concentrations of [^{3}H]spiperone (70.3 Ci mmol^{-1}; 10–3 000 pM final concentration) for 120 min at 22 °C in a total volume of 1 ml. For competition binding experiments, assays are initiated by the addition of 0.25 ml membrane and incubated in duplicate with various concentrations

of competing ligands (10^{-14}–10^{-3} M) and [^{3}H]spiperone (150–300 pM) either in the absence or the presence of 200 µM Gpp(NH)p for 120 min at 22 °C. Assays are terminated by rapid filtration through a Titertek cell harvester and filters then monitored for tritium. For all experiments, specific binding is defined as that inhibited by 10 µM (–)sulpiride.

EVALUATION

Both saturation and competition binding data are analyzed by the non-linear least-square curve-fitting program LIGAND run on a suitable PC.

MODIFICATIONS OF THE METHOD

Human recombinant dopamine $D_{4,2}$, $D_{4,4}$, $D_{4,7}$, and D_5 receptors

Van Tol et al. (1992) described multiple dopamine D_4 receptor variants in the human population.

Sunahara et al. (1991) reported the cloning of the gene for a human D_5 receptor.

Human recombinant dopamine $D_{4,2}$ receptor binding

In a radioligand binding assay the binding of [^{3}H]-spiperone to membranes prepared from COS cells transiently expressing a recombinant human dopamine $D_{4,2}$ re-ceptor is measured.

Fifteen µg of membrane is incubated with [^{3}H]-spiperone at a concentration of 0.7 nM for 2 h at 25 °C. Nonspecific binding is estimated in the presence of 10 µM haloperidol. Membranes are filtered and washed 3 times with binding buffer, and filters are counted to determine [^{3}H]- spiperone bound.

Human recombinant dopamine $D_{4,4}$ receptor binding

In a radioligand binding assay the binding of [^{3}H]-spiperone to membranes prepared from COS cells transiently expressing a recombinant human dopamine $D_{4,4}$ receptor is measured.

Twenty-five µg of membrane are incubated with [^{3}H]-spiperone at a concentration of 1.0 nM for 2 h at 25 °C. Nonspecific binding is estimated in the presence of 10 µM haloperidol. Membranes are filtered and washed 3 times with binding buffer, and filters are counted to determine [^{3}H]-spiperone bound.

Human recombinant dopamine $D_{4,7}$ receptor binding

In a radioligand binding assay the binding of [^{3}H]-spiperone to membranes prepared from COS cells transiently expressing a recombinant human dopamine $D_{4,7}$ receptor is measured.

Fifteen µg of membrane is incubated with[^{3}H]-spiperone at a concentration of 0.7 nM for 2 h at 25 °C. Nonspecific binding is estimated in the presence of 10 µM haloperidol. Membranes are filtered and washed 3 times with binding buffer, and filters are counted to determine [^{3}H]-spiperone bound.

Human recombinant dopamine D_5 receptor

In a radioligand binding assay the binding of [^{3}H]SCH 23 390 to membranes prepared from COS cells expressing a recombinant human dopamine D_5 receptor is measured.

Forty µg of membrane is incubated with [^{3}H]SCH 23 390 at a concentration of 2 nM for 2 h at 25 °C. Nonspecific binding is estimated in the presence of 10 µM *cis*-flupentixol. Membranes are filtered and washed 3 times with binding buffer, and filters are counted to determine [^{3}H]SCH 23 390 bound.

Several selective dopamine D_4 antagonists were described: Hikada et al. (1996), Merchant et al. (1996), Rowley et al. (1996), Bristow et al. (1997).

Some radioligands were proposed as being selective for dopamine D_4 receptors: [^{3}H]clozapine (Ricci et al. 1997a,b), [^{3}H]NGD 94-1 (Thurkauf 1997; Primus et al. 1997), RBI-257 (Kula et al. 1997).

E.5.1.6 Determination of dopamine autoreceptor activity

PURPOSE AND RATIONALE

The method describes the procedure to determine if a compound possesses autoreceptor blocking activity without the interference from postsynaptic effects. Striatal DOPA (3,4-dihydroxyphenylalanine), DOPAC (3,4-dihydroxyphenylacetic acid) and DA (dopamine) are quantitated following *in vivo* treatment with drug, apomorphine, gamma butyrolactone and NSD-1015. Antipsychotic compounds that block striatal dopaminergic presynaptic autoreceptors are believed to possess a greater liability for producing EPS.

PROCEDURE

Reagents

1. 0.1 M HCl
2. 1 N NaOH
3. 0.1 M perchloric acid (PCA) containing 4.3 mM EDTA
4. 2 mM solutions of DOPAC, DA and DOPA in 0.1 M HCl, 0.5 ml aliquots are stored at –60 °C until use.
5. Preparation of 2° standard mixture
   10 µM solution of DOPAC, DA and DOPA diluted from reagent 4 with 0.1 M PCA/EDTA);
   The 2° standard solution is used for the preparation of standard curves.
6. Mobile phase/MeOH-buffer (4 : 96, v/v) buffer: 0.012 mM sodium acetate, 0.036 M citric acid and 152 µM sodium octane sulfonate, mobile phase: methanol/buffer (80 ml + 1920 ml) is filtered through a 0.2 µm nylon 66 filter.
7. Preparation of dosing solutions
   a) Apomorphine (2 mg/kg) is prepared in saline containing 1% Tween 80 + 0.1% ascorbic acid to prevent oxidation.
   b) GBL (750 mg/kg) is prepared as a solution in saline containing 1% Tween 80.
   c) NSD-1 015 (100 mg/kg) is prepared as a solution in saline containing 1% Tween 80.

HPLC-Instrumentation

Consists of a

- pump, model SP8 810 (Spectra Physics),
- injector, WISP 710B (Waters Associates),
- detector, 5 100A electrochemical with a 5 011 analytical cell and 5 020 guard cell (ESA),
- integrator, D-2 000 (Hitachi), used as a back-up for the data collection/integrator, CS 9 000 (IBM) system
- analytical column: C18-ODS Hypersil, 3 µm, 100 × 4.6 mm (Shandon)

Tissue Preparation

Following treatment with test drug, rats are sacrificed by decapitation at the pre-determined time. The brain is rapidly removed, the striatum is dissected on ice and frozen on dry ice. The tissue is analyzed by HPLC the same day.

Tissue is homogenized in 500 µl 0.1 M PCA/EDTA. The homogenate is centrifuged for 6 min using a microcentrifuge (model 5 413, Eppendorf). The supernatant is transferred to 0.2 µm microfilterfuge™ tubes and cen-trifuged for 6–8 min as before. The filtrate is transferred to WISP vials. Standards are included every 12–15 samples.

Five µl of the striatum homogenate is injected into the HPLC column.

HPLC flow rate is 1.5 ml/min, run time is 20 min. Helium flow is constant in mobile phase.

For protein analysis, 1.0 ml 1 N NaOH is added to the tissue pellet. The next day, the protein analysis is performed as described by Bradford (1976) using the BioRad assay kit.

EVALUATION

Peak area is used for quantitation. The mg of protein and pmoles of DOPAC, DA and DOPA are calculated from linear regression analyses using the corresponding standard curve. Final data are reported as pmoles/mg protein.

E.5.1.7 Dopamine-sensitive adenylate cyclase in rat striatum

PURPOSE AND RATIONALE

Agonist stimulation of dopamine D_1 receptors leads to increased cAMP formation mediated by a guanine nucleotide-binding regulatory protein. This effect is blocked by selective antagonists like SCH 23 390.

Agonist stimulation of the dopamine D_2 receptor leads to a decreased cAMP formation mediated by a gua-nine nucleotide binding protein. Apomorphine is a potent agonist with full intrinsic activity at D_2 receptors. Phenothiazines block both D_1 and D_2 receptors, whereas butyrophenones and related drugs are very potent antagonists at D_2 receptors.

Studies on cAMP formation may be useful for differentiation of antipsychotic drugs.

PROCEDURE

Tissue preparation

Male Wistar rats are sacrificed by decapitation, the brains removed, and the striata dissected out and weighed. Striatal tissue from 2 rats is homogenized in 25 volumes of ice-cold 0.08 M Tris-maleate buffer, pH 7.4, containing 2 mM EGTA. Protein content of an aliquot is determined. A 50 µl aliquot is used in the cyclase enzyme assay.

Enzyme assay

The following volumes are placed in conical centrifuge tubes kept in an ice-water bath:

200 µl incubation buffer (equal amounts of 0.8 mM Tris-maleate, pH 7.4; 60 mM $MgSO_4$; 100 mM theophylline and 4 mM EGTA)
50 µl 1 mM dopamine HCl or water
25 µl test drug or water
125 µl distilled water
50 µl tissue homogenate

After incubation for 20 min at 0 °C, the enzyme reaction is started by addition of 50 µl of 15 mM ATP solution. The tube rack is placed in a shaking water bath preset at 30 °C for 2.5 min. The reaction is terminated by placing the tube rack in a boiling water bath for 4 min. Then, the tubes are centrifuged at 1 000 *g* for 10 min.

A 25 µl aliquot of the supernatant in each tube is removed and the cAMP determined using a commercial RIA kit (Amersham).

EVALUATION

Results are expressed as pmoles cAMP/mg protein of dopamine stimulated vs. non dopamine stimulated level. Percentage inhibition of this dopamine stimulated level by test drugs is calculated and IC_{50} values determined by log-probit analysis.

E.5.1.8 α_1-adrenergic receptor binding in brain

PURPOSE AND RATIONALE

The use of neuroleptic and antidepressant drugs is sometimes limited by their side effects, such as orthostatic hypotension and sedation. These side effects are attributed to blockade of central and peripheral adrenergic α-receptors. For neuroleptics the ratio between their dopamine antagonistic and their α-receptor antagonistic potencies should be taken into account rather than their absolute α-blocking effect. WB-4 101 is a specific and potent antagonist of the α_1-adreno-receptor, characterized *in vitro* in rat brain, heart, vascular smooth muscle and gastrointestinal smooth muscle.

The *in vitro* [^{3}H]-WB 4 101 receptor binding assay quantitates the α-adrenergic blocking properties of psychoactive agents and is used to assess a compound's potential to cause orthostatic hypotension and sedation as well as primary blood pressure lowering effects through α_1-receptor blockade.

PROCEDURE

Reagents

[Phenoxy-3-^{3}H(N)]-WB 4101 = (2,6-dimethoxyphenoxyethyl)-aminomethyl-1,4-benzodioxane, New England Nuclear, (specific activity 20–35 Ci/mmol).

For IC_{50} determinations [^{3}H]-WB 4 101 is made up to a concentration of 2 nM in Tris buffer and 500 µl is added to each tube (yields a final concentration of 0.5 nM in the 2 ml assay)

L-norepinephrine bitartrate (Sigma Chemical Company). A 800 µM solution is prepared in Tris buffer and 250 µl is added to each of 3 tubes to determine nonspecific binding. This yields a final concentration of 100 µM in the 2 ml assay.

Test compounds: A 80 µM stock solution is made up in a suitable solvent and serially diluted with Tris buffer, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Usually, seven concentrations are studied for each assay.

Tissue preparation

Male Wistar rats (100–150 g) are sacrificed by decapitation. The whole brain minus cerebellum is homogenized in 75 volumes of ice-cold 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 40 000 *g* at 4 °C for 15 min. The supernatant is discarded and the pellet is rehomogenized in fresh Tris buffer and recentrifuged at 40 000 *g* at 4 °C for 15 min. The final pellet is resuspended in the original volume of ice-cold 0.05 M Tris buffer. The final tissue concentration in the assay is 10 mg/ml. Specific binding is approximately 80% of total bound ligand.

Assay

1 200	µl	tissue suspension
500	µl	^{3}H-WB 4 101
250	µl	vehicle (for total binding) or
800	µM	L-norepinephrine bitartrate (for nonspecific binding) or appropriate drug concentration

Sample tubes are kept in ice for additions, then vortexed and incubated for 15 min at 25 °C. The binding is terminated by rapid vacuum filtration through Whatman GF/B filters, followed by three 5 ml washes with ice-cold 0.05 M Tris buffer. The filters are counted in 10 ml of Liquiscint scintillation cocktail.

EVALUATION

Specific WB 4 101 binding is defined as the difference between the total binding and that bound in the presence of 100 µM norepinephrine. IC_{50} calculations are performed using computer-derived log-probit analysis.

E.5.1.9 [^{3}H]Spiroperidol binding to 5-HT$_2$ receptors in rat cerebral cortex

PURPOSE AND RATIONALE

The purpose of this assay is to determine the anti-serotonin activity of neuroleptics, antidepressants and antihypertensive compounds, by measuring the displacement of [^{3}H]spiroperidol from serotonergic antagonist binding sites in cerebral cortical membranes. The regulation of 5-HT$_2$ receptor density by chronic antidepressant treatment is discussed in a separate protocol (see Sect. E.6.1.6).

The receptor binding of serotoninergic sites in the CNS has been investigated using [^{3}H]serotonin (5-HT) (Bennett and Snyder 1976), [^{3}H]LSD (Peroutka and Snyder 1979) and [^{3}H]spiroperidol (Peroutka and Snyder 1979; List and Seeman 1981; Leysen et al. 1978) as the radioligand. Receptor sites have been defined kinetically and classified as 5-HT$_1$ sites (labeled by [^{3}H]5-HT, displaced by agonists) and 5-HT$_2$ sites (labeled by [^{3}H]-spiroperidol and displaced by antagonists). [^{3}H]LSD labels both 5-HT$_1$ and 5-HT$_2$ binding sites (Peroutka and Snyder 1979). Of the brain regions tested, the frontal cerebral cortex contained the greatest density of 5-HT$_2$ binding sites. Lesioning studies indicate that 5-HT$_2$ binding sites are post synaptic and not linked to adenylate cyclase (Peroutka et al. 1979).

The inhibition of 5-HT$_2$ binding correlates with the inhibition of quipazine-induced head twitch, which may reflect decreased behavioral excitation. The physiological and pharmacological role of these receptors is not clear. Although numerous neuroleptics and antidepressants of varying chemical structures are potent inhibitors of 5-HT$_2$ binding, there is no clear-cut relationship to the efficacy of these drugs. Methysergide and cyproheptadine are both potent inhibitors of 5-HT$_2$ binding without having neuroleptic or antidepressant effects. However, potent interaction with 5-HT$_2$ receptors may indicate a reduced potential for catalepsy, since methy-sergide blocks catalepsy induced by haloperidol (Rastogi et al. 1981). The interaction of serotonergic neurons with cholinergic neurons in the striatum (Samanin et al. 1978) may also be decreased by potent 5-HT$_2$ antago-nists. In addition, the ratio of activity at D$_2$ and 5-HT$_2$ re-ceptors may be useful in the screening of atypical antipsychotic agents (Meltzer et al. 1989). Furthermore, it has been shown that ketanserin, a selective 5-HT$_2$ antagonist, is an effective hypotensive agent which blocks peripheral vascular 5-HT receptors.

5-HT$_2$ receptors have been subdivided into 5-HT$_{2A}$, 5-HT$_{2B}$ and 5-HT$_{2C}$ receptors. The new 5-HT receptor classification has been published by the VII. International Union of Pharmacology Classification of Receptors for 5-Hydroxytryptamine (Serotonin) (Hoyer et al. 1994). Further comments were given by Humphrey et al. (1993), Martin and Humphrey (1994), Saxena (1994), Tricklebank (1996).

PROCEDURE

Reagents

1. 0.5 M Tris buffer, pH 7.7
   a) 57.2 g Tris HCl
      16.2 g Tris base
      q.s. to 1 liter (0.5 M Tris buffer, pH 7.7)
   b) Make a 1 : 10 dilution in distilled H_2O
      (0.05 M Tris buffer, pH 7.7)
2. Tris buffer containing physiological ions
   a) Stock buffer

NaCl	7.014 g
KCl	0.372 g
$CaCl_2$	0.222 g
$MgCl_2$	0.204 g

   q.s. to 100 ml in 0.5 M Tris buffer
   b) Dilute 1 : 10 in distilled H_2O
      This yields 0.05 M Tris HCl, pH 7.7; containing NaCl (120 mM), KCl (5 mM), $CaCl_2$ (2 mM) and $MgCl_2$ (1 mM)
3. [Benzene-^{3}H] spiroperidol (20–35 Ci/mmol) is obtained from New England Nuclear. For IC_{50} determinations: ^{3}H-spiroperidol is made up to a concentration of 30 nM in 0.01 N HCl and 50 µl added to each tube (yields a final concentration of 1.5 nM in the 1 ml assay).
4. Methysergide maleate is obtained from Sandoz. Methysergide maleate stock solution is made up to 0.25 mM for determination of nonspecific binding.
   The final concentration in the assay is 5 µM, when 20 µl of the stock solution is added to the reaction tube.
5. Test compounds. For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay and higher or lower concentrations may be used, depending on the potency of the drug.

Tissue preparation

Male Wistar rats are decapitated and the cerebral cortical tissue is dissected, weighed and homogenized in 50 volumes of 0.05 M Tris buffer, pH 7.7 (buffer 1b) with the Brinkman Polytron, then centrifuged at 40 000 *g* for 15 min. The supernatant is discarded and the pellet resuspended and recentrifuged as described above. This pellet is resuspended in 50 volumes of buffer 2b and stored in an ice bath. The final tissue concentration is

10 mg/ml. Specific binding is 7% of the total added ligand and 50% of total bound ligand.

Assay

50 µl 0.5 M Tris-physiological salts (buffer 2a)
380 µl H_2O
20 µl vehicle (for total binding) or 0.25 mM methysergide (for nonspecific binding) or appropriate drug concentration
50 µl [^{3}H]spiroperidol
500 µl tissue suspension

The samples are incubated for 10 min at 37 °C, then immediately filtered under reduced pressure using Whatman GF/B filters. The filters are washed with three 5 ml volumes of ice-cold 0.05 M Tris buffer, pH 7.7 mM methysergide.

EVALUATION

IC_{50} calculations are performed using log-probit analysis. The percent inhibition at each drug concentration is the mean of triplicate determinations.

MODIFICATION OF THE METHOD

The receptor binding properties of the 5-HT_2 antagonist ritanserin were reported by Leysen et al. (1985).

Preclinical characterization of a putative antipsychotic as a potent 5-HT_{2A} antagonist was reported by Kehne et al. (1996).

Using [^{125}I]LSD and [^{3}H]5-HT binding assays Siegel et al. (1996) characterized a structural class of 5-HT_2 receptor ligands.

[^{3}H]Ketanserin has been described as a selective ^{3}H-ligand for 5-HT_2 receptor binding sites. (Leysen et al. 1981).

[^{3}H]RP 62 203, a potent and selective 5-HT_2 antagonist was recommended for *in vivo* labeling of 5-HT_2 receptors (Fajolles et al. 1992).

Other selective 5-HT_2 receptor radioligands were recommended:

[^{125}I]-EIL (radioiodinated D-(+)-N1-ethyl-2-iodolysergic acid diethylamide) (Lever et al. 1991); [^{3}H]-MDL100,907 (Lopez-Gimenez et al. 1998).

E.5.1.10 Serotonin 5-HT$_2$ receptor autoradiography (^{3}H-Spiperone binding)

PURPOSE AND RATIONALE

Autoradiography of ^{3}H-spiperone binding sites with selective labeling conditions permits the visualization of the anatomical locations of 5-HT$_2$ receptors (Palacios et al. 1981; Pazos et al. 1985; Altar et al. (1985). Quantitative measurements of the binding to receptors can be obtained with computer-assisted video analysis of the autoradiograms with a greater anatomical resolution and sensitivity than in membrane homogenates (Pazos et al. 1985; Altar et al. (1984). Using autoradiographic techniques, it has been demonstrated that there is a heterogeneous distribution of 5-HT$_2$ receptors, with much higher levels in telencephalic areas such as the neocortex and the claustrum than in meso- or metencephalic areas. Within the cortex, 5-HT$_2$ receptors are abundant in layers IV and V (Pazos et al. 1985). The high concentration of 5-HT$_2$ receptors in the frontoparietal motor area and the claustrum which connects to the motor cortex and other motor areas suggests a physiological role for 5-HT$_2$ receptors in some motor syndromes (Cadet et al. 1987; Costall et al. 1975; Kostowski et al. 1972). The high affinity of the atypical antipsychotic clozapine for 5-HT$_2$ receptors (Fink et al. 1984; Altar et al1986) and the down-regulation of 5-HT$_2$ receptors following chronic administration of clozapine (Reynolds et al. 1983; Lee and Tang 1984; Wilmot and Szczepanik 1989) suggests that 5-HT$_2$ receptor interaction may be a significant factor in the lack of extrapyramidal side effects and tardive dyskinesias with its clinical use.

Since ^{3}H-spiperone labels α_1-noradrenergic sites in the cerebral cortex, a masking concentration of the α_1-blocker prazosin is included to selectively define binding to 5-HT$_2$ receptors (Morgan et al. 1984). This is necessary if the test compound also inhibits α_1-receptors which may be present in the brain region of interest.

The assay is used to determine the direct interaction of potential antipsychotic compounds with the serotonin-5-HT$_2$ recognition site in discrete regions of the rat brain either *in vitro* or after *ex vivo* treatment of the whole animal.

PROCEDURE

Reagents

1a. 0.5 M Tris + 1.54 M NaCl, pH 7.4
1b. 0.05 M Tris + 0.154 M NaCl, pH 7.4
2. ^{3}H-spiperone (specific activity 70–90 Ci/mmol) is obtained from Amersham.
   - For IC_{50} determinations: ^{3}H-spiperone is made up to a concentration of 20 nM and 0.55 ml is added to each slide mailer (yields a final concentration of 1.0 nM in the 11.0 ml assay volume).
   - For saturation experiments: ^{3}H-spiperone is made up to a concentration of 20 nM. The final concentration should range from 0.5–2.5 nM. Typically, six concentrations are used by adding 0.55 ml or less to each mailer (for smaller volumes, add water to bring total addition of 0.55 ml).
3. Methysergide is used to determine nonspecific binding in brain sections of the frontal cortex.

   Methysergide maleate is obtained from Sandoz. A stock solution of 2.5×10^{-4} M is made by dissolving in distilled water. A volume of 0.22 ml of the stock solution is added to the nonspecific binding slide mailers (final concentration 5 µM). All other mailers receive 0.22 ml of vehicle (1 ml of 0.01 N acetic acid in a final volume of 10 ml with distilled water).

4. Ketanserin is used to determine nonspecific binding in those slide mailers containing sections with the nucleus accumbens and striatum.

   Ketanserin (free base or tartrate salt) is obtained from Janssen. A stock solution of 10^{-3} M is made by dissolving the ketanserin (free base) in 0.05 N acetic acid or the tartrate salt in distilled water. This is further diluted to 5×10^{-6} M (50 µM q.s 10 ml with distilled water). A volume of 0.22 ml is added to the slide mailers to give a final concentration of 100 nM.
5. Prazosin is used to mask α_1-receptors in cortical brain section.

   Prazosin HCl is obtained from Pfizer. A stock solution of 10^{-4} M is made by dissolving prazosin in 0.01 N acetic acid and bringing the final volume to 10 ml with distilled water. This is further diluted to 5×10^{-6} M (100 µM q.s 10 ml). A volume of 0.22 ml is added to those slide mailers to be used for cortical brain sections to give a final concentration of 100 nM.
6. Sulpiride is used to mask D_2 receptor binding in brain sections from the nucleus accumbens and striatum.

   Sulpiride is obtained from Sigma. A stock solution of 10^{-4} M is made by dissolving sulpiride in 1.0 ml of 0.01 N acetic acid and bringing the final volume to 10 ml with distilled water. A volume of 0.22 ml is added to the appropriate slide mailers to give a final concentration of 10 µM.
7. Test compounds (for *in vitro* IC_{50} determinations).

   For most assays, a 5×10^{-3} M stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the drug.

Tissue Preparation

Frontal cortical brain sections are collected from plates 5 through 8 and nucleus accumbens/striatal sections are collected from plates 9 (rostral n. accumbens) through plate 17 (caudal striatum) of "The Rat Brain Atlas in Stereotaxic Coordinates" by Paxinos and Watson.

1. For *in vitro* inhibition experiments, 3–5 sets of 10 slides are collected with 4–5 sections per slide.
2. For saturation experiments, 3–5 sets of 12 slides are collected with 4–5 sections per slide.
3. For *ex vivo* inhibition experiments, a set of 8 slides is used, 4 for total binding and 4 for nonspecific binding.
4. For experiments in which the tissue sections will be swabbed and counted with scintillation fluid, two sections per slide are collected.

Assay

1. Preparation of slide mailers (11.0 ml volume/slide mailer):

   Note: If slides with sections are to be wiped for scintillation counting, a final volume of 6.5 ml is sufficient to cover 2 sections. A proportional adjustment of the volumes to be pipetted is made.

a) *In vitro* inhibition experiments

   Separate mailers are prepared for total binding, nonspecific binding and 7–8 concentrations of test compound.

   1. For frontal cortical brain sections, prazosin is included in all mailers to mask the binding of [^{3}H]-spiperone to α_1-receptors and nonspecific binding is defined with 5 µM methysergide.
      - 5.50 ml buffer 1b
      - 0.55 ml buffer 1a
      - 0.55 ml [^{3}H]-spiperone, 1.0 nM final concentration
      - 3.96 ml distilled water
      - 0.22 ml prazosin 5×10^{-6} M, final concentration 100 nM or vehicle
      - 0.22 ml test compound, final concentration 10^{-8}–10^{-5} M or methysergide 2.5×10^{-4} M, final concentration 5 µM or vehicle
   2. For brain sections with the nucleus accumbens and striatum in which there is negligible binding of [^{3}H]-spiperone to α_1-receptors, prazosin is not included. Since levels of 5-HT_2 receptors in these brain areas are low, 10 µM sulpiride is included in all mailers to mask the binding of [^{3}H]-spiperone to D_2 receptors.

      Ketanserin, final concentration of 100 nM, is used to determine nonspecific binding since methysergide has a weak affinity for D_2 receptors (IC_{50} approximately 1–5 µM).
      - 5.50 ml buffer 1b
      - 0.55 ml buffer 1a
      - 0.55 ml [^{3}H]-spiperone, 1.0 nM final concentration
      - 3.96 ml distilled water
      - 0.22 ml sulpiride 5×10^{-4} M, final concentration 10 µM or vehicle
      - 0.22 ml test compound, final concentration 10^{-8}–10^{-5} M or ketanserin 5×10^{-5} M final concentration 100 nM or vehicle

b) *Ex vivo* inhibition experiments

   Separate mailers are prepared for total and nonspecific binding, as described above, including sulpiride to mask D_2 receptor binding with brain sections through the nucleus accumbens and striatum and prazosin to mask α_1-receptors in cortical brain sections.

c) Saturation experiments

Separate mailers are prepared for total and nonspecific binding at each radioligand concentration. Prazosin is not included in the mailers in saturation experiments, since specific binding is defined by methysergide which has negligible affinity for α_1-receptors.

5.50 ml buffer 1b
0.55 ml buffer 1a
0.55 ml [^{3}H]-spiperone, final concentrations 0.5–2.5 nM
4.18 ml distilled water
0.22 ml 2.5×10^{-4} M methysergide, final concentration 5 µM or vehicle

2. Slides are air-dried for 10–15 min at room temperature, preincubated in 0.05 M Tris + 0.154 M NaCl, pH 7.4 for 5 min and further incubated for 60 min with [^{3}H]-spiperone. Slides are then rinsed with ice-cold solutions as follows: dipped in buffer 1b, 2×5 min rinsed in buffer 1b, dipped in distilled water.

Slides used for wipes: both sections are wiped with one Whatman GF/B filter and radioactivity is counted after addition of 10 ml of scintillation fluid.

Slides used for autoradiography: slides are dried under a stream of air at room temperature and are stored in a desiccator under vacuum at room temperature (usually overnight). Slides are then mounted onto boards, along with ^{3}H-standards (Amersham RPA 506).

In the dark room under safelight illumination (Kodak GBX-2 filter), slides are exposed to Amersham Hyperfilm or LKB Ultrofilm for 14–17 days.

E.5.1.11 Binding to the sigma receptor

PURPOSE AND RATIONALE

Sigma receptors, as a class of binding sites in the brain, were originally described as a subtype of the opiate receptors. Efforts to develop less addicting opiate analgesics led to the study of several benzomorphan derivatives which produce analgesia without causing the classical morphine-induced euphoria. Unfortunately, these compounds, like N-allylnormetazocine (SKF 10,047) produced a variety of psychotic symptoms. This psychotomimetic effect is thought to be mediated by sigma receptors. This binding site is sensitive to many neuroleptics, most notably the typical antipsychotic haloperidol, leading to the hypothesis that drug interactions with the sigma site may be a new approach for the discovery of novel antipsychotics which are not dopamine receptor antagonists. D_2 receptor antagonism is thought to be linked with the occurrence of extrapyramidal symptoms in the form of hyperkinesia and Parkinson symptoms or tardive dyskinesia limiting the therapeutic use of traditional antipsychotic medication. It is hoped that ligands to the sigma receptor do not produce these adverse reactions. The sigma site is believed to be distinct from the binding site for the psychotomimetic drug phencyclidine.

PROCEDURE

Reagents

(+)-SKF 10,047 is prepared as a stock solution of 5×10^{-3} M with distilled water. 130 µl added to the 6.5 ml assay yields a final concentration of 10^{-4} M.

^{3}H-(+)-SKF 10,047 (specific activity 40 Ci/mmol) is obtained from New England Nuclear. A 200 nM stock solution is made up with distilled water for IC_{50} determinations. 325 µl added to each tube yields a final concentration of 10 nM in the 6.5 ml assay.

Test compounds

A 5 mM stock solution is prepared in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M.

Tissue preparation

The assay utilizes slide-mounted cross-sections of brain tissue from male Hartley guinea pigs. Whole brain sections of 10 µm thickness are obtained from the hippocampus, thaw-mounted onto gel-chrome alum subbed slides, freeze-dried and stored at –70 °C until use. On the day of the assay, the sections are thawed briefly at room temperature until the slides are dry and then used in the assay at a final volume of 6.5 ml.

Assay

Incubation solutions are prepared in plastic slide mailer containers as follows:

3.250 ml 0.05 M Tris buffer, pH 7.7
2.470 ml distilled water
0.325 ml 0.5 M Tris buffer, pH 7.7
0.130 ml (+)-SKF 10,047 or vehicle
0.325 ml [^{3}H](+)-SKF 10,047

Dried slides with tissue sections are added to the slide mailers and incubated at room temperature for 90 min. Non-bound radioligand is removed by rinsing the slides sequentially in two 5-min rinses in ice-cold 0.05 M Tris buffer and a dip in ice-cold distilled water. The sections are either swabbed with Whatman GF/B filters for scintillation counting of tissue-bound radioligand or exposed to tritium-sensitive film for autoradiography of the binding sites.

EVALUATION

Specific binding is determined from the difference of binding in the absence or presence of 10^{-4} M (+)-SKF 10,047 and is typically 60–70% of total binding. IC_{50} values for the competing drug are calculated by log-probit analysis of the data.

MODIFICATIONS OF THE METHOD

[^{3}H]-(+)-pentazocine has been recommended as a highly potent and selective radioligand for µ receptors (de Costa et al. 1989; DeHaven-Hudkins et al. 1992).

Classification of sigma binding sites into σ_1 and σ_2 receptors has been proposed (Walker et al. 1990; Quirion et al. 1992; Abou-Gharbia et al. 1993).

E.5.1.12 Simultaneous determination of norepinephrine, dopamine, DOPAC, HVA, HIAA, and 5-HT from rat brain areas

PURPOSE AND RATIONALE

To measure the effects of potential antipsychotic drugs on catecholamines and indols, a quantitative method for the determination of norepinephrine (NE), dopamine (DA), 3,4-dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA), 5-hydroxyindolacetic acid (5HIAA) and 5-hydroxytryptamine (5-HT) from rat brain regions is used. These catecholamines and indols are measured in rat brain prefrontal cortex, nucleus accumbens and striatum.

PROCEDURE

Reagents

1. 0.1 M HCl
2. 1 N NaOH
3. 2 mM solutions of NE, DOPAC, DA, HVA, 5HIAA and 5-HT in 0.1 M HCl;
   0.5 ml aliquots are stored at –60 °C until use.
4. Preparation of 2° Standard Mixture
   - 10 µM solution of NE, DOPAC, DA, HVA, 5HIAA and 5-HT (diluted from reagent 3) in mobile phase (reagent 5)
   - the 2° Standard solution is used for the preparation of standard curves.
5. Mobile phase/MeOH: buffer (7.5 : 92.5, v/v)
   - buffer: 0.07 M sodium acetate, 0.04 M citric acid, 130 µM EDTA and 230 µM sodium octane sulfonate
   - mobile phase: methanol/buffer (150 ml + 1 850 ml) is filtered through a 0.2 µm nylon 66 filter

HPLC-Instrumentation

- pump, model SP8 810 (Spectra Physics),
- injector, WISP 710B (Waters Associates),
- detector, 5 100A electrochemical with a 5 011 analytical cell and 5 020 guard cell (ESA),
- integrator, D-2 000 (Hitachi), used as a back-up for the data collection/integrator, CS 9 000 (IBM) system,
- analytical column: C18-ODS Hypersil, 3 µm, 100 × 4.6 mm (Shandon)

Animal treatment

Six rats per group (150–250 g) are dosed with 4–5 different concentrations of the putative antipsychotic drug; usual concentrations range from 0.03 to 30 mg/kg. At a predetermined time, usually 60 min, the rats are sacrificed.

Tissue preparation

Following treatment with test drug, rats are sacrificed by decapitation. The brain is rapidly removed and placed on ice. The striatum, nucleus accumbens and/or prefrontal cortex are dissected and placed in 1.5 ml microcentrifuge tubes. The tubes are capped and immediately placed in dry ice. The frozen brain sections are stored at –60 °C until HPLC analysis.

Tissue is homogenized in mobile phase (striatum: in 600 µl, nucleus accumbens and prefrontal cortex: in 300 µl). The homogenates are centrifuged for 6 min using a microcentrifuge (model 5 413, Eppendorf). The supernatants are transferred to 0.2 µm microfilterfuge™ tubes and centrifuged for 6–8 min as before. The filtrate is transferred to WISP vials. Standards are included every 12–15 samples.

The following volumes are injected to the HPLC column:

- striatum: 5 µl; nucleus accumbens: 20 µl; prefrontal cortex: 50 µl.
- HPLC flow rate is 1.0 ml/min, run time is 25 min. Helium flow is constant in mobile phase.

For protein analysis, 1 N NaOH is added to the tissue pellets as follows:

- striatum: 1.0 ml;
- nucleus accumbens and prefrontal cortex: 0.5 ml.

The next day, the protein analysis is run in duplicate with 5 µl of striatum. 20 µl of nucleus accumbens and prefrontal cortex as described by Bradford (1976) using the BioRad assay kit.

EVALUATION

Peak area is used for quantitation. The mg of protein and pmoles of NE, DOPAC, DA, HVA, 5HIAA and 5-HT are calculated from linear regression analysis using the corresponding standard curve. Final data are reported as pmoles/mg protein.

E.5.1.13 Measurement of neurotransmitters by intracranial microdialysis

PURPOSE AND RATIONALE

Methods to measure neurotransmitters and their metabolites in specific areas of the brain by microdialysis were introduced by Ungerstedt and his group (Ungerstedt et al. 1982; Zetterström et al. 1982, 1983; Zetterström and Ungerstedt 1983; Ungerstedt 1984; Stähle et al. 1991; Lindefors et al. 1989; Amberg and Lindefors (1989) and by Imperato and di Chiara 1984, 1985). In brain dialysis, a fine capillary fibre is implanted in a selected brain area. Low molecular weight compounds diffuse down their concentration gradients from the brain extracellular fluid into a physiological salt solution that flows through the capillary fibre at a constant rate. The fluid is collected and analyzed.

PROCEDURE

Several designs of dialysis probes have been used (Santiago and Westerink 1990; Kendrick 1991):

1. Horizontal probe

A straight tube (Vita Fiber, 3×50 Amicon) with an outer diameter of 0.34 mm and a molecular weight cut-off of 50 000 is used. The outer surface of the tube is porous and can easily be sealed by epoxy which is applied by passing the tube through a droplet of epoxy and then through a narrow hole corresponding to the outer diameter of the tube. The wall of the tube is sealed in this way except for the area where the dialysis is intended to take place. The length of this region can be varied from 2 to 8 mm depending upon which structure of the brain will be perfused. During the coating and all other handling of the tube it is supported by a thin tungsten or steel wire inserted into its lumen. One end of the tube is glued into a steel cannula (6 mm long, outer diameter 0.64 mm).

Male Sprague Dawley rats weighing 250–300 g are anesthetized with halothane and held in a stereotactic instrument. The animals are maintained under halothane anesthesia during the entire experiment.

Holes are drilled bilaterally (5.7 mm below and 1.5 mm in front of bregma) in the temporal bones after the temporal muscles have been retracted from the bones and folded away.

During the implantation, the cannula is held by the micromanipulator of the stereotactic instrument and the dialysis tube is passed horizontally through the brain through the holes drilled on both sides of the skull. A polyethylene tubing carrying the perfusion fluid is connected to the steel cannula. The perfusate is collected at the other end.

2. Loop probe

The probe is made of a flexible cellulosic tubing (Dow 50, outer diameter 0.25 mm). Both ends of the tube are inserted into 0.64 mm diameter steel tubes, one of which is bent in an angle. A very thin microsuture (0.1 mm in diameter) is inserted into the tube and positioned half between the steel tubes. Before implantation, the tube is moistened and bent in such a way that the two steel tubes are held closely together in the micromanipulator of the stereotactic instrument. A tungsten wire is inserted into the straight steel tube and passed down the lumen of the dialysis tube in order to stretch it and make it rigid enough to be implanted into the brain. The tube is implanted vertically and the steel cannulae are attached to the skull by dental cement. The tungsten wire is removed before starting the experiment. The cellulosic tube is flexible enough to withstand the bending at the lower end. The microsuture keeps the bend open.

Loop-shaped or U-shaped microdialysis probes have been used by several authors, e.g., Ichikawa and Meltzer (1990), Jordan et al. (1994), Westerink and Tuinte (1986), Auerbach et al. (1995).

3. Vertical probe

The probe is sealed at one end by epoxy. The other end is glued into a 0.64-mm diameter steel tube. A thin inner cannula made of a steel tube or a glass capillary carries the fluid to the bottom of the dialysis tube where it leaves the inner capillary and flows upwards and leaves the probe by a lateral tube. This vertical probe can also be coated with epoxy. It is especially suited for reaching ventral parts of the brain and performing dialysis in small nuclei of the brain.

A similar device has been described for continuous plasma sampling in freely moving rats by Chen and Steger (1993).

Most of the commercially available microdialysis probes are based on this principle.

4. Commercially available microdialysis probes

The microdialysis probes CMA/10, manufactured by Carnegie Medicine, Stockholm, Sweden, consist of a tubular membrane (polycarbonate; length: 3 mm; outside diameter: 0.50 mm; and inside diameter: 0.44 mm) glued to a cannula (outside diameter: 0.60 mm), and sealed with a glue at the tip (Stähle et al. 1991). The perfusion medium is carried to the dialyzing part of the probe by a thin cannula inside the probe. The medium leaves the inner cannula through two holes, flows back between the membrane and the inner cannula, and is collected at the outlet of the probe. The perfusion medium is delivered by means of a high precision micro-syringe pump.

This probe was used by several authors, e.g., Wood et al. (1988), Benveniste et al. (1989), Rollema et al. (1989), Scheller and Kolb (1991), Wang et al. (1993), Kreiss and Lucki (1995), Fink-Jensen et al. (1996).

CMA/11 probes were used by Boschi et al. (1995), Romero et al. (1996), Gobert et al. (1997).

Dialysis fibres with a semipermeable membrane AN 69-HF, Hospal-Dasco, Bologna, Italy, were used by de Boer et al. (1994), Rayevsky et al. (1995), Arborelius et al. (1996), Gainetdinov et al. (1996), Tanda et al. (1996).

EVALUATION

Samples of the dialysate are collected for different time intervals and analyzed for neurotransmitters. For the **evaluation of neuroleptics**, most authors measured dopamine, 3,4-dihydroxyphenyl acetic acid (DOPAC) and homovanillinic acid (HVA) by HPLC using appropriate detectors. See and Lynch (1996) analyzed dialysis samples for glutamate and GABA concentrations.

For the **evaluation of antidepressants** the concentrations of 5-hydroxytryptamine (5-HT), 5-hydroxy indole acetic acid (5-HIAA), dopamine (DA), dihydroxyphenylacetic acid (DOPAC), or noradrenaline (NA) were measured in the effluent by HPLC. Wood et al. (1988), Egan et al. (1996) used 3-methoxytyramine accumulation as an index of dopamine release.

CRITICAL ASSESSMENT OF THE METHOD

The results obtained from brain dialysis depend on at least three variables: type of probe, post-implantation interval, and whether anesthetized or freely moving animals are used (Di Chiara 1990).

Several authors analyzed the diffusion processes underlying the microdialysis technique and described the limitations of the experiments (Jacobson et al. 1985; Amberg and Lindefors 1989; Beneviste et al. 1989; Scheller and Kolb 1991; Le Quellec et al. 1995).

As a matter of fact, brain microdialysis has been used for the evaluation of many drugs in various indications, such as:

- for **neuroleptics** by Ichikawa and Meltzer 1990; Meil and See 1994; Hernandez and Hoebel 1994; See et al. 1995; Schmidt and Fadayel 1995; Semba et al. 1995; Rayevsky et al. 1995; Fink-Jensen et al. 1996; See and Lynch 1996; Gainetdinov et al. 1996; Egan et al. 1996; Klitenick et al. 1996,
- for **antidepressants** by de Boer et al. 1994; Jordan et al. 1994; Arborelius et al. 1995; Ascher et al. 1995; Auerbach et al. 1995; de Boer 1995, 1996; Casanovas and Artigas 1996; Gobert et al. 1995; Ichikawa and Meltzer 1995; Kreiss and Lucki 1996; Petty et al. 1996; Potter 1996; Romero et al. 1995; Sharp et al. 1996; Tanda et al. 1996a,b,
- for studies in **Parkinson** models by Rollema et al. 1989; Parsons et al. 1991.

MODIFICATIONS OF THE METHOD

Ferrara et al. (1990) continuously monitored ethanol levels in the brain by microdialysis.

Hernandez and Hoebel (1994) performed simultaneous cortical, accumbens, and striatal microdialysis in freely moving rats.

Hegarty and Vogel (1995) assayed dopamine, DOPAC and HVA in the brain of rats after acute and chronic diazepam treatment and immobilization stress.

Casanovas and Artigas (1996) implanted microdialysis probes simultaneously in six different brain areas of rats (frontal cortex, dorsal striatum, ventral hippocampus, dorsal hippocampus, dorsal raphe nucleus, median raphe nucleus).

Beneviste et al. (1984) determined extracellular concentrations of glutamate and aspartate in rat hippoc-

ampus during transient cerebral ischemia monitored by intracerebral microdialysis.

Boschi et al. (1995) showed that microdialysis of small brain areas in mice is feasible using the smallest commercially available probes.

E.5.1.14
Use of push-pull cannulae to determine the release of endogenous neurotransmitters

PURPOSE AND RATIONALE

Originally reported by Gaddum (1961), the push-pull cannula has become recognized and utilized as a powerful tool in conjunction with sufficiently sensitive assays to measure low levels of neuroregulator release in distinct brain areas *in vivo*. (Philippu 1984).

This method has been used for various purposes, e.g., to perfuse the ventricles of the brain with drugs, or to determine the release of labelled or endogenous compounds in the CSF (Bhattacharya and Feldberg 1958; Korf et al. 1976),

to perfuse distinct brain areas with drugs and to study their effects on functions of the central nervous system (Myers et al. 1976; Bhargava et al. 1978; Ruwe and Myers 1978),

to inject labelled monoamines or amino acids and to investigate the resting or induced release of radioactive compounds and their metabolites (Sulser et al. 1969; Strada and Sulser 1971; Kondo and Iwatsubo 1978),

to perfuse distinct brain areas with labelled transmitter precursors and to determine the patterns of release of the newly synthesized transmitters (Philippu et al. 1974; Chéramy et al. 1977; Nieoullon et al. 1977; Gauchy et al. 1980),

to perfuse distinct brain areas of anesthetized and conscious animals and to determine the release of endogenous neurotransmitters in the perfusate (Dluzen and Ramirez 1991).

PROCEDURE

The superfusion of the hypothalamus of the conscious, freely moving rabbit has been described by Philippu et al. (1981), Philippu (1984). Rabbits of both sexes are anesthetized with 40 mg/kg sodium pentobarbital i.p. Guide cannulae are mounted on a metal plate which is fixed on the skull with screws and dental cement. Some days after the operation, the guide cannulae are replaced with push-pull cannulae which are 4 mm longer than the guide cannulae, thus reaching the areas which are intended for superfusion. The push-pull cannulae are connected by tubing to two peristaltic pumps: one to push and another one to pull the fluid. The second pump is essential, because the superfusate is not directly collected from the side branch of the push-pull cannula, but from tubing which is connected to the side branch. The superfusate is automatically collected every 10 s in fraction collectors.

EVALUATION

The concentrations of neurotransmitters, e.g., epinephrine, norepinephrine, or dopamine are determined with appropriate analytical methods (Wolfensberger 1984) before and after stimulation.

MODIFICATIONS OF THE METHOD

Experiments in cats were described by Dietl et al. (1981), in rats by Tuomisto et al. (1983).

The cortical cup technique for collection of neurotransmitters has been described by Moroni and Pepeu (1984).

E.5.1.15 Fos protein expression in brain

PURPOSE AND RATIONALE

The proto-oncogene c-fos encodes a 55 000 mol wt, 380 amino-acid phosphoprotein (FOS) which, after translation in the cytoplasm, re-enters the nucleus and binds to DNA (Morgan and Curran 1989). C-fos induction can occur as a consequence of synaptic activation. An increase in fos immunoreactivity is associated with an increased metabolic demand on a neuron, i.e., a marker for neurons that are metabolically activated. Intermediate early genes such as c-fos have been tentatively classified or linked to third messengers, whose function is to produce a long-term effect on the recipient neuron.

Acute administration of antipsychotics induces c-fos expression in several areas of the rat forebrain as was shown with immunocytochemical methods (Dragunow et al. 1990; Nguyen et al. 1992; Robertson and Fibiger 1992; MacGibbon et al. 1994). Fos protein is believed to act as an initiator of long-term cellular changes (neural plasticity) in response to a variety of extracellular stimuli, including drugs (Graybiel et al. 1990; Rogue and Vicendon 1992). Typical (e.g. haloperidol) and atypical (e.g. clozapine) neuroleptic drugs have different antipsychotic effects and side-effects. A differential FOS-protein induction in rat forebrain regions after haloperidol and clozapine treatment was found (Deutch et al. 1992; Fibiger 1994; Fink-Jensen and Kristensen 1994; Merchant et al. 1994; Sebens et al. 1995). The induction pattern of Fos-like immunoreactivity in the forebrain could serve as predictor of atypical antipsychotic drug activity (Robertson et al. 1994).

PROCEDURE

Groups of 4–6 male Wistar rats weighing 350–450 g are injected subcutaneously with saline (control) or with various doses of the standard drugs or compounds with putative antipsychotic activity. After two hours, the animals are deeply anesthetized by intraperitoneal injection of 100 mg/kg pentobarbital and perfused with 200 ml saline followed by 200 ml of 4% paraformaldehyde in phosphate buffer solution (PBS). Each brain is removed immediately after perfusion and placed in fresh fixative for at least 12 h.

After the postfixative period, 30-µm sections are cut from each brain using a vibratome. Several antisera to detect Fos can be used, such as a sheep polyclonal antibody directed against residues 2 to 16 of the N-terminal region of the Fos molecule, or a polyclonal antiserum raised in rabbits against Fos peptide (4–17 amino acids of human Fos).

Sections are washed 3 times with 0.02 mM PBS and then incubated in PBS containing 0.3% hydrogen peroxide for 10 min to block endogenous peroxidase activity. Sections are then washed 3 times in PBS and incubated in PBS containing 0.3% Triton X-100, 0.02% azide and Fos primary antisera (diluted 1 : 200) for 48 h. The sections are then washed 3 times with PBS and incubated with a biotinylated rabbit antisheep secondary antibody (diluted 1 : 200) for 1 h. The sections are washed three times with PBS and incubated for 1 h with PBS containing 0.3% Triton X-100 and 0.5% avidin-biotinylated horseradish peroxidase complex. After 3 washes in PBS the sections are rinsed in 0.1 M acetate buffer, pH 6.0. Fos immunoreactivity is revealed by placing the sections in a solution containing 0.05% 3,3'-diaminobenzidine, 0.2% ammonium nickel sulfate and 0.01% H_2O_2. The reaction is terminated with a washing in acetate buffer. The sections are mounted on chrome-alum-coated slides, dehydrated and prepared for microscopic observation.

Drug induced changes in Fos-like immunoreactivity are quantified by counting the number of immunoreactive nuclei in the medial prefrontal cortex, nucleus accumbens, medial and dorsolateral striatum and the lateral septal nucleus. The number of Fos-positive nuclei are counted with a 550×550 µm grid placed over each of these regions with a 100× magnification.

Typical and atypical antipsychotics can be classified on the basis of difference between Fos-like immunoreactivity in the nucleus accumbens and lateral striatum. For this purpose, the data are corrected for the effects which are produced by the injection procedure itself. The injection corrected value for the dorsolateral striatum is subtracted from the corresponding accumbal value for each drug dose.

This manipulation yields a value termed the atypical index, i.e. number of Fos-positive neurons in the nucleus accumbens minus the number in the lateral striatum = atypical index. A negative index indicates the probability of side-effects, like extrapyramidal syndrome, exerted by the typical neuroleptics, a positive value to be devoid of it.

EVALUATION

A one-way analysis of variance is performed on the cell count data for each dose and the corresponding vehicle control. If the analysis of variance is significant, multiple comparisons are performed by using the Newman-Keuls test.

MODIFICATIONS OF THE METHOD

Graybiel et al. (1990) reported a drug-specific activation of c-fos gene in striosome-matrix compartments and limbic subdivisions of the striatum by amphetamine and cocaine.

Deutch et al. (1991) found that stress selectively increases Fos protein in dopamine neurons innervating the prefrontal cortex.

Gogusev et al. (1993) described modulation of C-fos and other proto-oncogene expression by phorbol diester in a human histiocytosis DEL cell.

Deutch et al. (1995) studied the induction of Fos protein in the thalamic paraventricular nucleus as locus of antipsychotic drug action.

E.5.1.16 Neurotensin

E.5.1.16.1 General considerations on neurotensin and neurotensin receptors

Neurotensin is a 13 amino acid peptide originally isolated from calf hypothalamus (Carraway and Leeman 1973). It is secreted by peripheral and neuronal tissues and produces numerous pharmacological effects in animals suggesting **analgesic** (Coguerel et al. 1988; Clineschmidt and McGuffin 1977; Smith et al. 1997), **cardiovascular** (Carraway and Leeman 1973; Schaeffer et al. 1998; Seagard et al. 2000), **hypothermic** (Bissette

et al. 1976; Benmoussa et al. 1996; Tyler-McMahon et al. 2000), and **antipsychotic** (Nemeroff 1986; Sarhan et al. 1997; Feifel et al. 1999; Kinkead et al. 1999; Cusack et al. 2000) actions. Neurotensin is even considered to be an endogenous neuroleptic (Ervin and Nemeroff 1988; Gully et al. 1995). Radke et al. (1998) studied synthesis and efflux of neurotensin in different brain areas after acute and chronic administration of typical and atypical antipsychotic drugs.

Neurotensin affects **gastrointestinal functions**, such as stimulating growth of various gastrointestinal tissues (Feurle et al. 1987), modulation of pre- and postprandial intestinal motility (Pellissier et al. 1996), inhibiting gastric acid secretion (Zhang et al. 1989a), inducing contractile responses in intestinal smooth muscle (Unno et al. 1999), maintaining gastric mucosal blood flow during cold water restraint (Zhang et al. 1989b; Xing et al. 1998).

Neurotensin acts as a **growth factor** on a variety of normal and cancer cells (Wang et al. 2000).

Like other neuropeptides, neurotensin is synthesized as part of a larger precursor which also contains neuromedin N, a six amino acid neurotensin-like peptide belonging to the gastrin-releasing peptide/bombesin family (see J.3.1.8).

Several peptidic and non-peptidic neurotensin agonists and antagonists have been synthesized and analyzed in pharmacological tests as potential drugs mainly in psychopharmacology (Gully et al. 1995, 1996, 1997; Azzi et al. 1996; Castagliuolo et al. 1996; Chapman and See 1996; Mule et al. 1996; Hong et al. 1997; Johnson et al. 1997; Sarhan et al. 1997; Betancur et al. 1998; Gudasheva et al. 1998; Schaeffer at al 1998). Furthermore, inhibitors of neurotensin-degrading enzymes were described (Bourdel et al. 1996).

E.5.1.16.2 Neurotensin receptor binding

PURPOSE AND RATIONALE

Neurotensin interacts with two cloned receptors that were originally differentiated on the basis of their affinity to the antihistaminic drug levocabastine (Schotte et al. 1986). The high sensitive, levocabastine-insensitive rat neurotensin receptor (*NTR1*) was cloned first (Tanaka et al. 1990) and shown to mediate a number of peripheral and central neurotensin responses, including the neuroleptic-like effects of the peptide (Labbé-Jullié et al. 1994). The human NTR1 has been cloned from the colonic adenocarcinoma cell line HT29 (Vita et al. 1993) and shown to consist of a 416 amino acid protein that shares 84% homology with rat NTR1. A second human NTR1 receptor differing only in one amino acid has been cloned from substantia nigra by Watson et al. (1993).

The lower-affinity, levocabastine-sensitive neurotensin receptor (*NTR2*) was cloned by Chalon et al. (1996), Mazella et al. (1996) and characterized by Yamada et al. (1998). Studies by Dubuc et al. (1999) indicate that NTR2 mediates neurotensin-induced analgesia.

A third neurotensin receptor (*NTR3*) was cloned from a human brain cDNA library (Mazella et al. 1998). It is identical with sortilin, a receptor-like protein, cloned from human brain (Petersen et al. 1997, 1999). The NT3/gp95/sortilin protein is a transmembrane neuropeptide receptor which does not belong to the superfamily of G-protein-coupled receptors.

Gully et al. (1997) described a binding assay for the neurotensin1 receptor.

PROCEDURE

Cell culture

CHO cells transfected with cDNA of the human neurotensin receptor cloned from HT 29 cells (h-NTR1-CHO cells) are cultured at 37 °C in modified Eagles medium without nucleosides, containing 10% fetal calf serum, 4 mM glutamine and 300 µg/ml geneticin (G418), in a humidified incubator under 5% CO_2 in O_2. The colonic adenocarcinoma HT 29 cell line (American Type Culture Collection, Rockville, MD) is cultured under similar conditions in Dulbecco's modified Eagle's medium/F-12 medium supplemented with 10% fetal calf serum, 4 mM glutamine, 200 IU/ml penicillin and 200 mg/ml streptomycin. One week after seeding, confluent monolayer cultures are washed three times with 3 ml PBS and harvested by enzymatic dissociation with trypsin. After dilution with PBS, cells are resuspended in the same culture medium at a density of 5×10^4 cells/ml and are plated into 35-mm-diameter, fibronectin-coated Petri culture dishes.

Membrane homogenate preparation and binding assay

Whole brains of male Sprague-Dawley rats albino guinea pigs or cell pellets are homogenized in 10 volumes of ice-cold 50 mM Tris-HCl buffer (pH 7.4) for 30 s, using a Polytron homogenizer (setting 5). After 20 min centrifugation at 30000*g*, the pellet is washed, centrifuged again under the same conditions, resuspended in a storage buffer containing 50 mM Tris-HCl

(pH 7.4), 1 mM EDTA, 0.1% BSA, 40 mg/liter bacitracin, 1 mM 1,10-orthophenanthroline and 5 mM dithiothreitol and stored as aliquots in liquid nitrogen until used.

Aliquots of membranes (10, 50, 300 and 500 µg of protein for h-NTR1-CHO cells, HT 29 cells, rat and guinea pig brain, respectively) are incubated for 20 min at 20 °C in the incubation buffer (0.5 ml final volume) containing appropriate concentrations of [^{125}I-Tyr^3]neurotensin (25–100 pM) and unlabeled drugs. After incubation, the assay medium is diluted with 4 ml of ice-cold 50 mM Tris-HCl buffer (pH 7.4) supplemented with 0.1% BSA and 1 mM EDTA, and the mixture is rapidly filtered under reduced vacuum through Whatman GF/B glass fibre filters that have been pretreated with 0.1% polyethyleneimine. The filters are washed under the same conditions three times and radioactivity is measured. Nonspecific binding is determined in the presence of 1 µM unlabeled neurotensin. All experiments are performed in triplicate, and data are expressed as the mean ±SEM of at least three separate determinations.

EVALUATION

The IC_{50} is the value of ligand that inhibits 50% of the specific binding and is determined using an iterative nonlinear regression program (Munson and Rodbard 1980).

MODIFICATIONS OF THE METHOD

Cusack et al. (1995) studied species selectivity of neurotensin analogs at the rat and two human NTR1 receptors.

Le et al. (1997) cloned the human neurotensin receptor gene and determined the structure.

Labbé-Jullié et al. (1998) attempted to identify residues in the rat NTR1 that are involved in binding of a nonpeptide neurotensin antagonist.

Souazé et al. (1997), Najimi et al. (1998) studied the effects of a neurotensin agonist and showed in human colonic adenocarcinoma HT 29 cells after short incubation an increase, after prolonged exposure a decrease of mRNA levels and in the human neuroblastoma cell line CHP 212 a high affinity neurotensin receptor gene activation.

Ovigne et al. (1998) described a monoclonal antibody specific for the human NTR1.

Nouel et al. (1999) found that both NT2 and NT3 neurotensin receptor subtypes were expressed by cortical glial cells in culture.

Cusack et al. (2000) developed a neurotensin analog, NT34, that can distinguish between rat and human neurotensin receptors, and exhibits more than a 100-fold difference in binding affinities.

Neuromedin N, a peptide belonging to the gastrin-releasing peptide/bombesin family (see J.3.1.7) shows a high affinity to brain neurotensin receptors and is rapidly inactivated by brain synaptic peptidases (Checler et al. 1990).

E.5.2 Behavioral tests

E.5.2.1 Golden hamster test

PURPOSE AND RATIONALE

"Innate behavior" of many species including man has been described by Lorenz (1943, 1966). The "Golden-hamster-test" (Ther, Vogel and Werner 1959) uses the innate behavior of this species (*Mesocricetus auratus*) for differentiation between neuroleptic and sedative – hypnotic activity. The aggressive behavior of male golden hamsters is suppressed by neuroleptics in doses which do not impair motor function.

PROCEDURE

Ten to 20 male golden hamsters with an average weight of 60 g are crowded together in Makrolon$^{(R)}$ cages for at least 2 weeks. During this time the animals develop a characteristic fighting behavior. For the test single animals are placed into glass jars of 2 liters. In this situation the hamsters assume a squatting and resting position during the day. If the animals are touched with a stick or a forceps they wake up from their daytime sleep and arouse immediately from the resting position. If one tries to hold the hamster with a blunted forceps, a characteristic behavior is elicited: The hamster throws himself onto his back, tries to bite and to push the forceps away with his legs, and utters angry shrieks. Touching the animals is repeated up to 6 times followed by punching with the forceps. Only animals responding to the stimulus with all three defense reactions (turning, vocalizing, biting) are included into the test.

The test compounds are applied either subcutaneously, intraperitoneally, or orally. Six animals are used for each dose.

EVALUATION

The stimuli are applied every 20 min for 3 h. The number of stimuli until response is recorded. Furthermore, the suppression of the defense reactions (turning, biting and vocalizing) is evaluated. An animal is regarded to be completely "tamed", if all defense reactions are suppressed even after punching with the forceps at least once during the test period.

After each stimulation the "tamed" animal is placed on an inclined board with 20 degree inclination. Normal hamsters and hamsters tamed by neuroleptics are able to support themselves or to climb on the board. Impaired motor function causes sliding down. This experiment is repeated three times after each testing of the defense reactions. An animal's coordination is considered to be disturbed if it falls three times during two tests of the experiments.

For each dose the number of tamed hamsters and the number of animals with impaired motor function is recorded. Using different doses, ED_{50} values can be calculated for the taming effect and for impairment of motor function.

The ED_{50} values of taming were 1.5 mg/kg for chlorpromazine s.c. and 0.2 mg/kg for reserpine s.c. Much higher doses (10 times of chlorpromazine and 5 times of reserpine) did not elicit motor disturbances. On the

contrary, while ED_{50} values of 10 mg/kg phenobarbital s.c. and 180 mg/kg meprobamate p.o. for the taming effect were found, these doses already caused severe motor disturbances. The taming dose of diazepam was 10 mg/kg p.o. which already showed some muscle relaxing activity. The term "neuroleptic width" indicates the ratio between the ED_{50} for taming and the ED_{50} for motor disturbances. Only for neuroleptic drugs are ratios found between 1 : 5 and 1 : 30.

CRITICAL ASSESSMENT OF THE METHOD

The method has the advantage that neuroleptics can easily be differentiated from sedative and hypnotic drugs. Anxiolytics with pronounced muscle relaxing activity also show no significant differences between taming and impaired motor function. Moreover, the method has the advantage that no training of the animals and no expensive apparatus is needed.

E.5.2.2 Influence on behavior of the cotton rat

PURPOSE AND RATIONALE

The "cotton-rat test" is another attempt to use the innate behavior as described for several animal species by Lorenz (1943, 1966) for the differentiation of psychotropic drugs (Vogel and Ther 1960). The cotton rat (*Sigmodon hispidus*) is a very shy animal which conceals himself at any time. This innate flight reflex is suppressed by centrally active drugs. Simultaneous evaluation of motor function allows the differentiation between neuroleptic and sedative drugs.

PROCEDURE

Cotton rats are bred in cages equipped with a clay cylinder of 20 cm length and 10 cm diameter. This cylinder is used by the animals for hiding, sleeping and breeding. Moreover, the animals which bite easily can be transported from one cage to another just by closing the cylinder on both ends. For the test young animals with a body weight of 40 g are used. Young animals are as shy as old ones but less vicious. Nevertheless, leather gloves have to be used for handling of cotton rats. Normal cages ($25 \times 30 \times 20$ cm) with a wire lid are used. A tunnel of sheet metal (half of a cylinder) 20 cm long and 7 cm high is placed into the cage. The cotton rats hide immediately in this tunnel. If the tunnel is lifted and placed on another site of the cage, the cotton rats immediately hide again.

Three rats are placed in one cage and tested for their behavior. Selective shaving of the fur enables the observer to recognize each animal. If the rats behave as described, they are then treated with the test compound subcutaneously or orally. At least 6 animals divided in two cages are used for each dose of test compound or standard. Fifteen min after application of the drug the test period of three h is started. The tunnel is lifted and placed to another site. If the animals do not show the immediate flight reflex an airstream of short duration is blown through the wire lid. If the animal still does not respond with the flight reflex it is considered to be positively influenced. Afterwards, the animal is placed on an inclined board with 35 degree of inclination and tested for disturbance of motor coordination. A normal animal is able to climb upwards. If coordination is disturbed the rat slides down.

EVALUATION

The test procedure is repeated every 15 min over a period of 3 h. The animals which show at least one suppression of the flight reflex during the test period are counted as well as those who slide down on the inclined board. Using different doses ED_{50} values are calculated for both parameters. The ratio between these two ED_{50} values is regarded as "neuroleptic width" which is 1 : 20 for chlorpromazine and 1 : 30 for reserpine whereas ratios of 1 : 2 for phenobarbital and 1 : 1.5 for meprobamate indicate the absence of neuroleptic activity.

CRITICAL ASSESSMENT OF THE METHOD

The method allows the differentiation of drugs with neuroleptic activity against other centrally active drugs. No training of the animals and no expensive equipment are necessary.

E.5.2.3 Artificial hibernation in rats

PURPOSE AND RATIONALE

Giaja (1938, 1940, 1953, 1954) studied the effects of reduced oxygen tension and cold environment on rats. The animals were placed in hermetically closed glass vessels which were submerged in ice-water. Due to the respiratory activity, the oxygen tension diminishes and the carbon dioxide content increases. Under the influence of cooling and of hypoxic hypercapnia, the rectal temperature falls to 15 °C and the animal is completely anesthetized and immobilized. The rat can survive in this poikilothermic state for more than twenty hours. Complete recovery occurs after warming up. This kind of artificial hibernation was augmented by chlorpromazine (Courvoisier et al. 1953; Giaja and Markovic-Giaja 1954). Vogel (1959), Ther et al. (1959, 1963) used these observations for evaluation of neuroleptics and opioid analgesics.

PROCEDURE

Male Wistar rats weighing 100–150 g are deprived of food with free access to tap water overnight. The test compounds are injected subcutaneously 15 min prior to the start of the experiment. First, the rats are placed in ice-cold water to which surfactant is added in order to remove the air from the fur for 2 min. Then, the animals are placed into hermetically closed glass vessels of 750 ml volume which are placed into a refrigerator at 2 °C temperature. During the following hour, the vessels are opened every 10 min for exactly 10 s allowing some exchange of air and reducing the carbon dioxide accumulation. At each time, animals are removed from the glass vessel and observed for signs of artificial hibernation which are not shown by control animals under these conditions. Treated animals, lying on the side, are placed on the back and further examined. An animal is considered positive, when it remains on the back, even if the extremities are stretched out. In this state, cardiac and respiration frequency are reduced and the rectal temperature has fallen to 12–15 °C. The rigor of the musculature allows only slow movements of the extremities. The animals recover completely within a few hours if they are brought to their home cages at room temperature. Artificial hibernation is induced dose-dependent by neuroleptics of the phenothiazine type and by some opioid analgesics like meperidine and methadone. In contrast, morphine shows only slight activity.

EVALUATION

Various doses are applied to groups of 10 animals. Percentage of positive animals is calculated for each group and ED_{50} values with confidence limits are estimated according to Litchfield and Wilcoxon.

E.5.2.4 Catalepsy in rodents

PURPOSE AND RATIONALE

Catalepsy in rats is defined as a failure to correct an externally imposed, unusual posture over a prolonged period of time. Neuroleptics which have an inhibitory action on the nigrostriatal dopamine system induce catalepsy (Costall and Naylor 1974; Chermat and Simon 1975; Sanberg 1980) while neuroleptics with little or no nigrostriatal blockade produce relatively little or no cataleptic behavior (Honma and Fukushima 1976). Furthermore, cataleptic symptoms in rodents have been compared to the Parkinson-like extrapyramidal side effects seen clinically with administration of antipsychotic drugs (Duvoisin 1976).

PROCEDURE

Groups of 6 male Sprague-Dawley or Wistar rats with a body weight between 120 and 250 g are used. They are dosed intraperitoneally with the test drug or the standard. Then, they are placed individually into translucent plastic boxes with a wooden dowel mounted horizontally 10 cm from the floor and 4 cm from one

end of the box. The floor of the box is covered with approximately 2 cm of bedding material. White noise is presented during the test. The animals are allowed to adapt to the box for 2 min. Then, each animal is grasped gently around the shoulders and under the forepaws and placed carefully on the dowel. The amount of time spent with at least one forepaw on the bar is determined. When the animal removes its paws, the time is recorded and the rat is repositioned on the bar. Three trials are conducted for each animal at 30, 60, 120 and 360 min.

EVALUATION

An animal is considered to be cataleptic if it remains on the bar for 60 s. Percentage of cataleptic animals is calculated. For dose-response curves, the test is repeated with various doses and more animals. ED_{50} values can be calculated. A dose of 1 mg/kg i.p. of haloperidol was found to be effective.

CRITICAL ASSESSMENT OF THE METHOD

The phenomenon of catalepsy can be used for measuring the efficacy and the potential side effects of neuroleptics.

MODIFICATIONS OF THE METHOD

Extrapyramidal syndromes after treatment with typical and atypical neuroleptics were measured in nonhuman primates (Cebus monkeys) by Casey (1989, 1991, 1993), Gerlach and Casey (1990).

E.5.2.5 Pole climb avoidance in rats

PURPOSE AND RATIONALE

The pole-climb avoidance paradigm is an avoidance-escape procedure used to separate neuroleptics from sedatives and anxiolytics. Whereas sedative compounds suppress both avoidance and escape responding at approximately the same doses, neuroleptic drugs reduce avoidance responding at lower doses than those affecting escape responding (Cook and Catania 1964).

PROCEDURE

Male rats of the Long-Evans strain with a starting body weight of 250 g are used. The training and testing of the rats is conducted in a $25 \times 25 \times 40$ cm chamber that is enclosed in a dimly lit, sound-attenuating box. Scrambled shock is delivered to the grid floor of the chamber. A 2.8-kHz speaker and a 28-V light are situated on top of the chamber. A smooth stainless-steel pole, 2.5 cm in diameter, is suspended by a counterbalance weight through a hole in the upper center of the chamber. A microswitch is activated when the pole is pulled down 3 mm by a weight greater than 200 g. A response is recorded when a rat jumps on the pole and activates the microswitch. The rat can not hold the pole down while standing on the grid floor because of the counterbalance tension and can not remain on the pole any length of time because of its smooth surface. The activation of the light and the speaker together are used as the conditioning stimulus. The conditioning stimulus is presented alone for 4 s and then is coincident with the unconditioned stimulus, a scrambled shock delivered to the grid floor, for 26 s. The shock current is maintained at 1.5 mA. A pole climb response during the conditioned stimulus period terminates the conditioned stimulus and the subsequent conditioned and unconditioned stimuli. This is considered an avoidance response. A response during the time when both the

conditioned and unconditioned stimuli are present terminates both stimuli and is considered an escape response. Test sessions consist of 25 trials or 60 min, whichever comes first. There is a minimum intertrial interval of 90 s. Any time remaining in the 30 s allotted to make the pole climb is added to the 90 s intertrial interval. Responses during this time have no scheduled consequences; however, rats having greater than 10 intertrial interval responses should not be used in the experiment. Before testing experimental compounds, rats are required to make at least 80% avoidance responses without any escape failures.

EVALUATION

Data are expressed in terms of the number of avoidance and escape failures relative to the respective vehicle control data. ED_{50} values can be calculated using different doses.

E.5.2.6 Foot-shock induced aggression

PURPOSE AND RATIONALE

The test as described by Tedeschi et al. (1959) using mice which fight after foot-shock induced stimulation is useful to detect neuroleptics but also shows positive effects with anxiolytics and other centrally effective drugs. The method has been used by several authors to test drugs with neuroleptic activity. The test is described in Sect. E.2.3.1.

E.5.2.7 Brain self stimulation

PURPOSE AND RATIONALE

In several species, electrical stimulation of selected brain loci produces effects which are positively reinforcing and pleasurable (Olds and Milner 1954; Olds 1961, 1972). Most of the data available have been obtained from experiments using rats with electrodes chronically implanted in the median forebrain bundle at the level of hypothalamus. Minute electrical pulses sustain a variety of operant behaviors such as lever pressing. Neuroleptics have been shown to be potent blockers of self stimulation (Broekkamp and Van Rossum 1975; Koob et al. 1978; Gallistel and Freyd 1987). Conversely, compounds that facilitate catecholaminergic transmission such as d-amphetamine and methylphenidate, will increase responding for such stimulation.

PROCEDURE

Male Wistar rats (350–400 g) are anesthetized with 50 mg/kg pentobarbital i.p. and their heads placed on a level plane in a Kopf stereotactic instrument. A midline incision is made in the scalp and the skin held out of the way by muscle retractors. A small hole is drilled in the scull with a dental burr at the point indicated by the stereotactic instrument for the structure it is desired to stimulate. Using bregma as a reference point, the electrode (Plastic Products # MS303/1) is aimed at the medium forebrain bundle according to the atlas of Paxinos and Watson (1986), using the coordinates of AP = –0.8 mm, Lat = +2.8 mm, and DV = –7.2 mm below dura. The assembly is then permanently affixed to the scull using stainless steel screws and bone cement.

After a minimum of 10 days for recovery, the animals are trained to bar press for electrical stimulation on a continuous reinforcement schedule in a standard operant box outfitted with a single lever. The reward stimulus is a train of biphasic square-wave pulses generated by a Haer stimulator (Pulsar 4i). The parameters are set at a pulse duration of 0.5 ms with 2.5 ms between each pulse pair. The train of pulses may vary between 16 and 30/s, and the intensity of the pulses that are delivered range from 0.1 to 0.5 mA using the lowest setting that will sustain maximal responding. After consistent baseline responding is obtained for 5 consecutive 30 min sessions, the animals are ready for testing with standard agents. Compounds are administered 60 min prior to testing. All data are collected on both cumulative recorders and counters.

EVALUATION

The number of drug responses are compared to the number of responses made during each animal's 30 min control session on the preceding day, which is considered to be equal to 100%. Testing various doses, ED_{50} values with 95% confidence limits can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

Since there is sufficient evidence that self-stimulation behavior is maintained by catecholamines the method gives indirectly insight into the catecholaminergic facilitating or blocking properties of a compound. Active neuroleptic drugs inhibit the self-stimulation behavior in very small doses. The relative potency observed in this test of clinically efficacious drugs parallels their potency in the treatment of schizophrenia.

MODIFICATIONS OF THE METHOD

Reinforcing brain stimulation by electrodes placed in the medial forebrain bundle of rats is decreased after lesion of the internal capsule in the region of the diencephalic-telencephalic border. This decrement in rewarding processing can be reversed by antidepressant drugs (Cornfeldt et al. 1982).

Depoortere et al. (1996) used electrical self stimulation of the ventral tegmental area to study the behavioral effects of a putative dopamine D_3 agonist in the rat.

Anderson et al. (1995) examined the interaction of aversive and rewarding stimuli in self stimulating rats in terms of duration and direction. The rats were implanted with two moveable electrodes, one in a region supporting self-stimulation (the ventral tegmental area) and another in a region supporting escape (the nucleus reticularis gigantocellularis).

E.5.3 Tests based on the mechanism of action

E.5.3.1 Amphetamine group toxicity

PURPOSE AND RATIONALE

It is well known that aggregation of mice in small cages greatly enhances the toxicity of amphetamine. The death rate can be reduced by pretreatment with neuroleptics.

This phenomenon is generally accepted as an indicator of neuroleptic activity. The increased toxicity results from increased behavioral activation due to aggregation inducing an increase of circulating catecholamines. The mechanism can be understood by the fact that amphetamine is an indirectly acting sympathomimetic amine that exerts its effects primarily by releasing norepinephrine from storage sites in the sympathetic nerves. After administration of high doses of amphetamine, mice exhibit an elevated motor activity which is highly increased by aggregation. This increased behavioral activation is followed by death within 24 h in 80–100% of control animals. Neuroleptics reduce this death rate. In contrast, non-neuroleptic sympatholytics and psychosedative agents like the barbiturates do not produce a dose-related protection. Moreover, anxiolytic agents like benzodiazepines are also found to be ineffective in the prevention of amphetamine group toxicity.

PROCEDURE

Ten male mice of the NMRI-strain are used for each group. They are dosed with the test compound or the standard either orally or intraperitoneally and all placed in glass jars of 18 cm diameter. Untreated animals serve as controls. The test has to be performed at room temperature of 24 °C. Thirty min after i.p. or 1 h after oral administration the mice receive 20 mg/kg d-amphetamine subcutaneously. The mortality is assessed 1, 4 and 24 h after dosing.

EVALUATION

The mortality of amphetamine only treated animals is at least 80%. If less than 80% die due to low ambient temperature the test has to be repeated. The estimation of ED_{50} values for protection and their confidence limits are calculated by probit analysis of the data using the number of dosed vs. the number of surviving animals. Doses of 10 mg/kg chlorpromazine p.o. and 1 mg/kg haloperidol have been found to be effective.

CRITICAL ASSESSMENT OF THE METHOD

The amphetamine group toxicity test has been used by many investigators and has been found to be a reliable method for detecting neuroleptic activity.

E.5.3.2 Inhibition of amphetamine stereotypy in rats

PURPOSE AND RATIONALE

Amphetamine is an indirect acting sympathomimetic agent which releases catecholamines from its neuronal storage pools. In rats the drug induces a characteristic stereotypic behavior. This behavior can be prevented by neuroleptic agents.

PROCEDURE

Groups of 6 Wistar rats with a body weight between 120 and 200 g are used. They are injected simultaneously with d-amphetamine (10 mg/kg s.c.) and the test compound intraperitoneally and than placed individually in stainless-steel cages ($40 \times 20 \times 18$ cm). The control groups receive d-amphetamine and vehicle. Stereotypic behavior is characterized by continuous sniffing, licking or chewing and compulsive gnawing. The animals are observed 60 min after drug administration. An animal is considered to be protected, if the stereotypic behavior is reduced or abolished.

EVALUATION

The percent effectiveness of a drug is determined by the number of animals protected in each group. A dose response is obtained by using 10 animals per group at various doses. ED_{50} values can be calculated. The standard neuroleptic drugs have the following ED_{50} values: chlorpromazine 1.75 mg/kg i.p and haloperidol 0.2 mg/kg i.p.

CRITICAL ASSESSMENT OF THE METHOD

Inhibition of amphetamine-induced stereotypies in rats can be regarded as a simple method to detect neuroleptic activity. However, this may reflect the effects in the corpus striatum which are thought to be responsible for the Parkinsonism-like side effects of neuroleptics.

MODIFICATIONS OF THE METHOD

Ljungberg and Ungerstedt (1985) described a rapid and simple behavioral screening method for simultaneous assessment of limbic and striatal blocking effects of neuroleptic drugs. A low dose of 2 mg/kg d-amphetamine i.p. induces both increased locomotion, thought to reflect an increased dopamine transmission in the nucleus accumbens, and weak stereotypies, thought to reflect an increased dopamine transmission in the neostriatum. The behavior is measured in a combined open field apparatus with holes on the bottom to measure nose-pocking and registration of time spent in the corners. Neuroleptics with less propensity to induce unwanted extrapyramidal side effects can be differenti-

ated from classical drugs with more extrapyramidal adverse reactions.

Machiyama (1992) recommended chronic methylamphetamine intoxication in **Japanese monkeys** (*Macaca fuscata*) as a model of schizophrenia in animals.

Ellenbroek (1991) described the ethological analysis of **Java monkeys** (*Macaca fascicularis*) in a social setting as an animal model for schizophrenia.

E.5.3.3 Inhibition of apomorphine climbing in mice

PURPOSE AND RATIONALE

Administration of apomorphine to mice results in a peculiar climbing behavior characterized initially by rearing and then full-climbing activity, predominantly mediated by the mesolimbic dopamine system (Costall et al. 1978). The ability of a drug to antagonize apomorphine-induced climbing behavior in the mouse has been correlated with neuroleptic potential (Protais et al. 1976; Costall et al. 1978).

PROCEDURE

Groups of 10 male mice (20–22 g) are treated i.p. or orally with the test substance or the vehicle and placed individually in wire-mesh stick cages. Thirty min afterwards, they are injected s.c. with 3 mg/kg apomorphine. Ten, 20 and 30 min after apomorphine administration, they are observed for climbing behavior and scored as follows:

0 = four paws on the floor,
1 = forefeet holding the vertical bars,
2 = four feet holding the bars.

EVALUATION

The average values of the drug-treated animals are compared with those of the controls, the decrease is expressed as percent. The ED_{50}-values and confidence limits are calculated by probit analysis. Three dose levels are used for each compound and the standard with a minimum of 10 animals per dose level.

CRITICAL ASSESSMENT OF THE TEST

Similar to the enhancement of compulsive gnawing of mice after apomorphine by antidepressant drugs, the suppression of climbing behavior of mice after apomorphine can be used for testing neuroleptic drugs. The test has been modified by various authors.

In contrast to other strains of mice, apomorphine climbing is not induced in DBA2 mice unless subchronic manipulations of brain dopamine transmission are performed (Duterte-Boucher and Costentin 1989).

Vasse M, Chagraoui A, Protais P (1988) Climbing and stereotyped behaviors in mice require the stimulation of D-1 dopamine receptors. Eur J Pharmacol 148:221–229

E.5.3.4 Inhibition of apomorphine stereotypy in rats

PURPOSE AND RATIONALE

Apomorphine induces a stereotyped behavior in rats, characterized by licking, sniffing and gnawing in a repetitive, compulsive manner, which is an indication of striatal dopaminergic stimulation (Anden et al. 1967; Ernst 1967; Costall and Naylor 1973). Compounds which prevent apomorphine-induced stereotypy antagonize dopamine receptors in the nigrostriatal system (Ljungberg and Ungerstedt 1978; Tarsy and Baldessarini 1974). Furthermore, antagonism of this behavior is predictive of propensity for the development of extrapyramidal side effects and tardive dyskinesias (Klawans and Rubivits 1972; Tarsy and Baldessarini 1974; Christensen et al. 1976; Clow et al. 1980).

PROCEDURE

For screening, groups of 6 male Wistar rats with a body weight between 120 and 200 g are used. The test drug or the standard are administered i.p. 60 min prior apomorphine dosage. Apomorphine HCl is injected s.c. at a dose of 1.5 mg/kg. The animals are placed in individual plastic cages. A 10 s observation period is used to measure the presence of stereotypic activity such as sniffing, licking and chewing 10 min after apomorphine administration. An animal is considered protected if this behavior is reduced or abolished.

EVALUATION

The percent effectiveness of a drug is determined by the number of animals protected in each group. With a group size of 10 animals dose response curves are obtained and ED_{50} values calculated. ED_{50} values were found to be 0.2 mg/kg s.c. for haloperidol and 5.0 mg/kg for chlorpromazine, whereas clozapine was ineffective even at high doses.

MODIFICATIONS OF THE METHODS

Puech et al. (1978) studied the effects of several neuroleptic drugs on hyperactivity induced by a low dose of apomorphine in mice.

Apomorphine induces stereotypic behavior in a variety of species including pigeons. The symptoms in pigeons are manifested as pecking against the wall of the cage or on the floor. Aksas et al. (1984) described a method registering the pecking after apomorphine by a microphone, amplification through a pulse preamplifier and registration with a polygraph. The effect of apomorphine was dose-dependent decreased by yohimbine and neuroleptics.

Stereotyped behavior in guinea pigs induced by apomorphine or amphetamine consisting in continuous gnawing and sniffing of the cage floor was described by Klawans and Rubovits (1972) and used as an experimental model of tardive dyskinesia.

E.5.3.5 Yawning/penile erection syndrome in rats

PURPOSE AND RATIONALE

Yawning is a phylogenetically old, stereotyped event that occurs alone or associated with stretching and/or penile erection in humans and in animals from reptiles to birds and mammals under different conditions (Argiolas and Melis 1998). The yawning-penile erection syndrome can be induced in rats by apomorphine and other dopamine autoreceptor stimulants (Ståhle and Ungerstedt 1983; Gower et al. 1984) and can be antagonized by haloperidol and other dopamine antagonists. Antagonism against this syndrome can be regarded as indication of antipsychotic activity (Furukawa 1996).

Besides the **dopaminergic** system in this behavior (Mogilnicka and Klimek 1977; Baraldi et al. 1979; Benassi-Benelli et al. 1979; Nickolson and Berendsen 1980; Gower et al. 1984, 1986; Dourish et al. 1985; Doherty and Wisler 1994; Kurashima et al. 1995; Bristow et al. 1996; Fujikawa et al. 1996a; Asencio et al. 1999) also the **serotoninergic** (Baraldi et al. 1977; Berendsen and Broekkamp 1987; Berendsen et al. 1990; Protais et al. 1995; Millan et al. 1997), the **cholinergic** (Yamada and Furukawa 1980; Fujikawa et al. 1996b), the **GABAergic** (Zarrindast et al. 1995), the **NO system** (Melis et al. 1995, 1996, 1997a,b), and **steroid** as well as **peptide hormones** (Bertolini and Baldari 1975; Bertolini et al. 1978; Holmgren et al. 1980; Berendsen and Nickolson 1981; Berendsen and Gower 1986; Gully et al. 1995) are involved (Argiolas and Melis 1998).

PROCEDURE

Naive male Wistar rats, weighing 220–280 g, are housed under controlled 12 h light-dark cycle with free access to standard food pellets and tap water. Rats are pretreated with subcutaneous injection of the antagonist 30 min prior to injections of the agonist, such as apomorphine (0.02 to 0.25 mg/kg s.c.) or physostigmine (0.02 to 0.3 mg/kg s.c. or i.p.). After administration of the agonist, rats are placed in individual transparent Perspex cages. A mirror is placed behind the row of observation cages to facilitate observation of the animals for penile erections and yawns. Yawning is a fixed innate motor pattern characterized by a slow, wide opening of the mouth. A penile erection is considered to occur when the following behaviours are present: repeated pelvic thrusts immediately followed by an upright position, an emerging, engorged penis which the rats proceeds to lick while eating the ejaculate. The number of penile erections and yawns is counted for 30 min following the last injection.

EVALUATION

The results are expressed as the mean number of yawns and of penile erections per group ±SEM The statistical significance is determined by comparing the results of each group with the results of the relevant control group using a non-parametric rank sum test.

CRITICAL ASSESSMENT OF THE METHOD

Ferrari et al. (1993) published some evidence that yawning and penile erection in rats underlie different neurochemical mechanisms. Nevertheless, the procedure can be regarded as an useful behavioral tool to study putative antipsychotic activity of new compounds.

MODIFICATIONS OF THE METHOD

Two sublines of Sprague Dawley rats were bred for high- and low yawning frequency in males (Eguibar and Moyaho 1997).

Apomorphine produced more yawning in Sprague Dawley rats than in F344 rats (Tang and Himes 1995)

Sato-Suzuki et al. (1998) evoked yawning by electrical or chemical stimulation in the paraventricular nucleus of anesthetized rats.

The yawning – penile erection syndrome in rats can be elicited by injections of 50 ng NMDA or AMPA (Melis et al. 1994, 1997b) into the paraventricular nucleus of the hypothalamus or intracerebroventricular injection of 50 ng oxytocin (Melis et al. 1997a) or ACTH (Genedani et al. 1994; Poggioli et al. 1998) or α-MSH (Vergoni et al. 1998).

Champion et al. (1997), Bivalacqua et al. (1998) studied the effect of intracavernosal injections of adrenomedullin and other peptide hormones on penile erections in **cats**.

Dopaminergic influences on male sexual behavior of **rhesus monkeys** were studied by Pomerantz (1990, 1992).

E.5.3.6 Inhibition of mouse jumping

PURPOSE AND RATIONALE

Lal et al. (1975) described a jumping response in mice after administration of L-dopa in amphetamine pretreated animals where the number of jumps can be objectively counted. The mouse jumping is due to dopaminergic overstimulation similar to that seen in rats when stereotypy is induced by higher doses of amphetamine. The phenomenon can be blocked by neuroleptics.

PROCEDURE

Male CD-1 mice weighing 22–25 g are injected with 4 mg/kg d-amphetamine sulfate, followed 15 min later by an i.p. injection of 400 mg/kg L-dopa. The mice spontaneously begin to jump at a high rate. A median of 175 jumps can be observed in these mice during 60 min. Since mice do not show any jumping after saline administration, the responses after drug administration are specific and can be measured automatically through a pressure-sensitive switch closure or properly positioned photoelectric beam disruptions. Test compounds are administered 60 min prior to L-dopa injection.

EVALUATION

Jumps of mice treated with test drugs or standard are counted and expressed as percentage of jumps in amphetamine/L-dopa treated animals. Using various doses, ED_{50} values with 95% confidence limits are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method has been found to be sensitive and rather specific for neuroleptic drugs.

E.5.3.7 Antagonism against MK-801 induced locomotion and falling in mice

PURPOSE AND RATIONALE

MK-801, a non-competitive NMDA antagonist, induces a characteristic stereotypy in mice marked by locomotion and falling behavior through both dopamine dependent and dopamine independent mechanisms (Carlson and Carlson 1989; Verma and Kulkarni 1992). Antipsychotic agents dose-dependent antagonize this MK-801 induced behavior.

PROCEDURE

Male CD-1 mice (20–30 g) are individually placed in activity boxes lined with wire mesh flooring and allowed to acclimate for 60 min. The animals are then dosed with compounds 30 min prior to subcutaneous administration of MK-801 at 0.2 mg/kg. The mice are observed for locomotion and the presence of falling behavior 15 min following MK-801 administration.

EVALUATION

ED_{50} values and 95% confidence limits are calculated by the Litchfield and Wilcoxon method.

MODIFICATIONS OF THE METHOD

Deutsch and Hitri (1993), Rosse et al. (1995) described methods to measure the MK 801-induced explosive behavior in mice, called “popping”.

E.5.3.8 Inhibition of apomorphine-induced emesis in the dog

PURPOSE AND RATIONALE

The blockade of centrally acting dopaminergic mechanisms is considered to play a major role in suppression of psychotic reactions in schizophrenia. Apomorphine, regarded as a direct dopaminergic agonist, produces a pronounced emetic effect in dogs and the blockade of apomorphine emesis is used as an indication of dopaminergic blockade. However, although both antiemetic activity and antipsychotic activity are thought to be due to dopaminergic blockade, the sites of action are in different brain areas and there is a lack of complete correlation of these activities.

PROCEDURE

Adult beagle dogs of either sex are used in treatment groups of three to nine dogs/dose. The dogs are given the test compounds in a gelatin capsule; they are then dosed with 0.15 mg/kg apomorphine s.c. at various intervals after administration of the test compound. The dogs are first observed for overt behavioral effects, e.g., pupillary response to light, changes in salivation, sedation, tremors, etc; then, after the administration of apomorphine, the dogs are observed for stereotypic sniffing, gnawing and the emetic response. Emesis is defined as wretching movements followed by an opening of the mouth and either attempted or successful ejection of stomach content.

EVALUATION

If the experimental compound is anti-emetic in the primary screen, the dose is progressively lowered to obtain a minimal effective dose or an ED_{50} value. The ED_{50} values for haloperidol and chlorpromazine were found to be 0.06 mg/kg p.o. and 2.0 mg/kg p.o., respectively. Clozapine was not effective at doses between 2 and 10 mg/kg. p.o.

CRITICAL ASSESSMENT OF THE METHOD

The method has been extensively used by several laboratories. However, since non-classical neuroleptics like clozapine did not show pronounced activity the test has been abandoned. Moreover, tests in higher animals like dogs are limited due to regional regulations.

E.5.3.9 Purposeless chewing in rats

PURPOSE AND RATIONALE

Purposeless chewing can be induced in rats by directly acting cholinergic drugs or cholinesterase inhibitors (Rupniak et al. 1983), which can be blocked by antimuscarinic agents. The chewing behavior has been proposed to be mediated through central M_2 receptors rather than via central M_1 sites (Stewart et al. 1989). Chewing can also be induced by chronic administration of neuroleptics in rats (Clow et al. 1979; Iversen et al. 1980). Purposeless chewing is mediated by dopaminergic and nicotinic mechanisms.

PROCEDURE

Male albino rats are housed 10 per cage at room temperature and kept on a 12 h light-dark cycle. For the experiments, rats are placed individually in a large glass cylinder (height 30 cm, diameter 20 cm) at 21 ±1 °C and allowed to habituate for 15 min before injection of drugs. The antagonists, e.g. sulpiride or mecamylamine as standards, are given at different doses 30 min before treatment either with 0.01 mg/kg nicotine or 1 mg/kg pilocarpine i.p. Number of chewings are counted by direct observation immediately after drug administration. The results are presented as number of chews in a 30 min period.

EVALUATION

Analysis of variance (ANOVA), followed by Newman-Keuls tests, are used to evaluate the significance of the results obtained. $P < 0.05$ is considered as significant.

E.5.3.10 Single unit recording of A9 and A10 midbrain dopaminergic neurons

PURPOSE AND RATIONALE

Interactions with central nervous system dopamine pathways are crucial for the expression of antipsychotic effects seen with clinically effective neuroleptics. These interactions also have a role in the expression of several of the neurological side effects seen with these agents. Extracellular single unit recording techniques of rat A9 (substantia nigra) and A10 (ventral tegmental area) dopamine neurons show that after acute treatment with neuroleptics the number of spontaneously firing cells is increased in both areas. After repeated treatment (21 days) a decrease was found with all neuroleptics in the A10 neurons, whereas in the A9 cell only compounds with clinically evident extrapyramidal side effects induced a decrease. Clozapine which is believed not to produce extrapyramidal side effects resulted in the depolarization inactivation of A10 neurons but not A9 cells. The method provides a prediction of a compound's anti-psychotic potential as well as potential neurological side effects (Chiodo and Bunney 1983).

PROCEDURE

Male Wistar rats weighing 280–360 g are anesthetized with chloralhydrate intraperitoneally. The animal is mounted in a stereotaxic apparatus (Kopf, model 900). The cranium is exposed, cleaned of connective tissue and dried. The skull overlying both the substantia nigra (A9: anterior (A) 3 000–3 400 µm, lateral (L) 1 800–2 400 µm from lambda), and the ventral tegmental area (A10: A 3 000–3 400 µm, L 400–1 000 µm from lambda) (Paxinos and Watson 1986) is removed. Using the dura as point of reference, a micropipette driven by a hydraulic microdrive is lowered through the opening of the skull at vertical 6 000–8 500 µm. Spontaneously firing dopamine neurons within both the substantia nigra and the ventral tegmental area are counted by lowering the electrode into twelve separate tracks (each track separated from the other by 200 µm) in each region. The sequence of these tracks is kept constant, forming a block of tissue which can be reproducibly located from animal to animal.

Extracellular neuronal signals are sampled using a single barrel micropipette approximately one µm at its tip, and filled with 2 M NaCl saturated with 1% pontamine sky blue dye (*in vitro* impedance between 5 and 10 MΩ). Electrical potentials are passed through a high-impedance preamplifier and the signal is sent to a window discriminator which converts potentials above background noise levels to discrete pulses of fixed amplitude and duration. Only cell whose electrophysiological characteristics match those previously established for midbrain dopamine neurons are counted. In an anesthetized rat, a neuron is considered to be dopaminergic if it displays a triphasic positive-negative-positive spike profile of 0.4 to 1.5 mV amplitude and 2.5 ms duration, firing in an irregular pattern of 3 to 9 Hz with occasional bursts characterized by progressively decreasing spike amplitude and increasing spike duration.

At the end of each experiment, the location of the last recorded track tip is marked by passing 25 microampere cathodal current through the recording micropipet barrel for 15 min in order to deposit a spot of dye. The rat is sacrificed, the brain is then removed, dissected and frozen on a bed of dry ice. Frozen serial sections (20 µm in width) are cut, mounted and stained with cresyl violet and examined using a light microscope.

Animals pretreated with vehicle prior to neuronal sampling serve as controls. For animals that are used in an acute single-unit dopamine neuron sampling assay, test compounds are administered intraperitoneally one hour prior to the beginning of dopamine neuron sampling. For animals used in a chronic single-unit dopamine sampling assay, the compounds are administered once a day for 21 days, and dopamine neuron sampling is begun 2 h after the last dose on the 21st day.

EVALUATION

Drug treatment groups are compared to vehicle groups with a one-way ANOVA with a post hoc Neuman-Keuls analysis for significance.

MODIFICATIONS OF THE METHOD

Nybäck et al. (1975) tested the influence of tricyclic antidepressants on the spontaneous activity of norepinephrine-containing cells of the locus caeruleus in anesthetized rats.

Scuvée-Moreau and Dreese (1979) studied the effect of various antidepressant drugs on the firing rate of locus caeruleus and dorsal raphe neurons of the anesthetized rat with extracellular microelectrodes.

Using the method of single-unit recording of spontaneous firing of locus caeruleus neurons in rats, Cedarbaum and Aghajanian (1977) studied the inhibition by micro-iontophoretic application of catecholaminergic agonists.

Marwaha and Aghajanian (1982) examined in single unit studies the actions of adrenoceptor antagonists at *alpha*-1 adrenoceptors of the dorsal raphe nucleus and the dorsal lateral geniculate nucleus and *alpha*-2 adrenoceptors of the nucleus locus caeruleus.

Mooney et al. (1990) studied the organization and actions of the noradrenergic input to the superior colliculus of the hamster using micro-iontophoretic techniques together with extracellular single unit recording.

Bernardini et al. (1991) studied *in vitro* with brain slices of mice the amphetamine-induced and spontaneous release of dopamine from A9 and A10 cell dendrites.

Santucci et al. (1997) investigated the effects of synthetic neurotensin receptor antagonists on spontaneously active A9 and A10 neurones in rats.

E.5.3.11 *In vivo* voltammetry

PURPOSE AND RATIONALE

Various groups (Lane et al. 1979, 1987, 1988; Blaha and Lane 1983, 1984, 1987; Crespi et al. 1984; Marsden et al. 1984; Maidment and Marsden 1987a,b; Armstrong-James and Millar 1979, 1984; Kawagoe et al. 1993) described *in vivo* voltammetry as an electrochemical technique that uses carbon fiber microelectrodes stereotactically implanted in brain areas to monitor monoamine metabolism and release. De Simoni et al. (1990) reported on a miniaturized opto-electronic system for telemetry of *in vivo* voltammetric signals in freely moving animals.

PROCEDURE

Carbon fibre working electrodes are made from pyrolytic carbon fibres supported in a pulled glass capillary (Armstrong-James and Millard 1979; Sharp et al. 1984) and electrically pretreated for simultaneous recording of ascorbic acid DOPAC and 5-HIAA (Crespi et al. 1984).

Male Sprague Dawley rats weighing 270–340 g are anesthetized with a 2–3% halothane O_2/NO_2 mixture (1 : 1) and held in a stereotactic frame. Reference and auxiliary electrodes are positioned on the surface of

the dura through 1 mm holes drilled in the cranium and held in place with dental cement. Holes, approx. 2 mm in diameter, are drilled in the cranium above the left or right nucleus accumbens and contralateral anterior striatum, and the underlying dura is broken with a hypodermic needle. A working electrode is lowered in one of the above regions and cemented in place. A second electrode is then implanted in the remaining structure. The coordinates, measured from the bregma, are as follows: nucleus accumbens–rostro-caudal +3.4 mm; medio-lateral ±1.4 mm; dorso-ventral –7 mm; striatum–rostro-caudal +2.8 mm; medio-lateral ±2.6 mm; dorso-ventral –5.5 mm.

Drugs are injected subcutaneously. Voltammograms are recorded using a Princeton Applied Research 174A polarographic analyzer alternatively from each region every 5 min and after a 1 h stabilization period.

EVALUATION

Voltammetric data are expressed as percentage changes from pre-injection control values using the mean of the last 6 peak heights before administration of drug as the 100% value. However, statistical analysis of the data is carried out on the absolute peak heights using a paired Student's *t*-test to compare 6 pre-injection control peak heights with those after administration of drug at selected time points.

MODIFICATIONS OF THE METHOD

Swiergiel et al. (1997) constructed voltammetric probes from stainless steel and fused silica tubing sheathing carbon fibers and compared them with commercially available glass-sealed IVEV-5 electrodes. This type of electrodes can be easily manufactured and does not require any special equipment.

Parada et al. (1994, 1995) described a triple-channel swivel suitable for intracranial fluid delivery and microdialysis experiments which can be equipped with three electrical channels for in-vivo voltammetry and measurement of intracranial temperature with a thermocouple.

Frazer and Daws (1998) used electrodes coated with a perfluorinated ion exchange resin (Nafion®) to assess serotonin transporter function *in vivo* by **chronoamperometry** whereby voltage is applied to the electrode in a pulsed manner and the current obtained measured as a function of time.

E.6
Antidepressant activity

E.6.0.1
General considerations

The first antidepressant drugs were detected by serendipity in clinical trials. Iproniazid was developed for the treatment of tuberculosis. The observation of mood-elevating effects was followed by the detection of the inhibition of the enzyme monoamine oxidase. During clinical investigation of phenothiazine analogs as neuroleptics, imipramine was found to be relatively ineffective in agitated psychotic patients but showed remarkable benefit in depressed patients. Later on, inhibition of uptake of biogenic amines was found to be the main mechanism of action resulting in downregulation of β-receptors (Vetulani et al. 1976). Influence on α_2-adrenoreceptors (Johnson et al. 1980) was discussed as well. Several lines of preclinical and clinical evidence indicate that an enhancement of 5-HT-mediated neurotransmission might underlie the therapeutic effect of most antidepressant treatments (Blier and de Montigny 1994).

Animal models of depression have been reviewed by Porsolt et al. (1991), Panksepp et al. (1991), Willner and Muscat (1991).

E.6.1 *In vitro* methods

E.6.1.1 Inhibition of [^{3}H]-norepinephrine uptake in rat brain synaptosomes

PURPOSE AND RATIONALE

As shown by Hertting and Axelrod (1961) the neuronal re-uptake mechanism for norepinephrine is the most important physiological process for removing and inactivating norepinephrine in the synaptic cleft. This uptake is inhibited by cocaine, certain phenylethylamines and antidepressants. This mechanism is considered as one of the most important modes of action of antidepressants leading to receptor down-regulation. In the brain, the hypothalamus shows the highest level and greatest uptake of noradrenaline. Therefore, this region is used for testing potential antidepressant drugs.

PROCEDURE

Tissue preparation

Male Wistar rats are decapitated and the brains rapidly removed. The hypothalamic region is prepared, weighed, and homogenized in 9 volumes of ice-cold 0.32 M sucrose solution using a Potter-Elvejhem homogenizer. The homogenate is centrifuged at 1 000 *g* at 0–4 °C for 10 min. The supernatant is decanted and used for the uptake experiments.

Assay

200 µl of tissue suspension are incubated with 800 µl 62.5 nM ^{3}H-norepinephrine in Krebs-Henseleit bicarbonate buffer and 20 µl of the appropriate drug concentration (or the vehicle) at 37 °C under a 95% O_2/5% CO_2 atmosphere for 5 min. For each assay, 3 tubes are incubated with 20 µl of vehicle at 0 °C in an ice bath. After incubation all tubes are immediately centrifuged at 4 000 *g* for 10 min. The supernatant fluid is aspirated and the pellets dissolved adding 1 ml of solubilizer (Triton X-100 + 50% ethanol, 1 : 4). The tubes are vigorously shaken, decanted into scintillation vials, and counted in 10 ml of liquid scintillation cocktail. Active uptake is the difference between cpm at 37 °C and 0 °C.

EVALUATION

The percent inhibition at each drug concentration is the mean of 3 determinations. IC_{50} values are derived from log-probit analysis. IC_{50} values for the standard drugs desipramine and nortriptyline are around 20 nM.

MODIFICATIONS OF THE METHOD

Pacholczyk et al. (1991) described the expression cloning of a cocaine- and antidepressant-sensitive human noradrenaline transporter.

Tejani-Butt (1992) recommended [3H]nisoxetine as radioligand for quantitation of norepinephrine uptake sites.

E.6.1.2 Inhibition of [^{3}H]-dopamine uptake in rat striatal synaptosomes

PURPOSE AND RATIONALE

High affinity, saturable, temperature and sodium-dependent transport of ^{3}H-dopamine has been observed in various tissue preparations from different brain regions. The area striata has a high content of dopamine and is suitable for uptake experiments. The ^{3}H-dopamine uptake is inhibited by cocaine, certain phenylethylamines and antidepressants like nomifensine and bupropion, but not by tricyclic antidepressants. The test can be used to characterize the mode of action of antidepressant drugs.

PROCEDURE

Tissue preparation

Male Wistar rats are decapitated and the brains rapidly removed. Corpora striata are prepared, weighed and

homogenized in 9 volumes of ice cold 0.32 M sucrose solution using a Potter-Elvejhem homogenizer. The homogenate is centrifuged at 1 000 *g* at 0–4 °C for 10 min. The supernatant is decanted and used for the experiments.

Assay

100 µl of tissue suspension are mixed with 900 µl 55.5 nM ^{3}H-dopamine solution in Krebs-Henseleit bicarbonate buffer and 20 µl of drug solution in appropriate concentration (or the vehicle as control). The tubes are incubated at 37 °C under a 95% O_2/5% CO_2 atmosphere for 5 min. For each assay, 3 tubes are incubated with 20 µl of vehicle at 0 °C in an ice bath. After incubation all tubes are immediately centrifuged at 4 000 *g* for 10 min. The supernatant fluid is aspirated and the pellets dissolved by adding 1 ml of solubilizer (Triton X-100 + 50% ethanol, 1 : 4). The tubes are vigorously shaken, decanted into scintillation vials, and counted in 10 ml liquid scintillation counting cocktail. Active uptake is the difference between cpm at 37 °C and 0 °C.

EVALUATION

The percent inhibition at each drug concentration is the mean of 3 determinations. IC_{50} values are derived from log-probit analyses. IC_{50} values for nomifensine are 460 nM, but >20 000 nM for tricyclic antidepressants.

MODIFICATIONS OF THE METHOD

Elsworth et al. (1993) differentiated between cocaine-sensitive and -insensitive dopamine uptake in various brain areas.

Cloning and pharmacological characterization of rat, bovine, and human dopamine transporters have been described (Giros et al. 1991; Kilty et al. 1991; Shimada et al. 1991; Usdin et al. 1991; Giros et al. 1992).

Binding characteristics of the dopamine transporter were studied (Reith et al. 1992; Rothman et al. 1992).

[^{3}H]-3β-(*p*-fluorophenyl)tropan-2β-carboxylic acid methyl ester ([^{3}H]WIN 35,428) is used as ligand for the dopamine transporter (Carroll et al. 1992; Cline et al. 1992).

[^{3}H]GBR12 935 (1-[2-(diphenylmethoxy)ethyl]-4-(3-phenylpropyl)piperazine) was used as labelled ligand by Richfield (1991), Nakachi et al. (1995).

Cocaine receptors are specifically labeled with [^{3}H]WIN 35,428 indicating the role of the dopamine transport system in mediating the behavioral effects and the abuse of cocaine (Madras et al. (1989).

Laruelle et al. (1993) reported **single photon emission computed tomography (SPECT)** imaging of dopamine and serotonin transporters in nonhuman primates.

E.6.1.3 Inhibition of [^{3}H]-serotonin uptake in synaptosomes

PURPOSE AND RATIONALE

Some authors have suggested that patients with serotoninergic hypofunction constitute a subgroup of depression and claim that altered serotoninergic function determines the mood changes associated with affective disorders. A number of clinically effective antidepressants block the reuptake of 5-HT. ^{3}H-5-HT transport in brain has been found to be saturable, sodium- and temperature-dependent, to be inhibited by several agents, such as ouabain, tryptamine analogs, and tricyclic antidepressants. Apparently, the 5-HT uptake can be differentiated from catecholamine uptake. Therefore, the test can be used to detect compounds that inhibit serotonin uptake into rat brain synaptosomes and may be potential antidepressants.

PROCEDURE

Tissue preparation

Male Wistar rats are decapitated and the brains rapidly removed. Either the whole brain minus cerebellum or the hypothalamus is weighed and homogenized in 9 volumes of ice-cold 0.32 M sucrose solution using a Potter-Elvejhem homogenizer. The homogenate is centrifuged at 1 000 *g* at 0–4 °C for 10 min. The supernatant is decanted and used for further uptake experiments.

Assay

Two hundred µl of tissue suspension are mixed with 800 µl 62.5 nM ^{3}H-5-HT solution in Krebs-Henseleit bicarbonate buffer and 20 µl of drug solution in the appropriate concentration (or the vehicle as control). The tubes are incubated at 37 °C under 95% O_2/5% CO_2 atmosphere for 5 min. For each assay, 3 tubes are incubated with 20 µl of the vehicle at 0 °C in an ice bath. After incubation all tubes are immediately centrifuged at 4 000 *g* for 10 min. The supernatant is aspirated and the pellets are dissolved by adding 1 ml of solubilizer (Triton X100 + 50% ethanol, 1 + 4). The tubes are vigorously shaken, decanted into scintillation vials, and counted in 10 ml of liquid scintillation counting cocktail. Active uptake is the difference between cpm at 37 °C and 0 °C.

EVALUATION

The percent inhibition of each drug concentration is the mean of 3 determinations. IC_{50} values are calculated from log-probit analyses. Standard drugs, such as chlorimipramine show IC_{50} values in the order of 10 nM for ^{3}H-5-HT uptake in rat synaptosomes from hypothalamus.

CRITICAL ASSESSMENT OF THE METHOD

Whereas many antidepressants inhibit the uptake of serotonin *in vitro*, some drugs like tianeptine were reported to enhance serotonin uptake in *ex vivo* experiments. Therefore, it seems doubtful to relate the therapeutic effect seen in man to a single mechanism of action observed *in vitro*.

MODIFICATIONS OF THE METHOD

Hallstrom et al. (1976) studied the platelet uptake of 5-hydroxytryptamine and dopamine in patients with depression.

Cloning of functional serotonin transporters has been described by Blakely et al. (1991) and by Hoffman et al. (1991).

MODIFICATIONS OF THE METHOD

The role of serotonin in the mode of action of antidepressant drugs has been discussed by Hyttel and Larsen (1985), Åsberg and Mårtensson (1993), Hyttel (1994), Blier and de Montigny (1997), Keane and Soubrié (1997).

E.6.1.4 Binding to monoamine transporters

PURPOSE AND RATIONALE

There is substantial clinical and experimental evidence that lesions in the serotonergic and noradrenergic systems are responsible for depression and that antidepressant treatment can reverse these alterations (Leonard 2000). Monoamine transporters are principle targets of widely used therapeutic drugs including antidepressants, psychostimulants and the addictive drug cocaine (Madras et al. 1996; Fleckenstein et al. 1999). The termination of neurotransmission is achieved by rapid uptake of the released neurotransmitter by high-affinity neurotransmitter transporters. Most of these transporters are encoded by a family of genes (Na^+/Cl^- transport-ers) having a similar membrane topography of 12 transmembrane helices. An evolutionary tree revealed five distinct subfamilies: GABA-transporters, monoamine transporters, amino acid transporters, "orphan" transporters and bacterial transporters (Nelson 1998).

Tatsumi et al. (1997) described the pharmacological profile of antidepressants at human monoamine transporters.

PROCEDURE

Expression of human transporters

The human serotonin transporter cDNA is directionally ligated into the expression vector pRc/CMV and transfected into HEK293 (human embryonic kidney) cells

by the Ca^{2+} method. The human dopamine transporter cDNA is directionally ligated into the expression vector pcDNA3 and transfected into HEK293 cells, also by the Ca^{2+} method.

Cell culture

The cell lines are grown, passaged, and harvested in 150 mm Petri dishes with 17.5 ml of Dulbecco's modified Eagle's medium containing 0.1 mM nonessential amino acid solution, 5% fetal clonebovine serum product and 1 U/µl penicillin and streptomycin solution. They are incubated in 10% CO_2, 90% air at 37 °C and 100% humidity. The selecting antibiotic geneticin sulfate (250 µg/ml) is used continuously for culture of cells expressing the norepinephrine transporter.

Membrane preparations

For the preparation of the homogenates, the medium is removed by aspiration. The cells are washed with 4 l modified Puck's D1 solution (solution 1) (Pfenning and Richelson 1990) and then incubated for 5 min at 37 °C in 10 ml solution 1 and 100 mM EGTA. Afterwards cells are removed from the surface by scraping with a rubber spatula, placed in a centrifuge tube, and collected by centrifugation at 110 *g* for 5 min at 4 °C. The supernatants are decanted. The pellets are resuspended in the respective binding assay buffer by use of a Polytron (Brinkman Instruments, Westbury, NY) for 10 s at setting 6. The mixture is then centrifuged at 35 600 *g* for 10 min at 4 °C. The pellets are suspended in the same volume of the respective buffer and the centrifugation is repeated. The supernatants are decanted and the final pellets are suspended in the respective buffer and stored at −80 °C until assayed. The final protein concentration is determined by the Lowry assay using bovine serum albumin as standard.

Radioligand binding assays

[^{3}H]imipramine
binding to human serotonin transporter

Radioligand binding assays are performed by a modification of the method of O'Riordan et al. (1990) with a binding buffer containing 50 mM Tris, 120 mM NaCl, and 5 mM KCl (pH 7.4). Compounds to be tested are dissolved in 5 mM HCl and run in duplicate over at least 11 different concentrations against 1 nM [^{3}H]imipramine (specific activity 46.5 Ci/mmol) with 15 µg/tube membrane protein for 30 min at 22 °C. Nonspecific binding is determined in the presence of 1 µM imipramine. With the use of a 48-well Brandel cell harvester, the assay is terminated by rapid filtration through a GF/B filter presoaked with 0.2% polyethylenimine. The filter strips are rinsed five times with ice-cold 0.9% NaCl. Finally, each filter is placed in a scintillation vial containing 6.5 ml of Redi-Safe (Beckman Instruments, Ful-lerton, CA) and counted in a liquid scintillation counter.

[^{3}H]nisoxetine
binding to human norepinephrine transporter

Radioligand binding assays are performed by a modification of the method of Jayanthi et al. (1993) in binding buffer containing 50 mM Tris, 300 mM NaCl and 5 mM KCl (pH 7.4). [^{3}H]nisoxetine (specific activity 85.0 Ci/mmol, from Amersham, Arlington Hts., IL) at 0.5 nM is incubated with competing drugs and 25 µg/tube membrane protein for 60 min at 22 °C. Nonspecific binding is determined in the presence of 1 µM nisoxetine. The remainder of the assay is exactly as described above.

[^{3}H]WIN35 428
binding to human dopamine transporter

Radioligand binding assays are performed using a modification of the method of Pristupa et al. (1994) in a binding buffer containing 50 mM Tris and 120 mM NaCl (pH 7.4). [^{3}H]WIN35 428 (Dupont New England Nuclear, Boston MA, specific activity 83.5 Ci/mmol) at 1 nM is incubated with competing drugs and 30 µg/tube membrane protein for 120 min at 4 °C. Nonspecific binding is determined in the presence of 10 µM WIN35 428. The remainder of the assay is exactly as described above.

EVALUATION

The data are analyzed using the LIGAND program (Munson and Rodbard 1980) for calculation of K_D values and Hill coefficients.

MODIFICATIONS OF THE METHOD

Using the same methods, Tatsumi et al. (1999) described the pharmacological profile of several neuroleptics at human monoamine transporters.

Gu et al. (1994) constructed stable cell lines expressing transporters for dopamine, norepinephrine and serotonin using parental LLC-PK_1 cells which do not express any of these neurotransmitter transporters.

Meltzer et al. (1997) described inhibitors of monoamine transporters using dopamine- and serotonin-transporter assays. Membranes were prepared from coronal slices from caudate-putamen of brain from adult cynomolgus monkeys.

Owens et al. (1997) measured the affinity of several antidepressants and their metabolites for the rat and human serotonin and norepinephrine transporters.

Inazu et al. (1999) characterized dopamine transport in cultured rat astrocytes.

Siebert et al. (2000) used rat neuronal cultures and transfected COS-7 cells to characterize the interaction

of haloperidol metabolites with neurotransmitter transporters.

Sato et al. (2000) studied the selective inhibition of monoamine neurotransmitter transporters by synthetic local anesthetics using cloned transporter cDNAs with transient functional expression in COS cells and stable expression in HeLa cells.

E.6.1.5 Antagonism of p-chloramphetamine toxicity by inhibitors of serotonin uptake

PURPOSE AND RATIONALE

p-Chloramphetamine causes selective toxicity to serotonin neurons. At 10 mg/kg i.p. p-chloramphetamine (p-CA) causes long-term decreases in 5-HT, 5HIAA, [^{3}H]-5-HT-uptake and tryptophan hydroxylase. After acute administration of p-CA, serotonin uptake into synaptosomes isolated from whole brain is reduced for several hours and returns to control values between 1 and 2 days, after which there is a marked long-lasting decrease due to toxic destruction of 5-HT neurones. The initial behavioral effects of p-CA are due to release of dopamine and serotonin. The serotonergic toxicity of p-CA requires active transport into 5-HT neurones where a cytotoxic intermediate compound is formed. Therefore, compounds which block 5-HT uptake will prevent this toxicity. Antagonism of the long-term p-CA induced reduction of synaptosomal ^{3}H-5-HT *in vitro* uptake is a highly useful index of a compound's ability to inhibit 5-HT re-uptake *in vivo*.

PROCEDURE

Reagents

Two mg/ml dextrose and 0.30 mg/ml iproniazid phosphate are added to Krebs-Henseleit bicarbonate buffer. The mixture is aerated for 1 h with carbogen.

Serotonin creatinine sulfate (Sigma Chemical Co) as a 0.1 mM stock solution in 0.01 N HCl is used to dilute the specific activity of the radiolabeled 5-HT.

A solution of 62.5 nM ^{3}H-5-HT (5-[1,2-^{3}H(N)]-hydroxytryptamine creatinine sulfate, specific activity 20–30 Ci/mmol, New England Nuclear) is prepared in Krebs-Henseleit bicarbonate buffer.

(d,l)-p-Chloramphetamine (Regis Chemical Co) is dissolved in 0.9% NaCl at a concentration of 10 mg/ml.

Drug treatment

Groups of 8 male Wistar rats, weighing 150–200 g are injected intraperitoneally with saline or molar equivalent doses of the test drug. For initial studies, the dose given is 37,5 µmol/kg (equivalent to 10 mg/kg desipramine base). After 30 min, 4 rats from each group are injected with saline or with p-CA 10 mg/kg i.p. Three days after treatment, the rats are sacrificed. For multiple dosing, the rats are pretreated with the test drug twice up to 4 times in 2 h intervals.

Tissue preparation

The rats are decapitated and the brains rapidly removed. Whole brain minus cerebellum is weighed and homogenized in 9 volumes of ice-cold 0.32 M sucrose using a Potter-Elvejhem homogenizer. The homogenate is centrifuged at 1 000 *g* at 0–4 °C for 10 min. The crude synaptosomal supernatant is decanted and used for uptake experiments.

Assay

800 µl Krebs-Henseleit bicarbonate buffer + [^{3}H]-5-HT
200 µl Tissue suspension

Tubes are incubated at 37 °C under a 95% O_2/5% CO_2 atmosphere for 5 min. For each assay, 3 tubes are incubated at 0 °C in an ice bath. After incubation all tubes are immediately centrifuged at 4 000 *g* at 0–4 °C for 10 min. The supernatant fluid is aspirated and the pellets dissolved by adding 1 ml of solubilizer (Triton X-100 and 50% ethanol, 1 : 4, v/v). The tubes are vigorously vortexed, decanted into scintillation vials, and counted in 10 ml of aqueous (Liquiscint) scintillation counting cocktail. Active uptake is the difference between cpm at 37 °C and 0 °C.

EVALUATION

The percent protection is calculated according to the following formula:

$$\%\ \text{protection} = \frac{cpm[(sal\ /\ sal) - (sal\ /\ pCA)]}{cpm[(sal\ /\ sal) - (sal\ /\ pCA)]} - \frac{cpm[(sal\ /\ sal) - (drug\ /\ pCA)]}{cpm[(sal\ /\ sal) - (sal\ /\ pCA)]}$$

E.6.1.6 Receptor subsensitivity after treatment with antidepressants: Simultaneous determination of the effect of chronic anti-depressant treatment on b-adrenergic and 5-HT$_2$ receptor densities in rat cerebral cortex

PURPOSE AND RATIONALE

The catecholamine and indolamine systems are thought to be involved in affective disorders such as depression. The effect of antidepressants on biogenic amine re-uptake *in vitro* is immediate; whereas the onset of clinical activity is delayed and parallels more closely the time course of receptor changes measured in animal studies. Therefore, the experiment is designed to determine the *in vivo* effects of chronic (10 days) treatment with known and potential antidepressants on the β-receptor, as a measurement of noradrenergic interaction, and on the 5-HT$_2$ receptor as a measurement of serotoninergic interaction in the rat brain. Both receptor densities are measured in cortical tissue from the same animal and compared after treatment with test compounds at doses similar to those of standard drugs.

PROCEDURE

Drug treatment

Groups of 4 male Wistar rats, receiving food and water at libitum are maintained on a 12-h diurnal light cycle and given i.p. injections twice daily for 10 days with saline or molar equivalent doses of the experimental drugs (equivalent to 10 mg/kg imipramine). Twenty-four hours after the last dose, the rats are decapitated and the cerebral cortices split along the mid-sagittal sinuses. One half is used for the (^{3}H)-DAH assay and the other half is used for the (^{3}H)-spiroperidol assay. This protocol allows the determination of effects of antidepressants on β-receptors and 5-HT$_2$-receptors in cerebral cortical tissue from the same animal.

Reagents

- (–)-[propyl-1,2,3-^{3}H]Dihydroalprenololol hydrochloride (45–52 Ci/mmol) is obtained from New England Nuclear.
- (±)-propranolol HCl is obtained from Ayerst.
- [Benzene-^{3}H]spiroperidol (20–35 Ci/mmol) is obtained from New England Nuclear.

Tissue preparation

^{3}H-Dihydroalprenolol (^{3}H-DHA) binding

The cerebral cortices are dissected free, weighed and homogenized in 50 vol of ice-cold 0.05 M Tris buffer, pH 8.0. This homogenate is centrifuged at 40 000 *g* and the supernatant decanted. The pellet is resuspended and again centrifuged at 40 000 *g*. The final pellet is resuspended in 0.05 M Tris buffer, pH 8.0. This tissue suspension is then stored on ice until use. The final tissue concentration is 10 mg/ml.

^{3}H-Spiroperidol binding

The cerebral cortices are dissected, weighed and homogenized in 50 vol of 0.05 M Tris buffer, pH 7.7, and then centrifuged at 40 000 *g* for 15 min. The supernatant is discarded, the pellet resuspended and again centrifuged at 40 000 *g*. The final pellet is resuspended in 50 vol of 0.05 M Tris buffer, pH 7.7 and stored in an ice bath. The final concentration in the assay is 10 mg/ml.

Assay

^{3}H-DAH binding

380 µl H_2O
50 µl 0.5 M Tris buffer pH 8.0
20 µl vehicle (for total binding) or 50 µM propranolol (for nonspecific binding)
50 µl ^{3}H-DAH stock solution
500 µl tissue suspension

The tissue homogenates are incubated for 15 min at 25 °C with varying concentrations of ^{3}H-DHA (0.25–4.0 nM). With each ligand concentration triplicate samples are incubated with 1 µM propranolol under identical conditions to determine nonspecific binding. The total added ligand is determined by counting 50 µl of each (^{3}H)-DHA concentration. The assay is stopped by vacuum filtration through Whatman GF/B filters which are washed 3 times with 5 ml of ice cold 0.05 M Tris buffer, pH 8.0. The filters are counted in 10 ml liquid scintillation cocktail.

^{3}H-Spiroperidol binding

50 µl 0.5 M Tris-physiological salts
380 µl H_2O
20 µl H_2O (for total binding) or 0.25 mM methysergide (for nonspecific binding)
50 µl ^{3}H-spiroperidol stock solution
500 µl tissue suspension

The tissue homogenates are incubated for 10 min at 37 °C with varying concentrations of ^{3}H-spiroperidol (0.1–3.0 nM). With each ligand concentration, triplicate samples are incubated in the presence of 5 µM methysergide under identical conditions to determine nonspecific binding. The total added ligand is determined by counting 50 µl of each (^{3}H)-spiroperidol concentration. The assay is stopped by vacuum filtration through Whatman GF/B filters which are washed 3 times with 5 ml of ice cold 0.05 M Tris buffer, pH 7.7. The filters are transferred to scintillation vials and counted in 10 ml of liquid scintillation cocktail.

EVALUATION

Specific binding is defined as the difference in CPM in the presence or absence of excess "cold" ligand. The free ligand concentration is the difference between the total added and the specifically bound fraction at each concentration. The equilibrium binding constants (K_d and B_{max}) are determined by Scatchard analyses using least square regression analysis of the binding data. The Scatchard plot shows "bound/free" versus "bound". The K_d value is the reciprocal of the slope and B_{max} is the x-intercept. Significant differences of drug treatment are determined by either Dunnett's or Tukey's test after one way analysis of variance.

MODOFICATIONS OF THE METHOD

Buckett et al. (1988) found a rapid down-regulation of β-adrenoceptors in brains of rats after 3 days of oral treatment with sibutramine.

E.6.1.7 Measurement of β-adrenoreceptor stimulated adenylate cyclase

PURPOSE AND RATIONALE

Noradrenaline stimulates the β-adrenoreceptor linked adenylate cyclaseβ in rat brain. Reduction of this stimulation after treatment with antidepressants is an indicator for receptor down-regulation.

PROCEDURE

Groups of male Sprague-Dawley rats are treated intraperitoneally twice daily for 14 days with saline, 10 mg/kg desimipramine or the test compound. The rats are decapitated and frontal cortices are removed, and placed into ice-cold Krebs physiological buffer (120 mM NaCl, 5 mM KCl, 2.5 mM $CaCl_2$, 2 mM KH_2PO_4, 2 mM $MgSO_4$, 25 mM $NaHCO_3$, 100 µM $Na_2S_2O_5$, 25 µM EDTA, and 10 mM glucose), pH 7.4. Cortices are cut 350 × 350 µ at right angles, added to 20 ml Krebs physiological buffer in 50 ml conical flasks, and separated by vortex mixing. The slices are incubated at 37 °C for 1 h in a shaking water bath with the buffer replaced by freshly oxygenated medium every 15 min. After this step, 20 µl [^{3}H]adenine is added to each flask. The flasks are capped, and the slices are incubated for an additional 30 min at 37 °C. This medium is then discarded and the slices are washed with 20 ml fresh buffer. Most of the medium is removed and 30 µl aliquots of the packed slices are pipetted into tubes containing 300 µM 3-isobutyl-1-methylxanthine in 270 µl Krebs physiological buffer. After incubation at 37 °C for 15 min, 30 µl of noradrenaline (final concentration 100 µM) or 30 µl buffer are added to each tube and incubated for an additional 10 min. The reaction is stopped by addition of 0.5 ml 1 M HCl. The tubes are placed in ice for 10 min before addition of 0.5 ml NaOH and then centrifuged at 3 000 *g* for 10 min at 4 °C. The supernatants are transferred to tubes containing [^{14}C]-cyclic AMP (approximately 10 000 cpm) to monitor the recovery of [^{3}H]-cyclic AMP. The radio-labelled cyclic nucleotides are separated by two-stage column chromatography on alumina neutral WN-3 and Dowex AG 50W-X4 anion exchange resin.

EVALUATION

The activity of adenylate cyclase is calculated as the conversion of [^{3}H]-adenine to [^{3}H]-cyclic AMP. After treatment with antidepressants, this conversion rate is

not altered without stimulation by noradrenaline, but significantly reduced in slices treated with the maximally stimulating concentration of 100 µM noradrenaline.

CRITICAL ASSESSMENT OF THE METHOD

Determination of β-adrenoreceptor stimulated adenylate cyclase is another parameter for measurement of down-regulation of adrenoreceptors by chronic treatment with antidepressants.

E.6.1.8 [^{3}H]Yohimbine binding to α_2-adrenoceptors in rat cerebral cortex

PURPOSE AND RATIONALE

This binding assay is used to investigate the interaction of compounds at central α_2 receptors and may indicate possible modes of action for antidepressant, antihypertensive and other classes of compounds.

[^{3}H]Yohimbine is a selective antagonist for α_2-receptors (Starke et al. 1975). The use of an antagonist radioligand avoids the complexity of saturation curves that can be observed with radio-labeled agonist ligands. Furthermore, a [^{3}H]antagonist label for the α_2 receptor permits a better evaluation of α_2/α_1 selectivity than a [^{3}H]agonist label, since α_1 affinities are measured with a [^{3}H]antagonist ([^{3}H]WB 4 101).

Chronic treatment with desipramine has been shown to decrease the binding of [^{3}H]DHA to rat brain cortical β-receptors. Some investigators have reported that co-administration of yohimbine causes β-receptor down-regulation to occur after fewer antidepressant treatments (Johnson et al. 1980; Scott and Crews 1983). Therefore, it may be of interest to investigate compounds with yohimbine-like properties as antidepressant candidates themselves or in conjunction with antidepressant candidates.

PROCEDURE

Reagents

1. 20-fold concentrated buffer:
   2.36 M NaCl137.92 g/liter
   100 mM KCl7.45 g/liter
   200 mM glucose 36.03 g/liter in 0.5 M Tris, pH 7.4
2. 2-fold concentrated buffer:
   - fold dilution of reagent 1 in deionized water
3. Standard buffer:
   - 20-fold dilution of reagent 1 in deionized water
4. [Methyl-^{3}H] yohimbine (72–86 Ci/mmol) is obtained from New England Nuclear
   - For IC_{50} determinations: [^{3}H] Yohimbine is diluted to 40 nM in deionized H_2O
   - Fifty µl of this solution is a 2-ml reaction volume gives a final concentration of 1 nM
5. L-NE bitartrate is made up to 10 mM in 0.01 N HCl. 20 µl of this solution gives a final concentration of 100 µM in 2 ml of reaction mixture.
6. Test compounds. For most assays, a 10 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-4} to 10^{-7} M. Six or seven concentrations are used routinely.

Tissue preparation

Male Wistar rats are decapitated and their brains rapidly removed. The cortices are weighed and homogenized in 9 volumes of ice-cold 0.32 M sucrose using a Potter-Elvehjem glass homogenizer fitted with a Teflon pestle (0.009–0.010 cm clearance). The homogenate is centrifuged at 1 000 *g* for 10 min (approximately

3 000 rpm using the Sorvall RC-5 centrifuge with heads SS-34 or SM-24). The supernatant is then recentrifuged at 17 000 *g* for 20 min (approximately 12 500 rpm using the Sorvall RC-5 centrifuge, and heads SS-34 or SM-24). The pellet (P_2) is resuspended in the original volume of 0.32 M sucrose and stored on ice.

Binding assay

430 µl H_2O
1 000 µl 2-fold concentration buffer (reagent 2)
20 µl drug or 10 mM L-NE bitartrate or vehicle
50 µl ^{3}H-yohimbine (reagent 4)
500 µl tissue

Tubes are vortexed and incubated at 25 °C for 10 min. Bound [^{3}H]yohimbine is captured via filtration under reduced pressure. The filters are washed three times with 5 ml aliquots of buffer (reagent 3). The filters are then counted in 10 ml of Liquiscint scintillation fluid.

EVALUATION

Specific binding of [^{3}H]yohimbine is the difference between total bound (in the presence of vehicle) and nonspecifically bound (in the presence of 100 µM L-NE bitartrate). Percent inhibition of specific [^{3}H]yohimbine binding is calculated for each concentration of test drug and IC_{50} values determined by computer-derived log-probit analysis.

E.6.1.9 Test for anticholinergic properties by [^{3}H]-QNB binding to muscarinic cholinergic receptors in rat brain

PURPOSE AND RATIONALE

Several tricyclic antidepressants exert considerable anticholinergic effects which limit the therapeutic use in some patients. Amitryptiline has the greatest incidence of these side effects and is the most potent in binding to muscarinic receptors. Desipramine, which exhibits less incidence of atropine like side effects shows a lower affinity for muscarinic receptors. Since there is no evidence that the anticholinergic effects contribute to the therapeutic efficacy, antidepressant drugs with low anticholinergic effects are desired.

Quinuclidinyl benzilate (QNB) is a specific muscarinic cholinergic antagonist in both peripheral and central tissues. The binding characteristics of ^{3}H-QNB were first described by Yamamura and Snyder (1974), who showed that this ligand was displaced by muscarinic antagonists, but not by nicotinic or non-cholinergic drugs. The levorotatory isomer being more potent than the racemate is used as the radioactive ligand.

PROCEDURE

Reagents

L-[Benzilic-4,4'-^{3}H]-quinuclidinyl benzilate (30–40 Ci/mmol) is obtained from New England Nuclear. For IC_{50} determinations [^{3}H]-QNB is made up to a concentration of 40 nM and 50 µl is added to each tube (yielding a final concentration of 1 nM in the assay).

Atropine sulfate is obtained from Sigma Chemical Co.

Test compounds: For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, so that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M.

Tissue preparation

Male Wistar rats are killed by decapitation and their brains rapidly removed. After removal of the cerebellum, each brain is homogenized in 10 volumes of ice-cold 0.32 M sucrose in a Potter-Elvejhem glass homogenizer. The homogenate is then centrifuged at 1 000 *g* for 10 min and the pellet discarded. The resultant supernatant is further dispersed and used for [^{3}H]-QNB binding studies. Specific binding is 20% of the total added ligand and approximately 95% of the total bound ligand.

Assay

100 µl 0.5 M Na/K phosphate buffer, pH 7.4 (134 g $Na_2HPO_4 \cdot 7\,H_2O + 68$ g KH_2PO_4)
780 µl H_2O
50 µl ^{3}H-QNB stock solution
20 µl vehicle (for total binding) or 2 mM atropine (for nonspecific binding)
1 000 µl 0.05 M Na/K phosphate buffer (1 : 10 diluted) pH 7.4
50 µl tissue suspension

Tissue homogenates are incubated for 60 min at 25 °C with 1 nM ^{3}H-QNB and varying drug concentrations. With each binding assay, triplicate samples containing 2 µM atropine sulfate are incubated under identical conditions to determine nonspecific [^{3}H]-QNB binding. After incubation, the samples are cooled and then rapidly filtered through glass filters (Whatman GF/B)

under reduced pressure. The filters are washed 3 times with 5 ml of ice-cold phosphate buffer and then placed in scintillation vials. After the addition of 10 ml of counting cocktail, radioactivity is assayed by liquid scintillation spectrophotometry.

EVALUATION

Specific [^{3}H]-QNB binding is determined by the difference between total [^{3}H]-QNB and bound radioactivity in the presence of 2 μM atropine sulfate. Data are con-verted to percent specific bound [^{3}H]-QNB displaced by test drugs and IC_{50} values obtained from computer derived log-probit analysis. The inhibition at each drug concentration is the mean of triplicate determinations.

E.6.1.10 Monoamine oxidase inhibition: Inhibition of type A and type B monoamine oxidase activities in rat brain synaptosomes

PURPOSE AND RATIONALE

The mood-elevating effects of the antituberculosis drug iproniazid have been observed clinically. The mode of action was elucidated to be the inhibition of the enzyme monoamine oxidase. This was followed by wide use of monoamine oxidase inhibitors for the treatment of depression. However, side effects due to interaction with dietary amines have been observed. The biological role of monoamine oxidase is to regulate the levels of endogenous amines (norepinephrine, dopamine and serotonin) and exogenously administered amines. Based on different substrate and inhibitor specificities two forms of monoamine oxidase (A and B) were described. Dopamine and tyramine are substrates for both types, serotonin and epinephrine are substrates for type A, and β-phenylethylamine and benzylamine are substrates for type B. Iproniazid and tranylcypromine are nonselective inhibitors, clorgyline is a selective inhibitor of type A, deprenyl and pargyline are selective inhibitors of type B. It has been suggested that treatment with selective blockers of type B results in less detrimental food interactions.

PROCEDURE

Tissue preparation

Male Wistar rats weighing 150–250 g are sacrificed and the brains rapidly removed. Whole brain minus cerebellum is homogenized in 9 volumes of ice-cold, phosphate-buffered 0.25 M sucrose, using a Potter-Elvejhem homogenizer. The homogenate is centrifuged at 1 000 *g* for 10 min and the supernatant decanted and recentrifuged at 18 000 *g* for 20 min. The resulting pellet (P_2) is resuspended in fresh 0.25 M sucrose and recentrifuged at 18 000 *g* for 20 min. The washed pellet is resuspended in the original volume of 0.25 M sucrose and serves as the tissue source for mitochondrial monoamine oxidase.

Assay

50 μl 0.5 M PO_4 buffer, pH 7.4
450 μl H_2O
100 μl H_2O or appropriate drug concentration
200 μl tissue suspension

The tubes are preincubated for 15 min at 37 °C and the assay is started by adding 100 μl of substrate (^{14}C-5-HT or ^{14}C β-phenylethylamine) at 10 s intervals. The tubes are incubated for 30 min at 37 °C and the reaction is stopped by the addition of 0.3 ml of 2 N HCl. Tissue blank values are determined by adding the acid before the substrate. Seven ml of diethylether are added, the tubes are capped and shaken vigorously for 10 min to extract the deaminated metabolites into the organic phase, which is separated from the aqueous phase by centrifugation at 1 000 *g* for 5 min. A 4 ml aliquot of the ether layer is counted in 10 ml of liquid scintillation counting cocktail.

EVALUATION

The percent inhibition at each drug concentration is the mean of triplicate determinations. IC_{50} values are determined by log-probit analyses.

For example, deprenyl shows IC_{50}-values of 3.9×10^{-6} against MAO A and 3.0×10^{-8} against MAO B.

MODIFICATION OF THE METHOD

Colzi et al. (1992) measured dopamine and 3,4-dihydroxyphenylacetic acid (DOPAC) outflow after a reversible MAO-A inhibitor with a brain microdialysis technique in rats.

Frankhauser et al. (1994) tested the interaction of MAO inhibitors and dietary tyramine by measurement of peak systolic blood pressure in conscious rats. The increase of blood pressure after oral application of tyramine was potentiated by pretreatment with MAO inhibitors. Reversible MAO inhibitors could be differentiated from non-selective, irreversible MAO inhibitors.

E.6.2 Behavioral tests

E.6.2.1 Catalepsy antagonism in chicken

PURPOSE AND RATIONALE

Observations about cataleptic behavior in chicken have first been described more than 300 years ago (Schwenter 1636; Kircher 1646), and again reported about 100 years ago (Czermak 1873; Heubel 1877; Verworn 1898). This phenomenon was used by Vogel and Ther (1963) as a simple method to detect antidepressants besides other central stimulants.

PROCEDURE

Adult white Leghorn chicken are used. The animal is grasped with both hands whereby the left hand pushes the chicken slightly down and the right hand supports the animal from the ventral side. Immediately, the chicken is turned on its back and hold with the right hand for 1 min. Usually, cataleptic numbness occurs immediately. The cataleptic state can be sustained by slight pushing the head of the animal on the table. After 1 min the right hand is carefully withdrawn. The chicken remains in the cataleptic state for several min up to 1 h. The cataleptic rigor is interrupted by noise or fast movements of the observer. Clapping of the hands above the head arouses the chicken which jumps up and runs away. The chicken is always aroused by pulling on the wings. The animals are pretested in order to be sure about the cataleptic behavior of an individual chicken. As already found by previous investigators, the experiment can be repeated several times. Control studies showed that in untreated animals the phenomenon could be elicited 6 times every 30 min during a period 5 days. After the control experiments, the animals are injected i.p. with the test compound or the vehicle. The test is performed 4 times every 30 min during 2 h.

EVALUATION

The test is considered to be positive if the cataleptic rigor does not occur after treatment or is interrupted spontaneously within 1 min at least twice during the 2 h test period. The suppression of the cataleptic phenomenon is the criterion for a positive response. Furthermore, the arousal after hand-clapping or pulling on the wings is recorded in order to register central sedative effects. In order to obtain dose – response curves 12 animals per group are treated with various doses. ED_{50} values are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The specificity of the method has been tested. Antidepressant agents like imipramine and ethyltryptamine-acetate or other monoamino-oxydase-inhibitors and d-desoxyephedrine show a dose dependent effect. Moreover, the effects were dependent on time. ED_{50} values decreased on consecutive days after imipramine and monoamino-oxydase inhibitors but not after d-desoxyephedrine. Therefore, the test can be considered as specific for central stimulants allowing the possibility to distinguish between antidepressants and central stimulants of the amphetamine type.

E.6.2.2 Despair swim test

PURPOSE AND RATIONALE

Behavioral despair was proposed as a model to test for antidepressant activity by Porsolt et al. (1977, 1978). It was suggested that mice or rats forced to swim in a restricted space from which they cannot escape are induced to a characteristic behavior of immobility. This behavior reflects a state of despair which can reduced by several agents which are therapeutically effective in human depression.

PROCEDURE

Male Sprague-Dawley rats weighing 160–180 g are used. They are brought to the laboratory at least one day before the experiment and are housed separately in Makrolon® cages with free access to food and water. Naive rats are individually forced to swim inside a vertical Plexiglas cylinder (height: 40 cm; diameter: 18 cm, containing 15 cm of water maintained at 25 °C). Rats placed in the cylinders for the first time are initially highly active, vigorously swimming in circles, trying to climb the wall or diving to the bottom. After 2–3 min activity begins to subside and to be interspersed with phases of immobility or floating of increasing length. After 5–6 min immobility reaches a plateau where the rats remain immobile for approximately 80% of the time. After 15 min in the water the rats are removed and allowed to dry in a heated enclosure (32 °C) before being returned to their home cages. They are again placed in the cylinder 24 h later and the total duration of immobility is measured during a 5 min test. Floating behavior during this 5 min period has been found to be reproducible in different groups of rats. An animal is judged to be immobile whenever it remains floating passively in the water in a slightly hunched but upright position, its nose just above the surface. Test drugs or standard are administered one hour prior to testing. Since experiments with the standard drug (imipramine) showed that injections 1, 5 and 24 h prior the test gave the most stable results in reducing floating these times are chosen for the experiment.

EVALUATION

Duration of immobility is measured in controls and animals treated with various doses of a test drug or standard. Antidepressant drugs, but also stimulants like amphetamine and caffeine, reduce duration of immobility. Dose-responses can be evaluated.

MODIFICATIONS OF THE METHOD

Wallach and Hedley (1979) reported positive results with antihistamines and Giardina and Ebert (1989) with an ACE-inhibitor. Differentiation is achieved by the simultaneous evaluation of motor activity.

Cervo and Samanin (1987) suggested potential antidepressant activities of a selective serotonin$_{1A}$ agonist based on anti-immobility activity in the forced swimming test in rats without effect on open-field activity.

Nishimura (1988, 1989, 1993) published a modification of the forced swim test using straw suspension in the water tank. The apparatus used was a vertical glass cylinder (height: 40 cm, diameter: 18 cm) equipped with 4 pieces of straw (length 24 cm, diameter: 0.4 cm) that were suspended from above. The cores of the straws were filled with cotton rope. The straws were painted black from the surface of the water to a height of 10 cm. The apparatus was filled with water to a height of 15 cm and maintained at 25 °C. Thirty min after treatment with drugs or saline, the rats were placed in the apparatus

without straw suspension and the total duration of immobility measured for a period of 5 min. Immediately thereafter, 4 pieces of straw were suspended and the total duration of immobility in the following 5-min observation period again measured.

Buckett et al. (1982) described an automated apparatus for behavioral testing of typical and atypical antidepressants in **mice**. A multichannel system can test 10 mice simultaneously. Each mouse is placed in the beam of a Doppler radar head and horn assembly. The moving mouse causes reflections of a frequency differing from the transmitted signal. Within the Doppler head these reflected waves are mixed with a proportion of transmitted waves to produce a difference signal proportional to the activity of the mouse within the beam. The output of each Doppler head is fed to an amplifier whose gain has been calibrated to compensate for differences in sensitivity between individual heads. The method is claimed to eliminate human error and bias and to allow the testing of large numbers of compounds.

Alpermann et al. (1992) used a slightly modified behavioral despair test in mice. Sixty min after administration of the test compounds, the animals are placed in glass cylinders containing water up to a height of 10 cm (water temperature 22–24 °C). From the second minute onward, immobility of each mouse is rated every 30 s. After 10 observations mean values and standard deviations in each treatment group are calculated. Compared with the immobility score of the control group percent reduction can be calculated.

Nomura et al. (1982) published a modification of the despair swim test in mice involving a small water wheel set in a water tank. Mice placed on this apparatus turned the wheel vigorously but, when they abandoned attempts to escape from the water, the wheel stopped turning. The number of rotations of the water wheel were counted.

Hata et al. (1995) studied the behavioral characteristics of SART (specific alterations of rhythm in temperature)-stressed mice in forced swimming tests and evaluated the effects of anxiolytics and antidepressants.

CRITICAL ASSESSMENT OF THE METHOD

The method has been used and modified by many authors, e.g. Kauppila et al. (1991, van der Heyden et al. 1991).

Advantages of the method are the relative simplicity and the fact that no interaction with other drugs is necessary. Like in other behavioral tests, e.g. the catalepsy test in chicken, not only antidepressants and monoamino-oxydase inhibitors but also central stimulants give positive results.

In a critical review of the forced swimming test, Borsini and Meli (1988) discussed the various modifications and proposed rats to be more suitable than mice for detecting antidepressant activity.

The model is purely behavioral without presuppositions concerning the mechanism of action of potential antidepressants. It is sensitive to a large number of atypical antidepressants otherwise inactive in the more classical tests. The rat version seems to be more selective (fewer false positives) and the mouse version more sensitive (fewer false negatives) (Porsolt et al. 1991).

Natoh et al. (1992) reviewed the theoretical background of the forced swimming test and the various factors which can possibly affect the results.

E.6.2.3 Tail suspension test in mice

PURPOSE AND RATIONALE

The "tail suspension test" has been described by Steru et al. (1985) as a facile means of evaluating potential antidepressants. The immobility displayed by rodents when subjected to an unavoidable and inescapable stress has been hypothesized to reflect behavioral despair which in turn may reflect depressive disorders in humans. Clinically effective antidepressants reduce the immobility that mice display after active and unsuccessful attempts to escape when suspended by the tail.

PROCEDURE

Male Balb/cJ mice weighing 20–25 g are used preferentially. They are housed in plastic cages for at least 10 days prior to testing in a 12 h light cycle with food and water freely available. Animals are transported from the housing room to the testing area in their own cages and allowed to adapt to the new environment for 1 h before testing. Groups of 10 animals are treated with the test compounds or the vehicle by intraperitoneal injection 30 min prior to testing. For the test the mice are suspended on the edge of a shelf 58 cm above a table top by adhesive tape placed approximately 1 cm from the tip of the tail. The duration of immobility is recorded for a period of 5 min. Mice are considered immobile when they hang passively and completely motionless for at least 1 min.

EVALUATION

The percentage of animals showing the passive behavior is counted and compared with vehicle treated controls. Using various doses, ED_{50} values can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

The tail suspension test has been found to be an easy method to test potential antidepressant compounds. However, it has been reported that several mouse strains are essentially resistant to tail-suspension induced immobility.

MODIFICATIONS OF THE METHOD

Chermat et al. (1986) adapted the tail suspension test to the rat.

Porsolt et al. (1987), Stéru et al. (1987) recommended the use of the automated tail suspension test for the primary screening of psychotropic agents. A specially developed computerized device automatically measures the duration of immobility of 6 mice at one time and at the same time provides a measure of the energy expended by each animal, the power of the movements.

E.6.2.4 Learned helplessness in rats

PURPOSE AND RATIONALE

Animals exposed to inescapable and unavoidable electric shocks in one situation later fail to escape shock in a different situation when escape is possible (Overmier and Seligman 1967; Maier and Seligman 1976). This phenomenon was evaluated as a potential animal model of depression (Sherman et al. 1979; Martin et al. (1986), Christensen and Geoffroy 1991; Tejedor del Real et al. 1991).

PROCEDURE

Learned helplessness is produced in male Sprague-Dawley rats (300 g) by exposure to electric shock (0.7 mA) for 1 h on a schedule of 10 s of shock/min. The apparatus is a $30 \times 45 \times 30$ cm box with a grid floor. At a height of 20 cm above the floor, a platform (7.5×7.5 cm) can be inserted through one side wall to allow a jump-up escape response. The platform is not available during training. After the appropriate treatment, the animals are tested for acquisition of a jump-up escape in the same apparatus. At the beginning of a trial, the platform is pushed into the box and a 0.4 mA shock initiated. Shock is terminated in 10 s if the animal has not escaped onto the platform by this time. If an escape response occurred, the animal is allowed to remain on the platform for the duration of 10 s, then returned to the grid floor. Ten such trials with an intertrial interval of 20 s are given. In a naive control group of rats, this training resulted in 80% acquiring learned helplessness behavior. Drugs are given before the training and the test period.

EVALUATION

A drug is considered to be effective, if the learned helplessness is reduced and the number of failures to escape is decreased. Imipramine was found to be active only after repeated applications. A benzodiazepine was effective, whereas chlorpromazine was ineffective.

CRITICAL ASSESSMENT OF THE METHOD

The "learned helplessness" in the rat can be regarded as an additional measure for antidepressant activity in addition to other tests. The test is time consuming and its specificity is questionable.

MODIFICATIONS OF THE METHOD

Vaccheri et al. (1984) used an apparatus with an lever to be pressed to interrupt the shock. Giral et al. (1988), Porsolt et al. (1990) Simiand et al. (1992) used shuttle-boxes for escape.

Curzon et al. (1992) described a similar rat model of depression. Rats were tested in an open field after being restrained by taping them to wire grids for two h on the preceding day. The reduced activity is antagonized by antidepressant drugs.

E.6.2.5 Muricide behavior in rats

PURPOSE AND RATIONALE

Horovitz et al. (1965) described a selective inhibition of mouse-killing behavior in rats (Karli 1956; Karli et al. 1969) by antidepressants. The test can be used to evaluate antidepressants such as tricyclics and MAO-inhibitors.

PROCEDURE

Male Sprague-Dawley rats (300–350 g) are isolated for 6 weeks in individual cages. They have access to food and water ad libitum. One mouse is placed into the rat's cage. About 10 to 30% of rats kill the mouse by biting the animal through the cervical cord. Only rats consistently killing mice within 5 min after presentation are used for the test. The mice are removed 15 to 45 s after they have been killed in order to prevent

the rats from eating them. Drugs are injected i.p. to the rats before the test. Mice are presented 30, 60 and 120 min after drug administration.

EVALUATION

Failure to kill a mouse within 5 min is considered inhibition of muricidal behavior. Performing dose-response experiments, the ED_{50} is defined as the dose which inhibits mouse killing in 50% of the rats.

MODIFICATIONS OF THE METHOD

Injections of 5,7-dihydroxytryptamine into the lateral hypothalamus increased mouse-killing behavior in rats (Vergnes and Kempf 1982).

Molina et al. (1985) considered rats isolated for at least one month which do not kill mice in a 30 min test period as spontaneous non-killer rats. In these animals, mouse-killing behavior could be induced by i.p. injection of 150 mg/kg p-chlorophenylalanine daily for 2 days or by electrolytic lesions in the dorsal and median raphe.

McMillen et al. (1988) studied the effects of housing and muricidal behavior on serotonergic receptors and interactions with novel anxiolytic drugs.

CRITICAL ASSESSMENT OF THE METHOD

The mouse-killing behavior is inhibited not only by antidepressants but also by central stimulants like d-amphetamine (Horovitz et al. 1966; Sofia 1969a,b), some antihistamines (Barnett et al. 1969), and some cholinergic drugs (McCarthy 1966; Vogel and Leaf 1972; Wnek and Leaf 1972). Neuroleptics and benzodiazepines are active only in doses which impair motor performance.

E.6.2.6 Behavioral changes after neonatal clomipramine treatment

PURPOSE AND RATIONALE

Vogel et al. (1988, 1990a), Hartley et al. (1990) reported that neonatally administered clomipramine produces changes in adult rats that resembles endogenous depression in man, based on earlier observations by Mirmiran et al. (1981), Rodriguez-Echandia and Broitman (1983). This phenomenon has been studied by several research groups in many respects (Neill et al. 1990; Vogel et al. 1990b–e, 1996a,b; Velazquez-Moctezuma and Diaz-Ruiz 1992; Yavari et al. 1993; Maudhuit et al. 1995, 1996; Prathiba et al. 1995, 1997, 1998, 1999; Feenstra et al. 1996; Kinney et al. 1997; Bonilla-Jaime et al. 1998; Dwyer and Rosenwasser 1998).

PROCEDURE

Three days after birth, all male pups of Sprague Dawley mother rats are cross-fostered and all female pups are killed. Cross-fostering consists of removing all pups from their biological mothers and placing them with another lactating female (the non-biological foster mother). Each litter is divided into two groups of approximately equal number. Each half of the litter is placed with a different lactating female (the foster mother), and each foster mother receives half the pups

from two litters. All pups with each foster mother receive the same treatment (clomipramine or saline) and the two pup groups of each original litter are assigned to different treatments. Thus, each original pup litter contributes equally to experimental and control groups. Each pup is injected subcutaneously between the shoulder blades with 15 mg/kg clomipramine hydrochloride or saline vehicle twice daily on postnatal days 8 through 21. At one month of age the pups are weaned and housed as litters until approximately 3 weeks prior testing, at which time they are individually housed.

All testing is conducted in a Coulbourn operant conditioning chamber (Lehigh Valley, PA) placed in a quiet area. The floor rods are connected with a shock generator and a shock scrambler.

Behavioral testing is commenced at 3 months postnatally. Each test pair consists of one clomipramine-treated and one vehicle-treated rat. Prior to testing, all clomipramine- and saline-treated rats are paired by body weight (within 5 grams) to diminish size differences that could affect behavioral results. Pairs remain the same throughout the testing.

For evaluation of drugs, clomipramine-treated rats are administered subcutaneously for 4 days twice daily saline, or standard drug (10 mg/kg imipramine), or test drug.

Tests are done daily for 4 days. On the first day, the animals are placed in the chamber for 12 min habituation. On days 2–4, the sessions start with a 2 min habituation period followed by 10 min of shock delivery. Shocks (1.33 mA, 0.5 s duration) are delivered on a variable schedule with a minimum of 5 and a maximum of 10 s shock intervals. This results in a total of 70–80 shocks within the 10-min session.

Two observers score simultaneously. Each watches one rat of the pair. The rats are identified by a red mark on the fur. The behaviors produced are almost totally in response to shock delivery; both animals are almost immobile between the shocks. Both observers are blind to the treatment conditions of the animals.

Offensive and defensive behaviors are scored including the following 4 behaviors:

1. An upright position which is part of a mutual upright posture in which the dominant rat towers over the submissive rat. The submissive rat rears on its hindlegs, with the head positioned at an upward angle, the forepaws extended toward the attacking animal, and the ventral surface of the body continually facing the opponent.
2. In the offensive crouch, the dominant animal turns its flank towards the subordinate; the submissive crouch is characterized by freezing in a motionless crouching position.
3. Mounting behavior is frequently seen and is the same as seen in the male prior to copulating with a female.
4. Leaps in response to the shock which are directed to the other rat are scored as aggressive responses.

Three defensive or submissive behaviors were observed:

1. Defensive upright posture;
2. submissive crouch;
3. a supine position in submission to the dominant rat.

In this system each offensive behavior by one rat is partly defined by a defensive behavior of the other rat and vice versa.

EVALUATION

The individual behaviors of the treatment and control groups are listed for offensive and defensive behavior on days 1, 2, and 3 and the total of scores calculated for each group. Analysis of variance is applied to offensive, defensive, difference (offensive minus defensive) and total (offensive plus defensive behavior scores. Rats treated postnatally with clomipramine have significantly fewer offensive and significantly more defensive behaviors. This effect is ameliorated by treatment with antidepressant drugs.

CRITICAL ASSESSMENT OF THE TEST

Not only clomipramine, but also other psychotropic drugs induce changes in behavior of adult rats after treatment in neonatal age (Drago et al. 1985; Frank and Heller 1997; Hansen et al. 1998), however, clomipramine induces the most pronounced effects (Velazquez-Moctezuma et al. 1993; Vogel and Hagler 1996; Hansen et al. 1997). Specificity of the procedure to evaluate potential antidepressant compounds remains to be established.

MODIFICATIONS OF THE METHOD

Neonatal treatment with clomipramine not only reduces shock induced aggression, but also induces REM sleep abnormalities (Mirmiran et al. 1981; Vogel et al. 1990b,c; Frank and Heller 1997), decreases intracranial self-stimulation (Vogel et al. 1990d), increases activity in open-field tests in adulthood (Hartley et al. (1990, Prathiba et al. 1997), increases immobility in the forced swim test (Velazquez-Moctezuma and Diaz-Ruiz 1992), reduces adult male rat sexual behavior (Neill et al. 1990; Velazquez-Moctezuma et al. 1993; Vogel et al. 1996; Bonilla-Jaime et al. 1998,), influences the hypothalamic-pituitary-adrenal axis in adult rats (Feenstra et al. 1996; Prathiba et al. 1998, 1999).

E.6.2.7 Antidepressant-like activity in differential-reinforcement of low rate 72-second schedule

PURPOSE AND RATIONALE

The differential-reinforcement-of low-rate (DRL) 72-s schedule has been recommended for evaluation of antidepressant drugs (O'Donnell and Seiden 1983).

PROCEDURE

Male Sprague Dawley rats weighing 350–450 g are housed in suspended wire cages in rooms maintained at 21–23 °C and 30% to 40% relative humidity having free access to laboratory chow except during experi-

mental sessions. Water is provided after each daily session in order to maintain body weights.

Apparatus

Model C Gerbrand operant-conditioning chambers (O'Donnell and Seiden 1983) or Coulbourn operant chambers (Pollard and Howard 1986) are used. A lever that operates a microswitch is mounted on one wall 3 cm from the side, 2.5 cm above a grid floor and 6.5 cm from an access port for a dipper that provides 0.025 ml of water. A houselight is mounted on the opposite wall. A downwards force equivalent to approximately 15 g operates the lever, constituting a response. When the schedule requirements are met, the dipper is lifted from a water trough to an opening in the floor of the access port for 4 s, constituting a reinforcer.

Rats are water-deprived for 22 h before each session. Each rat is initially trained under an alternative fixed-ratio 1, fixed-time 1-min schedule for water reinforcement. Thus, each response is reinforced, and reinforcement is also provided every min if no responding occurs. All rats are then placed under a DRL (differential-reinforcement-of-low-rate) 18 s schedule for 3 weeks. The schedule requirement is then increased to 72 s (DRL 72-sec). When performances on the DRL 72-sec schedule are stabilized (approximately 6 weeks), drug treatments are initiated.

Each group of 6 to 10 rats is subjected to a dose-response determination for one ore more drugs. Drugs are administered one h before testing by intraperitoneal injection.

EVALUATION

Data are expressed as percentages of non-injected controls. The control values are the response and reinforcement rates on those days immediately preceding the test day. The number of responses and reinforcers per session at each drug dose are tested for statistically significant differences from control values with paired t-tests using a two tailed criterion of statistical significance.

CRITICAL ASSESSMENT OF THE TEST

The method is rather time consuming. Moreover, the specificity as screening method for antidepressants has been challenged (Pollard and Howard 1986).

E.6.3
Tests for antidepressant activity based on the mechanism of action

E.6.3.1
Potentiation of norepinephrine toxicity

PURPOSE AND RATIONALE

Antidepressants block the re-uptake of biogenic amines into nervous tissue. In this way, the toxic effects of norepinephrine are potentiated.

PROCEDURE

Male NMRI mice (22–25 g) are randomly assigned to test groups of 10 subjects. The test drug, the standard or the vehicle are given orally 1 h prior to the s.c. injection of the sublethal dose of 3 mg/kg noradrenaline. The groups of 10 mice are placed into plastic cages with free access to food and water.

EVALUATION

The mortality rate is assessed 48 h post-dosing. ED_{50}, or dose which causes death of 50% of the treated subjects, is calculated by means of linear regression analysis.

CRITICAL ASSESSMENT OF THE METHOD

Several antidepressants block not only the uptake of noradrenaline, but also of dopamine and of serotonin. By definition, this test can only measure the noradrenaline-uptake inhibition.

One of the earliest observations on the pharmacology of antidepressants was by Sigg (1959), who showed that imipramine, as distinguished from other tricyclic substances known at this time, produced a profound potentiation of the cardiovascular effects of exogenously administered catecholamines in animals.

E.6.3.2 Compulsive gnawing in mice

PURPOSE AND RATIONALE
In man and in other species, like dogs, apomorphine induces emesis. Treatment of rodents with apomorphine causes compulsive gnawing instead of vomiting. The compulsive gnawing in mice induced by apomorphine is due to dopaminergic stimulation. Centrally acting anticholinergics shift the balance between acetylcholine and dopamine resulting in an enhancement of the apomorphine effect. Therefore, many compounds with psychotropic activity are known to have an apomorphine-synergistic effect. This enhancement is also found after administration of tricyclic antidepressants.

PROCEDURE
NMRI mice with a body weight between 18 and 20 g are injected s.c. with 10 mg/kg apomorphine. At the same time they are treated i.p. or s.c. with the test drug or the vehicle. For testing oral activity the animals are treated 30 min prior to apomorphine injection. Immediately after apomorphine injection 6 mice are placed into a cage $45 \times 45 \times 20$ cm with a wired lid. The bottom of the cage is covered with corrugated paper, the corrugation facing upwards. The mice start to bite into the paper causing fine holes or tear the paper. This behavior is enhanced by antidepressants. The mice remain 1 h in the cage.

EVALUATION
The number of bites into the corrugated paper is evaluated by placing a template upon the paper. The template has 10 rectangle windows divided into 10 areas of the same size. In a total of 100 areas the number of bites is checked. In this way percentage of damaged paper in calculated. Ten mg/kg apomorphine does not increase the biting rate of 5–10% which also occurs in normal animals. Likewise, atropine in doses of 40 and 80 mg/kg s.c. alone does not increase the biting behavior. In contrast, the combination of apomorphine and atropine greatly enhances the occurrence of gnawing. The same is true for antidepressants. For example, a dose of 25 mg/kg imipramine increases the damaged area by 40–70%. Percent gnawing of the test compound is compared with that of the standard.

CRITICAL ASSESSMENT OF THE TEST
Not only antidepressants, but also centrally acting anticholinergics and antihistaminics are active in this test. However, the test has the advantage of simplicity without any pretraining of the animals.

MODIFICATIONS OF THE METHOD
De Feo et al. (1983) reported on possible dopaminergic involvement in biting compulsion of mice induced by large doses of clonidine.

Stereotyped gnawing in mice is induced by methylphenidate (Pedersen and Christensen 1972). The phenomenon is potentiated by various drugs, such as benzodiazepines (Nielsen et al. 1991).

Stereotyped behavior in **guinea pigs** induced by apomorphine or amphetamine consisting in continuous gnawing and sniffing of the cage floor was described by Klawans and Rubovits (1972) and used as an experimental model of tardive dyskinesia.

Molander and Randrup (1974) investigated the mechanisms by which L-DOPA induces gnawing in mice.

E.6.3.3 Apomorphine- induced hypothermia in mice

PURPOSE AND RATIONALE
Apomorphine induces hypothermia in mice which can be prevented by antidepressants.

PROCEDURE
Male NMRI mice (20–22 g) are used and randomly assigned to test groups of 6 subjects. One hour after

oral administration of the test compounds or the vehicle a dose of 16 mg/kg apomorphine is injected s.c. The rectal temperature of each mouse is measured by an electronic thermometer immediately prior to apomorphine administration and 10, 20 and 30 min later. During the entire experiment, subjects are housed in groups of three in glass jars at room temperature.

EVALUATION

A time curve is constructed by plotting the temperature (mean of each group) against time in min. The AUC is calculated for all groups and converted into percent inhibition of apomorphine-induced hypothermia in the control group. An ED_{50} can be calculated by linear regression analysis.

CRITICAL ASSESSMENT OF THE METHOD

Antagonism against apomorphine-induced hypothermia can be regarded as a hint for antidepressant activity. Compounds with a marked noradrenergic or dopaminergic component are active against apomorphine-induced hypothermia but not antidepressants acting mainly through serotoninergic mechanisms.

MODIFICATIONS OF THE METHOD

Cox and Lee (1981) induced hypothermia in rats by intrahypothalamic injection of 5-hydroxytryptamine and recommended this as a model for the quantitative study of 5-hydroxytryptamine receptors.

E.6.3.4 Tetrabenazine antagonism in mice

PURPOSE AND RATIONALE

Tetrabenazine (TBZ) induces a depletion of biogenic amines (e.g. noradrenaline, dopamine, serotonin) without affecting their de novo synthesis. TBZ depletes noradrenaline from nerve terminals and prolongs re-uptake into the granula. Noradrenaline is degraded by monoamino-oxydase. Antidepressants inhibit the re-uptake of noradrenaline into the nerve terminals and increase thereby the noradrenaline concentration at the receptor site. In this way, the effect of TBZ is antagonized. Therefore, both MAO-inhibitors and tricyclic antidepressants are known to prevent or to antagonize these effects. The prevention of TBZ induced ptosis and catalepsy can be used for evaluation of antidepressants.

PROCEDURE

Groups of 5–10 male NMRI mice (20–22 g) are used. Sixty min after oral or 30 min after i.p administration of the test compound or the vehicle 40 mg/kg i.p. TBZ are injected. The animals are placed into individual cages. The test is started 30 min after TBZ administration and repeated every 30 min up to 2 h. Catalepsy and ptosis are used as criteria. A stair is formed with 2 cork stoppers having 2 steps of 3 cm height. The animals are placed head downwards with their hindlegs upon the top cork. As long as TBZ exerts its cataleptic effect the animals remain in this catatonic state. If the cataleptic effect is not antagonized after a limit of 60 s the animals are placed into a normal position.

EVALUATION

Thirty s after replacement the degree of ptosis is scored: eyes closed = 4, eyes ¾ closed = 3, eyes ½ closed = 2, eyes ¼ closed = 1, eyes open = 0. (Rubin et al. 1957) Similarly, the cataleptic effect is scored according to the duration of catalepsy. Catalepsy more than 60 s = 5, between 30 and 60 s = 4, between 10 and 30 s = 3, between 5 and 10 s = 1, less than 5 s = 0. The scores of the TBZ controls are taken as 100% and the percentage is calculated for the treated animals. Imipramine was found to be effective at a dose of 10 mg/kg s.c. or 20 mg/kg orally.

CRITICAL ASSESSMENT OF THE METHOD

The TBZ antagonism has been found to be a simple and reliable test for evaluation of classical antidepressants.

MODIFICATIONS OF THE METHOD

Ptosis in mice can be induced in a similar way by treatment with reserpine. Mice receive a single oral dose of the test compound followed by subcutaneous administration of 5 mg/kg reserpine 30 min later. Ptosis is observed for the next 1 or 2 h and scored in a similar way as in the TBZ test.

TBZ ptosis can also be elicited in rats. The test procedure and the evaluation is the same as in mice. Tetrabenazine-induced hyperthermia in mice has been proposed as test for antidepressant activity by Gylys et al. (1963).

E.6.3.5 Reserpine induced hypothermia

PURPOSE AND RATIONALE

Depletion of biogenic amines (noradrenaline, 5-hydroxytryptamine, dopamine) in the brain induces not only catalepsy and ptosis but also hypothermia in rodents. The decrease of body temperature induced by reserpine is antagonized by antidepressants, MAO-inhibitors and central stimulants. The subcutaneous administration of 2 mg/kg reserpine leads to a decrease of core temperature in mice to 20–23 °C after 18 h. The fall in temperature can be antagonized by antidepressants, but also by amphetamine-like drugs. However, the time course is different: tricyclic antidepressants have a slow onset of action and a long lasting effect, whereas amphetamine-like drugs have a quick onset of action and a short-lasting effect.

PROCEDURE

Groups of 5 male NMRI mice (19–21 g body weight) are used. On the day before testing, they are dosed with 2 mg/kg reserpine s.c. They are housed in a climate-controlled animal colony and have free access to food and water. Eighteen hours after reserpine administration, the animals are placed into individual cages. The initial rectal temperature is determined by insertion of an electronic thermometer (e.g. Ellab T-3) to a constant depth of 2 cm. Following administration of the test compound (either i.p. or p.o.), the rectal temperature is measured again at 60 min intervals for 7 h.

EVALUATION

Rectal temperature is recorded every hour. The difference in temperature from vehicle controls is calculated for each time and the maximal difference is scored. The differences are then statistically compared using the *t*-test.

MODIFICATIONS OF THE METHOD

The time course and the administration route can be changed. Male mice are treated with the test drug or the standard 1 h prior to intravenous injection of 2 mg/kg reserpine. Rectal temperature is measured by a rectal thermometer prior and every 60 min up to 6 h The animals are kept in groups of 3 in glass jars at a controlled temperature of 20–21 °C. Using a computer program the area under the curve is calculated by plotting the temperature (mean of each group) before and the decrease after reserpine against time in hours. Areas of treated groups are converted to percentage of controls.

Colpaert et al. (1975), Niemegeers (1975) described the antagonism of antidepressants and other drugs against Ro-4-1 284, a benzoquinolizine derivative which by itself exhibits reserpine-like activities.

CRITICAL ASSESSMENT OF THE METHOD

The test has been proven as a simple and reliable method to detect antidepressant activity. However, the reversal of hypothermia is not specific for antidepressants. The fall in body temperature can also be antagonized by amphetamines, and some antipsychotic agents (chlorpromazine). The different time course of antidepressants (slow onset of action, long-lasting effect) and amphetamine-like drugs (quick onset of action, short-lasting effect) allows differentiation between the two groups of drugs.

E.6.3.6 5-Hydroxytryptophan potentiation in mice

PURPOSE AND RATIONALE

According to the monoamine hypothesis of depression compounds exert antidepressant activity because they are capable of enhancing central noradrenergic and/or serotoninergic functions. Several antidepressant agents potentiate serotonin effects by a block of the re-uptake of serotonin. DL-5-Hydroxytryptophan is used as the precursor of serotonin. Enzymatic breakdown is inhibited by the MAO-inhibitor pargyline. In mice the characteristic symptom of head-twitches is observed.

PROCEDURE

Groups of 6 male mice (18–30 g) are used. They are treated i.p with the test drug or the vehicle. Thirty min later, the mice receive 75 mg/kg pargyline HCl s.c. Ninety min after pargyline the animals are injected wit 10 mg/kg DL-5-hydroxytryptophan (5-HTP) i.v.

EVALUATION

Animals positively influenced show a characteristic behavior of head twitches. A animal is considered to be positive if it shows head twitches 15 min after 5-HTP injection. Enhancement is observed after treatment with serotonin uptake blockers relative to animals pretreated with pargyline only.

CRITICAL ASSESSMENT OF THE METHOD

The test can be considered as additional evidence for antidepressant activity based on uptake inhibition.

MODIFICATION OF THE METHOD

The head-twitch in mice can also be elicited without a MAO-inhibitor by using higher doses (200 mg/kg) of DL-5-hydroxytryptophan.

Meert et al. (1988) studied partial and complete blockade of 5-hydroxytryptophan (5-HTP)-induced head twitches in the *rat* by serotonin S_2 antagonists.

Niemegeers et al. (1983), Awouters et al. (1988) used *mescaline* induced head twitches in the rat as an *in vivo* method to evaluate serotonin S_2-antagonists. Head twitches were counted for 15 min after intravenous injection of 20 mg/kg mescaline. Twitch counts of less than 2 were considered as inhibition and of less than 2 as blockade of the mescaline response.

E.6.3.7 5-Hydroxytryptophan potentiation in rats

PURPOSE AND RATIONALE

The inhibition of serotonin re-uptake by some antidepressants can be tested *in vivo* in rats by administration of the precursor 5-hydroxytryptophan and inhibition of its breakdown by the MAO-inhibitor pargyline. In contrast to mice exhibiting head twitches, rats show other symptoms such as continuous forelimb clonus.

PROCEDURE

Groups of 6 male Wistar rats weighing 150–200 g are used. Four hours prior to testing pargyline HCl is injected sc. at a dose of 75 mg/kg. Thirty min before i.p. injection of 1 mg/kg L-5-hydroxytryptophan, test compounds or standards are administered intraperitoneally. Fifteen min after the 5-hydroxytryptophan injection, the animals are observed for 15 min. An animal is considered to be positive if is exhibits continuous forelimb clonus.

EVALUATION

Enhancement is expressed as normalized percent increase relative to the vehicle control. Using various doses, ED_{50} values with 95% confidence limits can be determined by probit analysis.

MODIFICATIONS OF THE METHOD

Hallberg et al. (1985) developed a registration device based on accelerometry in order to accomplish an objective quantification of tremors in conscious unrestrained rats. Tremor intensity was continuously recorded by a small piecoresistive accelerometer mounted on the back of the freely moving rat. The accelerometer was connected to a Grass Polygraph. The integrated signals were further analyzed by a desk-top computer.

The behavior in rats induced by 10 mg/kg L-5-hydroxytryptophan i.p. can be antagonized by compounds having 5-HT_2 antagonist properties (Colpaert and Janssen 1983).

E.6.3.8 Yohimbine toxicity enhancement

PURPOSE AND RATIONALE

Yohimbine occupies central α_2-receptors, and prevents noradrenaline from binding to these receptors. Compounds with antidepressant properties are known to inhibit physiological inactivation of noradrenaline and other biogenic amines by blocking the re-uptake at nerve terminals. Administration of a test compound with antidepressant properties leads to an increase in noradrenaline concentration. Following the simultaneous administration of yohimbine and antidepressants the animals die of noradrenaline poisoning.

PROCEDURE

Groups of 10 male NMRI mice (25–28 g) are used. Mice are placed in plastic cages and receive the test compound or the vehicle by oral or i.p. administration. Thirty min later, a dose of 25 mg/kg yohimbine (a sublethal dose) is given s.c.

EVALUATION

Mortality rate is assessed 1 h, 2 h, 3 h, 4 h, 5 h, and 24 h after dosing. Lethality in the control group (Yohimbine only) is less than 10%, whereas 10 mg/kg desipramine-HCl causes death in about 90%. Using various doses ED_{50}-values can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

The test has been proven as a simple method to detect antidepressants with monoamine uptake inhibiting properties.

E.6.3.9 Tryptamine seizure potentiation in rats

PURPOSE AND RATIONALE

Monoamino-oxydase (MAO) inhibitors like iproniazid enhance seizures in rats caused by an intravenous infusion of tryptamine HCl. This procedure can be used to elucidate the *in vivo* MAO inhibiting properties of compounds.

PROCEDURE

Groups of 5 male Wistar rats weighing 150–200 g are used. Test compounds, standard or vehicle controls are administered intraperitoneally 0.5; 1; 2; and 4 h prior testing. At the time of testing 5 mg/kg tryptamine HCl freshly dissolved in saline are injected intravenously. Immediately after tryptamine HCl administration, the animals are observed individually for three min for the appearance of clonic "pedalling" movements of the forepaws which is considered a positive response. Frequently, these clonic seizures are preceded by a kyphotic curvature of the spine but this sign does not constitute a positive response.

In addition to the vehicle control group, a series of five positive control animals receiving tranylcypromine at 5 mg/kg i.p. with a 0.5 h pretreatment time are subjected to the test in order to check the effectiveness of the tryptamine HCl solution which is relatively unstable. A 100% response is expected. Fresh tryptamine HCl solution should be prepared hourly as needed.

EVALUATION

The normalized percent potentiation is calculated as follows:

$$100 \times \left[\frac{\%\ \text{animals potent. in drug group}}{1 - \%\ \text{animals potent. in vehicle group}} - \frac{\%\ \text{animals potent. in vehicle}}{1 - \%\ \text{animals potent. in vehicle group}} \right]$$

A dose-response is obtained in the same manner at the peak time of drug effect except that a group size of 10 animals is used and four different doses are tested in addition to the vehicle and the tranylcypromine groups.

An ED_{50} is calculated using probit analysis.

MODIFICATIONS OF THE METHOD

E.6.3.10 Serotonin syndrome in rats

PURPOSE AND RATIONALE

Compounds which stimulate serotonin receptors cause a series of behavioral changes in rats which is called the serotonin syndrome (Jacobs 1976; Green and Heal 1985; Tricklebank 1985) such as head weaving, increased locomotion, forepaw treading, flat posture and lower lip retraction. With increasing knowledge about the subtypes of serotonin receptors these symptoms were defined to be associated with 5-HT_{1A} receptors and their specific agonists (Smith and Peroutka (1986), Blanchard et al. 1993; Yu and Lewander 1997).

PROCEDURE

Time- and dose-dependence of **forepaw treading**, which is scored at 15, 30, 45, and 60 min according to a 3-point scale (0 = absent; 1 = periodic and weak; 2 = continuous) according to Arnt and Hyttel (1989) and Porsolt et al. (1992),

was measured by Deakin and Green (1978), Green et al. (1983), Goodwin and Green (1985), Goodwin et al. (1986), Berendsen and Broekkamp (1990), Schoeffter et al. (1993), Andersson and Larsson (1994), Forster et al. (1995), Kofman and Levin (1995), Lu and Nagayama (1996), O'Connell and Curzon (1966), Gaggi et al. (1997), Kleven et al. (1997), Yu and Lewander (1997),

of **flat body posture** by Deakin and Green (1978), Goodwin and Green (1985), Goodwin et al. (1986), Blanchard et al. (1993), Schoeffter et al. (1993), Andersson and Larsson (1994), Foreman et al. (1993, 1994, 1995), Forster et al. (1995), Kofman and Levin (1995), O'Connell and Curzon (1966), Gaggi et al. (1997), Kleven et al. (1997), Wolff et al. (1997), Yu and Lewander (1997),

of **hind limb abduction** by Deakin and Green (1978), Green et al. (1983), Goodwin and Green (1985), Goodwin et al. (1986), Kofman and Levin (1995),

of **increased motility** by Tricklebank (1985), Forster et al. (1995), Gaggi et al. (1997), O'Neill and Parameswaran (1997),

of **decreased body temperature** by Martin et al. (1992), Schoeffter et al. (1993), Simiand et al. (1993), Foreman et al. (1993, 1994, 1995), Forster et al. (1995), O'Connell and Curzon (1966), Bagdy and To (1997), Wolff et al. (1997), Yu and Lewander (1997),

of **head twitches** by Deakin and Green (1978), Green et al. (1983), Goodwin and Green (1985), Goodwin et al. (1986), Meert et al. (1988), Berendsen and Broekkamp (1990,) Kofman and Levin (1995), Gaggi et al. (1997), Kleven et al. (1997),

of **lower lip retraction**, which is scored according to Berendsen et al. (1989) after 15, 30, 45 min as follows: 0 = lower incisors not or hardly visible (not different from nontreated animals), 0.5 = partly visible, 1 = completely visible,

by Smith and Peroutka (1986), Berendsen et al. (1994, 1997), Porsolt et al. (1992), Blanchard et al. (1993), Andersson and Larsson (1994), Foreman et al. (1993, 1994, 1995), Moore et al. (1993), De Boer et al. (1995), Berendsen et al. (1966), Bagdy and To (1997), Groenink et al. 1997; Kleven et al. (1997), Wolff et al. (1997).

EVALUATION

Scores of each symptom are registered for each test animal. Average values of treated animals are compared with controls treated with vehicle alone. Dose-response and time response curves are evaluated.

CRITICAL ASSESSMENT OF THE TEST

Among the many symptoms of the serotonin syndrome in rats, forepaw treading, flat body posture and lower lip retraction were used by most authors to characterize agonists and antagonists of 5-HT_{1A} receptors.

MODIFICATIONS OF THE METHOD

Trulson et al. (1976) used the serotonin syndrome to test the supersensitivity after destruction of central serotonergic nerve terminals by intracerebral injection of 5,7-dihydroxytryptamine.

Blanchard et al. (1997) described the symptoms of selective activation of 5-HT_{1A} receptors in **mice**.

Locomotor activity of **guinea pigs** was increased in a dose-dependent manner by 5-HT_{1A} receptor agonists (Evenden 1994).

E.6.3.11
Hypermotility in olfactory-bulbectomized rats

PURPOSE AND RATIONALE

Bilateral olfactory bulbectomy in the rat is associated with changes in exploratory behavior that are reversed by chronic, but not acute treatment with antidepressant drugs (Cairncross et al. 1978, 1979; Leonard and Tuite 1981; Janscár and Leonard 1981).

PROCEDURE

Male Sprague Dawley rats are anesthetized with intraperitoneal injection of 2.5% tribromo-ethanol solution (Cairncross et al. 1977). Following exposure of the skull, a burr hole is drilled at points 7 mm anterior to the bregma and 2 mm either side of the midline at a point corresponding to the posterior margin of the orbit of the eye. The olfactory bulbs are removed by suction and the burr holes filled with hemostatic sponge. Tetramycin powder is then applied to the wound and the skin closed by surgical clips. Sham-operated animals are treated in the same way but although the dura above the bulbs is cut, the bulbs are left intact. The animals are allowed to recover for 14 days after surgery.

For drug evaluation the animals are treated subcutaneously with the test drug or the standard or the vehicle once daily at 09:00 for 14 days. In each experiment sham-operated controls treated with test drug, standard and vehicle are included.

The behavior of the animals is tested from the 12th day onwards. The rats are placed singly in the center of an open field apparatus. Ambulation (no. of squares crossed), rearing (forepaws raised from the floor), grooming and defecation (no. of fecal boli) scores are recorded for an 3 min period of observation.

EVALUATION

The results are analyzed statistically using Student's *t*-test (2 tail test), the significance being set at $P < 0.05$.

CRITICAL ASSESSMENT OF THE METHOD

The bulbectomized rat model has been shown to be highly selective for both typical and atypical antidepressants, however, the procedure is quite time consuming.

MODIFICATIONS OF THE METHOD

Various authors used this model to demonstrate antidepressant-like activity: such as Briley et al. (1996) for milnacipran, a serotonin and noradrenaline uptake inhibitor, Hancock et al. (1995) for A-80 426, an α_2-adrenoceptor antagonist with serotonin uptake blocking activity, McNamara et al. (1995) for the centrally active serotonin agonist 8-hydroxy-2-(di-n-propylamino) tetralin (8-OH-DPAT), Redmont et al. (1997) for dizocilpine (MK-801), Song and Leonard (1994) for the serotonin reuptake inhibitors fluvoxamine and sertraline, Song et al. (1996a) for centrally administered neuropeptide Y, Song et al. (1996b) for the H_1 receptor antagonist terfenadine.

Kelly and Leonard (1994, 1995) studied the effects of potential antidepressants, such as selective serotonin reuptake inhibitors, in olfactory bulbectomized rats.

Redmont et al. (1995) studied the effect of chronic antidepressant administration on the conditioned taste aversion to 8-OHDPAT in the olfactory bulbectomized rat.

Kelly et al. (1997) gave an update of the olfactory bulbectomized rat as a model of depression. Tricyclic antidepressants (amitryptiline, desimipramine), atypical agents (mianserin), selective serotonin reuptake inhibitors (paroxetine, sertraline, fluvoxamine), reversible inhibitors of monoamine oxidase A (moclobemide), as well as putative antidepressants, such as 5-HT_{1A} agonists (zalospirone, ipsapirone), noncompetitive NMDA antagonists (MK-801) and triazolobenzazepines (alprazolam, adinazolam), have demonstrated antidepressant-like activity in this model.

E.6.3.12 Sexual behavior in male rats

PURPOSE AND RATIONALE

Sexual behavior in male rats is stimulated by 5-HT_{1A} receptors agonists (Ahlenius et al. 1981; Gorzalka et al.

(1990), Foreman et al. 1993, 1994, 1995; Anderson and Larsson 1994; Tallentire et al. 1996; Ahlenius and Larsson 1997; Fernández-Guasti and Rodriguez-Manzo 1997) and inhibited by serotonin receptor antagonists (Mendelson and Gorzalka 1981) and by 5-HT_{1B} receptors antagonists (Fernández-Guasti et al. 1989). The test procedure was described in detail by Arnone et al. (1995).

PROCEDURE

Adult male and ovarectomized female Sprague Dawley rats are housed in sex-separated rooms at 21 ±1 °C in a reversed light-dark cycle with free access to food and water.

Mating behavior

Male rats of two levels of sexual performance are selected for drug testing: sexually naive and sexually experienced. The latter are given 4 mating pretests, twice a week. Only sexually active males that achieve at least two ejaculations per test, are included in the experiments.

The mating tests are performed between 12:30 and 17:00, during the dark phase of the lighting cycle. Drug is administered orally 1 h before the test to the male rat. The animal is allowed to adapt to the test area (60 cm diameter, 50 cm high) illuminated with a dim red light. Each behavioral test starts with the introduction of a stimulus female brought into sexual receptivity by s.c. treatment with estradiol benzoate (10 µg/rat), followed 48 h later by progesterone (500 µg/rat), 4–5 h before testing. The tests end either 20 min later or after the first post-ejaculatory mount (or 2 h later for sexual satiation).

The following behavioral parameters are recorded:

- **Mount and intromission latencies:** time interval from the first introduction of the female to the first mount or intromission, respectively. Mounts are accompanied by an average of three or four brief shallow thrusts, while the intromission, which succeeds this event, is marked by a single deep thrust indicative of penile insertion.
- **Mount frequency:** total number of pre-ejaculatory mounts with and without intromission.
- **Intromission frequency:** total number of pre-ejaculatory intromissions.
- **Ejaculatory latency:** time interval from the first intromission to ejaculation. A total of 1 200 s is scored for the latencies of rats failing to mount, intromit or ejaculate.

Sexual satiation

The mating pattern of the male rat consists of repeated mounts and intromissions, culminating in an ejaculation. The ejaculation is followed by a period of 4–5 min during which time the male remains refractory to sexual stimulation by the female. The sexual activity is thereafter resumed with a new series of mounts and intromissions followed by ejaculation. If uninterrupted, the rat may achieve five to six ejaculations before sexual satiation sets in. Sexually experienced male rats are allowed to copulated with a receptive female for 2 h. The behaviors are recorded on a videotape. The criterion for satiation is that the male fails to mount within 20 min post ejaculation. The latency to satiation and the number ejaculations are recorded.

Finally, for each ejaculatory series, the following parameters are recorded:

- **Copulation duration:** time interval between the first mount and the ejaculation.
- **Post ejaculatory interval:** time interval from the ejaculation to the first mount of the next series.

Penile erections

One hour before the experiment, male rats are allowed to adapt to the quiet observation room. One hour after oral drug administration, rats are placed in individual plastic cages (10.5 × 24 × 16 cm). Series of nine rats comprising, at random, control and drug-treated animals, are observed simultaneously for 45 min and the number of penile erections is counted. Penile erection is defined as a period of pelvic thrusting followed by an upright position with genital grooming and the display of the engorged penis. Animals are used only once.

EVALUATION

Data are analyzed using non-parametric statistics. The Fisher test is used for percentage responding. For quantified behavioral parameters, the Kruskal-Wallis test, followed by the Mann-Whitney *U*-test corrected by Holm's method is used for comparisons versus the control group. The Mann-Whitney *U*-test is used for comparison of a single treated group versus its own control group.

MODIFICATIONS OF THE METHOD

Pomerantz et al. (1993) studied the influence of 5-HT receptor agonists on male sexual behavior of **rhesus monkeys**.

E.7 Anti-Parkinsonism activity

E.7.0.1 General considerations

According to our present knowledge the fundamental lesion in Parkinson's disease is a marked deficiency in the dopaminergic innervation of the basal ganglia owing to degeneration of neurones in the substantia nigra. Enhancement of dopaminergic transmission restores al least partially motor function. The decrease in dopaminergic activity in the basal ganglia results in a relative excess of cholinergic influence. Therefore, dopaminergic agonists, such as levodopa, a precursor of dopamine, and cholinergic (muscarinic) antagonists can be combined in the treatment of Parkinson's disease. Parkinson-like syndromes also occur after depletion of central stores by reserpine and after treatment with phenothiazines and other antipsychotic drugs blocking dopamine receptors. Survey on methods being used have been given by Vernier (1964), Marsden et al. (1975), Duvoisin (1976). Parkinsonism induced by dopaminergic antagonists has been discussed by Hornykiewicz (1975) and antimuscarinic actions of neuroleptic drugs by Miller and Hiley (1975).

E.7.1 *In vivo* methods

E.7.1.1 Tremorine and oxotremorine antagonism

PURPOSE AND RATIONALE

The muscarinic agonists tremorine and oxotremorine induce parkinsonism-like signs such as tremor, ataxia, spasticity, salivation, lacrimation and hypothermia. These signs are antagonized by anticholinergic drugs.

PROCEDURE

Groups of 6–10 male NMRI mice weighing 18–22 g are used. They are dosed orally with the test compound or the standard (5 mg/kg benzatropine mesilate) 1 h prior the administration of 0.5 mg/kg oxotremorine s.c. Rectal temperature is measured before administration of the compound (basal value) and 1, 2 and 3 h after oxotremorine injection. Tremor is scored after oxotremorine dosage in 10 s observation periods every 15 min for 1 h.

Tremor	*Score*
absent	0
slight	1
medium	2
severe	3

Salivation and lacrimation are scored 15 and 30 min after oxotremorine injection.

absent	0
slight	1
medium	2
severe	3

EVALUATION

Hypothermia

The differences of body temperature after 1, 2 and 3 h versus basal values are summarized for each animal in the control group and the test groups. The average values are compared statistically.

Tremor

The scores for all animals in each group at the 3 observation periods are summarized. The numbers in the treated groups are expressed as percentage of the number of the control group.

Salivation and lacrimation

The scores for both symptoms for all animals in each group are summarized at the 2 observation periods. The numbers in the treated groups are expressed as percentage of the number of the control group.

CRITICAL ASSESSMENT OF THE METHOD

The oxotremorine antagonism has been proven to be a reliable method for testing central anticholinergic activity. The overt isomorphism between the animal model and the symptoms of Parkinson's disease recommend this test for screening of anti-Parkinson drugs. However, the model measures only central anticholinergic activity (Duvoisin 1976).

MODIFICATIONS OF THE METHOD

Matthews and Chiou (1979) developed a method for quantifying resting tremors in a rat model of limb dyskinesias. The model involved permanent cannulation of the caudate nucleus for the introduction of carbachol. Tremors were quantified with a small transducer and an electronic data collecting system. The system allows the construction of dose-response curves for tremor inhibition by potential antiparkinsonism drugs.

Johnson et al. (1986) developed a procedure for quantifying whole-body tremors in mice. Displacement of a free floating platform by animal movement created a change in resistance across a strain gauge. Administration of oxotremorine, 2.5 mg/kg, i.p, produced numerous high-frequency, high-intensity peaks within 5 min.

Clement and Dyck (1989) constructed and tested a tremor monitor that quantitates soman- and oxotremorine-induced tremors. The device consisted of a force transducer, from which a plastic beaker was suspended containing a mouse. The signal from the force transducer was fed into a tremor monitor and quantitated using the Applecounter from Columbus Instruments.

Coward et al. (1977) recommended N-carbamoyl-2-(2,6-dichlorophenyl)acetamidine hydrochloride (LON-954), a tremorigenic agent, as alternative to oxotremorine for the detection of anti-Parkinson drugs.

Rats treated with 3-acetylpyridine show a selective degeneration of neurons in the inferior olive nucleus and the olivo-cerebellar tract with characteristic motor incoordination and ataxia (Denk et al. 1968), Watanabe et al. 1997), Kinoshita et al. 1998). Similar motor dysfunction is seen in patients with olivo-ponto-cerebellar atrophy. To measure the effect of 3-acetylpyridine and the ameliorating effect of TRH agonists in rats the maximal height of vertical jump after stimulation by a foot shock was measured.

Stanford an Fowler (1997) used a special technique for measuring forelimb tremor in rats induced by low doses of physostigmine. The rats pressed a force-sensing operandum while a computer measured force output and performed Fourier analyses on resulting force-time waveforms.

E.7.1.2 MPTP model in monkeys

PURPOSE AND RATIONALE

N-MPTP (*N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) has been shown to cause symptoms of Parkinson's disease in exposed individuals. When administered to primates this compound causes a partial destruction of basal ganglia and a syndrome that resembles Parkinson's disease.

PROCEDURE

Burns et al. (1983) treated 8 adult rhesus monkeys weighing 5–8 kg over a period of 5–8 days with cumulative intravenous doses of *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (N-MPTP) up to 10–18 mg/kg. These animals showed a parkinsonism like disorder (akinesia, rigidity, postural tremor, flexed posture, eyelid closure, drooling) which was reversed by the administration of L-dopa. The pathological and biochemical changes produced by N-MPTP are similar to the well established changes in patients with Parkinsonism.

The N-MPTP intoxication was applied using marmosets by Nomoto et al. (1985, 1988), Temlett et al. (1989) and by Kebabian et al. (1992) to evaluate potential antiparkinson drugs.

EVALUATION

The severity of parkinsonian symptoms is rated by trained observers using a scale of 0 (normal) to 17 (maximum severity) that assesses movement (0: normal; 1: reduced; 2: sleepy), checking movements (0: present; 1: reduced; 2: absent), attention and blinking (0: normal; 1: abnormal), posture (0: normal; 1: abnormal trunk; 2: abnormal trunk and tail; 3: abnormal trunk, tail, and limbs; 4: flexed posture), balance and coordination (0: normal; 1: impaired; 2: unstable; 4: falls), reactions (0: normal; 1: reduced; 2: slow; 3: absent) and vocalizations (0: normal; 1: reduced; 2: absent).

MODIFICATIONS OF THE METHOD

Close and Elliott (1991) studied the behavioral effects of anti-Parkinsonian drugs in normal and MPTP-treated marmosets following central microinfusions.

Kebabian et al. (1992) tested a selective D_1 receptor agonist with antiparkinsonian activity in MTPT treated marmosets.

Domino and Sheng (1993) studied the relative potency of some dopamine agonists with varying selectivities for D_1 and D_2 receptors in MPTP-induced hemiparkinsonian monkeys.

Gnanalingham et al. (1995) used MTPT-treated marmosets and found differential effects with D_1 dopamine antagonists as compared with the effects in rats with unilateral 6-OGDA-induced lesions.

Doudet et al. (1993) used intravenous administration of ^{15}O-labeled water and 6-(^{18}F)-L-fluorodopa to assess abnormal striatal activity in monkeys after long-term recovery of unilateral lesions of the dopaminergic nigro-striatal system induced by MPTP. Positron emission tomography (PET) data were examined in relation to behavioral and biological parameters, such as cerebral blood flow.

Belluzzi et al. (1994) induced a hemiparkinsonian syndrome in *Macaca nemestrina* **monkeys** by unilateral infusion of MPTP into the right coronary artery.

Raz et al. (2000) recorded hand tremor and simultaneous activity of several neurons in the external and internal segments of the globus pallidus in **vervet monkeys** before and after treatment with MPTP.

Rollema et al. (1989) compared the effects of intracerebrally administered MPP^+ (1-methyl-4-phenylpyridinium) in three species (**mouse, rat** and **monkey**) by microdialysis determinations of dopamine and metabolites in the striatum.

Asin et al. (1997) tested a selective D_1 receptor agonist in **rats** previously given unilateral 6-hydroxydopamine injections and in **macaques** previously given unilateral, intracarotid infusions of MPTP.

Lange (1989, 1990) described circling behavior in old **rats** after unilateral intranigral injection of MPTP.

Fuxe et al. (1992) studied the protection against MPTP-induced degeneration of the nigrostriatal dopamine neurons in the **black mouse**.

E.7.1.3 Reserpine antagonism

PURPOSE AND RATIONALE

Reserpine induces depletion of central catecholamine stores. The sedative effect can be observed in mice shortly after injection, followed by signs of eyelid ptosis, hypokinesia, rigidity, catatonia, and immobility. These phenomena can be antagonized by dopamine agonists.

PROCEDURE

Male NMRI mice of either sex weighing 20–25 g are used. They are injected intraperitoneally with 5 mg/kg reserpine and tested 24 h later. Thirty min prior to observation the test compounds are injected. The animals are placed singly onto the floor of a Perspex container (30×26 cm, 20 cm high), situated on a Panlab proximity sensor unit. Horizontal movements are recorded for 10 min. Moreover, rearings and grooming episodes are registered by an experienced observer.

EVALUATION

Locomotor activity and grooming scores of drug treated animals are compared with controls treated with reserpine and vehicle only by analysis of variance.

MODIFICATIONS OF THE METHOD

Rats treated with reserpine develop spontaneous orofacial dyskinesia that has features similar to tardive dyskinesia in humans (Nisewander et al. 1994). The incidence of tongue protrusions was recorded to quantify the occurrence of oral dyskinesia.

E.7.1.4 Circling behavior in nigrostriatal lesioned rats

PURPOSE AND RATIONALE

Unilateral lesion of the dopaminergic nigrostriatal pathway in the rat by the neurotoxin 6-hydroxydopamine (6OHDA) induces hypersensitivity of the postsynaptic dopaminergic receptors in the striatum of the lesioned side. The rats rotate in a direction towards the lesioned side (ipsilateral) when an indirect acting compound such as amphetamine is administered but to the opposite direction (contralateral) when a direct acting dopamine agonist, e.g., apomorphine, or the dopamine precursor L-dopa is given. Therefore, this test can be used for the study of central dopamine function and the evaluation of dopamine antagonists and agonists, particularly the activity of novel antiparkinsonian drugs.

PROCEDURE

Male Wistar rats weighing 200–250 g at the time of surgery are used. The are housed individually in a controlled environment with free access to food and water.

The animals are anaesthetized with sodium pentobarbital. The head is placed in a stereotaxic device (DKI 900) and positioned according to the atlas of König and Klippel. After a sagittal cut is made in the skin of the skull, a 2 mm wide hole is drilled with an electrical trepan drill. Care is taken not to lesion the meninges. A 30 gauge stainless-steel cannula connected to a Hamilton syringe is aimed at the anterior zona compacta of the substantia nigra (coordinates anterior 4.1, lateral 1.0 and dorso-ventral –2.5 from instrument zero). A total of 8 µg of 6-OHDA in 4 γ/L of saline is injected at a rate of 1 γ/L/min. After the intracranial injection the wound is closed. The animal is allowed several weeks for recovery and for development of the lesion.

Specially constructed opaque plastic spheres attached to solid state programming equipment serve as test chambers. The number of full turns, either ipsilateral or contralateral to the lesion, are recorded on an automatic printout counter every 15 min for one- or two-hours test sessions.

To determine the control values for ipsilateral turning, each subject is administered 2.5 mg/kg of d-amphetamine and immediately placed in the circling chamber for 2 h. Control values for contralateral circling are determined by injecting apomorphine at 1 mg/kg s.c. and recording the rat's circling for 1 h.

Test compounds are given i.p or sc. and the animals placed into the circling chambers. Circling is recorded over a 1 h period.

EVALUATION

Percent change of drug turns from control turns is recorded. Using various doses ED_{50} values can be calculated.

MODIFICATIONS OF THE METHOD

Etemadzadeh et al. (1989) described a computerized rotometer apparatus for recording circling behavior. The digital pulses derived from the infrared photocell detector induced by the animal rotations were fed directly to a 20-megabyte microcomputer for on-line recording and were processed further to the Digital Equipment Corporation's VAX computer with the SAS software system for statistical and graphical analysis.

Hudson et al. (1993) described a 16-channel automated rotometer system for reliable measurement of turning behavior in 6-hydroxydopamine lesioned and transplanted rats. The system is preferable to more tedious methods such as videotaping and subsequent manual analysis or various other mechanical systems.

A rotometer differentiating clockwise and counterclockwise rotations with computerized evaluation is available from Technical & Scientific Equipment GmbH, D-61348 Bad Homburg, Germany.

Carey (1989) tested stimulant drugs as conditioned and unconditioned stimuli in a classical conditioning paradigm using drug-induced rotational behavior in rats with unilateral lesions of dopamine neurons.

The production of asymmetry and circling behavior following unilateral, intrastriatal administration of neuroleptics was discussed by Costall et al. (1983).

Rotational behavior produced by intranigral injections of bovine and human β-casomorphins in rats was described by Herrera-Marschitz et al. (1989).

Perese et al. (1989) created a hemiparkinsonian model in rats in which there is 6-OHDA-induced destruction of the dopaminergic nigrostriatal pathway but sparing of the dopaminergic mesolimbic pathway.

Garrett and Holtzman (1996) compared the effects of apomorphine, d-amphetamine, cocaine and caffeine on locomotor activity and rotational behavior in rats with unilateral 6-OHDA-induced lesions of the nigrostriatal tract.

McElroy and Ward (1995) reported that the high affinity and selective dopamine D_3 receptor ligand, 7-OH-DPAT, caused 6-OHDA-lesioned rats to rotate in a direction contralateral to the lesioned side similarly to the direct-acting dopamine agonist apomorphine.

Haque et al. (1996) directly infused the neurotrophins NT3 and NT4/5 intraparenchymally in close proximity to transplanted nigral tissue placed in the dopamine depleted striatum of 6-hydroxydopamine lesioned rats.

A survey on the unilateral 6-hydroxydopamine lesion model in behavioral brain research was prepared by Schwarting and Huston (1996).

Mele et al. (1997) studied alterations in striatal dopamine overflow by *in vivo* microdialysis during rotational behavior of rats induced by amphetamine, phencyclidine and MK 801.

Smith et al. (1996) reported contralateral turning in chronically cannulated rats after stimulation of glutamate receptors by unilateral intrastriatal injections of glutamate receptor agonists, such as kainate or AMPA.

Inhibition of sinistrotorsion induced in **guinea pigs** by injection of physostigmine into the right carotid artery was proposed as a method of screening central anticholinergic activity by De Jonge and Funcke (1962).

Behavioral quantification of striatal dopaminergic supersensitivity after bilateral 6-hydroxydopamine lesions in the **mouse** was reported by Mandel et al. (1992).

Worms et al. (1988), Poncelet et al. (1993) studied turning behavior in mice induced by intrastriatal injection of neuropeptides.

Fitzgerald et al. (1992) recommended the **chakragati mouse (ckr)** , a transgenic insertional mutant, which displays lateral circling, locomotor hyperactivity and hyperreactivity as a model to study aspects of neuropsychiatric disorders associated with dopaminergic abnormalities.

Emonds-Alt et al. (1995) injected 0.3 pg senktide into the striatum of **gerbils** inducing contralateral rotations which were antagonized by intraperitoneal or oral administration of a tachykinin NK_3 receptor antagonist.

Vernier and Unna (1963) tested drugs against the tremor induced by stereotactically-oriented electric lesions in the region of the subthalamus or the mesencephalic reticular formation in **monkeys**.

E.7.1.5 Elevated body swing test

PURPOSE AND RATIONALE

Borlongan and Sanberg (1995) proposed the elevated body swing test as a measure of asymmetrical motor behavior of hemiparkinsonian animals in a drug-free state.

PROCEDURE

Male, 8-week-old Sprague Dawley rats are anesthetized with sodium pentobarbital (60 mg/kg i.p.) and mounted in a Kopf stereotaxic frame. They are lesioned by injection of 8 µg 6-hydroxydopamine in 4 µl saline containing 0.02% ascorbic acid in the left substantia nigra (AP – 5.0, ML + 1.5, DV – 8.0). The solution is injected over a 4 min period and the needle left in place for an additional 5 min before retraction.

Seven days after the lesion, behavioral testing is performed. The animal is allowed to habituate in a Plexiglas box and attain a neutral position having all 4 paws on ground. The rat is held about 2.5 cm from the base of its tail and elevated 2.5 cm above the surface on which it has been resting. A swing is recorded whenever the animal moves its head out of the vertical axis to either side. Before attempting an other swing, the animal must return to the vertical position for the next swing to be counted. Swings are counted for 60 s over four consecutive 15 s segments. The total number of swings made to each side is divided by the overall total number of swings made to both sides to get percentages of left and right swings. The criterion of biased swing is set at 70% or higher. At 30 and 45 s, 6-OHDA-lesioned rats exhibit right-biased swings of 70% or higher compared to normal rats.

EVALUATION

A two-way ANOVA is used to analyze swing behavior data across the 15 s segments.

E.7.1.6 Skilled paw reaching in rats

PURPOSE AND RATIONALE

Montoya et al. (1990, 1991), Abrous et al. (1993, 1994), Nikkhah et al. (1993), Barnéoud et al. (1996) used the

skilled paw reaching test as a model of Parkinson's disease in the rat. The term "staircase test" mentioned in this context, has nothing to do with the staircase test described by Thiebot et al. (1973) for evaluating anxiolytic activity in rats (see E.2.4.6).

Unilateral injection of 6-OHDA into the medial forebrain bundle results in an impairment of paw reaching on both sides which can be ameliorated by drug treatment or transplantation of a nigral cell suspension.

The apparatus has been developed after earlier studies by Whishaw et al. (1986) who investigated the contributions of motor cortex, nigrostriatal dopamine and caudate-putamen to skilled forelimb use in the rat.

PROCEDURE

Apparatus

The apparatus consists of a clear Perspex chamber with a hinged lid. A narrower compartment with a central platform running along its length, creating a trough on either side, is connected to the chamber. The narrowness of the side compartment prevents rats from turning around, so they can use only their left paw for reaching into the left trough and their right paw for reaching into the right trough. A removable double staircase is inserted into the end of the box, sliding into the troughs on either side of the central platform. Each of the steps of the staircase contains a small well, and two 45 mg saccharin-flavored pellets are placed in each well.

Learning procedure

The week before the start of the training period, the rats are deprived of food and their body weight is stabilized at 85% of the weight of non-deprived rats. At the same time, they are gently manipulated and familiarized with the appetitive saccharin-flavored pellets.

The animals then begin to learn the paw reaching task. For four weeks they are placed in the test boxes once per day for 10–15 min. The number of pellets eaten during the test period indicates the rat's success in grasping and retrieving the pellets; the number of steps from which pellets have been removed provides an index of the attempts to reach the food and how far the rat can reach; the number of missed pellets remaining at the end of the test on the floor of the side compartment indicates a lack of sensorimotor coordination in grasping and retrieving the pellets. In addition to these three parameters, it is noted which forepaw the rat used for the first movement to reach the pellet on each test day. A first choice score of +1 corresponds to the paw contralateral to the lesion, a score of –1, to the paw ipsilateral to the lesion. Because rodents exhibit a "pawedness", it must be noted whether there is a preference for one paw.

Lesions

The mesotelencephalic system is lesioned by a stereotaxic unilateral injection of 6-OHDA into the medial forebrain bundle under equithesin anesthesia. 6-OHDA is injected in a volume of 1.5 µl and at a concentration of 4 µg/µl 0.9% saline and 0.01% ascorbic acid twice over 3 min via a 30-gauge stainless steel cannula at the stereotaxic coordinates: $L = 1.6$ mm, $AP = 0$ mm, $V = -7.6$ mm and $L = 1.6$ mm, $AP = -1$ mm, $V = -8$ mm. The coordinates AP and L are estimated relative to the bregma, and V is measured from the level of the dura, with the incisor bar set 5 mm above the interaural line. Following each injection, the cannula is left in place for an additional 4 min to allow the diffusion of the neurotoxin away from the injection site. The sham-operated group receives sham lesions by identical injection of ascorbate-saline solution alone.

Drug treatment

The animals are injected i. p. with the test drug or saline 30 min before the unilateral 6-OHDA lesion and 24 h thereafter.

EVALUATION

Test sessions are performed 4, 5, 7 and 8 weeks after 6-OHDA lesion. The parameters success, attempts and sensorimotor coordination are subjected to a two-way ANOVA with group as the independent measure and weeks as the dependent measure.

MODIFICATIONS OF THE METHOD

Fricker et al. (1996) investigated the effect of unilateral ibotenic acid lesions in the dorsal striatum, placed at either anterior, posterior, medial, or lateral loci, in the staircase test of skilled forelimb use.

Nakao et al. (1996) studied paw-reaching ability in rats with unilateral quinolinic acid lesions of the striatum as an animal model for Huntington's disease.

Barneoud et al. (1996) evaluated the neuroprotective effects of riluzole using impaired skilled forelimb use, circling behavior, and altered dopaminergic metabolism of the mesotelencephalic system in unilaterally 6-hydroxydopamine-lesioned rats.

Fricker et al. (1997) studied the correlation between positron emission tomography, using ligands to the D_1 and D_2 receptors, and reaching behavior in rats with ibotenic acid lesions and embryonic striatal grafts.

Grabowski et al. (1993), Marston et al. (1995) Sharkey et al. (1996) tested drug effects on skilled motor deficits produced by middle cerebral artery occlusion in rats using the paw reaching test.

Meyer et al. (1997) described a revolving food pellet test for measuring sensorimotor performance in rats.

An animal model of **Huntington's disease** was recommended by Borlongan et al. (1997). Systemic ad-

ministration of 3-nitropropionic acid, an inhibitor of the mitochondrial citric acid cycle, produces a very selective striatal degeneration and results in a progressive locomotor deterioration resembling that of Huntington's disease.

Intrastriatal injection of quinolate, a NMDA receptor agonist, replicates many neurochemical, histological, and behavioral features of Huntington's disease (Beal et al. 1986; DiFigla 1990; Pérez-Navarro 2000).

E.7.1.7 Stepping test in rats

PURPOSE AND RATIONALE

Schallert et al. (1992), Olsson et al. (1995) introduced the stepping test as a clinically relevant unilateral model of Parkinsonian akinesia. The 6-OHDA lesion induced marked and long-lasting impairments in the initiation of stepping movements with the contralateral paw which can be ameliorated by the systemic application of drugs.

PROCEDURE

6-OHDA lesion surgery

Female Sprague Dawley rats receive two stereotaxic injections of 6-hydroxydopamine (3.6 µg/µl in 0.2 µg/ml ascorbate-saline) into the right ascending mesostriatal dopamine pathway using a 10 µl Hamilton syringe at the following coordinates (in mm, with reference to bregma and dura):

1. 2.5 µl at AP –4.4, L 1.2, V 7.8, tooth bar –2.4;
2. 3.0 µl at AP –4.0, L 0.8, V 8.0, tooth bar +3.4 at an injection rate of 1 µl/min. The cannula is left in place for an additional 5 min before slowly retracted.

Experimental setup for stepping test

The tests monitoring initiation time, stepping time and step length are performed on a wooden ramp with a length of 1 m connected to the rat's home cage. A smooth-surfaced table is used for measuring adjusted steps.

During the first 3 days the rats are handled by the experimenter to become familiar with the experimenter's grip. During the subsequent 1–2 days the rats are trained to run spontaneously up the ramp to the home cage.

The stepping test comprises two parts: first, the time to initiation a movement of each forelimb, the step length, and the time required for the rat to cover a set distance along the ramp with each forelimb; and second the initiation of adjusting steps by each forelimb when the animal was moved sideways along the bench surface. Each test consists of two tests per day for 3 consecutive days and the mean of 6 subtests is calculated.

Initiation time, stepping time, and step length

The rat is held by the experimenter with one hand fixing the hindlimbs and slightly raising the hind part above the surface. The other hand fixes the forelimb not to be monitored. Time is measured until the rat initiates movement with the forelimb not fixed by the experimenter, using 180 s as break-off point. Stepping time is measured from initiation of movement until the rat reaches the home cage. Step length is calculated by dividing the length of the ramp by the number of steps required for the rat to run up the ramp. The sequence of testing is right paw testing followed by left paw testing, repeated twice.

Adjusting steps

The rat is held in the same position as described above with one paw touching the table, and is then moved slowly sideways (5 s for 0.9 m) by the experimenter, first in the forehand and then in the backhand direction. The number of adjusting steps is counted for both paws in the backhand and forehand direction of movement. The sequence of testing is right paw forehand and backhand adjusting stepping, followed by left paw forehand and backhand directions. The test is repeated twice each day.

The paw contralateral to the lesion is passively dragging when the rat is moved in the forehand direction, while the ipsilateral paw performs frequent stepping movements.

Drug application

Stepping tests are repeated as baseline weekly after the 6-OHDA lesion. The drug tests are administered during 1 day only. Various drugs can be evaluated in weekly intervals.

EVALUATION

Results are expressed as means SEM. For statistical evaluation, the data are subjected to one-factor analysis of variance (ANOVA) and Fisher post hoc test.

E.8 General anesthesia

E.8.1 Intravenous anesthesia

E.8.1.1 General considerations

PURPOSE AND RATIONALE

The first agents which could be used as intravenous anesthetics were **barbiturates**. Barbiturates with a duration of action appropriate to the requirements of surgery became available with the introduction of hexobarbital and thiopental (Volwiler and Tabern 1930; Miller et al. 1936). The studies with barbiturates were extended (Butler and Bush 1942; Christensen and Lee 1973). Intravenous anesthetics from other chemical groups were developed, such as **acetamidoeugenol** (Estil, Domenjoz 1959), steroid derivatives (Presuren = **hydroxydione sodium**, Laubach et al. 1955; **alfaxolone**, CT1 341, Child et al. 1971), **propanidid** (Epontol, Goldenthal 1971), **ketamine** (CI-581, Chen et al. 1966; Reich and Silvay 1989), **etomidate** (Janssen et al. 1975), **propofol** (ICI 35 868, Glenn 1980), **midazolam** (Pieri 1983; Reilly and Nimmo 1987).

E.8.1.2 Screening of intravenous anesthetics

PURPOSE AND RATIONALE

Screening of intravenous anesthetics or hypnotics is performed mostly in mice or rats. Doses for loss of righting reflex and lethal doses are determined. Onset of action and duration of action are the secondary parameters.

PROCEDURE

Male mice weighing 18–22 g are injected intravenously via the tail vein. The anesthetic activity is estimated from the number of animals that loose their righting reflex. The righting reflex is considered lost when the mouse, placed on its back, fails to recover from this position within 1 min. The acute toxicity is based on lethality within a 24-h observation period.

To determine onset and duration of action groups of 20 mice are used. They are placed in individual observation cages maintained at room temperature (24 ±1 °C). They are not stimulated during the interval between loss and recovery of the righting reflex. The onset is defined as the complete loss of the righting reflex, i.e., no attempt to move the head or body. Recovery is considered to have occurred when the animal after spontaneous righting would re-right itself within 15 s when placed on its back.

EVALUATION

The median anesthetic dose (AD_{50}) and the median lethal dose (LD_{50}) are determined from dose-response curves with at least 4 doses by the method of Litchfield and Wilcoxon (1949).

The data for onset and duration of action are analyzed statistically by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Volwiler and Tabern (1930) determined the minimum effective dose in rats after subcutaneous injection of various barbiturates not being awakened when outer ear passage was tickled with a straw.

Büch et al. (1968) studied the distribution, anaesthetic potency and metabolic elimination of the optical isomers of methylphenobarbital in rats.

Glenn (1977) described a method for the laboratory evaluation of the speed of onset of i.v. anesthesia in **mice**. Various clinically used intravenous anesthetics were compared. The technique involves a) determination of the medium hypnotic dose (HD_{50}) by plotting the probit value of the mice sleeping against dose on a logarithmic scale, b) plotting mean induction time over a range of doses against the logarithm of the dose and c) comparison of induction times at 1.25 HD_{50}. All doses were given over 1 s or 10 s. A 1-s injection was thought to be of most value in the of structure activity effects.

Chen et al. (1966) tested the anesthetic activity and the neuropharmacological spectrum of ketamine (CI-581) in mice, pigeons and monkeys.

Child et al. (1971) tested the anesthetic activity of alfaxolone (CT1 341) in **mice, rats, rabbits, cats, dogs** and **monkeys**.

Janssen et al. (1975) tested onset and duration of anesthesia after etomidate in mice, rats, guinea pigs and dogs.

New intravenous anesthetics were reviewed by Reilly and Nimmo (1987).

The anesthetic potency of remifentanil in dogs in terms of reduction of enflurane *MAC* was tested by Michelsen et al. (1996).

Dingwall et al. (1993) described the tolerometer as a fast, automated method for the measurement of righting reflex latency.

E.8.1.3 EEG threshold test in rats

PURPOSE AND RATIONALE

The electroencephalographic (EEG) threshold test has been used to determine and compare the potency of several CNS depressant agents (Bolander et al. 1984; Koskela and Wahlström 1989; Norberg and Wahlström 1988; Norberg et al. 1987). Korkmaz and Wahlström (1997) described in detail the protocol of the EEG burst suppression threshold test for the determination of CNS sensitivity to intravenous anesthetics in rats.

PROCEDURE

Adult Sprague-Dawley rats are housed at a reversed light/dark cycle and an ambient temperature of 23 ±1 °C. Twenty four hours prior to the EEG threshold test, the rats are placed in a tube restrainer. Twisted stainless steel wire and suitable surgical needles are used to sew the electrodes to the scalp above the frontal cortex. Since generalized changes in EEG recordings are used, this stainless steel material is adequate for recording purposes. Care is taken to prevent irritation of periosteal tissue. Since this procedure causes little discomfort, the use of local anesthetics and general anesthesia can be avoided.

For EEG threshold testing, the rat is placed on a warm cloth and held gently by the assistant. A needle is placed on one lateral tail vein and connected with an infusion pump. Crocodile clips are used to connect the electrodes to the EEG recorder and a crocodile clip is attached to one of the ears of the rats as a signal ground.

The EEG recording is closely observed by the technician. The changes in the EEG induced by the anesthetic agent are used to measure drug effects on the CNS. The normal EEG in an awake rat has a low amplitude and a frequency of approx. 30 cycles/s. During the first part of infusion, an increase in amplitude and a slight decrease in frequency are observed. At this stage of infusion, dependent on the anesthetic agent, jerks or sometimes convulsive episodes may occur. As the infusion continues, the frequency decreases and burst suppression periods appear. The loss of righting reflex occurs at this stage. When a burst suppression lasts one second or more, the threshold criterion which is called 'silent second' is reached and the time is recorded. After the threshold determination, the rats are placed in the recovery room.

EVALUATION

The threshold dose is calculated by multiplying the time required to reach the threshold criterion with the dose administration rate. Threshold doses are determined for each anesthetic at various dose administration rates indicating the optimal dose administration rate.

MODIFICATIONS OF THE METHOD

Wauquier et al. (1988) studied relationships between quantitative EEG measures and pharmacodynamics of alfentanil in dogs. Before, during and up to 3 h after infusion, the effects of 3 doses on 6 quantitative EEG measures (zero-crossing frequency, root mean square amplitude, spectral edge, relative delta, alpha and beta power) were assessed.

E.8.1.4 Efficacy and safety of intravenous anesthetics

PURPOSE AND RATIONALE

Besides determination of the ratio between anesthetic and lethal dose, intravenous anesthetics have to be tested for their influence on the cardiovascular and pulmonary system. Borkowski et al. (1990 described a method to compare intravenous anesthetics in rabbits.

PROCEDURE

Adult New Zealand White rabbits with a mean weight of 4.5 kg are used. To provide access for direct blood pressure measurement and arterial blood samples, an 18-gauge catheter is implanted into the left carotid artery under halothane anesthesia. Following a minimum 24-h recovery period, the rabbit is placed in a sling and a pneumograph is fitted around the rabbit's caudal thorax at the level of 10^{th} to 12^{th} ribs to monitor respiratory rate and pattern. From the arterial catheter blood is withdrawn for blood gas analysis. Then the catheter is connected to a blood-pressure transducer. A 10-min acclimatization period is allowed before control measurements are recorded. Each rabbit serves as its own control in that cardiopulmonary parameters and responses to noxious stimuli are determined before anesthesia is induced. The right marginal ear vein is catheterized with a 22-gauge catheter, which is secured with adhesive tape, flushed with physiologic sterile saline and used for the administration of the anesthetic agents.

One third of the dose of the anesthetic to be tested is injected manually over a 1-min period. When the rabbit is relaxed it is removed from the sling and is placed in left lateral recumbence on a heating blanket. The degree of muscle tension and reaction to noxious stimuli are determined while the rabbit is in the sling and at 15 min intervals following anesthesia. The assessments performed include those of jaw tone, leg muscle tone, palpebral reflex, corneal reflex, ear pinch reflex and pedal withdrawal reflex. Jaw tone is evaluated subjectively by pulling the lower jaw open by an index finger. Leg muscle tone is evaluated by flexion and extension of the right rear leg according to subjective scores. The corneal reflex is tested by placing a moistened cotton swab on the cornea. The palpebral reflex is tested by touching the medial canthus with a dry cotton swab. Assessment of the ear pinch reflex is performed by applying a compression force with an alligator clip. The pedal withdrawal reflex is determined by applying the same clip on the right rear fifth digit at the distal phalanx.

Cardiopulmonary parameters and rectal body temperature are determined while the rabbit is in the sling and also at 15 min intervals following induction of anesthesia with the rabbit in lateral recumbency. Heart rate, mean arterial blood pressure, respiratory rate and respiratory pattern are calculated from tracings from the physiological recorder. Arterial blood pH, partial pressure of oxygen (PaO_2), and partial pressure of carbon dioxide ($PaCO_2$) are determined from arterial blood samples.

EVALUATION

The heart rate, mean arterial blood pressure, respiratory rate, pH, PaO_2 and $PaCO_2$ are analyzed using a two-factor analysis on repeated measures. The control values are treated as covariate to allow standardization of the inherent variation between rabbits. The single *t*-test for paired differences is used to compare control values to data obtained during the later testing intervals. The standard error of the mean (SEM) is calculated for each variable at each time interval. Data for muscle tone and responses to noxious stimuli are calculated as frequency percentages. The Fisher's Exact test is used to compare between treatments. For all of the statistical analyses, a *p*-value of less than 0.05 is considered significant.

MODIFICATIONS OF THE METHOD

Details of anesthesia in the rabbit were also described by Murdock (1969).

Peeters et al. (1988) performed a comparative study of four methods for general anesthesia in rabbits.

Glenn (1980) examined the anesthetic activity of propofol (ICI 35 868) in mice, rats, rabbits, cats pigs and monkeys including cardiovascular and respiratory parameters and EEG studies.

E.8.2 Inhalation anesthesia

E.8.2.1 General considerations

PURPOSE AND RATIONALE

The efficacy and safety of new inhalation anesthetics has to be evaluated in pharmacological experiments.

Robbins (1946) defined the anesthetic AD_{50} as the concentration of anesthetic at which 50% of mice failed to right themselves for 15 s when placed in a rotating bottle with a known concentration of anesthetic. The concentration of the anesthetic that caused apnea in 50% of the mice in 10 min was defined as the LD_{50} and the ratio LD_{50}/AD_{50} as and an index of safety.

The term **"minimum alveolar anesthetic concentration" (MAC)** was coined by Merkel and Eger (1963) as an index to compare various anesthetic agents.

For man, Saidman and Eger (1964) defined *MAC* as the point at which 50% of the patients moved in response to a surgical incision.

The use of *MAC* which represents the partial anesthetic pressure in the brain has gained wide acceptance (Eger et al. 1965; Quasha et al. 1980).

A method for determining minimum alveolar concentration of anesthetic in the rat was published by Waizer et al. (1973).

Kashimoto et al. (1997) determined the minimum alveolar concentration of sevoflurane in rats.

Seifen et al. (1987) used *MAC* values for comparison of cardiac effects of enflurane, isoflurane, and halothane in the dog heart-lung preparation.

Determination of an anesthetic index (Apnea/*MAC*) in experiments in dogs has been proposed by Regan and Eger (1967).

Determination of the minimal alveolar concentration (*MAC*) of halothane in the white New Zealand rabbit was published by Davis et al. (1975).

Wolfson et al. (1972) recommended brain anesthetic concentration for construction of anesthetic indices.

Murphy and Hug (1982), Hall et al. (1987) used the reduction of enflurane *MAC* values in dogs as parameter for the anesthetic potency of fentanyl or sufentanyl, respectively.

Eger et al. (1988) determined minimum alveolar concentration of fluorinated anesthetics in pigs.

Fang et al. (1997) found that maturation decreases ethanol minimum alveolar anesthetic concentration (*MAC*) more than desflurane *MAC* in rats.

Ide et al. (1998) used airway occlusion in cats as a noxious respiratory stimulus that induces a visceral sensation of choking for determination of minimum alveolar anesthetic concentrations during halothane, isoflurane, and sevoflurane anesthesia. These values were compared with *MAC* values for somatic noxious stimuli such as toe pinch or tetanic stimulus. The authors recommended this method as a new concept for *MAC* determination.

E.8.2.2 Screening of volatile anesthetics

PURPOSE AND RATIONALE

A simple technique for preliminary testing of anesthetic agents is the introduction of a measured amount of volatile liquid into a covered glass container of known volume. If the density and molecular weight of the liquid are known, the volume % concentration of the anesthetic mixture can be calculated (assuming 1 mol of vapor = 22.4 l). Mice or rats are introduced into the chamber and the quality of anesthesia is noted. Conditions are then adjusted until the anesthetic concentration has been established.

PROCEDURE

Male NMRI mice weighing 20–25 g or male Wistar rats weighing 250–300 g are used. A wide-mouth, screw-cap glass jar of 3 Liter volume is flushed with oxygen for 1 min and a measured amount of the volatile substance is placed on the bottom through a suitable syringe. The amount is calculated to give 1.25 vol% concentration of vapor in the jar (or a logarithmic multiple of 1.25%, i.e., 0.63, 2.5, 5.0, 10.0). The jar is closed and evaporation of the substance is facilitated by gentle rotation of the jar. One rat or 5 mice are quickly placed from a beaker into the jar, and the jar is immediately closed. Every 15 s the jar is gently rotated and the time noted for each animal to become anesthetized (loss of righting reflexes). The procedure is repeated until all animals are anesthetized. Induction should occur not sooner than 30 s and not later than 5 min. The animals are allowed to remain in the anesthesia jar for 10 min, with testing of righting reflexes until they are quickly removed into room air. The time of recovery to righting or walking is recorded for each animal. Postanesthetic analgesia is tested by gently pressing the base of the tail every min until recovery has occurred. If induction time is shorter than 30 s or longer than 10 min, the concentration of anesthetic is decreased or increased until the proper concentrations is found.

EVALUATION

The results are reported as mean induction time and mean recovery time. Twenty-four-hour survival rate is recorded for latent toxicity.

MODIFICATIONS OF THE METHOD

Burns et al. (1961) used a simplified mouse test apparatus with a small container and an open circuit technique.

Raventós (1956) used cats, dogs and monkeys to evaluate the cardiovascular effects of fluothane.

E.8.2.3 Efficacy and safety of inhalation anesthetics

PURPOSE AND RATIONALE

To assess the safety margin of a inhalation anesthetic not only the ED_{50} values but also the maximally effective dose and the dose with a minimal danger of fatal outcome should be determined. In particular, *cardiovascular parameters* are observed.

PROCEDURE

Male Sprague Dawley rats weighing 300–350 g are placed into a clear chamber with the tail protruding from a special opening. An anesthetic-oxygen nonhumidified mixture is directed into the chamber at a rate of 4 l/min. The inhalation anesthetics, e.g., halothane or isoflurane, are vaporized in Draeger® vaporizers and the level in the chamber is monitored with a gas analyzer which is calibrated with a mass spectrometer. Rectal temperature is monitored and maintained at 37 °C with a heating pad. Each rat is exposed to only one pre-determined concentration of anesthetic for 30 min, at which time the presence or absence of the end point of anesthesia is determined. For the lethal end point, rats are tracheotomized and ventilated at 60 strokes/min through an endotracheal catheter. Tidal volume is adjusted to maintain Pa_{CO_2} at 40 ±5 mm Hg.

As endpoints of anesthesia are used:

- Loss of righting reflex. The test is regarded as positive if the animal fails to right itself with all four feet on the floor within 15 s after being placed in a side position.
- Prevention of purposeful movements response to a noxious stimulus. The animals are stimulated for 60 s by placement of a 1-kg weight on the middle of the tail. Only the purposeful movement of the head or legs is considered to be a response.
- Prevention of the heart rate increase to a noxious stimulus (ECG signals). An increase in heart rate of greater than 1% is regarded as a positive response.
- The end point for the lethal effect is 7 mm Hg in the femoral artery with artificial respiration.

With each of the anesthetics, four series of experiments are performed: to determine the righting reflex, purposeful movement response, heart rate response, and lethal effect. The concentrations of the test compounds and the standard are spaced equally between the abovementioned doses.

After determination of the heart rate effect and the lethal effect, the rats are sacrificed for determinations of brain tissue concentrations. The whole brain is re-

moved and tissue anesthetic concentration is determined by gas chromatography.

EVALUATION

For calculation of the dose-effect curves, the probit method of statistical analysis is used.

For the assessment of anesthetic safety, not only the therapeutic ratio (LD_{50}/ED_{50}) but also the standard safety margin

$$SSM = (LD_5 - ED_{95}) / ED_{95} \times 100$$

is used. This represents the percentage by which the ED_{95} has to be increased before LD_5 is reached.

CRITICAL ASSESSMENT OF THE METHOD

The standard safety margin has definitive advantages over therapeutic ratio. In contrast to the LD_{50}/ED_{50} index, the standard safety margin is influenced not only by the distance between central points of the anesthetic and lethal dose-effect curves, but also by the slope of these curves.

MODIFICATIONS OF THE METHOD

A similar concept, based on response to tail clamping, respiratory arrest and cardiovascular failure in the *rat* was published as anesthetic index by Wolfson et al. (1973).

An other attempt to determine anesthetic requirements in rats was published by White et al. (1974).

Kissin et al. (1984) studied the morphine-halothane interaction in rats.

Fukuda et al. (1996) investigated the effects of sevoflurane and isoflurane on bupivacaine-induced arrhythmias and seizures in rats.

Krantz et al. (1941, 1953) described an anesthetic index between surgical anesthesia (cornea and wink reflexes abolished) and respiratory failure in **dogs**.

Van Poznak and Artusio (1960a,b) determined the anesthetic properties of fluorinated compounds in dogs using a face mask for the induction of anesthesia and a cuffed endotracheal tube later on. ECG (lead II) and EEG were monitored.

Steffey and Howland (1978) determined the potency of enflurane in dogs in comparison with halothane and isoflurane.

Johnson et al. (1998) compared isoflurane with sevoflurane for anesthesia induction and recovery in adult dogs.

Salmempera et al. (1992) studied in dogs the potency of remifentanil, a short acting opioid analgesic, which is used as anesthetic adjunct by variable-rate infusion. Enfluorane minimal alveolar concentration was measured by the tail-clamp method in dogs before and after sequential infusion of various doses of remifentanil. The plasma concentration causing a 50% reduction of enfluorane minimal alveolar concentration was determined.

Kataoka et al. (1994) studied the negative inotropic effects of sevoflurane, isoflurane, enflurane and halothane in canine blood-perfused papillary muscles.

Hirano et al. (1995) compared the coronary hemodynamics during isoflurane and sevoflurane anesthesia in dogs.

Mutoh et al. (1997) compared the cardiopulmonary effects of sevoflurane with those of halothane, enflurane, and isoflurane, in dogs.

Hashimoto et al. (1994) examined the effects of sevoflurane and halothane on the effective refractory period and ventricular activation in a canine myocardial infarction model.

The effects of desflurane, sevoflurane and halothane on postinfarction spontaneous dysrhythmias in dogs were examined by Novalija et al. (1998).

Cardiopulmonary effects in **cats** were studied for desflurane by McMurphy and Hodgson (1996), for sevoflurane by Hisaka et al. (1997).

Saeki et al. (1996) determined the effects of sevoflurane, enflurane, and isoflurane on baroreceptor-sympathetic reflex in **rabbits**.

Hanagata et al. (1995) found that isoflurane and sevoflurane produce a dose-dependent reduction in the shivering threshold in rabbits.

The effects of multiple administrations of sevoflurane to cynomolgus **monkeys** were evaluated by Soma et al. (1995).

The effect of inhalation anesthetics on the **respiratory system** was investigated in several studies:

Mazzeo et al. (1996) compared the relaxing effects of desflurane and halothane at various *MAC*s on isolated proximal and distal airways of dogs precontracted with acetylcholine.

Hashimoto et al. (1996) compared the bronchodilating effect of sevoflurane, enflurane and halothane in dogs using a superfine fiberoptic bronchoscope. The dogs were anesthetized with pentobarbital, paralyzed with pancuronium, and the lungs were mechanically ventilated. The endotracheal tube had an additional lumen to insert the superfine fiberoptic bronchoscope (outer diameter 2.2 mm) which was located between a second and third bronchial bifurcation to continuously monitor the bronchial cross-sectional area of third or forth generation bronchi. Bronchoconstriction was produced by histamine injection and infusion. The bronchial cross-sectional area was printed out by a videoprinter at the end of expiration and was calculated on a computer using an image program after various *MAC*s of the different inhalation anesthetics.

Mitsuhata et al. (1994) induced systemic anaphylaxis in dogs sensitized to Ascaris suum by intravenous

injection of the antigen and measured pulmonary resistance and dynamic pulmonary compliance. Sevoflurane was as effective as isoflurane in attenuating bronchoconstriction associated with anaphylaxis in dogs.

Cervin and Lindberg (1998) examined the short-term effects of halothane, isoflurane and desflurane on mucociliary activity in the rabbit maxillary sinus *in vivo*.

Chapter F
Drug effects on learning and memory[1]

[1] Reviewed by W. H. Vogel, with contributions by F. J. Hock, F. P. Huger, J. D. Brioni, J. L. McGaugh (first edition) and E. Dere (second edition).

F.1 Introduction

It is easily understood that behavioral psychopharmacologies faced with the task of dealing with extremely complex behavioral disturbances. This holds true for both patient groups: young people with learning and memory problems and elderly patients with memory deficits. For the elderly, difficulties arise in designing appropriate animal models of human aging or the deficits occurring during human aging. One of the major

problems for experimental behavioral pharmacology is whether or not old animals are the appropriate models. At the first view it seems obvious that the study of potential geronto-psychopharmacologic drugs should be performed in old animals. However, the problem is much more complicated. Laboratory animals are not a homogenous population, especially when old. Most of these old animals who are one third survivors of a population have an individually different pathological history which is mostly unknown to the investigators. Some animals may be arthritic others may have bronchitis or cardiac deficiencies. If, for example, an arthritic rat is given a performance task associated with lever pressing, the animals may fail because of his rigid and painful joints and not because of a brain deficit or of the ineffectiveness of the test compound. Similar effects can be observed with old animals having a cataract in a visual discrimination task. Failure to perform a task may even be the result of both central and peripheral disturbances. Consequently it is impossible to describe the failure of one animal to perform the task to deficits in some parts of the brain or to pathological changes in the body.

Considerable evidence indicates that there are age-related changes in learning and memory (Gold and McGaugh 1975; Gold et al. 1975). For certain kinds of learning, there are specific developmental periods at which acquisition and retention are optimal; for example, imprinting in animals (Hess 1972; Scheich 1987) and language acquisition in humans (Lennenberg 1967). For other forms of learning and memory, acquisition and long-term retention in animals mature gradually with development (Campbell and Spear 1972). There is some evidence that aged organisms have impaired memory function. For example, in humans, performance on recent memory tasks appears to decay at shorter training-test intervals and is more susceptible to retroactive interference in elderly subjects than in young adult subjects (Craik 1977; Kubanis and Zornetzer 1971). Recent memory also appears to be deficient in aged non-human primates (Bartus et al. 1980).

Although drug discovery is based upon many factors, animal models provide a crucial part in identifying chemical compounds with potential for clinical efficacy. A number of important animal models of human disease have come into existence based upon "serendipitous" discoveries of their ability to identify chemicals with a particular set of therapeutic actions. However, in the absence of truly effective therapeutic agents for age-associated dementia to serve as standards, the development of appropriate animal models for dementia represents a serious challenge. In the case of Alzheimer's Disease or age-associated memory impairment, successful development of animal models may well depend upon our ability to accurately reproduce specific pathophysiological or etiologic factors.

It is generally agreed that an ideal animal model of human dementia would exhibit some or all the behavioral and neurological dysfunctions known to be associated with the clinical disorder, as well as the pathological processes leading to the demented condition. An early approach was the measurement of the spinal cord fixation time in rats as described by Giurgea and Mouravieff-Lesiusse (1971), Giurgea and Salama (1977).

Since cholinesterase inhibitors, such as physostigmine (Christie et al. 1981; David and Mohs 1982; Thal et al. 1983) and tacrine (Summers et al. 1986) have been shown to improve cognitive function in patients with Alzheimer's type dementive disorders and based on analytical data in brains of aged subjects, the cholinergic hypothesis of geriatric memory dysfunction has been established. Numerous attempts have been made to study the influence of potential drugs on the central cholinergic system, e.g., inhibition of acetylcholinesterase activity in rat striatum *in vitro*, differentiation of this activity versus the inhibition of butyrylcholinesterase activity, *ex vivo* cholinesterase inhibition in rat striatum, release of acetylcholine from rat brain slices after electrical stimulation, binding to muscarinic cholinergic receptors in rat forebrain, stimulation of phosphatidyl-inositol turnover via muscarinic receptors, binding to nicotinic cholinergic receptors in rat frontal cortex. Presynaptic cholinergic markers include choline acetyl-transferase and acetylcholinesterase activities, high-affinity transport of choline, acetylcholine synthesis, and muscarinic receptor binding. The high-affinity transport of choline is influenced by a cholinotoxin, ethylcholine aziridinium (AF64A) which induces *in vivo* a persistent central cholinergic hypofunction of presynaptic origin (Fisher and Hanin 1986).

Changeux et al. (1998) discussed the role of nicotinic acetylcholine receptors in the brain in learning and reinforcement.

These approaches may give hints for the discovery of new antidementic drugs. The "cholinergic hypothesis" (Bartus et al. 1982, 1987) is not unequivocal in the pathophysiology of Alzheimer's disease. The role of other transmitters has to be studied (Nordberg 1990). *In vitro* and *in vivo* studies have to be performed in parallel in order to find new approaches to treat Alzheimer's disease or Alzheimer's type dementia.

Several animal strains have been recommended to study age-dependent memory deficits, such as the **senescence-accelerated mouse (SAM)**, (Fujibayashi et al. 1994; Takeda et al. 1994, 1996, 1997; Maurice

et al. 1996; Nishiyama et al. 1997; Flood and Morley 1998; Markowska et al. 1998),

transgenic mice which overexpress S100β, a calcium binding astrocytic protein influencing hippocampal long-term potentiation (LTP) and depression (LTD) (Roder et al. 1996),

transgenic Cu/Zn-SOD mice overexpressing the gene encoding copper/zinc superoxide dismutase which is also overexpressed in human Down syndrome (Gahtan et al. 1998),

a mutant mice strain exhibiting delayed Wallerian degeneration (Fox and Faden 1998),

mice with a modified β-amyloid precursor protein gene (Tremml et al. 1998),

epileptic fowl having a hereditary form of primary generalized epilepsy characterized by tonic-clonic seizures (Gervais-Fagnou and Tuckek 1996).

Several authors reported impairment of memory functions after **cerebral lesions**:

Ennaceur (1998) studied the effects of electrolytic lesions of the Medial Septum/Vertical Diagonal Band of Broca, the Globus Pallidus and the Substantia Innominata/Ventral Pallidum on the performance of **rats** in object-recognition memory and radial-maze learning tasks.

Chambers et al. (1996) proposed lesioning of the ventral hypothalamus in neonatal rats as an experimental model of schizophrenia with learning deficits.

Chen et al. (1997) observed a remarkable impairment of passive avoidance response by bilateral dorsal hippocampal lesions in rats.

Abe et al. (1998) investigated the effect of a benzodiazepine receptor partial inverse agonist on the impairment of spatial memory in basal forebrain-lesioned rats.

Ishikawa et al. (1997) reported hippocampal degeneration inducing impairment of learning in rats after neonatal administration of monosodium glutamate or oral administration of trimethyltin.

Carli et al. (1997) caused impairment of spatial learning in rats by intrahippocampal administration of scopolamine or 7-chloro-kynurenic acid.

Stancheva et al. (1993) studied in rats the effect of neonatal 6-hydroxydopamine treatment on learning and retention and on the level of biogenic monoamines in some brain structures as well as the influence of nootropic drugs.

Nitta et al. (1997) reported that the continuous infusion of anti-nerve growth factor monoclonal antibody into the septum of rats produces an impairment of memory.

Misztal et al. (1996) produced a short-term working memory deficit in rats by intraventricular infusion of quinolinic acid via ALZET osmotic minipumps for 2 weeks.

Inagawa (1994) reported impairment of spatial working memory in rats induced by intracerebroventriular injection of the cholinergic neurotoxin, ethylcholine mustard aziridinium picrylsulfonate.

Bjugstad et al. (1998) gave chronic intraventricular infusions of tumor necrosis factor alpha to rats and found symptoms resembling the AIDS dementia complex in humans, including learning and memory impairment.

Beers et al. (1995) described spatial recognition memory deficits in Lewis rats following encephalitis after intranasal inoculation with herpes simplex virus type 1.

Yu et al. (1997) reported significant impairment of learning and memory ability in **mice** after hippocampal microinfusion with colchicine.

Chapman et al. (1998) observed spatial working memory impairment in apolipoprotein E-deficient mice.

English et al. (1998) showed that infection with the LP-BM5 murine leukemia virus causes an AIDS-like syndrome – murine acquired immunodeficiency syndrome – in C57B1/6 mice and impairs spatial learning without gross motor impairment.

In several studies **monkeys** were used:

Gaffan (1994) described a model of episodic memory impairment in monkeys with fornix transection.

Harder et al. (1996) produced a specific pattern of cognitive deficits in the marmoset by fornix transection.

Alvarez et al. (1994) studied memory functions in monkeys with lesions of the hippocampal formation and adjacent cortex.

Fernandez-Ruiz et al. (1995) studied the long-term cognitive impairment in MPTP-treated rhesus monkeys.

Ye et al. (1999) evaluated a reversible acetylcholinesterase inhibitor for its ability to reverse the deficits in spatial memory produced by scopolamine in young adult monkeys and those that are naturally occurring in aged monkeys in a delayed-response task.

F.2 *In vitro* methods

F.2.0.1 *In vitro* inhibition of acetylcholine-esterase activity in rat striatum

PURPOSE AND RATIONALE

The purpose of this assay is to screen drugs for inhibition of acetylcholine-esterase activity. Inhibitors of this enzyme may be useful for the treatment of Alzheimer's disease.

Acetylcholinesterase (AChE) which is sometimes called true or specific cholinesterase, is found in nerve cells, skeletal muscle, smooth muscle, various glands and red blood cells (Nachmansohn and Rothenberg 1945; Koelle et al. 1950; Ellman et al. 1961). AChE may be distinguished from other cholinesterases by substrate and inhibitor specificities and by regional distribution. Its distribution in brain roughly correlates with cholinergic innervation and subfractionation shows the highest level in nerve terminals.

It is generally accepted that the physiological role of AChE is the rapid hydrolysis and inactivation of acetylcholine. Inhibitors of AChE show marked cholinomimetic effects in cholinergically-innervated effector organs (Taylor 1996) and have been used therapeutically in the treatment of glaucoma, myasthenia gravis and paralytic ileus. However, recent studies (Christie et al. 1981; Summers et al. 1981; Davies and Mohs 1982; Atak et al. 1983) have suggested that AChE inhibitors may also be beneficial in the treatment of Alzheimer's dementia.

Augustinsson (1971) reviewed a number of methods for assaying cholinesterase activity and concluded that the method described by Ellman et al. (1961) was one of the best. The method described is a modification of Ellman's procedure.

PROCEDURE

Reagents

1. 0.05 M Phosphate buffer, pH 7.2
   a) 6.85 g $NaH_2PO_4 \cdot H_2O$/100 ml distilled H_2O
   b) 13.40 g $Na_2HPO_4 \cdot 7H_2O$/100 ml distilled H_2O
   c) add a) to b) until pH reaches 7.2
   d) Dilute 1 : 10
2. Substrate in buffer
   a) 198 mg acetylthiocholine chloride (10 mM)
   b) q.s. explain to 100 ml with 0.05 M NaH_2PO_4, pH 7.2 (reagent 1)
3. DTNB in buffer
   a) 19.8 mg 5,5-dithiobisnitrobenzoic acid (DTNB) (0.5 mM)
   b) q.s. to 100 ml with 0.05 M NaH_2PO_4, pH 7.2 (reagent 1)
4. A 2 mM stock solution of the test drug is made up in a suitable solvent and q.s. to volume with 0.5 mM DTNB (reagent 3). Drugs are serially diluted (1 : 10) such that the final concentration (in cuvette) is 10^{-4} M and screened for activity. If active, IC_{50} values are determined from the inhibitory activity of subsequent concentrations.

Tissue preparation

Male Wistar rats are decapitated, brains rapidly removed, corpora striata dissected free, weighed and homogenized in 19 volumes (approximately 7 mg protein/ml) of 0.05 M NaH_2PO_4, pH 7.2 using a Potter-Elvejhem homogenizer (Kontes, Vineland, NJ). A 25 µl aliquot of this suspension is added to 1 ml of the vehicle or various concentrations of the test drug and reincubated for 10 min at 37 °C.

Assay

Enzyme activity is measured with the Beckman DU-50 spectrophotometer. This method can be used for IC_{50} determinations and for measuring kinetic constants.

Reagents are added to the blank and sample cuvettes as follows:

Blank:	0.8 ml PO_4 buffer/DTNB
	0.8 ml buffer/Substrate
Control:	0.8 ml PO_4 buffer/DTNB/Enzyme
	0.8 ml PO_4 buffer/Substrate
Drug:	0.8 ml PO_4 buffer/DTNB/Drug/Enzyme
	0.8 ml PO_4 buffer/Substrate

Blank values are determined for each run to control for non-enzymatic hydrolysis of substrate and these values are automatically subtracted by the kindata program available on kinetics soft-pac module. This program (Beckman DU-50 series spectrophotometer, kinetics Soft-Pac™ module operation instructions: 1–7 also calculates the rate of absorbance change for each cuvette.

EVALUATION

For IC_{50} determinations: Substrate concentration is 10 mM diluted 1 : 2 in an assay yielding a final concentration of 5 mM. DTNB concentration is 0.5 mM yielding 0.25 mM final concentration

$$\% \text{ Inhibition} = \frac{\text{slope control} - \text{slope drug}}{\text{slope control}} \times 100$$

IC_{50} values are calculated from log-probit analysis.

F.2.0.2 *In vitro* inhibition of butyrylcholine-esterase activity in human serum

PURPOSE AND RATIONALE

This assay can be used in conjunction with the acetylcholine-esterase assay to determine the enzyme selectivity of various cholinesterase inhibitors.

Butyrylcholine-esterase (BChE), which is sometimes called pseudocholinesterase, preferentially hydrolyzes butyrylcholine. This enzyme is found in the highest amounts in serum, but its physiological role is not known (Chemnitius et al. 1983; Walker and Mackness 1983). Ethopropazine and tetra-isopropyl pyrophosphoramide (ISO-OMPA) are selective inhibitors of butyrylcholinesterase. In an *ex vivo* experiment with the selective BChE inhibitor, ISO-OMPA, it was shown that inhibition of butyrylcholinesterase was not correlated with any significant acute cholinomimetic effects.

PROCEDURE

Reagents

1. 0.05 M phosphate buffer, pH 7.2
   a) 6.85 g $NaH_2PO_4 \cdot H_2O$/100 ml distilled H_2O
   b) 13.40 g $Na_2HPO_4 \cdot H_2O$/100 ml distilled H_2O
   c) Add (a) to (b) until pH reaches 7.2
   d) Dilute 1 : 10
2. Substrate in buffer
   a) 225.8 mg s-butyrylthiocholine chloride
   b) q.s. to 100 ml with 0.05 M phosphate buffer, pH 7.2 (reagent 1)
3. DTNB in buffer
   a) 19.8 mg 5,5-dithiobisnitrobenzoic acid (DTNB) (0.5 mM)
   b) q.s. to 100 ml with 0.05 M phosphate buffer, pH 7.2 (reagent 1)
4. A 2 mM stock solution of the test drug is made up in a suitable solvent and q.s. to volume with 0.5 mM DTNB (reagent 3). Drugs are serially diluted (1 : 10) such that determined from the inhibitory activity of subsequent concentrations.

Enzyme Preparation

A vial of lyophilized human serum (Precilip, Biodynamics, Houston, Texas) is reconstituted in 3 ml of distilled water. A 25 ml aliquot of this suspension is added to 1 ml of the vehicle or various concentrations of the test drug and pre-incubated for 10 min at 37 °C.

Assay

Enzyme activity is measured with the Beckman DU-50 spectrophotometer. This method can be used for IC_{50} determinations and for measuring kinetic constants.

Reagents are added to the blank and sample cuvettes as follows:

Blank:	0.8 ml PO_4 buffer/DTNB
	0.8 ml buffer/Substrate
Control:	0.8 ml PO_4 buffer/DTNB/Enzyme
	0.8 ml PO_4 buffer/Substrate
Drug:	0.8 ml PO_4 buffer/DTNB/Drug/Enzyme
	0.8 ml PO_4 buffer/Substrate

Blank values are determined for each run to control for non-enzymatic hydrolysis of substrate and these values are automatically subtracted by the kindata program available on kinetics soft-pac module. This program also calculates the rate of absorbance change for each cuvette.

EVALUATION

For IC_{50} determinations: Substrate concentration is 10 mM diluted 1 : 2 in assay yielding final concentration of 5 mM. DTNB concentration is 0.5 mM yielding 0.25 mM final concentration

$$\% \text{ Inhibition} = \frac{\text{slope control} - \text{slope drug}}{\text{slope control}} \times 100$$

IC_{50} values are calculated from log-probit analysis.

F.2.0.3 *Ex vivo* cholinesterase inhibition

PURPOSE AND RATIONALE

This assay is used to determine the dose-response relationship and duration of action of cholinesterase inhibitors *in vivo.*

Cholinesterase inhibitors, including physostigmine (Christie et al. 1981; David and Mohs 1982; Thal et al. 1983) and tacrine (Summers et al. 1986) have been shown to improve cognitive functions in Alzheimer's disease. Physostigmine is a potent, but nonselective inhibitor of cholinesterase (Taylor 1996) and has a short duration of action. Tacrine also inhibits both acetylcholine-esterase (true) and butyrylcholine-esterase (pseudo), but is more potent as an inhibitor of the pseudo-enzyme (Heilbronn 1961).

The mechanism of inhibition of these two drugs is quite different. Physostigmine is a competitive inhibitor and blocks the active site of the enzyme by carbamylation of a serine hydroxyl group at the esteratic site of the enzyme (Taylor 1996; O'Brien 1969). This covalently bound carbamyl group then dissociates from the enzyme much more slowly than the acetyl group left by the natural substrate, but the inhibition is not irreversible like that of the organophosphates. The inhibition characteristics of physostigmine, i.e., submicromolar affinity for the enzyme and covalent binding of the inhibiting group, are ideal for *ex vivo* studies. Tacrine, however, is a mixed competitive inhibitor of cholinesterase (Heilbronn 1961), with lower apparent affinity than physostigmine for the enzyme (based on IC_{50} values at saturated substrate concentrations). Tacrine binds to the anionic site of cholinesterase through weak hydrophobic interactions (Steinberg et al. 1975).

Ideally, a dose-response for cholinesterase inhibition is determined first. Then a dose which gives a reasonable effect (>50% inhibition if possible) is chosen to do the time-course experiment. The effects on brain acetylcholinesterase activity are examined in striatal tissue, using 5 mM acetylthiocholine as a substrate (Ellman et al. 1961). Effects on butyrylcholine-esterase activity may be determined in plasma samples, with 5 mM butylthiocholine used as a substrate.

PROCEDURE

Reagents

1. 0.05 M Phosphate buffer, pH 7.2
   a) 6.85 g $NaH_2PO_4 \cdot H_2O$/100 ml distilled H_2O
   b) 13.40 g $Na_2HPO_4 \cdot 7\,H_2O$/100 ml distilled H_2O
   c) add a) to b) until pH reaches 7.2
   d) Dilute 1 : 10
2. DTNB in buffer
   a) 19.8 mg 5,5-dithiobisnitrobenzoic acid (DTNB) (0.5 mM)
   b) q.s. to 100 ml with 0.05 M phosphate buffer, pH 7.2 (reagent 1)
3. Substrate in buffer
   a) 198 mg acetylthiocholine chloride (10 mM)
   b) q.s. to 100 ml with 0.05 M phosphate buffer, pH 7.2 (reagent 1)

Drug treatment

Groups of four male Wistar rats are dosed i.p. or p.o. with vehicle or the test drug. For the initial dose response study, the rats are given varying doses of drug based on toxicity reported in primary overt effects testing and sacrificed at either 30 min or 1 h after dosing. The animals are observed and the occurrence of cholinergic signs is noted (piloerection, tremors, convulsions, salivation, diarrhea and chromodacryorrhea). For the time-course study, a dose of the test drug is given which gave significant inhibition of cholinesterase activity.

Tissue preparation

Male Wistar rats are decapitated, brains rapidly removed, corpora striata dissected free, weighed and ho-mogenized in 4 volumes of 0.05 M phosphate buffer, pH 7.2 using a Potter-Elvehjem homogenizer (Kontes, Vineland, NJ). A 12.5 ml aliquot of the homogenate is added to 1 ml 0.05 M phosphate buffer, pH 7.2/DTNB (reagent 2).

Assay

1. Enzyme activity is measured with the Beckman DU-50 spectrophotometer.

   Reagents are added to the blank and sample cuvettes as follows:

   Blank: 0.8 ml PO_4 buffer/DTNB (reagent 2)
   0.8 ml PO_4 buffer/Substrate (reagent 3)
   Control: 0.8 ml PO_4 buffer/DTNB/Enzyme from control animal
   0.8 ml PO_4 buffer/Substrate
   Drug: 0.8 ml PO_4 buffer/DTNB/Enzyme from treated animal
   0.8 ml PO_4 buffer/Substrate

   Blank values are determined for each run to control for non-enzymatic hydrolysis of substrate and these values are automatically subtracted by the kindata program available on kinetics soft-pac module. This program also calculates the rate of absorbance change for each cuvette.
2. Substrate concentration is 10 mM diluted 1 : 2 in the assay yielding final concentration of 5 mM. DTNB concentration is 0.5 mM yielding 0.25 mM final concentration.

EVALUATION

The percent inhibition at each dose or time is calculated by comparison with the enzyme activity of the vehicle control group.

$$\%\ \text{Inhibition} = \frac{\text{slope control} - \text{slope drug}}{\text{slope control}} \times 100$$

Ex vivo time course experiments for physostigmine

Physostigmine, 0.3 mg/kg, i.p.

Time (h)	% Inhibition striatum	Cholinergic signs
0.25	48.6	P,T,D
0.5	28.5	P,T,D
1.0	27.0	P,T
2.0	7.6	P,T
4.0	1.4	P,T

P = piloerection, *T* = tremors, *D* = diarrhea.

MODIFICATIONS OF THE METHOD

Antagonism of physostigmine-induced lethality in mice has been used by Gouret (1973) as a general indicator of central or peripheral anticholinergic activity. A low dose of physostigmine can be used for detecting procholinergic activity.

F.2.0.4 Molecular forms of acetylcholinesterase from rat frontal cortex and striatum

PURPOSE AND RATIONALE

Different molecular forms of acetylcholinesterase can be isolated from animal tissues after solubilization in buffers containing various detergent and salt concentrations. The number of forms isolated, their relative amounts and molecular characteristics depend on the tissue source and the conditions used for solubilization of the membrane bound enzyme (McIntosh and Plummer 1973; Reiger and Vigny 1976; Trevor et al. (1976). Bon et al. (1979) have classified these forms as globular (G_1, G_2 and G_4) and asymmetric (A_4, A_8 and A_{12}), where the subscripts indicate the number of catalytic subunits. The G_1 and G_4 forms, having sedimentation coefficients of approximately 4S and 10S, respectively, are the major forms contained in bovine caudate nucleus (Grassi et al. 1982). Under conditions of high salt concentrations and detergent, AChE is quantitatively extracted from rat brain, with 10S form being the predominant component (Reiger and Vigny 1976). After solubilization, the molecular forms may be separated according to sedimentation properties by density gradient centrifugation, molecular weight by gel filtration or by electrophoretic mobility.

Although most of these studies on molecular forms of AChE have focused on the physical differences, Chan et al. (1972) reported some difference in sensitivity of the low molecular weight form to physostigmine and fluoride ion, while Lenz and Maxwell (1981) showed differential sensitivity to soman of forms separated by isoelectric focusing. Studies showing selective increases in the 10S form during development (Muller et al. 1985) and selective loss in Alzheimer's disease (Atack et al. 1983) suggest that this form of the enzyme may be developmentally and functionally more important. Cortical and striatal areas show different patterns of cholinergic innervation; the cortex having primarily extrinsic innervation, while the striatal cholinergic pathways are predominantly intrinsic (Ceullo and Sofroniew 1984).

The purpose of this procedure is to determine the effects of various cholinesterase inhibitors on the two major molecular forms of acetylcholinesterase isolated from rat striatum and cerebral cortex.

PROCEDURE

The procedure is divided into three main parts:

I. Preparation and isolation of molecular forms of AChE,
II. Assays for the marker enzymes,
III. Enzyme inhibition studies.

I.a Preparation of molecular forms of AChE

Male Wistar rats (200–250 g) are sacrificed, their brains rapidly removed and frontal cortices or corpora striata removed. The brain areas are weighed and homogenized in 5 volumes (wt/vol) of 10 mM phosphate buffer, pH 7.1, containing 1 M NaCl and 1% Triton X-100, except were indicated. The homogenates are centrifuged at 20 000 *g* for 20 min at 4 °C. The supernatant is aspirated and marker enzymes for 16S (*E. coli* β-galactosidase), 11.3S (bovine catalase) and 4.8S (horse liver alcohol dehydrogenase) fractions are added. The supernatant is then centrifuged at 37 000 rpm (140 000 *g* max) for 17.5 h in a Beckman L5-65 ultracentrifuge with a SW-60 rotor. 15-drop fractions are collected for each centrifuge tube and assayed for protein, β-galactosidase, catalase, alcohol dehydrogenase and acetylcholinesterase activity. In addition, butyrylcholinesterase can be measured.

A 400 µl sample of the 20 000 *g*-supernatant is carefully layered on top of a 5–20% continuous sucrose gradient. This gradient is made up in a centrifuge tube from 1.65 ml of 20% sucrose and 1.65 ml of 5% sucrose in homogenizing buffer by means of a gradient maker. A 50% sucrose cushion (0.5 ml) is placed at the bottom of the tube.

Fractions are collected from the bottom of the tube, i.e, the densest fractions are collected first. Each fraction is 15 drops or approximately 24 fractions are collected per centrifuge tube.

I.b Analysis of fractions

β-Galactosidase, catalase and alcohol dehydrogenase are determined by enzymic activity (Hestrin et al. 1955; Chance and Maehly 1955; Bonnichsen and Brink 1955). Protein concentrations are determined by the method of Lowry et al. (1951). Acetylcholinesterase activity or butyrylcholinesterase activity are determined by a modification of the method of Ellman et al. (1961). Briefly, 10 µl aliquots of the fractions are added to 0.25 mM dithionitrobenzoic acid (DTNB) and 5 mM acetylthiocholine or 5 mM butyrylthiocholine in 0.05 M phosphate buffer, pH 7.2 and the absorbance is measured at 412 nm. Fractions of peak acetylcholinesterase activity are characterized by their sedimentation characteristics relative to the marker enzymes and peak fractions are pooled for enzyme inhibition studies or determination of kinetic constants.

II. Assays for marker enzymes

A Equine liver alcohol dehydrogenase (ADH), sedimentation coefficient 4.8 S

1. Enzyme: alcohol dehydrogenase from equine liver, crystallized and lyophilized (Sigma Chem. Co.)
2. Reagents:
   a) β-nicotinamide adenine dinucleotide (NAD) (Sigma Chem. Co.)
   b) 0.1 M glycine-NaOH buffer, pH 9.6
   c) absolute ethanol
   d) buffer-substrate-NAD mixture:
   875 µl NAD + 875 µl ethanol + 18.75 ml 0.1 M glycine-NaOH buffer, pH 9.6
3. Assay
   10 µl enzyme fraction and
   850 µl mixture (reagent 2d)
   are incubated for 5 min at room temperature. The reaction is stopped by adding:
   300 µl 1.5 M $ZnSO_4$
   Absorbance is read at 340 nm and enzyme units are determined from a standard curve using values of 1.25, 2.5, 5, 10 and 20 mU of ADH.

B Bovine liver catalase, sedimentation coefficient 11.3 S

1. Enzyme: catalase from bovine liver, purified powder (Sigma Chem. Co., C-10)
2. Reagents:
   a) 30% hydrogen peroxide
   b) 0.05 M sodium phosphate buffer, pH 7.0
   c) mixture: 111 µl 30% hydrogen peroxide + 100 ml buffer, yielding 0.033% peroxide.
3. Assay
   10 µl enzyme fraction
   2 990 µl peroxide-buffer mixture (reagent 2c)
   Wavelength is set to 240 nm, absorbance is adjusted to 0.480 units. The amount of time is recorded for absorbance to decrease from 0.450 to 0.400. This corresponds to 3.45 µmol of hydrogen peroxide in 3 ml solution. Total catalase activity in 3 ml is 3.45 µMol/min.

C *E. coli* β-galactosidase, sedimentation coefficient 16.0 S

1. Enzyme: β-galactosidase from *E. coli*, grade VI, partially purified, lyophilized (Sigma Chem. Co)

2. Reagents:
   a) substrate: 15 mg/ml O-nitrophenyl-β-D-galacto-pyranoside (Sigma Chem. Co.) in water
   b) 0.6 M Na_2CO_3, pH 7.25
   c) 1 M $NaCO_3$
3. Assay
   10 µl enzyme fraction,
   150 µl 0.6 M phosphate buffer, pH 7.25, and
   50 µl O-Nitrophenyl-β-D-galactopyranoside (12 mM in assay) are incubated for 25 min at 30 °C. The reaction is stopped by adding:
   500 µl 1 M Na_2CO_3, 1.75 ml water.

   Absorbance is read at 420 nm and enzyme units are determined from a standard curve using values of 0.015, 0.030, 0.525, 0.125 and 0.250 U of β-galactosidase.

III. Enzyme inhibition studies
   For the enzyme inhibition studies, 25 µl aliquots of the enzyme preparation are preincubated with varying concentrations of the inhibitor for 10 min at 25 °C and acetylcholinesterase activity is determined as previously described.

EVALUATION

Values for the IC_{50} are determined by log-probit analysis of the inhibition data using six to seven concentrations of the inhibitor and represent the means of 3 separate experiments.

F.2.0.5 Release of [^{3}H]ACh and other transmitters from rat brain slices

PURPOSE AND RATIONALE

Electrically stimulated release of [^{3}H]ACh is used as a biochemical screen for agents which may possibly enhance or inhibit release of [^{3}H]ACh through a direct muscarinic interaction or other indirect interactions.

Muscarinic autoreceptors have been shown to have a role in the regulation of ACh release in several areas of the CNS (Hadhazy and Szerb 1977; DeBelleroche and Gardiner 1982; Strittmatter et al. 1982; James and Cubeddu 1984). Direct stimulation of muscarinic receptors with muscarinic agonists or indirect stimulation with acetylcholinesterase inhibitors decreases ACh release evoked by either increased potassium concentration or electrical stimulation. Muscarinic antagonists can either block their inhibition, or, under certain conditions, enhance ACh release (James and Cubeddu 1987; Sethy et al. 1988). Furthermore, other neurotransmitters, most notably 5-HT and DA, can also inhibit [^{3}H]ACh release via interaction with 5-T_2 and D_2 heteroreceptors (Robinson 1983; Jackson et al. 1988; Muramatsu et al. 1988; Drukarch et al. 1989) and this inhibition can be reversed by the appropriate receptor antagonists. A compound's effect on [^{3}H]ACh release may provide evidence for a wide variety of releasing activities.

The advantages of using the electrically stimulated release technique on tissue slices have been described by Zahniser et al. (1986). This technique measures only presynaptic effects of test compounds.

PROCEDURE

This assay is based on the methods described by James and Cubeddu (1984, 1987).

Reagents

1. Krebs-Henseleit bicarbonate buffer, pH 7.4 (KHBB) Make a 2 liter batch, containing the following salts:

NaCl	13.84 g	118.4 mM
KCl	0.70 g	4.7 mM
$MgSO_4 \cdot 7\,H_2O$	0.58 g	1.2 mM
KH_2PO_4	0.32 g	2.2 mM
$NaHCO_3$	4.20 g	24.9 mM
$CaCl_2$	0.28 g	1.3 mM
Prior to use, add:		
Dextrose	4.00 g	11.1 mM

   Aerate for 60 min with 95% O_2/5% CO_2 on ice and check pH.
2. [Methyl-^{3}H]-choline chloride (80–90 Ci/mmol) is obtained from New England Nuclear. The final desired concentration of [^{3}H]choline is 100 nM. Add 0.25 nmol of [^{3}H]choline to 2.5 ml KHBB.
3. For most assays, a 10 mM stock solution of the test compound is prepared in a suitable solvent and diluted such that the final concentration in the assay is 10 µM. Higher or lower concentrations may be used depending on the potency of the test compound.
4. Hemicholinium-3 or HC-3 (Sigma): Make a 10 mM stock solution in H_2O. Two milliliters of this stock are then diluted to one liter in KHBB to give a final concentration of 20 µM.

Tissue preparation

Male Wistar rats (100–150 g) are decapitated, and cortical, striatal, or hippocampal tissue removed on ice and 0.4 mm slices are prepared with a McIlwain tissue slicer. The slices are made individually, placed in cold, oxygenated buffer (10–20 ml) and incubated at 35 °C for 30 min under oxygen. After this incubation, the buffer is decanted, leaving the slices behind. Then 2.5 ml of cold oxygenated buffer is added, and enough [^{3}H]choline to bring the final concentration to 100 nM. This is then incubated and shaken for 60 min at 35 °C under oxygen. After this step, the buffer is decanted and the "loaded" slices are immediately placed on nylon mesh in the stimulation chambers.

Assay

Control buffer is pumped through the chamber for 42 min at a flow rate of 0.7 ml/min, to establish a stable baseline. Under these conditions released [^{3}H]ACh is subject to hydrolysis by acetylcholinesterase. The perfusion buffer is changed to fresh KHBB containing 20 µM HC-3. The potent choline uptake inhibitor HC-3 is included to prevent the re-uptake of any [^{3}H]choline formed from the hydrolysis of released [^{3}H]ACh. This maintains the stoichiometry of the stimulated release. The evoked release has been shown to be mostly [^{3}H]ACh rather than [^{3}H]choline, whereas spontaneous release under control, drug-free conditions is mostly [^{3}H]choline (Richardson and Szerb 1974; Szerb et al. 1977; Supavilai and Karobath 1985; Saijoh et al. 1985; Nishino et al. 1987).

Special conditions

1. Stimulation parameters are set at 2 Hz (2 ms duration) for 120 s, with 1 ms delay and voltage setting of 750 SIU (250 Ω). Agonists are more potent modulators of [^{3}H]ACh release at low stimulation frequencies (5).
2. For striatal slices, 2 µM sulpiride is present in the buffer to prevent DA inhibition of ACh release.
3. In some experiments, 5 µM methysergide is present in the buffer to prevent the serotonergic inhibition of ACh release mediated by 5-HT_2 receptors.
4. In order to determine the muscarinic regulation of [^{3}H]ACh release, 10 µM atropine can be included in some experiments.
5. In some experiments, physostigmine is added to the perfusion buffer. This causes a marked inhibition of stimulated release via feedback at pre-synaptic receptors. Under these conditions, receptor antagonists enhance [^{3}H]ACh release.

After the experiment is completed, the chambers are washed with distilled water for at least 20 min, 200 ml of 20% methanol in distilled water and again with distilled water for at least 20 min.

EVALUATION

After conversion of dpm, percent fractional release is calculated for each fraction, using a Lotus program.

Percent fractional release is defined as the amount of radiolabeled compound released divided by the amount present in the tissue. "Spontaneous Release" (SP) values are the average of the two fractions preceding and the first fraction in that range after the stimulation period. "Stimulated" (S) values are the summed differences between the percent fractional release during stimulation and the appropriate SP value.

The effects of drugs can be reported as S_2/S_1 ratios. To normalize the data, drug effects can be estimated by first calculating S_2/S_1 values for control and drug-treated slices and then expressing the S_2/S_1 value for the drug-treated slices as a percentage of the S_2/S_1 value for the control slices for each experiment. Each condition should be tested in slices from the same animal.

MODIFICATIONS OF THE METHOD

Release of other neurotransmitters from brain tissue in vitro

Several authors (Harms et al. 1979; de Belleroche and Gardiner 1982; James and Cubeddu 1984; Raiteri

et al. 1984; Zahniser et al. 1986; Smith et al. 1984, 1994) studied the release of neurotransmitters from brain tissue *in vitro*.

Raiteri et al. (1974) described a simple apparatus for studying the release of neurotransmitters from synaptosomes.

De Boer et al. (1988) determined the release of noradrenaline and serotonin in synaptosomes from rat cerebral cortex.

Saijoh et al. (1985) studied the influence of hypoxia on release and uptake of the neurotransmitters dopamine and acetylcholine in guinea pig striatal slices.

PROCEDURE

[^{3}H]Norepinephrine release from cortical slices

Cortical slices (0.4 mm) from male Wistar rats are preincubated in Krebs buffer saturated with 95% O_2/5% CO_2, pH 7.4 for 30 min at 35 °C, and then incubated in fresh buffer containing 25 nM [^{3}H]NE (35 Ci/mmol) for 30 min at 35 °C. The slices are then placed in glass superfusion chambers containing platinum electrodes and perfused at 0.75 ml/min. Fractions are collected at 7 min intervals. Slices are electrically stimulated with unipolar pulses (15–30 mA) of 2 ms duration at 5 Hz for 60 s. Two rounds of stimuli are applied, separated by 10 fractions. Test compound is applied at fraction 14 (28 min after the first stimulation).

The fractions collected are counted for tritium in 10 ml of Liqiscint® scintillation fluid and corrected for quench. For measurement of remaining tritium, slices are dissolved overnight in 0.5 ml of Protosol®, buffered with 1 ml of Tris HCl, and counted. Percent fractional release is defined as the ratio of tritium released versus the amount present in the tissue.

[^{3}H]Norepinephrine release from cortical synaptosomes

Cortices from male Wistar rats are homogenized in 9 volumes of 0.32 M sucrose in a Potter-Elvejhem homogenizer and then centrifuged at 1 000 *g* for 10 min at 4 °C. The supernatant is recentrifuged at 17 000 *g* for 20 min, and the pellet is resuspended in 0.32 M sucrose at the original volume.

The freshly prepared synaptosomes are incubated with 50 nM [^{3}H]NE in Krebs buffer containing 10 mM pargyline for 10 min at 37 °C. The ratio of buffer to tissue suspension is 80 : 20. The [^{3}H]NE-loaded synaptosomes are then separated by centrifugation (17 000 *g* for 20 min), washed with buffer containing pargyline, recentrifuged, and then finally resuspended in 0.32 M sucrose at their original volume. The assay mixture consists of 900 ml Krebs buffer containing 10 mM pargyline, 100 ml of [^{3}H]NE-loaded synaptosomes, and 10 ml of vehicle or drug. This mixture is then vortexed and incubated for 5 min at either 37 °C or 0 °C (to define total versus non-specific release). After a 10 min centrifugation (3 000 *g*), the pellets are solubilized in a Triton X-100/ethanol mixture and transferred to scintillation vials, and counted in 10 ml of Liquiscint®.

The net disintegrations for the 37 °C and 0 °C incubations are calculated, and % increase values determined as $[(\text{control} - \text{drug}) / \text{control}] \times 100$.

Several chemical methods to measure acetylcholine (Israël and Lesbats 1982; Damsa et al. 1985; Stadler and Nesselhut 1986), or catecholamines and serotonin (Wagner et al. 1979; Magnusson et al. 1980; Nielsen and Johnston 1982; Wagner et al. 1982) are available.

F.2.0.6 [^{3}H]Oxotremorine-M binding to muscarinic cholinergic receptors in rat forebrain

PURPOSE AND RATIONALE

The muscarinic receptors are members of the superfamily of G-protein-coupled receptors. They are relatively abundant and mediate the diverse action of acetylcholine in the CNS, as well as throughout non-nervous tissues innervated by the parasympathetic nervous system. Five separate genes (m1–m5) encode muscarinic receptor proteins exhibiting the rhodopsin-like structural motif containing seven transmembrane domains. They show strong sequence homology with each other and with related G-protein-coupled receptors within the transmembrane spanning domains, but each receptor has unique amino acid sequences located at the extracellular amino end and in the third intracellular loop (Caulfield 1993; Jones 1993; McKinney 1993; Wess 1996).

The purpose of this assay is to determine the binding affinity of potential cholinomimetic drugs for muscarinic receptors in brain, using an agonist ligand.

Oxotremorine is a potent centrally and peripherally acting muscarinic cholinergic agonist (Chao et al. 1962; Bebbington et al. 1966), which has been shown to be active in isolated tissue preparations as well as *in vivo* (Rindahl and Jenden 1983). Both central and peripheral effects of oxotremorine are blocked by antimuscarinic drugs such as atropine (Chao et al. 1962; Bebbington et al. 1966). Structural modification of the oxotremorine molecular yields compounds which are full agonists, partial agonists and antagonists at muscarinic receptors (Rindahl and Jenden 1983). Oxotremorine-M (oxo-M), a quaternary nitrogen analog of oxotremorine, is a full agonist for the phosphatidyl-inositol response, while oxotremorine is a partial agonist (Fisher et al. 1984). Both oxotremorine and oxo-M are full agonists for inhibition of adenylate cyclase (Ehlert 1985; Olianas et al. 1983; Brown and Brown 1984). Of the muscarinic agonists, oxotremorine is the most potent inhibitor of [^{3}H]QNB binding, however, the IC_{50} is still only in the micromolar range. The apparent low affinity of agonist competition for [^{3}H]-antagonist binding sites is a common phenomena and is due to the existence of multiple agonist affinity states of the receptor, as described by Birdsall et al. (1978). For this reason, it is desirable to use an agonist ligand to measure the binding affinities of potential agonists.

Molecular methods have disclosed the existence of five muscarinic receptors which are coupled to different second messenger systems. At least four of them are expressed as functional receptor proteins in the neocortex and hippocampus formation (McKinney and Coyle 1991).

PROCEDURE

Reagents

1. 0.5 M Tris buffer, pH 7.4
   66.1 g of Tris HCl
   9.7 g of Tris base
   q.s. to 1 liter with deionized water
2. 0.05 M Tris buffer, pH 7.4
   (10-fold dilution of reagent 1)
3. [Methyl-^{3}H]-oxotremorine acetate (specific activity 83–85 Ci/mmol) is obtained from New England Nuclear.
   For IC_{50} determinations: [^{3}H]Oxotremorine-M is made up to a concentration of 100 nM. Fifty µl of this solution is added to each assay tube (yields a final concentration of 5 nM).
4. Atropine sulfate is obtained from Sigma Chemical Company. A 2 mM stock solution is made up in distilled water. Twenty µl is added to 3 tubes for determination of non-specific binding (yields a final concentration of 40 µM).
5. A 0.5% (w/v) solution of polyethylene-imine is prepared in distilled water. GF/C filters are soaked in this solution for at least three hours at room temperature. This is done to reduce the binding of the ligand to the filter strips.
6. Test compounds: For most assays, a 10 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 2×10^{-4} to 2×10^{-7} M.

Tissue preparation

Male Wistar rats are decapitated and their brains rapidly removed. The forebrains (all tissue forward of a vertical cut in front of the hypothalamus) are weighed (400–500 mg each) and homogenized in 10 volumes of 0.05 M Tris buffer, pH 7.4 (reagent 2) using a Potter-Elvehjem glass homogenizer fitted with a Teflon pestle. The homogenate is centrifuged at 1 000 *g* for 10 min. The supernatant is then centrifuged at 50 000 *g* for 60 min. The supernatant from this centrifugation is discarded and the pellet resuspended in the original volume of 0.05 M Tris buffer, pH 7.4, on the Polytron to 100 mg/ml (wet weight). Specific binding is roughly 1% of total added and 50% of total bound.

Binding assay

50 µl 0.5 M Tris buffer, pH 7.4 (reagent 1)
380 µl H_2O
20 µl drug or 2 mM atropine
50 µl ^{3}H-oxotremorine-M (reagent 3)
500 µl tissue

Tubes are vortexed and incubated at 30 °C for 45 min (2). Bound [^{3}H]-oxotremorine-M is captured by filtration under reduced pressure. The incubation mixture is diluted with approximately 4 ml ice-cold 0.05 M Tris buffer, pH 7.4 (reagent 2), then exposed to vacuum, and tubes washed once more with approximately 5 ml of reagent 2. The filters (GFC in 0.5% polyethylene-imine for more than 3 h, reagent 5) are then counted in 10 ml Liquiscint scintillation fluid.

EVALUATION

Specific binding is the difference between total bound (in presence of vehicle) and that bound in the presence of 40 µM atropine. Percent inhibition of specific [^{3}H]-oxotremorine-M is calculated for each concentration of test drug and IC_{50} values determined by computer-derived log probit analysis. The percent inhibition at each drug concentration is the mean of duplicate or triplicate determinations. Some day-to day variability is present in this assay, and IC_{50} values should be confirmed by repeat analysis.

MODIFICATION OF THE METHOD

[^{3}H]Pirenzepine has been used to identify muscarinic receptor subtypes in the brain (Watson et al. 1983a,b).

F.2.0.7 [^{3}H]-N-Methylscopolamine binding in the presence and absence of Gpp(NH)p

PURPOSE AND RATIONALE

G-protein-linked muscarinic receptors are converted by guanine nucleotides from a high-affinity binding state to a low-affinity binding state for muscarinic agonists (Gilman 1986), while the binding of muscarinic antagonists to the receptor is not affected. The effects of guanine nucleotides on muscarinic agonist affinity are brain region- and temperature-dependent (Aron-stram and Narayanan 1988). Therefore, incubation of cerebellar membranes with 50 μM 5'-guanylylimidophosphate (Gpp(NH)p), the non-hydrolyzable analog of GTP, causes a shift to the right (decreased affinity) of the muscarinic agonist inhibition curves when ^{3}H-NMS is used as the ligand.

The assay differentiates the interaction of muscarinic agonists and muscarinic antagonists with ^{3}H-N-methylscopolamine (^{3}H-NMS)-labeled receptors in cerebellar tissue based on the selective effect of guanine nucleotides on the affinity of muscarinic agonists for the receptor.

PROCEDURE

The procedure is based on ^{3}H-NMS rat brain binding assay described by Aronstram and Narayanan (1988).

Reagents

1. 0.5 M Tris-HCl buffer, pH 7.4
2. 0.05 M Tris-HCl buffer, pH 7.4
3. 0.05 M Tris-HCl buffer, pH 7.4 + 2 mM $MgCl_2$
4. 0.05 M Tris-HCl buffer, pH 7.4 + 2 mM $MgCl_2$ + 100 μM phenylmethylsulfonyl fluoride
5. Atropine sulfate is made up to 1 mM in distilled water and 20 μl is added to a 2 ml reaction mixture. This yields a final concentration of 10 μM. Atropine is used for nonspecific binding.
6. 5'-Guanylylimidodiphosphate (Gpp(NH)p) is made up to 2 mM in distilled water. The final concentration in the reaction mixture is 50 μM.

7. ^{3}H-N-Methylscopolamine (NMS) is obtained from Amersham and diluted to 4 nM in distilled water. The final concentration in the reaction mixture is 0.1 nM.
8. Test compounds
   For most assays, a 10 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-4} to 10^{-7} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the drug.

Tissue Preparation

Male Wistar rats are decapitated and their brains rapidly removed. The cerebella are dissected, weighed and homogenized in 10 volumes of 0.05 M Tris-HCl buffer, pH 7.4 + 2 mM $MgCl_2$ + 100 µM phenylmethylsulfonyl fluoride (buffer 4), using a Potter-Elvehjem glass homogenizer fitted with a Teflon pestle. The homogenate is centrifuged at 20 000 *g* for 20 min. The pellet is resuspended in 10 volumes of 0.05 M Tris-HCl buffer + 2 mM $MgCl_2$ (buffer 3).

Binding Assay

1 000 µl	0.05 M Tris buffer + 2 mM $MgCl_2$
780 µl	H_2O
20 µl	vehicle or 1 mM atropine or appropriate drug concentration
50 µl	H_2O or Gpp(NH)p
50 µl	[^{3}H]NMS
100 µl	tissue suspension

Tubes are incubated at 20 °C for 90 min. Bound [^{3}H]NMS is captured by vacuum filtration. The filters are washed three times with 5 ml aliquots of 0.05 M Tris buffer, pH 7.4. Filters are counted in 10 ml Liquiscint scintillation fluid.

EVALUATION

Specific binding of [^{3}H]NMS is the difference between total bound (in the presence of vehicle) and that bound in the presence of 1 mM atropine. Percent inhibition of specific [^{3}H]NMS binding is calculated for each concentration of test drug and IC_{50} values are determined by computer-derived log-probit analysis. The percent inhibition at each drug concentration is the mean of triplicate determinations.

F.2.0.8 Stimulation of phosphatidylinositol turnover in rat brain slices

PURPOSE AND RATIONALE

The purpose of this assay is to determine the ability of test compounds to stimulate the turnover of phosphatidylinositol (PI) in brain tissue. This assay can be used to determine agonist activity at a number of CNS receptors known to be linked to the PI response. A major interest is the evaluation of muscarinic cholinergic receptors.

Receptor-activated hydrolysis of inositol phospholipids is now recognized as an important second messenger system for muscarinic, alpha-adrenergic, histaminergic, serotonergic, excitatory amino acid and various neuropeptide receptors (Berridge and Irvine 1984; Nahorski et al. 1986; Fisher and Agranoff 1987). Furthermore, the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) yields at least two important biologically-active intermediates (Hirasawa and Nishizuka 1985; Berridge 1987). These include 1,4,5-inositol trisphosphate (IP_3), which acts to mobilize Ca^{2+} from the endoplasmic reticulum and diacylglycerol, which activates protein kinase C (PKC). These responses are associated with many cellular responses such as stimulus-secretion coupling, stimulus-contraction coupling and cell proliferation. The exact mechanism for receptor-mediated turnover of cell membrane PI is not well understood, but it seems to involve coupling through a G-protein (Cockcroft and Gomperts 1985) and requires extracellular Ca^{2+} to activate phospholipase C (Fisher et al. 1989).

Although the muscarinic receptor-PI link has been known for some time (Hokin and Hokin 1955), recent advances in knowledge of receptor mechanisms and increased interest in the muscarinic receptor have stimulated considerable research in this area. Even though muscarinic agonists can be shown to be weak partial agonists or full agonists for this response (Fisher et al. 1983) and there are brain regional differences in sensitivity (Fisher and Bartus 1985); attempts to show receptor subtype selectivity for stimulation of PI turnover in either heart (Brown et al. 1985) or brain tissue (Fisher and Bartus 1985) have been disappointing. However, recent experiments using cells transfected with genomic clones for the various muscarinic receptors have had more success (Shapiro et al. 1988; Conklin et al. 1988). These studies show that the m_1, m_3 and the m_5 receptor subtypes are linked to PI turnover.

Stimulation of PI turnover by agents such as veratridine, batrachotoxin and ouabain (Gusovsky et al. 1986) show that there are also non-receptor mechanisms that can cause the stimulation of PI turnover.

PROCEDURE

Equipment and materials

1. McIlwain tissue slicer
2. Disposable columns (Kontes, 200 mm)
3. Column rack (Kontes)
4. Disposable screw-cap tubes (Pyrex, 16 × 100 mm)
5. Disposable culture tubes (Fisher, 16 × 125 mm)

Reagents

1. Modified Krebs bicarbonate buffer

	g/l	mM
NaCl	8.30	142.0
KCl	0.42	5.6
$CaCl_2$	0.24	2.2
$NaHCO_3$	0.30	3.6
$MgCl_2 \cdot 6H_2O$	0.20	1.0
HEPES	7.15	30.0
Adjust pH to 7.4 with NaOH		
d-Glucose[a]	1.01	5.6

[a] Glucose added just before incubation.

2. Concentrated Krebs buffer + LiCl (9-fold concentrated ions, 10-fold concentrated Li^+), stock solution contains no glucose or Ca^{2+}.

	g/100 ml
NaCl	6.88 (amount adjusted to correct for Li^+)
KCl	0.38
$NaHCO_3$	0.27
$MgCl_2 \cdot 6H_2O$	0.18
HEPES	6.44
LiCl	0.42

   $CaCl_2$ (11 mg) and d-glucose (45 mg) are added to 5 ml of concentrated buffer before incubation.
3. Dowex AG-1-X8 (100–200 mesh) formate form (Biorad)
4. [^{3}H]Inositol (spec. act. 15 Ci/mmol) is obtained from American Radiolabeled Chemicals, Inc.
5. Myo-inositol (M.Wt. 180.2) is obtained from Sigma Chemical Co. A 5 mM solution is made (0.9 g/l).
6. 1 M Ammonium formate/0.1 M formic acid. Ammonium formate is obtained from Sigma Chemical Co.: 3.85 ml 99% formic acid + 63.1 g ammonium formate to 1 liter in H_2O.
7. $CHCl_3$/methanol (1 : 2, v/v).

Tissue preparation

Male Wistar rats, approximately 6/assay.

1. Remove surface blood vessels by rolling brain on filter paper.
2. Remove cerebral cortex and gently scrape myelin layer off.
3. Prepare 350 × 350 micron tissue slices with the McIlwain tissue chopper and place slices in buffer at 37 °C.
   Incubate for 10 min.
4. Disperse slices by aspirating into 1-ml pipet (cut off tip).
5. Allow slices to settle, aspirate supernatant, add buffer and repeat until the supernatant is clear.

Assay: Prelabeled method

1. Add to screw-cap tubes:
   50 µl tissue slices
   350 µl [^{3}H]inositol
2. Incubate for 90 min at 37 °C under O_2
3. Add:
   50 µl drug
   H_2O to a final volume of 500 µl
4. Incubate for 30 min at 37 °C under O_2.
5. Stop the reaction by the addition of 1.5 ml of $CHCl_3$: MeOH. Place in ice bath.

Assay: Continuous labeling method

1. Add to screw-cap tubes:
   50 µl tissue slices
   350 µl [^{3}H]inositol
   50 µl drug
   H_2O to a final volume of 500 µl
2. Incubate for 120 min. at 37 °C under O_2.
3. Stop the reaction by the addition of 1.5 ml of $CHCl_3$: MeOH. Place in ice bath.

For antagonist inhibition studies, the antagonist is usually preincubated with the slices before the agonist is added.

Extraction of total [^{3}H]inositol phosphates

1. Add 1 ml of $CHCl_3$ and 0.5 ml of H_2O to each tube. Cap and vortex.
2. Centrifuge at 3 000 rpm for 10 min.
3. Aspirate the aqueous phase and place in culture tubes.
4. Add 1.7 ml of H_2O and heat in water bath at 55 °C for 20 min.

5. Place samples in cold room overnight.
6. Add 0.5 ml of Dowex 50% slurry to each tube. Vortex 4 times.
7. Centrifuge at 3 000 rpm for 10 min.
8. Aspirate.
9. Add 2.5 ml of 5 mM myo-inositol, let the resin settle and aspirate. Repeat 5 times.
10. Centrifuge at 3 000 rpm for 10 min.
11. Add 1 ml of ammonium formate/formic acid, pH 4.8.
12. Put 0.7 ml of supernatant into scintillation vial, add 10 ml cocktail and count.

EVALUATION

The stimulation phosphatidylinositol turnover for each test compound is calculated as percent increase in total [^{3}H] inositol phosphates relative to the basal turnover rate of non-treated control brain slices. The EC_{50} values for agonists are determined by log-probit analysis of these data. IC_{50} values for antagonists are determined by log-probit analysis of the percent inhibition of stimulation by a full agonist.

F.2.0.9 [^{3}H]N-Methylcarbamylcholine binding to nicotinic cholinergic receptors in rat frontal cortex

PURPOSE AND RATIONALE

The purpose of this assay is to determine the binding affinity of potential nicotinic cholinergic agonists in brain, using an agonist ligand.

Nicotinic cholinergic receptors are classified as ligand-gated ion channels, and are found in skeletal muscle, autonomic ganglia and brain tissue. Nicotine itself has a variety of behavioral effects. Due to its rapid desensitization of the receptor, both stimulatory and depressant effects may result. Also, many of nicotine's effects are thought to be associated with release of neurotransmitter substances (Balfour 1982). Nicotine functions as a nicotinic cholinergic receptor agonist in the CNS and is thought to play a role in learning and memory (Clarke 1987). Reductions in nicotinic binding sites were found in post-mortem tissues from Alzheimer's patients by four separate groups of investigators (Whitehouse et al. 1988; Nordberg and Winblack 1986; Araujo

et al. 1988; Shimohama et al. 1986). Cognitive improvement in SDAT EXPLAIN? patients thirty minutes after a nicotine infusion was reported (Sunderland et al. 1988). Therefore nicotinic agonists may prove beneficial, however, clinical data are still quite limited. N-Methylcarbamylcholine (NMCC) is a nicotinic agonist which binds specifically and with high affinity to central nicotinic recep-tors and, like nicotine, causes an increase of acetylcholine release from certain cholinergic nerve terminals (Araujo et al. 1988; Lapchak et al. 1989). In addition, chronic nicotine treatment increases [^{3}H] NMCC binding sites in several rat brain regions, as it does with [^{3}H]nicotine and [^{3}H]ACh labeled sites (Lapchak et al. 1989). This is due to the loss of presynaptic nicotinic autoreceptor function (Lapchak et al. 1989). Pharmacological results reveal that along with its specificity and high affinity, [^{3}H]NMCC is selectively displaced by agonists (Araujo et al. 1988; Lapchak et al. 1989), making it a desirable ligand to screen for potential agonistic compounds.

Nicotinic acetylcholine receptors are a family of ligand gated ion channels that are classified on the basis of their activation by nicotine, although acetylcholine is the endogenous ligand. These conductance channels for Ca^{2+}, K^+ and Na^+ are pentameric in structure. They are members of a supergene family that also includes glycine, $GABA_A$, and 5-HT3 receptors. α, β, γ, and δ subunits constitute a pentameric neuronal receptor resulting in various receptor subtypes (Sargent 1993; Alkondon and Albuquerque 1993). Nine α (α1–α9) and three β (β2–β4) subunits have been cloned from mammalian and avian sources, each of which has a structural motif of four transmembrane spanning domains M1–M4 of which M2 lines the channel (Gotti et al. 1997).

PROCEDURE

Reagents

1. 0.5 M Tris buffer, pH 7.7
   a) 57.2 g Tris HCl
      16.2 g Tris Base
      q.s. to 1 liter with distilled water
   b) Make a 1 : 10 dilution in distilled H_20 (0.05 M Tris buffer, pH 7.7 at 25 °C)
2. Tris buffer containing physiological ions
   a) Stock buffer

NaCl	7.014 g
KCl	0.372 g
$CaCl_2$	0.222 g
$MgCl_2$	0.204 g q.s. to 100 ml with 0.5 M Tris buffer

   b) Dilute 1 : 10 in distilled H_20
      This yields 0.05 M Tris HCl, pH 7.7, containing NaCl (120 mM), KCl (5 mM), $CaCl_2$ (2 mM) and $MgCl_2$ (1 mM).
3. Methylcarbamoylcholine iodide, [N-Methyl-^{3}H]- is obtained from New England Nuclear
   For IC_{50} determinations [^{3}H]-NMCC is made up to a concentration of 100 nM in distilled H_2O and 50 µl added to each tube (yields a final concentration of 5 nM in the 1 ml assay).
4. (–)Nicotine ditartrate is obtained from Research Biochemicals Incorporated.
   A stock solution of (–)nicotine ditartrate is made up to a concentration of 0.5 mM in distilled H_2O. Twenty µl of stock is added to 3 tubes for the determination of nonspecific binding (yields a final concentration of 10 µM in the assay).
5. Test compounds. For most assays in 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 2×10^{-5} to 2×10^{-8} M. Seven concentrations are used for each assay and higher or lower concentrations may be used depending on the potency of the drug.
6. A 0.5% (w/v) solution of polyethyleneimine is prepared in distilled H_2O. GF/B filters are soaked in this solution for at least four hours at 4 °C. This is done to reduce binding of the ligand to the filter strips.

Tissue preparation

Male Wistar rats are decapitated, their frontal cortices removed, weighed and homogenized in 40 volumes of ice-cold 0.05 M Tris buffer, pH 7.7 (1 b). The homogenate is centrifuged at 48 000 *g* for 10 min. The pellet is rehomogenized in fresh buffer and recentrifuged at 48 000 *g* for 10 min two more times. The final pellet is resuspended in the original volume of buffer, but with physiological salts (2 b). This yields a final tissue concentration of 20 mg/ml in the assay.

Assay

130 µl	0.05 M Tris pH 7.7-physiological salts (2 b).
20 µl	Vehicle (for total binding) or 0.5 mM (–)nicotine ditartrate (for nonspecific binding) or appropriate drug concentration.
50 µl	N-[^{3}H]Methylcarbamylcholine stock solution
800 µl	tissue.

The tubes are incubated at 0 °C for 60 min. The assay is stopped by rapid filtration through Whatman GF/B filters which are then washed 4 times with 3 ml of ice-cold 0.05 M Tris buffer, pH 7.7. The filters are then counted in 10 ml of Liquiscint scintillation cocktail.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of the 10 µM

(–)nicotine ditartrate. Specific binding is about 1% of the total added ligand and 60–70% of the total bound ligand. IC_{50} calculations are performed using log-probit analysis. The percent inhibition at each drug concentration is the mean of triplicate determinations.

MODIFICATION OF THE METHOD

Pabreza et al. (1991) recommended [^{3}H]cytisine as a useful ligand for studying neuronal nicotinic receptors because of its high affinity and low nonspecific binding.

Badio and Daly (1994) determined [^{3}H]nicotine receptor binding in rat cerebral cortex membrane preparations. The authors concluded that the analgesic activity of epibatidine, an alkaloid originally characterized from frog skin, is due to its activity as nicotinic agonist.

F.2.0.10 Cultured neurons/astroglial cells

PURPOSE AND RATIONALE

Cultured brain cells can be used for many purposes such as investigation of synthesis and secretion of nerve growth factor or for testing neuroprotective drugs (Peruche and Krieglstein 1991). Nerve growth factor is required for the development and maintenance of peripheral and sensory neurons (Thoenen and Barde 1980). Nerve growth factor prevents neuronal death after brain injury (Hefti 1986; Williams et al. 1986; Kromer 1987), especially in basal forebrain nuclei involved in memory processes. Drug induced increase in nerve growth factor secretion may be beneficial in primary degenerative dementia.

Nerve growth factor belongs to the family of neurotrophins which includes besides of the nerve growth factor, the neurotrophin 3 (NT3), neurotrophin 4/5 (NT 4/5) and brain-derived neurotrophic factor (BDNF). Two types of neurotrophin transmembrane receptors are known: (1) a receptor termed p75, which is common to all neurotrophins and (2) a family of neurotrophin receptor tyrosine kinases trkA, trkB and trkC (Saragovi and Gehring 2000).

PROCEDURE

Whole brains of 8-day-old mice (ICR) are dissected out and cut into small pieces. The pieces are washed

with calcium- and magnesium-free phosphate-buffered saline, treated with 0.25% trypsin at 37 °C for 30 min, and triturated with a Pasteur pipette. The excess trypsin is removed by centrifugation at 200 *g* for 5 min. The cells or cell clumps from one brain are cultured in a culture bottle with Dulbecco's modified Eagle's minimum essential medium (DMEM) containing 10% fetal calf serum (FCS), 50 milliunits/ml penicillin, and 50 mg/ml of streptomycin at 37 °C in a humid atmosphere of 5% CO_2 for 1–2 weeks with medium changes every 3 days. After confluence is reached, the cells in each bottle are dissociated by trypsin treatment and recultured in new bottles. This procedure is repeated 3 times. The culture becomes composed of morphologically uniform cells.

Preparation of quiescent cells is performed by inoculating into 96-well plates and culture in FCS-containing DMEM until confluence is reached. Then, the cells are cultured for an additional week in FCS-free DMEM containing 0.5% BSA, with medium changes every 3 days. Because the cells never proliferate in FCS-free medium, most of the cells are arrested in the quiescent phase. Then, the medium is changed to DMEM containing 0.5% BSA with or without drugs, and the cells are cultured for 24 h.

Nerve growth factor (NGF) content in the culture medium is determined by a two-site enzyme immunoassay (Furukawa et al. 1983; Lärkfors and Ebendal 1987). Mouse β NGF isolated from male mouse submaxillary glands is purified by CM-Sephadex C-50 chromatography. Antiserum to this mouse β NGF is produced in New Zealand White rabbits by repeated subcutaneous injections of an emulsion in complete Freund's adjuvant over 18 months. Immunoglobin G is prepared from Anti-mouse β NGF antiserum by Sepharose chromatography. Antibody IgG is incubated with pepsin and chromatographed. Fab' fragments are coupled to β-D-galactosidase. IgG-coated solid phase is prepared in polystyrene tubes. The IgG-coated polystyrene tubes are incubated with 0.25 ml buffer containing various amounts of NGF with gentle shaking. After incubation for 18–24 h at 4 °C, each tube is washed twice with 1 ml of buffer and 0.13 milliunits of the Fab'-β-D-galactosidase complex in 0.25 ml buffer is added. After incubation for 18–24 h at 4 °C with gentle shaking each tube is washed as described above and β-D-galactosidase activity bound to the tube is assayed. The enzyme reaction is started by addition of 60 mM 4-methylumbelliferyl-β-D-galactoside and 0.1% Triton X-100 in 0.25 ml buffer. After 1-h incubation at room temperature, the enzyme reaction is stopped by the addition of 1.25 ml 0.1 M glycine-NaOH buffer (pH 10.3). The amounts of 4-methylumbelliferone formed are measured by fluorometry (Excitation wavelength 360 nm, emission wavelength 450 nm).

EVALUATION

Time-response curves of release of NGF into the medium are established after addition of drug and compared with controls. Dose-response curves can be prepared after addition of various amounts of test drug.

MODIFICATIONS OF THE METHOD

Cultured neurons from chick embryo hemispheres were used for testing cerebroprotective drug effects *in vitro* and for testing antihypoxic drug effects by Krieglstein et al. (1988), Peruche et al. (1990), Oberpichler-Schwenk and Krieglstein (1994).

Semkowa et al. (1996) found that clenbuterol protects mouse cerebral cortex and rat hippocampus from ischemic damage and attenuates glutamate neurotoxicity in cultured hippocampal neurons by induction of nerve growth factor.

Prehn et al. (1993, 1995) tested the prevention of glutamate neurotoxicity in neocortical cultures from rats. Mixed neuronal/glial primary cultures were derived from the cerebral cortices of neonatal Fischer 344 rats. Excitotoxic injury was induced after 14 days by L-glutamate following a procedure described by Choi et al. (1988), Koh and Choi (1988).

Kinoshita et al. (1991) used primary cultured neurons from 17-day-old rat fetuses.

Qi et al. (1997), Horton et al. (2001) described a novel catecholaminergic CAD CNS neuronal cell line in which neurotrophin-3 mediates the autocrine survival.

Shinpo et al. (1999) used cultured mesencephalic neurons from embryonic Sprague Dawley rats to study the protective effects of the TNF-ceramide pathway against glutamate neurotoxicity.

Matsumoto et al. (1990) described a method for quantifying the effects of neurotrophic factors on the number of surviving neurons and the total length of neurites in primary cultures from cerebral cortex and hippocampus of the brains from two-week old rats by using digital image processing techniques. Binary images of neuronal neurites were extracted from gray images of cultured neurons stained with Coomassie brilliant blue.

White et al. (1995) measured calcium transients in mouse cerebellar granule cells with the Ca^{2+}-sensitive probe indo-1/AM.

Beresini et al. (1997) developed two types of high throughput assays to identify small molecules that interact with neurotrophin receptors. The first, the receptor binding assay, is a competitive binding assay that uses a recombinant receptor fusion protein and biotinylated neurotrophin. This assay detects compounds that inhibit neurotrophin binding to the receptor; these compounds may be either agonistic or antagonistic. The second assay, the kinase receptor activation ELISA,

detects receptor autophosphorylation in response to sample- or neurotrophin-stimulation of receptor transfected cells. Receptor autophosphorylation is evaluated by analyzing lysates of the stimulated cells in a receptor-specific ELISA for phosphotyrosine residues. This assay is bioactivity based, and consequently, has the power of detecting as well as distinguishing receptor agonists and antagonists.

Höglinger et al. (1998) used free-floating roller tube cultures prepared from embryonic-day-14 rat ventral mesencephalon to study the influence of brain-derived neurotrophic factor treatment on dopamine neuron survival and function.

Nerve growth factor is crucial for survival of nociceptive neurons during development. Shu and Mendell (1999) investigated the acute effects of NGF on capsaicin responses of small-diameter dorsal root ganglion cells in culture.

For further studies with brain cell cultures see E.3.1.16.

F.2.0.11 Inhibition of respiratory burst in microglial cells/macrophages

PURPOSE AND RATIONALE

Activated phagocytes can produce large amounts of oxygen intermediates that result from a process during which NADPH oxidase reduces O_2 to the superoxide anion (O_2^-), which subsequently dismutates together with H^+ to H_2O_2 and O_2. H_2O_2 is then reduced to hypochlorous acid by myeloperoxidase (Bellavite 1988). The cascade of metabolic steps is known as respiratory bursts. The intracellular formation of reactive oxygen intermediates can be determined by measuring the oxidation of the membrane permeable and non-fluorescent dihydrorhodamine 123 to the cationic and intracellularly trapped, green fluorescent rhodamine 123 in single viable cells. Microglial/brain macrophage-mediated damage in the central nervous system is accompanied by an increased production of free radicals, which also seems important in primary degenerative dementia (Alzheimer's disease) (Banati et al. (1993). Inhibition of this process by drugs may indicate therapeutic value in Alzheimer's disease.

PROCEDURE

Cell culture

Cultures of new-born rat brain are prepared as described by Guilian and Baker (1986); Frei et al. (1987). Isolated cerebral cortices from new-born albino rats are stripped of the meninges, minced in culture medium and dissociated by trituration for 2 h in 0.25% trypsin solution. Cells are plated in 75 cm^2 plastic culture flasks containing 10 ml medium with 10% fetal bovine serum at a density of 85 000 cells/ml. After 7 days, confluent cultures are vigorously agitated on a rotary shaker at 37 °C for 15 h. Glial fibrillary acid protein positive astroglia remain adherent to the flasks. The resulting cell suspension, rich in ameboid microglia and oligodendroglia, is placed in plastic flasks and allowed to adhere at 37 °C. After a 1–3 h adhering interval, loosely adhering and suspended cells (most of which are oligodendroglia) are removed by gently shaking the flasks at room temperature. The strongly adherent microglia cells are then released by vigorous shaking in medium with 0.2% trypsin. Once the majority of microglia is suspended, fetal bovine serum is added (15% final volume), and the cell suspension added to new flasks. After a second 1–3 h interval to allow adhesion, the medium is removed, and adhering microglia are suspended using trypsin. Final preparation show a nearly homogeneous population of non-specific esterase positive cells.

Peritoneal macrophages are obtained from 12-week-old male Wistar rats.

For flow cytometric measurement, cells are suspended ($3–4 \times 10^6$ cells/ml) in Hank's buffered saline (HBS; Sigma Chemie, Deisenhofen, Germany) supplemented with N-2-hydroxyethylpiperazine-N'-2-ethanesulfonic acid (HEPES; 5 mM, pH 7.35; Serva Feinbiochemica, Heidelberg, Germany) (HBS-HEPES) and stored at 4 °C for a maximum of 2 h.

Flow cytometric measurement of respiratory burst

Dihydrorhodamine 123 (DHR) is obtained from Molecular Probes (Eugene, OR, USA) and dissolved to obtain a 1 mM stock solution in N,N-dimethylformamide (DMF; Merck, Darmstadt, Germany).

The cellular suspensions of peritoneal macrophages and microglial cells (10 µl) are each further diluted with 1 ml HBS-HEPES and stained for 5 min at 37 °C with 10 µl of a 100 µM DHR solution in HBS (1 mM stock solution in DMF). The DHR-loaded cells are incubated with the test drug at various concentrations for 15, 25, 35, 45, and 60 min with and without Con A (100 µg/ml; Sigma Chemie) stimulation. The DNA of dead cells is counter stained with 10 µl of 3 mM propidium iodide (Serva Feinbiochemica) solution in HBS 3 min before the flow cytometric measurement. To exclude effects from a possible release of endogenous adenosine, control experiments with incubation medium containing adenosine deaminase (200 U/mg, 5 µg/ml Sigma Chemie) are performed.

The forward scatter, side scatter and two fluorescences of at least 10 000 cells/sample are measured simultaneously on an FACScan flow cytometer (Becton Dickinson, San Jose, CA, USA). Rhodamine 123 green fluorescence (515–545 nm) and propidium iodide red fluorescence (>650 nm) are measured with the light from an argon laser of 488-nm excitation wavelength.

EVALUATION

The differences in respiratory burst activities caused by Con A stimulation and treatment with test drug are

tested for significance by unpaired *t*-test. The *t*-test is performed for each time point including the data of at least four independent experiments. Each single fluorescence value of each experiment is based on the measurement of at least 10 000 cells. Before each experiment the flow cytometer is calibrated with standardized yellow-green fluorescent microspheres of 4.3-µm diameter (Polysciences, St. Goar, Germany), thus ensuring the compatibility of the fluorescence values from different experimental series.

F.3 *In vivo* methods

F.3.1 Inhibitory (passive) avoidance

One of the most common animal tests in memory research is the inhibition to imitate activities or learned habits. The term "passive avoidance" is usually employed to describe experiments in which the animal learns to avoid a noxious event by suppressing a particular behavior. Netto and Izquierdo (1985) have discussed this term in a brief paper. The term "inhibitory avoidance" is used more often in later publications.

REFERENCES

Netto CA, Izquierdo I (1985) On how passive is inhibitory avoidance. Behav Neural Biol 43:327–330

F.3.1.1 Step-down

PURPOSE AND RATIONALE

An animal (mouse or rat) in an open field spends most of the time close to the walls and in the corners. When placed on an elevated platform in the center of a rectangular compartment, it steps down almost immediately to the floor to explore the enclosure and to approach the wall. The technique is employed in different modifications, which are described by Jarvik and Essmann (1960), Hudspeht et al. (1964), Chorover and Schiller (1965), Kubanis and Zornetzer (1981), Zornetzer et al. (1982), Abdel-Hafez et al. 1998).

PROCEDURE

Mice or rats of either sex are used. A rectangular box (50×50 cm) with electrifiable grid floor and 35 cm fits over the block. The grid floor is connected to a shock device which delivers scrambled foot shocks. The actual experiments can be performed in different ways. A typical paradigm consists of three phases: (1.) Familiarization: The animal is placed on the platform, released after raising the cylinder, and the latency to descend is measured. After 10 s of exploration, it is returned to the home cage. (2.) Learning: Immediately after the animal has descended from the platform an unavoidable footshock is applied (Footshock: 50 Hz; 1.5 mA; 1 s) and the animal is returned to the home cage, (3.) Retention Test: 24 h after the learning trial the animal is again placed on the platform and the step-down latency is measured. The test is finished when the animal steps down or remains on the platform (cut-off time: 60 s).

EVALUATION

The time of descent during the learning phase and the time during the retention test is measured. A prolongation of the step-down latency is defined as learning.

MODIFICATIONS OF THE TEST

This test procedure is employed in different modifications. One of the most common modifications is to induce amnesia in animals. There are different methods to do so including (i) electroconvulsive shock, (ii) scopolamine, (iii) alcohol, (iv) CO_2.

CRITICAL ASSESSMENT OF THE METHOD

The variability of this method is relative high, therefore, it is necessary to test large groups of animals (minimum 10 animals per group). There are some critical parts in the experimental procedure: (i) Placing the animal on the platform, since the tendency of the ani-

mal to escape the contact with the human hand may shorten the step-down latencies. (ii) Another important point is the timing of the electric shock. It must not be applied at the first contact of the animal with the floor, since the light touch with the forelimbs does not cause the required shock intensity. The duration and intensity of the shock should be constant. (iii) It is also necessary to keep the room sound-proof, and this can be done by using a white noise generator (60–70 dB). Due to all these critical variables the results of different authors are difficult to compare.

F.3.1.2 Step-through

PURPOSE AND RATIONALE

This test uses normal behavior of mice and rats. These animals avoid bright light and prefer dim illumination. When placed into a brightly illuminated space connected to a dark enclosure, they rapidly enter the dark compartment and remain there. The standard technique was developed for mice by Jarvik and Kopp (1967) and modified for rats by King and Glasser (1970). It is widely used in testing the effects of memory active compounds (Fekete and de Wied 1982; Hock and McGaugh 1985; Hock et al. 1989; Hock 1994).

PROCEDURE

Mice and rats of either sex are used. The test apparatus consists of a small chamber connected to a larger dark chamber via a guillotine door. The small chamber is illuminated with a 7 W/12 V bulb. The test animals are given an acquisition trial followed by a retention trial 24 h later. In the acquisition trial the animal is placed in the illuminated compartment at a maximal distance from the guillotine door, and the latency to enter the dark compartment is measured. Animals that do not step through the door within a cut-off time: 90 s (mice) or 180 s (rats) are not used. Immediately after the animal enters the dark compartment, the door is shut automatically and an unavoidable footshock (Footshock: 1 mA; 1 s – mice; 1.5 mA; 2 s – rat) is delivered. The animal is then quickly removed (within 10 s) from the apparatus and put back into its home cage. The test procedure is repeated with or without drug. The cut-off time on day 2 is 300 s (mice) or 600 s (rats), respectively.

EVALUATION

The time to step-through during the learning phase is measured and the time during the retention test is measured. In this test a prolongation of the step-through latencies is specific to the experimental situation. An increase of the step-through latency is defined as learning.

CRITICAL ASSESSMENT OF THE METHOD

Same as in step-down method

MODIFICATIONS OF THE TEST

This test procedure is employed in different modifications. To test drugs usually several test-groups can be tested. (i) CXC-group: vehicle – without amnesia – vehicle; (ii) DXD-group: drug – without amnesia – drug; (iii) CAC-group: vehicle – amnesia – vehicle; (iv) DAD-group: drug – amnesia – drug; (v) CAD-group: vehicle – amnesia – drug; (vi) DAC-group: drug – amnesia – vehicle. (The first figure means treatment on day 1; the third figure means treatment on day 2). There are different methods to induce amnesia: (i) electroconvulsive shock, (ii) scopolamine, (iii) al-cohol, (iv) CO_2 etc.

Step-through experiments were performed after unilateral ibotenic acid lesions in the right nucleus basalis magnacellularis as a rat model of Alzheimer disease by Fine et al. (1985).

Wan et al. (1990) recorded changes in heart rate and body temperature via a telemetry system during step through passive avoidance behavior in rats.

Picciotto et al. (1995) used gene targeting to mutate β2, the most widely expressed neuronal nicotinic acetylcholine receptor in the central nervous system for pharmacological and behavioural studies. Retention of the inhibitory avoidance response was better in mutant mice than in their non-mutant siblings.

F.3.1.3 Two compartment test

PURPOSE AND RATIONALE

A rodent in an open field tends to enter any recesses in the walls and to hide there. When placed into a large box, connected through a narrow opening with a small dark compartment, the animal rapidly finds the entrance into the small chamber, enters it and spends most of its time there. The times spent in the large and small compartments are measured. The latency of the first entrance into the dark chamber and the number of crossings from one compartment into the other can be used as auxiliary criteria. The technique described was developed by Kurtz and Pearl (1960) and modified by Bures and Buresova (1963).

PROCEDURE

Mice and rats of either sex and a rectangular box with a 50×50 cm grid floor and 35 cm high walls are used. In the centre of one wall is a 6×6 cm opening connecting the large compartment to a small 15×15 cm box with dark walls, electrifiable grid floor and removable ceiling. The connection between the two compartments can be closed with a transparent sliding door. Illumination is provided with a 100 W bulb placed 150 cm above the centre of the large compartment.

EVALUATION

The times the animal spends in the large and the small compartment are measured.

CRITICAL ASSESSMENT OF THE METHOD

Same as in step-down method.

F.3.1.4 Up-hill avoidance

PURPOSE AND RATIONALE

Many animal species exhibit a negative geotaxis, i.e. the tendency to orient and move towards the top when placed on a slanted surface. When placed on a tilted platform with head facing down-hill, rats and mice invariably turn around and move rapidly up the incline (Staubli and Huston 1978).

PROCEDURE

Rats of both sex were used and maintained under standard conditions. The experimental apparatus is a 50×50 cm box with 35 cm high opaque plastic walls. The box can be inclined at different angles. The floor consists of 10 mm diameter stainless steel grid bars placed 13 mm apart. To deliver the tail-shock, a tail-electrode is constructed, consisting of a wire clip connected to a constant current shock source. The animal is first fitted with the tail-electrode and then placed onto the grid with its nose facing down. During baseline-trials the animal's latency to make a 180° turn and ini-

tiate the first climbing response is measured. Thereafter the animal is returned to its home cage. During the experimental trials the latencies are measured and additionally a tail-shock (1.5 or 2 mA) was administered contingent on the first climbing response after the 180° turn. Immediately after the shock the animal is placed in its home cage. Retest is performed 24 h later.

EVALUATION
The latencies are measured.

CRITICAL ASSESSMENT OF THE METHOD
The up-hill avoidance technique promises to provide a useful addition to the existing arsenal of inhibitory (passive) avoidance methods. Its most obvious advantage is that it can be administered to animals debilitated in sensory-motor coordination by pharmacological or surgical treatments that would preclude use of other inhibitory (passive) avoidance tasks.

REFERENCES
Staubli U, Huston JP (1978) Up-hill avoidance: A new passive avoidance task. Physiol Behav 21:775–776

F.3.1.5 Trial-to-criteria inhibitory avoidance

PURPOSE AND RATIONALE
As animals experience different sensitivity to the footshock punishment applied in the dark area, immediately after the first trial the animal is returned to the lighted area to evaluate if the task has been acquired. A criteria is established to determine the learning of the test, usually requiring the animal to remain in the lighted area for a period of 30–60 s. (Decker et al. 1990). In this way, all the animals have a similar degree of learning independently of the amount of trials needed to attain it.

PROCEDURE
Mice or rats are generally used. The animals are trained in the same way as in the step-through version. They are placed in the lighted compartment and after they entered with the four paws into the dark area, the door is closed and a mild footshock is delivered. Immediately after the shock they are placed back in the lighted area for another trial. Training would continue this way until the animal remains in the lighted area for a certain period of time (30 or 60 s), a time at which the training is considered to be acquired by all the animals. The number of trials to attain criteria are counted as an indication of the speed of acquisition.

EVALUATION
Retention of the test is measured 24 or 48 Hs later. The animals are placed in the lighted area, the door opened and the latency to step with the four paws into the dark area is recorded. A cut-off latency of 180 or 300 s is usually imposed.

CRITICAL ASSESSMENT OF THE TEST
This modification of the classical inhibitory avoidance procedure is useful to determine the effect of drugs on acquisition as amnesic drugs significantly increase the number of trials to reach the criterion. Saline-treated animals generally need 1–2 trials to reach criterion while animals under diazepam or scopolamine need 3–6 trials. Once the animals have been trained to a predetermined criteria (i.e., 30 s. avoidance) any effect of the drug on the retention trial can be associated to drug effects on consolidation rather on the acquisition process (Brioni 1993; Decker et al. 1990). Alternatively, drugs could be administered before the test session in order to determine the effect of the drug on retrieval processes. Brain lesions differentially affect acquisition or retention (Hepler et al. 1985; Tomaz et al. 1992), and this task has also been used to demonstrate the effect of grafts on recovery of function (Fine et al. 1985).

MODIFICATIONS OF THE TEST
This test can also be performed as a continuous trial-to-criterion. In this procedure the door is not closed after the animal enters the dark area and upon delivery of the shock the animal can escape to the lighted area. The experimenter does not have to touch the animal to placed it in the lighted area for the next trial.

Kameyama et al. (1986) described a similar model for the study of learning and memory in mice using a step-down-type passive avoidance- and escape-learning method.

F.3.1.6 Scopolamine-induced amnesia in mice

PURPOSE AND RATIONALE

The administration of the antimuscarinic agent scopolamine to young human volunteers produces transient memory deficits (Drachman and Leavitt 1974). Analogously, scopolamine has been shown to impair memory retention when given to mice shortly before training in a dark avoidance task (Dilts and Berry 1967; Glick and Zimmerberg 1972; Schindler et al. 1984). The ability of a range of different cholinergic agonist drugs to reverse the amnesic effects of scopolamine is now well documented in animals and human volunteers. However, the neuropathology of dementia of the Alzheimer type is not confined to the cholinergic system (Iversen 1998).

PROCEDURE

The scopolamine test is performed in groups of 10 male NMRI mice weighing 26–32 g in a one-trial, passive avoidance paradigm. Five min after i.p. administration of 3 mg/kg scopolamine hydrobromide, each mouse is individually placed in the bright part of a two-chambered apparatus for training. After a brief orientation period, the mouse enters the second, darker chamber. Once inside the second chamber, the door is closed which prevents the mouse from escaping, and a 1 mA, 1-s foot shock is applied through the grid floor. The mouse is then returned to the home cage. Twenty-four hours later, testing is performed by placing the animal again in the bright chamber. The latency in entering the second darker chamber within a 5 min test session is measured electronically. Whereas untreated control animals enter the darker chamber in the second trial with a latency of about 250 s, treatment with scopolamine reduces the latency to 50 s. The test compounds are administered 90 min before training. A prolonged latency indicates that the animal remembers that it has been punished and, therefore, does avoid the darker chamber.

EVALUATION

Using various doses latencies after treatment with test compounds are expressed as percentage of latencies in mice treated with scopolamine only. In some cases, straight doses-response curves can be established whereas with other drugs inverse U-shaped dose-responses are observed (Schindler et al. 1984).

CRITICAL ASSESSMENT OF THE METHOD

In spite of the fact that the pathogenesis of primary degenerative dementia (Alzheimer's disease) in man has been only partially elucidated, the scopolamine-amnesia test is widely used as primary screening test for so-called anti-Alzheimer drugs.

MODIFICATIONS OF THE METHOD

Amnesia can also be induced by pretreatment with benzodiazepines (Porsolt et al. 1988).

Nabeshima et al. (1986) studied the antagonism against phencyclidine-induced retrograde amnesia in mice.

Lenègre et al. (1988) investigated the effects of piracetam on amnesias induced by scopolamine, diazepam and electroconvulsive shock.

Yamaoto et al. (1990) studied the effect of drugs on the impairment of working memory produced by scopolamine, ethylcholine aziridinium (AF64A) or cerebral ischemia using a repeated acquisition procedure in a three-panel runway apparatus.

Braida et al. (1998) investigated the short (120 min) and long-lasting (360 min) antagonism of scopolamine-induced amnesia in rats in an eight-arm radial maze by a cholinesterase inhibitor.

F.3.1.7 Memory impairment by basal forebrain lesions in rats

PURPOSE AND RATIONALE

Memory impairment can be produced by lesions caused by bilateral injections of ibotenic acid into the basal forebrain of rats. Water maze tasks, habituation tasks, passive avoidance tasks with a light/dark compartment apparatus, and the inhibition of the decrease of choline acetyltransferase activity in the cortex can be used to evaluate the effect of drugs (Fuji et al. 1993a).

PROCEDURE

Male Wistar rats weighing 270–310 g are anesthetized with sodium pentobarbital (45 mg/kg i.p.) and placed in a stereotaxic apparatus. Neurotoxic lesions of the basal forebrain are produced by injection of ibotenic acid. An injection needle connected to a 5-µl microsyringe is inserted into the basal forebrain, identified according to the Paxinos and Watson (1986) atlas of rat brain (1.5 mm posterior, 2.8 mm bilateral to the bregma, 7.3 mm below the dura). Ibotenic acid is dissolved in 50 mM Na phosphate buffer at a concentration of 12 µg/ml, and then 0.5 ml (6 µg per side) is infused for 5 min. The injection needle is left in place for an additional 5 min to allow the toxin to diffuse away from the needle tip. One week later, the contralateral side is treated in the same manner. The same procedure is used to administer microinjections of 50 mM Na phosphate buffer into the basal forebrain of sham-operated rats. The lesion sites are mainly distributed in the ventromedial globus pallidus.

Three to 5 weeks after the first lesion, the animals are tested on the acquisition of a task in a Morris water maze (Morris 1981), on a habituation task in a novel situation, and in a passive avoidance task with light and dark compartments. The rats are treated once a day during the experiment.

After the behavioral experiments, the animals are sacrificed for determination of choline acetyltransferase activity in the brain according to Fonnum (1975). The tissue is homogenized (4% w/v) in cold 50 mM Na phosphate buffer (pH 7.4), and Triton X-100 (0.55, v/v) is added to homogenates to ensure enzyme release. To 75 µl of enzyme solution, 125 µl of substrate mixture (0.4 mM [^{14}C]acetyl- Co A (50.6 mCi/mmol), 300 mM NaCl, 50 mM Na phosphate buffer (pH 7.4), 8 mM choline chloride, 20 mM EDTA-2Na, and 0.1 mM physostigmine) is added in a scintillation vial and the mixture is incubated at 37 °C for 30 min. After the incubation, 0.8 ml of cold 50 mM phosphate buffer, 0.5 ml of acetonitrile containing 2.5 mg of tetraphenylborate and 2.0 ml toluene are added to the scintillation vial. The vials are shaken lightly and allowed to stand overnight before radioactivity is determined.

EVALUATION

Data are evaluated by usual statistical means. All analyses are followed by a Bonferroni's test.

MODIFICATIONS OF THE METHOD

Fuji et al. (1993b) studied autoradiographically the influence of drugs on alterations in muscarinic cholinergic receptor [^{3}H]QNB binding induced by basal forebrain lesion in rats.

Harder et al. (1996) performed bilateral transsection of the fornix in young adult marmosets producing a specific pattern of cognitive deficits, notably a lack of ability to recall visuospatial tasks learnt preoperatively, and a deficit in acquiring new visuospatial tasks following transsection. This impairment could be ameliorated by cholinergic agonists and 5-HT$_{1A}$ antagonists.

F.3.1.8 Ischemia-induced amnesia in gerbils

PURPOSE AND RATIONALE

Impairment of cerebral metabolism induced by reduced blood supply is known to induce cognitive deficits (Gibson et al. 1981). Because of the absence of posterior communicating arteries in the brain of Mongolian gerbils, complete forebrain ischemia can be produced by occluding both common carotid arteries resulting in amnesia (Levine and Sohn 1969; Schindler 1983; Chandler et al. 1985).

PROCEDURE

Male Mongolian gerbils (strain Hoe:Gerk) weighing 50–70 g are anesthetized by i.p. pentobarbital injection. Both common carotid arteries are exposed through a ventral neck incision and occluded for 5 or 10 min with miniature aneurysm clips. In sham-operated controls, the common carotid arteries are exposed but not occluded. Twenty-four hours after occlusion, each animal is placed in the bright part of a light/dark-chambered apparatus for training. After a brief orientation period, the gerbil enters the second, dark chamber. Once inside the second chamber, the door is closed which prevents the animal from escaping, and a 100 V, 2-s foot shock is applied through the grid floor. The gerbil is then returned to the home cage. Twenty-four hours later, testing is performed by placing the animal again in the bright chamber. The latency in entering the second dark chamber within a 5 min test session is measured electronically. The latency compared with sham-operated controls is decreased depending on the duration of ischemia. After drug treatment, an increase of latency in entering the dark compartment indicates good acquisition.

EVALUATION

Using various doses a dose-dependent increase of latency can be found after active drugs, sometimes resulting in inverse U-shaped dose-response curves.

F.3.1.9 Cognitive deficits on chronic low dose MPTP-treated monkeys

PURPOSE AND RATIONALE

Röltgen and Schneider (1994), Schneider et al. (1990, 1993, 1994a,b) described the effect of chronic low-dose 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) exposure on cognitive functions in monkeys. These animals develop cognitive deficits and difficulties in performing previously learned tasks, such as delayed response, delayed matching-to-sample, delayed alternation, visual discrimination reversal, and object retrieval, as well as dopamine depletions in several brain areas without severe Parkinsonian signs as found after high MPZP doses (Burns et al. 1983), see E.7.1.2. In addition, these animals exhibit other behavioral changes such as decreased task persistence, increased restlessness and decreased attention.

PROCEDURE

Adult Macaca monkeys are trained to perform a delayed response task while seated in a restraining chair placed inside a sound attenuating modified Wisconsin General Test apparatus. The monkey sits behind an opaque screen that when raised allows access to a sliding tray that contains recessed food wells with identical sliding white Plexiglas covers that serve as stimulus plaques that can be displaced by the animal to obtain rewards (raisins). Monkeys are trained to retrieve a raisin from one of the food wells after observing the experimenter baits the well. Right and left wells are baited in a randomized, balanced order. Animals are maintained on a restricted diet during the week and tested while food deprived. Training is accomplished with a non-correction procedure with 0 s delay and progressing to 5 s delay. Animals are trained until performance with a 5 s delay is 90% correct or better for at least 5 consecutive days. Each daily session consists of 25 trials. A response is scored a 'mistake' if the monkey makes its response choice to a well that is not baited with reward. A 'no response' error is scored if the monkey fails to respond to a trail within 30 s.

Once the animals are performing at criterion level, MPTP is administered intravenously in doses ranging from 0.05 mg/kg at the start of the study to 0.20 mg/kg. Animals receive cumulative doses up to 60 mg over periods up to one year.

Pharmacological data are obtained after animals consistently show at least a 15% performance deficit on delayed response. Drugs are administered subcutaneously. Delayed response testing begins 8 min after dug administration. On drug testing days, animals receive drug or saline and are tested for delayed response performance, administered drug (or saline), and retested on the delayed response task.

EVALUATION

Delayed response performance after drug administration is compared with matched control performance obtained on the same day prior to drug administration.

The total number of correct responses as well as the number of mistakes and 'no response' errors are tabulated for each session. Date are then expressed as mean (± standard deviation) performance. All animals serve as their own controls. Statistical analysis consists of analysis of variance, repeated measures design, with post hoc comparisons (Bonferroni *t*-test).

F.3.2 Active avoidance

Active avoidance learning is a fundamental behavioral phenomenon (Herrnstein 1969; Brush 1971; Campbell and Church 1969; D'Amato 1970). As in other instrumental conditioning paradigms the animal learns to control the administration of the unconditioned stimulus by appropriate reactions to the conditioned stimulus preceding the noxious stimulus. The first stage of avoidance learning is usually escape, whereby a reaction terminates the unconditioned stimulus.

F.3.2.1 Runway avoidance

PURPOSE AND RATIONALE

A straightforward avoidance situation features a fixed aversive gradient which can be traversed by the animal. The shock can be avoided when the safe area is reached within the time allocated (Munn 1950; Capaldi and Capaldi 1972; Hock and McGaugh 1985).

PROCEDURE

Mice or rats of either sex are used and maintained under standard conditions and handled for several days before the experiment. The same box as used in the step-through model can be used in this experiment. The apparatus is uniformly illuminated by an overhead light source. A loudspeaker, mounted 50 cm above the start-box, serves for presenting the acoustic conditioned stimulus (CS; an 80 dB, 2 000 Hz tone from an audiogenerator). The footshock is employed by the same source as in the step-through avoidance. The animal is allowed to explore the whole apparatus for 5 min. The guillotine door is then closed and the animal is placed into the light starting area. After 10 s the acoustic CS is applied and the door is simultaneously opened. Shock is turned on after 5 s. The CS continuous until the animal reaches the safe area. It is left there for 50–70 s (intertrial interval, ITI) before returned to the same area again. The procedure starts again. The training is continued until the animal attains the criterion of 9 avoidances in 10 consecutive trials. On the next day the procedure is repeated until the same learning criterion is reached. The time needed to reach the safe area is measured.

EVALUATION

The time the animal needs to reach the safe area on both days is measured. In addition, the number of errors (not reaching the safe area) is recorded.

MODIFICATIONS OF THE TEST

Several modifications are described in the literature. The CS also can be a light signal. The number of trials and the criterion can be changed.

CRITICAL ASSESSMENT OF THE METHOD

Same as in step-down method.

F.3.2.2 Shuttle box avoidance (two-way shuttle box)

PURPOSE AND RATIONALE

Compared to runway avoidance, shuttle box avoidance (two-way-shuttle-box) is a more difficult task. Since the animal is not handled between trials, the shuttle-box can be easily automated (Capaldi and Capaldi 1972).

PROCEDURE

Rats of both sex are used and maintained under standard conditions. The apparatus used consists of a rectangular box 50×15 cm with 40 cm high metal walls, and an electrifiable grid floor. The box is divided by a wall with a manually or solenoid-operated guillotine door (10×10 cm). into two 25×15 cm compartments. Each compartment can be illuminated by a 20 W bulb mounted in the hinged Plexiglas lids. A fixed resistance shock source with an automatic switch (0.5 s on 1.5 s off) is used. Simple programming equipment provides for automatic delivery of the conditioned stim-ulus (CS) and the unconditioned stimulus (US). The apparatus is placed in a dimly lit room with a masking noise background (white noise) of 60 dB. The animal is allowed to explore the apparatus for 5 min with the connecting door open and the compartment lights switched off. The guillotine door is then closed. After 20 s the light is switched on in the compartment containing the animal, and the door is opened. A tone (CS) is presented and 5 s later the floor shock is applied in the illuminated compartment and continued until the animal escapes to the dark side of the compartment, the connecting door is closed and the shock discontinued. After a variable intertrial interval (ITI; 30–90 s) the light is switched on in the previous dark compartment, the door is opened and the animal is required to cross to the other side. The training is continued until the animal reaches the criterion of 9 avoidances in 10 consecutive trials. Retention is tested at different intervals after the original training by retraining the animal to the same criterion again.

EVALUATION

The time the animal needs to reach the safe area on both days is measured. In addition, the number of errors (not reaching the safe area) are recorded.

CRITICAL ASSESSMENT OF THE METHOD

The task is rather difficult due to the lack of a permanent safe area, lack of a simple instrumental response, presence of a variable aversive gradient and increased weight of emotional factor.

MODIFICATIONS OF THE METHOD

Salmi et al. (1994) described a computer-assisted two-way avoidance conditioning equipment for rats.

F.3.2.3 Jumping avoidance (one-way shuttle box)

PURPOSE AND RATIONALE

Since a high degree of automation and minimum handling are additional requirements for this model, the obvious solution is a simplified one-way avoidance, allowing for the spontaneous or forced return of the animal to the start. In order to enhance the start-goal distinction a vertical gradient is introduced which requires the animal to perform a discrete response of an all-or-none character, such as the jump, which clearly differs from the more continuous translational movements required in the usual avoidance tasks (Tenen 1966; McKean and Pearl 1968).

PROCEDURE

Rats of both sex are used and maintained under standard conditions. The apparatus used consists of a rectangular box 40×25 cm with 40 cm high metal walls, an electrifiable grid floor and a Plexiglas ceiling. A $12 \times 12 \times 25$ cm opaque plastic pedestrial, mounted onto one of the narrow walls of the box provides the isolated goal area. Flush with the horizontal surface of the pedestal moves a vertical barrier, which can either be retracted to the rear wall of the apparatus to expose the goal area or pushed forward to block access to the goal completely. The animal is placed into the apparatus for 5 min with the goal area exposed (barrier re-

tracted). The barrier is then moved forwards and the goal is blocked for 2 s. The first trial starts by exposing the goal area and applying an acoustic CS (1 000 Hz, 85 dB). Electric shocks – US (1.0 mA; 50 Hz; 0.5 s) – are applied 5 s later (once per 2 s), and continued together with the CS until the animal jumps onto the platform. After 30 s the barrier pushes the animal off the platform onto the grid floor. The sequence is repeated until the criterion of 10 consecutive avoidances is reached. Retention is tested on the next day until the animal reaches criterion.

EVALUATION

The time the animal needs to reach the safe area on both days is measured. In addition, the number of errors (not reaching the safe area) is recorded.

CRITICAL ASSESSMENT OF THE METHOD

In automated procedures extinction is more rapid, especially when short inter test intervals are used.

F.3.3 Discrimination learning

In the experiments described above the animals have no choice between the conditioned stimuli. They have only one conditioned stimulus. The following examples illustrate the special techniques employed for discrimination among different stimulus modalities. The experiments can be classified either as simultaneous or successive discrimination paradigms. An exhaustive survey of discrimination studies can be found in Gilbert and Sutherland (1969).

F.3.3.1 Spatial habituation learning[2]

PURPOSE AND RATIONALE

The open-field test utilizes the natural tendency of rodents to explore novel environments in order to open up new nutrition, reproduction and lodging resources (Birke and Archer 1983; Cerbone and Sadile 1994). The rate of exploratory behaviors exhibited in an unfamiliar environment is limited through the inherent necessity to avoid potential dangers. The observed behavior therefore is always a compromise between these conflicting interests and is regulated in part by the momentary physiological needs (Gerlai 1999; Groves and Thompson 1970). Spatial habituation learning is defined as a decrement in reactivity to a novel environment after repeated exposure to that now familiar environment. This reduction in exploratory behaviors during re-exposures is interpreted in terms of remembering or recognition of the specific physical characteristics of the environment. The test can be used to examine short-term spatial memory (within-trial reductions in exploratory activity) and/or long-term spatial memory (between-trial reductions in exploratory activity after a retention interval of 24, 48 or 96 h after the initial exposure) (Lát 1973).

PROCEDURE

The open-field apparatus is a rectangular chamber (rats: $60 \times 60 \times 40$ cm, mice: $26 \times 26 \times 40$) made of painted wood or grey PVC. A 25 W red or green light bulb is placed either directly above or beneath the maze to achieve an illumination density at the centre of approximately 0.3 lx. Masking noise is provided by a broad spectrum noise generator (60 dB). Prior to each trial, the apparatus is swept out with water containing 0.1% acetic acid. Housing room and the testing location are separated and animals are transported to the testing room 30 min before testing. The digitized image of the path taken by each animal is stored and analyzed post hoc with a semi-automated analysis system (e.g. Ethovision, Noldus, The Netherlands or Truscan, Coulbourn Instruments, Allentown, PA). In aged or hypoactive rodents testing is performed during the animals dark phase of day. The rodent is placed on the center or in a corner of the open-field for 5–10 minute sessions (mice: up to 20 min, because of the high basal activity level). The animals are re-exposed to the open-field 24 and 96 h after the initial trial (Thiel et al. 1999; Schwarting et al. 1999).

[2] Contribution by E. Dere.

EVALUATION

The exploratory behaviours registered are: (1) Rearings or vertical activity: the number of times an animal was standing on its hind legs with forelegs in the air or against the wall. (2) The duration of single rearings as a measure of non-selective attention (Aspide et al. 2000) (3) Locomotion or horizontal activity: the distance in centimeters an animal moved.

MODIFICATIONS OF THE TEST

In order to assess emotionality parameters either in interaction with spatial novelty (a single exposure) or in interaction with spatial habituation learning (repeated exposures), the aversivity of the open-field can be varied by increasing the size (inducing agoraphobia) and/or the illumination density (inhibits exploration) of the apparatus (File 1980). Rodents exposed to a big sized brightly lit open field tend to spent more time in the corners or close to the wall and avoid the central part of the apparatus. The emotional behaviors registered are: (1) Corner time: the time spent in the 4 corner squares (rats: 15×15 cm; mice: 6.5×6.5 cm). (2) Wall time: the time an animal spent close to the wall as a measure for thigmotaxis (scanning the walls of the apparatus with the vibrissae). (3) Center time: the time spent in the center of the open field (rats: 20×20 cm; mice: 10×10 cm). (4) Defecation: number of boli deposited. (5) Freezing: the time the animal stays completely immobile except for movements associated with respiratory activity (Hall 1936; Frisch et al. 2000). To assess habituation learning not only by decrements in exploratory behaviors but also via increments, one can place an object in the center of the open-field. The number of entries into and the time spent in the center increases from exposure one to exposure two without affecting other indices of spatial habituation (Dai et al. 1995).

CRITICAL ASSESSMENT OF THE TEST

The open-field paradigm is a well validated, simple and time economical test, which has been widely used to examine the neurobiological foundations subserving spatial memory, general activity and emotionality in rodents with different approaches including: lesions, drugs, electrophysiology, neuroanatomy, and neurogenetics.

F.3.3.2 Spatial discrimination

PURPOSE AND RATIONALE

In the simplest case of discrimination learning the animal distinguishes between two symmetric stimulus-response sets, the equal probability of which has been changes by differential reinforcement events. Position of the cues with respect to the animal's body defines the CS^+ and CS^-. Usually left-right discrimination is employed, while axial orientation of the body is ensured by the construction of the apparatus (Siegel 1969).

PROCEDURE

Rats and mice of both sex are used and maintained under standard conditions. The apparatus used is usually a simple T- or Y-maze, with an electrifiable grid floor. The last 10 cm of each arm are separated from

the rest of the apparatus by a swing-door which prevent the animal from seeing the food cup or the plastic sheet covering the grid in the goal area. A fixed resistance shock source is connected to an automatically operated switch. In an aversively motivated spatial discrimination learning the animal is trained to escape and/or to avoid foot shocks by always going to the right. Training starts by allowing the animal to explore the apparatus. Then the animal is placed on the start and after 5 s electric shocks (0.5 s, 50 Hz, 1.0 mA) are applied at 3 s intervals. The animals are trained to a criterion. On the following day the animal is retrained to the same criterion. After a 60 min interval the safe goal area is shifted to the other arm of the maze and the discrimination is reversed.

EVALUATION

Errors are scored. An error means that the animal enters the wrong arm with all four legs. During retention the number of trials until the animal makes correct choices are counted.

CRITICAL ASSESSMENT OF THE METHOD

The ecology of rodents makes these animals specially proficient in spatial discrimination learning, which is usually mastered in a few trials. Most of the initial errors are not due to the inability of the animal to remember the correct solution, but rather to its tendency to explore alternative pathways.

MODIFICATIONS OF THE TEST

Barnes (1979) and others introduced the radial maze as a modification of spatial discrimination. This method is now well established and widely used.

Ingram et al. (1994a,b) recommended the Stone 14-unit T-maze to find new pharmacological approaches for cognitive enhancement.

F.3.3.3 Spatial learning in the radial arm maze

PURPOSE AND RATIONALE

Olton and co-workers have developed a spatial discrimination task for rodents that has been extensively used in learning and memory studies, and that has served as the basic task for one of the most important theories on the role of the hippocampus (Olton et al. 1979; Olton and Samuelson 1976). The rat uses spatial information provided by the distal cues in the room to efficiently locate the baited arms. The radial arm-maze allows the study of spatial reference and working memory processes in the rat. In reference memory procedures, information is useful for many sessions/days and may usually be needed during the entire experiment. On the contrary, working memory procedures have a major temporal component as the information presented in the maze (arms baited) is useful for one session but not for subsequent ones; the rat has to remember the information during a delay interval (min to h). Correct choices in the radial arm-maze are rewarded by food.

PROCEDURE

The apparatus is a wooden elevated eight-arm radial maze with the arms extending from a central platform 26 cm in diameter. Each arm is 56 cm long and 5 cm wide with 2 cm high rails along the length of the arm. The maze is well illuminated and numerous cues are present. Food pellets (reward) are placed at the end of the arms. During the test, rats are fed once a day and their body weights maintained at 85% of their free-feeding weight to motivate the rat to run the maze. Animals are trained on a daily basis in the maze to collect the food pellets. The session is terminated after 8 choices and the rat has to obtain the maximum number of rewards with a minimum number of errors.

EVALUATION

The number of errors (entries to non-baited arms) are counted during the session.

MODIFICATIONS OF THE TEST

Depending on the hypothesis being tested in the radial arm-maze (1) animals can be trained extensively and then receive specific brain lesions (hippocampus, septum or fimbria-fornix); after recovery from the surgery the rats are re-trained to determine the cognitive

ability or the speed of recovery as these lesions severely disrupt processing of spatial information (Olton et al. 1978). (2) In working memory studies animals are forced to obtain reward in specific arms (4 arms), and after a time delay they have to either return to the same arms (win-stay) or to avoid these arms and obtain the food in the rest of the arms (win-shift). (3) Animals are trained to find food in only one arm, and after a delay they are required to return to the same arm. Many versions of the maze exist with differences in the shape, arm-length or the number of arms (12 or 24 arm-mazes), but all of them are appetitively-motivated. An aversively-motivated maze was developed by locating an 8-arm maze in a water tank (Buresova et al. 1985). Extensive modifications on the arm-maze were also developed by Kesner and co-workers and are the basis of the multidimensional attribute theory that characterize mnemonic functions (Kesner 1980, 1986).

CRITICAL ASSESSMENT OF THE TEST

The radial arm-maze has been widely used to determine the neurobiological mechanisms underlying spatial learning in rodents and to evaluate the effect of drugs. The deleterious effects of scopolamine, atropine, ethanol, benzodiazepines, haloperidol, ketamine, PCP, as well as the facilitatory effects of physostigmine, nicotine, pramiracetam, picrotoxin, naloxone have been reported in the literature (Levin 1988). One of the disadvantages of the test is that hypothalamic lesions or the anorectic effect of certain drugs (amphetamine) affect the appetitive nature of the maze and animals do not master the maze for this reason.

F.3.3.4 Visual discrimination

PURPOSE AND RATIONALE

Vision is better than any other sensory system for the analysis of spatial relationships in the environment of the animal. From the retina to the cerebral cortex, the organization of the visual system ensures processing of visual information according to simple principles, i.e. by fitting the distribution of light over the receptive surface to elementary geometrical concepts and by comparing these patterns with images stored in the memory. Visual pattern recognition is one of the most challenging problems of contemporary neurophysiology and experimental psychology, with significant implications for mathematical and technical modeling of perceptual phenomena (artificial intelligence). For review and details see Grüsser and Klinke (1971) and Sutherland (1969). Experimental studies of pattern discrimination must take into account the visual capability of the given species and present the discriminanda under conditions compatible with light sensitivity and acuity of the eye. The constructions of the apparatus should ensure that the discriminanda are viewed from one optimum distance and for a sufficient period of time. A thorough discussion of the pattern discrimination technique is to be found in Munn (1950).

PROCEDURE

Rats and mice of both sexes are used and maintained under standard conditions. The apparatus consists of a square 10×10 cm start area separated by a Plexiglas sliding door from the choice area, which is connected by swing doors to the goal compartment. The grid floor in the starting and the choice areas is electrifiable. The stimulus (mostly plastic cards 8×8 cm) can be attached to the swing doors. The patterns are black on a white background and have different forms. The apparatus is illuminated by a dim light. The animal is placed into the apparatus with all doors open and allowed to explore it. Then it is placed in the start and after 5 s released by raising the Plexiglas door. After another 5 s, electric shocks (1 mA, 50 Hz, 0.5 s, 1/3 s) are applied until the animal escapes through either of the open doors to the safe goal compartment where it is left for some seconds. As soon as this preliminary step is mastered, the stimulus cards are inserted, the negative door is locked and the grid section in front of this door is electrified. The animal is trained to a criterion. On the next day the animal is retrained to the same criterion and retention is expressed in savings. Another parameter which can be used to evaluate the savings is the cumulative number of errors until the criterion is reached (Thompson 1969).

EVALUATION
The number of correct answers as well as the number of trials until the criterion is reached are counted.

CRITICAL ASSESSMENT OF THE METHOD
The method is time consuming and only useful to address a specific hypothesis.

F.3.3.5 Spatial learning in the water maze

PURPOSE AND RATIONALE
A task was developed where rats learn to swim in a water tank to find an escape platform hidden under the water (Morris 1984). As there are no proximal cues to mark the position of the platform, the ability to locate it efficiently will depend on the use of a configuration of the cues outside the tank. Learning is reflected on the shorter latencies to escape and the decrease on the length of the path to find the platform. Although rodents can find the platform by using non-spatial strategies, the use of a spatial strategy is the most efficient way to escape and young animals develop the spatial strategy after a small number of trials.

PROCEDURE
Different strains of rats are generally used (Long Evans, Wistar, Sprague-Dawley). The apparatus is a circular water tank filled to a depth of 20 cm with 25 °C water (Brioni et al. 1990; Morris 1984). Four points equally distributed along the perimeter of the tank serve as starting locations. The tank is divided in four equal quadrants and a small platform (19 cm height) is located in the centre of one of the quadrants. The platform remains in the same position during the training days (reference memory procedure). The rat is released into the water and allowed 60–90 s. to find the platform. Animals usually receive 2–4 trials per day for 4–5 days until they escape onto the platform. Well-trained rats escape in less than 10 s.

EVALUATION
The latency to reach the escape platform is measured during the training days. A free-swim trial is generally performed after the training days where the escape platform is removed and the animal is allowed to swim for 30 s. With the help of a video system, the latency to reach the previous position of the platform, the number of annulus crossings as well as the time the rat spent in the training quadrant are measured. Well-trained rats show short latencies, a large number of annulus crossings and bias to the quadrant where the escape platform was located during the training sessions.

MODIFICATIONS OF THE TEST
In the "cue" version of the water maze, the platform is clearly visible over the water and allows the evaluation of the motor and motivational aspects of the rat under study, as the animals should easily find the visible platform in 10–15 s. As circling or other non-spatial strategies can be used to find the platform, alternative measures of learning were developed (Gallagher et al. 1993), like the use of brief probe trials during training (rather than at the end), the use of proximity measures (an index of search error or deviations from the optimal path), and the learning index (proximity measures during weighted probe trials). Buresova and co-workers have developed the use of a collapsible platform to improve the accuracy of the water maze (Buresova et al. 1985). To evaluate working memory processes in the water maze, the rat can be trained to find a new platform position and later its performance is tested after a short delay (2–4 h). A spatial discrimination version of the water maze was also developed (Decker et al. 1992; Morris 1984), where the rat has to discriminate between two similar platforms based on spatial differences (one platform provides a mean to escape while the other sinks upon contact).

CRITICAL ASSESSMENT OF THE TEST
This test allows the researcher to study working and reference memory processes, and to dissociate the memory deficits induced by brain lesions or drug injections from the motor, motivational or sensory deficits. This test has been used to study the effect of drugs on memory (Brioni et al. 1991; Brioni et al. 1990. Decker et al. 1992), the participation of the hippocampus, septum, amygdala and nucleus basalis magnocellularis (Morris et al. 1986; Morris 1989), catecholamine depletions, as well as recovery of function (McNamara and Skelton 1993). It has been particularly sensitive to demonstrate that aged rats exhibit deficits in the acquisition of spatial information when compared to young or middle age controls (Rapp et al. 1987). The major advantages of the water maze over the radial arm-maze are: (1) that animals can be trained

in a significantly shorter period of time (one week) while the arm-maze studies require several weeks of training; (2) intramaze cues like odor trails are eliminated in the pool; (3) large dose-response studies can be conducted in a week's time; (4) the motor or motivational problems in the rat can be detected in a cue trial; and (5) that the animals are not food-deprived during the test. From a theoretical point of view, the water maze is an aversively-motivated task while the arm-maze is appetitively-motivated.

MODIFICATIONS OF THE METHOD

Nitta et al. (1994, 1996; Nabeshima 1995) found an impairment of the performance of the water maze task in rats treated by infusion into the cerebral ventricle for 14 days with β-amyloid protein which consisted of senile plaques of Alzheimer's disease. The authors recommended that β-amyloid protein-treated rats as an animal model for Alzheimer's disease.

F.3.3.6 Olfactory learning

PURPOSE AND RATIONALE

Odors provide rodents with important information on the environment and the learning of successive olfactory discrimination problems in rats is closely related to the acquisition rules of higher primates. Odor-reward associations are learned in few trials as odors exert more discriminative control over other sensory modalities like tones or lights (Nigrosh et al. 1957). Animals have to learn to discriminate an arbitrary designated positive odor (i.e., banana) from a negative one (i.e., orange) to receive a reward.

PROCEDURE

Rats (Sprague-Dawley or Long Evans) are generally used. In procedures described in the literature (Eichenbaum et al. 1992; Roman et al. 1993), animals are deprived of water for 48 h before the training and during the test they receive ad libitum water for only 30 min. The olfactory apparatus is a rectangular box ($30 \times 30 \times 55$ cm) with a photosensitive cell mounted on top of the water spout/odor outlet. Rats are trained to approach the water spout and to brake the light beam. Responses to the positive odor are rewarded with water while responses to the negative odor results in the presentation of a light flash. The intertrial interval before the presentation of a new odor is usually 15 s. and the sessions last 30 min. per day. Sessions are terminated when the rat makes 90% correct choices or after 400 trials.

EVALUATION

The animal is rewarded with 0.05 ml of water when it brakes the beam to the positive odor or when it does not respond to the negative odor. Incorrect responses ("no go" to the positive odor or "go" to the negative odor are followed by a flash and a longer intertrial interval). Results are reported as the % correct responses or as a logit transformation of the % correct/incorrect response ratio.

CRITICAL ASSESSMENT OF THE TEST

The anatomical connections from the olfactory bulbs to cortical as well as subcortical areas are fairly well

known, and brain lesions that impair olfactory discrimination learning (Otto et al. 1991; Roman et al. 1993; Stäubli et al. 1984) could be used as models of amnesia. Systemic injections of scopolamine disrupts the performance of rats during long delays with no effect on immediate recall, data that are consistent with the effect of scopolamine in humans (Ravel et al. 1992). Antagonists of the NMDA receptor impair acquisition of odor discriminations and block LTP, an electrophysiological correlate of memory (Lynch and Stäubli 1991). The test can also be used to evaluate the cognitive effects of drugs such as ACTH analogs that facilitate the storage of olfactory information (Roman et al. 1989).

MODIFICATIONS OF THE TEST

A T-maze with controlled access to the reward compartment was developed (Ravel et al. 1992), that allows the test to evaluate working memory processes after time delays (1–3 min.).

Willer et al. (1992) examined the effects of a competitive NMDA agonist on the ability of rats to acquire potentiated aversions to the odor element of a taste-odor compound.

Larson et al. (1995) studied in rats the facilitation of olfactory learning by a modulator of AMPA receptors.

F.3.3.7 Aversive discrimination in chickens

PURPOSE AND RATIONALE

One to 2-days old chicks have been extensively used to study learning and memory. The chicks are trained to discriminate between an aversive and a non-aversive stimulus (colored glass beads) in a single 10–15 s learning trial. Following this learning trial, retention is monitored over a comprehensive range of learning-retention intervals to chart the course and to differentiate possible stages of memory formation. Three behaviorally sequentially dependent stages have been identified: a short-term memory stage, lasting approximately 10 min after learning; an intermediate-memory stage, available between 20 and 50 min post-learning, and a long-term memory stage available from 60 min after learning. The three stages are behaviorally separated by transient retention deficits occurring at around 15 and 55 min post-training. Gibbs and Barnett (1976), Gibbs and Ng (1976, 1979), Rickard et al. (1994), Bennett et al. (1996), Ng et al. (1997) used a three-stage model to test the influence of drugs on memory formation.

PROCEDURE

Day-old, male, White-leghorn black-Australop chickens are housed at an ambient temperature of 28 °C. In a single passive avoidance learning trial, chicks are pre-trained to peck at a 4 mm chromed bead, dipped in water and presented for 10 s. A similar bead, dipped in the chemical aversant methyl anthranilate, is the presented for 10 s. Data from chicks failing to peck the bead on this trial or not showing characteristic disgust responses after pecking are eliminated from subsequent data analysis. Retention is tested by presenting for 10 s a dry bead similar to that used for the pre-training trail.

In a discrimination paradigm, chicks are trained to avoid a red bead and are tested on red and blue beads successively and discrimination ratios registered.

In an additional discrimination paradigm, chicks are given two aversive beads – a chrome and a red bead. They are trained on one of the aversive beads sometime before drug treatment. The other aversive bead is associated with drug treatment and the chicks are subsequently tested with all three beads.

Twenty different chicks are used for each data point. Retention in both paradigms is indexed by the proportion of chicks avoiding the aversive bead, with the proviso that in the discrimination paradigm is indicated by the avoidance of the red bead and pecking on the blue bead. Retention is tested at various times between 5 and 180 min after learning or at 24 h.

Drugs are administered in 0.1 ml volumes subcutaneously into a fold of skin on the ventral side of the rib cage.

EVALUATION

Discrimination ratios of treated animals after various time intervals following administration of drugs are statistically compared with saline treated controls.

CRITICAL ASSESSMENT OF THE METHOD

The test has been used with slight modifications successfully by many authors in several research groups (e.g., Hölscher and Rose 1992; Sandi and Rose 1994; Stephenson and Andrew 1994; Zhao et al. 1994; Deyo and Hittner 1995; Crowe and Shaw 1997; Venero and Sandi 1997; Bennett et al. 1998; Tiunova et al. 1998; Rose and Stewart 1999)

MODIFICATIONS OF THE TEST

Bourne et al. (1991) compared the taste and odor aversant methyl anthranilate with the odorless quinine as averants.

Clements and Bourne (1996) and Stamatakis et al. (1998) injected drugs, e.g., GABA agonists or α_2-noradrenergic agonists and antagonists, directly into the intermediate median hyperstriatum ventrale of day-old chicks, prior to training on a chrome bead dipped in either methyl anthranilate or quinine.

Colombo et al. (1997) injected enkephalins into 2 regions of the 2-day-old chick brain: the intermediate medial hyperstriatum and the lobus parolfactorius.

Tiunova et al. (1996) trained chicks to discriminate between edible chick crumbs and arrays of colored bead glued to the floor of their cage.

Gilbert et al. (1989) reported a simple, one-trial, learning paradigm in young chicks. Chicks were separated from their brood mates and placed in a small isolation chamber. A T-maze connected the isolation chamber to the brood space, allowing the chick to escape isolation stress and rejoin the brood. When the chick successfully negotiated the corridor, the latency to perform this task was recorded. On a subsequent trial, any improvement in the speed of performance was recorded to reflect the chick's memory of the task.

F.3.4 Conditioned responses

F.3.4.1 Conditioned nictitating membrane response in rabbits

PURPOSE AND RATIONALE

The rabbit's classically conditioned eyeblink response has become a widely used model system for studying associative learning in mammals (Gormezano et al. 1987) and to find drugs potentially useful in the treatment of age-related memory disorders (Ghoneim et al. 1994; Woodruff-Pak et al. 1994a,b, 1997; Solomon et al. 1988, 1995a,b).

PROCEDURE

Animals

New Zealand white albino rabbits weighing 2.0 kg are housed individually under consistent light with free access to food and water.

Apparatus and general procedure

A small loop of surgical nylon is sutured into the right nictitating membrane, and the surrounding hair is removed. One day later, the rabbit is placed in a Plexiglas restrainer, and two stainless-steel wound clips are applied to the skin over the parietal region. The rabbit is fit with a headmount that supports a photoresistive assembly for recording the nictitating membrane response by physical coupling with a length of thread to the nylon loop in the nictitating membrane. The transducer assembly converts nictitating membrane movements into elec-trical signals that are subjected to an analog-to-digital conversion using a 5-ms sampling rate and a resolution of 0.06 mm actual membrane extension. The animal is then positioned in a ventilated, sound-attenuated chamber facing a stimulus panel containing an 11.4-cm speaker and two 6-W, 24-V DC house lights, one mounted at each side of the speaker. During the course of the experiment, two stimuli are employed as conditioned stimulus: a) a 1000-ms, 1-kHz, 84-dB tone; b) a 1000-ms, intermittently presented light produced by interruption of the house lights at 10 Hz to yield a change in illumination, measured at the eye level of the rabbit from 32.11 to 8.01. The unconditioned stimulus is a 100-ms, 3-mA, 60Hz shock delivered to the wound clips by a constant current shock generator.

Drugs

Drug solutions or saline are injected subcutaneously into the cervical area of the rabbit via an infusion pump at a rate of 3 ml/min, 30 min before behavioral testing.

Procedure

Experimentally naive rabbits are random-ly assigned in equal numbers to each of the treatments ($n = 10$ per treatment). The experiment consists of two phases: Phase 1 is an adaptation day followed by 9 days of acquisition training. No stimuli are presented during the 60-min adaptation session. Subjects are injected with their assigned treatment 30 min before each acquisition session. Each acquisition session consists of 30 tone-shock and 30 light-shock trials presented in a randomized sequence within 10 trial blocks, with the restriction that no more than three consecutive tone or light trials can occur. On each conditioned stimulus – unconditioned stimulus trial, the offset of the 1 000-ms tone or light conditioned stimulus occurs simultaneously with the onset of the 100-ms unconditioned stimulus. The inter-trial interval is about 60 s. A response is defined as at least a 0.5-mm extension of the nictitating membrane. Responses occurring during the tone or light conditioned stimulus, but before the unconditioned stimulus are recorded as conditioned response; those occurring after the unconditioned stimulus onset are recorded as unconditioned response.

EVALUATION

The data are analyzed by repeated measures analyses of variance and Tukey tests. The significance level is set at $p < 0.05$.

CRITICAL ASSESSMENT OF THE METHOD

The rabbit nictitating membrane response has been used widely to study the effects of drugs on learning (Schindler and Harvey 1990).

MODIFICATIONS OF THE TEST

Several authors used a corneal airpuff as unconditioned stimulus (Robinson et al. 1993; Solomon et al. 1995, 1996).

Scavio et al. (1992) studied post-training effects of several drugs, such as amphetamine, chlorpromazine, ketamine, and scopolamine, on the acquisition and extinction of the rabbit's conditioned membrane response.

The effects of modulating tone frequency, intensity, and duration on the classically conditioned rabbit nictitating membrane response were studied by Kehoe et al. (1995).

Solomon et al. (1996) described behavioral paradigms for delay, trace, and long-delay conditioning.

Various drugs influence the nictitating membrane response in rabbits, such as morphine (McEchron and Gormezano 1991), cocaine (Marshall-Goodell and Gormezano 1991), sodium pentobarbital (Chen et al. 1992), haloperidol (Sears and Steinmetz 1990), MDA (3,4-methylenedioyamphetamine) (Kirkpatrick-Steger

et al. 1991; Romano and Harvey 1993), harmaline (Harvey and Romano 1993; Du and Harvey 1997), ketamine (Ghoneim et al. (1994), isoflurane (El-Zahaby et al. 1994), L-NAME (nitric oxide synthesis inhibitor, Du and Harvey 1996), serotonin antagonists and agonists (Welsh et al. 1998a,b), calcium antagonists (Woodruff-Pak et al. 1997), nitrous oxide (Ghoneim et al. 1999).

F.3.4.2 Automated learning and memory model in mice

PURPOSE AND RATIONALE

Vanover and Barrett (1998) developed and validated pharmacologically an automated, relatively rapid, and reproducible behavioral model of learning and memory using an autoshaped procedure in mice. Autoshaping procedures were first described for pigeons by Brown and Jenkins (1968) and have been used subsequently as a means to assess learning and memory in monkeys (Sidman and Fletcher (1968), in rats (Steckler et al. 1993; Oscos et al. 1998), and in mice (O'Connell 1980).

PROCEDURE

Naive male mice weighing 25–35 g are randomly assigned to experimental groups. They are housed at approximately 22 °C at a 12 : 12 light/dark cycle with food and water continuously available. Twenty-four hours before each test, mice are isolated into individual cages and all food is removed. Water remains continuously available. Tests are conducted on two consecutive days. Mice are fed 1.5 g food immediately after the first session (day 1).

For experimental sessions, mice are placed in sound-attenuating enclosures containing specially designed operant chambers ($12.5 \times 11 \times 12.5$ cm) equipped with a recess (dipper well; 2.2 cm diameter, 1.3 cm deep) for dipper accessibility on one wall of the chamber and two additional smaller holes (1.3 cm diameter, 0.9 cm deep) on either side of the dipper well. The dipper can be raised into the dipper well for a sucrose solution (110 g/1.0 l water) reinforcer presentation. Each recess has a photocell monitoring nose-poke responses. In addition, a speaker capable of sounding a stimulus tone is located on the wall opposite to the dipper and a house-light is on the ceiling. A computer and associated interface controls stimulus events and records nose-poke responses.

Five to 9 mice per group are tested in a 2-day procedure designed to measure acquisition and retention of nose-poke response under an autoshaping schedule of reinforcement. Experimental sessions are conducted at the same time each day for 2 consecutive days. Both the acquisition session (day 1) and the retention session (day 2) are identical.

During the autoshaping procedure which is used to measure acquisition and retention of the response reinforcement for nose-poking a tone is added. This tone sounds on a variable-interval schedule of presentation (mean of 45 s, range 4–132) and stays for either 6 s or until a nose-poke in the dipper well is made before the end of the 6 s period, at which time the tone is turned off and a dipper with sucrose solution is presented. If a mouse fails to make a dipper well nose-poke during the tone, the dipper is automatically presented at the termination of the tone. A dipper well nose-poke response made during the presence of the tone is counted as reinforced response. Dipper well nose-poke responses made while the tone is off are counted but have no consequence. Each sessions lasts for 2 h or until 20 reinforcers have been earned, whichever comes first. In addition to dipper well nose-poke responses, nose-pokes in the smaller holes to the left and right of the dipper are counted but have no consequence.

Drugs in various doses or vehicle are administered i.p. immediately before the session.

Rates of nose-poke responses made in the small holes on either side of the dipper well serve as a measure of general activity. The computer presents tones on a variable interval with a mean of 45 s and 10 possible intervals (4, 10, 15, 22, 29, 38, 49, 64, 87, 132 s) chosen randomly without replacement until all intervals have been used.

The latency of the response to the 10^{th} reinforcer is considered as a measure of acquisition and retention, because all mice have been exposed to all possible intervals (in random order) by the 10^{th} tone. In order to eliminate the variance due to the variability of the first reinforcer, it is necessary to adjust any measure of acquisition and retention according to the response latency to the first reinforcer. The 10^{th} response latency measure is thus adjusted by subtracting the response latency to the first reinforcer (L-10−1) in order to ensure all mice have been exposed to the reinforcement contingency.

An other measure of acquisition and retention consists of the rate of nose-poke responding in the dipper well during the total session.

EVALUATION

The mean and standard error of the mean are calculated for every group. Two-tailed Student *t*-tests are used to compare two independent groups on any one dependent variable. In addition, two-tailed paired *t*-tests are conducted to compare data from day 1 to data from day 2 for any one group. One way analyses of variance (ANOVA) are conducted across groups for effects of dose on acquisition (day 1 performance). One way analyses of covariance (ANCOVA) are conducted across groups for effects of dose for retention (day 2 of performance) with the performance on day 1 as the covariate. When an ANOVA or ANCOVA shows statistical significance, post-hoc Duncan's multiple range tests are conducted with every group compared with vehicle. *P* values less or equal to 0.05 are considered statistically significant.

F.3.5 Studies in aged monkeys

PURPOSE AND RATIONALE

Nonhuman primates have the closest taxonomic relationship to humans, sharing many morphologic and physiologic similarities in the central nervous system. These similarities increase the likelihood that studies in aged nonhuman primates will provide information about drugs that is relevant to humans. Nonhuman primates offer additional advantages for neurobehavioral animal models of aging in that many of the behavioral processes thought to be affected by aging (e.g. reaction time, attention, learning and memory) can be studied easily in nonhuman primates. Evidence is beginning to accumulate suggesting that certain neurological and behavioral deficits are observed in aged human and in nonhuman primates (Bartus 1979; Struble et al. 1982; Wisniewski et al. 1973).

PROCEDURE

The apparatus developed specifically for the series of studies used to develop the primate model was the Automated General Experimental Device (AGED), the rationale upon which its development was based and its application to geriatric research have been discussed in detail elsewhere (Bartus 1979; Bartus and Dean 1981; Dean et al. 1983). The AGED is a totally automated, computer-controlled testing system, whose prominent feature consists of a 3×3 matrix of stimulus response (SR) panels. Each SR panel is hinge-mounted directly in front of the reinforcement well so that when a panel is pushed, a red switch is magnetically activated and a reinforcement well is exposed. Both colored and patterned stimuli can be projected onto the SR panels. A plastic partition with a stimulus window and armholes separates the monkey from the SR matrix. The stimulus observation window is equipped with a photocell and an infrared light source to detect when the monkey's head is oriented toward the stimuli.

EVALUATION

The monkey must remember the stimulus location to get a reinforcement. Number of correct answers will be counted as well as the time until the monkey answers correctly.

CRITICAL ASSESSMENT OF THE METHOD

This system provides an accurate and objective means of collecting data under a number of behavioral paradigms. Further, this system provides experimental control over a number of variables that might confound behavioral measures (especially in drugged or aged subjects), thus simplifying the interpretation of differences observed and increasing the likelihood that these interpretations are accurate.

MODIFOCATIONS OF THE METHOD

Cai and Arnstein (1997) described dose-dependent effects of Dopamine D1 receptor agonists on spatial working memory in aged monkeys.

F.3.6 Electrophysiological methods

F.3.6.1 Long-term potentiation in hippocampal slices

PURPOSE AND RATIONALE

Long-term potentiation (LTP) in the hippocampus is perhaps the most dramatic example of activity-dependent synaptic plasticity that has yet been identified in the mammalian brain (Landfield and Deadwyler 1988; Bashir et al. 1994). A brief tetanus to any one of a number of monosynaptic excitatory pathways in the hippocampus can enhance the amplitude of evoked responses in the tetanized pathway for h or days thereafter. The fact that it occurs in the hippocampus has done much to stimulate interest in LTP as a synaptic model of memory, since the importance of the hippocampus for memory processing has been evident ever since the discovery that its bilateral removal in man causes a profound impairment in the ability to lay down new memories (Scoville and Milner 1957; Milner 1972).

The particular popularity of the slice preparation prepared from the rodent hippocampus rests on its lamellar and laminar organization (Teyler 1980).

PROCEDURE

Transverse slices, 400 mm thick, are cut from the hippocampus of male albino guinea pigs weighing 250–300 g and prepared for electrophysiological recordings (Teyler 1980; Tanaka et al. 1989, 1990). Slices are incubated for 90–120 min in the recording chamber to allow equilibration with artificial cerebrospinal fluid. They are submerged, placed on a nylon mesh and perfused at a flow rate of 2–2.5 ml/min with oxygenated (95% O_2/5% CO_2) cerebrospinal fluid having the following composition (in mM): NaCl 124, KCl 3.3, $CaCl_2$ 2.5, KH_2PO_4 1.25, $MgSO_4$ 2, $NaHCO_3$ 25,7, glucose 10. The recording chamber is maintained at 33 ±2 °C. The extracellular population spike is obtained using glass microelectrodes filled with 2 M NaCl, which have resistances of 2–5 MΩ. The electrodes are placed into the stratum pyramidale of CA1 or CA3. The signal is amplified and stored on magnetic discs for later analysis. The evoked responses are averaged and analyzed off-line using a personal computer. The magnitude of the population spike is evaluated by taking the voltage difference between the negative peak and the following positive peak. Either mossy fibers in the hilus fasciae or commissural/associational fibers in the stratum radiatum are activated via bipolar, sharpened silver wire electrodes insulated except for the tips. Constant current pulses (100 ms) are delivered with a frequency of 0.2 Hz, only during the test intervals. The stimulation intensity is adjusted to elicit the population spike of about 40% and 80% of its maximal amplitude in CA1 and CA3, respectively. After the baseline is recorded for 10–20 min, LTP is induced by repetitive stimulation of 100 pulses at 20 Hz for 5 s in CA1 and at 50 Hz for 2 s in CA3 at the same strength as for the test pulses. Responses by test pulses are recorded 0, 10, 20 and 30 min after repetitive stimulation. The test drugs are dissolved in the artificial cerebrospinal fluid and applied extracellularly at various concentrations by switching perfusion reservoirs.

EVALUATION

The time course of LTP is registered for CA1 and CA3. The mean percent increase in the amplitude of the population spike from baseline responses after drug application is compared with controls.

MODIFICATIONS OF THE METHOD

Fujii et al. (1997) studied the effects of an adenosine A_1 receptor antagonist, 8-cyclopentyltheophylline, on the reduction of long-term potentiation in CA1 neurons of **guinea pig** hippocampal slices. Reduction of long-term potentiation (depotentiation) was achieved by delivering a train of low-frequency afferent stimuli 20 min after the tetanus.

Behnisch and Reymann (1993) employed slices of hippocampal area CA1 in the **rat** to test the hypothesis that the activation of metabotropic glutamate receptors during tetanization is necessary for the maintenance of long-term potentiation.

Akhondzadeh and Stone (1995) studied the phenomenon of hippocampal long-term depression. Extracellular recordings were made in the CA1 pyramidal cell layer of **rat** hippocampal slices following orthodromic stimulation of Schaffer collateral fibres in stratum radiatum.

Oomura et al. (1996) measured long-term potentiation in hippocampal slice preparations after a brief tetanic stimulation at the Schaffer collateral/-commissural afferents of senescence-accelerated **mice** which were treated from 3 weeks of age up to 10 months either with subcutaneous injections of acidic fibroblast growth factor or saline.

F.3.6.2 Long term potentiation *in vivo*

PURPOSE AND RATIONALE

Placing recording and bipolar stimulating electrodes in the granule cell layer of the dentate gyrus and angular bundle allows the evaluation of long-term-potentiation *in vivo*, even in freely moving animals, and the comparison with effects on learning.

PROCEDURE

Female Sprague Dawley rats weighing 225–250 g are anesthetized with 1.5 g/kg urethane (i.p.) and placed in a Kopf stereotaxic instrument. The recording and bipolar stimulating electrodes are placed in the granule cell layer of the dentate gyrus and angular bundle, respectively (from bregma and cortical surface: Dentate: A.P. –4.0 mm, M.L. +2.4 mm, D.V. 3.0 mm. Angular bundle: A.P. –7.9 mm, M.L. +4.0 mm, D.V. –3.0 mm, incisor bar –5.0 mm). The recording electrodes are pulled from thin-walled glass capillary tubes, filled with 150 mM NaCl, and adjusted to resistances ranging from 2.0 to 4.0 MΩ. Stimulating electrodes are made from twisted nichrome wire with Teflon insulation, and approximately 0.75 mm separated each tip. The recording electrode is first lowered into area CA1 of the dorsal hippocampus. The stimulating electrode is then placed into the ipsilateral angular bundle. As the recording electrode is lowered further, field potentials are evoked to determine when the recording electrode enters the dentate granule cell layer.

All rats are maintained at 37 °C. Responses are evoked using a Grass S-88 stimulator and a Microprobe System M-7 070A amplifier, and are recorded on a Nicolet 310 oscilloscope.

Once the electrodes are appropriately placed, field potentials are generated over a range of stimulus intensities to generate an input/output (I/O) curve (pulse duration = 1 ms). The field potentials are quantified in two ways: The population spike (PS) is expressed as the distance from the deepest point (in mV) of negativity to the preceding highest positivity on the left and right side of the response, and then averaged. The slope of the rising phase of the population excitatory postsynaptic potential (pESP) is measured in mV/ms. The amplitude of the test pulse is based is based on the I/O curve being 25% of the current intensity which evokes the maximal population spike. Long-term-potentiation is induced using three theta-burst stimulus trains, each delivered 1 min apart. Each train consists of five groups of four pulses at 100 Hz, separated by an interval of 150 ms. Each train is delivered at the stimulus intensity which evokes the maximal population spike at the I/O curve.

At the end of the experiment, the electrode placements are verified using standard histological techniques.

EVALUATION

Student's *t*-tests are used to assess the significance of differences between the means of both the population spike amplitudes and the pESP slopes.

CRITICAL ASSESSMENT OF THE METHOD

Hölscher et al. (1997a,b) argued that high-frequency stimulation-induced long-term potentiation and low-frequency stimulation-induced depotentiation in area CA1 of the hippocampus are not good models for learning.

MODIFICATIONS OF THE METHOD

Errington et al. (1987) perfused a NMDA receptor antagonist through a push-pull cannula into the dentate gyrus of anesthetized **rats** in order to observe its effect on the induction and maintenance of long-term potentiation and on the increase in release of endogenous glutamate associated with long-term potentiation.

Bennett et al. (1992) recommended cytochrome oxidase inhibition as an animal model of Alzheimer's disease. Rats were infused chronically with the selective inhibitor of cytochrome oxidase, sodium azide, delivered via subcutaneously implanted minipumps. The azide treatment impaired both spatial and non-spatial learning. Further, the azide treatment inhibited a low-threshold form of hippocampal long-term potentiation, primed burst potentiation.

Croll et al. (1997) used this model to study time course and corresponding pathology of learning deficits in rats.

Namgung et al. (1995) described the characteristics of long-term potentiation in the intact **mouse**. Perforant

path stimulation evoked both a population excitatory postsynaptic potential and a population spike potential from the hippocampal dentate gyrus in urethane anesthetized animals. Long-term potentiation, as measured by increased population-spike amplitude and population excitatory postsynaptic potential slope, was successfully induced and reliably maintained at a stable level for at least 12 h.

Davis et al. (1997) described a simple method for inducing and monitoring long-term potentiation at perforant path-granule cell synapses in the dentate gyrus of freely moving mice using readily available miniaturized components. Tetanic stimulation induced long-term potentiation of the field excitatory postsynaptic potential and the population spike which persisted for more than 24 h but was not present 10 days after the tetanus.

Jibiki et al. (1993) and Kubota et al. (1994) studied the drug-induced blockade of induction of long-term potentiation in perforant path-dentate gyrus pathway in chronically prepared **rabbits**.

Gutnikov and Gaffan (1996) studied the effects of a NMDA receptor antagonist on memory acquisition and retrieval of visual-reward associations in the object-in-place memory task and on NMDA neurotoxicity in **rhesus monkeys**.

F.3.6.3 Long latency averaged potentials

PURPOSE AND RATIONALE

Wirtz-Brugger et al. (1986, 1987) studied long latency averaged evoked potentials (P300) in anesthetized rats as a possible model for detecting memory-enhancing drugs. The P300 waveform is described as a positive long-latency (~300 ms) potential believed to reflect endogenous cognitive processes rather than exogenous physical parameters of the stimulus. Compounds that have been shown clinically to enhance cognitive ability also significantly increase the integrated area under the P300 wave.

PROCEDURE

Male Wistar rats weighing 300–500 g are anesthetized with 120 mg/kg i.p. Inactin®. Stainless steel screws serve as recording electrodes located at the surface of the cortex of seven distinct brain areas: posterior: Pz (midline), P3, P4 (lateral); central: Cz (midline); and frontal: Fz (midline, F3, F4 (lateral). A linked reference is provided with platinum needle electrodes behind the ears. All leads are fed into a digital averaging computer. Event-related potentials are elicited in response to an oddball paradigm of two tones (500 Hz frequent and 3 KHz rare) randomly presented with a probability of 10% for the rare tone. The intensity of the tones is 95 bB, pulse duration 100 ms, rise/fall 9.9 ms. The auditory stimuli are delivered bilaterally at a rate of 0.3/s through special Nicolet tubal tip inserts into the ear of each subject. One repetition of the paradigm consists of 300 tones. It is presented twice, before and after drug application. Evaluation of the rare responses consists of defining and comparing the P300 in terms of integrated area before and after drug. P300 area is calculated by integration of area under the curve.

EVALUATION
Values are expressed as means and standard error per group and percent changes from control. Statistical evaluation consists of paired t-tests to demonstrate significant differences.

MODIFICATIONS OF THE METHOD
Caudle (1993) demonstrated long latency potentials in the CA1 regions of the rat hippocampal slice suggesting that the *in vitro* P3 is an *in vitro* version of the long latency evoked potential known as the P300 in electroencephalogram studies.

Ikeda et al. (1995) studied the effect on a nootropic compound on event-related potential P300 in rats with lesions of the nucleus basalis magnocellularis.

Antal et al. (1994) studied the influence of cholinergic agents on visual discrimination and P300 in the behaving **monkey**. P300 latency was increased following scopolamine administration. Acetyl-L-carnitine increased P300 amplitude and decreased its latency.

In **squirrel monkeys**, clonidine significantly decreased the area and increased the latency of P300-like potential (Swick et al. 1993).

Kaga et al. (1992) studied P300 and choline acetyltransferase immunohistochemistry in septohippocampal neurons of **cats**.

Wang et al. (1999) reported that P300-like potential depends on muscarinic receptor activation in **rabbits**.

F.3.7
Metabolic influence

F.3.7.1
Sodium nitrite intoxication ($NaNO_2$)

PURPOSE AND RATIONALE
The manipulation of brain metabolism was used to show the beneficial effects of substances which influence learning and memory. Gibson et al. (1976, 1978), during investigations of sodium-nitrite ($NaNO_2$) on brain metabolism, demonstrated a close relationship between oxidative metabolism and cholinergic function. From the results of their studies, the possibility cannot be excluded that an induction of impairment of the cholinergic transmission in addition to a deficiency in brain metabolisms was induced (Schindler et al. 1984).

PROCEDURE
Male or female mice are used and maintained under standard conditions. Chemical hypoxia is induced by the injection of sodium nitrite ($NaNO_2$: 250 mg/kg s.c.) which reduces the oxygen-carrying capacity of the blood by converting hemoglobin to methemoglobin. This lethal dose (lethality 100% of controls) is injected 60 min after drug treatment. Immediately after the $NaNO_2$-injection the animals are placed in small Makrolon® cages and the time between injection of $NaNO_2$ and cessation of respiration is recorded (Hock 1993).

EVALUATION
The time between injection of $NaNO_2$ and cessation of respiration is recorded. The prolongation of survival time is expressed in percent.

MODIFICATIONS OF THE METHOD
Using lower doses of $NaNO_2$ mice are submitted to a positive reinforcement paradigm (Schindler et al. 1984). Groups of 10 mice are water deprived for 24 h. The mice are treated with the test compound 45 min before they are placed individually in a large chamber. On one wall of the chamber, there is a small compartment that contains a water bottle. The mouse easily finds the bottle and is allowed to drink for 30 s. Each mouse then receives a subcutaneous injection of 75 mg/kg $NaNO_2$ before being returned to the home cage. Twenty-four hours later, retention testing is performed by placing the mouse in the large chamber, but at this time, the small compartment is kept empty. The duration and frequency of the mouse's exploration of the small compartment while searching for water is evaluated over a period of 3 min. An increase in duration and frequency correlates with improved learning

The tight rope test (Barclay et al. 1981) was used to test the effect of $NaNO_2$ with and without treatment on performance in mice (Peterson and Gibson 1982; Gibson et al. 1983).

Chapter G
Effects on peripheral nerve function

G.1
Local anesthetic activity

G.1.0.1
General considerations

One has to generally distinguish between conduction anesthesia, infiltration anesthesia, and surface anesthesia (Fromherz 1922; Schaumann 1938), and special pharmacological tests have been developed for each of these.

The mode of action of local anesthetics has been reviewed by Ritchie and Greengard (1966), Ritchie (1971), Borchard (1977), Steiner (1978), Butterworth and Strichartz (1990).

G.1.1 Conduction anesthesia

G.1.1.1 Conduction anesthesia in the sciatic nerve of the frog

PURPOSE AND RATIONALE

Based on earlier studies by Sollmann (1918), Fromherz (1922), Fußgänger and Schaumann (1931), and Bülbring and Wajda (1945) on plexus anesthesia in frogs, Ther (1953a,b, 1958) described a method for conduction anesthesia of the sciatic nerve in frogs.

PROCEDURE

Frogs (*Rana temporaria*) of either sex are used and are kept at 4 °C. The frog is decapitated with a pair of scissors. The skin is incised in the thigh region at both sides and the sciatic nerves are carefully exposed in the thigh, avoiding any stretching and injury of the nerve. The frog is suspended on a vertical board. Small pieces of white cotton are soaked with different concentrations of the test preparations (between 0.05% and 1%) or the standard and placed gently around the sciatic nerve for 1 min. Then the cotton swab is removed and the frog is placed with its extremities into a bath with 0.65% NaCl solution. This allows testing for duration and reversibility of the local anesthetic effect. One side is used for the test preparation and the other for the standard (e.g., 0.25% butanilicaine). Every 3 min the frog is removed from the bath and the toes of the legs or the ankle joint are pinched three times with a small forceps. The reflex contraction is abolished when conduction anesthesia is effective. The stimuli are repeated every 3 min until anesthesia vanishes. Two to 5 frogs are used for each concentration.

EVALUATION

Time of onset and duration of anesthesia are recorded for each concentration. Time-response and dose-response curves can be established.

MODIFICATIONS OF THE METHOD

In the original method by Bülbring and Wajda (1945) the frogs were decapitated and the upper part of the spinal cord was destroyed down to the level of the third vertebra. The viscera are removed exposing the lumbar plexus without damaging it. The frog was pinned to a vertical board and the solution of the local anesthetic dissolved in 0.7% saline is put into the pocket formed by the lower abdomen. Different concentrations of HCl are used as stimuli into which the feet of the frog were immersed every min.

Idänpään-Heikkilä and Guilbaud (1999) used a **rat** model of trigeminal neuropathic pain where the neuropathy is produced by a chronic constriction injury of the infra-orbital branch of the trigeminal nerve, and studied the effects of various drugs on this purely sensory model of neuropathic pain (see H.1.2.11)

For mechanical stimulation, a graded series of ten of von Frey filaments with a bending force between 0.217 and 12.5 g was used. The stimuli were applied within the infra-orbital nerve territory, near the center of the vibrissal pad, on the hairy skin surrounding the mystacial vibrissae. Local injection of an local anesthetic (articaine) into the rostral orbital cavity of the lesioned side, into the close proximity of the ligated infra-orbital nerve increased the mechanical threshold to the upper level. The duration of the effect was dose-dependent.

G.1.1.2 Conduction anesthesia in the sciatic nerve of the rat

PURPOSE AND RATIONALE

Based on earlier studies (Truant 1958; Truant and Wiedling 1958/59, Åström and Persson 1961) Camougis and Takman (1971) have written a detailed description for testing conduction anesthesia of the sciatic nerve in the rat.

PROCEDURE

Male Wistar or Sprague Dawley rats weighing 125 to 175 g are used. The animal is suspended in a prone position by grasping the base of the tail and thoracic cage. A hind limb is extended to its full length and the depression for needle insertion is located by palpation with the left index finger. The site of injection is the area under the skin at the junction of the biceps femoris and the gluteus maximus muscles. The sciatic nerve is blocked in the midthigh region with 0.2 ml of the drug solution administered by a 24- to 25-gauge needle attached to a 0.25 ml tuberculin syringe. Usually a 1% solution of the test drug in 0.9% NaCl is used as a test solution. The other leg is used for a control drug (e.g., procaine or lidocaine). Immediately after the injection, repeated checks of the digit of the foot and the walking behavior are performed. In the normal foot, the digits are wide apart, while in the blocked leg the digits of the foot are close together. Also the successful block is evidenced by dragging of the leg and an ina-bility of the animal to use the leg in walking up the inclined wire mesh cover of the cage. After the time of block for each leg is noted, each animal is examined every 5 to 10 min in order to note the time of recovery.

EVALUATION

From the data, averages for onset and duration of action are calculated, plus the frequency of blocks are noted. Using various doses of test compound and standard, dose-response curves can be established and potency ratios calculated.

MODIFICATIONS OF THE METHOD

With a similar technique Lembeck (1953) tested the effect of the added vasoconstringent agents adrenaline, noradrenaline and Corbasil® to procaine.

Luduena and Hoppe (1952) used guinea pigs to test sciatic nerve block by local anesthetics.

Siems and Soehring (1952) described a model in **guinea pigs** resembling peridural and paravertebal anesthesia in man.

Sciatic nerve blockade in the **rat** was used by Feldman and Covino (1988) to study comparative motor-blocking effects of bupivacaine and ropivacaine.

Grant et al. (1992) used a rat sciatic nerve model for independent assessment of sensory and motor block induced by local anesthetics. Motor block was assessed by measuring hindpaw grip strength with a dynamometer. Sensory block was determined by measuring hindpaw withdrawal latency from radiant heat.

Åkerman et al. (1988) used sciatic nerve block and brachial plexus block in **guinea pigs** for primary evaluation of a local anesthetic.

Rosenberg and Heinonen (1983) found a differential sensitivity of A and C nerve fibres to long-acting local anaesthetics.

The Local Anesthetics for Neuralgia Study Group (1994) designed a surgically implantable nerve irrigation system for intermittent delivery of local anesthetics and evaluated long-term performance and histocompatibility in rats.

Leszczynska and Kau (1992) used a sciatic nerve blockade method in **mice** to differentiate drug-induced local anesthesia from neuromuscular blockade. The drugs were injected into the popliteal space of the right hind-limb. A positive local anesthetic activity was recorded when a mouse was only able to walk using three limbs on an inverted wire mesh screen and the injected limb was hanging in the air. A positive neuromuscular blockade was recorded when a mouse could walk normally on the top of the wire mesh screen but was unable to stay on the inverted screen.

Åkerman et al. (1988) used **guinea pigs** to determine brachial plexus block. The syringe was directed towards a line between the head of the humerus and the manubrium of the sternum and the first ribs. The needle was inserted about 1.5 cm into the pocket felt as a depression by palpation between the head of the humerus and sternum and associated structures. Following retraction of the needle by a few millimeters, 0.2 ml of the solution was injected. The orientation of the needle was changed 3–4 times during the injection to enable all branches of the plexus to be reached. Assessment was made of motor and sensory blockade.

Thut et al. (1995) used the **rabbit** tooth-pulp assay (see H.1.2.8) to quantify efficacy and duration of antinociception by local anesthetics infiltrated into maxillary tissues.

G.1.1.3 Conduction anesthesia on the mouse tail

PURPOSE AND RATIONALE

The radiant heat method as being used for evaluation of systemic analgesic activity (D'Armour et al. 1941; Ther et al. 1963; Grant et al. 1993) can also be used for determination of conduction anesthesia by injecting the local anesthetic into the root of the tail.

PROCEDURE

Groups of 10 mice (NMRI-strain) of both sexes with a weight between 18 and 22 g are used for each dose. Before administration of the test compound or the standard the normal reaction time is determined. The animal is placed into a small cage with an opening for the tail at the rear wall. The tail is hold gently by the investigator. By opening of a shutter, a light beam exerting radiant heat is directed to the proximal third of the tail. After about 6 s, the reaction of the animal is observed by the investigator. The mouse tries to pull the tail away and turns the head. The shutter is closed with a switch when the investigator notices this reaction. Mice with a reaction time of more than 6 s are not used in the test.

The test compounds and the standard are injected in a volume of 0.1 ml on both sides in the area of the tail root. The animals are submitted to the radiant heat again after 10 min. The area of heating is about 1.5 cm distal to the injection site. For each individual animal the reaction time is noted.

EVALUATION

There are two possibilities for evaluation:

1. The average values of reaction time after each time interval are calculated and compared with the pretest value by analysis of significance.
2. At each time interval only those animals which show a reaction time twice as high or higher as the pretest value are regarded as positive. Percentages of positive animals are counted for each time interval and each dose and ED_{50} values are calculated according to LITCHFIELD and WILCOXON.

MODIFICATIONS OF THE METHOD

The tail flick procedure using **rats** as test animals has been proposed by Herr et al. (1953).

Madan et al. (1970) determined conduction anesthesia by a tail-pinch technique in rats. The local anesthetic was injected subcutaneously bilaterally at the root of the tail. The test for local anesthesia was begun 15 min after injection by pinching with a polyethylene sheathed artery forceps and repeated every 15 min. The number of animals failing to remove the forceps by biting was recorded.

Grant et al. (1993) quantified the duration of the local anesthetic-induced conduction block in the mouse using the tail flick test.

Kamerling et al. (1985) described a method for studying cutaneous pain perception and analgesia in **horses**. This method was used by Harkins et al. (1996, 1997) for determination of highest no effect dose (HNED) for local anaesthetic responses to procaine, cocaine, bupivacaine, benzocaine and of a plant extract. A heat projection lamp was used as noxious stimulus directed onto the pastern to elicit a flexion-withdrawal reflex. Hoof withdrawal latency was defined as the time between lamp illumination and with-

drawal of the hoof. The local anesthetic drugs were injected into the area of the palmar nerve where it passes lateral to the sesamoid bone.

G.1.1.4 Rabbit tooth pulp assay

PURPOSE AND RATIONALE

The rabbit tooth-pulp assay (see H.1.2.8) has been used successfully to evaluate the potency, efficacy, and duration of antinociception of analgesics (Yim et al. 1955; Piercey and Schroeder 1980; Wynn et al. 1984). Thut et al. (1995) described a method for administration of local anaesthetic drugs to the maxillary arch of rabbits and subsequent measurement of antinociceptive action.

PROCEDURE

Pulp chambers are exposed close to the facial gingival line of the two central incisors in New Zealand White male rabbits (1.5–2.0 kg) using a high-speed dental drill and 0.5-mm round burr immediately after the i.v. administration of 30 mg/kg ketamine. All experiments are conducted 48 h or more after pulp exposure. A linear ramp function stimulator is used as the direct current voltage source. The rabbit is slightly restrained, and the current is applied to the pulp via fine-wire platinum electrodes held in each of the cavities. Linearly rising voltage is applied at a rate of 0.33 V/s until a patterned lick-chew response occurs. Mean threshold voltages are established for controls using an average of 3 determinations, and then obtained after treatment using a single determination up to a maximum of 10 V. Rabbits having control values greater than 3 V are excluded from the study. The injection site of the test drug is 1.5 cm posterior to the central incisors and 4 mm below the roof of the maxillary buccal vestibule. The buccal vestibule is the area where the cheek and the top of the maxillary tissue join. The tip of a 27-Ga x 1/2" syringe needle is inserted until it contacts the cancellous bone. The volume of injection is 0.4 ml. Injections are made bilaterally so that the total volume injected is 0.8 ml. The animals can be used chronically, but no rabbit should be exposed to the same drug or the same dose more than once, and non should be injected more frequently than very third day. One animal is used per dosage when analgesia is observed to be either 0% or 100%. Two or 3 animals are used for dosages with effects between 0% and 100%. When more than one animal is used, data are averaged and treated as a single observation. Pulp chambers have to be re-exposed when the drilled openings disappear because of incisor growth (approximately after 3 weeks).

EVALUATION

The percentage of maximum effect (*MPE*) for each observation time is calculated from the following equation:

$$MPE = (TV - CV) / (10V - CV) \times 100$$

TV is the voltage after treatment, *CV* is the control voltage, and *10V* are the maximum volts applied. The voltage that elicits the response is recorded at zero time and 5, 10, 15, 30, 60, 120, and 180 min after injection. The *MPE* is calculated for each observation time. Graphs of the *MPE* values versus time are constructed, and the maximal effect and time of the maximal effect are recorded. Further, the duration of each dosage is defined as the length of time that that dose achieved a *MPE* greater than 25%. Data are regressed between observed time points to provide estimates of the time when 25% *MPE* is first achieved and also the time when 25% *MPE* is no longer observed. A computer program or the standard method of Litchfield and Wilcoxon (1949) can be used to calculate ED_{50}, ED_{90}, and ED_{95} values with 95% confidence limits.

G.1.1.5 Retrobulbar block in dogs

PURPOSE AND RATIONALE
Defalque and Stoelting (1976) published a method to determine latency and duration of action of local anesthetics after retrobulbar injection in dogs.

PROCEDURE
Young female mongrel dogs weighing 13–15 kg are used. Twenty-four h before the test, 0.25% eserine ointment is placed in each conjunctival sac of the dog. Pentobarbital (25 mg/kg) is administered intravenously, then repeated with 10 mg/kg at hourly intervals, thus maintaining the animal in light anesthesia (corneal reflex present). Ten min after induction, the dog is put into 30-degree head-down position, and 20 ml of 0.05% tetracaine is forced into the epidural space through the interarcuate ligament. Horner's syndrome occurs within 5 min.

A 150-watt surgical lamp is now focused upon the eye from an 1 meter distance. Fifteen min later, a retrobulbar block is performed: The sclera is seized with an ophthalmic forceps and the eyeball is pulled downward and medially; a 23-gauge needle is then introduced through the superior rectus muscle, tangentially to the globe, and is immobilized as soon as a click indicates penetration of the retrobulbar space; correct placement is confirmed by free motion of the needle tip and protrusion-rotation of the eyeball upon injection of 1 ml of air.

After aspiration, 2 ml of the tested anesthetic is then injected at a rate of 0.5 ml per second. The pupil dilates and reaches its maximal diameter (6 mm) within a few minutes. This apparent diameter is estimated with a 2-cm long ruler calibrated in millimeters, whose center is gently applied to the corneal center. The pupil is measured every 15 s for 5 min, then every 5 min until reappearance of maximal miosis (pinpoint and asymmetrical), a precise endpoint which generally coincides with corneal reflex and lacrimation.

EVALUATION
Drug latency (in min) and duration (in 5-min units) are averaged for both eyes of each animal, and the mean and standard deviation then calculated for all test animals. Analysis of variance is performed to find significant differences between various local anesthetics.

G.1.1.6 Isolated sciatic nerve preparation of the frog

PURPOSE AND RATIONALE
Isolated nerves are immersed between stimulating and recording electrodes in solutions containing local anesthetics which allows electrophysiological measurements (Paterson and Hamilton 1970).

PROCEDURE
A large frog is sacrificed by decapitation with a pair of scissors, and the spinal cord severed. The skin around the entire body in the region immediately posterior to the forelimbs is cut, and the abdomen and hind legs are skinned by peeling the skin in a posterior direction. The fat, muscles, and other tissues are cut at the posterior end of the body so as to expose the nerves extending posteriorly from the cord. The muscles of the thigh are cut and retracted so as to expose the sciatic nerve. Finally, the gastrocnemius muscle is removed and the peroneus muscle is extended laterally from the tibiofibula. The entire sciatic nerve with branches should now be exposed. A thread with a loop next to the nerve is tied around the nerve in the region of the sacral vertebra. The nerve is then cut anterior to the thread. During the isolation procedure the nerve is kept moist with frog Ringer solution. The connective tissue and the nerve branches are cut carefully. The nerve is finally cut near the distal end of the tibiofibula and extended on a filter paper previously soaked with Ringer solution. With the nerve anchored by the thread, the remaining connective tissue is peeled back toward the distal end of the nerve. Any remaining branches are cut at the point of their bifurcation. The distal end of the nerve is tied with a length of thread. The sciatic-peroneal nerve preparation is mounted in a nerve chamber for recording.

Electrodes for stimulation are placed on the proximal end of the nerve while recording electrodes are placed at the distal end. The nerve is immersed in a trough containing frog Ringer solution as bathing fluid. The stimuli are applied with a commercial stimulator (e.g., Grass Model S4) with a duration of 5 ms, a frequency between 30/s, and 1.5 to 15 mV. The recording electrodes are connected with an amplification and display system. Stimulation of the nerve produces a display on the oscilloscope. Adjusting the voltage setting on the stimulator will cause the action potential to increase and decrease correspondingly on the scope. After pinching the nerve between the last two recording sites, the action potential should be monophasic and appear entirely above the base line. The spike is observed periodically for several min to ascertain its stability.

The bathing trough is changed to a trough containing the local anesthetic dissolved in Ringer solution. At one or 2 min intervals the amplitude of the spike is read and recorded on a polygraph. After 5 min treatment, the drug trough is removed and the nerve is immersed in the Ringer solution of the bathing trough. Amplitudes are measured in periodic intervals and thus the recovery process is recorded.

EVALUATION

Block and recovery curves are achieved with various concentrations of the test compound and the standard. Dose-response curves can be obtained.

MODIFICATIONS OF THE METHOD

Specialized techniques with isolated nerves (desheathed nerves, equilibrium blocks, single nerve fibres) have been described by Camougis and Takman (1971).

Den Hertog (1974) used the **desheathed cervical vagus of the rabbit** mounted in a single sucrose gap apparatus and measured changes in the membrane potential and compound action potential. The ratio of the distance between stimulation and recording electrode (15 mm) and the time between stimulation of the nerve and the top of the action potential was taken as an index for the mean conduction velocity.

Salako et al. (1976) tested a new anti-arrhythmic drug as a local anesthetic on desheathed **frog** nerve.

Lee-Son et al. (1992) used the sucrose-gap method on desheathed isolated frog peripheral nerves to study the stereoselective inhibition of neuronal sodium channels by local anesthetics.

Lambert et al. (1994) studied the reversibility of conduction blockade in desheathed bullfrog sciatic nerves, using the sucrose gap method for recording compound action potentials, before and during exposure to local anesthetics and during drug washout.

Isolated nerves from other species have been used for the study of local anesthetics, such as those from rabbits by Ritchie et al. (1965a,b), or from rats by Condouris and Lagomarsino (1966), Štolc and Mai (1993).

Gissen et al. (1980) observed differential sensitivities of mammalian nerve fibers to local anesthetic agents in rabbits. A fibers were blocked at the lowest drug concentrations, the intermediate B fibers were blocked at a higher drug concentration, and the smallest, slowest-conducting C fibers required the highest drug concentration for conduction blockade.

Fink and Cairns (1984) showed differential slowing and block of conduction by lidocaine in individual afferent myelinated and unmyelinated axons in rabbits.

Åkerman et al. (1988) studied the block of evoked action potential in the isolated sheathed sciatic nerve of the frog for primary evaluation of a local anesthetic compound.

G.1.1.7 Isolated mammalian sciatic nerve preparation

PURPOSE AND RATIONALE

Karlsson et al. (1994) tested the localanesthetic-like effects of an NK_1 receptor antagonist in a mammalian sciatic nerve preparation using guinea pigs.

PROCEDURE

Male guinea pigs weighing 250–400 are sacrificed and the sciatic-tibial nerves immediately excised and cleaned in buffer equilibrated with 95% O_2 + 5% CO_2 under a dissecting microscope. The nerve is mounted in a Plexiglas chamber consisting of three connecting wells. The central well is perfused with buffer at a rate of 5 ml/min and contained the grounding electrode (Ag/AgCl), the in- and outlet of the peristaltic pump driven perfusion system and a thermistor probe. The two lateral wells (one for stimulating, the other for recording) are filled with mineral oil. Stimulating and recording electrodes are made from bare platinum-iridium wire. The passages between the central and lateral wells are sealed with petroleum jelly. The length of the nerve exposed to the drug in the central well is 8 mm. The nerve chamber is kept at a temperature of 27.0 ±0.5 °C.

A constant current supramaximal stimulus of 50 µs duration is used throughout the experiment. The intensity of the stimulus is ten times greater than the threshold intensity required to elicit a compound action potential. Throughout the experiment the nerve is stimulated at the low frequency of 1/min to determine basal compound action potential amplitude. Once the response has stabilized, a single burst of pulses (pulse train duration 250 ms, at 40 Hz) is applied approximately 5 min before drug application (control train) and again after drug application to determine the extent of frequency dependent block. The compound action potentials are digitized with a computer interface and a software program and recorded on a PC. A two channel storage oscilloscope is used to follow the experiment and to automatically sample and calculate the amplitudes of the compound action potentials.

The drugs are dissolved in buffer and applied approximately 5 min after the control train. The development of basal block following drug application is followed with 0.0167 Hz stimulation. In the case of lidocain, the maximal inhibition is reached 20–30 min after application. The basal block is allowed to reach equilibrium, which is defined as the condition in which the difference in amplitude between the first and the last of five consecutive responses is less than 1% of the control compound action potential amplitude obtained prior to drug application. To assess frequency dependent block, a second stimulus is given after equilibrium is reached. Once basal and frequency dependent block has been determined, the nerves are washed with fresh buffer.

EVALUATION

The magnitude of the basal block (%) is calculated by comparing the average peak amplitude of the last three compound action potentials with the average peak amplitude of the last three compound action potentials prior to drug application. Similarly, frequency dependent block is expressed in percent of the control train, and is effectively the basal block plus the additional decrease in compound action potential amplitude. Dose-response curves for the standard and the test drugs are constructed by plotting basal block and frequency dependent block against drug concentration. The pIC_{50} values (the negative logarithm of the molar concentration of the drug producing 50% inhibition of the compound action potential amplitude) are estimated by linear regression analysis of the results in the 10–90% interval of the dose-response curves.

The dose-response data obtained with the standard and the test drugs and the effect of a single concentration (0.5 mM) of all compounds on basal block and frequency dependent block are analyzed by ANOVA. The values of latency to the peak of compound action potential are analyzed by paired t-test.

MODIFICATIONS OF THE METHOD

Fink and Cairns (1984) studied differential slowing and block of conduction by lidocaine in individual afferent myelinated and unmyelinated axons.

G.1.1.8 Effect of local anesthetics on different nerve fibres

PURPOSE AND RATIONALE

Wildsmith et al. (1989) examined the *in vitro* sensitivities of different types of fibres in rabbit vagus nerves to local anaesthetic block with a range of local anaesthetic drugs at high and low frequency stimulation. Rapidly conducting, myelinated (A) fibres are more sensitive than more slowly conducting, unmyelinated (C) fibres.

PROCEDURE

The cervical portions of the vagus nerves of rabbits weighing 2.5 kg are removed, desheathed and mounted in an airtight chamber which is maintained at 37 °C by a water jacket. A central 1-cm section of the nerve chamber is perfused at 0.5 ml/min with carbonated Liley solution (pH 7.4 ±0.02 after equilibration with 5% carbon dioxide in oxygen). A tap system allows the perfusate to be changed to test solution without admission of air.

A square wave generator is used to apply supramaximal electrical stimuli (10–15 V for 1 ms) at a rate of 0.0167 Hz during a 30-min period of stabilization. Two trains of stimuli (duration 0.25 s) are applied, one at 20 Hz and the other at 40 Hz. The preparation is considered valid only if there is less than 5% decrement in height of the action potential during stimulation at 40 Hz. The signals from the nerve are amplified, digitized (Unilab 532.001 interface sampling at 40 µs intervals for 8 ms, then at 200 µs intervals for 50 ms) and recorded with a microcomputer based system. The numeric derivative of the signal can be printed out immediately or stored on disc for subsequent processing. Signals are monitored also on a storage oscilloscope.

A submaximal blocking concentration of the hydrochloride salt of a test drug dissolved in carbonated Liley solution is applied. Only one concentration of one drug is applied to each nerve. The stimulation rate remains at 0.0167 Hz until any changes in the compound action potential are complete (minimum period 30 min), when the trains of high frequency stimulation are repeated. Drug effect is measured as the percent decreases in the height of the three components (A, B and C fibres) of the compound action at each frequency of stimulation. At 20 and 40 Hz, the last signal produced by each train of stimulation is used for analysis. An experiment is considered valid only if the action potentials recover to more than 90% of control height on washing the drug from the nerve.

EVALUATION

From the data obtained, the ED_{50} (and its SE) for the effect of each drug on each fibre type at each rate of stimulation is determined by log-probit analysis. Plots of the development of block while the nerves are being stimulated at 0.0167 Hz are also made. From these an index of the rate of development of A and C fibre block is derived ($T_{1/2B}$). This is defined as the time taken to develop 50% of the eventual maximum degree of block for the particular fibre type in each experi-ment.

MODIFICATIONS OF THE METHOD

Scurlock et al. (1975) examined the relative sensitivity of sympathetic preganglionic and postganglionic axons, B and C fibres, respectively, to structurally dissimilar local anaesthetics. Cervical sympathetic trunks from adult rabbits were submerged in Krebs-Henseleit solution except during the brief recording periods, when they were stimulated electrically with twice maximal square-wave pulses of 0.15 ms (B fibres) or 0.5 ms (C fibres) duration. After control records, the bath chambers were filled with various concentrations of local anaesthetics and the action potentials recorded at 5-min intervals. The decrease of action potentials of the B- and C-fibres was recorded separately.

G.1.1.9 Measurement of sodium and potassium conductance in voltage clamp experiments

PURPOSE AND RATIONALE

Voltage clamp experiments on single nodes of Ranvier can be performed with single myelinated nerve fibers from the sciatic nerve of the frog (Stämpfli 1954, 1968; Nonner 1969; Nonner et al. 1975; Stämpfli and Hille 1976; Borchard and Drouin 1978). Sodium, potassium and leakage currents (I_{Na}, I_K, I_L) can be measured.

Descriptions of structure and function of voltage-gated sodium channels were given by Catterall (1988, 1992), Stühmer (1991), Narahashi and Herman (1992), Cohen and Barchi (1993).

PROCEDURE

Single myelinated nerve fibers are dissected from the sciatic nerve of the frog (*Rana esculenta*). The fibers are bathed in a Ringer solution containing 110 mM NaCl, 2.5 mM KCl, 1.8 mM $CaCl_2$, 5.0 mM Tris, pH 7.3, at 15 °C. For measurement of sodium, potassium and leakage currents (I_{Na}, I_K, I_L), the nodal membrane is clamped to a holding potential of –30 mV (relative to the resting potential of –70 mV). Hyperpolarizing prepulses (–40 mV, 50 ms) followed by 2 ms test pulses (60 mV) are applied every 5 s to record peak sodium currents, I_{Na}, and to avoid the influence of accumulation of frequency-dependent block. Every second pulse is followed by an afterpulse (120 mV, 20 ms) to measure steady state I_K. The leakage current, I_L, is measured at the end of the hyperpolarizing prepulse and recorded every 10 s.

After superfusion of the nodal membrane with a local anesthetic, a quick and then a slow decrease of the peak sodium current (I_{Na}) occurs. When the application of the local anesthetic is stopped, I_{Na} increases quickly and then slowly within min indicating a reversible action of the local anesthetic on the nerve fiber. With local anesthetics, the potassium current (I_K) behaves similarly, whereas the leakage current (I_L) remains unchanged.

Dose dependent action of local anesthetics on I_{Na}-V relations

The holding potential is set at –30 mV. A hyperpolarizing prepulse (–40 mV, 50 ms) is followed by a depolarizing test pulse (30 ms) with varying amplitudes. Local anesthetics induce a dose-dependent reduction of sodium-inward and -outward currents over the whole range of voltage clamp steps. The measurements are performed at extracellular pH 7.3.

Dose dependent action of local anesthetics on I_K-V relations

Potassium currents, I_K, are measured at the end of depolarizing test pulses of 30 ms duration. Local anesthetics induce a dose-dependent decrease of potassium currents at extracellular pH 7.3.

EVALUATION

The effects on sodium, potassium and leakage currents (I_{Na}, I_K, I_L), the dose dependence of action on I_{Na}-V relations, and the dose dependence of action on I_K-V relations of various local anesthetics are compared.

G.1.2 Infiltration anesthesia

G.1.2.1 Infiltration anesthesia in guinea pig's wheals

PURPOSE AND RATIONALE

Based on earlier work by McIntyre and Sievers (1937) and Sievers and McIntyre AR (1938), the use of intracutaneous wheals in guinea pigs was recommended by Bülbring and Wajda (1945). This method has become a standard operating procedure for testing local anesthetics.

PROCEDURE

Adult guinea pigs of either sex weighing 250–300 g are chosen. On the day preceding the experiment the hair on the back is clipped and two areas of 4–5 cm diameter are shaved. This produces a certain amount of irritation which disappears overnight. The sensitivity of the skin is greatest in the midline and slightly more so in the front than in the back area. For this reason each concentration of a local anesthetic must be tested in both areas. Six tests using three guinea pigs can be performed simultaneously. The doses of local anesthetics are always injected intracutaneously in 0.1 ml saline. Three guinea pigs receive one dose in the front area and another dose in the back area; the size of the wheal is marked with ink. One side is used for the test preparation, the other side for the standard (e.g., 1% butanilicaine). The reaction to pin prick is tested 5 min after injection in the following way. After observing the animal's normal reaction to a prick applied outside the wheal, six pricks are applied inside the wheal and the number of pricks is counted to which the guinea pig fails to react. The pricks are applied at intervals of about 3–5 s. Six pricks are applied every 5 min for 30 min. Having completed the test on 3 guinea pigs, the same solutions are injected into 3 other guinea pigs, but the solution which was used for the front is now used for the back area and vice versa.

EVALUATION

The number of times the prick fails to elicit a response during the 30 min period is added up, and the sum, out of possible 36, gives an indication of the degree of anesthesia. Using various doses, dose-response curves can be established. For time-response curves, the prick tests are repeated every 10 min. Half-life times are calculated as the time, when after complete anesthesia 3 out of 6 pricks elicit again a response (Ther 1953a,b).

MODIFICATIONS OF THE METHOD

The test can also be used to study the influence of vasoconstrictors, such as adrenaline.

G.1.3 Surface anesthesia

G.1.3.1 Surface anesthesia on the cornea of rabbits

PURPOSE AND RATIONALE

Following the pioneering work of Sollmann (1918), block of the rabbit corneal reflex as described by Régnier (1923) has become a standard test method for evaluating local anesthetics (Quevauviller 1971).

PROCEDURE

Albino rabbits of either sex weighing 2.5–3 kg are placed into rabbit holding cages. The upper and lower eyelashes are carefully clipped. The conjunctival sac

of one eye is held open, thus forming a pocket. From a 1 ml syringe with a 22-gauge needle, 0.5 ml of a solution of the anesthetic is applied into the conjunctival sac for 30 s. Then the procedure is repeated, so that 1.0 ml is applied within 1 min. One ml of the standard (0.1% solution of tetracaine hydrochloride) is applied to the other eye. Effective local anesthetics extinguish the corneal reflex (blinking) elicited by any touch of the cornea. For quantitative purposes, the irritation with a bristle according to von Frey (1894, 1896, 1922) has been recommended. An equine hair bending at a load of 230 mg is attached perpendicularly to a glass rod. Within 25 s, the cornea is touched 100 times. The summation of many stimuli applied this way gives better results than a single touch with a glass rod (Ther and Mügge 1953). The test is started 5 min after application of the drug and repeated every 5 min until anesthesia vanishes and blinking occurs again. The time between disappearance and reappearance of the corneal reflex is registered.

EVALUATION

Using the time of loss of the corneal reflex as parameter after application of different doses, dose-response curves can be established and potency ratios versus the standard calculated.

MODIFICATIONS OF THE METHOD

Chance and Lobstein (1944) used **guinea pigs** for testing surface anesthesia by the corneal reflex.

Bartsch and Knopf (1970) described an electrically operated stimulator with a bristle allowing variable frequencies to evaluate surface anesthesia on rabbit cornea.

Hotovy (1956) investigated the synergism between the local anaesthetic compound dibucaine hydrochloride applied to the conjunctival sac of rabbits and intravenously administered analgesics using Régnier's method

G.1.3.2 Suppression of sneezing reflex in rabbits

PURPOSE AND RATIONALE

Nieschultz et al. (1958), Åström und Persson (1960) used the sneezing reflex in rabbits to test local anesthetic activity.

PROCEDURE

Groups of male rabbits weighing 3 kg are used. Using a cotton tampon, the test solution is applied to the mu-

cous membrane of one nostril. The solution of a standard local anesthetic is administered to the nasal mucosa of the other nostril. After 2 min the mucous membrane is stimulated by a fine pencil. Loss of the sneezing reflex is regarded as sign of complete anesthesia. The stimulation is repeated after 3, 6, 10 and 15 min and continued every 5 min until the sneezing reflex reappears. Various concentrations of test compound and standard are applied.

EVALUATION

Using the loss of the sneezing reflex as parameter after application of different doses, dose-response curves can be established and potency ratios versus the standard calculated. Furthermore, the duration of activity can be evaluated.

G.1.4 Epidural anesthesia

G.1.4.1 Epidural anesthesia in guinea pigs

PURPOSE AND RATIONALE

Activity and tolerability of new local anesthetics after epidural injection have to be studied in various animal species in order to predict both parameters in patients. A method to test epidural anesthesia in guinea pigs was described by Åkerman et al. (1988).

PROCEDURE

Male guinea pigs weighing 300–500 g are anesthetized by means of an intraperitoneal injection of an aqueous solution of chloral hydrate 42.5 g/l; ethanol 90 g/l; propylene glycol 428 g/l; sodium pentobarbitone 9.75 g/l; and magnesium chloride 21 g/l. A skin incision is made from the level of the lumbosacral fossa and approximately 1.5 cm down in order to expose the sacral area in the mid-line. With the vertebral column flexed, the lumbosacral intervertebral ligament is carefully incised. Through this small opening a polyethylene catheter (PE 10) is inserted maximally 1.5 cm along the roof of the vertebral canal to the L4–L5 region. The catheter is sutured to the overlying lumbar fascia which is then closed. The catheter is tunneled under the skin and exteriorized through an incision in the neck region. After fixation of the catheter to the fascia of the neck muscles and suturations of the incisions, the catheter is filled with saline and sealed.

After a recovery period of at least 1 day, 0.1 ml of 2.0% lidocaine is injected over a period of 1 min, and the motor and sensory blocks are assessed. The injection of lidocaine which results in a bilateral, reversible blockade indicates a successful preparation. A minimum of 8 animals are used in the further experiments for each test solution.

EVALUATION

Mean time to onset of block and mean duration of block are calculated from number of legs blocked.

MODIFICATIONS OF THE METHOD

Siems and Soehring (1952) described a model in **guinea pigs** resembling peridural and paravertebal anesthesia in man.

A technique for epidural administration in the **dog** was described by Feldman and Covino (1988).

Defalque and Stoelting (1966) used a standard veterinary epidural technique to study latency and duration of action of some local anesthetic mixtures in **dogs**. The animals, prone and with their spread-out extremities attached to the table, were placed in 40-degree Trendelenburg position. Under sterile conditions, the epidural space was penetrated through the interarcual ligament with a short-beveled No. 22 spinal needle. After identification of the epidural space (aspiration, air injection), 4 ml of the investigated solution were injected with a constant injection rate of 2 ml per sec. Absence to skin-twitch response to pinching with an Allis clamp was considered analgesia. This was tested on both flanks, along a line 2 cm off the spine. Disappearance of contraction of the anal sphincter in response to stroking all quadrants of the anal margin closely correspond to complete analgesia at the level of the interarcual ligament; since this was an easily measurable parameter, disappearance and recurrence of this reflex was chosen as endpoint of latency and duration of action, respectively.

Chernyakova et al. (1994) studied the effects of azacaine during epidural anesthesia in **rabbits**.

Hughes et al. (1993) described a rabbit model for the evaluation of epidurally administered local anaesthetics. A "loss of resistance technique" similar to that employed in caudal epidural injection in humans was used. The rabbit was carefully restrained by an assistant. The readily palpable cranial dorso-iliac spines, lying on either side of the prominent spinous process of the seventh lumbar vertebra, served as landmarks. The thumb and the middle finger of the left hand were

placed on the two crests and the left index finger used to palpate the midline, L7 spine and the depression over the lumbosacral fossa. With the index finger in position on the L7 spine to serve as a guide, a short bevel 1.5 cm 20 gauge spinal needle was introduced a right angles to the skin in the midline with the bevel aligned longitudinally. After passage through the skin, only minor resistance was felt until the ligamentum flavum was reached. When passing through the ligament, a definite "pop" was felt and resistance to advancement of the needle was lost. When correctly placed, the needle was at a depth of approximately 0.75 to 1.0 cm and firmly held by the ligament. The stylet was then withdrawn and the hub inspected for the presence of blood or cerebrospinal fluid. If absent, the needle was rotated through 90° to direct the bevel caudally, a 1.0 ml syringe was attached and 0.1 ml of air injected. Accurate placement was indicated by the absence of resistance to injection and lack of subcutaneous crepitus. A syringe containing the desired dose of the local anesthetic was attached and the solution injected over a 5–10 s period. The pharmacodynamic responses were assessed by (1) sensory loss, (2) loss of weight-bearing ability, and (3) flaccid paresis.

G.1.5 Intrathecal (spinal) anesthesia

G.1.5.1 Spinal anesthesia in rats

PURPOSE AND RATIONALE

Activity and tolerability of new local anesthetics after intrathecal injection have to be studied in various animal species in order to predict both parameters for spinal (subarachnoid) anesthesia in patients. Intrathecal injections to rats or mice are performed according to the method of Hylden and Wilcox (1980) or Åkerman (1985) as being used by Ossipov et al. (1988).

PROCEDURE

Male Sprague-Dawley rats weighing 50–75 g are used. The rat is held firmly by the pelvic girdle. A 30-gauge needle is attached to a 25-µl Hamilton syringe is inserted into the tissue on one side of the L5 or L6 spinous process at an angle of about 20°. The needle is advanced to the groove between the spinous and transverse processes and then moved forward the intervertebral space at an angle of about 10°. About 0.5 cm of the needle is then in the vertebral column. Correct placement of the needle is indicated by an arching of the tail. Drugs are dissolved in saline or water and administered in a volume of 5 µl.

Antinociception is determined in a modification of tail flick assay in rats by placing the tail of the rat under a focused radiant heat source.

EVALUATION

The degree of antinociception is defined as the percentage of maximum possible effect. This percentage is determined for each dose at each time measured allowing to calculate ED_{50} values.

MODIFICATIONS OF THE METHOD

Omote et al. (1995) studied the effects of verapamil on spinal anesthesia induced by local anesthetics administered via a chronic intrathecal polyethylene catheter in **rats**. The catheter was inserted 15 mm cephalad into the lumbar subarachnoid space at the L4-5 vertebrae with the tip located near the lumbar enlargement of the spinal cord. The catheter was tunneled subcutaneously and externalized through the skin in the neck region. At least 6 days of postsurgical recovery was allowed before animals were used in experiments. The tail-flick and the mechanical paw pressure tests were used to assess thermal and mechanical nociceptive thresholds.

Mestre et al. (1994) described a method for performing direct intrathecal injections in **rats** without introducing a spinal catheter.

Yaksh and Rudy (1976) described a procedure of chronic catheterization of the spinal subarachnoid space in **rats** and **rabbits**. A polyethylene catheter (PE-10) was inserted through a puncture of the atlanto-occipital membrane into the spinal channel in anesthesia and secured to the skull. In this way, drugs could be administrated into the spinal subarachnoidal space of unanesthetized animals.

Cole et al. (1990) used this model to determine the influence of spinal tetracaine on central nervous system metabolism during nociceptive stimulation in **rats**.

Bieter et al. (1936) described a method of inducing spinal anesthesia in the **rabbit** and determined threshold anesthetic and lethal concentrations. Injections were performed at the lumbo-sacral union between the spinous process of the last lumbar vertebra and the first sacral spinous process. A dose of 0.02 ml per centimeter of spinal length was chosen as standard volume for determining minimal anesthetic and minimal lethal doses.

Langerman et al. (1991) studied the duration of anesthesia after a single subarachnoid injection of a local anesthetic in **rabbits**. Tetracaine 1% 0.5 mg/kg was administered in 10% glucose or in lipid solution via catheters chronically implanted in the subarachnoid space. The pharmacologic effect was assessed by evaluating the intensity and duration of motor blockade according to a three-stage scale.

Bahar et al. (1984) performed chronic implantations of nylon catheters into the subarachnoid space of Wistar **rats** and **marmosets** and tested the effects of local anesthetics.

Åkerman et al. (1988a,b) used **mice** to study spinal morphine antinociception potentiation by local anesthetics.

A simple technique for intrathecal injections by lumbar puncture in unanesthetized **mice** was described by Hylden and Wilcox (1980).

This model has been used by Langerman et al. (1994) to evaluate the potency of various local anesthetics. Adult Swiss Webster male mice were slightly anesthetized with halothane and the skin overlying the dorsal lumbar spine was opened using a transverse incision 8–10 mm. Animals were allowed to recover for 1 h before the evaluation of the baseline nociceptive response latency. Thirty min after baseline testing, intrathecal local injections were performed with an automatic syringe fitted with a 30-gauge needle. Fourth spinal space was identified and the needle was inserted between the two spinal processes in a cephalad direction at a 20° angle. Resistance encountered at approximately 5–6 mm from the skin indicated proper location of the needle in the spinal canal. A fixed 10 µl volume of injectate was used. Analgesia was measured using the tail-flick test based on tail withdrawal in response to heat generated gy a light beam focused on the ventral tail surface.

A chronic model for investigation of experimental spinal anesthesia in the **dog** was described by Feldman and Covino (1981).

Dohi et al. (1987) inserted a polyethylene catheter into the lumbar subarachnoid space in **dogs** through a small hole in the dura for administration of drugs. The tip of the catheter was placed approximately 2–3 cm cephalad to the lumbar electrode introduced for recording of hydrogen clearance to measure spinal cord blood flow.

Kozody et al. (1985) measured spinal cord and spinal dural blood flow in the cervical, thoracic and lumbosacral regions in **dogs** using the microsphere technique. Measurements were taken 20 and 40 min after lumbar subarachnoidal injection through the L5-L6 or L6-L7 interspace.

The technique of evaluation of spinal anesthesia by a local anesthetic in the **Rhesus monkey** was described by Denson et al. (1981).

Kyles et al. (1992) described a simple and noninvasive method for the chronic implantation of intrathecal catheters in the **sheep**.

G.1.5.2 Blockade of urethral reflex in rabbits

PURPOSE AND RATIONALE

For evaluation of spinal anesthetics the test substance has to be injected into the spine. For the study of local anesthetics for which conduction anesthesia has been verified, intraspinal injection provides more complete information. Spinal anesthesia has been studied in rabbits (Bieter et al. 1936; Luduena and Hoppe 1951; Luduena 1957; Gonzalez and Luduena 1961; Turner RA 1965), cats (Sechzer 1965), and dogs (Dvorak and Manson 1930). If the solution of test substance is injected intrathecally to male rabbits, the presence of anesthesia may be determined by the urethral reflex (Luduena 1957).

PROCEDURE

Male Chinchilla rabbits weighing 3.0–3.5 kg are used. The volume administered intrathecally is 0.02 ml per centimeter of spinal length. It is injected at a rate of 1 ml per min with a 22-gauge needle that is 3.8 cm long. The needle is introduced between the sixth and seventh lumbar vertebrae, and not through the lumbosacral space. The needle, held as lightly as possible between the thumb and forefinger, is introduced slowly until a typical sharp and sudden twitch occurs. This indicates penetration into the subarachnoidal space. A one ml tuberculin syringe is then attached to the needle. It is not possible to aspirate fluid after insertion of the needle. However, it is possible to aspirate a portion of the injected solution. Very little pressure is required for injection of 0.4 to 0.6 ml of anesthetic solution while the animal is restrained in a canvas hammock. A catheter is inserted into the urethra, where it is kept without digital pressure. At 15- or 20-s intervals, 2 to 3 ml of water, at room temperature, are injected rapidly into the catheter. This causes the "urethral reflex", consisting of retraction of the penis and contraction of the anal sphincter. The water runs out of the urethra around the catheter. Without medium or high concentrations of the anesthetics the reflex is absent on the first reading. After loss of the urethral reflex, the test is repeated every minute or two for 15 min, and thereafter at longer intervals. The duration of urethral areflexia is taken as the time of the first positive reading (reflex absent) to the middle of the interval between the last positive and the first negative reading. This duration varies linearly with the logarithm of concentration.

EVALUATION

The threshold anesthetic concentration in grams per 100 ml for abolition of the urethral reflex for 5 min, the TAC_5, is a standard for comparison. There is a correlation between activity and systemic toxicity. The ratio of the activity to the irritancy is the most important parameter.

MODIFICATIONS OF THE METHOD

Burdyga and Magura (1986) studied the effects of local anesthetics on the electrical and mechanical activity of the guinea-pig ureter.

G.1.6 Endoanesthetic effect

PURPOSE AND RATIONALE

Endoanesthesia has been described as the effect of local anesthetics on viscero-afferent receptors, located predominantly in the lung as distension receptors (Meier and Bein 1950; Zipf 1953, 1957, 1959, 1966. 1968; Zipf et al. 1955; Zipf and Oehler 1955; Reichertz et al. 1957; Zipf and Reichertz 1957; Zipf et al. 1963; Wellhöner and Conrad 1965; Siemoneit et al. 1966; Dittmann and Zipf 1973; Borchard 1979). The endoanesthetic effect has been claimed to be the basis of an antitussive action of local anesthetics (Bucher 1956; Bein and Bucher 1957; Kraushaar et al. 1964).

PROCEDURE

Male guinea pigs weighing 300–400 g are anesthetized by intraperitoneal injection of 1.25 g/kg urethane. The studies are carried out on spontaneously breathing or artificially respirated monovagotomized or bivagotomized animals. Intravenous injections are given via a catheter into the jugular vein. The flow rate of the respiratory air is measured with a Fleisch tube connected to a pneumotachograph. In experiments with positive pressure respiration, the open end of the Fleisch tube is attached to a respiratory pump (40 strokes per min). A cannula is inserted into the carotid artery and connected to a pressure transducer.

The left nervus vagus is exposed from the thorax aperture until his entry into the foramen jugulare and cut in the middle of the distance. Both ends are placed over 3 wires of Ag/AgCl 6-way electrodes. The edges of the skin wound are pulled upwards with clamps and the space around the trachea is filled with paraffin to prevent the nerve from drying out. The afferent and efferent vagus potentials and also their integration curve (Zipf and Reichertz 1957) are recorded on a direct recorder. In addition, the ECG in the second lead is recorded continuously. The animal is shielded electrically with the aid of a Faraday cage.

The nervus vagus conducts not only afferences from the lung but also from other organs to the brain. The base points of the integral curve, which correspond to the vagus action potentials being synchronous with inspiration and issued by the pulmonary distension receptors, therefore lie above the baseline of the recorder tracing. The vagus afferences which remain after subtraction of the vagus activity synchronous with respiration ("inspiratorial activity") are called "residual activity". The level of inspiratorial activity depends both on the bronchial width (degree of inflation of the lungs) and on the functional state of the pulmonary receptors and of the afferent pathway. The occurrence of a bronchospasm is detectable from the decrease in the pneumotachogram, if the respiratory rate is not reduced at the same time.

EVALUATION

The following parameters are evaluated:

Afferent and efferent inspiratorial vagal activity, maximum flow rate of the respiratory air during inspiration and expiration, tidal volume, duration of the respiratory phases (inspiration = t_i, expiration = t_e, respiratory pause = t_p), heart rate and blood pressure.

The decrease of electrical activity after various doses of standard and test drugs is calculated at different time intervals after drug administration. Maximum of activity and decay with time are registered.

Statistical analysis is performed using the paired and non-paired *t*-test, after the applicability has been first checked with the F-test.

CRITICAL ASSESSMENT OF THE METHOD

The correlation between antitussive and local anesthetic activity has been challenged by Sell et al. (1958) and by Ther and Lindner(1961).

MODIFICATIONS OF THE METHOD

Bein and Bucher (1967), Wellhöner and Conrad (1955) tested various compounds for their anesthetic effect on pulmonary stretch receptors of **rabbits**.

G.1.7 Effect on electroretinogram

PURPOSE AND RATIONALE

The retina, which belongs in ontogenesis to the central nervous system, can be prepared without damaging the parenchyma. The transretinal potential which can be induced by a light flash can be used as an objective criterion for the functional state (Sickel et al. 1960). The multi-phase potential path of the electroretinogram consists of an initial a-wave, a subsequent b-wave and an e-wave which starts with a delay after the end of the stimulus. While the amplitudes of the a- and e-wave are in the order of 50 μV, the amplitude of the b-wave (ϕ_b) is 500–1 000 μV. The electroretinogram can be used for various purposes, such as the evaluation of local anesthetics (Borchard 1979).

PROCEDURE

Frogs (*Rana esculenta*) are kept in dark for 1 h before beginning of the preparation. The frog is sacrificed by decapitation, the eyeball excised in dim red light and cut into two halves with the aid of a rotating blade. The retina together with the pigmented epithelium and choroid is removed from the rear half of the eye and transferred to a dish with Tyrode solution. The retina is then detached from the pigmented epithelium by careful shaking and spread out on a Monodur net. The net is fixed to a round carrier with a narrow ring and the chamber is transferred to a flow-through apparatus. An electrical pump is used for superfusion of the retina with Tyrode solution.

In order to apply the local anesthetic only to the receptor or vitreous body side of the retina, an apparatus is used in which the tissue on a silk net is stretched as the partition between two chamber halves which can perfused separately (Borchard and Erasmi 1974).

The electroretinogram is recorded with Ag/AgCl electrodes. After amplification, the signal is registered on a recorder or an oscillograph. Light stimuli of 10 ms are generated. The light from a low-voltage light source is focused on a electromagnetic shutter with a stimulus frequency of 0.1 Hz. Light stimuli of 1 s duration are used at intervals of 3 min to measure the influence of the local anesthetics on the electroretinogram as a function of light intensity.

All experiments are performed after adaptation to darkness and at room temperature. The amplitude of the b-waves (ϕ_b) which is measured from the lowest point of the a-wave to the maximum of the b-wave is used for evaluation. In order to obtain stationary test conditions, the experiment is started after a 45 min adaptation period. The stimulus signal is recorded by means of a photocell inserted in the light path.

Various concentrations of the local anesthetics are applied and various light intensities are used. The decrease of the b-wave starts immediately and then progresses slowly and continuously. After changing over to Tyrode solution, the decrease in the exposure potential is completely reversible.

EVALUATION

After various doses, time-response curves can be drawn and for a given time interval ED_{50} values can be calculated. Moreover, the influence of local anesthetics on the b-wave at various light intensities can be estimated.

MODIFICATIONS OF THE METHOD

Isolated retina for electroretinogram has been used not only from **frogs** but also from **rats** (Huang et al. 1991; Doly et al. 1993), **rabbits** (Mochizuki et al. 1992; Maynard et al. 1998) and from **beef** (Gosbell et al. 1996; Walter et al. 1999).

Moreover, the electroretinogram has been used as parameter for many *in vivo* studies with different purposes, e.g., on the effect of drugs after retinal ischemia, in various animal species, such as **rats** (Sugimoto et al. 1994; Hotta et al. 1997; Biró et al. 1998; Block and Schwarz 1998; Estrade et al. 1998; Ettaiche et al. 1999; Li et al. 1999), **rabbits** (Takei et al. 1993; Zemel et al. 1995; Horiguchi et al. 1998; Jarkman et al. 1998; Liang et al. 1998), **cats** (Imai et al. 1991; Ostwald et al. 1997; Kim et al. 1998), **dogs** (Jones et al. 1995; Yanase and Ogawa 1997) or **monkeys** (Tagliati et al. 1994).

G.2 Neuromuscular blocking activity

G.2.0.1 General considerations

Neuromuscular transmission is mediated by mediated by nicotinic acetylcholine receptors for which various subtypes are described (Sargent 1993; McGehee and Role 1995; Karlin and Akabas 1995; Alexander et al. 2001).

Neuromuscular blocking agents are distinguished by whether or not they cause depolarization of the motor end plate. They are classified either as competitive (stabilizing) agents, of which d-tubocurarine is the classical example, or as depolarizing, desensitizing agents such as succinylcholine.

The **rabbit head-drop method** was described by Varney et al. (1948, 1949), Burn et al. (1952), Levis et al. (1953). Rabbits were given an interrupted intravenous injection at a rate of 0.1 ml every 15 s until the muscles supporting the head become sufficiently relaxed to prevent the head to be raised when the back is stimulated. This method has been replaced by the rabbit sciatic nerve-gastrocnemius muscle preparation, the isolated phrenic nerve diaphragm preparation of the rat, and the chick sciatic nerve-tibialis anticus muscle preparation.

The method described by Allmark and Bachinski (1949) used an inclined screen for testing curare-like activity in **rats**.

Skinner and Young (1947) placed **mice** weighing 15–17 g in sloping rotating cylinders. Mice falling away during 20 min after subcutaneous injection were considered as reactors. Dose response-curves and potency ratios could be calculated from the logarithmic dose-response curves using different doses of test compound and the standard tubocurarine chloride.

Collier et al. (1949) used a rotating drum to assess the activities of paralysant, convulsant and anaesthetic drugs in mice.

Fatt and Katz (1951) performed an extensive study on neuromuscular junction by recording end-plate potentials from curarized frog sartorius motor end-plates, using a KCl-filled microelectrode inserted into the muscle fiber in the region of the motor end-plate.

Electrophysiological analysis of transmission at the skeletal neuromuscular junction was reviewed by Prior et al. (1993).

A review on new neuromuscular blocking drugs was given by Hunter (1995).

G.2.0.2 Isolated phrenic nerve diaphragm preparation of the rat

PURPOSE AND RATIONALE

The isolated phrenic nerve diaphragm preparation of the rat was originally described by Bülbring (1946) to study the influence of adrenaline on tissue functions normally elicited by acetylcholine. The method has been modified and is widely used by many investigators for studying drugs affecting the neuromuscular transmission.

PROCEDURE

Adult male Wistar rats are used. The animal is sacrificed and the blood is drained. The skin is removed from the middle of the chest. The thorax is opened and the front part of the left thoracic wall is removed. The phrenic nerve can bee seen quite distinctly. The nerve is cut just below the thymus and a thread is attached to the cut end. The nerve is than freed carefully from the attached tissue. However, no attempt is made to clean the nerve completely from all attached tissue. An incision is made in the left abdominal wall just below the diaphragm. Two converging cuts are made through the diaphragm and the ribs towards the tendinous part of the diaphragm with the phrenic nerve attached to the center of the diaphragm. The fan-like preparation is about 3 mm wide at the tendinous end and is about 15 mm wide at the costal margin. A thread is attached to the tendinous part of the diaphragm.

The preparation is fixed by a stainless steel rod with a pair of pins hooked to the rib. It is lowered into an organ bath and the thread from the muscle is attached to a force transducer. The nerve is stimulated with a pair of electrodes with a hole about 1 mm wide. The right phrenic nerve-diaphragm preparation is isolated in the same manner. The organ bath containing Tyrode solution with 2.0 g/l glucose is oxygenated at 37 °C with 95% O_2 and 5% CO_2. The nerve is stimulated 12 times per min by rectangular-wave pulses of 0.5 ms duration at 3–5 V. Contractions are isometrically recorded

through a transducer on a polygraph. The test drugs are left in the organ bath either for short periods of time (3–8 min) or for as long as the maximum effect can be observed. After a wash-out period of 3–5 min, the next dose can be added.

EVALUATION

The force of contractions after addition of various doses of the test drug is compared with the effect seen prior to drug application. Dose-response curves can be established.

CRITICAL ASSESSMENT OF THE METHOD

The isolated phrenic nerve diaphragm preparation of the rat is an excellent method for determining the potency of a drug to block or facilitate neuromuscular transmission. However, it is not a good preparation for differentiating between depolarizing and non-depolarizing neuromuscular blocking agents because, in many cases, depolarizing blocking agents fail to demonstrate initial facilitation and fail to reverse the effect of non-depolarizing blocking agents. For differentiating between depolarizing and non-depolarizing blocking agents the chick sciatic nerve-tibialis anticus muscle preparation is preferred. In this preparation, the curare-like drugs produce a neuromuscular blockade whereas the decamethonium-like drugs induce a contracture of the slow fiber when the neuromuscular transmission is blocked.

MODIFICATIONS OF THE METHOD

Colbert et al. (1990) studied the effects of temperature on the experimental reliability of the isolated rat phrenic nerve/diaphragm preparation.

Van Riezen (1968a,b) described the sciatic nerve-tibialis anticus muscle preparation in **chicks**. Three to 8 day old chicks are decapitated and the skin of the legs is rapidly removed. The leg is separated from the body by cutting through the hip joint. The muscles of the thigh are dissected and the sciatic nerve with the superficial peroneal branch is freed from the upper leg tissue. The fascia is removed from the lower leg and the tibialis anticus tendon identified. A thread is attached to the tendon of the muscle and the tibialis anticus muscle is freed towards but not up to the knee joint attachment where the nerve enters into this region. The upper and lower leg bones are then cut off leaving the muscle with its nerve attached to the knee joint. The tendon is fasted by a hook to a ring in the bottom of the organ bath. A thin steel rod is attached to the knee joint. The contractions of the muscle are recorded isometrically. The nerve is passed through an electrode similar to that used in the rat phrenic nerve-diaphragm method. The nerve is stimulated six times per min for 0.5 ms duration at supramaximal voltage.

Jenden et al. (1954) described the isolated lumbrical muscle of the **rabbit** as a preparation which is sensitive to competitive (*d*-tubocurarine-like) and depolarizing (decamethonium-like) blocking agents. This muscle is cylindrical in shape, about 18 mm long and 1 mm in diameter and has a wet weight of about 15 mg.

Jenden (1955) used the isolated diaphragm of **guinea pigs** to study the effect of drugs upon neuromuscular transmission.

Hoppe (1955) reviewed the potency of neuromuscular blocking agents in various species.

Birmingham and Hussain (1980) used the phrenic nerve-diaphragm and the hypogastric nerve-vas deferens preparation of the guinea pig for comparison of the skeletal neuromuscular and autonomic ganglion-blocking potencies of non-depolarizing relaxants.

Wessler and Kilbinger (1986), Wessler and Steinlein (1987), Wessler et al. (1992) described a modified **rat** phrenic nerve-hemidiaphragm preparation whereby most of the muscle was cut off (end-plate preparation).

Muir et al. (1989) used biventer cervicis nerve-muscle preparations from **young chickens** and phrenic nerve-hemidiaphragm preparations from **rats** to evaluate neuromuscular blocking agents. Micro-electrode recordings were obtained from the nerve-hemidiaphragm preparation of the rat and from the costocutaneous nerve-muscle preparation of the North American **garter snake** (*Thamnophis sirtalis*). The later preparation is particularly suitable for voltage clamp recording from the neuromuscular junction because it possesses large diameter fibres which aid visualization and penetration of endplates. This, coupled with compact endplates, allows good control of membrane voltage over the entire endplate region when using the two-microelectrode voltage clamp technique.

In order to record evoked endplate currents without accompanying muscle contraction, cut fibre preparations were used. Dissection and cutting of muscle fibres was performed at low K^+ (2 mmol/L) physiological solution perfused for approximately 30 min. Snake nerve-muscle preparations were mounted in a physiological salt solution of pH 7.1–7.2 containing (mmol/l) NaCl 159, KCl 4.2, $CaCl_2$ 1.5, $MgCl_2$ 4.2, HEPES 10. Rat nerve-muscle preparations were mounted in Krebs solution of the same composition as that used for tension experiments. The muscles were mounted in a Sylgard-coated Perspex dish and endplates were voltage clamped using glass capillary microelectrodes (resistance 2–10 MΩ). Voltage recording electrodes were filled with potassium chloride 3 mol/l and current passing electrodes were filled with potassium sulphate 0.6 mol/l.

The nerves were stimulated through platinum electrodes at a frequency of 0.5 Hz with rectangular pulses of 0.05 ms duration and of strength sufficient to pro-

duce evoked endplate currents. The evoked endplate currents were filtered by a 5-kHz low pass filter and recorded on magnetic tape. The currents were amplified and digitized by a laboratory interface connected to a computer at a digitization rate of 25 kHz. Ten to 20 evoked endplate currents were collected and averaged after alignment at the middle of their rising phase. Evoked endplate currents decayed as a single exponential function according to the following relationship:

$$I(t) = I(0)\exp^{-t/\tau}$$

where $I(t)$ is the current amplitude at time t after the peak, $I(0)$ is the peak current amplitude and τ is the decay constant.

Experiments were carried out at room temperature. Drug solutions were perfused through the tissue bath for 10 min by peristaltic pump, ensuring a complete exchange of solution.

G.2.0.3 Sciatic nerve-gastrocnemius muscle preparation in the rabbit

PURPOSE AND RATIONALE

Levis et al. (1953), Long and coworkers (1959, 1967, 1969) described the sciatic nerve-gastrocnemius muscle preparation in the rabbit as an *in vivo* model for testing neuromuscular blocking agents.

PROCEDURE

Dutch rabbits, weighing 1–2 kg, are anesthetized with 200 mg/kg of phenobarbital administered slowly into the marginal ear vein. The sciatic nerve is ligated and cut, and a shielded electrode is placed on the peripheral portion of the nerve. The gastrocnemius muscle is freed as completely as possible from surrounding muscles and a thread is attached to the tendon of the muscle. The twitches of the muscle are elicited by supramaximal stimulation and are recorded through a force transducer. The parameters for interrupted tetanic stimulation are 250 c.p.s. with pulse durations of 1 ms at 15 V applied for 0.2 s every 10 s. The test drugs are administered intravenously into the marginal ear vein.

EVALUATION

The force of contraction after injection of various doses of the test drug is compared to the values obtained prior drug administration.

CRITICAL ASSESSMENT OF THE METHOD

The preparation has the advantage of studying the drug effects under conditions similar to clinical use.

MODIFICATIONS OF THE METHOD

There are two other preparations, the **cat soleus muscle** preparation and the **cat tibialis anticus muscle** preparation that very useful. They can be prepared in a method similar to that described for gastrocnemius muscle except that close arterial injection can be made using the tibialis anticus preparation. Also, soleus muscle consists primarily of slow muscle, whereas tibialis anticus is fast muscle. The experimental procedures for these two preparations are described in detail by Brown (1938), Bowman et al. (1962), Salafsky (1968).

Bowman et al. (1988) investigated structure:action relationships among some desacetoxy analogues of pancuronium and vecuronium in the anesthetized **cat**. Blockade of sciatic nerve-induced contraction of the tibialis and soleus muscles, as well as the effects on vagal-induced bradycardia and on sympathetically induced contractions of the nictitating membrane, were studied.

Khuenl-Brady et al. (1990) used anesthetized **cats** to study the effects of two new nondepolarizing neuromuscular blocking drugs. The indirectly evoked twitch tension of the anterior tibialis muscle elicited by supramaximal square-wave stimuli applied to the peroneal nerve was continuously quantitated by means of a force-displacement transducer and recorded. Onset time (from injection of muscle relaxant to maximum depression of twitch tension), duration of action and recovery index were determined.

Muir et al. (1989) used tibialis anterior and soleus muscle/sciatic nerve preparations in anesthetized **cats** and **pigs** to evaluate neuromuscular blocking agents.

Hoppe (1950) used a nerve-muscle preparation in **dogs** to evaluate curarimimetic drugs. Diaphragmatic respiration was recorded directly by means of a light thread from a suture imbedded in the peritoneal aspect of the right hemi-diaphragm. Stimulation of the peripheral end of the sectioned tibial nerve was accomplished by an induced current once every ten seconds. Muscle contraction was recorded from the Achilles tendon being severed just proximal to the calcaneus.

Hughes and Chapple (1976a,b, 1981; Hughes 1984) used nerve-muscle preparations of cats, dogs and rhesus monkeys.

Ono et al. (1990) recorded the twitch tension of the gastrocnemius-soleus muscle in **rats** after stimulation of the distal stump of the tibial nerve under the influence of a centrally acting muscle relaxant.

Cullen et al. (1980) described two mechanical techniques to measure neuromuscular activity in the intact, anesthetized **dog**. Simultaneous stimulation of the dorsal buccal branch of the facial nerve and ulnar nerve was performed and the evoked mechanical muscle responses measured.

Keesey (1988) discussed the use of single-fiber electromyography (SFEMG) by the AAEE minimonograph 33 as an electrodiagnostic approach to defects of neuromuscular transmission.

G.2.0.4 Evaluation of neuromuscular blockade in anesthetized mice

PURPOSE AND RATIONALE

Electromyographic investigations of the neuromuscular junction are relatively easy to perform in large animal species such as the dog (Cullen et al. 1980). A simple *in vivo* method for the quantitative evaluation of neuromuscular blockade in anesthetized mice has been described by Lefebvre et al. (1992).

PROCEDURE

Female BALB/c mice, 7–9 weeks old, are anesthetized by intraperitoneal administration of 50 mg/kg etomidate or 250 mg/kg mephenesin. Hair is removed from the sciatic area and hindleg by application of a depilatory cream. A lamp is placed 30 cm above the anesthetized animal to maintain a constant body temperature. Two monopolar needle-stimulating electrodes are subcutaneously inserted into the sciatic notch area and two monopolar recording electrodes subcutaneously over the gastrocnemicus belly and in the vicinity of the tendo calcaneus communis, respectively. A ground electrode is inserted under the skin between recording and stimulating electrodes. Stimulation is carried out using a square signal of 0.2-ms duration. The supramaximal stimulation of the sciatic nerve consists of a train of 10 stimuli, lasting 3.3 s with a frequency of 3 Hz. Stimulation intensity is fixed to a value 50% higher than that required to attain the maximal evoked potential response. Two control trains of stimulation are applied before test-drugs administration and then repeated at 1-min intervals until the end of anesthesia which is assessed by reflex movement after pinching the toes or the tail.

Muscle action potentials are recorded using an electromyograph. The low and high cut-off frequencies are set to 16 Hz and 10 kHz, respectively. The electromyogram signal is amplified and plotted on an oscilloscope screen and printed. Evoked active potentials are analyzed using an 8 bits digitizer and the area under the response wave is evaluated for each stimulus (S).

The neuromuscular blocking agents are administered by intraperitoneal route.

EVALUATION

The effects of the test drugs are quantified by measuring the ratio of the fifth response (S5) to the first one (S1) in a given train (S5/S1 response) according to Keesey (1989). These values are almost not influenced by etomidate anesthesia. Neuroblocking agents of competitive type, such as alcuronium, or depolarizing type, such as suxamethonium, decrease this ratio significantly. These effects can be blocked by neostigmine, but not the effect of the snake venom alpha-bungarotoxin.

Chapter H
Analgesic, anti-inflammatory, and anti-pyretic activity[1]

[1] Reviewed and amended by R. Schleyerbach, contributions to the first edition by K. U. Weithmann and R. R. Bartlett.

H.1 Central analgesic activity

H.1.0.1 General considerations

Pain is a symptom of many diseases requiring treatment with analgesics. Severe pain due to cancer metastases needs the use of strong analgesics, that means opioid drugs. The addiction liability of opioids led to intensive research for compounds without this side effect. Many approaches have been used to differentiate the various actions of strong analgesics by developing animal models not only for analgesic activity but also for addiction liability. Several types of opioid receptors have been identified in the brain allowing *in vitro* binding tests. However, the *in vitro* tests can only partially substitute for animal experiments involving pain. Pain is a common phenomenon in all animals, at least in vertebral animals, similar to that felt by man. Analgesic effects in animals are comparable with the therapeutic effects in man. Needless to say, that in every instance painful stimuli to animals must be restricted as much as possible. Painful stimuli can consist of direct stimulation of the efferent sensory nerves or stimulation of pain receptors by various means such as heat or pressure. The role of endogenous peptides such as enkephalins and endorphins gives more insight into brain processes and the action of central analgesics.

Pain can also be elicited by inflammation. Progress has been made in elucidating the role of various endogenous substances such as prostaglandins and peptides in the inflammatory process. Most of the so called non-steroidal anti-inflammatory agents have also analgesic activity. Lim and Guzman (1968) differentiated between antipyretic analgesics causing analgesia by blocking impulse generation at pain receptors in the periphery while the narcotic analgesics block synaptic transmission of impulses signaling pain in the central nervous system. An old but excellent survey on methods being used to test compounds for analgesic activity has been provided by Collier (1964). Today, the classification into central and peripheral analgesics is definitively too simplified (Bannwarth et al. 1993) but provides a guide for differentiation by pharmacological methods.

H.1.1 *In vitro* methods for central analgesic activity

H.1.1.1 Survey

In 1973, high-affinity stereospecific binding of radiolabeled opiate compounds by CNS membrane preparations was reported (Pert and Snyder 1973; Simon et al. 1973; Terenius 1973). The *in vivo* pharmacological potency of opiate agonists and antagonists parallels the *in vitro* displacement of ^{3}H-naloxone, a potent narcotic antagonist. Based on these findings, the ^{3}H-naloxone binding assay was introduced for evaluation of potential analgesics with opiate-like properties. According to different pharmacological profiles of opiates, several receptor types have been identified designated as μ, κ, δ, and σ receptor.

For the **μ receptor, subtypes named μ_1 and μ_2** have been described (Fowler and Fraser 1994; Traynor 1994). Analgesia is thought to involve activation of μ receptors (largely at supraspinal sites) and κ receptors (principally within the spinal cord); δ receptors may also be involved at the spinal and supraspinal level. Other consequences of μ activation include respiratory depression, miosis, reduced gastrointestinal motility, and euphoria. The μ_1 receptors are postulated to mediate the supraspinal analgesic action and the μ_2 receptors to mediate respiratory depression and suppression of gastrointestinal motility. Moreover, different effects on heart rate were described (Paakkari et al. 1992). Two endogenous peptides were described, named **endomorphins**, as agonists with high specific affinity for the μ-receptor (Hackler et al. 1997; Zadina et al. 1997, 1999).

Several studies provide evidence for the existence of **δ-opioid receptor subtypes** (Sofuoglu et al. 1991; Porreca et al. 1992; Horan et al. 1993; Miyamoto et al. 1993; Tiseo and Yaksh 1993). Binding studies with δ opioid receptors have been performed by Mosberg et al. (1983). Endogenous ligands for δ receptors are **enkephalins**.

A rat **κ opioid receptor** has been cloned (Meng et al. 1993). Evidence for different subtypes of the κ-opioid receptor is available (Zukin et al. 1988; Clark et al. 1989; Rothman et al. 1989, 1992, 1993; Wollemann et al. 1993). Endogenous ligands for κ receptors are **dynorphins**.

With the development of highly selective ligands it has become possible to label selectively each of the μ-, δ-, and κ-opioid binding sites.

The **μ-binding sites** are labeled with [^{3}H]-[Tyr-D-Ala^2,MePhe^4,Gly-ol^5]enkephalin (Kosterlitz and Paterson 1981), ^{125}I-FK 33-824 (Moyse et al. 1986), [^{3}H]-Tyr-Pro-MePhe-D-Pro-NH_2 (PL O17; Hawkins et al. 1987), or [^{3}H]-[H-D-Phe-Cys-Tyr-D-Trp-Orn-Thr-Pen-Thr-NH_2] (CTOP); Hawkins et al. 1989), the **δ-binding sites** with [^{3}H]-[D-Pen^2,D-Pen^5]enkephalin (Akiyama et al. 1985; Cotton et al. 1985; Mosberg et al. 1987); [^{3}H]-D-Ser^2 (O-*tert*-butyl),Leu^5]enkephalyl-Thr^6 (Delay-Goyet et al. 1988) or [^{3}H]-[D-Pen^2-pClPhe^4,D-Pen^5]enkephalin (Vaughan et al. 1989); [^{3}H]TIPP (Nevin et al. 1993), and the **κ-sites** with [^{3}H]-U-69 593 (Lahti et al. 1985; Maguire et al. 1992), [^{3}H]-PD117 302 (Clark et al. 1988), or [^{3}H]-CI-977 (Boyle et al. 1990) or [^{3}H]norBNI (Marki et al. 1995).

Cloning and molecular biology of opioid receptors has been reviewed (Reisine and Bell 1993).

The opioid receptors were reclassified according to recommendations of IUPHAR (Dhawan et al. 1996, 1998; Alexander and Peters 2000). This nomenclature applies an abbreviation of the generic term for the family (OP for opioid) and a subscript number. **OP_1 stands for δ, OP_2 for κ, and OP_3 for μ receptor.**

OTHER RECEPTORS

There is some evidence that other opioid receptors may exist, such as a β-endorphin-sensitive **ε receptor** (Wüster et al. 1981). The **ζ receptor** (Zagon et al. 1991) and a high affinity binding site referred to as the **λ site** (Grevel et al. 1985) may also be part of the opioid receptor system.

The existence of a **σ receptor** was first postulated by Martin et al. (1976) to account for the psychotomimetic effects of N-allylnormetazocine (SKF 10,047) in the chronic spinal dog. σ Binding sites were proposed to be identical to phencyclidine binding sites based on the finding that phencyclidine generalized to (+)-SKF 10,047 in drug discrimination tests. Further work led to the application of the **term σ to an unique class of non-opiate, non-phencyclidine sites** that may serve as receptors for an as yet unidentified neuromodulator or neurotransmitter (Monnet et al. 1994). At least two subtypes of binding sites, σ_1 and σ_2, are proposed (Bowen et al. 1989; Itzhak and Stein 1991; Karbon et al. 1991; Knight et al. 1991; Connick et al. 1992; Quirion et al. 1992; Leitner et al. 1994). Radioligands for σ receptors (Weber et al. 1986; de Costa et al. 1989) and for subtype σ_1 (Matsuno et al. 1996) and subtype σ_2 (Mach et al. 1999) were described. Pharmacological studies indicate a role of σ receptors not only in analgesia (Mach et al. 1999), but also in motor function (Walker et al. 1993), schizophrenia (Debonnel and

de Montigny 1996; Guitard et al. 1998; Takahashi et al. 1999) and learning and memory (Maurice et al. 1999).

The heterogeneity of opioid receptors has been studied in **isolated tissue preparations** in which neurotransmission is sensitive to inhibition by opioids. The relative potencies of opioid agonists are assessed by their ability to inhibit the electrically evoked contractions of isolated tissue preparations from five different species: the contractions of the mouse **vas deferens** are inhibited by μ-, δ-, and κ-agonists (Maguire et al. 1992), those of **the guinea-pig myenteric plexus-longitudinal muscle** preparation by μ- and κ-agonists (Berzetei-Gurske 1992), those of the **rabbit vas deferens** by κ-agonists, and those of the **hamster vas deferens** by δ-agonists (Sheehan et al. 1986). The contractions of the **rat vas deferens** are inhibited mainly, but not exclusively, by δ-agonists. The actions of β-endorphin in the rat vas deferens are mediated by a further type of opioid receptors, termed **ε-receptor** (Wüster et al. 1981; Corbett et al. 1992; Smith and Leslie 1992).

H.1.1.2 ^{3}H-Naloxone binding assay

PURPOSE AND RATIONALE

A good correlation between the *in vivo* pharmacological potency of opiate agonists and antagonists with their ability to displace radiolabeled naloxone has been reported. The later discovery that Na^+ (100 mM) enhances the binding of antagonists and reduces the binding of agonists has led to the development of an assay which is used to classify compounds as opiate agonists, mixed agonist-antagonists and antagonists by determining the IC_{50} values for ^{3}H-Naloxone in the presence or absence of Na^+.

PROCEDURE

Reagents

[N-allyl-2,3-^{3}H] Naloxone (38–58 Ci/mmol) is obtained from New England Nuclear.

For IC_{50} determinations ^{3}H-naloxone is made up to a concentration of 100 nM and 50 μl is added to each tube yielding a final concentration 5 nM in the assay.

Levorphanol tartrate is obtained from Hoffmann LaRoche. A stock solution of 1 mM levorphanol is made up in distilled water. This stock is diluted 1 : 200 in distilled water and 20 μl is added to 3 tubes to determine stereospecific binding yielding a final concentration of 0.1 μM in the assay.

Dextrorphan tartrate is obtained from Hoffmann LaRoche. A stock solution of 1 mM dextrophan is made up in distilled water. This stock is diluted 1 : 200 in distilled water and 20 μl is added to the tubes containing the various concentrations of test drug and the tubes for total binding.

Test compounds: For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. At least 7 concentrations are used for each assay. Higher or lower concentrations may be used, depending on the potency of the drug.

Tissue preparation

Male Wistar rats are decapitated and their brains rapidly removed. Whole brains minus cerebella are weighed and homogenized in 50 volumes of ice-cold 0.05 M Tris buffer with a Tekmar tissue homogenizer. The homogenate is centrifuged at 40 000 *g* for 15 min, the supernatant is decanted and the pellet resuspended in fresh buffer and recentrifuged at 40 000 *g*. The final pellet is resuspended in the original volume of fresh 0.05 M Tris buffer. This yields a tissue concentration in the assay of 10 mg/ml.

Assay

310 μl	H_2O
20 μl	5 μM dextrorphan (total binding) or 5 μM levorphanol (non-specific binding)
50 μl	2 M NaCl or H_2O
50 μl	0.5 M Tris buffer, pH 7.7
20 μl	drug or vehicle
50 μl	^{3}H-naloxone
500 μl	tissue suspension.

The tubes are incubated for 30 min at 37 °C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed 3 times with ice-cold 0.05 M Tris buffer, pH 7,7. The filters are then counted in 10 ml of Liquiscint liquid scintillation cocktail. Stereospecific binding is defined as the difference

between binding in the presence of 0.1 µM dextrorphan and 0.1 µM levorphanol. Specific binding is roughly 1% of the total added ligand and 50% of the total bound in the absence of Na^+ and 2% of the total added ligand and 65% of the total bound ligand in the presence of Na^+ (100 mM). The increase in binding is due to an increase in specific binding.

EVALUATION

Data are converted into % stereospecific ^{3}H-naloxone binding displaced by the test drug. IC_{50} values are determined from computer-derived log-probit analysis. The sodium shift is calculated from IC_{50} values with and without NaCl. High sodium shifts are found with agonists, low values with antagonists and medium values with mixed agonists-antagonists.

Data can be analyzed using a computer program as described by McPherson (1985).

H.1.1.3 ^{3}H-Dihydromorphine binding to µ opiate receptors in rat brain

PURPOSE AND RATIONALE

µ Receptors are considered to mediate the supraspinal activity of opioids. ^{3}H-Dihydromorphine (^{3}H-DHM) exhibits some selectivity for the µ receptor, a high affinity opiate binding site. The test is used to detect compounds that inhibit binding of ^{3}H-DHM in a synaptic membrane preparation obtained from rat brain.

PROCEDURE

Reagents

[1,7,8-^{3}H]Dihydromorphine (^{3}H-DHM) (specific activity 69 Ci/mmol) is obtained from Amersham.

For IC_{50} determinations a 20 nM stock solution is made up. Fifty µl are added to each test tube to yield a final concentration of 0.5 nM in the 2 ml assay.

Levallorphan tartrate is used for the determination of nonspecific binding. A 0.1 mM stock solution is prepared in deionized water. Twenty µl added to each of 3 tubes yields a final concentration of 0.1 µM in the 2 ml assay.

A 1 mM stock solution is made up of the test compounds in a suitable solvent and serially diluted, such that the final concentrations in the assay range from 10^{-6} to 10^{-9} M. At least 7 concentrations are used for each assay.

Tissue preparation

Male Wistar rats are sacrificed by decapitation. Whole brains minus cerebella are removed, weighed and homogenized in 30 volumes of ice-cold 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 48 000 *g* for 15 min, the supernatant is decanted and the pellet resuspended in the same volume of buffer. This homogenate is then incubated for 30 min at 37 °C to remove the endogenous opiate peptides and centrifuged again as before. The final pellet is resuspended in 50 volumes of 0.05 M Tris buffer, pH 7.7.

Assay

1 850 µl tissue suspension
80 µl distilled water
20 µl vehicle, or levallorphan, or appropriate concentration of drug
50 µl [^{3}H]DHM.

Tubes are incubated for 30 min at 25 °C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are washed twice with 5 ml of 0.05 M Tris buffer. The filters are then placed into scintillation vials with 10 ml Liquiscint scintillation cocktail and counted.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 0.1 mM levallorphan. IC_{50} values are calculated from the percent specific binding at each drug concentration.

The K_D value for [^{3}H]DHM binding was found to be 0.38 nM by Scatchard analysis of a receptor saturation experiment. The K_i value may be calculated from the IC_{50} by the Cheng-Prusoff equation:

$$K_i = IC_{50} / 1 + L / K_D$$

H.1.1.4 ^{3}H-Bremazocine binding to κ opiate receptors in guinea pig cerebellum

PURPOSE AND RATIONALE

κ Receptors are thought to be involved in the analgesic activity of opiates mainly within the spinal cord, whereas μ receptors are predominately located at supraspinal sites. The pharmacological effects of κ agonists differ from the μ agonists in various analgesic tests, effects on diuresis, sensitivity to naloxone and propensity to cause respiratory depression. κ Agonists may induce water diuresis (Salas et al. 1992). The receptor subtype selectivity can be determined by testing the affinity of new compounds for the κ opiate receptor and comparing these results with the data from the μ receptor assay.

Although the benzomorphanes, such as ethylketocyclazocine and bremazocine, are potent κ agonists, they are not selective for this receptor subtype. To demonstrate specific binding of these ligands to κ receptors, the assay must be done in a tissue where the κ subtype predominates, such as the guinea pig cerebellum. Moreover, binding to μ and δ receptors is prevented by inclusion of the peptide DAGO (Tyr-D-Ala-Gly-N-Me-Phe-Gly-ol) to mask the μ receptor and of [D-Pen^{2,5}]-enkephalin (Tyr-D-Pen-Gly-Phe-D-Pen) to mask the δ receptor.

PROCEDURE

Reagents

Bremazocine(–)-[9-^{3}H] (specific activity 21–28 Ci/mmol), is obtained from, New England Nuclear.

For IC_{50} determinations a 24 nM stock solution is made up. Fifty μl are added to each tube to yield a final concentration of 0.6 nM in the 2 ml assay.

U50,488H is made up to a 500 μM stock solution in deionized water. Twenty ml are added to each of the 3 tubes for determination of unspecific binding yielding a final concentration of 5.0 μM in the 2 ml assay.

Opiate peptides of the μ- and δ-type are included in the assay to prevent binding of the radioligand and the test drug to these receptors. DAGO and [D-Pen^{2,5}]-enkephalin are obtained from Penninsula Laboratories. Concentrated stock solutions of 10^{-3} M are made up in deionized water and further diluted to 10^{-5} M. Twenty μl of this solution are added to each tube to result in a final concentration of 100 nM of each in the 2 ml assay.

For the assays a 1 mM stock solution of test compounds is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. At least 7 concentrations are used for each assay.

Tissue preparation

Male guinea pigs are sacrificed and cerebella are removed, weighed and homogenized in 10 volumes of ice-cold 0.05 M Tris-buffer, pH 7.4. The homogenate is centrifuged at 48 000 *g* for 10 min, the supernatant decanted and the pellet resuspended in 20 volumes of buffer. This homogenate is then incubated for 45 min at 37 °C to remove endogenous opiate peptides and centrifuged again as before. This pellet is resuspended in 200 volumes of 0.05 M Tris buffer, pH 7.4.

Assay

1 850 µl tissue suspension
60 µl distilled water
20 µl peptide solution
20 µl vehicle, or U50,488H, or test drug
50 µl [^{3}H]bremazocine

Tubes are incubated for 40 min at 25 °C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed 3 times with 5 ml of 0.05 M Tris buffer. The filters are then placed in scintillation vials with 10 ml Liquiscint scintillation cocktail and counted.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 5.0 µM U50,488H. IC_{50} values are calculated from the percent specific binding at each drug concentration.

The K_D value for [^{3}H]bremazocine binding was found to be 0.14 nM by Scatchard analysis of a receptor saturation experiment. The K_i value may be calculated from IC_{50} by the Cheng-Prusoff equation:

$$K_i = IC_{50} / 1 + L / K_D$$

H.1.1.5 Inhibition of enkephalinase

PURPOSE AND RATIONALE

Since the discovery of brain peptides with pharmacological properties similar to morphine (Hughes 1975), the metabolic breakdown of enkephalins has been studied (Malfroy et al. 1978; Llorens and Schwartz 1981; Mumford et al. 1981; Malfroy and Schwartz 1982; Roques 1982; Schwartz 1983). Roques BP et al. (1980), Costentin et al. (1986) found that the enkephalinase inhibitor thiorphan shows antinociceptive activity in mice. A highly sensitive fluorometric assay for "enkephalinase", a neutral metalloendopeptidase that releases tyrosine-glycine-glycine from enkephalins has been developed by Florentin et al. (1984). A fluorogenic peptide, dansyl-D-Ala-Gly-Phe(pNO$_2$)-Gly (DAGNPG) was synthesized as a selective substrate for the neutral metalloendopeptidase involved in enkephalin metabolism. This enzyme, designated "enkephalinase" cleaves the Gly-Phe(pNO$_2$) peptide bond of DAGNPG leading to a fluorescence increase related to the disappearance of intramolecular quenching of the dansyl fluorescence by the nitrophenyl residue.

Enkephalinase induces inactivation of atrial natriuretic factor (ANF). The protection of endogenous ANF against inactivation may result in therapeutic applications (Schwartz et al. 1990).

PROCEDURE

Fresh rat kidney is homogenized in 10 vol of cold 0.05 M Tris-HCl buffer, pH 7.4, using a Polytron homogenizer. The homogenate is centrifuged for 5 min at 1 000 g. The pellet is discarded and the supernatant

centrifuged at 60 000 *g* for 60 min. The resulting pellet is resuspended in 50 mM Tris-HCl buffer, pH 7.4, and used as the enzyme source.

Standard assays for "enkephalinase" activity using DAGNPG are carried out at 37 °C in hemolysis tubes. A 0.1-ml amount of 50 mM Tris-HCl buffer, pH 7.4, containing 50 µM DAGNPG is preincubated 15 min at 37 °C. The reaction is initiated by addition of 50 µl of the enzyme preparation together with 0.5 µM Captopril. The tubes are incubated for 30 min in a water bath with constant shaking. The enzymatic reaction is stopped by boiling at 100 °C for 5 min. The samples are then diluted with 1.35 ml of Tris HCl buffer and centrifuged at 500 *g* for 30 min. An aliquot of 1 ml of the supernatant is transferred to thermostated cells of a spectrofluorometer. Readings are performed at 562 nm with an excitation wavelength of 342 nm. A calibration curve is prepared by adding increasing concentrations of DNS-D-Ala-Gly and decreasing concentrations of the substrate in Tris-HCl buffer containing the denaturated enzymatic preparation. For the assay of "enkephalinase" inhibition, the test compound or the standard thiorphan = [(*R*-,*S*-)-3-mercapto-2-benzylpropanoyl]glycine is added in various concentrations.

MODIFICATIONS OF THE METHOD

The inhibitory potencies of test compounds are compared with the standard.

MODIFICATIONS OF THE METHOD

Ksander et al. (1989) incubated synaptic membranes from rat striatum with ^{3}H-Tyr-Leu-enkephalin for 15 min at 30 °C, pH 6.5, in the presence of 10^{-6} M bestatin. The reaction was stopped by the addition of 30% acetic acid and the reaction product ^{3}H-Tyr-Gly-Gly was separated from unreacted ^{3}H-Tyr-Leu-enkephalin on a Porapak Q column followed by a Cu^{2+} chelex column. The ^{3}H-Tyr-Gly-Gly was counted by liquid scintillation.

The antinociceptive effects of intrathecally administered SCH32 615, an enkephalinase inhibitor were studied in the rat by Oshita et al. (1990).

H.1.1.6 Nociceptin

H.1.1.6.1 General considerations on nociceptin

PURPOSE AND RATIONALE

A heptadekapeptide (nociceptin or orphanin FQ) has been isolated as endogenous agonist of the **opioid receptor-like ORL$_1$ receptor** (Reinscheid et al. 1995; Meunier et al. 1995) which shows high structural homology with opioid peptides, especially dynorphin A (Calò et al. 2000). Nociceptin activates a specific receptor which has been cloned in man and animals and has been shown to be structurally similar to opioid receptors (Mollereau et al. 1994; Calò et al. 2000; Hawkinson et al. 2000). At the cellular level, the nociceptin receptor has been shown to act through the same mechanisms as classical opioid receptors, namely the inhibition of adenylyl cyclase, the activation of potassium

channels and inhibition of calcium channels (Connor et al. 1996a,b). *In vitro* and *in vivo* studies have demonstrated that nociceptin mediates a variety of biological actions (Civelli et al. 1998; Darland et al. 1998). Nociceptin induces analgesia when administered intrathecally (Stanfa et al. 1996; Xu et al. 1996), while it causes hyperalgesia and reversal of opioid induced analgesia when given intracerebroventricularly; nociceptin stimulates food intake (Polidori et al. 2000) and produces anxiolysis. Depending on the dose, nociceptin stimulates or inhibits locomotor activity. Nociceptin inhibits long-term potentiation, memory processes, induces bradycardia, hypotension and diuresis. In addition, nociceptin inhibits neurotransmitter release both at central and peripheral sites. Intracavernosal injection of nociceptin induces a potent and relatively long-lasting erectile response in the cat (Champion et al. 1997, 1998). Intrathecal injection of nociceptin elicits scratching, licking and biting in mice (Sakurada et al. 1999, 2000). Synthetic agonists and antagonists of the nociceptin receptor have been reported (Guerrini et al. 1998; Salvadori et al. 1999; Calò et al. 2000; Hashimoto et al. 2000; Meunier 2000; Ozaki et al. 2000).

H.1.1.6.2 Receptor binding of nociceptin

PURPOSE AND RATIONALE

The nociceptin receptor has been termed by different groups of investigators as ORL1, LC132, ROR (see Meunier 1997). Based on the structural and transductional similarities between receptors for nociceptin and those for opioids, Hamon (1998) proposed to include the nociceptin receptor in the opioid receptor family with the name OP_4.

Varani et al. (1999) tested synthetic nociceptin analogs for their displacement at the nociceptin- and at classical opioid receptors. The displacement of [^{3}H]$NCNH_2$ ([^{3}H]nociceptin amide, ORL1 site), and of the selective opioid receptor ligands [^{3}H]DAMGO (μ site), [^{3}H]deltorphin II (δ site), and [^{3}H]U69 593 (κ site) was studied.

PROCEDURE

Membrane preparation

Guinea pigs are decapitated and the whole brain (without cerebellum) rapidly removed. The tissue is disrupted in a Polytron homogenizer (setting 5) in 50 mM Tris HCl, pH 7.4, to prepare membranes for the classic opioid receptor studies. The homogenate is centrifuged at 4 000 *g* for 10 min and the pellet is resuspended with a Polytron PTA 10 probe (setting 5) in the same ice-cold buffer. To study the binding to ORL1 receptor, the tissue is homogenized in 50 mM Tris HCl, 2 mM EDTA and 100 μM phenylmethylsulphonylfluoride HCl (PMSF) at pH 7.4. The suspension is centrifuged at 40 000 *g* for 10 min and the pellet is resuspended in the same buffer. After 30 min of incubation at 37 °C the membranes are centrifuged at 40 000 *g* for 10 min and the pellets are stored at –70 °C. The protein concentration is determined with bovine albumin as standard.

Binding assays

Classic opioid receptors, μ, δ and κ, are studied according to Bhargava and Zhao (1996). Saturation binding experiment are carried out using 8–10 different concentrations of [^{3}H]DAMGO ranging from 0.15 nM to 15 nM, [^{3}H]deltorphin II from 0.1 nM to 10 nM, and [^{3}H]U69 593 from 0.15 nM to 15 nM, respectively. Inhibition experiments are carried out in duplicate in a final volume of 250 μl in test tubes containing either 1.5 nM [^{3}H]DAMGO or 1.0 nM [^{3}H]deltorphin II or 1.5 nM [^{3}H]U69 593, 50 mM Tris HCl at pH 7.4, guinea pig brain membranes (150–200 μg of protein/assay) and at least 8–10 different concentrations of the ligands under study. Binding assays to the ORL1 receptor are carried out according to Varani et al. (1998). In saturation studies, membranes are incubated with 8–10 different concentrations of [^{3}H]$NCNH_2$ ([^{3}H]nociceptin amide) ranging from 0.1 mM to 10 mM. Inhibition experiments are carried out in duplicate in a final volume of 250 μl in test tubes containing 1 mM [^{3}H]$NCNH_2$, 50 mM Tris HCl, 2 mM EDTA, 100 μM phenylmethylsulphonylfluoride HCl (PMSF) at pH 7.4, guinea pig membranes, and at least 8–10 different concentration of the compound under examination. The incubation time is 1 h for [^{3}H]DAMGO and [^{3}H]U69 593 and 2 h for [^{3}H]deltorphin II and [^{3}H]$NCNH_2$. Nonspecific binding is defined as the binding measured in the presence of 100 μM bremazocine for classic opioid receptors and 10 μM $NCNH_2$ for ORL1 receptors.

Bound and free radioactivity are separated by filtering the assay mixture through Whatman GF/B glassfibre filters, previously treated with PEI 0.1%; the incubation mixture is diluted with 3 ml of ice-cold incubation buffer, rapidly filtered by vacuum, and the filter washed three times with 3 ml of incubation buffer. The filter-bound radioactivity is measured in a Beckman LS-1 800 Spectrometer.

EVALUATION

The inhibitory binding constant (K_i) values are calculated from the IC_{50} values according to the Cheng and Prusoff equation. The weighted non-linear last-squares curved fitting program LIGAND (Munson and Rodbard 1980) is used for computer analysis of saturation and inhibition experiments.

MODIFICATIONS OF THE METHOD

Seki et al. (1999) analyzed the pharmacological properties of κ-opioid receptor-selective agonist TRK-820 using Chinese hamster ovary cells expressing cloned rat μ-, δ- and κ-opioid receptors and human nociceptin receptor.

Mouledous et al. (2000) reported a site-directed mutagenesis study of the ORL1 receptor transmembrane-binding domain.

H.1.1.6.3 Bioassays for nociceptin

PURPOSE AND RATIONALE

Nociceptin receptors in the periphery can be characterized by studies in isolated organs (Guerrini et al. 1998; Bigoni et al. 1999): the guinea pig ileum according to Paton (1957) (see J.4.3.1), the mouse vas deferens according to Hughes et al. (1975), the rabbit vas deferens according to Oka et al. (1980) (see A.1.2.3), the guinea pig renal pelvis (Giuliani and Maggi 1996) (see C.4.2.1).

PROCEDURE

Tissues are taken from male Swiss mice (25–30 g), guinea pigs (300–350 g) Sprague Dawley rats (300–350 g) and New Zealand albino rabbits (1.5–1.8 kg). They are suspended in 10 ml organ baths containing Krebs solution oxygenated with 95% O_2 and 5% CO_2. The temperature is set at 33 °C for the mouse vas deferens and at 37 °C for the other tissues. A resting tension of 0.3 g is applied to the mouse deferens, 1 g to the guinea pig ileum, rats vas deferens, and rabbit vas deferens and 0.15 g to the guinea pig renal pelvis. For experiments at the mouse vas deferens a Mg^{2+}-free Krebs solution is used and for rat vas deferens experiments a Krebs solution containing 1.8 mM $CaCl_2$. Guinea pig renal pelvis experiments are performed in the presence of indomethacin (3 μM).

The mouse vas deferens, guinea pig ileum, rat vas deferens, and rabbit vas deferens are continuously stimulated through two platinum ring electrodes with supramaximal voltage rectangular pulses of 1 ms duration and 0.1 Hz frequency. The electrically evoked contractions are measured isotonically with a strain gauge transducer and recorded on a multichannel chart recorder. After an equilibration period of about 60 min the contractions induced by electrical field stimulation are stable; at this time, cumulative concentration response curves to nociceptin or opioid peptides are performed (0.5 log unit steps).

The guinea pig renal pelvis is stimulated through two platinum ring electrodes with 100 V square wave pulses of 1 ms duration at a frequency of 5 Hz for 10 s. The spontaneous activity and the positive inotropic responses to electrical field stimulation are measured by an isotonic transducer and recorded by a two channel recorder. The experiments are started following a 60 min equilibration period. Four electrical field stimulation are performed with each tissue at 30 min intervals. Agonists are added to the bath 5 min, and antagonists 15 min before the next stimulus. The contractile responses to electrical field stimulation are expressed as % increment the spontaneous activity of the tissue; the biological effects of the application of agonists or antagonists are expressed as % inhibition of electrical filed stimulation-induced contraction.

EVALUATION

Data are expressed as means ±SEM of *n* experiments and statistically analyzed with Student two-tailed *t*-test of one way ANOVA plus Dunnett test. The agonist potencies are given as pE_{50}, which is the negative logarithm to base 10 of the agonist molar concentration that produces 50% of the maximal possible effect of that agonist. The E_{max} is the maximal effect that an agonist can elicit in a given preparation. Antagonist potencies are expressed in terms of pA_2, which is the negative logarithm to base 10 of the antagonist molar concentration that makes it necessary to double the agonist concentration to elicit the original submaximal response.

MODIFICATIONS OF THE METHOD

Rizzi et al. (1999) studied nociceptin and nociceptin analogs in the isolated mouse colon.

Bigoni et al. (1999) used nociceptin, a series of nociceptin fragments, naloxone as well as [$Phe^1\Psi(CH_2\text{-}NH)Gly^2$]nociceptin(1-13)$NH_2$ and [$Nphe^1$]nociceptin (1-13)NH_2 to characterize nociceptin receptors in peripheral organs, such as mouse and rat vas deferens (noradrenergic nerve terminals), in the guinea pig ileum (cholinergic nerves) and renal pelvis (sensory nerves) and *in vivo* by measuring the blood pressure and heart rate in anesthetized rats.

Menzies et al. (1999) described the agonist effects of nociceptin and [$Phe^1\Psi(CH_2\text{-}NH)Gly^2$]nociceptin (1-13)$NH_2$ in the mouse and rat colon and in the mouse vas deferens.

Kolesnikov and Pasternak (1999) found an ED_{50} of 16.3 μg after peripheral administration of nociceptin in the tail flick test in mice.

Bertorelli et al. (1999) found anti-opioid effects of nociceptin and the ORL1 ligand [$Phe^1\Psi(CH_2\text{-}NH)Gly^2$]nociceptin(1-13)$NH_2$ in the Freund's adjuvant-induced arthritic rat model of chronic pain.

Yamamoto and Sakashita (1999) studied the effect of nocistatin, a 17 amino acid peptide which is processed from prepronociceptin and its interaction with nociceptin in the rat formalin test.

H.1.1.7 Vasoactive intestinal polypeptide (VIP) and pituitary adenylate cyclase-activating peptide (PACAP)

PURPOSE AND RATIONALE

Several peptides are considered to play a role in the altered transmission of sensory information in neuropathic conditions, such as neuropathic pain arising from trauma or compression injury of peripheral nerves (Zhang et al. 1998).

Vasoactive intestinal polypeptide (VIP), isolated by Nakajima et (1970), is a neuropeptide of 28 amino acids with widespread distribution in both the central and peripheral nervous system (Fahrenkrug 1979; Gafvelin 1990).

Together with the structurally related pituitary adenylate cyclase-activating peptide (PACAP) this peptide is considered to play an important role in the somatosensory processing of pain (Dickinson and Fleetwood-Walker 1999). PACAP-38 (a 38 amino-acid polypeptide) and the C-terminally truncated form PACAP-37 share 68% amino acid homology at their N-terminal domain with VIP. A shorter peptide with 27 amino acids, named as PACAP27 was described by Miyata et al. (1990). These peptides are members of a superfamily of hormones that includes glucagon, glucagon-like peptide, secretin and growth hormone releasing factor.

Three G-protein-coupled receptors are described: the $VPAC_1$ receptor, originally described as the VIP receptor and subsequently designated as VIP_1 receptor; the $VPAC_2$ receptor, previously designated VIP_2; and the PAC_1 receptor, previously known as PACAP type I receptor (Buscail et al. 1990; Guijarro et al. 1991; Felley et al. 1992; Calvo et al. 1994; Van Rampelbergh et al. 1996; Harmar et al. 1998; Robberecht et al. 1999).

Many peripheral activities of VIP/PACAP are described, such as stimulation of pancreatic secretion (Onaga et al. 1997; Ito et al. 1998; Soo Tek Lee et al. 1998); stimulation of duodenal bicarbonate secretion (Takeuchi et al. 1998); relaxation of smooth muscle cells in the intestinal tract, e.g., gall bladder (Pang and Kline 1998), cecal circular smooth muscle (Motomura et al. 1998), internal anal sphincter (Rattan and Chakder 1997); on duodenal motility (Onaga et al. 1998); enhancement of insulin secretion (Yada et al. 1997; Filipsson et al. 1998); bronchodilation (Linden et al. 1998; Shigyo et al. 1998; Okazawa et al. 1998). Centrally administered PACAP showed an anorectic effect (Mizuno et al. 1998).

Agonists (Gourlet et al. 1997a,b) and antagonists (Gozes et al. 1991; Gourlet et al. 1997c) for VIP were described. Further studies are aimed to development of drugs for neuropathic analgesia, ultimately of non-peptide nature, using $VPAC_1$, $VPAC_2$, and PAC_1, receptors as drug targets (Dickinson and Fleetwood-Walker 1999).

PROCEDURE

CHO cell lines expressing the rat VIP_1 receptor (Ciccarelli et al. 1994), the human VIP_2 receptor (Sreedharan et al. 1993), the rat PACAP I receptor (Ciccarelli et al. 1995), and the rat secretin receptor (Ishihara et al. 1991) are used.

Transfected CHO cells are harvested with a rubber policeman and pelleted by low speed centrifugation.

The supernatant is discarded and the cell lysed in mM $NaHCO_3$ solution and immediate freezing in liquid nitrogen. After thawing, the lysate is first centrifuged at 4 °C for 10 min at 400 *g* and the supernatant is further centrifuged at 20 000 *g* for 10 min. The pellet, resuspended in 1 mM $NaHCO_3$ is used immediately as a crude membrane fraction.

Binding is performed using [^{125}I]VIP (specific radioactivity of 0.5 Ci/nmol), [^{125}I]Tyr^{25} secretin (specific radioactivity of 1.0 Ci/nmol) and [^{125}I-Ac-His^{1}] PACAP-27 (specific radioactivity of 0.7 Ci/nmol) as tracers. In all cases, non-specific binding is defined as the residual binding in the presence of 1 μM of the unlabeled peptide corresponding to the tracer. Binding is performed at 37 °C in a 20 mM Tris-maleate, 2 mM $MgCl_2$, 0.1 mg/ml bacitracin, 1% bovine serum albumin (pH 7.4) buffer. Bound radioactivity is separated from free by filtration through glass-fibre GF/C filters presoaked for 24 h in 0.1% polyethyleneimine and rinsed three times with a 20 mM (pH 7.4) sodium phosphate buffer containing 1% bovine serum albumin.

EVALUATION

The IC_{50} values (in mM) for each peptide on each receptor are calculated from complete dose-effect curves performed on three different membrane preparations using the LIGAND program.

MODIFICATIONS OF THE METHOD

Schmidt et al. (1993) studied the binding of PAPAC, VIP and analogues of VIP and PAPAC in rat AR 4-2J pancreatic carcinoma cells and isolated pancreatic acini to the PAPAC-1 receptor, abundantly expressed in AR 4-2J pancreatic carcinoma cells, and to the VIP/PAPAC-2 receptor. Simultaneously, biological effects (lipase secretion and cAMP production) in pancreatic acini were determined. PAPAC was regarded as a potent ligand for both receptor types and as a potent VIP-like secretagogue.

H.1.1.8 Cannabinoid activity

H.1.1.8.1 General considerations on cannabinoids

In the centuries since hashish and marijuana (*Cannabis sativa*) were used as psychoactive drugs the most significant discoveries in regard to the mechanism of action were made with the isolation of (−)-trans-Δ^9-tetrahydrocannabinol (Δ^9-THC) as the principal active ingredient (Mechoulam et al. 1970), the characterization and localization of the cannabinoid receptor in the brain (Devane et al. 1988), the cloning of its gene (Matsuda et al. 1990), and the identification of an endogenous ligand (Devane et al. 1992). Most cannabinoid effects occur receptor mediated in the CNS (Martin 1986; Herkenham et al. 1990). The recognized CNS responses to cannabinoids include alterations in cognition and memory, euphoria and sedation (Howlett 1995). Cannabinoids have been shown to produce analgesia without the respiratory problems associated with opioid analgesics (Buxbaum 1972; Martin 1985; Dewey 1986; Razdan 1986; Compton et al. 1992; Meng et al. 1998; Strangman et al. 1998) which may be of value for therapeutic applications (Hollister 1986; Izzo et al. 2000a; Pertwee 2000). Simultaneous administration of cannabinoid receptor agonists and μ- or κ-receptor agonists indicate a cannabinoid-opioid interaction in anti-nociception (Manzanares et al. 2000). Baker et al. (1990, 2000) described experimental allergic encephalomyelitis with relapsing-remitting episodes, spasticity and tremor similar to multiple sclerosis in human beings in Biozzi AB/H mice. These symptoms could be antagonized by cannabinoids.

A multiple-evaluation paradigm of *in vivo* mouse assays is employed to test for cannabimimetic effects. This paradigm includes assays for reduction in spontaneous activity, and the production of hypothermia, catalepsy, and antinociception measured by tail-flick assay (Compton et al. 1992; Welch et al. 1998). The behavioral effects of Δ^9-THC and related cannabinoids in mice have been termed the "popcorn" effect. That is, groups of mice are in a sedated state with little or no movement until a stimulus causes one mouse to jump (hyper-reflexia). This animal falls on another mouse which in turn jumps so that this repeated hyper-reflexic jumping looks like corn popping in a machine. Subsequently, all mice will be sedated until another stimulus reinitiates the process (Dewey 1986). Like the opioids, cannabinoids inhibit electrically evoked contractions of the mouse vas deferens and the guinea pig ileum,

but unlike the opioids, these effects are not antagonized by naloxone (Pertwee et al. 1992; Hillard et al. 1999).

In addition to the effects in the CNS, peripheral effects of cannabinoids are known (Lynn and Herkenham 1994) including actions on the **endocrine system** (Patra and Wadsworth 1990, (Block et al. 1991; Wenger et al. 2000), on the **digestive tract** (Rosell and Agurell 1975; Izzo et al. 1990a,b, 2000; Coutts et al. 2000), on **ingestive behavior** (Giuliani et al. 2000), on the **pulmonary and cardiovascular system** (Stengel et al. 1998; White and Hiley 1998; Niederhoffer and Szabo 1999; Liu et al. 2000), and on **immune modulation** (Kaminski et al. 1992; Lynn and Herkenham 1994; Achiron et al. 2000).

An endogenous cannabinoid was isolated from porcine brain by Devane et al. (1992) and found to be an unsaturated fatty acid ethanolamide, arachidonylethanolamide, also called **anandamide**, which activates CB1 receptors (Devane et al. 1992) and produces similar effects as Δ^9-tetrahydrocannabinol including anti-nociception, hypothermia, hypomotility and catalepsy in mice (Smith et al. 1994). The brain enzyme hydrolyzing and synthesizing anandamide has been characterized by Ueda et al. (1995).

Similar effects are produced by other polyunsaturated N-acetylethanolamines, such as N-palmitoylethanolamine, which activates the CB-2-like receptor subtype (Hanu et al. 1993; Facci et al. 1995). Both endogenous cannabinoids (called endocannabinoids) derive from cleavage of a precursor phospholipid, N-acylphosphatidylethanolamine, catalyzed by Ca^{2+}-activated D-type phosphodiesterase activity (Cadas et al. 1996). 2-Arachidonylglycerol was described as a further endogenous ligand for cannabinoid receptors (Ameri and Simmet 2000; Sigiura et al. 2000)

Numerous synthetic analogs and cannabimimetic compounds have been evaluated as agonists and antagonists by *in vitro* and *in vivo* pharmacological methods (Martin et al. 1991; D'Ambra et al. 1992; Melvin et al. 1993; Barth and Rinaldi-Carmona 1999; Hillard et al. 1999).

H.1.1.8.2 Receptor binding of cannabinoids

PURPOSE AND RATIONALE

After the discovery of cannabinoid receptors in brain (Howlett et al. 1988; Devane et al. 1988; Pertwee 1993), two cannabinoid receptor subtypes were identified: CB1 and CB2. Cannabinoid receptors and were reviewed by Felder and Glass (1998), Pertwee (1999, 2001).

CB1 has an amino acid sequence consistent with a tertiary structure typical of the seven transmembrane-spanning proteins that are coupled to G proteins (Gerard et al. 1990, 1991; Howlett et al. 1990; Matsuda et al. 1990). The CNS responses to cannabinoid compounds are apparently mediated exclusively by CB1, since CB2 transcripts could not be found in brain tissue. CB1 transduces signals in response to CNS active constituents of *Cannabis sativa*, as well as synthetic bicyclic and tricyclic analogs, aminoalkylindole, and eicosanoid cannabimimetic compounds. CB1 is coupled to G_1 to inhibit

adenylate cyclase activity and to a pertussis-sensitive G protein to regulate Ca^{2+} currents. Zimmer et al. (1999) produced a mouse strain with a disrupted CB1 gene. These CB1 knockout mice had a significantly increased mortality rat and displayed reduced locomotor activity, increased ring catalepsy, and hypoalgesia in hot plate and formalin tests.

CB2, the second cannabinoid-binding seven-transmembrane spanning receptor, exhibits 68% identity to CB1 within the helical regions, and 44% identity throughout the total protein. The CB2 clone was derived from a human promyelocytic leukemia cell lin HL60 cDNA library (Munro et al. 1993), also expressed in human leukocytes (Bouaboula et al. 1993). The gene for the rat CB2 receptor was cloned, expressed, and its properties compared with those of mouse and human CB2 receptors (Griffin et al. 2000).

Receptor binding of cannabinoids in correlation to *in vivo* activities was described by Compton et al. (1993).

PROCEDURE

Membrane preparation

Male Sprague Dawley rats weighing 150–200 g are decapitated and the brain rapidly removed. The cortex is dissected free using visual landmarks following reflection of cortical material from the midline and immersed in 30 ml of ice-cold centrifugation solution (320 mM sucrose, 2 mM Tris-EDTA, 5 mM $MgCl_2$). The process is repeated until the cortices of five rats are combined. The cortical material is homogenized with a Potter-Elvehjem glass-Teflon grinding system. The homogenate is centrifuged at 1 600 *g* for 15 min, the supernatant saved and combined with the two subsequent supernatants obtained from washing and 1 600 *g* centrifugation of the P_1 pellet. The combined supernatant fractions are centrifuged at 39 000 *g* for 15 min. The P_2 pellet is resuspended in 50 ml buffer (50 mM Tris-HCl, 2 mM Tris EDTA, 5 mM $MgCl_2$, pH 7.0), incubated for 10 min at 37 °C, then centrifuged at 23 000 *g* for 10 min. The P_2 membrane is resuspended in 50 ml of buffer A, incubated again except at 30 °C for 40 min, then centrifuged at 11 000*g* for 15 min. The final wash-treated P_2 pellet is resuspended in assay buffer B (50 mM Tris-HCl, 1 mM Tris EDTA, 3 mM $MgCl_2$, pH 7.4) to a protein concentration of approximately 2 mg/ml. The membrane preparation is divided into 4 aliquots and quickly frozen in a bath solution of dry ice and 2-methylbutane and then stored at -80 °C.

Binding assay

Binding is initiated by the addition of 150 mg of P_2 membrane to test tubes containing [^{3}H]CP-55,940 (79 Ci/mmol), a cannabinoid analog, (for displacement studies) and a sufficient quantity of buffer C (50 mM Tris-HCl, 1 mM Tris EDTA, 3 mM $MgCl_2$, 5 mg/ml BSA) to bring the total incubation volume to 1 ml. The concentration of [^{3}H]CP-55,940 in displacement studies is 400 pM, whereas that in saturation studies varies from 25 to 2500 pM. Nonspecific binding is determined by the addition of 1 mM unlabeled CP-55,940. The standard CP-55,940 and other cannabinoid analogs are prepared in suspension buffer C from a 1 mg/ml ethanolic stock without evaporation of the alcohol.

After incubation at 30 °C for 1 h, binding is terminated by addition of 2 ml ice-cold buffer D (50 mM Tris-HCl, 1 mg/ml BSA) and vacuum filtration through pretreated filters in a 12-well sampling manifold. Reaction vessels are washed once with 2 ml of ice-cold buffer D, and the filters washed twice with 4 ml of ice-cold buffer D. Filters are placed into 20-ml plastic scintillation vials with 1 ml of distilled water and 10 ml of Budget-Solve (RPI Corp., Mount Prospect, IL). After shaking for 1 h, the radioactivity present is determined by liquid scintillation photometry.

EVALUATION

The B_{max} and K_d values obtained from Scatchard analysis are determined via a suitable computer program. Displacement IC_{50} values are determined by unweighted least squares linear regression of log concentration-percent displacement data and then converted to K_I values.

MODIFICATIONS OF THE METHOD

To further characterize neuronal cannabinoid receptors, Thomas et al. (1998) compared the ability of cannabinoid analogs to compete for receptor sites labeled either with [^{3}H]SR141 716A or[^{3}H]CP-55 940.

Rinaldi-Camora et al. (1998) tested the affinity of an antagonist of the CB2 cannabinoid receptor for rat spleen and cloned human CB2 receptors.

H.1.1.9 Vanilloid (capsaicin) activity

H.1.1.9.1 General considerations on vanilloids

PURPOSE AND RATIONALE

Several authors reviewed the recent development of capsaicin and vanilloid receptors (Holzer P 1991; Bíró et al. 1997; Sterner and Szallasi 1999; Szallasi and Blumberg 1999; Caterina and Julius 2001; Piomelli 2001). Capsaicin was isolated by Thresh (1846). The chemical structure was determined by Nelson (1919). The analgesic use of capsaicin was reviewed by Lembeck (1987). Capsaicin excites a subset of primary sensory neurons with somata in the dorsal root ganglion or trigeminal ganglion. As a general rule, these vanilloid-sensitive neurons are peptidergic, small diameter (50 μm) neurons, giving rise to thin, unmyelinated C fibers. Among sensory neuropeptides, the tachykinin Substance P shows the best correlation with vanilloid sensitivity. Vanilloid-sensitive neurons transmit noxious information (usually perceived as itching or pain) to the CNS, whereas peripheral terminals rare sites of release of a variety of pro-inflammatory neuropeptides. Among irritant compounds acting on primary sensory neurons, capsaicin and related vanilloids are unique in that the initial stimulation by vanilloids is followed by a long lasting refractory state. Neurotoxicity has been observed when capsaicin as given to newborn rats (Jancsó et al. 1977; Nagy and van der Kooy 1983).

Besides capsaicin, several natural vanilloid agonists were described (Jonassohn and Sterner 1997; Liu et al. 1997; Sterner and Szallasi 1999; Mendes et al. 2000). The irritant principle from *Euphorbia resinifera*, named resiniferatoxin, was isolated by Hergenhahn et al. (1975). In several assays, resiniferatoxin and its derivatives are several thousand-fold more potent than capsaicin (Szolcsanyi et al. 1990; Ács et al. 1995), which is explained by specific receptor binding (Szallasi and Blumberg 1990; Ács et al. 1994). Lee et al. (2001) described simplified resiniferatoxin derivatives as potent vanilloid receptor agonists with potent analgesic activity and reduced pungency.

The high affinity of vanilloid receptors argues for the existence of endogenous vanilloids. Hwang et al. (2000), Piomelli (2001) reported a direct activation of capsaicin receptors by products of lipogenases. Pain-inducing substances, such as bradykinin, may activate phospholipase-linked receptors in sensory neurons, mobilizing arachidonic acid from phospholipids and generating 12-HPETE. This lipid second messenger interacts in turn with a cytosolic domain of the VR1 receptor channel, increasing its opening probability and causing the sensory neuron to become depolarized.

The endogenous ligand of CB_1 cannabinoid receptors, anandamide, is also a full agonist at vanilloid VR1 receptors (Zygmunt et al. 1999; Maccarrone et al. 2000; Smart et al. 2000; DePetrocellis et al. 2001). Premkumar and Ahern (2000) showed that activation of protein kinase C activates VR1 channel activity.

The first capsaicin or vanilloid receptor, termed VR1, was cloned by Caterina et al. (1997). Hayes et al. (2000) reported the cloning and functional expression of a human orthologue of rat vanilloid receptor 1. Pharmacological differences between the human and rat vanilloid receptor 1 were observed (McIntyre et al. 2001). VR1 functions as a molecular integrator of painful chemical and physical stimuli including capsaicin, noxious heat and low pH (Tominaga et al. 1998; Michael and Priestley 1999; Davis et al. 2000; Welch et al. 2000). In mice lacking the capsaicin receptor impaired nociception and pain sensation was observed (Caterina et al. 2000).

Vanilloid receptors are differently distributed in the central and peripheral nervous system (Szallasi 1995; Szallasi et al. 1995; Mezey et al. 2000; Ichikawa and

Sugimoto 2001). Bíró et al. (1998) reported characterization of functional vanilloid receptors expressed by mast cells. Biological and electrophysiological data indicate heterogeneity within the vanilloid receptors. Caterina et al. (1999) described a capsaicin-receptor homologue, named vanilloid-receptor-like protein (VRL-1) with a high threshold for noxious heat. A novel human vanilloid receptor-like protein, named VRL-2 was identified and characterized by Delany et al. (2001).

Several vanilloid antagonists were described, such as capsazepine (Bevan et al. 1992; Walpole et al. 1994) or iodo-resiniferatoxin (Wahl et al. 2001).

H.1.1.9.2 Vanilloid receptor binding

PURPOSE AND RATIONALE

Ács et al. (1994) described [^{3}H]resiniferatoxin binding by the human vanilloid (capsaicin) receptor. Receptor types and species differences of the vanilloid receptor were described by Szallasi et al. (1994, 1996). The rat vanilloid receptor (rVR1) was cloned and stably expressed in HEK293 cells by Jerman et al. (2000). A detailed pharmacological characterization was conducted using the Ca^{2+}-sensitive dye, Fluo3AM in a fluorimetric imaging plate reader (FLIPR). Ross et al. (2001) studied structure-activity relationship for the endogenous cannabinoid, anadamide, and certain of its analogues at vanilloid receptors in transfected CHO cells.

PROCEDURE

Cell culture

Rat vanilloid receptor (rVR1) transfected CHO cells are maintained in MEM Alpha minus media containing 2 mM L-glutamine supplemented with 10% hyclone fetal bovine serum, 350 µg/ml G418 (Sigma-Aldrich), 100 units/ml penicillin and 100 µg/ml streptomycin. Cells are maintained in 5% CO_2 at 37 °C and passed twice a week using non-enzymatic cell dissociation solution. For the radioligand binding assay, cells are removed from flasks by scraping and then frozen as a pellet at –20 °C for up to one month.

Radioligand binding experiments

Assays are performed in DMEM containing HEPES (25 mM) and BSA (0.25 mg/ml). Total assay volume is 500 µl containing 20 µg of cell membranes. Binding is initiated by addition of [^{3}H]resiniferatoxin ([^{3}H]-RTX). Assays are carried out at 37 °C for 1 h, before termination by addition of ice-cold wash buffer (50 mM Tris-buffer, 1 mg/ml BSA, pH 7.4) and vacuum filtration using a 12-well sampling manifold (Brandell cell harvester) and Whatman GF/B filters that have been soaked in wash buffer at 4 °C for at least 24 h. Each reaction is washed 9 times with a 1.5 ml aliquot of wash buffer. The filters are oven-dried and then placed in 5 ml scintillation fluid. Radioactivity is quantified by liquid scintillation spectrometry. Specific binding is determined in the presence of 1 µM unlabelled RTX. Protein assays are performed using a Bio-Rad De Kit. Unlabelled compounds are added in a volume of 50 µl after serial dilution using assay buffer from a 10 mM stock in ethanol or DMSO. [^{3}H]-RTX is also added in a 50 µl volume following dilution in assay buffer.

EVALUATION

The K_D value and B_{max} for [^{3}H]-RTX and the concentration of competing ligands to produce 50% displacement of the radioligand (IC_{50}) from specific binding sites are calculated using GraphPad Prism (GraphPad Software, San Diego). Dissociation constant (K_i) values are calculated using the Cheng and Prussoff equation.

MODIFICATIONS OF THE METHOD

Wardle et al. (1997) used a 96-well plate assay system to characterize pharmacologically the vanilloid receptor in the dorsal spinal cord of the rat.

Hayes et al. (2000) described the cloning and functional expression of a human orthologue of rat vanilloid receptor-1.

H.1.1.9.3 Evaluation of vanilloid receptor antagonists

PURPOSE AND RATIONALE

Several vanilloid receptor antagonists were described, such as capsazepine (Bevan et al. 1992; Walpole et al. 1994) or iodo-resiniferatoxin (Wahl et al. 2001). Kirschstein et al. (1999) described the inhibition of rapid heat responses in nociceptive primary sensory neurons of rats by vanilloid receptor antagonists.

PROCEDURE

Adult Sprague Dawley rats of both sexes are deeply anesthetized with diethyl ether and rapidly decapitated. The spine is chilled at 4 °C in F12 Dulbecco's modified Eagle's medium saturated with carbogen gas and additionally containing 30 mM $NaHCO_3$, 100 000 units/l penicillin and 100 mg/l streptomycin. Thoracic and lumbar dorsal root ganglions are quickly dissected and freed from connective tissue. Neurons are dissociated in an incubation chamber enriched with carbogen gas at 37 °C using collagenase CLS II (5–10 mg/ml, 10–12 min) and trypsin (0.2–1 mg/ml, 10–12 min) dissolved in F12 medium. After trituration (4–6 times with a Pasteur pipette) neurons are plated in 35-mm culture dishes, which also serve as recording chambers, and stored at 37 °C in a humidified 5% CO_2 atmosphere before used for electrophysiological recordings.

Only round or oval-shaped neurons without any processes are included in the study. The average of the major and the minor diameter is used to measure the size of oval shaped neurons. Whole cell patch-clamp experiments are performed in carbogen gas saturated F12 medium (pH 7.4) at room temperature using an Axopatch 200A amplifier (Axon Instruments) in voltage-clamp mode at a holding potential of –80 mV controlled by pCLAMP6 software. Data are also registered on a chart recorder. Patch pipettes are fabricated from borosilicate glass using a horizontal micropipette puller and filled with a solution containing (in mM) 160 KCl, 8.13 EGTA, 10 HEPES (pH 7.2, $R_{Tip} = 5.3 \pm 0.2$ MΩ, mean ±SE). Cell diameter, cross sectional area, and membrane capacitance are measured, and excitability is tested by depolarizing voltage steps for each neuron. Cells lacking a fast inward current with a reversal potential close to the equilibrium potential of sodium followed by a prolonged outward current are excluded from further investigation. Experiments in current-clamp mode are performed to measure the resting membrane potential of each neuron and to investigate single action potentials elicited by short (3 ms) depolarizing current pulses in neurons that are hyperpolarized by constant current injection resulting in membrane potentials between –70 and –80 mV. Inflections in the repolarizing phase are qualitatively detected as second negative peak in the first derivative (dV/dt) of each action potential; the duration of repolarization is quantitatively assessed by the 10–90% decay time.

Applications of ~50 µl of heated extracellular solution through a puffing system fixed on a micromanipulator is used to elicit heat-evoked currents. Control measurements with a fast temperature sensor (BAT-12, Physitemp; $\tau = 5$ ms) in place of the neurons are made revealing an effective temperature of ~53 °C, a rise time of ~250 ms, and a decay with a time constant of ~20 s. Effects are compared with those of application of the same amount of medium at room temperature. Heat stimuli with or without vanilloid receptor antagonists and control applications at room temperature are repeated 2–10 times, and the elicited currents are averaged. A neuron is considered as heat sensitive when the heat-evoked inward current is significantly greater than any fluctuations caused by superfusion of solution at room temperature. Heating the buffered solution may change its pH, and acid solution of pH 6.2 are known to activate nociceptive dorsal root ganglion neu-

rons (Bevan and Yeats 1991). The pH of a HEPES-buffered solution decreases while heating (e.g., pH 7.1 at 50 °C). In contrast, higher temperatures increase the pH of a $NaHCO_3/CO_2$ buffer, because the solubility of CO_2 is reduced and thus reverses the HEPES effect. The pH of the F12 medium maximally changes in a range of 7.28–7.52 while heating to 50 °C and cooling down to room temperature. The membrane conductance is measured in voltage-clamp mode by hyperpolarizing pulses (5 mV, 10 ms, 50 s^{-1}), and conductance changes are determined at the maximum amplitude of heat evoked currents.

Reversal potentials of heat- and capsaicin-induced currents are measured as described by Liu et al. (1997) using fast depolarizing ramps (–80 to +30 mV in 22 ms every 550 ms). Patch pipettes are filled with a potassium-free solution containing (in mM) 140 CsCl, 10 HEPES, 10 EGTA, and 4 $MgCl_2$ (adjusted to pH 7.2). Tetrodotoxin (100 µM) and nifedipine (1 µM) are added to the extracellular solution to block voltage gated Na^+ and Ca^{2+} channels. Capsaicin is dissolved in ethanol, diluted to its final concentration with F12 medium, and applied through the puffing system. Capsazepine (dissolved in DMSO) and ruthenium red are prepared as concentrated stock solutions, diluted to final concentration in F12 medium, and applied either at room temperature or at ~53 °C. Reversibility of antagonist action is tested by reapplication of heated extracellular solution without any agents.

EVALUATION

Off-line measurements and statistical analysis is done using pCLAMP6 (Axon Instruments) and EXCEL 5.0 (Microsoft). Data are presented as means ±SE. Treatment effects are statistically analyzed by Student's *t*-test for paired data and χ^2 test for analysis of incidences.

MODIFICATIONS OF THE METHOD

Nagy et al. (1983) described dose-dependent effects of capsaicin on primary sensory neurons in the neonatal rat.

Lopshire and Nicol (1998) performed whole-cell and single-channel studies in rat sensory neurons and found a prostaglandin E_2 induced enhancement of the capsaicin elicited current.

Jung et al. (1999) performed patch-clamp experiments in dorsal root ganglion neurons of neonatal rats and concluded that capsaicin binds to the intracellular domain of the capsaicin-activated ion channel.

Nagy and Humphrey (1999) compared the membrane responses of rat sensory neurons to noxious heat and capsaicin, using electrophysiological and ion flux measurements.

Baumann and Martenson (2000) found that extracellular protons both increase the activity and reduce the conductance of capsaicin-gated channels.

Liu et al. (2001) investigated mechanisms underlying capsaicin-mediated inhibition of action potentials and modulation of voltage-gated sodium channels in cultured trigeminal ganglion neurons.

H.1.2 *In vivo* methods for testing central analgesic activity

H.1.2.1 General considerations

Although the *in vivo* methods have been used more extensively in the past, they are still necessary in present research analgesic tests in animals before a compound can be given to man. Mostly, rodents, such as

mice or rats, are used for analgesic tests, but in some instances experiments in higher animals such as monkeys are necessary.

Several methods are available for testing central analgesic activity, such as

- HAFFNER's tail clip method in mice,
- tail flick or other radiant heat methods,
- tail immersion tests,
- hot plate methods in mice or rats,
- electrical stimulation (grid shock, stimulation of tooth pulp or tail),
- monkey shock titration,
- formalin test in rats.

H.1.2.2 HAFFNER's tail clip method

PURPOSE AND RATIONALE

The method was described as early as 1929 by Haffner who observed the raised tail (Straub phenomenon) in mice treated with morphine or similar opioid drugs and found the tail after drug treatment to be less sensitive to noxious stimuli. He already described the high sensitivity of this method to morphine. Since then, the method has been used and modified by many authors.

PROCEDURE

An artery clip is applied to the root of the tail of mice and the reaction time is noted. Male mice (Charles River strain or other strains) with a weight between 18 and 25 g are used. The control group consists of 10 mice. The test compounds are administered subcutaneously to fed mice or orally to fasted animals. The test groups and the control group consist of 7–10 mice. The drug is administered 15, 30 or 60 min prior testing. An artery clip is applied to the root of the tail (approximately 1 cm from the body) to induce pain. The animal quickly responds to this noxious stimuli by biting the clip or the tail near the location of the clip. The time between stimulation onset and response is measured by a stopwatch in 1/10 seconds increments.

EVALUATION

A cut-off time is determined by taking the average reaction time plus 3 times the standard deviation of the combined latencies of the control mice at all time periods. Any reaction time of the test animals which is greater than the cut-off time is called a positive response indicative of analgesic activity. The length of time until response indicates the period of greatest activity after dosing. An ED_{50} value is calculated at the peak time of drug activity. ED_{50} values found by this method were 1.5 mg/kg s.c. for morphine and 7,5 mg/kg for codeine s.c.

CRITICAL ASSESSMENT OF THE TEST

The test does not need any sophisticated equipment but a skilled, preferably "blind", observer. Peripheral analgesics of the salicylate type are not detected by this test.

MODIFICATIONS OF THE METHOD

Bartoszyk and Wild (1989) described a modification of the original Haffner clip test using pressure on the tail of rats instead of mice. Additionally hyperalgesia was induced by injection of carrageenan suspension into the tail. In this case not only an effect of a nonsteroidal anti-inflammatory agent but also a potentiation by B-vitamins could be shown.

Takagi et al. (1966) published a modification of HAFFNER's method for testing analgesics.

Ossipov et al. (1988) used the Haffner test to compare the antinociceptive effects of intrathecally administered opiates, α_2-adrenergic agonists, and local anesthetics.

Yanagisawa et al. (1984) described a tail pinch method *in vitro* for testing antinociceptive drugs consisting of an isolated spinal cord, spinal nerve roots and the functionally connected tail of a new-born rat. Changes of electric potential in the ventral root are induced by noxious pressure on the tail. In addition, responses after electric stimulation of the dorsal root were recorded. The authors recommend the method for studying actions of analgesic drugs.

Pinch of the toes of guinea pigs was recommended as a test for opioid analgesics by Collier (1965).

Tail-pinch feeding in rats after intracerebroventricular injection of various opioid antagonists has been used to differentiate opioid receptor subtypes (Koch and Bodnar 1993).

Person et al. (1985) used three different techniques of mechanical tail stimulation (reaction threshold determined with an Analgesy-meter at two different cut-off values and HAFFNER's tail clip) to study morphine-caffeine analgesic interaction in rats.

Arndt et al. (1984) studied pain responses (increase of heart rate and arterial pressure, respiratory effects) to tail clamping in trained unanesthetized spontaneously breathing dogs after administration of fentanyl.

H.1.2.3 Radiant heat method

PURPOSE AND RATIONALE

Originally, the method was developed by Schumacher et al. (1940), Wolff et al. (1940) for quantitative measurements of pain threshold in man against thermal radiation and for evaluation of analgesic activity of opiates. Later on, the procedure has been used by many authors to evaluate analgesic activity in animal experiments by measuring drug-induced changes in the sensitivity of mice or rats to heat stress applied to their tails. The test is very useful for discriminating between centrally acting morphine-like analgesics and non-opiate analgesics.

Mice are placed into cages leaving the tail exposed. A light beam is focused to the proximal third of the tail. Within a few seconds the animal flicks the tail aside or tries to escape. The time until this reaction occurs is measured.

PROCEDURE

The method was described by Ther, Lindner and Vogel (1963) as a modification of earlier publications (D'Armour and Smith 1941). Groups of 10 mice (NMRI-strain) of both sexes with a weight between 18 and 22 g are used for each dose. Before administration of the test compound or the standard the normal reaction time is determined. The animal is put into a small cage with an opening for the tail at the rear wall. The tail is held gently by the investigator. By opening of a shutter, a light beam exerting radiant heat is directed to the proximal third of the tail. For about 6 s the reaction of the animal is observed by the investigator. The mouse tries to pull the tail away and turns the head. With a switch the shutter is closed as soon as the investigator notices this reaction. Mice with a reaction time of more than 6 s are not used in the test. The escape reaction which is the endpoint of this test can be regarded as a complex phenomenon mediated by the brain. In contrast, the simple tail flick as an endpoint of this test may be mediated as a spinal reflex. Therefore the observation of the escape reaction can be regarded as a true assessment of the influence of the drug on the brain.

The test compounds and the standard are administered either orally or subcutaneously. The animals are submitted to the same testing procedure after 30, 60 and eventually 120 min. For each individual animal the reaction time is noted. Other time intervals can be used according to the question to be investigated.

EVALUATION

There are two possibilities for evaluation:

- The average values of reaction time after each time interval are calculated and compared with the pretest value by analysis of significance.
- At each time interval only those animals which show a reaction time twice as high or higher as the pretest value are regarded as positive. Percentages of positive animals are counted for each time interval and each dose and ED_{50} values are calculated according to LITCHFIELD and WILCOXON.

As standards codeine, pethidine and morphine can be used. The ED_{50} values of these drugs are:

- Codeine 12 mg/kg s.c.
- Pethidine 12 mg/kg s.c.
- Morphine 2 mg/kg s.c.

CRITICAL ASSESSMENT OF THE TEST

The radiant heat test on the tail of mice is very effective to estimate the efficacy and potency of central acting analgesic drugs. With pyrazolones ED_{50} values still can be calculated but these are achieved only with relatively high doses. Compounds like acetylsalicylic acid

and phenyl-acetic acids show only slight effects making it impossible to calculate ED_{50} values.

MODIFICATIONS OF THE METHOD

Originally, the method has been described for testing analgesic properties in the rat (D'Armour and Smith 1941, Winter et al. 1954, Harris and Pierson 1964). Goldstein and Malseed (1979) adapted the procedure for utilization in **cats**. The effect of morphine could be antagonized by naloxone in this test. No response to sodium salicylate or pentobarbital was observed.

Lutz et al. (1994) used a modification of the rat tail withdrawal test to investigate the structure-activity profile of a series of opioid analgesics. One day before testing, polyethylene tubings were implanted in the femoral vein and externalized behind the neck for intravenous application of test substances.

Various instruments have been described for measuring tail flick latencies by several authors, e.g., Davies et al. 1946; Owen et al. (1981), Isabel et al. (1981), Walker and Dixon (1983), Yoburn et al. (1984), Harris et al. (1988).

Tail flick analgesy meters are commercially available (e.g., IITC Life Science, Woodland Hills, CA, USA).

Green and Young (1951) compared the heat and pressure analgesiometric methods in rats. Mohrland et al. (1983) described an ultrasound-induced tail-flick procedure.

Hargreaves et al. (1988), Costello and Hargreaves (1989), Hylden et al. (1991) exposed the plantar surface of hindpaws of unrestrained rats to a beam of radiant heat applied through the glass floor of a testing chamber. Paw withdrawal latency was automatically recorded by a photocell.

This method was also used by Schuligoi et al. (1994).

Taylor et al. (1997) used this method to investigate the brief (phase 1) and persistent (phase 2) nociceptive responses of rats after injection of dilute formalin into the hindpaw.

Carmon and Frostig (1981) used brief laser induced heat applied to the rat ear for pharmacological testing of analgesics.

Perkins et al. (1993), Perkins and Kelly (1993) used ultra-violet-induced hyperalgesia in rat paw. Female Sprague-Dawley rats weighing about 100 g were exposed on the plantar surface of one hind paw to UV light (intensity maximum 365 nm, 69 mW/cm^2) for 90 s and this was repeated 18 h later. On the following days, each group of rats was placed in a transparent Perspex box and the withdrawal threshold to a focused beam of radiant heat applied to the underside of each hind paw was measured.

McCallister et al. (1986) directed radiant heat to the **ears of rabbits** and measured ear-withdrawal time.

H.1.2.4 Hot plate method

PURPOSE AND RATIONALE

The paws of mice and rats are very sensitive to heat at temperatures which are not damaging the skin. The responses are jumping, withdrawal of the paws and licking of the paws. The time until these responses occur is prolonged after administration of centrally acting analgesics, whereas peripheral analgesics of the acetylsalicylic acid or phenyl-acetic acid type do not generally affect these responses.

PROCEDURE

The method originally described by Woolfe and Mac Donald (1944) has been modified by several investigators. The following modification has been proven to be suitable:

Groups of 10 mice of either sex with an initial weight of 18 to 22 g are used for each dose. The hot plate, which is commercially available, consists of a electrically heated surface. The temperature is controlled for 55° to 56 °C. This can be a copper plate or a heated glass surface. The animals are placed on the hot plate and the time until either licking or jumping occurs is recorded by a stop-watch. The latency is recorded before and after 20, 60 and 90 min following oral or subcutaneous administration of the standard or the test compound.

EVALUATION

The prolongation of the latency times comparing the values before and after administration of the test compounds or the values of the control with the experimental groups can be used for statistical comparison using the *t*-test. Alternatively, the values which exceed the value before administration for 50% or 100% can be regarded as positive and ED_{50} values can be calculated.

Doses of 7.5 mg/kg s.c. morphine hydrochloride, 30 mg/kg s.c. codeine hydrochloride, 30 mg/kg s.c. pethidine hydrochloride and 400 mg/kg s.c. phenazone were found to be effective, whereas aspirin showed no effect even at high doses.

CRITICAL ASSESSMENT OF THE TEST

The hot plate test has been used by many investigators and has been found to be suitable for evaluation of centrally but not of peripherally acting analgesics. Mice as well as rats have been used. The method has the drawback that sedatives and muscle relaxants (Woolfe and MacDonald 1944) or psychotomimetics (Knoll 1967) cause false positives, while mixed opiate agonists-antagonists provide unreliable results. The validity of the test has been shown even in the presence of substantial impairment of motor performance (Plummer et al. 1991). Mixed opiate agonists-antagonists can be evaluated if the temperature of the hot plate is lowered to 49.5 °C (O'Callaghan and Holtzman 1975; Zimer et al. 1986).

MODIFICATIONS OF THE METHOD

O'Neill et al. (1983) described an automated, high-capacity method for measuring jump latencies on a hot plate. A hot-plate test with increasing temperature was recommended by Tjølsen et al. (1991).

Hot plate analgesy meters are commercially available (e.g., IITC Life Science, Woodland Hills, CA, USA).

H.1.2.5 Tail immersion test

PURPOSE AND RATIONALE

The method has been developed to be selective for morphine-like compounds. The procedure is based on the observation that morphine-like drugs are selectively capable of prolonging the reaction time of the typical tail-withdrawal reflex in rats induced by immersing the end of the tail in warm water of 55 °C.

PROCEDURE

Young female Wistar rats (170–210 g body weight) are used. They are placed into individual restraining cages leaving the tail hanging out freely. The animals are allowed to adapt to the cages for 30 min before testing. The lower 5 cm portion of the tail is marked. This part of the tail is immersed in a cup of freshly filled water of exactly 55 °C. Within a few seconds the rat reacts by withdrawing the tail. The reaction time is recorded in 0.5 s units by a stopwatch. After each determination the tail is carefully dried. The reaction time is determined before and periodically after either oral or subcutaneous administration of the test substance, e.g., after 0.5, 1, 2, 3, 4 and 6 h. The cut off time of the immersion is 15 s. The withdrawal time of untreated animals is between 1 and 5.5 s. A withdrawal time of more than 6 s therefore is regarded as a positive response.

EVALUATION

ED_{50} values can be calculated for each compound and time response curves (onset, peak and duration of the effect) be measured. All the morphine-like analgesics have been shown to be active at doses which do not produce gross behavioral changes. For example, an ED_{50} of 3.5 mg/kg s.c. for morphine and an ED_{50} of 1.7 mg/kg s.c. methadone was found. Acetylsalicylic acid at a dose of 640 mg/kg p.o., phenylbutazone at a dose of 160 mg/kg s.c. as well as nalorphine at a dose of 40 mg/kg s.c. were inactive.

CRITICAL ASSESSMENT OF THE METHOD

The test is useful to differentiate central opioid like analgesics from peripheral analgesics.

MODIFICATIONS OF THE TEST

Ben-Bassat et al. (1959) described the receptacle method in mice. Each mouse was inserted in a conoid paper receptacle with its tail protruding, the cone being closed by a stapler. The protruding tail was entirely immersed in a water bath (58 °C) and the time until withdrawal of the tail was measured by a stop watch.

Pizziketti et al. (1985) modified the tail immersion test in rats in this way that they used a 1 : 1 mixture of ethylene-glycol and water **cooled** to a temperature of minus 10 °C as noxious stimulus. Linear dose-response curves were found with levo-methadone and morphine. Low ceiling effects or curvilinear dose-response curves were obtained with narcotic agonist- antagonist analgesics such as pentazocine. Diazepam and aspirin were inactive.

Tiseo et al. (1988) could show that the endogenous kappa agonist dynorphin A was inactive in the rat tail immersion test at 55 °C, but gave dose-response curves in the cold water version of the test.

Abbott and Melzack (1982) examined the effects of brainstem lesions on morphine analgesia using the formalin test which produced moderate pain that lasted about 2 h, and the tail-flick hot water-immersion test which measured brief threshold-level pain.

Abbott and Franklin (1986) used two forms of the rat tail flick test: In the restrained form of the test rats were placed in wire restraining tubes from 10 min before drug injection till the end of the test. In the unrestrained form of the test rats were left free in their home

cages and handheld during each test for approximately 30 s. Responses to the thermal pain stimulus were assessed by the latency with which the rat removed its tail from 55 °C water. Two types of morphine analgesia have been postulated in animals: One type, exemplified in rats that are restrained during tail flick testing, is sensitive to an interaction between morphine and brain 5-HT, the level of which is elevated by restrained stress (Kelly and Franklin 1984).

Luttinger (1985) determined the antinociceptive activity of drugs using different water temperatures in a tail-immersion test in mice. The results roughly paralleled the differences in the severity of pain for which various analgesics are effective.

Dykstra et al. (1986, 1987) described a tail withdrawal procedure for assessing analgesic activity in **Rhesus monkeys** by immersion of the tail into water of 55 °C. This procedure was used by Rothman et al. (1989) to determine the pharmacological activities of optically pure enantiomers of the κ opioid agonist, U50,488, and its cis diastereomer.

Using this method, Ko et al. (1999) found that activation of peripheral κ opioid receptors inhibits capsaicin-induced nociception in Rhesus monkeys.

H.1.2.6 Electrical stimulation of the tail

PURPOSE AND RATIONALE

Since the tail of mice is known to be sensitive to any stimulus, a method of electrical stimulation has been described as early as 1950 by Burn et al. The stimulus can be varied either by the duration of the electric shock or by an increase in the electric current.

PROCEDURE

As described by Kakunaga et al. (1966), male mice with a weight of 20 g are placed into special cages. A pair of alligator clips is attached to the tail whereby the positive electrode is placed at the proximal end of the tail. Rectangular wave pulses from a constant voltage stimulator at an intensity of 40–50 V are applied. The frequency of the stimulation is 1 shock/s, and the pulse duration 2.5 ms. The normal response time range of the stimuli is 3–4 s. Following administration of the drug, the response time is registered at 15 min intervals until the reaction time returns to control levels.

EVALUATION

The data for each animal are plotted with reaction times on the ordinate and time intervals following administration on the abscissa. The area under the time response curve is calculated. In control animals the reaction time remains fairly constant and the area under the curve is

approximately zero. Effects of morphine at 5 mg/kg s.c. and meperidine 30 mg/kg s.c. could easily be demonstrated.

CRITICAL ASSESSMENT OF THE METHOD

The effect of central analgesics can be clearly demonstrated, however also the activity of peripheral analgesics given at higher doses can be detected.

MODIFICATIONS OF THE METHOD

Vidal et al. (1982) measured the thresholds of 3 nociceptive reactions (tail withdrawal, vocalization, vocalization afterdischarge) following electrical stimulation of the tail.

A variation of the test has been introduced by Yanaura et al. (1976), using ultrasonic stimulation instead of electric stimulation. The method is considered to be fast, simple, and precise. The stimulus can be applied repeatedly without causing injury to the tissue.

A vocalization test in rats with electrical stimulation of the tail has been described by Hoffmeister (1968).

Ludbrook et al. (1995) described a method for frequent measurement of sedation and analgesia in sheep using the response to a ramped electrical stimulus. Sheep were placed in a canvas sling in their metabolic crates to allow their limbs to partially bear weight in order to minimize spontaneous limb movements. Two needles were placed subcutaneously 0.5 cm apart in the anterior aspect of the lower third of the sheep's hind and connected to the nerve stimulator. The current ramp rate was set at one mA per sec. As soon as limb withdrawal was observed, the stimulus was switched off and the highest current and ramp duration were recorded.

H.1.2.7 Grid shock test

PURPOSE AND RATIONALE

The electric grid shock test in mice has been described by Blake et al. (1963) as a modification of an earlier approach (Evans 1962) to measure the analgesic properties by the "Flinch-jump" procedure in rats.

PROCEDURE

Male mice with a weight between 18 and 20 g are individually placed into clear plastic chambers. The floor of the box is wired with tightly strung stainless steel wire, spaced about 1 mm apart. The stimulus is given in the form of square wave pulses, 30 cycles per second with a duration of 2 ms per pulse. The output of the stimulator has to be connected to alternate wires of the grid. A fixed resistance is placed in series with the grid and in parallel to an oscilloscope to allow calibration in milliamperes. With increasing shock intensities the mice flinch, exhibit a startling reaction, increase locomotion or attempt to jump. The behavior is accurately reflected on the oscilloscope by marked fluctuations of the displayed pulse and defined as pain threshold response. Pain thresholds are determined in each individual mouse twice before administration of the test drug and 15, 30, 60, 90 and 120 min after dosing. Groups of 10 animals are used for control and for the test drugs.

EVALUATION

The current as measured in milliamperes is recorded for each animal before and after administration of the drug. The average values for each group at each time interval are calculated and statistically compared with the control values. Placebo treated controls show a slight increase of threshold over time. Morphine sulfate in a dose of 10 mg/kg p.o. but also acetylsalicylic acid in a dose of 200 mg/kg p.o. definitely increase the threshold.

CRITICAL EVALUATION OF THE METHOD

The modification of the method as described by Blake et al. (1963) showed an effect not only of morphine but also of acetylsalicylic acid which is not easily picked up by other tests based on stimulation by physical means.

MODIFICATIONS OF THE TEST

Weiss and Laties (1961) in a "fractional escape" procedure trained animals to press a lever to reduce the intensity of shock delivered continuously through the floor grids of the experimental chamber. Each time, the rat depresses the lever, it reduces the intensity of the shock. An external timer is programmed to increase the intensity of the shock every few seconds. If the animal fails to press the lever, the shock continues to increase in intensity until lever-pressing behavior drives it down. Thus, the level of shock fluctuates depending on the rat's lever pressing. The action of an analgesic in altering the level of shock which the rat will "tolerate" can than be measured by comparing the average level at which the rat maintains the shock under control conditions with the average level at which the rat maintains the shock during treatment.

Painful stimulation of the paws of mice placed into cages equipped with metal bands for electrical stimulation was described by Charlier et al. (1961) as "pododolorimetry".

A modification of the jump-flinch technique for measuring pain sensitivity in rats based on four cate-gories of responses was described by Bonnet and Peterson (1975).

Eschalier et al. (1988) described an automated method to analyze vocalization of unrestrained rats submitted to noxious stimuli.

H.1.2.8 Tooth pulp stimulation

PURPOSE AND RATIONALE

The method has been first described by Kohl and Reffert (1938) and by Ruckstuhl and Gordanoff (1939) for testing central analgesic activity in rabbits and has since applied by several authors to various animal species. Stimulation of the tooth pulp induces characteristic reactions, such as licking, biting, chewing and head flick which can be observed easily.

PROCEDURE

Rabbits of either sex with an weight between 2 and 3 kg are anaesthetized with 15 mg/kg thiopental or 0.2 mg/kg fentanyl-citrate intravenously. Pulp chambers are exposed close to the gingival line in the lateral margins of the two front upper incisors with a high-speed dental drill. On the day of the experiment, clamping electrodes are placed into the drilled holes. After an accommodation period of 30 min stimulation is started to determine the threshold value. The stimulus is applied by rectangular current with a frequency of 50 Hz and a duration of the stimulus of 1 s. The electrical current is started with 0.2 mA and increased until the phenomenon of licking occurs. In some cases, the current has to be increased and than to be decreased again in order to find the appropriate threshold. For assessing the basic value, the threshold is determined 3 times in each animal. Each animal serves as its own control. For testing analgesic activity of a new drug and determination of an ED_{50} 8 to 10 animals are used for each dose of the analgesic. The test substance is either injected intravenously or given orally by gavage. The threshold as the indicator of the antinoci-ceptive effect is determined again after 15, 30, 60 and 120 min. The animals serve as their own controls. Threshold current is determined again 5, 15, 30, 45 and 60 min after intravenous application and 15, 30, 60 and 120 min after oral application.

EVALUATION

For screening procedures the increase of threshold, expressed in mV, is the indicator of intensity and duration of the analgesic effect. For determination of the ED_{50}, 8 to 10 rabbits are used for each dose, using 3 doses, which provided effects between 10 and 90%. An antinociceptive effect is defined as an increase of

the threshold versus the initial control by a factor of 2 or more.

CRITICAL ASSESSMENT OF THE METHOD

Central analgesics, especially opioid agonists, have been found to be very active in this test. Compared with other tests for central analgesic activity, like the hot plate test in mice, the tests result in lower ED_{50}-values indicating a high sensitivity of the method. In addition, non-opiate analgesics like ketamine and peripheral analgesics like pyrazolone derivatives gave a positive response.

MODIFICATIONS OF THE METHOD

The method has been performed primarily in rabbits (Hertle et al. 1957; Hoffmeister 1962, 1968; Piercey and Schröder 1980), but also **dogs** (Koll and Fleischmann 1941; Skinkle and Tyers 1979) and **cats** (Mitchell 1964) have been used.

Among several methods in different species, Fleisch and Dolivo (1953) found the electrical stimulation of the tooth pulp in the rabbit as the only satisfactory method to test the efficacy of different analgesic drugs.

The effects of tooth pulp stimulation in the thalamus and hypothalamus of the **rat** have been investigated by Shigena et al. (1973).

The method has been adapted for freely moving rats (Steinfels and Cook 1986). Medium effective doses could be determined for μ and κ agonists. Non-steroidal anti-inflammatory drugs were also effective in this test procedure, but the slopes of the dose-response curves for these compounds were lower than for the opioid analgesics.

Microinfusion of bradykinin solution onto the tooth pulp of unrestrained rats was described by Foong et al. (1982) as a reliable method for evaluating analgesic potencies of drugs on trigeminal pain.

Kidder and Wynn (1983) described an automatic electronic apparatus for generating and recording a ramp stimulus for analgesia testing.

Thut et al. (1995) used the rabbit tooth-pulp assay to quantify efficacy and duration of antinociception by local anesthetics infiltrated into maxillary tissues.

Shyu et al. (1984) studied the role of central serotoninergic neurons in the development of dental pain in the **monkey**.

H.1.2.9 Monkey shock titration test

PURPOSE AND RATIONALE

Generally, analgesic tests in rats and mice result in correlation with the analgesic activity of a drug in man. To clarify the mode of action in more detail and to find a suitable dose for therapy in man, experiments in monkeys may be necessary.

PROCEDURE

This test has been recommended by Weiss and Laties (1958) and later developed further by several authors. The monkeys are seated in restraining chairs. Electrical current is delivered by a Coulbourn Instrument Programmable Shocker through electrodes coupled to two test tube clamps which are attached to a shaved portion of the tail. The current ranges from 0 to 4 mA through 29 progressive steps. The monkey presses a bar to interrupt the shock. A stable baseline shock level is established for each monkey on the day prior to drug administration. After drug administration shock titration activity is rated according to the change in maximum level of median shock intensity attained for drug as compared to control levels. Doses of 3.0 mg/kg i.m. morphine, 1.7 mg/kg i.m. methadone and 10 mg/kg i.m. pentazocine were found to be effective.

CRITICAL ASSESSMENT

The monkey shock titration test may be used for final evaluation of a new compound before administration to man. For screening activities the procedure can not be recommended since the test is too time consuming and the apparatus too complicated. Furthermore, higher animals such as monkeys should only be used if absolutely necessary.

H.1.2.10 Formalin test in rats

PURPOSE AND RATIONALE

The formalin test in rats has been proposed as a chronic pain model which is sensitive to centrally active analgesic agents by Dubuisson and Dennis (1977).

PROCEDURE

Male Wistar rats weighing 180–300 g are administered 0.05 ml of 10% formalin into the dorsal portion of the front paw. The test drug is administered simultaneously either sc. or orally. Each individual rat is placed into a clear plastic cage for observation. Readings are taken at 30 and 60 min and scored according to a pain scale. Pain responses are indicated by elevation or favoring of the paw or excessive licking and biting of the paw. Analgesic response or protection is indicated if both paws are resting on the floor with no obvious favoring of the injected paw.

EVALUATION

Using various doses, ED_{50} values for protection can be calculated. Doses of 1.7 mg/kg morphine s.c. and 15 mg/kg s.c. pethidine were found to be effective.

CRITICAL ASSESSMENT

The formalin test identifies mainly centrally active drugs, whereas peripherally acting analgesics are almost ineffective. Therefore, the formalin test may allow a dissociation between inflammatory and non-inflammatory pain, a rough classification of analgesics according to their site and their mechanism of action (Chau 1989). Cowan (1990) underlined the aspect that the formalin-test is a model of chronic pain whereas most other methods measure only the effect on acute pain.

MODIFICATIONS OF THE METHOD

Murray et al. (1988) used **mice** instead of rats. They injected 0.020 ml of 5% formalin solution into the subplantar region of the hind paw. Morphine at a dose of 2.1 mg/kg s.c. and pentazocine at a dose of 23.8 mg/kg s.c. were active whereas the cyclooxygenase inhibitor zomepirac was inactive even at a dose of 100 mg/kg s.c.

Hunskaar et al. (1986), Hunskaar and Hole (1987) injected a small amount of formalin (20 µl of 1% so-

lution) under the skin of the dorsal surface of the right hind paw of mice. A biphasisic response with an early (0–5 min) and a late (20–30 min) phase with high licking activity was observed. Central acting analgesics were active in both phases, whereas non-steroidal antiinflammatory drugs and corticosteroids inhibited only the late phase. Acetylsalicylic acid and paracetamol were antinociceptive in both phases.

Shibata et al. (1989) again used lower concentrations of formalin (0.025 ml of 0.5% formalin solution) and also mice instead of rats. They found a characteristic biphasic pain response. Centrally acting drugs such as morphine inhibited both phases, whereas according to their data peripherally acting drugs such as acetylsalicylic acid, oxyphenylbutazone and corticosteroids inhibited only the second phase.

Abbott et al. (1995) used the formalin test for scoring properties of the first and second phases of the pain response in rats.

Abbadie et al. (1997) determined the pattern of c-fos expression in the rat spinal cord to study the two phases of the formalin test.

Clavelou et al. (1989) and Dallel et al. (1995) used a modification of the formalin test for assessing pain and analgesia in the **orofacial region of the rat**. After injection into the upper lip, pain intensity was evaluated by the animal's behavior of rubbing of the injected area. A subcutaneous injection of 0.05 ml of 0.92% formaldehyde solution was made into the upper lip, just lateral to the nose. Following injection, the rat was immediately brought back in a test box equipped with a videocamera for a 45 min observation period. The recording time was divided into 15 blocks of 5 min and a pain score was determined for each block, by measuring the number of seconds that the animals spent rubbing the injected area with the ipsilateral fore- or hindpaw. The animals were sacrificed after the end of the experiment to avoid unnecessary suffering.

Tjølsen et al. (1992) attributed the early phase to C-fibre activation, whereas the late phase appeared to be dependent on the combination of an inflammatory reaction in the peripheral tissue and functional changes in the dorsal horn of the spinal cord.

Alreja et al. (1984) used the formalin test for assessing pain in **monkeys** after volunteering of one of the authors to carry out the same procedure on himself.

Corrêa and Calixto (1993) studied the participation of B_1 and B_2 kinin receptors in the formalin-induced nociceptive response in the **mouse**. Pain response was increased after ACE-inhibition and decreased by bradykinin receptor antagonists.

Herman and Felinska (1979) proposed a rapid test for screening of narcotic analgesics in mice by evaluation of behavioral symptoms after subcutaneous injection of EDTA.

Legat et al. (1994), Dumas et al. (1997) induced hyperalgesia in rats by subplantar injection of collagenase (100 µg in 100 µl saline) and rated the behavioral reactions after treatment with analgesics according to a modified formalin-test.

H.1.2.11 Experimental neuropathy

PURPOSE AND RATIONALE

Partial injury to somatosensory nerves sometimes causes causalgia in humans. Causalgia is characterized by spontaneous burning pain combined with hyperalgesia and allodynia and usually follows an incomplete peripheral nerve injury. Allodynia, a pain sensation due to normally innocuous stimulation, is a particularly troublesome symptom in patients. Bennet and Xie (1988) described a peripheral neuropathy due to nerve constriction in the rat that produces disorders of pain sensation like those seen in man. This method with slight modifications was used by Davar et al. (1991), Mao et al. (1992), Munger et al. (1992), Yamamoto and Yaksh (1992), Tal and Bennet (1993) and reviewed by Bennett (1993).

PROCEDURE

Anesthesia is induced in male Sprague-Dawley rats by inhalation with halothane 4% and maintained at a concentration of 2–3% as needed. After a local incision, the biceps femoralis of each leg is bluntly dissected at midtigh to expose the sciatic nerve. Each nerve is then mobilized with care taken to avoid undue stretching. Four 4-0 chromic gut sutures are each tied loosely with a square knot around the right sciatic nerve. The left sciatic nerve is only mobilized. Both incisions are closed layer to layer with silk sutures and the rats allowed to recover. During the next days, the animals show a mild eversion of the affected paw and a mild-to-moderate degree of foot drop.

The thermal nociceptive threshold is measured according to the method of Hargreaves et al. (1988), (see H.1.2.3). The rats are placed beneath a clear plastic cage ($10 \times 20 \times 24$ cm) upon an elevated floor of clear glass. A radiant heat source (halogen projector lamp) is placed beneath the glass floor on a movable holder and positioned such that is focuses at the plantar area of one hind paw. The time interval between the application of the light beam and the brisk hind paw withdrawal response is measured to the nearest 01. sec.

The maximum hyperesthesia occurs between 7 and 14 days after nerve ligation. Before intrathecal injection of the drug or vehicle, the hind paws are tested 3 times alternatively with 5-min intervals as the baseline data. The left and right test sequence is carried out at 5, 15, 30, 60 and 90 min after injection.

EVALUATION

The mean ±SEM of the paw withdrawal latency (PWL) is plotted. To analyze the magnitude of hyperesthesia, the difference score (DS) is calculated by subtraction the maximum PWL of the control side (left side) from the maximum PWL of the affected side (right side). Maximum PWL is defined as the PWL which was the maximum during the first 30 min after injection. To analyze the drug effects in hyperesthetic rats, the dose is plotted against the change in DS (post-drug difference score minus pre-drug difference score).

MODIFICATIONS OF THE METHOD

The first animal model of painful neuropathy was reported by Wall et al. (1979a,b).The sciatic nerve of rats or mice was sectioned and either tied or implanted in a polyethylene tube sealed at its far end. Moreover, in one modification also the saphenous nerve was cut, such that the hind paw was completely denervated. This procedure which is known as the neuroma model is believed to replicate the human syndromes seen after amputation (phantom pain) or after nerve transection in an intact limb (anesthesia dolorosa). Within several days, the animals begin to self-mutilate the hindpaw on the side of the nerve transection: a behavior named 'autotomy'.

Seltzer et al. (1990) ligated only one half of the sciatic nerve in rats unilaterally. The withdrawal thresholds to repetitive von Frey hair stimulation at the plantar side were decreased bilaterally as were the withdrawal thresholds to CO_2 laser heat pulses. The contralateral phenomena resemble the 'mirror image' pains in humans with causalgia.

DeLeo et al. (1994) performed cryoneurolysis of the sciatic nerve in the rat using a cryoprobe cooled to –60 °C in a 30/5/30 s freeze-thaw-freeze sequence. Autotomy was observed after 4 to 14 days.

Kim and Chung (1992) described an experimental model for peripheral neuropathy produced by segmental spinal nerve ligation in the rat. Either both the L_5 and L_6 spinal nerves or the L_5 spinal nerve alone of one side of the rat were tightly ligated.

Zochodne et al. (1994) induced a segmental chronic pain syndrome by lumbar intrathecal NMDA infusion.

Malmberg and Yaksh (1992) reported that hyperalgesia mediated by spinal glutamate or substance P receptor is blocked by spinal cyclooxygenase inhibition.

Sotgiu et al. (1996) performed laminectomy from L1 to S2 in anesthetized rats with sciatic chronic constriction injury. For extracellular recording, two tungsten microelectrodes were positioned under a dissecting microscope on the surface of the spinal cord at L2 and L5–L6 level ipsilaterally to the injured nerve, and were advanced at steps of 2 µm. Neuronal activity was conventionally recorded and then digitized; frequency histograms were constructed by computer programs. The search stimulus for dorsal horn neurons at L2 and L5-6 segments was the electrical stimulation of saphenous and sciatic nerve peripheral territories. Natural stimuli (brushing of the skin) and noxious stimuli (calibrated pinching) were defined. After the responses to saphenous stimuli in the neurons were recorded, a small pad of gel-foam soaked with 0.5 ml lidocaine was placed around the intact epineurium proximally to the ligatures on the sciatic nerve. The saphenous stimulation was repeated during the block and after complete recovery of the preblock baseline activity. In this way, the effect of the local anesthetic on the on the spontaneous activity and on the response to a noxious stimulus could be evaluated.

Idänpään-Heikkilä and Guilbaud (1999) used a rat model of **trigeminal neuropathic pain**, developed by Gregg (1973), Jacquin and Zeigler (1983), Vos and Maciewicz (1991), Vos et al. (1994), Vos and Strassman (1995), where the neuropathy is produced by a chronic constriction injury of the infra-orbital branch of the trigeminal nerve, and studied the effects of various drugs on this purely sensory model of neuropathic pain. The head of the rat, which was anesthetized with sodium pentobarbital 50 mg/kg i.p. and treated with 0.4 mg/kg atropine i.p., was fixed in a stereotaxic frame. A mid-line scalp incision was made exposing skull and nasal bone. To expose the intra-orbital part of the left infra-orbital nerve, the edge of the orbit, formed by the maxillary, frontal, lacrimal and zygomatic bones, was dissected free. To give access to the infra-orbital nerve, the orbital contents were gently deflected with a cotton-tipped wooden rod. The infra-orbital nerve was dissected free at its most rostral extent of the orbital cavity, just caudal to the infra-orbital foramen. Two chromic catgut (5-0) ligatures (2 mm apart) were loosely tied around the infra-orbital nerve. The ligatures reduced the diameter of the nerve by just a noticeable amount and retarded, but did not interrupt the epineural circulation. The scalp incision was closed with silk sutures.

Before the first actual stimulation session, the rats were allowed to adapt to the observation cage and to the testing environment. During this period, the experimenter reached slowly into the cage to touch the walls with a plastic rod, similar to the ones on which the von Frey filaments were mounted.

For mechanical stimulation, a graded series of ten of von Frey filaments with a bending force between 0.217 and 12.5 g was used. The stimuli were applied within the infra-orbital nerve territory, near the center of the vibrissal pad, on the hairy skin surrounding the mystacial vibrissae. The complete series of von Frey hair intensities was presented in an ascending series and either a brisk withdrawal of the head or an attack/escape reaction was considered as the mechanical threshold. Local injection of an local anesthetic (articaine) into the rostral orbital cavity of the lesioned side, into the close proximity of the ligated infra-orbital nerve increased the mechanical threshold to the upper level. The duration of the effect was dose-dependent.

In order to simulate pain experienced by humans in migraine attacks, Storer and Goadsby (1997) developed a model of **craniovascular pain in cats** by stimulating the superior sagittal sinus and monitoring trigeminal neuronal activity using electrophysiological techniques.

Cats were anesthetized with α-chloralose (60 mg/kg i.p.), paralyzed (gallamine 6 mg/kg i.v.) and ventilated. The superior sagittal sinus was accessed and isolated for electrical stimulation by a mid-line circular craniotomy. The region of the dorsal surface of C_2 spinal cord was exposed by a laminectomy and an electrode placed for recording evoked activity from sinus stimulation and spontaneous activity of the same cells. Signals were amplified and monitored on-line. Cells were recorded that were activated by stimulation of the sinus and were also spontaneously activated. Cells fired with latencies consistent with Aδ and C fibres, generally firing three or four times per stimulus (0.3 Hz, 250 µs duration, 100 V) delivered to the sinus. Both evoked and spontaneous firing could be inhibited iontophoresis of serotonin $(5\text{-HT})_{1B/1D}$ agonists.

Mice that lack protein kinase C gamma (PKCγ) displayed normal response to acute pain stimuli, but they almost completely failed to develop a neuropathic pain syndrome after partial sciatic nerve section, and the neurochemical changes that occurred in the spinal cord after nerve injury were blunted (Malmberg et al. 1997).

H.1.3 Side effects of central analgesic drugs

H.1.3.1 General considerations

Morphine as the prototype of a central analgesic drug has characteristic side effects relevant to the treatment of patients. These are:

- Respiratory depression,
- Decrease of body temperature,
- Tolerance,
- Physical dependence,
- Abuse liability.

Since the ratio between therapeutic effect and side effects is already different between morphine and codeine, both natural alkaloids from opium, great effort has been made to synthesize compounds with a better ratio of analgesic activity versus side effects. Therefore, methods had to be developed to quantify these side effects in animal pharmacology. Moreover, the detection of a multitude of distinct types of receptors that can interact with opioid drugs or endogenous peptides (e.g. μ, κ, and δ receptor) allows a more selective classification of agonists, antagonists, or agonist-antagonists.

H.1.3.2 Test for respiratory depression

PURPOSE AND RATIONALE

Respiratory depression is one of the most troublesome side effects of opioids. Recent studies suggest that respiratory depression is mediated through μ_2 receptors. The frequency of breathing and the inspiratory volume can be affected differently and have to be measured.

PROCEDURE
Male or female rabbits with a body weight between 2.5 and 3 kg are placed in restraining cages. A mask is placed over the nose of the animals which is connected with a valve opening on exhaling and closing on inhaling. The frequency of breathing is recorded from the opening and closing of the valve. The inspiratory volume is measured with a gasometer. Intravenous injection of morphine hydrochloride in doses between 1 and 10 mg/kg results in a dose-dependent decrease respiratory frequency and respiratory volume. The doses are increased logarithmically after the effect of the preceding dose has subsided.

EVALUATION
Three animals are used for the test compound and the standard. Dose-response curves of the effect on respiratory frequency and volume are compared.

MODIFICATIONS OF THE METHOD
Nelson and Elliott (1967) compared the effects of morphine, morphinone and thebaine on respiration and oxygen consumption in rats.

Ling et al. (1983, 1985) measured blood gas values (pO_2, pCO_2, pH) in unrestrained rats via an arterial cannula. pO_2 and pH decreased whereas pCO_2 increased after morphine.

H.1.3.3 Decrease of body temperature

In rats a single injection of morphine produces a significant fall in body temperature which is more prominent in restrained than in freely moving animals. Since this side effect of opioid drugs is shared by several other compounds with no central analgesic activity, the test can not be regarded as specific.

H.1.3.4 Methods for the study of tolerance

PURPOSE AND RATIONALE
The radiant heat or the hot plate method for testing analgesic activity in mice is adopted to measure drug induced changes in the sensitivity to a noxious stimulus.

PROCEDURE
Male mice with an initial weight of 18–20 g are used. They are placed in restraining cages. A painful stimulus is produced by an intense light beam directed to the proximal part of the tail. The subject quickly responds to this stimulus by flicking its tail. The reaction time, the interval between stimulus onset and response, is automatically measured in $\frac{1}{10}$-s increments. Prior to drug administration, 2 control readings of reaction time are measured for each animal. After administration of the drug the test is repeated 15, 30, and 60 min after subcutaneous injection or 30, 60 and 120 min after oral administration. In this way, time of peak activity can be found. Mice showing a reaction time of the average control value plus 2 times the standard deviation in the control experiment are regarded as positive. Running dose-response experiments, ED_{50} values are calculated. Subsequently, the animals are treated for 5 days once every day with a dose which is 4 times higher than the ED_{50} in the first experiment. On the following day, dose-response curves are determined using at least 3 doses. The ED_{50} is calculated again.

EVALUATION
The increase of the ED_{50} values before and after subchronic treatment indicates the phenomenon of tolerance.

CRITICAL ASSESSMENT OF THE TEST
The phenomenon of tolerance is observed not only with opioid analgesics but with many other drugs such as barbiturates, benzodiazepines or ethanol. The measurement of analgesia after single and repeated administration, therefore, has to be regarded as a primary test. Demonstration that a new analgesic does not show a decrease of effectiveness after subchronic treatment with high doses indicates that it is free of the need to escalate dosage to maintain efficacy and represents the first step for establishing the absence of tolerance liability.

MODIFICATIONS OF THE METHOD

Other authors (e.g. Glassman 1971) injected the dose which induced complete analgesia in mice twice daily for a period of 21 days and evaluated the stepwise decay of effectiveness. After 21 days, the effect of 10 mg/kg morphine or 30 mg/kg meperidine i.p. decreased to approximately 50% of the value of the first day.

Langerman et al. (1995) evaluated the acute tolerance to continuous morphine infusion up to 8 h in the rat with various doses using the hot plate and the tail flick assay. Tolerance was observed with the hot plate assay but not with the tail flick assay indicating a supraspinal level of tolerance development.

H.1.3.5 Tests for physical dependence

PURPOSE AND RATIONALE

Abstinence phenomena similar to those in man after abrupt cessation of chronic treatment with opioid analgesics have been reported in rats and monkeys. On this basis, tests for drug dependence have been developed for monkeys (Seevers and Deneau 1963), for rats (Buckett 1964), and for mice (Way et al. 1969; Von Voigtlander and Lewis 1983).

Villarreal et al. (1977), Rodríguez at al (1978), Collier et al. (1979), Cruz et al. (1991) tested opiate abstinence responses in the guinea pig ileum made dependent *in vitro*.

Opiate abstinence responses in the guinea pig ileum made dependent *in vitro*

A 40-cm long segment of the small intestine of male guinea pigs weighing 600–900 g is removed and placed in a low-magnesium Krebs solution. The terminal section of the guinea pig ileum is used after discarding the portion of 10 cm closest to the ileo-caecal junction. The ileum is cut in eight 3-cm long segments. The intestinal content is gently removed with the aid of an glass rod. To produce opiate dependence, segments are incubated in 500 ml Erlenmeyer flasks containing 480 nM morphine in 250 ml Krebs solution saturated with a 95% O_2/5% CO_2 gas mixture at a temperature ranging between 4° and 6 °C for 1 to 48 h. One h before completion of the incubation time, the segments are removed, placed in glass chambers with 50 ml Krebs solution bubbled with 95% O_2/5% CO_2 gas mixture at 36 °C, mounted on a vertical nickrome electrode with one edge fixed to the chamber plug and the opposite fixed to an isometrical force transducer (Grass FT 03) connected to a polygraph for recording the contractile activity of the longitudinal muscle. The ilea are set up with an initial tension of 1 g and left for a period of 30 min for stabilization. Thereafter, all segments are electrically stimulated with supramaximal rectangular pulses (10–40 V) of 0.5-ms duration at a frequency of 0.1 H.

The response to naloxone is recorded by administration up to 100 nM after morphine exposition is completed. Five min before naloxone administration, the electrical stimulation is suspended. The response to the antagonist is recorded for 20 min and thereafter the electrical stimulation is reinitiated and maintained for 10 min.

Thirty-five min after naloxone administration, various doses of nicotine are administered.

For comparisons, a concentration-response curve for nicotine (1, 31., 5.6, 10, 31, and 56 μM) is obtained in fresh ilea. Moreover, the concentration-response curve for nicotine is obtained in ilea (1) exposed to 10 nM naloxone for 20 min; (2) exposed to 480 nM of morphine for 1 h; and pretreated 10 min with 3 or 10 nM of naloxone and exposed to 480 nM of morphine for 1 h. concentration-response curves for nicotine are depressed after pretreatment with morphine. This effect is dose-dependent antagonized by naloxone.

A correlation between the response to supramaximal electrical stimulation and the abstinence precipitated with 100 nM naloxone as well as a correlation between abstinence and nicotine response after long-term exposure (12–48 h) with 480 nM morphine.

Test for physical dependence in rats

Male albino rats are administered either morphine or saline intra-abdominally twice daily. The starting dose of morphine is 20 mg/kg followed by 40 mg/kg increments daily until by day 11 the level is 420 mg/kg. Maintenance at 400 mg/kg is continued through day 20. The test compound is similarly administered to groups of 10 rats. The daily increments have to be adjusted to a maximum level that is not lethal for the duration of the experiment.

Physical dependence capacity is measured on days 11 and 17 by injecting all animals with 10 mg/kg nal-

orphine i.p. in the morning. Withdrawal symptoms are recorded during a 30 to 60 min period. A 10 point score is used: writhing, 3; squealing, either spontaneous or provoked by touch, 2; diarrhea, 2; teeth chattering, 1; eyelid ptosis, 1; wet-dog-type shaking 1.

Physical-dependence sustaining potency is evaluated by substituting from day 20 through day 23 the test compound in the morphine-dependent rats and scoring for suppression of the abstinence syndrome.

Test for physical dependence in monkeys

Groups of 3 rhesus monkeys (1.5–2.8 kg body weight) are injected subcutaneously twice daily. Morphine is started at 2 mg/kg and increased by increments of 2 mg/kg until by day 20 each injection is 40 mg/kg. The test compound is similarly administered to groups of 3 monkeys. For the test compound, the daily increments are adjusted to a level that is not lethal for the duration of the experiment. The groups are then maintained at their appropriate dose levels through 112 days. On days 35, 60, and 91, 5 mg/kg nalorphine is injected subcutaneously in the morning. On days 50 and 112 all doses are omitted for 24 h. Precipitation of the abstinence syndrome due to either withdrawal from treatment or nalorphine injection is evaluated as 4 degrees: mild, moderate, severe, very severe.

CRITICAL ASSESSMENT OF THE METHOD

The Rhesus monkey has been used for this purpose by several authors. For opioids, an excellent correlation between humans and rhesus monkeys has been shown. However, some discrepancies have been noted. For example, meperidine shows higher physical dependence in monkeys compared with humans and dogs (Aceto 1990). Monkeys were also used for testing dependence liability of several sedative-hypnotic agents by self-administration. According to recent studies, for drug evaluation drug discrimination tests are preferred to self-administration studies (Woods et al. 1993).

MODIFICATIONS OF THE METHODS

Mouse jumping as a simple screening method to estimate the physical dependence capacity of analgesics has been recommended by Saelens et al. (1971). Mice receive seven intraperitoneal injections over 2 days. The test compound is given at doses increasing in multiples of two until a maximally tolerated dose is reached. Two hours after the last injection the animals receive an i.p. injection of 100 mg/kg naloxone and are placed individually into glass cylinders. The number of jumps is recorded during 10 min.

Yoshimura et al. (1993) studied the physical dependence on morphine induced in **dogs** via the use of mini-osmotic pumps. Naloxone-precipitated withdrawal signs were recorded such as hyperactivity, biting, digging, tremors, nausea, hyperthermia, and increased wakefulness, and by EEG activation in the amygdala and hippocampus, followed by a dissociation of the EEG in the cortex (fast wave) from that in the limbic (slow wave) system, increased heart rate, and raised blood pressure. Withdrawal signs were more severe in animals with mini-osmotic pumps than in those receiving the same dose by syringe injections.

Pierce and Raper (1995) studied the effects of laboratory handling procedures on naloxone-precipitated withdrawal behavior in **morphine-dependent rats**.

Pierce et al. (1996) used slow release emulsion formulations of methadone to induce dependence in rats. Withdrawal was induced following intraperitoneal challenge with either naloxone or saline, and dependence was assessed in terms of the presence/absence of 13 nominated withdrawal behaviors.

H.1.3.6 Tests for addiction liability

H.1.3.6.1 General considerations

Psychological dependence or addiction has been defined as strong preference of the subject to experience the effects of a drug (Deneau 1964). Methods have been developed to characterize the addiction phenomenon in animals as a model for addiction in man. Brain-stimulation reward has been used for drug-induced euphoria by Kornetsky and Bain (1990) based on the early observations of Olds et al. (1956, Olds 1979) on intracranial self-stimulation. Self-administration methods have been used to study the reinforcing effects of drugs (Deneau et al. 1969; Hoffmeister 1979; Littmann et al. 1979; Woolverton and Schuster 1983; Bozarth 1987; Meisch and Carroll 1987; Weeks and Collins 1987; Yokel 1987; Woolverton and Nader 1990). Furthermore, discrimination methods have investigated the potential for drug abuse (Holtzman 1983; Brady et al. 1987; Colpaert 1987; Overton 1987; Hoffmeister 1988; Holtzman 1990).

H.1.3.6.2 Drug discrimination studies

PURPOSE AND RATIONALE

Several authors used discrimination methods to investigate the potential for drug abuse (Shannon and Holtzmann 1976; Holtzman 1983; Brady et al. 1987; Shannon and Holtzmann 1986; Colpaert 1987; Overton 1987; Hoffmeister 1988; Carboni et al. 1989; Holtzman 1990).

PROCEDURE

Rats are trained to press one of two choice levers to avoid or to escape electric shocks which are delivered intermittently beginning 5 s after the start of the trial. The occurrence of a trial is signaled by illuminating light in the operant chamber. A third (observing) lever is mounted in the wall of the chamber opposite the two choice levers and must be pressed before the choice response is made. This contingency prevents the rat from hovering by the appropriate choice lever; thus, the choice response in each trial is relatively independent of the consequences of choice responses in the preceding trials of the session. The rats are tested in 20-trial sessions. The animals should be trained to discriminate a prototype of the drug of interest. Morphine and fentanyl have served well as training drugs for exploring the discriminative effects of classical opiates and other drugs. In order to speed up the procedure, the dose of the training drug should be the highest one that does not impair behavior. For discrimination training, the animal is placed in the operant chamber and trained to perform the required response. In two-choice procedures, the left and the right choice lever are designated for drug and vehicle, respectively, for half of the animals in a group; the designation of choice lever are reversed for the other half of the animals. Acquisition of the discrimination is a function of training sessions rather than the number of days of training. Training continues until the subject reaches a predetermined performance criterion, such as 85–95% of responses during 10 consecutive sessions prior to the first reinforcement. Thirty–eighty training sessions or 6–12 weeks are needed to train the animal. Once stable discrimination performance has been achieved, tests of generalization to novel drug conditions can be interposed among the training sessions. One or two times a week test sessions are conducted to determine the ability of subjects to generalize stimulus control of behavior from the training drug to another drug. At 2 sessions per week, 2–3 weeks are needed to construct a complete stimulus-generalization (i.e., dose response) curve for one drug in one subject.

EVALUATION

Results of the stimulus-generalization test usually are evaluated with the quantitative or graded method, whereby the amount of responding on the choice lever appropriate for the training drug (standard) is expressed as a percentage of the total number of responses during a test (i.e., drug-appropriate plus vehicle appropriate responses). This percentage is than compared with the percentage of drug-appropriate responses normally engendered by the training drug (standard). The discriminative effects of the test drug substitute for those

of the training drug if the 2 percentages are not significantly different from each other. When stimulus control of behavior transfers from one drug to another, it can be inferred that the test drug produced discriminative effects that are similar to those of the training drug.

CRITICAL ASSESSMENT OF THE METHOD

Drug discrimination procedures display a high degree of pharmacologic specificity. While test drugs that resemble the training drug result in dose-dependent drug-appropriate lever selections, drugs that are pharmacologically dissimilar to the training drug typically cause responding on the choice lever appropriate for the drug vehicle. Drugs classified as morphine-like agonists produced dose-dependent morphine-like discriminative effects, with the expected potency mediated by the μ-opioid receptor.

MODIFICATIONS OF THE METHOD

Drug discrimination studies were also performed in other species including **squirrel monkeys, Rhesus monkeys**, and **pigeons** (Hein et al. 1981; Herling and Woods 1981; Bertalmio et al. 1982, 1987; Dykstra et al. 1987, 1988). Monkeys trained to discriminate injections of the μ-agonists codeine, etorphine, or alfentanil generalize to other μ-agonists. On the other hand, monkeys trained to these μ-agonists do not generalize to non-opioid drugs, to opioid antagonists, or to opioid agonists which produce their behavioral effects in the rhesus monkey through opioid receptors other than the μ-receptor. Conversely, monkeys trained to discriminate ethylketazocine, which is a κ-agonist in the rhesus monkey, generalize to κ-opioid agonists, but not to μ-opioid agonists, opioid antagonists, or nonopioid drugs (Wood et al. 1993). Apparently, drugs that are self-administered by rhesus monkeys are μ-agonists, and these are the drugs that also show abuse liability in humans. Iwamoto and Martin (1988) discuss the question whether or not drug self-administration studies in monkeys, used for a long time as scientific approach, can predict the abuse potential of drugs. There are several examples that drugs that are self-administered by animals, such as procaine and nomifensine, are not abused by humans. One the other hand, animals show little tendency to self-administer drugs abused by humans, such as THC, LSD, or DOM. Consequently, for drug evaluation the drug discrimination tests have to be preferred in comparison to self-administration studies.

Meert et al. (1989) used drug discrimination studies to characterize risperidone as a complete LSD antagonist.

Meert and Janssen (1989), Meert et al. (1990) showed differences between ritanserin and chlordiazepoxide in drug discrimination procedures.

Δ^9-Tetrahydrocannabinol discrimination in rats has been proposed as model for cannabis intoxication in humans (Balster and Prescott 1990)

An attempt was made to measure opiate abstinence responses in the guinea pig ileum made dependent *in vitro* (Cruz et al. 1991).

The drug discrimination method has also been applied to study anxiolytic drugs using pentylenetetrazol at subconvulsive doses (Sherman and Lal 1979, 1980; Sherman et al. 1979; Lal and Sherman 1980).

The conditioned taste aversion procedure has been described as a more rapid alternative to two-lever operant procedures in drug discrimination research (Garcia et al. 1955; van Heest et al. 1992).

H.1.3.6.3 Place conditioning paradigm

PURPOSE AND RATIONALE

The place conditioning paradigm has proven successful in identifying the neural mechanisms of drug reinforcement (van der Kooy 1987; Hoffman 1989; Self and Stein 1992). Two classes of drugs, opiates and psychomotor stimulants, have received the most attention, and in each case an important role of dopamine neurons in the mesolimbic system has been established. Moreover, both receptor subtypes, D_1 and D_2, appear to be involved. Intact serotonergic transmission seems to be important in morphine place conditioning, but has not been observed with amphetamine place conditioning.

To induce place preference, a food-deprived animal is exposed to a box which consists of two compartments (which differ in floor texture and wall color) often joined by a small tunnel. Food delivery is paired with confinement to one compartment and not to the other. Later, in the absence of the rewarding stimulus, the animal demonstrates a relative increase in the amount of time spent in the environment previously associated with food compared to the neutral environment. Conditioning to drugs involves the differential pairing of drug administration to one compartment and vehicle with the other. Most authors (Amalric et al. 1987; Bals-Kubik et al. 1998, 1990; Iwamoto 1988; Shippenberg and Herz 1987) applied the drugs via intracerebroventricular injections.

PROCEDURE

Male Sprague-Dawley rats weighing 250–300 g are anesthetized with 60 mg/kg i.p. sodium hexobarbital and stereotaxically implanted with 23 gauge guide cannulae aimed at the lateral ventricle ($AP = -0.9$ mm, $L = +1.5$ mm, $DV = 3.5$ mm) (Paxinos and Watson 1982).

Place conditioning commences one week after cannula implantation. The apparatus consists of $30 \times 60 \times 30$ cm wooden shuttle-boxes with a clear Plexiglas front. For conditioning sessions, each box is divided into two equal-sized compartments by means of a sliding wall. One compartment is white with a textured floor, the other black with a smooth floor. For testing, the central wall is raised 12 cm above the floor and a 5×2 cm 'neutral' steel mesh is inserted along the line separating the two compartments.

Conditioning sessions are conducted once a day for 6 days and consist of injecting drug or its vehicle on alternate days. The rats are immediately confined to one compartment of the shuttle-box following drug injection and to the other compartment following vehicle injection. All conditioning sessions last 40 min. Test sessions are carried out one day after the last training session, in the drug-free state. The rats are placed on the 'neutral' platform of the test box and allowed free access to both sides of the box for 15 min. A videocamera with integrated stop-watch is used for data recording. The time spent in a particular place (drug, vehicle or neutral platform) is assessed by visual analysis of the recorded videotape.

The intracerebroventricular injections are given with a 30 gauge injection needle attached to a microsyringe via polyethylene tubing. The drug solutions are administered over a 60 s period and the injection needles are left in place for and additional 30 s to ensure complete delivery of the solution. For antagonism tests, groups of rats are intracerebroventricularly injected with the antagonist or vehicle 10 min before the microinjection of the conditioning drug.

At the end of the experiments, the rats are anesthetized and sacrificed by decapitation. The brains are removed and sectioned in a cryostat to verify the location of the cannulae.

EVALUATION

Condition scores represent the time spent in the drug-paired place minus the time spent in the vehicle-paired place, and are expressed as means ±SE. Dose-response curves are analyzed with a one-way random factorial analysis of variance. The Wilcoxon test, in which the time spent in the drug associated place is compared to that in the vehicle-paired place, is used to determine whether individual doses produce significant conditioning. A one-way analysis of variance (ANOVA) followed by the Student Newman-Keul's test is used to determine the statistical significance of effects of the antagonist pretreatment.

MODIFICATIONS OF THE METHOD

In order to distinguish place **preference** and place **aversion**, place conditioning behaviours are expressed by 'post – pre', which is calculated as: [(post value) – (prevalue)], where post and pre values are the difference in time spent in the preferred and the non-preferred sides in the post-conditioning and pre-conditioning tests, respectively. Positive values are indicative for preference, negative values for aversion (Kitaichi et al. 1996).

In addition to place preference, Mucha and Herz (1985) used **taste preference** conditioning.

Perks and Clifton (1996) used sucrose solution to generate a place preference which was subsequently devalued using a LiCl taste aversion procedure.

Brockwell et al. (1996) described a computerized system for the simultaneous monitoring of place con-

ditioning and locomotor activity in rats consisting of 4 independent conditioning boxes, each equipped with 6 pairs of photosensors connected to an Experiment Controller, an electronic board containing a microprocessor, a programmable timer, and 16 K of RAM used to store both instructions and data.

Steinpreis et al. (1996) investigated place preference in Sprague Dawley rats treated with graded intraperitoneal doses of methadone. Place preference for methadone peaked at 4 mg/kg and aversion was produced at 10 mg/kg.

Using the conditioned place paradigm, Mamoon et al. (1995) assessed the rewarding properties of butorphanol in comparison to morphine after unilateral microinjections into the ventral tegmental area of male Lewis rats.

Gaiardi et al. (1997) assessed rewarding and aversive effects of buprenorphine by place preference and taste aversion conditioning. After subcutaneous doses of 0.025, 0.050 and 0.100 mg/kg, buprenorphine caused a significant increase in the amount of time spent on the conditioned side, but no significant decrease of saccharin consumption. Rewarding and aversive effects did not occur within a similar dose range.

Contarino et al. (1997) found no tolerance to the rewarding properties of morphine if the effect of repeated i.p. injections of morphine in prolonged conditioned place preference trials.

Tsuji et al. (1996) studied the effect of microinjections of GABA-agonists and -antagonists into the ventral tegmental area of Sprague Dawley rats on morphine-induced place preference.

Sufka (1994) recommended the conditioned place preference paradigm as a novel approach for analgesic drug assessment against chronic pain which was induced in rats by unilateral injections of Freund's adjuvant into the hind paw.

Conditioned place avoidance was found after naloxone which was attenuated by clonidine (Kosten 1994).

Besides morphine and opioids, other drugs with known or putative addiction liability were tested in the place conditioning paradigm, e.g., cocaine (Lepore et al. 1995; Suzuki and Misawa 1995; Calcagnetti et al. 1996; Martin-Iverson and Reimer 1996; Martin-Iverson et al. 1997), caffeine (Brockwell et al. 1991; Brockwell and Beninger 1996), cannabinoids (Lepore et al. 1995; Sañudo-Peña et al. 1997), LSD (Parker 1996), methamphetamine (Suzuki and Misawa 1995), amphetamine (Hoffman and Donovan 1995; Turenne et al. 1996), methylphenidate (Gatley et al. 1996), fenfluramine (Davis and Parker 1993), 7-OH-DPAT (Khroyan et al. 1995; Chaperon and Thiébot 1996), gamma-hydroxybutyric acid (Martellotta et al. 1997), propofol (Pain et al. 1997), NMDA receptor antagonists (Steinpreis et al. 1995; Papp et al. 1996).

Furthermore, 5-HT_3 antagonists (Acquas et al. 1990), 5-HT_3 receptor agonists (Higgins et al. 1993), dopamine release inhibitors (Schechter and Meehan 1994), D1 receptor antagonists (Acquas and Di Chiara 1994), D3-preferring agonists (Khoyan et al. 1997), antiemetic agents (Frisch et al. 1995) were studied in the place-conditioning paradigm.

Suzuki et al. (1991, 1993) and del Pozo et al. (1996) studied opioid-induced place preference in **mice**.

H.2 Peripheral analgesic activity

H.2.0.1 General considerations

Most of the so called peripheral analgesics possess anti-inflammatory properties and in some cases also anti-pyretic activity besides analgesia. For many of them the mode of action has been elucidated as an inhibition of cyclooxygenase in the prostaglandin pathway. Nevertheless, new peripheral analgesics have to be tested not only for their *in vitro* activity on cyclooxygenase but also for their *in vivo* activity.

The most commonly used methods for measuring peripheral analgesic activity are the writhing tests in mice (various modifications) and the RANDALL-SELITTO-test in rats.

H.2.0.2 Writhing tests

PURPOSE AND RATIONALE

Pain is induced by injection of irritants into the peritoneal cavity of mice. The animals react with a characteristic stretching behavior which is called writhing. The test is suitable to detect analgesic activity although some psychoactive agents also show activity. An irritating agent such as phenylquinone or acetic acid is injected intraperitoneally to mice and the stretching reaction is evaluated. The reaction is not specific for the irritant.

PROCEDURE

Mice of either sex with a weight between 20 and 25 g are used. Phenylquinone in a concentration of 0.02% is suspended in a 1% suspension of carboxymethylcellulose. An aliquot of 0.25 ml of this suspension is injected intraperitoneally. Groups of 6 animals are used for controls and treated mice. Preferably, two groups of 6 mice are used as controls. Test animals are administered the drug or the standard at various pretreatment times prior to phenylquinone administration. The mice are placed individually into glass beakers and five min are allowed to elapse. The mice are then observed for a period of ten min and the number of writhes is recorded for each animal. For scoring purposes, a writhe is indicated by stretching of the abdomen with simultaneous stretching of at least one hind limb. The formula for computing percent inhibition is: average writhes in the control group minus writhes in the drug group divided by writhes in the control group times 100%. The time period with the greatest percent of inhibition is considered the peak time. A dose range is reserved for interesting compounds or those which inhibit writhing more than 70%. Compounds with less than 70% inhibition are considered to have minimal activity.

EVALUATION

A dose range is run in the same fashion as the time response except 8 animals/ group are tested at the peak time of drug activity. Four drug groups and a vehicle control group are employed. Animals are dosed and tested in a randomized manner. An estimated ED_{50} is calculated. Doses of 1.0 mg/kg p.o. indomethacin, 30 mg/kg p.o. acetylsalicylic acid, 40 mg/kg p.o. amidopyrine and 80 mg/kg p.o. phenacetin have been found to be ED_{50} values.

CRITICAL ASSESSMENT OF THE TEST

In this test both central and peripheral analgesics are detected. The test, therefore, has been used by many investigators and can be recommended as a simple screening method. However, it has to be mentioned that other drugs such as clonidine and haloperidol also show a pronounced activity in this test. Because of the lack of specificity, caution is required in interpreting the results, until other tests have been performed. Nevertheless, a good relationship exists between the potencies of analgesics in writhing assays and their clinical potencies.

MODIFICATIONS OF THE METHOD

Instead of a phenylquinone suspension, 0.1 ml of a 0.6% solution of acetic acid is injected intraperitoneally to mice with an weight between 18 and 25 g (Koster et al. 1959; Taber et al. 1969). The response is similar to that after phenylquinone. Some authors have used this method together with observation of changes in capillary permeability in order to distinguish between narcotic and non-narcotic analgesics (Whittle 1964).

Eckhardt et al. (1958), Collier et al. (1968), Loux et al. (1978) showed that several substances are able to elicit the writhing response. For example, Amanuma et al. (1984) as well as Nolan et al. (1990) used as irritant intraperitoneal injections of acetylcholine.

Emele and Shanaman (1963), Burns et al. (1968) proposed bradykinin being a endogenous transmitter of pain as irritant.

Sancillo et al. (1987) induced abdominal constriction in mice by intraperitoneal injection of 31.6 µg/kg of prostaglandin E_1.

Bhalla and Bhargava (1980) described a method for assessing aspirin-like activity using aconitine to induce writhing.

Adachi (1994) described a device for automatic measurement of writhing in mice.

Analgesic effects of non-acidic non-steroidal anti-inflammatory drugs in the acetic acid writhing test after intracisternal administration have been found by Nakamura et al. (1986).

The writhing phenomenon can also be observed in **rats** (Fukawa et al. 1980). The writhing responses were induced by intraperitoneal injection of 4% sodium chloride solution. Narcotic and non-narcotic analgesics, antipyretic and nonsteroidal anti-inflammatory drugs were effectively evaluated at relatively low doses. Methamphetamine also showed an analgesic action. VonVoigtlander and Lewis (1982, 1983) induced writhing in rats by injection of 7 ml air or 6% aqueous saline into the peritoneal cavity.

Ethacrinic acid-induced writhing response in rats was used by Björkman et al. (1992).

Schweizer et al. (1988) described a photoelectronic motility monitoring apparatus to measure automatically the writhing movements. A good correlation was found between ED_{50} values after oral administration in mice and the clinically effective oral doses in man.

Heapy et al. (1993) induced the abdominal constriction response in mice by intraperitoneally injecting 0.4 ml of either 0.25% acetic acid, 7.5 mg/ml kaolin suspension, 2.4 mg/ml zymosan solution, or 25 µg/ml bradykinin solution.

H.2.0.3 Pain in inflamed tissue (RANDALL-SELITTO-test)

PURPOSE AND RATIONALE

This method for measuring analgesic activity is based on the principle that inflammation increases the sensi-

tivity to pain and that this sensitivity is susceptible to modification by analgesics. Inflammation decreases the pain reaction threshold and this low pain reaction threshold is readily elevated by non-narcotic analgesics of the salicylate-amidopyrine type as well as by the narcotic analgesics. Brewers yeast has been used as an inducer for inflammation which increases pain after pressure.

PROCEDURE

Groups of male Wistar rats (130 to 175 g) are used. Only for oral testing the animals are starved 18 to 24 h prior to administration. Otherwise, the route of administration can be intraperitoneal or subcutaneous. To induce inflammation, 0.1 ml of a 20% suspension of Brewer's yeast in distilled water is injected subcutaneously into the plantar surface of the left hind paw of the rat. Three hours later, pressure is applied through a tip to the plantar surface of the rat's foot at a constant rate by a special apparatus to the point at which the animal struggles, squeals or attempts to bite. The apparatus being used has been modified by various authors such as using the Analgy Meter (Ugo Basile, Apparatus for Biological Research, Milan, Italy). Each animal is tested for its control pain threshold. Any animal with a control pain threshold greater than 80 g is eliminated and replaced.

For a time response, groups of at least 7 animals are used, four groups for the agent to be tested and one for the vehicle control. The tests are done at 15 min intervals after subcutaneous administration and at 30 min intervals after oral administration for any change in pain threshold. The interval of time which indicates the greatest increase in pain threshold is regarded as the peak time.

A dose range is obtained in the same manner as the time response. The drug to be tested is administered in a randomized manner. The pain threshold is recorded at time zero and again at the determined peak time.

EVALUATION

The mean applied force is determined for each time interval tested. The percentage increase in pain threshold is calculated by subtracting the applied force of the vehicle control from the applied force of the drug group which is divided by the applied force of the vehicle control in order to give the percentage of increase in pain threshold of the drug group. Doses of 50 mg/kg s.c. Na salicylate, 50 mg/kg amidopyrine, 3 mg/ kg s.c. morphine, 12.5 mg/kg s.c. codeine or pethidine have been found to be effective.

CRITICAL ASSESSMENT OF THE METHOD

The method originally described by RANDALL and SELITTO has been used by many investigators and has been proven to detect central analgesics as well as peripheral analgesics. Peripherally acting analgesics such as the nonsteroidal anti-inflammatory drugs increase only the threshold of the inflamed paw, whereas opiate analgesics increase also the threshold of the intact paw (Dubinsky et al. 1987). In most modifications, the assay has a shallow dose-response curve. Nevertheless, the ED_{50} values of nonsteroidal anti-inflammatory drugs in this test showed a good correlation with human doses (Romer 1980).

MODIFICATIONS OF THE METHOD

The test has been modified by various authors. In some instances the pressure on the inflamed paw has been omitted. Instead the animals were allowed to walk on a metal grid. The gait of the animals is assessed by an observer using a scoring system:

- 0 = three-legged gait
- 0.5 = marked limping
- 1 = normal gait.

The scores are transformed into percent analgesia. Other noxious stimuli were used to induce inflammation and hyperalgesia, such as carrageenin (Winter et al. 1962), Freund's adjuvant or prostaglandin E_2 (Ferreira et al. 1978a).

Vinegar et al. (1990) injected 0.1 ml of 0.25% solution of trypsin into the subplantar region and applied the load force 60 min later. They found a biphasic hyperalgesia and relatively low ED_{50} values for central and peripheral analgesics.

Technically, the method has been improved by several authors, such as Takesue et al. (1969).

Chipkin et al. (1983) modified the test by decreasing the rate of acceleration of the noxious stimulus (mechanical pressure) on the inflamed paw from 20 to 12.5 mm Hg/s and an extension of the cut-off time from 15 to 60 s. This modification is claimed to discriminate analgesics active against mild to severe clinical pain (narcotic-like) from those only useful against mild to moderate pain (non-narcotic-like).

Randall-Selitto analgesy meters are commercially available (e.g., IITC Life Science, Woodland Hills, CA, USA).

Central and peripheral analgesic action of aspirin-like drugs has been studied with a modification of the Randall-Selitto method applying constant pressure to the rat's paw by Ferreira et al. (1978b).

A modification of an analgesia meter for paw pressure antinociceptive testing in neonatal rats was described by Kitchen (1984).

Learning and retention has been tested in rats by Greindl and Preat (1976) inducing pain by a light quantifiable pressure applied to the normal hind paw.

Hargreaves et al. (1988) described a sensitive method for measuring thermal nociception in cutaneous hyperalgesia in rats. One paw was injected with 0.1 ml carrageenan solution, the other paw with saline. The rats were placed in chambers with glass floor and radiant heat was directed to the paws. A photoelectric cell detected the light reflected from the paw and turned off the radiant heat when paw movement interrupted the reflected light.

Perkins et al. (1993) described hyperalgesia after injection of 100 µl of Freund's adjuvant into the knee of anesthetized rats. After 64–70 h the animal was placed with each hind paw on a pressure transducer and a downward force was exerted until the uninjected leg was bearing 100 g. At this point animals were less tolerant to a load on the injected leg, indicating a hyperalgesic response.

Davis et al. (1996) induced mechanical hyperalgesia by injection of substance P and capsaicin in the rat knee joint and measured the download force tolerated by the injected leg.

Ferreira et al. (1993a,b) induced hyperalgesia by intraplantar injection in the hindpaw of rats of various agents, e.g., bradykinin, carrageenin, LPS, PGE_2, dopamine, TNFα, IL-1β, IL-6 and IL-8. A constant pressure of 20 mm Hg was applied to the hind paws and discontinued when the rats presented a typical freezing reaction.

Subplantar injection of 0.1 µg of serotonin in the rat results in a brief period (up to 20 min) of increased pain sensitivity to an applied force (hyperalgesia) which precedes a longer period of decreased pain sensitivity (hypoalgesia). Vinegar et al. (1989) used this phenomenon for pharmacologic characterization of the algesic response.

Similarly, a biphasic algesic behavior after subplantar injection of 250 µg of trypsin was described by Vinegar et al. (1990)

Courteix et al. (1994) proposed the Randall-Selitto paw pressure test in rats with streptozocin-induced diabetes as a model of chronic pain with signs of hyperalgesia and allodynia that may reflect signs observed in diabetic humans.

Amann et al. (1955, 1996) evaluated local edema and effects on thermal nociceptive threshold after intraplantar injection of nerve growth factor into the rat hind paw and studied the effect of a 5-lipoxygenase inhibitor in this test.

Zhou et al. (1996) tested the effects of peripheral administration of NMDA, AMPA or KA on pain behavior in rats. A 28-gauge needle was inserted in the skin of rats proximal to the footpads and advanced about 1 cm so that the tip reached the base of the third toe. A bolus of 20 µl containing concentrations between 1 and 10 000 µM of KA, NMDA or AMPA. For behavioral testing, each animal was placed in a Plexiglas box on a wire mesh screen. Mechanical stimuli were applied using four von Frey filaments with different bending forces. Each von Frey filament was applied 10 times to the skin on the base of the third toe. The paw withdrawal was rated as scores allowing dose-response curves for the hyperalgesic effects of excitatory amino acids. Furthermore, using the highest concentration of the stimulant, effects of antagonists were tested.

H.2.0.4 Mechanical visceral pain model in the rat

PURPOSE AND RATIONALE

Animal models designed to test the effectiveness of analgesic agents against visceral pain typically rely on noxious chemical irritation of the peritoneum, e.g., acetic acid and phenylquinone induced writhing tests based on acute inflammation. Ethical constraints prevent repeated assessments in a single animal, thereby compounding the difficulty of assessing development of tolerance to analgesic agents. To overcome these constraints, a model for mechanical visceral pain was developed based on repeatable and reversible distension of duodenum in the rat (Coburn et al. 1989; deLeo et al. 1989).

PROCEDURE

A one-piece balloon catheter is prepared composed of PE 50 tubing with a terminal latex rubber balloon which is 7.5 mm long and distensable to hold more than 1.5 ml fluid. Male Sprague Dawley rats weighing 175–200 g are anesthetized with N_2O and halothane. The abdomen is shaved and an 2.5 cm incision is made transversely just below the left costal margin. On the greater curvature of the stomach an incision is made 10 to 20 mm above the pylorus and a purse string is accomplished with 4–0 silk prior to gastrostomy. Through a 2 mm gastrostomy the catheter is introduced and advanced through the pylorus to the first portion of the duodenum (approximately 15–20 mm from the pylorus). The purse string is tied snugly closing the gastrostomy around the catheter. The catheter is tunneled to the base of the scull, externalized and anchored to the dermis with a silicon sleeve and suture. The animals recover from anesthesia within 5 min. Following a 4–5 days recovery period, the duodenal distension volume is determined by the mean threshold that produces writhing (usually 0.5 to 0.7 ml). For the test, the animals are randomized and administered either saline, the standard (0.1, 0.25, 1, and 10 mg/kg indomethacin i.p.) or the test drug in various doses prior to challenging. The animals are placed in a polypropylene box and challenged by inflating the balloon with saline, using a 1 ml calibrated syringe, pulsed 5 times over 30 s and then distended for 1 min. Behavioral responses are scored:

- 0 = Normal behavior defined as exploration, escape attempts and resting
- 1 = Slightly modified behavior defined as cessation of exploration, focusing, wet-dog shake, excessive facial grooming, teeth chattering and deep breathing
- 2 = Mildly to moderately modified behavior defined as retching-like activity, hunching, abdominal grooming or nipping and immobility of the hind limbs (disappears with removal of the stimulus).
- 3 = Severely modified behavior defined as stretching of the hindlimbs, arching and dorsoflection of the hind paws.
- 4 = Intensive visceromotor activity defined as repetitive stretching of the body, extension of the hind limbs, and pelvis, frequent rotating sideward, i.e., writhing.

EVALUATION

The average scores of the groups are plotted on semi log paper and ED_{50} values are determined by best line fit.

CRITICAL ASSESSMENT OF THE METHOD

In the mechanical visceral pain model in the rat, morphine and indomethacin have been found to be active but not other agents involved in prostaglandin inhibition, like acetylsalicylic acid and mefenamic acid. Other mechanisms besides those involving the arachidonic acid cascade have to be investigated.

MODIFICATIONS OF THE METHOD

Ness and Gebhart (1988) used colorectal distension as a noxious visceral stimulus in awake, unanesthetized, unrestrained rats. A 7–8 cm flexible latex balloon was inserted intra-anally under ether anesthesia and kept in position by taping to the base of the tail. Opening a solenoid gate to a constant pressure air reservoir initiated

a 20 s, constant pressure stimulus in the descending colon and rectum. Femoral arterial and venous catheters were tunneled subcutaneously and exteriorized at the back of the neck. Teflon-coated stain-less steel wire electrodes were stitched into the external oblique musculature immediately superior to the inguinal ligament for electromyographic recordings. Blood pressure and heart frequency increase were proportional to the degree of colorectal distension. These effects could be dose-dependently antagonized by morphine and clonidine.

Renal pelvis distension with a pressure of 80 cm H_2O causes a decline in mean arterial blood pressure in pentobarbital-anesthetized rats. Brasch and Zetler (1982) used this blood pressure response, which disappears rapidly after cessation of the distension, to study the effects of analgesic drugs known to be effective in renal colic pain in man.

Moss and Sanger (1990) measured falls in diastolic blood pressure and intragastric pressure after distension of the duodenum by rapid application of intraluminal pressure (10–75 cm H_2O) in anesthetized rats. The distension-induced responses were blocked by pretreatment with morphine, an action reversible by injection of naloxone. Bilateral cervical vagotomy reduced the distension-evoked fall in intragastric pressure but had no effect on the corresponding fall in blood pressure.

H.2.0.5 Antagonism against local effects of bradykinin

PURPOSE AND RATIONALE

Guzman et al. (1962) and Lim et al. (1964) described the responses (vocalization, respiratory and blood pressure changes) to intra-arterial injection of bradykinin and other algesic agents in cats and dogs. Deffenu et al. (1966) and Blane (1968) used the bradykinin-induced effects after intra-arterial injection in rats as an assay for analgesic drugs. Paravascular sensory nerves which accompany blood vessels throughout the body to end in unmyelinated free-branching terminals close to the capillaries and venules most likely carry the chemoreceptors of pain (Lim 1970). Due to rapid enzymatic degradation, bradykinin is ineffective as noxious stimulus after intravenous or oral administration.

PROCEDURE

Male Wistar rats weighing 280–320 g are lightly anesthetized with ether. A polyethylene catheter with an internal diameter of 0.5 mm is inserted centripetally into the right carotid artery. The catheter is passed through the subcutaneous tissues to protrude from the back of the animal. One hour after recovery from anesthesia, the first dose of bradykinin is injected into the catheter producing dextro-rotation of the head, flexing of the forelimb and occasionally squeaking. For each rat the minimum dose of bradykinin is determined necessary to provoke these effects. The test compounds are applied subcutaneously or intraperitoneally 15 min prior to injection of the threshold dose of bradykinin. The bradykinin injections are repeated in 5 min intervals until the bradykinin effect reappears. Each rat receives one drug at one dose level.

EVALUATION

The criterion for protection is the disappearance of the bradykinin effect after at least 2 consecutive doses of bradykinin. Using groups of 10 rats for various dose levels, ED_{50} values are calculated.

CRITICAL ASSESSMENT OF THE METHOD

Not only narcotic analgesics, but also pyrazolones and phenacetin or acetylsalicylic acid are active in this test. In some animals, the bradykinin-induced response can be diminished after repeated injections, classified as the noxious-adaptable group (Satoh et al. 1979).

MODIFICATIONS OF THE METHOD

Haubrich et al. (1990) tested analgesic activity by the intracarotid bradykinin-induced head/forepaw flexion in the rat. Male Charles River rats (280–320 g) fasted overnight were prepared surgically under light ether anesthesia by insertion of a capped polyethylene cannula (PE-60) centripetally into the right carotid artery and then exteriorizing the cannula to a harness on the back, to permit repeated i.a. injections. The rats were allowed to recover at least 2 h from the surgery, and then given single i.a. injections of bradykinin (triacetate salt in 0.2 ml 0.9% NaCl per injection) at 10-min in-

tervals to determine the threshold dose which produced marked dextrorotation of the head and flexion of the right forepaw of each rat. This response was elicited by threshold doses of bradykinin ranging from 0.1 to 0.5 µg/injection. After administration of the test drugs, the response of the threshold dose of bradykinin was determined at 10-min intervals for 1 h and then at 20-min intervals during the second hour. ED_{50} values were determined by probit analysis of the maximum percentage of rats that failed to respond to bradykinin at each dose of test drug any time within the 2-h test period.

Collier and Lee (1963) described nociceptive responses of **guinea pigs** to intradermal injections of bradykinin and kallidin-10.

Vargaftig (1966) measured the effect of non-narcotic analgesics on the hypotension induced by intra-arterial injection of bradykinin in **rabbits**.

Adachi and Ishii (1979) used the response to injection of bradykinin into the femoral artery of guinea pigs for quantitative assessment of analgesic agents.

Griesbacher and Lembeck (1987) and Lembeck et al. (1991) used the reflex hypotensive response as an indicator of nociception after injection of bradykinin into the ear artery of anesthetized rabbits. Rabbits were anes-thetized and the blood pressure was recorded from the carotid artery. The central artery of one ear was cannulated and the ear was separated from the head with the exception of the auricular nerve, which remained connected to the head. The ear was perfused with Tyrode solution to which acetylcholine and bradykinin were added. The reflex fall in blood pressure induced by bradykinin and acetylcholine were monitored. The effect could be inhibited by bradykinin antagonists.

Heapy et al. (1993) tested the effects of the bradykinin antagonist HOE140 on the abdominal constriction response after intraperitoneal injection of bradykinin to **mice**.

Further methods used to study the role of bradykinin and bradykinin antagonists in inflammation and algesia

Teixeira et al. (1993) investigated the mechanisms of inflammatory response induced by extracts of *Schistosoma mansoni* larvae in guinea pig skin. *Biomphalaria glabrata* snails with patent *Schistosoma mansoni* infections were induced to shed cercariae by exposure to light and water with a temperature of 31 °C. The cercariae were concentrated, homogenized and extracts prepared. Purified eosinophils or neutrophils obtained from peritoneal exudates were radiolabeled by incubation with ^{111}In chelated to 2-mercaptopyridine-*N*-oxide. Radiolabeled leukocyte infiltration and edema formation were measured simultaneously at injected skin sites. [^{125}I]Human serum albumin was added to the labeled leukocytes and these were injected i.v. into anesthetized guinea pigs. After 15 min the extracts of cercariae were locally injected with/or without the inhibitors. After 2 h, the animals were sacrificed and the injected sites were punched out with a 17-mm punch. Serum exudation and leukocyte infiltration were measured by counting the two isotopes. The bradykinin antagonist HOE 140 reduced substantially the extract-induced inflammation.

Ahluwalia et al. (1994) induced plasma protein extravasation in the rat urinary bladder by i.p. injection of cyclophosphamide mediated by capsaicin-sensitive primary afferent neurons which could be significantly inhibited by the bradykinin B_2 receptor antagonist HOE140 and the tachykinin NK_1 receptor antagonist RP67,580.

Davis and Perkins (1994a,b) described a model of persistent inflammatory mechanical hyperalgesia using intra-articular injections of bradykinin or cytokines into the knee joint of rats.

Lecci et al. (1995) analyzed the local and reflex responses to bradykinin on rat urinary bladder motility *in vivo*.

H.2.0.6 Effect of analgesics on spinal neurons

PURPOSE AND RATIONALE

The mode of action of peripheral analgesics is still a matter of debate. Besides inhibition of the arachidonic acid derived pathway, activities on the spinal and central level have been discussed. Schaible and Schmidt (1983a,b, 1985, 1987, 1988) performed electrophysiological experiments in anesthetized cats and rats after local mechanical stimulation and after induction of acute arthritis of the knee joint. With this method Xe et al. (1990a,b), Neugebauer et al. (1994) found evidence for a spinal antinociceptive action of antipyretic analgesics, such as dipyrone.

PROCEDURE

In cats weighing 2.0–4.0 kg anesthesia is induced by i.m. injection of 15–30 mg/kg ketamine hydrochloride followed by i.v. injection of 60 mg/kg α-chloralose. After immobilization with i.v. pancuronium bromide the cats are artificially ventilated. The skin of the right thigh is incised from rostral of the inguinal fossa to a point below the medial condyle of the tibia. The tendon of the sartorius muscle is cut close to its insertion at the capsule of the knee joint. The muscle is removed to expose the medial aspects of the joint and the medial articular nerve (MAN). The thigh is rigidly fixed to the mounting table by a threaded bolt fitted through the femur so that the lower leg can be flexed and extended in the horizontal plane. The saphenous nerve is cut in the inguinal fossa for recording. Bipolar electrodes are inserted at the MAN near the knee for en passent stimulation of articular afferents. **Extracellular recordings from single MAN units** in the saphenous nerve are performed using platinum wire electrodes. According to their conduction velocities units are classed as group IV afferents (<2.5 m/s, unmyelinated axons) or group III afferents (2.5–20 m/s, thinly myelinated axons).

For **recordings from spinal cord neurons** the spinal segments T12–L7 are exposed by laminectomy. The spinal cord is transected at the lower thoracic region after injection of 0.1 ml of 1% procaine hydrochloride solution to prevent mechanical activation of axons in the long spinal tracts. The animals are fixed to a rigid frame with spinal and pelvic clamps. A pool is formed by skin flaps and filled with warm paraffin oil. The upper lumbar spinal cord is mounted on a pair of platinum wire stimulating electrodes surrounding the whole cord. Ascending tract neurons are identified by electrical stimulation (Neugebauer and Schaible 1990). Single spinal neurons that can be excited by mechanical stimulation of the knee joint tissue are recorded extracellularly using glass-insulated carbon filament electrodes. The neurons are either nociceptive specific neurons responding only to noxious mechanical stimuli or wide dynamic range neurons responding to innocuous stimuli but showing strongest responses to stimuli of noxious intensity.

Acute arthritis in the right knee joint is induced several hours before recordings are started by injecting 0.3–0.5 ml of 4% kaolin suspension and 15–20 min later 0.3 ml of 2% carrageenan solution. Acute arthritis develops within 1–3 h.

Action potentials are displayed on a storage oscilloscope, amplified, filtered, fed to a window discriminator and processed using an interface and a personal computer for construction of peristimulus time histograms. After a control period of at least 40 min during which a stable discharge rate of the afferent or spinal cord unit is obtained, the test substances are administered i.v. in various doses. Effects of the test substance on ongoing and mechanically evoked activity (by movements, pressure stimuli) are determined.

EVALUATION

Ongoing activity is counted every min. The means and standard deviations in 10 min periods are calculated before and after drug application. The values after drug injection are calculated as percentage of control values. To calculate the net effects of the different mechanical stimuli, the number of impulses in the preceding 30 s is subtracted from the total discharges during the stimulus. The responses to at least 4 stimuli before drug application are averaged and set to 100%. The responses to the different mechanical stimuli after drug administration are expressed as a percentage of the controls. Statistical significance is evaluated using the *t*-test for unpaired samples.

MODIFICATIONS OF THE METHOD

Several other electrophysiological methods have been applied to elucidate the mode of action of non-opioid analgesic agents. Carlsson et al. (1986, 1988), Jurna and Brune (1990) recorded the activity from single neurons in the dorsomedial part of the ventral nucleus of the thalamus in rats. Activity was elicited by supramaximal stimulation of nociceptive afferents in the sural nerve. In addition, activity was recorded in ascending axons of the spinal cord.

Chapman and Dickenson (1992) studied the spinal and peripheral roles of bradykinin and prostaglandins in nociceptive processing in the rat by recording C-fibre activity in the dorsal spinal horn after injection of formalin into the center of the respective field of the toe of the hind paw.

Dray et al. (1992) described a preparation of the neonatal rat spinal cord with functionally connected tail maintained *in vitro*. The preparation was placed in a chamber and the spinal-cord and tail were separately superfused with a physiological salt solution. Peripheral nociceptive fibers were activated by superfusion of the tail with bradykinin, capsaicin or by a superfusate heated to 48–50 °C (noxious heat). The activation of peripheral fibres was assessed by measuring the depolarization produced in a spinal ventral root.

Malmberg and Yaksh (1992) described a direct analgesic action of NSAIDs through spinal cyclooxygenase inhibition by blocking the thermal hyperalgesia in rats induced after intrathecal administration of excitatory amino acids or substance P.

A simple technique for intrathecal injections by lumbar puncture in unanesthetized mice was described by Hylden and Wilcox (1980).

Mestre et al. (1994) described a method for performing direct intrathecal injections in rats without introducing a spinal catheter.

Bahar et al. (1984) performed chronic implantations of nylon catheters into the subarachnoid space of Wistar rats and marmosets and tested the effects of local anesthetics.

McQueen et al. (1991) investigated the effects of paracetamol and lysine acetylsalicylate on high-threshold mechano-nociceptors by recording neural activity from the inflamed ankle joint in anesthetized rats with mild adjuvant-induced mono-arthritis.

Yamamoto and Yaksh (1992) studied the effects of excitatory amino acid antagonists administered through chronically implanted lumbar intrathecal catheters on the thermal hyperesthetic state induced by unilateral partial ligation of the sciatic nerve in rats.

Hashimoto and Fukuda (1990) described a spinal cord injury model produced by spinal cord compression in the rat.

Aanonsen and Wilcox (1987) tested effects of spinally administered opioids, phencyclidine and sigma agonists on the action of intrathecally administered NMDA in the tail-flick, hot-plate and biting and scratching nociceptive tests in **mice**.

Brambilla et al. (1996) demonstrated that intrathecal administration of AMPA produced a dose-dependent behavioral syndrome in mice characterized by caudally directed biting, which could be antagonized by peripheral administration of AMPA-receptor and NMDA-receptor antagonists.

Aanonsen and al (1990) tested the effect of iontophoretically applied excitatory amino acid agonists, such as NMDA, AMPA, quisqualate and kainate, on the firing rate of rat spinal neurons after peripheral noxious stimulation.

Cumberbatch et al. (1994) studied the roles of receptors for AMPA in spinal nociceptive and non-nociceptive transmission on dorsal horn wide dynamic range neurones in anesthetized spinalized rats. The effects of systemically administered competitive and non-competitive AMPA antagonists were examined on responses to peripheral noxious heat and non-noxious tap stimuli as well as to iontophoretic AMPA and NMDA.

With this technique, Chizh et al. (1994) studied the effects of intravenous administration of AMPA antagonists to iontophoretically applied excitatory amino acids.

Watkins et al. (1994) induced hyperalgesia in rats by intraperitoneally administered lipopolysaccharides as measured by radiation heat tail flick in rats. Intrathecal catheters were implanted into the subdural space surrounding the spinal cord to test the involvement of excitatory amino acids, substance P, CCK and opioids assessing the effects of antagonists.

Mjellem et al. (1993) produced a behavioural syndrome of caudally directed biting in mice by intrathecal injection of either NMDA or AMPA.

H.3
Anti-inflammatory activity

H.3.0.1
General considerations

Inflammation was characterized two thousand years ago by Celsus by the four Latin words: Rubor, calor, tumor and dolor. Inflammation has different phases: the first phase is caused by an increase of vascular permeability resulting in exudation of fluid from the blood into the interstitial space, the second one by infiltration of leukocytes from the blood into the tissues and the third one by granuloma formation. Accordingly, anti-inflammatory tests have to be divided into those measuring acute inflammation, subacute inflammation and chronic repair processes. In some cases, the screening is directed to test compounds for local application. Predominantly, however, these studies are aimed

to find new drugs against polyarthritis and other rheumatic diseases. Since the etiology of polyarthritis is considered to be largely immunologically, special tests have been developed to investigate various immunological and allergic factors (see Chapter I).

H.3.1 *In vitro* methods for anti-inflammatory activity

H.3.1.1 General considerations

An array of physiological substances, sometimes called autacoids, are involved in the process of inflammation and repair. These include histamine, serotonin, bradykinin, substance P, and the group of eicosanoids (prostaglandins, thromboxanes and leucotrienes), the platelet-activating factor (PAF) as well as cytokines and lymphokines. Their discovery makes the use of *in vitro* studies possible. The influence of non-steroidal anti-inflammatory agents on the eicosanoid pathway gave rise to numerous studies.

H.3.1.2 ^{3}H-Bradykinin receptor binding

PURPOSE AND RATIONALE

Tissue injury or trauma initiates a cascade of reactions which results in the proteolytic generation of bradykinin and kallidin from high-molecular-weight precursors, kininogens, found in blood and tissue. The rapid enzymatic cleavage of kininogens is accomplished by the kallikreins, a group of proteolytic enzymes which are present in most tissues and body fluids. Bradykinin produces pain by stimulating A and C fibers in the peripheral nerves, participates in the inflammatory reaction and lowers blood pressure by vasodilatation. Since its breakdown occurs via the same enzyme responsible for converting angiotensin I into angiotensin II some of the effects of converting enzyme inhibitors may be due to presence of bradykinin. The ^{3}H-bradykinin receptor binding is used to detect compounds that inhibit binding of ^{3}H-bradykinin in membrane preparations obtained from guinea-pig ileum. Two types of bradykinin receptors (BK_1 and BK_2 receptors) are known (Feres et al. 1992; Bascands et al. 1993; Tropea et al. 1994). The existence of a pulmonary BK_3 receptor has been proposed by Farmer et al. (1989). Evidence was obtained for the existence of three subtypes of B_2 receptors, B_{2a}, B_{2b}, and B_{2c} (Seguin et al. 1992; Seguin and Widdowson 1993).

PROCEDURE

Ileum from guinea pigs is cleaned from its content and cut into pieces of 2 cm length. They are homogenized for 30 s in ice-cold TES buffer, pH 6.8, containing 1 mM 1,10-phenanthroline, in a Potter homogenizer. The homogenates are filtered through 3 layers of gauze and centrifuged twice at 50 000 *g* for 10 min with an intermediate rehomogenization in buffer.

For routine studies the final pellets are resuspended in 40 vol of incubation buffer (25 mM TES buffer, pH 6.8, containing 1 mM 1,10-phenanthroline, 0.1% bovine serum albumin, 140 µg/ml bacitracin, 1 mM dithiothreitol, 0.1 µM captopril). In the competition experiment, 50 µl ^{3}H-bradykinin (one constant concentration of $0.5–2 \times 10^{-9}$ M), 50 µl test compound (6 concentrations, $10^{-5}–10^{-10}$ M) and 150 µl membrane suspension from guinea pig ileum (approx. 6.6 mg wet weight/ml) per sample are incubated in a shaker bath at 25 °C for 90 min.

Saturation experiments are performed with 12 concentrations of ^{3}H-bradykinin ($14.2–0.007 \times 10^{-9}$ M). Total binding is determined in the presence of incubation buffer, non-specific binding is determined in the presence of non-labeled bradykinin (10^{-6} M).

The reaction is stopped by rapid vacuum filtration through glass fibre filters. Thereby the membrane-bound radioactivity is separated from the free one. The retained membrane-bound radioactivity on the filter is measured after addition of 3 ml liquid scintillation cocktail per sample in a liquid scintillation counter.

EVALUATION

The following parameters are calculated:

- total binding of ^{3}H-bradykinin
- non-specific binding in the presence of 10 µM bradykinin
- specific binding = total binding – non-specific binding
- % inhibition: 100 – specific binding as percentage of control value

Compounds are first tested at a single high concentration (10 000 nM) in triplicate. For those showing more than 50% inhibition a displacement curve is constructed using 7 different concentrations of test compound. Binding potency of compounds is expressed either as a relative binding affinity (*RBA*) with respect to the standard compound (bradykinin) which is tested in parallel or as an IC_{50}.

$$RBA = \frac{IC_{50}\ \text{standard compound}}{IC_{50}\ \text{compound}} \times 100\%$$

The dissociation constant (K_i) and the IC_{50} value of the test drug are determined from the competition ex-

periment of ^{3}H-bradykinin versus non-labeled drug by a computer-supported analysis of the binding data (McPherson 1985).

Tests for bradykinin receptor types and subtypes

Bradykinin B_1 receptors have been studied in the isolated rabbit carotid artery (Pruneau and Bélichard 1993) and in the rabbit urinary bladder (Butt et al. 1955).

A potent bradykinin B_1 receptor antagonist has been described by Wirth et al. (1991).

Heterogeneity of B_1 receptors has been suggested by Wirth et al. (1992).

Drummond and Cocks (1995) used rings of bovine left anterior descending coronary artery to study endothelium-dependent relaxations mediated by inducible B_1 and constitutive B_2 kinin receptors.

The production of cyclic GMP via activation of B_1 and B_2 kinin receptors in cultured bovine aortic endothelial cells was described by Wiemer and Wirth (1992).

Pharmacological characterization of bradykinin receptors in canine cultured tracheal smooth muscle cells has been reported by Yang et al. (1995).

Bradykinin B_2 receptors and their antagonists have been studied in human fibroblasts by Alla et al. (1993), with the high affinity radioligand [^{125}I]PIP HOE 140 by Brenner et al. (1993), in guinea pig gall bladder by Falcone et al. (1993), in the smooth muscle of **guinea-pig taenia caeci** by Field et al. (1994), in guinea pig ileum membranes by Graneß and Liebmann (1994), Liebmann et al. (1994a), in isolated blood vessels from different species by Félétou et al. (1994), in endothelial cells by Wirth et al. (1994).

The role of B_1 and B_2 receptors and of nitric oxide in bradykinin-induced relaxation and contraction of isolated rat duodenum was studied by Rhaleb and Carretero (1994).

Campos et al. (1996) investigated the effect of pretreatment with bacterial endotoxin on the bradykinin B_1 and B_2 receptor-induced edema in the rat paw and the interaction of B_1-mediated responses with other inflammatory mediators.

Characterization of kinin receptors by bioassays was described by Gobeil and Regoli (1994). Molecular cloning, functional expression and pharmacological characterization of a human bradykinin B_2 receptor gene was performed by Eggerickx et al. (1992).

Simpson et al. (2000) characterized bradykinin analogues on recombinant human bradykinin B_1 and B_2 receptors using a high throughput functional assay which measures intracellular Ca^{2+} responses.

Bradykinin B_2 receptor subtypes were discussed by Liebmann et al. (1994b) and Regoli et al. (1994).

Evidence for a pulmonary B_3 bradykinin receptor has been given by Farmer et al. (1989).

Bradykinin B_3 receptors have been described by Field et al. (1992) in the smooth muscle of the guinea-pig *taenia caeci* and trachea.

H.3.1.3 Substance P and the tachykinin family

H.3.1.3.1 General considerations

Substance P belongs to the tachykinin family of peptides that share a common carboxy-terminal sequence (Phe-X-Gly-Leu-Met-NH_2). It was first described by von Euler and Gaddum (1931) as a brain and gut extract that stimulates smooth muscle contraction. Bioassay extracts from spinal dorsal roots implicated substance P as a pain neurotransmitter (Lembeck 1953; Lembeck and Holzer 1979). After determination of the amino acid sequence (Chang et al. 1971) the distribution of substance P in the CNS could be studied (Hökfelt et al. 1975). Neurokinins belong like substance P to a group of neuropeptides named tachykinins. Following the discovery of neurokinin A and neurokinin B, three distinct G protein-coupled receptors, NK_1, NK_2 and NK_3, were described (Maggi et al. 1993; Mussap et al. 1993; Patacchini and Maggi 1995).

Neurokinin A and substance P are preferred agonists of the tachykinin NK_1 and NK_2 receptors, whereas neurokinin B preferentially interacts with the tachykinin NK_3 receptor. The receptor sensitivity of these peptides is relatively poor, and it is possible that their actions could be mediated by interactions with their less preferred receptors.

Nomenclature of tachykinins and tachykinin receptors has been discussed repeatedly (Henry 1987; Maggi 2000).

Tachykinin NK_1 antagonists are potent antiemetics, however other possible therapeutic uses, including rheumatoid arthritis, asthma, migraine, pain and psychiatric disorders, were suggested (Longmore et al. 1995). The P-preferring NK_1 receptor has attracted most interest as a CNS target because it is the predomi-nant tachykinin receptor expressed in the human brain, while NK_2 and NK_3 receptor expression is in extremely low abundance or absent. Several NK_1 receptor agonists antagonists were synthesized and evaluated (Snider et al. 1991; Emonds-Alt et al. 1993; Cascieri et al. 1992; Sakurada et al. 1993; Bristow and Young 1994; Jung et al. 1994; Rupniak and Williams 1994; Smith et al. 1994; Vassout et al. 1994; Patacchini and Maggi 1995; Bonnet et al. 1996; Chapman et al. 1996; Herbert and Bernat 1996; Palframan et al. 1996; Ren et al. 1996).

Moreover, agonists and antagonists at the NK_2 receptor (Hagan et al. 1991, 1993; Beresford et al. 1995; Robineau et al. 1995; Kudlacz et al. 1997; Lecci et al. 1997) and at the NK_3 receptor (Guard et al. 1990; Edmonds-Alt et al. 1995; Patacchini et al. 1995; Nguyen-Le et al. 1996; Beaujouan et al. 1997; Sarau et al. 1997) were reported (Longmore et al. 1995; Rupniak 1999).

Understanding the role of substance P in the brain has been complicated by marked species differences in the distribution of the tachykinin receptor types. There appears to be a relative increase in NK_1 receptor density during evolution, such that NK_3 receptors ara abundant in lower vertebrates and mammals but, like NK_2 receptors, are apparently absent in human brain. Preclinical studies with substance P receptor antagonists have been hindered not only by phylogenetic differences in tachykinin receptor expression, but also by pharmacological heterogeneity of the NK_1 receptor and the NK_2 receptor. An other confounding feature of neurokinin receptor antagonist is the blockade of Na^+ and Ca^{2+} channels at high doses which produces effects in various assays that are independent of receptor antagonism (Patacchini and Maggi 1995; Rupniak 1999). Most developments were guided by the effects of substance P as a pain neurotransmitter. Surprisingly, most clinical studies of analgesic activity of NK_1 receptor antagonists were negative (Rupniak and Kramer 1999). However, clinical findings indicated that substance P receptor antagonists ara able to alleviate depression and anxiety in patients suffering from major depressive disorder (Kramer et al. 1998).

H.3.1.3.2 ^{3}H-Substance P receptor binding

PURPOSE AND RATIONALE

Substance P is an undekapeptide which is widely distributed in the central and peripheral nervous systems and functions as a neurotransmitter/neuromodulator in a variety of physiological processes. Substance P is released from neurons in the midbrain in response to stress where it facilitates dopaminergic neurotransmission and from sensory neurons in the spinal cord in the response to noxious stimuli, where it excites dorsal neurons. In the periphery, release of substance P from sensory neurons causes vasodilatation and plasma extravasation, suggesting a role in neurogenic inflammation. Selective antagonists to substance P found in receptor binding studies may elucidate the physiological role of substance P and may be candidates for anti-inflammatory and analgesic drugs.

PROCEDURE

Fresh porcine brains are obtained from the slaughterhouse. Striata are dissected and homogenized (Ultraturrax®) in 50 mM ice-cold Tris-HCl buffer, pH 7.4) containing 150 mM NaCl, 150 mM KCl, 12 mM EDTA, 200 µM phenylmethylsulfonylfluoride, 40 µg/ml bacitracin, 4 µg/ml leupeptin, and 2 µg/ml chymostatin. These homogenates are then incubated for 30 min at 4 °C before being centrifuged at 30 000 *g* for 20 min at 4 °C and washed twice with 50 mM Tris-HCl (pH 7.4) buffer. Pellets are resuspended in 0.32 M sucrose containing 200 µM phenyl-methyl sulfonylfluoride and 40 µg/ml bacitracin before storage at –80 °C until use.

Sixty-minute incubations are carried out at room temperature in 50 mM Tris-HCl buffer, pH 7.4, containing various concentrations of [^{3}H]substance P ([^{3}H]SP) (0.05–20 nM), 5 mM $MgSO_4$, 40 mg/ml bacitracin, 4 mg/ml leupeptin, and 2 mg/ml chymostatin in the presence of 0.8–1 mg of membrane protein in a final volume of 1 ml. Total binding and nonspecific binding are determined in triplicate in the absence or presence of 1 mM unlabeled substance P. Incubations are terminated by adding 4 ml of ice-cold Tris-HCl buffer (pH 7.4) and membranes are filtered on Whatman glass fiber filters that are presoaked in 0.5% polyethylenimine for a minimum of 3 h to reduce absorption. Filters are then washed three times (5 ml each) using ice-cold Tris-HCl buffer (pH 7.4). Bound radioactivities are determined using a liquid scintillation counter.

EVALUATION

Saturation and competition data are analyzed using a computer program as described by McPherson (1985).

H.3.1.3.3 Neurokinin receptor binding

PURPOSE AND RATIONALE

The actions of tachykinins are mediated through three subtypes of neurokinin receptors belonging to the G protein-linked receptor family, namely, NK_1, NK_2 and NK_3. Substance P displays highest affinity to NK_1 receptors, whereas neurokinin A and neurokinin B preferably bind to NK_2 and NK_3 receptors, respectively. NK_1 receptors are expressed in a wide variety of peripheral tissues and in the CNS. NK_2 receptors are expressed primarily in the periphery, while NK_3 receptors are primarily expressed in the CNS.

PROCEDURE

Tachykinin NK_1 receptor binding assay is performed in intact Chinese hamster ovary (CHO) cells expressing the human tachykinin NK_1 receptor (Cascieri et al. 1992). The receptor is expressed at a level of 3×10^5 receptors per cell. Cells are grown in a monolayer culture, detached from the plate with enzyme-free cell dissociation solution (Specialty Media), and washed prior to use in the assay. ^{125}I[Tyr^8]substance P (0.1 nM, 2 000 Ci/mmol; New England Nuclear) is incubated in the presence or absence of test compounds (dissolved on 5 µl DMSO) with 5×10^4 CHO cells. Ligand binding is performed in 0.25 ml of 50 mM Tris-HCl, pH 7.5, containing 5 mM $MnCl_2$, 150 mM NaCl, 0.02% bovine serum albumin, 40 µg/ml bacitracin, 0.01 mM phosphoramidon and 4 µg/ml leupeptin. The incubation proceeds at room temperature until equilibrium is achieved (>40 min) and the receptor ligand complex is harvested by filtration over GF/C filters presoaked in 0.1% polyethylenimine using a Tomtek 96-well harvester. Nonspecific binding is determined using excess substance P (1 µM) representing <10% of total binding.

For **NK_2 receptor binding assays** membranes of CHO cells transfected with human ileum NK_2 receptor are used (Hagan et al. 1993; Beresford et al. 1995). The membrane suspensions (5 µg protein) in assay buffer (Tris base (50 mM), $MnCl_2$ (3 mM), bovine serum albumin (0.05%), chymostatin (2 µg/ml) and leupeptin 4 µg/ml, pH 7.4) are incubated for 90 min at room temperature with wash buffer (Tris base (50 mM), $MnCl_2$ (3 mM), lauryl sulphate (0.01%), pH 7.4) or test compound, and [^{3}H]-GR100 679 (0.5 nM final concentration). Nonspecific binding is defined by use of GR159 897 (1 µM).

For *NK_3* **receptor binding assays** guinea pig cortical membranes (Guard et al. 1990) are incubated at room temperature for 60 min with HEPES wash buffer or test compound and [^{3}H]-senktide (final concentration 0.8–1.0 nM). Non-specific binding is defined by addition of eledoisin (10 µM).

EVALUATION

Inhibition curves are analyzed and pIC_{50} values calculated by use of a curve fitting program. pIC_{50} values are converted to inhibition constants (pK_i values) using the Cheng Prussoff equation

$$K_i = IC_{50} / (1 + L / K_D)$$

where L is the ligand concentration and K_D is the dissociation constant. The K_D and B_{max} (maximum number of binding site per mg of tissue) are determined from saturation curves and analyzed by a curve fitting program. Values are expressed as means ±SEM.

MODIFICATIONS OF THE METHOD

Watson et al. (1955) performed substance P binding assays in **ferret brain membranes** and assessed neurokinin NK_1 receptor binding using human lymphoblasts (IM-9 cells).

Rupniak et al. (1997) studied displacement of ^{125}I-[Tyr^8]substance P binding to cloned human tachykinin NK_1 receptors and to ferret brain membranes *in vitro*.

Beattie et al. (1995) used U373 MG cell membranes and cerebral cortical membranes from rat, ferret and gerbil and [^{3}H]substance P for NK_1 receptor binding assays.

Bonnet et al. (1996), McLean et al. (1996) used the IM9 lymphoblastoma cell line expressing the human NK_1 receptor.

Emonds-Alt et al. (1995) studied binding of [^{125}I] Bolton-Hunter labelled substance P to **NK_1 receptors** of rat brain cortex, human lymphoblast cells (IM9), and human astrocytoma cells (U373MG, STTG1), binding of [^{125}I]iodohistidyl-NKA (or [^{125}I]neuropeptide γ) to **NK_2 receptors** of rat or hamster urinary bladder or guinea pig ileum, binding of [^{125}I]iodohistidyl-[Me-Phe^7]NKB (or [^{125}I]Eledoisin) to tachykinin **NK_3 receptors** of rat, guinea pig and gerbil brain cortex., and of [^{125}I]iodohistidyl-[Me-Phe^7]NKB to the human NK_3 re-ceptor, cloned and expressed in CHO cells (Buell et al. 1992).

Cascieri et al. (1992) described the binding of a potent, selective, radioiodinated antagonist to the human neurokinin-1 receptor.

A radioligand of the tachykinin NK_2 receptor was described by Renzetti et al. (1998).

Jordan et al. (1998) evaluated the Cytosensor microphysiometer, a system that measures the extracellular acidification rate as an index of the integrated functional response to receptor activation, as a method to study NK_3 receptor pharmacology and used this system to assess the functional activity of novel compounds at this receptor.

Appell et al. (1998) reported biological characterization of neurokinin antagonists discovered through screening of a combinatorial library. Using stably transfected CHO-K1 cell lines expressing human NK-1, NK-2 and NK-3 receptor subtypes and europium time-resolved fluorescence, primary receptor binding assays were designed to define active compounds. In addition, a secondary, functional assay measuring intracellular calcium flux with the calcium-sensitive fluorophore, fluo-3, in CHO cells transfected with the human NK-1 or NK-2 receptor was used to determine agonist or antagonist activities.

H.3.1.3.4 Characterization of neurokinin agonists and antagonists by biological assays

PURPOSE AND RATIONALE

Several biological assays have been used to characterize neurokinin agonists and antagonists on their receptors (Review by Regoli et al. 1994).

The following functional assays are recommended for evaluation of antagonists:

For NK_1 receptors

- Inhibition of [Sar^9,$Met(O_2)^{11}$]substance P-induced endothelium-dependent **relaxation of rabbit pulmonary artery**, previously contracted with 0.1 μM noradrenaline (D'Orléans-Juste et al. 1986; Rubino et al. 1992; Emonds-Alt et al. 1993),
- inhibition of [Sar^9,$Met(O_2)^{11}$]substance P or [Sar^9] substance P sulfone-induced contractions of **guinea pig ileum** in the presence of 3 μM atropine and 3 μM mepyramine and indomethacin (Dion et al. 1987; Emonds-Alt et al. 1993; Patacchini et al. 1995; Hosoki et al. 1998; Walpole et al. 1998),
- **rabbit vena cava** stimulated by substance P or [Sar^9, $Met(O_2)^{11}$]substance P (Nantel et al. 1991; Regoli et al. 1994; Gitter et al. 1995; Robineau et al. 1995; Bonnet et al. 1996; Nguyen-Le et al. 1996),
- inhibition of substance P-induced **relaxation of the isolated dog carotid artery** previously contracted with norepinephrine (Snider et al. 1991),
- **rat urinary bladder**, stimulated by the selective agonist [Sar^9,$Met(O_2)^{11}$]substance P and treated with SR 48986 (1.7×10^{-7} mol/l) to eliminate NK-2 functional sites (Rouissi et al. 1993; Nguyen-Le et al. 1996),
- inhibition of **substance P-induced plasma extravasation in the bladder and bronchi** of the guinea pig (Bonnet et al. 1996),
- inhibition of **substance P-induced vasodilation in the nasal mucosa of pigs** using an acoustic rhinometer (Rinder and Lundberg 1996),
- inhibition of **[Sar^9,$Met(O_2)^{11}$]substance P-induced plasma extravasation in guinea-pig bronchi** (Cirillo et al. 1998),
- inhibition of **methacholine-induced contractions of isolated rat tracheal strips** (Tian et al. 1997),
- inhibition of **cyclophosphamide- and radiation-induced damage in the rat and ferret organs** (Alfieri and Gardner 1997, 1998),
- inhibition of **edema formation induced by substance P and antigen in rat skin** (Herbert and Bernat 1996),
- inhibition of **reciprocal hindlimb scratching after in-tracerebroventricular injection of substance P, [Sar^9, $Met(O_2)^{11}$]substance P or septide in mice (Jung et al. 1994) or gerbils** (Smith et al. 1994),
- inhibition of **turning behavior after intracerebroventricular injection of substance P, [Sar^9,$Met(O_2)^{11}$] substance P or septide in mice** (Jung et al. 1994),
- inhibition of **hind paw tapping and chromodacryorrhea after intracerebroventricular injection of ta-chykinin agonists in gerbils** (Graham et al. 1993; Bristow and Young 1994; Rupniak and Williams 1994; Rupniak et al. 1995, 1997; Vassout et al. 1994),

- inhibition of **cis-platin-induced emesis in ferrets** (Rupniak et al. 1997; Singh et al. 1997; Minami et al. 1998).

For NK_2 receptors

- Inhibition of neurokinin A-induced contraction of **isolated rabbit aorta** (Snider et al. 1991),
- inhibition of neurokinin A-induced contraction of **isolated endothelium-deprived rabbit pulmonary artery or hamster trachea** (D'Orléans-Juste et al. 1986; Emonds-Alt et al. 1993; Patacchini et al. 1995),
- the **hamster urinary bladder** (Dion et al. 1987; Maggi et al. 1990; Regoli et al. 1994; Emonds-Alt et al. 1997; Tramontana et al. 1998),
- inhibition of **motor responses induced by intravesival administration of capsaicin** in rats *in vivo* (Lecci et al. 1997),
- **rat esophageal tunica muscularis** (Croci et al. 1995),
- inhibition of **turning behavior induced by intrastriatal injection of Nle^{10}-neurokinin A in mice** (Emonds-Alt et al. 1997).

For NK_3 receptors

- Inhibition of **senktide- or neurokinin B-induced contractions of the rat portal vein** (Mastrangelo et al. 1987; Snider et al. 1991; Emonds-Alt et al. 1993; Patacchini et al. 1995),
- antagonism against **senktide-induced contractions in the isolated rabbit iris sphincter muscle** (Medhurst et al. 1997; Sarau et al. 1997),
- inhibition of **colonic propulsion in rats** (Broccardo et al. 1999)
- inhibition of **turning behavior induced by intrastriatal injection of senktide in gerbils** (Emonds-Alt et al. 1994),
- inhibition of **citric acid-induced cough in guinea pigs** (Daoui et al. 1998).
- The failure of NK_1 receptor antagonists in most clinical tests for analgesia in spite of clear preclinical data is a matter of discussion (Hill R 2000a,b; Urban and Fox 2000).

H.3.1.4 Assay of polymorphonuclear leukocyte chemotaxis *in vitro*

PURPOSE AND RATIONALE

Leukocyte accumulation is an important aspect of host defense mechanisms. Chemotactic factors attract leukocytes to an infected or inflamed site. The method of Boyden (1962) has been widely employed to measure the chemotactic effects on polymorphonuclear leuko-

cytes. Watanabe et al. (1989) described a rapid assay of polymorphonuclear leukocyte chemotaxis *in vitro*.

PROCEDURE

Two 96-well tissue-culture plates are utilized as one set of multiple Boyden chambers. One plate as multiple lower compartments and the other plate upside down as multiple upper compartments can be tightly sandwiched with the aid of 12 sets of bolts. The holes, into which bolts are set and polymorphonuclear leukocytes (PMN) suspensions are introduced, are opened by a heated stick. Eight sets of 6 holes are made on the bottom of the upper plate to serve as multiple upper compartments for introducing PMN suspensions. Eight sets of polycarbonate filter (approximately 3.2×2.2 cm), cut from a round filter (Nuclepore Co.) with pores of 2 μm in diameter, are sandwiched between the upper and lower plates. One sheet of the filter can separate six sets of the upper compartments from the lower ones. Silicon grease is spread on all the plate surfaces that attach to the filters. The lower compartments are filled with a chemoattractant (400 μl/well) diluted in RPMI-1 640 medium. The eight sheets of filter paper are carefully placed on each set of the lower compartments to avoid air bubbles. The upper plate is positioned over the lower plate and fastened with bolts. The upper compartments are filled with 0.3 ml of PMN suspension (at 10^7 cells/ml). The assembly is incubated at 37 °C for 60 min in a humidified atmosphere containing 5% CO_2. Then the fluid in the upper compartment is decanted and the upper compartments are completely washed with a jet of water. The lower plate is centrifuged at 2 400 rpm for 5 min at room temperature and the supernatant in the well is decanted. The pellet of PMNs is dispersed in 200 μl of phosphate buffered saline containing 0.1% EDTA. Absorbance at 660 nm of each well containing PMN suspension is determined with a 96-well microplate reader. The number of PMNs in the lower compartments is further determined by a Coulter counter.

EVALUATION

The migration rate is calculated as percentage from the number of PMNs in the lower compartment/number of PMNs applied in the upper compartment. The migration rate is dependent on the concentration of the chemoattractant (e.g., zymosan-activated serum). Moreover, a dose dependent decrease of migration rate is achieved by chemotaxis inhibitors.

MODIFICATIONS OF THE METHOD

Nelson et al. (1975) described chemotaxis under agarose as a simple method for measuring chemotaxis and spontaneous migration of human polymorphonuclear leukocytes and monocytes.

Migration of PMNs in agarose gel was measured after fixation with glutaraldehyde and staining with Giemsa by Shalaby et al. (1987).

Optimal conditions for simultaneous purification of mononuclear and polymorphonuclear leukocytes from human blood were described by Ferrante and Thong (1980).

PMN chemotaxis was measured in multiwell microchemotaxis chambers separated by 5-μm pore size polyvinylpyrrolidone-free polycarbonate membranes by Harvath et al. (1980), Figari et al. (1987).

H.3.1.5 Polymorphonuclear leukocytes aggregation induced by FMLP

PURPOSE AND RATIONALE

Aggregation of polymorphonuclear leukocytes (PMNs) can be induced by FMLP (formyl-L-methionyl-L-leucyl-L-phenylalanine). The aggregation can be inhibited by xanthine derivatives.

PROCEDURE

PMNs cell suspensions are prepared from peritoneal exudates obtained 17 h after intraperitoneal injection of 10 ml 6% sodium caseinate into Sprague Dawley rats. The cells are washed twice in Geys-balanced-salt-solution (Gibco GBSS) and resuspended to a final concentration of 15×10^6 cells/ml. The test compounds and the standard (pentoxiphylline) are dissolved in GBSS. FMLP (formyl-L-methionyl-L-leucyl-L-phenylalanine) is dissolved in DMSO. The further dilutions are made up to a final concentration of 10^{-7} mol FMLP in GBSS. Before addition of FMLP, the cell suspensions are preincubated for 10 min with the drugs. PMNs aggregation is carried out in a Born aggregometer.

EVALUATION

The results are expressed as change in transmittance, measured in mm on the recorder. The mean peak of the untreated cells is set 100%.

MODIFICATIONS OF THE METHOD

Moqbel et al. (1986) measured the activation of human leukocytes after FMLP in a rosette assay by the change in the expression of complement (C3b) and IgG (Fc) receptors and in a cytotoxic assay by the *in vitro* capacity to adhere to and kill the complement-coated larvae (schistosomula) of Schistosoma mansoni.

Bradford and Rubin (1986) determined the effect of various drugs on IP_3 accumulation evoked by FMLP in neutrophils from New Zealand white rabbits.

Bourgoin et al. (1991) studied the influence of granulocyte-macrophage colony-stimulating factor (GM-CSF) on phosphatidylcholine breakdown by phopsholipase D in human neutrophils.

H.3.1.6 Constitutive and inducible cellular arachidonic acid metabolism *in vitro*

PURPOSE AND RATIONALE

The various metabolites of arachidonic acid are involved in many inflammatory processes. Arachidonic acid is released from the cellular phospholipid fraction by the action of phospholipase A_2, and subsequently metabolized via two major routes: the cyclooxygenase pathway yielding the primary prostaglandins and thromboxane, and the 5-lipoxygenase pathway yielding the leukotrienes. Thromboxanes, prostaglandins, and leukotrienes play a pathophysiological role in many diseases. Receptor assays for these autocoids were developed (Haluska et al. 1989). Murata et al. (1997) produced mice lacking the prostaglandin receptor which showed increased susceptibility to thrombosis and altered pain reception and inflammatory response.

The therapeutic mode of action of the classical nonsteroidal anti-inflammatory drugs (NSAID), such as aspirin or indomethacin, is primarily explained by their inhibitory effect on cyclooxygenase, the key enzyme of the prostaglandin pathway. Inhibitors of the 5-lipoxygenase pathway have attracted considerable attention as potential anti-inflammatories with high potency. Appropriate assay systems for the determination of the different eicosanoids allow to study the influence of drugs towards the specific pathways of the arachidonic acid cascade in various cellular systems (Samuelsson 1986; Vane and Botting 1987).

According to recent discoveries there are two forms of cyclooxygenase (Xie et al. 1992; Lee et al. 1992; Gierse et al. 1996). Cyclooxygenase-1 (COX-1) is found as a constitutive enzyme in most tissues including blood platelets. Prostaglandins generated by constitutive pathways may exert cytoprotective effects, and are involved in maintaining vital functions in vascular hemostasis, gastric mucosa and kidney.

The inhibition of these prostaglandins by the classical cyclooxygenase inhibitors is now generally accepted as an explanation of their adverse side effects.

COX-2 which shares about 62% amino acid homology with COX-1, is only expressed after cell activation, especially by mitogenic or inflammatory stimuli

(Herrmann et al. 1990; Funk et al. 1991; Crofford 1997). Thus, specific suppression of the COX-2-pathway may represent a superior target for the evaluation of new antiinflammatory drugs. Drugs which have a high potency on COX-2 and a favorable COX-2/COX-1 ratio have potent anti-inflammatory activity with fewer side effects (Riendeau et al. 1997; Vane 1998; Hawkey 1999; Song et al. 1999; Chan et al. 1999).

H.3.1.6.1 Formation of leukotriene B_4 in human white blood cells *in vitro*

PROCEDURE

Human white blood cells are prepared according to the standard procedure published by Salari et al. (1984): 40 ml freshly drawn citrated blood are admixed with 8 ml of PM16-buffer, containing 6% (v/v) dextran (MW = 480 000), and incubated at room temperature for one hour. The supernatant containing the white blood cell fraction is removed, diluted 1 : 1 (v/v) with PM16 and centrifuged for 15 min at 300 *g*. The precipitate is resuspended in PM16 and adjusted to 10^{10} cells/l (Counter HT, Coulter Electronics, Krefeld, FRG).

The metabolism of endogenously bound arachidonic acid to LTB_4 is measured in a total volume of 0.3 ml of the cell suspension at 37 °C. The reaction tube contains 2 mmol/l $CaCl_2$, 0.5 mmol/l $MgCl_2$ and the investigational drug. After 15 min pre-incubation the reaction is started by addition of 12.5 µg of the Ca-ionophore A 23 187 and 2 µg glutathione. After 5 min the reaction is stopped with 30 µl 0.1 M HCl at 0 °C. After centrifugation for 2 min at 0 °C, aliquots of the supernatant are subjected to HPLC, similarly as described by Veenstra et al. (1988), using a C-18 Nucleosil column (5 µm, 100 × 3 mm, Chrompack GmbH, Frankfurt, FRG) and, at a flow rate of 0.7 ml/min, a solvent mixture consisting of 725 ml methanol, 275 ml water and 0.1 ml acetic acid. Authentic standard drugs are used to identify cis-, trans- and epi-LTB_4. The separation of the three isomers can be followed photometrically at the UV-maximum of 278 nm.

EVALUATION

The peak areas of cis-, trans- and epi-LTB_4 are measured as a function of drug concentration, and related to a control experiment without drug.

CRITICAL ASSESSMENT

The tested pathway involves the enzymatic steps of phospholipase A_2 and the 5-lipoxygenase. Thus inhibitors of these enzymes are to decrease formation of the three isomers of LTB_4. The step of phospholipase A_2 can be circumvented by the addition of exogenous arachidonic acid (1 µmol/l).

Inhibitors of LTA_4-hydrolase which catalyzes the intermediary conversion of LTA_4 to the biologically active cis-LTB_4, can also be identified by this assay. Such drugs are to exhibit an increased formation of the non-enzymatic hydrolysis products trans- and epi-LTB_4 at the expense of decreased cis-LTB_4.

MODIFICATIONS OF THE METHOD

Winkler et al. (1988) used differentiated U-937 cells expressing LTB_4 receptors to study Ca^{2+} mobilization in response to LTB_4.

Jones et al. (1995) tested inhibition of [^{3}H]leukotriene D_4 specific binding in guinea pig lung, sheep lung, and dimethylsulfoxide-differentiated U837 cell plasma membrane preparations.

H.3.1.6.2 Formation of lipoxygenase products from ^{14}C-arachidonic acid in human polymorphonuclear neutrophils (PMN) *in vitro*

PROCEDURE

PMN are prepared by the standard procedure of Böyum (1976). The first steps are carried out at room temperature: 50 ml citrated human blood are centrifuged at 130 *g* for 15 min. The pellet is resuspended in 20 ml Dulbecco's minimal essential medium, and subsequently underlayered with 15 ml lymphoprep. After centrifugation at 400 *g* for 25 min the pellet is resuspended in 28 ml Dulbecco's HBSS containing 3% dextran. After incubation at 0 °C for 120 min the decanted supernatant is centrifuged at 400 *g* for 15 min. The pellet is resus-pended in 1 ml Dulbecco's PBS, containing 11 µmol/l glucose, to a leukocyte count of 2×10^{10}/l.

The method of HPLC determination of cellular metabolites of exogenous 1-C-14-arachidonic acid, as published by Borgeat and Samuelsson (1979), is modified as briefly described:

0.1 ml of the leukocyte suspension are incubated in Dulbecco's phosphate buffered saline (DPBS) at 37 °C with the test drugs for 15 min. The incubation is then interrupted by cooling in an ice bath. Calcium ionophore A 23187 (final concentration 7×10^{-5} mol/l) and 1-C-14-arachidonic acid (final concentration 8.4×10^{-5} mol/l, 0.5 µCi) are added, and, after a second incubation period of 15 min at 37 °C, terminated by the addition of 0.4 ml methanol. The assay mixture is then extracted with chloroform. The chloroform is evaporated, and, after redissolving the residue in a minor amount of methanol/water, analyzed by HPLC and radiomonitoring for the C-14-eicosanoids.

HPLC-conditions are as follows: Column: Nucleosil C-18, 5 µm; organic phase: 700 ml methanol, 300 ml water, 0.1 ml acetic acid; after 35 min change to pure methanol. Flow: 1 ml/min, 2 000 psi. Radiomonitor: LB 507 (Berthold, Wildbad, FRG).

A viability assay (trypan blue exclusion) ascertains that cells remain intact during incubation periods.

EVALUATION

The radioactivity of the separated 5-HETE and LTB_4 is measured as a function of drug concentration, and related to a control experiment without drug. Two further lipoxygenase products, 12-HETE and 15-HETE, which are additionally generated under the test conditions, can be quantified in a similar way.

CRITICAL ASSESSMENT

The measured reaction sequence starts with arachidonic acid, and involves its transformation to 5-HETE by 5-lipoxygenase, as well as the subsequent enzymatic hydrolysis to LTB_4. Inhibitors of 5-lipoxygenase exhibit a decreased formation of 5-HETE and LTB_4. Effects of drugs on the side products 12-HETE and 15-HETE can also be studied in this test system.

H.3.1.6.3 Formation of eicosanoids from ^{14}C-arachidonic acid in human platelets *in vitro*

PROCEDURE

Blood is drawn from the vena brachialis of healthy volunteers and collected into plastic tubes containing sodium citrate (0.38% final concentration (w/v)). After centrifugation at 100 *g* for 15 min the platelet rich plasma (PRP) containing about $2{,}5 \times 10^{11}$ platelets/l (Counter HT, Coulter Electronics, Krefeld, FRG) is saved, and kept at 20 °C no longer than one hour until the experiment is started. Metabolism of ^{14}C-arachidonic acid is followed by the HPLC procedures published by Weithmann et al. (1994), modifying the method of Powell (1985). PRP is mixed with the same volume of a citrate/D-glucose solution (27.35 g trisodium citrate · 2 H_2O, 1.47 g citric acid and 27.74 g D(+)-glucose · H_2O ad 1 l water) and centrifuged at 1000 *g* for 20 min (4 °C). The saved precipitate is resuspended in Dulbecco's solution (DPBS, Serva, Heidelberg, FRG) in the original volume. 0.495 ml of this platelet suspension is incubated at 37 °C for 15 min with the test compound. Subsequently eicosanoid formation is started by the addition of 5 µl of 1-^{14}C-arachidonic acid solution (50 Ci/mol, 9×10^{-4} Ci/l, NEN, Dreieich, FRG). After 5 min (37 °C) the reaction is stopped by adding 0.5 ml of chilled acetone/0.1 ml 1n HCl, cooled to 0 °C, and extracted two times with 3 ml ethylacetate. The combined organic extracts are evaporated and the residue redissolved in 0.2 ml methanol. Aliquots are separated by HPLC at a flow rate of 1.5 ml/min, using a C-18 Nucleosil column (5 µm, 125×4.6 mm, Bischoff, Leongang, FRG) connected with a pre-column C-18 Nucleosil (5 µm, 20×4.6 mm) of the same type. The formed ^{14}C-eicosanoids are analyzed using a liquid scintillation flow detector LB 507 (Berthold, Wildbad, FRG). The radiochromatogram is analyzed by comparison with tritiated authentic eicosanoids (NEN, Dreieich, FRG). The elution system consists of the following solvent mixtures (elution time in parenthesis): I 725 ml water/275 ml acetonitrile/1 ml acetic acid (40 min), II 700 ml methanol/300 ml H_2O/1 ml acetic acid (40 min), III pure methanol (20 min)

EVALUATION

The radioactivity of the separated TXB_2 and PGE_2 is measured as a function of drug concentration, and related to a control experiment without drug addition.

A further lipoxygenase product, 12-HETE, which is additionally generated under the test conditions, can be quantified in a similar way.

Lasché and Larson determined PGI_2 by a bioassay based on its generation by aortic rings and assay by its ability to inhibit platelet aggregation.

CRITICAL ASSESSMENT

The measured reaction sequence starts with arachidonic acid, and involves its transformation to prostaglandin endoperoxides, which is catalyzed by cyclooxygenase. The unstable and short-living endoperoxides transform immediately into thromboxane A_2 by the action of thromboxane isomerase. TXA_2 is unstable, too, and yields the stable non-enzymatic hydrolysis product TXB_2.

Inhibitors of cyclooxygenase exhibit a decreased formation of TXB_2. Specific inhibition of the thromboxane isomerase step results in an accumulation of the mentioned endoperoxide intermediates, which due to their chemical instability are non-enzymatically transformed to the primary PGE_2. Thus, inhibitors of the TXA_2-isomerase lead to a significant increase of the PGE_2-peak at the expense of the TXB_2-peak. Effects of drugs on the side product 12-HETE can also be studied in this test system.

H.3.1.6.4 Stimulation of inducible prostaglandin pathway in human PMNL

PROCEDURE

The procedure of Herrmann et al. (1990) with the modification of Weithmann et al. (1994), is used to stimu-

late cyclohexamide-inhibitable generation of PGE_2 in human PMNL by LPS.

H.2.5×10^9 PMNL/l culture medium (RPMI 1 640, completed with 1 mmol/l sodium pyruvate, 5% FCS (w/v), 2 mmol/l glutamine and each 100 U/ml penicillin/streptomycin) are incubated with 100 µmol/l acetylsalicylic acid for 60 min (37 °C, 5% CO_2), and the latter subsequently removed by four times washing with medium. 0.25 ml-aliquots (containing 2.5×10^9 PMNL/l medium) are incubated with 0.1 mg/ml LPS (lipopolysaccharide from Salmonella abortus equii, Sigma GmbH, Deisenhofen, FRG) along with the test compound for 18 h (96-well plates, 37 °C, 5% CO_2). The generation of eicosanoids is induced by the administration of 7×10^{-5} mol/l of the calcium ionophore A 23 187. After incubation for 30 min at 37 °C the plates are centrifuged at 400 *g* for 15 min. PGE_2 is determined in the supernatant, using an ELISA-kit commercially available from several distributors. Alternatively the test compound is added along with the calcium ionophore. At least 90% of the cells remain intact during incubation times (trypan blue exclusion assay).

EVALUATION

The PGE_2-concentration in the sample is determined from appropriate calibration curves. The PGE_2-concentration is measured as a function of drug concentration, and related to a control experiment without drug.

CRITICAL ASSESSMENT

Long term activation with LPS or other inflammatory effectors leads in human polymorphonuclear neutrophils to the stimulation of a prostaglandin synthesizing capacity, which under normal conditions is not present in this system. The described assay system detects compounds which interfere with this activation process.

Incubation of drugs with already activated cells allows to search for drugs that directly influence the enzyme activity.

H.3.1.6.5 COX-1 and COX-2 inhibition

PURPOSE AND RATIONALE

Several assays were described to characterize COX-1 and COX-2-inhibitors, such as *in vitro* COX enzyme assay (Seibert et al. 1994), COX-2 protein extraction and analysis (Anderson et al. 1996), a human whole blood assay using LPS-induced PGE_2 production as an index for cellular COX-2 activity (Riendeau et al. 1997) or whole-cell assays with transfected Chinese hamster ovary cells expressing COX-1 and COX-2 or COX-2 specific (osteosarcoma cells) and COX-1 specific (U937 cells) making use of PGE_2 production after arachidonic challenge as an index of cellular potency and selectivity of cyclooxygenase inhibitors (Chan et al. 1999).

PROCEDURE

Inhibition studies with recombinant human COX-1 and COX-2

Microsomal preparations of recombinant human COX-1 and COX-2 are prepared from a vaccine virus-COS-7 cell expression system (O'Neill et al. 1994). Recombinant human COX-1 and COX-2 are expressed in baculovirus-Sf9 cells, and enzymes are purified (Ouellet and Percival 1995; Cromlish and Kennedy 1996). Enzymatic activity is monitored continuously by either a fluorescence assay measuring the appearance of the oxidized form of the reducing agent cosubstrate homovanillic acid or by oxygen consumption (Ouellet and Percival 1995).

HPLC assay for oxygenation of radiolabelled arachidonic acid by COX-1

Purified recombinant human COX-1 (50 µl of 1 µg/ml in 100 mM Tris-HCl, pH 8.0, 5 mM EDTA, 1 mM phenol, 1 µM hematin) is preincubated with 2 µl of the inhibitor solution (50 fold concentrated stock in DMSO, 0–2.5 mM) for 15 min. The reaction is then initiated by the addition of 5 µl of 1 µM [^{14}C]-arachidonic acid (0.005 µCi) to obtain a final concentration of 0.1 µM. After 7 min incubation at room temperature, the reaction is stopped by the addition of 5 µl 1 M HCl and 50 µl acetonitrile. Aliquots of 50 µl of each reaction mixture are analyzed for substrate conversion by reverse phase HPLC onto a C-18 Nova-Pak column (3.9×150 mm) which is developed with acetonitrile/water/acetic acid (85 : 15 : 0.1) at 2 ml/min. Arachidonic acid metabolites and arachidonic acid eluted at 0.6–1 min and 2.2–2.5 min, respectively, are quantitated by a Packard radiochromatography detector. Percentages of inhibition are calculated from the difference in conversion of arachidonic acid to prostaglandin metabolites between inhibitor-treated samples and controls exposed to DMSO vehicle.

Determination of the stoichiometry of inhibitor binding

Aliquots of purified COX-2 (0.25 mg/ml, concentration of subunit of 3.4 mM) are incubated in buffer (100 mM Tris-HCl, pH 8.0, 5 mM EDTA, 1 mM phenol) in the presence of various inhibitors (0–8 µM) for 15 or 30 min. An aliquot (20 µl) is then removed for determination of the cyclo-oxygenase activity which is monitored continuously by oxygen consumption by a Clark-type polarographic oxygen probe. The oxygen chamber is filled with 0.6 ml of reaction buffer (100 mM Tris-HCl, pH 8.0, 5 mM EDTA, 1 µM hematin,1 mM

phenol, 100 μM arachidonic acid at 30° or 37 °C) and the reaction is initiated by the addition of 20 μl of a solution of 4 mM hydrogen peroxide and 0.5 mM N,N,N',N'-tetramethyl-p-phenylenediamine (TMPD) in assay buffer. Enzyme concentration is determined by amino acid concentration following acid hydrolysis.

Determination of the dissociation rate constant of the enzyme-inhibitor complex

Purified COX-2 (2.0 nmol, 2 ml) in 20 mM Tris-HCl, pH 8.0, 0.1 mM EDTA, 2 μM hematin, 0.1% β-octyl-glucoside is treated with 2.0 nmol [^{14}C]-DFU (18 Ci/mol) and incubated at 20 °C for 3 h. A control (0.7 ml) is removed and 13 nmol unlabelled DFU is added to the remaining 1.3 ml of the mixture containing COX-2 and [^{14}C]-DFU. At timed intervals, 0.1 ml (in duplicate) is transferred to a Microcon-30 micro concentration device (Amicon) and the free inhibitor is separated from enzyme-bound inhibitor by centrifugation at 14 000 *g* for 6 min at 4 °C. Buffer (0.1 ml) is added to the retentate and the centrifugation repeated. The filtrate and retentate are then removed and mixed with 10 ml scintillation fluid and counted in a liquid scintillation counter.

An aliquot of purified COX-2 (1.0 nmol) is treated with 1.25 mol equivalents of inhibitor or with DMSO vehicle control and incubated at 20 °C for 1 h. The enzyme-inhibitor mixture is then transferred to a Pierce Microdialyzer 100 apparatus and dialyzed continuously against 2 l of buffer (20 mM Tris-HCl, pH 8.0, 0.1 mM EDTA, 0.1 mM phenol, 0.1% octylglucoside) for 5 h at 22 °C during which aliquots are moved and frozen at −70 °C until assayed for cyclyo-oxygenase activity by oxygen uptake as described above.

Recovery of inhibitor from the COX-2-inhibitor complex

Purified COX-2 (0.79 nmol) is treated with 1.0 mol equivalent of inhibitor and the mixture is incubated for 60 min at room temperature. The remaining activity at this time is 4% that of a vehicle-treated control. The sample is then divided in two and the protein denaturated by treatment with four volumes of ethyl acetate/methanol/1 M citric acid (30 : 4 : 1). After extraction and centrifugation (10 000 *g* for 5 min), the organic layer is removed and the extraction repeated. The two organic layers are combined and dried under N_2. The extract is dissolved in 10 μl of HPLC solvent mixture consisting of water/acetonitrile/acetic acid (50 : 41 : 0.1) and 50 μl are injected onto a Novapak C-18 column (3.9 × 150 mm) and developed at 1 ml/min. The inhibitor is detected by absorption at 260 nm and eluted with a retention time of 6.6 min in this system. Control experiments for inhibitor recovery are performed with incubation of the inhibitor in the absence of enzyme and processing of the samples in an identical fashion before quantitation by HPLC.

Spectrophotometric assay of recombinant human COX-2

Enzymatic activity of the purified COX-2 is measured using a chromogenic assay based on the oxidation of N,N,N',N'-tetramethyl-p-phenylenediamine (TMPD) during the reduction of PGG_2 to PGH_2 (Copeland et al. 1994). The assay mixture (180 μl) contains 100 mM sodium phosphate, pH 6.5, 1 μM hematin, 1 mg/ml gelatin, 2 to 5 μg/ml of purified COX-2, and 4 μl of the test compound in DMSO. The assay is also performed in the presence of the detergent Genapol X-100 at a final concentration of 2 mM. The mixture is preincubated at room temperature (22 °C) for 15 min before the initiation of the enzymatic reaction by the addition of 20 μl of a solution of 1 mM arachidonic acid and 1 mM TMPD in assay buffer (without enzyme or hema-tin). For assays in the presence of Genapol, the arachidonic acid and TMPD solution is prepared in 50% aqueous ethanol. The enzyme activity is measured by estimation of the initial velocity of TMPD oxidation over the first 36 s of the reaction as followed from the increase in absorbancy at 610 nm. A low rate of non-enzymatic oxidation is observed in the absence of COX-2 and is subtracted before the calculation of the percentage of inhibition.

Whole-cell assays with transfected Chinese hamster (CHO) cells expressing COX-1 and COX-2

Stably transfected CHO cells expressing human COX-1 and COX-2 are cultured and assayed for the production of PGE2 after stimulation with arachidonic acid (Kargman et al. 1996). Cells (0.3×10^6 cells in 200 μl) are pre-incubated in HBSS containing 15 mM HEPES, pH 7.4, with 3 μl of the test drug or DMSO vehicle for 15 min at 37 °C before challenge with arachidonic acid. Cells are challenged for 15 min with an arachidonic acid solution (10% ethanol in HBSS) to yield final concentrations of 10 μM arachidonic acid in the CHO[COX-2] assay and 0.5 μM arachidonic acid in the CHO[COX-1] assay. In the absence of addition of exogenous arachidonic acid, levels of PGE_2 in samples from CHO[COX-1] are <30 pg $PGE_2/10^6$ cells. In the presence of 0.5 μM exogenous arachidonic acid, levels of PGE_2 in samples from CHO[COX-1] cells increase to 260 to 1 500 pg $PGE_2/10^6$ cells. After stimulation with 10 μM exogenous arachidonic acid, levels of PGE_2 in samples from CHO[COX-2] cells increase from <120 to 700 to 1 600 pg $PGE_2/10^6$ cells. Compounds are tested in eight concentrations in duplicate using 3-fold serial dilutions in DMSO. COX activity in the absence of test compounds is determined as the difference in PGE_2 levels of cells challenged with arachidonic acid versus PGE_2 levels in cells mock-challenged with ethanol vehicle.

Whole-cell assays with osteosarcoma cells (COX-2) and U937 cells (COX-1)

The human osteosarcoma cell line has been shown to selectively express COX-2 by reverse transcription-polymerase chain reaction and immunoblot analysis, whereas undifferentiated human lymphoma U937 cells selectively express COX-1. The production of PGE_2 by these cells after arachidonic acid challenge is used as an index of cellular COX-2 and COX-1 activity, respectively. Test substances are preincubated for 5 to 15 min with the cells under serum-free conditions (HBSS) before a 10-min stimulation with 10 µM arachidonic acid and measurement of PGE_2 production (Wong et al. 1997). COX activity in each cell line is defined as the difference in PGE_2 concentrations in samples incubated in the presence or absence of arachidonic acid.

Human whole blood assay

For the COX-2 assay, fresh heparinized human whole blood is incubated with lipopolysaccharide from *E. coli* at 100 µg/ml and with 2 µl of vehicle or a test compound for 24 h at 37 °C (Brideau et al. 1996). PGE_2 levels in the plasma are measured using radioimmunoassay after deproteination. For the COX-1 assay, an aliquot of fresh blood is mixed with either DMSO or test compound and is allowed to clot for 1 h at 37 °C. TBX_2 levels in the serum are measured using an enzyme immunoassay after deproteination.

MODIFICATIONS OF THE METHOD

Berg et al. (1997) developed a cell assay system using the human erythroleukemic cell line HEL as a source for COX-1 and the human monocytic cell line Mono Mac 6 as a source for COX-2.

H.3.1.7 Induced release of cytokines (Interleukin-1alpha, IL-1beta, IL-6, IL-8 and TNF-alpha) from human white blood cells *in vitro*

PURPOSE AND RATIONALE

Cytokines represent a class of different, biologically highly potent peptides, that are endogenously synthesized upon stimulation. They are involved in numerous cellular processes, such as inflammation, immunological responses and many others. Their broad pleiotrophic biological activities are best characterized by their former classification as

- B-cell activating and differentiating factor, endogenous pyrogen, osteoclast activating factor, thymocyte proliferation factor, monocyte cell factor, leukocyte endogenous factor (IL-1);
- hepatocyte stimulatory factor, hybridoma growth factor, haematopoietic cell stimulatory factor (IL-6);
- neutrophil chemotactic factor and adhesion inhibitor (IL-8);
- tumor necrosis factor (TNFalpha).

There are presently 18 cytokines with the name interleukin (IL) (Dinarello 2000). The concept of proinflammatory cytokines and antiinflammatory cytokines (IL-4,IL-10,IL-13) is fundamental to cytokine biology and novel drug discovery strategies.

Blocking IL-1 or TNF has been highly successful in patients with rheumatoid arthritis, inflammatory bowel disease, or graft-vs.-host disease.

The following procedure is used to detect compounds that interact with the lipopolysaccharide in ced cytokine release from human mononuclear blood cells. The cytokines measured are interleukines 1alpha, 1beta, 6 and 8, as well as TNFalpha.

PROCEDURE

According to Böyum (1976)10 ml of freshly prepared human citrated blood is diluted 1 : 1 with PM 16-buffer (Serva, Heidelberg, FRG), and underlayered with 15 ml Lymphoprep® (Molter GmbH, Heidelberg, FRG), and subsequently centrifuged at 20 °C with 400 *g* (Minifuge®, Heraeus, Hanau, FRG) for 30 min. The cell fraction appearing as a white ring between the two phases is carefully removed by means of a syringe, diluted 1 : 1 (v/v) with PM 16 and again centrifuged for 15 min. The pellet is washed with 10 ml of RPMI 1 640 (Gibco, Berlin, FRG), containing in addition 300 mg/l L-glutamine. The washed cell fraction is taken up in 1 ml RPMI 1 640, containing in addition 300 mg/l L-glutamine, 25 mmol/l HEPES, 5% FCS and 100 IU/ml penicillin/streptomycin (Gibco). Using a cell counter (type IT, Coulter Diagnostics, Krefeld, FRG) the cell suspension which consists of about 90% lymphocytes and 10% monocytes is adjusted to approx. 5×10^9 cells/ml.

Synthesis and release of cytokines according to Tiku et al. (1986) is performed in 96 wells microtiter plates. To 0.23 ml of the cell fraction 500 ng LPS (lipopolysaccharide from Salmonella abortus equii, Sigma GmbH, Deisenhofen, FRG), dissolved in 0.01 ml dimethyl-sulfoxide/water (1 : 10, v/v), and the investigational drug, dissolved in 0.01 ml, are added. The cell suspension is now kept at 37 °C/5% CO_2 in a common incubator. Incubation time is usually 20 h (for Il-6 and Il-8 only four or one hour, respectively). The reaction is stopped by placing the microtiter plate into an ice bath. The plate is then centrifuged at 2 000 rpm for 2 min. The cytokine levels are determined in various aliquots of the supernatant using the appropriate ELISA-kit, which is commercially available from several distributors.

EVALUATION

The cytokine-concentration in the sample is determined from appropriate calibration curves. The cytokine-concentration is measured as a function of drug concentration, and related to a control experiment without drug.

In general, Hostacortin® (10 to 0,1 µmol/l) is used as the standard compound.

CRITICAL ASSESSMENT

Drugs interfering with LPS-activation, biosynthesis and cellular release of cytokines are to exhibit activity in these assay systems. Usually cell viability is not altered, as assessed by the lactate-dehydrogenase test.

MODIFICATIONS OF THE METHOD

Van der Pouw-Kraan et al. (1992) examined the regulation of interleukin (IL)-4 production by human peripheral blood T cells. Production of IL-4 as measured by ELISA was shown to be regulated differently from IL-2 and INF-γ (also measured by ELISA).

H.3.1.8 Flow cytometric analysis of intracellular cytokines

PURPOSE AND RATIONALE

Flow cytometry is a powerful analytical technique in which individual cells can be simultaneously analyzed for several parameters, including size an granularity, as well as the expression of surface and intracellular markers defined by fluorescent antibodies. Fluorescent anti-cytokine and anti-chemokine monoclonal antibodies are very useful for the intracellular staining and multiparameter flow cytometric analysis of individual cytokine-producing cells within mixed populations. Multicolor immunofluorescent staining with antibodies against intracellular cytokines and cell surface markers provides a high resolution method to identify the nature and frequency of cells which express particular cytokines (Sander et al. 1991, 1993; Jung 1993).

PROCEDURE

Cells and cell culture

Peripheral blood is obtained from healthy human volunteers. Mononuclear cells are isolated by Ficoll gradient centrifugation. For purification of T cells or further cell sorting, mononuclear cells are incubated with neuraminidase treated sheep red blood cells and centrifuged over Ficoll. Erythrocytes are eliminated by ammonium chloride lysis. For isolation of memory cells or naive cells, T cells are incubated with a cocktail of antibodies containing anti-CD16, anti-CD56, anti-CD20, anti-CD14, (anti-CD8), and anti-CD45RA or anti-CD45R0. Cell sorting is done with the magnetic cell sorter (MACS) according to Abts et al. (1989), Miltenyi et al. (1990) using rat anti-mouse IgG1 or Ig2a antibodies labeled with superparamagnetic beads (Miltenyi, Bergisch Gladbach, Germany). Depleted cells are highly enriched with $CD4^+(CD3^+)CD45R0^+$ or $CD4^+(CD3^+)CD45R0^-CD45RA^+$ cells (>95%) and are referred to as memory cells and naive cells ($CD4^+CD45R0^-CD45RA^+$) respectively. Only depleted cells are used for experiments.

Cells (2×10^5/100 ml) are cultured in 96 well flat bottom plates for various periods of time at 37 °C and 8% CO_2 in RPMI 1 640 supplemented with 2 mM glutamine, 1 mM sodium pyruvate, 100 IU/ml penicillin, 100 µg/ml streptomycin, 2×10^{-5} M mercaptoethanol and 10% AB serum. Cells are stimulated with phorbol

12-myristate 13-acetate 1–10 ng/ml + 1 μM ionomycin, phytohemagglutinin 2.4 μg/ml or phytohemagglutinin 2.4 μg/ml + phorbol 12-myristate 13-acetate 1 ng/ml in the presence or absence of 3 μM monensin (Sigma).

Staining

Cultured cells are washed twice in Hanks' balanced solution (HBSS) and then fixed in ice-cold HBSS containing 4% paraformaldehyde for 10 min. After two further washes in HBSS the cells are resuspended to 2×10^5 in 300 μl HBSS containing 0.1% saponin, 10% AB serum, 100 μg/ml goat IgG and 0.01 M HEPES buffer. After 10 min, the cells are spun down and cytokine specific antibodies diluted in HBSS with 0.1% saponin and 0.1 M HEPES buffer (saponin buffer) are added at a concentration of 1 μg/ml for 30 min at room temperature. Cells are washed twice in saponin buffer and subsequently incubated with isotype-specific second step antibodies in a concentration ranging from 0.5 to 5 μg/ml for 20 min in the dark. Cells are washed in saponin buffer and stained with streptavidin conjugates or in the case of surface staining incubated with 200 μg/ml mouse IgG diluted in saponin buffer for 15 min. After subsequent washing in saponin buffer cells are washed twice in HBSS and stained for 20 min with different antibodies in order to determine their surface phenotype. As a last step, cells are washed in HBSS.

Flow cytometry

A FACScan flow cytometer (Becton Dickinson, Mountain View, USA) equipped with a 15 mW argon ion laser and filter settings for fluorescein-isothiocyanate (530 nm), phycoerythrin (585 nm) and TRI-Color (Medac, Hamburg, Germany) or PerCP (Becton Dickinson, USA) emitting in the deep red (>650 nm) is used.

EVALUATION

5 000–10 000 cells are computed in list mode and analyzed using the FACScan research software (Becton Dickinson)

MODIFICATIONS OF THE METHOD

Slauson et al. (1999) combined the analytical power of flow cytometry with mitogen-driven, whole blood lymphocyte activation and proliferation assays to investigate the *in vitro* mechanism of action of malononitrilamides.

Protocols for immunofluorescent staining of intracellular cytokines for flow cytometric analysis are provided by BD Phar Mingen, Life Science Research Europe, Heidelberg, Germany.

Ashcroft and Lopez (2000) highlighted the opportunities in high throughput flow cytometry (HTFC) which are opened by commercial high speed machines. The specifications of these machines are cell analysis rates over 100 000 cells/s and cell sorting rates of 55 000 cells/s with high purity.

H.3.1.9 TNF-alpha antagonism

PURPOSE AND RATIONALE

There are two distinct types of tumor necrosis factors, TNF-alpha (cachectin) and TNF-beta (lymphotoxin), with biological activities going beyond the necrosis of tumor cells. Some of the known activities include the induction of interleukin 1, activation of PMNs, modulation of endothelial cell functions, and augmentation of specific immune functions. The complex sequence of hemodynamic and metabolic collapse which leads to shock and death during lethal endotoxinemia appear to represent the response of the infected host to the acute, systemic release of TNF-alpha. Thus, drugs that antagonize the activity of this mediator could be of clinical value in combating its fatal effects.

PROCEDURE

Twenty hours before the initiation of the experiments, L 929 cells are harvested from stock cultures and are plated in 96 well culture plates (2×10^4 cells/well) and incubated at 37 °C and 5% CO_2 in air. For each group 6 wells are set up. The cells are then preincubated for 30 min with test substances or solvent before TNF-

alpha is added (between 1 and 10 IU/well). After an additional incubation time of 20 h, the culture plates are flicked out and the remaining living cells are lysed by the addition of bidistilled water (100 µl). After 30 min incubation at room temperature, 100 µl of LDH reagent are given to each culture well. After 15 min, the enzyme activity is determined photometrically at 490 nm.

EVALUATION

The percent inhibition is calculated according to the formula:

$$\% \text{ inhibition} = 100\% - \frac{\text{ext. test group} - \text{ext. spontaneous lysis}}{\text{ext. positive control} - \text{ext. spontaneous lysis}}$$

The positive control is the group which receives vehicle and TNF-alpha. The spontaneous lysis is based on cultures which receive vehicle without TNF-alpha.

MODIFICATIONS OF THE METHOD

Maloff and Delmendo (1991) measured the binding of tumor necrosis factor (TNF-α) to the human TNF receptor. Membranes were prepared from HeLa S3 human cervical epithelioid carcinoma cells. An aliquot of 0.2 mg of membrane preparation was incubated with 62 pM [^{125}I]TNF-α for 3 h at 4 °C. Nonspecific binding was measured in the presence of 50 nM TNF-α. Membranes were filtered and washed 3 times and the filters were counted to determine the bound [^{125}I]TNF-α

H.3.1.10 Binding to interferon receptors

PURPOSE AND RATIONALE

The interferons (IFNs) were discovered in 1957 as biological agents interfering with virus replication. They are a family of secreted proteins occurring in vertebrates and can be classified as cytokines. The IFNs are multifunctional and are components of the host defense against viral and parasitic infections and certain tumors. They affect the functioning of the immune system in various ways and also affect cell proliferation and differentiation.

IFNs were initially classified by their sources as leukocyte, fibroblast, and immune IFNs. Leukocyte and fibroblast IFNs, together, were also designated as Type 1 IFNs and immune IFN as Type 2 IFN. The recent nomenclature designates leukocyte IFNs as IFN-α and IFN-ω (earlier α-1 and α-2, respectively) fibroblast IFN as IFN-β, and immune IFN as IFN-γ.

Interferons bind to receptors on the cell surface and induce the synthesis of specific proteins. Littman et al. (1985) found that recombinant IFN-γ produced in bacteria, which is not glycosylated, binds to cellular receptors with an affinity similar to that of natural IFN-γ.

PROCEDURE

Human lymphoblastoid cells (Daudi, MOLT-4 and Raji) are grown in stationary cultures in Dulbecco's medium with 10% heat-inactivated horse serum. HeLa cells are grown in Eagle's medium with 7% horse serum.

The following interferons are used: Purified recombinant interferon-γ (rIFN-γ) (Genentech, antiviral activity 1.2×10^7 units/mg); natural human INF-β (Interferon Working Group of the NCI, antiviral activity 2×10^5 roentgen units/mg); rIFN-2α (Schering, antiviral activity 2×10^8 reference units/mg); rIFN-β (Cetus Corp., antiviral activity 2.6×10^8 reference units/mg).

Fifty micrograms of rIFN-γ are reacted for 2 h at 0 °C with 1 mCi of ^{125}I-Bolton-Hunter reagent (2 000 Ci/mmol) in 0.25 ml of sodium borate buffer, pH 8.0. The reaction is stopped by the addition of glycine to a final concentration of 0.2 M and applied to a 26×0.7 cm column of Sephadex G-75 equilibrated with phosphate-buffered saline, pH 7.4, containing 0.25% gelatin. The reaction vial is washed with 20-µl aliquots of this buffer containing 40% ethylene glycol and then with buffer alone. The washes are added to the column and 0.32 ml fractions are collected. The fractions containing ^{125}I-rIFN-γ are pooled and diluted with 1/10 volume of 10-fold concentrated Eagle's medium containing 10 mg/ml bovine serum albumin and 0.1 mM dithiothreitol.

Cells harvested from exponentially growing cultures are centrifuged and resuspended at 8×10^6/ml in their own medium supplemented with 10 mM HEPES buffer, pH 7.4. Standard binding assays contain 3 to 5×10^6 cells and 0.46 nM ^{125}I-rIFN-γ. At the end of the reaction, the cells are centrifuged through 10% sucrose at 10 000 rpm in Microfuge tubes and the cell pellet is counted. A blank value is determined by incubating and processing in the same way an equal amount of ^{125}I-rIFN-γ in the absence of cells; this blank is subtracted from the cpm bound.

EVALUATION

The binding data are analyzed using the LIGAND program developed by Munson and Rodbard (1980).

MODIFICATIONS OF THE METHOD

Blatt et al. (1996) described the biological activity of consensus interferon, a wholly synthetic type I interferon, developed by scanning several interferon-alpha nonallelic subtypes and assigning the most frequently observed amino acid in each position.

IFN-τ, a new class of type I interferon was described by Pontzer et al. (1994), Alexenko et al. (1997, 1999), Martal et al. (1998), Swann et al. (1999).

Thiam et al. (1998) reported the agonist activities of a lipopeptide derived from INF-γ on murine and human cells by analysis and quantification of cell surface markers using flow cytometry and cell-ELISA.

Bosio et al. (1999) reported efficacy of type I interferon in cytomegalovirus infections *in vivo*. Oral administration of type I interferons (murine INF-α and INF-β) reduced early replication of murine cytomegalovirus in both the spleen and liver of infected BLB/c mice.

Tovey and Maury (1999) found a marked antiviral activity of murine interferon-α/β or individual recombinant species of murine INF-α, INF-β, or INF-γ or recombinant human INF-α1-8 in mice challenged systemically with a lethal dose of encephalomyocarditis virus, vesicular stomatitis virus, or varicella zoster virus. Oromucosal administration of INF-α also exerted a marked antitumor activity in mice injected i.v. with highly malignant Friend erythroleukemia cells or other transplantable tumors, such as L1 210 leukemia, the EL4 tumor, or the highly metastatic B16 melanoma.

To gain more insight into similarities of different INF-α species, Viscomi et al. (1999) evaluated neutralization and immunoactivity of a variety of INF preparations with various monoclonal antibodies obtained through immunization with recombinant, lymphoblastoid, and leukocyte INF-α.

Reporter transgenic mice expressing the luciferase gene under the control of separate TCR-response elements from the INF-γ promoter or expressing the green fluorescent protein gene under the control of an INF-γ minigene were employed by Zhang et al. (1999) to explore the basis for IL-12 regulation of INF-γ gene transcription.

Poynter and Daynes (1999) studied the influence of constitutively expressed INF-γ on age-associated alterations in inducible nitric oxide synthase regulation using cell cultures from mouse spleen for nitrite and cytokine analysis.

H.3.1.11 Screening for interleukin-1 antagonists

PURPOSE AND RATIONALE

Interleukin-1-α and -β are potent regulators of inflammatory processes. The naturally occurring interleukin-1 receptor antagonist (IL-1ra) is effective *in vitro* and *in vivo* in modulating biological responses to IL-1 (Schreuder et al. 1995). Using a combination of anion exchange, gel filtration, and reverse-phase HPLC, three species of native IL-1ra were identified. An unglycosylated,

intracellular isoform is designed as icIL-1ra (Lennard 1995; Arend et al. 1998).

A cell-free, nonisotopic assay has been developed to discover molecules that compete with the natural ligands for binding to the active sites of the type-I interleukin-1 receptor. The key reagents are the interleukin-1 receptor antagonist, a recombinant soluble form of the receptor (sIL-1R), and a specific anti-sIL-1R nonneutralizing monoclonal antibody (Sarrubi et al. 1996).

PROCEDURE

Proteins

The extracellular portion of the type-I interleukin-1 receptor (sIL-1R) is expressed on the membrane of Chinese hamster ovary cells using a phosphatidinyl-inositol-glycan linkage (PIG-tail). Its expression, cleavage with phosphoinositol-specific phospholipase C, and purification is performed according to Whitehorn et al. (1995).

The three interleukin-1 ligands are expressed in *Escherichia coli* using synthetic genes (Dower et al. 1989; Yanofsky and Zurawski 1990). The purification of IL-1ra and IL-β is accomplished according to Schreuder et al. (1995) and Yem et al. (1988).

IL-1α is purified as follows: *E. coli* cell sonicates are precipitated with 2 M ammonium sulfate, and the pellet is resuspended in TE (25 mM Tris/HCl, pH 8.9, 1 mM EDTA), dialyzed vs. the same buffer and loaded on a DEAE-Sepharose column equilibrated with TE. The protein is eluted with a linear NaCl gradient to 300 mM. Ammonium sulfate to 0.8 M is added to the IL-1α containing fractions which are loaded onto a phenyl-Sepharose column equilibrated with TE containing 0.8 m ammonium sulfate. The elution is performed with a linear gradient to TE with no salt. IL-1α-containing fractions are concentrated and chromatographed on a Sephacryl S-200 column in PBS (phosphate buffered saline: 20 mM sodium phosphate, pH 7.3, 150 mM sodium chloride).

Fluorescein-labeled IL-1α is obtained by incubating 1 mg/ml IL-1α with 1 mg/ml fluorescein isothiocyanate in PBS for 2 h at room temperature in the dark. The reaction solution is passed directly over a G-25 column (Pharmacia) equilibrated with PBS to remove unreacted fluorescein isothiocyanate.

The monoclonal antibody Mab79 is used as direct dilutions $1:10^5$–10^6) of ascitic fluid in PBSA (PBS containing 0.3% bovine serum albumin). Horse-radish peroxidase-linked anti-mouse IgG polyclonal antibody is used.

Protein concentrations are determined using the Bio-Rad protein assay kit, based on the dye-binding procedure according to Bradford (1976). BSA is used as reference protein.

Immobilized-ligand IL-1 receptor binding assay

Essentially the same procedure can be used for both manual and automated versions of the assay, with all steps and incubations performed at room temperature. In the automated assay a Beckman Biomek 1 000 WorkStation was used for all steps, from coating to spectrophotometric measurements.

Ligand immobilization is obtained by incubation 3.6 µg/ml IL-1ra in 50 µl PBS in flat-bottomed culture-treated microplate wells, equivalent to 10 pmol/well of IL-1ra. After overnight incubation microplates are emptied and 250 µl/well of 3% BSA in PBS is added to block unreacted sites. After 2 h of incubation and three washes with an excess of PBS, the ligand-coated microplates are ready for the receptor binding reaction.

In separate microplates with U-shaped wells, 12 µl of samples (containing up to 50% DMSO or DMF) or controls (the same solution without compound) is mixed with 48 µl of 150 pM sIL-1R in PBSA. Fifty microliters of these mixtures is transferred to the IL-1ra-coated plates (equivalent to 6 fmol/well of sIL-1R) and incubated for 2 h. Microplates are then washed twice with PBS and 50 µl of 1 : 500 000 dilution of Mab79 ascitic fluid in PBSA is added to each well. After 1 h of incubation, 25 µl of 1 : 100 dilution of HRP-labeled anti-mouse IgG in PBSA is added and the incubation prolonged for an additional hour. Plates are finally washed four times with PBS and bound peroxidase activity is measured spectrophotometrically, suing either o-phenylenediamine (OPD) or tetramethylbenzidine (TMB) as substrate. In the first case, 150 µl of 1 mg/ml OPD in 0.1 M citric acid, pH 5.0, containing 0.03% of a 35% solution of hydroperoxide is added and, after color development, the reaction is stopped with 50 µl of 4.5 M sulfuric acid. Alternatively, 100 µl of 0.1 mg/ml TMB in 25 mM citric acid and 50 mM sodium phosphate, containing 0.02% hydrogen peroxide (35% solution) is added and the reaction is stopped with 50 ml of 2.5 M sulfuric acid.

EVALUATION

Absorbance (at 492 nm for OPD and 450 nm for TMB) is measured either in a Titertek microplate reader (for the manual procedure) or directly by the Biomek 1 000 WorkStation (in the automated version). IC_{50} values can be calculated from dose-response curves.

CRITICAL ASSESSMENT OF THE METHOD

Since no cells or cell membranes are used, the assay is very robust, with no interference from membrane-perturbing agents and high resistance to the organic solvent normally used to resuspend compounds of chemical libraries.

MODIFICATIONS OF THE METHOD

High affinity type I interleukin 1 receptor antagonists were discovered by screening recombinant peptide libraries (Yanosfky et al. 1996).

Akeson et al. (1996a) developed an *ex vivo* method for studying inflammation in cynomolgus monkeys using whole blood for analysis of IL-1 antagonists administered *in vivo*. Animals were given an i.v. infusion of IL-1ra, and blood samples were taken pre-infusion and during the infusion. The samples were incubated with of without IL-1β and the subsequent *ex vivo* induction of IL-6 determined. This allows the analysis of *in vivo* efficacy of antagonists without exposing the animals to IL-1.

A novel low molecular weight antagonist, selectively binding type I interleukin (IL)-1 receptor and blocking the *in vivo* responses to IL-1 was described by Akeson et al. (1996b).

Evaluation of the interleukin-1 receptor antagonist IL-1ra in a rodent abscess model of host resistance was published by Colagiovanni and Shopp (1996).

Blocking monoclonal antibodies (mAbs) specific to mouse interleukin-1 receptor antagonist (IL-1ra) were prepared by immunizing Armenian hamsters with recombinant mouse IL-1ra by Fujioka et al. (1995). A sensitive and specific ELISA against mouse IL-1ra was established.

Miesel et al. (1995) tested the anti-arthritic reactivity of the IL-1 receptor antagonist IL-1ra in male DBA/1xB10A(4R) mice with arthritis induced by intraplantar injection of potassium peroxochromate. Three µmol/kg K_3CrO_8 were administered topically into the left hind paws. One h after the induction of arthritis, 2 mg/kg IL-1ra were administered intraperitoneally which was repeated on day 2. An arthritis index was determined daily.

H.3.1.12 Inhibition of interleukin-1β converting enzyme (ICE)

PURPOSE AND RATIONALE

Programmed cell death (apoptosis) is effected through a cascade of intracellular proteases, kwon as caspases (Alnemri et al. 1996). The interleukin-1β-converting enzyme (ICE), alternatively known as capsase-1, was the first such protein identified on the basis of sequence its homology to the pro-apoptotic *Caenorhabditis elegans* gene product, ced-3 (Yuan et al. (1993). The caspase family includes 10 reported human homologues

of ICE. By sequence homology comparisons three caspase subfamilies have been identified. The ICE subfamily includes three caspases: ICE, TX (caspase-4), and TY (caspase-5). The CPP32 subfamily includes CPP32 (caspase-3), CMH-1 (caspase-7), and MCH-2 (caspase-6). A third caspase subfamily includes ICH-1 (caspase-2), FLICE (caspase-8) and caspases-9 and -10.

ICE processes pro-IL-1β to yield active IL-1β, which plays a pivotal role in inflammatory cell activation (Dinarello 1996) and is known to inhibit the expression of apoptosis (Tatsuda et al. 1996). Inhibition of IL-1β formation is an approach for treatment of inflammatory disorders such as rheumatoid arthritis. Livingstone (1997) presented a review on *in vitro* and *in vivo* studies of peptidyl ICE inhibitors.

PROCEDURE

Neutrophil isolation

Neutrophils are isolated from healthy volunteers by dextran sedimentation and centrifugation through a discontinuous Ficoll gradient (Lee et al. 1993). Isolated neutrophils are resuspended in polypropylene tubes at a concentration of 1×10^6 cells/ml in DMEM supplemented with 10% FCS, 1% glutamine, and 1% penicillin/streptomycin solution. Neutrophil purity is assessed by size and granularity on flow cytometry.

Quantification of apoptosis

Neutrophil apoptosis is quantified by flow cytometry as the percent of cells with hypodiploid DNA (Nicoletti et al. 1991). Cells are centrifuged at 200 *g* for 10 min, gently resuspended in 500 µl of hypotonic fluorochrome solution (50 µg/ml propidium iodide, 3.4 mM sodium citrate, 1 mM Tris, 0.1 mM EDTA, and 0.1% Triton X-100) and stored in the dark at 4 °C for 3 to 4 h before analysis using a Coulter Epics XL-MCL cytofluorometer. A minimum of 5 000 events are collected and analyzed. Apoptotic nuclei are distinguished from normal neutrophil nuclei by their hypodiploid DNA; neutrophil debris is excluded from analysis by raising the forward threshold. Apoptotic nuclei appear as a broad hypodiploid DNA peak which is easily discernible from the narrow peak of cells with normal diploid DNA content. Apoptosis is assessed at 24 h after treatment.

Assay of caspase-1 activity

Cell lysates are prepared from the membrane fraction of 20×10^6 neutrophils following experimental manipulation. Aliquots of the lysates (10 µl) are diluted in assay buffer (100 mM HEPES (pH 7.4), 10% sucrose, and 0.1% 3-([3-cholamidopropyl]dimethylammonio]-1-propanesulfonate) containing 20 µM Ac-Tyr-Val-Ala-Asp-7-amino-4-methylcoumarin (Calbiochem) and then incubated for 45 min at room temperature. The release of 7-amino-4-methylcoumarin is detected by continuous measurement using a Perkin-Elmer LS50 luminescence spectrometer with an excitation of 380 nm and an emission slit at 460 nm. Specific ICE (caspase-1) activity is measured as pmol/s per milligram of protein.

EVALUATION

Individual experiments are repeated a minimum of four times; results are expressed as the mean ±SD. Analysis is performed using the Student *t*-test or ANOVA with Scheffè's correction.

H.3.2 *In vivo* methods for anti-inflammatory activity

H.3.2.1 General considerations

The inflammatory process involves a series of events that can be elicited by numerous stimuli, e.g., infectious agents, ischemia, antigen-antibody interactions, chemical, thermal or mechanical injury. The response is accompanied by the clinical signs of erythema, edema, hyperalgesia and pain. Inflammatory responses

occur in three distinct phases, each apparently mediated by different mechanisms:

- an acute, transient phase, characterized by local vasodilatation and increased capillary permeability,
- a subacute phase, characterized by infiltration of leukocytes and phagocytic cells,
- and a chronic proliferative phase, in which tissue degeneration and fibrosis occur.

According to these phases, pharmacological methods have been developed.

Methods for testing acute and subacute inflammation are:

- UV-erythema in guinea pigs
- Vascular permeability
- Oxazolone-induced ear edema in mice
- Croton-oil ear edema in rats and mice
- Paw edema in rats (various modifications and various irritants)
- Pleurisy tests
- Granuloma pouch technique (various modifications and various irritants)

The proliferative phase is measured by methods for testing granuloma formation, such as:

- Cotton wool granuloma
- Glass rod granuloma
- PVC sponge granuloma.

Furthermore, methods for testing immunological factors have been developed, such as:

- Adjuvant arthritis in rats (various modifications)
- Experimental allergic encephalomyelitis
- Schultz-Dale-reaction
- Passive cutaneous anaphylaxis
- Arthus type immediate hypersensitivity
- Delayed type hypersensitivity

(see Chapter I).

H.3.2.2 Methods for testing acute and subacute inflammation

H.3.2.2.1 Ultraviolet erythema in guinea pigs

PURPOSE AND RATIONALE

The test was first described by Wilhelmi (1949) who was able to delay the development of ultraviolet erythema on albino guinea pig skin by systemic pretreatment with clinically equivalent doses of phenylbutazone and other nonsteroidal anti-inflammatory agents. The test procedure was further developed by Winder et al. (1958) and since that time modified by various investigators.

PROCEDURE

Albino guinea pigs (Pirbright white strain) of both sexes with an average weight of 350 g are used. Eighteen h prior testing, the animals are shaved on both flanks and on the back. Then they are chemically depilated by a commercial depilation product or by a suspension of barium sulfide. Twenty minutes later, the depilation paste and the fur are rinsed off in running warm water. On the next day, the test compound is dissolved (or suspended) in the vehicle and half the dose of the test compound is administered by gavage (at 10 ml/kg) 30 min before ultraviolet exposure. Control animals are treated with the vehicle alone. Four animals are used for each treatment group and control. The guinea pigs are placed in a leather cuff with a hole of 1.5×2.5 cm size punched in it, allowing the ultraviolet radiation to reach only this area. An original Hanau ultraviolet burner Q 600 is warmed up for about 30 min prior to use and placed at a constant distance (20 cm) above the animal. Following a 2 min ultraviolet exposure, the remaining half of the test compound is administered. The investigator has to protect himself/herself by gloves and ultraviolet glasses. The erythema is scored 2 and 4 h after exposure.

EVALUATION

The degree of erythema is evaluated visually by 2 different investigators in a double-blinded manner. The followings scores are given:

- 0 = no erythema,
- 1 = weak erythema,
- 2 = strong erythema,
- 4 = very strong erythema.

Animals with a score of 0 or 1 are considered to be protected. The scoring after 2 and after 4 h gives some indication of the duration of the effect. ED_{50} values can be calculated. Doses of 1.5 mg/kg indomethacin p.o., 4 mg/kg phenylbutazone p.o. and 60 mg/kg acetylsalicylic acid p.o. have been found to be effective.

CRITICAL ASSESSMENT

The test has the advantage of simplicity but needs training of the investigators. Attempts to use reflection photometers in order to eliminate subjective scoring were unsuccessful. Corticosteroids after systemic application are rather ineffective in this test, however, can be

evaluated after topical administration. The test is not particularly useful to study the duration of the anti-inflammatory effect.

MODIFICATIONS OF THE TEST

Yawalkar et al. (1991) tested several steroids after local application in the ultraviolet-induced dermatitis inhibition in guinea pigs. Clobetasol propionate was more effective than hydrocortisone, halobetasol propionate was superior to both corticosteroids.

Woodward and Owen (1979) used the albino guinea-pig ear as the site of inflammation produced by UV radiation. Ear temperature, water content of the ear and vascular permeability were measured. Indomethacin, phenylbutazone and aspirin given subcutaneously were active but paracetamol was not.

Warren et al. (1993) studied the role of nitric oxide synthase and cyclo-oxygenase in the skin blood flow to UVB irradiation in the shaved dorsal skin of anesthetized male **Sprague Dawley rats** with a laser Doppler flow probe. Topical application of clobetasol-17-propionate immediately after irradiation inhibited the 18 h UVB response in a dose-dependent manner.

Gloxhuber (1976) measured skin thickness using calipers in **hairless mice** after UV-irradiation of the back and treatment with anti-inflammatory drugs.

Woodbury et al. (1994), Kligman (1994) described a rapid assay of the anti-inflammatory activity of topical corticosteroids by inhibition of a UVA-induced neutrophil infiltration in hairless mouse skin. Skh-hairless mice were irradiated with UVA light on an area of 2×2 cm square on the dorsal trunk fore 200 min in anesthesia. Steroid treatment was once daily for 7 days. Irradiation was on the 8^{th} day. Neutrophils were counted microscopically in punch biopsies.

H.3.2.2.2 Vascular permeability

PURPOSE AND RATIONALE

The test is used to evaluate the inhibitory activity of drugs against increased vascular permeability which is induced by a phlogistic substance (Miles and Miles 1992). Mediators of inflammation, such as histamine, prostaglandins and leucotrienes are released following stimulation e.g. of mast cells. This leads to a dilation of arterioles and venules and to an increased vascular permeability. As a consequence, fluid and plasma proteins are extravasated and edemas are formed. These effects are counteracted by H_1- antihistaminics, inhibitors of arachidonic acid metabolism and by leucotriene receptor antagonists. In addition, membrane-stabilizing drugs are able to reduce capillary permeability. Vascular permeability is increased by intracutaneous injection of the mast cell-degranulating compound 48/80. The increase of permeability can be recognized by the infiltration of the injected sites of the skin with the vital dye Evan's blue.

PROCEDURE

Male Sprague-Dawley rats with a body weight between 160 and 200 g are used. The ventral sides of the animal are shaved. Five ml/kg of an 1% solution of Evan's blue are injected intravenously. One hour later the animals are dosed with the test compound orally or intraperitoneally or with the vehicle. Ten animals are used for each test group and the control. Thirty minutes later, the animals are briefly anaesthetized with ether and 0.05 ml of an 0.01% solution of compound 48/80 are injected intracutaneously at 3 sites both at the left and ventral side. Ninety minutes after the injection of compound 48/80 the animals are sacrificed by ether anesthesia. The abdominal skin is removed and the dye-infiltrated areas of the skin are measured.

EVALUATION

The diameter of the dye-infiltrated areas is measured in millimeters in two perpendicular directions and the mean values of all injection sites in one animal are calculated. The percent inhibition in the treated animals as compared to the control group is calculated. A treated animal which shows values less than 50% of controls can be considered as positive. ED_{50} values can be calculated in this way. Phenylephrine at a dose of 15 mg/kg has been found to be effective.

CRITICAL ASSESSMENT OF THE METHOD

The test for vascular permeability is useful for characterization of a new anti-inflammatory compound.
Since compounds with sympathomimetic activity have a pronounced effect this test cannot be regarded as a primary screening test for anti-inflammatory products. Together with an observation of writhing or "squirming" of mice, Whittle (1964) has proposed to be able to distinguish between narcotic and non narcotic analgesics.

MODIFICATIONS OF THE METHOD

Shionoya and Ohtake (1975) described a simple method for extraction of extravasated dye (Evan's blue) in the skin.

Frimmer and Müller (1962) presented a critical survey on the use of dye methods for quantitative determination of increased capillary permeability following intracutaneous injection of active substances.

McClure et al. (1992) used the Olympus CUE-2 Image Analyzer to quantify vascular permeability in the Miles assay in guinea pigs.

Zentel and Töpert (1994) used oxazolone-induced Evans blue extravasation for preclinical evaluation of topical corticosteroids. Female **NMRI-mice** were sensitized by topical application of 50 µl of 40% oxazolone in ethanol to 4 cm^2 of the left flank. After 13 days the animals were injected intravenously with 0.2 ml of 0.5% Evan's blue in water and 20 µl of 4% oxazolone in ethanol were topically applied to 6 cm^2 of the right flank immediately after injection. Three h later the challenged skin was treated with various corticosteroids in ointment. The animals were sacrificed 24 h after treatment and the challenged skin removed. Evans blue extravasation was measured spectrophotometrically at 623 nm.

Teixeira et al. (1993) studied acute inflammatory reactions in **guinea pig skin** measuring infiltration of ^{111}In-labelled eosinophils and neutrophils and edema formation by extravasation of ^{125}I-human serum albumin.

Fujii et al. (1996) quantified vascular permeability by the extravasation of pontamine sky blue in the skin of male ddY mice after subcutaneous injection of lipopolysaccharides.

Blackham and Woods (1986) measured extravasation of pontamine sky blue in the **mouse** peritoneal cavity.

Cambridge et al. (1996) investigated 6-hydroxydopamine-induced plasma extravasation in **rat skin** after intravenous injection of ^{125}I-human serum albumin and Evan's blue.

Rouleau et al. (1997) measured the inhibition of capsaicin-induced plasma extravasation by a histamine H_3 receptor agonist prodrug by analysis of extravasated Evan's blue in skin, eye conjunctiva, nasal mucosa, trachea, main bronchi, esophagus and urinary bladder of rats.

Watanabe et al. (1984) used fluorescein isothiocyanate-labeled bovine serum albumin as tracer to measure vascular permeability in the **carrageenin air pouch of rats**.

Collins et al. (1993) studied the pro-inflammatory properties of the human recombinant vascular permeability factor containing 165 amino acids in **rabbits**.

Urinary bladder cystitis induced by cyclophosphamide was used as model of intestinal inflammation and pain by several authors (Ahluwahlia et al. 1994; Bon et al. 1996; Boucher et al. 1997; Alfieri and Gardner 1997). Male Wistar rats weighing 300–400 g were treated first with test drug or saline subcutaneously or intraperitoneally and then injected 5 min later with 150 mg/kg i.p. cyclophosphamide. One h later, anaesthesia was induced by 40 mg/kg i.p. pentobarbitone and 50 mg/kg Evans blue were injected into the jugular vein. Fifteen min later, the rat was exsanguinated by infusion of 50 ml saline into the left cardiac ventricle. The urinary bladder, the left kidney, the superior lobe of the left lung and approximately 1-cm portions of the duodenum and jejunum were removed and blotted before dry weighing. The content of Evens blue dye was determined by spectrophotometry at 620 nm after extraction in known volumes of formamide at 60 °C for 60 h.

Ferrets were treated in the same way, but the dose of cyclophosphamide was 125 mg/kg and the volume of exsanguination was 300 ml.

Hirota et al. (1995) induced **chemical peritonitis in rats** by applying 0.02 M HCl on the surface of the cecum or appendix and quantified the inflammation by measuring the extravasation of intravenously injected Evan's blue bound to albumin extracted from those tissues.

H.3.2.2.3 Inhibition of leukocyte adhesion to rat mesenteric venules *in vivo*

PURPOSE AND RATIONALE

Reversible adherence of leukocytes to endothelium, basement membranes and other surfaces is an essential event in the establishment of inflammation. Their entry into tissues is controlled by the dynamic interaction between adhesion molecules expressed by these cells and the endothelium. White cells circulating in the blood have the tendency to adhere to the walls of blood vessels and this tendency is greatly increased in states of inflammation. Normally, when leukocytes collide with the vessel wall, the collision behaves elastically and the cells bounce off and back into the lumen. However, biochemical changes in inflamed tissues results in inelastic collisions of cells and an increase in their adhesion, thus initiating rolling of leukocytes along the endothelial surface. As adhesion further increases, rolling is slowed and may be followed by the cells coming to a complete stop and their migration out of the vessel. This can be observed by preparing a mesenteric venule of an anesthetized rat and following the flow and rolling of leukocytes by means of a microscope, thus allowing in-vivo studies. In this test procedure, adhesion of leukocytes, to the vessel wall, is artificially induced by the application of the formyl-methionyl peptide fMet-Leu-Phe (FMLP). Formyl peptides are released from bacteria and mitochondria of damaged tissue, so these peptides provide a specific signal marking the presence of invading bacteria or tissue damage. The density of FMLP receptors ranges from 10^4 to 10^5 per cell, depending on the cell type. Activation of leukocytes through this receptor results in rapid expression of preformed L-selectin (LECAM-1) on the cell surface which causes the cells to roll along the endothelial surface. LECAM-1 are very rapidly shed from the surface of leukocytes, however, and integrins take over to maintain further adhesion and migration into the tissue.

PROCEDURE

Sprague-Dawley rats are anesthetized by administration of Nembutal®. The trachea, jugular vein and caro-

tid artery are prepared free, the abdominal cavity is opened and a section of ileum is pulled out and draped over a heated microscope table. Prior to test compound administration, the number of spontaneous adhering leukocytes is counted, every 5 min, in a defined section of a venule (covered with paraffin oil) during a 30-min period (control). Blood pressure, body temperature and velocity of blood flow are also registered. The test compound is administered via continuous infusion during the entire test procedure beginning at $t = -30$ min. Following the determination of control values for spontaneous adhesion, FMLP (f-Met-Leu-Phe, 10^{-4} M) is dripped twice ($t = -30$ min and $t = 0$ min) on the preparation and the number of adhering leukocytes is determined every 5 min over a 90 min period, beginning with the second application of FMLP ($t = 0$ min). Each test group consists of at least 10 animals. The mean leukocyte count of every rat prior to FMLP and/or test substance application is taken as the 100% value to obtain the baseline for further comparisons. The test compounds are dissolved in 0.9% NaCl shortly before application.

EVALUATION

Following the second topical application of FMLP (10^{-4} M), the number of adhering leukocytes in the mesenteric venule section is counted 30 min after the stimulus is given, and again at the end of the observation period of 2 h. The influence of a continuous i.v. infusion of the test drug is compared with the positive control group (FMLP stimulation, without drug).

MODIFICATIONS OF THE METHOD

A simple, rapid, *in vitro* assay for granulocyte adherence was developed by MacGregor et al. (1974). Heparinized whole blood is filtered through nylon fibers packed in Pasteur pipettes, and the percentage of granulocytes adhering was calculated.

Neutrophil adherence was tested *in vitro* by Burch et al. (1992). Human umbilical vein endothelial cells were plated at $5 \acute{} 10^4$ cells/well into collagen coated culture plates and grown to confluence. Neutrophils were labeled with ^{51}Cr. Experimental agents were added to the neutrophils before their activation with FMLP. After 15 min incubation at 37°C, the non-adherent leukocytes were removed by gentle aspiration followed by a wash with saline. The adherent neutrophils were lysed by 1 N NaOH and the radioactivity was quantitated.

H.3.2.2.4 Oxazolone-induced ear edema in mice

PURPOSE AND RATIONALE

The oxazolone-induced ear edema model as first described by Evans (1971) in mice is a model of delayed contact hypersensitivity that permits the quantitative evaluation of the topical and systemic anti-inflammatory activity of a compound following topical administration.

PROCEDURE

Mice of either sex with a weight of 25 g are used. Before each use a fresh 2% solution of oxazolone (4-ethoxymethylene-2-phenyl-2-oxazolin-5-one) in acetone is prepared. The mice are sensitized by application of 0.1 ml on the shaved abdominal skin or 0.01 ml on the inside of both ears under halothane anesthesia. The mice are challenged 8 days later again under anesthesia by applying 0.01 ml 2% oxazolone solution to the inside of the right ear (control) or 0.01 ml of oxazolone solution, in which the test compound or the standard is solved. Special pipettes of 0.1 ml or 0.01 ml are used. Groups of 10 to 15 animals are treated with the irritant alone or with the solution of the test compound. The left ear remains untreated. The maximum of inflammation occurs 24 h later. At this time the animals are sacrificed under anesthesia and a disc of 8 mm diameter is punched from both sides. The discs are immediately weighed on a balance. The weight difference is an indicator of the inflammatory edema.

EVALUATION

Average values of the increase of weight are calculated for each treated group and compared statistically with the control group. A 0.003% solution of hydrocortisone and a 1% solution of indomethacin were found to be active.

CRITICAL ASSESSMENT OF THE METHOD

The method is suitable for both steroidal and non-steroidal compounds as well as for the evaluation of various topical formulations

MODIFICATIONS OF THE METHOD

Griswold et al. (1974) applied a 3% solution of oxazolone to the left paw of mice. The edema was assessed plethysmographically

Various cutaneous models of inflammation for the evaluation of topical and systemic pharmacological agents have been discussed by Young and Young (1989).

Bailey et al. (1995) described a contact hypersensitivity model in mice for rank-ordering formulated corticosteroids. Male Swiss Webster mice were sensitized with 20 µl of 2% oxazolone on the inner and outer aspects of each ear (10 µl each side). Mice were challenged 7 days later with 2% oxazolone in acetone : olive oil (4 : 1) on both sides of the right ear. Animals were topically treated with corticosteroids or non-steroidal antiinflammatory drugs or 20 mg formulated corticosteroids immediately after challenge. The mice were sacrificed after 24 h and edema and myeloperoxidase activity were determined. Edema was measured by taking the weight of 6 mm trephine punch biopsies of the right and left ears. Inhibition was calculated from change in ear weight of control or drug treated ears versus placebo treated ears. Myeloperoxidase activity was assessed spectrophotometrically (Williams et al. 1983) on tissue homogenates. In a delayed-type hypersensitivity model animals were treated as in the contact hypersensitivity model, except the mice were sensitized with 40 µl of 2% oxazolone in acetone:olive oil (4 : 1) on the unshaved inguinal areas.

Meingassner et al. (1997) studied anti-inflammatory activity using allergic contact dermatitis im **mice, rats** and **pigs**. Mice were sensitized on the shaved abdomen with 50 µl of 2% oxazolone solution in acetone. After 7 days, they were challenged with 10 µl of 2% (for topical testing) or 0.5% (for systemic testing) oxazolone on the inner surface of the right ears. Pinnal weight was taken as a measure of inflammatory edema 24 h after challenge. Female Sprague Dawley *rats* were sensitized by application of 80 µl of 2,4-dinitrofluorobenzene solution applied in 20 µl volumes to the inner surface of both ear lobes and to both shaved inguinal regions on day 1. Allergic contact dermatitis was elicited with 30 µl of 0.5% 2,4-dinitrofluorobenzene applied to the test sites of ≈15 mm in diameter on both shaved flanks on day 12. Animals were treated by gavage 2 h before and immediately after challenge. Dermatitis was evaluated by measuring the thickness of the lifted skin fold at the test sites with a spring-loaded micrometer. Domestic **pigs** were sensitized wit 400 µl of 10% 2,4-dinitrofluorobenzene applied to four areas on both ears and groins. Challenge reactions were elicited 12 days later with 15 µl of 2,4-dinitrofluorobenzene (1%) applied topically to test sites arranged in four craniocaudal lines on the dorsolateral shaved back (24 or 32 per pig). Test sites were treated twice either with 20 µl solution of test compound or with ≈50 mg of a cream formulation applied topically 30 min and 6 h after challenge. One day after challenge the test sites were visually evaluated for intensity and extent of erythema and induration.

H.3.2.2.5 Croton-oil ear edema in rats and mice

PURPOSE AND RATIONALE

The method has been developed primarily as a bioassay for the concomitant assessment of the antiphlogistic and thymolytic activities of topically applied steroids by Tonelli et al. (1965)

PROCEDURE

For tests in mice the irritant is composed as follows (v/v): 1 part Croton oil, 10 parts ethanol, 20 parts pyridine, 69 parts ethyl ether. For tests in rats the following mixture is prepared (v/v): 4 parts Croton oil, 10 parts ethanol, 20 parts pyridine, 66 parts ethyl ether. The standards and the test compounds are dissolved in

this solution. For tests in mice male NMRI-mice with an weight of 22 g, for tests in rats male Sprague-Dawley rats with a weight of 70 g are used. Ten animals are used for controls and each test group. The test compounds are dissolved in a concentration of 0.03 mg/ml to 1 mg/ml for mice and in a 3 to 10 times higher concentration for rats in the irritant solution. On both sides of the right ear 0.01 ml in mice or 0.02 ml in rats are applied. Controls receive only the irritant solvent. The left ear remains untreated. The irritant is applied under ether anesthesia. Four hours after application the animals are sacrificed under anesthesia. Both ears are removed and discs of 8 mm diameter are punched. The discs are weighed immediately and the weight difference between the treated and untreated ear is recorded indicating the degree of inflammatory edema. In the originally described method the ears are removed by sharp, straight scissors 6 h after application and weighed as total. The animals were sacrificed 48 h after topical ad-ministration and the thymus glands were removed, weighed and expressed as mg thymus/100 g body weight.

EVALUATION

The antiphlogistic effect can be determined by expressing the increase in weight of the treated ear as percentage of the weight of the contralateral control ear. The difference of both weights is divided by the weight of the contralateral ear times 100. Otherwise, the difference between both ears or excised discs is calculated as the average values for treated and control groups and the effect is evaluated by statistical methods. Concentration of 0.5 to 1 mg/ml hydrocortisone have been proven to be effective.

CRITICAL ASSESSMENT OF THE METHOD

The method is useful for evaluation of anti-inflammatory topical steroids especially in the modification when thymus weight is determined simultaneously. The method also can be used for topically applied nonsteroidal antiphlogistics.

MODIFICATIONS OF THE METHOD

Wilhelmi and Domenjoz (1951) tested various drugs using Croton oil induced ear edema in mice and rabbits.

Tubaro et al. (1985) tested various anti-inflammatory drugs in the Croton oil test in mice. Granulocyte infiltration in plugs taken from the inflamed ears was assessed by measuring peroxidase activity.

Zentel and Töpert (1994) used Croton oil-induced ear edema in rats to evaluate topical corticosteroids. A plastic collar was fixed around the neck of Wistar rats of either sex (160–200 g body weight) to exclude oral uptake of the compounds. Fifty µl of 5% Croton oil in ethanol or ethanol alone were topically applied to both ears. In the treatment groups drugs were coapplied with Croton oil. Five h after treatment the animals were sacrificed by CO_2 gas and the ears removed. Edema formation was measured by the increase in wet weight.

Iwasaki et al. (1995) measured the inhibition of Croton oil-induced ear edema in Wistar rats by locally applied clobetasol-17-propionate, a synthetic glucocorticoid, and the influence of simultaneously applied RU 486.

Weirich et al. (1977) measured skin temperature, ear thickness and weight of excised punches after Croton oil induced edema in the ears of **white rabbits** and calculated phlogostasis values as the products of the percent reduction in skin temperature, auricular thickness and tissue weight in relation to controls. The authors recommended this model for the primary evaluation of topical anti-inflammatory agents.

Colorado et al. (1991) described an apparatus to measure Croton oil induced ear edema in mice using precisely reproducible pressure on the ear. The device allows to follow the time course of inflammation by repeated measurements.

Akiyama et al. (1994) studied staphylococcus aureus infection on experimental Croton oil-inflamed skin in mice. Staphylococcus aureus cells were inoculated on the surface of skin inflamed by application of Croton oil in cyclophosphamide-treated mice. Skin specimens were taken at 1, 3, 6, 12, and 24 h after inoculation and examined by microscopy. The staphylococcus aureus cells which attached to the surface of the skin immediately after inoculation had invaded the horny layer within 1 h. The cells gradually penetrated deeper into the epidermis. Application of corticosteroid ointments decreased the number of staphylococcus aureus cells in the lesions.

Anderson and Groth (1984) induced **toxic contact reactions** to Croton oil or dinitrochlorobenzene (DNCB), or **allergic contact reactions** to DNCB or oxazolone in guinea pig skin and tested the effect of various locally applied corticosteroids by macroscopic assessment and microscopic evaluation of cellular infiltrates.

Tarayre et al. (1984) used a 0.25% solution of **cantharidin** in acetone and applied 0.025 ml to one mouse ear. Two phases of inflammation were observed. After local application nonsteroidal drugs showed effects in the first phase only, whereas steroids influenced both phases.

De Young et al. (1987) induced ear inflammation in rats by intradermal injection of 10 ng **recombinant human interleukin-1β** in 10 µl of saline.

Maloff et al. (1989) injected 20 µl of interleukin-1 solution into the left ear of mice and found a dose-dependent increase of ear thickness and myeloperoxidase activity which reached the maximum after 24 h. These

effects were reduced by high doses of glucocorticoids but not by nonsteroidal anti-inflammatory drugs.

Chang et al. (1987) applied 4 µg **tetradecanoyl phorbol acetate** and test drugs dissolved in acetone to the right ear of mice. Ear edema was calculated by subtracting the thickness of the left ear (vehicle control) from the right ear (treated ear).

De Young et al. (1989) examined the temporal patterns of edema and accumulation of the polymorphic nuclear cell marker enzyme myeloperoxidase following application of tetradecanoyl phorbol acetate to mouse ears. Topical and oral corticosteroids inhibited both edema and myeloperoxidase accumulation, whereby clobetasol propionate was more effective than fluocinolone and dexamethasone. Cyclo-oxygenase and lipoxygenase inhibitors were very effective against myeloperoxidase accumulation but were inactive or moderately active vs. edema.

Topical application of arachidonic acid to mouse ear has become a widely used test (Young et al. 1983, 1984; Opas et al. 1985; Crummey et al. 1987; Hensby et al. 1987; Tomchek et al. 1991) One mg arachidonic acid is applied to the right ear of mice and vehicle to the left ear of each animal. Drugs are topically applied in acetone to the ear 30 min prior to the arachidonic acid application. Ear swelling was measured using a caliper one hour after arachidonic acid.

Griswold et al. (1995) induced inflammation in mice by local application of arachidonic acid or phorbol ester. Besides ear thickness, myeloperoxidase and DNA content was measured.

H.3.2.2.6 Paw edema

PURPOSE AND RATIONALE

Among the many methods used for screening of antiinflammatory drugs, one of the most commonly em-

ployed techniques is based upon the ability of such agents to inhibit the edema produced in the hind paw of the rat after injection of a phlogistic agent. Many phlogistic agents (irritants) have been used, such as brewer's yeast, formaldehyde, dextran, egg albumin, kaolin, Aerosil®, sulfated polysaccharides like carrageenin or naphthoylheparamine. The effect can be measured in several ways. The hind limb can be dissected at the talocrural joint and weighed. Usually, the volume of the injected paw is measured before and after application of the irritant and the paw volume of the treated animals is compared to the controls. Many methods have been described how to measure the paw volume by simple and less accurate and by more sophisticated electronically devised methods. The value of the assessment is less dependent on the apparatus but much more on the irritant being chosen. Some irritants induce only a short lasting inflammation whereas other irritants cause the paw edema to continue over more than 24 h.

PROCEDURE

Male or female Sprague-Dawley rats with a body weight between 100 and 150 g are used. The animals are starved overnight. To insure uniform hydration, the rats receive 5 ml of water by stomach tube (controls) or the test drug dissolved or suspended in the same volume. Thirty minutes later, the rats are challenged by a subcutaneous injection of 0.05 ml of 1% solution of carrageenan into the plantar side of the left hind paw. The paw is marked with ink at the level of the lateral malleolus and immersed in mercury up to this mark. The paw volume is measured plethysmographically immediately after injection, again 3 and 6 h, and eventually 24 h after challenge.

Apparatus

Various devices have been developed for plethysmography of the paw. Winter et al. (1963) used mercury for immersion of the paw. A more sophisticated apparatus has been described by Hofrichter et al. (1969). Alpermann and Magerkurth (1972) described an apparatus based on the principle of transforming the volume being increased by immersion of the paw into a proportional voltage using a pressure transducer. Webb and Griswold (1984) reported a sensitive method of measuring mouse paw volume by interfacing a Mettler DeltaRange top-loading balance with a microcomputer. Several authors used a commercially available plethysmometer from Ugo Basile, Varese, Italy (Damas and Remacle-Volon 1992; Braga da Motta et al. 1994; Legat et al. 1994; Griesbacher et al. 1994).

EVALUATION

The increase of paw volume after 3 or 6 h is calculated as percentage compared with the volume measured immediately after injection of the irritant for each animal. Effectively treated animals show much less edema. The difference of average values between treated animals and control groups is calculated for each time interval and statistically evaluated. The difference at the various time intervals give some hints for the duration of the anti-inflammatory effect. A dose- response curve is run for active drugs and ED_{50} values can be determined.

MODIFICATIONS

Many agents can be used as irritants to induce paw edema in rats or mice. These are:

- 0.05 ml undiluted fresh egg white (Randall and Baruth 1976)
- 0.1 ml of 1% ovalbumin solution (Turner 1965)
- 0.1 ml of 1% formalin (Turner 1965)
- 0.1 ml of 0.2% carrageenan solution (Schönhöfer 1967)
- 0.1 ml of 1% carrageenan solution plus 100 ng PGE_2 or PGI_2 (Higgs et al. 1978; Portanova et al. 1996)
- 0.1 ml of 1 to 3% dextran solution (Turner 1965)
- 0.1 ml of 2.5% brewer's yeast powder suspension (Tsumuri et al. 1986)
- 0.1 ml of 0.5% ß-naphthoylheparamine solution (Peterfalvi et al. 1966)
- 0.1 ml of 0.1% trypsin solution (Kalbhen and Smalla 1977)
- 0.1 ml of 0.1% collagenase solution (Souza Pinto et al. 1995)
- 0.1 ml of 0.1% solution of collagenase from *Clostridium histolyticum* (Legat et al. 1994)
- 0.1 ml of solution of 100 IU hyaluronidase (Dewes 1955, Kalbhen and Smalla 1977)
- 0.1 ml of complete Freund's adjuvant
- 0.05 ml of 0.02% serotonin solution (Kalbhen and Smalla 1977)
- 0.1 ml of 0.005% bradykinin solution (Damas and Remacle-Volon 1992)
- 0.1 ml of 0.1 mg/ml prostaglandin E2 (Nikolov et al. 1978)
- 0.1 ml of 2.0 µg/ml prostaglandin E2 (repeated injections, Willis and Cornelsen 1973)
- 0.1 ml of 1% concanavalin A solution (Lewis et al. 1976)
- 0.1 ml of 2.5% suspension of Aerosil®
- 0.1 ml of 5% suspension of kaolin (Lorenz 1961; Wagner-Jauregg et al. 1962)
- 0.05 ml of bentonite gel (Marek 1980)
- 0.1 ml of nystatin 15 000 units (Schiatti et al. 1970, Arrigoni-Martelli et al. 1971)
- 0.1 ml of 1% phytohaemagglutinin-P solution (Lewis et al. 1976)

0.01 ml of 0.5% adriamycin (mouse paw) (Siegel et al. 1980)
0.1 ml of 0.001–0.1% solutions of various phospholipases A2 (Cirino et al. 1989)
0.1 ml of 0.1% Zymosan solution (Gemmell et al. 1979)
0.1 ml of 0.05% anti-IgG solution (Gemmell et al. 1979)
0.1 ml of 2.5% mustard powder suspension (Tsumuri et al. 1986)
0.1 ml of solution containing 1 unit of cobra venom factor (Leyck and Parnham 1990)
0.05 ml of 0.02–0.2% sonic extract from *Porphyromonas gingivalis* (Griesbacher et al. 1994)
0.1 ml of 0.25% suspension of papaya latex (Gupta et al. 1994)

The edema induced by the various irritants lasts for different times such as a few hours after serotonin and up to 2 days after Aerosil® or after kaolin. These irritants therefore are suitable to study not only the degree but also the duration of the anti-inflammatory action.

Standards

Depending on the irritant steroidal and nonsteroidal anti-inflammatory drugs have a pronounced effect in the paw edema test. With carrageenan as irritant doses of 50 to 100 mg/kg phenylbutazone p.o. have been found to be effective.

CRITICAL ASSESSMENT OF THE METHOD

The paw edema method has been used by many investigators and has been proven to be suitable for screening purposes as well as for more in depth evaluations. Dependent on the irritant steroidal and nonsteroidal anti-inflammatory drugs, antihistaminics and also, to a lesser degree, serotonin antagonists are active in the paw edema tests. Since so many different irritants have been used by the various investigators the results are often difficult to compare.

FURTHER MODIFICATIONS OF THE METHOD

Besides paw volume Shirota et al. (1984) determined the surface temperature of the inflamed paw in rats using a special cage with rolling rods.

Brooks et al. (1991) used anesthetized **dogs** and demonstrated that a significant inflammatory response can be elicited in the dog paw by subcutaneous injection of carrageenan. The increase in paw volume can be quantitatively measured as a pressure change recorded via a water-filled balloon fixed against the paw with nonexpandable tape. Effective doses of non-steroidal antiinflammatory drugs were closer to human therapeutic doses in dogs than in rats.

Oyanagui and Sato (1991) described an **ischemic paw assay in mice**. A commercial rubber ring (1×1 mm, $d = 42$ mm) was bound 14 times to the right hind leg of mice just above the articulation. After 20 min of ischemia, the rubber was cut off with scissors. Paw swelling was measured after an other 20 min of natural blood recirculation.

Wirth et al. (1992) described a **thermic edema** which was induced in anesthetized Sprague-Dawley rats by immersing paws of the right and left hindlimb into water of 55 °C. Immediately thereafter, the rats received the test drug (the bradykinin antagonist Hoe 140) intravenously. Paw volume was measured at regular intervals by plethysmography.

Braga da Motta et al. (1994) described drug modulation of **antigen-induced paw edema in guinea-pigs**. Male short-haired guinea pigs weighing 250–350 g received on day 0 a single dorsal s.c. injection of 1 ml of phosphate buffered saline containing 20 µg of ovalbumin, dispersed in 1 mg $Al(OH)_3$. The animals were boosted with a similar injection of antigen on days 14, 21, and 28. Thirty five days after the first injection of antigen or $Al(OH)_3$, the animals received an intraplantar injection of 0.5, 5, 50, or 200 µg ovalbumin, diluted in 100 µl of phosphate buffered saline. Edema was measured 2, 4, 6, 8, 24, and 48 h after the challenge.

H.3.2.2.7 Pleurisy test

PURPOSE AND RATIONALE

Pleurisy is a well known phenomenon of exudative inflammation in man. In experimental animals pleurisy can be induced by several irritants, such as histamine, bradykinin, prostaglandins, mast cell degranulators, dextran, enzymes, antigens, microbes, and nonspecific irritants, like turpentine and carrageenan (Survey by DeBrito 1989). Carrageenan-induced pleurisy in rats is considered to be an excellent acute inflammatory model in which fluid extravasation, leukocyte migration and the various biochemical parameters involved in the inflammatory response can be measured easily in the exudate.

PROCEDURE

Male Sprague-Dawley rats weighing 220–260 g are used. The animal is lightly anaesthetized with ether, placed on its back and the hair from skin over the ribs of the right side is removed using animal clippers. The region is swabbed with alcohol. A small incision is made into the skin under the right arm between the seventh and eighth rib. The wound is opened and a further shallow incision is made into the exposed intercostal muscle. 0.1 ml of 2% carrageenin solution is injected into the pleural cavity through this incision. The injection needs to be made swiftly to avoid the risk of injuring the lung. The wound is closed with a Michel clip.

One hour before carrageenan injection and 24 and 48 h thereafter, groups of 10 rats are treated with the standard or the test compound subcutaneously or orally. A control group receives only the vehicle of medication. The animals are sacrificed 72 h after carrageenin injection by ether inhalation. The animal is pinned on a dissection board with the forelimbs fully extended. An incision in the skin over the xiphosternal cartilage is made to free the cartilage from overlying connective tissue. The cartilage is lifted with a forceps and a small cut is made with scissors in the body wall below to gain access into the pleural cavity. One ml of heparinized Hank's solution is injected into the pleural cavity through this cut. The cavity is gently massaged to mix its contents. The fluid is aspirated out of the cavity using a pipette. This is made easier if the dissection board is raised to an angle of 45–60°; the contents then pool in the corners of the cavity. The aspirated exudate is collected in a graduated plastic tube.

EVALUATION

One ml (the added Hank's solution) is subtracted from the measured volume. The values of each experimental group are averaged and compared with the control group. ED_{50} values can be calculated using various doses. Several other parameters can be used:

- Measuring the white blood cell number in the exudate using a Coulter counter or a hematocytometer,
- Determination of lysosomal enzyme activities,
- Determination of fibronectin,
- Determination of PgE_2.

CRITICAL ASSESSMENT OF THE METHOD

The pleurisy model has been accepted as a reliable method to study acute and subacute inflammation allowing the determination of several parameters simultaneously or successively. The activity of steroids as well as of non-steroidal drugs can be measured (Tomlinson et al. 1994; Harada et al. 1996).

MODIFICATIONS OF THE METHOD

The Evans blue-carrageenan-induced pleural effusion model has been proposed by Sancilio (1969, 1973) for screening of compounds with anti-inflammatory activity.

Meyers et al. (1993) tested the effect of treatment with interleukin-1 receptor antagonist on the development of carrageenan-induced pleurisy in intact and adrenalectomized rats.

H.3.2.2.8 Granuloma pouch technique

PURPOSE AND RATIONALE

The method originally invented by Selye has been developed for screening by Robert and Nezamis (1957) using croton oil as irritant. An aseptic inflammation resulting in large volumes of hemorrhage exudate is elicited which resembles the subacute type of inflammation. Instead of croton oil carrageenan can be used as irritant.

PROCEDURE

Male or female Sprague-Dawley rats with a body weight between 150 and 200 g are used. Ten animals are taken for controls and for test groups. The back of the animals is shaved and disinfected. With a very thin needle a pneumoderma is made in the middle of the dorsal skin by injection of 20 ml of air under ether anesthesia. Into the resulting oval airpouch 0.5 ml of a 1% solution of Croton oil in sesame oil is injected avoiding any leakage of air. Forty-eight hours later the air is withdrawn from the pouch and 72 h later any resulting adhesions are broken. Instead of croton oil 1 ml of a 20% suspension of carrageenan in sesame oil can be used as irritant. Starting with the formation of the pouch, the animals are treated every day either orally or subcutaneously with the test compound or the standard. For testing local activity, the test compound is injected directly into the air sac at the same time as the irritant. On the 4^{th} or the 5^{th} day the animals are sacrificed under anesthesia. The pouch is opened and the exudate is collected in glass cylinders. Controls have an exudate volume between 6 and 12 ml, which is reduced dose dependent in the treated animals.

EVALUATION

The average value of the exudate of the controls and the test groups is calculated. Comparison is made by statistical means. A clear dose response curve could be found by s.c. injection of 0.5, 1.0 and 2.0 mg hydrocortisone acetate/rat. Also doses of 1.5 mg/kg indomethacin were found to be active.

CRITICAL ASSESSMENT OF THE METHOD

The method has been very useful to estimate the potency of anti-inflammatory corticosteroids both after local and after systemic application. By injection of a depot-preparation and induction of the granuloma pouch after various time intervals up to 4 weeks the duration of action can also be determined (Vogel 1963, 1965).

MODIFICATIONS OF THE METHOD

Carrageenin was used to induce exudate formation (Boris and Stevenson 1965).

Bobalik and Bastian (1967) developed a modified granuloma pouch technique in which *Mycobacterium butyricum* (adjuvant) was used as phlogistic agent.

Moreno (1993) sensitized rats by subcutaneous injection of methylated bovine serum albumin emulsified in complete Freund's adjuvant one week prior to the preparation of air pouches which were reinflated 4 days later. Seven days after formation of the air pouches inflammation was induced in the pouches by injection of 1 mg methylated bovine serum albumin.

Martin et al. (1994) described an air pouch model in the 6-day-old rat by injection of carrageenan. Besides the usual parameters, leukocyte influx and the level of prostaglandin E_2 in the pouch exudate were measured.

In order to measure the effects of different classes of proteinase inhibitors, Karran and Harper (1995) studied collagen degradation in subcutaneous air pouches in rats. The air pouches were formed in the dorsal region and were inflamed 6 to 8 days later by injecting λ-type carrageenan. Degradation of ^{14}C-collagen was followed in the inflammatory exudate fluid of the air pouches.

Sugio and Tsurufuji S (1981) re-evaluated the vascular constriction hypothesis as the mechanism of anti-inflammatory action of glucocorticoids. Rats were injected with 8 ml of air subcutaneously on the dorsal sur-face under light ether anesthesia to make an oval air sac. After 24 h, 4.0 ml of 2% heat-sterilized solution of carrageenin in 0.9% NaCl solution was injected into the air sac (day 0). Drug effects were tested on day 7. Vascular permeability in the granuloma pouch was measured using ^{125}I-HSA and ^{131}I-HSA. About 1 μCi of purified ^{125}I-HSA in 0.2 ml saline was injected into the femoral vein. After 30 min, 1.0 ml of the pouch fluid was withdrawn to measure the leakage of ^{125}I-HSA into the pouch fluid. After administration of the drug, about 1 μCi of purified ^{131}I-HSA was injected into the femoral vein. After 30 min, 1.0 ml of the pouch fluid was again withdrawn to measure the concentration of ^{131}I-HSA. The ratio of ^{125}I-HSA/^{131}I-HSA was taken as an index of vascular permeability change induced by drug treatment.

Atkinson et al. (1962) implanted compressed pellets of carrageenin subcutaneously to rats and measured the effects of some anti-inflammatory substances on wet weight of the pellets.

Bowers et al. (1985) described a method to induced a **granuloma in the rat lung** by instillation of a 2% carrageenan solution into one lower lobe of the lung via the trachea. No respiratory impairment was noticed during this procedure.

Further phlogistic agents inducing specific inflammatory cascades such as zymosan (complement activation) or lipopolysaccharide (cytokine release) have been used for pharmacological evaluation of antiinflammatory agents (Erdö 1994; Miller 1997).

H.3.2.2.9 Urate-induced synovitis

PURPOSE AND RATIONALE

The importance of urate in gout and the deposition of sodium urate in gouty tophi is well known. Faires and McCarty (1962) reported that they themselves were the subjects for a study injecting 20 mg sodium urate crystal suspension in their own knee-joint. They experienced severe pain and prostration which resembled an acute gouty attack. Based on this experience they developed an experimental model in dogs for testing anti-inflammatory compounds (McCarty et al. 1963, 1966).

PROCEDURE

Preparation of sodium urate crystals

0.4 g (0.01 Mol) sodium hydroxide pellets are dissolved in 400 ml distilled water in a glass beaker; 1.68 g (0.01 Mol) uric acid is added. The resultant opaque preparation is allowed to remain overnight at room temperature. The next morning, the crystals are harvested by decanting the supernatant solution and are then washed 3 times in cold saline, resuspended in saline and sterilized in an autoclave. Suspensions for injections are kept in rubber-stoppered, multi-dose vials containing 15 to 24 mg of urate per ml.

Unanesthetized healthy dogs weighing between 18 and 25 kg are used. They are trained to lie quietly on their backs in a dog cradle under light restraint. The skin above one knee is shaved, disinfected and a sterile 21-gauge needle inserted into the joint. Slight aspiration produces a small amount of clear, viscous synovial fluid, indicating entry into the joint. The needle is left in place, a syringe containing the urate suspension is attached and volumes from 0.1 to 0.5 ml are injected into the joint (approximately 2–10 mg urate).

One hour before the injection of urate crystals the animals are treated with the test compound or the standard. Experiments are designed so that a pair of dogs is tested on each of 2 days. On the first day, only one dog receives the drug. One week later the opposite knee of each dog is injected, but the other dog is treated.

EVALUATION

A scoring system is adopted in which inflammatory symptoms ranging from tenderness, limping, occasional 3-legged gait to complete 3-legged gait are scored from 1+ to 4+.

CRITICAL ASSESSMENT OF THE METHOD

In spite of the fact that the experiment originally has been performed in human volunteers and that the method closely resembles pathological conditions in man, due to animal protection law conditions the method can be recommended only for special investigations.

MODIFICATIONS OF THE METHOD

Carlson et al. (1986) developed an automated microcomputer-based system for determining canine paw pressure quantitatively in the dog synovitis model.

According to Phelps et al. (1967) dogs are anesthetized and placed on their sides with the hind leg firmly fixed with tape so that the femur and tibia form a 90-degree angle. The knee is punctured with a needle. When a few drops of synovial fluid can be withdrawn indicating a correct puncture of the joint, 6–10 ml of saline are injected to distend the joint and a polyethylene catheter is inserted through the needle, which is then withdrawn. 0.5 ml of a 0.02% sodium urate suspension are injected into the joint. The catheter is attached to a pressure transducer. Constant pressure recordings can be taken during the acute phase of inflammation. Pressure changes are plotted against time, whereby each dog is compared with his own control. Treatment with nonsteroidal anti-inflammatory drugs, such as indomethacin, show a considerable reduction of intraarticular pressure.

Fujihira et al. (1971) injected the urate suspension into the knee joint of a hind leg of well trained Beagle dogs. They were placed on three weighing machines whereby both forelegs rested on one balance, and the hindlegs individually on other balances. In this way, the relative change of weight on each hindleg after intraarticular injection of urate suspension can be measured, indicating a decrease of weight in the injected leg, counterbalanced to the other leg. Time response curves could be found after non-steroidal anti-inflammatory drugs.

Rosenthale et al. (1972) found a long-lasting inflammatory effect of prostaglandins PGE_1 and PGE_2 after injection in the knee joint of dogs.

Schaible and Schmidt (1985) induced an acute experimental arthritis in the knee joint of anesthetized **cats** by intraarticular injection of a 4% kaolin suspension and recorded the activity of single fine afferent units from filaments of the saphenous nerve.

Perkins and Campell (1992) injected either sodium urate crystals or Freund's complete adjuvant into one knee of **rats**. The maximum tolerated pressure was determined with or without treatment by analgesic drugs after 18–24 h (urate injections) or 64–70 h (Freund's complete adjuvant).

Daniel and Jouvin (1984) induced inflammation of the **guinea pig palatal mucosa** by injection of a microcrystalline suspension of monosodium urate.

Botrel et al. (1994) induced chronic inflammation in the knee joint of Beagle dogs by intra-articular injection of Freund's complete adjuvant. Besides body temperature, differences in skin temperature, difference in stifle diameter, the vertical force exerted by the arthritic hind limb measured by a force plate was chosen as parameter.

Schött et al. (1994) induced monoarthritis in rats by injection of 300 µg carrageenan in 50 µl saline into the right tibio-tarsal joint. Weight bearing was found to be an objective measure of arthritic pain.

Carleson et al. (1996) induced acute inflammation in the temporomandibular joint of rats by intraarticular injection of substance P and measured neurokinin A, calcitonin gene-related peptide and neuropeptide Y in the perfusate.

H.3.2.3 Methods for testing the proliferative phase (granuloma formation)

H.3.2.3.1 Cotton wool granuloma

PURPOSE AND RATIONALE

The method has been described first by Meier et al. (1950) who showed that foreign body granulomas were provoked in rats by subcutaneous implantation of pellets of compressed cotton. After several days, histologically giant cells and undifferentiated connective tissue can be observed besides the fluid infiltration. The amount of newly formed connective tissue can be measured by weighing the dried pellets after removal. More intensive granuloma formation has been observed if the cotton pellets have been impregnated with carrageenin.

PROCEDURE

Male Wistar rats with an average weight of 200 g are anaesthetized with ether. The back skin is shaved and disinfected with 70% ethanol. An incision is made in the lumbar region. By a blunted forceps subcutaneous tunnels are formed and a sterilized cotton pellet is placed on both sides in the scapular region. The pellets are either standardized for use in dentistry weighing 20 mg or pellets formed from raw cotton which produce a more pronounced inflammation than bleached cotton. The animals are treated for 7 days subcutaneously or orally. Than, the animals are sacrificed, the pellets prepared and dried until the weight remains constant. The net dry weight, i.e. after subtracting the weight of the cotton pellet is determined.

EVALUATION

The average weight of the pellets of the control group as well as of the test group is calculated. The percent change of granuloma weight relative to vehicle control group is determined.

CRITICAL ASSESSMENT OF THE METHOD

The method has been useful for evaluation of steroidal and nonsteroidal anti-inflammatory drugs. For testing corticosteroids, the test can be performed in adrenalectomized rats.

MODIFICATIONS OF THE METHOD

Bush and Alexander (1960) produced granulomata in rats by means of cotton-wool pellets which have been impregnated with carrageenin.

Tanaka et al. (1960) implanted filter paper pellets soaked with 7% formalin solution in rats.

Hicks (1969) implanted pellets impregnated with irritant substances, such as capsicum oleoresin.

Instead of cotton pellets, paper disks have been implanted (Tsurumi et al. 1986).

Roszkowski et al. (1971) immersed the cotton pellets in a 1% carrageenan solution, dried overnight and soaked in a 0.25 oxytetracycline solution before implantation.

D'Arcy and Howard (1967) induced a localized inflammatory reaction in the chorio-allantoic membrane of the chick embryo by the implantation of a sterile filter paper disc, followed by re-incubation *in situ* for 4 days.

Rudas (1960) described a method for quantitative evaluation of the granulation tissue formed in experimental wounds. Plastic rings were incorporated into the wounds on the back of rats inhibiting contraction of the wound edges and epithelialization of the wound. The growth of granulation tissue inside the rings was measured.

H.3.2.3.2 Sponge implantation technique

PURPOSE AND RATIONALE

The sponge implantation technique was described first by Saxena (1960) for short term experiments but was used subsequently to study the formation of granulomata using long-term implantation.

PROCEDURE

Sponges used for implantation are prepared from polyvinyl foam sheets (thickness 5 mm). Discs are punched out to a standard size and weight (10.0 ±0.02 mg) using a 13 mm cork borer. The sponges are then soaked in 70% v/v ethanol for 30 min, rinsed four times with distilled water and heated at 80 °C for 2 h. Prior to implantation in the animal, the sponges are soaked in sterile 0.9% saline in which either drugs, antigens or irritants have been suspended. Typical examples include 1% carrageenan, 1% yeast, 1% Zymosan A, 6% dextran, heat killed *Bordetella pertussis* (4×10^9 to 5×10^{10} organisms/ml) or 0.5% heat killed mycobacterium tuberculosis.

Sponges are implanted in female Wistar rats weighing 150–200 g under ether anesthesia. A 20 mm dorsal incision is made and the dermis separated from the underlying muscle layer by insertion of blunt forceps to form separate cavities into which sponges are inserted. Up to 8 sponges may be implanted per rat. The dorsal incision is closed with Michel clips and the animals are maintained at a constant temperature of 24 °C.

For short term experiments, the animals are treated with test drug or standard once before implantation orally or subcutaneously. For long term experiments, the rats are treated daily up to 3 weeks.

EVALUATION

For estimation of the fluid phase of sponge exudates, e.g. protein content, enzyme levels and biological mediators such as prostaglandins as well as for leukocyte migration, the sponges are removed already after 9 h.

For studying the chronic phase of inflammation besides dry weight DNA, indicating cell content, hexosamine, indicating glycosaminoglycane content, and hydroxyproline, indicating collagen content, can be determined.

CRITICAL ASSESSMENT OF THE METHOD

The sponge implantation technique has been proven to be a versatile method which was used and modified by many investigators.

MODIFICATIONS OF THE METHOD

Boucek and Noble (1955) implanted polyvinyl sponges in rats, hamsters, rabbits and humans.

Holm-Pedersen and Zederfeldt (1971) implanted 2 cubes $10\times10\times10$ mm of cellulose sponge connected with a silk suture. After various implantation periods, the sponges were dissected free and the strength of the connection between the two parts of the sponge was determined after removal of the connecting suture.

Paulini et al. (1974, 1976) implanted polyester-polyurethane sponges which were inserted at both ends of a 15 mm long PVC tube separated by a cotton wool plug.

Bonta et al. (1979) used polyether sponges measuring $4\times1.5\times0.5$ cm. A thin polyethylene cannula is inserted into a hole of the sponge and fixed with two stitches. After implantation of the sponge the cannula is pulled through a subdermal tunnel to a neck incision where about 1.5 cm is exteriorized and closed with a tube sealer. One ml of a 2% carrageenin solution is injected into the sponge via the cannula. To study the local effect of drugs, the test compounds can be injected together with the carrageenin. The drugs can be administered repeatedly at any time.

The cannulated sponge method was further modified by Bragt et al. (1980) using a subdermally implanted Teflon cylinder. This cylinder is provided with holes to ensure contact and exchange between the inner chamber and the surrounding tissue and with two cannulae allowing injection of material and withdrawal of exudate at any given stage of granuloma development.

Damas and Remacle-Volon (1992) implanted in rats sterilized polyester sponges which were removed after 4 h and weighed.

H.3.2.3.3 Glass rod granuloma

PURPOSE AND RATIONALE

The glass rod granuloma as first described by Vogel (1970) reflects the chronic proliferative inflammation. Of the newly formed connective tissue not only wet and dry weight, but also chemical composition and mechanical properties can be measured.

PROCEDURE

Glass rods with a diameter of 6 mm are cut to a length of 40 mm and the ends rounded off by flame melting. They are sterilized before implantation by boiling in water. Male Sprague-Dawley rats with an initial weight of 130 g are anaesthetized with ether, the back skin shaved and disinfected. From an incision in the caudal region a subcutaneous tunnel is formed in cranial direction with a closed blunted forceps. One glass rod is introduced into this tunnel finally lying on the back of the animal. The incision wound is closed by sutures. The animals are kept in separate cages. The rods remain *in situ* for 20 or 40 days. Treatment with drugs is either during the whole period or only during the last 10 or 2 days. At the end the animals are sacrificed under CO_2 anesthesia. The glass rods are prepared together with the surrounding connective tissue which forms a tube around the glass rod. By incision at one end the glass rod is extracted and the granuloma sac inverted forming a plain piece of pure connective tissue. Wet weight of the granuloma tissue is recorded. The specimens are kept in a humid chamber until further analysis. For measurement of the mechanical properties the specimens are fixed into the clamps of the Instron$^{(R)}$ instrument allowing a gauge length of 30 mm. The load until break is recorded with a crosshead speed of 50 mm/min. In order to calculate tensile strength (N/mm^2), the value of load at rupture (N) is divided by cross sectional area (measured as volume = wet weight divided by length). Finally, the granuloma tissue is dried and the dry weight is recorded. In addition, biochemical analyses, such as determination of collagen and glycosaminoglycans, can be performed.

EVALUATION

Several parameters can be determined by this method. Granuloma weight was reduced by corticosteroids depending on dose and time of administration and was also diminished after treatment with nonsteroidal anti-inflammatory agents and lathyrogenic compounds. Furthermore, antiproliferative terpenoids reduced the granuloma weight. The mechanical parameters showed different results after these drugs indicating a different mode of action. Treatment with corticosteroids increased tensile strength. Only after long term treatment with toxic doses a decrease was found. Anti-inflammatory compounds, such as acetylsalicylic acid or indomethacin and antiproliferative terpenoids showed an increase of strength at medium and high doses.

CRITICAL ASSESSMENT OF THE METHOD

In contrast to most other granuloma methods, the glass rod granuloma measures the late proliferative phase of inflammation. Since the newly formed connective tissue is not contaminated with the irritant biochemical analyses can be performed. The peculiar feature is the possibility to study the mechanical properties of newly formed proliferative connective tissue.

H.3.3 Side effects of anti-inflammatory compounds

H.3.3.1 General considerations

Gastrointestinal side effects are among the most frequent of the untoward or adverse reactions associated with orally ingested anti-inflammatory or anti-arthritic agents. The risk of gastrointestinal ulceration, bleeding and even perforation with non-steroidal anti-inflammatory drug therapy is well known. The mechanisms by which these drugs cause gastro-intestinal irritation are complex (Rainsford 1989). Deleterious effects may result from local actions, which cause inju-

ries to the submucosal capillaries with subsequent necrosis and bleeding, or from inhibition of the formation of protective prostaglandins.

H.3.3.2 Ulcerogenic effect in rats

PURPOSE AND RATIONALE

Gastric irritation properties of orally administered compounds are evaluated in fasted rats. Following treatment the animals are sacrificed after predetermined time intervals. The stomachs are removed and inspected for irritation and ulcers.

PROCEDURE

Groups of 10 male Wistar rats with an weight between 150 and 175 g are used. They are starved 48 h (water ad libitum) prior to drug administration. The test drugs are administered orally in 10 ml/kg as aqueous solution or suspension. Doses are chosen which are highly active in the anti-inflammatory tests in rats. The animals are sacrificed 3, 5 or 7 h post drug. Control animals are sacrificed after 7 h. Stomachs are removed and placed on saline-soaked filter paper until inspection. A longitudinal incision along the greater curvature is made with fine scissors. The stomach is inverted over the index finger and the presence or absence of gastric irritation is determined. The presence of a single or of multiple lesions (erosion, ulcer or perforation) is considered to be positive. The number of ulcers and the occurrence of hyperemia is noted.

EVALUATION

The number of animals with one or more lesions of the stomach is calculated as percentage of the animals of the test group. Running various doses, an ED_{50} value can be calculated. Standard compounds which produce gastric lesions are: Acetylsalicylic acid (10–100 mg/kg); naproxene (5–50 mg/kg); indomethacin (1–10 mg/kg).

CRITICAL ASSESSMENT OF THE METHOD

A good correlation between gastro-intestinal side effects in man and the ulcerogenic effects in rats has been found. The anti-inflammatory compounds of the pyrazolone type, like phenylbutazone, are almost devoid of these effects, whereas non-steroidal anti-inflammatory compounds of the classical phenyl acetyl type show ulcerogenic properties which parallel their therapeutic effect.

MODIFICATIONS OF THE METHOD

Gastro-intestinal irritation afflicts not only the stomach but also the small intestine. These lesions are easier to detect after repeated doses than after a single administration. Therefore, the animals are treated once a day orally for 4 days. During this period, they have free access to food and water. On day 5 (24 h after the last dose being given), the animals are sacrificed and the stomachs and small intestines removed. A longitudinal incision along the lesser curvature is made. The stomach and the small intestine are rinsed in running water and the presence or absence of ulcers is determined.

A computer-planimetric analysis of the areas of lesions has been published by Szabo et al. (1985). The stomachs are formalin fixed *in situ* by oral dosing upon death and after opening are pinned on to a small cork base with mucosa upwards. The cork base and stomach are placed in a Petri dish under a stereomicroscope and illuminated from above with a cold-light source on flexible fiberoptic leads. An extension tube from the microscope projects the image from this onto an adjacent planimeter (Microplan II), which is essentially a digitized tablet with built-in microprocessor enabling data to be calculated for subsequent printout digitally. The output indicates area, number, length, or width of the lesions as totals.

In addition to evaluation of gastric lesions, Goburdhun et al. (1978) measured the decrease of intestinal tensile strength which occurred after two oral doses of indomethacin but not of aspirin.

Another refinement of the method is the assay for gastro-ulcerogenic activity of non-steroidal anti-inflammatory drugs in cholinomimetic-treated mice using visual image analysis as published by Rainsford (1987).

Alich et al. (1992) assessed the gastric mucosal damage due to aspirin and copper aspirinate by gastric mucosal potential difference changes.

Ford et al. (1995) assessed the intestinal permeability changes induced by nonsteroidal anti-inflammatory drugs in the rat. A subcutaneous air pouch was formed by injection of 10 ml sterile air prior to the experiment. Five ml of a 0.4% carrageenan solution were injected into the pouch simultaneously with a subcutaneous injection of various doses of the non-steroidal anti-inflammatory drug and the rats allowed access to food. After various time intervals, different markers were given orally and urine collected for 5 h. The use of [^{51}Cr]-EDTA as marker was found to be the most sensitive and reproducible method. The results correlated well with data of ulcer formation.

Scarpignato et al. (1995) evaluated NSAID-induced gastric mucosal damage by continuous measurement of gastric potential difference in the rat. The method allows simultaneous measurement of gastric potential difference and intragastric pH with an automatic data analysis.

H.3.3.3 Measurement of gastric mucosal damage by intragastric inulin

PURPOSE AND RATIONALE

Wittmers et al. (1990) used intragastric inulin as a measure of mucosal damage caused by aspirin. The movement of inulin out of the gastric contents into the stomach wall and into the vascular compartment is an estimate of mucosal damage.

PROCEDURE

Adult male Sprague-Dawley rats are anesthetized with sodium pentobarbital and functionally nephrectomized by placing a ligature around both renal pedicles in order to prevent loss of inulin by renal clearance. One cannula is inserted in the carotid artery, another into the stomach. The duodenum is ligated 1 cm distal to the gastro-duodenal junction. The stomach is rinsed with saline and then the test solutions (total volume 2 ml/100 g body weight) are given intragastrally. The control solution contains 0.01 g/100 ml inulin and 0.30 μCi/ml ^{3}H-inulin. Test solutions contain the irritant, e.g. 100, 200, or 500 mg/kg aspirin. During the exposure period of 90 min blood is withdrawn in 15 min intervals. At the end of the exposure period a sample of gastric contents is obtained, the esophagus ligated at its junction with the stomach, and the animal sacrificed. The stomach is removed, opened along the lesser curvature, rinsed with saline, and pinned across a rubber stopper. Ten full thickness tissue samples are removed with a No. 2 cork bore in a predetermined pattern. The samples of tissue, plasma, and gastric content are digested and bleached with 0.2 ml 60% perchloric acid and 0.5 ml 30% hydrogen peroxide at a temperature of 80 °C for 20–30 min. Ten ml of liquid scintillation cocktail is added and ^{3}H-inulin is determined by liquid scintillation counting.

EVALUATION

The ^{3}H-inulin radioactivity is expressed as disintegrations per min per ml of plasma or per gram of tissue. Plasma ^{3}H-Inulin levels being dose-dependent increased after treatment are plotted versus time in comparison with control. ^{3}H-Inulin content in the gastric wall is dose-dependent increased after treatment especially in the antrum region.

H.3.3.4 Determination of blood loss

PURPOSE AND RATIONALE

Use of non-steroidal anti-inflammatory drugs induces micro bleeding which is not detected by observation of overt ulcers. Moreover, determination of the amount of lost blood may give a better quantitative assessment of gastrointestinal side effects.

PROCEDURE

Male Sprague-Dawley rats with an weight of 180–200 g are used. They are fasted in wire-floor cages for 24 h with free access to water. The animals receive the test drug or the standard compound (300 mg/kg acetylsalicylic acid) by gavage in 1 ml of 1% Arabic gum. For determination of fecal blood loss, the rats are kept in individual metabolism cages and food is given to them 5 h after treatment. Feces from each rat are collected separately every 24 h for 5 days. Heme is extracted from the feces and determined spectrophotometrically. For determination of the site of gastrointestinal bleeding the rats are sacrificed 5 h after treatment by ether inha-

lation. The stomach is tied on both the esophageal and pyloric ends, removed and washed free of external blood. The stomach content is released into a graduated test tube. Then the stomach is rinsed with 5 ml of saline. Similarly, the intestine is cut into 3 portions, each being tied at both ends. The contents after flushing the intestines twice with saline are collected. In the fluid of stomach and intestine content heme is determined spectrophotometrically.

EVALUATION
Time course of blood loss in the feces and dose-depended increase of blood in the content of stomach and intestine are determined.

CRITICAL ASSESSMENT OF THE METHOD
The determination of the time course of blood loss and the site of bleeding is interesting for in depth investigations but has to be regarded as a secondary screen.

H.4 Antipyretic activity

H.4.0.1 General considerations

Treatment with antipyretics has been very important in the pre-antibiotic era. Nevertheless, for treatment of acute viral diseases and for treatment of protozoal infections like malaria reduction of elevated body temperature by antipyretics is still necessary. For anti-inflammatory compounds, an antipyretic activity is regarded as a positive side effect. To evaluate these properties, fever is induced in rabbits or rats by injection of lipopolysaccharides or Brewer's yeast.

H.4.0.2 Antipyretic testing in rats

PURPOSE AND RATIONALE
The subcutaneous injection of Brewer's yeast suspension is known to produce fever in rats. A decrease in temperature can be achieved by administration of compounds with antipyretic activity.

PROCEDURE
A 15% suspension of Brewer's yeast in 0.9% saline is prepared. Groups of 6 male or female Wistar rats with a body weight of 150 g are used. By insertion of a thermocouple to a depth of 2 cm into the rectum the initial rectal temperatures are recorded. The animals are fevered by injection of 10 ml/kg of Brewer's yeast suspension subcutaneously in the back below the nape of the neck. The site of injection is massaged in order to spread the suspension beneath the skin. The room temperature is kept at 22–24 °C. Immediately after yeast administration, food is withdrawn. 18 h post challenge, the rise in rectal temperature is recorded. The measurement is repeated after 30 min. Only animals with a body temperature of at least 38 °C are taken into the test. The animals receive the test compound or the standard drug by oral administration. Rectal temperatures are recorded again 30, 60, 120 and 180 min post dosing.

EVALUATION
The differences between the actual values and the starting values are registered for each time interval. The maximum reduction in rectal temperature in comparison to the control group is calculated. The results are compared with the effect of standard drugs, e.g. aminophenazone 100 mg/kg p.o. or phenacetin 100 mg/kg p.o.

CRITICAL ASSESSMENT OF THE METHOD
The antipyresis test in rats in can be regarded as a classical method in pharmacology.

MODIFICATIONS OF THE METHOD
Stitt and Shimada (1991), Shimada et al. (1994) induced fever in rats by microinjecting 20 ng PGE_1 directly into one of the brain's circumventricular organs of the rat known as the organum vasculosum laminae terminalis.

Luheshi et al. (1996) induced fever by intraperitoneal injection of 100 µg/kg lipopolysaccharide into rats and measured the inhibition of fever by interleukin-1 receptor antagonist.

Telemetry has been used to record body temperature in animals (Riley et al. 1978; Gallaher et al. 1985; Clement et al. 1989; Guillet et al. 1990; Kluger et al. 1990; Bejanian 1991; Watkinson et al. 1996; Miller et al. 1997).

H.4.0.3 Antipyretic testing in rabbits

PURPOSE AND RATIONALE

Lipopolysaccharides from Gram-negative bacteria, e.g. *E. coli*, induce fever in rabbits after intravenous injection. Only lipopolysaccharide fractions are suitable, which cause after 60 min an increase of body temperature of 1 °C or more at a dose between 0.1 and 0.2 µg/kg. In the rabbit, two maxima of temperature increases are observed. The first maximum occurs after 70 min, the second after 3 h.

PROCEDURE

Rabbits of both sexes and of various strains with a body weight between 3 and 5 kg can be used. The animals are placed into suitable cages and thermocouples connected with an automatic recorder are introduced into the rectum. The animals are allowed to adapt to the cages for 60 min. Then 0.2 ml/kg containing 0.2 µg lipopolysaccharide are injected intravenously into the rabbit ear. Sixty min later the test compound is administered either subcutaneously or orally. Body temperature is monitored for at least 3 h.

EVALUATION

A decrease of body temperature for at least 0.5 °C for more than 30 min as compared with the temperature value before administration of the test compound is regarded as positive effect. This result has been found after 45 mg/kg phenylbutazone s.c. or 2.5 mg/kg indomethacin s.c.

CRITICAL ASSESSMENT OF THE METHOD

Measurement of body temperature in rabbits with polysaccharide induced fever is a more sensitive test than the yeast fever in rats. Furthermore, the method is used as a decisive test for the absence of pyrogens in parenteral drugs by several pharmacopoeias such as USP 23 (1955).

MODIFICATIONS OF THE METHOD

Cashin and Heading (1968) described a simple and reliable assay for antipyretic drugs in **mice**, using intracerebral injection of pyrogens.

Davidson et al. (1991) tested the effect of human recombinant lipocortin on the pyrogenic action of the synthetic polyribonucleotide polyinosini: polycytidylic acid in rabbits.

Yeast-induced pyrexia in **rats** has been used for antipyretic efficacy testing by Loux et al. (1982) and Cashin et al. (1977).

van Miert et al. (1977) studied the effects of antipyretic agents on fever and ruminal stasis induced by endotoxins in **conscious goats**.

Petrova et al. (1978) used turpentine-induced fever in rabbits to study antipyretic effects of dipyrone and acetylsalicylic acid.

Lee et al. (1985) studied the antipyretic effect of dipyrone on endotoxin fever of **macaque monkeys**.

Loza Garcia et al. (1993) studied the potentiation of chlorpromazine-induced hypothermia by the antipyretic drug dipyrone in anesthetized rats.

Shimada et al. (1994) studied the mechanism of action of the mild analgesic dipyrone preventing fever induced by injection of prostaglandin E_1 or interleukin-1β into the organum vasculosum terminalis of rat brain.

Chapter I
Antiarthrotic and immunmodulatory activity[1]

I.1
Anti-arthrotic activity[2]

I.1.0.1
General considerations

Multifactorial causes can lead to osteoarthritis (OA), and its pathogenesis is not clearly understood as yet. The main characteristics of OA are the slowly progressing deterioration of the articular cartilage, accom-

[1] Reviewed and amended by R. Schleyerbach, with contributions to the first edition by R. X. Raiss and R. R. Bartlett.

[2] Contributions in the first edition by R. X. Raiss.

panied by intermitted painful inflammatory episodes, and a continuous subchondral bone remodeling, often resulting in osteophyte formation in non-weight-bearing joint areas. Because of the lack of innervation and vascularization of cartilage, the destruction of this specific tissue remains unnoticed until other joint compartments are involved such as synovial membranes, answering with reactive synovitis to cartilage debris, or mechanoreception changes in the underlying bone, or until the diminution of articular cartilage results in a radiographically detectable joint space narrowing.

Therefore, analgesic and anti-inflammatory therapy has been the major treatment for OA in the past, and NSAIDs still constitute 92% of the drugs used against OA. Intraarticular injections of corticosteroids are also applied, although with geographically variable emphasis. Nevertheless they are still considered a useful tool in severe cases. Both classes of drugs are now reviewed more carefully with regard to their potentially harmful effects on cartilage maintenance and chondrocyte function – which leads to a more critical approach in drug selection. So-called 'chondroprotective' drugs, mainly sulfated polysaccharides, played a certain role in the pharmacotherapy of OA in Central Europe and some Eastern countries, but failed to demonstrate clinical efficacy, and now have lost significance.

Anti-oxidative enzymes or drugs such as superoxide dismutase or diacerein are also considered to influence osteoarthritic conditions. Recently, matrix metalloprotease-inhibitors (MMP-I), originally designed to inhibit tumor cell invasion, have shown promising results in counteracting the progressive enzymatic cartilage degradation, and some compounds are being developed for this indication. A further treatment gaining interest are derivatives of hyaluronic acid, which are applied intraarticularly in a series of injections. Their mechanism, however, is not clear yet, and most preparations have been filed as 'devices' rather than 'drugs', claiming a viscosupplementation with anti-inflammatory, analgesic, and chondroprotective properties.

I.1.1 *In vitro* methods for anti-osteoarthritic activity

I.1.1.1 General considerations

Since most of the drugs in use for OA were originally selected for other (e.g. arthritic) indications and only subsequently claimed to be effective in OA, they have not been primarily selected and optimized by *in vitro* assays specific for this condition. Thus, the indication lacks commonly agreed upon *in vitro* assays as well as clearly defined standard drugs to evaluate such models. Correspondingly, the variety of assay systems used to test compounds for their effect on cartilage maintenance and/or degradation is large, and the list below reflects this multitude.

The *in vitro* systems applied to assess drug effects upon chondrocytes range from homogenates of cartilage (Yu et al. 1991; Vignon et al. 1991; Zafarullah et al. 1992) over chondrocyte monolayers at different culture conditions and passages, suspensions of aggregated chondrocytes or clusters, cells cultured in or over an artificial matrix like agarose to cartilage explants and even organ cultures (Korver et al. 1989) like mouse patellas (Verschure et al. 1994). The species used in these studies vary over an equally wide range from mouse (Mohamed-Ali 1992), rat (Ismaiel et al. 1991; Seed et al. 1993; Seong et al. 1994; Srinivas et al. 1994), rabbit (Akatsuka et al. 1993; Collier, Ghosh 1991; Shimazu et al. 1993), dog (Venn et al. 1990), cattle, to human tissues (Bulstra et al. 1992; Green et al. 1995) derived from normal as well as osteoarthritic conditions. The chondrocyte and cartilage explant culture systems used for several years are described in more detail below with special emphasis on comparability and standardization.

PURPOSE AND RATIONALE

Articular chondrocytes not only control the regular balance of matrix synthesis and degradation in healthy cartilage turnover, but are also regarded as key players in the enhanced degradation and finally reduced synthesis of matrix components in pathological conditions like OA. The two main cartilage constituents are collagen type II fibrillar network, and proteoglycans attached to hyaluronic acid filaments, also termed aggrecans. The latter are the more sensitive and the first ones to change in cartilage degradation. Therefore, the *in vitro* assays are performed mainly with chondrocytes, and the parameters measured focus on proteogly can synthesis and/or degradation.

The exact mechanisms of cartilage pathophysiology are not yet elucidated, but enzymatic degradation involving metallo-proteinases are considered the main events. *In vitro*, interleukin-1 and retinoic acid induce enhanced matrix degradation as well as reduced matrix synthesis, as observed in OA. Their role in the actual disease process *in vivo*, however, remains obscure. They therefore are used rather as tools to induce a disease-relevant condition *in vitro* than being subject of direct pharmacological intervention. Thus, the *in vitro* assays described here are suitable to compare and select a variety of drugs for their effect upon the main biological activity of articular chondrocytes. To address the respective mechanisms of drug action, more spe-

cific follow-up assays like enzyme inhibition or cytokine release or inhibition tests should be applied.

I.1.1.2 Modulation of cellular proteoglycan metabolism

PURPOSE AND RATIONALE

In primary cultures, articular chondrocytes grown in an artificial matrix after digestion of the original bone, maintain their characteristic synthesis and turnover rate of cartilage matrix macromolecules for a long time. These metabolic processes can be influenced pharmacologically. In the following assay, compounds are tested for their effect upon the normal turnover of cartilage matrix by chondrocytes. The test is used to detect stimulation of matrix formation, but also to check for potential impairment of cartilage function. Specific matrix staining reveals the amount of newly formed matrix remaining around the cells at the end of treatment. Alternatively, incorporation of radiolabeled sulfate into the newly formed proteoglycans allows to quantitate the anabolic activity at the end of the experiment.

PROCEDURE

Reagents

A 1% (w/v) solution of Pronase from Boehringer in Ham's F12 is prepared, filtered under sterile conditions, and supplemented with 10% FCS.

A 0.025% (w/v) solution of Collagenase type II, activity 242 U/mg, from Worthington, corresponding to an activity of 6 U/ml in Ham's F12 is prepared, filtered under sterile conditions, and supplemented with 10% FCS.

Hank's balanced salt solution (HBSS) is obtained from Biochrome.

Ham's F12 is supplemented with 50 µg/ml gentamycine and 2.5 µg/ml amphotericin B.

A sterile stock solution of 5 mg/ml ascorbic acid in Ham's F12 is prepared, and aliquots are stored at –20 °C.

A 2% solution of low melting agarose from Seaplaque in 0.9% NaCl is prepared by heating in a microwave, and stored in a water bath at about 50 °C.

A buffer of 25 mM sodium-acetate (2.051 g/l) with 0.4 M magnesium-chloride 6-hydrate (81.32 g/l) is prepared, and adjusted with acetic acid to pH 5.6.

A staining solution is prepared with 0.1 g of alcian-blue, obtained from Sigma, in 67.5 ml buffer, filtered, and supplemented with 10 ml of a 25% solution of glutaraldehyde.

An 8 M guanidinium-hydrochloride solution is prepared.

Tissue and cell preparation

Fetlocks of freshly slaughtered steers (age 18 to 20 months) are skinned and the metacarpo-phalangeal joint opened under semi-sterile conditions. With a sterile scalpel, articular cartilage is then carefully removed from the underlying bone from all accessible cartilaginous regions and transferred into a sterile Ham's F12 solution at +4 °C. The tissue is washed with Ham's F12 to remove adherent synovial fluid. The pieces are then transferred into a 150 ml trypsinizing flask, containing the pronase solution including the added serum, and incubated with gentle stirring for 1 h at 37 °C and 95% humidity. The fluid is then removed, and the collagenase solution including the added serum is incubated with gentle stirring overnight. The resulting cell suspension is first filtered through a 90 µm and then a 50 µm Nylon filter and then centrifuged at 800 rpm for 10 min. Resuspension and washing is performed with HBSS and cells are counted and checked for vitality under the microscope using the Eosin staining. The vitality level should reach at least 95%. A cell suspension is prepared of 4×10^6 cells/ml Ham's F12 supplemented with 20% FCS.

To prepare the agarose cell cultures, 24 well plates are coated with 0.2 ml/well of a 1 : 1 mixture of the 2% agarose solution with preheated Ham's F12 and left at room temperature to gel. Then 0.1 ml/well (0.2 ml/well for radiolabeling) of a 1 : 1 mixture of the above described cell suspension with the 2% agarose solution is added. Care has to be taken to maintain an even cell suspension, and not to overheat the cells during this procedure. After gel formation at room temperature, the multiwell plates are placed in the incubator, and 0.5 ml/well medium is added either 4 h later or the following day. The medium consists of Ham's F12 supplemented with 5% FCS and 25 µg/ml ascorbic acid, and is changed every second day.

Assay

The assay starts 5 days after cell preparation. Compounds are added to the medium in a final concentration of 10 µM with 6 to 8 replicae per compound, and added anew with each change of medium over a total period of 8 days. The concentration can be varied according to the expected potency of the drug studied. An untreated control group as well as standard compound groups are always included. As standard compound, pentosane polysulfate to check for matrix increase, or retinoic acid to cause matrix decrease, can be applied.

At the end of treatment, the medium is removed, the wells washed 3× with 500 µl of medium without supplements, and 1 ml/well of the staining solution is added for 48 h. After removal of the supernatant, the following washing steps are performed for 10 min each:

- 3×500 µl/well 3% acetic acid,
- 1×500 µl/well3% acetic acid in 25% ethanol,
- 2×500 µl/well 50% ethanol,
- 1×500 µl/well70% ethanol.

With 500 µl/well of 8 M guanidinium hydrochloride solution, the bound stain is then extracted for 24 h at +4 °C. After shaking the plates gently for 10 min, 100 µl/well of each supernatant is then transferred to round-bottom microtiter-plates, and the extinction photometrically assessed in the plate-reader at a wavelength of 610 nm.

EVALUATION

The extinction is expressed in percentage as staining density with the control values defined as 100%. Values ≥ 110% are interpreted as stimulation of matrix formation, values lower than 80% as inhibition of matrix formation. Experiments with 8 wells/treatment usually exhibit a standard deviation below 7%.

CRITICAL ASSESSMENT OF THE TEST

The described method is suitable to compare up to 50 drugs in one experiment. The price for this is the limited quantification, as the staining is not strictly stoichiometric, and does not allow the distinction between matrix synthesis and degradation. For more detailed assessment, radiolabeling is the better choice. The limitation of these primary culture assays lies in the elaborate preparation and isolation of the chondrocytes. Several attempts to immortalize this differentiated mesenchymal cell type have resulted in the loss of cartilage-specific properties. A new cell line developed by MB Goldring (Green et al. 1995) might overcome this difficulty, but has not yet been reported to be modified pharmacologically.

MODIFICATIONS OF THE TEST

The agarose culture system for chondrocytes, originally described by Benya and Schaffer (1982), has been well characterized by Aydelotte et al. (1988, 1992), and the effects of different agarose densities have been studied by Verbruggen et al. (1990).

Instead of agarose gel cultures, some authors use 3D chondrocyte clusters in suspension (Bassleer et al. 1990, 1992; Henrotin et al. 1992), or suspensions over agarose (Archer et al. 1990), or embedded in collagen gels (Malemud et al. 1994).

Alternatively, encapsulation in alginate beads, either directly after isolation (Guo et al. 1989), even as primary culture for several months (Häuselmann et al. 1994), or after expansion in monolayers (Bonaventure et al. 1994), offers the opportunity to recover the chondrocytes later by depolymerization of the alginate.

Monolayers of articular chondrocytes can be used as well, but preferentially short-term (up to three days of culture), as under this culture condition chondrocytes tend to dedifferentiate to a fibroblast-like appearance and metabolic program. Authors using this modification are e.g. Kolibas, Goldberg (1989), Lane et al. (1992), and McCollum et al. (1991). The importance of culture conditions is addressed in the study by Seid et al. (1993), and that of culture duration in the paper by van der Kraan et al. (1992).

A dot blot assay by cuprolinic blue precipitation has been described by Jortikka et al. (1993), which is restricted to serum free conditions. Instead of matrix staining, radiolabeling can be applied as described in the next assay. In this case, the amount of cells should be doubled per well to assure sufficient label incorporation.

I.1.1.3 Cellular chondrocytic chondrolysis

PURPOSE AND RATIONALE

In this assay a disease-relevant situation is achieved by adding interleukin-1 (IL-1) to articular chondrocytes grown in agarose gel. IL-1 suppresses proteoglycan (PG) synthesis as well as increases their degradation, and thus results in a process which is also observed in degradative joint diseases *in vivo*. This process is termed chondrocytic chondrolysis. The test is used to detect the potential interference of a drug with this pathological process. Effect upon PG synthesis is studied by radiolabeling at the end of the experiment, and measuring the amount of incorporated sulfate. The effect upon PG degradation, and its release from the cellular environment, can be examined by prelabeling with $Na_2{}^{35}SO_4$, and following the amount of released incorporated sulfate over time from the supernatant with each or every second medium change.

PROCEDURE

Reagents

A 1% (w/v) solution of Pronase from Boehringer in Ham's F12 is prepared, filtered under sterile conditions, and supplemented with 10% FCS.

A 0.025% (w/v) solution of Collagenase type II, activity 242U/mg, from Worthington, corresponding to an activity of 6 U/ml in Ham's F12 is prepared, filtered under sterile conditions, and supplemented with 10% FCS.

Hank's balanced salt solution (HBSS) is obtained from Biochrome.

Ham's F12 is supplemented with 50 µg/ml gentamycin and 2.5 µg/ml amphotericin B.

A sterile stock solution of 5 mg/ml ascorbic acid in Ham's F12 is prepared, and aliquots are stored at –20 °C.

A 2% solution of low melting Agarose from Seaplaque in 0.9% NaCl is prepared under heating and microwave application, and stored in a water bath at about 50 °C.

Human recombinant interleukin-1 (IL-1)α or β from Genzyme is stored in aliquots at –20 °C.

For radiolabeling, $Na_2{}^{35}SO_4$ is purchased from Amersham.

A 4 M and 8 M guanidinium-hydrochloride (GuHCl) solution is prepared.

Tissue and cell preparation

Tissue and cell preparations are performed as for the previous assay, except the initial number of cells/well should be 400 000, corresponding to a cell-containing gel volume of 0.2 ml/well, and the medium added is supplemented with 10% FCS and 25 µg/ml ascorbic acid. It is changed every second day.

Assay

The assay starts 6 days after cell preparation. Except for a control group, interleukin-1α is added in a concentration of 3 U/well, and added anew with each consecutive medium change. Except for the IL-1-control group, compounds are added to the medium in a final concentration of 10 µM with 4 replicae per compound, and with the subsequent medium changes. The concentration can be varied according to the expected potency of the drug studied. At the end of an 8 day treatment, the medium is replaced by medium containing 1 µCi $Na_2{}^{35}SO_4$/well and incubated for 24 h. The supernatant is then removed, mixed 1 : 1 with 8 M GuHCl, and separated with a PD10-Sephadex column into free versus incorporated sulfate. The multiwell plates with the remaining gels are deep frozen for at least 24 h to facilitate solubilization, thawed and then extracted with 500 µl/well 8 M GuHCl supplemented with inhibitors. The content of each well is then centrifuged at 13 000 rpm for 30 min. After this step, the supernatant contains the matrix trapped around the cells. This is equally separated by a PD10 Sephadex column into free versus incorporated radiolabel. The probes containing the incorporated sulfate and derived from both fractions (medium and gel) are then mixed with scintillating fluid and assessed in a β-scintillation counter.

EVALUATION

Counts per minute (cpm) from medium and gel fraction are calculated and related to the total well content. They are added if total incorporation is measured, or left separately, in case the ratio between released versus retained label is of interest. The data are converted into percent incorporation, with the values of the untreated control group or those of the IL-1 control group serving as 100%.

CRITICAL ASSESSMENT OF THE TEST

This is a sensitive test, in which an adequate labeling protocol can provide detailed information. The time- and material-consuming separation of free from incorporated radiolabel at the end, however, limits the size of the experiments and number of compounds to be studied.

In both cellular tests drug effects should be checked for (anti)proliferative activity in a separate proliferation test.

MODIFICATIONS OF THE TEST

If the catabolic response to a drug is of more interest than the anabolic one, the radiolabeling can be shifted to a time point prior to treatment, and the release of incorporated sulfate into the supernatant will allow to follow the time course and amount of PG degradation. This prelabeling should not start earlier than 4 days after plating to assure a comparable matrix synthesis rate. Because IL-1 suppresses PG synthesis at a lower concentration than it stimulates its degradation, a double to triple amount of IL-1 should be used in this modification.

Instead of bovine, human chondrocytes can be used (Raiss et al. 1992). One should allow 4 days of adjustment in the agarose system before starting treatment with human cells. If available, human serum gives a higher PG synthesis rate than fetal calf serum (Oestensen et al. 1991). The heterogeneity of responses depends on the individual source and should be considered (Verbruggen et al. 1989).

When using human instead of bovine cells, the stimulation of degradation and inhibition of synthesis is more effective with IL-1β than IL-1α: a concentration of 0.1 U/ml results in a reduction of PG synthesis of ca 50% (Raiss et al. 1995). When incubating with radiolabeled sulfate, the exposure time should be doubled to 48 h to yield sufficient incorporation.

To exclude direct interference of a drug with interleukin-1, all-trans retinoic acid can be used instead of this cytokine.

I.1.1.4 Cartilage explant chondrolysis

PURPOSE AND RATIONALE

Chondrocytes vary in their metabolic activity and cytokine response depends on the relative location within the joint (surfacial vs deep, weight-bearing vs non-weight-bearing, etc). Therefore, the cellular assays are a homogeneous mixture of an otherwise heterogeneous cell population. Two reasons suggest a verification of the cellular results obtained in tissue culture assays: First, chondrocytes are more reactive after isolation compared to those in tissue culture, which may lead to false positive results. Second, intact cartilage matrix acts as barrier for certain compounds of high molecular size and fixed charge, so that they may not reach their target cells. Therefore, explant assays are recommended as a follow-up to the cellular tests.

PROCEDURE

Reagents

Ham's F12 medium is supplemented with 50 µg/ml gentamycin and 2.5 µg/ml amphotericin B.

A sterile stock solution of 5 mg/ml ascorbic acid in Ham's F12 is prepared, and aliquots are stored at –20 °C.

Human recombinant interleukin-1 (IL-1)α or β from Genzyme is stored in aliquots at –20 °C.

For radiolabeling, $Na_2{}^{35}SO_4$ is purchased from Amersham.

A 4 M and 8 M guanidinium-hydrochloride (GuHCl) solution is prepared.

Tissue preparation

Fetlocks of freshly slaughtered steers (age 18 to 20 months) are skinned and the metacarpo-phalangeal joint opened under semi-sterile conditions. With a sterile punch (as used for obtaining skin biopsies) full thickness disks of cartilage are obtained from all accessible cartilaginous areas and their wet weight is assessed. In each well, 1 ml of medium is added, consisting of Ham's F12 supplemented with 10% FCS and 25 µg/ml ascorbic acid, and approximately 30 mg wet weight of cartilage are transferred corresponding to 3 discs of 4 mm diameter.

Assay

The assay is started 1 to 2 days after tissue preparation. Except for a control group, interleukin-1α is added in a concentration of 8 U/well, and with each of the following medium changes (every second day). Except for an IL-1-control group, compounds are added to the medium in a final concentration of 10 µM with 6 to 8 replicae per compound, which are also added with each medium change. The concentration can be varied according to the expected potency of the drug studied. At the end of an 8 day treatment, the medium is replaced by a medium containing 15 µCi $Na_2{}^{35}SO_4$/well and incubated for 24 h. The supernatant is removed, mixed 1 : 1 with 8 M GuHCl, and separated with a PD10-Sephadex column into free versus incorporated sulfate. The explants are washed three times with Ham's F12 at +4 °C, and extracted with 1 ml/well 4 M GuHCl supplemented with inhibitors for 48 h, and then a second time with 0.5 ml/well for 24 h. Both fractions are mixed, and separated with a PD10 Sephadex column into free versus incorporated sulfate. The samples containing the incorporated sulfate derived from medium as well as explant extraction are then mixed with scintillating fluid and assessed in a β-scintillation counter.

EVALUATION

Counts per minute (cpm) from medium and explant fractions are calculated related to mg wet weight of cartilage of the respective wells. They are either added if total incorporation is measured, or left separately, in case the ratio between released versus retained matrix is of interest. The data are converted into percent incorporation in comparison with the values of the untreated control or of the IL-1 control group serving as 100%.

CRITICAL ASSESSMENT OF THE TEST

Punched discs of similar size standardize the surface/volume ratio, and give more reproducible results than chips of cartilage obtained by scalpel dissection. A disadvantage is the greater amount of cartilage needed, which makes it unsuitable for human tissue obtained from joint replacement surgery. When using human

tissue, interpretation and comparison of results should be restricted to the same source: striking differences occur between specimens from surgery or postmortem, between different joints (hip vs knee), and different ages of the donor (young or adolescent vs 35 years and older), as well as different stages of severity and the duration of degenerative joint diseases in cases of surgical specimens.

MODIFICATIONS OF THE TEST

The effect of serum concentrations on proteoglycan synthesis has been studied by McQuillen et al. (1986), and the effect of different concentrations of DMSO and glycerol, of importance for cryopreservation, has been examined on human fetal hip cartilage by Yang and Zhang (1991).

Some authors (Nixon et al. 1991) use bovine nasal septum as cartilage source, but the convenient homogeneity and mass of this tissue is outweighed by a matrix composition and biomechanical properties clearly distinct from articular cartilage.

Several authors use human cartilage from joint replacement surgery (e.g. Pelletier et al. 1989; Pelletier, Martel-Pelletier 1989), and some compare drug effects upon visually normal cartilage to those with fibrillated or osteoarthritic cartilage (Lafeber et al. 1992, 1993; Verbruggen et al. 1989, 1990).

A step towards organ culture represents the culture of full thickness cartilage with subchondral bone, cultured for 24 h on moist lens tissue (Chayen et al. 1994).

I.1.2 *In vivo* methods for anti-osteoarthritic activity

I.1.2.1 General considerations

The current availability of animal models of osteoarthritis (OA) for pharmacological assessment is impeded in several aspects: Firstly, the difficulty to address a generally slow progression of cartilage destruction and deterioration of joint function as encountered in human OA with an animal model achieving sufficient similarity to human pathology in an acceptable time frame. Secondly, the discrepancy between the need of mild, reversible pathological changes, which can be modified therapeutically, and the paucity of reliable parameters with which to determine normal versus disease stages with a gradable range large enough to assess drug effects. This includes also the lack of validation (clinically as well as in animal models) of noninvasive methods to assess disease progression. Thirdly, the lack of a true disease-modifying standard drug with which to validate the pharmacological effects in respect to the predicted clinical outcome.

This results in a situation that animal models closer to human pathology like the spontaneous OA in the Hartley strain of guinea pigs or the surgically inflicted joint instability in the Pond-Nuki dog model are too elaborate to be used routinely for drug selection. On the other hand, models like the chymopapain-induced cartilage degradation in rabbits, are suitable to study drugs, but are limited in their predictive value.

It should be noted that differences exist in the pathomechanisms of cartilage destruction between rheumatoid arthritis (RA) and OA. The destruction occurring in RA is closely linked to the inflammatory process, synovial tissue proliferation and transgression across the cartilage surface, degrading cartilage proteoglycans and collagens simultaneously. In OA inflammation is only an intermitted event, not instrumental in the degenerative cartilage destruction, in which proteoglycan degradation is the early event, and collagen loss occurs at a distinctly later stage. Therefore, animal models with a predominant inflammatory component as the air pouch model or other arthritis models, even

those focusing on cartilage destruction, are not discussed in this chapter (see Sect. H.3). They are described in detail by Greenwald and Diamond (1988) and recently reviewed by Greenwald (1991, 1993).

PURPOSE AND RATIONALE

As a multitude of different events can lead to OA, equally different techniques have been used to initiate osteoarthritic conditions in animal models: Surgical methods are used to either stiffen the joint in a defined position (Palmoski, Brandt 1982; Konttinen et al. 1990; Meyer-Carrive and Ghosh 1992) or inflict joint instability by partial meniscectomy or anterior crucial ligament (ACL) dissection. They are performed mainly in dogs, rabbits (Colombo et al. 1983; Moskowitz et al. 1973, 1979), and guinea pigs (Schwartz 1985; Meacock et al. 1990). Chemical modifications like intraarticular injections of iodoacetate, cytokines like IL-1, or enzymes like chymopapain or stromelysin, are carried out mainly in rabbits (Williams et al. 1992) and chicken (Kalbhen 1983, 1987). Mechanical forces are applied on bent or opened joints like impulse loading on sheep (Lindenhayn et al. 1984) or rabbit (Farkas et al. 1987; Mazière et al. 1984) knees, resulting in trauma models of OA. Spontaneously occurring OA is described in horses (Todhunter and Lust 1992; Haakenstad 1969), some breeds of dogs (Lust et al. 1985), rhesus macaques (Pritzker et al. 1989), guinea pigs (Bendele, Hulman 1988) and several strains of mice. For pharmacological purposes only guinea pigs and STR/1N (Walton 1965; Raiss et al. 1992), STR/ORT (Dunham et al. 1989), and C57 black (Pataki et al. 1990) mice have been adapted. In all models mentioned (except horses), the relevant joint is the knee.

Since there exist recent extensive and critical reviews of OA models (Burton-Wurster et al. 1993; Pritzker 1994; Moskowitz 1990, 1992; Adams and Billingham 1982; Oegema et al. 1999), also with respect to reversibility (Pita et al. 1986), with special emphasis on drug testing (Hess, Herman 1986), and in perspective to cartilage research and markers (Malemud 1993; Carney 1991), only some representative models of each category are described here.

I.1.2.2 Canine anterior cruciate ligament (ACL) transection model

PURPOSE AND RATIONALE

Similar to human ACL ruptures, ACL transection in the dog knee and the subsequent joint instability results in progressive cartilage erosion, fibrillation, and formation of osteophytes. This elaborate model is well characterized, and regarded of high predictive value. It is mostly known as the "Pond-Nuki dog model". These authors achieved the ACL transection originally through a lateral stab incision, whereas others also performed the ligament transection after opening the joint. Both versions lead to similar morphological and biochemical changes, and are described and illustrated in detail by Adams and Pelletier (1988).

PROCEDURE

Animals

Mongrels, beagles, greyhounds, and foxhounds are reported to be suitable, provided purebred strains are used. In general, younger animals display more repair phenomena, whereas older ones seem to show more rapid degeneration. As the epiphyses fuse at the age of 13 months, and as pronounced changes require up to 4 months to fully develop, careful planning ahead is essential.

Operation

The dogs are initially anesthetized with 30 mg/kg sodium pentobarbital i.v., followed by a continuous inhalation of 1% halothane with 1 l/min N_2O and 2 l/min O_2. After shaving and sterilizing the knee joint externally, it is fixed in a bent position at 90°, and a scalpel blade is inserted medially deep into the joint space diagonally posterior to the ACL, and parallel to the lateral border of the patellar ligament. By rotation of the blade, the ACL is then dissected, the blade withdrawn, and the wound closed. In the contralateral knee, a sham operation is performed to inflict similar disturbance to the joint tissue, but without harming the ACL. The ACL dissection results after 8 to 12 weeks, in contrast to the sham-operated contralateral knee, in fibrillation and erosion of the cartilage, more pronounced on the tibial plateau than on the femoral condyles. Also observed histologically is a loss of metachromatic staining, and a fissured surface with cell clones appears. A marked osteophytosis and subchondral sclerosis has also developed at that time. Proteoglycan content and overall cartilage thickness, however, seems to remain stable (Pelletier and Martel-Pelletier 1985) or even increase not only for several months (McDevitt et al. 1977; Vignon et al. 1983; Brandt and Adams 1989), but for up to 3 years after transection, as Brandt, Myers et al. (1991) could show. At later stages, however, severe cartilage thinning and loss is recorded (Brandt, Braunstein et al. 1991).

EVALUATION

Macroscopic inspection of cartilage and osteophytes are recorded. Histological grading based on the Mankin score has been reported to be modified by drug treatment over 7 weeks (Abatangelo et al. 1989; Schiavinato et al. 1989). As levels and activity of neutral matrix metalloproteases are elevated in cartilage and synovium (Pelletier, Martel-Pelletier 1985), they might be additional parameters of interest to profile the test compounds.

CRITICAL ASSESSMENT OF THE TEST

In this instability model, a polysulfated glycosaminoglycan preparation (Arteparon®), as well as intra-articular injections of a hyaluronic acid preparation induced some morphological and biochemical changes, whereas low-dose prednisone had no effect. As there seems to prevail an anabolic response to the instability in the articular cartilage for quite a long time, the selected time points and parameters to assess disease

progression and therapeutic success require careful consideration.

MODIFICATIONS OF THE TEST

Caron et al. (1996), Pelletier et al. (1997) investigated the *in vivo* effect of the recombinant human interleukin-1 receptor antagonist on the development of lesions in the anterior cruciate ligament transection model in dogs.

ACL transection can be performed also in an arthrotomy operation as described by Adams and Pelletier (1988), and an instability can be achieved equally by meniscectomy (Hannan et al. 1987).

The **rabbit** is the main other species used for instability models, as described in detail for partial medial meniscectomy by DiPasquale et al. (1988), and for partial lateral meniscectomy in connection with ligament transection by Colombo (1988).

Obara et al. (1993) induced osteoarthritis by surgical dissection of the anterior cruciate ligament in rabbits and investigated fluorescence distribution after intra-articular administration of fluorescein-labeled sodium hyaluronate.

A partial medial meniscectomy with ligament transection is described for the **guinea pig** by Schwartz (1988).

Layton et al. (1987) produced biomechanical stress-induced hip osteoarthritis in guinea pigs by extra-articular myectomy and tendotomy.

I.1.2.3 Chymopapain-induced cartilage degeneration in the rabbit

PURPOSE AND RATIONALE

Intraarticular injection of chymopapain into the rabbit knee joint results in cartilage degradation with rapid loss of proteoglycans. A transient inflammation shortly after injection normally subsides after 1–2 days. Severity and reversibility of the cartilage damage can be altered using different protocols (Williams et al. 1992).

PROCEDURE

Most authors use New Zealand White rabbits at the age of 2 to 4 months. Male Chinchilla and Chinchilla Bastard rabbits are preferred, as they display a thicker cartilage than the New Zealand strain. The animals with an initial body weight of ca 2.5 kg are anesthetized with a continuous inhalation of 4% halothane – 3 l/min N_2O – 1.8 l/min O_2. Both knee joints are carefully shaved and moisturized with 70% alcohol. With a sterile syringe a volume of 0.1 ml of the following solution is injected laterally into the joint space: eighteen mg chymopapain (Sigma) are dissolved in 1 ml 0.9% NaCl, and 50 mg l-cysteine-HCl is added for activation. The preparation is then passed under sterile conditions through a 0.22 µm Millipore filter, and tested for activity prior to each operation. (Potential direct interference of the therapeutic agent to be tested with the chymopapain can also be addressed at that point). One injection of 1.8 mg chymopapain in 0.1 ml per joint usually results in a proteoglycan loss/cartilage dry weight of ca 40% after 10 to 12 days. Two to 4 animals per experiment receive chymopapain in 0.9% NaCl in one joint, and 0.9% NaCl into the contralateral knee to assess the proteoglycan loss caused by the enzyme. Care is taken with all injections to apply the same volume to both joints, as the contralateral serves as internal control. If the drug is given orally, only one knee receives chymopapain treatment, whereas if the drug is applied intraarticularly into one knee (1 to 5 injections of 0.1 ml volume each, vehicle into contralateral joint, in a period of 5 to 10 days), both knees are treated with chymopapain. The animals are sacrificed after 10 to 14 days, and from defined regions of weight-bearing areas in the joint full thickness samples are obtained for histology and assessment of proteoglycan content.

Histology is performed on full thickness sections of the articular cartilage, fixed with 3% formalin, embedded in paraffin, and stained routinely with safranin-O/fast green, or with toluidin-blue (Romeis 1989).
